The infrared absorption spectra were measured in the frequency region 2500—400 cm^{-1} with a Hitachi EPI-2G spectrophotometer by the KBr disk method. The sample heated to a given temperature was cooled to room temperature and its spectrum was recorded. A Hitachi EPS-3T spectrophotometer equipped with a standard integrating sphere attachment was used for the measurements of the reflectance spectra in the frequency range 30000—15000 $cm.^{-1}$ MgO was used as a reference material.

The evolved gas (EG) curves were obtained by conductometric technique at a heating rate of 5 °C/min in a helium atmosphere with a 50 ml/min flow rate. Evolved gas analyses (EGA) were carried out for each EG peak with an active charcoal column (2 meters long) and a helium carrier gas (50 ml/min). Procedures for EG and EGA were described previously.[2]

Results and Discussion

TG and DTA Studies. The TG curves for the

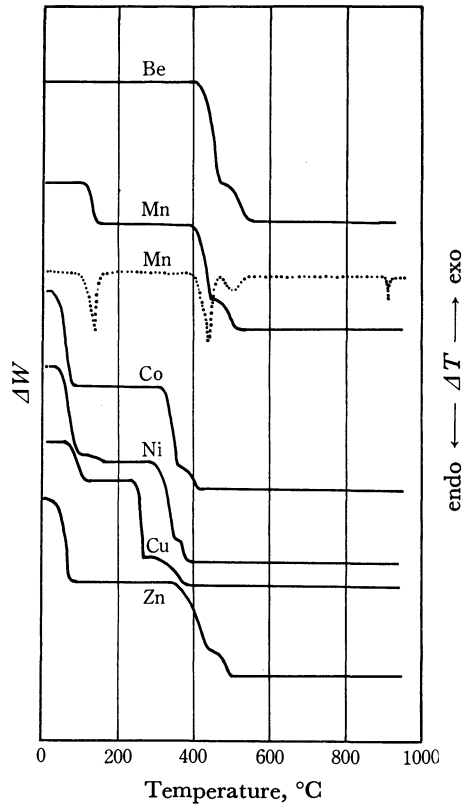

Fig. 1. TG(solid line) and DTA(dotted line) curves of dioxalato complexes in a flowing nitrogen atmosphere.

Be(II), Mn(II), Co(II), Ni(II), Cu(II), and Zn(II) complexes are given in Fig. 1. Curves for Be(II), Mn(II), Co(II), and Ni(II) complexes seem to have been given for the first time. For the sake of comparison, the curves of the remaining complexes[1] were reproduced under the conditions of the present work. The DTA curves were also obtained for all the complexes. As an example, the curve of $K_2[Mn(C_2O_4)_2]\cdot 2H_2O$ is given in Fig. 1. All the complexes decomposed through two or three steps. The initial weight-loss temperatures (t_i) and DTA peak temperatures (t_m) for each stage are summarized in Table 1 and the wieght-loss data (ΔW) in Table 2.

Except for the Be(II) complex, the complexes liberate the water molecules contained in the order of increasing temperature, Zn(II)<Co(II)<Ni(II)<Cu(II)<Mn-(II), giving well-defined plateaus for the anhydrous complexes (dehydration—stage 1) on the TG curves. Dehydration of Ni(II) and Zn(II) complexes gave two

Table 1. Initial weight-loss temperatures (t_i) and DTA peak temperatures (t_m)

Complex	Dehydration (°C)		Decomp. of complex (°C)		Decomp. of $K_2C_2O_4$ (°C)

Ni(II)	23.1	25.7	20.2	20.9 ($2CO_2$)	6.1	6.7 (CO)
Cu(II)	9.2	10.2	23.4	24.9 ($2CO_2$)	7.2	7.9 (CO)
Zn(II)	22.0	22.0	16.5	17.7 ($CO+CO_2$)	6.3	6.8 (CO)

peaks on each DTA curve, suggesting that all the waters are not held in the same way. The values of t_i of the dehydration varied over the range 18—112 °C with the central metals. The relation between t_i (t_{H_2O}) and $1/r$, where r is ionic radius, is given in Fig. 2. Except for $K_2[Mn(C_2O_4)_2]\cdot 2H_2O$, t_i increased almost linearly with the increase of $1/r$, suggesting that an electrostatic interaction exists to some extent between the water molecules and the central metal ions. Dehydration of the Mn(II) complex took place at the highest temperature, the point (Fig. 2) deviating a great deal from linearity. Thus, two water molecules of the Mn(II) complex might coordinate directly to the metal ion, and the complex should be formulated as $K_2[Mn(H_2O)_2(C_2O_4)_2]$.

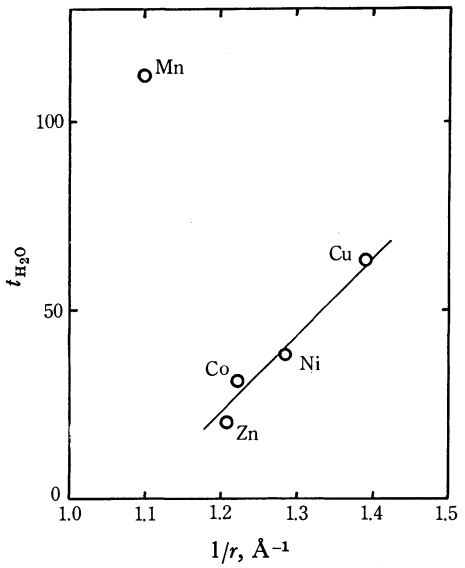

Fig. 2. Relation of initial weight-loss temperatures of the dehydration (t_{H_2O}) with $1/r$ for dioxalato complexes.

The anhydrous complexes then decomposed on further heating to give metal oxides or metals and potassium oxalate (decomposition of anhydrous complex—stage II). The weight-loss data (Table 2) indicate that Be(II), Mn(II), and Zn(II) complexes gave BeO, MnO, and ZnO, respectively, and $K_2C_2O_4$, while Co(II), Ni(II), and Cu(II) complexes gave Co, Ni,

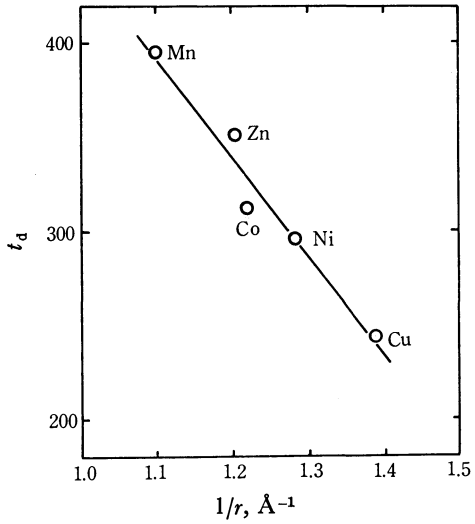

Fig. 3. Relation of initial weight-loss temperatures of the decomposition of the anhydrous dioxalato complexes (t_d) with $1/r$.

and Cu, respectively, and $K_2C_2O_4$. The values of t_i of the anhydrous complexes varied a great deal with the central metals. The plots of $t_i(t_d)$ *versus* $1/r$ are given in Fig. 3. Except for the Be(II) complex, t_i decreased with an increase in $1/r$, irrespective of the metals or the metal oxides formed as a solid decomposition product. This differs from the result obtained for the metal oxalate,[4] where the compounds giving metals decomposed at lower temperatures with an increase in $1/r$, while those giving the metal oxides decomposed in the reverse order.

Stage II which showed no well-defined plateau was followed by the decomposition of $K_2C_2O_4$ formed. The weight-loss data (Table 2) indicate that $K_2C_2O_4$ decomposed to K_2CO_3 to evolve one molecule of carbon monoxide (decomposition of $K_2C_2O_4$—stage III). It should be pointed out that the thermal stability of the potassium oxalate formed was influenced strongly by the metals or the metal oxides included in the decomposition products.

A small endotherm at 916—920 °C without any weight-loss was observed for all the complexes investigated. This corresponded to the melting point of K_2CO_3 formed. Pure K_2CO_3 also gave the same peak at 918 °C.

DSC Study. The enthalpy changes corresponding to the dehydration (ΔH_w), the decomposition of the anhydrous complexes (ΔH_{comp}) and the decomposition of $K_2C_2O_4$ (ΔH_{ox}) are given in Table 3. Since the number of water molecules contained in the complexes varied from 2 to 6, the values given for ΔH_w are the mean value per one mole of water. ΔH_w of the Mn(II) complex, dehydrated at the highest temperature, was the largest. ΔH_w decreased in the order Mn(II)> Cu(II)>Zn(II)>Co(II)>Ni(II), in line with that of ΔH_w of the metal oxalates.[4]

EG and EGA Studies. The EG curves of the complexes in a flowing helium atmosphere are given in Fig. 4, together with the EG curve of pure $K_2C_2O_4$. The evolved gas analyses for each EG peak are given in Table 4. The decomposition of anhydrous complexes can be divided into two types: the complexes of Be(II), Mn(II), and Zn(II) evolved one mole of carbon monoxide and one mol of carbon dioxide, while those of Co(II), Ni(II), and Cu(II) evolved two moles of carbon dioxide. This is consistent with the results from the TG in Table 2.

Although the TG curves indicate that stage III corresponds to the reaction

$$K_2C_2O_4 \longrightarrow K_2CO_3 + CO, \quad (1)$$

the EGA (Table 4) indicate the presence of CO_2 in addition to CO. The compositions of the gaseous mixtures varied with the complexes. For the com-

plexes of Mn(II), Cu(II), Zn(II), and Be(II), the major gaseous product was CO, CO_2 being less than 20% (mol %) of the total products. On the other hand, the percentage of CO_2 for the complexes of Co(II) and Ni(II) reached 50—60%. Thus, the following reaction might be considered in addition to Reaction (1).

$$K_2C_2O_4 \longrightarrow K_2CO_3 + 1/2C + 1/2CO_2 \qquad (2)$$

The presence of carbon in the solid products was confirmed by chemical analyses after removal of K_2CO_3.

Infrared Absorption and Diffuse Reflectance Spectroscopic Studies. The infrared absorption spectra of the hydrated complexes with those of the anhydrous ones are compared in Figs. 5 and 6. For the complexes of Mn(II) and Co(II), the spectra of the hydrated complex differ a great deal from those of the anhydrous complex, suggesting that structural changes occurred in the course of dehydration. In the region 1500—1200 cm^{-1}, $K_2[Mn(C_2O_4)_2]\cdot 2H_2O$ exhibited two C–O stretching vibrations[5] at 1447 and 1303 cm^{-1}, while $K_2[Mn(C_2O_4)_2]$ showed absorptions at 1418, 1387(w), 1332, and 1282 cm^{-1}. The bands of the hydrated complex, and those at 1418 and 1282 cm^{-1} of the anhydrous complex could be assigned to the C–O stretching vibrations of the bidentate oxalate group (I); those at 1387(w) and 1332 cm^{-1} of the anhydrous complex would be due to the quadridentate oxalate group (II).

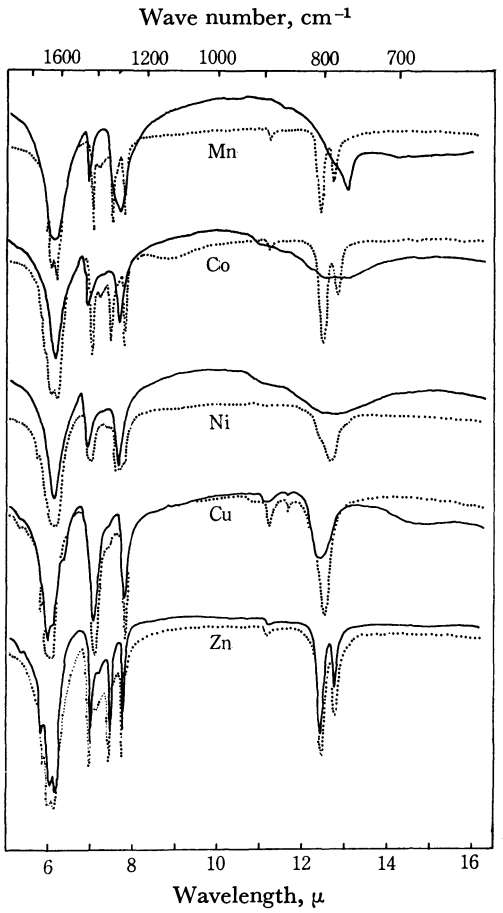

Fig. 5. Infrared absorption spectra of dioxalato complexes before and after the dehydration: —— indicates $K_2[M(C_2O_4)_2]\cdot nH_2O$ and ·····, $K_2[M(C_2O_4)_2]$.

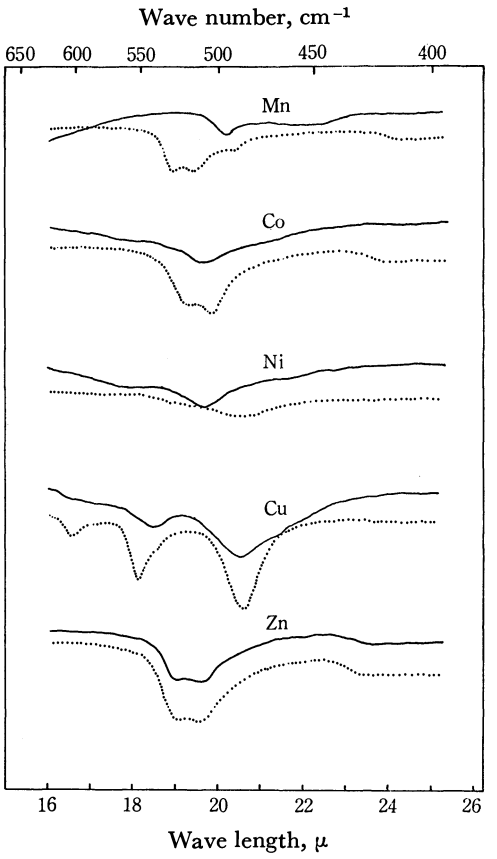

Fig. 6. Infrared absorption spectra of dioxalato complexes before and after the dehydration: —— indicates $K_2[M(C_2O_4)_2]\cdot nH_2O$ and ·····, $K_2[M(C_2O_4)_2]$.

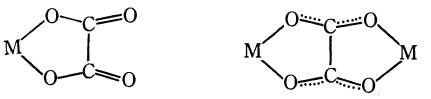

I II

The assignments are supported by comparison of the spectra of the anhydrous complex with those of MnC_2O_4 and $K_6(C_2O_4)_2Mn(OX)Mn(C_2O_4)_2$, where OX denotes a quadridentate oxalate group.[6] The oxalate groups in MnC_2O_4 are also confirmed to act as quadridentate groups by X-ray analysis.[3] Manganese oxalate shows only two bands at 1337(w) and 1319 cm^{-1}, while $K_6(C_2O_4)_2Mn(OX)Mn(C_2O_4)_2$ shows absorptions at 1415, 1385(w), 1310, and 1285 cm^{-1}.[6] In the region 900—650 cm^{-1}, considerable differences were observed in the spectra of $K_2[Mn(C_2O_4)_2]\cdot 2H_2O$ and its anhydrous complex: the hydrated complex gave two broad bands at 766 and 696 cm^{-1}, and the anhydrous complex three narrow bands at 885, 798, and 780 cm^{-1}. The bands at 696 cm^{-1} in the hydrated complex might correspond to coordinated waters; $MnC_2O_4\cdot 2H_2O$ also shows a characteristic band of the coordinated waters at 724 cm^{-1}. This is consistent with results from TG (the hydrated complex should be formulated as $K_2[Mn(H_2O)_2(C_2O_4)_2]$). The bands appearing in the region 600—400 cm^{-1} give direct information on the coordination bond. Oxalato complexes, in general, exhibit M–O stretching modes in this region.[5] The spectrum of the anhydrous complex in this region

differes from that of the hydrated one, suggesting a change of the bonding structure by dehydration.

Comparison of the infrared absorption spectra of the complexes of other metals in a similar way give valuable information on the prediction of the bonding structures of the complexes. The spectra of the anhydrous complexes of Co(II) and Zn(II) and also the hydrated complex of Zn(II) are very similar to that of the anhydrous manganese(II) complex in the range 2000—400 cm^{-1}, indicating that these complexes have essentially the same structure.

The anhydrous complexes of Ni(II) and Cu(II) show no characteristic bands of the bridging oxalate group. Each oxalate ligand might essentially act as a bidentate group.

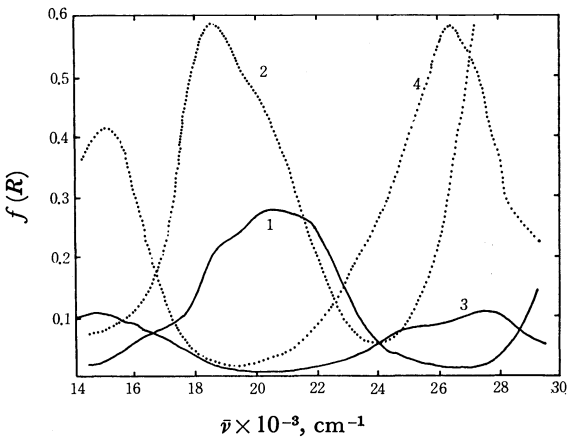

Fig. 7. Reflectance spectra of (1) $K_2[Co(C_2O_4)_2]\cdot 6H_2O$, (2) $K_2[Co(C_2O_4)_2]$, (3) $K_2[Ni(C_2O_4)_2]\cdot 6H_2O$ and (4) $K_2[Ni(C_2O_4)_2]$.

The diffuse reflectance spectra in the visible region (Fig. 7) were obtained in order to study the structures of the colored complexes. The spectrum of the hydrated complex of Ni(II) was similar to that of $NiC_2O_4\cdot 2H_2O$, the nickel ion of which is surrounded octahedrally with six oxygen atoms. $[Ni(H_2O)_6]^{2+}$ in aqueous solution also gives a similar absorption pattern. Thus, the hydrated nickel(II) complex has an octahedral coordination structure. It is blue while the anhydrous nickel(II) complex is bluish green. The spectrum of the latter is similar to that of the hydrated complex, except for the change in apparent intensities and the relatively small shifts of the absorption bands. Thus the Ni(II) ion in the anhydrous complex is also in an approximately octahedral structure, probably due to the formation of weak Ni–O bonds between the non-coordinated oxygen atoms of one $[Ni(C_2O_4)_2]^{2-}$ unit and Ni ions in adjacent units; Appearance of somewhat broad bands of the anhydrous complex might be due to this effect. As to the Co(II) complexes, the spectrum of the hydrated complex is similar to that of $CoC_2O_4\cdot 2H_2O$ and of $[Co(H_2O)_6]^{2+}$, the spectrum of the anhydrous complex not differing very much either. This indicates the essentially octahedral structures of both hydrated and anhydrous complexes. In the case of the copper complex, it seems that there is no remarkable structural change in the course of dehydration. The

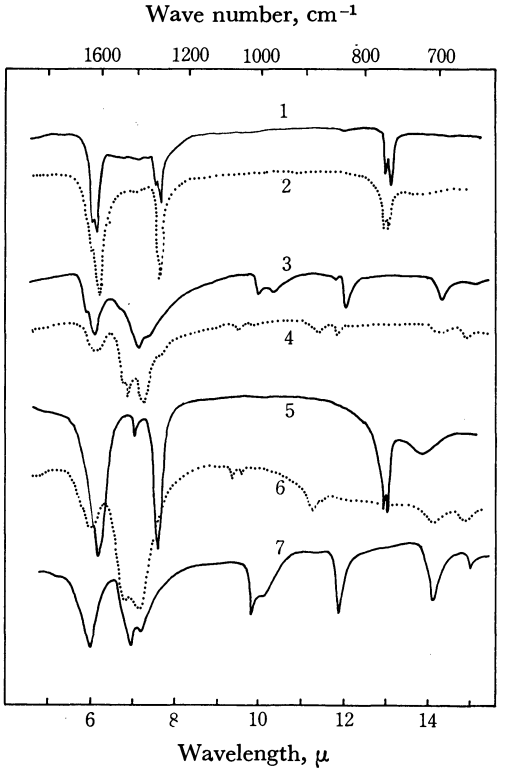

Fig. 8. Infrared absorption spectra of (1) products of the cobalt complex at the stage II, (2) products of the copper complex at the stage II, (3) products of the cobalt complex at the stage III, (4) products of the copper complex at the stage III, (5) $K_2C_2O_4$, (6) K_2CO_3, and (7) $KHCO_3$.

copper(II) ion seems to be surrounded square-planarly with four oxygen atoms of two bidentate oxalate groups, since a copper(II) ion usually tends to form such square planar (or tetragonal distorted) complexes. Thus, the infrared spectrum of the copper(II) complex in the region 600—400 cm^{-1} differs a great deal from that of the anhydrous Ni(II) complex.

The solid products formed at stages II and III were confirmed by means of infrared absorption spectra. The infrared spectra of Co(II) and Cu(II) complexes at each stage are given in Fig. 8, together with those of pure $K_2C_2O_4$, K_2CO_3, and $KHCO_3$. The spectra of the decomposition products at stage II (curves 1 and 2, Fig. 8) were similar to the spectrum of pure $K_2C_2O_4$ (curve 5). The spectra at stage III (curves 3 and 4) showed the presence of $KHCO_3$ in addition to K_2CO_3. Formation of $KHCO_3$ might be due to the reaction between K_2CO_3 formed and H_2O in air, since the spectra were recorded after cooling the heated samples to room temperature in air. The infrared absorption data thus support the results obtained from TG and EGA.

In conclusion, all the spectral data indicate the following structures.

Mn(II) Complexes. The hydrated complex is formulated as $K_2[Mn(H_2O)_2(C_2O_4)_2]$, while the anhydrous one has a polymeric structure with both quadridentate and bidentate oxalate ligands.

Co(II) Complexes. The infrared spectra show a

similar situation to that for the Mn(II) complexes, although the water molecules in the hydrated complex are held only loosely (Fig. 2). Both the complexes containing Co(II) in approximately octahedral environments.

Cu(II) Complexes. Both the hydrated and anhydrous complexes seem to be monomeric. Dehydration causes no remarkable change in the states of the central Cu(II), probably because of the tetragonal distortion of the complexes.

Zn(II) Complexes. Both the hydrated and anhydrous complexes have polymeric structures like $K_2Mn(C_2O_4)_2$; the water molecules are held extremely loosely, so that the dehydration occurs most easily.

Ni(II) Complexes. A similar situation to that for the Cu(II) complexes is seen, but here both complexes have essentially octahedral structures. A certain interaction between the $[Ni(C_2O_4)_2]^{2-}$ units in the anhydride should be postulated.

The authors wish to thank Prof. Kozo Sone for valuable discussions and Mr. Mitsuo Sato for the measurement of infrared absorption spectra. Expenses for the research were defrayed by a grant from the Ministry of Education.

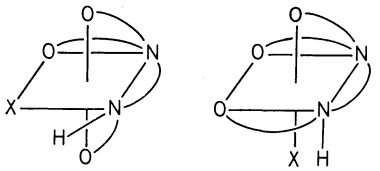
Metal Complexes of EDTA and Its Related Compounds. I. Geometric Isomers of [Co(X)(*N*-methyl-trimethylenediamine-*N*, *N'*, *N'*-triacetate)] Complexes with X=H_2O, NH_3, Cl^- or CN^-

Myung-Ki Doh,* Junnosuke Fujita,** Hiroshi Ogino, and Kazuo Saito
Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980
(Received August 23, 1974)

Two isomers of the complexes of the type, [Co(X)(*N*-Me-trdtra)] (*N*-Me-trdtra=*N*-methyl-trimethylenediamine-*N*,*N'*,*N'*-triacetate) have been isolated for each X=H_2O, NH_3, and Cl^-. The structures have been assigned from their PMR and absorption spectra and from the results of kinetic studies. The isomers have equatorial-skew and polar-chair structures and no indication of the formation of polar-skew isomer was observed. Isomerization reaction of the aqua complex in an aqueous solution indicated that the polar-chair isomer is more stable than the equatorial-skew isomer. Only the polar-chair isomer of H[Co(CN)(*N*-Me-trdtra)] has been obtained.

When a quinquedentate ligand such as ethylenediaminetriacetate (edtra^{3-}) forms a cobalt(III) complex together with a unidentate ligand, there are two possible geometric isomers as shown in Fig. 1. A similar

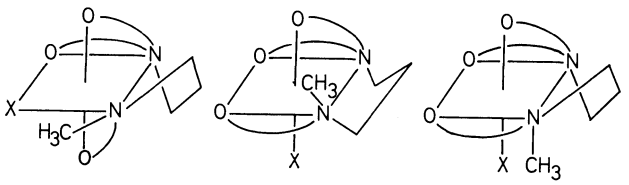


equatorial isomer polar isomer

Fig. 1. Two geometric isomers of [Co(X)(edtra)].

situation arises in ethylenediaminetetraacetate (edta^{4-}) complexes when one acetate group remains uncoordinated. Recent PMR studies,[1] however, have disclosed that all these complexes exist only in the equatorial form. Most recently Bell and Blackmer[2] confirmed this form for K[Co(NO_2)(edtra)]·1.5H_2O by the X-ray analysis. The acetate arm in the plane involving the two amino nitrogen atoms seems to be more strained as compared with that axial to the plane; the Co–O bond length in the plane is 1.919 Å, while that out of the plane, 1.883 Å. A similar difference in the Co–O bond lengths was found in [Co(edta)]$^-$.[3] The differences in the Co–O bond lengths in these complexes may be closely related to the conformation of the ethylenediamine moiety and the valence bond angles of the amino nitrogen atoms. It is, therefore, interesting to examine the geometrical isomerism in cobalt(III) complexes of trimethylenediaminetriacetate, since the trimethylenediamine moiety forms a six-membered chelate ring with conformations different from those of the ethylenediamine moiety of edtra^{3-} ligand.

As a first step of studying such an isomerism, we have attempted to prepare cobalt(III) complexes of *N*-methyl-trimethylenediamine-*N*,*N'*,*N'*-triacetate, [Co(X)(*N*-Me-trdtra)] (X=unidentate ligand). The complexes of this type have three possible geometric isomers as shown in Fig. 2. They are designated as equatorial-skew, polar-skew or polar-chair, depending on the position of the unidentate ligand and on the conformation



equatorial-skew polar-chair polar-skew

Fig. 2. Three geometric isomers of [Co(X)(*N*-Me-trdtra)].

of the six-membered trimethylenediamine chelate. Other forms involving equatorial-chair or boat conformations of the diamine may not be yielded owing to steric conditions.[4] In the present study, we have obtained two geometric isomers for each [Co(X)(*N*-Me-trdtra)] (X=H_2O, NH_3, and Cl^-) and one isomer of [Co(CN)(*N*-Me-trdtra)]$^-$. This paper deals with the preparation and isolation of these complexes and their geometric structures as determined by PMR and ultraviolet absorption spectroscopy. A kinetic study of the isomerization reaction of [Co(H_2O)(*N*-Me-trdtra)] has also been carried out to give support to the assignment of structures.

Experimental

Preparation of sodium N-*methyl-trimethylenediamine*-N,N',N'-*triacetate* (*Na_3N-Me-trdtra*). Na_3*N*-Me-trdtra was prepared by a method similar to that for *N*-methyl-ethylenediamine-*N*,*N'*,*N'*-triacetate by Van Saun and Douglas.[5] To a cold solution of monochloroacetic acid (37.8 g) in water (100 ml) was added dropwise a cold solution of sodium hydroxide (28 g) in water (70 ml) with steady stirring to keep temperature of the reacting solution below 15 °C. *N*-Methyl-trimethylenediamine (8.8 g) (Tokyo Kasei Co.) was then added. The solution was heated at 80 °C for 40 min, concentrated under reduced pressure at 70 °C and filtered to remove sodium chloride. The filtrate was used directly for the preparation of each cobalt(III) complex without isolating the free ligand. This procedure was justified by analyses of the complexes obtained.

Preparation of Complexes. [*Co(H_2O)(*N*-Me-trdtra)*]·H_2O. An aqueous solution (50 ml) of Co(NO_3)$_2$·6H_2O (29.1 g) was added to the previously prepared *N*-Me-trdtra solution which had been diluted to 500 ml and acidified to pH 6 with conc. hydrochloric acid. Activated charcoal (5 g) and 30% hydrogen peroxide (6 ml) were added and a stream of air was

* On leave from Yeung Nam University, Korea.

** Present address: Department of Chemistry, Faculty of Science, Nagoya University, Nagoya.

bubbled through the mixture for 3 days to complete the oxidation of the cobalt(II). After removal of the charcoal, the solution was diluted to about 20 l and the pH adjusted to about 5 with conc. hydrochloric acid. The solution was passed through a column of Dowex 50 WX8 cation exchange resin in H^+ form (700 ml) and then through a column of Dowex 1X8 anion exchange resin in Cl^- form (700 ml) to remove electrolytes and to obtain hydrochloric acid solution of the chargeless complex [Co(H_2O)(*N*-Me-trdtra)]. The blue violet solution was evaporated to almost dryness under reduced pressure at 50 °C. The residue was again dissolved in 100 ml of water and treated with silver oxide to remove chloride ions. The product was filtered, evaporated to a small volume, and poured carefully on a column ($\phi 3 \times 60$ cm) of Dowex 50 WX8 cation exchange resin in H^+ form. Elution with water gave two separate bands, blue and violet, the former being eluted faster. Blue and violet crystals were obtained by evaporating each eluate to dryness under reduced pressure below 40 °C. The blue complex was highly soluble, but the violet one moderately soluble in water. The latter gave higher yield than the former.

Found: Blue complex, C, 33.43; H, 5.38; N, 7.67%. Violet complex, C, 33.51; H, 5.34; N, 7.95%. Calcd for [Co(H_2O)(*N*-Me-trdtra)]·H_2O, ($C_{10}H_{19}N_2O_8Co$): C, 33.91; H, 5.41; N, 7.91%.

[Co(NH$_3$)(N-Me-trdtra)]·2H$_2$O. Violet and red isomers of the complex were obtained by the same method as that for the aqua complexes except that 28% aqueous ammonia (100 ml) was added to the solution containing cobalt(II) ions and the ligand. On the separation of two isomers by column chromatography (column, $\phi 3 \times 60$ cm), the violet isomer was eluted faster and followed by the red isomer. The former was much more soluble in water than the latter.

Found: Violet complex, C, 32.35; H, 5.71; N, 10.95%. Red complex, C, 32.81; H, 5.80; N, 11.40%. Calcd for [Co(NH_3)(*N*-Me-trdtra)]·2H_2O, ($C_{10}H_{22}N_3O_8Co$): C, 32.35; H, 5.97; N, 11.32%.

H[Co(Cl)(N-Me-trdtra)]·nH$_2$O. Greenish blue and bluish green isomers of the complex were prepared from the blue and the violet aqua complex, respectively, by treating with hydrochloric acid. A solution of each aqua complex in a small amount of conc. hydrochloric acid was warmed at 50 °C for 1 hr, and then evaporated to dryness under reduced pressure. The residue was dissolved in a small amount of water and poured on a column of Dowex 1X8 anion exchange resin in Cl^- form. The column was washed with water, and eluted with 0.5 M hydrochloric acid. The eluate was evaporated to a small volume under reduced pressure and stored in a vacuum desiccator over phosphorus pentoxide and sodium hydroxide. Both chloro complexes were very soluble in water.

Found: Greenish blue complex, C, 29.79; H, 5.65; N, 6.32%. Calcd for H[Co(Cl)(*N*-Me-trdtra)]·3H_2O, ($C_{10}H_{22}N_2O_9ClCo$): C, 29.39; H, 5.43; N, 6.86%.

Found: Bluish green complex, C, 30.60; H, 4.72; N, 6.77%. Calcd for H[Co(Cl)(*N*-Me-trdtra)]·2H_2O, ($C_{10}H_{20}N_2O_8ClCo$): C, 30.74; H, 5.16; N, 7.17%.

H[Co(CN)(N-Me-trdtra)]·2H$_2$O. A dimethylsulfoxide (DMSO) (30 ml) solution containing the violet aqua complex (1×10^{-3} mol) and potassium cyanide (1.5×10^{-3} mol) was warmed at 70 °C for 3 hr. The solution was passed through a column of Dowex 1X8 anion exchange resin in Cl^- form. The column was washed with water and the adsorbed red band was eluted with 0.3 M hydrochloric acid. Red crystals were obtained by evaporating the eluate under reduced pressure. The same cyano complex was obtained by the reaction of the blue aqua complex with potassium cyanide.

Found: C, 34.59; H, 5.17; N, 10.58%. Calcd for H[Co(CN)(*N*-Me-trdtra)]·2H_2O, ($C_{11}H_{20}N_3O_8Co$): C, 34.65; H, 5.29; N, 11.02%.

Measurements. Visible and ultraviolet absorption spectra were recorded with a Hitachi 323 recording spectrophotometer. PMR spectra were recorded with Varian A-60 and Varian HA-100 spectrometers in a deuterium oxide solution containing sodium 3-(trimethylsilyl)-1-propanesulfonate (TMS*) as the internal standard. All the measurements were made at room temperature.

Results and Discussion

Blue and violet complexes which gave correct analytical values as [Co(H_2O)(*N*-Me-trdtra)]·H_2O were obtained as shown in the Experimental part. Since each complex was confirmed to consist of a single species as described later, these complexes will be two of the three possible geometric isomers shown in Fig. 2. As Fig. 3 and Table 1 show, their absorption spectra differ notably from each other in the first absorption band region. However, no structural assignment can be made from the spectra at present, because both complexes belong to the same *cis*-[CoN_2O_4] type. On the other hand, the spectrum of the violet isomer in an aqueous solution was found to change on heating. Figure 4 shows an example of such spectral changes. Two isosbestic points are observed at 520 and 468 nm. Spectrum E in the figure agrees satisfactorily with that of the blue isomer. The spectrum of the blue isomer in water remained unchanged over a prolonged heating of the aqueous solution. These results indicate that the violet isomer isomerizes to the blue isomer and that the reverse reaction can be neglected. The isomerization between the equatorial-skew and the polar-chair isomer will occur by interchanging the coordination sites of one acetate arm and the aqua ligand. On

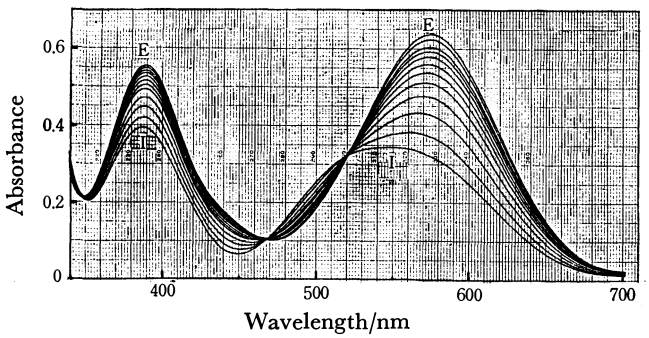

Fig. 4. Spectral change of violet-[Co(H_2O)(*N*-Me-trdtra)] in aqueous solution at 70 °C, pH=1.22 ($HClO_4$) and I=0.10 ($NaClO_4$–$HClO_4$). (I); t=0, (E); $t=\infty$.

the other hand, the isomerization reactions between the equatorial-skew and the polar-skew, and between the polar-chair and the polar-skew isomer will require less feasible change; *i.e.* interchange between the coordination sites of two acetate arms, or the inversion of configuration of the methyl and the acetate groups at the nitrogen atom. The first isomerization would take place more easily than do those of the latter two. Thus, the spectral changes described above may correspond to the isomerization reaction of the equatorial-skew into the polar-chair isomer or *vice versa* and the two isolated isomers can be concluded to have the equatorial-skew and the polar-chair structure.

Kinetic investigation for the isomerization reaction was carried out at an ionic strength (I) of 0.10 ($NaClO_4$–$HClO_4$). The reaction rate was independent of the hydrogen ion concentration over the range from 7×10^{-3} to 0.1 M. The acid independent rate constant was 2.08×10^{-4} s^{-1} at 70 °C, and $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ were 35.0 kcal/mol and +26.5 e.u., respectively.

In order to determine which isomer corresponds to the equatorial-skew or the polar-chair, we have utilized PMR spectroscopy in D_2O. The 100 MHz PMR spectrum of the blue isomer exhibits three AB patterns due to the acetate protons with coupling constants, 16.0, 16.2, and 19.0 Hz (Fig. 5 and Table 2). The grouping of these AB patterns was confirmed by comparison with the spectrum in 60 MHz. In [Co(edta)]$^-$ and its related complexes, it is known that the magnitude of the geminal coupling constant for the in-plane acetate protons is about 16 Hz, while that for the out-of-plane acetate protons about 18 Hz.[1] Therefore, the blue isomer should have two in-plane and one out-of-plane acetate arms and can be assigned to the polar-chair structure. The violet isomer, on the other hand, shows PMR signals corresponding to two out-of-plane acetate arms (J=17.5 and 18.5 Hz) and one in-plane acetate arm (J=16.5 Hz) as shown in Fig. 5 and Table 2, and thus, the violet isomer is assigned to the equatorial-skew structure in agreement with the previous discussion.

Two isomers, violet and red [Co(NH_3)(*N*-Me-trdtra)]·2H_2O were obtained similarly in the present study. Although neither of them isomerized without decomposition under a condition similar to that for the aqua complex, they could be assigned to the equatorial-skew and the polar-chair isomers as in the case of the aqua complexes. Figure 6 shows the absorption

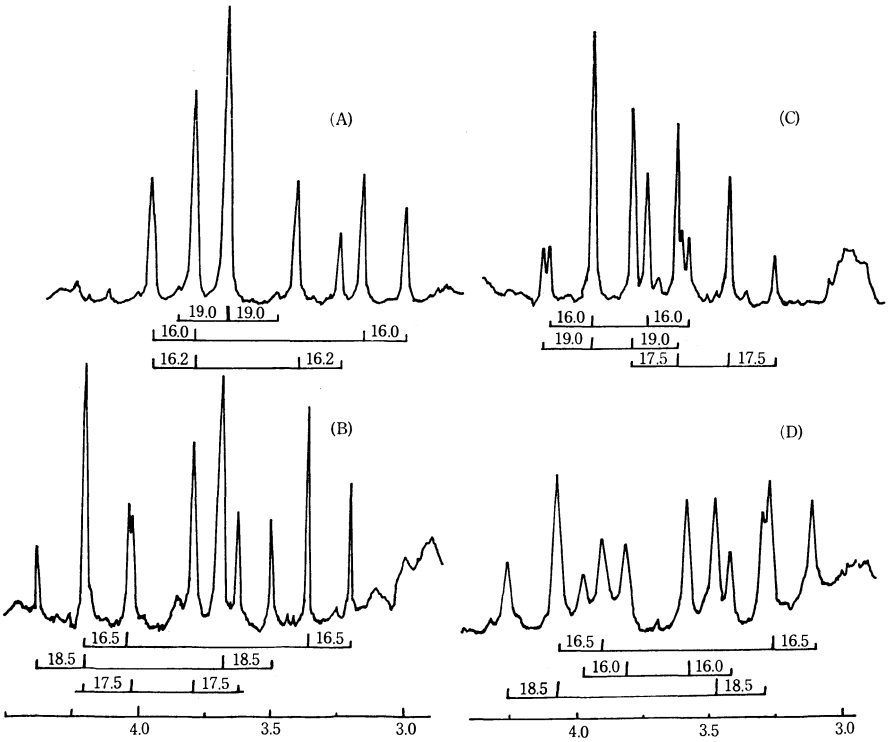

Fig. 5. PMR spectra (100 MHz) of blue (polar-chair) [Co(H_2O)(*N*-Me-trdtra)] (A), violet (equatorial-skew) [Co(H_2O)(*N*-Me-trdtra)] (B), violet (equatorial-skew) [Co(NH_3)(*N*-Me-trdtra)] (C), and [Co(CN)(*N*-Me-trdtra)] (D) in D_2O. Numerical values given in the figure indicate coupling constants in Hz for acetate protons.

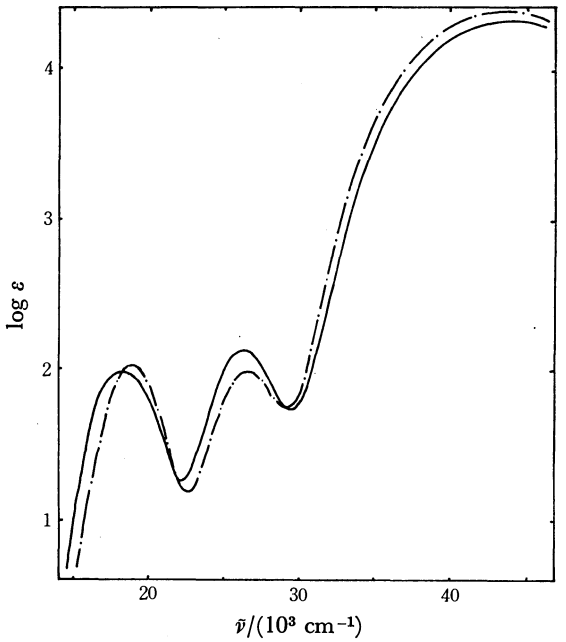

Fig. 6. Absorption spectra of violet (equatorial-skew) (——) and red (polar-chair) (– – –) isomers of [Co(NH_3)(*N*-Me-trdtra)] in water.

spectra of these ammine complexes. The first absorption band of the red isomer is narrower than that of the violet isomer. The polar-chair and the equatorial-skew [Co(NH_3)(*N*-Me-trdtra)] belong to *fac*- and *mer*-[CoN_3O_3] type, respectively, with respect to the configuration of the nitrogen and the oxygen atoms around the metal ion. A *fac*-[CoN_3O_3] complex exhibits a narrow and symmetrical first absorption band as compared with a *mer*-[CoN_3O_3] complexes.[6] Therefore, the red and the violet isomer may be assigned to *fac*-(polar-chair) and *mer*-(equatorial-skew) structure, respectively. This assignment will be supported by the PMR spectra. The PMR spectrum of the highly soluble violet isomer shows three AB patterns with coupling constants, 16.0, 17.5, and 19.0 Hz (Fig. 5 and Table 2). The AB pattern with 16.0 Hz is attributed to the in-plane acetate protons and those with 17.5 and 19.0 Hz to the out-of-plane acetate protons. Thus, the violet isomer is assigned safely to the equatorial-skew structure in agreement with the conclusion obtained from the absorption spectra. The red isomer was not soluble enough in D_2O to obtain PMR spectrum.

Greenish blue and bluish green isomers of H[Co(Cl)-(*N*-Me-trdtra)] have been obtained from the blue and the violet aqua complex, respectively, by warming with hydrochloric acid. The reactions should proceed without isomerization under the given condition, since each chloro complex liberates the chloride ion gradually in a neutral aqueous solution to give the corresponding original aqua complex. Therefore, the greenish blue and bluish green isomer are assigned to the polar-chair and the equatorial-skew structure, respectively. This assignment will be supported by the fact that the shape of the first absorption band of the greenish blue isomer is very similar to that of [Co(Cl)(*R*,*S*-2,4-

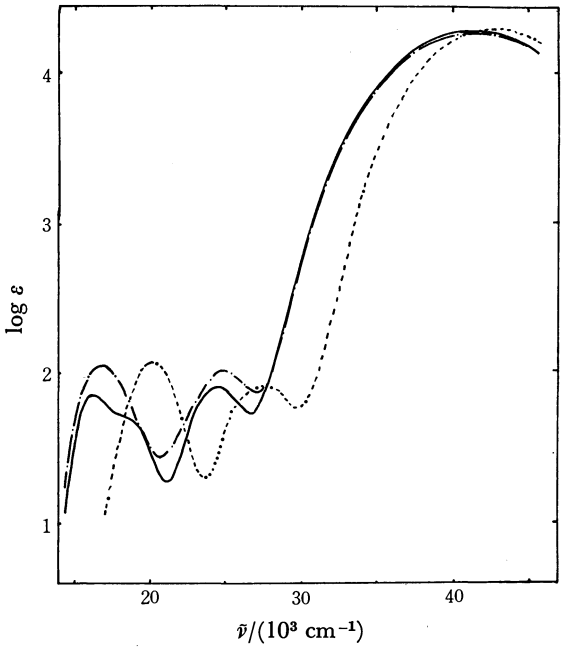

Fig. 7. Absorption spectra of bluish green (equatorial-skew) (——) and greenish blue (polar-chair) (– – –) isomers of [Co(Cl)(*N*-Me-trdtra)]⁻ in 0.1 M HCl and [Co(CN)(*N*-Me-trdtra)]⁻ (– · –) in water.

ptnta)]⁻ (*R,S*-2,4-ptnta=*R,S*-2,4-pentanediaminetetraacetate ion) which takes the polar-chair structure stereospecifically.[4] These polar-chair complexes do not show any splitting in the first absorption band in contrast to the distinct splitting observed for the bluish green, equatorial-skew isomer (Fig. 7). There seems to be a relation between the absorption spectra and the structure of the *N*-Me-trdtra complexes as discussed later.

Only one red complex, H[Co(CN)(*N*-Me-trdtra)]·$2H_2O$ was obtained by the reaction of the violet and the blue aqua complex with potassium cyanide in DMSO. Its PMR spectrum shows three AB patterns due to the acetate protons. The coupling constants are 16.0, 16.5, and 18.5 Hz, and the complex may be assigned to the polar-chair structure (Fig. 5 and Table 2). The complex shows a sharp and symmetrical first absorption band, being identified as the polar-chair structure (Fig. 7). The polar-skew isomer is not likely to be yielded by analogy with other *N*-Me-trdtra complexes.

For each aqua, ammine and chloro complex, no indication for the presence of more than two isomers was found in the present syntheses. The reason why the polar-skew isomers are not produced is not clear at present. The methyl group in the polar-skew structure takes an axial orientation to the chelate ring formed by the diamine moiety in a skew conformation, while that in the equatorial-skew structure an equatorial orientation to the same ring. However, such a difference will not be important in the present complexes, becasue the polar-chair isomer has an axially oriented methyl group to the diamine chelate ring. Further, the equatorial-skew isomer of [Co(H_2O)(*N*-Me-trdtra)] (violet) isomerizes in water into the polar-chair isomer (blue) by heating, and the reverse reaction does not take place under the same condition. This indicates that the polar-chair isomer is more stable thermodynamically than the equatorial-skew isomer. As stated in the Experimental part, the fact that the latter is produced much more than the former, may owe to a kinetically prefered route to form the equatorial-skew isomer favorably. The absence of the polar-skew isomer may also be related to such a prefered route in the complex formation. On the other hand, it should be noted that in the skew isomers the in-plane acetate arm seems to be still more strained than the out-of-plane acetate arm as seen in the [Co(edta)]⁻ and [Co(X)(edtra)] (*vide ante*). It was deduced that the six-membered diamine chelate ring in K[Co(trdta)]·$2H_2O$ (trdta=trimethylenediamine-tetraacetate ion) takes a skew conformation.[7] According to the X-ray analysis, the Co–O distances in the plane and axial to the plane are 1.904 and 1.861 Å, respectively.[8] The difference in these two bond distances is smaller than that reported for [Co(edta)]⁻ (1.912 and 1.833 Å), but it may still be big enough to prevent the formation of the polar-skew isomer.

The absorption spectra of all the complexes we prepared are shown in Figs. 3, 6, and 7. The maximum frequencies of the first and the second absorption bands depend on the kind of the unidentate ligand, and shift in accordance with the spectrochemical series.[9] On the other hand, the first absorption bands of the equatorial-skew isomers are broader than those of the polar-chair isomers. The equatorial-skew isomer of the chloro complex shows the first absorption band split apparently into two components. The origin of the difference in the band shape between the two geometric isomers is not clear at present. Yamatera's theory[6] on the band splitting for a cobalt(III) complex will not be applicable to the present complexes. The first absorption bands of both isomers of the aqua complex differ considerably from each other, although the isomers belong to the same *cis*-[CoN_2O_4] configuration, as stated previously.

One of the authors (M.-K.D.) is grateful to the Ministry of Education for the Japanese Goverment Scholarship.

Isomerism of the Metal Complexes Containing Multidentate Ligands. V.[1] Preparation and Properties of Optically Active Tris-(diaminosuccinato)cobaltates(III)

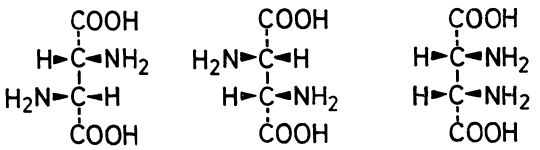
Masaaki KOJIMA, Yuzo YOSHIKAWA, and Kazuo YAMASAKI

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya, 464

(Received August 28, 1974)

Tris(diaminosuccinato)cobaltates(III) with *meso*, *racemic*, and *laevorotatory* ligands were prepared and resolved by column chromatography on DEAE-cellulose and by the use of cinchonidine. The resolved complexes and their absolute configurations, assigned on the basis of the electronic and circular dichroism spectra, and on the basis of the elution order in cellulose column chromatography, are Δ-$(-)_{589}$-$[Co(mdas)_3]^{3-}$, Λ-$(+)_{589}$-$[Co(mdas)_3]^{3-}$, $\Lambda(lel)$-$[Co(ldas)_3]^{3-}$, and $\Lambda(ob)$-$[Co(ldas)_3]^{3-}$.

2,3-Diaminosuccinic acid is able to coordinate to metals with either amino groups or carboxyl groups. The copper and nickel complexes were studied in a previous report.[2] In the present paper, the preparations and properties of tris(diaminosuccinato)cobaltates(III) coordinating with amino groups will be described. The abbreviations $mdasH_2$, $rdasH_2$, and $ldasH_2$ are used for *meso*, *racemic*, and *laevorotatory* (589 nm) 2,3-diaminosuccinic acids respectively. Figure 1 shows three possible isomers of the ligand.



ldas H_2 (2*R*, 3*R*) ddasH_2 (2*S*, 3*S*) mdasH_2 (2*R*, 3*S*)

Fig. 1. Three possible isomers of 2,3-diaminosuccinic acid.

Experimental

Ligands. 2,3-Diaminosuccinic acid was prepared by the method of Toi *et al.*[3], while the *meso* and *racemic* forms were separated by the procedure of Farchy and Tafel.[4] To resolve racemic diaminosuccinic acid, the less soluble diastereoisomer of the benzoylated ligand[5] with cinchonidine was recrystallized several times from a 2:1 mixture of water and ethanol. Then cinchonidine was precipitated by adding aqueous ammonia. The filtrate was acidified to obtain $(-)_{589}$-*N*,*N*′-dibenzoyldiaminosuccinic acid, which was then hydrolyzed with 6 M HCl to give $ldasH_2$.[6]

Preparation of the Complexes. The complexes with mdas, rdas, and ldas were prepared in a similar manner. To 2.4 g (9 mmol) of $[Co(NH_3)_6]Cl_3$ dissolved in 50 ml of water, a 4 g portion (27 mmol) of the ligand dissolved in 100 ml of the 0.5 M NaOH solution was added. After adding 0.5 g of active charcoal, the mixture was stirred for a few days at room temperature. The reaction mixture was then filtered, and the filtrate was subjected to column ($\phi 2.7 \times 120$ cm) chromatography on DEAE-Sephadex (A-25), with a 0.1 M sodium perchlorate as the eluent. A pink band was eluted first; it is a complex probably coordinating through both oxygen and nitrogen atoms of the ligand, but no further investigation of this complex was done. The main orange band, eluted slowly, was collected, and the effluent was evaporated to dryness *in vacuo*. After removing sodium perchlorate by extraction with methanol, the sodium salt was converted to the potassium salt by Dowex 50 W-X8 (K-form). The chemical compositions of the complexes thus prepared are given in Table 1.

Table 1. Chemical compositions of the isomers

Complex	Co (%)	N (%)	H_2O (%)
$K_3[Co(rdas)_3]\cdot 6H_2O$	8.06 (8.16)	11.31 (11.63)	14.57 (14.96)
$K_3[Co(mdas)_3]\cdot 6H_2O$	8.49 (8.16)	11.51 (11.63)	15.11 (14.96)
$(+)_{589}$-$Na_3[Co(ldas)_3]\cdot 6H_2O$	8.49 (8.74)	— —	16.03 (16.02)
$(-)_{589}$-$Na_3[Co(mdas)_3]\cdot 6H_2O$	8.75 (8.74)	12.59 (12.46)	15.88 (16.02)

Calculated values are given in parentheses.

Resolution of the mdas Complex with Cinchonidine. By the fractional crystallization of the diastereoisomers from water, the less soluble $(-)_{589}$-(cinchonidine)$_2$K$[Co(mdas)_3]\cdot 8\frac{1}{2}H_2O$ was obtained; it was then converted into the sodium salt by adsorption on DEAE-Sephadex and by subsequent elution with a 0.5 M sodium perchlorate solution (*cf.* Table 2). The resolved complex has the chemical composition of $(-)_{589}$-$Na_3[Co(mdas)_3]\cdot 6H_2O$ (Table 1).

Table 2. Absorption and circular dichroism spectra

Complex		Absorption $\tilde{\nu}_{max}$ (cm^{-1})	Absorption ε_{max}	CD $\tilde{\nu}_{max}$ (cm^{-1})	CD $\Delta\varepsilon_{max}$
$(+)_{589}$-$Na_3[Co(ldas)_3]\cdot 6H_2O$ Λ (lel) configuration	First Band	21100(473 nm)	110	20300(493 nm)	+3.21
	Second Band	29400(340 nm)	134	29000(345 nm)	−0.14
	CT Band	41700(240 nm)	10900	40000(250 nm)	−18

CT: Charge transfer

Partial Resolution of the mdas Complex by Column Chromatography. The partial resolution of the mdas complex was accomplished by column chromatography on DEAE-cellulose, using a 0.1 M $NaClO_4$ solution as the eluent. The active complex resolved by the use of cinchonidine did not show any further increase in rotation when subjected to column chromatography on DEAE-cellulose, indicating a complete resolution.

The rdas complex too was resolved only partially by column chromatography.

Separation of the ldas Complex into Isomers. When the reaction mixture of $[Co(ldas)_3]^{3-}$ was eluted on a DEAE-cellulose column by the use of a 0.1 M $NaClO_4$ solution, it was separated into the fast-moving isomer I and the slow-moving isomer II. The chemical composition of the isomer II, which shows $(+)_{589}$, is given in Table 1. The isomer I, with a rotation of $(-)_{589}$, was obtained in only a minute amount, and so no chemical analysis has been done.

Measurements. All the measurements were carried out in the way described in previous papers.[1]

Results and Discussion

The mdas Complexes. The absorption (AB) and circular dichroism (CD) spectra of $(-)_{589}$-$Na_3[Co(mdas)_3]\cdot 6H_2O$ are shown in Fig. 2, while the data are listed in Table 2. This complex was tentatively assigned the Δ configuration, because it shows the following features required for that configuration: (a) The tris(diamine)cobalt(III) complex which has five-membered chelate rings and shows a major negative CD peak in the octahedral $^1T_{1g}\leftarrow{}^1A_{1g}$ absorption region and a positive peak in the charge-transfer region generally has the Δ configuration, and (b) The tris(diamine)cobalt(III) complex, which is eluted first by HCl in a P-cellulose column, generally has the Δ configuration.[7]

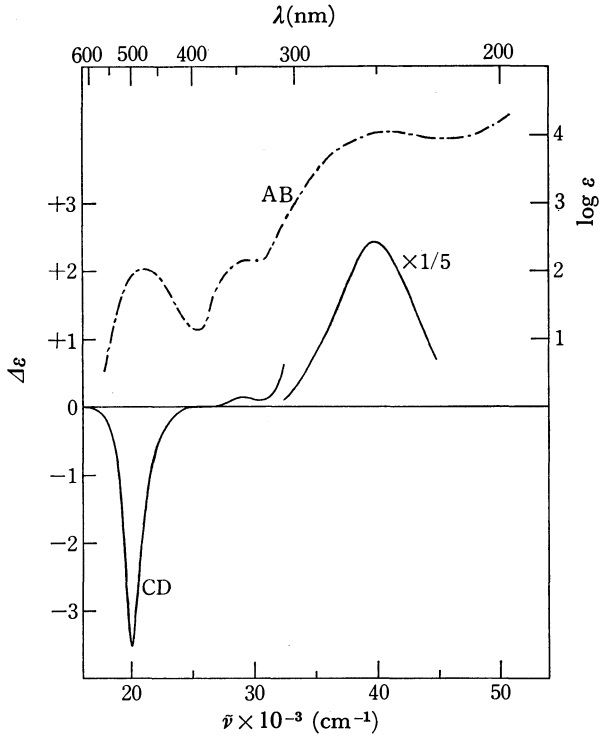

Fig. 2. AB and CD spectra of $(-)_{589}$-$Na_3[Co(mdas)_3]\cdot 6H_2O$.

For the mdas complex, two geometric isomers, *meridional* and *facial*, are possible from the alignment of the asymmetric carbons (*R* and *S*) for each of the absolute configurations, Δ and Λ. These isomers have not been detected by chromatography, although such isomers have been isolated for the tris(*meso*-2,3-butanediamine)cobalt(III) complex, which has a related structure.[8]

The ldas Complex. In Fig. 3 the AB and CD spectra of the isomer II, $(+)_{589}$-$Na_3[Co(ldas)_3]\cdot 6H_2O$, are shown, while the data are listed in Table 2. For the $\Lambda(lel)$-$[Co(d\text{-}pn)_3]^{3+}$ ion, a strong negative peak in the charge-transfer region has been found to be due to the contributions from both the configurational and vicinal effects with the same negative sign.[9] On the basis of this fact, and on the features mentioned above for the mdas complex, the absolute configuration $\Lambda(lel)$ was assigned to the isomer II.

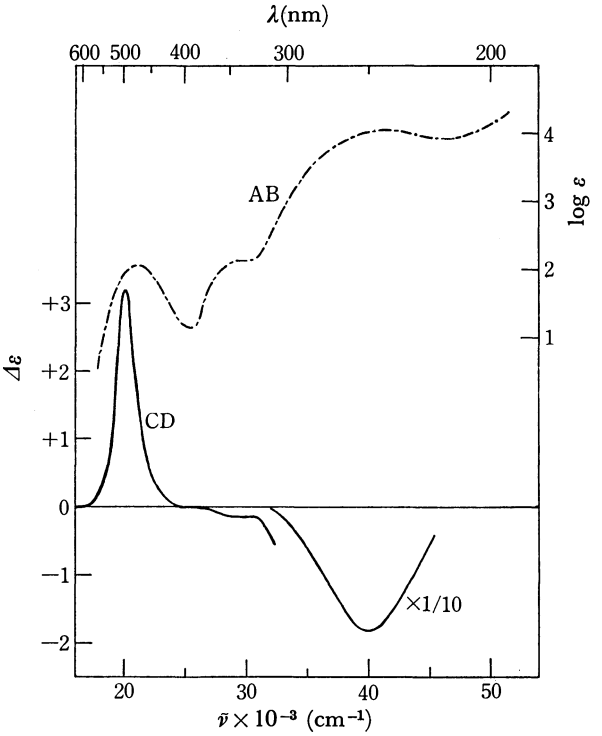

Fig. 3. AB and CD spectra of $(+)_{589}$-$Na_3[Co(ldas)_3]\cdot 6H_2O$.

As the $\Lambda(lel)$ isomer was formed stereoselectively in a predominant amount, the absolute configuration of the ligand, $ldasH_2$, has been determined to be 2*R*,3*R* (Fig. 1). In this $(+)_{589}$-$\Lambda(lel)$ complex, two carboxyl groups of the ligand assume equatorial positions with the $\delta(lel)$ conformation.

The CD spectrum of the isomer I, with the rotation of $(-)_{589}$, shows a negative peak at 480 nm in the d-d absorption region, and a negative and a positive peak in the charge-transfer region at 235 and 215 nm respectively. Taking into account the fact[9] that, in the charge-transfer region, the $\Delta(ob)$-$[Co(d\text{-}pn)_3]^{3+}$ ion has a small negative CD peak at 240 nm and a relatively large positive peak at 212 nm, the isomer I is assigned the $\Delta(ob)$ configuration. The $\Lambda(ob)$-$[Co(l\text{-}pn)_3]^{3+}$ ion

also shows almost the identical CD spectrum with the sign opposite to that of the $\Delta(ob)$-$[Co(d\text{-}pn)_3]^{3+}$ ion.[10]

The CD peak (480 nm) corresponding to the $^1E_a \leftarrow {}^1A_1(D_3)$ transition of the isomer I(*ob*) is at a shorter wavelength than that (493 nm) of the isomer II(*lel*); such a tendency has also been observed for the *lel* and *ob* isomers of the $[Co(d\text{-}pn)_3]^{3+}$ [9] and $[Co(l\text{-}pn)_3]^{3+}$.[10] The spectral data for the isomer I lack the intensity values because it is available in only a minute amount, and so no chemical analysis has been done.

Comparison between the mdas and ldas Complexes. For the tris(2,3-butanediamine)cobalt(III) ion, the $(+)_{589}$-bn complex has an absorption maximum (467 nm)[11] at a shorter wavelength than the *meso*-bn complex (473 nm).[8] This fact is consistent with the forced axial position of one of the two methyl groups for the latter complex, regardless of the chelate-ring conformation (δ or λ). For the das complex, however, the maximum of the octahedral $^1T_{1g} \leftarrow {}^1A_{1g}$ absorption of $\Lambda(lel)$-$[Co(ldas)_3]^{3-}$ is at almost the same wavelength as that of $[Co(mdas)_3]^{3-}$ (Table 2), although the latter has one axial carboxyl group. This spectral feature of the mdas complex is understandable on the basis of a hydrogen-bond formation between the oxygen atom of the axial carboxyl group and the hydrogen atom of the amino group on the adjacent chelate ring. In an acid solution, hydrogen bonds are usually weakened due to protonation. Actually, in 5 M HCl the first band maximum of the mdas complex* is shifted to a longer wavelength (483 nm) than that (479 nm) of the rdas complex.* A similar difference was observed in the solid state as well: 474 nm (mdas complex) and 470 nm (rdas complex).

For the complex, $[Co(ldas)_3]^{3-}$ two carboxyl groups are in the equatorial positions and it is difficult for strong intramolecular hydrogen bonds to be formed between the oxygen atom of the carboxyl group and the hydrogen atoms of the amino groups.

PMR Spectra. The PMR spectra for the mdas and rdas complexes* were measured in D_2O–D_2SO_4 at 60 MHz. The results, however, proved unfruitful, since no signal attributable to carboxyl groups was found down to 15 ppm, and furthermore other signals observed were too complicated and too broad to be analyzed.

* In acid solutions these complexes are converted into the cations, $[Co(mdasH_2)_3]^{3+}$ and $[Co(rdasH_2)_3]^{3+}$ respectively. For the electronic and PMR spectral measurements where it is permissible, the rdas complex was used instead of the ldas complex because it is readily available.

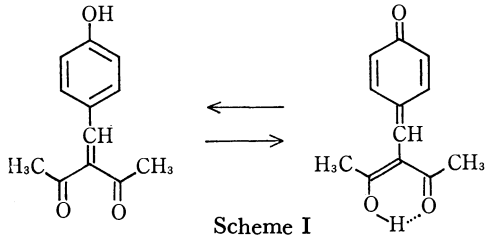
(Received September 4, 1974)

A thallous compound of 3-(*p*-hydroxybenzylidene)-2,4-pentanedione was synthesized and its structure was determined by means of the infrared and proton magnetic resonance spectra. This compound was regarded as a thallous phenolate derivative; however, the effect of chelation by the 2,4-pentanedionate moiety due to a long-range anionotropy was observed. The acetyl proton exchange of the Tl(I) compound in D_2O was observed by a PMR investigation. It was found that the methyl-proton exchange was inhibited by chelation.

Metal chelates of 2,4-pentanedione (acetylacetone), which behaves as an enol, have been well-studied. When two protons at the 3-position of acetylacetone are substituted, no stable metal chelates can be formed, since no such enolization can occur. Although 3-(*p*-hydroxybenzylidene)-2,4-pentanedione (POBAA) has no proton at the 3-position since it is occupied by a benzylidene linkage, it can be drawn as a pair of tautomers, in one of which the 2,4-pentanedione moiety enolizes by a long-range conjugation through the *p*-hydroxyphenyl group, as is shown in Scheme I. It can, therefore, be assumed that the tautomer forms metal chelates as ordinary acetylacetonates.



Scheme I

3-(*o*-Hydroxybenzylidene)-2,4-pentanedione was also considered to enolize in the same sense. It had been synthesized by the condensation of salicylaldehyde with acetylacetone.[1] It, however, turned out in our investigation that the product was not the diketo compound but a ketol, *i.e.*, 3-acetyl-2-hydroxy-2-methyl-2*H*-chromene. It is, therefore, omitted from the present investigation; the structure proof will be reported elsewhere.

Several attempts were made to isolate transition metal chelates of POBAA; however, they all resulted in failure. Only a thallous salt was isolated as crystals, and spectroscopic observations of it revealed that it was not a simple phenolate but was characteristic of a complex salt; the Tl(I) ion showed some interaction with the 2,4-pentanedione moiety, as had been expected. This paper will deal with the structure determination of the Tl(I) compound by means of electronic, infrared, and proton magnetic resonance spectroscopy. A thallous salt of 3-(*m*-hydroxybenzylidene)-2,4-pentanedione (MOBAA) was also investigated for the sake of comparison.

Experimental

All the melting points are uncorrected. The IR spectra were determined in potassium bromide disks with a Hitachi EPI-S2 spectrophotometer, while the electronic spectra were measured in ethanol with a Hitachi EPS-3T spectrophotometer. The PMR spectra were recorded at 60 MHz in $CDCl_3$, methanol, dimethylsulfoxide, and a D_2O solution with a Hitachi Model R-24 NMR spectrometer. The chemical shifts are quoted as τ values relative to tetramethylsilane in $CDCl_3$ or DSS (sodium 2,2-dimethyl-2-silapentane-5-sulfonate) in D_2O.

3-(p-Hydroxybenzylidene)-2,4-pentanedione (POBAA). A solution of 12.2 g (0.1 mol) of *p*-hydroxybenzaldehyde and 10.2 g (0.1 mol) of acetylacetone in 30 ml of ethanol was cooled to −15 °C; 30 drops of piperidine were then added to the solution at a temperature below −10 °C. After the solution had stood in a refrigerator for several days, the resulting yellow solid was collected and recrystallized from dilute ethanol to give 11.2 g (55.8%) of pale yellow needles; mp 125—127 °C.

Found: C, 70.86; H, 5.96%. Calcd for $C_{12}H_{12}O_3$: C, 70.58; H, 5.92%.

This compound is hydrolyzed to its original components by repeated recrystallizations from dilute ethanol.

3-(m-Hydroxybenzylidene)-2,4-pentanedione (MOBAA). *m*-Hydroxybenzaldehyde was used in place of *p*-hydroxybenzaldehyde; otherwise the procedure was the same as in POBAA synthesis. The product was recrystallized from ethanol to give 16.7 g (83.2% yield) of colorless crystals; mp 128—129 °C.

Found: C, 70.68; H, 6.07%. Calcd for $C_{12}H_{12}O_3$: C, 70.58; H, 5.92%.

Thallous Salt of POBAA and MOBAA. To a solution of POBAA or MOBAA in absolute ethanol we added an equimolar amount of freshly prepared thallous ethoxide[2] in absolute ethanol at room temperature. The resulting orange or yellow crystals were filtered and washed with absolute ethanol and dried over P_2O_5 at 50 °C in a vacuum.

POBAA-Tl (I), Found: C, 35.14; H, 2.77%. MOBAA-Tl (I), Found: C, 35.08; H, 2.75%. Calcd for $C_{12}H_{11}O_3Tl$: C, 35.34; H, 2.72%.

Results and Discussion

According to the molecular model of 3-benzylidene-2,4-pentanedione (BAA),[3] it seems to be impossible that all the double bonds including the two carbonyl groups are in one conjugated system, because the planarity of the molecule is impaired by the steric hindrance between the benzene ring and the *syn*-acetyl group. The methine proton exhibits a PMR peak in the low magnetic field at τ 2.51. This indicates that the proton and the benzene ring are coplanar.

There are two singlets, at τ 7.72 and τ 7.60, which are due to the two acetyl groups. The peak in the higher magnetic field can be assigned to the conjugation-free acetyl group which is at the *syn*-position to the phenyl group, and the lower one, to another acetyl group which is conjugated with the styryl moiety. In the region of carbonyl and olefinic stretching vibrations, BAA exhibits IR absorptions at 1711 (strong), 1662 (strong), 1620 (medium), and 1576 (weak) cm^{-1}. The absorption at 1711 cm^{-1} is assigned to the conjugation-free acetyl carbonyl, while the others are due to another acetyl carbonyl, an olefinic bond, a benzene ring, or their conjugated stretching vibrations.

In the cases of POBAA and MOBAA, the PMR spectra are shown in Fig. 1. The assignments of the peaks can be understood in the same way as those of BAA; the coplanar methine proton resonance appears at τ 2.60 in the former and at τ 2.50 in the latter. The singlets at τ 7.66 and τ 7.60 for POBAA and the singlets at τ 7.69 and τ 7.60 for MOBAA are assigned to the conjugation-free and the conjugated acetyl groups. The peak due to hydroxyl proton appears at τ 2.89 and at around τ 2.8 respectively. The infrared spectra of POBAA and MOBAA are shown in Fig.2, in which the stretching vibration of the conjugation-free acetyl carbonyl appears at 1705 cm^{-1} for the former and at 1702 cm^{-1} for the latter; in addition, the OH stretching vibrations are at 3350 cm^{-1} and at 3230 cm^{-1} respectively.

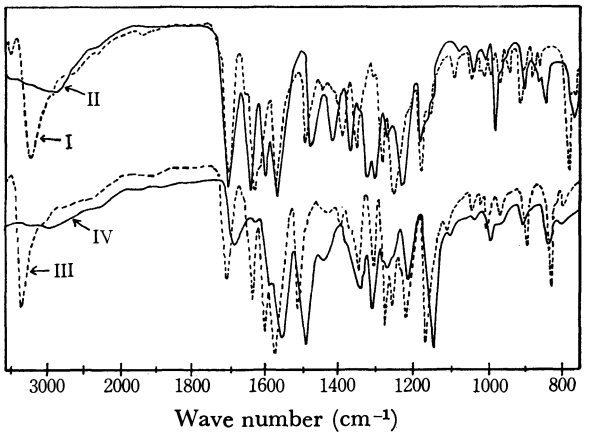


Fig. 1. IR spectra of I: MOBAA, II: MOBAA-Tl(I), III: POBAA, and IV: POBAA-Tl(I).

The ultraviolet absorption maxima of BAA, MOBAA, and POBAA in ethanol are: BAA: 208 nm (log ε: 3.99), 220 (3.92), 284 (4.24); MOBAA: 217 (4.11), 245 (3.98), 287 (4.21), around 330 (shoulder); POBAA: 218 (3.88), 235 (3.96), 327 (4.35). These strong absorptions due to π-π^* transitions indicate the presence of a long conjugated system. Judging from the highest degree of red shift in POBAA, the electronic contribution of the *p*-hydroxyl group is included in the conjugated system.

The Tl(I) salts of POBAA and MOBAA are soluble in polar solvents; however, their electronic absorption spectra in solution resemble those of the parent compounds. It is, therefore, assumed that POBAA-Tl(I) and MOBAA-Tl(I) both dissociate incompletely into the Tl(I) ion and the anion of POBAA or MOBAA in the solution. The PMR spectra of POBAA-Tl(I) and MOBAA-Tl(I) in D_2O are shown in Fig. 2. The PMR pattern of MOBAA-Tl(I) is nearly equal to that of MOBAA except for the absence of the peak due to a hydroxyl proton and the induced chemical shifts of the methine and phenyl peaks by the Tl(I) ion in MOBAA-Tl(I); it also exhibits the methine proton resonance at τ 2.31 and the two acetyl proton resonances at τ 7.67 and τ 7.56 respectively. It can be said that there is no fundamental difference in structure between MOBAA and MOBAA-Tl(I).

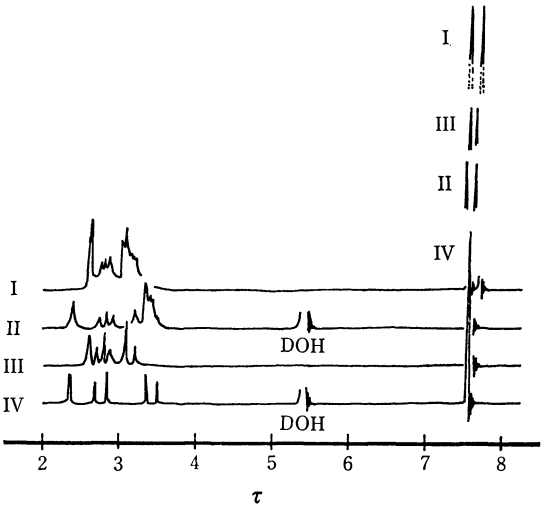

Fig. 2. PMR spectra of I: MOBAA and III: POBAA in $CDCl_3$, and II: MOBAA-Tl(I) and IV: POBAA-Tl(I) in D_2O.

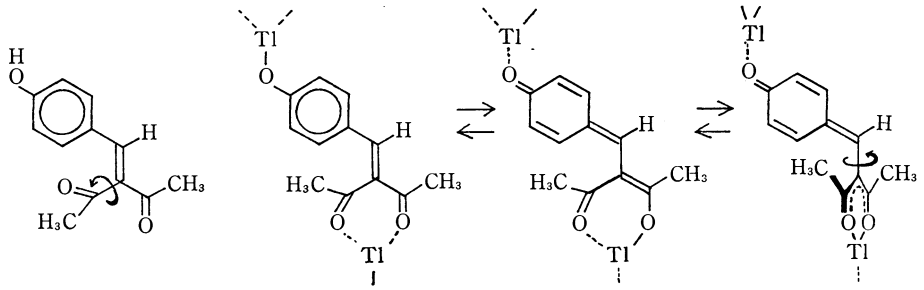
Between the PMR spectrum of POBAA and that of POBAA-Tl(I), a marked difference was observed. Two peaks due to the two kinds of acetyl protons in POBAA became one sharp peak at τ 7.59 in the Tl(I) salt in D_2O, while the methine proton peak shifted to the lower magnetic field and appeared at τ 2.37. The formation of such a singlet at around τ 7.5 was observed in methanol and dimethylsulfoxide as well as in D_2O. This means that all the acetyl protons of POBAA-Tl(I) are equivalent. Judging from the low τ value of the methine peak, the methine proton and the benzene ring are maintained in a coplanar configuration. If the molecule is fixed as a phenolate structure, the steric situation of the two acetyl groups, one of which is in the same plane as the benzene ring, while the other is out of the plane, can not differ from that of POBAA. The equivalence of the acetyl protons can be understood provided the acetyl groups are rapidly interconverted by a flip rotation of the 2,4-pentanedione moiety, as is shown in Scheme II. This explanation leads to the conclusion that the benzylidene C=C bond must have a single-bond character; hence, a long-range anionotropy should exist in the anion of POBAA.

The IR spectra of POBAA-Tl(I) and MOBAA-Tl(I) were compared with those of POBAA and MOBAA (Fig. 1). The band due to a hydroxyl group is necessarily absent in the Tl(I) compounds. Most remarkable is the difference between the IR peaks of POBAA-Tl(I)



POBAA POBAA–Tl(I)

Scheme II

and those of POBAA in the double-bond stretching region. The peaks of POBAA–Tl(I) are found to be broad and to shift to lower wave numbers compared with those of POBAA. This difference in the absorption pattern clearly reveals a change in the bond character from POBAA to POBAA–Tl(I), in which the electron delocalization or coordination of the diketone moiety to the Tl(I) ion takes part. The structure of POBAA–Tl(I) seems to consist of the planes of the anions of POBAA chained together by the Tl(I) ions. On the contrary, these situations are not observed in MOBAA–Tl(I).

It can thus be concluded that MOBAA–Tl(I) is a simple phenolate, while in POBAA–Tl(I), as a result of a long-range anionotropy, the diketone moiety interacts in part with the Tl(I) ion, as in acetylacetonates.

We also attempted to prepare transition-metal chelates of POBAA. When POBAA was heated in ethanol with each acetate of copper(II), nickel(II), and cobalt(II), or each chloride of cobalt(II) and iron(III), no complexes were obtained, and the hydrolysis of the ligand took place slowly in every case. The metal-ion-exchange reaction with POBAA–Tl(I) was thus examined. A mixture of POBAA–Tl(I) and anhydrous cobalt(II) chloride or anhydrous ferric chloride in absolute ethanol gave white precipitates of thallous chloride; however, all attempts to isolate the desired complex from the resulting filtrate were unsuccessful.

During the course of the PMR investigation of

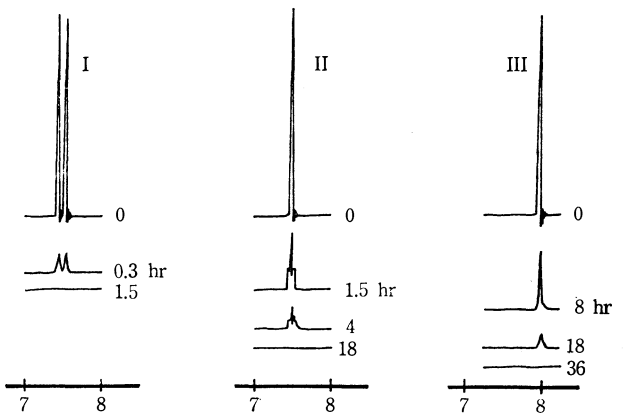


Fig. 3. PMR peaks due to acetyl protons of I: MOBAA–Tl(I), II: POBAA–Tl(I) and III: Tl(I)-acetylacetonate recorded at 35.5 °C at appropriate time intervals (hour) after being dissolved in D_2O.

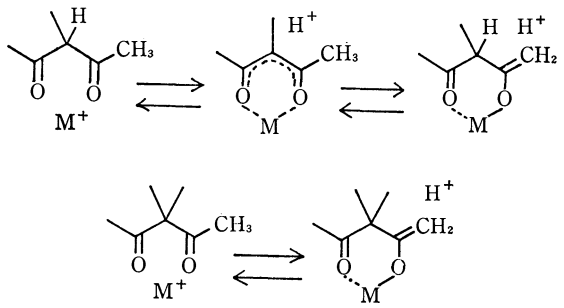

Scheme III

POBAA–Tl(I) in D_2O, a decrease in the intensity of the peak due to acetyl protons were observed with the time. This is clearly due to a hydrogen-deuterium exchange reaction in solution. The exchange rate was, therefore, compared with those of MOBAA–Tl(I) and Tl(I)–acetylacetonate;[4] the results are shown in Fig. 3. The decreasing order of the rate of the acetyl proton exchange is: MOBAA–Tl(I)>POBAA–Tl(I)>Tl(I)–acetylacetonate. This order is opposite to that of the stability of the complexes. From an inspection of the mechanism of the proton dissociation shown in Scheme III, it can readily be understood that the proton dissociation from the methyl group is necessary for MOBAA to form a chelate. In other words, the methyl proton of MOBAA is activated by the neighboring metal ion. On the other hand, acetylacetone forms stable metal chelates by the dissociation of the methylene proton at the 3-position. The methyl-proton activation, therefore, is inhibited by metal-chelate formation. The situation of POBAA–Tl(I) is in between, since the chelate ring stabilization is possible but incomplete because it can take place only with the long-range anionotropy, as has been discussed above. Since the relationship between such a proton exchange rate and the degree of activation of methyl protons has not yet been investigated, the systematic investigation of various thallous compounds is now in progress.

The Crystal Structure of α-Barium 12-Tungstosilicate, α-$Ba_2SiW_{12}O_{40}\cdot 16H_2O$

Akiko KOBAYASHI and Yukiyoshi SASAKI

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received August 1, 1974)

α-$Ba_2SiW_{12}O_{40}\cdot 16H_2O$ is monoclinic, space group C2/c, with $a=25.09(5)$, $b=12.10(2)$, $c=18.79(3)$ Å, $\beta=122.5(3)°$; $D_m=4.95$ g cm^{-3} and $D_x=4.78$ g cm^{-3} for $Z=4$. The crystal consists of the well known Keggin ion $SiW_{12}O_{40}^{4-}$, having a SiO_4 tetrahedron in the center, bound by Ba^{2+} and water molecules to form a three-dimensional framework. Four water molecules could not be located on electron-density maps, which seem to be disordered or "*zeolitic*". The structural relationship of the Keggin ion to its isomer, the β-$SiW_{12}O_{40}^{4-}$ polyanion found in β-$K_4SiW_{12}O_{40}\cdot 9H_2O$, is discussed. Mutual transformation between α- and β-isomers can occur through rotation of a W_3O_{13} group which is a building-unit of both α- and β-polyanions.

It was already known in the last century, that 12-tungstosilicic acid and its salts had two isomers referred to as α- and β-forms (or normal and iso-forms).[1] Acidification of an aqueous solution containing sodium silicate and sodium tungstate gives the α-isomer of the $SiW_{12}O_{40}^{4-}$ ion, while addition of acid to sodium tungstate solution prior to mixing with sodium silicate yields the β-isomer.[2,3]

Recent absorption spectrophotometric and polarographic studies have revealed that a number of related compounds, such as 12-tungstoborate,[2] 12-tungstogermanate,[3] 12-molybdosilicate,[4,5] 12-molybdogermanate,[6] 12-molybdophosphate, and 12-molybdoarsenate,[7,9] show a similar isomerism. In order to clarify the structural relationships between these pairs of isomers, we have undertaken a series of single crystal X-ray diffraction studies.

To start with, we have chosen α- and β-salts of 12-tungstosilicic acid. Owing to the presence of many heavy tungsten atoms, these salts are not suitable for an accurate structure determination. However salts of this acid are favorable for comparative study, since both α- and β-isomers are stable even in aqueous solutions and both can be obtained as separate crystalline samples. Other acids, particularly β-polyanions containing molybdenum atoms, seem to be short lived in aqueous solutions and are quickly converted into the corresponding α-forms.[4-9] The present paper deals with the structure of the α-isomer of 12-tungstosilicate, α-$Ba_2SiW_{12}O_{40}\cdot 16H_2O$. The structure of a β-isomer, β-$K_4SiW_{12}O_{40}\cdot 9H_2O$ was published elsewhere.[10]

The α-salts were widely believed to contain the well known "*Keggin molecules*", or more correctly "*Keggin polyanions*", even though a definite proof was lacking.[11] The guess was based on the fact that $CsHSiW_{12}O_{40}\cdot nH_2O$ ($n=0$ or 2) was isomorphous with $H_3PW_{12}O_{40}\cdot 5H_2O$[13] which was the first example of the "*Keggin structure*".[14]

Experimental

The α-form of 12-tungstosilicate was prepared by mixing a solution of sodium tungstate, sodium silicate and hydrochloric acid.[16] For purification, α-$SiW_{12}O_{40}^{4-}$ was treated with hydrochloric acid and extracted with ether, the extract was then converted to aqueous solution. The barium salt was obtained by neutralization of the polyacid solution with solid barium carbonate. The colorless tabular crystals were obtained from the neutral aqueous solution at >30 °C.

The α-$Ba_2SiW_{12}O_{40}\cdot 16H_2O$ crystals were chosen because of their stability in air and because of the absence of twin formation which is frequently encountered in heteropoly compounds. The crystals are stable at room temperature but begin to loose a part of the water of crystallization at 40 °C.

Thermogravimetric analysis and DTA have shown endothermic reactions at 120, 190 and 250 °C corresponding to the loss of eight, twelve and sixteen water molecules. For the purpose of the X-ray diffraction work a specimen in the form of an irregular rhombus with a maximum dimension of 0.25 mm was used. The intensities of reflections were measured on a Rigaku four-circle diffractometer with Mo$K\alpha$ radiation. The ω-2θ scan technique was employed and 2952 significant independent reflections for which $|F_o|\geq 141.0$ (F_o :absolute scale) up to $2\theta=60°$ were obtained. The data were corrected for Lorentz and polarization effects. No corrections were made for absorption. The crystal data are as follows:

α-$Ba_2SiW_{12}O_{40}\cdot 16H_2O$
F. W. 3438.7
monoclinic
a = 25.09 (5) Å
b = 12.10 (2) Å
c = 18.79 (3) Å
β = 122.5 (3)°
V = 4813 Å^3
space group C2/c
Z = 4 (D_m = 4.95 g cm^{-3}, D_X = 4.78 g cm^{-3})
μ (Mo$K\alpha$: 0.7107 Å) = 320 cm^{-1}

Since Wilson's statistics indicated the presence of a center of symmetry, the space group C2/c was assumed. The structure was solved by the heavy atom method. The atomic positions and anisotropic temperature factors of tungsten, barium and silicon atoms were refined by the block-diagonal least-squares method. At this stage the R-value was reduced to 0.16. After several refinement cycles including oxygen atoms of the anion with isotropic temperature factors, the R value was reduced to 0.14. There are eight crystallographically independent water molecules, of which six were found by a difference Fourier synthesis. After several further cycles, the structure converged to $R=0.13$.

A weighting scheme, $w=0.2$ for $|F_o|\leq 253.0$ and $w=1$, otherwise was employed. Atomic scattering factors were taken from "International Tables for X-ray Crystallography,"[15] and those for W and Ba were corrected for anomalous dispersion.[15]

Results and Discussion

The atomic parameters and their estimated standard deviations are listed in Table 1. The final F_o-F_c table

TABLE 1. ATOMIC PARAMETERS AND THEIR ESTIMATED STANDARD DEVIATIONS

The positional parameters of all the atoms and their anisotropic thermal parameters have been multiplied by 10^4. The anisotropic temperature factor is of the form $\exp[-(h^2B_{11}+k^2B_{22}+l^2B_{33}+2hkB_{12}+2hlB_{13}+2klB_{23})]$.

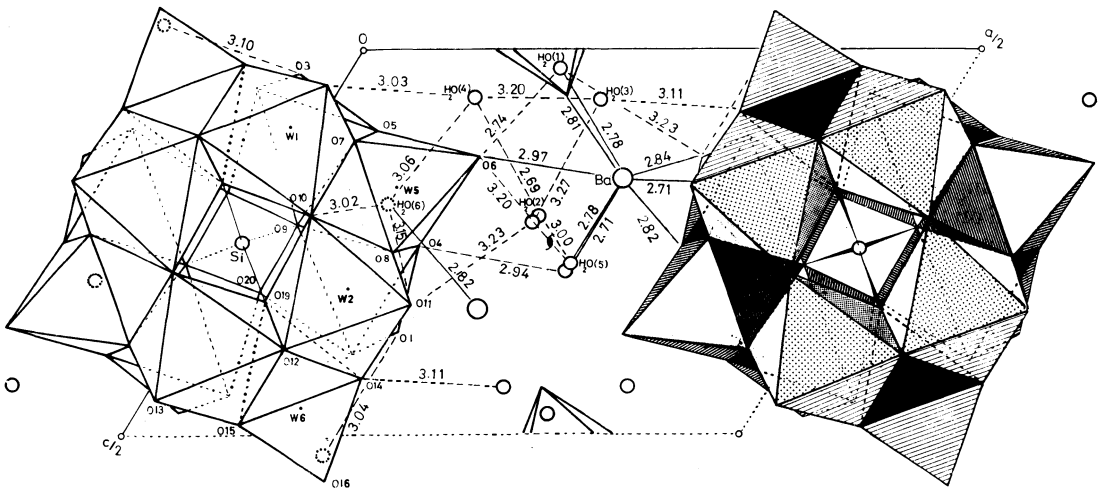

Fig. 1. A view of the structure as projected onto the (010) plane. Large circles represent Ba^{2+} ions and small circles water molecules. The coordination bonds around Ba^{2+} are designated by full lines, other close contacts by dotted lines.

is held by the office of the Chemical Society of Japan as Document No. 7504. The crystal structure projected along the b-axis is shown in Fig. 1. As is shown in this figure, the crystal consists of α-$SiW_{12}O_{40}^{4-}$ anions, Ba^{2+} cations and water molecules of crystallization. The center of the anion lies on a twofold rotation axis at $y=1/4$.

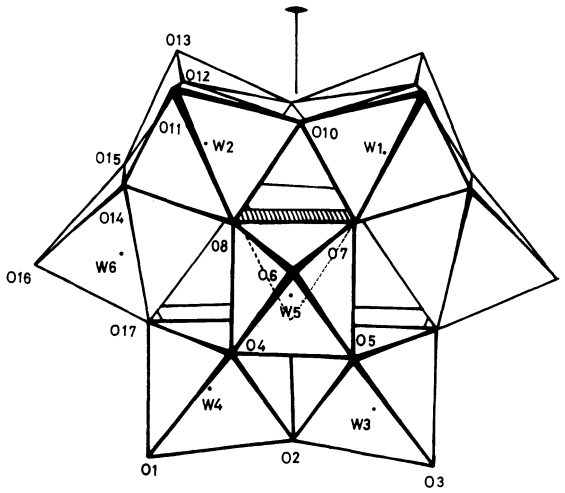

Fig. 2. A perspective view of the α-$SiW_{12}O_{40}^{4-}$ anion. Deformed octahedra represent WO_6 groups. The central SiO_4 tetrahedron, shaded on the figure, is only partly seen.

a) E.s.d.'s in parentheses in Tables 2 and 3 are in units of the last significant digit. b) Oa: the oxygen atom bound to one silicon and at the same time to three tungsten atoms. Ob: the oxygen atom bridging two tungsten atoms of two neighboring W_3O_{13} moieties. Oc: the bridging oxygen atom shared between two tungsten atoms belonging to a same W_3O_{13} group. Od: the terminal oxygen atom bonded to only one tungsten atom. c) Atoms with a prime are associated with those in Table 1 by a twofold axis.

Structure of α-$SiW_{12}O_{40}^{4-}$ Ion. A perspective drawing of α-$SiW_{12}O_{40}^{4-}$ anion is presented in Fig. 2. Interatomic distances and their e.s.d.'s within the anion are listed in Table 2. The anion consists of a central SiO_4 tetrahedral group in which each of the oxygen atoms is replaced by a W_3O_{13} unit constructed from three WO_6 octahedra sharing edges. Thus, the anion has the expected Keggin structure. This result confirms the proposed model for the structure of this anion in aqueous solution from a liquid X-ray diffraction study.[16] The structural relationships between α- and β-$SiW_{12}O_{40}^{4-}$ are now clear: the α-polyanion has the well known Keggin structure, whereas the β-anion has a lower symmetry and is a geometrical isomer of the Keggin structure. If a model of the α-polyanion is built with idealized polyhedra, a corresponding β-model can be obtained by a 60° rotation of one of the W_3O_{13} groups of the α-model.[10] All the WO_6 octahedra in α-$Ba_2SiW_{12}O_{40}\cdot 16H_2O$ are distorted. The bond lengths of W–Oa, W–Ob, W–Oc, and W–Od are 2.2—2.4, 1.8—2.0, 1.7—2.0, and 1.6—1.8 Å respectively as are listed in Table 2. Oa represents the oxygen atom attached to one silicon atom and to three tungsten atoms, Ob is shared between tungsten atoms of different W_3O_{13} units, Oc is also bound to two tungsten atoms but belonging to the same unit, and Od is the unshared terminal oxygen atom bonded to only one metal atom. These classifications of the oxygen atoms conform to those given by Evans.[17] These data seem to indicate that the octahedra are elongated in the direction of Oa, the oxygen atom attached to the central silicon atom, moreover the tungsten atoms are displaced outward from the diagonal line Oa—Od, as if the tungsten atoms are repulsing each other within a W_3O_{13} group, the Ob–W–Oc diagonal angles being 150(3)—161(3)°. Detailed discussion of the O–O distances was not possible, since the standard deviation was as large as 0.15 Å. The central SiO_4 tetrahedron is not quite regular. The bond distances are listed in Table 2.

Coordination Around Barium Cation. As shown in Table 3 and indicated by broken lines in Fig. 1, each barium ion is coordinated by eight oxygen atoms at distances of 2.7—2.9 Å, four from water molecules and four oxygen atoms (Od) from three adjacent $SiW_{12}O_{40}^{4-}$ anions. Table 3 shows oxygen-oxygen distances around $H_2O(1)$—$H_2O(6)$ and barium-oxygen distances. Six oxygen atoms form a distorted trigonal prism around a barium cation while the other two stick out of two rectangular faces of the prism.

Water of Crystallization. In general, crystals of polytungstates and polymolybdates contain many water molecules. Although it is important to clarify the role of these water molecules in the crystal structure, their position can not always be fixed with sufficient accuracy because of the presence of many heavy atoms. In the present case, twelve out of sixteen water molecules in the chemical formula, could be located while the remaining four are still missing. These water molecules might be "*zeolitic*", having large thermal vibration factors, and be correlated with the loss of water at a temperature as low as 40 °C.[18] Of the twelve water

a) Classification of oxygen atoms in the polyanion: see text and footnote of Table 2.

molecules whose position could be fixed, eight coordinate to two barium cations and at the same time some of them form hydrogen bonds with polyanions. The rest of the water molecules have some close contacts with the polyanion or with water molecules which are coordinated to barium ions. Thus barium cations and polyanions build up a three dimensional framework, accommodating water molecules in interstices.

Comparison of α-$Ba_2SiW_{12}O_{40}\cdot 16H_2O$ *with* α-$K_4SiW_{12}O_{40}\cdot 17H_2O$. The main difference between the crystal structures of the two tungstosilicates is that the barium salt consists of a three dimensional framework with mobile water molecules in interstices, while the potassium salt crystals contain one dimensional spiral chains made of alternate potassium cations and polyanions. There are large channels parallel to the spirals, and the three potassium ions and fifteen water molecules which could not be found by neutron and X-ray diffraction techniques are probably in random or mobile zeolitic state in these spaces; this structure explains the efflorescent nature of the potassium salt.

The calculations were performed on a HITAC 8700/8800 computer at the Computer Center of the University of Tokyo using a local version of UNICS.[20]

The authors wish to thank Dr. Hitoshi Iwasaki for reading through the manuscript and for his criticism. The work was financially supported by a Grant-in-aid for Cooperated Scientific Research of the Ministry of Education.

Structure of Polyvanadotungstates. I. The Crystal Structure of α-$(CN_3H_6)_4V_2W_4O_{19}$

Keiko NISHIKAWA,* Akiko KOBAYASHI, and Yukiyoshi SASAKI

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received September 26, 1974)

Crystals of α-$(CN_3H_6)_4V_2W_4O_{19}$ are monoclinic, space group $P2_1$, with the cell dimensions, $a=14.85(2)$, $b=19.48(2)$, $c=9.48(1)$ Å, $\beta=92.6(2)°$. The X-ray structure determination showed that $V_2W_4O_{19}^{4-}$ anion has the hexaniobate-type structure consisting of 6 edge-shared MO_6 octahedra. Each M position is randomly occupied by vanadium and tungsten atoms with a 2:4 probability. This randomness makes it impossible to determine whether $V_2W_4O_{19}^{4-}$ anion has the *cis* or *trans* configuration or both. The final R value was 0.086 with anisotropic temperature factors for metals and isotropic factors for other lighter atoms.

In an acidic aqueous solution, the orthotungstate ion WO_4^{2-} is condensed to isopolytungstate polyanions and the metavanadate ion VO_3^- forms isopolyvanadates. Isopolytungstate anions have no tendency to form an infinite polymer structure in crystals, and the existence of discrete anions with formulas $W_6O_{19}^{2-}$,[1] $W_{10}O_{32}^{4-}$,[2] $H_2W_{12}O_{40}^{6-}$ (metatungstate),[3] and $H_2W_{12}O_{42}^{10-}$ (paratungstate)[4] has been reported in the solid phase. On the other hand, it is known that isopolyanions containing vanadium(V) very often have infinite chain or sheet structures in crystals. The crystals of KVO_3 contain chains of VO_4 tetrahedra connected by sharing corners, and $KVO_3 \cdot H_2O$ has a chain structure made of VO_5 trigonal bipyramids sharing edges.[5]

There are no discrete $V_3O_8^-$ nor $V_5O_{14}^{3-}$ ions in CsV_3O_8[6] and $K_3V_5O_{14}$[7] crystals. In $[V_3O_8^-]_\infty$, VO_6 octahedra form plane sheets by sharing edges, and in $[V_5O_{14}^{3-}]_\infty$, VO_5 square pyramids and VO_4 tetrahedra are bound by sharing corners. The only discrete isopolyvanadate ion which has been reported is $V_{10}O_{28}^{6-}$ built by VO_6 octahedra sharing edges.[8,9] But when vanadium(V) and tungsten(VI) are both present in an acidic solution, crystals of "polyvanadotungstates", which are sometimes called "mixed isopolyanions", may be obtained. It has been reported that the composition of the vanadotungstates varies with the pH and the constitution of the solution.[10–17] Table 1 gives the analytical formulas of vanadotungstate anions so far reported as salts in crystals. No crystal structure work has been published on the vanadotungstate salts and it has not yet known whether these mixed isopolyanions have polymeric structures like the polyvanadates or contain discrete polyanions.

The present paper reports the structure of the guanidinium salt of $V_2W_4O_{19}^{4-}$ polyanion, $(CN_3H_6)_4V_2W_4O_{19}$, obtained from single crystal X-ray diffraction.

Experimental

The guanidinium salt was obtained by mixing a solution of guanidinium perchlorate at pH 4—6 with that of $Na_4V_2W_4O_{19} \cdot 14H_2O$. The sodium salt was prepared by concentration of an aqueous solution at pH 4—6 containing sodium salts of vanadate and of tungstate in the ratio of 1:2.[15]

Repeated preparations revealed the existence of three different guanidinium salts, which are denoted here α, β and γ. The α and β forms, having the same chemical formula $(CN_3H_6)_4V_2W_4O_{19}$, always precipitate together from solution at pH 4—6 as needles-like orange crystals. After several recrystallizations, almost pure α-form was obtained but the β-form could not be prepared in a pure state. The γ form precipitates from the same solution after a week as polyhedral crystals, but loses water of crystallization quickly in air. The crystal data for the α- and β-forms are shown in Table 2.

TABLE 2. CRYSTAL DATA FOR α- AND β-$(CN_3H_6)_4V_2W_4O_{19}$

α-$(CN_3H_6)_4V_2W_4O_{19}$	β-$(CN_3H_6)_4V_2W_4O_{19}$
F.W. 1381.3	F.W. 1381.3
Monoclinic	Orthorhombic
$a=14.85(2)$ Å	$a=14.43$ Å
$b=19.48(2)$	$b=20.49$
$c=9.48(1)$	$c=9.26$
$\beta=92.6(2)°$	
$V=2733$ Å^3	$V=2738$ Å^3
Space group $P2_1$	Space group $Pnm2_1$, $Pn2_1m$ or $Pnmm$
$Z=2$ (for $[(CN_3H_6)_4V_2W_4O_{19}]_2$)	$Z=4$ (for $(CN_3H_6)_4V_2W_4O_{19}$)
$D_m=3.38$ g/cm^3	
$D_x=3.39$ g/cm^3	
μ(MoKα)$=199.0$ cm^{-1}	

Reflection data for a specimen of the pure α-form were collected on a Rigaku four-circle diffractometer with MoKα radiation monochromated by a graphite crystal ($\lambda=0.7107$ Å).

* Present address: Department of Chemistry, Faculty of Science, Gakushuin University, Mejiro, Toshima-ku, Tokyo 171.

An ω-2θ scan technique was employed and 2362 independent reflections whose intensities are larger than 3σ up to $2\theta=60°$ were obtained. The data were corrected for Lorentz and polarization factors but not for absorption. The dimensions of the specimen used were approximately $0.1\times0.08\times0.14$ mm.

Structure Determination

The structure was solved by the heavy atom method. Twelve metal atoms forming two independent octahedral M_6 units were easily located. The coordinates of these two polyanions are related by pseudo-two fold screw axes parallel to the *a* and *c* axes which cause the observed extra extinction rule: *h*00 and 00*l* are absent or very weak if *h* or *l* is odd.

The positions of oxygen peaks suggested that six MO_6 octahedra are connected in a compact way by sharing edges to form the M_6O_{19} polyanion. Each M_6O_{19} anion must contain two vanadium atoms in either the *trans*- or *cis*-configuration,[18] but it was impossible to distinguish vanadium from tungsten on the Fourier maps. The best agreement between F_o and F_c was obtained by assuming that the twelve metal positions (M1—M6, M1′—M6′) are randomly occupied by vanadium and tungsten atoms with a 2:4 probability. Thus our data could be explained by randomly orientated *trans*- or *cis*-$V_2W_4O_{19}^{4-}$, and no conclusion could be drawn about the configuration of the $V_2W_4O_{19}^{4-}$ anion.

All the 82 atoms—12 metal, 38 oxygen, 8 carbon, and 24 nitrogen (hydrogen atoms were excluded)—are crystallographically independent. Of these, 70 atoms could be located. Three guanidinium ions were omitted as described in the Results and Discussion.

The atomic parameters were refined to $R=0.086$ by the block-diagonal least-squares method, using anisotropic temperature factors for the metal atoms and isotropic ones for the other atoms. The final positional parameters and temperature factors are shown in Tables 3 and 4. The F_o—F_c table is held by the Chemical Society of Japan as Document No. 7505.

The calculations were performed on a HITAC 8700/8800 computer at the Computer Center of the University of Tokyo using a local version of UNICS.[20]

The atomic scattering factors were taken from *International Tables for X-ray Crystallography*.[21] A weighting scheme with $w=1$ for $|F_o|\geq 101.3$ and $w=0.4$ otherwise was employed.

Results and Discussion

In Fig. 1, the $M_6O_{19}^{4-}$ ion (M=(2V+4W)/6) is shown as a "coordination polyhedral model" consisting of 6 edge-shared MO_6 octahedra. This is identical with the "hexaniobate structure" found by Lindqvist in $Nb_6O_{19}^{8-}$ [22] and by Henning and Hüllen in $W_6O_{19}^{2-}$.[1]

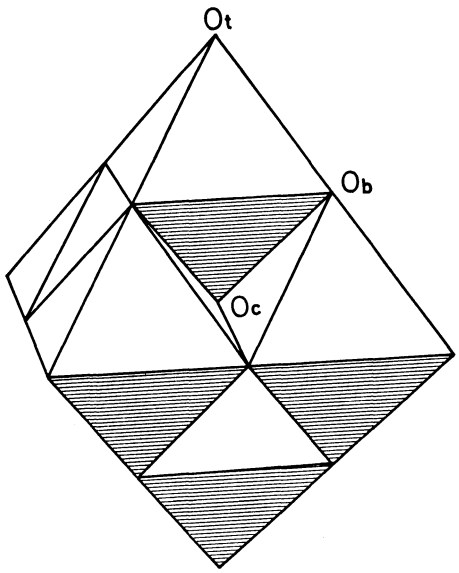

Fig. 1. The coordination polyhedral model of $M_6O_{19}^{4-}$ ion.

The distances between two adjacent metal atoms shown in Table 5 suggest that the M_6 octahedra are slightly deformed, but the reason for this is unknown. The metal atoms are not exactly at the center of each MO_6 octahedron but are displaced outward as if they are repulsing each other.

The oxygen atoms are classified according to the bonding pattern into three groups, Oc, Ob, and Ot. The M–Oc bond length ranges from 2.2 to 2.4 Å,

M–Ob 1.78—2.08 Å, M–Ot 1.60—1.82 Å (Table 6). The Oc oxygen atoms at the center of the polyanions are bound to six metal atoms, Ob is bound to two metal atoms forming a bridge, and Ot is the terminal oxygen atom and is bonded to only one metal atom.

The bond lengths shown in Tables 5 and 6 should be understood as averaged values of W–W and V–W or V–O and W–O distances because of the randomness

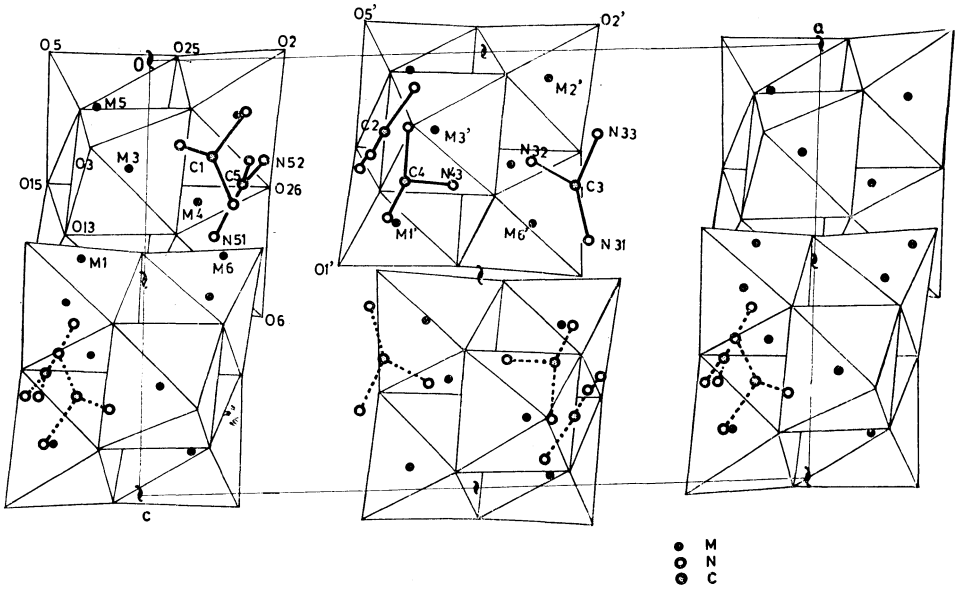

Fig. 2. A view of the structure as projected down the b axis. The dotted lines of guanidinium cations show that they are behind the anions.

already mentioned. In $W_6O_{19}^{2-}$, which has a similar structure, the W–W distances lie between 3.22 and 3.34 Å.[1] The $V_6O_{19}^{8-}$ ion seems to be too unstable to be isolated but V–V distances in the $V_{10}O_{28}^{6-}$ anion range from 3.05 to 3.19 Å.[8,9] It is understandable that the present crystals have intermediate values.

The guanidinium cation, $(CN_3H_6)^+$, has a flat triangular shape. Most of the NH groups form hydrogen bonds to Ob and Ot with O–N distances of 2.7—3.0 Å. Two diffuse peaks corresponding to guanidinium ions found in the Fourier map suggest a rotational disorder around the threefold axis. One of the guanidinium cations could not be found at all.

Flynn and Pope divided the vanadotungstates into two groups, namely the $Nv+Nw=6$ series and the $Nv+Nw=13$ series (Nv: number of vanadium atom, Nw: number of tungsten atom). They proposed the "hexaniobate structure" [22] for the first series, $V_nW_{6-n}O_{19}^{-(n+2)}$, and the Keggin structure $V^tV_nW_{12-n}O_{40}^{-(n+3)}$, for the second series, where V^t is the tetrahedrally coordinated central vanadium atom in a Keggin ion.[23] The present study, together with our unpublished structure determination of $K_7V_5W_8O_{40}\cdot 12H_2O$ crystals having the Keggin structure,[19] provides proof of Flynn and Pope's theory on the composition of vanadotungstates. The isopolytungstate, $W_{16}O_{19}^{2-}$ is unstable in aqueous solution and is easily hydrolyzed.[24] On the other hand, $V_2W_4O_{19}^{4-}$ is stable at pH 4—6 and $VW_5O_{19}^{3-}$ at 4. The latter ion will be isostructural to $W_6O_{19}^{2-}$ and to $V_2W_4O_{19}^{4-}$. The unstable $W_6O_{19}^{2-}$ ion seems to be stabilized by substitution of one or two tungsten atoms by vanadium.

The authors are indebted to Professor J. Fuchs of the Freie Universität Berlin, for his suggestion about Raman spectra, and to Dr. I. Harada of The University of Tokyo for his help in measuring Raman spectra. Thanks are also due to Professor M. T. Pope for his interest in the present work.

Thermal Products in the System of $NaPO_3$ Glass-Al_2O_3

Makoto WATANABE, Shoji SATO, and Hajime SAITO*

Department of Industrial Chemistry, Chubu Institute of Technology, Matsumoto-cho, Kasugai-shi, Aichi 487
**Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464*

(Received October 2, 1974)

The glassy and crystalline products were made by heating a mixture of aluminum oxide and sodium metaphosphate glass with P/Al ratios in the range from 1.0 to 300 at 1000 °C for 3 hr. The crystalline substance was present in the products with P/Al ratios smaller than 5.0 and was, except for aluminum oxide, always aluminum orthophosphate. The quantitative analysis and the measurement of the average chain length of the phosphates contained in the soluble parts of the products showed that aluminum oxide reacts with sodium metaphosphate to make Al–O–P linkages. A theoretical treatment of the average chain length of the polyphosphates present in the aluminate-phosphates was also made. By comparing the calculated average chain length with the measured one, it has been concluded that the most reasonable chemical structure of the glassy products of the aluminate-phosphates is $Al(OP)_3$. By the analysis of the infrared spectra of the thermal products, four-way branching points may be said to exist in the glassy products.

From the viewpoint of pure chemistry, the thermal products of arsenate-phosphates,[1] silicate-phosphates,[2] vanadate-phosphates,[3] and borate-phosphates[4,5] have been studied in to obtain some information on the reactivity between these oxo-acid salts at a moderately high temperature and on the chemical structures of the products. By analyzing the hydrolysis products, it has been revealed that there is a P–O–As, P–O–Si, P–O–V, or P–O–B linkage in each of the products. The authors also studied antimonate–phosphates,[6–8] molybdate–phosphates,[9] and tungstate–phosphates;[9] it has been concluded that they have a P–O–Sb, P–O–Mo, or P–O–W linkage respectively. The most reasonable chemical structure of the glassy products has also been reported.

It is well known that aluminum ions react with orthophosphoric acid to form an aggregation polymer, which have three-dimensional networks, in water.[10] In aluminate-phosphates or borate-phosphates, the presence of a four-way branching point was pointed out by Van Wazer.[11] In the present paper, the thermal products of the $NaPO_3$–Al_2O_3 system have been made in an attempt to obtain some information on the structure of the products in connection with the information mentioned above.

Experimental

Materials and Procedure. All the materials used other than sodium metaphosphate were of a commercial grade. The sodium metaphosphate was made by heating monosodium orthophosphate in a platinum crucible at 1000 °C for 3 hr and by then quenching the melt by placing the crucible in ice water. A mixture of sodium metaphosphate and α-aluminum oxide with P/Al ratios in the range from 1.0 to 300 was heated in a platinum crucible at 1000 °C for 3 hr; the resulting product was quenched by the method used in the preparation of sodium metaphosphate.

Paper Chromatography. One-dimensional paper chromatography was used for the separation of phosphate species contained in the products by using acidic and basic solvents. The compositions of the solvents are listed in Table 1. The acidic solvent was used for the separation of ortho-, pyro-, tri-, and long-chain phosphates, while the basic solvent was used for the separation of trimeta- and tetrametaphosphates. About one gram of the product was placed in 50 ml of water, and then the mixture was stirred for one hour at room temperature. The insoluble parts were then filtered off, dried, and weighed for the measurement of the solubility of the product. About 5 μl of the sample solution was spotted on a filter paper of Toyo No. 51A (2 by 50 cm) and developed for 40 hr at 5 °C. After the filter paper had then been dried at 75 °C for more than 30 min, a perchloric acid-molybdate solution was sprayed on the paper. The paper was dried again and exposed to ultraviolet rays until blue spots appeared. The identification of each spot on the chromatogram was made by comparing the spots with those of known phosphates.

TABLE 1. COMPOSITION OF THE SOLVENTS USED FOR THE PAPER CHROMATOGRAPHY

Acidic solvent	Isopropyl alcohol	70 ml
	25% aqueous trichloroacetic acid	20 ml
	Water	10 ml
	28% aqueous ammonia	0.3 ml
Basic solvent	Isopropyl alcohol	38.7 ml
	Isobutyl alcohol	20 ml
	Water	40 ml
	28% aqueous ammonia	0.5 ml

Colorimetric Determination of Phosphates. The determination of the phosphates on a chromatogram was carried out by the colorimetric method described in a previous paper.[6]

The Measurement of the Average Chain Length of Polyphosphates. The method used in our previous paper[6] was adopted for the measurement of the average chain length of polyphosphates contained in the thermal products, but since aluminum ions present in the sample solution strongly affected the pH titration of the solution, the aluminum ions were previously removed by the oxine method.[12]

X-Ray Diffractometry. The samples were ground with an agate mortar until they could pass through a 150 mesh sieve. Their X-ray diffraction patterns were taken by means of a powder method using a Toshiba X-ray diffractometer, ADG-102.

Infrared Spectral Measurement. The infrared spectra of the products were recorded on a JASCO infrared spectrophotometer, model IR-G, by the KBr tablet method.

Results and Discussion

Solubility and Identification of Crystalline Products by X-Ray Diffractometry. The results of the measurement of the solubility of the products and of the identification of the crystalline products by X-ray diffractometry are listed in Table 2. The identification was carried out by comparing the X-ray diffraction peaks of the products with those on ASTM cards. All the X-ray peaks of the products were due to aluminum oxide and/or aluminum orthophosphate. According to the above results, it could be concluded that the P–O–P linkages of high polyphosphate in this system are broken to make aluminum orthophsophate at 1000 °C. The insoluble parts in the products with the P/Al ratios in the range from 7.0 to 15 were amorphous.

TABLE 2. AMOUNT OF WATER-SOLUBLE PARTS OF THE PRODUCTS AND IDENTIFICATION OF THE CRYSTALLINE PRODUCTS BY X-RAY DIFFRACTOMETRY

P/Al	X-Ray diff.	Water-soluble parts (%)
1.0	Al_2O_3, $AlPO_4$	3.1
2.0	Al_2O_3, $AlPO_4$	3.6
2.5	$AlPO_4$	13
3.0	$AlPO_4$	29
5.0	$AlPO_4$	67
7.0	glassy	87
10	glassy	98
15	glassy	99
20—300	glassy	100

80	0.5	0.3	1.0	2.8	2.1	93.3
100				3.5	2.3	94.2
150				2.6	2.5	94.9
200				2.8	3.1	94.1
300				3.0	2.9	94.1

Distribution of Phosphates. The results of the colorimetric determination of phosphates in the soluble parts of the products are shown in Table 3. The contents of ortho-, pyro-, and tripolyphosphates decrease with an increase in the P/Al ratio, while those of high-polyphosphates increase with an increase in the P/Al ratio. This tendency is the same as that reported in previous papers.[1–4,6–9] By analogy with the previous papers, it can reasonably be concluded that sodium metaphosphate reacts with aluminum oxide to make an Al–O–P linkage at 1000 °C and that the Al–O–P linkage of the water-soluble products is readily hydrolyzed in a water solution. Since the contents of trimeta- and tetrametaphosphates so not change much with the variation in the P/Al ratio, the formation of the metaphosphates may be little affected by aluminum.

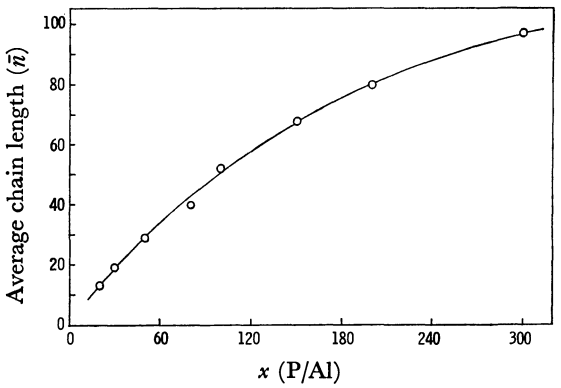

Fig. 1. Variation of average chain length of polyphosphates present in the products with P/Al ratios larger than 20

Average Chain Length of Polyphosphates and the Chemical Structure of Glassy Products. In aluminate-phosphates, the coordination number of aluminum can be four. The behavior of aluminum in the glassy products studied in the present paper can be examined by measuring the correlation between the average chain length of polyphosphates and the P/Al ratio. To obtain the correlation, it is necessary that the thermal product is dissolved completely in water. Therefore, the average chain length of the polyphosphates present in the glassy products with P/Al ratios larger than 20 were measured; the results are shown in Fig. 1. It may clearly be seen that the average chain length of the polyphosphates contained in the glassy products increases with an increase in the P/Al ratio. This tendency is the same as that found in the colorimetric determination of phosphates. The correlation between the coordination number of aluminum and the average chain length of polyphosphates in the thermal products can be considered theoretically by the method described in previous papers.[2,6–9] According to the theory, the relation between the P/Al ratio and the average chain length of polyphosphates can be written as follows:

$$(\bar{n}+2)/\bar{n} = (x+y-z+fx)/x$$

where $\bar{n}$ is the average chain length of polyphosphates, where x, y, and z are, respectively, the number of phosphorus atoms, P–O–Al linkages, and Al–O$^-$ linkages per atom of aluminum, and where f is the factor shortening the chain length of the polyphosphates, given with respect to an atom of phosphorus. It is known by previous experiments[2,6–9] that the value of f is in the range from 0.01 to 0.025 under the conditions employed in this experiment. The bonding formulas

a) The models refer to Table 4.

of aluminum with phosphates in glassy products are shown in Table 4. Other structures could be described for the system, but it can readily be seen in the following discussion that the other structures are unreasonable for the system. The calculated values of $\bar{n}$ based on the chemical structures in Table 4 are listed in Table 5. As may clearly be seen in the table, when the f factor is 0.01, the calculated values of $\bar{n}$ based on the IA structure in Table 4 are very close to the measured ones throughout the range of P/Al ratios from 20 to 300. From these results, it may reasonably be concluded that the chemical structure of the glasses of the Al_2O_3–$NaPO_3$ system with P/Al ratios larger than 20 is the IA structure in Table 4. This also means that the valence of aluminum, which contributes to the shortening of the chain length of polyphosphates, is three.

Infrared Spectra. The infrared spectra of sodium metaphosphate glass and the glassy products with P/Al ratios of 3.0, 5.0, and 7.0 are shown in Fig. 2. Since the infrared spectra of the glassy products with P/Al ratios larger than 7.0 are the same as that of sodium metaphosphate, the existence of the absorption of the Al–O–P linkages in the glassy products with P/Al ratios larger than 20 can not be discussed. According to Corbridge and Lowe,[13] the absorption of 1270 cm^{-1} in the spectrum of sodium metaphosphate may be

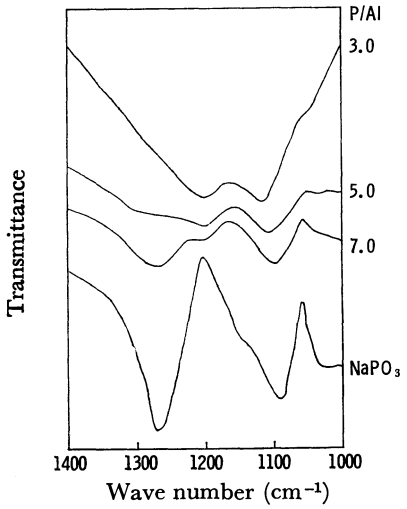

Fig. 2. IR spectra of the products with P/Al ratios from 3.0 to 7.0 and $NaPO_3$ glass

considered to be due to P=O stretching. When the P/Al ratio decreases from 7.0 to lower values, this absorption shifts to lower wave numbers in the spectra of the products. It can be concluded that the bonding force of the P=O bond decreases with a decrease in the P/Al ratio. This phenomenon can be explained as a P=O bond transfers to the P=O=Al bond by the coordination of aluminum. By extending this result to the glassy products with P/Al ratios larger than 10, it can be said that four-way branching points may exist in the glassy products.

(Received October 22, 1974)

The hydrolysis of long-chain polyphosphates (Graham's salt) was carried out in water and dioxane–water solvents at various pHs in the range from 3.0 to 11.0 and at 30, 50, and 70 °C. The rates of the hydrolytic degradation of the polyphosphates into shorter chains and into trimetaphosphate obeyed the first-order kinetics with respect to the concentration of the polyphosphates. In acidic media, a small solvent effect was perceived on the rates of both the processes. On the other hand, in basic media the effect was very remarkable; that is, the rates of both the processes in the dioxane–water solvent were more rapid than in water. The results show that the rate of the hydrolysis of both the processes in basic media may be very dependent on the step of the nucleophilic attack of a water molecule on the phosphorus atom of phosphates, while in acidic media other factor, for example, the folding of the chains to a helix, may affect the overall rate. The activation energies for the two processes have been found to be 22—26 kcal/mol in the pH range from 3.0 to 7.0.

The hydrolysis of long-chain polyphosphates has been studied by several investigators.[1–4] According to them, there are two processes for the hydrolytic degradation of the polyphosphates. One is the hydrolysis into shorter chains, and the other is the degradation into trimetaphosphate. Both the processes have been found to be pH-dependent and to be catalytically accelerated by metal ions. The catalytic effect increases in this order; K<Na<Li<Ba<Sr<Ca<Mg<Al. Their kinetic studies also prove that the processes follow a first-order law with respect to the concentration of polyphosphates. In our own previous paper,[5] the solvent effect on the hydrolysis of pyro- and tripolyphosphates was examined from the viewpoint of the nucleophilicity of a water molecule. In the present paper, the solvent effect on the hydrolysis of the polyphosphates will be examined by using dioxane–water and water as solvents at various pH values and temperatures. Since the hydrolysis of the polyphosphates at a low temperature is very slow, only the hydrolysis at 70 °C was achieved for all the pH values.

Experimental

Materials and Procedure. All the materials used other than the glassy, high-molecular-weight polyphosphates (Graham's salt) were of a commercial grade. The polyphosphates were prepared by heating monosodium orthophosphate in a platinum crucible at 1000 °C for 3 hr and by then rapidly quenching the resulting melt by placing the crucible in ice water. Since the polyphosphates invariably contained 2—3% (as phosphorus %) of trimetaphosphate, the corresponding adjustment was made to the analytical results of the contents of the hydrolysis products. Water and 15 vol% aqueous dioxane were employed as solvents. The initial concentration of the polyphosphates was 0.025 mol/l. About 25 ml of the solution was transferred into a test tube, and the pH of the solution was controlled at a reaction temperature by adding nitric acid and aqueous tetramethylammonium hydroxide or sodium hydroxide by means of a Hitachi-Horiba pH meter, F-5. The test tube was stoppered to prevent evaporation of the solvent. The tube was then placed in water in a thermostat, and the temperature was maintained at 30, 50, or 70±0.05 °C. A measured sample of this solution was withdrawn by using a microsyringe as soon as the treatment mentioned above was finished; this sample was spotted on to chromatograms. At measured intervals of time, further samples were similarly taken out for quantitative chromatographic analysis. The pH of the solutions was periodically measured and maintained at the required pH by adding nitric acid, aqueous tetramethylammonium hydroxide, or aqueous sodium hydroxide. The pH adjustment of the solution by adding sodium hydroxide was made only at pH 11.0. Since the sodium ion affects the rate of the hydrolysis of the polyphosphates, the quantity of the sodium ion in water and dioxane–water solvents was made identical. The pH adjustment was done within ±0.2 pH unit of the required value.

Chromatography. One-dimensional paper-chromatographic separation were carried out by using filter paper of Toyo No. 51A of 2×50 cm. Sample solutions (8 μl) were placed at the starting point of the filter paper and developed at 3 °C for 50 hr by using an acidic or basic solvent. After the development, the chromatograms were dried in an oven at 75 °C for more than 30 min and then sprayed with a perchloric acid molybdate solution.[6] The papers were subsequently dried for about 10 min at 50 °C and exposed to ultraviolet rays until blue zones appeared. The compositions of the acidic and basic solvents are tabulated in Table 1. The former was used for the separation of ortho-, pyro-, tripoly-, and long-chain polyphosphates, while the latter was used for the separation of trimeta- and tetrametaphosphates.

Quantitative Analysis of Phosphates on Chromatograms. The contents (P%) of phosphates on the chromatograms were determined by means of the same colorimetric method used in our previous paper,[5] using a Hitachi 101 spectrophotometer.

Table 1. Composition of the solvents used for paper chromatography

Acidic solvent	Isopropyl alcohol	70 ml
	25% aqueous trichloroacetic acid	20 ml
	Water	10 ml
	28% aqueous ammonia	0.3 ml
Basic solvent	Isopropyl alcohol	20 ml
	Dimethylformamide	20 ml
	Methyl ethyl ketone	20 ml
	Water	39.1 ml
	28% aqueous ammonia	0.9 ml

Results and Discussion

All attempts to obtain high-molecular-weight polyphosphates free from a trimeta-ring were unsuccessful. The average chain length of the polyphosphates was measured by the pH titration method[7,8] and found to be about 100. The straightforward hydrolytic degradation of the polyphosphate chains into shorter chains and their degradation to trimetaphosphate occurred according to a first-order law with respect to the concentration of polyphosphates under all the conditions studied. The values of the specific rate constants, k_H for the hydrolysis of polyphosphates, and k_D for the splitting out of trimetaphosphate, are listed in Table 2 for the various temperatures and pH values. Since the rates of the hydrolysis of trimetaphosphate at pH 3.0 and 11.0 can not be ignored in comparison with that of the formation of trimetaphosphate from the polyphosphates, k_D was not measured at those pH values. In the case of the hydrolysis of the polyphosphates in a water solvent, both the rate constants decrease with an increase in the pH value at any reaction temperature. This tendency has been well substantiated.[1-4] However, the decrease at 50 and 70 °C in the pH range from 7.0 to 9.0 seems to be less than that obtained by Gill and Riaz.[4] This may be attributed to the difference in cations added to the polyphosphate solutions for the adjustment of the background pH. As for the hydrolysis of the polyphosphates in the dioxane–water solvent, the pH-dependency of both the reaction constants is not the same as that in a water solvent. In an acidic medium, both the rate constants of the reactions in the dioxane–water solvent are the same as, or a little smaller than, those of the reactions in a water solvent at the same pH value. On the other hand, in the polyphosphate solutions with pH values larger than 7.0, the reaction rates of both the processes in the aqueous dioxane are faster than those in a water solvent; the larger the pH value of the solution, the more remarkable is this tendency.

In our previous paper,[5] the solvent effects on the hydrolysis of pyro- and tripolyphosphates have been studied, and it has been concluded that a water molecule in aqueous dioxane has a larger nucleophilicity than in water throughout the pH range from 1.0 to 2.5. From the results of the examination of the catalytic effect of metal cations on the polyphosphate degradation, Wieker and Thilo proposed a mechanism for the degradation.[3] According to them, a positivation of the phosphorus atoms of the polyphosphates may be supposed to be the reason for the catalytic effect of the metal cations. In our previous work,[5] taking into account the findings that the hydrolyses of pyro- and tripolyphosphates are acid-catalyzed reactions, the same positivation of the phosphorus atoms of the phosphates was also proposed for the hydrolysis of the phosphates. On the basis of these results, and considering that the hydrolysis of the polyphosphates is also an acid-catalyzed reaction, one can describe a series of elementary reactions for the hydrolysis of the polyphosphates as follows:

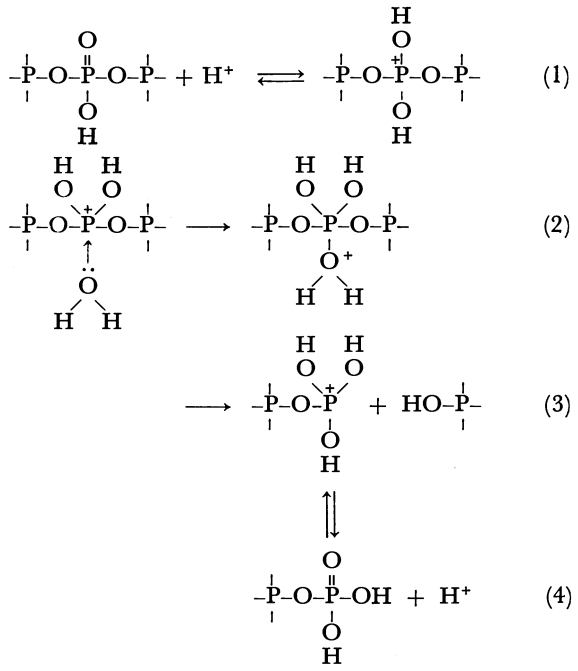

Table 2. Rate constants (min^{-1}) of the degradation of polyphosphates

pH	Solvent[a]	Reaction temp. (°C) 30 k_H	30 k_D	50 k_H	50 k_D	70 k_H	70 k_D
3.0	S_1	2.90×10^{-5}		4.29×10^{-4}		4.74×10^{-3}	
	S_2	2.73×10^{-5}		4.07×10^{-4}		4.39×10^{-3}	
5.0	S_1			1.10×10^{-5}	4.52×10^{-6}	1.97×10^{-4}	5.51×10^{-5}
	S_2			1.14×10^{-5}	3.56×10^{-6}	1.74×10^{-4}	4.40×10^{-5}
7.0	S_1	6.80×10^{-7}	4.04×10^{-7}	6.99×10^{-6}	4.40×10^{-6}	5.50×10^{-5}	3.62×10^{-5}
	S_2	7.80×10^{-7}	5.48×10^{-7}	7.84×10^{-6}	5.31×10^{-6}	6.40×10^{-5}	4.02×10^{-5}
9.0	S_1			6.55×10^{-6}	3.02×10^{-6}	5.40×10^{-5}	3.55×10^{-5}
	S_2			9.79×10^{-6}	5.45×10^{-6}	8.38×10^{-5}	5.41×10^{-5}
11.0	S_1			5.79×10^{-6}		5.31×10^{-5}	
	S_2			1.00×10^{-5}		9.57×10^{-5}	
11.0	S_1Na					1.09×10^{-4}	
	S_2Na					1.95×10^{-4}	

a) S_1 and S_2 stand for water and 15 vol % aqueous dioxane respectively, and Na represents that the pH of the solution is controlled by aqueous sodium hydroxide.

For the hydrolysis of the polyphosphates in a basic solution, the second step can be considered to be the rate-determining step, because the rate of the hydrolysis of both the processes is very dependent on the nucleophilicity of a water molecule.

Because of the formation of ring phosphates larger than trimetaphosphate as hydrolysis products of polyphosphates, it has been concluded that, when polyphosphates are dissolved into water, the folding of the chain into a helix occurs with a random number of PO_4 tetrahedra in the repeating units, and that in the repeating unit of three PO_4 tetrahedra is statistically the most likely. In an acidic medium, it can hardly be considered that the first, second, and fourth steps influence the rate of the overall-hydrolytic reaction of polyphosphates, because the steps may be very rapid reactions. Since no solvent effect as in a basic medium is recognized in acidic systems, the rate of the overall reaction may be little dependent on the third step. Therefore, the overall-reaction rate seems to reflect the effects of other factors—for example, the folding of the chain into a helix. In order to examine the idea, the activation energies and log A (A; frequency factor) at pH 3.0 (for k_H) and 7.0 (for k_H and k_D) were calculated by the use of an Arrhenius plot; they are listed in Table 3. For the overall-hydrolytic degradation of the polyphosphates, in spite of the increase in the reaction rate, the activation energy increases with a decrease in the pH value. This result suggests that the contribution of an entropy term to the rate of the degradation is more important than that of an energy term in an acidic solution, and seems to support the consideration concerning the hydrolytic mechanism of polyphosphates presented above. The activation energies, listed in Table 3, of the degradation of the polyphosphates into trimetaphosphate at pH 7.0 are very similar to that obtained by Gill and Riaz.[4]

Table 3. Activation energy, ΔE_A (kcal/mol) and log A (A; frequency factor) of the hydrolysis of polyphosphates

pH	Solvent[a]	Process[b] P_1 ΔE_A	P_1 log A	P_2 ΔE_A	P_2 log A
3.0	S_1	26.2	14.4		
	S_2	26.2	14.3		
7.0	S_1	22.7	10.2	23.3	10.4
	S_2	22.4	10.0	22.1	9.7

a) S_1 and S_2 represent water and 15 vol% aqueous dioxane respectively. b) P_1 and P_2 stand for the hydrolysis of polyphosphates and the hydrolytic splitting out of trimetaphosphate respectively.

The results of the hydrolytic degradation of the polyphosphates in an aqueous sodium hydroxide solution are also listed on the lowest two lines in Table 2. It can clearly be seen that sodium ions have a catalytical effect on the hydrolysis of polyphosphates and that the solvent effect is also very remarkable.

Analysis of Metals by Solid-Liquid Separation after Liquid-Liquid Extraction. Spectrophotometric Determination of Some Metals by Extraction of Metal Complexes with Molten Naphthalene

Taitiro FUJINAGA, Masatada SATAKE, and Tatsuo YONEKUBO*

Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

**Faculty of Engineering, Fukui University, Fukui 910*

(Received October 25, 1974)

A procedure is described for the spectrophotometric determination of metals after extraction with molten naphthalene. Some metal ions react in aqueous solution with complex-forming reagents such as oxine, 2-methyloxine, dimethylglyoxime or α-benzil dioxime to form water-insoluble complexes in certain pH ranges, the complexes being easily extracted into molten naphthalene. The extracted mixture of metal complex and naphthalene is dissolved in dimethylformamide and the amount of each metal is determined spectrophotometrically. The working range of metal ion concentration and effect of various factors such as pH, amount of reagent and naphthalene were studied, and the molar absorptivity, sensitivity and relative standard deviation evaluated.

Spectrophotometric determination of metals in aqueous solution after extraction of their complexes with organic solvent have been widely employed in the analysis of trace amount of metal ions. However, the method is not applicable when the solubility of the complexes in the solvent is small.

We have developed a new method "solid-liquid separation after liquid-liquid extraction," and have applied it to the determination of copper,[1,2] zinc,[3] magnesium,[4] and cadmium[5] with oxine as the complex-forming reagent, and to that of nickel[6] and palladium[7] with dimethylglyoxime. The method is based on the formation of metal complex which is extractable quantitatively with molten naphthalene. After the mixture of solidified complex and naphthalene have been cooled, it is dissolved in adequate organic solvent and the amount of metal in the solution is determined spectrophotometrically. The method is useful for the determination of metals such as zinc, magnesium or cadmium, since direct extraction of the complex with conventional solvents such as benzene or chloroform is very difficult owing to its hydrated structure. Each complex is easily extracted at high temperature merely by being put in contact with molten naphthalene. The extract is easily dissolved in dimethylformamide to develop intense coloration of the stable complex. In the present paper, successful extraction of the following complexes into molten naphthalene is presented: oxine complex of copper, zinc, magnesium and cadmium, 2-methyloxine complex of copper, dimethylglyoxime complex of nickel, and α-benzildioxime complex of nickel.

Experimental

Reagents. Standard 0.01 M metal solutions. Stock solutions of copper, zinc, magnesium, cadmium and nickel were prepared by dissolving copper sulfate, zinc sulfate, magnesium chloride, cadmium chloride and nickel sulfate of reagent grade in water weakly acidified with a few drops of concentrated sulfuric acid or hydrochloric acid and standardized chelatometrically. It was diluted suitably before use.

1% oxine and 2-methyloxine solutions. Prepared by dissolving 1.0 g of oxine or 2-methyloxine in 2 ml of glacial acetic acid on a water bath and diluting to 100 ml with water.

0.5% dimethylglyoxime and 0.02% α-benzil dioxime solutions in ethanol.

Buffer solutions. Mixtures of 1 M acetic acid and 1 M sodium acetate, 0.5 M disodium hydrogen phosphate and 0.5 M potassium dihydrogen phosphate, or 1 M ammonia water and 1 M ammonium chloride.

Redistilled demineralized water was used.

Naphthalene, dimethylformamide and all other reagents were of analytical reagent grade and used without further purification.

Apparatus. A Hitachi Model 124 spectrophotometer was used for the absorbance measurements with matched 10 mm glass cells. A Toa-Dempa HM-6A pH meter equipped with combined glass and calomel electrodes was used for pH measurements.

Procedure. Transfer an aliquot of standard metal solution to a tightly stoppered 80 ml Erlenmeyer flask and

dilute to about 30 ml with water. Add the complex-forming reagent and then adjust the pH with a buffer solution. Mix the solution well and allow it to stand for 15 min and then warm gently on a water bath at 60 °C until a precipitate of the metal complex appears. Add 2.0 g of naphthalene and heat the mixture to 90 °C. Shake it vigorously till naphthalene solidifies forming fine crystals. Melt it again and shake well, then allow it to cool to room temperature. Warm it again and slowly melt the very fine solidified crystals suspended in the solution, letting them grow to a larger crystalline deposit. After cooling it at room temperature, separate the solidified deposit on a filter paper, wash with water and blot the surplus water with a dry filter paper. Dissolve the deposit with dimethylformamide. Transfer the solution to a 25 ml volumetric flask, fill with dimethylformamide up to 25 ml, and measure the absorbance of the solution in a 10 mm cell against the reagent blank.

Results and Discussion

Figures 1 and 2 show the absorption spectra of metal complexes in naphthalene–dimethylformamide solution against the reagent blank. These complexes have their absorption maxima in the range 370—410 nm, whereas the reagent shows no absorption above 370 nm.

Figure 3 shows the effect of pH on the absorbance of metal complexes in naphthalene–dimethylformamide

TABLE 1. SPECTROPHOTOMETRIC DETERMINATION OF METALS IN NAPHTHALENE-DMF

Metal complexes	Max. wavelength (nm)	pH of extraction	Amount of reagent (ml)	Calibration curve (ppm)	Molar absorptivity ($l \cdot mol^{-1} \cdot cm^{-1}$)	Sensitivity (g/cm^2)	Relative standard deviation (%)

Naphthalene: 2.0 g, Solvent: Chloroform for Pd, Dimethylformamide for other metals

solution against the reagent blank. The pH values of the aqueous solution after extraction were measured at room temperature. The pH values were adjusted with acetate, phosphate or ammonia buffer solution except for the extraction of cadmium.

The amounts of naphthalene were varied from 0.5 to 3.0 g, extraction operation being carried out by the recommended procedure. Addition of naphthalene above 1.5 g gave no effect on the results. 2.0 g of naphthalene was adequate for complete extraction of each metal complex.

Variation of absorbance with the amount of complex-forming reagent was relatively small over the large amount of the reagent. The amount of buffer solution, 0.5—5 ml, had no effect on the absorbance. Acetate and ammonium salts gave considerable error, both positive and negative, for cadmium determination. Since the speed of extraction of metal complexes into molten naphthalene is great owing to high temperature, extraction is completed merely by contact with molten naphthalene or by slight shaking. It is not necessary to remove water on naphthalene crystals with anhydrous sodium sulfate, since dimethylformamide is miscible with water. The results obtained are summarized in Table 1. The calibration curve for each metal was derived at a proper wavelength against the reagent blank. The molar absorptivity, sensitivity and relative standard deviation on each metal were also calculated for ten determinations.

Preparation of *cis*- and *trans*-Dicyanobis(ethylenediamine)chromium(III) Complexes and Optical Resolution of the *cis* Isomer

Sumio KAIZAKI, Jinsai HIDAKA, and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received November 11, 1974)

Two geometrical isomers, *cis* and *trans*, of $[Cr(CN)_2(en)_2]^+$ were prepared and the *cis* isomer was resolved into optical isomers. The ligand field absorption and circular dichroism spectra were discussed and the absolute configuration of *cis*-$(+)_{546}$-$[Cr(CN)_2(en)_2]^+$ was determined to Λ on the basis of the circular dichroism sign in the first spin-allowed d-d band region.

There has been known only one series, though incomplete, of mixed cyano chromium(III) complexes, *i.e.*, aquacyano complexes, $[Cr(CN)_n(OH_2)_{6-n}]^{3-n}$,[1-2] which have been studied in solution, but not isolated as solid complexes. No mixed cyanoamine or cyanoammine chromium(III) complexes have been known.

In the present paper, the preparation and characterization of an isomeric pair of dicyanobis(ethylenediamine)chromium(III) perchlorate or chloride, *cis*- and *trans*-$[Cr(CN)_2(en)_2]X$, and the optical resolution of the *cis* isomer will be reported. Their infrared and visible absorption and circular dichroism (CD) spectra will be discussed in connection with the other dianionobis(ethylenediamine)chromium(III) complexes and in comparison with the corresponding mixed cyano cobalt(III) complexes.

Experimental

Preparation of cis- *and* trans-*Dicyanobis(ethylenediamine) chromium (III) Complexes.* Twenty grams of $[Cr(en)_3]Cl_3 \cdot 3.5H_2O$ and 4.8 g of NaCN were dissolved in 80 ml of water and to this solution was added 2 g of activated charcoal. The mixture was kept with stirring at room temperature for a week. After removing the activated charcoal, a yellow compound (*ca.* 6 g) was deposited by adding methanol and acetone to the filtrate. This was filtered off, because the yellow compound was confirmed to be the unreacted complex, $[Cr(en)_3]Cl_3$, by absorption measurement. The filtrate was condensed by a vacuum rotatory evaporator. Then about 4 g of another yellow precipitate was obtained by adding acetone. This yellow compound showed an absorption band at 438 nm. The aqueous solution of the product was poured into a column (300×20 mm) of a strong-acid cation-exchange resin (Dowex 50 W×8, 200—400 mesh, lithium form), and the column was swept with water. When the adsorbed band was eluted with 0.5 M aqueous solution of lithium perchlorate, two yellow bands were eluted. From the first eluate, yellow leaflet crystals were obtained by condensing and cooling. The second eluate was concentrated by a vacuum rotatory evaporator. To the condensed solution was added acetone–methanol mixture. Then yellow powder was obtained. The yield was about 1 g for the first eluate and about 2 g for the second eluate. The product from the second eluate (isomer II) was found to be more soluble than the one from the first eluate (isomer I). These complexes were recrystallized from warm water–methanol mixture. Found for the isomer I (*trans* form): C, 22.64; H, 5.06; N, 25.81%. Found for the isomer II (*cis* form): C, 22.01; H, 5.19; N, 25.48%. Calcd for $[Cr(CN)_2(en)_2]ClO_4$: C, 22.27; H, 4.98; N, 25.96%. In order to obtain more soluble complex salts, the perchlorates were converted to chlorides by using an anion-exchange resin of chloride form. The chlorides of isomer I and II were found to be anhydrous and monohydrated, respectively, from the elemental analyses. Found for the isomer I: C, 27.34; H, 6.28; N, 32.01%. Calcd for $[Cr(CN)_2(en)_2]Cl$: C, 27.75; H, 6.21; N, 32.36%. Found for the isomer II: C, 26.19; H, 6.30: N, 30.69%. Calcd for $[Cr(CN)_2(en)_2]Cl \cdot H_2O$: C, 25.95; H, 6.53; N, 30.26%.

Optical Resolution of the Isomer II. The chloride of isomer II, $[Cr(CN)_2(en)_2]Cl \cdot H_2O$ (0.544 g, 0.002 mol) was dissolved in 5 ml of warm water. To this solution was added $(+)_{589}$-ammonium α-bromocamphor-π-sulfonate (NH_4·*d*-BCS) (0.328 g, 0.001 mol) in 5 ml of water. Then yellow crystals of the least soluble diastereomer were precipitated. The yield was about 0.4 g. $[\alpha]_{546}=+94.7°$, $[\alpha]_{589}=+66.8°$. Found: C, 35.90; H, 5.68; N, 15.70%. Calcd for $[Cr(CN)_2(en)_2]$·*d*-BCS: C, 35.96; H, 5.66; N, 15.73%. The diastereomer was converted to the perchlorate and chloride by the following procedure. The *d*-BCS salt was suspended in a small amount of cold 70% $HClO_4$, and then the perchlorate was deposited by the addition of cold methanol. $[M]_{546}=+19°$. Found: C, 22.09; H, 5.02; N, 25.75%. Calcd for $(+)_{546}$-$[Cr(CN)_2(en)_2]ClO_4$; C, 22.27; H, 4.98; N, 25.96%. The *d*-BCS salt was converted to the chloride by using an anion exchange resin of chloride form. The crude complex obtained was recrystallized from water–ethanol. Found: C, 26.70; H, 6.57; N, 31.01%. Calcd for $(+)_{546}$-$[Cr(CN)_2(en)_2]Cl \cdot 0.5H_2O$: C, 26.83; H, 6.38; N, 31.28%.

Measurements. The visible absorption spectra were obtained with a Shimadzu UV-200 spectrophotometer. The CD spectra were recorded on a Jasco MOE-1 spectropolarimeter. A Yanagimoto spectropolarimeter, Model 185, was used to check optical rotatory power. The infrared spectra in the region of 4000—600 cm^{-1} were measured with a Jasco DS-402G spectrophotometer. The far-infrared spectra in the region of 700—200 cm^{-1} were obtained by a Hitachi FIR-3 far-infrared spectrophotometer.

Results and Discussion

a) The Preparative Method. In general, the syntheses of dianionobis(ethylenediamine)chromium(III) complexes, especially, of the *trans* forms, are rather difficult. Among the known methods a relatively efficient and convenient one is the thermal decomposition of $[Cr(en)_3]X_3$, which yields $[CrX_2(en)_2]X$.[3] O'Brien and Bailar[4] attempted the thermal decomposition of $[Cr(en)_3](CN)_3$, but failed in obtaining $[Cr(CN)_2(en)_2]CN$. Recently the progress has been made of the syntheses of mixed cyano-ammine or -amine complexes of cobalt(III) by four or more methods.[5-8] In the present work, two of them were applied to the chromium(III) analogues. One is based

on the reaction of *cis*- or *trans*-$[CoCl_2(en)_2]Cl$ with NaCN in dimethyl sufoxide,[5] and the other on the reaction of $[Co(en)_3]Cl_3$ with NaCN in an aqueous solution in the presence of activated charcoal.[6] By the application of the latter method $[Cr(CN)_2(en)_2]^+$ was successfully prepared, whereas the application of the former method was unsuccessful. The formation of *cis*-$[Cr(CN)_2(en)_2]Cl\cdot H_2O$, however, was confirmed by Matsumoto *et al.*[9] from the reaction of $[Cr(en)_3]Cl_3$ and NaCN in dimethyl sulfoxide. In the present method, the yield of *cis*-$[Cr(CN)_2(en)_2]^+$ was about twice as high as that of *trans* one. The abundance of *cis* isomer was also found in the corresponding cobalt(III) complexes.[6]

b) Identification. The two isomers isolated in this work have the same chemical composition, but exhibit differences in their solubilities, elution behaviors on cation-exchange column chromatography and crystalline forms.

Although the geometrical isomers of most dianionobis(ethylenediamine) complexes can be distinguished from each other by the spectral behavior in the first absorption band region, the present complexes give quite similar absorption spectra (but with different intensities as in Fig. 1 and Table 1) as in the case of *cis*- and *trans*-$[Cr(NCS)_2(en)_2]^+$.[10] That is, there is no clue for the assignment of geometrical configurations in the absorption spectra. However, since the second eluate (isomer II) was resolved into the enantiomers through its $(+)_{589}$-α-bromocamphor-π-sulfonate, this isomer is the *cis* form, and consequently the first eluate (isomer I) is to be assigned to the *trans* form.

Table 1. Absorption (AB) and CD data for chromium(III) complexes in the d–d transitions
(Wave numbers are in 10^3 cm^{-1})

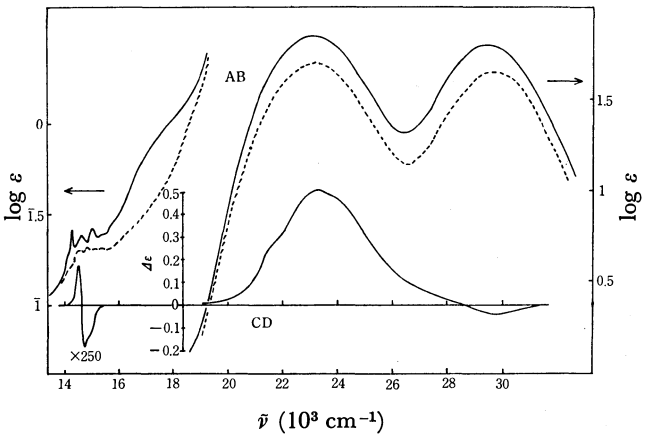

Fig. 1. Absorption curves of *cis*- (——) and *trans*-$[Cr(CN)_2(en)_2]^+$ (– – –), in water. CD curve of *cis*-$(+)_{546}$-$[Cr(CN)_2(en)_2]^+$ (——) in water.

It is generally found that *cis*-dianionobis(ethylenediamine)chromium(III) perchlorate is more soluble than the *trans* one.[11] This is also the case for the present complexes. The column chromatographic elution order also agrees with that generally recognized for *cis*- and *trans*-isomers of bis(ethylenediamine) type complexes.[6,12]

The infrared absorption spectrum of the *trans* isomer exhibits a simpler pattern than that of the *cis* one in the region of 4000—200 cm^{-1}, as in the case of the similar type chromium(III) and cobalt(III) complexes.[13] Particularly, the NH_2 bending near 1600 cm^{-1} and the CH_2 rocking bands at 800—900 cm^{-1} can discriminate between two geometrical isomers of dianionobis(ethylenediamine) complexes. In the isomer II, the former bands are observed at 1582 and 1605 cm^{-1} and the latter at 860 and 880 cm^{-1}, while in the isomer I only one component at 1600 cm^{-1} and undefinitely split ones at about 880 cm^{-1}. Hughes *et al.*[14] measured the far-infrared spectra of various kinds of bis(ethylenediamine) chromium(III) complexes, and found that there is a compatible difference between the spectra of *cis* and *trans* isomers in the region of 550—395 cm^{-1}, where the δ-Cr–N+ring deformation may occur. In fact, four bands are observed for *cis*-$[Cr(CN)_2(en)_2]Cl\cdot H_2O$ in the corresponding region and three bands for the *trans* one. In the Cr–C and Cr–N stretching band region (360—220 cm^{-1}), the *cis* isomer shows more splitting components than the *trans* one as in the other bis(ethylenediamine) complexes.[14] All the facts of the infrared absorption spectra support the present assignment of geometrical configurations. While the corresponding cobalt(III) complexes, *cis*- and *trans*-$[Co(CN)_2(en)_2]^+$, give a strong and sharp CN stretching band near 2100 cm^{-1},[6] the present chromium(III) complexes give very weak bands in this region. It has been revealed that the CN stretching band of $K_3[Cr(CN)_6]$ is about one-nineth as weak in intensity as $K_3[Co(CN)_6]$, probably owing to the difference in the M–CN π-bonding.[15] Thus, it seems plausible that the mixed cyano chromium(III) complexes also show this phenomenon.

c) The Absorption and CD Spsctra. The ligand field absorption spectra of *cis*- and *trans*-$[Cr(CN)_2(en)_2]^+$ are nearly identical with each other as mentioned in b). That is, the first and the second absorption bands of *cis*-$[Cr(CN)_2(en)_2]^+$ locate at 23.1 and 29.48 kK, respectively, while those of the *trans* isomer at 23.15 and 29.67 kK. The molar absorptivities of the *cis* isomer are larger than those of the *trans* isomer for both the first and second band region, as in Fig. 1 and Table 1. This intensity order coincides with the other cases found in literature for the *cis*- and *trans*-dianionobis(ethylenediamine) complexes, for example *cis*- and *trans*-$[Cr(NCS)_2(en)_2]^+$.[10]

The angular overlap model[16] or Yamatera's rule[17] predicts that the first excited quartet state ($^4T_{2g}$) in O_h

symmetry splits into the nondegenerate ($^4A_1$) component at 24.18 kK and the accidentally degenerate ($^4A_2$ and $^4B_2$) one at 23.01 kK for the *cis* isomer of C_{2v} symmetry, while the *trans* isomer of D_{4h} symmetry has the nondegenerate ($^4B_{2g}$) component at 21.85 kK and the degenerate (^4E_g) one at 24.18 kK. On the other hand, Perumareddi[18] has predicted from the ligand field theory the absorption maxima of *cis*- and *trans*-$[Cr(CN)_2(NH_3)_4]^+$, of which the ligand field parameters are very close to those of *cis*- and *trans*-$[Cr(CN)_2(en)_2]^+$; that is, *cis*-$[Cr(CN)_2(NH_3)_4]^+$ has two split components at 24.025 and 22.788 kK and the *trans* one at 23.802 and 21.550 kK. The theoretically predicted energy interval between the degenerate and the nondegenerate components in the first band region of the *trans* dicyano complex is about twice as large as that of the *cis* one and comparable to the splitting of *trans*-$[Cr(OH_2)_2(en)_2]^{3+}$, of which the first band has been reported to split largely.[10] The present *trans* complex, however, exhibits no splitting and its half-width is equal to that of the *cis* one. The absorption maxima of both the *trans*- and *cis*-complexes agree fairly well with the weighted mean value of the predicted components as in Table 2. A discrepancy between the theoretical prediction and observation has also been found for the corresponding *trans* dicyano cobalt(III) complexes.[6] The second absorption band maxima of both the present isomers are close to the value obtained from the weighted mean expression or the rule of the average environment.[19]

TABLE 2. THE PREDICTED POSITIONS OF THE FIRST ABSORPTION BAND IN UNIT OF 10^3 cm^{-1}

Ligand field theory[a]		Yamatera's rule[b]	
cis-$[Cr(CN)_2(en)_2]^+$			Weighted mean
$^4A_2$, $^4B_2$	22.788	23.01	23.40
$^4A_1$	24.025	24.18	
trans-$[Cr(CN)_2(en)_2]^+$			
$^4B_{2g}$	21.550	21.85	23.40
^4E_g	23.802	24.18	

a) The value of the tetraammine complexes after Perumareddi[18] b) Using the parameters, $\delta(en)=0$ and $\delta(CN)=10Dq(CN)-10Dq(en)=4.66$

The CD spectrum of $(+)_{546}$-$[Cr(CN)_2(en)_2]^+$ shows a positive band with an undefined inflection in the first absorption band region and a negative band in the second absorption band region as shown in Fig. 1 and Table 1. Since the positive CD band in the first absorption band region is due to the $^4E(^4T_{2g})$ parentage of the parent trigonal complex, the absolute configuration of this $(+)_{546}$-isomer is assigned to *A*.

In the near-infrared region around 14—15 kK, where the quartet-doublet spin-forbidden transitions occur, the narrow and sharp but weak absorption bands are observed as in Fig. 1. The absorption bands in this region for the *cis* and *trans* isomers differ in their patterns from each other. Three distinct peaks are observed for the *trans* isomer, while some uncertain structural inflections appear for the *cis* one. In the corresponding region, two CD peaks, (+) and (−) from the longer wavelength side, are observed for the *cis*-$(+)_{546}$-isomer. It is found that their CD intensities are about 0.1% of that in the first spin-allowed band region. Provided that the theoretical relationship between rotational strengths for the spin-forbidden and spin-allowed transitions, which has been presented recently for the trigonal chromium(III) complexes,[20] may be applicable also to the *cis*-dianionobis(ethylenediamine) complexes, the positive CD component at the longer wavelength side may be due to the $^2E \leftarrow {}^4A_2$ transition and the remaining negative one to the split component of the $^2T_1$, $\bar{E}_b$. Since the rotational strength for the spin-forbidden transitions is contributed from that for the spin-allowed transitions with same signs,[20] the intensity of negative CD component in the spin-forbidden band region should originate from the negative CD component in the first spin-allowed band region. Therefore, the CD in the first band region may consist of two components with opposite signs, and then it is supposed that a negative minor CD band may be destructively superimposed on the positive major CD band. On the other hand, for the corresponding cobalt(III) complex, $A(+)_{589}$-$[Co(CN)_2(en)_2]^+$, the CD spectra in the first band region give two positive components.[21] Accordingly, it is suggested that the CD behavior of the present chromium(III) complex differs considerably from that of the corresponding cobalt(III) complex, although current CD theories propose that the rotational strengths of low spin cobalt(III) complexes behave analogously to those of chromium(III) complexes.[22]

The Extraction of Bis(8-picolylideneaminoquinoline)iron(II) Perchlorate into Nitrobenzene[1)]

Makoto Otomo and Kazunobu Kodama

Department of Synthetic Chemistry, Nagoya Institute of Technology, Showa-ku, Nagoya 466

(Received November 14, 1974)

The green chelate cation of bis(8-picolylideneaminoquinoline)iron(II) can be extracted into nitrobenzene as the form of the ion-pair with various univalent anions. The extractability with these anions is decreased in the order of $B(C_6H_5)_4^- \approx ClO_4^- > SCN^- > I^- \gg NO_3^- > Br^- > Cl^- \gg CH_3COO^-$. The extractive reaction with perchlorate ions has been applied to the spectrophotometric determination of minute amounts of iron(II). The nitrobenzene extract gives two characteristic charge-transfer ($d \rightarrow \pi^*$) bands at 663 and 569 nm. Under the optimum conditions of pH, ligand concentration and shaking time, Beer's law is obeyed up to 1.2×10^{-4} M iron(II) in the organic phase. The molar absorptivity is 7.04×10^3 l·mol^{-1}·cm^{-1} at 663 nm. The proposed method is selective and can be used for the determination of iron(II) in the presence of fairly large amounts of various ions, provided high concentrations of the ligand or suitable masking agents are used. A kinetic study made to obtain an information on the extraction mechanism of the ion-pair of this type showed that the rate equation can be represented as

$$-\frac{d[Fe^{2+}]}{dt} = k_0[Fe^{2+}][8\text{-PAQ}]_{org}^2(1 + k_1[ClO_4^-])$$

where k_0 and k_1 are respectively the rate constant and a constant.

2,2′,2″-Terpyridine, an important colorimetric reagent for iron(II), has been known as a representative tridentate ligand which contained the functional grouping N=C–C=N–C·C·N (points denote single or double bonds). Lions and his coworkers[2)] reported briefly on the preparation and use of 8-picolylideneaminoquinoline (abbreviated as 8-PAQ) as a tridentate chelating agent with constitutional features similar to those of terpyridine and showed that it coordinated with iron(II) salts similarly to the latter. They also showed that bis(8-PAQ)iron(II) iodide is obtained as a diamagnetic crystalline solid, which gives an intense green color when dissolved in water. Later, Kurmholz[3)] recorded the visible absorption spectra of iron(II) complexes with a series of "terpyridine-like" tridentate imine ligands including 8-PAQ and interpreted the observed spectral patterns on the basis of the molecular models and the geometrical considerations.

We have found that the iron(II) chelate of 8-PAQ can be quantitatively transferred into nitrobenzene as the form of the ion-pair in the presence of such anions as perchlorate, iodide, thiocyanate, or tetraphenylborate ions. This paper deals mainly with the application of 8-PAQ to the extractive spectrophotometric determination of minute amounts of iron(II) in the presence of perchlorate ions. The method proposed here is simple and highly selective for iron(II). The interference from certain metals can be avoided by adding suitable masking agents or by using a large excess of the ligand. The only interfering metal that forms a colored chelate with the ligand is cobalt(II). In order to get a semi-quantitative information on the extraction mechanism of the ion-pair of this type, a kinetic study has also been made spectrophotometrically. The extraction rate was found to be first order with respect to the concentration of iron(II) in the aqueous phase, and second order with respect to the ligand concentration in the organic phase. The rate of the extraction is also affected by the concentration of perchlorate ions in the aqueous phase.

Experimental

Reagents. 8-PAQ and bis(8-PAQ)iron(II) perchlorate were prepared according to the procedures described in the literature. The latter, sparingly soluble black needles, decomposed above 271 °C. Found: C, 49.65; H, 3.24; N, 11.37; Cl, 9.87%. Calcd for $Fe(C_{15}H_{11}N_3)_2(ClO_4)_2 \cdot 0.5H_2O$: C, 49.34; H, 3.17; N, 11.51; Cl, 9.71%.

A stock solution of iron(II) sulfate was standardized complexometrically. Sodium perchlorate was prepared and purified as described previously.[4)] Nitrobenzene obtained from the Katayama Kagaku Co. was distilled under reduced pressure. All the other reagents used were of analytical grade.

Apparatus. The absorbance measurements were made with a Hitachi model 124 double-beam spectrophotometer equipped with quartz cells of 10 mm pathlength. The pH determinations were carried out with a Toa Dempa model HM-6A pH meter.

General Procedure. All of the extraction procedures and the absorbance measurements were made at 25 °C. A centrifuging tube (volume, 50 ml) with a glass stopper was used to equilibrate the organic and aqueous phases. The aqueous phase contained solutions of iron(II) sulfate, ascorbic acid, sodium perchlorate and an acetate buffer. A 5.0 ml portion of the aqueous solution and a 5.0 ml portion of 8-PAQ in nitrobenzene were placed in the tube, and the two phases were agitated vigorously by a mechanical shaker for a required period. When the agitation was stopped, the two phases in the tube were immediately centrifuged for 2 min at 1000 rpm. The iron contents in the two phases were determined from the initial iron concentration and the absorbance of the organic phase at 663 nm.

Results and Discussion

The Extraction of Iron(II) into Nitrobenzene with 8-PAQ in the Presence of Various Anions. In Fig. 1 the extraction behavior of iron(II) on changing counter anion is shown by plotting the percentage extraction of iron(II) as a function of the concentration of the anion. The order of extractability as a measure of half-extrac-

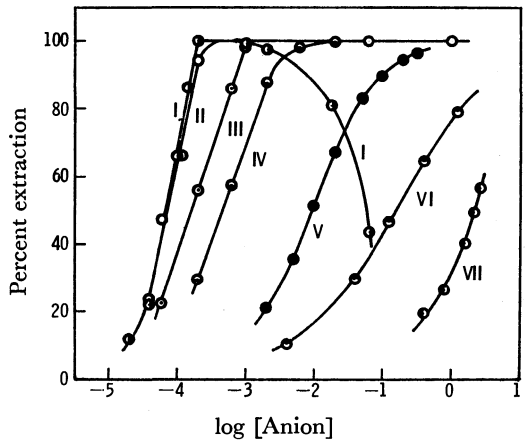

Fig. 1. Extraction of iron(II) as the 8-PAQ chelate with various anions.
Fe^{2+}, 8.0×10^{-5}M; anion ----I, $B(C_6H_5)_4^-$: II, ClO_4^-: III, SCN^-: IV, I^-: V, NO_3^-: VI, Br^-: VII, Cl^-: pH, 3.20; 8-PAQ in $C_6H_5NO_2$, 5.0×10^{-3}M

tion is as follows: $B(C_6H_5)_4^-\approx ClO_4^->SCN^->I^-\gg NO_3^->Br^->Cl^-\gg CH_3COO^-$, SO_4^{2-}. This sequence suggests that the enthalpy of hydration of the anion is the major factor governing the extractability of the iron(II)–8-PAQ chelate cation as the form of the ion-pair. The percentage extraction increases remarkably when the enthalpy of hydration of the anions is below 70—80 kcal/mol. With strongly hydrated anions, such as acetate and sulfate ions, the iron(II) chelate is scarcely extracted at all. This result is in good agreement with those obtained by Gibson and Weatherburn[5] with the quaternary phosphonium and arsonium cations, by Biswas and Mandal[6] with surfactant cations, and by Takamatsu[7] with the tris(1,10-phenanthroline)-ruthenium(II) cation.

In addition, as is evident in Fig. 1, an abnormal decrease in the percentage extraction at higher concentrations of sodium tetraphenylborate is observed.

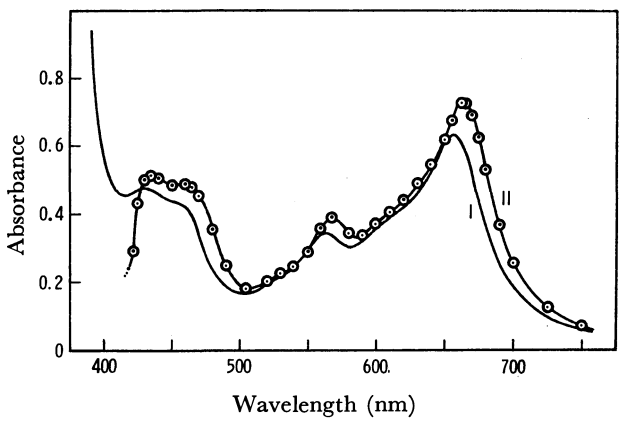

Fig. 2. Visible absorption spectra of 1.03×10^{-4}M $Fe(8\text{-}PAQ)_2(ClO_4)_2$ in 50 v/v % aqueous methanol and nitrobenzene.
I, solid $Fe(8\text{-}PAQ)_2(ClO_4)_2$ dissolved in 50 v/v % aqueous methanol; II, solid $Fe(8\text{-}PAQ)_2(ClO_4)_2$ dissolved in nitrobenzene; —, prepared by extracting 1.03×10^{-4}M iron(II) from a pH 3.2 solution containing 0.02 M $NaClO_4$

A similar result has been obtained in the extraction of tris(1,10-phenanthroline)ruthenium(II) into various organic solvents with tetraphenylborate ions.[7] This phenomenon, therefore, may be explained in terms of the hydrotropism[8,9] which is often encountered in the solution of an electrolyte with a large ion.

Absorption Spectra. The visible absorption spectra of 50 v/v% aqueous methanol and nitrobenzene solutions of bis(8-PAQ)iron(II) perchlorate are shown in Fig. 2.

It has generally been accepted that the visible absorption of diamagnetic iron(II) complexes of tridentate imine ligands as well as that of α-diimine ligands is caused by an electron migration from the filled 3d orbitals of the metal to the lowest vacant molecular orbitals of the ligands. In a 50 v/v% aqueous methanol solution, the main absorption band of the iron(II) complex of 8-PAQ is found at 657 nm (molar absorptivity, $\varepsilon=6.35\times10^3$). This peak is accompanied by a weak shoulder toward shorter wavelengths. A distinct second peak, which is not found in the visible absorption spectrum of the bis(terpyridine)iron(II) complex, is found at 563 nm ($\varepsilon=3.38\times10^3$), also accompanied by a weak shoulder toward shorter wavelengths. The appearance of the second transition has been assigned to the splitting of the filled T_{2g} orbitals by non-cubic field components.[3] An additional absorption band appearing in the 410—470 nm region ($\varepsilon=4.61\times10^3$ at 427 nm) may probably be attributed to the charge-transfer from the 3d orbitals of iron(II) to the second lowest vacant molecular orbitals of the ligand.[10]

In nitrobenzene, as is shown in Fig. 2, the main and the second peaks are shifted toward longer wavelengths along with an increase in intensity. These are found at 663 ($\varepsilon=7.04\times10^3$) and 569 nm ($\varepsilon=3.82\times10^3$) respectively. Figure 2 also shows that the visible absorption spectrum of the nitrobenzene extract obtained according to the general procedure is completely identical with that of the synthesized complex. In both the aqueous methanol and the organic solvent, the free ligand did not show any absorption in the visible region above 450 nm.

The ultraviolet absorption spectrum of the iron(II) complex measured in a 50 v/v% aqueous methanol solution is composed of three intense peaks at 372 ($\varepsilon=4.42\times10^4$), 352 ($\varepsilon=4.24\times10^4$), and 232 nm ($\varepsilon=5.98\times10^4$) and two shoulders at about 332 ($\varepsilon=2.9\times10^4$) and 315 nm ($\varepsilon=1.9\times10^4$). The magnitude of the molar absorptivities suggests that all the absorption bands are caused by $\pi\rightarrow\pi^*$ transitions.

Application to the Spectrophotometric Determination of Iron(II). The Effect of pH: The absorbance of the organic phase was measured as a function of pH of the aqueous phase, the result being shown in Fig. 3. The iron(II)–8-PAQ chelate is formed above pH 1. The absorbance of the extract is at its maximum at pH 2.0—4.2. It is of interest to note that the ion-pair once extracted into nitrobenzene can not be decomposed in the presence of perchlorate ions, unless high concentrations of hydrochloric acid (above 6 M) or sodium hydroxide (above 0.5 M) are used.

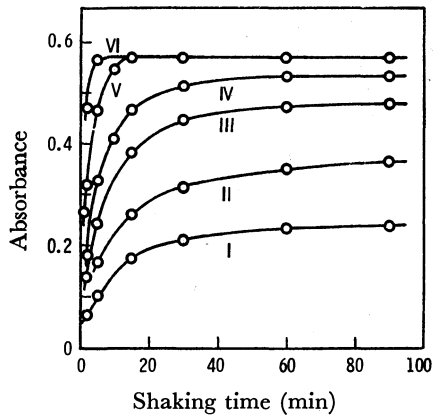

Fig. 4. Effect of the ligand concentration and the shaking time.
Fe^{2+}, 8.0×10^{-5}M; $NaClO_4$, 0.02 M; pH, 3.20; 8-PAQ in $C_6H_5NO_2$——I, 1.25×10^{-3}M: II, 1.59×10^{-3}M: III, 2.01×10^{-3}M: IV, 2.50×10^{-3}M: V, 3.75×10^{-3}M: VI, 6.25×10^{-3}M

The Effects of the Ligand Concentration and the Shaking Time: Figure 4 shows the effects of the ligand concentration and the shaking time on the extraction of iron(II). A shaking period of about 15 min is enough to obtain the maximum extraction, when the initial concentration of the ligand in nitrobenzene is 3.75×10^{-3} M which is about 50 fold molar excess over iron(II). The shaking period can be reduced by using the higher concentrations of the ligand.

The Effect of Solvents and the Stability of the Color: Several organic solvents were examined for their ability to extract the ion-pair. Of all the solvents tested, chloroform, 1,2-dichloroethane and nitrobenzene were capable of extracting the ion-pair, while in the other cases a precipitate was observed at the interface. In chloroform and 1,2-dichloroethane, however, the green color of the ion-pair tended to fade away gradually. The absorbance of the nitrobenzene extract did not change at all for at least 48 hr, indicating that the ion-pair is very stable in nitrobenzene.

The Effect of Volume of the Aqueous Phase: The absorbance of the organic phase was decreased with increasing the volume of the aqueous phase to organic phase, but it could be avoided by using higher concentrations of the ligand or by lengthening the shaking time.

Adherence to Beer's Law: To the series of sample solutions containing up to 34 μg (1.2×10^{-4} M in the final concentration) of iron(II or III), the general procedure described above was applied. The conditions used were: 8-PAQ in nitrobenzene, 5.0×10^{-3} M; sodium perchlorate, 0.02 M; ascorbic acid added as a reducing agent for iron(III), 0.4%; pH of the aqueous phase, 3.20; shaking period, 15 min. It was found that Beer's law is obeyed between the absorbance of the organic phase and the concentration of iron over

Table 1. Effect of diverse ions for the determination of 22.4 μg (0.4 μmol) of iron

a) Reagent concentration: 1.0×10^{-2} M b) 1 ml of 0.2 M sodium thiosulfate solution was added. c) 1 ml of 0.2 M sodium tartrate solution was added.

the entire range examined.

The Effect of Diverse Ions: The extent of interference by a number of metal ions and anions in the determination of 22.4 μg of iron(II) was studied. The following metal ions did not interfere, even if they were present at a concentration level of several ten times that of iron: silver, thallium(I), beryllium, magnesium, calcium, strontium, barium, mercury(II), tin(II), lead, manganese(II), yttrium, lanthanoid, aluminum, gallium, indium, bismuth, chromium(III, VI), osmium(VIII), rhodium, irridium, platinum(II, IV), thorium, titanium, zirconium, vanadium(IV, V), and uranium(VI).

Table 1 shows the effect of several metal ions and anions on the determination of iron. Zinc, cadmium, nickel, copper(II), ruthenium(III), and molybdenum(VI) do not interfere up to concentrations of several times that of the amount of iron. The negative errors observed in the presence of larger amounts of these ions may be due to the consumption of the reagent by the formation of colorless complexes with these cations; the error can be eliminated by the use of a fairly large amount of the reagent, except for copper(II) which still interferes to some extent. The interference from copper(II) can be eliminated by the addition of thiosulfate. The addition of tartrate is also effective to prevent the interference from molybdenum and tungsten. The most difficult interference is that from cobalt(II), which forms an extractable brown complex with the reagent and gives a positive error. The extraction of cobalt(II) seemed to be accompanied by a transformation of $Co(8\text{-}PAQ)_2(ClO_4)_2$ into an inert complex such as $Co(8\text{-}PAQ)_2(ClO_4)_3$. Anions, such as fluoride, tartrate, thiosulfate and phosphate do not interfere, even when they are present at a large concentration. However, as is expected for iron(II), EDTA and a large amount of oxalate interfere with the determination by the formation of complexes with iron(II).

It is clear from these results that 8-PAQ is highly selective for iron(II), and that this reagent, although it is not very stable, can be used as a spectrophotometric reagent for iron in the presence of fairly large amounts of various ions.

A Kinetic Study. Statistical Treatments: Assuming that the diffusion or the transport of materials can be neglected from consideration, the rate of the extraction of iron(II) with the ligand and perchlorate ions may be generally described as follows:

$$-\frac{d[Fe^{2+}]}{dt} = k_0[Fe^{2+}]^a[8\text{-}PAQ]_{org}^b[H^+]^c[ClO_4^-]^d \quad (1)$$

As the concentrations of the ligand and perchlorate ions are in considerably excess to iron(II), and as the aqueous phase is buffered, the rate can be described as follows:

$$-\frac{d[Fe^{2+}]}{dt} = q[Fe^{2+}]^a \quad (2)$$

where q is the multiplication of the rate constant, k_0, and the other concentrations which are kept at certain values. When the reaction order with respect to iron(II) is unity, Eq. (2) can be rewritten by integration as:

$$-\log [Fe^{2+}] = q \cdot t + c_0 \quad (3)$$

where c_0 is a constant. Equation (3) shows that the $\log [Fe^{2+}]$ *vs.* t plot should be a straight line with a slope of $-q$.

The reaction order with respect to the other species can be determined from the rate measurements when two of the concentrations out of these three are kept at certain values. For example, when the concentrations of the hydrogen and perchlorate ions are kept at C and D, then the quantity q_L can be defined as follows:

$$\log q_L = \log k_0 C^c D^d + b \log [8\text{-}PAQ]_{org} \quad (4)$$

Thus, the reaction order with respect to the ligand, b, can be determined by plotting $\log q_L$ *vs.* $\log [8\text{-}PAQ]_{org}$.

By similar treatments, the rest of the values of the c and d reaction orders can be determined from the slope of the plot given by the following equations:

$$\log q_{H^+} = \log k_0 B^b D^d + c \log [H^+] \quad (5)$$

$$\log q_{ClO_4^-} = \log k_0 B^b C^c + d \log [ClO_4^-] \quad (6)$$

However, as will be seen below, the reaction order with respect to the perchlorate ions, d, was not a constant, but changed as the perchlorate concentration was changed; the following equation should therefore be used instead of Eq. (6):

$$\log q_{ClO_4^-} = \log k_0 B^b C^c + \log (1 + k_1[ClO_4^-] + \cdots + k_n[ClO_4^-]^n) \quad (6a)$$

The Reaction Order with Respect to Fe^{2+}: In Fig. 5 are shown some of the experimental values of $-\log [Fe^{2+}]$ as a function of t. It is seen that the points lie on straight lines, indicating that the reaction order with respect to iron(II) is always unity.

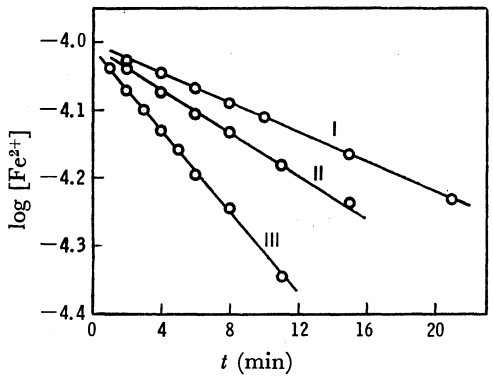

Fig. 5. Dependence of the rate of iron(II) extraction on the Fe^{2+} concentration.
pH, 3.30; $NaClO_4$, 0.1 M; 8-PAQ in $C_6H_5NO_2$——
I, 1.13×10^{-3}M: II, 1.33×10^{-3}M: III, 1.52×10^{-3}M

The Reaction Order with Respect to the Ligand: The rate of extraction was determined in the ligand concentration range between 0.95×10^{-3} M and 2.3×10^{-3} M, the results being plotted in Fig. 6. As may be seen from Fig. 6, the rate of extraction was concluded to be proportional to the square of the ligand concentration under these conditions.

The Reaction Order with Respect to the Hydrogen Ion: The pH of the aqueous phase was varied from 3.02 to 4.50 while the concentrations of the ligand and the perchlorate were kept at 1.35×10^{-3} M and 0.1 M

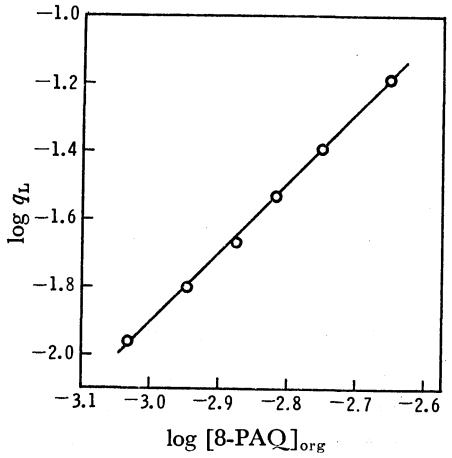

Fig. 6. Dependence of the rate of iron(II) extraction on the 8-PAQ concentration in the organic phase.
pH, 3.30; $NaClO_4$, 0.1 M

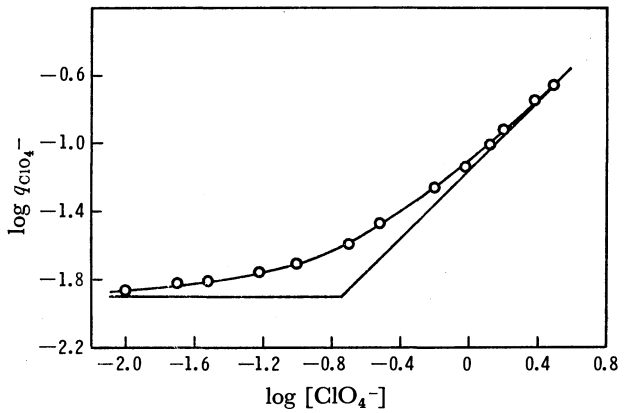

Fig. 7. Dependence of the rate of iron(II) extraction on the perchlorate-ion concentration.
pH, 3.30; 8-PAQ in $C_6H_5NO_2$, 1.35×10^{-3}M. The curve fitted is log $q_{ClO_4^-}=-1.88+\log(1+5.0[ClO_4^-])$. The intersect of the two asymptotes is (−0.72, −1.88).

respectively. As the result, it was found that the rate of extraction was almost independent of the hydrogen ion concentration of the aqueous phase under these conditions.

The Effect of Perchlorate Ions: The rate was determined as a function of the perchlorate-ion concentration in the aqueous phase when the ligand concentration of the organic phase was 1.35×10^{-3} M and when the pH of the aqueous phase was 3.30. Figure 7 gives the log $q_{ClO_4^-}$ *vs.* log [ClO_4^-] plot. The data in this figure were also analysed by the curve fitting method.[11,12] As may be seen from Fig. 7, the slope for the plot approaches zero in the lowest log [ClO_4^-] region, but it increases with the increase in log [ClO_4^-] until it approaches unity. The increase in $q_{ClO_4^-}$ with the perchlorate concentration should not seem to be due to the ionic strength effect. Thus, it was concluded that there are two mechanisms for the extraction and they can be represented by Eq. (6b).

$$\log q_{ClO_4^-} = \log k_0 B^b C^c + \log(1+k_1[ClO_4^-]) \quad (6b)$$

The first order dependence of the rate on the perchlorate concentration is probably due to the first-step association of $Fe(8\text{-}PAQ)_2^{2+}$ chelate cation with perchlorate ions in the aqueous phase. This is contradictory to the conclusion of Yamamoto[13] in a similar study with tris(1,10-phenanthroline)iron(II) perchlorate; he concluded that this ion-pair is completely dissociated in water and also in nitrobenzene. On the other hand, it has also been found that the ion-pairs formed between tris(1,10-phenanthroline)ruthenium(II) and anions such as perchlorate, iodide, and thiocyanate are extracted into various organic solvents mainly as the associated form and that the degree of association is considerable even in water.[7]

The rate equation, therefore, can be expressed as:

$$-\frac{d[Fe^{2+}]}{dt} = k_0[Fe^{2+}][8\text{-}PAQ]_{org}^2(1+k_1[ClO_4^-]) \quad (7)$$

Syntheses and Properties of 2'-Aminobiphenyl-2-ol and Its Copper(II) Complexes

Iwao Mori

Department of General Education, University of the Ryukyus, Naha, Okinawa 903

(Received November 18, 1974)

A new bidentate ligand, 2'-aminobiphenyl-2-ol(Habp), was synthesized. An examination of its behavior toward metal ions proved that, depending on the reaction conditions, the ligand gave mononuclear or polynuclear copper(II) complexes with seven-membered chelate rings. The complexes of the following compositions were thus characterized: $Cu(abp)_2$, $Cu(abp)_2 \cdot H_2O$, $Cu(abp)_2 \cdot C_6H_6$, $Cu(abp)_2 \cdot CH_3COOC_2H_5$, and $Cu_5(abp)_8(OH)_2 \cdot 3H_2O$.

Only a few examples of mononuclear metal complexes[1] with seven-membered chelate rings derived from bidentate ligands have been reported. It is generally accepted that the complexes with chelate rings of more than six members are often unstable and tend to give polynuclear complexes. 2-Aminophenol is a well-known complexing agent, and so the author was tempted to examine the seven-membered analogue of bis-(2-aminophenolato) copper(II) from the above point of view.

The present report will describe the syntheses and characterizations of the new ligand, 2'-aminobiphenyl-2-ol (abbreviated as Habp), and its copper(II) complexes; these studies led to the conclusion that the ligand gives mono- or polynuclear complexes, depending on the reaction conditions.

The aminophenol (**3**) was synthesized according to the scheme shown in Fig. 1. The dissolving-metal reduction of 2-methoxy-2'-nitrobiphenyl (**1**) with Raney alloy led to 2-amino-2'-methoxybiphenyl (**2**), which was then demethylated with boiling hydrobromic acid giving Habp (3) in a fair yield.

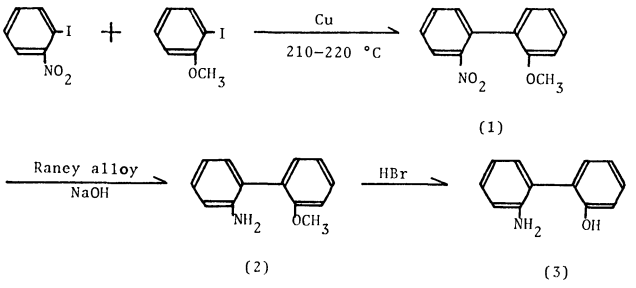

Fig. 1. The synthetic scheme of Habp.

When the ligand was treated with copper(II) ions in an ammoniacal aqueous ethanolic solution, the complex of the composition, $Cu(abp)_2 \cdot H_2O$, was obtained in the form of brown needles. The complex gave $Cu(abp)_2 \cdot C_6H_6$ or $Cu(abp)_2$ when heated with benzene, and $Cu(abp)_2 \cdot CH_3COOC_2H_5$ when heated with ethyl acetate. As will be discussed below, an examination of the IR, UV, and magnetic susceptibilities showed that the complexes had mononuclear structures. On the other hand, however, when the ligand was reacted with copper acetate in an aqueous ethanolic solution, a copper complex of a different composition was obtained; it was confirmed to have a polynuclear, probably a pentanuclear structure, by a study of its elementary analytical, spectral, and magnetic properties.

Experimental

Syntheses. *2-Methoxy-2'-nitrobiphenyl (1)*:[2] *o*-Iodonitrobenzene[3] (200 g), *o*-iodoanisole[4] (200 g), and copper powder[5] (200 g) were mixed and heated at 210—220 °C in an oil bath under stirring for one and a half hour. The reaction mixture was then cooled and extracted with benzene. The benzene solution was distilled, and the fraction between 160—190 °C, 7 mmHg was treated with cold methanol, from which most of the 2,2'-dimethoxybiphenyl crystallized out. The filtrate gave, after concentration and the addition of water, crude methoxynitrobiphenyl (**1**), which was subsequently purified by recrystallization from aqueous methanol. Pale yellow needles; mp 78 °C; 61.2 g, (31.2%). Found: C, 68.09; H, 4.78; N, 6.32%. Calcd for $C_{13}H_{11}O_3N$: C, 68.11; H, 4.84; N, 6.11%.

2-Amino-2'-methoxybiphenyl (2): 2-Methoxy-2'-nitrobiphenyl (**1**) (20 g) was dissolved in a mixture of ethanol (95%, 100 ml) and an aqueous sodium hydroxide solution (20%, 100 ml) by warming. Raney alloy (powder, 20 g) was added, little by little, to the above solution under stirring. After the addition had been completed, the mixture was stirred for a further 20 min and filtered while hot. The subsequent concentration of the filtrate separated an oil which solidified on cooling. It was then distilled under diminished pressure, and the fraction which distilled between 157—159 °C/5.5 mmHg was recrystallized from aqueous methanol. Colorless needles; mp 78—79 °C; 13.6 g (78%). (The yield was 56% when iron powder and hydrochloric acid were used for the reduction.) Found: C, 77.93; H, 6.57; N, 7.83%. Calcd for $C_{13}H_{13}NO$: C, 78.39; H, 6.53; N, 8.04%.

2'-Aminobiphenyl-2-ol (Habp) (3): A mixture of 2-amino-2-methoxybiphenyl (**2**) (10 g) and hydrobromic acid (48%, 40 ml) was gently refluxed for one hour. The mixture was then cooled and poured into water. The aqueous solution was neutralized with a dilute aqueous ammonium hydroxide solution, and the precipitate was collected by filtration and washed with water. The precipitate was then further purified by sublimation under reduced pressure. Colorless needles; mp 91—92 °C; 6.5 g, (70%). IR, Table 1. UV; λ_{max}, 263 nm (no appreciable absorption in the visible region). NMR; δ (ppm) 4.29 (singlet, 3H, $N\underline{H}_2$ and $O\underline{H}$), 7.12 (multiplet, 8H, aromatic protons). Mass Spectrum; *m/e* 186 (M+1, 14% of M+), 185 (M+), 168, 156, 154, 139, 129, 89, 77 and 65. Found: C, 77.84; H, 6.02; N, 7.63%. Calcd for $C_{12}H_{11}NO$: C, 77.81; H, 5.98; N, 7.56%.

$Cu(abp)_2 \cdot H_2O$: Copper acetate (33 mg) was dissolved in water (3 ml) containing an aqueous ammonium hydroxide solution (28%, 0.5 ml) and kept at 50—60 °C. A solution

of Habp (62 mg) in ethanol (1 ml) was then added to the above solution. The precipitate was filtered and washed with water and then with a small amount of ethanol. Reddish orange needles; 65 mg, (91%). Found: C, 64.29; H, 4.82; N, 6.22; Cu, 13.94%. Calcd for $C_{24}H_{20}N_2O_2Cu \cdot H_2O$: C, 64.03; H, 4.93; N, 6.22; Cu, 14.13%.

Cu(abp)$_2$·C$_6$H$_6$: Cu(abp)$_2$·H$_2$O was warmed in benzene at 60 °C for 40 min. The precipitate was filtered, washed with benzene, and air-dried for a short time. Brown needles. Found: C, 70.08; H, 5.10; N, 5.52; Cu, 12.42%. Drying loss (80 °C, 5 mmHg, 8 hr), 14.9%. Calcd for $C_{24}H_{20}N_2O_2Cu \cdot C_6H_6$: C, 70.05; H, 5.10; N, 5.62; Cu, 12.67; C_6H_6, 15.30%.

Cu(abp)$_2$; When Cu(abp)$_2$·H$_2$O was boiled with benzene for one hour, an anhydrous complex was obtained in the form of dark brown needles. Found: C, 66.73; H, 4.70; N, 6.15; Cu, 14.53%. Calcd for $C_{24}H_{20}N_2O_2Cu$: C, 66.74; H, 4.67; N, 6.49; Cu, 14.71%.

Cu(abp)$_2$·CH$_3$COOC$_2$H$_5$: This complex was prepared from Cu(abp)$_2$·H$_2$O by boiling it in ethyl acetate. Glistening brown needles. Found: C, 64.08; H, 5.48; N, 5.35; Cu, 14.50%. Calcd for $C_{24}H_{20}N_2O_2Cu \cdot CH_3COOC_2H_5$: C, 64.66; H, 5.44; N, 5.38; Cu, 14.70%.

Cu$_5$(abp)$_8$(OH)$_2$·3H$_2$O; To a solution of copper acetate (82 mg) in water (4 ml), we added a solution of Habp (122 mg) in ethanol (3 ml), after which the mixture was kept at 50—60 °C. The precipitate was then filtered and washed with water. Brownish green needles; 131 mg (85%). The complex was insoluble in water and slightly soluble in organic solvents. Found: C, 61.36; H, 4.65; N, 5.67; Cu, 16.97%. Calcd for $Cu_5(abp)_8(OH)_2 \cdot 3H_2O$: C, 61.34; H, 4.72; N, 5.69; Cu, 16.90%. Calcd for $Cu_3(abp)_5(OH) \cdot 3H_2O$: C, 60.87; H, 4.90; N, 5.91; Cu, 16.10%.

Measurements; The infrared spectra were taken by means of a Hitachi EPI-S2 spectrophotometer in the 650—4000 cm^{-1} region, mostly on a KBr disk. The electronic spectra in solutions and on solid samples were measured with a Hitachi EPI-3T recording spectrophotometer. The NMR spectrum was taken with a Hitachi R-24 spectrometer (60 MHz, $CDCl_3$, reference TMS), and the mass spectrum, with a Hitachi RMU-6L mass spectrometer.

The magnetic susceptibilities of the complexes were measured by the Faraday method. The temperature variation in the magnetic susceptibility was measured by the Gouy method in the range from the temperature of liquid nitrogen to room temperature. The effective magnetic moments, μ_{eff}, were determined by means of this equation;

$$\mu_{eff} = 2.83\sqrt{(\chi_A - N_\alpha)T}$$

where χ_A is the atomic susceptibility corrected by the use of Pascal's constants[6] for diamagnetism, and N_α, the temperature-independent paramagnetism of the copper(II) ion (60×10^{-6} cgs, emu).[7]

Results and Discussion

An examination of the UV, IR, NMR, and mass spectra of Habp did not reveal any particular deviation from the expected properties as a normal aromatic aminophenol with Structure (3).

In the IR spectrum of Habp, the band due to the O–H stretching vibration of the phenolic hydroxyl group was found at 3400 cm^{-1}. The bands in the 2500—2700 cm^{-1} region cannot be assigned definitely at present. These bands, however, could not be observed in the spectra of the copper(II) complexes. Instead a new band was observed around 1550 cm^{-1}. It is known that such a new band appears when the phenolic oxygen is involved with the coordination. The N–H stretching vibrations were shifted to a lower-frequency region by 65—105 cm^{-1} by the complex formation. These facts indicate that both the phenolic oxygen and amino nitrogen of Habp participate in the coordination, and that Habp acts as a bidentate chelating agent to form copper(II) complexes with seven-membered chelate rings. The band at 685 cm^{-1} for Cu(abp)$_2$·C$_6$H$_6$ and the bands at 1705 and 1380 cm^{-1} for Cu(abp)$_2$·CH$_3$COOC$_2$H$_5$ may be attributed to the benzene and ethyl acetate molecules respectively.

The water molecule in Cu(abp)$_2$·H$_2$O is not considered to be coordinated to the copper(II) ion, since it is easily removable at a relatively low temperature. The reflectance spectrum of this complex (given in Fig. 2) shows the d-d band at 13.9×10^3 cm^{-1}; it is

Table 2. The effective magnetic moments (B.M.) over a temperature range of $Cu_5(abp)_8(OH)_2 \cdot 3H_2O$

T(K)	76.4	96.0	119.1	142.1	170.3	200.0	219.0	241.5	274.7	295.7
$\chi_A \cdot 10^6$	2737	2190	1824	1557	1351	1206	1122	1065	967	925
μ_{eff}	1.27	1.28	1.29	1.30	1.33	1.35	1.36	1.40	1.41	1.43

significantly lower in energy than that of bis-(2-aminophenolato) copper(II) (*ca.* 16×10^3 cm^{-1}). This indicates that the configuration of $Cu(abp)_2 \cdot H_2O$ is considerably distorted from the square-planar structure. Since it is well established that the red shift in the d-d band takes place when the geometry around the copper(II) ion is distorted from planarity,[8] the pseudo-tetrahedral configuration of this complex can also be expected in the examination of the molecular model.

The benzene molecule in $Cu(abp)_2 \cdot C_6H_6$ and the ethyl acetate molecule in $Cu(abp)_2 \cdot CH_3COOC_2H_5$ are also considered to be kept between crystal lattices, since the coordination of benzene to copper(II) ion seems unlikely and since it is clear from the IR spectrum that the ethyl acetate molecule is not coordinated to the copper(II) ion. In fact, the reflectance spectra of $Cu(abp)_2$, $Cu(abp)_2 \cdot C_6H_6$, and $Cu(abp)_2 \cdot CH_3COOC_2H_5$ (given in Fig. 2) are very similar to each other, demonstrating that they have nearly the same molecular structure. Although the d-d bands of these complexes are not well-defined, it is assumed, considering the steric requirement of the ligand, that the complexes have pseudo-tetrahedral structures. The absorption band around the 20×10^3 cm^{-1} region which is common in all these complexes is thought to be a kind of charge-transfer band between the ligand and the copper(II) ion. The effective magnetic moments of $Cu(abp)_2 \cdot H_2O$, $Cu(abp)_2$, $Cu(abp)_2 \cdot C_6H_6$, and $Cu(abp)_2 \cdot CH_3COOC_2H_5$ at room temperature are 1.77, 1.78, 1.88, and 1.85 B.M respectively.

The d-d band of the polynuclear complex appears at 15.1×10^3 cm^{-1}. The effective magnetic moment at room temperature was 1.43 B.M., significantly lower than that of the spin-only value (1.73 B.M.). As can be seen in Table 2, the effective magnetic moment of the complex decreases with a decrease in the temperature and approaches 1.27 B.M. near the temperature of liquid nitrogen. This fact implies that this is a polynuclear copper(II) complex composed of an odd number of copper(II) ions, in which an antiferromagnetic spin-exchange interaction operates (spin-doublet ground state). Therefore, the magnetic property of the polynuclear complex is consistent with the composition of the complex, $Cu_5(abp)_3(OH)_2 \cdot 3H_2O$, as determined by elementary analysis.

The author wishes to express his deep thanks to Professor Yoneichiro Muto of Saga University and Associate Professor Hisashi Okawa of Kyushu University for their help in the physical measurements and for their valuable discussions, and to Professor Masaru Yamaguchi of Kyushu University for his encouragement throughout the work.

Photo-ethoxycarbonylation of Anisole, Dimethylaniline and Thiophene in Carbon Tetrachloride-Ethanol Solutions*

Takeo AKIYAMA, Osamu IKARASHI, Koji IWASAKI, and Akira SUGIMORI

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioi-cho 7, Chiyoda-ku, Tokyo 102

(Received February 14, 1974)

UV-Irradiation of anisole, dimethylaniline and thiophene with carbon tetrachloride in ethanol produced ethoxycarbonylated compounds. In general, this photo-ethoxycarbonylation proceeds effectively when a charge transfer complex between aromatic compound and carbon tetrachloride is excited. Attack of trichloromethyl radicals formed by the sensitized decomposition of carbon tetrachloride also occurs in parallel with the charge transfer mechanism.

The authors have reported that ferrocene undergoes photo-ethoxycarbonylation, formylation and ethoxymethylation in carbon tetrachloride–, chloroform–, and dichloromethane–ethanol solutions, respectively.[1a] These photoreactions result from the excitation of the charge transfer complexes of ferrocene with halogenated hydrocarbons.[1b]

Recently, Hirao and Yonemitsu reported the photochemical introduction of formyl group into phenol and diethylaniline during UV-irradiation in chloroform–methanol solutions.[2] They also described the formation of methyl hydroxybenzoates during UV-irradiation of phenol and carbon tetrachloride in aqueous methanol solution.

This paper deals with the photo-ethoxycarbonylation of anisole, dimethylaniline and thiophene in carbon tetrachloride–ethanol solutions.

Experimental

Materials. Commercially available anisole and *N,N*-dimethylaniline (Wako Junyaku E. P. grade reagents) were purified by distillation under reduced pressure and checked by thin layer chromatography after the distillation. Thiophene (Wako Junyaku E. P. grade reagent) was purified by distillation under atmospheric pressure. Carbon tetrachloride was purified as described previously.[1a] Spectro-grade cyclohexane (Wako Junyaku Dotite Spectrosol) was used for the measurement of UV-spectra.

Irradiation. The irradiation procedure was similar to that described previously.[1a]

Separation of the Photoproducts (General Procedure). The irradiated solution was washed with aqueous sodium hydrogen carbonate solution and water after which the organic layer was extracted with ether. The ether solution was dried and then the ether was removed under reduced pressure by a rotary evaporator. The residue was chromatographed on a silica gel column. The eluate was further purified by successive thin layer chromatography on silica gel (Merck, GF-254).

Identification of the Photoproducts. The photoproducts were identified by comparing their IR and NMR spectra, and gas chromatograph retention times with those of authentic samples.

Quantitative Analysis. The products were analyzed with a Yanagimoto GC-550F gas chromatograph equipped with a 1.5 m glass column of Carbowax 20 M on Diasolid L (20%, 60—80 mesh), at 150—184 °C. The analyses listed in Table 1 are the averages of at least three separate experiments.

Measurements. IR spectra were recorded with a Hitachi 215 grating infrared spectrophotometer. UV spectra were recorded with a Hitachi 124 spectrophotometer. NMR spectra were measured with a Hitachi R-24 (60 MHz) or a Hitachi R-22 (90 MHz) spectrometer.

Results and Discussion

The UV-spectra of dimethylaniline, anisole and thiophene in cyclohexane and in carbon tetrachloride are shown in Figs. 1, 2, and 3.

In dimethylaniline, the enhancement of the UV-absorption near 300 nm in the presence of carbon tetrachloride is attributed to the formation of a charge

transfer complex of dimethylaniline with carbon tetrachloride, as was proposed by Davis and Farmer.[3]

Anisole also shows a slight enhancement of UV-absorption at 250—260 nm and at 270—290 nm. Thiophene also shows a slight enhancement near 250 nm. The linear correlation between ionization potential and wavelength of absorption maximum of the charge transfer band was reported for alkylbenzene-carbon tetrachloride systems.[4,5] Since the ionization potentials of anisole (8.20 eV)[6] and thiophene (8.86 eV)[6] are close to those of hexamethylbenzene (8.15 eV,[7] $h\nu_{CT}$ 240—246 nm[5]) and *m*-xylene (8.9 eV,[7] $h\nu_{CT}$ 232—238 nm[5]), respectively, the enhancement of the UV-absorption of anisole in carbon tetrachloride near 250 nm or that of thiophene in this region can be ascribed to the formation of charge transfer complexes with carbon tetrachloride.

The UV-irradiation of anisole, dimethylaniline and thiophene with carbon tetrachloride in ethanol solution gave the corresponding ethoxycarbonylated compounds, as in the irradiation of the ferrocene–carbon tetrachloride–ethanol system. In the case of anisole and dimethylaniline, the yields of photoproducts and the ratios of isomers obtained are changed significantly by changing the wavelength of irradiating light. The results are summarized in Table 1.

Photoreaction of Dimethylaniline. Irradiation with 254, 313, and 365 nm light gave both *o*- and *p*-dimethylaminobenzoates. Irradiation with 254 nm light resulted in an *o*/*p* ratio of 3.7. An irradiation with 254 nm light, the incident light was mostly absorbed by uncomplexed dimethylaniline. The addition of cyclohexene, a radical scavenger, markedly suppressed the formation of ethyl dimethylaminobenzoates, especially the *ortho* isomer: the *o*/*p* ratio in the presence of cyclohexene was 0.47. Irradiation with light of longer wavelength gave different results: lower *o*/*p* ratio (1.31 and 1.78) were obtained on irradiation with 313 and 365 nm light. The *o*/*p* ratios in the presence of cyclohexene are similar on irradiation with 254 and 313 nm light (0.47 and 0.39). The photo-ethoxycarbonylation of dimethylaniline with 313 nm light, which was not affected by added cyclohexene, can be considered to proceed in the solvent cage. The value of the *o*/*p* ratio, 1.31, obtained on irradiation with 313 nm light is closer to 0.47 and 0.39 than to the 3.7 obtained on irradiation with 254 nm light. In the photo-ethoxycarbonylation of dimethylaniline with 313 nm light, the charge transfer complex between dimethylaniline and carbon tetrachloride contributes greatly to the photo-substitution. Irradiation with 365 nm light also gave an *o*/*p* ratio, 1.78, which is close to that obtained on irradiation with 313 nm light.[8]

Higher yields of the ethoxycarbonylated products were obtained in the presence of cyclohexene than in its absence on irradiation with 313 nm light. The reason for this effect of cyclohexene is still not clear.

The formation of hydrogen chloride during the reaction may cause the decomposition of dimethylaniline to give *N*-methylaniline and an anilinum cation which reacts with dimethylaniline photochemically to give biphenyl derivatives.[9] Although a quantitative analy-

a) The total volume of the sample solution was 50 ml. b) The values listed in this table are averages of at least three separate experiments. The yields were calculated from glpc data on the basis of starting materials consumed. c) The isomer distributions are as follows: 254 nm, *o*-: *m*-: *p*- =34.8: 5.3: 59.8, 254 nm with cyclohexene, *o*-: *m*-: *p*- =41.4: 11.7: 46.8, 265 nm, *o*-: *m*-: *p*- = 58.4: 7.1: 34.3, 265 nm with cyclohexene, *o*-: *m*-: *p*- =31.7: 4.0: 64.1. d) Ethyl salicylate was taken as an *ortho*-isomer. e) The values in parentheses are the yields on the basis of starting material. f) The yield based on starting material used.

sis was not made, *N*-methylaniline was detected by gas chromatography, but no biphenyl derivatives were detected.

Photoreaction of Anisole. For anisole, the ratio of the photoproducts also changed with the wavelength of the irradiating light; irradiation with 254 nm light gave *p*-chloroanisole and ethyl methoxybenzoates (*o*-: *m*-: *p*-=34.8: 5.3: 59.8) as the main products, whereas irradiation with 265 nm light gave ethyl methoxybenzoates and ethyl salicylate (*o*-: *m*-: *p*-=58.4: 7.1: 34.3, ethyl salicylate was considered as an *ortho*-substituted product) as the main products. The yield of *p*-chloroanisole on irradiation with 265 nm light was nearly one third of that on irradiation with 254 nm light. Cyclohexene was observed to have a marked effect on product formation as in the case of dimethylaniline. The addition of cyclohexene diminished the yields of ethyl methoxybenzoates and *p*-chloroanisole upon irradiation with 265 nm light, whereas the ethoxycarbonylation with 254 nm light was retarded to a lesser extent. In general, the *o*/*p* ratio of the isomers in the free radical substitution of anisole is greater than 1.[10] The *o*/*p* ratio on irradiation with 265 nm light was 1.71 and the addition of cyclohexene lowered the *o*/*p* ratio to 0.50. This indicates that the photoethoxycarbonylation with 265 nm light proceeds mainly *via* a free radical mechanism. On the other hand, the *o*/*p* ratio on irradiation with 254 nm light is less than 1 and the value was affected by cyclohexene to a lesser extent. These results indicate that on irradiation with 254 nm light the ethoxycarbonylated products are not formed *via* free radical attack on anisole but are probably formed by the combination of radical cations of anisole and trichloromethyl radicals produced by the excitation of the charge transfer complex in the solvent cage. This was considered to be the case for dimethylaniline irradiated with 313 nm light which excites mainly charge transfer complexes.

The formation of *p*-chloroanisole on irradiation with 254 nm light can be explained by the attack on anisole by a chlorine atom which is produced either by sensitized decomposition[11] of carbon tetrachloride or by electron transfer between a cation radical and a chloride anion.[12] The possible reaction mechanisms of the

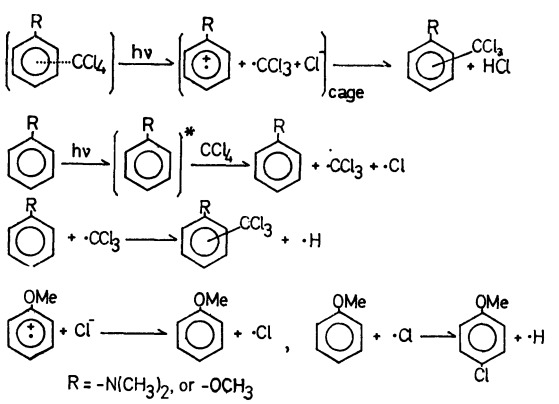

photo-ethoxycarbonylation of dimethylaniline and anisole are shown in the following schemes.

Photoreaction of Thiophene. Thiophene undergoes a similar photo-ethoxycarbonylation upon irradiation with 254 nm light giving ethyl 2-thiophenecarboxylate. In this case, the substitution at the 2-position occurred selectively and no chlorothiophene was detectable. Polymeric substances were also obtained. The addition of cyclohexene did not reduce the yield of ethyl 2-thiophenecarboxylate. The UV-spectrum of thiophene and carbon tetrachloride in ethanol solution showed a slight enhancement of absorption near 254 nm. These results and the effect of cyclohexene on the photoproduct suggest that the trichloromethyl radicals which are formed by the dissociation of the charge transfer complex between thiophene and carbon tetrachloride attack the radical cation of thiophene in the solvent cage.

An attempt to isolate the intermediate trichloromethylthiophene was unsuccessful, but when thiophene was irradiated in carbon tetrachloride and ethanol was then added to the reaction mixture after the irradiation, ethyl 2-thiophenecarboxylate was detected by gas chromatography. As reported,[13] the trichloromethyl group is solvolyzed rapidly during UV-irradiation. The isolation of trichloromethylated compounds may thus be quite difficult. The possible reaction processes for the photo-ethoxycarbonylation of thiophene is shown in the following schemes.

Resins from Formaldehyde. 103.[1] Reaction of Naphthalene with Aqueous Formaldehyde Solution*

Tatsuro OUCHI, Saburo OTSUKA, and Minoru IMOTO

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Senriyama, Suita-shi, Osaka 564

(Received March 7, 1974)

The reaction of naphthalene(N) with formaldehyde(F) was carried out in dioxane or an acetic acid/water solution, using sulfuric acid as the catalyst. The rate of the consumption of F is proportional to $[N]^{1.12}[F]^{1.05}[H_2SO_4]^{1.05}$. The activation energies and entropies of the reaction of N, α- and β-naphthyl carbinol(NC) with F were estimated to be 21.4, 15.3, and 16.0 kcal/mol and −19.1, −36.2, and −33.2 e.u., respectively. The reaction products were isolated and their structures were identified as α-NC, αα′-, αβ′-dinaphthylmethane, three- and four-nuclear compounds, which are linked to each other with methylene or methylene ether bonds at the α- or β-positions; identified was done by means of the IR, NMR, and UV spectra, molecular-weight measurements, elemental analysis, and thin-layer chromatography. In addition to the compounds described above, acetyl esters were obtained when the reaction was carried out in the presence of acetic acid. The reactivities of the α-position of N and its derivatives was larger than those of the β-position. Moreover, the resin formation from N and F was studied by means of gel-permeation chromatography. On the bases of these results, the reaction route of N with F to resin was deduced.

Almost seventy years ago, Bohn[2] found that the condensation resin of naphthalene(N) with formalin gave a resinous matter which could be used as a drying oil. According to his patent, when the molar ratio of formaldehyde(F) to naphthalene becomes larger, the resulting resin has a larger molecular weight, a large melting point, and a lower oxygen content. The resin was assumed to be composed of compounds with methylene linkages.

A German patent[3] in 1918 described that the reaction product of N with F was white resin and could be dissolved in acetone, benzene, solvent naphtha, carbon tetrachloride, and carbon disulfide. In 1962, Imoto *et al.*[4] studied kinetically the reactions of N and methylnaphthalene with F in the presence of perchloric acid, using acetic acid as the solvent.

The present paper will deal with acid-catalyzed reaction of N with an aqueous F solution in dioxane or acetic acid. Moreover, some intermediate compounds to resinous matter were isolated; the reaction mechanism will be discussed.

Experimental

Materials. N of a special grade was purified by sublimation. Formalin containing 41.51% of F and less than 0.8% of methanol, supplied by the Mitsubishi Gas Chemical Co., Ltd., was purified in order to remove the formic acid by passing it through an ion-exchange resin column.

Five kinds of authentic compounds (α-NC, β-NC, αα′-DNM, αβ′-DNM, and ββ′-DNM) were synthesized according to the scheme shown in Fig. 1. Their melting points and their R_f values in thin-layer chromatography (tlc) are listed in Table 1. A thin-layer chromatogram on silica gel (Wakogel B5F) was activated by heating at 130 °C for a period of 4 hr.

Measurement of the Reaction Rate. N or its derivative was dissolved in dioxane. After adding 5 N-sulfuric acid, the measuring flask was warmed at a definite temperature,

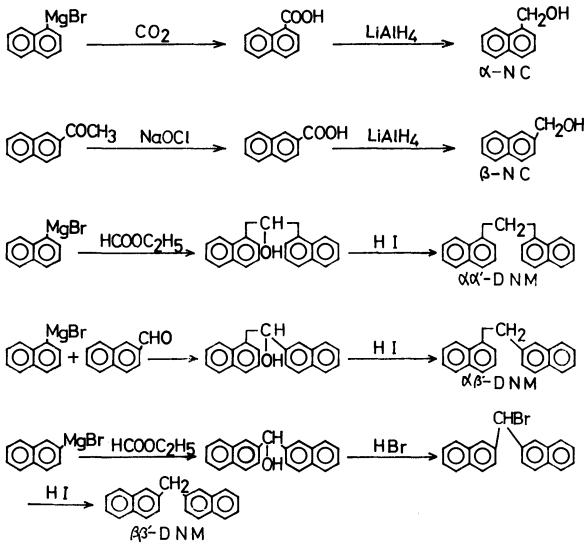

Fig. 1. Syntheses of authentic compounds.

TABLE 1. MELTING POINT AND R_f VALUE OF NAPHTHALENE DERIVATIVES

Compounds	mp (°C) Found	mp (°C) Lit	R_f value[a]
Naphthalene (N)	79.5—80.5	80.2	0.6
α-Naphthylcarbinol (α-NC)	60—61.5	59.5—60[6]	0.1
β-Naphthylcarbinol (β-NC)	80.5—81.5	80—80.5[6]	0.1
α,α′-Dinaphthylmethane (α,α′-DNM)	105—105.5	107—108,[8] 109[9]	0.6
α,β′-Dinaphthylmethane (αβ′-DNM)	94.5—95.5	96[9]	0.6
β,β′-Dinaphthylmethane (ββ′-DNM)	91.5—92.5	93[9]	0.6

a) Benzene–carbon tetrachloride mixture (1: 1) was used as a solvent

an F solution at the same temperature was added, and the solution was diluted to exactly 50 ml with dioxane. The time thirty seconds after the mixing in of F was considered as the starting point of the reaction. An aliquot portion (3 ml) of the reaction mixture was taken up from time to time and quenched with a sufficient volume of a 0.5 M–NaOH solution to neutralize the above mixture. The concentration of the remaining unreacted F was determined by means of the sodium-sulfite method.

Fractionation of the Reaction Product. The reaction products were fractionated by column chromatography and tlc. The R_f values of tlc were obtained by using benzene–CCl_4 (1:1 in vol.) as the developing solvent. The three kinds of DNM showed almost the same R_f values of tlc as that of N. Accordingly, when the separation of DNM from N by tlc was carried out, the chromatogram was allowed to stand under an atmosphere at room temperature for about 20 hr in order to sublime the N. The spot of tlc was determined by the UV-fluorescence method or by coloration with iodine.

Molecular Weights. The molecular weights were determined by the vapor-pressure osmometer (VPO) method at 37 °C, using benzene as the solvent.

Results and Discussion

Kinetics of the Reaction of Naphthalene with Formaldehyde. At first, a kinetic experiment was conducted on the rate of the reaction of N with F in a dioxane–water mixture (1:1) at 80 °C in order to derive the rate equation.

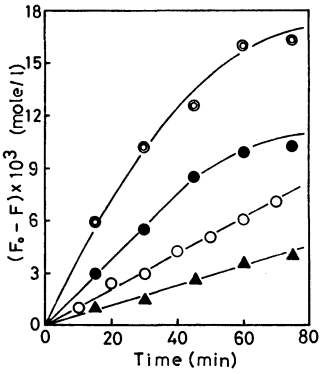

Fig. 2. $[N]_0$ *vs.* consumed [F] at 80 °C. $[F]_0=0.0568$ mol/l, $[H_2SO_4]=0.483$ mol/l, $[N]_0$ ▲: 0.0250 mol/l, ○: 0.0500 mol/l, ●: 0.0750 mol/l, ◎: 0.100 mol/l
solvent: dioxane–water (80:20 in vol)

When the concentration of N was varied from 0.0250 to 0.100 mol/l, while the initial concentrations of F and sulfuric acid were kept at 0.0568 and 0.483 mol/l respectively, the consumption of F increased linearly with the reaction time, as is shown in Fig. 2.

When the F and catalyst concentrations were changed, linear relationships were also obtained between the consumption of F and the reaction time. In addition, the dependence of the initial concentration on the rate was drawn (Fig. 3).

From this figure, the rate equation of the reaction of N with F in aqueous dioxane in the presence of sulfuric acid was concluded to be as follows:

$$R_0 = -\mathrm{d[F]/d}t = k[\mathrm{N}]_0^{1.12}[\mathrm{F}]_0^{1.05}[\mathrm{H_2SO_4}]^{1.05} \quad (1)$$

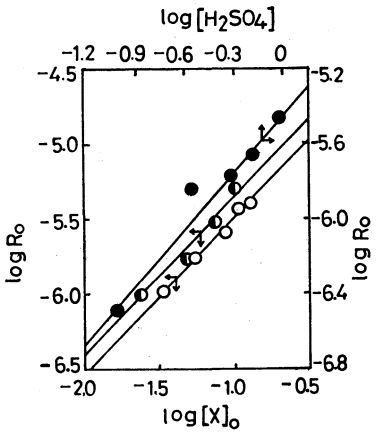

Fig. 3. Dependence of initial concentration on reaction rate.
○: X=N, $[F]_0=0.0568$ mol/l, $[H_2SO_4]=0.483$ mol/l, $[N]_0=0.0250$—0.100 mol/l
◐: X=F, $[N]_0=0.0500$ mol/l, $[H_2SO_4]=0.438$ mol/l, $[F]_0=0.0341$—0.1363 mol/l
●: $[F]_0=0.0568$ mol/l, $[N]_0=0.500$ mol/l, $[H_2SO_4]=$ 0.0966—0.966 mol/l
Solvent: dioxane–water (80:20 in vol) Temp: 80 °C

Equation (1) agreed well with Eq. (2), which was formerly[4] obtained by the acidic reaction of N with F carried out in acetic acid by one of the present authors (M. Imoto). Moreover Eq. (2) is a usual rate equation for the acidic reaction of F with many phenolic compounds and aromatic hydrocarbones.

$$-\mathrm{d[F]/d}t = k[\mathrm{N}]_0[\mathrm{F}]_0[\mathrm{H_2SO_4}] \quad (2)$$

By using Eq. (2), the average value of the rate constant, k, at 80 °C was calculated to be 1.29×10^{-3} $l^2\,mol^{-2}\,s^{-1}$.

Reactivities of Naphthalene and its Derivatives with Formaldehyde. As has been mentioned above, F was concluded to react with N in the presence of sulfuric acid according to Eq. (2). This equation can be also applied to the N derivatives which may be generated as intermediates during the so-called addition-condensation of N with F to from naphthalene-resin.

The reaction was carried out at 80 °C in aqueous dioxane, keepting the initial concentrations of N or its derivatives, F and, H_2SO_4 constant at 0.0500, 0.0568, and 0.483 mol/l respectively.

The experiments to determine the rate constant, k, were repeated twice. The averages of k listed in Table 2 were thus obtained. From the results shown in

Table 2. Reactivities of naphthalene and its derivatives.
$[N]_0$ or [N derivatives]$_0=0.0500$ mol/l, $[F]_0=0.0568$ mol/l, $[H_2SO_4]=0.483$ mol/l; 80 °C
solvent: dioxane–water (80:20 in vol)

Compounds	$k\times10^3$ (l^2/mol^2 s)
N	1.24
α-NC	1.21
β-NC	2.01
αα′-DNM	1.61
αβ′-DNM	3.65
ββ′-DNM	4.62

Table 2, it can be concluded that the α-position of N is more reactive than the β-position. These results are explicable with reactive parameters calculated by means of the molecular-orbital method.

Estimations of E_a and ΔS^* on the Acidic Reactions of Naphthalene and its Carbinols with Formaldehyde. The rate constants of the reaction of N, α-NC, and β-NC with F in aqueous dioxane were determined at 80 °C; they are listed in Table 2. Similarly, the values of the rate constants at 60, 70, and 90 °C were determined. Arrhenius plots were thus drawn, as is shown in Fig. 4. From these lines, the overall activation energies (E_a) and entropies (ΔS^*) were calculated; they are listed in Table 3.

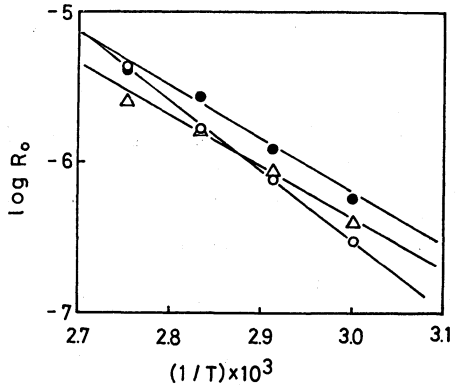

Fig. 4. Arrhenius plots of the reaction of F with N, α-NC and β-NC in aqueous dioxane. ○: N, △: α-NC, ●: β-NC

Table 3. E_a and ΔS^*

Compounds	E_a (kcal/mol)	ΔS^* (80 °C) (e.u.)
N	21.4	−19.1
α-NC	15.3	−36.2
β-NC	16.0	−33.2

The E_a of the reaction of N with F was estimated to be 21.4 kcal/mol. One of the present authors (M. I.) has formerly reported that the activation energies of the reactions of phenol, cresols, and their polynuclear compounds with F were generally close to 23 kcal/mol.[11] It is interesting that the value of 21.4 kcal/mol obtained in the case of naphthalene was also close to 23 kcal/mol.

The E_a and ΔS^* of the reaction of F with NC were found to be smaller than those with N. This may be a result of the activation of the cationic attack on the naphthalene nucleus and the intermolecular hydrogen bond by the introduction of the CH_2OH group into N.

Isolation of Initial Products of the Reaction of Naphthalene with Formaldehyde. Various amount of glacial acetic acid, 12.8 g of N, 5.4 g of 41.51% formalin, and 5 g of 18M-sulfuric acid were mixed thoroughly and warmed (Table 4). After the reaction time has elapsed, the mixture was neutralized with a sodium hydroxide solution and extracted with benzene. The extract was washed repeatedly with water, concentrated to about 100 ml, and then distilled by steam. The unreacted N was then distilled off, and the residue was extracted with benzene. The separation of the components in the extract was carried out by column chromatography, using carbon tetrachloride–benzene (5:1) as the eluent.

Fraction I: Fraction I in Table 4 was fractionated once more into five portions by column chromatography, using the above solvent. The first portion (i) has the largest R_f-value, while the fifth portion (v) has the smallest R_f-value.

Fraction (i): Repeated recrystallizations from an equivolume mixture of benzene and methanol gave needle crystals; mp 104.5—107 °C; R_f of tlc 0.6 (benzene–CCl_4 1:1 in vol.). Mixing with an authentic sample of αα′-DNM showed the same mp, without any depression. IR (KBr disk) 2925, 2875 cm^{-1} (CH_2); NMR (CCl_4) τ 5.16 (s, Ar–CH_2–Ar).

Found: C, 93.81; H, 5.70%; mol wt, 265. Calcd for $C_{21}H_{16}$: C, 93.99; H, 6.10%; mol wt, 268.

Fraction (ii): The powder-like crystals were collected by recrystallization from a benzene–methanol mixture; mp 94.5—95.5 °C; R_f of tlc 0.6. No depression of the mp was observed after mixing with an authentic sample of αβ′-DNM. IR (KBr disk) 2925, 2875 cm^{-1} (CH_2); NMR (CCl_4) τ 5.46 (s, Ar–CH_2–Ar).

Found: C, 94.02; H, 5.79%; mol wt, 263. Calcd for $C_{21}H_{16}$: C, 93.99; H, 6.01%; mol wt, 268.

An alternative reaction of N with F under the conditions shown for Experiment No. 2 in Table 4 was carried out. Fractions (I-i) and (I-ii) were thus isolated. They were distilled under a vacuum (bp 258—265 °C/10 mmHg) and fractionated by recrystallization from a benzene–methanol mixture into αα′-DNM and αβ′-DNM. The quantity of αα′-DNM was assumed to be larger by 15—20 times than that of αβ′-DNM.

Fraction (iii): Repeated fractional recrystallizations from diethyl ether gave powder-like crystals as the most difficultly soluble fraction: mp 137—140 °C; R_f of tlc 0.6; IR (KBr disk) 2925, 2875 cm^{-1} (CH_2); NMR (CCl_4) τ 5.20 (s, Ar–CH_2–Ar–CH_2–Ar).

Found: C, 94.27; H, 5.64%; mol wt, 405. Calcd for $C_{32}H_{24}$: C, 94.08; H, 5.92%; mol wt, 408.

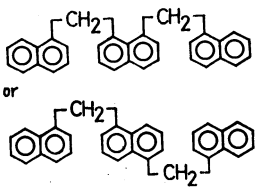
The absorptions due to the methylene group at 2925 and 2875 cm^{-1} very much resembled that of αα′-DNM,

Table 4. Fractionation of reaction products of naphthalene with formaldehyde

Exp. No.	N (g)	F (g)	Acetic acid (ml)	Temp (°C)	Unreacted N (g)	Fractions from column chromatography (g)				
						I	II	III	IV	V
						R_f 0.6	0.4	0.25	0.2	0
1	12.8	5.4	200	90	4.7[a)]	6.1	—	0.1	1.8	—
2	12.8	12.0	150	100	4.8[a)]	6.3	0.04	0.04	1.6	0.4

a) Including the portion of R_f 0—0.1 of the column chromatography.

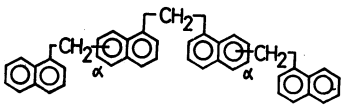
but the different absorption appeared at about 800 cm^{-1}. By this absorption in IR and a singlet signal due to protons of CH_2 in NMR, it was considered that this compound has a symmetrical structure. Accordingly, it may be concluded that this crystal is a three-nuclear compound linked with methylene groups at the α-positions, as is shown below.



Fraction (iv): Powder-like crystals were obtained by repeated reprecipitations from a benzene solution with methanol; mp 214—220 °C; R_f of tlc 0.6; IR (KBr disk) 2925, 2875 cm^{-1} (CH_2): NMR (CCl_4) 5.15 (s, Ar–CH_2–Ar–CH_2–Ar–CH_2–Ar–CH_2–Ar).

Found: C, 93.27; H, 5.91%; mol wt, 526. Calcd for $C_{43}H_{32}$: C, 94.12; H, 5.88%; mol wt, 549.

From the data of IR and NMR, this fraction was assumed to be composed mainly of the four-nuclear compound, linked with CH_2 groups at the α-positions.



Fraction (v): Repeated reprecipitations from benzene and methanol gave the following five fractions; the mps ranged between 120 and 190 °C, and the R_f values between 0.6 and 0.5; IR (KBr disk) 2925, 2875 cm^{-1} (CH_2).

Found: (a) C, 93.64; H, 5.81%; mol wt, 524; (b) C, 93.38; H, 5.70%; mol wt, 548; (c) mol wt, 649; (d) C, 93.81; H, 5.69%; mol wt, 683; (e) C, 93.16; H, 5.49%; mol wt, 869.

Fraction II: This fraction was obtained as a viscous liquid, with an R_f value of about 0.4. Repeated reprecipitations from benzene and methanol gave a white powder. It started to melt at 78 °C without showing any definite temperature. The IR spectrum has signals at 1730 cm^{-1} (C=O) and 1225 cm^{-1} (C–O), showing that the fraction is composed of an acetylester of NC or DNM.

Found: C, 88.30; H, 6.35%.

Fraction III: This fraction was also assumed to be an ester: mp>117 °C, R_f 0.25. Signals of IR agreed with those of the acetic ester.

Found: C, 89.22; H, 5.58%.

Fraction IV: Fraction IV (R_f 0.2) was a highly viscous liquid. It was purified by reprecipitation from benzene and methanol, and then fractionated by column chromatography, using carbon tetrachloride and chloroform as the solvents. The most abundant fraction was purified by the reprecipitation method, using carbon tetrachloride and methanol. A white powder was thus obtained; mp 142—164 °C; R_f 0.2; IR: 1730 cm^{-1} (C=O), 1225 cm^{-1} (C–O).

Found: C, 90.32; H, 5.63%; mol wt, 600. Calcd for $C_{46}H_{36}O_2$: C, 89.00; H, 5.85%; mol wt, 621.

$C_{46}H_{36}O_2$ corresponds to an acetate of the four-nuclear methylol compound.

Fraction V: A viscous liquid was obtained as a fraction with an R_f value of 0.0—0.06. Reprecipitation from a benzene solution with methanol gave the following three fractions.

Found: (i) C, 88.02; H, 5.40%; mol wt, 790, (ii) C, 86.63; H, 5.38; mol wt, 874, (iii) C, 85.09; H, 5.46; mol wt, 1028.

The oxygen contents of these fractions were very large, and it was assumed from, the IR spectra that oxygen existed as an acetate group or as a dimethylene ether group.

Fraction having R_f of 0.1: In another experiment, the reaction product of N with 41.51% formalin under the same conditions as an Exp. No. 2 in Table 4 was distilled under a vacuum. The fraction boiling at 150—170 °C/15 mmHg was again fractionated by column chromatography, using carbon tetrachloride as the solvent. A fraction with an R_f value of 0.1 was recrystallized from a carbon tetrachloride–methanol solution (1 : 1 in vol.) to give needle crystals: mp 60.5—61.5 °C. IR (KBr disk) 3350, 1000 cm^{-1} (OH), 2925, 2875 cm^{-1} (CH_2).

Found: C, 83.21; H, 6.08%. Calcd for $C_{11}H_{10}O$: C, 83.51; H, 6.37%.

No depression of mp was shown upon mixing with an authentic sample. Accordingly, this crystal may be concluded to be α-naphthyl carbinol.

Formation of Two-nuclear Dimethylene Ether Compound from β-Naphthyl Carbinol. A solution of 2 g of β-NC in 25 ml of dioxane was heated at 100 °C for 22 hr in the presence of 10 ml of 5 M-sulfuric acid. After the reaction, the mixture was extracted with benzene, washed with water, and then neutralized with an 1 M-NaOH solution. The benzene was evaporated almost completely. The residue, diluted with carbon tetrachloride was then submitted to column chromatography. A fraction with an R_f value of 0.35 was recrystallized from a mixture of carbon tetrachloride and petroleum ether. Needle-like crystals were thus obtained; mp 123—125.5 °C (121—123 °C[12]).

Found: C, 88.58; H, 6.23%; mol wt, 292. Calcd for $C_{22}H_{18}O$: C, 88.56; H, 6.08%; mol wt, 298.

From the IR and NMR results, the fraction was concluded to be di-β-naphthylmethylene ether.

Formation of Dinaphthylmethane from Naphthylcarbinol and Naphthalene. Formation of αα′-DNM: α-NC, N, and sulfuric acid were dissolved in acetic acid. Their concentrations were 0.0500, 0.0500, and 0.483 mol/l respectively. After the solution has been warmed at 80 °C for 5 hr, αα′-DNM was isolated from the reaction mixture by column chromatography in a yield of 20 wt% of the α-NC. The αα′-DNM thus isolated was confirmed by comparing its UV spectrum with that of an authentic sample: λ_{max}=285 nm (ε=16200). *Formation of αβ′-DNM*: β-NC was reacted with N in a way similar to that used in the case of α-NC. The yield of αβ′-DNM isolated was about 10 wt%. Its identity as αβ′-DNM was confirmed by studing the UV spectrum: λ_{max}=273 nm (ε=14400).

Assumed Route for the Reaction of Naphthalene with

Formalin to Resin. As has been mentioned above, α-NC, αα'-DNM, αβ'-DNM, and three- and four-nuclear compounds, which are all linked to each other with methylene bonds, predominantly in the positions of α, were isolated. Thus, it was concluded that the formation reaction of naphthalene-formaldehyde resin is also included in the so-called "addition-condensation" reaction. First, NC, especially α-NC, is generated by the reaction of N with F; then NC is condensed with N to give αα'-dNM. These two reactions occur laternatively in preparing a higher nuclear compound. Accordingly, the reaction route may be shown as in Fig. 5.

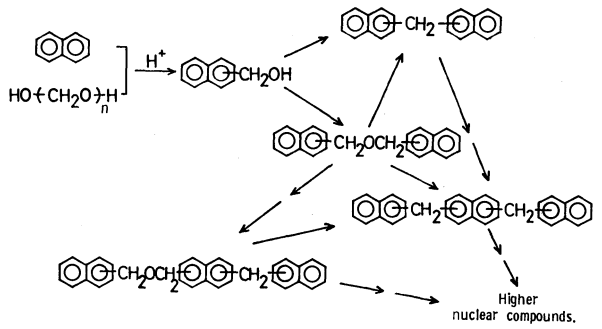


Fig. 5. Reaction route of naphthalene with formaldehyde in acidic medium

Studies of the Resin Formation from Naphthalene and Formaldehyde by Gel-permeation Chromatography. Calibration curve for GPC-analysis: Separation was carried out by means of the apparatus of Waters' Associates, GPC 501, using tetrahydrofuran (THF) as the solvent. The injected samples had an average concentration of 0.1—0.5 wt%. The two columns used were 4 ft long and 1/2 in. in diameter, and were packed with polystyrene gels whose porosities were 100 and 60 Å respectively.

Using synthesized authentic samples and fractionated higher-molecular-weight compounds, a calibration curve was prepared. As is shown in Fig. 6, α- and β-Naphthyl carbinols deviated from the line. Such deviations may be due to the increases in the molecular sizes as a results of the loose complexing of naphthyl carbinol with THF.*

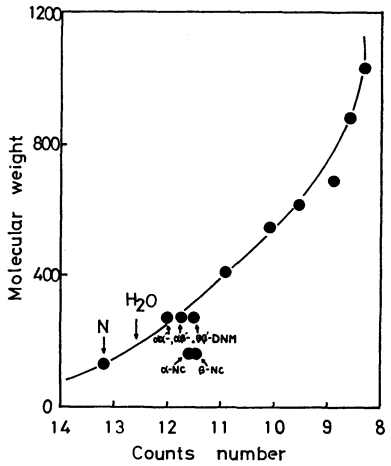

Fig. 6. GPC calibration curve.

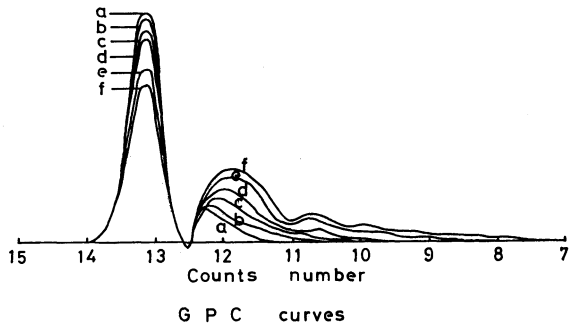

Fig. 7. GPC curves.
Reaction time a: 0 min, b: 30 min, c: 60 min, d: 90 min, e: 150 min, f: 180 min

Change in the GPC-curve of the Reaction Products with Reaction Time: A solution of 19.2 g of N, 9 g of 41.51% formalin, and 7.5 g of 81 M-sulfuric acid in 300 ml of glacial acetic acid was heated at 90 °C. After a definite time, an aliquot of the solution was pipetted

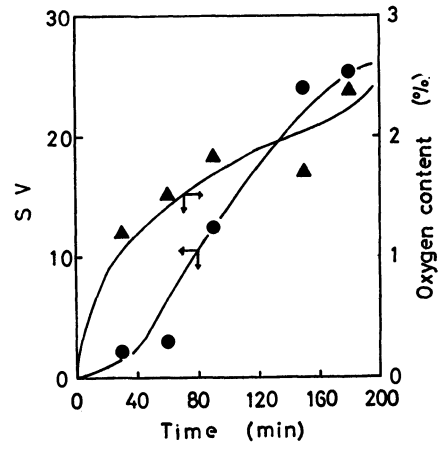

Fig. 8. Saponification values and oxygen contents *vs.* reaction time.

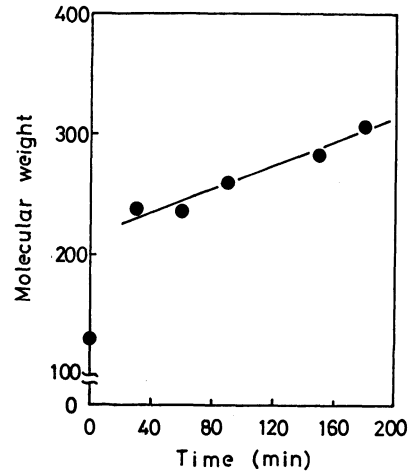

Fig. 9. Molecular weights *vs.* reaction time.

* It had been found that a solution of α- or β-naphthylcarbinol in THF shows a new IR signal of the hydrogen bond at 3420 cm^{-1}.[13]

out, extracted with benzene and carefully washed with water. The benzene layer was then concentrated to almost dryness. The residue was dissolved in THF and used as an injection solution for GPC. The results are shown as Fig. 7. It may be seen that the peak around 13 counts become lower, while the peaks around 12 counts become higher, with the reaction time.

Changes in the Oxygen Contents, Saponification Values and Molecular Weights of the Products with the Reaction Time. The products used for GPC analyses were also submitted to measurements of their oxygen content and saponification value (SV) without and further purification in order to avoid the loss of any components. The oxygen content was estimated by an elemental analysis of the carbon and hydrogen. As the products contained unreacted N, the oxygen contents were not so high as has been expected. The SV was calculated by the usual saponification method, using alcoholic potassium hydroxide in a solvent of benzene–ethanol mixture as the solvent. The molecular weight of the product, after the removal of the unreacted N by steam distillation, was determined by the VPO method, using benzene as the solvent. The results are shown in Figs. 8 and 9.

The Photochemical Reaction of Benzo[*c*]cinnoline. I. The Photoreduction and Subsequent Reactions in Acidified Alcohols

Hiroyasu INOUE, Tetsuo SAKURAI, and Fujio TANAKA

Department of Applied Chemistry, Faculty of Technology, Kanagawa University, Kanagawa-ku, Yokohama 221

(Received May 25, 1974)

The photoinduced reaction of benzo[*c*]cinnoline (BCC) in strongly acidic aqueous alcohols, in which BCC exists in a monoprotonated form ($BCCH^+$), was investigated. The initial step of the photoreaction was the hydrogen abstraction, which gave rise to 5,6-dihydro$BCCH^+$, irrespective of the excitation wavelengths and the kind of alcohol (methanol, ethanol, or 2-propanol) used as a solvent. The subsequent reaction occurred upon irradiation by a light longer than 400 nm to afford 2,2′-diaminobiphenyl in ethanol, but not in methanol and 2-propanol. The 1-hydroxyethyl radical formed in the initial photoreduction appeared to participate in this reaction, donating its hydrogen atom to the ground-state 5,6-dihydro$BCCH^+$. On the other hand, ultraviolet irradiation caused the subsequent photoreaction of 5,6-dihydro$BCCH^+$, thus giving carbazole accompanied by the liberation of ammonia.

The photochemistry of a variety of nitrogen heterocyclic compounds has been studied.[1,2] Hitherto, however, little has been known concerning the photochemical behavior of *ortho*-diazines. Chen *et al.*[3] studied the photoreaction of 4-methylcinnoline in ethers, and showed that the 1,4-addition of the ethers occurred. According to Davis and Cohen,[4] benzo[*c*]cinnoline (BCC) undergoes photoreduction to give 5,6-dihydrobenzo[*c*]cinnoline (5,6-dihydroBCC) in benzene containing triethylamine as a hydrogen donor. 5,6-DihydroBCC is very susceptible to oxidation to BCC;[5] hence, it is not isolated. However, in a previous paper[6] it has been found that 5,6-dihydroBCC is fairly stable in a polyvinyl alcohol film, thus permitting the observation of its ultraviolet spectrum, when it is produced photochemically in the film. As has been briefly reported,[7] the ultraviolet irradiation of BCC in strongly acidic aqueous 2-propanol (3.75 M HCl), interestingly, affords carbazole in a fairly high yield. However no carbazole formation is observed when irradiation is carried out on a neutral solution of BCC in 2-propanol.

The purpose of the present paper is to present the experimental results on the photoreaction of $BCCH^+$ in strongly acidic alcohol under nitrogen. Since the photoreaction has been found previously to depend on the excitation wavelengths and on the kind of alcohol used as a solvent (methanol, ethanol, or 2-propanol), particular attention is paid to these points.

Results and Discussion

In an acidic solution stronger than 3 M HCl, BCC exists in the monoprotonated form ($BCCH^+$) and has the absorption spectrum shown in Fig. 1. Although the n-π^* band is at the longest wavelength for BCC,[8] the 420 nm band of $BCCH^+$ is of the π-π^* type. All irradiations were carried out on such strongly acidic solutions of BCC.

Photoreaction of BCC in 2-Propanol and Methanol upon Visible-light Irradiation. A 1.6×10^{-4} M solution of $BCCH^+$ in acidic aqueous 2-propanol was irradiated with visible light longer than 400 nm in an atmosphere of nitrogen at room temperature by using a filter whose percent transmittance is shown in Fig. 1. The spectral change in the solution caused by the irradiation is shown in Fig. 2. The reaction was completed in 180 min of irradiation, giving rise to a compound with absorption bands at 240, 270, and 316 nm. The compound thus produced readily reverted quantitatively to BCC when the irradiated solution was neutralized or bubbled with air, while it was fairly stable in the acidic solution under nitrogen. These facts may indicate that the photoreduction of $BCCH^+$ takes place to give 5,6-dihydroBCC, which is known to be susceptible to oxidation to BCC.[5] The product was identified on the basis of the absorption spectrum. That is to say, as BCC has been found to be photoreduced to 5,6-dihydroBCC in a polyvinyl alcohol film,[6] the absorption spectrum of the acidified film containing 5,6-dihydro$BCCH^+$ was measured. The spectrum thus obtained is almost identical with that of the product under consideration in the acidic solution.

Also, in acidic methanol the visible-light irradiation led to the photoreduction of $BCCH^+$ into 5,6-dihydro-$BCCH^+$. The rate of the reaction in the methanol solution was much slower than that in the 2-propanol solution, in agreement with the difference in the ease

of photochemical hydrogen abstraction from primary and secondary alcohols.

Judging from the absorption spectrum (Curve V in Fig. 2), 5,6-dihydroBCC seems to be protonated at one of the two nitrogen atoms in the acidic solution. In the methanol and 2-propanol solutions, no subsequent reaction was observed.

Photoreaction of BCC in Ethanol upon Visible-light Irradiation. Figure 3 shows the spectral change in an acidic ethanol solution of $BCCH^+$ (1.0×10^{-4} M) caused by irradiation with visible light longer than 400 nm. As may be seen from this figure, 5,6-dihydroBCCH^+ is formed in the initial stage of the reaction; subsequently, the absorption bands of 5,6-dihydroBCCH^+ decrease in intensity with prolonged irradiation, giving rise to a compound with a tail of a band in the short-wavelength region. When the irradiated solution was neutralized, the absorption band appeared at 294 nm. Therefore, it is evident that the initially produced 5,6-dihydroBCCH^+ takes part in the subsequent reaction. The final product was isolated in the preparative experiments; it was identified as 2,2′-diaminobiphenyl.

By the analysis of the absorption spectra,[9] the changes in the concentrations of BCC, 5,6-dihydroBCC, and 2,2′-diaminobiphenyl with the lapse of irradiation time were determined; the results are presented in Fig. 4. As can be seen from this figure, during the first period of 30 min the formation of 2,2′-diaminobiphenyl is not observed, although the photoreduction of $BCCH^+$ occurs to give 5,6-dihydroBCCH^+ rapidly. This implies that the conversion of 5,6-dihydroBCCH^+ into 2,2′-diaminobiphenyl is initiated after a certain amount of 5,6-dihydroBCCH^+ is produced. The yield of 2,2′-diaminobiphenyl in relation to the BCC used

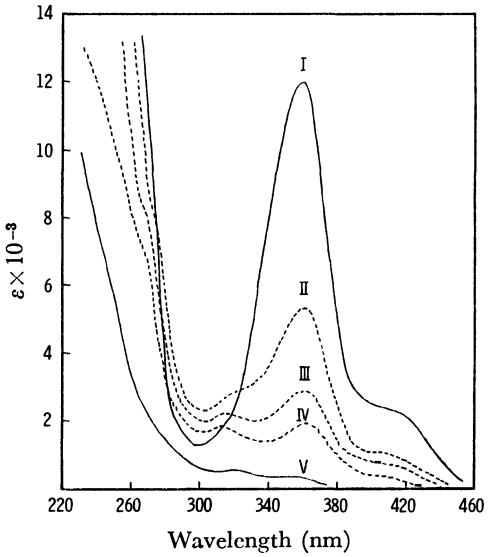

Fig. 3. Spectral change caused by visible light irradiation upon 4N HCl ethanol solution.

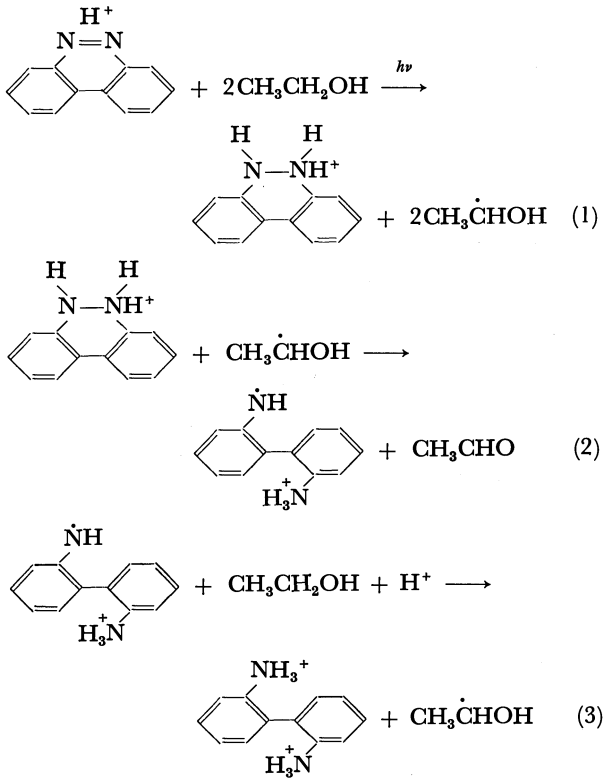
initially was 34% upon irradiation for 3 hr.

It should be noted that 5,6-dihydroBCCH^+ has no absorption in the visible region longer than 400 nm, as is shown in Fig. 2. Therefore, it can be said that the ground-state 5,6-dihydroBCCH^+ is probably involved in the subsequent reaction. Nevertheless, this reaction did not take place without continued irradiation even after a sufficient concentration of 5,6-dihydroBCCH^+ was reached. In view of this and the fact that 5,6-dihydroBCCH^+ fails to take part in this reaction in the 2-propanol and methanol solutions, the disproportionation between the 5,6-dihydroBCCH^+ molecules can be ruled out as the mechanism of the reaction. Moreover, the ground-state 5,6-dihydroBCCH^+ can not abstract a hydrogen atom from acetaldehyde as well as ethanol; a hydrogen donor participating in the conversion should be a transient species generated in the initial photoreduction of $BCCH^+$. That is to say, the 1-hy-

droxyethyl radical, $CH_3\dot{C}HOH$, is considered to play an essential role in furthering the reaction. Consequently, the mechanism of the 2,2′-diaminobiphenyl formation, which explains the results presented here, can be visualized as is shown in Scheme 1.



Scheme 1.

The conversion is initiated by the hydrogen abstraction of 5,6-dihydroBCCH$^+$ from the 1-hydroxyethyl radical (Reaction (2)). This reaction does not proceed until a certain amount of 5,6-dihydroBCCH$^+$ is formed, because a relatively short-lived species, $CH_3\dot{C}HOH$, takes part in the reaction. This is the reason for the appearance of the induction period between the first formation of 5,6-dihydroBCCH$^+$ and that of 2,2′-diaminobiphenyl. The successive reproduction of the radical, $CH_3\dot{C}HOH$, is performed in Reaction (3).

The observed solvent dependence of the reaction can be attributed to the different reactivities of the radicals resulting from alcohols in the initial photoreduction. In the cases of 2-propanol and methanol solutions, the resulting radicals are the 1-hydroxy-2-propyl, $(CH_3)_2\dot{C}OH$, and the 1-hydroxymethyl, $\dot{C}H_2OH$, radicals respectively; these radicals apparently have no ability to donate a hydrogen to 5,6-dihydroBCCH$^+$ under the present experimental conditions, probably because other decay processes occur more rapidly than does the hydrogen donation to 5,6-dihydroBCCH$^+$. However, it is a problem to be settled from what such a difference arises.

Photoreaction of BCC upon Ultraviolet Irradiation. In the case of ultraviolet irradiation by light shorter than 380 nm, the main product was carbazole, regardless of the kind of alcohol used here. Figure 5 shows the spectral change of a 1.0×10^{-4} M solution

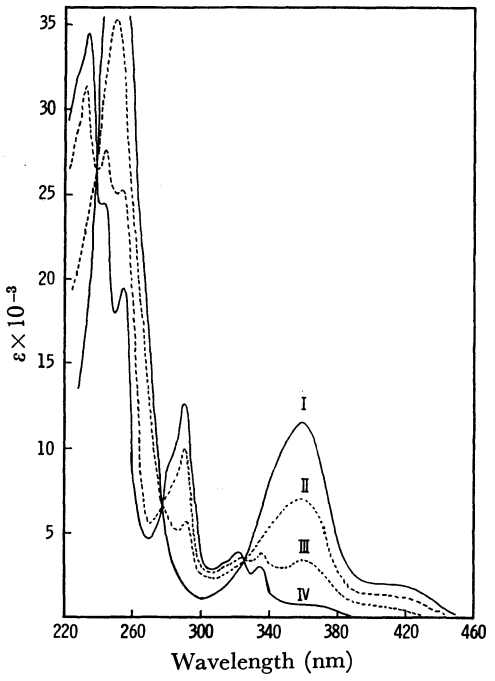


Fig. 5. Spectral change caused by ultraviolet irradiation upon 4M HCl 2-propanol solution.
Initial concentration of BCC: 1.0×10^{-4}M. Irradiation time (hr); I: 0, II: 1, III: 2, IV: 3

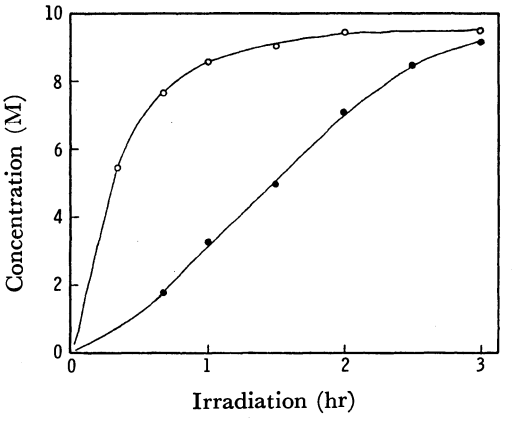

Fig. 6. Rate of the carbazole formation.
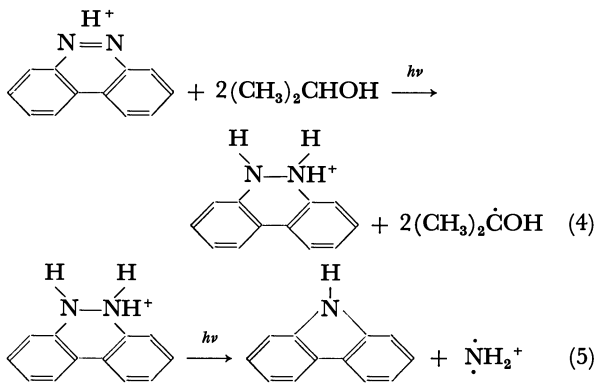
●: from BCCH$^+$, ○: from 5,6-dihydro BCCH$^+$

of BCCH$^+$ in acidic 2-propanol upon ultraviolet irradiation by means of a high-pressure mercury lamp. Irradiation for 3 hr resulted in the conversion of BCCH$^+$ into carbazole in about a 92% yield. Although the absorption bands of 5,6-dihydroBCCH$^+$ are apparently not observed in the course of the reaction, as can be seen from Fig. 5, the following fact clearly indicates that this is an intermediate product in the carbazole formation also: when the ultraviolet irradiation was carried out upon a 2-propanol solution in which BCCH$^+$ has previously been photoreduced to 5,6-dihydroBCCH$^+$ with the visible-light irradiation, as has been described above, carbazole was produced much faster than in the case of the ultraviolet irradiation of the BCCH$^+$ solution. The rate of the reactions in these different irradiation manners are compared in Fig. 6.

Consequently, 5,6-dihydroBCCH$^+$ is an intermediate product in the formations of both 2,2′-diaminobiphenyl and carbazole. However, in the case of the latter, the intermediate is considered to participate in the reaction through an excited state, judging from its absorption spectrum (Fig. 2).

It was found that the carbazole formation was attended by the liberation of ammonia. The ammonium ion was detected in the irradiated solution by the Nesler test. Therefore, we may expect that carbazole is produced by photoinduced disproportionation between the excited and ground-state 5,6-dihydroBCCH$^+$ molecules. However, this pausible mechanism can be ruled out, in view of the fact that carbazole is produced in an acidified polyvinyl alcohol film containing the substrate in a concentration of about 10^{-3} M, in which the substrate seems to be very difficult to diffuse. In addition, it is evident that the protonation of 5,6-dihydroBCC is essential for the carbazole formation. In fact, ultraviolet irradiation upon a polyvinyl alcohol film containing 5,6-dihydroBCC not being protonated does not lead to the formation of carbazole.

At the present time, it is considered that carbazole is produced by the photoinduced elimination of an imino radical (N̈H) from 5,6-dihydroBCCH$^+$, and that the resulting radical gives ammonia. The mechanism of the reaction proposed is shown in Scheme 2.



Scheme 2.

Experimental

The ultraviolet absorption spectra were measured with a Shimadzu Spectrophotometer, UV-200, using 1 cm quartz cells. The infrared absorption spectra were recorded on a Hitachi Infrared Spectrophotometer, EPI-G3, in a KBr disk.

Materials. The BCC was prepared from 2,2′-dinitrobiphenyl according to the method of Badger *et al.*;[10] it was purified by repeated recrystallizations from benzene, by treatment with active charcoal, and finally by recrystallization from ethanol; mp 155 °C (lit,[10] 156 °C). 2,2′-Diaminobiphenyl was prepared by the reduction of 2,2′-dinitrobiphenyl with zinc in HCl aqueous ethanol; it was purified by repeated recrystallizations from aqueous ethanol; mp 78.5 °C (lit,[10] 78.5 °C). The polyvinyl alcohol film was prepared from commercially available powder (mean degree of polymerization: 1500).

Irradiation. The irradiation by visible-light longer than 400 nm was carried out by means of a 500 W super-high-pressure mercury arc lamp (Ushio USH-500) and a Corning glass filter CS-3-73 (transmittance percentage shown in Fig. 1). The ultraviolet irradiation was carried out by means of a 450 W high-pressure mercury arc lamp (Ushio UM-452). In the preparative experiment with ultraviolet irradiation, a solution was placed in a 500 ml cylindrical Pyrex vessel, and a high-pressure immersion mercury arc lamp was used as the light source. All the irradiations were carried out at room temperature; the solution of BCCH$^+$ was flushed with nitrogen passed through a pyrogallol solution for 30 min prior to irradiation and continued throughout the irradiation. For the reaction in the polyvinyl alcohol film, the sample film was prepared by the method described elsewhere.[11]

Photoreaction of BCC in Acidic Ethanol upon Visible-light Irradiation. A 2×10^{-3} M solution of BCCH$^+$ in 100 ml of 3.75 M HCl aqueous ethanol was irradiated with visible light longer than 400 nm for 20 hr. After irradiation, the solution was neutralized with an NaOH aqueous solution. The neutral solution was then extracted with diethyl ether. These procedures were carried out for five runs, after which the ethereal solutions were combined. After the solvent has then been evaporated to dryness, the crystalline solid thus obtained was subjected to silica-gel thin-layer chromatography, using a mixture of benzene, cyclohexane, and acetic acid (1:1:1) as the developing solvent. The R_f value for the main product was 0.27. The product thus obtained was further purified by recrystallization from aqueous ethanol; it was identified as 2,2′-diaminobiphenyl; mp 77.0—77.5 °C. Found: C, 77.2; H, 6.6; N, 14.6%. Calcd for $C_{12}H_{12}N_2$: C, 78.2; H, 6.6; N, 15.2%. The UV and IR spectra of the product were identical with those of the authentic sample.

Photoreaction of BCC in Acidic 2-Propanol upon Ultraviolet Irradiation. BCC (120 mg) dissolved in 400 ml of 3.75 M HCl aqueous 2-propanol in a Pyrex vessel was irradiated with a high-pressure immersion mercury arc lamp (Ushio UM-102) for 2 hr. The solvent was then removed by evaporation under reduced pressure to afford a crystalline solid, which was subsequently washed with water. The product thus obtained was dissolved in a mixed solvent of benzene, *n*-hexane, and 2-propanol (2:2:1) and chromatographed on a silica gel column, using the same solvent as the eluent. Final purification was accomplished by recrystallization from ethanol. The product was identified as carbazole; mp 246—247 °C. Found: C, 87.0; H, 5.2%. Calcd for $C_{12}H_9N$: C, 86.2; H, 5.4%. The UV and IR spectra of the product were identical with those of commercially available carbazole.

Studies of the *cis-trans* Isomerization of 3-Aryl-1,2,3-oxathiazolidine-2-oxides

Tomihiro NISHIYAMA and Fukiko YAMADA

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Senriyama, Suita, Osaka 564

(Received July 10, 1974)

The isomerization of the *cis*- or *trans*-3-aryl-1,2,3-oxathiazolidine-2-oxides was investigated under various conditions. The isomerization proceeded in carbon tetrachloride, chloroform, and benzyl chloride solutions at a low temperature. On the other hand, in other organic solvents, such as benzene, acetone, pyridine, *N*,*N*-dimethylformamide, and chlorobenzene, isomerization did not occur. The results can be explained by the mechanism which yields the open-chain halosulfamic acid anion by the attack of a halogen ion on the 5-position. The anion can close to *cis*- or *trans*-oxathiazolidine.

In recent years, a number of studies have been reported on the *cis-trans* isomerization of some heterocyclic compounds. For example, the *cis-trans* isomerization of 3-*t*-butyl-1,2,3-oxathiazolidine-2-oxides in the presence of tetrabutylammonium bromide results in the inversion of sulfoxide, with the preservation of the stereochemistry at the 4- and 5-carbons.[1]

Cyclic sulfoxides have also been inverted by photochemical means or by treatment with hydrogen chloride.[2,3] Cyclic sulfites have been equilibrated thermally.[4]

In a previous paper, we reported that the reaction of *N*-sulfinylanilines with propylene oxide or epichlorohydrin in the presence of catalysts led to 3-aryl-5-methyl- or 3-aryl-5-chloromethyl-1,2,3-oxathiazolidine-2-oxide respectively.[5] These oxathiazolidines exist in the *cis* and *trans* configurations between the S=O group and the methyl or chloromethyl group in the 5-position, and it is possible to determine the substituent geometry of the isomeric pairs by means of NMR spectroscopy.

This paper will describe the *cis-trans* isomerization of oxathiazolidines under various reaction conditions and a possible isomerization mechanism.

Experimental

Measurements. The NMR spectra were recorded at 60 MHz with a Japan Electron Optics JNM-3H-60 spectrometer. The chemical shifts (δ) were described in ppm downfield from the internal TMS. The change in the % age composition of the isomers was followed by the NMR method. A constant-temperature water or oil bath was employed; it was equipped with an immersion heating element that made possible a temperature control of ± 0.2 °C.

Materials. The oxathiazolidines, 3-aryl-5-methyl-1,2,3-oxathiazolidine-2-oxides (R=H **1b**, *o*-CH_3 **2b**, *m*-CH_3 **3b**, *p*-CH_3 **4a**, *o*-Cl **5a**, *m*-Cl **6b**, and *p*-Cl **7b**) and 3-aryl-5-chloromethyl-1,2,3-oxathiazolidine-2-oxides (R=H **8a**, *o*-CH_3 **9a**, *m*-CH_3 **10b**, *p*-CH_3 **11a**, *o*-Cl **12a**, *m*-Cl **13b**, and *p*-Cl **14a**) were prepared by a previously reported method.[5] *Cis* and *trans* isomers are represented by the notations of **a** and **b** respectively. All the reagents used were of an analytical grade.

Results and Discussion

Isomerization. Experiments on the isomerization of oxathiazolidines in chloroform were carried out as follows. A definite amount of oxathiazolidine was dissolved in chloroform (2.0 mol/l). This solution was then divided into test tubes and sealed. The sealed tubes were then shaken at a constant temperature, the progress of the isomerization being periodically checked by measuring the NMR spectrum. The isomerization rate of each oxathiazolidine can be obtained from the integrated data of the *cis* and *trans* 5-methyl or methine proton signals in its NMR spectrum. In the isomerization of the **6b** oxathiazolidine in chloroform, the changes in the NMR spectra with the reaction time are shown in Fig. 1. The NMR spectrum of **6b** exhibits a methyl proton signal at 1.65 ppm (d, J=6.0 Hz), one methylene signal, Ha, at 3.31 ppm (dd, t observed, J *trans*=8.5 Hz), another methylene signal, Hb, at 3.93 ppm (q, J *cis*=5.2 Hz), a methine signal at 5.26—5.68 ppm (m), and a ring proton signal at 6.8—7.34 ppm (m). In the early stages of this isomerization, new peaks appeared at 1.79 ppm (d, J=6.0 Hz), 3.78 ppm (d, J=6.3 Hz), 3.80 ppm (d, J=7.8 Hz), and 4.85—5.23 ppm (m). These new peaks gradually increased with the reaction time, and after about 2 hr the mixture reached equilibrium. These new peaks are the same as those of *cis* 3-(*m*-chlorophenyl)-5-methyl-1,2,3-oxathiazolidine-2-oxide **6a** reported previously.[5] Plots of the conversion *versus* the reaction time for the oxathiazolidines are shown in Fig. 2. These results indicate that the equilibrium

constant is influenced by the two kinds of substituents, R and R', and that the constants of the 5-chloromethyl-substituted oxathiazolidines are larger than those of the 5-methyl group.

Solvent Effects. The isomerizations of oxathiazolidines at 30 °C in various solvents, such as carbon tetrachloride, chloroform, benzyl chloride, acetone, pyridine, benzene, chlorobenzene, and *N,N*-dimethylformamide, were carried out in sealed tubes. From the results obtained, it was found that the isomerization rates of the oxathiazolidines depend upon the nature of the organic solvent. Figure 3 shows plots of the *trans* content *versus* the reaction time of **6b** in various organic solvents (2.0 mol/l). As is shown in Fig. 3, the isomerization proceeded in carbon tetrachloride, chloroform, and benzyl chloride solutions. On the other hand, in other organic solvents, such as benzene, acetone, pyridine, *N,N*-dimethylformamide, and chlorobenzene, the isomerization did not occur. These facts may indicate, therefore, that the solvents containing active halogen atoms markedly affect the isomerization of the *cis* or *trans* oxathiazolidines. In the case of chlorobenzene, the chlorine atom is stabilized by resonance with the benzene ring. The oxathiazolidine ring interacts with a chlorine atom of the solvent, and then the *cis-trans* isomerization occurs.

a) solvent: *N,N*-dimethylformamide, catalyst: LiCl.

The Effect of Catalysts. Catalytic isomerizations at 40 °C were carried out by a procedure similar to that used in the absence of catalysts. The results under the influence of lithium chloride (LiCl) and tetraethylammonium bromide (NEt_4Br) are given in Table 1 in terms of the equilibrium constants. In all the cases, equilibrium was reached within 20 min. The results indicate that the *trans* isomer is more stable than the *cis* isomer. This is also brought out clearly by a comparison of the values of the equilibrium constants shown in Table 1.

In an *N,N*-dimethylformamide solution, the isomerization did not occur in the absence of a catalyst, but it proceeded rapidly in the presence of LiCl.

It is well known that the chloride ion equilibrates cyclic sulfoxides[6] and alkoxysulfonium salts.[7] It can, therefore, be thought that the halogen ion is related to the isomerization of oxathiazolidines.

The present isomerization is further illustrated by the action of dry HCl. When a sample of oxathiazolidine in a benzene solution was exposed to a trace amount of dry HCl at room temperature, equilibrium was reached within 5 min in all cases. For example, when a sample of the pure *trans* oxathiazolidine, **6b**, was exposed to dry HCl, the equilibrium composition was 74% *trans* and 26% *cis*, based on the integration of the NMR signal of the methyl protons. After the reaction

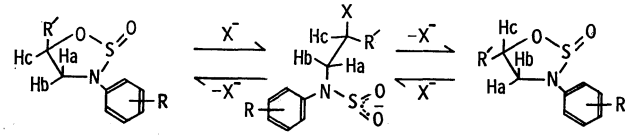
mixture had reached equilibrium, the temperature was raised to 80 °C. More dry HCl was passed through until a precipitate appeared. The precipitate was subsequently filtered and recrystallized with chloroform to give a colorless crystal (mp 104—106 °C; 78%), which was identified as *N*-(*β*-chloropropyl)-*m*-chloroaniline hydrochloride. These results are summarized in Tables 2 and 3.

Effect of Temperature. The effects of the temperature and of the solvents are given in Table 4. In all of the oxathiazolidines, the isomerization did not occur below about 100 °C. As is shown in Table 4, the isomerization proceeded at about 120 °C.

For the isomerizations of the *trans* oxathiazolidines, **1b** and **10b**, the polar solvents have no appreciable effect. On the other hand, in the *cis* oxathiazolidines, **4a** and **9a**, the isomerization occurs rapidly. Therefore, it is clear that the isomerization is affected by the starting *cis*- or *trans*-form rather than by the R and R′ substituent at higher temperatures.

Possible Isomerization Mechanism. On the basis of the results mentioned above and other considerations,[1] a possible reaction mechanism for the isomerization can be described as follows:



cis-form anion *trans*-form

X: halogen

The above open-chain halosulfamic acid anion may be expected to be formed by the attack of the halogen ion, which is produced from the solvent or the catalyst. Then, this anion can become close to *cis*- or *trans*-oxathiazolidine.

A similar mechanism involving a bromosulfite anion has been proposed in the reaction of oxirans with sulfur dioxide in the presence of NEt_4Br.[8]

Reactions of 1,8-Dehydronaphthalene with Cyclic Polyenes

Masahiko KATO, Shigeru TAKAOKA, and Toshio MIWA
Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558
(Received July 18, 1974)

The reactivities of 1,8-dehydronaphthalene (**1**) to cyclic polyenes, *i.e.*, cycloheptatriene, cyclopentadiene, 6,6-dimethylfulvene, furan, and norbornadiene, were examined. It was found that the C–H insertion reaction at the end of the conjugated systems, a new type of reaction of **1**, as well as the 1,2-cycloaddition reaction occurs in every conjugated cyclic polyene. A stepwise mechanism for the formation of the C–H insertion product was proposed.

According to the MO calculations,[1] the peri-electrons of 1,8-dehydronaphthalene (**1**), one of the arynes, occupy an antisymmetric combination of 1,8-dehydro-orbital in the ground state, whereas the *ortho*-electrons of 1,2-dehydrobenzene (**2**) do a symmetric one. Accordingly these two species must show different reactivities towards olefinic compounds, and these were in line with the experimental results by Rees and Storr[2] Thus the reaction of **1** afforded acenaphthene derivatives in a stereospecific manner, whereas the reaction of **2** afforded benzocyclobutene derivatives in a non-stereospecific fashion.[3] As for cyclic polyenes, only the reaction of **1** with cyclopentadiene was reported.[4]

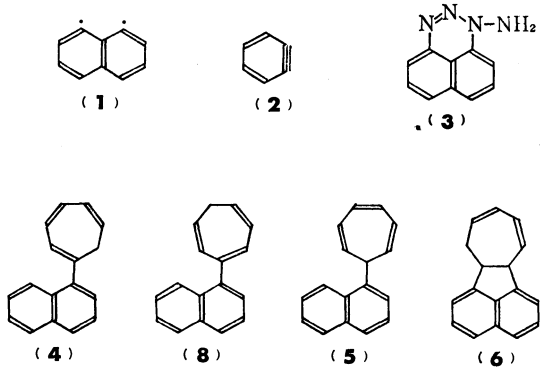
Present authors were interested in the reactivities of **1** to cyclic polyenes compared with those of **2**,[5] because the opposite character of the electronic ground states might be reflected in the difference between the reactivities of these species. By using cycloheptatriene, dimethylfulvene, furan, norbornadiene, and also cyclopentadiene as cyclic polyenes, we found that the insertion of **1** to a C–H bond of a conjugated polyene was also an important pathway as well as the cycloaddition reaction. A kind of such reaction was seen in the reaction of **1** with benzene to give α-phenylnaphthalene.[2]

Reaction Conditions and the Structures of the Products. Compound **1** was generated from 1-aminonaphtho-[1,8-*d*,*e*]triazine (**3**) by oxidation with lead tetraacetate in dichloromethane[2] in the presence of excess substrate under −20 °C or dry ice–acetone temperature, because the substrates were assumed to be susceptible to oxidation near room temperature.[6]

Reaction with Cycloheptatriene: Besides naphthalene, three products, (**4**), (**5**), and (**6**) [**4**: (**5**+**6**)=8: 10] (total yield 5.3%) were characterized as follows after partial separation by column chromatography of the reaction mixture.

The compound **5** was not formed when the separation was carried out in the dark. Catalytic hydrogenation (10% Pd–C) of the oily product **4** (mass spectrum, M^+ *m*/*e* 218) gave 1-cycloheptylnaphthalene which was identical with the authentic sample.[7] The structure **4** was selected among possible structures by consulting the NMR integral ratio of the olefinic proton signals to the aliphatic proton signals and the multiplicity of methylene proton signal. The structure was finally confirmed by the independent synthesis through **5**.

Owing to the difficulty of separation of the compound **6** from **4**, the mixture, enriched in **6** by chromatography in the dark, was subjected to the reaction.



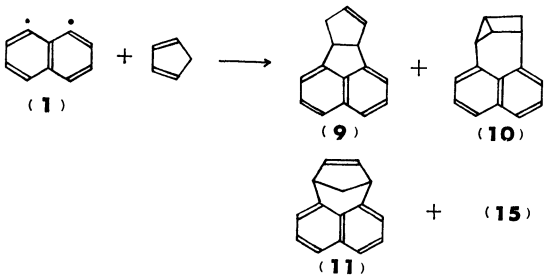
Scheme 1.

Catalytic reduction of the mixture gave, besides 1-cycloheptylnaphthalene originated from **4**, *cis*-1,2-pentamethyleneacenaphthene (**7**), which was identified by comparison with a sample prepared from cycloheptene and **1** and had to be formed from **6**. The NMR spectrum of **6** [δ ppm (CCl_4) 2.20—2.60 (2H, m), 4.21 (2H, m), 5.80—6.04 (2H, m), 6.12—6.20 (2H, m), 7.0—8.0 (6H, m)], obtained by a subtraction of the spectrum of **4** from that of the mixture, is consistent with the unsymmetrical structure rather than the other possible symmetrical ones.

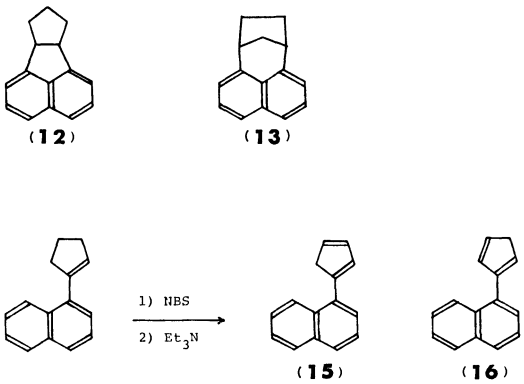
When a mixture of **4** and **6** in carbon tetrachloride was irradiated for a short peirod with a high-pressure mercury lamp through Pyrex filter, it was revealed by NMR spectrum that **4** was transformed almost completely to **5** while **6** remained unaltered. The structure **5**, an isomer of **4**, was obtained directly from consideration of the NMR spectrum and this was confirmed by its synthesis from tropylium fluoroborate[7] and α-naphthylmagnesium bromide. When heated for 15 hr at 125 °C, **5** gave a new compound **8** by 1,5-hydrogen shift, but when the temperature was raised to 160 °C, it gave mainly **4** by two series of 1,5-hydrogen shifts.[9] Irradiation[10] of **4** in carbon tetrachloride using a low pressure mercury lamp for 62 hr gave a mixture of **4** and **5** (4.6: 1).

Reaction with Cyclopentadiene: Meinwald and Gruber reported three kinds of cycloaddition products **9**—**11** from the reaction of **1** with cyclopentadiene.[4] The present authors expected the formation of an insertion product in the reaction as in the case of cycloheptatriene and reexamined the reaction. The resulting hydrocarbon fraction, separated by silicic acid chromatography, was hydrogenated catalytically. Thus, in addition to the products **12** and **13**,[4] 1-cyclopentylnaph-

thalene (**14**)[11] was obtained in almost equal quantity to the total amount of the other products. Although an insertion product (**15**), the precursor of **14**, could not be separated by solution chromatography (tlc or column) and by preparative glc, it was possible by comparing the NMR spectrum of the product mixture with those of **9** and **10** to obtain the spectral data of a new compound **15**. The structure was confirmed by obtaining **15** as a minor product, along with a main product (**16**), (1 : 3) from 1-(1-cyclopentenyl)naphthalene[11] by treatment with NBS in carbon tetrachloride followed by dehydrobromination with triethylamine in ether.



Scheme 2.

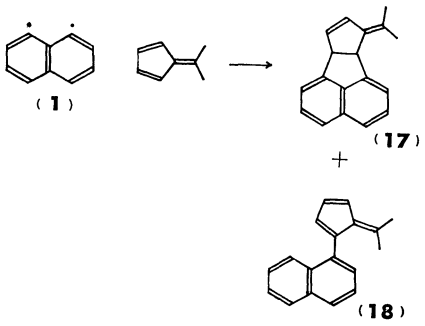


Scheme 3.

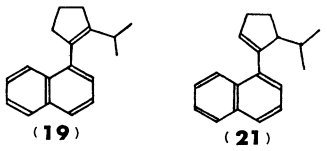
Reaction with 6,6-Dimethylfulvene: The reaction afforded compound **17** and **18** (1 : 2) (total yield 3%), which were separated by glc (3% Silicone OV-17, 1/4 in×6 ft, 170 °C). These compounds showed the same molecular ion peak at *m/e* 232 in their mass spectra (1 : 1 adducts of dimethylfulvene and **1**). The proton signal ratio (Ar–H: olefinic–H: benzylic–H: methyl–H=6: 2: 2: 6) and the unsymmetrical feature of the NMR spectrum of **17** supported the structure.

A yellow solid **18**, mp 110—113 °C, showed an NMR spectrum [δ ppm (CCl_4) methyl proton signals at 1.36 (3H, s), 2.18 (3H, s), olefinic at 6.24—6.46 (3H, m) and aromatic at 7.2—7.44 (7H, m)] characteristic to the ring-substituted dimethylfulvene. The position of α-naphthyl group on dimethylfulvene was confirmed by the catalytic hydrogenation to a tetrahydro derivative [M^+ *m/e* 236; δ ppm (CCl_4) 0.90 (6H, d, J= 6 Hz), 1.8—2.9 (7H, m), 7.0—7.8 (7H, m)], which was identical with 1-(α-naphthyl)-2-isopropylcyclopentene (**19**) prepared by dehydration of 1-(α-naphthyl)-2-isopropylcyclopentan-1-ol (**20**).[13]

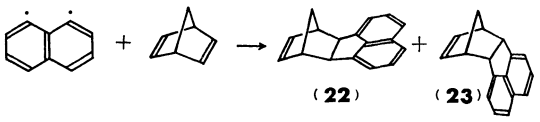
Reaction with Furan: The reaction was carried out in a usual way, and 2-(α-naphthyl)-furan[14] was obtained in 3% yield as a sole isolable product.



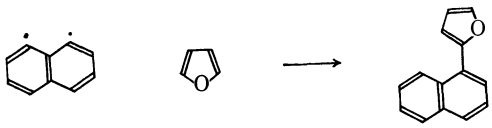
Scheme 4.



Scheme 5.



Scheme 6.



Scheme 7.

Reaction with Norbornadiene: It is known that norbornadiene sometimes reacts with other reagents as a homoconjugated diene owing to the interaction between two double bonds.[5f] Silicic acid chromatography of the reaction mixture gave two products **22** and **23** (total yield 7%), which were reported earlier by Baker and Mason.[15]

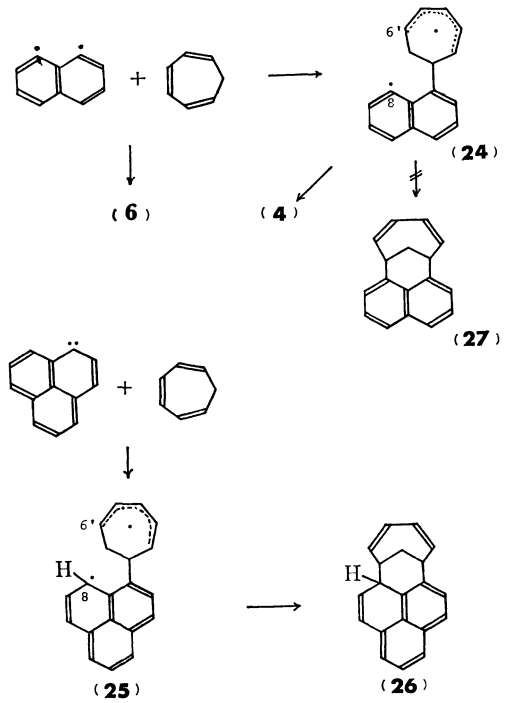
Discussion

Since the reactive intermediates like *o*-benzyne or 1,8-dehydronaphthalene are short-lived and react irreversively with other reagents, it may safely assumed that the reactivities are directly reflected to the yields of the products.[16]

Cycloaddition Reactions: It is well known that **2** reacts with cyclic diene to give Diels-Alder reaction products.[5] On the contrary, it is found that **1** gives [$\pi 2_s + \pi 2_s$] cycloaddition product instead of [$\pi 2_s + \pi 4_s$] product as described above.

Cycloheptatriene reacted with **2** rather abnormally to give a 1,2-cycloaddition product and an ene reaction product.[5g,5h,17] With **1**, it reacted to give a 1,2-cycloaddition product (**6**) and an insertion product (**4**). If the products were formed by a stepwise mechanism, the intermediate will be formulated as **24**,

which is stereochemically very similar to the proposed intermediate (**25**) for the reaction of cycloheptatriene and phenalenylidene.[18] The latter forms exclusively a [$_\pi$2+$_\pi$6] product (**26**). From the examination of the molecular model, successive overlap between the electrons on C-6′ of the cycloheptatrienyl and on C-8 of the naphthalene ring is thought to be slightly easier in **24** than in **25**. Nevertheless, the product (**27**), corresponding to **26**, was not detected in the products of **1** with cycloheptatriene. Thus the formation of **6** might occur through another pathway without forming **27**, *via* concerted process rather than the stepwise one. The principal formation of **6**, among 1,2-cycloaddition products, may be explained by the two-fold statistical advantage for the addition to C_1–C_2 compared with that to C_3–C_4 bond in cycloheptatriene and by the thermodynamical stability of **6** over the symmetrical one.



Scheme 8.

Dimethylfulvene with **1** gave a 1,2-cycloaddition product (**17**) and a C–H insertion product (**18**). The exclusive addition to C_1–C_2 double bond rather than the C_5–C_6 double bond is explained also by the same reason discussed above in the case of the formation of **6**, in addition to the steric hindrance to disturb approaching to the tetrasubstituted C_5–C_6 double bond.

With norboranadiene, a homoconjugated diene, **1** reacted exclusively in a manner of [$_\pi$2+$_\pi$2] cycloaddition. Because the rearranged products, as in the case of a radical reaction to substituted norbornadienes,[19] were not detected, the intermediacy of a diradical with a considerable life time cannot be anticipated.

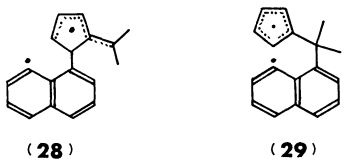
Furthermore, from the steric consideration of the reaction, there is no reason to assume that an *endo*-cycloaddition to 1,2-bond surpasses over a homoconjugate addition to C_1 and C_5 of norbornadiene under a stepwise mechanism. In the concerted mechanism, the orbital symmetry consideration may well conclude the symmetry allowed process for the former and the forbidden process for the latter. The exclusive formation **22** and **23** strongly supports that the reaction might be a concerted one. The abundant formation of **22** over **23** may be recognized by the steric reason, that is, easier approach from the *exo* side than from the *endo* side.

The C–H Insertion Reaction: To clarify whether **1** reacts directly with C_1 carbon atom of cycloheptatriene to form the C–H insertion product or not, its reaction with cycloheptatriene-7-d_1 was carried out and **4**-d_1 was isolated. Investigation of the NMR spectrum revealed that the deuterium in **4**-d_1 was found at a sole position C_7 of the cycloheptatriene ring.

In every conjugated polyene case we examined, the C–H insertion products were formed in considerable amount and this reaction seemed to proceed by the attack of a radical of **1** to a position with the largest value of the free valence in the polyene system.[20]

In the reaction with cycloheptatriene, the intramolecular hydrogen abstraction by an aryl radical in **24**, giving **4**, might occur much faster than the cyclization to **27**. On the other hand, the ability of H-abstraction of allylic radical in **25** could be small owing to the delocalization of the radical electron over the phenalene ring.

In case of dimethylfulvene, two biradical intermediates **28** and **29** are possible, but any products through **29**, which can not be derived to any C–H insertion product, are not observed.



Scheme 9.

Experimental[21]

Reaction of 1,8-Dehydronaphthalene. Reaction with Cycloheptatriene: To a stirred CH_2Cl_2 (5 ml) solution of cycloheptatriene (3.37 g, 37 mmol) cooled externally with dry ice–acetone was added lead tetraacetate (1.5 g, 3.4 mmol) in one portion and followed by dropwise addition of **3** (564 mg, 3.1 mmol) in CH_2Cl_2 (20 ml) over 30 min. After the addition had been completed, the mixture was allowed to come to room temperature and filtered. The filtrate was washed successively with water and saturated salt solution and dried (anhyd. Na_2SO_4). The residue was chromatographed ($CHCl_3$) on silicic acid (60 g) in the dark: Fractions were collected in every 30 ml. Fractions 2—3 contained a liquid (218 mg), which was rechromatographed (*n*-hexane) on silicic acid (20 g) in the dark. Fractions were collected in every 10 ml: Fractions 7—10 contained compounds **4** and **6** (30 mg, 8: 10), which were further chromatographed (*n*-hexane) on neutral alumina (10 g). Fractions were collected in every 10 ml. Fractions 11—13 contained pure **4** (16 mg), which was identical with a sample of **4** described below.

Compound (**4**): NMR δ ppm (CCl_4) 2.76 (2H, d, J=8 Hz), 5.36 (1H, t-d, J=8, 6 Hz), 6.08—6.30 (2H, m), 6.52—6.64

(2H, m), 7—8 (7H, m); mass spectrum *m/e* (%) 218 (100), 217 (94), 215 (38), 203 (63), 202 (63), 152 (21); λ_{max}^{EtOH} nm (log ε) 225.5 (4.54), 295 (3.81).

Reaction with Cyclopentadiene: To a stirred CH_2Cl_2 (30 ml) solution of lead tetraacetate (3.8 g, 8.5 mmol) cooled externally with dry ice–acetone was added cyclopentadiene (5.1 g) in one portion and followed by dropwise addition of CH_2Cl_2 (50 ml) solution of **3** (1.3 g, 7.0 mmol) over 25 min. After stirring at the temperature for 30 min, the mixture was warmed up to 0 °C, treated with ice–water, and then filtered through Hyfrosupercel. The filtrate was washed successively with 5% aq. $NaHCO_3$, H_2O and brine. After drying (anhyd. Na_2SO_4) and concentrating the organic layer, the residue was chromatographed ($CHCl_3$) on silicic acid (40 g), fractions were collected in every 10 ml. Fractions 3—4 (536 mg) were rechromatographed (*n*-hexane) on silicic acid (30 g); fractions were collected in every 10 ml. Fractions 8—12 gave 220 mg of a mixture of **9**, **10** and **15** (1: 0.5: 2). This mixture was characterized by hydrogenation as described below.

Reaction with 6,6-Dimethylfulvene: To a stirred CH_2Cl_2 (15 ml) solution of dimethylfulvene (5.3 g, 50 mmol) cooled at −20 °C was added dropwise alternately a CH_2Cl_2 (40 ml) solution of **3** (916 mg, 5.0 mmol) and a CH_2Cl_2 (15 ml) solution of lead tetraacetate (2.55 g, 5.6 mmol). After usual work-up, the residue was chromatographed (*n*-hexane) on silicic acid (100 g), fractions were collected in every 100 ml. Fractions 8—9 gave a mixture of **17** and **18** (23 mg, 1: 2.8), fraction 10 gave a pure **18** (10 mg). The glc separation of **17** and **18** was carried out using a column of 3% Silicone OV-17 (1/4 in × 5 ft, He 60 ml/min) at 200 °C. Retention time **17**, 8.0 min; **18**, 8.44 min. **17** mp 110—113 °C; mass spectrum *m/e* (%) 232 (86), 217 (100), 202 (46); NMR δ ppm (CCl_4) 1.36 (3H, s), 2.18 (3H, s), 6.24—6.46 (3H, m), 7.2—7.84 (7H, m); λ_{max}^{EtOH} nm (log ε) 222 (4.84), 273 (4.27). **18** mp 119—120 °C; mass spectrum *m/e* (%) 232 (100), 217 (84), 165 (32); NMR δ ppm (CCl_4) 1.84 (3H, s), 2.22 (3H, s), 4.82 (2H, bq), 5.94 and 6.24 (2H, broad AB type), 7.2—7.6 (6H, m).

Reaction with Furan: To a stirred CH_2Cl_2 (30 ml) solution of lead tetraacetate (4.87 g, 11 mmol) cooled externally with dry ice–acetone, was added furan (6.8 g, 100 mmol) in one portion and followed by a dropwise addition of **3** (1.84 g, 10 mmol) in CH_2Cl_2 (40 ml). After usual work-up and chromatography (*n*-hexane/silicic acid 30 g), 2-(α-naphthyl)-furan 56 mg (3.2%) was obtained and identified with an authentic sample;[14] NMR δ ppm (CCl_4) 6.48 (1H, d-d, J=2, 3.5 Hz), 6.64 (1H, d, J=3.5 Hz), 7.32—7.88 (7H, m), 8.28—8.44 (1H, m).

Reaction with Norbornadiene: To a CH_2Cl_2 (20 ml) solution of norbornadiene (5.0 g, 50 mmol) cooled at −20 °C was added dropwise, alternately a solution of **3** (923 mg, 5 mmol) in CH_2Cl_2 (50 ml) and a solution of lead tetraacetate (2.44 g, 5.5 mmol) in CH_2Cl_2 (25 ml) over 45 min. After usual work-up, the product was chromatographed (*n*-hexane) on silicic acid (100 g) to give **22**[15] (75 mg, 7.5%), and **23**[15] (10 mg, 1%).

Reaction with Cycloheptene: To a stirred CH_2Cl_2 (5 ml) solution of cycloheptene (443 mg, 4.5 mmol) cooled externally with dry ice–acetone was added lead tetraacetate (931 mg, 2.1 mmol) in one portion followedby a dropwise addition of CH_2Cl_2 (5 ml) solution of **3** (276 mg, 1.5 mmol) over 15 min. Usual work-up and chromatography (*n*-hexane) on neutral alumina (10 g) gave **7** (10 mg, 3%). [Mass spectrum, *m/e* (%) 222 (100), 179 (53), 166 (25), 165 (66), 153 (20); NMR spectrum, δ ppm (CCl_4) 1.1—2.4 (10H, m), 3.6—3.9 (2H, m), 7.0—7.6 (6H, ABC type); λ_{max}^{EtOH} nm (log ε) $223^{infl.}$ (4.72), 228 (4.84), 244 (3.21), 281 (3.75), 289 (3.80), 301 (3.50), 306 (3.49), 315.5 (3.04), 320 (3.11).

*Catalytic Hydrogenation of a Mixture of Compounds **4** and **6**.* A mixture of **4** and **6** (30 mg), obtained above, was hydrogenated in ethanol over 10% Pd–C (100 mg) at room temperature for 4.5 hr. The mixture was filtered and evaporated *in vacuo*. Repeated chromatography (*n*-hexane/neutral alumina) of the residue gave a mixture (1: 1, 15 mg) of 1-(1-cycloheptenyl)naphthalene[7] and 1-cycloheptylnaphthalene[7] and **7** (16 mg). These were characterized by direct comparison with the authentic samples synthesized independently.

*7-(α-Naphthyl)cycloheptatriene (**5**).* To a stirred suspension of tropylium fluoroborate (2.1 g, 12 mmol) in anhyd. THF (10 ml) was added dropwise α-naphthylmagnesium bromide in ether (8 ml), prepared from α-bromonaphthalene (2.88 g, 11 mmol) and Mg (245 mg, 10 mgatom) at room temperature. Insoluble material was filtered and the filtrate was concentrated *in vacuo* The residue (2.4 g) was chromatographed (*n*-hexane) on silicic acid (70 g), fractions were collected in every 50 ml; fractions 10—18 gave **5** (904 mg, 30%). [Found: C, 93.46; H, 6.54%. Calcd for $C_{17}H_{14}$: C, 93.53; H, 6.47%: Mass spectrum; *m/e* (%) 218 (100), 217 (76), 215 (32), 203 (61), 202 (61): NMR spectrum, δ ppm (CCl_4) 3.36 (1H, t, J=5 Hz), 5.47 (2H, d-d, J=9, 5 Hz), 6.08—6.32 (2H, m), 6.52—6.76 (2H, m), 7.2—8.0 (7H, m): λ_{max}^{EtOH} nm (log ε) 224.5 (4.97), $263^{infl.}$ (3.91), 272 (4.01), 282 (4.06), $292^{infl.}$ (3.91).

*Thermal Rearrangement of 7-(α-Naphthyl)cycloheptatriene (**5**).* When **5** (30 mg) dissolved in DMSO-d_6 (0.4 ml) in an NMR tube was heated at 125 °C for 15 hr.[22] The NMR measurement revealed that **5** was transformed almsot completely to **8**, which was further transformed to **4** by heating it at 160 °C for 4 hr. **8** was isolated by chromatography (*n*-hexane) on neutral alumina (1 g); fractions were collected in every 1 ml. Fraction 5 gave almost pure **8**. Sublimation at 90 °C/1 mmHg. **8** Found: C, 93.35; H, 6.56%. Calcd for $C_{17}H_{14}$: C, 93.53; H, 6.47%. Mass spectrum; *m/e* (%) 219 (19), 218 (100), 217 (71), 215 (33), 203 (54), 202 (56). NMR spectrum; δ ppm (CCl_4) 2.46 (2H, t, J=6 Hz), 5.2—5.6 (2H, m), 6.1—6.4 (2H, m), 6.63 (1H, d, J=5 Hz), 7.2—7.8 (7H, m).

*Photochemical Interconversion of Compounds **4** and **5**.* The CCl_4 solution (0.4 ml) of **5** in a quartz NMR tube was irradiated with a low pressure mercury lamp at room temperature and the reaction was followed by NMR method. The ratios of **4** and **5** in the mixture were observed in the course of the irradiation time as follows; **5**: **4**=16: 1 (18 hr), 5: 1 (38 hr), 4.6: 1 (62 hr).

When a CCl_4 (0.4 ml) solution of **4** (30 mg) was irradiated with a high pressure mercury lamp (UM-452) through Pyrex filter for 30 min, **4** was transformed to **5**, giving a ratio of 23: 1 (**5** to **4**).

*Catalytic Reduction of a Mixture of **9**, **10** and **15**.* A mixture of **9**, **10** and **15** (199 mg, 1: 0.5: 2) dissolved in 95% EtOH (15 ml) was hydrogenated over 10% Pd–C (46 mg) for 2 hr. The glc separation (10% Apiezone L, 1/4 in × 5 ft, 185 °C) of the residue gave almost equal amounts of a mixture of **12** and **13**[4] (4: 3) and **14**, which was identified with the authentic sample[11] [NMR δ ppm (CCl_4) 1.72 (6H, m), 2.0—2.3 (2H, m), 3.5—3.8 (1H, m), 7.12—7.72 (6H, m), 7.8—8.0 (1H, m); λ_{max}^{EtOH} nm (log ε) 225.5 (4.88), 272 (3.79), 283 (3.87), 293 (3.70)].

Dehydrogenation of 1-(1-Cyclopentenyl)naphthalene. 1-(1-Cyclopentenyl)naphthalene[11] (193 mg, 1 mmol), NBS (178 mg, 1 mmol) and benzoylperoxide (10 mg) in CCl_4 (3 ml) was refluxed for 2 hr. The cooled mixture was filtered and the residue dissolved in anhyd. ether (5 ml) was treated with Et_3N (3 ml). After refluxing the mixture for 2 hr and evaporation of the solvent, the residue (261 mg) was chromato-

graphed (*n*-hexane) on silicic acid (3 g); fractions were collected in every 3 ml. Fractions 4 and 5 gave a mixture of **15** and **16** (58 mg, 1:3) [NMR; charasteristic methylene signals at δ 3.38 (q, J=1.1 Hz) and 3.15 (q, J=1.1 Hz) ppm]. The spectral data of the former were identical with the sample obtained from the reaction of cyclopentadiene with **1**. Because of their instability, further purification of **15** was not effected. Catalytic hydrogenation (10% Pd-C/EtOH) of the mixture gave **14** as a sole product.

Catalytic Hydrogenation of 1-(α-Naphthyl)-6,6-dimethylfulvene (18). A solution of **18** (10 mg) in gracial acetic acid (10 ml) was hydrogenated over 5% Pd-C (50 mg) for 3 hr to give a tetrahydro derivative **19** (8 mg), which was identified with the authentic sample described below.

Synthesis of 1-Isopropyl-2-(α-Naphthyl)cyclopentene (19). A solution of **20** (2.3 g, 9.1 mmol)[13] in bromobenzene (20 ml) was heated at 180 °C in the presence of $KHSO_4$ (1.3 g) until the separation of water had ceased. After evaporation of bromobenzene, the residue was chromatographed (*n*-hexane) on silicic acid (25 g); fractions were collected in every 25 ml. Fractions 3—5 gave a mixture of products (1.17 g), which was further chromatographed (*n*-hexane) on neutral alumina (35 g); 20 ml-fractions were collected and fractions 2—5 (948 mg) contained **19** and **21**. The pure samples of **19** and **21** were obtained by glc (5% SE-30, 1/4 in×5 ft, 156 °C, He 40 ml/min). Retention time; **19** 7.2 min, **21** 11.5 min. [**19** Found: C, 91.34; H, 8.55%. Calcd. for $C_{18}H_{20}$: C, 91.47; H, 8.53%. NMR spectrum: δ ppm (CCl_4); 0.90 (6H, d, J=6 Hz), 1.8—2.9 (7H, m), 7.0—7.8 (7H, m). Mass spectrum: *m/e* (%) 236 (62), 221 (100), 193 (41), 179 (30), 178 (24), 165 (37). λ_{max}^{EtOH} nm (log ε) 226 (4.82), $274^{infl.}$ (3.77), 284 (3.86), $293^{infl.}$ (3.79). **21** Found: C, 91.46, H, 8.26%. NMR spectrum: δ ppm (CCl_4); 0.67 (3H, d, J=7 Hz), 0.79 (3H, d, J=7 Hz), 1.6—2.7 (5H, m), 3.1—3.4 (1H, m), 5.82 (1H, bq, J=2 Hz), 7.1—7.42 (4H, m), 7.54—7.8 (2H, m), 7.9—8.16 (1H, m). Mass spectrum: *m/e* (%) 236 (34), 221 (9), 194 (18), 193 (100), 192 (9), 191 (9), 179 (9), 178 (32), 165 (19). λ_{max}^{EtOH} nm (log ε) 226 (4.73), 286 (3.87), 294 (3.86)].

The authors are grateful to Mr. Jun-ichi Goda for the analytical data and Mr. Misao Uegaki for his skillful technical assistance. The authors wish to thank Dr. Yoshio Hirose of the Institute of Food Chemistry for mass spectral measurements.

(Received October 22, 1974)

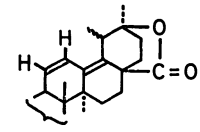
From the leaves of *Ilex latifolia* Thunb., two new bitter glycosides, latifoloside, A and B, have been isolated. The acid hydrolysis of A afforded three triterpenoid aglycones, which have been formulated by spectroscopic and chemical evidence as I, II, and III respectively.

In the course of an investigation of the bitter principles of Aquifoliaceae plants, the constituents of the leaves of *Ilex latifolia* Thunb., which have an intense bitter taste, have been examined. A methanol extract of fresh leaves was treated with *n*-butanol, the subsequent chromatography of the soluble material over silicic acid led to the isolation of two bitter glycosides, latifoloside A (0.009% yield) (mp 235—236 °C (decomp.), $[\alpha]_D^{25}$ −33° (*c* 1.0, ethanol)) and B (0.001% yield) (mp 210—211 °C (decomp.), $[\alpha]_D^{16}$ −11° (*c* 0.1, pyridine)). Latifoloside A, which has been obtained in a major amount, yielded three triterpenoid aglycones, I, II, and III, on hydrolysis with methanol–1M sulfuric acid. In this paper, we will deal with the structural elucidation of these three compounds.

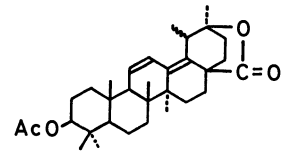
Results and Discussion

Aglycone I, $C_{31}H_{46}O_4$ (mp 269—270 °C, $[\alpha]_D^{25}$ −110° (*c* 1.0, ethanol)), shows a hydroxylic absorption in the IR spectrum at 3400 cm^{-1} and forms a monoacetate IV, $C_{33}H_{48}O_5$ (mp 272—273 °C), the IR spectrum of which no longer exhibits a hydroxyl group. The NMR spectrum of IV shows signals due to an acetyl group at δ 2.04 and a methoxyl group at δ 3.12. In addition, the signal of the methine proton on the oxygenated carbon of I at δ 3.22 shifts to 4.49 on acetylation. These observations indicate that the hydroxyl group of I is secondary, and the methoxyl group, tertiary.

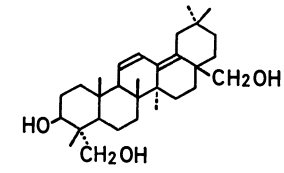
On the other hand, I exhibits UV maxima at 253 (shoulder), 261, and 270 (shoulder) nm (ε 24500, 30000, and 21500 respectively), an IR band at 1750 cm^{-1}, and NMR signals at δ 1.41 (3H, s), 5.74 (1H, dd, J=11 and 2 Hz), and 6.77 (1H, dd, J=11 and 3 Hz). The similarity of these spectral data to those of the dienelactone V[2] suggests the presence of the partial structure Ia. Further evidence in support of this partial structure was provided by the following chemical transformations. The reduction of I with lithium aluminum hydride, followed by acetylation, gave a monoacetate VI, $C_{33}H_{50}O_4$ (mp 210—211 °C), the UV absorptions of which are quite similar to those of VII.[3] The treatment of the epoxide VIII[4] in the same way as in the formation of V[2] afforded a lactone IX, $C_{34}H_{48}O_6$ (mp 241—242 °C), which exhibits UV maxima at 252, 260, and 269 nm (ε 19300, 23800, and 16600 respectively), an IR band at 1750 cm^{-1}, and NMR signals at δ 1.40 (3H, s), 5.68 (1H, dd, J=11 and 2 Hz), and 6.10 (1H, dd, J=11 and 3 Hz), all supporting the partial structure Ia for aglycone I.



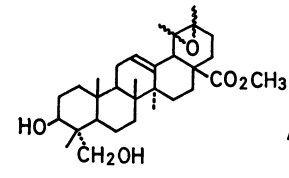
Ia



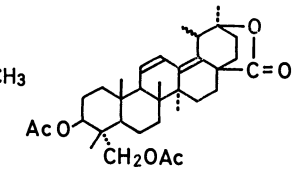
V



VII



VIII



IX

These facts and the analogy with the structures of the congeners isolated from *Ilex latifolia* Thunb.[5] lead to the assignment of the ursane skeleton for I, in which the partial structure Ia would constitute the C, D, and E-rings.

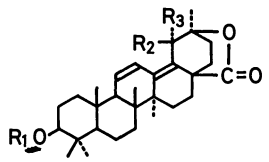
The location and the configuration of the tertiary methoxyl group were proved as follows. In the NMR spectrum of IX, the signal due to the C-19 methyl protons appears as a doublet at δ 1.08 as a result of the coupling with the allylic methine proton, which appears as a quartet at δ 2.66. On the other hand, the NMR spectrum of I does not show the corresponding signals, but a singlet at δ 1.45 assigned to the methyl protons on an oxygenated carbon. Hence, the methoxyl group in question must be located at C-19. In the

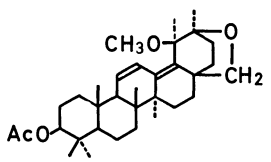
* Present address: Kinki University, Kowakae, Higashi-Osaka, Osaka 577.

NMR spectrum of VI, the signal of the C-19 methyl protons shifts to a higher field (δ 1.36) compared with that of IV, while the signal of the methoxyl group appears at a lower field (δ 3.26) than that of IV. Taking account of the anisotropy of the lactonic carbonyl group, these observations indicate that the C-19 methyl group lies near the plane of the carbonyl group (α-oriented) and the methoxyl group above the plane (β-oriented).

On biogenetic grounds, it is most reasonable to place the secondary hydroxyl group in I at the C-3 position. Moreover, the NMR spectrum of IV shows a signal due to the methine proton attached to the carbon atom bearing an acetoxyl group at δ 4.49 (1H, t-like, W1/2 18 Hz), the shape and position of which correspond to those found in the spectra of C-3 equatorial acetates in the polyterpenes.[6]

Finally, the structure was confirmed by correlation with vanguerolic acid lactone, X.[2] The hydrogenolysis of I in glacial acetic acid over a platinum catalyst did give X, $C_{30}H_{46}O_3$ (mp and mixed mp 263—267 °C), along with a dihydro-compound which forms a monoacetate XI, $C_{33}H_{50}O_5$ (mp 247—249 °C). Therefore, the I structure must represent aglycone I.





I R_1=H, R_2=OCH_3, R_3=CH_3 VI

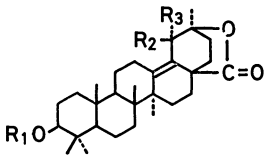
II R_1=H, R_2=OH, R_3=CH_3

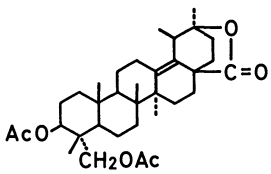
III R_1=H, R_2=CH_3, R_3=OH

IV R_1=Ac, R_2=OCH_3, R_3=CH_3

XV R_1=Ac, R_2=OH, R_3=CH_3

XVI R_1=Ac, R_2=CH_3, R_3=OH





X R_1=H, R_2=CH_3, R_3=H XIX

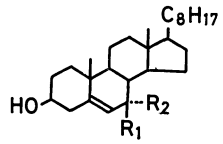
XI R_1=Ac, R_2=OCH_3, R_3=CH_3

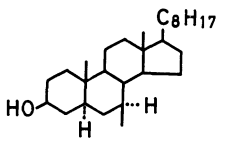
XVII R_1=H, R_2=OH, R_3=CH_3

XVIII R_1=H, R_2=CH_3, R_3=OH

Furthermore, the conversion of I into X determines the configurations at C-19 of not only X, but also V** and IX, which have hitherto remained unknown. Callow and Thompson have reported that the hydrogenolysis of XII over a platinum catalyst gave XIII in glacial acetic acid and XIV in ethyl acetate, with an inversion at C-7 by means of the S_N2 mechanism.[7]

** The hydrogenation of V affords X under the same conditions.[2]





XII R_1=OH, R_2=CH_3 XIII

XIV R_1=CH_3, R_2=H

These facts suggest that C-19 methyl groups of X, V, and IX are β-oriented.

Aglycone II, $C_{30}H_{44}O_4$ (mp 227—229 °C, $[\alpha]_D^{18}$ −90° (c 0.15, ethanol)), exhibits UV maxima at 251 (shoulder), 259, and 268 (shoulder) nm (ε 21000, 26900, and 19100 respectively), IR bands at 3500 and 1730 cm^{-1}, and NMR signals at δ 1.42 and 1.51 (3H each, s), 3.20 (1H, t-like, W1/2 18 Hz), 5.74 (1H, dd, J=11 and 2 Hz), and 6.83 (1H, dd, J=11 and 3 Hz), suggesting the presence of the same partial structure as in I. II forms a monoacetate XV, $C_{32}H_{46}O_5$ (mp 259—261 °C), the IR spectrum of which still shows a hydroxylic absorption at 3420 cm^{-1}. These observations indicate the presence of a hydroxyl group at C-19 in II instead of the methoxyl group in I.

A close structural similarity of aglycone III, $C_{30}H_{44}O_4$ (mp 265—267 °C, $[\alpha]_D^{18}$ −147° (c 0.1, ethanol)), to II is indicated by the spectral data, showing UV maxima at 253 (shoulder), 261, and 270 (shoulder) nm (ε 16500, 20100, and 14200 respectively), IR bands at 3440 and 1720 cm^{-1}, and NMR signals at δ 1.38 and 1.45 (3H each, s), 3.21 (1H, t-like, W1/2 18 Hz), 5.78 (1H, dd, J=11 and 2 Hz), and 6.88 (1H, dd, J=11 and 3 Hz). III forms a monoacetate XVI, $C_{32}H_{46}O_5$ (mp 268—270 °C), the IR spectrum of which still shows a hydroxylic absorption at 3400 cm^{-1}. From these data, it may be concluded that II and III are epimers with respect to C-19.

In order to determine the configuration at C-19, the hydrogenolysis of II and III was attempted in a way similar to that used with I. Thus, II afforded X along with a dihydro-compound XVII, $C_{30}H_{46}O_4$ (mp 247—249 °C), whereas III yielded only a dihydro-compound XVIII, $C_{30}H_{46}O_4$ (mp 259—261 °C). In addition, the UV absorptions of II characteristic of the partial structure Ia disappeared after 4 hr, while those of III disappeared within 1 hr. In the hydrogenolysis reaction of I, which gave X and a dihydro-compound, as has been mentioned above, the disappearance of UV absorptions was observed after 3 hr, while IX gave a dihydro-compound XIX after 1 hr. If we assume that the hydrogenolysis of the allylic C–O bond occurs with inversion by means of the S_N2 mechanism and that the hydrogenation rate is affected only by the ease in approach to the catalyst, these results suggest that the configuration at C-19 of II is similar to that of I, while III and IX have the same configuration at C-19. The catalyst would attack the α-face of the molecule because of the steric hindrance due to the methyl groups at C-8 and C-10. The α-oriented methyl group at C-19 prevents the approach to the catalyst, whereas the α-oriented hydroxyl group promotes the reaction through its affinity for the catalyst metal.

Experimental

The NMR spectra were determined on a JEOL PS-100 (100 MHz) spectrometer in deuterochloroform solutions, with tetramethylsilane as the internal standard. The IR spectra were recorded on a JASCO model IR-S spectrophotometer. The UV data were measured in ethanol solutions with a Hitachi EPS-3T spectrophotometer. A Rex Optical Works apparatus, model NEP-2, was used for the measurement of the rotations. Column chromatography was performed using Mallinckrodt silicic acid. The mps were determined in glass capillaries and are uncorrected.

Isolation. The fresh leaves of *Ilex latifolia* Thunb. (26 kg), collected in Kochi City in July, 1973, were chopped up and extracted with hot methanol (120 l). After treatment with activated carbon, the extract was concentrated up to about 6 l, leaving an aqueous solution. This solution, after filtration, was extracted with ethyl acetate (1.5 l×3) and then with *n*-butanol (1.5 l×3). The *n*-butanol layer, which has an intense bitter taste, was evaporated *in vacuo* to afford a dark brown residue, which was dissolved in methanol (600 ml). The methanol solution was poured into ether (9 l), and the resulting precipitates were collected by filtration, washed with ether, and dried to give a yellowish-white powder (432 g). This powder was repeatedly chromatographed over silicic acid, with chloroform–methanol–water (80:20:2) as the eluent, to give latifoloside A and B.

Latifoloside A. The combined fractions (3.663 g) were recrystallized from acetone–methanol (2:1) at 50—55 °C to give pure latifoloside A as needles (2.256 g); mp 235—236 °C (decomp.), $[\alpha]_D^{24}$ −33° (*c* 1.0, EtOH), Molisch test (+), IR (KBr) 3400, 1720, and 1045 cm^{-1}.

Latifoloside B. The more polar fractions (1.107 g) were recrystallized from methanol to yield pure latifoloside B as needles (255 mg); mp 210—211 °C (decomp.), $[\alpha]_D^{16}$ −11° (*c* 0.1, pyridine), Molisch test (+), IR (KBr) 3400, 1695, and 1075 cm^{-1}.

Hydrolysis of Latifoloside A. To a solution of latifoloside A (2.0 g) in methanol (200 ml), we added 1 M sulfuric acid (200 ml). The mixture was refluxed for 5 hr and then extracted with ether (600 ml). The extract was washed with a sodium bicabonate solution and with water, dried over magnesium sulfate, and evaporated to dryness. The residue (948 mg) was chromatographed over silicic acid; subsequent elution with chloroform gave aglycone I, II, and III, in that order.

Aglycone I. The earliest fractions (284 mg) were recrystallized from methanol to give I as needles (180 mg); mp 269—270 °C, $[\alpha]_D^{25}$ −110° (*c* 1.0, EtOH), UV (EtOH) 253 (shoulder), 261, and 270 (shoulder) nm (ε 24500, 30000, and 21500 respectively), IR (KBr) 3400 and 1750 cm^{-1}, NMR ($CDCl_3$) δ 1.41 and 1.45 (3H each, s, C_{20} and C_{19}–CH_3), 3.12 (3H, s, O–CH_3), 3.22 (1H, t-like, C_3–H), 5.74 (1H, dd, J=11 and 2 Hz, C_{12}–H), and 6.77 (1H, dd, J=11 and 3 Hz, C_{11}–H), (Found: C, 75.45; H, 9.67%. Calcd for $C_{31}H_{46}O_4 \cdot 1/2H_2O$: C, 75.72; H, 9.63%).

Aglycone II. The middle fractions (254 mg) were recrystallized from aqueous methanol to yield II as prisms (168 mg); mp 227—229 °C, $[\alpha]_D^{18}$ −90° (*c* 0.15, EtOH), UV (EtOH) 251 (shoulder), 259, and 268 (shoulder) nm (ε 21000, 26900, and 19100 respectively), IR (Nujol) 3500, 1730, and 1050 cm^{-1}, NMR ($CDCl_3$) δ 1.42 and 1.51 (3H each, s, C_{20} and C_{19}–CH_3), 3.20 (1H, t-like, W1/2 18 Hz, C_3–H), 5.74 (1H, dd, J=11 and 2 Hz, C_{12}–H), and 6.83 (1H, dd, J=11 and 3 Hz, C_{11}–H), (Found: C, 77.34; H, 9.63%. Calcd for $C_{30}H_{44}O_4$: C, 76.88; H, 9.46%).

Aglycone III. The last fractions (300 mg) were recrystallized from aqueous methanol to give III as plates (204 mg); mp 265—267 °C, $[\alpha]_D^{16}$ −147° (*c* 0.1, EtOH), UV (EtOH) 253 (shoulder), 261, and 270 (shoulder) nm (ε 16500, 20100, and 14200 respectively), IR (KBr) 3440, 1720, and 1080 cm^{-1}, NMR ($CDCl_3$) δ 1.38 and 1.45 (3H each, s, C_{20} and C_{19}–CH_3), 3.21 (1H, t-like, W1/2 18 Hz, C_3–H), 5.78 (1H, dd, J=11 and 2 Hz, C_{12}–H), and 6.88 (1H, dd, J=11 and 3 Hz, C_{11}–H), (Found: C, 76.45; H, 9.56%. Calcd for $C_{30}H_{44}O_4$: C, 76.88; H, 9.46%).

Acetylation of I. A solution of I (40 mg) in acetic anhydride (2 ml) and pyridine (1 ml) was allowed to stand at room temperature overnight and then worked up in the usual way to give a white precipitate which was subsequently recrystallized from methanol to yield a monoacetate IV as needles (29 mg); mp 272—273 °C, IR (CCl_4) 1750, 1730, and 1245 cm^{-1}, NMR ($CDCl_3$) δ 1.41 and 1.45 (3H each, s, C_{20} and C_{19}–CH_3), 2.04 (3H, s, O–CO–CH_3), 3.12 (3H, s, O–CH_3), 4.49 (1H, t-like, W1/2 18 Hz, C_3–H), 5.71 (1H, dd, J=11 and 2 Hz, C_{12}–H), and 6.77 (1H, dd, J=11 and 3 Hz, C_{11}–H), (Found: C, 75.38; H, 9.33%. Calcd for $C_{33}H_{48}O_5$: C, 75.53; H, 9.22%).

Acetylation of II. II (37 mg) was treated with acetic anhydride (1 ml) and pyridine (1 ml) as has been described above, and the resulting precipitates were recrystallized from methanol to give a monoacetate XV as needles (30 mg); mp 259—261 °C, IR (Nujol) 3420, 1740, and 1255 cm^{-1}, NMR ($CDCl_3$) δ 1.41 and 1.51 (3H each, s, C_{20} and C_{19}–CH_3), 2.03 (3H, s, O–CO–CH_3), 4.51 (1H, t-like, W1/2 18 Hz, C_3–H), 5.76 (1H, dd, J=11 and 2 Hz, C_{12}–H), and 6.84 (1H, dd, J=11 and 3 Hz, C_{11}–H), (Found: C, 75.20; H, 9.15%. Calcd for $C_{32}H_{46}O_5$: C, 75.26; H, 9.08%).

Acetylation of III. III (50 mg) was treated with acetic anhydride (2 ml) and pyridine (2 ml) as has been described above, and the resulting precipitates were recrystallized from methanol to yield a monoacetate XVI as needles (35 mg); mp 268—270 °C, IR (Nujol) 3400, 1735, 1715, and 1235 cm^{-1}, NMR ($CDCl_3$) δ 1.38 and 1.45 (3H each, s, C_{20} and C_{19}–CH_3), 2.05 (3H, s, O–CO–CH_3), 4.51 (1H, t-like, W1/2 18 Hz, C_3–H), 5.78 (1H, dd, J=11 and 2 Hz, C_{12}–H), and 6.92 (1H, dd, J=11 and 3 Hz, C_{11}–H), (Found: C, 75.33; H, 9.17%. Calcd for $C_{32}H_{46}O_5$: C, 75.26; H, 9.08%).

Reduction of I with Lithium Aluminum Hydride. To a solution of I (50 mg) in tetrahydrofuran (5 ml), we added lithium aluminum hydride (10 mg) in tetrahydrofuran (5 ml). The mixture was stirred at room temperature for 1 hr and then poured into ether floated on water. The organic layer was washed with dilute hydrochloric acid and then with water. The subsequent drying and evaporation of the solution left a residue (48 mg) which no longer showed the lactonic band in the IR spectrum. The acetylation and recrystallization of the product from aqueous methanol afforded a monoacetate VI as needles (19 mg); mp 210—211 °C, UV (EtOH) 244, 253, and 262 nm (ε 18000, 25600, and 16000 respectively), IR (CCl_4) 1735 and 1245 cm^{-1}, NMR ($CDCl_3$) δ 1.16 (3H, s, C_{20}–CH_3), 1.34 (3H, s, C_{19}–CH_3), 2.04 (3H, s, O–CO–CH_3), 3.26 (3H, s, O–CH_3), 3.40 (2H, s, O–CH_2–), 4.51 (1H, t-like, C_3–H), 5.62 (1H, dd, J=11 and 2 Hz, C_{12}–H), and 6.85 (1H, dd, J=11 and 3 Hz, C_{11}–H), (Found: C, 75.60; H, 9.79%. Calcd for $C_{33}H_{50}O_4 \cdot 2/3H_2O$: C, 75.82; H, 9.77%).

Formation of the Lactone IX. The procedure of Barton *et al.*[2] was followed: the epoxide VIII (220 mg) in glacial acetic acid (18 ml) containing concentrated hydrochloric acid (2 ml) was heated at 100 °C for 10 min. The mixture was then worked up in the usual manner, and the resulting precipitates (236 mg) were recrystallized from aqueous methanol

to give a lactone IX as flakes (104 mg); mp 241—242 °C, UV (EtOH) 252, 260, and 269 nm (ε 19300, 23800, and 16600 respectively), IR (CCl_4) 1750 and 1245 cm^{-1}, NMR ($CDCl_3$) δ 1.08 (3H, d, J=7 Hz, C_{19}-CH_3), 1.40 (3H, s, C_{20}-CH_3), 2.02 and 2.06 (3H each, s, O-CO-CH_3), 2.66 (1H, q, J=7 Hz, C_{19}-H), 3.77 (2H, s, O-CH_2-), 4.77 (1H, m, C_3-H), 5.68 (1H, dd, J=11 and 2 Hz, C_{12}-H), and 6.10 (1H, dd, J=11 and 3 Hz, C_{11}-H), (Found: C, 73.92; H, 8.86%. Calcd for $C_{34}H_{48}O_6$: C, 73.88; H, 8.75%).

Hydrogenolysis of I. I (80 mg) and hydrated platinum oxide (40 mg) were stirred in glacial acetic acid (16 ml) under a hydrogen atmosphere at room temperature and normal pressure; after 3 hr, the UV absorptions at 250—270 nm almost disappeared. The catalyst was removed by filtration, and then the filtrate was evaporated. The residue was dissolved in ether, washed with a sodium bicarbonate solution and water, dried over magnesium sulfate, and evaporated to dryness. The residue was chromatographed over silicic acid; subsequent elution with chloroform gave a demethoxy-compound and a dihydro-compound.

The crude demethoxy-compound (32 mg) was recrystallized from aqueous methanol to yield vanguerolic acid lactone X as plates (25 mg); mp and mixed mp with an authentic sample,*** 263—267 °C, $[\alpha]_D^{16}$ −70° (c 0.1, EtOH).

The crude dihydro-compound (43 mg) was acetylated as has been described above, and the product was recrystallized from methanol to give a monoacetate XI as plates (21 mg); mp 247—249 °C, UV (EtOH) 231 nm (ε 5000), NMR ($CDCl_3$) δ 1.39 (6H, s, C_{19} and C_{20}-CH_3), 2.03 (3H, s, O-CO-CH_3), 3.27 (3H, s, O-CH_3), and 4.48 (1H, t-like, W1/2 18 Hz, C_3-H), (Found: C, 75.88; H, 9.72%. Calcd for $C_{33}H_{50}O_5$: C, 75.24; H, 9.57%).

Hydrogenolysis of II. II (78 mg) and hydrated platinum oxide (39 mg) in glacial acetic acid (16 ml) were treated as has been described above; after 4 hr, the UV absorptions at 250—270 nm almost disappeared. The residue was chromatographed over silicic acid; subsequent elution with chloroform–methanol (99: 1) yielded a deoxy-compound and a dihydro-compound.

The crude deoxy-compound (12 mg) was recrystallized from aqueous methanol to give X as plates (8 mg); mp and mixed mp with an authentic sample, 263—267 °C.

The crude dihydro-compound (48 mg) was recrystallized from aqueous methanol to yield XVII as plates (31 mg); mp 247—249 °C, UV (EtOH) 231 nm (ε 8600), IR (nujol) 3560 and 1735 cm^{-1}, (Found: C, 76.61; H, 9.89%. Calcd for $C_{30}H_{46}O_4$: C, 76.55; H, 9.85%).

*** This sample was obtained by the method described in the literature[2] from methyl vanguerolate acetate, which has kindly been provided by Prof. D. H. R. Barton.

The acetylation of XVII (22 mg) and recrystallization of the product from chloroform–methanol afforded a monoacetate as needles (13 mg); mp 325—330 °C, IR (Nujol) 3510 and 1740 cm^{-1}, (Found: C, 75.16; H, 9.05%. Calcd for $C_{32}H_{48}O_5$: C, 74.96; H, 9.44%).

Hydrogenation of III. III (51 mg) in glacial acetic acid (10 ml) was hydrogenated in the presence of hydrated platinum oxide (26 mg) as has been described above; after 1 hr, the UV absorptions at 250—270 nm completely disappeared. The residue was recrystallized from methanol to give XVIII as prisms (39 mg); mp 259—261 °C, UV (EtOH) 229 nm (ε 5100), IR (Nujol) 3440 and 1715 cm^{-1}, (Found: C, 73.03; H, 10.18%. Calcd for $C_{30}H_{46}O_4 \cdot 5/4H_2O$: C, 73.06; H, 9.91%).

The acetylation of XVIII (33 mg) and recrystallization of the product from chloroform–methanol gave a monoacetate as needles (25 mg); mp 320—325 °C, IR (Nujol) 3470, 1740, and 1715 cm^{-1}, (Found: C, 75.02; H, 8.98%. Calcd for $C_{32}H_{48}O_5$: C, 74.96; H, 9.44%).

Hydrogenation of IX. IX (70 mg) and hydrated platinum oxide (35 mg) in glacial acetic acid (14 ml) were treated as has been described above; after 1 hr, the UV absorptions at 250—270 nm almost disappeared. The residue was recrystallized from aqueous methanol to yield XIX as needles (36 mg); mp 226—228 °C, UV (EtOH) 227 nm (ε 5100) IR (Nujol) 1740 cm^{-1}, NMR ($CDCl_3$) δ 1.10 (3H, d, J=7 Hz, C_{19}-CH_3), 1.37 (3H, s, C_{20}-CH_3), 2.01 and 2.05 (3H each, s, O-CO-CH_3), 2.55 (1H, qd, J=7 and 2 Hz, C_{19}-H), 3.70 and 3.86 (1H each, AB q, J_{AB}=12 Hz, O-CH_2-), and 4.77 (1H, t-like, W1/2 18 Hz, C_3-H), (Found: C, 73.60; H, 9.19%. Calcd for $C_{34}H_{50}O_6$: C, 73.61; H, 9.09%).

We are grateful to Professor Takashi Tokoroyama, Osaka City University, for his valuable help and suggestions.

Effect of Solvent Viscosity on the Decomposition of 1,1,4,4-Tetraphenyl-2-tetrazene

Kazuo SUGIYAMA, Tadao NAKAYA,* and Minoru IMOTO**

Department of Applied Chemistry, Faculty of Engineering, Kinki University, Kure, Hiroshima 737-01

(Received August 9, 1974)

The rate of decomposition of 1,1,4,4-tetraphenyl-2-tetrazene (TPT) was measured in the polyethylene glycol (PEG) thickened dimethylformamide (DMF) of varying viscosities. The observed rate constant for the decomposition of TPT decreases with the viscosity of the DMF/PEG solvent system. A compensating change was found in the enthalpy and entropy of activation. It was also found that the decomposition of TPT occurs by the scission of only one N–N single bond, and undergoes cage return in the solvent system by recombination of radicals.

2-Tetrazenes decompose thermally and photochemically to form two neutral amino radicals and nitrogen.[1] The basic nature of 2-tetrazenes and their reactions with electrophilic reagents have been extensively investigated.[2-4] Nelsen *et al.*[1e] prepared 1,4-dimethyl-1,4-diphenyl-2-tetrazene and several of its bis-*p*-substituted derivatives to obtain information about electronic and thermodynamic factors of the decomposition of 2-tetrazenes. With electron withdrawing substituents, it was found that the decrease in the rate of decomposition is not due to the ΔH^* term, but to the ΔS^* term. However, the rate of decomposition increases with the polarity of the solvent in the radical decomposition of 1,4-dimethoxycarbonyl-1,4-diphenyl-2-tetrazene.[5] The enthalpy of activation is a linear function of the entropy of activation over quite a wide range in various solvents.

There has also been some interest in the effect of viscosity on the rate of bond homolysis.[6] Herk *et al.*[6a] studied the cage reaction of acetyl peroxide and azomethane. Pryor *et al.*[6d] have also investigated the decomposition of a wide variety of free radical initiators in a series of alkane solvents of varying viscosities. However, there has been no systematic investigation of the effect of viscosity on the decomposition of 2-tetrazene.

In earlier works,[1h] we reported that 1,1,4,4-tetraphenyl-2-tetrazene (TPT) acts as an effective inhibitor for the radical polymerization of vinyl monomers. As an extension of our study of the decomposition of TPT, our interests were directed to the effect of solvent viscosity on the decomposition. The present paper is mainly concerned with a detailed study on the decomposition of TPT in polyethylene glycol (PEG) thickened dimethylformamide (DMF) of varying viscosities.

Experimental

Materials. TPT was prepared by oxidizing 1,1-diphenylhydrazine with manganese dioxide, according to the method of Bhatnagar.[8] DMF and PEG were purified in the usual manner.

Viscosity Studies. The stock PEG thickened DMF solution were prepared by dissolving 10 g of PEG of various degrees of polymerization in 100 ml of DMF. The degrees of polymerization of PEG used in this work were 200, 1000, 2000, 4000, 6000, and 20000. The viscosities of the solvent systems, DMF/PEG, were determined at 65, 70, 75, and 80 °C by using an Ostwald viscometer. The rates of decomposition of TPT in DMF and in the six DMF/PEG systems were determined by measuring the amount of nitrogen evolved, according to Overberger *et al.*[9]

Thermodynamic Parameters.[10] The Arrhenius energy of activation E_a, was calculated from a plot of log k_{obsd} *vs.* $1/T$. The enthalpy of activation was obtained from the equation $\Delta H^* = E_a - RT$. ΔS^* was evaluated from the Eyring's equation, $k_{obsd} = T/h \exp(-\Delta H^*/RT)\exp(\Delta S^*/R)$.

Theory for Qualititative Viscosity Test. The mechanism for the decomposition of TPT has been given as follows.[6d]

$$\begin{array}{ccc} & & 2\cdot N(C_6H_5)_2 + N_2 \\ & & \uparrow k_D \\ (C_6H_5)_2N\text{-}\overset{\alpha}{\underset{}{|}}\text{-}N{=}N\text{-}\overset{\beta}{\underset{}{|}}\text{-}N(C_6H_5)_2 & \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} & (\text{Cage}) \\ & & \downarrow k_B \\ & & (\text{Cage-B}) + HN(C_6H_5)_2 \end{array}$$

where k_1, k_{-1}, k_D, and k_B represent the rate constants for the bond homolysis, recombination of original geminate radicals, diffusive separation of the geminate radicals, and any other scission that competes with diffusion and cage return. In this case, the observed rate constant for the decomposition of TPT is given as

$$k_{obsd} = k_1(k_D + k_B)/(k_{-1} + k_D + k_B) \quad (1)$$

The viscosity of DMF/PEG may be written as[10]

$$\eta = A_{vis} \exp(E_{vis}/RT) \quad (2)$$

while the temperature dependence of the rate constant for the diffusion, k_D, can be expressed as[6d]

$$k_D = A_D \exp(-E_D/RT) \quad (3)$$

According to Pryor,[6d] the following relationship can be obtained for the decomposition of TPT in high viscosity media

$$1/k_{obsd} = 1/k_1 + (k_{-1}/k_1A_D)(\eta/A_{vis})^{1/2} \quad (4)$$

Equation 4 suggests that the decomposition of TPT maybe divided into two classes.[6d] i) $k_{-1}=0$, TPT decomposes by the synchronous scission of both α- and β-bonds to produce two diphenylamino radicals. The rate of decomposition may be independent of the solvent viscosity. ii) $k_{-1} \neq 0$, TPT decomposes by the scission of the α-bond only to give cage return in whichever solvent system by radical recombination. In this case, the k_{obsd} decreases as the viscosity of the solvent system increases.

Results and Discussion

In order to use the viscosity test, it is necessary to adopt a solvent system in which the viscosity can be varied without sharply changing any other properties of the solvent. In this work, we chose DMF/PEG. There is no serious difficulty in using DMF/PEG in the application of the viscosity test to TPT, as discussed below.

Measurements of the Viscosity of DMF/PEG. The viscosities of DMF/PEG were measured over a temperature from 60 to 80 °C, and are listed in Table 1.

Arrhenius-like plots of the relative viscosity gave straight lines, from which the activation parameters, E_{vis} and A_{vis}, in Eq. (2) were calculated: they are also listed in Table 1.

Table 1. Activation parameters and relative viscosities of DMF/PEG at various temperatures

Pn of PEG[a]	Temperature 80 °C	75 °C	70 °C	65 °C	E_{vis} (kcal/mol)	A_{vis}
DMF alone	1.000[b]	1.045	1.075	1.128	2.30	0.0189
200(a)	1.022	1.264	1.325	1.406	2.58	0.0146
1000(b)	1.454	1.533	1.617	1.712	2.65	0.0158
2000(c)	1.722	1.817	1.911	2.037	2.79	0.0162
4000(d)	1.994	2.107	2.233	2.359	2.69	0.0220
6000(e)	3.223	3.484	3.669	3.895	3.22	0.0168
20000(f)	7.990	8.525	9.134	9.783	3.47	0.0285

a) Degree of polymerization of PEG as the high viscosity component in DMF. (See Experimental Section)
b) Absolute viscosity 0.507 cps.

Measurements of the Rate of Decomposition of TPT. The kinetics of decomposition of TPT were measured in DMF/PEG at various temperatures. The reaction rate was strictly first-order in TPT-concentration under our conditions.[11] The first-order rate constants are listed in Table 2.

Table 2. First-order rate constants (k_{obsd}) for the decomposition of TPT in DMF and DMF/PEG at various temperatures

Solvent[a]	$k_{obsd} \times 10^5$ (s^{-1}) 80 °C	75 °C	70 °C	65 °C
DMF alone	119	115	102	66.4
(a)	24.3	17.7	16.3	12.6
(b)	19.3	16.7	13.2	10.4
(c)	18.7	15.0	11.9	9.23
(d)	16.3	12.8	11.8	7.91
(e)	15.9	12.4	9.89	8.00
(f)	12.6	10.7	—	7.67

a) See Table 1.

As can be seen from Tables 1 and 2, the observed rate constant for the decomposition of TPT decreases with the viscosity of the solvent system. It may be concluded that the macroscopic viscosity reflects the resistance to translational motion of monomeric radicals in this solvent system.

Arrhenius plots of the data in Table 2 yielded straight lines, from which the thermodynamic parameters were calculated by the method described in the Experimental Section. The results are shown in Table 3.

Table 3. Thermodynamic parameters for the decomposition of TPT in various solvent systems

Solvent[a]	ΔH^* (kcal/mol)	ΔS^* (kcal/mol)	ΔG^* (kcal/mol)
DMF alone	5.40	−58.9	26.2
(a)	8.85	−52.3	27.3
(b)	9.24	−51.7	27.5
(c)	10.1	−49.2	27.5
(d)	10.7	−47.8	27.6
(e)	11.0	−47.2	27.6
(f)	12.5	−43.3	27.8

a) see Table 1.

From the effect of the viscosity of the solvent system on the activation parameters, a compensating change[12] was found in the enthalpy and entropy of activation for the decomposition of TPT, as shown in Fig. 1.

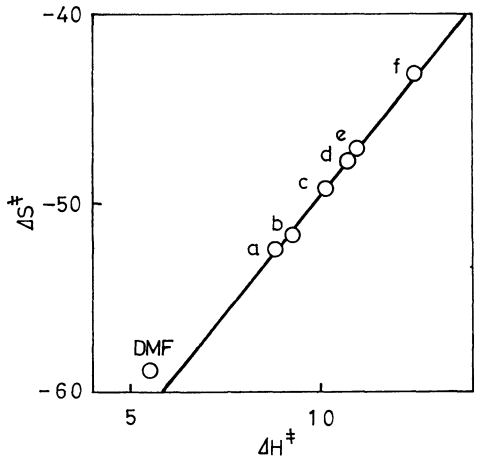

Fig. 1. Relationship between ΔH^* and ΔS^* in the decomposition of TPT
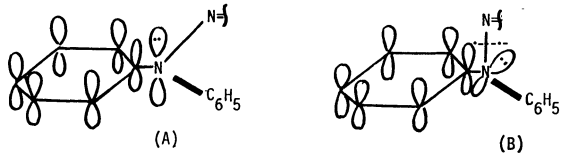
The solvent system are DMF, (a), (b), (c), (d), (e), and (f). (See Table 1.)

This finding suggests that a single mechanism is operative for the thermal decomposition of TPT in the DMF/PEG. Accordingly the variation in k_{obsd} with viscosity is not due to different decomposition mechanisms. It is suggested that the variation in ΔH^* does not depend on the different reaction mode, but depends on the change in apparent rate of decomposition, k_{obsd}.

On the other hand, the factor favoring the dissociation of the N–N single bonds of TPT is mainly responsible for the stability of the nitrogen radical. Large negative entropies of activation were observed in the decomposition of 2-tetrazenes. Nelsen[1e] reported that some 1,4-diaryl-1,4-dimethyl-2-tetrazenes decompose thermally in cumene with negative entropies. In the decomposition of 1,4-dimethoxycarbonyl-1,4-diphenyl-2-tetrazene the entropies were −14.2 cal/K in acetonitrile and −30.5 cal/K in dioxane.[5] It is considered that the delocalization of an odd electron on

nitrogen should compete with that of a lone pair on the diphenylamino group at the time of decomposition of TPT. According to Nelsen,[1e] TPT is in conformation A with the lone pair electrons in a p orbital which overlaps with π system of phenyl ring. But the conformation B is needed for maximum stabilization of the odd electron of the diphenylamino radicals in the decomposition of TPT



It is obvious that the steric factor plays an important role in the bond homolysis of TPT. The change in $\Delta H^{\ddagger}$ is balanced by a corresponding change in $\Delta S^{\ddagger}$.

Viscosity Test. In order to check whether TPT decomposes by the initial scission of only one N–N bond (α-scission) or the synchronous scission of two single N–N bond (α,β-scission), k_{obsd} was plotted against the viscosity term.

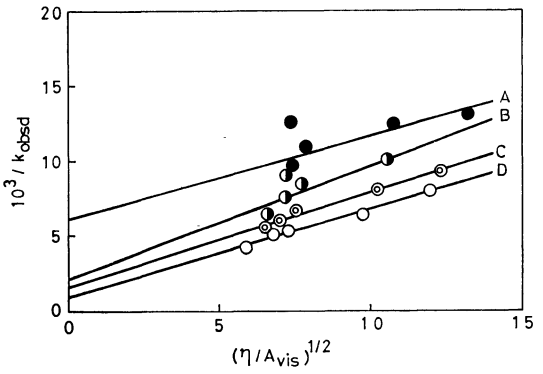


Fig. 2. Relationship between $1/k_{obsd}$ and $(\eta/A_{vis})^{1/2}$ for the decomposition of TPT in DMF/PEG at various temperatures. A; 65, B; 70, C; 75, D; 80 °C.

It was found that k_{obsd} decreased regularly as the solvent changed from low viscosity to high viscosity, as shown in Table 2. As can be seen from Fig. 2, the slopes of the lines are not zero in the decomposition of TPT in DMF/PEG. From Eq. (4), it may be concluded that TPT does not decompose by a concerted mechanism but decomposes by a two step mechanism. That is, TPT decomposes by the scission of only one N–N single bond, and undergoes cage return by recombination of radicals. The following mechanism of the decomposition is proposed to account for our observations:

$$(C_6H_5)_2N\text{–}N{=}N\text{–}N(C_6H_5)_2 \rightleftarrows [(C_6H_5)_2N\text{–}N{=}N\cdot \cdot N(C_6H_5)_2]$$

$$\downarrow$$

$$(C_6H_5)_2N\cdot + N_2 \longleftarrow (C_6H_5)_2N\text{–}N{=}N\cdot + \cdot N(C_6H_5)_2$$

The Crystal and Molecular Structure of (+)-1,2-Dibromo-2-phenylethyl *p*-Tolyl Sulfoxide

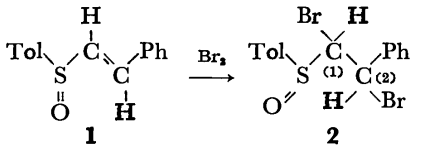
Fujiko IWASAKI, Shuichi MITAMURA,* and Gen-ichi TSUCHIHASHI*

Department of Materials Science, The University of Electro-Communications, Chofu-shi, Tokyo 182
**Sagami Chemical Research Center, Nishi-Ohnuma, Sagamihara, Kanagawa 229*

(Received November 11, 1974)

The crystal structure of (+)-1,2-dibromo-2-phenylethyl *p*-tolyl sulfoxide, a dominant isomer formed by the ionic bromination of (+)-*trans*-*β*-styryl *p*-tolyl sulfoxide, has been determined by the X-ray diffraction method. The crystal is monoclinic; space group, $P2_1$; $a=16.193$, $b=5.706$, $c=8.541$ Å, $\beta=93.51°$, and $Z=2$. The final R value is 0.087 for 792 observed reflections. The absolute configuration has been established to be $S_S, S_{C(1)}, S_{C(2)}$ from the Cu$K\alpha$ anomalous scattering of the bromine and sulfur atoms. The sulfinyl oxygen is *gauche* to the bromine atom across the S–C(1) bond, and the non-bonding distance between the both atoms is 3.13 Å. The bromine atom is *trans* to another bromine across the C(1)–C(2) bond. Based on the assigned structure, a mechanism which involves the preferential formation of an intermediary bromonium ion is elucidated for the bromination. The configuration at the sulfur atom is retained during the reaction.

The ionic bromination of (+)-*trans*-*β*-styryl *p*-tolyl sulfoxide (**1**) results in a dominant formation of one isomer in four diastereomers of (+)-1,2-dibromo-2-phenylethyl *p*-tolyl sulfoxide (**2**). The high selectivity



1 **2**

of the addition is attributed to the preferential formation of a bridged bromonium ion by the electronic demand of the adjacent chiral sulfinyl group.[1] In order to elucidate such a specific reaction mechanism, it is important to study the stereochemistry of sulfur centers; however, the steructures of relatively few sulfoxides have been determined. An X-ray study was, therefore, undertaken to establish the absolute configuration and the molecular conformation of **2**.

Experimental

The dominant isomer of **2** was recrystallized from a *n*-hexane–ethanol solution. The crystals are colorless needles and are stable in air. The cell dimensions were calibrated with copper powder lines superposed on Weissenberg photographs (CuK, $\alpha=1.5418$, $\alpha_1=1.5405$ Å).

The crystal data are: $C_{15}H_{14}Br_2SO$, M.W.=402.14; monoclinic, $a=16.193$ (8)[2], $b=5.706$ (12), $c=8.541$ (8) Å, $\beta=93.51$ (5)°, $V=787.6$ Å^3, $Z=2$, $D_x=1.695$ g cm^{-3}, $D_m=1.68$ g cm^{-3}; $F(000)=396$; $\mu=75.7$ cm^{-1} (Cu$K\alpha$); Spase group, $p2_1$; $[\alpha]_D^{22}$ +261.8° (c 0.527, $CHCl_3$); mp 161—163 °C.

The intensity data were collected from integrated equi-inclination Weissenberg photographs around the b and c axes, *h0l*—*h3l* and *hk*0—*hk*5, using Cu$K\alpha$ radiation. The intensities were estimated visually by comparison with a standard scale. A total of 792 non-zero reflections were observed. Lorentz, polarization and spot-shape corrections were made, but because of the size of specimens (max. $\mu R=0.2$) no absorption corrections were applied.

Structure Determination

The positions of the two bromine atoms in an asymmetric unit were found by an inspection of a three-dimensional Patterson map. For the heavy atoms alone, the R value was 0.31. The calculation of Fourier synthesis allowed coordinates to be assigned to all the other atoms. The atomic parameters were refined by least-squares methods, first with isotropic temperature factors to an R value of 0.15 and then with anisotropic temperature factors for all the non-hydrogen atoms to an R value of 0.090. The positions of the hydrogen atoms, other than those of the methyl group, were calculated with a C–H distance of 1.08 Å. These hydrogen parameters were included in the structure-factor calculations, though they were not refined. The isotropic thermal parameters for hydrogen atoms were assumed to be 5.0 Å^2. Further refinement of atomic parameters was carried out for all the non-hydrogen atoms with anisotropic temperature factors. The final R value was 0.087 for all the observed reflections. The weighting scheme used was: $w=0.7$ if $|F_o|<6$, $w=1$ if $6\leq|F_o|\leq25$ and $w=(25/|F_o|)^2$ if $|F_o|>25$. The atomic scattering factors for non-hydrogen atoms were taken from "International Tables for X-ray Crystallography".[3] For the bromine atom, the scattering factor was corrected for dispersion using the expression: $|f|=\sqrt{\{(f_0+\Delta f')^2+(\Delta f'')^2\}}$. For hydrogen, the values given by Stewart, Davidson, and Simpson[4] were used.

The final atomic parameters and their estimated standard deviations are given in Table 1. The observed and calculated structure factors are listed in Table 2.[5]

Absolute Configuration. The absolute configuration has been determined by the anomalous dispersion method, with Cu$K\alpha$ radiation. The values of the real and imaginary dispersion correction terms of the scattering factor were taken as $\Delta f'_{Br}=-0.96$, $\Delta f'_S=0.31$, $\Delta f''_{Br}=1.46$, and $\Delta f''_S=0.58$.[6] The calculated values of the intensity ratio between the Friedel pair of reflections agreed with those observed on the b-axis oscillation photographs if one takes the right-handed coordinate system. A comparison of the observed and calculated intensity ratios is given in Table 3. The figures shown in this paper are drawn with the correct absolute configuration obtained above.

Table 1. Final atomic parameters

(a) Atomic coordinates ($\times 10^4$) and thermal parameters ($\times 10^3$) of non-hydrogen atoms with their estimated standard deviations.[a] The anisotropic temperature factors are of the form:
$\exp\{-2\pi^2(U_{11}h^2a^{*2}+U_{22}k^2b^{*2}+U_{33}l^2c^{*2}+2U_{12}hka^*b^*+2U_{13}hla^*c^*+2U_{23}klb^*c^*)\}$.
The B_{eq} values are the equivalent isotropic temperature factors.[b]

Results and Discussion

The bond distances and angles are shown in Fig. 1. The three sulfur bonds form a shallow pyramid. The dihedral angle between the planes defined by the C(1)–S–C(9) and O–S–C(9) atoms is 109°. The C(1)–S–O and C(9)–S–O angles are 105 and 107° respectively; the corresponding angles in (+)-methyl *p*-tolyl sulfoxide (**3**) have been reported to be 105.5 and 106.5° respectively.[7] The C(1)–S–C(9) angle is 100°, which agrees well with the values for symmetrical sulfoxides[8] and **3**.[7] The S–O distance is 1.47 Å, which is slightly shorter than those (1.49 and 1.53 Å) in other sulfoxides.[7,8] The S–C(1) and S–C(9) distances are 1.82 and 1.75 Å. They are slightly different from each other, while in **3** the corresponding values for the S–C lengths are 1.796 and 1.797 Å respectively.

The C(1)–C(2) distance is 1.53 Å, and the C(2)–C(3) distance is 1.50 Å. They are similar to the accepted values for single C(sp^3)–C(sp^3) (1.526 Å) and C(sp^3)–C(sp^2) (1.501 Å) bonds.[9] The lengths for C(1)–Br(1) and C(2)–Br(2) are 2.00 and 1.98 Å respectively. They are slightly longer than those for ethyl bromide (1.950 Å),[10] for 2-bromopropane (1.957 Å)[11] in the gas phase, and for hexabromoethane (1.944 Å)[12] in the solid phase.

The average values for C–C bonds in aromatic rings are 1.39 (phenyl) and 1.40 Å (tolyl) respectively. The length of C(12)–C(15), 1.48 Å, is close to the corresponding value for toluene.[13] The least-squares planes are listed in Table 4. The dihedral angle between these planes is 69°.

		S[a]	208

a) Atoms not used to define the least-squares plane.

The conformation of groups across the bonds, C(1)–C(2), S–C(1), S–C(9), and C(2)–C(3), are shown in Fig. 2. The oxygen atom is *gauche* to Br(1) across the S–C(1) bond, and the torsion angle, O–S–C(1)–Br(1), is 45°. The lone-pair orbital of the sulfur atom is *trans* to Br(1). Br(2) is *trans* to Br(1) across the C(1)–C(2) bond. The non-bonding distances, Br(1)···O, Br(1)···C(8), Br(1)···C(9), and O···C(14), are 3.13, 3.44, 3.37, and 2.86 Å respectively.

The absolute configuration is rigorously determined to be *S* at the sulfur atom, *S* at C(1), and *S* at C(2). Therefore the structure of the dominant isomer derived from the ionic bromination of (+)-*trans*-β-styryl *p*-tolyl

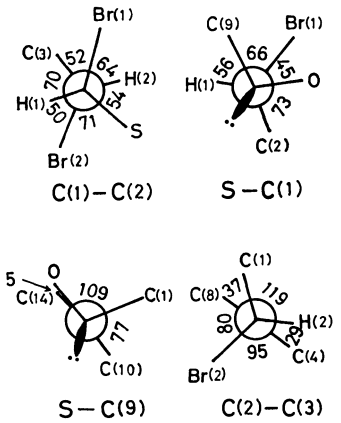

Fig. 2. Torsion angles in the molecule.

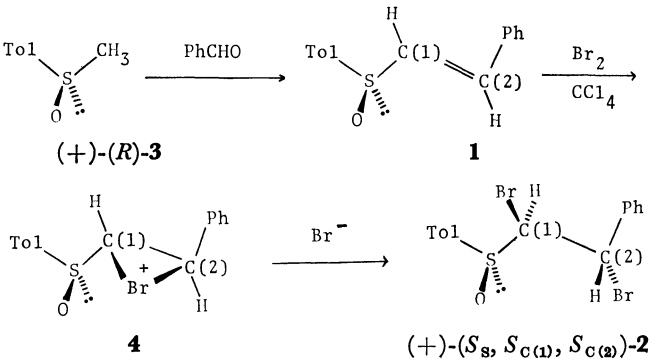
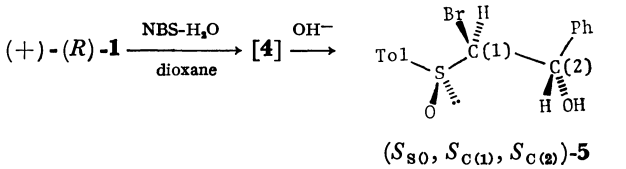
sulfoxide (**1**) is (+)-(S_S, $S_{C(1)}$, $S_{C(2)}$)-1,2-dibromo-2-phenylethyl *p*-tolyl sulfoxide (**2**).

(+)-*trans*-β-Styryl *p*-tolyl sulfoxide (**1**)[1a] was obtained by the condensation reaction of benzaldehyde with (+)-(*R*)-methyl *p*-tolyl sulfoxide (**3**), whose configuration has been unequivocally established as *R* by the chemical transformation to sulfoxides of a known absolute configuration[14,15] and by the X-ray diffraction method.[7] Since the **3** to **1** transformation does not involve the chiral center, and since the configuration at the sulfur atom of **2** is *S*, the ionic bromination of **1** proceeds with the retention of the configuration at the sulfur atom.



Scheme 1.

An inspection of the molecular structure of (+)-(S_S, $S_{C(1)}$,$S_{C(2)}$)-**2** revealed that the bromination proceeds in the *trans* manner, giving a product in which the bromine atom at C(1) is in the *gauche* position to the oxygen atom in the adjacent sulfinyl group. The formation of this product can be explained in terms of the preferential formation of an intermediary bromonium ion (**4**), followed by the attack of the bromide anion at C(2), as is shown in Scheme 1. The same bromonium ion, **4**, was proposed as an intermediate of the bromo-



(S_{SO}, $S_{C(1)}$, $S_{C(2)}$)-**5**

Dehydrobromination of 16-Bromodihydroenmein-type Compounds

Takahiko Isobe and Takashi Kubota*

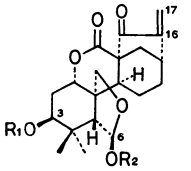
Hyogo College of Medicine, Mukogawa-cho, Nishinomiya-shi, Hyogo 663

**Faculty of Medicine, Kinki University, Nishiyama, Sayama-cho, Minamikawachi-gun, Osaka 589*

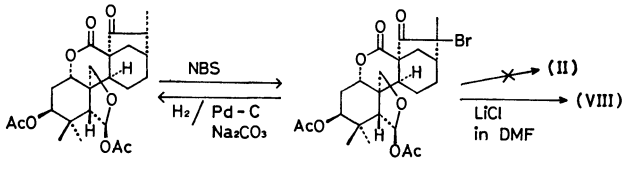
(Received November 18, 1974)

16-Bromodihydroenmein diacetate (IV) obtained from dihydroenmein diacetate (III) by bromination with *N*-bromosuccinimide was dehydrobrominated with lithium chloride in dimethylformamide to give a product, the structure of which was elucidated as the intermolecular ether (VIII). The dimeric ether compound was also formed by similar reactions from the derivative of isodocarpin.

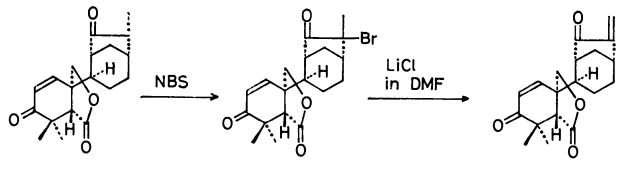
About 10 years ago, during experiments for structual elucidation of enmein (I),[1] an attempt was made to revert 16-bromodihydroenmein diacetate (IV), obtained by bromination of dihydroenmein diacetate (III),[1,2,3] to enmein diacetate (II) by dehydrobromination. Unexpectedly, however, a structually unknown compound (VIII) of mp 282—283 °C (decompn.) was obtained instead of enmein diacetate (II). On the other hand, the dehydrobromination of VI gave an expected unsaturated compound (VII).[1] In order to elucidate the structure of VIII and to find what kind of reaction had occurred in the case of IV, the following experiments were carried out.



(I) $R_1 = R_2 = H$
(II) $R_1 = R_2 = Ac$
(XIII) $R_1 = Ac$, $R_2 = Et$
(XIV) $R_1 = Ac$, $R_2 = Me$
(XVII) $R_1 = Ac$, $R_2 = H$



(III) (IV)

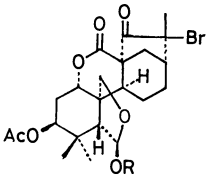


(V) (VI) (VII)

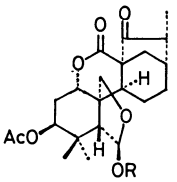
Bromination of dihydroenmein diacetate (III) was carried out repeatedly. But the results were not the same, although the experimental conditions were similar, *i.e.*, the material was treated with *N*-bromosuccinimide in chloroform in the presence of benzoyl peroxide, giving one of the three products (never a mixture of these in one experiment), $C_{24}H_{31}O_8Br$ (IV), mp 235 °C, $C_{24}H_{33}O_7Br$ (IX), mp 223 °C (decompn.), or $C_{23}H_{31}O_7Br$ (X), mp 220—222 °C (decompn.).

In the NMR spectra of IV, IX, and X, the signal for C_{17} secondary methyl present in III was no longer observed, and a signal for tertiary methyl group having a bromine in α-position appeared at δ 1.93, 1.85, and 1.82, respectively. The signal for C_6–H in III was shifted to higher magnetic field in the spectra of IX and X, suggesting an ether linkage in these compounds.[5]

Catalytic reductions of IV, IX, and X over palladium-charcoal–sodium carbonate catalyst afforded dihydroenmein diacetate (III), dihydroenmein 3-acetate 6-ethyl acetal (XI), and dihydroenmein 3-acetate 6-methyl acetal (XII), respectively, which confirmed that bromination had occurred at C_{16} position in these cases. In addition, the acetoxyl group at C_6 position had been converted to ethoxyl or methoxyl group by ethanol or methanol contaminated in chloroform to form IX or X, respectively.



(IX) R=Et
(X) R=Me
(XXII) R=H



(XI) R=Et
(XII) R=Me

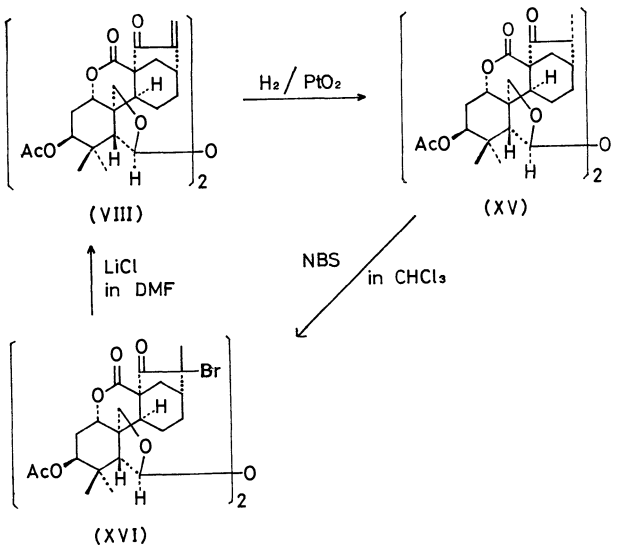
Dehydrobromination of the ethyl- and methyl-acetal type monobromo compound (IX and X) normally gave enmein 3-acetate 6-ethyl acetal (XIII)[5] and enmein 3-acetate 6-methyl acetal (XIV), respectively.

The dehydrobromination of IV with lithium chloride in dimethylformamide was not successful for preparing the expected enmein diacetate (II), but instead gave a high melting substance (VIII). Experiments were also carried out under the following conditions: with (i) pyridine, (ii) collidine, (iii) lithium chloride–pyridine, (iv) lithium carbonate–dimethylformamide, and (v) lithium bromide–dimethylformamide. Under the reaction conditions (i) to (iv) only the starting material was recovered, while in the case of (v) a small amount of VIII was obtained.

The UV, IR, and NMR spectra of VIII were almost identical with those of enmein diacetate (II), with

exception that the peak due to C_6–H in II appearing at δ 6.07 in its NMR spectrum shifted to δ 5.21 in the spectrum of VIII. The compound VIII was not reduced with palladium-carbon catalyst but was reduced to XV over platinum oxide catalyst. Bromination of XV with *N*-bromosuccinimide and dehydrobromination of the bromo compound (XVI), mp 277—278 °C (decompn.), with lithium chloride-dimethylformamide gave VIII.

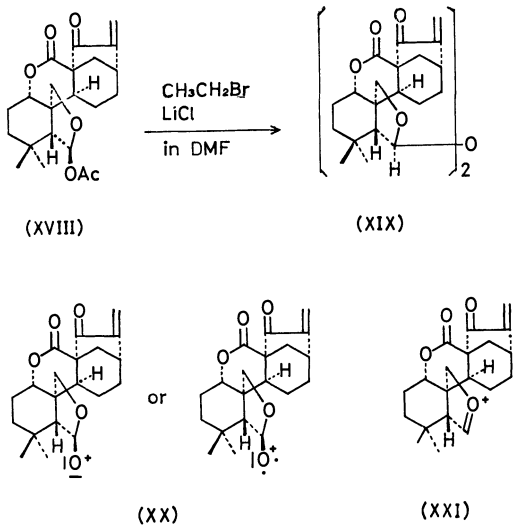
The reaction and spectral data of VIII suggested etherification of C_6-acetate in II, as in XIII and XIV. Hydrolysis of VIII with acetic acid afforded enmein 3-acetate (XVII).[6] The most plausible explanation for the structure of VIII is an intermolecular ether formation between two molecules of enmein 3-acetate. Molecular weight of VIII was therefore measured by the vapor pressure depression method, as the mass spectral method was not effective, and a value of 794 (calcd 791) was obtained. Consequently, VIII must have been formed from two molecules of enmein 3-acetate (XVII) by ether linkage of the hydroxyl group at C_6 position.



(VIII) (XV) (XVI)

This conclusion is supported from the following experiments. Treatment of dihydroenmein diacetate (III) with lithium chloride-dimethylformamide recovered the starting material, but addition of ethyl bromide in this reaction resulted in etherification to give XV. The same was true in the case of enmein 3-acetate (XVII), recovering the starting material with the use of lithium chloride-dimethylformamide but on addition of ethyl bromide affording VIII.

The same reaction on isodocarpin acetate (XVIII)[5,7] also gave an intermolecular ether (XIX). The IR and NMR spectra did not show the presence of any acetyl group in its molecule, and a diamagnetic shift of C_6–H signal was observed when compared with that of XVIII. (See experimental section.) The mass spectrum of XIX showed the molecular ion peak at *m/e* 674 and characteristic fragment ion peaks at *m/e* 345 and 329, respectively assignable to XX and XXI. Thus, it was confirmed that XIX was an intermolecular ether of two isodocarpin molecules.



(XVIII) (XIX) (XX) (XXI)

The formation of the dimeric ethers can be accounted for the catalytic action of hydrogen bromide generated *in situ* from ethyl bromide. Thus, the ether (VIII) was also obtained from enmein 3-acetate (XVII) with dry hydrogen bromide in dimethylformamide.

It is concluded from the results of these experiments that, in the bromination of C_{16}–H and dehydrobromination of C_{16}–bromo derivatives in enmein analogs, bromination and dehydrobromination progresses without any abnormal reaction, but a variety of etherification takes place at the acetal-hydroxyl group in C_6 position. Also, the present series of experiments has finally realized a plan made 10 years ago to convert dihydroenmein (II) to enmein (I) *via* 6-acetate derivative.

Experimental

NMR spectra were determined on a JEOL HL-60 (60 MHz) spectrometer in deuterochloroform solutions. IR spectra were recorded on Nujol mull with a Japan Spectroscopic IR-S spectrophotometer. Melting points were measured on a Yanagimoto micromelting point determination apparatus, and uncorrected. Column chromatography was performed with Mallinckrodt silicic acid.

(i) 16-Bromodihydroenmein Diacetate (IV). A mixture of dihydroenmein diacetate (III)[1,2,3] (550 mg), *N*-bromosuccinimide (230 mg), a few mg of benzoyl peroxide, and chloroform (20 ml) was heated under reflux for 3.5 hr. The reaction mixture was chromatographed on silica gel (10 g). Elution with chloroform yielded a crystalline product, which was recrystallised from ethanol to give 16-bromodihydroenmein diacetate (IV) (350 mg) as colorless prisms, mp 235 °C, ν_{max} 1760, 1730, 1240, and 1045 cm^{-1}, δ 1.04 and 1.06 (each 3H, s, *tert*-CMe), 1.93 (3H, s, >C(Br)-CH_3), 1.98 and 2.12 (each 3H, s, OAc), 4.08 (2H, s, -O-CH_2-C<), 4.68 (1H, dd, J=11 and 7 Hz, $H_{1\beta}$), 4.92 (1H, br.s, $H_{3\alpha}$), 6.18 (1H, s, H_6).

(ii) 16-Bromodihydroenmein 3-Acetate 6-Ethyl Acetal (IX). The procedure was same as (i). 16-Bromodihydroenmein 3-acetate 6-ethyl acetal (IX) obtained was colorless plates, mp 223 °C (decompn.), Found: C, 56.11; H, 6.58%. Calcd for $C_{21}H_{33}O_7Br$: C, 56.16; H, 6.50%, ν_{max} 1760, 1730, 1250, and 1045 cm^{-1}, δ 0.95 and 0.99 (each 3H, s, *tert*-CMe), 1.04 (3H, t, J=7.5 Hz, *sec*-CMe), 1.85 (3H, s, >C(Br)-CH_3), 2.06 (3H, s, OAc), 3.52 (2H, q, J=7.5 Hz, -OCH_2CH_3),

3.78 and 3.99 (each 1H, AB-q, $J=10.5$ Hz, $-O-CH_2-C\lessgtr$), 4.60 (1H, dd, $J=11$ and 7 Hz, $H_{1\beta}$), 4.72 (1H, m, $H_{3\alpha}$), 4.81 (1H, s, H_6).

(iii) 16-Bromodihydroenmein 3-Acetate 6-Methyl Acetal (X). The procedure was same as (i). 16-Bromodihydroenmein 3-acetate 6-methyl acetal (X) obtained was colorless prisms, mp 220—222 °C (decompn.), Found: C, 55.29; H, 6.28%. Calcd for $C_{23}H_{31}O_7Br$: C, 55.52; H, 6.26%, ν_{max} 1760, 1730, 1240, and 1045 cm^{-1}, δ 1.00 and 1.04 (each 3H, s, *tert*-CMe), 1.82 (3H, s, $>C(Br)-CH_3$), 2.13 (3H, s, OAc), 3.27 (3H, s, OMe), 3.90 and 4.10 (each 1H, AB-q, $J=9.5$ Hz, $-O-CH_2-C\lessgtr$), 4.70 (1H, dd, $J=11.5$ and 7.5 Hz, $H_{1\beta}$), 4.82 (1H, s, H_6), 4.91 (1H, t, $J=3.5$ Hz, $H_{3\alpha}$).

(iv) Hydrolysis of 16-Bromodihydroenmein 3-Acetate 6-Ethyl Acetal (IX). A mixture of 16-bromodihydroenmein 3-acetate 6-ethyl acetal (IX) (2 g), acetic acid (65 ml), and water (25 ml) was heated at 100 °C for 3 hr. The mixture was extracted with chloroform, and the solution was washed with water, 10% sodium carbonate aqueous solution and water, successively, and dried over anhydrous sodium sulfate. The solvents were removed to give 16-bromodihydroenmein 3-acetate (XXII), ν_{max} 3440, 1760, 1720, 1240, and 1040 cm^{-1}.

(v) Acetylation of 16-Bromodihydroenmein 3-Acetate (XXII). It was carried out with pyridine and acetic anhydride in the usual way. The product was recrystallised from ethanol to give 16-bromodihydroenmein diacetate (IV) as colorless plates, which was identical with an authentic sample derived from dihydroenmein diacetate (III) by bromination in IR.

(vi) Attempted Dehydrobromination of 16-Bromodihydroenmein Diacetate (IV). (a) A mixture of 16-bromodihydroenmein diacetate (IV) (150 mg) and pyridine (5 ml) was refluxed under nitrogen gas for 4 hr. The mixture was extracted with diethyl ether. The solution was washed with 2M-hydrochloric acid and water, and dried over anhydrous sodium sulfate. After evaporation of solvents, the residue was recrystallized from ethanol to give crystals (94 mg), which were identical with IV in IR.

(b) A mixture of 16-bromodihydroenmein diacetate (IV) (200 mg) and collidine (3 ml) was refluxed under nitrogen gas for 1 hr. The mixture was extracted with chloroform. The chloroform layer was washed with 2M-hydrochloric acid and water, and dried over anhydrous sodium sulfate. The solvent was removed and the concentrate was chromatographed on silica gel. Elution with chloroform–methanol (99: 1) yielded a crystalline product (91 mg), which was recrystallised from ethanol. This compound was identical with IV in IR.

(c) A mixture of 16-bromodihydroenmein diacetate (IV) (200 mg), lithium chloride (50 mg), and pyridine (1.5 ml) was heated at 100 °C under nitrogen gas for 2 hr. The mixture was diluted with water. The precipitate formed was collected by filtration, dried and chromatographed on silica gel. Elution with chloroform yielded a crystalline product (114 mg), which was recrystallized from ethanol. This compound was identical with IV in IR.

(d) When the reaction time was extended to 5 hr in the case of (vi-c), 16-bromodihydroenmein diacetate (IV) was recovered.

(e) A mixture of 16-bromodihydroenmein diacetate (IV) (200 mg), lithium chloride (140 mg), and pyridine (4 ml) was heated at 100 °C under nitrogen gas for 3 hr. The mixture was treated in a similar manner as (vi-c) to recover IV.

(f) A mixture of 16-bromodihydroenmein diacetate (IV) (200 mg), lithium carbonate (43 mg), and dimethylformamide (1.5 ml) was heated at 100 °C under nitrogen gas for 5 hr. The mixture was treated in a similar manner as (vi-c) to recover IV.

(g) A mixture of 16-bromodihydroenmein diacetate (IV) (500 mg), lithium chloride (120 mg), and dimethylformamide (3 ml) was heated at 110 °C under nitrogen gas for 3.5 hr. The mixture was treated in a similar manner as (vi-c). The crude product was chromatographed on silica gel (10 g), Elution with chloroform–methanol (99: 1) yielded a crystalline product, which was recrystallised from ethanol to give VIII (198 mg) as colorless prisms, mp over 295 °C, Found: C, 65.97; H, 6.94%; mol wt (vapor pressure depression method), 794. Calcd for $C_{44}H_{54}O_{13}\cdot 1/2H_2O$: C, 66.07; H, 6.93%; mol wt, 790.9, λ_{max} (ethanol) 233 nm (ε 14040), ν_{max} 1750, 1710, 1640, 1230, and 1050 cm^{-1}, δ 0.80 and 0.98 (each 6H, s, *tert*-CMe), 2.03 (6H, s, OAc), 3.08 (2H, m, H_{13}), 3.88 and 4.01 (each 2H, AB-q, $J=10$ Hz, $-O-CH_2-C\lessgtr$), 4.57 (2H, dd, $J=10.5$ and 7 Hz, $H_{1\beta}$), 4.81 (2H, br.s, $H_{3\alpha}$), 5.21 (2H, s, H_6), 5.40 and 5.95 (each 2H, s, $>C=CH_2$).

(h) A mixture of 16-bromodihydroenmein diacetate (IV) (200 mg), lithium bromide (70 mg), lithium carbonate (30 mg) and dimethylformamide (2 ml) was heated at 100 °C under nitrogen gas for 6 hr. Treating in a similar manner as (vi-g) gave a few amount of VIII.

(vii) Catalytic Hydrogenation of VIII. In dioxane (20 ml), VIII (800 mg) was hydrogenated over platinum oxide (93 mg). The crude product was chromatographed on silica gel. Elution with chloroform yielded a crystalline product (346 mg), which was recrystallised from ethanol to give XV as colorless needles, mp over 300 °C, Found: C, 65.12; H, 7.53%. Calcd for $C_{44}H_{58}O_{13}\cdot H_2O$: C, 65.01; H, 7.44%, ν_{max} 1735, 1240, and 1040 cm^{-1}, δ 0.95 and 1.03 (each 6H, s, *tert*-CMe), 1.11 (6H, d, $J=7$ Hz, *sec*-CMe), 2.75 (6H, s, OAc), 3.98 (4H, t, $J=10.5$ Hz, $-O-CH_2-C\lessgtr$), 4.58 (2H, dd, $J=10.5$ and 7 Hz, $H_{1\beta}$), 4.87 (2H, br.s, $H_{3\alpha}$), 5.30 (2H, s, H_6).

(viii) Bromination of XV. A mixture of XV (200 mg), *N*-bromosuccinimide (85 mg), a few mg of benzoyl peroxide, and chloroform (15 ml) was refluxed for 3.5 hr. The mixture was concentrated, and chromatographed on silica gel (5 g). Elution with chloroform yielded a crystalline product (134 mg), which was recrystallised from ethanol to give XVI as colorless needles, mp 277—278 °C (decompn.), ν_{max} 1750, 1725, and 1235 cm^{-1}, δ 0.92 and 1.03 (each 6H, s, *tert*-CMe), 1.87 (6H, s, $>C(Br)-CH_3$), 2.08 (6H, s, OAc), 4.01 (4H, t, $J=11$ Hz, $-O-CH_2-C\lessgtr$), 4.64 (2H, dd, $J=11$ and 7.5 Hz, $H_{1\beta}$), 4.88 (2H, br.s, $H_{3\alpha}$), 5.27 (2H, br.s, H_6).

(ix) Dehydrobromination of XVI. A mixture of XVI (60 mg), lithium chloride (15 mg) and dimethylformamide (0.5 ml) was heated at 110 °C under nitrogen gas for 5 hr. The mixture was diluted with ice–water, and the precipitates collected by filtration were chromatographed on silica gel. Elution with chloroform–methanol (99: 1) yielded a crystalline product (27 mg) which was recrystallized from ethanol to give colorless prisms. This compound was identical with VIII derived from 16-bromodihydroenmein diacetate (IV) by dehydrobromination in IR and NMR.

(x) Hydrolysis of VIII. To VIII (200 mg) acetic acid (10 ml) and water (5 ml) were added, and heated at 110 °C for 45 hr. The mixture was extracted with chloroform, and the extract was washed with water, 10% sodium carbonate aqueous solution, and water, successively, and dried over sodium sulfate. After concentration the residue was recrystallised from ethanol to give enmein 3-acetate (XVII) (63 mg) as colorless needles, ν_{max} 3420, 1750, 1710, 1640, and 1270 cm^{-1}. Enmein 3-acetate (XVII) obtained as above was identical with an authentic sample[6] in IR.

(xi) Reaction of Dihydroenmein Diacetate (III) with Lithium Chloride and Dimethylformamide. A mixture of dihydroenmein diacetate (III) (210 mg), lithium chloride (60 mg), and dimethylformamide (1.5 ml) was heated at 110 °C under

nitrogen gas for 3.5 hr. The mixture was treated in a similar manner for VIII shown in (vi-g). The crude product was chromatographed on silica gel. Elution with chloroform yielded a crystalline product (125 mg), which was recrystallised from ethanol. This compound was identical with III in IR.

(xii) Reaction of Dihydroenmein Diacetate (III) with Lithium Chloride, Dimethylformamide, and Ethyl Bromide. A mixture of dihydroenmein diacetate (III) (250 mg), lithium chloride (60 mg), dimethylformamide (1.5 ml) and ethyl bromide (1.5 ml) was heated at 110 °C under nitrogen gas. After 2 hr, ethyl bromide was added to the mixture and the heating was continued for 2 hr. The mixture was treated in a similar manner for VIII shown in (vi-g), to give XV (71 mg), which was identical with an authentic sample (XV) obtained from VIII by hydrogenation in IR.

(xiii) Reaction of Enmein 3-Acetate (XVII) and Dimethylformamide. Enmein 3-acetate (XVII)[6] (200 mg) in dimethylformamide (1.5 ml) was heated at 110 °C for 4 hr. The product was identical with XVII in IR.

(xiv) Reaction of Enmein 3-Acetate (XVII) with Lithium Chloride, Dimethylformamide, and Ethyl Bromide. A mixture of enmein 3-acetate (XVII) (200 mg), lithium chloride (40 mg), dimethylformamide (1.5 ml), and ethyl bromide (1 ml) was heated at 110 °C under nitrogen gas for 4 hr. After 2 hr, ethyl bromide was added to the mixture and the heating was further continued for 2 hr. The mixture was treated as usual and the crude product was chromatographed on silica gel. Elution with chloroform yielded a crystalline product, which was recrystallized from ethanol to be identical with VIII in IR.

(xv) Reaction of Isodocarpin Acetate (XVIII) with Lithium Chloride, Dimethylformamide and Ethyl Bromide. A mixture of isodocarpin acetate (XVIII)[5,7] (150 mg), lithium chloride (40 mg), dimethylformamide (1.5 ml), and ethyl bromide (1 ml) was heated at 110 °C under nitrogen gas for 4 hr. After 2 hr, ethyl bromide was added to the mixture. The reaction mixture was diluted with water, and the precipitates formed were collected by filtration, dried and chromatographed on silica gel. Elution with chloroform yielded a crystalline product, which was recrystallised from ethanol to give XIX (59 mg) as colorless needles, mp over 300 °C, Found: C, 70.65; H, 7.50%. Calcd for $C_{40}H_{50}O_9 \cdot 1/3H_2O$: C, 70.56; H, 7.50%, *m/e* 674 (M^+), ν_{max} 1750, 1710, 1640, and 995 cm^{-1}, δ 0.85 and 0.96 (each 6H, s, *tert*-CMe), 3.11 (2H, dd, $J=9$ and 4 Hz), 3.87 and 4.07 (each 2H, AB-q, $J=9.5$ Hz, $-O-CH_2-C\lessgtr$), 4.34 (2H, t, $J=8.5$ Hz, $H_{1\beta}$), 5.20 (2H, s, H_6), 5.45 and 5.98 (each 2H, s, $>C=CH_2$).

(xvi) Reaction of Enmein 3-Acetate (XVII) in Dimethylformamide under Hydrogen Bromide Gas. Enmein 3-acetate (XVII) (200 mg) in dimethylformamide (4 ml) was heated at 110 °C under dry hydrogen bromide gas for 2.5 hr. The reaction mixture was diluted with water, and the precipitates collected by filtration were treated by the preparative thin-layer chromatography on silica gel. Elution with chloroform–methanol (9: 1) yielded two crystalline products which were recrystallised from ethanol, respectively. The first product as colorless prisms (44 mg) was identical with VIII in IR, and the second compound as colorless prisms (43 mg) was the starting material (XVII).

We are grateful to Dr. T. Kamikawa, Osaka City University, for valuable discussions.

The Synthesis of Heterocyclic Compounds by the Reaction of Tin(II) Bis(acetylacetonate) with Isocyanates

Ikuko WAKESHIMA and Ichiro KIJIMA

Department of Industrial Chemistry, Faculty of Engineering, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received May 2, 1974)

It was found that phenyl isocyanate reacted with tin(II) bis(acetylacetonate) to yield triphenyl isocyanurate, 5-acetyl-6-methyl-2-oxo-3-phenyl-4-phenylimino-3,4-dihydro-2*H*-1,3-oxazine, and *N,N'*-diphenylurea, while ethyl isocyanate reacted with tin(II) bis(acetylaceonate) to afford only 2,4-dioxo-6-ethylimino-1,3,5-triethylhexahydro-1,3,5-triazine.

It has recently been reported that some monomeric tin(II) compounds containing Sn–OC bonds reacted smoothly with *n*-alkyl iodides to give the oxidative addition compounds.[1-2] While there have already been reports on the reaction of tin(II) compounds containing Sn–OC bonds with some isocyanate,[3-5] the reaction with metal acetylacetonate has not yet been studied. It is of interest to investigate the behavior of tin(II) bis(acetylacetonate) toward compounds containing activated double bonds such as isocyanate. In this paper, we will describe the synthesis of heterocyclic compounds by the reaction of tin(II) bis(acetylacetonate) with phenyl and ethyl isocyanates.

From the reaction of phenyl isocyanate (PhNCO) with a catalytic amount of tin(II) bis(acetylacetonate), $Sn(acac)_2$, triphenyl isocyanurate was obtained in a yield of 33%. The product was identified on the basis of the elemental analyses and its IR spectrum. In order to obtain further information on the behavior of $Sn(acac)_2$ toward PhNCO, the reaction was carried out while varying the molar ratio of PhNCO to $Sn(acac)_2$ from 1:1 to 4:1.

The reaction in a molar ratio of 1:1 gave two colorless compounds which were found to be $C_{19}H_{16}N_2O_3$ (I) and $C_{13}H_{12}N_2O$ (II). The infrared spectrum of (I) showed bands ascribable to $\nu_{C=O}$ at 1723, and 1689, to $\nu_{C=C}$ at 1660, to $\nu_{C=N}$ at 1419, to ν_{C-N} at 1345, to δ_{S-CH_3} at 1435, and to δ_{as-CH_3} at 1365 cm^{-1}. Its NMR spectrum in $CDCl_3$ displayed bands at 2.56 (3H, $CH_3C=$) and 2.03 (3H, CH_3CO) ppm, besides the aromatic proton (10H). From these data, (I) was found to be 5-acetyl-6-methyl-2-oxo-3-phenyl-4-phenylimino-3,4-dihydro-2*H*-1,3-oxazine. This assingment was also supported by the mass spectral data—*i.e.*, the peaks of M^+, M^+-1, CH_3CO, and C_6H_5 at *m/e* 320, 319, 43, and 77 respectively. There were also observed fragment ions resulting from the loss of a methyl or carbonyl group from the molecular ion. Compound (II) could also be assinged to *N,N'*-diphenylurea by a comparison of the melting point with that of an authentic sample.

The reaction of $Sn(acac)_2$ with PhNCO in a molar ratio from 1:2 to 1:4 yielded (I) and (II) in equal amounts, which increased with the ratio of PhNCO to $Sn(acac)_2$ (Table 1).

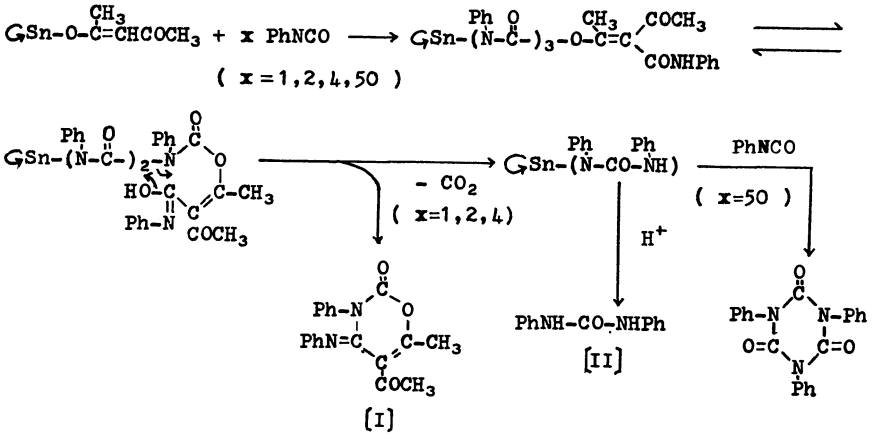
Table 1. Results of the reaction of $Sn(acac)_2$ (0.1 mol) with PhNCO in various molar ratios

Molar ratio PhNCO/$Sn(acac)_2$	Yields (mol)	
	(I)	(II)
1	0.0062	0.0060
2	0.0363	0.0334
4	0.0801[a]	0.0721

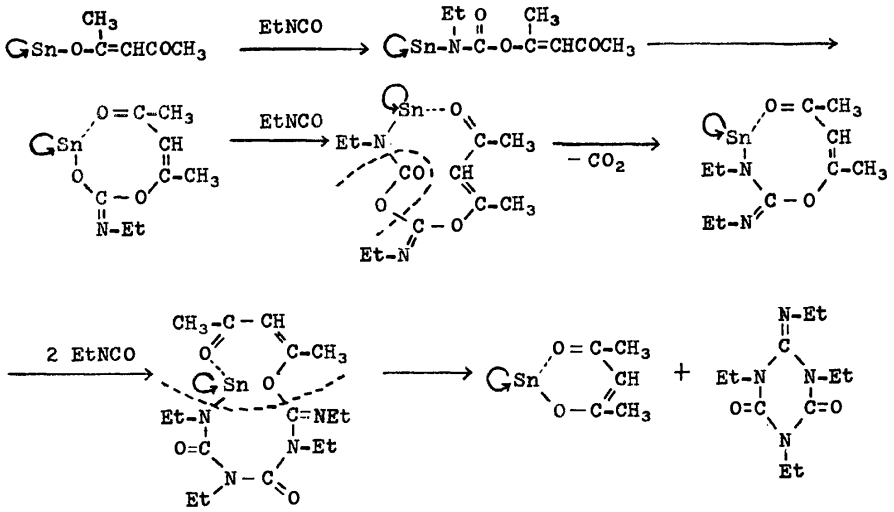
a) Triphenyl isocyanurate was detected in a small quantity.

Therefore, as for the formation of (I), (II), and triphenyl isocyanurate, we tentative propose the process depicted in Scheme 1.

Contrary to the reaction with PhNCO, $Sn(acac)_2$ reacted easily with various molar ratios of ethyl isocyanate (EtNCO) at 67—72 °C to give only 6-ethyl-



Scheme 1



Scheme 2.

imino-1,3,5-triethylhexahydro-1,3,5-triazine in a high yield, with the quantitative recovery of $Sn(acac)_2$. The structure was confirmed by the IR and NMR spectra, by elemental analyses, and by a molecular-weight determination. The IR spectrum exhibited a band at 1672 cm^{-1} which can be ascribed to the carbonyl group. The NMR spectrum showed triplets at 1.18 (9H, $-\underset{|}{N}-CH_2C\underline{H}_3$) and 1.25 (3H, $>C=N-CH_2C\underline{H}_3$) ppm, and quartets at 3.35 (2H, $>C=N-C\underline{H}_2-$), 3.85 (2H, $\begin{matrix}-CO\\-CO\end{matrix}\!\!>\!N-C\underline{H}_2-$), and 3.89 (4H, $\begin{matrix}-CN\\-CO\end{matrix}\!\!>\!N-C\underline{H}_2-$) ppm. A further proof of the structure was provided by its conversion into triethyl isocyanurate by hydrolysis with alcoholic hydrochloric acid. The IR spectrum was identical with that of an authentic sample prepared by the trimerization of EtNCO with a catalytic amount of $Sn(OC_2H_5)_2$. The formation of 6-ethylimino-1,3,5-triethylhexahydro-1,3,5-triazine seems to involve the processes shown in Scheme 2.

Although a detailed explanation cannot be offered for the remarkable difference between the reaction of PhNCO and that of EtNCO with $Sn(acac)_2$, it is clearly possible that the reaction between PhNCO and the methine proton on the C-3 of the Chelate ring leads to the formation of the 1,3-oxazine derivative.

Experimental

The experiments were carried out under a dry nitrogen atmosphere. The IR spectra were recorded on a Hitachi EPI-S2 infrared spectrometer as KBr disks or liquid films. The NMR spectra were determined by means of a Hitachi R-24 spectrometer (60 MHz) in CCl_4 or $CDCl_3$, using TMS as the internal standard. The chemical shifts are expressed in δ values. The mass spectra were measured on a Hitachi RMU-7 model double-focusing spectrometer. The elemental analyses were carried out with a Yanagimoto CHN analyzer, Model MT-2.

Materials. Tin(II) bis(acatylacetonate) was prepared in accordance with the method of a previous paper.[6] The other were commercially available.

Reaction Procedures. *The Reaction of PhNCO in the Presence of a Catalytic Amount of $Sn(acac)_2$*: A solution of PhNCO (46 g, 0.386 mol) and $Sn(acac)_2$ (2.9 g, 9.15 mmol) in benzene (92 ml) was stirred at 80—81 °C for 3 hr. The solids thus precipitated were filtered off and recrystallized from ethanol. Triphenyl isocyanurate was obtained in a 33% yield; mp 269—270 °C (lit, 275 °C[7]). IR (KBr) $\nu_{C=O}$ 1710 cm^{-1}.

The Reaction of PhNCO with $Sn(acac)_2$ in a Molar Ratio of 1: 1—4: 1: Phenyl isocyanate was added, drop by drop, to a *n*-hexane of solution of $Sn(acac)_2$ (0.1 mol) at 26—27 °C, and then the solution was heated with stirring in an oil bath for 3 hr. An evolution of carbon dioxide was observed throughout the reaction. The precipitated yellow solids were isolated by filtration, treated with 2M-HCl at room temperature and extracted with benzene using a Soxhlet extractor. The subsequent evaporation of the benzene from the extract left a solid residue. The recrystallization of the residue from methanol and then acetone gave a product (I) as white crystals; mp 213—213.3 °C (Found: C, 71.54; H, 4.97; N, 8.60%. Calcd for $C_{19}H_{16}N_2O_3$: C, 71.24; H, 5.04; N, 8.75%). IR (KBr): 1723, 1689, 1660, 1435, 1419, 1365, and 1345 (cm^{-1}). NMR ($CDCl_3$): 2.03, 2.56, and 7.0—7.67 ppm. Mass spectra: *m/e* 320 (M^+), 319, 77, and 43. The yellow powders remaining in the Soxhlet extractor were recrystallized from acetone. White needles (II) were thus obtained as the product; mp 234—235 °C (lit, 235 °C[8]). *m/e*: 212 (M^+). IR: 3310 and 1648 cm^{-1}.

On the other hand, $Sn(acac)_2$ was recovered by distilling the evaporation residue of the filtrate in a vacuum.

The Reaction of EtNCO with $Sn(acac)_2$: A mixture of $Sn(acac)_2$ (0.1 mol) and EtNCO (0.2, 0.4, 0.8, and 5.0 mol) in benzene (150 ml) was refluxed for 3 hr at 64—72 °C with stirring in an oil bath. An evolution of carbone dioxide was observed throughout the reaction. After the removal of the solvent in a vacuum, the residue was distilled, giving a mixture of triazine and $Sn(acac)_2$ in a quantitative yield. The mixture was then treated with 1—2 ml of water in acetone (30 ml), and the resulting white solids were separated centrifugally. The acetone solution was distilled *in vacuo* to give a light yellow viscous liquid in an 82—89% yield; bp 84—87 °C/0.5 mmHg (Found: C, 54.52; H, 8.40; N, 21.04%. Mol wt 228 (cryoscopically in benzene). Calcd for $C_{11}H_{20}N_4O_2$: C, 54.99; h, 8.38; N, 21.04%, Mol wt 240). IR (liquid films): 1672 cm^{-1}. NMR (CCl_4): 1.18, 1.23, 1.25, 3.35, 3.85, and 3.89 ppm.

Tris(benzimidazo)-1,3,5-triazine from the Thermolysis of 2-Aryloxybenzimidazoles

Sadahiro ISHIDA, Yoshiaki FUKUSHIMA, Shizen SEKIGUCHI, and Kohji MATSUI
Department of Chemistry, Gunma University, Kiryu, Gunma 376
(Received August 23, 1974)

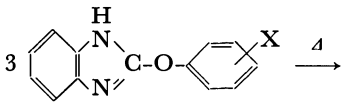
2-Aryloxybenzimidazoles gave tris(benzimidazo)-[1,2-*a*: 1′,2′-*c*: 1″,2″-*e*]-1,3,5-triazine and phenol in almost quantitative yields upon heating at 230—250 °C, while in the reaction in cumene small amounts of 2-aryloxy-1,2′-dibenzimidazole and dicumyl were obtained along with the major products. On the other hand, 2-phenylthiobenzimidazole gave diphenyl disulfide and 1,2′-dibenzimidazole, together with tris(benzimidazo)-1,3,5-triazine. The thermolysis is assumed to proceed by step-by-step radical processes involving the formation of such intermediates as 2-aryloxy-1,2′-dibenzimidazole and 2-aryloxy-1,2′-1′,2″-trisbenzimidazole.

In a previous paper,[1] we reported that 2-aryloxybenzazoles rearrange photochemically to give 2-(2- and/or 4-hydroxyphenyl)benzazoles upon irradiation with a low-pressure mercury lamp, and that 2-(2-aminophenoxy)benzazoles undergo a photo-Smiles rearrangement. During the course of our studies of the reactions of 2-substituted benzazoles, it was found that 2-aryloxybenzimidazoles undergo an interesting thermal reaction. This paper will report on the thermal decomposition of 2-aryloxybenzimidazoles.

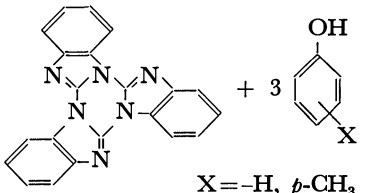
Results and Discussion

Thermal Decomposition of 2-Aryloxybenzimidazoles. Ordinary 2-aryloxybenzazoles are thermally stable; in the cases of 2-aryloxy derivatives of benzoxazole and benzothiazole, no decomposition took place upon heating at 200 °C for 5 hr. However, not only 2-aryloxy derivatives of benzoxazole and benzothiazole, but also 2-aryloxybenzimidazoles gradually decomposed above 200 °C, and the TG curves showed a weight loss. Although the weight losses of the derivatives of benzoxazole and benzothiazole during heating were not simple, the TG curves of 2-aryloxybenzimidazoles (I) showed a weight loss, just corresponding to a fission of the phenol moiety; in fact, by heating 2-aryloxybenzimidazoles at 230—250 °C for 5 hr, the corresponding phenol and a product of a high melting point (above 360 °C) were obtained in almost quantitative yields.

The same product with a high melting point was obtained even when benzimidazole derivatives of different aryloxy components (phenol and *p*-cresol were used as the phenol components) were decomposed; it was found to be a cyclic trimer of the benzimidazolyl residue (tris(benzimidazo)-[1,2-*a*: 1′,2′-*c*: 1″,2″-*e*]-1,3,5-triazine) (II) (hereafter we will call the compound merely a trimer), as is shown below:



(I)



(II)

Recently, similar thermal trimerizations have been observed with 2-chlorobenzimidazole and related derivatives,[2] although the yields of the trimers were quite low. The mechanisms of these reactions, however, have not been investigated.

The thermal trimerization of 2-aryloxybenzimidazoles took place also in various organic solvents, such as cumene, toluene, *o*-dichlorobenzene, and ethanol, as is shown in Table 1; when 2-phenoxybenzimidazole was heated in cumene at 250 °C under pressure, a small amount of dicumyl was obtained along with the trimer and phenol, suggesting that the reaction took place *via* a radical process. However, at present the details of the solvent effect are not clear.

Effect of Substituent on the Thermal Trimerization of 2-Substituted Benzimidazoles. When the substituent of benzimidazole at the 2-position is –OH, –SH, $-NH_2$, or $-NHC_6H_5$, the compounds are thermally very stable; even after heating at 250 °C for a long period, no decomposition to give the trimer was observed. On the other hand, 2-chloro, 2-phenylthio, and 2-phenoxy derivatives gave the trimer under similar reaction conditions, as is shown in Table 2. The derivatives of benzimidazole substituted at the 1-position, such as 1-methyl-2-chlorobenzimidazole, did not yield the trimer upon heating, as might have been anticipated.

From these results, it is obvious that the thermal trimerization of 2-substituted benzimidazoles depends remarkably upon the substituent at the 2-position; when the hetero atom of the 2-substituent possesses an active hydrogen atom, the trimerization became difficult. This is considered to be due to an increase in the bond strength between the ring carbon and hetero

Table 1. Yields of trimer in the thermolysis of 2-phenoxybenzimidazole in organic solvents

Solvent	Yield of trimer (%)[a]
Cumene	81.8
Toluene	38.0
o-Dichlorobenzene	34.4
Ethanol	21.7

a) Yield of trimer when heated at 250 °C for 5 hr.

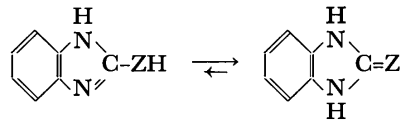
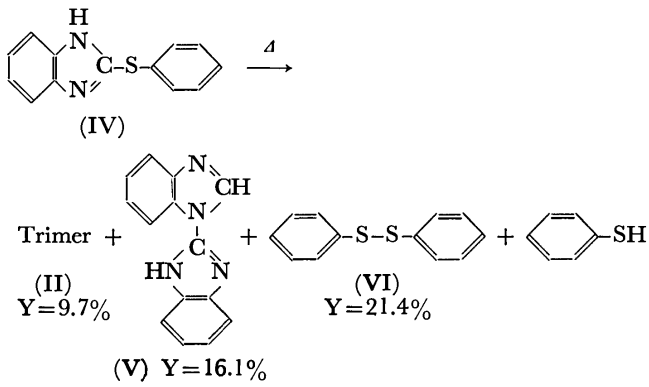
atoms, because these compounds (III) are known to exist as their tautomers (III)', as is shown below:



(III) (III')

Z=-S-, -NH-, -O-, $-\overset{|}{N}C_6H_5$, *etc.*

Although 2-Cl, -OAr, and 2-SAr benzimidazoles all underwent the thermal trimerization, the reactivity to give the trimer differed significantly from one to the other; among them, -OAr was the best and -SAr was the worst substituent for the reaction, as can be seen in Table 2. When the 2-phenylthio derivative (IV) was heated at 230 °C for 2.5 hr, the trimer (II) was obtained in a low yield, along with 1,2'-dibenzimidazole (V), diphenyl disulfide (VI), and the undecomposed starting material.



(IV)

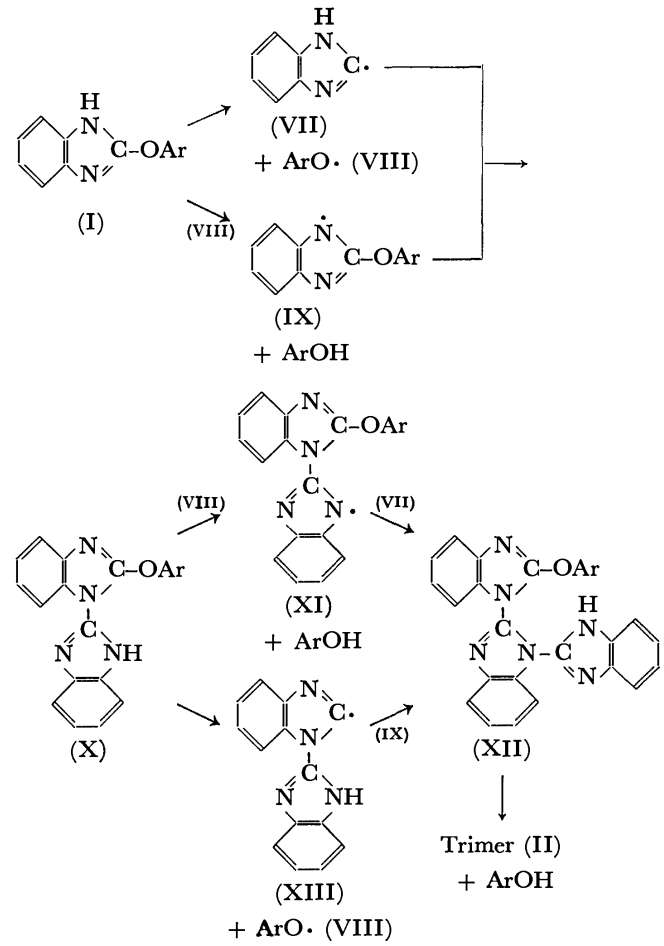
(V) Y=16.1%

1,2'-Dibenzimidazole (V) should be formed by a combination between 2- and 1-benzimidazolyl radicals; the former may be produced by a homolytic fission of the C–S bond of the starting material, while the latter may be formed by an intramolecular N→C migration of the hydrogen atom in the former. However, it is unlikely that Compound (V) is a necessary intermediate for the trimerization, and dibenzimidazole of the 1,1'- or 2,2'-type and benzimidazole were not obtained.

On the other hand, in the case of 2-phenoxybenzimidazole, the thermal trimerization took place almost quantitatively, without any appreciable side reaction, and in the reactions in organic solvents, only a small amount of a dimer of the benzimidazolyl residue possessing one phenoxy group (2-phenoxy-1,2'-dibenzimidazole) (X) was obtained, along with the major products (II), as can also be seen in the reaction in cumene; benzimidazole and dibenzimidazole containing no phenoxy group of 1,1'-, 2,2'-, or 1,2'-type were not obtained in this case. 2-Phenoxy-1,2'-dibenzimidazole is considered to be not a mere by-product, but an intermediate for the trimerization, as will be discussed later; the difference in thermal reactivity between phenoxy and phenylthio derivatives is considered to depend mainly upon the difference in readiness for dimerization between the phenoxy and phenylthiyl radicals; the phenylthiyl radical produced by the homolytic fission of the C–S bond would dimerize readily to give diphenyl disulfide. Consequently, in the case of phenylthio derivative, the abstraction of the NH hydrogen would be incomplete in the production of the trimer (II) in a good yield.

On the other hand, in the case of the phenoxy derivative, the phenoxy radical (VIII) once produced by a homolytic cleavage of the C–O bond would rapidly abstract the NH hydrogen atom from the starting material to give phenol and the 1-(2-phenoxy)benzimidazolyl radical (IX), which may then react with the 2-benzimidazolyl radical (VII) to give 2-phenoxy-1,2-dibenzimidazole (X).

However, 2-alkoxy- and 2-alkylthiobenzimidazoles behave in different manners upon heating. For example, 2-ethoxybenzimidazole is known to decompose thermally to give 1-ethyl-2-ethoxybenzimidazole and



2-(3*H*)-benzimidazolinone upon heating at 200—230 °C,[3] indicating that the bond fission took place at O–C_2H_5. In the case of the aryloxy derivative, the bond fission may occur more readily at C–OAr than at O–Ar, because the O–Ar bond should be stronger than the C–OAr bond as a result of the overlap of the lone pair of electrons on the oxygen with the aromatic π electrons; in addition, the stabilization of the resultant radical by the aryl group may favor the fission at C–OAr. When 2-methylthiobenzimidazole was heated at 230 °C, a decomposition took place to give various decomposition products, although in this case the (II) trimer was not detected in the reaction mixture, showing that substituents at the 2-position consisting of a hetero atom and an alkyl group are not suitable for the thermal trimerization. It can be said that the aryloxy group is the best substituent for the thermal trimerization of 2-substituted benzimidazoles.

Reaction Sequences of the Thermal Trimerization of 2-Aryloxybenzimidazoles. From the results described above, it seems reasonable to assume that the thermal trimerization of 2-substituted benzimidazoles proceeds homolytically by step-by-step processes such as are shown in the case of 2-aryloxybenzimidazoles.

1. The homolytic fission of the C–O bond of 2-aryloxybenzimidazole (I) to give aryloxy (VIII) and 2-benzimidazolyl radicals (VII).

2. The abstraction of the NH hydrogen of I by VIII to give the 1-(2-aryloxy)benzimidazolyl radical (IX) and phenol.

3. The combination of IX and VII to give 2-aryloxy-1,2′-dibenzimidazole (X).

4. From the dimer (X), several possible routes can be considered. A trimer possessing one aryloxy group (2-aryloxy-1,2′-1′-2″-trisbenzimidazole) (XII) is the most probable intermediate, even though it has not been isolated. For the formation of XII, two routes are possible; one is a combination of XIII, produced by a homolytic fission of the C–O bond of X, with IX, while the other is a reaction of XI, formed by an abstraction of the NH hydrogen of X by VIII, with VII. The actual reaction would proceed *via* both of the two routes.

5. The formation of the final product from XII by a fission of the C–O bond and an abstraction of the NH hydrogen by the resulting phenoxy radical therefrom, followed by an intramolecular combination of the resultant biradical.

Experimental

All the melting points are uncorrected. The NMR spectra were taken on a Varian A-60D spectrometer, using tetramethylsilane as the internal standard. The IR spectra were measured in potassium bromide discs on a Jasco D-301 spectrometer. The UV spectra were recorded on a Hitachi-124 UV-VIS spectrometer. The Mass spectra were recorded on a JEOL-JMS-07 mass spectrometer. The elemental analyses were performed in the Micro-analytical Center of Gunma University. The structural assignments of the reaction products were done by means of their NMR, IR, UV, and MS spectra and by elemental analyses.

Materials, Preparation of 2-Substituted Benzazoles; 2-Aryloxybenzazoles were prepared by the condensation of 2-chlorobenzazoles with the equimolar corresponding phenolates.[1] A typical procedure will be described in the case of 2-phenoxybenzimidazole.

After 10.0 g (0.066 mol) of 2-chlorobenzimidazole and 10.0 g (0.086 mol) of sodium phenoxide in 150 g of phenol had been heated at 150 °C for 7 hr, the reaction mixture was steam distilled and the residue was filtered and washed with a 1% aqueous NaOH solution and water. The precipitate was then recrystallized from ethanol to give an analytical sample of 2-phenoxybenzimidazole.

Other 2-substituted benzimidazoles were prepared by the methods described in the literature: 2-OH, mp 312—313 °C (ethanol) (lit,[4] 307—308 °C); 2-SH, mp 302—303 °C (ethanol) (lit,[5] 303—304 °C); 2-NH_2, mp 223—224 °C (ethanol) (lit,[6] 222 °C); 2-NHC_6H_5, mp 190—191 °C (benzene) (lit,[7] 190 °C); 2-OC_6H_5, mp 229—230 °C (ethanol) (lit,[1] 228—229 °C); 2-OC_6H_4–CH_3(p), mp 257—258 °C (dioxane) (lit,[1] 259—260 °C); 2-SC_6H_5, mp 202—203 °C (benzene) (lit,[8] 201—202 °C); 2-Cl, mp 191—193 °C (ethanol–water) (lit,[9] 180 °C, lit,[10] 210—212 °C; Found: C, 55.35; H, 3.33%. Calcd for $C_7H_5ClN_2$: C, 55.11; H, 3.31%); 2-Cl, 1-CH_3, mp 113—115 °C (petroleum ether) (lit,[9] 114—116 °C). 2-Methylthiobenzimidazole was prepared by the condensation of 2-mercaptobenzimidazole with methyl iodide in the presence of potassium hydroxide in a mixture of ethanol and water, as in the case of the 2-nonylthio derivative.[11] Mp 203—204 °C (benzene). Yield, 25%. Found: C, 58.56; H, 4.93%. Calcd for $C_8H_8N_2S$: C, 58.51; H, 4.92%.

Thermolyses of 2-Substituted Benzimidazoles; The thermolyses were carried out both without and with a solvent, as follows.

a) Thermolysis of 2-substituted benzimidazoles without a solvent; A 0.5 g portion of 2-substituted benzimidazole was heated in a small test tube under an atmosphere of nitrogen. The decomposed mixture was then treated with dioxane to give the trimer as a sparingly soluble product. Recrystallization from a large amount of dioxane gave an analytical sample. Mp>360 °C. IR (KBr disc) cm^{-1}, 1624 (–C=N); 1600, 1578, 1480 (phenyl). NMR (in trifluoroacetic acid) δ 7.85 (m, 6H), 8.10 (m, 3H), 8.64 (m, 3H). *M/e* 348.1138 (Calcd for $C_{21}H_{12}N_6$=348.1124). UV $\lambda_{max}^{Dioxane}$ (nm) ($\varepsilon \times 10^4$) 282 (7.8), 260 (9.8). Found: C, 72.61; H, 3.64; N, 24.06%. Calcd for $C_{21}H_{12}N_6$: C, 72.40; H, 3.47; N, 24.12%. The compound is identical with that obtained in the thermolysis of 2-chlorobenzimidazole.[2a]

Decomposed products soluble in dioxane were purified by thin-layer chromatography on silica gel, using benzene as the developing solvent. Thus, in the case of the 2-phenylthio derivative, diphenyl disulfide (yield, 21.4%; mp 60—61 °C) and 1,2′-dibenzimidazole (yield, 16.1%) were obtained from the filtrate. The latter was recrystallized from benzene. Mp 212—213 °C. *m/e* 234 (Calcd for $C_{14}H_{10}N_4$=234). NMR (DMSO-d_6) δ 8.91 (s, 1H), 8.50 (broad, 1H), 7.60 (m, 8H). Found: C, 71.69; H, 4.33; N, 23.98%. Calcd for $C_{14}H_{10}N_1$: C, 71.79; H, 4.30; N, 23.91%.

b) Thermolysis of 2-aryloxybenzimidazoles in organic solvents. A typical run is shown below in the decomposition of 2-phenoxybenzimidazole in cumene. A mixture of 1.0 g of 2-phenoxybenzimidazole and 50 ml of cumene was heated in an autoclave at 250 °C for 5 hr. After the mixture had stood at room temperature for 1 night, the crystals which had separated out were filtered and washed with ether to give the crude trimer (II) in an 81.8% yield. The filtrate was extracted with a 10% aqueous sodium hydroxide solution, and the aqueous layer was acidified with hydrochloric acid to give 2-phenoxy-1,2′-dibenzimidazole (V) in a yield of 13%. Recrystallization from ethanol gave an analytical sample of

(V). Mp 228—230 °C. *m/e* 326 (Calcd for $C_{20}H_{14}N_4O$= 326). NMR (DMSO-d_6) δ 8.20 (broad, 1H), 7.55 (m, 13H). Found: C, 73.36; H, 4.48; N, 17.11%. Calcd for $C_{20}H_{14}N_4O$: C, 73.60; H, 4.32; N, 17.17%.

The cumene layer was evaporated *in vacuo*, and the residue was purified by vacuum sublimation to give 3.0 mg of dicumyl (mp 118—119 °C),[12] which was identified by a mixed-melting-point test with an authentic sample.

Asymmetric Induction in Friedel-Crafts Reaction with (+)-1,2-Epoxybutane and (−)-2-Chloro-1-butanol

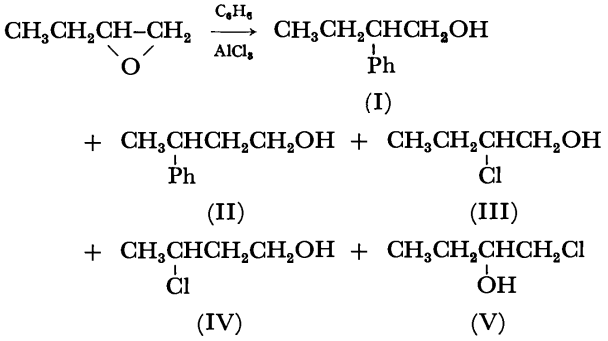
Tadashi NAKAJIMA, Yoshiaki NAKAMOTO, and Sohei SUGA

Department of Industrial Chemistry, Faculty of Technology, Kanazawa University, Kanazawa 920

(Received September 5, 1974)

The alkylation of benzene with (+)-1,2-epoxybutane in the presence of Lewis acid gave a mixture of optically active 2-phenyl-1-butanol (I) and 3-phenyl-1-butanol (II) together with a mixture of optically active 2-chloro-1-butanol (III), 3-chloro-1-butanol (IV) and 1-chloro-2-butanol (V). The formation of (−)-I and (−)-III suggests that the ring opening of the epoxide proceeds with an inversion of configuration, while that of optically active II and IV suggests an asymmetric induction at the carbon adjacent to the terminal methyl group of the epoxide. The reactions with aluminum chloride at 20 °C and with stannic chloride at −20 °C gave (+)-II in 10% and (−)-IV in 56% optical yield, respectively. In the reaction of (−)-III with benzene, such an asymmetric induction was also found to give (+)-II in 21—24% optical yield. The probable mechanism of this induction was discussed on the basis of the stability of the transition state conformations.

The Friedel-Crafts alkylation of aromatic hydrocarbon with 1,2-epoxyalkane is known to give 2-aryl-1-alkanol by fission of the secondary C–O bond in the epoxide.[1,2] A similar reaction of 1,2-epoxybutane with benzene was found to give 2-phenyl-1-butanol (I), 2-chloro-1-butanol (III), and 1-chloro-2-butanol (V) together with 3-phenyl-1-butanol (II) and 3-chloro-1-butanol (IV) as products of the isomerized type.[3]



Friedel-Crafts reactions in the presence of Lewis acid are accompanied by isomerization, *e.g.*, the reaction of hex-2-enoic acid, and pent-2-enoic acid with benzene in the presence of aluminum chloride gives a mixture of 3-, 4-, and 5-phenylhexanoic acid,[4] and 3-, and 4-phenyl pentanoic acid,[5] respectively. These results are rationalized on the basis of the mechanism involving the initial carbonium ion formation followed by a series of 1,2-hydride ion shifts. Hata *et al.* reported a similar isomerization in the reaction of 1,2-epoxyoctane with benzene by a Lewis acid catalyst, and concluded that it proceeds through a phenonium ion intermediate.[6] However, the reaction of (+)-propylene oxide in the presence of Lewis acid proceeded with complete inversion of configuration at the secondary carbon atom in the epoxide. Thus the mechanism involving a free carbonium ion should be ruled out in the reaction of epoxide in the presence of Lewis acid.[7]

These studies prompted us to investigate the stereochemistry of the reaction of (+)-1,2-epoxybutane with benzene in the presence of Lewis acid. 3-Phenyl-1-butanol (II) and 3-chloro-1-butanol (IV) were obtained in the reaction in an optically active form, besides (−)-2-phenyl-1-butanol (I) and (−)-2-chloro-1-butanol (III). The formation of optically active II and IV indicates the asymmetric induction at the carbon adjacent to the terminal methyl group of the epoxide. Such an induction in the presence of Lewis acid has not been reported. Its mechanism was discussed on the basis of the stability of the transition state conformations. The stereochemistry of conversion of 2-chloro-1-butanol (III) into 3-phenyl-1-butanol (II) was also investigated.

Results

The reaction of (+)-1,2-epoxybutane with benzene in the presence of Lewis acid was carried out in carbon disulfide at −20—+30 °C. After three hours, the resulting mixture was worked up as reported previously,[3] a mixture of I and II together with a mixture of III, IV, and V being obtained. The structures of these products were identified by comparison of IR and NMR spectra and retention time in gas chromatogram with those of authentic samples. The isomers were separated by means of preparative glpc or recrystallization of the α-naphthylurethane derivatives. The isomer composition in the products was determined by glpc. The results are given in Table 1.

The total yield of the phenylbutanols (I and II) and the relative amount of II to I increased with an increase in temperature, while that of the chlorobutanols (III, IV, and V) decreased with a rise of temperature. The chlorobutanols were scarcely formed at 20—30 °C.

Treatment of III with benzene in the presence of aluminum chloride gave II.[3] In carbon disulfide, the reaction of III with aluminum chloride and bromide gave IV and a mixture of 2-bromo-1-butanol and 3-bromo-1-butanol, respectively (see Experimental). However, no conversion of I into II occurred under these conditions.[3] Thus, if the conversion of III into IV is possible in the reaction of the epoxide with benzene at a higher temperature (0—30 °C), IV formed should react immediately with benzene to afford II, IV thus being scarcely formed.

Stereochemistry. (−)-I and (−)-III, formed by fission of the secondary C–O bond in the (+)-1,2-epoxybutane, were obtained in almost 100% and 55—56% optical yields, respectively (Table 2). The absolute configuration of (+)-1,2-epoxybutane, (−)-I, and (−)-

a) Starting (+)-1,2-epoxybutane: $[\alpha]_D^{26}$ +8.3° (neat), 93% optical purity.[8b] b) Rotations were taken on the samples which contain II in the following percentage; 7, 9, 3, 4, and 4% in run 1, 2, 3, 7, and 8, respectively. c) Calculated from the reported rotation[9] $[\alpha]_D$ −19.5° (neat) or $[\alpha]_D$ −13.8° (*c* 5.9, C_6H_6) of (−)-II, and the optical purity of (+)-1,2-epoxybutane used. These values were uncorrected for the optical rotation due to II contained. d) Calculated from the reported rotation $[\alpha]_D^{25}$ +23.9° (neat)[9] of (+)-III and the optical purity of (+)-1,2-epoxybutane used. e) This fraction contains 4% of V and 2% of IV.

III has been established as *R*,[8] *R*,[9] and *S*,[10] respectively. It is apparent that the formation of (−)-I and (−)-III from (+)-1,2-epoxybutane proceeds with inversion of configuration in analogy with the reaction of (+)-propylene oxide. The lower optical yield of (−)-III obtained can be interpreted by the exchange of chlorine atom. The secondary halohydrin (V) formed by fission of the primary C–O bond in the epoxide was obtained in too low an yield to permit polarimetric measurement. However, V might be optically pure since the asymmetric center of the starting epoxide remains unchanged.

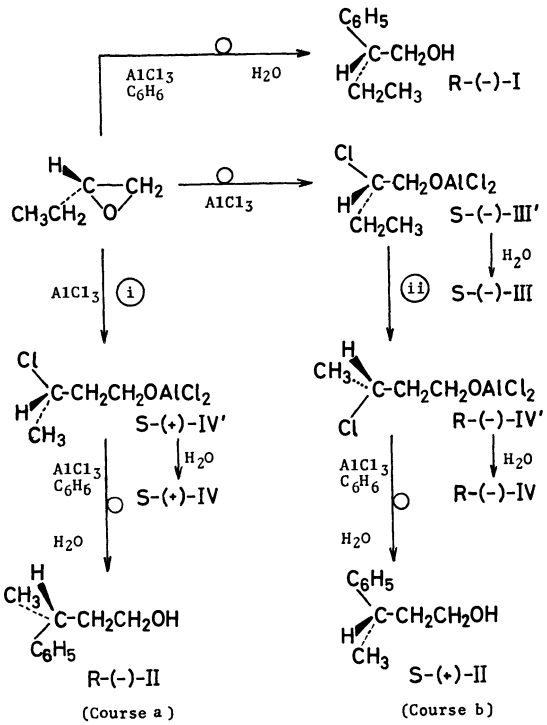
Both II and IV were obtained in optically active form (Table 3). The glpc fraction corresponding to II was treated with α-naphthyl isocyanate to give its urethane, since a pure sample of II could not be isolated by means of preparative glpc. After repeated recrystallization of the urethane, the optical rotation was measured to determine the optical yield of II.

In the presence of aluminum chloride at 20 °C, (+)-II was obtained in 10.2% optical yield, while the reaction at −10 °C gave (−)-enantiomer of II in excess (1.1%) and (+)-IV in 20% optical yield. On the other hand, the reaction with stannic chloride gave (+)-IV in 56% optical yield at −20 °C and hardly any II even at elevated temperature. The results suggest that a new chiral center was formed in the carbon adjacent to the terminal methyl group in the epoxide.

In order to ascertain the possibility of asymmetric induction in the reaction of III to II, (−)-III was allowed to react with benzene in the presence of aluminum chloride. (+)-II was obtained in reasonable optical yield (24—25%) (Table 4). When (+)-II was treated with aluminum chloride in benzene under the same conditions, the specific rotation of (+)-II remained unchanged before and after the reaction. Thus successive racemization of (+)-II should not occur in the reaction with (−)-III.



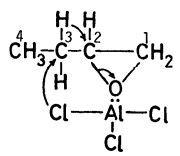
Scheme 1.

Discussion

The reaction of optically active IV with benzene by an aluminum chloride catalyst proceeded with inversion of configuration to give II in 20% optical yield.[11] The absolute configurations of (+)-II and (+)-IV have been established as *S*.[10,12] Thus the aluminum chloride salt of III or IV (III′ or IV′) would play an important role as an intermediate in the reaction of *R*-(+)-1,2-epoxybutane to optically active II.

In the overall reaction, two competing courses for the formation of II would be possible (Scheme 1). In course **a**, the ring opening reaction of *R*-(+)-1,2-epoxybutane yields directly *S*-(+)-IV′ (path i) which alkylates benzene with the inversion of configuration to give *R*-(−)-II. In course **b**, *S*-(−)-III′ was initially formed by the fission of the secondary C–O bond of epoxide, and then converted into *R*-(−)-IV′ (path ii) which reacts with benzene to give *S*-(+)-II. Paths i and ii should involve asymmetric induction at the carbon adjacent to the terminal methyl group of the epoxide. The other pathways, *R*-(+)-1,2-epoxybutane →*R*-IV′ and *S*-III′→*S*-IV′, should be excluded.

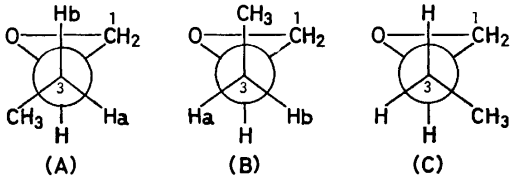
Formation of S-(+)-*IV from* R-(+)-*1,2-Epoxybutane.* The free carbonium ion mechanism was ruled out in the ring opening reaction of epoxide by the Lewis acid catalyst. This asymmetric induction may be rationalized as follows. The epoxide reacts initially with aluminum chloride to give a complex in which the secondary C–O bond is released and either of the hydrogens on C_3 migrates to C_2 from the back of the C_2–O bond to form a hydrogen bridge. Thus, the rotation about the C_2–C_3 bond would be restricted, and the chlorine atom of the complexing aluminum chloride would then attack intramolecularly C_3 from the back of the migrating hydrogen. If the C_2–O bond and the



migrating hydrogen are in one plane and *trans* to each

other, the hydrogen on C_3 would migrate easily to C_2 as in the case of E_2 elimination.[13]

The Newman projections **A**, **B**, and **C** show the possible conformations of *R*-(+)-1,2-epoxybutane in the ground state. The conformational stability of **A**



and **C** seems to be nearly equal, while **B** is less stable because of *gauche* interaction between three bulky groups (CH_3–, –O–, and $–CH_2$). However, the conformation **C**, in which the methyl group is *trans* to the C_2–O bond, should not participate in the asymmetric induction since the formation of the hydrogen bridge between C_2 and C_3 is unfavorable. The preferred conformation of epifluorohydrin has also been found to be type **A** by NMR spectroscopy.[14]

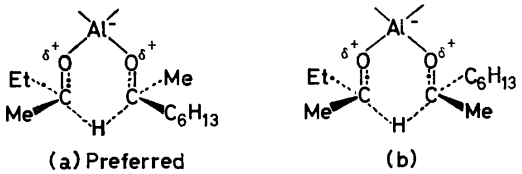
Thus the reaction from the stable **A** involves the bond breaking of C_2–O and the hydrogen bridging of Ha between C_2 and C_3, accompanied by an attack of chloride anion at C_3 from the back of Ha to give *S*-(+)-IV′, while the reaction from **B** should form *R*-(−)-IV′ by displacement of Hb from C_3 to C_2.

The enantiomeric product ratio (*S*/*R*) calculated from the optical yield of IV depends on the free energy difference between the two transition states:

$$\Delta\Delta G^{\ddagger} = \Delta G_S^{\ddagger} - \Delta G_R^{\ddagger} = -RT \ln (S/R)$$

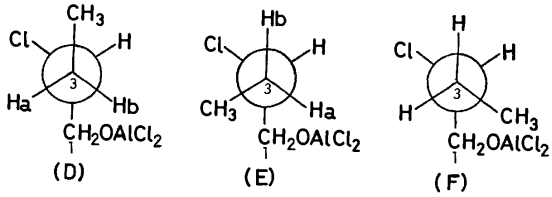
where $\Delta G_S^{\ddagger}$ and $\Delta G_R^{\ddagger}$ are the activation free energy for the formation of *S* and *R* enantiomer, respectively. For example, the optical yield (21%) of *S*-(+)-IV in run 6 corresponds to 0.22 kcal/mol of free energy difference. The value implies the difference of steric interaction of the substituents on C_2 and C_3. Since the conformation in the transition state seems to reflect that in the ground state of the epoxide, the reaction from **A** should preferentially proceed to give *S*-(+)-IV in excess.

In the Meerwein-Ponndorf-Verley reduction of methyl isohexyl ketone with (+)-2-butanol to (+)-methylisohexylcarbinol in the presence of aluminum 2-butoxide, the asymmetric induction has been rationalized in terms of an optimal steric fit of the reagents involved, and the free energy difference between the two possible transition states, (a) and (b), have been reported to be 0.2 kcal/mol.[15] Thus, the above value of $\Delta\Delta G^{\ddagger}$ is reasonable.



When stannic chloride was used as a catalyst, *S*-(+)-IV was obtained in 56% optical yield ($\Delta\Delta G^{\ddagger}$=0.64 kcal/mol). This might be interpreted in terms of the enhanced steric hindrance in the transition state due to the bulkiness of stannic chloride as compared with the case of aluminum chloride.

Formation of S-*(+)-II from* S-*(−)-III′ (or III).* The Lewis acid salt of *S*-(−)-III (III′) also has three conformations of *gauche* type, **D**, **E**, and **F**, in the ground state. In **D** and **E**, the C_2–Cl bond and the migrating



hydrogen are in one plane and *trans* to each other, while the C_2–Cl bond and the methyl group in **F** are *trans* to each other. Thus, the conformation **D** is more stable than **E** because of *gauche* interaction between three bulky groups (Cl–, CH_3–, and $-CH_2OAlCl_2$), and **F** should be ruled out in this asymmetric induction for the same reason as that in the case of conformation **C**.

The first step of the reaction from the stable **D** involves the bond breaking of C_2–Cl and the hydrogen bridging of Hb between C_2 and C_3, accompanied by the attack of chloride anion at C_3 from the back of Hb to give *R*-(−)-IV′. The intermediate then alkylates benzene with inversion of configuration in the presence of aluminum chloride to produce *S*-(+)-II. A similar reaction from **E**, which affords *S*-(+)-IV′ and then *R*-(−)-II, can be ruled out because of its unstable conformation.

On the other hand, *R*-(−)-II could be formed also from *S*-(+)-IV′ in course **a**. The final optical yield of II obtained should therefore be determined by difference of the reaction rate between courses **a** and **b**. Taking into account the preferential formation of *S*-(+)-II in this experiment, the reaction through course **b** would proceed in preference to that through course **a** except at low temperature.

In contrast, at low temperature (run 5, −10 °C) *R*-(−)-II was obtained in 1.1% optical yield. This can be rationalized by considerating that the ability of the catalyst to polarize the C_2–Cl bond of III′ so weakened that the rate of conversion of III′ into IV′ slowed down as compared with the above case.

The reaction with stannic chloride catalyst at low temperature gave two chlorobutanol isomers (III and IV) and 2-phenyl-1-butanol (I), but scarcely any 3-phenyl-1-butanol (II). This might be due to the minor catalytic ability of stannic chloride in the alkylation of benzene with IV (or IV′).

Experimental

All the melting points and boiling points are uncorrected. The optical rotations were taken on a REX photoelectric polarimeter with use of 0.5 and 1 dm tubes. The NMR spectra were determined on a JEOL JNM PS-100 spectrometer operating at a frequency of 100 MHz. Chemical shifts are given in ppm down field from internal TMS. The IR spectra were determined on a JASCO DS-301 spectrometer. Glpc analyses were carried out on a 3 m column of

10% Carbowax 20 M on Diasolid L with a Shimadzu GC-3A instrument. Preparative glpc was carried out on a 3 m column of 25% Carbowax on C-22 with a Yanagimoto GCG-5DH instrument.

Materials. Benzene was washed with concentrated sulfuric acid and distilled after drying on sodium ribbon. Carbon disulfide was distilled over phosphorus pentachloride. Anhydrous aluminum chloride was prepared from high purity aluminum and dry hydrogen chloride. Commercial GR grade stannic chloride was used without further purification.

(+)-1,2-Epoxybutane was prepared by the method of Levene and Walti[8b] and Price and Spector[16] as follows: 1-hydroxy-2-butanone prepared from 1-chloro-2-butanone and potassium formate in methanol, was reduced microbiologically by the reductase of baking yeast to (+)-1,2-butanediol (bp 98—100 °C/18 mmHg, $[\alpha]_D^{26}$ +14.1° (*c* 10, EtOH), lit,[8b] $[\alpha]_D^{25}$ +12.6° (*c* 11, EtOH), 67% yield). The 1,2-butanediol was converted into (−)-1-bromo-2-butanol with dry hydrogen bromide at 0 °C (bp 75—78 °C/20 mmHg, α_D^{26} −8.3° (neat, 1 dm), lit,[8b] α_D^{22} −11.8° (neat, 1 dm), 40% yield). The bromobutanol containing 17% 2-bromo-1-butanol was treated with 50% aqueous solution of potassium hydroxide for conversion into (+)-1,2-epoxybutane. After being dried over anhydrous calcium sulfate (Drierite) and redistillation, the epoxybutane indicated bp 61 °C and α_D^{26} +8.40° (neat, 1 dm) (lit,[8b] α_D^{24} +8.75° (neat, 1 dm)).

Typical Reaction Procedure and Product Indentification. To a stirred mixture of benzene (39 g, 0.5 mol) containing aluminum chloride (8.0 g, 60 mmol) and carbon disulfide (39 g, 0.5 mol) was added a solution of (+)-1,2-epoxybutane (3.6 g, 50 mmol) in benzene (39 g, 0.5 mol). The reaction temperature was maintained at −10 °C throughout the course of addition, which required 1 hr. After the addition the resulting mixture was allowed to stand at −10 °C for 2 hr with stirring and was then poured onto a mixture of crushed ice and 20 ml of concentrated hydrochloric acid. The benzene layer was separated, washed with 6 M hydrochloric acid and then water, and dried over anhydrous sodium sulfate. After removal of solvent, the residue was distilled *in vacuo* to give 0.5 g of a chlorobutanols fraction (bp 82—85 °C/90 mmHg) and 3.9 g of a phenylbutanols fraction (bp 108—115 °C/20 mmHg). After purification by boric ester method,[17] the phenylbutanols fraction showed bp 75—79 °C/4 mmHg. The water layer was extracted five times with 50 ml portions of ether. The combined extracts were dried over anhydrous sodium sulfate. After careful removal of ether, the residue was distilled *in vacuo* to give 0.8 g of a mixture of chlorobutanols (bp 83—95 °C/71 mmHg). The chlorobutanols obtained from benzene and water layer were combined.

Determination of isomer percentages and separation of each isomer by glcp were carried out on a 10% Carbowax column (temperature: 210 °C for the phenylbutanols and 150 °C for the chlorobutanols) and a 25% Carbowax column (temperature: 230 °C for the phenylbutanols and 180 °C for the chlorobutanols), respectively. The isomer percentages and the optical rotations of each isomer are given in Tables 1, 2, and 3.

(−)-2-Phenyl-1-butanol (I): IR(neat); 3340 (νOH), 1050 (νC–OH), 700 and 760 cm^{-1} (δCH, mono-substituted phenyl). NMR ($CDCl_3$, 5%); δ 0.81 (triplet, 3H, $-CH_3$), 1.71 (quintet, 2H, $-CH_2-$), 1.56 (singlet, 1H, −OH), 2.68 (quintet, 1H, −CH=), 3.72 (doublet, 2H, $-CH_2O$), 7.22 (5H, phenyl). α-Naphthylurethane of (−)-I; mp 72 °C; $[\alpha]_D^{26}$ +29° (*c* 1.4, C_6H_6), (Found: C, 78.10; H, 6.70; N, 4.14%).

(+)-3-Phenyl-1-butanol (II): IR(neat); 3340 (νOH), 1050 (νC–OH), 700 and 760 cm^{-1} (δCH, mono-substituted phenyl). NMR ($CDCl_3$, 5%); δ 1.26 (doublet, 3H, $-CH_3$), 1.50 (singlet, 1H, −OH), 1.84 (quartet, 2H, $-CH_2-$), 2.88 (sextet, 1H, −CH=), 3.54 (triplet, 2H, $-CH_2O-$), and 7.20 (5H, phenyl). α-Naphthylurethane of (+)-II; mp 86—87 °C; $[\alpha]_D^{26}$ +4.6 (*c* 10, CH_3COCH_3), (Found: C, 78.47; H, 6.62; N, 4.53%).

(−)-2-Chloro-1-butanol (III): The glpc retention time and IR were identical with those of an authentic sample prepared by the method of Markownikoff[18] and Freudenberg and Lwowski.[10] NMR ($CDCl_3$, 7%); δ 1.06 (triplet, 3H, $-CH_3$), 1.64—1.96 (multiplet, 3H, $-CH_2-$), 2.29 (singlet, 1H, −OH), and 3.56—4.08 (multiplet, 3H, $-CH_2O-$ and −CH=).

(+)-3-Chloro-1-butanol (IV): The glpc retention time and IR were identical with those of an authentic sample prepared by the lithium aluminum hydride reduction of 3-chlorobutanoic acid.[19,20] NMR ($CDCl_3$, 7%); δ 1.56 (doublet, 3H, $-CH_3$), 1.84—2.06 (multiplet, 2H, $-CH_2-$), 2.24 (singlet, 1H, −OH), 3.81 (triplet, 2H, $-CH_2O-$), and 4.25 (sextet, 1H, −CH=).

1-Chloro-2-butanol (V): The glpc retention time and IR were identical with those of an authentic sample prepared by the lithium aluminum hydride reduction of 1-chloro-2-butanone. NMR ($CDCl_3$, 7%); δ 0.98 (triplet, 3H, $-CH_3$), 1.59 (quintet, 2H, $-CH_2-$), 2.27 (singlet, 1H, −OH), and 3.37—3.85 (multiplet, 3H, $-CH_2Cl$ and −CH=).

Reaction of (−)-2-Chloro-1-butanol (III) with Benzene. To a stirred mixture of benzene (29 g, 0.38 mol) containing aluminum chloride (1.81 g, 14 mmol) and carbon disulfide (21 g, 0.28 mol) was slowly added a solution of (−)-III (1.23 g, 11.3 mmol, $[\alpha]_D^{26}$ −12.7—−17.1° (neat)) in benzene (15 g, 0.09 mol). The reaction mixture was maintained at 10—20 °C throughout the course of addition. The resulting mixture was worked up as mentioned above. The results are given in Table 4.

Reaction of a Mixture of 2-Chloro-1-butanol (III) and 1-Chloro-2-butanol (V) with Aluminum Chloride. To a stirred mixture of carbon disulfide (42 g, 0.56 mol) containing aluminum chloride (1.6 g, 12 mmol) was added a solution of III and V (III: V=66: 34, 1.1 g, 10 mmol) in carbon disulfide (10 g, 0.13 mol) at 5 °C. After the resulting mixture was treated as mentioned above, a mixture of III, IV and V was obtained (0.44 g, bp 80—90 °C/70 mmHg, III: IV: V= 1: 58: 41).

Reaction of a Mixture of 2-Chloro-1-butanol (III) and 3-Chloro-1-butanol (IV) with Aluminum Bromide. To a stirred solution of carbon disulfide (42 g, 0.56 mol) containing aluminum bromide (3.2 g, 12 mmol) was added a solution of III and IV (III: IV=58: 42, 1.1 g, 10 mmol) in carbon disulfide (10 g, 0.13 mol) at 5 °C. After the resulting mixture was treated as mentioned above, a mixture of 2-bromo-1-butanol (VI) and 3-bromo-1-butanol (VII) was obtained (1.2 g, bp 90—100 °C/40 mmHg, VI: VII=25: 75).

The authors wish to thank Professor Katsuhiko Ichikawa and Professor Toshio Sugita of Kyoto University for their valuable discussions and encouragement. Financial support from the Saneyoshi Science Foundation is acknowledged.

Studies of Saturated Heterocyclic Compounds. II.[1] The Preparation and PMR Spectroscopic Study of Mono- and Di-substituted-1,3-dioxolan-4-ones

Yoshihiro ASABE, Shoji TAKITANI, and Yojiro TSUZUKI*

Faculty of Pharmaceutical Sciences, Science University of Tokyo, Ichigayafunagawara-machi, Shinjuku-ku, Tokyo 162
**Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162*

(Received November 2, 1974)

The relationship of the configurations and the magnitude of the long-range spin coupling constants between the 2-H and 5-H, $J_{2,5}$, of 1,3-dioxolan-4-ones has been elucidated, the $J_{2,5}(trans)$ value being always larger than the $J_{2,5}(cis)$ value. Geometrical isomers of several 2,5-disubstituted derivatives have been separated by means of preparative tlc and assigned by means of PMR spectroscopy, especially by the use of their $J_{2,5}$ values. The sign of the $J_{2,5}$ values for a 2-trichloromethyl derivative has been determined by a partial decoupling experiment, both $J_{2,5}$ (*cis*) and $J_{2,5}$' (*trans*) being positive.

In a previous paper,[1] we reported that the magnitudes of the long-range coupling constants between 2-H and 5-H, $J_{2,5}$, of 1,3-dioxolan-4-ones may be useful for determining the configurations of geometrical isomers of 2,5-disubstituted derivatives because the derivatives containing phenyl and trichloromethyl groups showed fairly large $J_{2,5}$ values as a result of a dual-path mechanism[2,3] between 2-H and 5-H across the oxygen atoms, $J_{2,5}(trans)$ being larger than $J_{2,5}$ (*cis*).[4] Since stereochemical studies of 1,3-dioxolan-4-ones have been left undeveloped because of the difficulty of the isolation and identification of each isomer,[5–8] the measurement of the $J_{2,5}$ can be expected to be an effective method of their stereochemical assignments. Therefore, a detailed study has now been made with other derivatives.

In this paper, we will first examine whether configurational assignments using differences in phenyl-proton chemical-shifts in some *p*-substituted phenyl derivatives agree with those[1] previously obtained by using the spectral patterns of phenyl protons. Secondly, we will elucidate the relationship between the $J_{2,5}$ values and the configurations of these compounds. Next, the configurational assignments for geometrical isomers of several 2,5-disubstituted derivatives by PMR spectroscopy will be reported. Finally, the determination of the signs of $J_{2,5}(cis)$ and $J_{2,5}(trans)$ for a 2-trichloromethyl derivative by means of a partial decoupling experiment will be described.

Experimental**

*Preparation of Materials.*** 5-Substituted- and 2,5-disubstituted-1,3-dioxolan-4-ones were prepared from the corresponding *dl*-α-hydroxycarboxylic acids and aldehydes; each isomer of the 2,5-disubstituted derivatives was separated from the reaction mixture by means of preparative tlc.[1] The physical constants of these compounds are listed in Table 1. 2-Trichloromethyl-1,3-dioxolan-4-one (Bp 94.5—96 °C/7 mmHg, Mp 40—41 °C) was prepared by the reaction of glycolic acid and chloral.[7,9] All the sample were purified by repeated distillations or by recrystallization from suitable solvents before the measurement, and the 1,3-dioxolan-4-one ring was identified by means of its IR spectra ($\nu_{C=O}$).

Measurements. The PMR spectra were measured with a Varian A-60 spectrometer and a JNM 4H-100 spectrometer at room temperature. Carbon tetrachloride, chloroform-*d*, and acetone-d_6 were used as solvents (concentration: *ca.* 40—50 mg/0.5 ml), and TMS was used as an internal reference. The chemical shifts and coupling constants were recorded in δ and Hz respectively. The solutions were degassed for the partial decoupling experiments, but were not degassed for the other measurements. The mass spectra were measured with a Hitachi RMU-7M spectrometer (ionizing potential: 70 eV; chamber temperature: 150 °C), and the millimass data were calculated against the standard peaks (PFK or *n*-eicosane), using a Hitachi 002-type datalizer connected with the spectrometer. Since, in the low-mass spectra, no distinguishable difference between the geometrical isomers was observed under the present conditions, the measurements of the millimass spectra were carried out with only one of each pair. The IR spectra were measured using a Hitachi-Perkin Elmer 225 spectrometer in a carbon tetrachloride solution (*ca.* 0.2 mol/l, 0.1 mm KRS-5 cell) or KBr discs.

Results and Discussion

Table 2 shows the PMR spectral data for the phenyl protons of several 5-*p*-substituted phenyl derivatives; a higher-field part of the spectrum was used in an approximate analysis of the AA'BB' system in order to avoid complications due to additional larger couplings caused by 5-H. Moreover, the ring protons were assigned by the use of their benzylic couplings with 5-H: the higher-field part of the AA'BB' spectrum was attributable to the protons (A protons) *ortho* to the substituent group, while the lower-field part was attributable to the *meta*-protons (B protons).

By comparing the differences in chemical shifts between the A and B protons $|\Delta\delta_{AB}|$ obtained for the 2-trichloromethyl-5-*p*-substituted phenyl derivatives (Compounds **5** and **6**) in $CDCl_3$, the $|\Delta\delta_{AB}|$ values of the isomers with lower R_f values were found to be larger than those with higher R_f values, which are similar to the $|\Delta\delta_{AB}|$ values of 5-*p*-substituted phenyl derivatives (Compounds **2** and **3**). The same trend continues in the other solvents, although the chemical

** All the melting points and boiling points are uncorrected.

*** All the compounds except for the Compound **1** and the 2-trichloromethyl derivative are unknown.

a) In CCl_4. b) KBr disc. c) R_f values were determined on a silica gel plate, which was coated with silica gel HF_{254} (Merck) at 0.25 mm thickness and activated at 110 °C, 40 min. (developer: benzene; detection: UV light at 254 nm).

shifts (δ) of the phenyl protons in $(CD_3)_2CO$ shift toward a lower-field side than those in CCl_4 or $CDCl_3$. Accordingly, the isomers with lower R_f's, whose phenyl protons show larger $|\Delta\delta_{AB}|$ values, can be assigned to a *cis*-configuration, because the protons should be subject to the larger magnetic anisotropy of the *cis* 2-trichloromethyl group;[4] this assignement is in accordance with those previously reported.[1] In the case of compounds without any highly anisotropic substituent, such as the 2-methyl-5-*p*-methoxyphenyl derivative (Compound **10**), however, the $|\Delta\delta_{AB}|$ values are not useful for assigning the configuration because of an ambiguous difference between the *cis* and the *trans* isomer. Therefore, the $J_{2,5}$ values can be a more significant measure for this purpose, as will be discussed later. In all the compounds, no significant solvent effect on the coupling constants of the phenyl protons is observed.

Table 3 lists the PMR spectral data of the 5-substituted- and 2,5-disubstituted-1,3-dioxolan-4-ones used in this study. The $J_{2,5}$ values of the *trans* forms of Compounds **5** and **6** ($|J|$=1.4—1.6 Hz) are larger than those ($|J|$=1.0—1.2 Hz) of the *cis* forms. These J values are barely affected by the *p*-substituent on the 5-phenyl group or by the solvents. Although the $J_{2,5}$ values of the 5-substituted derivatives (Compounds **1**—**4**) are smaller than those of the 2,5-disubstituted ones, there is a distinguishable difference between the $J_{2,5}$(*trans*) and the $J_{2,5}$(*cis*) values. The assignment based on the $J_{2,5}$ values for the methylene protons of Compounds **1**—**4** are in agreement with that made on the basis of the deshielding effects of their phenyl group. The same relationship between $J_{2,5}$ values has been found in the corresponding compound, with the 2- and the 5-substituents being exchanged for one another,[1] and also in the 2-phenyl[1] and 2-trichloromethyl derivatives. In general, therefore, the isomers with larger $J_{2,5}$ values can be assigned to the *trans*-configuration.

a) *cis* to the 5-substituent group. b) *trans* to the 5-substituent group. c) *cis* to the 2-substituent group. d) *trans* to the 2-substituent group. *a*: in CCl_4, *b*: in $CDCl_3$, *c*: in $(CD_3)_2CO$. s: singlet or almost single peak, c: complicated singals, d: doublet, t: triplet, q: quartet, m: multiplet more than quartet, and for example, dd: doubly doublet.

On this basis, the configurations of the geometrical isomers of several 2,5-disubstituted derivatives (Compounds **7**—**12**) can be confirmed by the $J_{2,5}$ values.

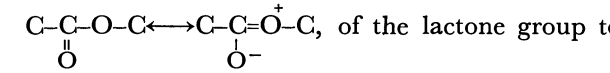
In 2-trichloromethyl (or 2-tribromomethyl)-5-phenyl (or benzyl) derivatives (Compounds **5**—**8**), all of the *trans* isomers show higher R_f values than the *cis* isomers on the tlc coated with silica gel, whereas in the corresponding 2-methyl (or 2-ethyl) derivatives (Compounds **9**—**12**) the isomers with smaller $J_{2,5}$ values appeared at the upper band on the tlc. Thus, in the latter the isomers assigned as *cis* isomers give higher R_f values than those of the *trans* isomers. The R_f values of the methyl (or ethyl) derivatives listed in Table 1 are shown to be lower than those of the corresponding trichloromethyl (or tribromomethyl) derivatives. A different behavior among the methyl (or ethyl) derivatives and the trichloromethyl (or tribromomethyl) derivatives was also observed on the chemical shifts of the 2-H and 5-H signals; the 2-H and 5-H signals in 2-trichloromethyl (or 2-tribromomethyl)-5-phenyl (or benzyl) derivatives (Compounds **5**—**8**) both appear at a slightly higher field in the *cis* than in the *trans* isomer, except for the 2-H signal of Compound **7**. However, in 2-methyl (or 2-ethyl) derivatives (Compounds **9**—**12**) the 2-H and 5-H signals both appear at a higher field in the *trans* than in the *cis* isomer.

Finally, since no report has been found on the signs of the $J_{2,5}$, we aimed at determining them by a partial

decoupling experiment. For this purpose, the 2-trichloromethyl derivative is the most suitable because a further complication due to additional couplings is eliminated; the PMR spectrum of this compound can be analyzed as an ABX system, in which only twelve transitions were observed. The analysis gave the following results by the usual procedure: $\nu_A-\nu_B=15.0$ Hz, $\nu_B-\nu_X=126.9$ Hz, $|J_{AB}|=15.1$ Hz, $|J_{AX}|=0.2$ Hz, $|J_{BX}|=1.4$ Hz (at 100 MHz), and J_{AX} and J_{BX} are of the same sign. Since the J_{AB} value corresponds to a normal J_{gem} value, it is possible to assume a negative sign for the J_{AB}. Thus, a partial decoupling experiment on this spectrum has been carried out according to the usual method.[10] The experiment showed that J_{AX} and J_{BX} are both positive.

Further, on the basis of the magnetic anisotropy of the 2-trichloromethyl group,[7] the signals at the lower field (B proton) were assigned to one of the 5-methylene protons *cis* to the 2-trichloromethyl group, while the signals at the higher field (A proton) were assigned to the *trans* proton. Those assignments are in agreement with those made on the basis of the $J_{2,5}$ values.

The facts that both of the $J_{2,5}$ values have the same positive sign, and that the *trans* coupling constant has a larger value than the *cis* one, are in accordance with the empirical generalization found in 2,5-dihydrofurans[11] and 2,5-dihydropyrroles,[12] which may be considered to be isoelectronic with 1,3-dioxolan-4-ones. Therefore, in view of a resonance contribution, such as



of the lactone group to the ring-planarity, as has been pointed out by Barfield *et al.*[13] the coupling mechanisms may be considered to be the same as those of 2,5-dihydrofurans.

The present work was supported in part by a Grant for the Encouragement of Scientific Research from the Ministry of Education. The authors wish to thank Mr. Hiroshi Toyama and Mr. Teruo Suzuki of the Japan Electron Optics Laboratory Co., Ltd., for their co-operation in the partial decoupling experiments, and also Prof. Nobuo Mori of this University for his helpful advice.

Electrical Properties of 1,1-Diphenyl-2-picrylhydrazine and 2,2-Diphenyl-1-picrylhydrazyl Disks

Yoshiro SAKAI and Yoshihiko SADAOKA

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Bunkyo-cho, Matsuyama, Ehime 790

(Received April 30, 1974)

The electrical properties of 2,2-diphenyl-1-picrylhydrazyl (DPPH) disk were studied in the temperature range 18—60 °C over frequencies 3×10—3×10^6 Hz in comparison with those of 1,1-diphenyl-2-picrylhydrazine (DPPHn). The frequency dependence of conductance (σ_{ac}) for both DPPH and DPPHn can be explained in terms of the hopping conduction caused by localized states and/or shallow traps. At low frequencies, the strong dispersion of the capacitance of DPPH was observed while conductivity remained constant. This was accounted for by hyperelectronic polarization. The difference in electrical properties between DPPH and DPPHn indicates that the unpaired electrons in DPPH play an important role in the frequency independent conductance (σ_{dc}), but not in the frequency dependent conductance (σ_{ac}).

In 1962, Pollak showed[1] that the band type conduction should be essentially frequency-independent, whereas hopping conductivity should increase with increasing frequency of applied field.

It is known[2] that the monotonic increase of conductivity with an increase in frequency can be interpreted in terms of a hopping conduction mechanism in which carriers transit from one localized state to another. The localized states are formed when the interaction between molecules is weak.

Ac measurement is useful for studying the character of conduction since the ac currents are basically different for hopping and band conduction. Many workers have reported[3–5] that the apparent conductivity of aromatic compounds can be expressed as the sum of the frequency independent component (band conduction) and the frequency dependent component (hopping conduction).

2,2-Diphenyl-1-picrylhydrazyl (DPPH) is a well-known solid organic free radical and a semiconductor, but the frequency dependence of both conductivity and dielectric constant has not been studied in detail. We have studied the effects of unpaired electrons in DPPH on the electrical properties by measuring the frequency and the temperature dependence of conductivity and dielectric constant of both DPPH and 1,1-diphenyl-2-picrylhydrazine (DPPHn).

Experimental

DPPH was prepared by the method reported by Inokuchi *et al.*[6] and purified by repeated recrystallization from carbon disulfide which forms no molecular complex with DPPH.[7] DPPHn was purified by repeated recrystallization from ethyl ether. Samples were dried for one day *in vacuo* (about 10^{-5} Torr). Pulverized samples (about 200 mg) were compressed between stainless steel electrodes under pressure of about 220 kg/cm^2 *in vacuo* in order to eliminate the contact resistance and capacitance. The size of a sample was 0.05 cm$\times$3.14 cm^2. The sample was held *in vacuo* (about 10^{-3} Torr) in order to avoid the effect of adsorption of oxygen gas during the course of electrical measurements. Measurements were carried out with an ac bridge TR 10C (Ando Electric. Co. Ltd.). The dc conductivity of the DPPH was measured with an electrometer TR 8651 (Takeda Riken). The temperature of the sample was varied from 15 to 70 °C. It was found by ESR measurement that the purified DPPHn contains trace amounts of paramagnetic substance, probably DPPH, the concentration of which was estimated to be less than 10^{-6} spins/mol. The g value of impurity was determined to be 2.0036 by use of the frequency counter in ESR measurement.

Results and Discussion

In previous papers[8,9] it was shown that the frequency dependence of ac conductivity for aromatic compounds is expressed as

$$\sigma = \sigma_{ac} + \sigma_{dc} = A\omega^n + \sigma_0 \exp(-E/kT) \quad (1)$$

where $\sigma_{ac}(A\omega^n)$ and $\sigma_{dc}(\sigma_0\exp(-E/kT))$ are the frequency dependent and independent components, respectively. ω is the angular frequency ($\omega=2\pi f$). Lakatos and Abkowitz[2] have shown that if hopping takes place between a random distribution of localized states, σ_{ac} should be proportional to ω^n when $0.5<n<1.0$. n takes the lower value for multiple hops and the higher one for a single hop. Multiple hops occur frequently, at a high temperature, while the single hop predominates at a low one.

The frequency dependence of the apparent ac conductivity of DPPHn and DPPH is shown in Figs. 1 and 2, respectively. In the low frequency region

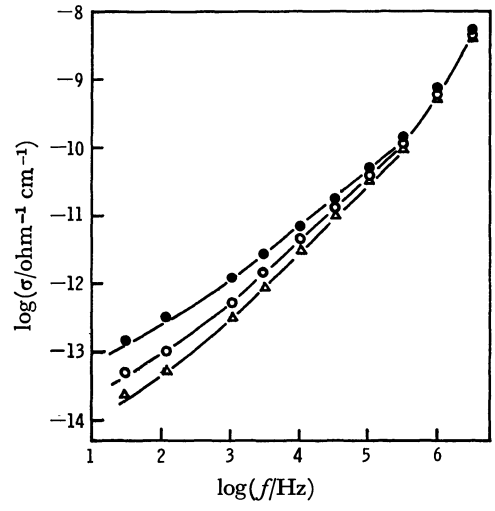

Fig. 1. Frequency dependence of observed conductivity of DPPHn at various temperatures.

(below 3×10^3 Hz) the difference between the observed value for DPPHn and the straight line drawn by extrapolation from the high frequency region (1 kHz—1 MHz), on the assumption that σ_{ac} is proportional to ω^n, is defined as σ_{dc}. The value of σ_{dc} thus obtained is independent of the frequency within experimental error. The dc conductivity of DPPHn could not be measured by the usual dc method because of low conductivity (*i.e.*, specific conductivity $<10^{-13}$ ohm^{-1}·cm^{-1}).

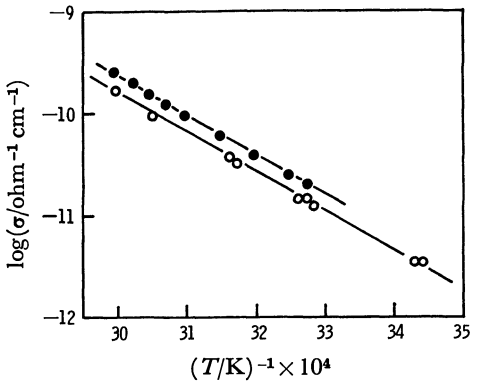

Fig. 3. Temperature dependence of dc and ac (30 Hz) conductivity of DPPH.
(○) ac method (applied frequency: 30 Hz)
(●) dc method (applied voltage: 10 V)
The difference of the conductivity between dc and ac methods is probably due to the difference of the standard resistance.

In the case of DPPH, at 30 Hz frequency the observed conductivity is about 10—10^2 times larger than that obtained by the extrapolation from high frequency region on the assumption that the relation $\sigma_{ac}=A\omega^n$ holds. The observed conductivity at 30 Hz is in good agreement with that obtained by the dc method (Fig. 3). We can thus assume that it is approximately equal to σ_{dc}, *viz.*, the frequency independent component.

The frequency dependence of σ_{ac} of DPPH was obtained by use of the value of σ_{dc}. The values of n in the relation $\sigma_{ac}=A\omega^n$, which were graphically obtained, are given in Table 1 for DPPHn and DPPH. The values are consistent with the thermally assisted hopping conduction mechanism in which n is expected to be between 0.5 and 1.0. The fact that the effect of temperature on σ_{ac} decreases with an increase in frequency indicates that the localized states (and/or shallow traps) are strongly affected by the frequency.

Table 1. Values of n for DPPHn and DPPH disks

DPPHn		DPPH	
Temp. °C	n in σ_{ac}	Temp. °C	n in σ_{ac}
18	0.9_0	18	0.8_0
35	0.8_0	32	0.6_5
70	0.7_5	42	0.5_0
85	0.6_5	54	0.5_0
		60	0.5_0

Since no distinct difference in σ_{ac} of DPPHn and DPPH was observed, the ac conduction of DPPH might be caused by the localized states produced by structural defects, impurities and/or π-electrons but not unpaired electrons.

In the higher frequency region (above 1 MHz) the conductivity is proportional to the square of frequency. This holds when the hopping distance becomes shorter as the frequency increases[10] and in extreme cases it becomes less than the distance between localized states. However, the electrical properties of ω^2 region can not be discussed in detail since the frequency dependence of the conductivity was not measured in a region higher than 3 MHz.

From the results shown in Fig. 3, the activation energy and pre-exponential factor σ_0 in Eq. (1) was estimated to be 0.75 ± 0.05 eV and 10 ohm^{-1} cm^{-1}, respectively. The dc conduction of DPPH should be due to the carriers excited into the localized states at the band edge (E_A) because the value of σ_0 thus obtained is smaller than that expected for the intrinsic band conduction by a factor of 10^2.[11] If the main carriers are thermally excited electrons in DPPH, and conduction is caused by hopping, we have

$$\sigma_{dc}=\sigma_0\cdot\exp\left[-(E_A-E_F+\Delta W_1)/kT\right], \qquad (2)$$

where ΔW_1 is the activation energy for hopping and E_A is the energy at the band edge (Fig. 4), the value of σ_0 being expected to be of the order 10—10^{-2} ohm^{-1}·cm^{-1}.[11] Since the activation energy of the photo-

conduction of DPPH film prepared by solvent evaporation has been estimated to be 0.16 eV by Eley and his co-workers,[12] it is expected that the activation energy for hopping (ΔW_1) takes the value of the order 0.1 eV.

On the other hand, the dielectric constant of DPPH shows a strong dispersion for frequency of the applied field and increases with increasing temperature while that of DPPHn remains constant (Fig. 5). The fact that in the case of DPPH the dielectric constant shows a strong dispersion in the low frequency region but conductivity does not can be explained in terms of interfacial polarization and/or hyperelectronic polarization. Since the observed dielectric constant is not a function of sample thickness (Table 2) and σ_{dc} obeys Ohm's law up to 10^3 V cm^{-1} at 50 °C, it is expected that the hyperelectronic polarization rather than the interfacial polarization takes place for DPPH.

Pohl *et al.*[13] showed that the strong dispersion of dielectric constant at low frequency can be explained by hyperelectronic polarization. Large molecules are expected to give high values of dielectric constant if the transit of electrons is more unlikely to occur between molecules than within molecules. The low value of σ_0 obtained above is in line with the assumption of hyperelectronic polarization since the thermally excited unpaired electron must pass over the activation energy for hopping. It is expected that the observed mobility takes a lower value than that expected for intrinsic band conduction. The assumption of hyperelectronic polarization can be confirmed by the fact that the conductivity is strongly dependent on pressure[14] and weakly dependent on frequency of the applied field. Hyperelectronic polarization is most likely to occur for DPPH in the low frequency region and low mobility may be explained by the electronic hopping between DPPH molecules. Since no similar tendency could be observed for DPPHn, the hyperelectronic polarization should be due to the unpaired electrons in DPPH.

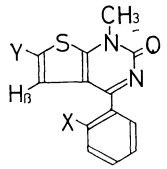
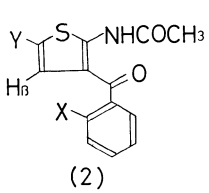
(Received June 27, 1974)

Proton–fluorine coupling over six bonds has been observed between fluorine and H_β of the thiophene ring in *ortho* fluorophenyl derivatives of 4-phenylthienopyrimidines (**1**), 2-acetylamino-3-benzoylthiophenes (**2**), 5-phenyl-1,4-thienodiazepines (**3**) and 5-phenyl-1,4-thienodiazepine-4-oxides (**4**). The solvent effect and the *N*-methylation effect on the coupling constant can be explained by considering that the H–F coupling is a through space coupling. The value of coupling constant (J_{HF}: 0.5 Hz to 4.1 Hz) depends upon the geometry of the ring system condensed at 2-C and 3-C of thiophene ring, decreasing in the order of **1**>**2**>**3**>**4**. A discussion is given on the manner of steric repulsion between the benzene ring and some atoms on the other moiety of these compounds.

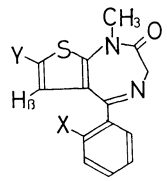
In a previous paper,[1] we reported on the ring current effect of the benzene ring on H_β and H_α (when Y=H_α) of the thiophene ring in 4-phenylthienopyrimidines (**1**), 2-acetylamino-3-benzoylthiophenes (**2**), 5-phenyl-1,4-thienodiazepines (**3**) and 5-phenyl-1,4-thienodiazepine-4-oxides (**4**).



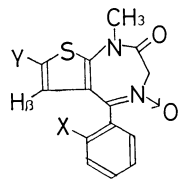
(1)



(2)

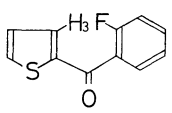


(3)



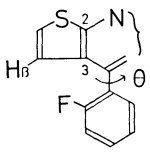
(4)

We have found that the H_β signal exhibits an extra splitting only when *ortho* substituent (X) of the benzene ring is fluorine, and that the amount of splitting is independent of the field. This indicates that there is a long range coupling over six bonds between H_β of the thiophene ring and fluorine on the benzene ring. Martin *et al.* did not mention such a H–F coupling between H_3 and fluorine in their NMR study of 2-(*o*-fluorobenzoyl)-thiophene (**5**).[2-3] The H–F coupling



(5)

found in compounds (**1**)—(**4**) is considered to be a through space coupling. Compounds (**1**)—(**4**) are suitable for obtaining information on a H–F through space coupling, because each has a ring system condensed at 2-C and 3-C of the thiophene ring (*i.e.* compound (**2**) has a ring system by an intramolecular hydrogen bonding; see formula [IV] as well as Part I[1]) and has only one degree of freedom of internal rotation



[I]

(*i.e.* torsional angle between the benzene ring plane and the thiophene ring plane; θ in formula [I]). The internuclear distance between H_β and fluorine in each of these compounds is simply related with θ, and the value of θ was estimated on the basis of ring current effect of the benzene ring on H_β.[1]

4aI

We have prepared *o,o'*-difluorophenyl derivatives (**1aI**, **1bI**, **2aI**, **2bI**, **3aI**, and **4aI**), and also 2-acetylamino-3-(*o*-fluorobenzoyl)thiophene derivatives (**2iB**, **2jB**, and **2kB**). They also supply information on the H–F through space coupling. Long range proton–fluorine through space coupling over five bonds or more has been a subject of interest.[4-10] Investigations have

2iB (Y = NO_2, R_1 = H)
2jB (Y = NO_2, R_1 = CH_3)
2kB (Y = Cl, R_1 = CH_3)

been made on the relation between J_{HF} and the spacial proximity of the coupled nuclei.[4,8–10] In this paper, we present our experimental results of these new compounds.

Results

NMR data for the fluorophenyl derivatives of compounds (**1**)—(**4**) are collected in Table 1. We see that the J_{HF} of *o*-fluorophenyl derivatives of compounds (**1**)—(**4**) is independent of substitution Y. The J_{HF} of compound (**3**) is also independent of the kind of substitution R_1. It depends, however, greatly upon the kind of ring system condensed at 2-C and 3-C of the thiophene ring. Thus, in the *o*-fluorophenyl derivatives, it is 0.5 Hz in compound (**4**), 1.2 Hz in compound (**3**), 2.7 Hz in compound (**2**) and 4.1 Hz in compound (**1**). In the *o,o'*-difluorophenyl derivatives, the H–F coupling is observed as a triplet. This may be explained by considering that H_β couples with two

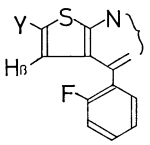
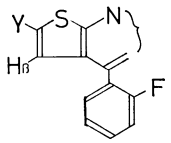
equivalent fluorine nuclei.[11] In compound **4aI**, H_β signal is observed as a broad singlet instead of a triplet. This suggests that the coupling constant is smaller than 0.5 Hz. In Table 2, the effect on J_{HF} by *N*-methylation of compound (**2**) is summarized. Each *N*-methyl compound (**2**) shows a smaller J_{HF} than the corresponding *N*-hydrogen compound. The solvent effect on J_{HF} of compounds (**1**)—(**4**) is summarized in Table 3. When the *o*-fluorophenyl derivatives of compounds (**1**)—(**4**) are measured in dimethylsulfoxide-d_6 solution, J_{HF} is found to be smaller than that in chloroform-*d* solution. In compound **2aB**, H_α couples with amide proton not only in chloroform-*d* but also in dimethylsulfoxide-d_6. This indicates that the carbonyl oxygen forms intramolecular hydrogen bonding with an amide proton to form a six membered ring also in dimethylsulfoxide-d_6, as well as in chloroform-*d* (see formula [IV] as well as Part I[1]).

Discussion

In order to explain the results of J_{HF}, let us assume as follows: of the two possible conformers [II] and [III], [II] is much more predominant in the *o*-fluorophenyl derivatives of Compounds (**1**)—(**4**). This is understandable, since [III] should be much less stable because of the Coulombic repulsion between the fluorine and imino nitrogen in compounds (**1**) and (**3**), carbonyl oxygen in compound (**2**), or oxygen atom of *N*-oxide in compound (**4**).[4] The assumption does not mean



[II]



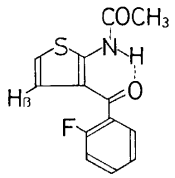
[III]

that the torsional angle θ between the benzene ring plane and thiophene ring plane is exactly zero degree in [II]. Let us define that [II] is a conformer in which $0° \leqq \theta < 90°$ and that [III] is a conformer in which $90° \leqq \theta < 180°$.

Proton-fluorine through Space Coupling. The observed proton-fluorine coupling is considered to be a through space coupling on the basis of the following observations.

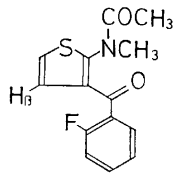
Solvent Effect on J_{HF}: We see from Table 3 that changing the solvent from chloroform-*d* to dimethylsulfoxide-d_6 causes a significant reduction in the J_{HF} of the *o*-fluorophenyl derivatives of compounds (**1**)—(**4**). According to Adcock *et al.*,[4] such a solvent effect can be taken as indicating that the proton-fluorine coupling is a through space coupling; changing the solvent from chloroform-*d* to dimethylsulfoxide-d_6 should cause an increase in the dielectric of the medium as well as dipole-dipole interaction, and therefore, should cause dampening of the intramolecular Coulombic repulsion which controls conformational preference. Thus, the population of conformer [III] should increase on changing the solvent. Since in [III], the internuclear distance between H_β and fluorine is much greater than that in [II], the J_{HF} value should decrease by changing the solvent, if the coupling takes place through space. This is what was actually found.

Effect of N-Methylation on J_{HF}: *N*-Methylation of every compound in the series of compound (**2**) causes a lowering of the J_{HF} value to 60%. On the other hand, *N*-methylation of compound (**3**) causes no change in the J_{HF} value (*i.e.* compound **3cB**, $J=1.2$ Hz; compound **3aB**, $J=1.3$ Hz; see Table 1). The NH group of compound (**2**) forms an intramolecular hydrogen bonding with the carbonyl oxygen, so that a six membered ring is formed, as shown in formula [IV].

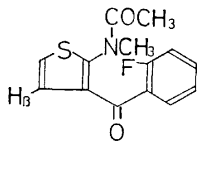


[IV]

On *N*-methylation, however, this hydrogen bonding is broken and there would be two possible conformers [V] and [VI]. In [VI], the internuclear distance



[V]



[VI]

between H_β and fluorine is much greater than in [V] or [IV]. In compound (**3**), on the other hand, no conformational change is expected by *N*-methylation. Thus it is understandable that no change in J_{HF} was observed.

Torsional Angle (θ) between the Benzene Ring Plane and Thiophene Ring Plane. The internuclear distance between H_β and fluorine in each of compounds (**1**)—(**4**) is considered to be related with the torsional angle between the thiophene and benzene ring planes (θ in formula [I]). The shielding effect of the benzene ring on H_β is also considered to be related with the torsional angle θ (see Part I[1]).

o-Fluorophenyl Derivatives of Compounds (1)—(4): As is seen from Table 1, J_{HF} of the *o*-fluorophenyl derivatives of compounds (**1**)—(**4**) decreases in the order of **1** ($J=4.1$ Hz)>**2** ($J=2.7$ Hz)>**3** ($J=1.2$ Hz)>**4** ($J=0.6$ Hz). As has been discussed in Part I,[1] the ring current effect of the benzene ring on H_β increases on going from compound (**1**) to compound (**4**) through compounds (**2**) and (**3**). It was thus assumed that the torsional angle θ increases in the order of **1**→**2**→**3**→**4**. Therefore, the internuclear distance between H_β and fluorine should increase in the order of **1**<**2**<**3**<**4**, and the J_{HF} value should decrease in this order, which is what was actually observed. This may be taken as an additional piece of evidence that the coupling between H_β and fluorine takes place through space. It also supports our previous conclusion that the torsional angle θ increases in the order of **1**<**2**<**3**<**4**.

TABLE 4. COMPARISON OF THE BENZENE RING CURRENT EFFECT ON H_β AND $J_{H_\beta \cdot F}$ BETWEEN *o*-FLUOROPHENYL COMPOUND AND *o,o'*-DIFLUOROPHENYL COMPOUND

Compound	**1b**	**2**[a]	**3a**	**4a**
J_{HF}(F) (Hz)	4.2	2.7	1.3	0.6
J_{HF}(FF) (Hz)	1.6	1.4	0.8	—
$J_{HF}(FF)/J_{HF}(F)$	38%	52%	62%	—
$\Delta\delta'$ (ppm)	0.16	0.10	0.03	−0.03

a) Average value of compounds **2a** and **2b**.

o,o'-Difluorophenyl Compounds (1)—(4): Let us next compare the J_{HF} value of *o,o'*-difluorophenyl compounds (**1**)—(**4**) (*i.e.* J_{HF}(FF)) with the one of the corresponding *o*-fluorophenyl compounds (*i.e.* J_{HF}(F)) (Table 4). J_{HF}(FF) is always smaller than the corresponding J_{HF}(F). This can be explained by considering that the torsional angle θ in the *o,o'*-difluorophenyl compound is greater than that in the corresponding *o*-fluorophenyl compound. The greater θ causes greater internuclear distance between H_β and fluorine, and therefore should cause a smaller J_{HF} value. This phenomenon can be explained by considering that the steric and Coulombic repulsion should be greater in *o,o'*-difluorophenyl compound than in *o*-fluorophenyl compound.[4] Let us examine the amount of decrease in the J_{HF} value on going from a *o*-fluorophenyl compound to the corresponding *o,o'*-difluorophenyl compound. The $J_{HF}(FF)/J_{HF}(F)$ values are given in Table 4 for compounds (**1**)—(**3**). The value becomes greater in the order of **1** (38%)<**2** (52%)<**3** (62%). Let us define $\Delta\theta$ as the amount of increase in θ on going from a *o*-fluorophenyl compound to the corresponding *o,o'*-difluorophenyl compound. Then, what has just been observed may be taken as indicating that the $\Delta\theta$ value is the greatest for compound (**1**).

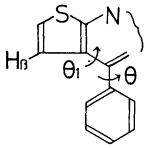
For a comparison of the chemical shift of H_β of *o,o'*-difluorophenyl compounds (**1**)—(**4**) (*i.e.* δH_β(FF)) with that of the corresponding *o*-fluorophenyl com-

pounds (*i.e.* $\delta H_\beta(F)$), let us define $\Delta\delta'$ as $\Delta\delta' = \delta H_\beta(F) - \delta H_\beta(FF)$. As may be seen from Table 4, the $\Delta\delta'$ value becomes smaller in the order of **1**>**2**>**3**>**4**. This order of the $\Delta\delta'$ value must mean that the $\Delta\theta$ value becomes smaller in this order. Thus, the result is in accordance with that obtained from the $[J_{HF}(FF)/J_{HF}(F)]$ value.

The Steric Effect by the Ring System Condensed at 2-C and 3-C of the Thiophene Ring. It has become clear that the torsional angle between the benzene ring plane and thiophene ring plane increases in the order of **1**<**2**<**3**<**4**. This fact should be taken as indicating that the amount of steric hindrance depends on the geometry of the ring system condensed at 2-C and 3-C of the thiophene ring in each molecule.

The difference in steric hindrance between compounds (**3**) and (**4**) can be explained as follows. From a comparison of 5-phenyl-1,4-thienodiazepine (**3**) with the corresponding *N*-oxide compound (*i.e.* compound (**4**)), we see that the torsional angle between the benzene and thiophene ring planes should be greater for (**4**), since in compound (**4**) the steric hindrance exists between the benzene ring and oxygen atom of *N*-oxide, which is near the benzene ring. This extra steric repulsion forces the benzene ring out of the plane of the thiophene ring. An analogous steric hindrance was reported in the case of *p*-bromobenzophenone oxime *o*-picrylethers.[12]

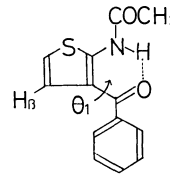
It should be mentioned that in the preceding discussion we assumed that the ring system condensed at 2-C and 3-C of the thiophene ring is in the same plane as the thiophene ring plane in each series of compounds (**1**)—(**4**) (see Part I[1]). On the basis of this assumption, we have defined the torsional angle between the benzene ring plane and the thiophene ring plane as θ (see formula [I]). This assumption should be true for compound (**1**); the thienopyrimidine ring is considered to be flat. However, in compounds (**2**)—(**4**), it seems that the ring system condensed at 2-C and 3-C of the thiophene ring is not completely flat and that the thiophene ring plane is to some extent twisted out of the C–CO–C or C–(C=N)–C plane. Thus in order to discuss the degrees of the torsional angle between the benzene ring plane and the thiophene ring plane in more detail, it is necessary to define the torsional angle more correctly. Let us define the torsional angle between the thiophene ring plane and C–CO–C or C–(C=N)–C plane as θ_1 and the torsional angle between the benzene ring plane and C–CO–C or C–(C=N)–C plane as θ (see formula [VII] as well as formula [I]).



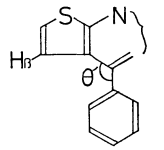
[VII]

In the subsequent discussion, the following point is tacitly assumed. Conformations where the benzene ring and the carbonyl group or imino group are coplanar (maximum π-π overlap) become strongly preferred whenever structurally possible.[17]

In compound (**2**), the thiophene ring plane is considered to be to some extent twisted out of the C–CO–C plane by a steric hindrance between H_β of the thiophene ring and the benzene ring, because the six membered ring by the intramolecular hydrogen bonding may not be so rigid. An analogous steric hindrance was reported in the case of 2-amino-*p*-bromobenzophenone.[13] Thus, there may be some freedom of rotation around C–C bond (expressed as θ_1 in formula [VIII]). Accordingly, in compound (**2**), the torsional angle between the benzene and thiophene ring planes can be expressed as θ_1 plus θ. In compound (**1**), θ_1 (see formula [VII]) is considered to be zero and thus the torsional angle can be expressed as θ (see formula [VII]). From experimental results, we can state that θ_1 plus θ in compound (**2**) is greater than θ in compound (**1**). The reason for this is as follows. Dreiding models of compounds (**1**) and (**2**) indicate that the bond angle C–CO–C or C–(C=N)–C (expressed as θ' in formula



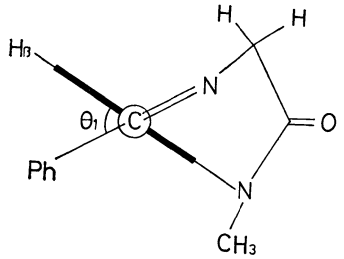
[VIII]



[IX]

[IX]) is a little smaller in compound (**2**). This should cause greater steric hindrance between H_β of the thiophene and benzene rings, thus causing a greater torsional angle between the benzene and thiophene ring planes in compound (**2**) than in compound (**1**).

Compound (**3**) is considered to take a boat form known in benzodiazepines.[14] In this conformation, the thiophene ring plane is considered to be to some extent twisted out of the C–(C=N)–C plane by θ_1 (see formula [X]). Accordingly, the torsional angle



[X]

between the benzene and thiophene ring planes can be expressed as θ_1 plus θ. Experimental results suggest that θ_1 plus θ in compound (**3**) is greater than θ in compound (**1**). Presumably, θ_1 in compound (**3**) may be greater than θ in compound (**1**), and therefore θ_1 plus θ in compound (**3**) is greater than θ in compound (**1**).

Experimental

^{1}H NMR spectra were recorded at 60 MHz on a Hitachi NMR spectrometer R-20-B or 100 MHz on a JNM-4H-100 (Japan Electron Optics Lab.) in dilute deutero chloroform solution (about 10% w/v). The probe temperature was 35 °C. TMS was used as an internal reference standard. The chemical shifts are expressed in δ-values (ppm) downfield from TMS, and were measured directly from the spectra or from a frequency counter with a precision of $\pm$0.01 ppm. The coupling constants, measured by repeated sweeping at an expanded width (60 or 120 Hz), are expressed numerically in Hz with an accuracy of $\pm$0.1 Hz. IR spectra were recorded as Nujol mulls on a Hitachi Infrared Spectrophotometer, EPI-G-3 and are expressed as wave numbers. UV spectra were determined in 95% ethanol with an ultraviolet spectrophotometer, Hitachi-323, being expressed as λ_{max} mμ (ε). Melting points were measured on a Thomas-Hoover melting point apparatus and are uncorrected.

The synthetic procedures for the following compounds were reported in Part I.[1] 4-(*o*-Fluorophenyl)-1-methyl-1,2-dihydrothieno[2,3-*d*]-pyrimidin-2-one (**1aB**). 6-Chloro-4-(*o*-fluorophenyl)-1-methyl-1,2-dihydrothieno[2,3-*d*]-pyrimidin-2-one (**1bB**). 2-Acetamido-3-(*o*-fluorobenzoyl)-thiophene (**2aB**). 2-Acetamido-5-chloro-3-(*o*-fluorobenzoyl)-thiophene (**2bB**). 5-(*o*-Fluorophenyl)-1-methyl-1,3-dihydro-2*H*-thieno[2,3-*e*]-1,4-diazepin-2-one (**3aB**). 7-Chloro-5-(*o*-fluorophenyl)-1-methyl-1,3-dihydro-2*H*-thieno[2,3-*e*]-1,4-diazepin-2-one (**3bB**). 5-(*o*-Fluorophenyl)-1,3-dihydro-2*H*-thieno[2,3-*e*]-1,4-diazepin-2-one (**3cB**). 5-(*o*-Fluorophenyl)-1-methyl-1,3-dihydro-2*H*-thieno[2,3-*e*]-1,4-diazepin-2-one-4-oxide (**4aB**). 7-Chloro-5-(*o*-fluorophenyl)-1-methyl-1,3-dihydro-2*H*-thieno-[2,3-*e*]-1,4-diazepin-2-one-4-oxide (**4bB**).

The other compounds were prepared by the following methods.

*2-Acetamido-3-(o,o'-difluorobenzoyl)-thiophene (**2aI**).* This was prepared from 2-methyl-4*H*-thieno[2,3-*d*][1,3]-oxazin-4-one and *m*-difluorobenzene with *n*-buthyllithium according to the procedure applied to the synthesis of 2-acetamido-5-chloro-2',6'-difluorobenzophenone reported by Lemke *et al.*,[15] Yield 7.4%: mp 129—130 °C (from ether). IR: 3250, 3100, 3050, 1686, 1624. NMR: 2.33 (3H, s, $COCH_3$). UV: 238 (14100), 276 (11700), 346 (9500). Found: C, 55.69; H, 3.26; N, 4.84%. Calcd for $C_{13}H_9NO_2SF_2$: C, 55.51; H, 3.22; N, 4.98%.

2-Amino-3-(o,o'-difluorobenzoyl)-thiophene. (Method: see Part I, Experimental part, Method 1B). Yield 39.9%: mp 128.5—129.5 °C (from IPA). IR: 3350, 3250, 3150, 1620, 1590.

*2-Acetamido-5-chloro-3-(o,o'-difluorobenzoyl)-thiophene (**2bI**).* (Method: see Part I, Method 3). Yield 25.9%: mp 135—137 °C (from *n*-hexane–ether). IR: 3260, 3120, 1697, 1640, 1633. NMR: 2.32 (3H, s, $COCH_3$). UV: 245 (19300), 335 (9400). Found: C, 49.31; H, 2.43; N, 4.20%. Calcd for $C_{13}H_8NO_2SClF_2$: C, 49.46; H, 2.55; N, 4.44%.

4-(o,o'-Difluorophenyl)-1,2-dihydrothieno[3,2-d]-pyrimidin-2-one. (Method: see Part I, Method 4A). Yield 44.4%: It was used to the next step without further purification.

*4-(o,o'-Difluorophenyl)-1-methyl-1,2-dihydrothieno[2,3-d]pyrimidin-2-one (**1aI**).* (Method: see Part 1, Method 4A). Yield 11.6%: mp 212—213 °C (from ether). IR: 3055, 1645. NMR: 3.79 (3H, s, *N*-CH_3). UV: 245 (31300), 347 (5800). Found: C, 56.09; H, 2.90; N, 10.12%. Calcd for $C_{13}H_8N_2OSF_2$: C, 56.11; H, 2.90; N, 10.07%.

*6-Chloro-4-(o,o'-difluorophenyl)-1-methyl-1,2-dihydrothieno[2,3-d]-pyrimidin-2-one (**1bI**).* (Method: see Part 1, Method 5) Yield 22.2%: mp 150.5—151.5 °C (from Ethanol–Ether). IR: 3080, 3050, 1670. NMR: 3.72 (3H, s, *N*-CH_3). UV: 250.5 (28600), 355 (6400). Found: C, 49.94; H, 2.17; N, 8.91%. Calcd for $C_{13}H_7N_2OSClF_2$: C, 49.93; H, 2.66; N, 8.96%.

3-(o,o'-Difluorophenyl)-2-(N-phthalimidoacetyl)-aminothiophene. (Method: see Part I, Method 7B). Yield 73.2%: mp 184—189 °C (from acetone). IR: 3200, 1775, 1620.

3-(o,o'-Difluorophenyl)-2-(N-methyl-N-phthalimidoacetyl)-aminothiophene. (Method: see Part 1, Method 7B). Yield 54.7%: mp 192—193 °C (from acetone). IR: 3110, 3060, 1775, 1715, 1685, 1660, 1615.

*5-(o,o'-Difluorophenyl)-1-methyl-1,3-dihydro-2H-thieno[2,3-e]-1,4-diazepin-2-one (**3aI**).* (Method: see Part I, Method 7B). Yield 54.7%: mp 97.5—99.5 °C (from ether). IR: 3125, 3060, 1701, 1669, 1616. NMR: 3.54 (3H, s, *N*-CH_3), 4.52 (2H, s, CH_2). UV: 240 (22700), 315 (3000). Found: C, 57.50; H, 3.39; N, 9.69%. Calcd for $C_{14}H_{10}N_2OSF_2$: C, 57.53; H, 3.45; N, 9.58%.

2-(N-Acetyl-N-methyl)-amino-3-(o-fluorobenzoyl)-thiophene. (Method: see Part I, Method 4B). Yield 56.9%: mp 94—95 °C (from ether). IR: 3100, 1660, 1640, 1600.

*2-(N-Acetyl-N-methyl)-amino-5-chloro-3-(o-fluorobenzoyl)-thiophene (**2kB**).* (Method: see Part I, Method 3). Yield 71.4%: oil. IR: 1670, 1605. NMR: 1.98 (3H, s, $COCH_3$), 3.13 (3H, s, *N*-CH_3), 6.93 (1H, d, H_β).

*2-Acetamido-3-(o-fluorobenzoyl)-5-nitrothiophene (**2iB**).* This was prepared from 2-acetamido-3-(*o*-fluorobenzoyl)-thiophene (**2aB**) (already reported in Part I) with fuming nitric acid in the presence of acetic acid and acetic anhydride, according to the procedure applied to the synthesis of 2-nitrothiophene.[16] Yield 31.0%: mp 162—164 °C (from ethanol). IR: 3210, 3120, 1691, 1642, 1614. NMR: 2.39 (3H, s, $COCH_3$), 7.79 (1H, d, H_β), 12.12 (1H, s, NH). UV: 247 (15500), 343 (14400). Found: C, 50.35; H, 3.25; N, 8.93%. Calcd for $C_{13}H_9N_2O_4SF$: C, 50.65; H, 2.94; N, 9.09%.

*2-(N-Acetyl-N-methyl)-3-(o-fluorobenzoyl)-5-nitrothiophene (**2jB**).* This was prepared by the same method as that for **2iB** from 2-(*N*-acetyl-*N*-methyl)-amino-3-(*o*-fluorobenzoyl)-thiophene with fuming nitric acid. Yield 75.5%: mp 123—124.5 °C (from ethanol). IR: 3090, 1680, 1665, 1605. NMR: 2.11 (3H, s, $COCH_3$), 3.29 (3H, s, *N*-CH_3), 7.85 (1H, d, H_β). UV: 247 (16000), 323 (7100). Found: C, 52.02; H, 3.43; N, 8.62%. Calcd for $C_{14}H_{11}N_2O_4SF$: C, 52.17; H, 3.44; N, 8.69%.

*5-(o,o'-Difluorophenyl)-1-methyl-1,3-dihydro-2H-thieno[2,3-e]-1,4-diazepin-2-one-3-oxide (**4aI**).* (Method: see Part I, Method 9). Yield 54.9%: mp 104—107 °C (from ethanol). IR: 1682, 1627. NMR: 3.61 (3H, s, CH_3), 4.83 (2H, s, CH_2). UV: 248 (20500), 264 (17700), 310 (6400). Found: C, 54.60; H, 3.33; N, 8.92%. Calcd for $C_{14}H_{10}N_2O_2SF_2$: C, 54.54; H, 3.27; N, 9.09%.

The authors express their deep gratitude to Prof. Masamichi Thuboi, the University of Tokyo, and Dr. Makoto Sunagawa of this laboratory for their guidance and encouragement throughout this work. They are also indepted to Mr. Koichi Moriguchi for the measurement of 100 MHz NMR spectra and to Mr. Hiromi Sato for his co-operation in the synthetic experiments.

CNDO/2 Calculations of the Ionization Potentials and Electronic Spectra of Some Unsaturated Hydrocarbons

Toshio HAYASHI and Takeshi NAKAJIMA

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

(Received July 23, 1974)

A modified CNDO/2 method in which local core matrix elements are taken to be empirical parameters is presented. Using this method, the ionization potentials and electronic spectra of some unsatutated hydrocarbons, ethylene, *trans*-, *cis*-1,3-butadienes, cyclobutene, cyclopentadiene, benzene and naphthalene, were calculated. The results are in general agreement with the previously available experimental information.

SCF MO methods including all valence-shell electrons have already been advanced by many authors.[1] It is, however, known that the traditional SCF calculations in *ab initio* and semiempirical frameworks are not always reliable in reproducing the electronic spectra and the ionization potentials at the same time.

The Complete Neglect of Differential Overlap method (CNDO), which is the simplest one among the SCF methods including all valence-shell electrons, was developed by Pople and his co-workers.[2-4] Although this method is quite successful in predicting ground-state geometries, it is not so useful in calculating electronic spectra and in interpreting ionization potentials through the use of Koopmans' theorem.[5]

In view of these facts, Tinland,[6] Clark,[7-8] and Del-Bene and Jaffé[9-11] have introduced empirical elements into the original CNDO/2 method and have thus obtained results which reproduce well the observed excitation energies. A new parameter set for reproducing ionization potentials has recently been proposed by Ohno *et al.*[13] It should be noted, however, that these modifications do not lead to a good result in predicting both the electronic spectra and the ionization potentials at the same time.

Under these circumstances, we wish now to propose a new parameter set to calculate both the ionization potentials and the electronic spectra within the framework of the CNDO approximation. We will apply this method to some unsaturated hydrocarbons and will compare the predicted electronic spectra with those obtained using the π-electron approximation and the calculated ionization potentials with those of other SCF MO calculations.

Method of Calculation

Tajiri *et al.*[14] and Ohmichi *et al.*[15] have calculated the electronic spectra of a number of saturated and unsaturated compounds using a modified CNDO/2 method which is a compromise between the methods of Bene-Jaffé[9-11] and of Sichel-Whitehead.[12]

Our method differs from the above one in the following points:

1) In the above method, as in the original CNDO/2 scheme, the local core matrix element, $U_{\mu\mu}$, of the atomic orbital, μ, is estimated from the atomic data:

$$U_{\mu\mu} = -\frac{1}{2}(I_\mu + A_\mu) - \left(Z_A - \frac{1}{2}\right)\gamma_{AA}$$

where I_μ and A_μ are the ionization potential and the electron affinity of the appropriate average atomic state respectively and where γ_{AA} is the average interaction energy between two electrons in any valence atomic orbital of the A atom. We consider this matrix element as an additional empirical parameter and adjust its value, together with the selected values of the bonding parameters and the separation constant (*vide infra*), so that a wide range of ionization potentials for ethylene may be reproduced.

2) According to the approximation proposed by Del Bene and Jaffé.[9-11] the core matrix element, $\beta_{\mu\nu}$, between the orbitals, μ and ν, on the A and B atoms respectively is assumed to be proportional to the overlap between them and is given by:[17]

$$\beta_{\mu\nu} = -\frac{1}{2}(\beta_A^\circ + \beta_B^\circ)(S_{\mu\nu}^\sigma + kS_{\mu\nu}^\pi)$$

where β_A° is the bonding parameter, which depends only on the nature of the A atom. $S_{\mu\nu}^\sigma$ is a σ component of the overlap which arises from the projection of the orbitals, μ, and ν, onto the bond axis, and $S_{\mu\nu}^\pi$ is a π component of the overlap which arises from the projections of μ and ν normal to the bond axis. k is the σ-π separation constant. The values of the parameters, $U_{\mu\mu}$, β_A°, and k, adopted in this paper are summarized and compared with those of previous authors in Table 1.

Table 1. Parameter values[a]

Parameter	Method	H	C
U_{ss}	CNDO/2[b]	−17.38	−70.3
	Ohmichi *et al.*[c]	−13.60	−50.69
	This method	−13.60	−42.0
U_{pp}	CNDO/2		−61.8
	Ohmichi *et al.*		−41.53
	This method		−40.0
β_A°	CNDO/2	9	21
	Ohmichi *et al.*	8	15
	This method	9	15
k	Ohmichi *et al.*		0.75
	This method		0.70

a) Values for U_{ss}, U_{pp} and β_A° are in eV units. b) Ref. 2—4. c) Ref. 15.

The molecular geometries used in this calculation were mostly taken from Sutton's tables;[18] the co-ordinates are shown in Fig. 1.

All the calculations were carried out on the NEAC 2200 model 700 computer of TOHOKU University, using the program of our modification of the CNDO/2

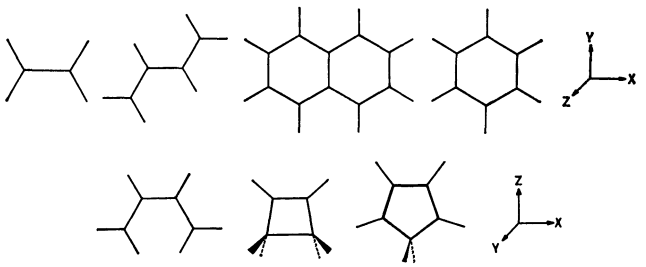

Fig. 1. Co-ordinate systems for calculated molecules.

method, including configuration interactions restricted to the 28 lowest singly excited configurations.

Results and Discussion

In Tables 2—7, the calculated orbital energies are given in comparison with the observed vertical ionization potentials (I.P.'s) and with the other calculated values.

Table 2. Ionization potentials of ethylene (eV)

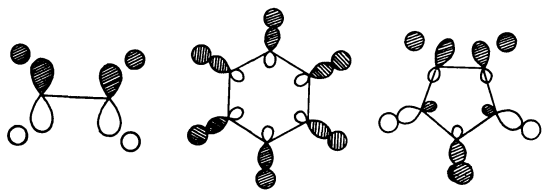
a) T. Darrah Thomas, *J. Chem. Phys.*, **52**, 1373 (1970).
b) The orbital symmetries are not given in Ref. 20.

For ethylene (Table 2) the calculated energy of the lowest occupied orbital with the a_g symmetry is rather closer to the observed value than other calculations. This may be due to the facts that the main contribution to this orbital is by carbon 2s atomic orbitals and that the value of U_{ss} for the carbon atom chosen here is considerably smaller than that used in other methods (see Table 1). Both the present method and the earlier CNDO method by Ohno *et al.*[13] lead to a predicted energy of the b_{2u} orbital larger by about 3 eV than the observed value. It seems that this is due to the large relaxation energy of the ionized state inherent in this orbital. We have actually calculated the relaxation energies of the various ionized states of ethylene using the second-order perturbation method, and have



(a) (b) (c)

Fig. 2. The atomic-orbital arrangement of; a) the b_2-orbital of ethylene predicted at 18.52 eV, b) the a_1-orbital of benzene predicted at 20.50 eV and c) the a_1 orbital of cyclopentadiene predicted at 18.50 eV.

shown that the relaxation energy of this orbital is considerably larger than those of the other orbitals.[24] This is probably related to the atomic-orbital arrangement characteristic of this orbital, shown in Fig. 2; in this orbital, carbon 2p orbitals which are normal to the bond axis and which lie in the molecular plane are mutually bonding: at the same time, they are also bonding with the nearest hydrogen 1s orbitals.

a) Taken from the He I spectrum by Brundle and Robin (Ref. 22)

Table 3 shows that the first three bands of *trans*-1,3-butadiene are attributed to the π, σ, and π electrons, in the order of increasing energy. This interpretation differs from those of the earlier SCF MO calculations, but is consistent with the analysis of Brundle and Robin, who observed that the second ionization potential should be attributed to the σ electron because it suffers a large shift to a higher energy on fluorination (the perfluoro-effect).[22] Indeed, using the present method, we found that the second highest orbital with the symmetry, a_g, of *trans*-1,3-butadiene shifts to a

a) The bond lengths and the bond angles except the dihedral angle were assumed to be those of *trans*-1,3-butadiene. b) The geometry was assumed to be (in Å unit); C_1, C_4 (± 0.77, -1.5167); C_2, C_3 (± 0.67, 0); H_1, H_2, H_5, H_6 (± 1.2463, -1.7917, ± 0.9526); H_3, H_4, (± 1.22, 0.9526).

lower energy on fluorination,[25] while the first and third highest orbitals suffer no substantial change.

In Table 4, the results for *cis*-1,3-butadiene and cyclobutene, which are isomers of *trans*-1,3-butadiene, are given. The first I.P. of the *trans*-1,3-butadiene obtained is higher by about 0.04 eV than that of its planar *cis* form. This result is in agreement with that of the *ab initio* calculation by Buenker,[23] while the calculations of the MINDO and the π-electron approximation[26] show that the first I.P. of the *cis* form is higher by 0.03 eV than that of the *trans* form. The first two I.P.'s of cyclobutene obtained are attributed to the π and σ electrons, in good agreement with the experimental results.[27]

TABLE 5. IONIZATION POTENTIALS OF BENZENE (eV)

Obsd[29]	Orbital	This work	CNDO[13]	CNDO[7]	*ab initio*[31]
9.3π	e_{1g}	9.41π	9.77π	9.40π	10.31π
11.4	e_{2g}	11.34	11.48	9.79	14.30
12.1π	a_{2u}	13.93π	12.55π	12.99π	14.64π
13.8	e_{1u}	13.95	14.68	13.81	17.04
14.7	b_{2u}	14.79	15.30	14.26	17.96
15.4	b_{1u}	15.27	16.34	15.15	18.33
16.9	a_{1g}	20.50	20.93	19.64	20.16
19.2	e_{2g}	20.77	22.50	20.10	23.09
	e_{1u}	25.21	28.18	24.81	28.38
	a_{1g}	33.14	35.74	31.18	31.94

In Table 5, the calculated results of benzene are given, together with those of the photoelectron spectra which were studied and discussed by Lindholm and Jonsson;[29] also given are the results obtained from the viewpoint of the angular distribution by Carlson and Anderson.[30] The calculated order of orbitals is in general agreement with the experimental results, but the energies of the two levels are predicted to be rather larger than the observed values. One is the lower nondegenerate π orbital with the symmetry, a_{2u}, predicted at 13.93 eV, while the other is the a_{1g} orbital predicted at 20.50 eV, which is larger by about 3 eV than the experimental value. In case of the a_{1g} orbital, the disagreement may be related to the fact that the atomic-orbital arrangement of this orbital resembles that of the b_{2u} orbital of ethylene, for which the predicted I.P. is larger by 3 eV than the observed one (see Fig. 2).

TABLE 6. IONIZATION POTENTIALS OF CYCLOPENTADIENE (eV)

Obsd[32]	Orbital	This work	SPINDO[33]	EH[32]
8.57	a_2	8.77π	9.20π	12.6π

12.2	a_1	11.63	12.24	13.5
12.6	b_2	12.05	12.38	13.8
13.2	b_2	12.81	13.30	14.0
13.8	a_1	13.21	12.87	13.9
14.8	b_1	16.85π	14.54π	15.6π
16.4	a_1	18.50	16.55	16.4
17.5	b_2	18.63	16.98	17.5
18.4	a_1	19.44	17.75	18.1
22.0	b_2	23.29	22.03	22.5
22.3	a_1	24.28	21.51	22.3
	a_1	33.85	26.17	26.5

As is shown in Table 6, the present results for cyclopentadiene are in good agreement with the values of the photoelectron spectra observed by Derrick *et al.*[32] and by Fridh *et al.*,[33] and also with those of the SPINDO calculation by Fridh *et al.*[33] except for the orbital symmetries of the two levels, which are found experimentally at 13.2 and 13.8 eV. The lowest π-orbital (b_1) predicted at 16.85 eV should correspond to the band observed at 14.8 eV, since, in our method, the energy of the lowest π-orbital is usually calculated to be larger by about 2 eV than the observed one. Furthermore, considering that the calculated energies for the b_{2u} orbital of ethylene and the a_{1g} orbital of benzene are higher by about 3 eV than the observed values, the a_1 orbital predicted at 18.50 eV may be assigned to the observed band at 16.4 eV, since this orbital includes the part resembling the b_{2u} orbital of ethylene (see Fig. 2).

The photoelectron spectra of naphthalene are more complicated, and the assignment of the higher I.P.'s is considerably difficult. From the discussion for the lowest π orbitals in benzene and cyclopentadiene, it seems that the lowest π orbital with the symmetry, b_{1u}, of naphthalene corresponds to the band at about 13 eV (Table 7).

TABLE 7. IONIZATION POTENTIALS OF NAPHTHALENE (eV)

with the observed ones. It may be noted here that the first two excited states of ethylene calculated are attributed to σ-π^* transitions, whereas the first excited state was observed as the Rydberg state by Willkinson.[36] If an extended basis set is used, then the Rydberg state might be calculated as the first excited state.

In our calculations, the triplet states are generally found to be lower by 0.5—1.0 eV than the experimental values. This point will not be discussed here.

In the following papers we will apply this method to the calculation of the electronic spectra and the ionization potentials of the unsaturated compounds containing O, N, and F atoms.

Photochemistry in the Adsorbed Layer. III. Photolysis of Acetone Adsorbed on Porous Vycor Glass

Masakazu ANPO, Sōzi HIROHASHI, and Yutaka KUBOKAWA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Mozu-Umemachi, Sakai, Osaka 591

(Received September 9, 1974)

Photolyses of acetone adsorbed showed that the ratio of ethane to methane in the products as well as the kinetic isotope effect for the methane formation is much smaller than that in the gas phase photolysis. The methane formed from acetone-d_6 contains a considerable amount of CD_3H. Ethane formation is quenched more efficiently by nitric oxide than methane formation. It is proposed that there are two types of methyl radicals, *i.e.*, long- and short-lived ones, the ethane resulting from the long-lived radicals. The results suggest that methane arises from hydrogen abstraction from surface OH groups as well as disproportionation reaction $CH_3+CH_3CO \longrightarrow CH_4+CH_2CO$, in addition to hydrogen abstraction from acetone molecules.

Studies were carried out on the photochemistry of alkyl ketones adsorbed on porous Vycor glass, general characteristics of the photochemistry in the adsorbed layer being found.[1] In the case of 2-pentanone the photolysis was seriously affected by the surface OH groups. The studies are concerned mainly with 2-pentanone and methyl ethyl ketone and very little with acetone. In the present work a detailed study has been made of acetone photolysis. We carried out nitric oxide quenching as well as isotopic studies in order to obtain information on the nature of the methane and ethane formation processes. The role of surface OH groups in the photolysis has been clarified by the study of acetone-d_6 photolysis.

Experimental

A conventional vacuum system was used in conjunction with a special quartz cell for studying the spectra and photolysis in the adsorbed layer. The specimen of porous Vycor glass (Corning, No. 7930) which had been heated in oxygen to remove carbonaceous impurities was placed inside the cell and degassed at 500 °C for 7 hr. After acetone had been adsorbed on the specimen at room temperature, photolysis was carried out with an ultra high pressure mercury lamp without filter. Prior to this, a small amount of acetone remaining in the gas phase was removed by means of a liquid nitrogen trap. When photolysis was completed, the reaction products were desorbed together with unreacted acetone and analyzed by gas chromatography. The BET surface area of the adsorbent was found to be 160 m^2/g. The amount of adsorbed acetone of 1.0 cm^3/g corresponded to $\theta=0.05$ using 25 A^2 as the area occupied by each molecule.

Acetone (Tokyo Kasei Kogyo Co., Ltd., Grade SG. 99.5 mol%) was dried by well-degassed molecular seive 4A and purified by bulb to bulb distillation. Acetone-d_6 of 99.5 mol% isotopic purity (E. Merck, Darmstadt.) was used without further purification.

Isotopic analysis of the deuterated methane was carried out with a Shimadzu MASPEQ-070 mass spectrometer using low-voltage electron (10—20 eV) in just sufficient amount to produce the ion of the parent mass. The CD_4/CD_3H ratio was determined by measurement of the parent peaks at $m/e=19$ [CD_3H^+] and $m/e=20$ [CD_4^+].

Results

1) Products of Acetone Photolysis in the Adsorbed Layer. The rates of methane and ethane formation plotted against the amount of acetone adsorbed are given in Fig. 1. It is seen that methane formation increases with an increase in the amount of acetone adsorbed. Ethane formation appears to level off to a constant value. The ratio of the amount of methane to that of ethane ranged from 0.6 to 4.3, being larger than the corresponding value in the gas phase photolysis.[2] Our results with acetone-d_6 photolysis (25 °C, 5.05 Torr) showed this ratio to be 0.067. This suggests that the recombination of methyl radicals was suppressed and their hydrogen abstraction reaction enhanced in the adsorbed layer. A slight formation of carbon monoxide as well as greatly reduced efficiency of photolysis compared to the gas phase are other features of acetone photolysis in the adsorbed layer.

2) Isotopic Analysis of the Methane Formed. The CD_3H content of methane formed by the photolysis of acetone-d_6 adsorbed is shown in Fig. 2. A large frac-

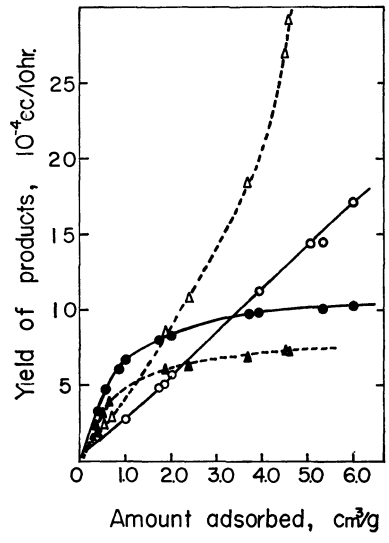

Fig. 1. Yield of products from the acetone photolysis. Irradiation time, 10 hr.; Temperature, 25 °C; △: methane, ▲: ethane (acetone), ○: methane, ●: ethane (acetone-d_6).

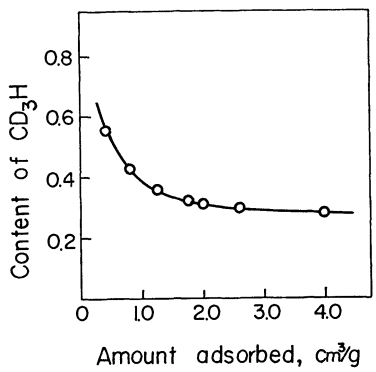

Fig. 2. The CD_3H content of the methane formed from the photolysis of acetone-d_6.

tion of the methane consists of CD_3H, decreasing with increasing amount of acetone-d_6 adsorbed. It appears that light hydrogen in the methane comes from the surface OH groups. The hydrogen atom abstraction reaction from the surface OH groups by methyl radicals, *i.e.*, $CD_3+[Si-OH]\rightarrow CD_3H+[Si-O]$, should be mentioned as the most probable process. Its activation energy is less than 9 kcal/mol,[3] being smaller than the corresponding value for the hydrogen atom abstraction from acetone molecules.[4] Thus, the hydrogen atom abstraction from the OH groups is expected to occur more easily. There is some possibility that light hydrogen atom is transferred according to the following steps:

$$CD_3COCD_3 + [Si-OH] \longrightarrow CD_2HCOCD_3 + [Si-OD] \text{ (Exchange Reaction)},$$

$$CD_2HCOCD_3 + h\nu \longrightarrow \dot{C}D_2H + CD_3\dot{C}O,$$

$$\dot{C}D_2H + CD_3COCD_3 \longrightarrow CD_3H + \dot{C}D_2COCD_3.$$

However, this could be excluded since the exchange reaction was found to be slow even under irradiation.[5] The occurrence of hydrogen atom abstraction from the surface OH groups suggests that porous Vycor glass should be regarded not only as an adsorbent but also as a photochemical reactant in the adsorbed layer.

3) Kinetic Isotope Effects for Methane Formation. In order to clarify the nature of the methane formation, the primary kinetic isotope effect for the photolysis of acetone adsorbed was investigated. The values of $R_{methane}/\sqrt{R_{ethane}}=A$[6] are plotted against the amounts of acetone adsorbed (Fig. 3). Marked isotope effects can hardly be expected for the recombination of methyl radicals in the adsorbed layer, suggesting that the observed isotope effects are attributable to the methane formation reaction. The difference in A values is negligibly small at very small amounts adsorbed, but increases with increasing amount adsorbed, the ratio k_H/k_D approaching 3~4. It has been reported that the ratio k_H/k_D for the hydrogen atom abstraction reaction from acetone molecules by methyl radical in the gas phase is more than 10,[7] which is much larger than the corresponding value in the adsorbed layer. This indicates that in the photolysis of acetone adsorbed the mechanism of methane formation differs from that in the gas phase. It appears that hydrogen atom abstraction from acetone molecules is not the main reaction leading to methane formation especially in the range of small amounts of acetone adsorbed.

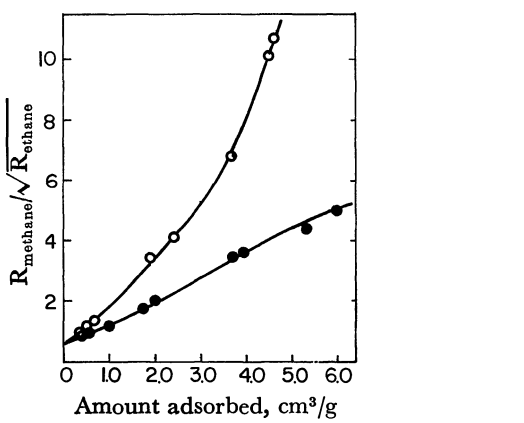

Fig. 3. The primary kinetic isotope effects for the photolysis of acetone adsorbed.

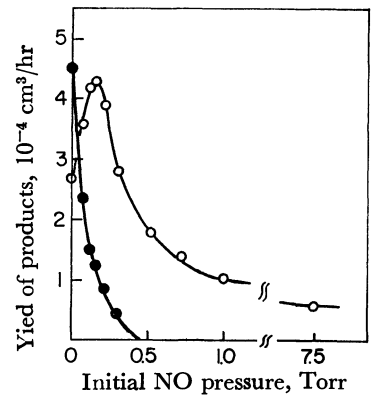

Fig. 4. Effect of nitric oxide upon the photolysis of acetone.
Amount of acetone-d_6 adsorbed, 1.91 cm³ S.T.P./g.
○: methane, ●: ethane.

4) Effect of Nitric Oxide upon Photolysis. Figure 4 shows the change in the rate of methane and ethane formation caused by added nitric oxide. The rate of ethane formation approaches zero with increasing pressure of nitric oxide, while the rate of methane formation increases at first, passes through a maximum and then decreases. Apart from a rate maximum observed in methane formation the rate decrease caused by added nitric oxide is attributable to its scavenging action of methyl radicals.[8] The pressure range in which the rate decreases is higher for methane formation than for ethane formation, suggesting that different types of

Table 1. Effect of nitric oxide upon the content of CD_3H

0.80	22.0
1.00	20.5

Amount of acetone-d_6 adsorbed, 1.91 cm³ S.T.P./g.

methyl radicals are operative in both formations. It was found that the CD_3H content in the methane formed decreased with increasing pressure of nitric oxide (Table 1).

Discussion

The following interpretation might be given as regards the two types of methyl radicals. Geminate radical pairs are held in a fixed position for a relatively long time before they separate from each other. The methyl radicals present in such radical pairs would be short-lived because of an efficient radical recombination leading to acetone formation. This primary recombination has been discussed in solution phase photochemistry. Leermakers *et al.*[9] postulated the occurrence of such phenomena in the adsorbed layer. Under such circumstances, a disproportionation reaction such as $CD_3+CD_3CO\rightarrow CD_4+CD_2CO$ would be expected to occur in addition to the recombination reaction. Such a reaction has been reported to take place to a small extent in gas[2] and solution phase[10] photolyses of acetone. The small kinetic isotope effect in methane formation (Fig. 3) suggests that methane is formed *via* a process having a small activation energy such as disproportionation of radicals. A small amount of ketene was found by mass spectroscopy in the reaction products, supporting the above conclusion. Methane formation is expected to be quenched less efficiently than reactions originated from other types of methyl radicals described below.

A methyl radical separated from its partner radical would be long-lived since it is sensitive to quenching by nitric oxide. Such methyl radicals would react in two ways, recombination to from ethane and hydrogen abstraction from acetone molecules. In cases where the abstraction reaction is the sole methane source, the rate of methane formation is expected to be larger for undeuterated acetone than for acetone-d_6 owing to its lower activation energy. As a result the rate of ethane formation will be larger for acetone-d_6. Such a behavior has been observed in the range of the amounts of acetone adsorbed above 1.0 cm^3/g (Fig. 1).

Hydrogen abstraction from the surface OH groups would be associated with both types of methyl radicals, since on addition of nitric oxide there is no marked change in the CD_3H content of the methane formed, its value decreasing from 35 to 20%.

The contribution of the three processes to the overall methane formation varies with the amount of acetone adsorbed. The contribution of hydrogen abstraction from the surface OH groups decreases with increasing amount of acetone-d_6 adsorbed (Fig. 2). Some information on the contribution of the disproportionation reaction to the overall methane formation would be obtained from the isotope effects in the formation reaction, since little or no isotope effect is expected for the disproportionation reaction as well as the hydrogen abstraction from surface OH groups in contrast with the large isotope effect for hydrogen abstraction from acetone molecules. From the marked change in isotope effects with the amount of acetone adsorbed (Fig. 3), it is concluded that below the amount adsorbed of 0.3 cm^3/g little or no hydrogen abstraction from acetone molecules takes place. Most of the CD_4 results from the disproportionation reaction, while above the amount adsorbed of 3.0 cm^3/g the predominant process in the CD_4 formation may be the hydrogen abstraction from acetone molecules.

The Viscosity of Gaseous Sulfur Dioxide

Hiroji IWASAKI and Mitsuo TAKAHASHI

The Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira, Sendai 980

(Received September 19, 1974)

The viscosity of sulfur dioxide was measured in the range from 25 to 160 °C over the pressure range from 1 atm to near the saturation pressure at 25—150 °C and up to 80 atm at 160 °C by means of the oscillating-disk method. The accuracy of the measurement is, at worst, ±0.25%, except that the accuracy is ±0.3% for the range above 66 atm at 160 °C. It is found that, at temperatures from 25 to 75 °C, the viscosity of sulfur dioxide shows a steady decrease with the pressure (or density) and that at 100 and 125 °C it passes through a minimum. On the contrary, the isotherms at 150 and 160 °C show a steady increase with the pressure (or density). The data were fitted to the polynomials of the density at each temperature investigated. The coefficient of the first-order density term in the equation, which indicates the degree of the initial density dependence, changes its sign from negative to positive at a temperature of about 135 °C.

The present paper continues the work on the experimental determination of the viscosity of polar gases and constitutes a sequel to our paper on ammonia.[1] Investigations of the effect of the pressure on the viscosity of sulfur dioxide have been made by several investigators,[2-4] but the results have not indicated any definite relation between the viscosity of sulfur dioxide and the pressure (or density). Therefore, the measurements of the viscosity of sulfur dioxide were undertaken in the range from 25 to 160 °C over the pressure range from 1 atm to near the saturation pressure at 25—150 °C and up to 80 atm at 160 °C.

a) Suspension wire used for 50 °C is different from that used for other temperatures.

Experimental

Measurements were made by the Maxwell-type oscillating-disk method. The apparatus as well as the experimental procedures was identical with those described in Ref. 1 and so need not be repeated here.

The characteristics of the suspension system are recorded in Table 1.

Materials. The sulfur dioxide was obtained from the Showa Denko Co., which reported a purity of about 99.9%. It was purified and dried by several distillations, with a generous rejection of the head and tail fractions, and finally by distillation through phosphorus pentoxide tubes.

Evaluation of Results

The results of measurements were evaluated with the aid of Newell's theory in a manner similar to, but not quite identical with, that used in Ref. 1. In this experiment, the evaluations were made by means of Eqs. (1) and (2), not by Eq. (4) as in Ref. 1. This was because the neglect of the terms containing a, f, and h in Eq. (2) in Ref. 1 was found to cause a discrepancy over 0.3% in the results evaluated by Eqs. (1) and (2) in Ref. 1 in the high-density region at temperatures over 125 °C.

It was confirmed that the present measurements satisfactorily fulfill the conditions under which Eqs. (1) and (2) in Ref. 1 will yield the required accuracy

24.917	0.052812	30.200	3.4803	186.00	0.1300	3.358
34.909	0.079639	30.342	3.5492	188.95	0.1067	2.756
43.707	0.10884	30.298	3.6268	193.53	0.0924	2.386
53.640	0.14859	30.384	3.7875	201.77	0.0807	2.085
60.677	0.18891	30.468	4.0019	212.86	0.0735	1.900
67.291	0.25354	30.533	4.4360	235.93	0.0668	1.726

of 0.1%. For example, the experimental results at 150 °C are shown in Table 2. All of the δ/b values were larger than 1.25.

The apparatus constant, C_N, was determined experimentally using air and nitrogen at 1 atm and 25 °C respectively. The values of C_N obtained by the two methods showed a good agreement, the discrepancy being only 0.04%.

The mean value of

$$C_N = 1.13124$$

was adopted for further calculation. However, for the measurement at 50 °C the suspension wire was different from that for the other temperatures and the check measurements of the instrument constant, C_N, were made following the method described above. The following value was obtained, showing a very slight discrepancy from the above value, and was used for the calculation at 50 °C:

$$C_N = 1.12881.$$

The accuracy of the present experiments is at worst ±0.25%, considering the uncertainty in the determination of Δ and T, and other sources of error, except that the accuracy is ±0.3% for the range above 66 atm at 160 °C for a reason to be described later.

Results and Discussion

The experimental results are presented in Table 3 and in Figs. 1 and 2. The density of sulfur dioxide was calculated using the compressibility data given by Kang *et al.*[5]

The densities marked * in Table 3 have an uncertainty of 10% at most, because of the difficulty of the estimation by the interpolation of the P–V–T data given by Kang *et al.*, the region being near the critical state. Therefore, the viscosity data in this range were

excluded from the viscosity *vs.* density curves (Fig. 2).

In order to assess the extent of the deviations in viscosity values resulting from the uncertainty in the density, it will be necessary to refer to the effect of the density on the calculation of the viscosity using Eqs. (1) and (2) in Ref. 1. The density of the gas appears in the final, working equation (1) in Ref. 1. However, for this purpose the value of the density need not be known extremely accurately, because it affects the value of β^2 taken from Eq. (2) in Ref. 1 approximately proportionately, thus nearly cancelling the direct effect upon the viscosity, η, in Eq. (1). A test calculation was performed for the range of pressures higher than 66 atm at 160 °C in the case of the densities increased by 5% and then by 10% of those listed in Table 3. The results are recorded in Table 4. Thus, considering the uncertainty of the density, the accuracy of the viscosity in the range discussed above is assumed to be better than ±0.3%.

The diagram in Fig. 1 represents the variation in the viscosity of sulfur dioxide with the pressure for the given temperatures. The viscosity of sulfur dioxide shows a steady decrease with the pressure at the temperatures from 25 to 75 °C. The viscosities at 100 and 125 °C pass through a minimum. On the contrary, the isotherms at 150 and 160 °C show a steady increase with the pressure; $(\delta\eta/\delta T)_P>0$ at low pressures and $(\delta\eta/\delta T)_P<0$ at high pressures.

The diagram in Fig. 2 representing the variation in the viscosity of sulfur dioxide with the density is similar to that in Fig. 1, but $(\delta\eta/\delta T)_\rho>0$ under the present experimental conditions.

Figures 1 and 2 show that the initial pressure (or density) dependency of the viscosity of sulfur dioxide changes its sign from negative to positive as the temperature increases. This relation can be clarified by representing the viscosity of sulfur dioxide in the polynomials of density as follows:

$$\eta = \eta_0 + b\rho + c\rho^2 + d\rho^3. \quad (1)$$

The constants of Eq. (1), η_0, b, c, and d, were evaluated using the measured values of the viscosity at each temperature; they are recorded in Table 5. These equations reproduce the measured values with a deviation not exceeding ±0.1% except for the several measured values in the high-pressure region at 150 °C, which were also reproduced within the limits of experimental error. The initial density dependence of the viscosity of sulfur dioxide, b, and the viscosity at zero density, η_0, are both given against the temperature in Fig. 3. This figure shows that the relation between the

●, Trautz and Weizel[6]; △, Titani[7]; ◑, Trautz and Winterkorn[8]; ■, Chakraborti and Gray[9]; □, Pal and Barua[10]; ▲, Stewart and Maass[11]; ○, present work.

initial density dependence and the temperature is linear and changes its sign from negative to positive at about 135 °C, and that the relation between the viscosity at zero density and the temperature is also linear.

The measurements of the viscosity of sulfur dioxide at high densities were performed by Awbery and Griffiths[2] for the liquid region, by Shimotake and Thodos[3] at 200 °C, and by Stakelbeck.[4] The measurements by Stakelbeck were performed not only for the liquid region but also for the gaseous region up to 40 °C, using the falling-body method, and so can be compared directly. However, his data indicate a rapid increase in the viscosity with an increase in the pressure, in disagreement with the present measurements.

In Fig. 4, the relation between the viscosity of sulfur dioxide at 1 atm and the temperature is given. Here, the data given by other investigators[6-11] are limited to those obtained in the same temperature range as that of the present measurement, thus making it possible to compare directly.

The data plotted show a good agreement within 1% among all the investigators, except that the value at 25 °C by Chakraborti and Gray[9] and those by Pal and Barua[10] show a large discrepancy.

Dielectric Relaxation and Molecular Structure. XIII. The Dielectric Behavior of Mixtures of 1-Propanol with Hydrogen-bonding and Non-hydrogen-bonding Solvents

Taro KOSHII, Hiroaki TAKAHASHI, and Keniti HIGASI
Department of Chemistry, Waseda University, Shinjuku, Tokyo 160
(Received September 26, 1974)

The dielectric constants and losses of 1-propanol and its mixtures with benzene, chlorobenzene, 1,4-dioxane, and pyridine have been measured in the frequency range of 1—0.35 GHz in the temperature range of 10—40 °C. The concentrations of the mixture lie between 1—0.6 mol fractions of the alcohol. The dielectric relaxations of the observed systems in the above frequency range are all of the Debye type. The measured data were used to calculate the activation enthalpy, ΔH^*, and the entropy, ΔS^*. The dependence of ΔH^* and ΔS^* upon the concentration differs with the nature of the solvent. Both ΔH^* and ΔS^* decrease upon the addition of a hydrogen-bonding solvent, while they increase slightly upon the addition of a non-hydrogen-bonding solvent. The mechanism of the principal relaxation of 1-propanol is discussed on the basis of these observations.

Since Mizushima[1] made his classic study of alcohols, the dielectric properties of mono-alcohols have been extensively investigated by a number of workers using a wide range of both frequencies and temperatures. The dielectric dispersions of primary aliphatic alcohols in the liquid state are now known to have three different absorptions.[2] The most important of these absorptions is the principal Debye-type dispersion on the low-frequency side; it is regrettable, however, that we have still no reliable explanation for the true mechanism of this principal dispersion.

The activation enthalpy, ΔH^*, and the entropy, ΔS^*, have been well studied for liquid alcohols,[3,4] but seldom for solutions except for those in non-polar solvents.[5,6]

In the preceding papers,[7,8] dielectric measurements at 25 °C were described. In this report, we shall deal with the dielectric measurements of 1-propanol in the same set of solvents (benzene, chlorobenzene, 1,4-dioxane, and pyridine) and in the same frequency range at four or three temperatures; we shall also discuss the ΔH^* and ΔS^* derived therefrom. Emphasis will be placed upon the solvent interactions of the alcohol with hydrogen-bonding solvents.

Experimental

The experimental materials were purified as described previously.[7] The dielectric constants and losses were measured by the use of a UHF apparatus of the coaxial-slotted-line type, the details of which were given in a preceding report.[7] The relaxation time, τ, and the limiting low- and high-frequency dielectric constants, ε_0 and ε_∞ respectively, were calculated from the Debye equation (1):

$$\varepsilon' - j\varepsilon'' = \varepsilon_\infty + \frac{\varepsilon_0 - \varepsilon_\infty}{1 + j\omega\tau} \qquad (1)$$

by an iterative method using an electronic computer. In order to determine the activation enthalpy, ΔH^*, and the entropy, ΔS^*, from the temperature dependence of the relaxation time, τ, $\log_{10}(\tau T)$ was plotted against $1/T$ using Eq. (2)[9]:

$$\tau = \frac{h}{kT} \exp\left(\frac{\Delta H^* - T\Delta S^*}{RT}\right) \qquad (2)$$

where h, k, and R are the Planck, the Boltzmann, and the gas constants respectively, and where T is the absolute temperature. A straight line fitting best with the points was obtained by the use of the least-square method. ΔH^* was obtained from the slope of this line, and ΔS^*, from its intercepts with the $\log_{10}(\tau T)$ axis.

Results

The Cole-Cole plots[10] for 1-propanol mixtures with benzene and pyridine are shown in Fig. 1. It may be seen that almost all the measured points lie exactly on the Debye semicircles; hence, they can be considered to be associated with the principal dispersions of the alcohols.[7]

The low- and the high-frequency intercepts of the Debye semicircle with the ε' axis, ε_0 and ε_∞, are compared with the static dielectric constants, ε_0, and the square of refractive indices, n^2 (for the H_α-line) in the literature respectively, in Tables 1 and 2. The low-frequency intercepts, ε_0, obtained in this work are in fair agreement with the real static dielectric constants, ε_0 (Table 1), while the high-frequency intercepts, ε_∞, are much larger than the squares of the refractive indices, n^2 (Table 2). The appreciable differences, $\varepsilon_\infty - n^2$, are due to the existence of minor dispersions of alcohols in the higher-frequency range.[2] In Fig. 1(a), we find that the limiting high-frequency dielectric constants, ε_∞, remain almost constant with an increase in

TABLE 1. LIMITING LOW FREQUENCY DIELECTRIC CONSTANTS ε_0 OF LIQUID 1-PROPANOL

Temp. (°C)	ε_0 (This work)	ε_0 (Literatures)			
10.0	21.0±0.2	(22.2)[11]	(22.6)[12]	(22.8)[13]	
20.0	20.9±0.5	20.8[11]	21.1[12]	(21.2)[13]	21.3[3]
30.0	19.6±0.2	19.4[11]	(19.8)[12]	19.7[13]	
40.0	18.9±0.3	18.2[11]	18.5[12]	18.4[13]	

The values in parentheses were obtained from the literature by inter- or extrapolation of values given at different temperatures.

Table 3. Relaxation times τ ($\times 10^{-2}$ ps) of liquid 1-propanol

Temp. (°C)	τ (This work)	τ (Literatures)	
10.0	5.7±0.2	(6.50)[12]	
20.0	4.1±0.3	4.30[12]	5.31[3]
30.0	2.8±0.2	(3.34)[12]	
40.0	2.0±0.2	2.86[12]	

Regarding the values in parentheses see the note below Table 1.

the amount of non-polar solvent (benzene), while in Fig. 1(b) they increase considerably with an increase in the polar solvent (pyridine). The difference in the latter parallels the amount of pyridine added and must be due largely to the main dispersion of pyridine* in the high-frequency region.[11]

The dependence of the dielectric relaxation time, τ, upon the concentration is examined in Fig. 2. The relaxation times, τ, decrease gradually and linearly in mixtures with benzene (a), while they decrease sharply in mixtures with pyridine (b), the curves becoming concave in the latter mixtures. The dependence of the relaxation time upon the concentration in mixtures with chlorobenzene (●) seems to coincide with that in mixtures with benzene (○), while the points for mixtures with 1,4-dioxane (▲) lie on the curves for mixtures with pyridine (△).

The principal relaxation times, τ, of liquid 1-propanol are recorded in Table 3, together with those obtained by other workers. The disagreement with the literature[12] values might be due to the difference in the frequency ranges; the frequency range of this study is higher than in most of the works concerned.

Some representative plots of $\log_{10}(\tau T)$ against $1/T$ are shown in Fig. 3. The ΔH^* and ΔS^* values obtained are plotted against the concentration of the alcohol in Fig. 4. For liquid 1-propanol, ΔH^* is obtained as 5.5 kcal/mol, which compares well with the literature values of 5.0,[12] 5.3,[3] 5.4,[5] 5.5[4] kcal/mol, while the ΔS^* of the present work, 1.7 e.u., lies between the values of 1.2[12] and 2.1[3]—3.0[5] e.u. of the other workers.

B., ⊕ indicates limits of assessed accuracy of measurement.

Discussion

The activation enthalpies, ΔH^*, and the entropies, ΔS^*, obtained in the present experiment are plotted against the concentration of propyl alcohol, in Fig. 4. We find that both ΔH^* and ΔS^* increase slightly upon

the addition of benzene or chlorobenzene. On the contrary, though, these two parameters decrease rapidly with the amount of hydrogen-bonding solvent; moreover, the decrease upon dilution with pyridine is more pronounced than that with 1,4-dioxane.

Polar chlorobenzene ($\mu=1.7$ D) has a high dielectric constant ($\varepsilon_0=5.62$), while non-polar benzene has a low dielectric constant ($\varepsilon_0=2.27$). 1,4-Dioxane is similar to benzene in having a low dielectric constant ($\varepsilon_0=2.21$) and a low polarity ($\mu=0$—0.4 D), while pyridine has $\varepsilon_0=12.3$ and $\mu=2.25$ D. It is evident at a glance at Fig. 4 that neither the static dielectric constant nor the polarity of the solvent play any important role in the relaxation processes.

The size of the solvent relative to that of the alcohol will be considered next. Since the molar volumes of benzene (M.V.=89) and chlorobenzene (M.V.=102) are larger than that of 1-propanol (M.V.=75), a larger size of the solvent might be expected to increase these parameters.[5,6] However, this expectation is not supported here; the two hydrogen-bonding solvents also have larger molar volumes than 1-propanol—*i.e.*, 1,4-dioxane has M.V.=85 and pyridine M.V.=81. The size of the solvent relative to that of the alcohol is, thus, not an important factor in the observed relaxation processes.

Changes in the ΔH^* on the addition of non-polar solvents have been well studied. For a number of normal alcohols (methanol, ethanol, 1-propanol, 1-butanol, and 1-heptanol), Gemert *et al.*[5] found that ΔH^* becomes higher on the addition of non-polar, inert solvents (benzene, carbon tetrachloride, cyclohexane, and hexane); their finding on a benzene solution for propyl alcohol is in good agreement with the present observation. A similar increase in the ΔH^* on dilution with cyclohexane was observed,[6] while decreases on dilution with non-polar solvents have also been reported and discussed.[15–17]

Recently, the dielectric properties of solutions of water in straight-chain heptanols were studied by Tjia,[18] who concluded that the relaxation times of these alcohols decrease upon an addition of a small amount of water and that the energy of activation also decreases with an increase in the quantity of water added—the latter statement was definitely proved for both heptanol-2 and heptanol-4. His observation seems to be parallel with our results for propanol mixtures with hydrogen-bonding solvents.

In order to explain why the principal dielectric relaxation of mono-alcohols is of a pure Debye type, Brot,[19,20] and Bauer and Magat[21] introduced a hypothesis that hydrogen-bond breaking is the controlling step in this relaxation and that the activation energy for the principal lower-frequency relaxation must be identical with the energy necessary to break the hydrogen bond.

The so-called switch-over mechanism was introduced by Sagal,[6] who stated: "The hydrogen bond will break when another molecule approaches with its oxygen atom oriented favorably for a switch. It is reasonable to assume that the presence of this third oxygen atom will lower the energy barrier for breaking the hydrogen bond." According to this assumption, the addition of a non-hydrogen-bonding solvent (benzene or chlorobenzene) to alcohols would increase the energy necessary to break the hydrogen bond, because it would decrease the possibility of the approach of a third oxygen atom for a switch over. Contrary to this, the addition of a strongly hydrogen-bonding solvent (1,4-dioxane or pyridine) would provide a new possibility of a switch over to the electronegative atom of the solvent; hence, this would help lower the energy of activation. Sagal's mechanism seems to agree partially with the observations of this work. Furthermore, we note that the variations in ΔH^* and ΔS^* with the two different kinds of solvents are all in the same direction with those of the g factors and the reduced relaxation times, τ/η.[8] However, we shall have to refrain from discussing the possible mechanism in detail since we do not have sufficient evidence at present.

We wish to thank the Science and Engineering Research Laboratory, Waseda University, for its financial aid.

Adsorption of Neutral Organic Substances Evaluated from Electrocapillary Curves and Double Layer Capacities

Katsumi NIKI

Department of Electrochemistry, Yokohama National University, Ohoka, Minami-ku, Yokohama 233

(Received November 30, 1974)

Adsorption of neutral organic substances on mercury electrode was evaluated from both electrocapillary curves and differential capacities of the double layer. The results were compared for the adsorption of *n*-aliphatic alcohols, phenol, and *o*-cresol in 0.5 M H_2SO_4. There was some evidence that the electrode potential was more favorable than the charge on the electrode as an electrical variable in the adsorption of the *n*-aliphatic alcohols. However, the values deduced from the Frumkin model were generally larger than the θ's obtained from the electrocapillary curves. This discrepancy is probably due to the deviation from the two-condensers-in-parallel model, because, the two condensers were not independent in an actual system. Neither the two-condensers-in-parallel model nor the three-condensers-in-parallel model were applicable to the adsorption of aromatic compounds.

It is well known that there are two methods to evaluate the adsorption of organic molecules on mercury electrodes. One is purely thermodynamic, while the other, proposed by Frumkin[1] in 1926, is non-thermodynamic.

The surface excess Γ can be determined thermodynamically from the electrocapillary cruves; that is;

$$\Gamma_A = -(\partial\gamma/\partial\mu_A)_E \quad (1)$$

where γ is the interfacial tension at the mercury electrode-solution interface and μ is the chemical potential of the surface active organic molecules in the solution. The activity coefficient of organic substances in the electrolyte solution is assumed to be unity.

Frumkin's model treated the electrical double layer as a two-plate-condensers-in-parallel, which is strictly equivalent to a potential congruency isotherm at a constant amount adsorbed (Frumkin isotherm);

$$C_\theta = C_0(1-\theta) + C'\theta \quad (2)$$

where C_0 and C' are the differential capacities of the uncovered and fully covered electrode, respectively. The differential capacity of the electrode, C_θ, varies linearly with the surface coverage, θ. A potential-congruent isotherm leads to the equation for the charge on the electrode as a sum of the charges on the covered and uncovered parts of the electrode

$$q_\theta = q_0(1-\theta) + q'\theta \quad (3)$$

where q_0 is the electrode charge when $\theta=0$ and q' is the charge at $\theta=1$. Differentiation of Eq. (3) gives:

$$C_\theta = C_0(1-\theta) + C'\theta\,(q'-q_0)\mathrm{d}\theta/\mathrm{d}E \quad (4)$$

The capacity at a constant amount adsorbed Eq. (4) gives Eq. (2).

Breiter and Delahay[2] compared values of θ calculated from Eq. (3) with the thermodynamic surface excess for the adsorption of *n*-amyl alcohol from 1 M $NaClO_4$+ 0.001 M $HClO_4$ and found that the two sets of θ's are comparable but the values deduced from Eq. (3) are generally larger than the θ's obtained from the surface excess. The two methods for the evaluation of θ from the charge computed by graphical integration of the differential capacity curves at zero frequency and differential capacities compliment each other; *i.e.*, the differential capacity method (Eq. (2)) can be applied in the region of the adsorption maximum, in which the charge method becomes very uncertain. Hansen and his co-workers[3] confirmed that the double layer capacitance was linear in Γ for all the Γ's near the electrocapillary maximum for both the *n*-amyl alcohol- and phenol-containing systems in 0.1 M $HClO_4$. When the electrode charge was chosen as an independent variable, as has been shown by Parsons,[4] a charge-congruent isotherm is analogous to Eq. (3);

$$E_\theta = E_0(1-\theta) + E'\theta \quad (5)$$

where E_0 and E' are the potentials corresponding to $\theta=0$ and $\theta=1$ respectively at a constant charge. On differentiation, the differential capacity at a constant amount adsorbed is given by:

$$1/C_\theta = (1-\theta)/C_0 + \theta/C' \quad (6)$$

The charge congruent model shows a linear dependence of E on θ, as is shown by Eq. (5). On the other hand, in the case of the potential congruent model, the dependence of E on θ is not linear. This is shown by rewriting Eq. (2) as Eq. (7).

$$E = (q+C'E_N\theta)/[C'\{C_0(1-\theta)/C'+\theta\}] \quad (7)$$

where the potential E is referred to the potential of zero charge for $\theta=0$ and E_N is the shift of the point of zero charge (p.z.c.) as θ changes from 0 to 1. Frumkin *et al.*[5] found that the experimental evidence of Eq. (7) holds at $q=0$ for the case of the adsorption of *n*-propanol and *n*-caproic acid on mercury, in which the θ's were evaluated by using both thermodynamic and differential capacitance methods. A direct comparison of Eqs. (3) and (5) was made by Dutkiewicz *et al.*[6] for simple aliphatic compounds with four carbon atoms. It was found that, for 1,4-butanediol and 2-butyne-1,4-diol, both equations, (3) and (5), fit equally well. On the other hand, neither equation can represent the data for *n*-butanol and diethyl ether. However, Frumkin *et al.*[5] showed that the isotherms obtained for *n*-butanol are congruent with respect to charge. The discrepancy between these results is probably due to the fact that Frumkin *et al.*[5] used Eqs. (3) and (5) for calculating the adsorption isotherm (or Eqs. (2) and (6) were used at the p.z.c.) in the θ *vs.* concentration of *n*-butanol plots both at E=const. and q=const. On the other hand, Dutkiewicz *et al.*[6] used the thermodynamical method to evaluate the surface excess. As has already

been mentioned by Breiter and Delahay in their pioneer work[2] and in our previous work,[7] the surface coverages deduced from Eq. (3) are generally larger than the θ's obtained from Eq. (1) for *n*-amyl alcohol.

In the present work, (i) the reproducibility of the values is examined by comparing the results of previous works with those of the present work and (ii) the validity of Eq. (2) at a constant amount adsorbed is studied by a comparison of the values of θ directly obtained from Γ.

Experimental

The Lipmann electrometer used in the present experiment has been described previously.[8] The double layer capacitance was measured with a Yokogawa BV-Z-103-A universal bridge at 1000 Hz. The surface active organic substances were of an analytical reagent grade (Tokyo Kasei); no further purification was made. Solutions were made up of 0.5 M H_2SO_4 solution. The solutions were de-aerated with nitrogen purified by passing through a vanadous solution. The purified nitrogen was pre-saturated by passing it through a solution identical with that being studied and then to the cell. The radius of the capillary at the null point was determined by standardization against a solution of known surface tension.[9] All measurements were made at 25±0.1 °C. The potentials were measured against a saturated calomel electrode.

Results and Discussion

n-*Amyl Alcohol.* Electrocapillary curves for the solutions of *n*-amyl alcohol and the interfacial tension *vs.* the logarithm of the concentration of *n*-amyl alcohol are shown in Figs. 1 and 2, respectively. Reproducibility of these electrocapillary curves was studied by comparing the results obtained independently by two persons with a different capillary. The difference between these results was, at most, 1.1 dyne/cm in the potential range between −0.4 and −0.8 V (*vs.* SCE). The surface excess of the alcohol was determined by graphical differentiation of the electrocapillary curves. The error in the surface excess was within 10%. The adsorption isotherm of *n*-amyl alcohol at the potential of electrocapillary maximum in 0.5 M H_2SO_4 is shown in Fig. 3; it is generally in accord with that obtained by Hansen *et al.*[3]

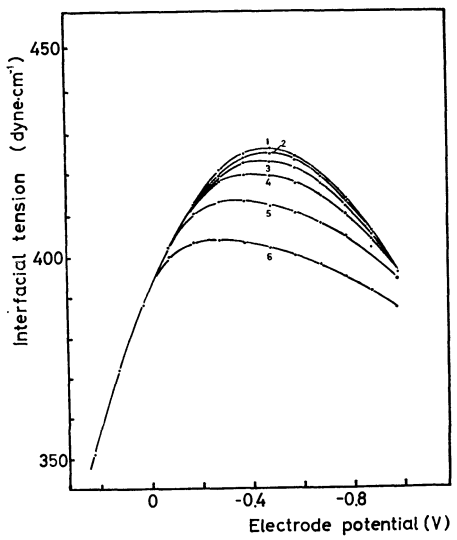

Fig. 1. Electrocapillary curves for *n*-amyl alcohol at various concentrations in 0.5 M H_2SO_4. (1) base solution; (2) 2.0 mM; (3) 5.0 mM; (4) 10 mM; (5) 20 mM; (6) 50 mM.

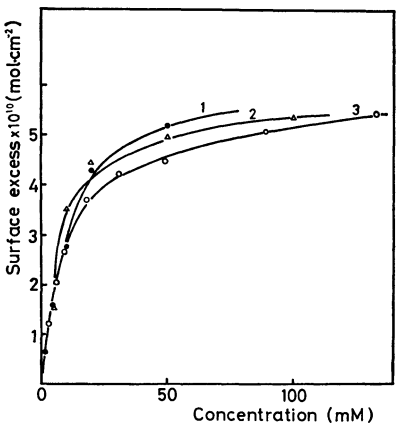

Fig. 3. Adsorption isotherms of *n*-amyl alcohol on mercury electrode calculated from the electrocapillary measurement at p.z.c. in the base solution. (1) present work I; (2) present work II; (3) Hansen *et al.*[3]

The adsorption isotherms determined by both electrocapillary and differential capacitance measurements at the potential of electrocapillary maximum for the base solutions are shown in Fig. 4. We should notice that the agreement between the isotherms evaluated by the same method is very good regardless of the type of supporting electrolyte in the solution. This is probably because neither sulfate ions nor perchlorate ions were adsorbed specifically on mercury electrode near the p.z.c. On the other hand, the isotherms obtained by the electrocapillary measurement agreed poorly with those determined by the differential capacitance method, as is shown in Fig. 4.

Equation (6) was tested by plotting the shift of the electrocapillary maximum against Γ (Fig. 5). In this

case, the surface excess was evaluated by using the Gibbs equation (Eq. (1)) for the electrocapillary measurements and by using Eq. (2) for the differential capacitance measurements. The experimental values of the electrocapillary measurements agreed well with the calculated values using Eq. (7), where the parameters were $C/C'=4.03$ and $E_N=0.245$ V. The values obtained by the differential capacitance measurement, however, showed a systematical deviation from the calculated curve (*i.e.*, from the values determined by the electrocapillary measurement). That is, at lower concentrations of *n*-amyl alcohol the coverage evaluated by the differential capacitance measurement showed a smaller value than that evaluated by the electrocapillary measurement. On the other hand, at higher concentrations of the alcohol it showed a larger value; agreed with the statement of Breiter and Delahay.[2] This result also agreed with the observation by Frumkin *et al.* for *n*-butyl alcohol.[5]

The systematic deviation of the measured values, as determined by means of the differential capacitance measurement, from those of the calculated values by using Eq. (7) can be explained as follows. When the surface excess of the adsorbed species is small, the adsorbed molecules can move rather freely and they are not necessarily oriented perpendicularly to the electrode. Some of them may be flat, some in a vertical position, and some in intermediate position. The center of the dipole of these adsorbed molecules (the -OH group) is, as the average, closer to the electrode surface than that of the perpendicularly oriented molecules. The contribution to the displacement of the p.z.c. by these molecules becomes larger than that by the perpendicularly oriented molecules. That is, the capacitance of the condenser filled with randomly oriented molecules, C_1', must be greater than that filled with molecules with a fixed orientation (perpendicularly oriented to the electrode), C'. Accordingly, C_0/C_1' with the configuration of the low coverage type becomes smaller than C/C' for the saturated adsorption. This leads to a negative deviation of the measured values from the calculated values according to Eq. (7).

At higher coverages, on the other hand, the positive deviation of the measured values suggests a larger value for C_{0h}/C' than for C_0/C', where C_{0h} is the double layer capacitance of the uncovered part of the electrode at a higher coverage. The capacitance of the condenser filled with water molecules in the presence of a large amount of the adsorbed *n*-amyl alcohol, C_{0h}, is con-

sidered to be larger than that at the electrode without an adsorbed species on the electrode. At the electrode with higher coverages by *n*-amyl alcohol, the hydrocarbon end is in contact with the electrode surface and the molecule is normal to the surface. The inductive effect by the oriented alcohol molecules may influence the orientation of water molecules at the electrode surface. As in the case of the repulsive interaction between the dipoles at the electrode surface,[11] this effect causes an increase in the capacitance of the condenser filled with water molecules from C_0 to C_{0h}.

The adsorption isotherms for *n*-butyl alcohol and *n*-hexyl alcohol are shown in Figs. 6 and 7. These isotherms also showed the same tendency as in the case of *n*-amyl alcohol. The negative deviation from Eq. (7) at lower coverages decreased with an increase in the chain length of the alcohol molecule, and the positive deviation increased with the chain length. This behavior can easily be explained by the arguments used in the case of *n*-amyl alcohol. The plot of the shift of the p.z.c. against the surface excess of the alcohol showed an excellent agreement with Eq. (7) for both *n*-butyl and *n*-hexyl alcohols when the surface excess was determined thermodynamically.

Phenol. The adsorption isotherms of phenol from 0.5 M H_2SO_4 solution at the potential of electrocapillary maximum of the base solution are shown in Fig. 8, together with the adsorption isotherms obtained by Hansen *et al.*[3] and by Blomgren *et al.*[12] All of these isotherms were determined from the electrocapillary measurements, and they showed a good agreement between them. The adsorption isotherms for phenol

calculated by using Eq. (2) at the p.z.c. for the base solution are shown in Fig. 9. The surface coverages determined by the electrocapillary measurement coincided with those determined by the differential capacitance measurement. This agreement has also been reported by Elliott.[17]

The two-condensers-in-parallel model was tested by plotting the shift of the potential of zero charge against Γ, as is shown in Fig. 10. The plots were far from this model. The shift of the electrocapillary maximum was nearly linear with respect to the surface excess of phenol. Similar behavior was also observed in the case of *o*-cresol in 0.5 M H_2SO_4, as is shown in Figs. 11 and 12. The surface excess evaluated from Eq. (2) coincided with the values evaluated thermodynamically. The two-condensers-in-parallel model was also inapplicable to this model, as is shown in Fig. 12.

The displacement of the potential of zero charge with respect to the surface excess was analyzed by using a three-condensers-in-parallel model[17] (the orientation of the adsorbed aromatic molecule changes from flat to vertical upon an increase in the concentration of the adsorbed species). The shift of the potential of zero charge is given by:

$$E = \theta E_{N1} \frac{(E_{N2}/E_{N1})(1-\theta)+\theta}{(C_0/C')(1-\theta)+\theta} \tag{8}$$

where E_{N1} and E_{N2} are, respectively, the shift of the potential of zero charge upon transition from the base solution to $\theta_1=1$ (when the electrode is fully covered by the vertically oriented molecules) and to $\theta_2=1$ (when the electrode is fully covered with the molecules of a flat orientation). E_{N2} was calculated by using this equation[17]

$$\beta = -\frac{C_1(E_{N1}-E_{N2})}{A} \tag{9}$$

where C_1 is the differential capacitance when $\theta_1=1$. The parameters used for the calculation were $\beta=-2.05\ V^{-1}$,[18] $A=1.22\ \mu J/cm^2$ ($A=RT\Gamma_{max}$, $\Gamma_{max}=4.93\times10^{-10}$ mol/cm^2), $C_1=7.00\ \mu F/cm^2$, and $E_{N1}=-0.140$ V. The calculated $E_{N2}=-0.498$ V. The plot of the three-condensers-in-parallel model is shown in Fig. 10. The plot showed a linear dependence of the displacement of the potential of zero charge on Γ. The three-condensers-in-parallel model does not explain the large displacement of the p.z.c. at lower coverages of the electrode with phenol. As has been stated by Damaskin,[17] the shape of the E *vs.* θ curve varies with the values of (E_{N2}/E_{N1}) and (C_0/C_1); that is, its convex or concave side is turned toward abscissa axis. Equation (8), however, does not explain the large shift of the p.z.c. at low θ values regardless of the values of (E_{N2}/E_{N1}) and (C_0/C_1). This has also been reported by Damaskin on the basis of their data.[18] *o*-Cresol behaved much like to phenol.

The author wishes to thanks Messrs. Y. Inoue, Y. Akimoto, and Y. Yamada for their extensive assistance during this work. This work was supported by the Ministry of Education of Japan for a Scientific Research Grant-in-aid.

Radiation Synthesis of Ethylamine from Ethane-Ammonia Systems. Effect of Nitric Oxide Addition

Saburo SHIMIZU, Yasumasa IKEZOE, and Shoichi SATO
Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki 319-11
(Received August 1, 1974)

Formation of ethylamine was observed in the γ-radiolysis of the ethane–ammonia system: the maximum G value was 0.5. Using oxygen as a radical scavenger, it was found that the ethylamine was formed *via* radical and ion intermediates. Addition of excess nitric oxide suppressed the ethylamine yield, but $G(C_2H_5NH_2)$ increased to 1.2 on addition of an optimum amount. This was attributed to the reduction of acetaldoxime by hydrogen atoms or alkyl radicals, after acetaldoxime had been formed by the reaction between ethyl radicals and the nitric oxide added as a scavenger.

Radiolysis of mixtures of hydrocarbons and ammonia has been studied by many workers. Ethylamine was produced in the irradiated ethylene–ammonia system[1] and propylamine was reported to be formed in the *n*-butane–ammonia system.[2]

In this study, the radiolysis of the ethane–ammonia system and especially the mechanism of ethylamine formation was examined. When an optimum amount of nitric oxide was added to the ethane–ammonia system, the ethylamine yield was enhanced, but when added in excess, the usual radical scavenging action of nitric oxide was observed. A mechanism was proposed for the formation of the amine in the presence of the additive.

Experimental

Ethane (99.7%, Takachiho Chemical) was used after purification by trap to trap distillation in a vacuum line. Ammonia (99.99%, Matheson) was dried with sodium metal and purified likewise. Nitric oxide (99.8%, Takachiho Chemical) was used after removal of non-condensible gases at −196 °C. Oxygen (99.7%) was used without further purification.

Gases were irradiated at room temperature by ^{60}Co gamma rays at 5.4×10^5 R/hr, in 40 ml Pyrex glass ampoules. The dose of gamma rays was measured with a Fricke dosimeter. The G value was calculated assuming that the mass absorption coefficient was proportional to the total number of electrons in the system.

Radiolysis products, amines and hydrocarbons were analyzed by a gas chromatograph equipped with a flame ionization detector at 70 °C. To obtain reproducible results with ethylamine, grease, metal and rubber were eliminated as much as possible, and nitrogen gas mixed with 10% ammonia was used as carrier gas. The column consisted of a 2 m (10% KOH+10% TEPA on Porapak Q) and a 1 m (10% KOH+10% Quadrol on Porapak Q) column. Nitric oxide, hydrogen and methane were analyzed by volumetry and mass spectrometry.

Results and Discussion

Ethylamine Formation from Ethane–Ammonia System. When ethane–ammonia mixtures were irradiated, hydrogen, nitrogen methane, propane, *n*-butane and methylamine were formed besides ethylamine. Yield of ethylamine, *n*-butane and others are shown in Fig. 1 as a function of the mixing ratio. The yield of *n*-butane increased with increasing ammonia concentration until $C_2H_6/NH_3=90/10$, then decreased almost linearly on further addition of ammonia. The yield of ethylamine showed similar characteristics with a maximum G value of 0.5 at the same ammonia content.

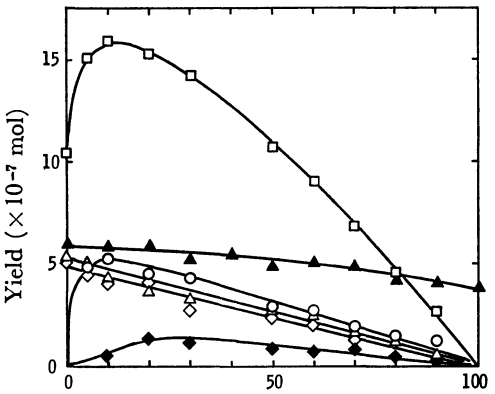

Fig. 1. Composition dependence of product yields.
○; ethylamine, □; *n*-butane, ◆; methylamine, △; methane, ◇; propane, ▲; hydrogen (×0.1)
Gamma rays; total dose 10 Mrad. Irradiated gas; total amount $C_2H_6+NH_3=3.43\times10^{-3}$ mol, pressure 2 kg/cm², in 40 ml glass ampoules.

The effect of addition of oxygen to this system was studied. The yield of *n*-butane was effectively reduced on addition of the radical scavenger, oxygen, as shown in Table 1. Therefore, *n*-butane should be formed predominantly by the following radical reaction:

Table 1. Effect of added oxygen in the radiolysis of the ethane–ammonia system

% added oxygen	Yields	
	ethylamine ($\times10^{-7}$ mol)	*n*-butane ($\times10^{-7}$ mol)
0	4.90	13.65
0.48	4.45	4.10
1.20	3.63	1.10
3.12	3.02	0.75
6.72	3.37	0.73
12.72	3.30	0.75

Gamma rays; total dose=8.64 Mrad; Irradiated gas; composition $C_2H_6/NH_3=90/10$, pressure=2 kg/cm, in 40 ml glass ampoules.

$$C_2H_5\cdot + C_2H_5\cdot \longrightarrow n\text{-}C_4H_{10} \quad (1)$$

On the other hand, the ethylamine formation was considerably suppressed by addition of 3.12% oxygen, but not further affected by further addition of oxygen. This suggests the following two reactions for ethylamine formation: the radical reaction 2, which is inhibited by the presence of oxygen, and the ionic reaction 3, which is not.

$$C_2H_5\cdot + NH_2\cdot \longrightarrow C_2H_5NH_2 \quad (2)$$

$$C_2H_5^+ + NH_3 \longrightarrow C_2H_5NH_3^+ \xrightarrow{e^-} C_2H_5NH_2 + H \quad (3)$$

In the radiolysis[1] and the photolysis[3] of the ethylene–ammonia system, ethylamine formation has been attributed to the radical reaction. An ionic reaction similar to Reaction 3 has been suggested for propylamine formation in the radiolysis of the *n*-butane–ammonia system.[2]

Ethylamine Formation in the Presence of Nitric Oxide. The effect of added nitric oxide on the radiolysis of the ethane–ammonia system was studied for the mixture containing 10% ammonia (the composition at which the maximum yield of ethylamine was observed (Fig. 2)).

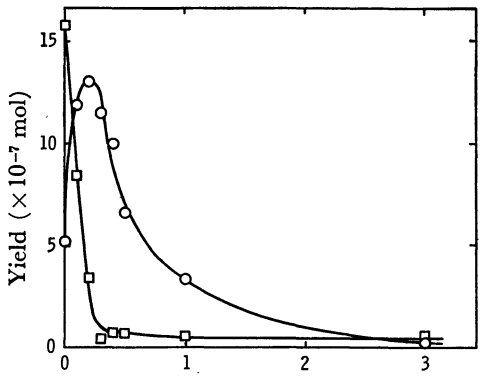

Fig. 2. Effect of added nitric oxide on product yields.
○; ethylamine, □; *n*-butane
Gamma rays; total dose 10 Mrad. Irradiated gas; composition $C_2H_6/NH_3=90/10$, pressure 2 kg/cm², in 40 ml glass ampoules.

The yield of ethylamine increased significantly on adding small amounts of nitric oxide, then decreased on further addition, while the yield of *n*-butane decreased monotonically. The maximum $G(C_2H_5NH_2)$ value, 1.2, obtained with 0.2% added NO was 2.4 times larger than that obtained without the additive.

It is difficult to interpret the increase of the ethylamine yield with a slight addition of nitric oxide according to the mechanisms (2) and (3). Nitric oxide addition should suppress ethylamine formation by either the radical or ionic reaction 2 or 3, because nitric oxide is able to scavenge ethyl and amino radicals, or because it interacts with ethyl cations due to its very low ionization potential (IP=9.24 eV). Therefore, a third mechanism must be considered for the enhanced formation of amine (See following section).

Effect of Dose in the Presence of Nitric Oxide. At

initial concentration of nitric oxide, ○; 0%, ◐; 0.1%, ◑; 0.2%, ●; 0.4%.
Experimental conditions; same as in Fig. 3.

nitric oxide concentrations of 0.1, 0.2, and 0.4%, the effect of absorbed dose on the radiolysis of the ethane–ammonia–nitric oxide system was studied. The yield of *n*-butane and the amount of nitric oxide which remained are shown in Fig. 3, and the yield of ethylamine in Fig. 4. In each system, the nitric oxide concentration decreased rapidly. An initial $G(-NO)$ value of 22.5 was obtained for the system containing 0.4% nitric oxide.

In the formation of *n*-butane, induction periods appeared. Their length was closely related to the initial concentration of nitric oxide. The longest period was observed with 0.4% nitric oxide. Reaction 1 is suppressed during the induction period when nitric oxide is present. After all the nitric oxide is consumed, the amount of *n*-butane formed increases linearly with the absorbed dose.

The ethylamine yield in the absence of nitric oxide

increased linearly with the absorbed dose at relatively low doses and was close to saturation at about 30 Mrad. On addition of 0.1 and 0.2% nitric oxide, the yield over the whole range of absorbed dose was about 1.2 and 2 times larger, respectively, than in the system without the additive. On addition of 0.4% nitric oxide, the yield of ethylamine was smaller than that of the system without nitric oxide up to an absorbed dose of 10 Mrad. The region where the yield of ethylamine was smaller may be regarded as the induction period for ethylamine formation. After the induction period, *i.e.* after the nitric oxide had disappeared, the yield of ethylamine increased significantly. It must be noted that this phenomenon is similar to that in the *n*-butane formation.

Again, this increase in the amine yield at high dose for large initial nitric oxide concentration can not be explained by the two amine formation mechanisms (2) and (3). After the induction period, the nitric oxide may be assumed to be exhausted and alkyl radicals be formed without being scavenged. Therefore, a third mechanism was studied which explained the increased amine formation with these assumptions.

Role of Acetaldoxime in Ethylamine Formation. It has been known that a nitroso compound or its oxime tautomer is formed when an alkyl radical is scavenged by nitric oxide.[4] The formation of cyclohexylamine has been reported in the radiolysis of liquid cyclohexane with nitric oxide added.[5] The reaction pathway consisted of the scavenging of a cyclohexyl radical by nitric oxide and the reduction of the tautomer, cyclohexanonoxime, by alkyl and hydrogen radicals. Similarly, the following reactions may be expected to give ethylamine in the ethane–ammonia system;

$$C_2H_5\cdot + NO \longrightarrow C_2H_5NO \quad (4)$$

$$C_2H_5NO \rightleftarrows CH_3CH{=}NOH \quad (5)$$

$$CH_3CH{=}NOH \xrightarrow{R\cdot,\ H\cdot} C_2H_5NH_2 \quad (6)$$

Table 2. Effect of additives on $G(C_2H_5NH_2)$

Reaction system	$G(C_2H_5NH_2)$
$C_2H_6(90)+NH_3$ (10)	0.5
$C_2H_6(90)+NH_3(10)+NO$ (0.2%)	1.2
$C_2H_6(100)+NO$ (0.1–1%)	<0.1
$C_2H_6(90)+NH_3(10)+CH_3CH{=}NOH$ (2%)	1.2
$C_2H_6(100)+CH_3CH{=}NOH$ (2%)	≈ 0.1
$NH_3(100)+CH_3CH{=}NOH$ (2%)	0.3

Gamma rays; total dose=10 Mrad. Irradiated gas; pressure 2 kg/cm, in 40 ml glass ampoules.

Reaction 6 could occur in the gas phase, since the vapor pressure of acetaldoxime is 10.0 Torr at 25.8 °C.

Table 2 shows the $G(C_2H_5NH_2)$ values which were obtained for various combinations of the reactants, ethane and ammonia, as well as the additives, nitric oxide and acetaldoxime. For ethane–ammonia mixtures above, the maximum G value was 0.5, but was 1.2 in the presence of 0.2% nitric oxide. The value was also 1.2 for the ethane, ammonia and 2% acetaldoxime mixture.

The direct reaction between ethane and nitric oxide or acetaldoxime and that between ammonia and acetaldoxime can be excluded from the mechanism for the enhanced ethylamine formation. Acetaldoxime added to the ethane–ammonia mixture plays the role of the intermediate in ethylamine formation as effectively as nitric oxide does. Thus, the third mechanism (expressed by Reactions 4, 5, and 6) seems plausible from these qualitative results. As shown in Figs. 2 and 4, the ethylamine yield increased at an optimum amount of nitric oxide, and decreased with addition of excess. These observations are also consistent with the proposed mechanism.

Nitric oxide has been used as a radical scavenger in radiolysis. However, it has been noted that its use sometimes makes the main reaction scheme more complex.[6] This study exemplifies a case in which the scavenging reaction of nitric oxide results in yields of the product that are the same as those obtained without the additives, clearly showing the necessity of taking care in using this compound in the study of radiolysis. At the same time, it has been demonstrated that a radical scavenger could be used to enhance the formation of a reaction product, as has been shown in one other system.[7] This point is of interest for preparative radiation chemistry.

Properties of Protective Films Formed on an Iron Surface by Dialkyl Phosphate as a Corrosion Inhibitor

Satoru NAKAGAWA and Genzo HASHIZUME

Industrial Research Institute of Hyogo Prefecture, Suma-ku, Kobe 654

(Received October 18, 1974)

The properties of films formed on an iron surface by di-*n*-dodecyl phosphate were studied. The inhibition effects for iron specimens treated with dodecyl phosphate were estimated from the losses in weight of iron specimens in 5% NaCl aqueous solutions. The Fe L_α, L_β X-ray emission spectra of the iron surface were obtained by electron microprobe X-ray analysis. The value of the intensity ratio, Fe L_β/L_α, of the untreated iron specimen was 0.17, while that of the treated iron specimen was 0.28. The infrared spectrum of the treated iron surface was similar to that of tribasic orthophosphate. The content of Fe in the film formed on the iron surface by di-*n*-dodecyl phosphate was from 4.3% to 6.98%. From these results, it was inferred that di-*n*-dodecyl phosphate reacted with iron atoms at the iron surface in a cyclohexane solution and that the main component of the film formed on the iron surface was $[(RO)_2POO]_2Fe$ or $[(RO)_2POO]_3Fe$.

Corrosion inhibitors for recirculating cooling water are grouped into three classes—that is, inhibitors which passivate the metal surface, those which precipitate on the metal surface, and those which are adsorbed on the metal surface, by the formation mechanism of the film on the metal surface.[1] It is thought[2] that dialkyl phosphate is adsorbed on an iron surface with the orthophosphate ion, but the mechanism of film formation by dialkyl phosphate has not yet been studied in detail. In this paper, the properties of the films formed on an iron surface by di-*n*-dodecyl phosphate $(C_{12}H_{25}O)_2PO(OH)$ were studied by measurements of the Fe L_α, and L_β X-ray emission spectra, the infrared spectra, and the contents of the film formed on the iron surface.

Experimental

Materials. The iron specimens used were the same as those used in the previous work.[3] The di-*n*-dodecyl phosphate was synthesized by a known procedure[4] and was purified by recrystallization. No significant impurities were detected in the mass spectrum of the di-*n*-dodecyl phosphate used in these experiments.

Procedures. Iron specimens were placed in C_6H_{12}, CCl_4 and $CHCl_3$ solutions of dodecyl phosphate at 35 °C; then they were taken out of the solutions, washed in the solvent, and wiped with gauze. The inhibition effects of dodecyl phosphate on iron specimens were estimated from the losses in weight of the iron specimens (55×15×0.7 mm) in 5% NaCl aqueous solutions (15 ml) during 24 hr at 35 °C and from the percentage of the rusted surface as estimated by a visual observation of the iron specimens (30×80×1.0 mm) after a humidity test at 40 °C and 95% RH for 48 hr. The Fe L_α, and L_β spectra of the surfaces of iron specimens (10×10×1.0 mm) were measured by means of a Shimadzu-ARL electron microprobe X-ray analyzer EMX-SM with RAP crystals. When the iron specimens were placed in a C_6H_{12} solution of dodecyl phosphate at 35 °C for 7 days, a viscous liquid material adhered to the iron surface. Therefore, the iron specimens were taken out of the solution, as they were, and were placed in a desiccator without washing and wiping; they were then dried at room temperature in the evacuated desiccator. A white film was thereupon separated from the iron surface. The infrared spectra of these films were measured by the tablet method with KBr, and the contents of Fe and P in the C_6H_{12} solutions dissolved from these films were determined by fluorescent X-ray analysis. The preparation of the sample for the analysis was carried out as follows; 200 μl of a solution was dropped onto the miller film and then evaporated to dryness by using an infrared lamp. The intensity of Fe K_α was measured at 57.50° with an LiF crystal and a Cr target, while that of P K_α was measured at 141.05° with a Ge crystal and a Cr target. The infrared spectra of the surfaces of iron specimens (19×56×1.0 mm and 19×47×1.0 mm) treated with dodecyl phosphate were measured by the ATR method.

Results and Discussion

Inhibition Effects of di-n-Dodecyl Phosphate. The inhibition efficiencies of dodecyl phosphate, as estimated from the losses in weight of the iron specimens and from visual observations of the iron surface, are shown in Table 1. The inhibition effects on iron specimens treated in C_6H_{12} solutions of dodecyl phosphate were more than those on iron specimens treated in other solutions. On the basis of these data, subsequent experiments were carried out in the cyclohexane solutions.

TABLE 1. THE EFFECTS OF SOLVENTS ON THE INHIBITION EFFICIENCIES OF DI-*n*-DODECYL PHOSPHATE FOR IRON SPECIMENS

Solvent[a]	Percent inhibition[b] %	Rusted surface[c] %
C_6H_{12}	66	10
CCl_4	33	70
$CHCl_3$	0	100

a) Concentration of inhibitor is 0.5%. b) By total immersion tests in test tube (15×110 mm, in aerated 5% NaCl solution) at 35 °C for 24 hr. c) By humidity tests in desiccator at 40 °C and 95% RH for 48 hr.

Adsorption-Time Curve of the Dodecyl Phosphate for Iron. The intensity of the P K_α line of the iron surface treated with dodecyl phosphate, as measured by fluorescent X-ray analysis, was introduced instead of the amount of dodecyl phosphate adsorbed on the iron surface. The P K_α intensities of the iron surface are plotted as a function of the time in Fig. 1. The P K_α intensity of the iron surface reached a maximum after 7 days. Therefore, subsequent experiments were carried out by treating the surface fors 7 days; the concentration was 0.5%.

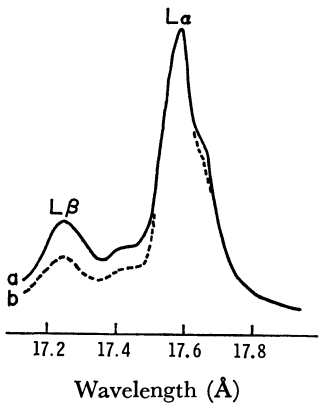

Fig. 2. Fe Lα, Lβ band spectra for iron specimens.
(a) Iron specimen treated with di-*n*-dodecyl phosphate,
(b) non treated iron specimen.

Fe L_α and L_β X-Ray Emission Spectra of an Iron Surface. The Fe L_α and L_β spectra of an untreated iron surface and a treated iron surface are shown in Fig. 2. These spectra differ from one another in the Fe L_β/L_α intensity ratio. This intensity ratio varies with the Fe-oxidation state.[5] For example,[6] the Fe L_β/L_α intensity ratio of Fe-metal is 0.17, while that of Fe-oxide (Fe_3O_4) is 0.51. The spectra in Fig. 2 show that the ratio for the untreated iron surface is 0.17, while the ratio for the treated iron surface is 0.28. The ratio varies not only with the Fe-oxidation state, but also with the self-absorption effect or with the absorption effects of elements in the film on the surface. The spectra in Fig. 2 were obtained under the same conditions at 10 kV and 0.04 μA, so the self-absorption effect is negligible. The value of the ratio for an iron surface is obtained as only 0.18 instead of 0.17 by the correction of the absorption effects of the components in the film on the iron surface, carbon, oxygen, and phosphorus atoms in dodecyl phosphate. Therefore, the increase in the ratio observed in this experiment shows that the chemical state of the iron atom at the surface is made to vary by the treatment with dodecyl phosphate.

Infrared Spectra. The infrared spectrum of the surface of an iron specimen treated with dodecyl phosphate, as obtained by the ATR method, is shown in Fig. 3, together with the spectrum of the surface of phosphating steel obtained by Sato.[7] Both spectra show broad peaks at about 1100 cm^{-1}. The infrared

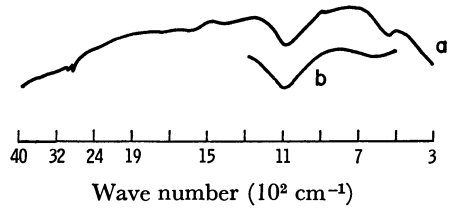

Fig. 3. IR spectra of iron treated with di-*n*-dodecyl phosphate by ATR method (a) and phosphating steel by Sato (b).

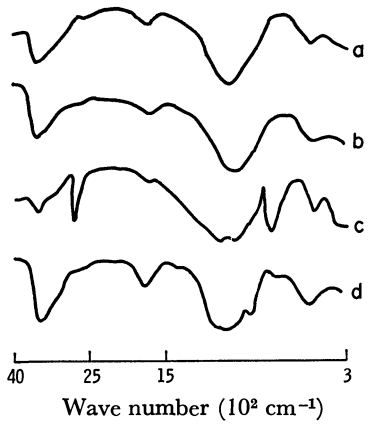

Fig. 4. IR spectra of the products obtained by precipitation reactions of $FeCl_3$ with NaH_2PO_4 (a), Na_2HPO_4 (b), NaH_2PO_4 (c) and $Na_4P_2O_7$ (d).

spectra of the products obtained by the precipitation reactions of ferric chloride with monosodium phosphate, disodium phosphate, sodium hypophosphite, or sodium pyrophosphate are shown in Fig. 4. The spectrum (a) in Fig. 3 is similar to the (a) and (b) spectra in Fig. 4—that is, the spectra of orthophosphate. The spectra of tribasic, dibasic and monobasic orthophosphate were reported by Miller and Wilkins.[8] The (a) spectrum in Fig. 3 is similar to the spectrum of tribasic orthophosphate, which has no OH group. The infrared spectrum of a white film separated from the iron surface, as obtained by the tablet method with KBr, is shown in Fig. 5, together with the spectrum of the di-*n*-dodecyl phosphate used in this experiment. In the (a) spectrum in Fig. 5, a peak at about 1200 cm^{-1} disappears and a peak at about 1150 cm^{-1} appears. These peaks cannot be definitely assigned for the present, but the spectra show that dodecyl phosphate varies at the iron surface. From these infrared spectra, it can be thought that the iron atom is substituted for

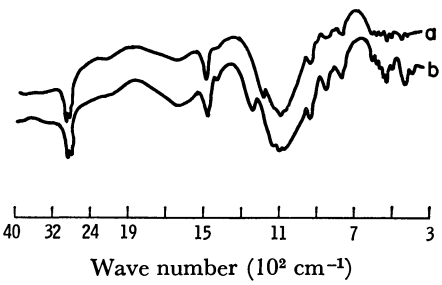

Fig. 5. IR spectra of white film separated from iron surface (a) and di-*n*-dodecyl phosphate (b).

TABLE 2. THE CONTENT OF Fe AND P IN THE SOLUTION DISSOLVED FROM WHITE FILM SEPARATED FROM THE IRON SURFACE[a)]

Sample	Fe mg/cm³	dodecyl phosphate mg/cm³	Fe content in phosphate %
film A	0.025	0.575[b)]	4.30[c)]
film B	0.030	0.425[b)]	6.98[c)]
dodecyl phosphate	0.0013	1.50	0.08

a) Film separated from iron surface was dissolved in cyclohexane b) Content of dodecyl phosphate was calculated from the PK_α intensity. c) Weight of film separated from iron surface was calculated from content of dodecyl phosphate, supposing that film consisted of dodecyl phosphate.

one hydrogen atom in dodecyl phosphate at the iron surface.

Determination of Fe and P. The contents of Fe and P in the films separated from the iron surface are shown in Table 2. The content of the Fe impurity in the dodecyl phosphate used in this experiment is 0.08%. The content of Fe in the white film separated from the iron surface is between 4.3 and 6.9%. The composition in the films was not constant, but the Fe content in the films showed values in the range from about 4.3 to 6.9% in several experiments. The calculated value of the Fe content in the film is 4.3%, supposing that two molecules of dodecyl phosphate combine with the iron atom as Fe^{2-}, while the value is 6.4%, if we suppose that three molecules of dodecyl phosphate combine with the iron atm as Fe^{3-}. From these results, it was inferred that di-*n*-dodecyl phosphate reacted with the iron atom at the iron surface in the C_6H_{12} solution, that the iron atom was substituted for two or three molecules of dodecyl phosphate, and that the main component of the film formed on the iron surface was $[(RO)_2POO]_2Fe$ or $[(RO)_2POO]_3Fe$.

The Crystal Structure of Sodium Molybdate Dihydrate, $Na_2MoO_4 \cdot 2H_2O$

Kazuko MATSUMOTO, Akiko KOBAYASHI, and Yukiyoshi SASAKI

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received August 1, 1974)

$Na_2MoO_4 \cdot 2H_2O$ is orthorhombic, with the space group of Pbca and with cell constants of $a=8.463(3)$, $b=10.552(3)$, and $c=13.827(6)$ Å; $U=1234.8$ Å^3; $Z=8$. The crystals are composed of alternate layers of MoO_4^{2-} tetrahedra and water molecules. The layers are connected by interlinking sodium cations and hydrogen bonds. The MoO_4^{2-} tetrahedron is slightly elongated in the direction of the hydrogen bonds.

Recent structure determinations of $Na_6Mo_5P_2O_{23} \cdot 13H_2O$,[1] $Na_4H_2Mo_5P_2O_{23} \cdot 10H_2O$,[2] and $Na_6Mo_7O_{24} \cdot 14H_2O$[3] have revealed the remarkable basic character of the oxygen atoms, which are octahedrally attached to the molybdenum atoms to form not only hydrogen bonds with water, but also coordination bonds with sodium ions.

Our main interest in the present structural study of $Na_2MoO_4 \cdot 2H_2O$ lies in the coordination of the oxygen atoms in the tetrahedral MoO_4^{2-} anion to Na^+ cations in comparison with those in octahedral MoO_6 groups in the heteropoly- and isopoly-anions.

About $Na_2MoO_4 \cdot 2H_2O$, the unit-cell dimensions and the space group,[4] the Raman spectra, and the infrared spectra data[5] have already been reported.

Experimental

Suitable crystals of $Na_2MoO_4 \cdot 2H_2O$ were selected from the reagent-grade chemicals commercially available from the KOSO Wako Company. Preliminary oscillation and Weissenberg photographs showed that the crystals were orthorhombic, with the space group Pbca; this confirmed the results of the preliminary measurements made by Poljak and Becka.[4]

The intensities of the reflections were measured on a Rigaku automated four-circle diffractometer. Graphite monochromatized Mo$K\alpha$ radiation was used. The ω-2θ scan technique was employed. The scan range was calculated from this formula: $1.2+0.5\tan\theta$; the scan speed was 0.5° per min in ω, and background counts of 10 s were taken at both limits of the scan. Three reference reflections, 220, 020, and 002, were measured for every 50 reflections. The net counts of these reflections altered only within 1% over the period of data collection. A total of 2104 independent intensities were measured up to $2\theta=60°$ ($0\leq h\leq 11$, $0\leq k\leq 14$, $0\leq l\leq 19$); those reflections of which the $|F_o|$ value was less than 7.9 (absolutely scaled value) were regarded as unobserved in view of the accuracy of the measurement. The remaining 1497 reflections were adopted for the structure determination. The unit-cell dimensions and their standard deviations, as measured on the Rigaku diffractometer (Mo$K\alpha$, $\lambda=0.71069$ Å), were $a=8.463$ (3), $b=10.552$ (3), $c=13.827$ (6) Å; $U=1234.8$ Å^3 at 23 °C; $D_m=2.51$ and $D_x=2.60$ g cm^{-3} for $Z=8$; M.W.=241.9 and μ for Mo$K\alpha=23.2$ cm^{-1}. As the dimensions of the specimen used were approximately $0.15\times 0.1\times 0.2$ mm, the absorption correction was not made.

Structure Determination

The structure was solved by the heavy-atom technique and was refined by the least-squares method, the function minimized being $\sum\omega(|F_o|-k|F_o|)^2$. A weighting scheme, $w=0.2$ for $|F_o|<11.9$ and otherwise $w=1$, was employed. The refinements of the parameters of all the non-hydrogen atoms were carried out by the block-diagonal least-squares method. In the last cycle

H_2O(2)	71(8)	29(5)	21(3)	7(11)	−9(8)	−5(6)

of least-squares refinement with anisotropic temperature factors, the R index ($R=\Sigma||F_o|-|F_o||/\Sigma|F_o|$) converged to 0.037. A difference Fourier synthesis was calculated at this stage; some faint electron density peaks were detected, but their positions were inadequate for hydrogen atoms. The atomic scattering factors used were taken from the International Tables for X-ray Crystallography Vol. III.[19] Corrections for the anomalous dispersion were not made. The atomic coordinates and temperature factors are listed in Tables 1 and 2. The F_o-F_o table is kept at the office of this Bulletin as Document No. 7507.

Results and Discussion

Description of the Structure. The crystal structure

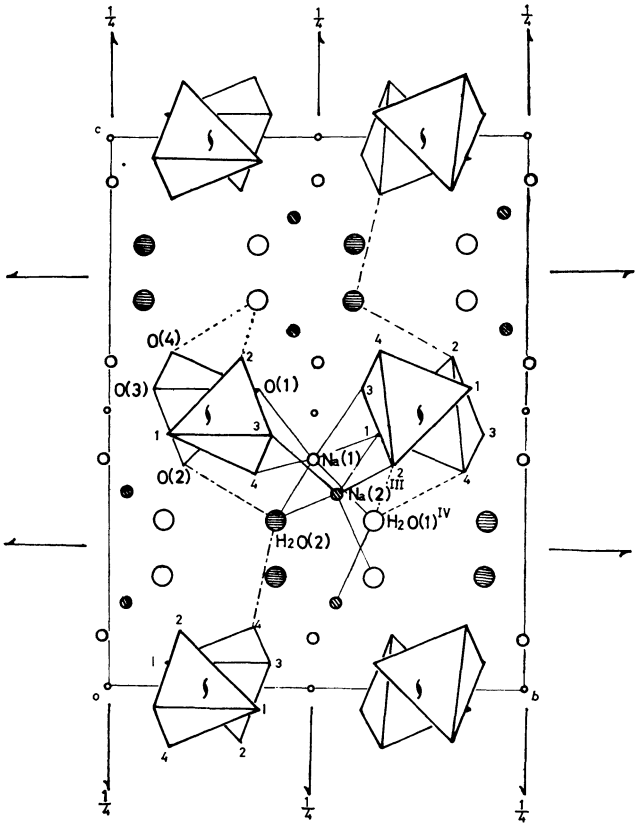

Fig. 1. The structure viewed along the a axis. Water layers and molybdate anion layers are seen alternately. Tetrahedra represent MoO_4^{2-} anions. The coordination bonds around Na^+ cations are shown with full lines. Dotted lines are O(2)···H_2O(1)···O(4) hydrogen bonds between two MoO_4^{2-} anions in the same layer. Dot-dash lines are O(2)—·—H_2O(2)—·—O(4) type hydrogen bonds bridging adjacent layers. The small letters 1, 2, 3, and 4 represent oxygen atoms equivalent to O(1), O(2), O(3), and O(4). The Na(2) atoms are shaded only in Fig. 1. Parameter transformations are as follows.

I	$1/2+x$	$1/2-y$	$-z$
II	$1/2-x$	$1/2+y$	z
III	$-x$	$-y$	$-z$
IV	$-x$	$1/2+y$	$1/2-z$
V	x	$1/2-y$	$1/2+z$

$NaOH \cdot 4H_2O$	5 (2.36—2.37)		13)

is considered to consist of alternate layers of MoO_4^{2-} tetrahedra parallel to (001) and of water molecules; it is shown in three projections in Figs. 1, 2, and 3. The MoO_4^{2-} tetrahedra within a layer are connected by interlinking Na(1) and Na(2), as well as by the hydrogen bonding, O(2)···H_2O(1)···O(4). The adjacent layers are bridged by interlinking cations and hydrogen-bonding O(2)-·-·-H_2O(2)-·-·-O(4) linkages, as is shown in Figs. 1 and 2.

Coordination around Sodium Ions. The oxygen coordinations around the two crystallographically-independent sodium atoms are remarkably different, as is shown in Fig. 4. The Na(1) ion is surrounded by two water oxygen atoms and four MoO_4^{2-} oxygen atoms, each of which belongs to a different MoO_4^{2-} group, thus form a distorted octahedron. The Na(2) ion is surrounded by two water oxygen atoms and three MoO_4^{2-} oxygen atoms in the form of a distorted trigonal bipyramid. The mean distance of Na(1)–O is 2.439 Å, while that of Na(2)–O is 2.335 Å; the difference is presumably attributable to the different coordination numbers, 6 and 5.

Table 3 gives the coordination numbers of the sodium atoms and the Na–O distances in some hydrated sodium salts of oxyacids. It shows that the most common coordination number of sodium atoms is six and that the pentacoordinated sodium ion as in $Na_2MoO_4 \cdot 2H_2O$ is rare.[12,13] Another example is found in Na_2SiO_3,[11] where the sodium ion is coordinated to form a distorted trigonal bipyramid and where the Na–O distances are 2.370, 2.303, 2.282, 2.549, and 2.404 Å. The Na(2)–H_2O(1) distance, 2.297 Å, in $Na_2MoO_4 \cdot 2H_2O$ is, along with the Na–O distance in the above-mentioned Na_2SiO_3 and along with that of the hexacoordinated sodium ion in $Na_2OGeO_2 \cdot 6H_2O$, 2.28 Å,[14] one of the shortest Na–O distances reported thus far. Some of the compounds listed in Table 3 have sodium ions coordinated entirely by water oxygens. In hydrated sodium salts of oxyacids which contain elements of Group 4, 5, or 6 in the periodic table and which have sodium ions coordinated both by water and anion oxygens, the Na–O(H_2O) distance is generally a little longer than that of the Na–O(anion). However, in $Na_2MoO_4 \cdot 2H_2O$ there is no appreciable difference between the Na–O(H_2O) and Na–O(anion) distances.

Water of Crystallization. The hydrogen bondings and H_2O–Na coordinations are depicted in Figs. 2 and 3. Table 4 shows their distances and angles. Around $H_2O(1)$ and $H_2O(2)$, oxygen atoms from two MoO_4^{2-} anions and two sodium cations construct a distorted tetrahedron; this suggests that two lone pairs of a water oxygen atom point to the two sodium ions. The $O(2)^{vi}\cdots H_2O(1)\cdots O(4)^{v}$ angle differs noticeably from the water H–O–H angle in gas phase, 104.5°; this implies that the O–H···O hydrogen bonding is not linear. The $O(2)$–$H_2O(2)$–$O(4)^{v}$ angle is near to 104.5°, and O–H···O in this case can be considered to be almost linear. Judging from the infrared spectra data, it would seem that the O–H···O distances of 2.78 and 2.87 Å can be predicted from the O–H stretching frequencies, 3250 and 3450 cm^{-1},[5] by the aid of the empirical relationships proposed by Nakamoto.[15] Actually, these values agree fairly well with the present structural data.

The Structure of the MoO_4^{2-} Anion. The Mo–O distances and O–Mo–O angles are listed in Tables 5 and 6. The shape of the anion is a slightly deformed tetrahedron, and the Mo–O distances in the MoO_4^{2-} anion are almost equal to those found in the anhydrous K_2MoO_4 crystals (1.74(1) and 1.78(1) Å).[16] The four oxygen atoms in MoO_4^{2-} are crystallographically unique. The O(2) atom which is coordinated to the Na(2) cation forms two hydrogen bonds with two water molecules, and O(4) also accepts two hydrogen bonds and is attached to Na(1); on the other hand, O(1) and O(3) form no hydrogen bonding, each oxygen atom being coordinated to Na(1) and to Na(2). The bond lengths, Mo–O(2) (1.788(6) Å) and Mo–O(4) (1.781(6) Å), appear to be significantly longer than Mo–O(1) (1.768(5) Å) and Mo–O(3) (1.752(6) Å). The O(2)–Mo–O(4) angle (112.74(26)°) is larger than any other O–Mo–O angle by 3.23—5.12(26)°. The MoO_4^{2-} tetrahedra appear to be elongated, as if pulled by the hydrogen bonds, on pushed by sodium cations. However, an example of the deformation of SO_4^{2-} anions in the opposite direction was found in the $CaSO_4\cdot 2H_2O$ crystal,[17] containing two kinds of crystallographically independent sulfate oxygens, O_I and O_{II}, the former one with two hydrogen bonds to water molecules, and the later one with a close Ca^{2+} neighbor. Here elongation is observed in the direction of the Ca^{2+} cations, and the hydrogen bonds to the water molecules do not seem stretch the SO_I bond. Therefore, we need still more examples before we can undertake a general discussion of the effect of hydrogen-bond or coordination-bond formation on the shape of tetrahedral oxyanions.

Comparison with Octahedral MoO_6 Unit in Polymolybdates. In the present study, the Na–O (belonging to tetrahedral MoO_4^{2-}) bond lengths were found to lie between 2.29 and 2.48 Å, and in the literature those of the Na–O (belonging to MoO_6 unit) in the polymolybdates, $Na_6Mo_5P_2O_{23}\cdot 12H_2O$,[1] $Na_4H_2Mo_5P_2O_{23}\cdot 12H_2O$,[2] and $Na_6Mo_7O_{14}\cdot 14H_2O$,[3] range from 2.27 to 2.55 Å. These ranges agree with that of the Na–O(H_2O) bond lengths found in the above-mentioned four compounds. It seems that there is no distinct difference between the oxygen atoms in the MoO_4^{2-} anion and those of the MoO_6 unit in polymolybdate anions and water molecules in the coordination-bond distance to the Na^+ cation.

Crystal Structure of $Na_2WO_4\cdot 2H_2O$. The structure determination of $Na_2WO_4\cdot 2H_2O$ was also started at the same time in this laboratory; it was found that the crystals were exactly isostructural, with slightly larger unit-cell dimensions. However, it was impossible to find well-formed crystals for accurate experiments, and so further detailed computation was abandoned. Later the structure was reported by Okada, Morikawa, Iwai, and Marumo[18] independently.

The calculations were performed on a HITAC 8700/8800 computer at the Computer Centre of the University of Tokyo, using a local version of UNICS.[20]

The authors are indebted to Professor N. Ingri of the University of Umeå for sending us papers from his Institute prior to publication.[1-3] Thanks are also due to Professors H. Kuroya and S. Ooi of the Osaka City

University for reading through the manuscript and for their advice.

Infrared Spectra and Structure of Substituted Unsaturated Carbonyl Compounds. XVIII. *N*-Alkyl-enamino Thiones

Urszula DABROWSKA and Janusz DABROWSKI
Institute of Organic Chemistry, Polish Academy of Sciences, 00-961 Warsaw, Poland
(Received January 7, 1974)

Skeletal and N–H bending vibrations have been investigated in enamino thiones having the general formula $R^1C(S)CH=C(R^3)NHR^4$ (R=alkyl) and compared with those of the oxygen analogues (enamino ketones).

Previous work[1] has shown that the interpretation of IR spectra of enamino ketones, in the region where absorptions due to skeletal vibrations occur, is made very difficult by the presence of strong vibrational coupling. The effect encompasses all the bonds present in the main chain of molecules of this type (O=C–C=C–N<H). This also applies to bending vibrations of the amino group: these are uncharacteristic, due undoubtedly to strong vibrational interactions with the skeleton.

Replacing oxygen by sulphur, whilst effectively not changing the mesomerism within the molecule, does lead to a change in the frequencies of skeletal vibrations. It seemed likely that this would afford a better opportunity of studying the absorptions corresponding to bending vibrations of the >NH group. Such was the main reason why the present work on the IR spectra of a number of secondary enamino thiones and their deuterated derivatives (listed in Table 1) was undertaken. Their oxygen analogues (enamino ketones) have been included for comparison. Moreover, an attempt has been made to assign the absorption bands for other vibrations of the above system, especially the stretching vibrations of the thione group. Previous assignments[2] with $\nu_{C=S}$=1260—1300 cm^{-1} are incorrect.[3]

Experimental

The syntheses of 4-ethylaminobuten-3-thione-2 (I) and 1-methylaminopenten-1-thione-3 (II) have been described in a previous paper.[2] 4-Propylaminobuten-3-thione-2 (III) and 4-propylaminopenten-3-thione-2 (IV) were obtained in a similar way. Infrared spectra were recorded on a VEB Carl Zeiss (Jena) UR-20 double beam spectrometer using NaCl and KBr prisms. Solvents and concentrations are reported in Tables 2 and 3.

Results and Discussion

The >NH stretching region is specifically dealt with in a separate paper;[4] in the present work the 1800—400 cm^{-1} region has been studied. Here, in theory, four bands due to skeletal stretching vibrations of the S=C–C=C–N< system are to be expected, together with two bands derived from >NH bending (assuming there is no strong interaction with other oscillators).

It has been considered appropriate to retain the nomenclature previously used for the skeletal bands, *i.e.* "Amide Vinylogue Bands," AV-I, AV-II, AV-III, and AV-IV.[1] However, whereas in enamino ketones the AV-I frequency (mainly $\nu_{C=O}$) was the highest the analogous AV-I frequency in the thiones is the lowest of the four (Tables 2 and 3). AV-II is a skeletal vibration, chiefly of $\nu_{C=C}$ character but with a significant contribution from NH bending. AV-III and AV-IV are coupled vibrations dominated by C–C and C–N stretching. Apart from these four bands one other due to a vibration dominated by N–H bending has been identified. In recent papers Taylor[5,6] has discussed our previous results, and in particular our nomenclature, obviously without being aware of some of the arguments presented in the references cited by him, and also of our subsequent papers[1c–h] where the infrared spectroscopy of enamino carbonyl compounds has been further discussed. Thus, in contrast to Taylor's assesment,[5] we were able in many cases to obtain a complete separation of isomers[1a,d,e] and there is really no ground for the statement[5] that: "Up to the present time no detailed infrared study based on compounds of known configuration has appeared." As to the nomenclature, Taylor supposed that our reason for not naming directly the bands $\nu_{C=O}$ and $\nu_{C=C}$ was due possibly to the "··· prejudice that existed, and still exists, against assigning the strongest band in the 6 μm region to anything other than carbonyl".[6]

In fact we did not consider intensity as a factor in the discrimination between the $\nu_{C=O}$ or $\nu_{C=C}$ character of any of the bands under discussion. On the contrary, we showed, that a band, which is conventionally assigned $\nu_{C=C}$, can be both more intense than "$\nu_{C=O}$" (for the *trans-s-cis*[1c] and *cis-s-cis* forms[1c,e]) as well as less intense (for the *trans-s-trans* form[1e]). The main reason for proposing a nomenclature similar to that employed for amides (*i.e.* the avoidance of a simplified

a) Band position was determined for neat compounds.

group frequency nomenclature) was the pronounced vibrational coupling in amide vinylogues; the coupling manifests itself in both isotopic[1a,c-h] and solvent shifts[1a,b] of the bands and is unexplanable within a simple concept of characteristic group frequencies.

The skeletal bands of compounds I, II, and III manifest themselves as described below.

AV-II, dominated by C=C coordinate, appears in solution spectra (in C_2Cl_4) at frequencies between 1622—1631 cm^{-1}, *i.e.* 39—47 cm^{-1} higher than in the case with the oxo analogues (comparison of I, II, and III with Ia, IIa, and IIIa in Tables 2 and 3). This can be explained in terms of a "repulsive" interaction between C=O and C=C oscillators in the oxo compounds. At the same time, this frequency is lower by some 30 cm^{-1} than $\nu_{C=C}$ is in olefins since the conjugation with the thione group is comparable to that with the carbonyl group.

The positions of bands AV-III at 1492—1495 cm^{-1} and AV-IV at 1266—1291 cm^{-1} differ little from those of the corresponding bands in the enamino ketones. This is to be expected since, as has already been stated, there is no inherent difference in the bond orders within the two skeletons being compared. It should be added that under the conditions described above, both classes of compounds exist in the *cis* form.

As for the bending vibrations of the >NH group, with solution spectra (in C_2Cl_4) of the thioketones I, II, and III the appropriate band is not observed as a separate entity. On the other hand, the pure substances (which according to NMR data, also exist exclusively in the *cis* form) exhibit an additional band in the region 1585—1587 cm^{-1}. This disappears on deuteration while a new band arises at 1156—1160 cm^{-1} (see Figs. 1 and 2). This band is also absent in the Ni(II) complex of I. Another consequence of deuteration is the shift of AV-II to 1592—1599 cm^{-1}, *i.e.* 29—36 cm^{-1} towards lower frequencies.

The fact that two bands are affected by deuteration permits us to assume that both represent some complex form of vibration with contributions from skeletal and NH bending modes. In the deutero derivative these

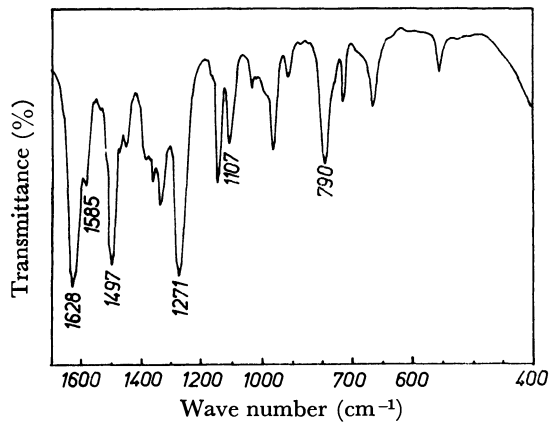

Fig. 1. Infrared spectrum of 4-ethylaminobuten-3-thione-2 (I); capillary film.

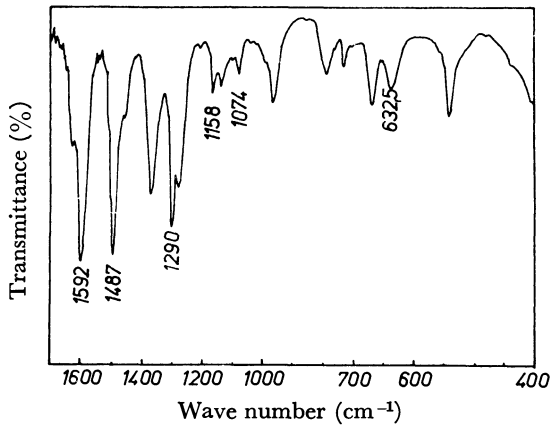

Fig. 2. Infrared spectrum of deuterated 4-ethylaminobuten-3-thione-2 (Id_1): capillary film.

vibrations are no longer coupled to an appreciable degree; thus, the band above 1500 cm^{-1} corresponds to a large extent to sketetal vibrations and the 1156—1160 cm^{-1} band to δ_{N-D} vibrations.

Remarkably, compound IV (having, β to the thiocarbonyl group, a methyl group instead of hydrogen) exhibits spectral characteristics which differ somewhat from those of compounds I, II, and III. The AV-II frequency is lowered by 26 cm^{-1} (for neat liquid) which indicates a lowered C=C bond order. Instead of two separate bands of the δ_{N-H} and AV-III type one band was found at 1537 cm^{-1} which exhibits features characteristic of both the skeletal stretching and NH bending vibrations. This assignment is based on the results of deuteration of the compound IV: in place of the disappeared 1537 cm^{-1} band two bands, *viz.*, a strong AV-IIId_1 band at 1476 cm^{-1} and a δ_{N-D} one at 1216 cm^{-1} occur. Obviously, a decoupling of the complex AV-III$+\delta_{N-H}$ vibration resulted from deuteration.

In order to understand the unusual spectral behaviour of compound IV one must take into account the great degree of stabilization achieved by the *cis* form. There is then a complementary increase in the strength of the intramolecular hydrogen bonding as compared with compounds I, II, and III (this has been shown in a previous paper[4]). We can thus postulate greater intramolecular charge delocalization and further, an equalization of the bond energies within the skeleton. This may be the reason for the exceptional nature of the IR absorption of compound IV.

In the literature[7,8] dealing with the absorptions of the thiocarbonyl group it is stated that the C=S band appears at 1170—1220 cm^{-1} in aromatic thioketones and at 1244—1270 cm^{-1} in aliphatic thioketones.[8] Clearly the position of the band depends on the coupling present (assuming, of course, that the assignments are correct).

The problem is particularly difficult in the compounds here investigated because, due to the strong coupling of the skeletal vibrations, there cannot exist a vibration localized solely within the C=S group. For this same reason no resemblance to the spectra of thiones described in the literature is expected.

For the purpose of detecting such a band in which the contribution of C=S stretching predominates, (designated AV-I, according to our nomenclature) we utilized the changes that take place in the spectrum when, in a medium of dimethylsulphoxide, the *cis* form changes to the *trans*. NMR spectra have confirmed, unequivocally, that a partial *cis-trans* isomerisation takes place under these conditions. In the IR spectrum a new AV-I band is expected at higher frequencies, the hydrogen bonds, >N–H···S=C< having been broken by dimethylsulphoxide. In the region under discussion the 1106—1115 cm^{-1} band undergoes a definite change (*cf.* the spectra in Table 2). In dimethylsulphoxide solution this band contracts while at the same time a new band appears at higher frequencies (1130—1135 cm^{-1}). The first of these would thus correspond to the AV-I vibration of the *cis* form and the second to that of the *trans* form. As we have already communicated[3] our previous assignments[2] of the AV-I ("$\nu_{C=S}$") band were incorrect.

Another characteristic feature of the spectra of enamino thiones, found in all the examples studied is the presence of intense wide band in the region 786—802 cm^{-1}. This is probably an out-of-plane deformation of the NH group since deuteration causes a decrease in the intensity of the band together with the appearance of a new band at 630 cm^{-1}.

The authors thank Dr. Jacek Chudy (University of London) for assistance in preparing the manuscript. The work carried out is part of the Polish Academy of Sciences programme for structural research (PAN-3).

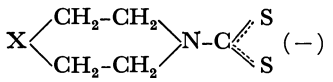
Dithiocarbamate Complexes of Rhodium(III), Iridium(III), Palladium(II) and Platinum(II)

G. MARCOTRIGIANO, G. C. PELLACANI, C. PRETI,* and G. TOSI
Istituto di Chimica Generale ed Inorganica, University of Modena, 41100 Modena, Italy
(Received June 12, 1974)

The complexes of rhodium(III), iridium(III), palladium(II) and platinum(II) with piperidine-, piperazine-, *N*-methylpiperazine-, morpholine- and thiomorpholine-dithiocarbamate have been prepared and characterized by spectroscopic methods. From the electronic absorption spectra the values of the ligand field parameters were determined. The nephelauxetic parameters are indicative of a strong covalency in the metal-ligand bond. A monomeric structure for the complexes is suggested. All the new compounds here reported are diamagnetic.

In a previous paper[1] we have discussed the complexes of many transition metals with piperidine-, thiomorpholine- and *N*-methylpiperazine-dithiocarbamate. We report now the preparation and the characterization of new complexes of rhodium(III), iridium(III), palladium(II) and platinum(II) with:



X=CH_2	Pipdtc
X=NH	Pzdtc
X=N-CH_3	CH_3-Pzdtc
X=O	Morphdtc
X=S	Timdtc

in order to investigate particularly the spectrochemical properties of these compounds. This paper is the extension of the previously reported studies on the dithiocarbamates in order to further our present knowledge and to gain new informations concerning the behaviour of the different ligands by substituting the dialkyl derivatives for the heterocyclic dithiocarbamates.

The complexes have been characterized on the basis of vibrational (conventional and far infrared) and electronic spectroscopy and magnetic measurements.

During the first draft on this manuscript Sceney and Magee[2] reported the complexes $Pd(Pipdtc)_2$ and $pd(Morphdtc)_2$ that we have included for comparison purposes only.

Results and Discussion

The complexes obtained and some physical properties are reported in Table 1. Solid state electronic spectra are given in Tables 2 and 3. The most important infrared bands are summarized in Table 4.

The metal dithiocarbamates were prepared using the appropriate sodium dithiocarbamate and rhodium trichloride, ammonium esachloroiridate(III), palladium(II) nitrate and potassium tetrachloroplatinate(II) according to the methods described in the experimental section.

The compounds are micro-crystalline, soluble in acetone, *N*,*N*-dimethylformamide and chloroform.

The trisdithiocarbamate derivatives of rhodium(III) and iridium(III) are low-spin type (t^6_{2g}). Solid state electronic spectra confirm an octahedral configuration

a) Ref. 2

of the central atom, Table 2.

The bands positions are similar to those reported with other sulphur coordinating ligands.

The band at somewhat higher energies in the iridum derivatives, *ca.* 31000 cm^{-1}, can be attributed to a charge transfer transition[3,4].

Studies on the electronic spectra of IrS_6 complexes are rare, the assignments of the transitions in our complexes were made with the aid of previous reports.[5,6]

The ratios ν_2/ν_1 are in the range 1.19—1.23 and are equal to 1.06 for rhodium and iridium complexes respectively, in very good agreement with the literature data of diethyldithiophosphate derivatives.[7]

The ligand field parameters Δ, B′ and β have been calculated by means of the equations

$$\nu_1 = \Delta - 4B' + 86(B')^2/\Delta \quad \nu_2 = \Delta + 12B' + 2(B')^2/\Delta$$

and are reported in Table 2. The B' values are of the order of 40—50% of the free ion value in rhodium complexes, and of 15% of the free ion value in iridium derivatives. This fact suggests that there is a considerable orbital overlap with a strong covalency in the metal-ligand σ bond.

The nephelauxetic effect is quite in line with other sulphur-containing chelating agents, which give a very pronounced nephelauxetic decrease of β[6]. It is well known that decreasing values of β are associated with a reduction in the effective positive charge of the metal ion and with an increasing tendency to be reduced to the next lower oxidation state. For the second-row transition metals the variation of the Racah interelectronic repulsion parameter with cation charge Z*, and the number q of electrons in the partly filled d shell, is well-expressed by the relation:

$$B'(cm^{-1}) = 472 + 28q + 50(Z^*+1) - 500/(Z^*+1)$$

The effective ionic charges of the rhodium complexes have been found (Table 2) to lie in the range 0.27—0.47, considerably below the formal +3 oxidation state of rhodium. Rhodium(III) complexes with oxygen donors have effective charges[8] in the range 1.65—2.03.

In the electronic spectra of palladium(II) derivatives, recorded in solid state as nujol mulls, only the first band, mostly a shoulder, at 22300—22700 cm^{-1}, can be considered a d-d transition. The great intensity of the second band suggests that it may be charge-transfer in character rather than ligand-field. The d-d band can be assigned to the $^1A_g\rightarrow{}^1B_{1g}$ (x^2–$y^2\rightarrow xy$) transition.[9] By assuming a value of $F_2=10F_4=$ 600 cm^{-1} for the Slater-Condon interelectronic repulsion parameters,[10] it is possible to derive from the first spin-allowed d-d transition the value of Δ_1 being

$\nu_1+3.5F_2=\Delta_1$ (Table 3). The fact that the first d-d band is at higher energy for palladium(II) (22300—22700 cm^{-1}) than for nickel(II) (16000—16100 cm^{-1})[1] agrees with the spectrochemical order of these metal ions.

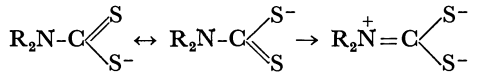
Infrared spectral studies of dithiocarbamates have not been carried out in detail, it is quite difficult to assign the bands being most of them very highly coupled. A normal coordinate analysis has been carried out by Nakamoto[11] for the complex $[Pt(S_2CNH_2)_2]$ and by Dugarprased[12] for the derivative $[Ni(Me_2dtc)_2]$.

The ν(C=N) and ν(C=S) stretching frequencies for the free ligand sodium salts and for our complexes are reported in Table 4. The medium band present in all the studied complexes in the range 835—790 cm^{-1} is assigned to a C–S stretching coupled with the NH_2 rocking mode.

Very little differences have been observed in the infrared spectra of the complexes on changing the heterocyclic ring in the system.

The ν(C=N) stretching mode of the dithiocarbamate used as ligands in this work is at lower wave numbers than ν(C=N) of diethyldithiocarbamate, 1477 cm^{-1}. This difference is reflected in the complexes too, in fact if we compare the dithiocarbamates of iridium, palladium and platinum we observe that ν(C=N) follows the order: $Me_2dtc>Et_2dtc>Pipdtc>nPr_2dtc>nBu_2dtc>CH_3$-Pzdtc>Pzdtc>Morphdtc > Timdtc $>iPr_2dtc>iBu_2dtc>CycHex_2dtc$.

The structure of the dithiocomplexes can be represented by the following formalism:



(a) (b) (c)

The extent to which resonance form (c) contributes to the structure and its effects on the physical and chemical properties of the complexes has been extensively studied. Chatt and co-workers[13] concluded that resonance form (c) does indeed contribute to the structure to a considerable extent.

From the above reported sequence of ν(C=N) we could conclude that the contribution of structure (c) is greatest for the corresponding dialkyl complexes, lower for more complex aliphatic chain and it is relatively small for heterocyclic derivatives. Perhaps because of the rigid heterocyclic ring system which shows less tendency to release electrons to the nitrogen-carbon bond and, as consequence, this bond has a less double-bond character.

In the far infrared region the bands of the ligands appear unchanged in the complexes spectra. New bands appear in the rhodium derivatives at *ca.* 330 cm^{-1} and at *ca.* 325 cm^{-1} in iridium complexes (Table 4). These absorption bands, absent in the spectra of the free ligand and in the spectra of palladium and platinum derivatives, are to be due to a metal ligand interaction. We could tentatively assign these values to a ν(Rh-S) and ν(Ir-S) stretching vibrations respectively.

According to Sceney[2] and Nakamoto[11] we can assign the palladium-sulphur and platinum-sulphur vibration modes in the ranges 353—340 cm^{-1} and 380—345 cm^{-1}, 300—290 cm^{-1} respectively, the bands at 300—290 cm^{-1} in platinum complexes being coupled with a ring deformation mode.

Experimental

Preparation of the Ligands. The sodium salt of the piperidine-, thiomorpholine- and *N*-methylpiperazinedithiocarbamate have been prepared as previously described.[1] The sodium morpholinedithiocarbamate has been prepared by treating morpholine in dry ethyl ether with carbon disulphide and adding under vigorous stirring sodium hydroxide during four hr. Molar ratios amine : CS_2 : NaOH= 1 : 1 : 1. The crude product was recrystallized from isopropyl alcohol. The sodium piperazinedithiocarbamate has been prepared by the same method, starting with piperazine dissolved in dry ethyl ether and isopropyl alcohol. The crude product was recrystallized from methanol/ethyl ether.

Preparation of the Complexes. The complexes have been obtained by adding an aqueous solution of rhodium trichloride, ammonium esachloroiridate(III), palladium nitrate, potassium tetrachloroplatinate(II) to the dithiocarbamate dissolved in methanol or water, at room temperature. The precipitate was filtered, washed with methanol and dried over P_4O_{10}.

Infrared Spectra. The IR spectra have been recorded in the range 4000—200 cm^{-1} with Perkin-Elmer 457 and 225 spectrophotometers as KBr discs and nujol mulls between polyethylene sheets. Atmospheric water was removed from the spectrophotometer housing by flushing dry nitrogen.

Visible and UV Spectra. Solid state electronic spectra have been recorded with a Shimadzu MPS-50L spectrophotometer.

Magnetic Susceptibility Measurements. These were carried out by Gouy's method. Molecular susceptibilities were corrected for diamagnetism of the component atoms by use of the Pascal's constants. All the complexes resulted diamagnetic.

We thank Dr. G. P. Benassi for his experimental work and the National Research Council (C.N.R.) of Italy for financial support.

ESR Study of MoO_3 Obtained from Thermal Decomposition of Ammonium Molybdate

R. S. MANN and K. C. KHULBE

Department of Chemical Engineering, University of Ottawa, Ottawa, Canada

(Received August 7, 1974)

The thermal decomposition of ammonium molybdate, between 100—600°C was studied by ESR technique. At 250 °C all ammonium molybdate was decomposed into molybdenum trioxide. Samples taken at 250, 300, 350, 400 and 450 °C all gave ESR signals. Samples at other temperatures (higher and below of this temperature range) did not give any ESR signal. The ESR signals were due to the formation of Mo^{5+} and Mo^{3+} ions. The maximum ESR intensity was observed for the sample (MoO_3) at 300 °C. The different colouration of molybdenum trioxide formed at different temperature, was due to Mo^{5+} and Mo^{3+} ions.

Molybdenum trioxide catalyst is usually prepared in the laboratory by thermal decomposition of ammonium molybdate. Onchi and Ma[1] studied the gases evolved during thermal decomposition of ammonium molybdate by using the omegatron mass spectrometer at 395°C. No electron spin resonance (ESR) study has been reported during the formation of MoO_3 from thermal decomposition of ammonium molybdate. It is well known that pure MoO_3 does not give ESR spectra being a higher oxide[2]. In the present paper we report the formation of Mo^{5+} and Mo^{3+} during the MoO_3 formation from ammonium molybdate at different temperature.

Experimental

The MoO_3 was prepared by heating ammonium molybdate (B.D.H.A.R. Grade). Ammonium molybdate was dissolved in minimum quantity of warm water and the solution evaporated over a hot plate with a magnetic stirrer at low heat. The residue was dried for 12 hr at 60°C. The temperature was increased and maintained successively for 24 hr at 100, 150, 200, 250, 300, 350, 400, 450, 500, and 600°C. The samples were taken from the bulk before increasing the temperature. The ESR measurements were carried out by using Bruker 416 spectrometer in which the microwave frequency was in the X band. All measurements were made at room temperature. The Phillips difractometer was used for X-ray analysis of the samples. Measurements were carried out by Debye Sherrer method at room temperature using a cobalt target and an iron filter.

Results

a) X-Ray Analysis. The following table (Table 1) gives the results of X-ray analysis of the thermal decomposition of ammonium molybdate at different temperatures. At 250°C all ammonium molybdate was decomposed and pure MoO_3 formed. There were no other phases (other molybdenum oxides) present except molybdenum trioxide. The colour of the mass changed from white to bluish or gray and again to white as the temperature was raised. The colour of the molybdenum trioxide obtained at 300 °C was sharper than other samples of molybdenum trioxide obtained at other temperature.

b) ESR Measurements. Samples taken at 250, 300, 350, 400, and 450 °C all gave ESR signals. Samples at other temperatures (higher and below this range) did not give any ESR signals. Well resolved hyperfine structure was obtained for molybdenum trioxide at 300 °C obtained from the thermal decomposition of ammonium molybdate (Fig. 1), after which the individual hyperfine line broadened out

TABLE 1. RESULTS OF THE PHASE ANALYSIS

Sample at °C	Identified by	Colour
100	Molybdenum-Ammonia-Oxide-Hydrate (NH_3), $Mo_5O_{15}2H_2O$	White
150	$(NH_3)_4Mo_5O_{15}2H_2O$	White
200	$(NH_4)Mo_8O_{26}$ [b]	Grayish white
250	Molybdite, (MoO_3) [c]	Grayish white
300	Molybdite	Gray or bluish
350	Molybdite	Gray or bluish
400	Molybdite	Grayish white
450	Molybdite	Grayish white
500	Molybdite	Grayish white
550	Molybdite	Yellowish white
600	Molybdite	White

TABLE 2. ESR INTENSITY WITH TEMPERATURE

Sample at 0 °C	ESR signal intensity (main line) rel. units
100	0
150	0
200	4
250	11
300	54
350	13
400	6
450	2.5
500	2.0
550	~0
600	~0

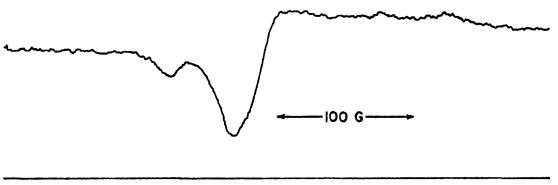

Fig. 1. ESR spectrum of MoO_3 formed at 300 °C.

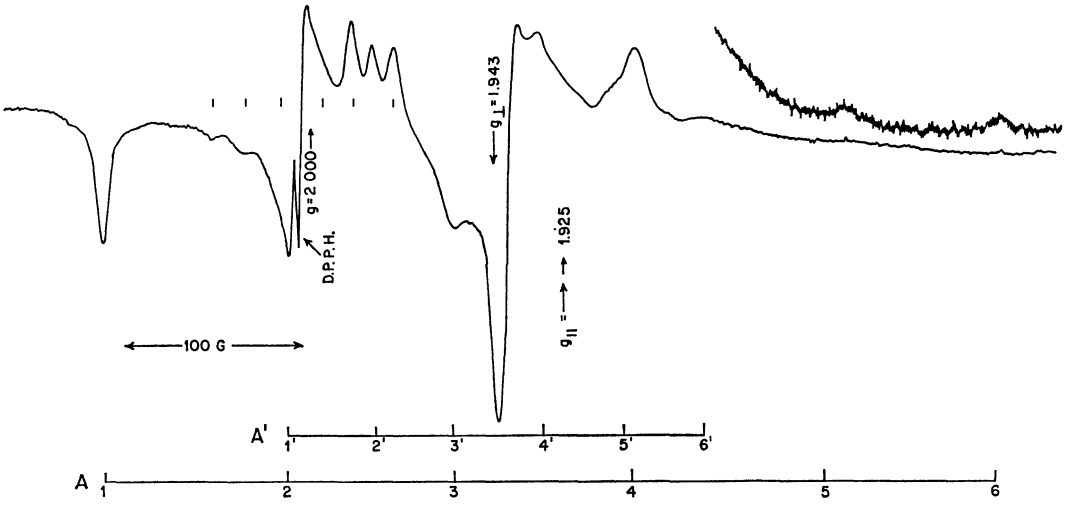

Fig. 2. ESR spectrum of MoO_3 formed at 450 °C.

to form a single broad line near the centre of the spectral pattern (Fig. 2). On the spectrum of the even numbered isotopes there is superimposed hyperfine structure from the uneven numbered isotopes ^{95}Mo and ^{97}Mo (Fig. 1). The quantum number which describe the spectrum are $S=1/2$ and $I=5/2$, and the appropriate axial spin Hamiltonian is:

$$H = \beta[g_{\parallel} H_z S_z + g_{\perp}(H_x S_x + H_y S_y)] + A I_z S_z + B(I_x S_x + I_y S_y)$$

where the terms have their usual meaning. The spin Hamilton parameters were calculated as shown in Table 3.

TABLE 3. A COMPARISON OF RESULTS OBTAINED

Ref.	g_1	$g_{\parallel}$	A	B
Maksimovskya *et al.*[5]	1.932	1.88	98±3	52±3
Sultanov *et al.*[6]	1.93	1.88		
Present case	1.943	1.925	100±6	49±2

The effect of the temperature on the ESR signal was investigated. It is apparent from Table 1 and Table II that the maximum signal intensity is observed for a sample at 300 °C when the colour of the molybdenum trioxide was sharper (bluish) than others.

Discussion

Natural molybdenum is a mixture of isotopes, 25% of which consists of two isotopes (^{95}Mo—15.7 and ^{97}Mo—9.4) with nuclear spin of 5/2. The interaction of an unpaired electron with the nuclear magnetic moments of these two isotopes should lead to hyperfine splitting of the spectrum into six components. The remaining isotopes do not have nuclear spins, and should give a spectrum consisting of one line only. Accordingly, the ESR spectrum of the Mo ion should consist of seven lines, the central line being about 25 times as intense as others.

Molybdenum can exist in any of four valency, 6^+, 5^+, 4^+ and 3^+ corresponding to d^0, d^1, d^2 and d^3 configuration. Hexavalent molybdenum if diamagnetic and, therefore gives no ESR signal. The tetravalent molybdenum, even if it were paramagnetic would not be observed except at very low temperatures. Also it would be expected that any observed resonance due to d^2, would have a large zero field splitting and therefore would give a very broad signal. Hence the observed signals must be due to Mo(V) and Mo(III).

The patterns of line shown in Fig. 1 are characteristic of Mo^{5+} ion and Mo^{3+}. Landry[3] studied Mo(III) in Al-Zn-phosphate-glass and reported a very broad spectrum at g_{eff} of 4.19. Griffiths, Owen and Ward[4] studied hydrated and unhydrated chloro and fluro complexes of Mo(III) and have reported isotropic g value around 1.96. In the present spectra there are six hyperfines including the main signal at around $g=2.000$. Further the hyperfine lines are approximately at equal spacing *i.e.* around 20±.5 G. Thus it is confirmed that this line *i.e.* at around $g=2.000$ with 6 hyperfine lines is due to Mo^{3+} ion and is not from a free electron.[5] The rest of the spectra is due to Mo^{5+} ion. The g value and other parameters are calculated and are given in Table 3. These are approximately the same as observed by others.[6,7] Thus it is confirmed that the Mo^{5+} and Mo^{3+} are formed during the thermal decomposition of ammonium molybdate.

It is well known that molybdenum trioxide (MoO_3) forms a number of nonstoichiometric oxides on heat treatment in vacuum or in a reducing atmosphere. The departure from stoicheometry is generally associated with the formation of colour centre or can acquire a blue colouration, the so called "Molybdenum blue". The general interpretation had been that the colouration is due to crystal field spectra of electrons in the Mo^{5+} state. The mechanism of the colouration process is not well understood. Deb and Chopoorian[5] suggested that the colour centres in MoO_3 are formed as a result of the free electrons being trapped in oxygen ion vaccancies. An attempt to detect the presence of a one electron centre by the ESR studies on UV irradiated thin film of MoO_3 had failed. In the repeated

experiment[8] a new weak ESR absorption at $g=2.000\pm0.005$ was observed which is close to the free electron value. In the present study the absorption at $g=2.00$ has six hyperfine lines (Fig. 1) which are due to Mo^{3+} not a free electron. The maximum ESR intensity was observed for the sample MoO_3 at 300 °C (Table 2) and also the colour of the sample was sharper than others (Table 1). The intensity of the ESR signals and the colour decreased with the increase of temperature. It may be possible that the colouration is due to Mo^{5+} and Mo^{3+} (may be Mo^{4+} ion too) ions, and not due to the trapped electrons at anion vaccancies as suggested by Deb and Chopoorian.[5]

We are greatly indebted to Dr. A. Manoogian (Physics Department, University of Ottawa, Ottawa) for discussion and encouragement. The authors are also grateful to National Research Council for financial assistance for the project.

Complexing Behaviour of 5-Amino-1,3,4-Thiazole-2-thiol. II. Complexes of Ni(II), Rh(I), Pd(II), Pt(II), Au(III) and Cu(II)

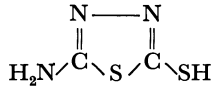
M. R. GAJENDRAGAD and U. AGARWALA*

Department of Chemistry, Indian Institute of Technology, Kanpur-208016, India

(Received July 30, 1974)

Complexes of Ni(II), Rh(I) Pd(II), Pt(II), Au(III) and Cu(II) with 5-Amino-1,3,4-thiadiazole-2-thiol have been prepared. Probable structures have been proposed for the complexes on the basis of visible and infrared spectral and magnetic susceptibility data and results of chemical analysis. Crystal field parameters have been calculated wherever possible.

In our previous communication[1] we had indicated our interest in the study of metal complexes with 5-amino-1,3,4-thiadiazole-2-thiol (I).



(I)

This has been used earlier as an analytical reagent.[2-4] Structure elucidation of the metal complexes of this ligand have not so far been done and the present work is an attempt an investigating the structural aspects of metal complexes with this ligand. In this communication, we report the preparation and characterisation of the complexes of Ni(II), Rh(I), Pd(II), Pt(II), Au(III) and Cu(II) with the ligand in question.

Experimental

The chemicals used were all of Analar or chemically pure grade.

I *Preparation of the Ligand.* *(a) 5-Amino-1,3,4-thiadiazole-2-thiol*: This was prepared by the method given by Sandstrom.[5] The ligand is hereafter referred to as (Htta) in the abbreviated form.

(b) Deuterated form of 5-Amino-1,3,4-thiadiazole-2-thiol: About 0.1 g of (I) was dissolved in 25 ml hot D_2O and the resulting solution refluxed for 6 hr under dry nitrogen. On cooling, the deuterated ligand crystallized. The crystals were separated by centrifugation and dried in a vacuum desiccator overnight, and finally in an oven at 105°C for 4 hr.

II *Preparation of the Metal Complexes.* *(a) Bis(5-amino-1,3,4-thiadiazole-2-thiolato)diaquonickel (II)*: A solution of 1.8 g (~5 mmol) of $NiCl_2 \cdot 6H_2O$ in 25 ml water was added to a solution of 1.4 g (~10 mmol) of (I) in about 60 ml mixture of alcohol and water (1 : 1), neutralised with NH_4OH solution. A bluish green complex was immediately formed. The product was digested on a water bath for an hour, centrifuged, washed repeatedly with hot water, warm alcohol and finally with ether. The residue was dried in a vacuum desiccator about 6 hr.

(b) Chloro(5-amino-1,3,4-thiadiazole-2-thiolato)dipyridinenickel(II): About 10 ml of pyridine was added to a solution of 1.8 g (~5 mmol) of $NiCl_2 \cdot 6H_2O$ in 25 ml water. A deep blue solution resulted. This was then added to a solution of 1.4 g (~10 mmol) of (I) in about 60 ml mixture of alcohol and water (1 : 1), neutralised with NH_4OH solution. A greyish green complex was slowly formed on heating the solution on a water bath. The product was digested on the water bath for an hour, centrifuged, washed and dried as described in II(a).

(c) Chlorobis(5-amino-1,3,4-thiadiazole-2-thiol)triphenylphosphine rhodium(I): Chlorotris(triphenylphosphine)rhodium(I) was first prepared by the method given in literature.[6]

A solution of 0.6 g (~0.67 mmol) of $Rh(P\emptyset_3)_3Cl$ in 25 ml warm benzene was added to a solution of 0.4 g (~3 mmol) of (I) in 50 ml alcohol. The resulting solution was digseted on a water bath for an hour when a reddish brown complex was formed. The product was centrifuged, washed repeatedly with hot benzene, warm alcohol and finally with ether. The residue was dried in a vacuum desiccator overnight.

(d) Bis(5-amino-1,3,4-thiadiazole-2-thiolate)palladium(II): A solution of 0.35 g (~2 mmol) of $PdCl_2$ was prepared in 50 ml warm water containing KCl. This was added to a solution of 0.35 g (~4 mmol) of (I) in a 50 ml mixture of alcohol and water (1 : 1). A chocolate red complex was immediately formed. It was digested on a water bath, centrifuged, washed and dried as described in II(a).

(e) Bis(5-amino-1,3,4-thiadiazole-2-thiolate)platinum(II): K_2PtCl_4 was first prepared by the method given in the literature.[7]

A solution of 0.4 g (~1 mmol) of K_2PtCl_4 in 20 ml water was added to a solution of 0.30 g (~2 mmol) of I in 25 ml alcohol. A rose red complex was formed when the solution was heated on a water bath. The rest of the procedure was the same as that described in II(a).

(f) Tris(5-amino-1,3,4-thiadiazole-2-thiolate)gold(III): A solution of 0.45 g (~1 mmol) $AuCl_3$ in about 10 ml water was added to a solution of 0.4 g (~3 mmol) of (I) in 30 ml alcohol. A pale yellow complex was immediately formed. The product was digested on a water bath for an hour, centrifuged, washed and dried as described in II(a).

(g) Bis(5-amino-1,3,4-thiadiazole-2-thiolato)copper(II): A solution of 0.8 g iodine in 50 ml alcohol was added to a solution of 1.2 g (~6 mmol) of $CuCl_2\ 2H_2O$ in 30 ml alcohol. The resulting solution was then added to a solution of 1.6 g (~12 mmol) of (I) in 100 ml alcohol. A green complex was immediately formed on mixing. The product was digested on a water bath, centrifuged, washed and dried as described in II(a).

Analyses. The sulphur, phosphorus and chloride (wherever present) in the ligand and the complexes were estimated by standard method.[8,9] The analyses of the metal ions in the complexes were carried out by the methods given in literature.[9,10]

Carbon, hydrogen and nitrogen were analysed by the microanalytical section of the Indian Institute of Technology, Kanpur.

The results of all the analyses are given in Table 1.

Magnetic Susceptibilities. Magnetic susceptibilities of the complexes were determined at room temperature with a Guoy balance. Mercurytetrathiocyanatocobaltate(II) was used as a magnetic susceptibility standard. Diamagnetic

* To whom all correspondence should be addressed.

corrections were calculated by the method given in literature.[11] The values of the magnetic moments are given in Table 1.

Spectra. *(i) Visible and Ultraviolet*: The absorption spectra of the ligand and the complex were recorded with a Cary-14 recording spectrophotometer in alcoholic solution and nujol mull respectively in the range 1600—300 nm. The absorption bands are given in Table 2.

(ii) Infrared: The infrared spectra of the ligand and the complexes were taken with the help of a Perkin-Elmer 521 Grating Infrared Spectrophotometer in the range 4000—250 cm^{-1}, using KBr pellets of the samples. The major infrared bands are given in Table 3.

Results and Discussion

Magnetic moments. *(i) Complexes of Ni(II)*: The experimental values of the magnetic moments of $Ni(tta)_2(H_2O)_2$ and $Ni(py)_2(tta)Cl$ as given in Table 1 are close to those reported in literature for other octahedral Ni(II) complexes.

(ii) Complexes of Rh(I), Pd(II), Pt(II), and Au(III): All these complexes are found to be diamagnetic. The diamagnetism of these complexes supports the square planar arrangement of the ligand molecules around the central metal ion.

(iii) Cu(II) Complexes: This complex is diamagnetic. Only in a few Cu(II) complexes, the paramagnetism equivalent to one unpaired electron is completely quenched ($\mu_{eff}=0$) at room temperature,[12,13] as against partial quenching observed in the case of several Cu(II) complexes.[14–16]

Since the complex is prepared in the presence of stoichiometric amounts of I_2, reduction of Cu^{2+} to Cu^{+} and hereby the diamagnetic behaviour of the complex appears to be highly unlikely. Also the complex of Cu(I), prepared (and reported elsewhere)[17] by reducing Cu^{2+} ions with SO_2 solution followed by treatment with the ligand, has totally different physical porperties and stoichiometry in contrast to the Cu(II) complex.

With a view to knowing the oxidation state of the metal ion in the Cu(II) complex, the authors dissolved the Cu(II) complex in pyridine and determined the magnetic susceptibility of the solution, when the complex showed a magnetic moment of 1.77 B.M. Since pyridine is not an oxidising agent is it unlikely that the Cu^{+} ions, if present at all, in the complex, could have been oxidised to Cu^{2+} to account for the observed paramagnetism in pyridine solution.

The spin-pairing in the complex may be explained by the overlap of the d_{z^2} or $d_{z^2-y^2}$ orbitals of the Cu^{2+} ions resulting in σ or δ bond formation,[18–20] or by super-exchange mechanism.[21] In complexes with ligands containing sulphur as donor atom, bonding of the metal ion with the easily polarizable sulphur atom of the ligand may result in a large transfer of electron density from sulphur to the metal ions with the consequent increase in the overlap of the metal orbitals.[22] Hence a direct metal-metal bond is preferred for the quenching of the paramagnetism over super exchange mechanism. However, it is only tentative.

Electronic Spectra. *(i) Complexes of Ni(II)*: The visible spectrum of $Ni(tta)_2(H_2O)_2$ shows three bands whose positions are characteristic of those found for other octahedral complexes of Ni(II). In the spectrum of $Ni(py)_2(tta)Cl$, only two bands are seen. The third band, expected around 27000 cm^{-1}, may be masked by the intense charge transfer band due to pyridine molecule. The positions of these bands together with their assignments are given in Table 2. These are taken as evidence in support of the octahedral geometry of the ligand molecules around the central metal ion.

Besides these bands, a shoulder appears at 875 nm

Table 1. Analytical data, magnetic moments and solubilities of the ligand and the complexes

a) present in $Ni(tta)_2(H_2O)_2$. b) present in $Ni(Py)_2(tta)Cl$. c) multiple bands well resolved. d) perhaps due to some protons remaining over unexchanged with deuterium. e) present in Pt(II) and Cu(II) complexes. f) present in Pd(II) complex. g) due to $\delta_{(NH)}$ (major contribution)+$\nu_{(CN)}$ (minor contribution. h) due to $\delta_{(HH)}$ (minor contribution)+$\nu_{(C=N)}$ (major contribution). i) due to $\nu_{(C-N)}$; j) due to $\nu_{(C=S)}$.
s=strong, m=medium, mb=medium broad, w=weak, shoulder.

in the case of the aquo complex and 970 nm in the case of the pyridine complex. These could be assigned to departure from O_h towards D_{4h} symmetry, on the assumption that the water or the pyridine molecules are *trans* to each other in the respective complexes. In the D_{4h} symmetry, all the three bands should split. But the spectrum of the aquo complex does not show any such splitting of the bands at 625 nm and 400 nm. This may be because both the terms $^3T_{1g}(F)$ and $^3T_{1g}(P)$ yield $^3A_{2g}$ and ^3E_g terms in D_{4h} symmetry. In the strong fields the components of the $^3T_{1g}(F)$ level lies in the sequence $^3A_{2g}<{}^3E_g$, while those of the $^3T_{1g}(P)$ level are inverted ($^3E_g<{}^3A_{2g}$). Thus, when configurational interactions are taken into consideration, the splittings tend to cancel out[23] and it would be difficult to resolve the bands due to these transitions. The amount of splitting in the 1050 nm band may be taken as a measure of the degree of distortion.[24,25]

The values of D_q^E, D_q^A and D_t have been calculated using the expressions given in the literature[23] (Table 2). In these calculations the field strengths due to water and pyridine have been assumed respectively to be less than and greater than that due to ligand.

It may be noted that the values of B and β are quite low. This puts the ligand towards the strong end of the nephelauxetic series. As was pointed out by Schaffer[26] and later on by Jørgensen[27] the low value of β independently suggests bonding through sulphur.

(ii) Complexes of Rh(I), Pd(II), Pt(II) and Au(III): Metal ions of d^8 system exhibit square planar structure in most of their complexes.[28] In D_{4h} symmetry of the field, the d orbitals split into four levels, *viz.*, b_{1g}, b_{2g}, a_{1g}, and e_g. The ground state for the low spin d^8 system is $^1A_{1g}$ ($=a_{1g}^2 \cdot e_g^4 \cdot b_{2g}^2$).[28] The ligand field excited states are $^3A_{2g}$, $^1A_{2g}$ ($b_{2g}\rightarrow b_{1g}$), ^3E_g, ^1E_g($e_g\rightarrow b_{1g}$) and $^3B_{1g}$, $^1B_{1g}$ ($a_{1g}\rightarrow b_{1g}$). Therefore, one should expect three spin allowed and three spin forbidden transitions in these cases. In the electronic spectra of the Rh(I), Pd(II), Pt(II) and Au(III) complexes, the bands obtained together with their probable assignments are given in Table 2. Owing to the forbidden nature of the singlet→triplet transitions, it is quite probable that they may not appear at all in the electronic spectra some of the complexes in nujol mull.

The low intensity bands arising out of transition, $a_{1g}\rightarrow b_{1g}$ could not be assigned unambiguously, since the intense charge transfer bands (L→M) masks the forbidden d–d transition bands. The shift of the intense charge transfer bands in the spectra of some of the complexes is in accordance with the optical electronegativity values,[29] with the result that all the d–d transition bands in the case of Rh(I) complex are masked by the charge transfer bands. The metal ions with next higher optical electronegativity values are Pt(II) and Au(III). Charge transfer bands in the case of complexes of these metal ions start from 450 nm, with the result that the d–d transition bands in these cases appear only as shoulders. The spectrum of Pd(II) ion having highest value of the optical electronegativity exhibits bands due to d–d transition in the visible region.

Assuming the value of B to be 750 cm^{-1}, the values of C, Δ_1 and Δ_2 were calculated on the basis of the assignments given in Table 2. These values compare quite well with those cited in literature for other complexes of these metal ions. This suggests that the field around the metal ion should be tetragonal (D_{4h}-symmetry). This is also in conformity with the preferred orientation of the ligand molecules in the complexes of these metal ions.[30]

It is interesting to note that the value of Δ_1 is much larger than that of Δ_2. This means that similar to other σ or π donor molecules, the ligand molecules cause a marked destabilization of the b_{1g} level ($d_{x^2-y^2}$ orbital) as compared to other d orbitals. This is what one should expect in the square planar geometry.

The value of Δ_1 depends on the relative energy of $b_{1g}(d_{y^2-x^2})\sigma^*$ and $b_{2g}(d_{xy})\pi^*$ levels and therefore, both σ and π bonding are the contributing factors (π acceptor ligands cause destabilization of the b_{1g} level, keeping the b_{2g} level essentially non-bonding). Table 2 also shows Δ_1 value of the Pd(II) complex to be less than the Δ_1 value of Pt(II) complex. The increase in the value of Δ_1 for Pt(II) complex may be due to the increasing σ-bond strength in the order $4d\sigma < 5d\sigma$. This result is quite in conformity with existing results. Also the values of Δ_1 for Pt(II) and Au(III) complexes are nearly the same. This reslt is also in agreement with the results of molecular orbital calculations.[31]

(iii) Cu(II) Complex: As already discussed, the Cu(II) complex is diamagnetic. Harris, *et al.*[32] have proposed a structure for the diamagnetic Cu(II) complex of diazoaminobenzene in which there is metal-metal interaction and the Cu^{2+} ion has squareplanar geometry. The electronic spectrum of this complex shows two bands at 670 nm and 530 nm. These were assigned by them tentatively to $d_{xy}\rightarrow d_{z^2}$ and $d_{xy}\rightarrow d_{x^2-y^2}$ transitions. Tsuchida *et al.*[33,34] have observed a band around 375 nm in all the diamagnetic carboxylate complexes of Cu(II). They have suggested that these bands are characteristic of metal-metal interaction.

The Cu(II) complex reported here has in its electronic spectrum, a shoulder at 700 nm, a weak and broad band at 620 nm and a well defined band at 425 nm. Assuming a square planar arrangement of the ligand molecules around Cu^{2+} ion, these bands are assigned to $d_{xy}\rightarrow d_{z^2}$, $d_{xy}\rightarrow d_{x^2-y^2}$ and metal-metal bond respectively. The assignments, however, are tentative.

Infrared Spectra. From the analytical, electronic spectral and magnetic susceptibility data given in Tables 1 and 2, it appears that the ligand is acting as bidentate in most of the complexes reported here. This is quite in keeping with the preferred geometries the metal ions would take in their complexes.

In solution the ligand can exist either in the thiol form or in the thione form or both. It is believed that it exists as tautomers. Infrared spectral studies were made, with a view to ascertaining the existence of tautomerism and to know the mode of linkage with metal ions in the complexes.

In order to confirm our assignments, the IR spectrum of the deuterated ligand was also studied. Since shifts due to isotopic effect could be expected in the positions of only those bands which arise due to fun-

damental modes of vibration of the NH and the SH groups, comparison of these two spectra confirms not only the assignment but also the existence of the ligand in the thiol form (Table 3).

A close look at the infrared spectra of the complexes suggests that the complexes can be classified into groups on the basis of the direction of shifts in the positions of the major bands in their spectra. The spectra of all the complexes in any group are similar so far as the direction of shifts in the band positions is concerned. It is reasonable to expect the bonding scheme in these complexes to be the same. The following is a brief groupwise discussion regarding the shifts in the positions of the major bands in the spectra of the complexes.

(i) Complexes of Ni(II). The major shifts in the positions of bands were found to be similar to those of cobalt(II)[1] and therefore, the mode of bonding in nickel complex (Fig. 1) should be the same as that of cobalt complex.[1]

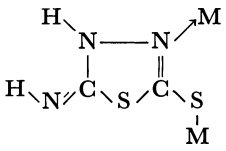

Fig. 1.

(ii) Complexes of Pd(II), Pt(II), and Cu(II). In the spectra of this group of complexes, the shifts in the position of the bands are similar to those found in the spectra of the complexes of Ru(III), Rh(III), Ir(III), Pd(IV).[1] Thereby the mode of linkage in these complexes as shown in Fig. 2 should be identical with those in Rh(III), Ru(III), Ir(III) and Pd(IV) complexes.[1]

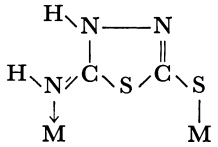

Fig. 2.

(iii) Rh(I) Complexes. (a) The band at 2750 cm^{-1} in the spectrum of the ligand is also seen in that of the complex. (b) Bands due to $\nu_{(N-H)}$, $\delta_{(N-H)}$ and $\tau_{(N-H)}$ appear in the spectrum of the complex at about the same positions as in the spectrum of the ligand. (c) Thioamide band II shifts slightly towards higher wave number side. (d) Thioamide band III remains practically unchanged. (e) Thioamide band IV shifts towards lower wave number side. (f) New bands appear in the region of 400 cm^{-1}. (g) All bands due to triphenylphosphene molecule appear in the spectrum of the complex with slight shifts in their positions.

These results can be explained if the mode of bonding is as shown in Fig. 3.

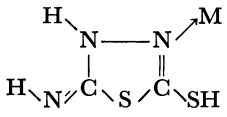

Fig. 3.

From this type of bonding it is evident that the positions of the bands due to (a) $\nu_{(S-H)}$ should not disappear and (b) $\nu_{(N-H)}$, $\delta_{(N-H)}$ and $\tau_{(N-H)}$ should not shift. The bond order of (C=N) should increase, while that of (C=S) should decrease and $\nu_{(M-N)}$ coupled with other bending modes of vibration of the ligand molecule should appear.

(iv) Au(III) Complex. The infrared spectrum of this complex is quite complicated because most of the bands are either split or broadened. In the spectrum of the Au(III) complex, the positions of most of the major bands are the same as those present in the spectra of Pd(II) and Ni(II) complexes (except those of water or pyridine in the latter complex). This behaviour is not quite unexpected because three ligand molecules as required by stoichiometry can be arranged in a square planar geometry around the metal ion (as determined from magnetic and visible spectral data) only in one way and that is two of the ligand molecules act as monodentate whereas the third one, as bidentate as shown in Fig. 4.

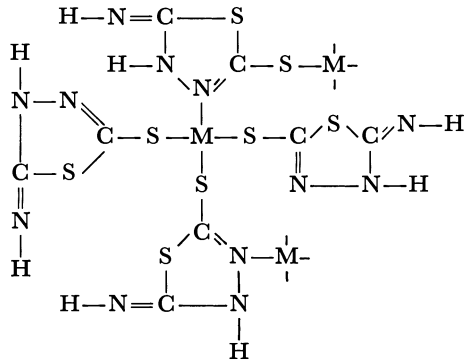

Fig. 4.

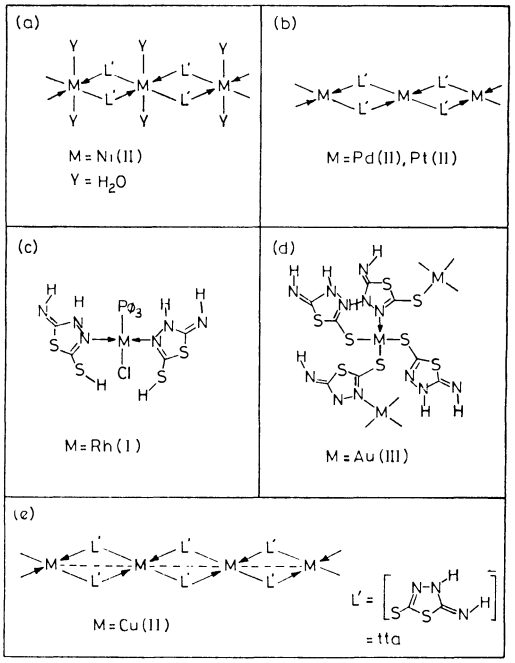
It is evident from this mode of bonding that the bond orders of (C=N) of the bonded N=C–SH and the unbonded H–N–C=N–H groups in the mono and bidentate ligand molecules should be different (next page).

It is reasonable to expect that the fundamental modes of vibrations of (C=N) bonds with different bond orders in the same ligand molecule interact strongly while those in different ligand molecules would interact rather weakly. As a result of these interactions, thioamide band II would appear considerably split bands should appear at higher wave number, one at slightly higher wave number and one at lower wave number. The appearance of bands at 1420, 1390, and 1320 cm^{-1}, assigned to thioamide band II is in keeping with the results expected. Besides, the shift of thioamide band IV towards lower wave number side lends support to the bonding scheme proposed. (next page)

With the exception of Rh(I) complex which is very slightly soluble in alcohol, all the other complexes reported here are insoluble in water and other common non-coordinating organic solvents. This suggest that they are polymeric in nature.

Therefore, on the basis of the analytical, magnetic and spectral data as well as the preferred geometries the metal ions would take in their complexes, the following plausible polymeric structures are proposed for the complexes.



Scheme.

The authors are thankful to Dr. S.N. Tandon, Reader in Chemistry, Roorkee University (India) for providing a sample of the ligand. One of the authors (MRG) grateful to the Govt. of India and the Karnataka Regional Engineering College, Suratkal (India) for the Fellowship under the Quality Improvement Programme for serving teachers in Engineering colleges. He is indebted to the Director, Indian Institute of Technology, Kanpur for providing research facilities.

Synthesis of Dialkylaminomethylenediphosphonic Acids

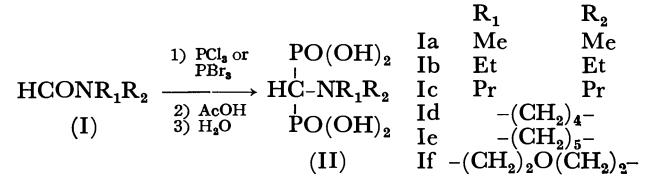
Masahiro FUKUDA, Yoshiki OKAMOTO, and Hiroshi SAKURAI

The Institute of Scientific and Industrial Research, Osaka University, Yamada-kami, Suita shi, Osaka 565

(Received May 10, 1974)

Synopsis. *N,N*-Dialkylformamides reacted with phosphorus trichloride or phosphorus tribromide to give the corresponding dialkylaminomethylenediphosphonic acids.

Although the reaction of amides with phosphoryl chloride has been studied as Vilsmeiyer reaction,[1] little is known concerning of the reaction of amides with phosphorus trichloride or phosphorus tribromide. In this paper, we wish to report the synthesis of dialkylaminomethylenediphosphonic acids by successive treatment of *N,N*-dialkylformamides with phosphorus trichloride and with acetic acid. In this experiment, the following amides were employed; *N,N*-dimethylformamide (Ia), *N,N*-diethylformamide (Ib), *N,N*-dipropylformamide (Ic), *N*-formylpyrrolidine (Id), *N*-formylpiperidine (Ie), and *N*-formylmorpholine (If). Phosphorus tribromide reacted also with the formamides to give the same products.



(I) (II)

	R_1	R_2
Ia	Me	Me
Ib	Et	Et
Ic	Pr	Pr
Id	$-(CH_2)_4-$	
Ie	$-(CH_2)_5-$	
If	$-(CH_2)_2O(CH_2)_2-$	

These results are summarized in Table 1.

TABLE 1. PROPERTIES OF DIALKYLAMINOMETHYLENEDIPHOSPHONIC ACIDS

Product	Yield (%)	Dp(°C)	pK_{a_1}	pK_{a_2}	pK_{a_3}
IIa	53.5	255	2.5	5.2	9.5
IIb	39.6	190—200	2.5	5.2	9.0
IIc	33.9	195—200	3.2	5.6	9.2
IId	44.0	220—225	2.7	5.3	9.5
IIe	28.9	250—255	3.0	5.5	9.4
IIf	15.7	250—260	3.0	5.2	9.0

The structure of IIa was confirmed to be dimethylaminomethylenediphosphonic acid by direct comparison with an authentic sample[2] by NMR and by dissociation constant (pK_a). The structures of the other products (IIb—IIf) were identified by elemental analysis and by alkalimetry.

Experimental

Preparation of Dimethylaminomethylenediphosphonic Acid (IIa). General Procedure: *N,N*-Dimethylformamide (7.3 g) was added dropwise to phosphorus trichloride (68.5 g) under cooling with ice-water. After stirring for an hour, the mixture was treated with 100 ml of glacial acetic acid. This was allowed to stand for several hours at room temperature with protection from moisture. After removal of the upper layer containing acetyl chloride by decantation, the lower layer was poured into 150 ml of ice-water, and this was concentrated to syrup under reduced pressure. After addition of absolute ethanol (300 ml), precipitate separated and it was filtered (17.5 g) and recrystallized from water. Mp 255 °C (dec.). NMR (D_2O): δ 3.12 (s, 6H, N-CH_3), 3.74 (t, 1H, P_2C-H, J_{PCH} 20 Hz). pK_{a1} 2.5, pK_{a2} 5.2, and pK_{a3} 9.5. Found: C, 15.22; H, 5.98; N, 5.87; P, 26.20%. Calcd for $C_3H_{11}NP_2O_6 \cdot H_2O$: C, 15.19; H, 5.49; N, 5.91; P, 26.16%.

In a similar manner, compounds IIb, IIc, IId, IIe, and IIf were obtained, as shown in Table 1.

Molten-state Absorption Spectra of Weakly Interacting Donor-Acceptor Mixtures[1)]

Jun-ichi AIHARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received February 14, 1974)

Synopsis. Absorption spectra of equimolecular mixutres of bulky electron donors, such as triphenylamine, and typical electron acceptors, such as *sym*-trinitrobenzene (TNB) and chloranil, in the molten state are reported. Though the components do not interact in the solid, the melts display distinct charge-transfer absorption bands in the visible region.

Several years ago, Hammond and Burkardt studied extensively various aspects of a series of weak donor-acceptor complexes.[2)] According to their visual observations, some electron-donating molecules having bulky substituents do not form charge-transfer complexes with any of the typical electron acceptors in the solid state. A mixture of a bulky electron donor, such as triphenylamine, with most electron acceptors, however, has a deep color in the melt. The color of the melt vanishes on freezing, and the cycle can be repeated many times. In order to extend our understanding of this phenomenon, we measured the electronic spectra of this kind of donor-acceptor mixtures in the molten state.

Two bulky donor compounds, triphenylamine (TPA) and diphenylamine (DPA), were used in this study. The samples for the measurements of the solid- and molten-state spectra were prepared by solidfying the molten mixtures of the bulky electron donors with equimolar amounts of electron acceptors. The molten-state absorption spectra were taken near 150 °C at which temperature the mixtures were sure to be totally molten. The absorption spectra of the methylene chloride solutions were taken for comparison. A Beckman DK-2A spectrophotometer was used.

Figures 1–5 show the visible absorption spectra of mixtures of TPA with five electron acceptors. TPA is a pronounced example of a bulky electron donor. The gaseous ionization potential (I_g) of this compound is as low as 6.84 eV,[3)] and it is customarily considered as an excellent electron donor. Furthermore, this compound is very suitable for the present experiment because it is thermally stable.

In general, the solution spectrum of the donor-acceptor mixture in the visible region displays an absorption band characteristic of a charge-transfer complex. Fortunately, absorption peaks of the charge-transfer bands were observed in the solution spectra of the two mixtures, the TPA-chloranil and the TPA-TNB. These absorption peaks ($h\nu_{CT}$) should be re-

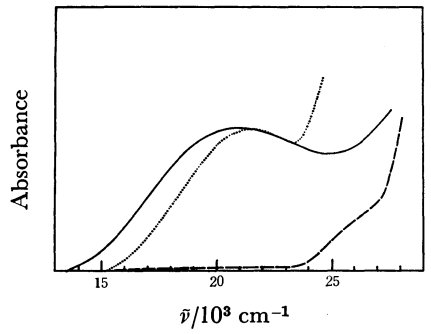

Fig. 1. The absorption spectra of the TPA-TNB mixture in the solid state (——), in the molten state (——), and in solution (·····).

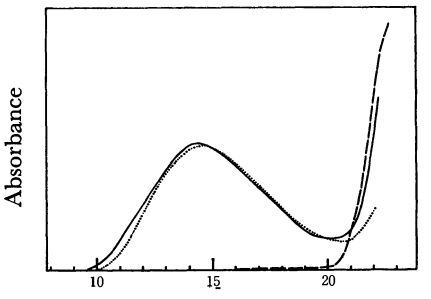

Fig. 2. The absorption spectra of the TPA-chloranil mixture in the solid state (——), in the molten state (——), and in solution (·····).

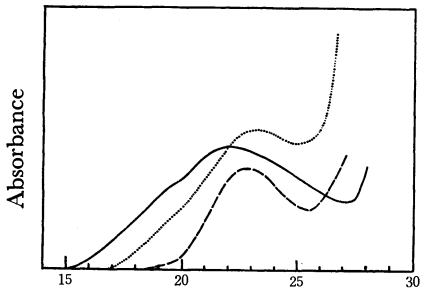

Fig. 3. The absorption spectra of the TPA-DMBQ mixture in the solid state (——), in the molten state (——), and in solution (·····).

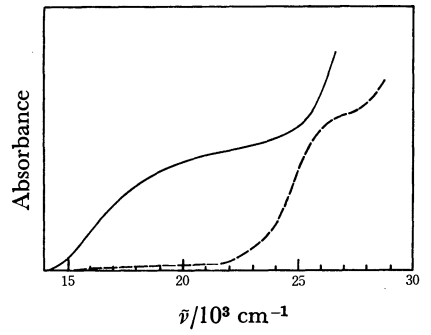

Fig. 4. The absorption spectra of the TPA-picric acid mixture in the solid state (——-), and in the molten state (——).

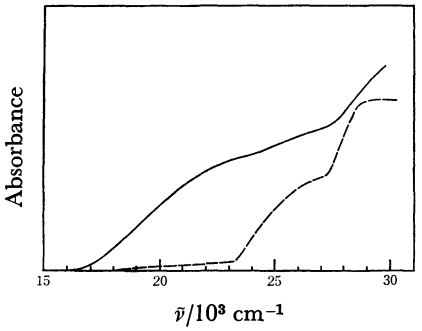

Fig. 5. The absorption spectra of the TPA-*m*-dinitrobenzene mixture in the solid state (——), and in the molten state (——).

produced by the empirical expressions such as:

$$h\nu_{CT} = aI_g - b, \quad (1)$$

where a and b are constants associated with a given electron acceptor. For example, a and b are 0.853 and 3.51 eV, respectively, for a group of TNB complexes in chloroform. The absorption maximum of the TPA-TNB system in chloroform is located at 2.60 eV, whereas the value estimated from Eq. (1) is 2.32 eV. The deviation of the observed value from the estimated one is 0.28 eV. A deviation of this extent is properly ascribed to the bulky substituent effect, as was suggested before for the tetracyanoethylene complexes of methylbenzenes.[4]

On the other hand, the solid donor-acceptor mixtures appear almost colorless, indicating that the intermolecular charge-transfer interaction is substantially suppressed even in the domains of the solid solutions which may be present in the mixtures. The weak absorption tail which often appears in the energy region where there should be a charge-transfer band is supposedly due to incidental formation of a charge-transfer complex in the mixture.

An almost colorless mixture of TPA with TNB turned deep red on melting, and a mixture of TPA with chloranil was deep green in the molten state. Other molten mixtures were all reddish. This is in marked contrast to the behavior observed for ordinary charge-transfer complexes on raising the temperature above the melting point; in this case, the colored solid melts with little color change.[5]

As is shown in Figs. 1–5, the color change of the present mixtures is in accord with the appearance of the charge-transfer bands in the molten state. The absorption peaks are located at 20700 cm^{-1} for the molten TPA-TNB and at 14300 cm^{-1} for the molten TPA-chloranil. The astonishing coincidence of the spectral shapes between the molten-state and solution spectra strongly suggests that the colored species in the melt is similar to that in solution. In addition, the coincidence of the absorption peaks of the TPA-chloranil mixture in the melt and in solution suggests that the dielectric properties of the mixture, which are presumably associated with the solvatochromism of the charge-transfer band, are quite similar to those of the solvent (methylene chloride). Therefore, the intermolecular interactions appear to be still very weak in the melt. As was suggested by Lower for the solid complex,[6] the excitation might be localized in each donor-acceptor pair in the melt.

For the other molten mixtures containing TPA, the charge-transfer bands are found to overlap more or less with the absorption bands of the component molecules. For example, in the molten-state spectrum of the TPA-DMBQ (2,5-dimethyl-*p*-benzoquinone) system, the charge-transfer band is located above 15000 cm^{-1}, partially overlapping with the n-π^* transition of the benzoquinone. Since the relative intensities of both absorption bands are apparently comparable in the melt, the extinction coefficient of the charge-transfer band is estimated to be of the same order of magnitude as that of the n-π^* transition ($\varepsilon_{max}=\sim 20$).[7] Such a small extinction coefficient is consistent with weak intermolecular interactions which are insufficient to form a complex in the solid state.

Mixtures of DPA with various electron acceptors display similar spectral changes on melting. However, they are very reactive in the molten state, and readily decompose. An absorption spectrum could be obtained of only the DPA-DMBQ mixture. Every aspect of the molten-state spectrum resembles that of the spectrum of the TPA-DMBQ mixture.

In a previous paper, we suggested that the charge-transfer interaction is not always a primary factor in determining the structure of the condensed phase.[8] It is noteworthy that the self-complex formation which is often attained to 100 percent in the *o*-anisyl-*p*-benzoquinone crystal is completely disturbed by the fluidity of the melt.[9] On the contrary, the fluidity of the melt is needed to allow the intermolecular charge-transfer interaction in the present donor-acceptor mixtures. Since the heat of complex formation (~0.30 kcal/mol)[2] is much less than the typical heat of sublimation (~30 kcal/mol),[10] the charge-transfer interaction, at all events, seems to be of secondary importance in the solid mixtures.

A Flash Photolytic Investigation of the Interaction between Halide Anions and the Triplet Eosin

Takeshi AKIYAMA,* Mamoru KAMIYA, and Yukio AKAHORI
Shizuoka College of Pharmacy, Oshika, Shizuoka-shi 421
(Received may 16, 1974)

Synopsis. The quenching effect of the iodide ion to the triplet eosin in oxygen-free aqueous solution was strongly enhanced at 10^{-1}—10^{-2} M, but the effects of bromide and chloride ions were negligibly small at 10^{-1}—10^{-4} M. The above-mentioned results were found directly by means of a flash photolytic method.

Halide anions work as typical quenchers of the fluorescence of an eosin aqueous solution. In this case, the quantity of the quenching rate constant suggests that the energy transfer from the photoexcited eosin to the halide anion is a diffusion-controlled process.[1] It has also been found that the iodide ion strongly quenches the dye phosphorescence in a viscous glycerol solution.[2] Hence, we can expect that the halide anion quenches the triplet eosin as well as the singlet eosin. This postulation is supported also by the intermolecular heavy-atom effect of the halogen atom.

Experimental

Commercial eosin-Y was purified chromatographically according to the method of Koch.[3] A 6.2 μM eosin solution was prepared using a 1/15 M phosphate buffer at pH=7.0. Sodium iodide, sodium bromide, and sodium chrolide (G.R.) were used without further purification. Repeated cycles of freezing and thawing under a high vacuum were adopted in order to degass the sample solutions. The flash irradiation source consisted of two xenon lamps, Ushio-103 type. The lamps were used at 2 μF and 6 kV. A cylindrical quartz cell 20 cm in length and 2 cm in diameter was used. The monitoring lamp was a 500-W xenon arc lamp, Ushio-UXL-500D. The changes in the optical density after the flash irradiation were followed by means of a 1P28 photomultiplier coupled to a Hitachi QV-50 spectrophotometer. The decay of the triplet eosin was followed by selecting the wavelength of 436 nm, according to the method of Zwicker and Grossweiner.[4] The kinetic data were taken only from the initial flash irradiation of a freshly-prepared solution.

Results

Figures 1 and 2 show the decay curves of the transient absorbance of the triplet eosin. The initial decays were well fitted by exponential decay curves, which gave first-order decay constants. Without the quencher, the decay constant is of the same order as that obtained by Zwicker and Grossweiner.[4] The origin of the irreversible absorbance change which is seen at the period of ms order after the flash irradiation is not known. We consider, however, that it can not necessarily be attributed to another transient product whose spectrum overlaps that of the triplet eosin, because a permanent increase in the absorbance in this wavelength region is observed. It is of interest to note that

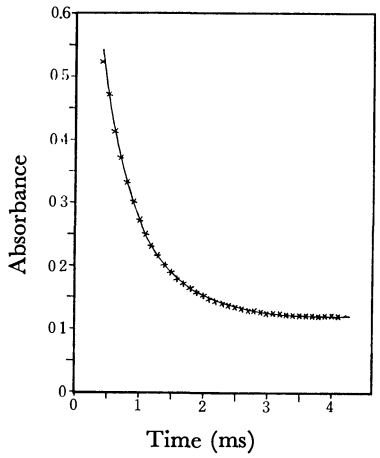

Fig. 1. Time-dependence of absorbance at 436 nm as measured by Flash-photolysis of eosin-Y in buffer solution (pH=7.0).
Concentration of eosin-Y: 6.19×10^{-6} mol/l.

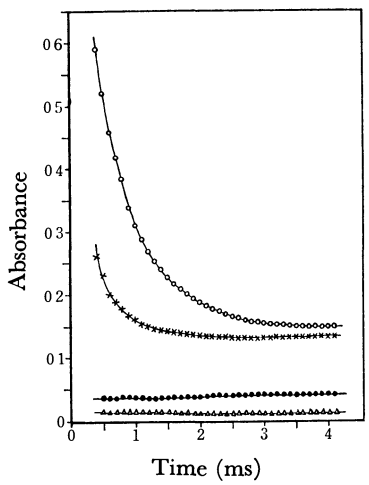

Fig. 2. Time-dependence of absorbance at 436 nm as measured by flash-photolysis of eosin-Y and quencher (NaI) in buffer solution (pH=7.0).
Concentration of eosin-Y: 6.19×10^{-6} mol/l.
Concentration of NaI
△: 1.03×10^{-1} mol/l ●: 1.08×10^{-2} mol/l
×: 1.08×10^{-3} mol/l ○: 1.06×10^{-4} mol/l

the quenching effect of the iodide ion is enhanced at 10^{-1}—10^{-2} M to such an extent that the triplet eosin can not be observed within ms time after the flash irradiation. The quenching effects of the bromide and chloride ions are negligibly small at 10^{-1}—10^{-4} M.

* Present address: Japan IBM Co. Inc., 2-6-1, Nishishinjuku, Shinjuku-ku, Tokyo 160.

The remarkable concentration dependence of the quenching effect of the iodide ion gives definitive evidence of a specific interaction between the triplet eosin and the iodide ion. This finding is in accord with the earlier suggestion of a charge-transfer interaction between the photoexcited eosin and the iodide ion.[5]

Table 1. The kinetic data of the decay constants of the triplet eosin

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48 (3), 1035—1036 (1975)

The Formation of Crystalline Molecular Complexes between Inosine and Several Phenols

Yoshihisa SUZUKI, Kentaro HARA, and Tsuneo HIRAHARA

Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki 210

(Received July 4, 1974)

Synopsis. Inosine has been found to form 1:1 crystalline molecular complexes with phenol, *p*-nitrophenol, and 1,2,3-trihydroxybenzene respectively, and to be inactive with *o*-, *m*-nitrophenol, 1,2,4-, 1,3,5-benzenetriol, benzenediols, aminophenols, and cresols.

Since the formation of a crystalline molecular complex between inosine and tryptophan was shown for the first time between 1968 and 1970 by Suzuki *et al.*,[1,2] inosine is known to have a strong ability of complex-formation among several ribonucleosides. The formation of a specific crystalline molecular complex is useful for industrial isolation processes. It is also known that flavins with indoles[3] including tryptophan form molecular complexes similar to the flavin-phenol complexes.[4] Indoles are considered to be poorer electron donors to flavins than are phenols. These facts suggested the probability of some crystalline complex-formation of inosine with phenols. This paper will deal with the formation of molecular complexes between inosine and several phenols, which are of interest in relation to the above background.

Results and Discussion

Table 1 shows the results of the crystalline complex formation between inosine and several phenols. Phenol, *p*-nitrophenol, and 1,2,3-benzenetriol (pyrogallol) were confirmed to form 1:1 complexes with inosine. Table 2 shows their X-ray powder diffraction data.

The inosine-*p*-nitrophenol complex is easily obtained from an equimolecular aqueous solution of inosine and *p*-nitrophenol. However, both inosine–phenol and inosine–pyrogallol complexes are incongruent and could not be obtained in a pure form from an equimolecular aqueous solution of the two components, from which the crystals of inosine were usually precipitated with or without those of the complexes. The crystallization of the complex without any contamination of the inosine crystals was performed from an aqueous solution which contained 1 mol of inosine and 2 mol (or more) of phenol, or 1 mol of inosine and 4 mol (or more) of pyrogallol, respectively.

a) The scale of the intensity is so chosen as to make the most intense line have the value 100.

Inosine is known to crystallize with such solvents of crystallization as water,[5] pyridine,[6] *N,N*-dimethylformamide,[6] and dimethyl sulfoxide.[7] Among the several phenols investigated in the present study, only phenol is liquid at room temperature and can be used as a solvent of inosine. The complex between inosine and phenol was also obtained from a pure phenol solution of inosine as well as from the aqueous phenol solution described above. Considering these facts, the phenol in the complex may be interpreted as a solvent of crystallization.

The presence of the specific interactions of inosine with *p*-nitrophenol and phenol in the present study, and the absence of that with *o*-nitrophenol, are of interest in view of the facts that *p*-nitrophenyl phosphate and phenyl phosphate were good donors, while *o*-nitrophenyl phosphate was not, in the phosphorylation of inosine by the bacterial nucleoside phosphotransferase.[8,9]

The information now available to us is insufficient to explain why these three phenols form crystalline complexes with inosine from among many other phenol

compounds. The ionization constants of phenol (1.3×10^{-10})[10] and pyrogallol (9.68×10^{-10})[11] are of the same order as those of unreacted phenols, such as 1,3,5-benzenetriol (4.5×10^{-10}),[10] *o*-aminophenol (2.18×10^{-10})[12] and benzenediol ($1.1—3.6\times10^{-10}$).[10] *p*-Nitrophenol has an ionization constant (6.5×10^{-8})[13] similar to those of the *o*-isomer (7.5×10^{-8})[13] and *m*-isomer (1.0×10^{-8}).[13] These facts suggest that acid-base interaction makes little contribution to these molecular complex-formations. The effect of hydrogen bonding or sterical arrangement may be proposed.

Experimental

Examination of the Complex-Formation. Inosine and one of the phenols were dissolved (in a molar ratio of 1:1) into water, and the mixture was evaporated to dryness in a desiccator. The resultant solids were examined with the X-ray (CuK_α) powder diffraction method. When their data did not coincide with those of the mechanical mixture of the two components, the complex may be formed; further confirmation was done.

The Crystallization of the Complexes. *Inosine–Phenol Complex*: Inosine (3.3 g) was dissolved in a mixture of water (6 ml) and 90% aqueous phenol (15 ml) with heating. When the resultant solution was cooled to room temperature, prism crystals were precipitated. They were filtered and analyzed.

Inosine–p-Nitrophenol Complex: Inosine (6.7 g) was dissolved in water (80 ml) with heating, and then *p*-nitrophenol (3.25 g) was stirred into this solution at 40 °C over a 2-hr period. The crystals thus precipitated were filtered and analyzed.

Inosine–Pyrogallol Complex: Inosine (13.4 g) was dissolved in water (160 ml) with heating, and then pyrogallol (25.2 g) was added to this solution. The resultant mixture was stirred for 2 hr at 5 °C. The crystals thus precipitated were filtered and analyzed.

Paper Chromatography. The components of the crystals were determined by paper chromatography on Toyo-Roshi No. 51A, with the *n*-butanol–acetic acid–water (4:1:1) solvent system. The UV absorbance of the spots was determined at the maximum wavelength compared with that of the standard references.

Analysis. *Inosine–Phenol Complex*: Mp 143—145 °C. Found: C, 53.02; H, 5.07; N, 15.28%. Calcd for $C_{10}H_{12}N_4O_5\cdot C_6H_6O$: C, 53.03; H, 5.01; N, 15.46%.

Inosine–p-Nitrophenol Complex: Mp 189—191 °C. Found: C, 47.18; H, 4.21; N, 17.15; Inosine, 66.3; *p*-Nitrophenol, 33.4%. Calcd for $C_{10}H_{12}N_4O_5\cdot C_6H_5NO_3$: C, 46.91; H, 4.31; N, 17.19; Inosine, 65.9; *p*-Nitrophenol, 34.1%.

Inosine–Pyrogallol Complex: Mp 167—171 °C. Found: C, 51.22; H, 4.58; N, 14.33; Inosine, 70.4; Pyrogallol, 30.4%. Calcd for $C_{10}H_{12}N_4O_5\cdot C_6H_6O_3$: C, 51.80; H, 4.60; N, 14.21; Inosine, 68.1; Pyrogallol, 31.9%.

Molecular Vibrations and Force Fields of Alkyl Sulfides. XII. Skeletal Conformations of Several Simple Aliphatic Sulfides

Masaru OHSAKU

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received July 9, 1974)

Synopsis. A normal coordinate treatment of methyl propyl, methyl butyl, ethyl propyl, ethyl butyl, and dipropyl sulfides has been carried out. From the observed and calculated frequencies, the conformation about each of six C–C bonds—CSC–CC, CSC–CCC, CCSC–CC, CCSC–CCC, and CC–CSC–CC— was confirmed to be the T form in the annealed crystalline state.

It is very difficult to analyse completely the skeletal conformations for longer molecules. In the present study, we have determined the conformations about the C–C bonds adjacent to the C–S bonds for five sulfides: methyl propyl (CSCCC), methyl butyl (CSCCCC), ethyl propyl (CCSCCC), ethyl butyl (CCSCCCC), and dipropyl (CCCSCCC) sulfides.

A normal coordinate treatment has been carried out, using a modified Urey-Bradley force field. The molecular parameters, the potential terms—except the bending and repulsion constants, H(CCC) and F(CCC), and the bond-interaction term, p_C, between the adjacent C–C bonds— and the force constants used were all the same as those of the previous paper.[1] The additional constants were assumed to be H(CCC)=0.275 mdyn/Å, F(CCC)=0.335 mdyn/Å, and $p_C=-0.100$ mdyn/Å. For the longer sulfides, except for CSCCC, normal coordinates were treated here only in the cases of the typical forms.

The observed infrared and calculated frequencies of the C–S stretching and skeletal deformation regions are shown in Fig. 1.

CSCCC. The C–S stretching frequencies observed in the solid state are reproduced well by those calculated for the TT or GT form. The frequencies of the skeletal deformation bands appearing in the solid state are also explained well by these forms.

CSCCCC. The frequencies of the two solid-state bands observed in the C–S stretching region can be explained by the frequencies calculated for the TTT, GTT, TTG, or GTG form. From the data of the skeletal deformation region, however, we cannot obtain any clear and conclusive information on the skeletal

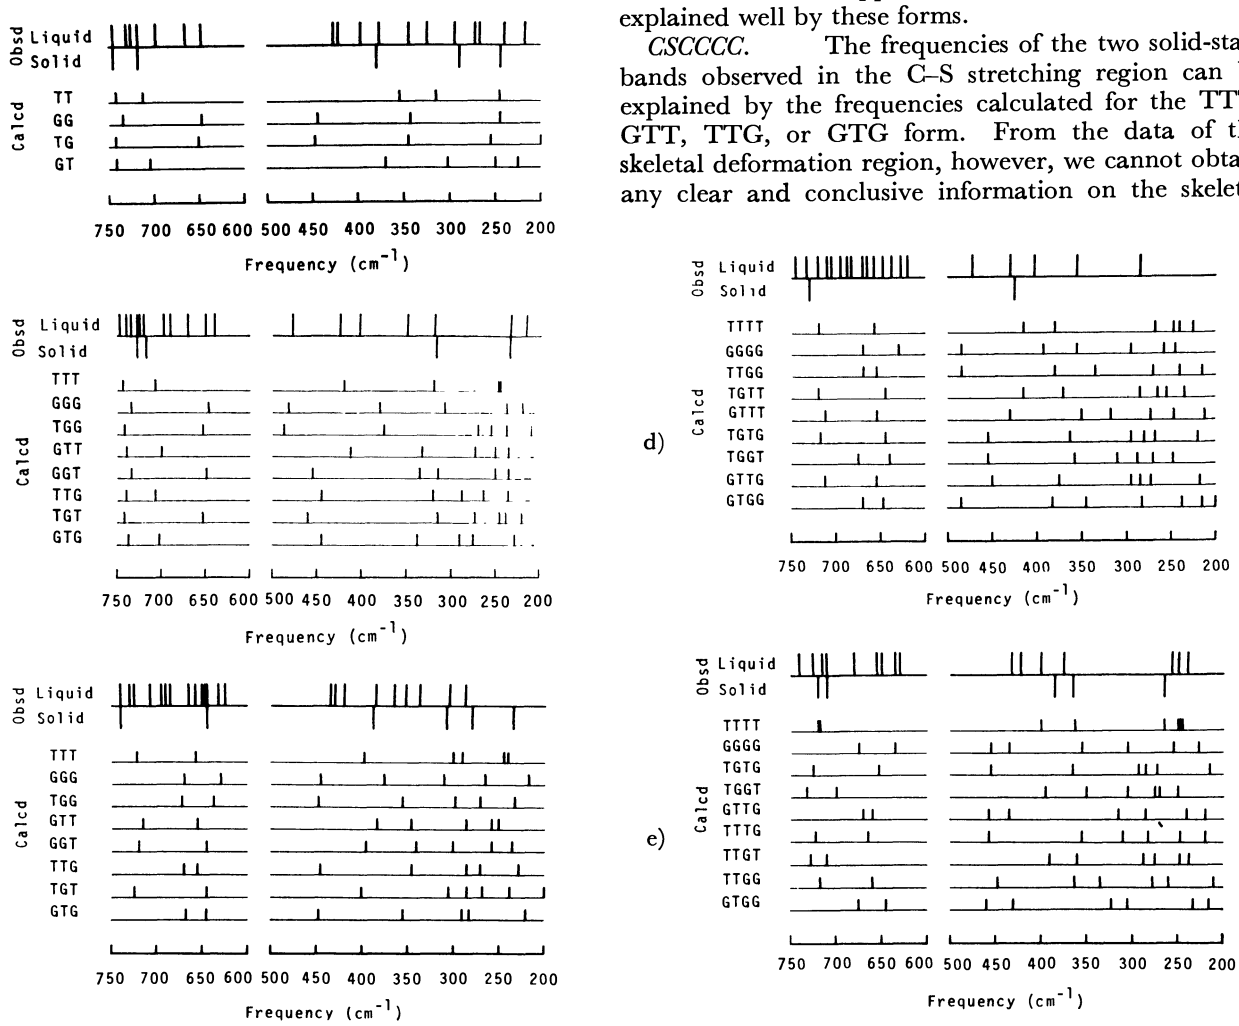

Fig. 1. Observed and calculated frequencies in the C–S stretching and skeletal deformation regions of a) CSCCC, b) CSCCCC, c) CCSCCC, d) CCSCCCC, and e) CCCSCCC.

forms.

CCSCCC. The observed frequencies in the C–S stretching region in the solid state are reproduced well by the frequencies calculated for the TTT, GTT, GGT, or TGT form. The frequencies of the four bands observed in the skeletal deformation region in the solid state can also be reproduced well by those calculated for one of these forms.

CCSCCCC. One each of the bands appeared in the C–S stretching and skeletal deformation regions in the solid-state spectra. The frequencies of these bands are reproduced well by the frequencies calculated for the TTTT, TGTT, GTTT, TGTG, or GTTG form.

CCCSCCC. Two and three bands appeared in the C–S stretching and skeletal deformation regions respectively in the solid-state spectra. The frequencies of these bands fit well to those calculated for the TTTT, TGGT, or TTGT form.

In this note, we are concerned with the skeletal conformations about the C–C bonds adjacent to the C–S bond, *i.e.*, CSC–CC, CSC–CCC, CCSC–CC, CCSC–CCC, and CC–CSC–CC. As we have mentioned above, the frequencies of the C–S stretching and skeletal deformation vibrations can be reasonably explained by the frequencies calculated only for the forms which have the *trans* conformation about the C–C bonds. We may, therefore, conclude that the stable forms in the crystalline state for these sulfides are as follows:

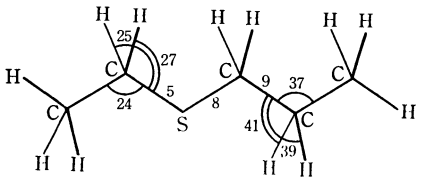
$$CSC_{\bar{T}}CC,\ CSC_{\bar{T}}CCC,\ CCSC_{\bar{T}}CC,\ CCSC_{\bar{T}}CCC,$$

$$\text{and } CC_{\bar{T}}CSC_{\bar{T}}CC.$$

Let us consider in some detail the relation between the C–S stretching frequency and the conformation about the C–C bond adjacent to the C–S bond. The frequencies and separations of two C–S stretching bands observed in the solid state are closely related to the conformation about this bond. The conformations about the other bonds do not much affect the C–S stretching frequencies. From the Jacobian matrix, the force constants which affect the C–S stretching frequencies with different conformations about these C–C bonds are, in general, H(CCC), H(CCH), H(SCC), F(SCH), Y_{C-C}, and p'. There are three questions which arise from these results: a) why do these force constants mainly affect the C–S stretching frequency?, b) why is the C–S stretching frequency affected by the conformation about the C–C bond adjacent to the C–S bond?, and c) why is the C–S stretching frequency not so much affected by the conformation about the C–S bond?

The ***F***-matrix elements themselves do not vary much with the different conformations. On the other hand, for some ***G***-matrix elements, different values appear with different conformations. Now let us consider the values of these elements, taking CCSCCC as an example. A part of the ***G***-elements now of interest are shown above, along with the coordinate numbering. In the off-diagonal elements, *e.g.*, R_8–R_{24}, R_8–R_{25}, R_8–R_{37}, and R_8–R_{41}, and also in the diagonal and off-diagonal elements in relation to the coordinates of C–S and C–C torsions, a different value appears with the T or G conformation about the C–C bond—R_9. These elements are directly related to the force constants, as has been mentioned above. Therefore, the main parts of the first two questions, a) and b), can be explained reasonably. The values of, for example, R_8–R_{24}, R_8–R_{25}, and R_8–R_{27} are much smaller than those of R_8–R_{37}, R_8–R_{41}, and R_8–R_{39}, since the atomic mass of the sulfur atom is much larger than that of carbon. This gives an answer to the c) question. As a result, it seems that most of the contribution to the C–S stretching frequency is due to the conformation about the 9—bond.

	TTT	GGG	
R_8–R_{24}	−1.7019	0.8509	($\times 10^{-2}$)
R_8–R_{25}	0.8509	−1.7019	
R_8–R_{27}	0.8509	0.8509	
R_8–R_{37}	−5.0970	2.5485	
R_8–R_{41}	2.5485	−5.0970	
R_8–R_{39}	2.5485	2.5485	
R_8–R_{52}	−0.0000	−0.0442	



52: torsion—9

The stable conformations in the solid state about the C–S bonds[1] for CS–CC and CC–S–CC and about the C–C bonds[2] for *n*-alkanes were established to be *trans*. Consequently, it can be expected that the stable conformations in the solid state for these sulfides are all of the *trans* form. However, we cannot decide exactly the whole conformation for these sulfides at present. Detailed treatments are now in progress; the results will be published elsewhere in the near future.

Thanks are due to Professor Hiromu Murata and Associate Professor Yuji Shiro for their valuable comments.

An EMF Study of Certain Orthoferrites: $YFeO_3$, $GdFeO_3$ and $SmFeO_3$

Shigeru YAMAUCHI, Kazuo FUEKI,* Takashi MUKAIBO, and Chiaki NAKAYAMA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo 113
Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received August 20, 1974)

Synopsis. The EMF of a solid electrolyte galvanic cell on the formation of orthoferrites, $LnFeO_3$, was measured for Ln=Y, Gd and Sm at 1200—1400 K. The free energy change of the $(1/2)Fe_2O_3+(1/2)Ln_2O_3 \rightarrow LnFeO_3$ reaction was calculated.

Since the pioneering work by Kiukkola and Wagner,[1] many studies have been carried out in an effort to obtain free energy data from the EMF of a solid electrolyte galvanic cell. The present investigation aims to obtain, by means of the EMF method, thermodynamic data relevant to the formation of orthoferrites, which have attracted much attention as magnetic materials.

Experimental

The orthoferrites were synthesized by a solid-state reaction of ferric oxide and rare earth sesquioxide. A pellet of a mixture of 99.99% pure Fe_2O_3 and Ln_2O_3 was fired at 1300 °C to form orthoferrite. The product was ground to powder and pressed to a pellet at 5 kg/cm^2. Then it was fired again at 1400 °C.

A high-temperature galvanic cell was constructed by using a stabilized zirconia tube as an electrolyte. The arrangement of the cell is shown in Fig. 1. The open end of the stabilized zirconia tube(e) was kept at room temperature and connected to a stainless steel head(h) with a O-ring vacuum seal fitting(g). A mixture of Ni and NiO powders was used as a reference electrode (b), which was placed inside the zirconia tube. The test electrode of mixed powders(a) was placed outside the electrolyte. O-ring vacuum seal fittings(g) were used to separate the gas atmospheres inside and outside the zirconia tube(e) and the quartz glass tube (c). After the cell was arranged as is shown in Fig. 1, the whole system was evacuated to 10^{-4}—10^{-5} Torr through Pyrex tubings(i,j). Then the cell was vacuum-sealed and disconnected from the evacuation system.

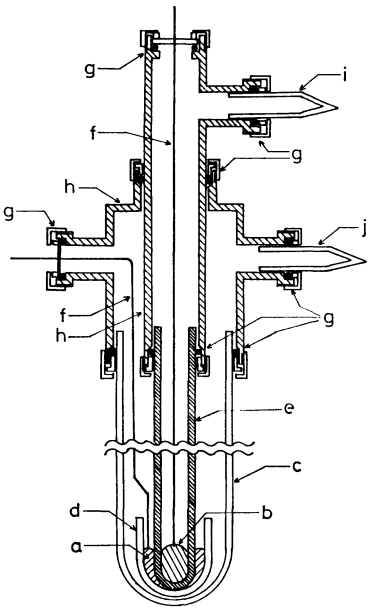

Fig. 1. Arrangement of cell.
a: test electrode powder, b: reference electrode powder, c: quartz glass tube, d: quartz glass container of test electrode powder, e: calcia-stabilized zirconia tube, f: platinum lead wire, g: O-ring vacuum seal fittings, h: stainless steel head, i: Pyrex tubing for an evacuation of reference electrode compartment, j: Pyrex tubing for an evacuation of test electrode compartment.

The cell was heated in a resistance furnace, controlled to ±0.5 °C. The cell temperatures were measured using a Pt/0.13Rh+Pt thermocouple. The EMF of the cell and that of the thermocouple were measured by using a Yokogawa high-precision potentiometer, Model 2722.

As a preliminary run, the EMF of the

$$Pt|Fe, FeO|ZrO_2\text{-}CaO|Ni, NiO|Pt \text{ cell} \quad (I)$$

was measured. The observed values agreed within 0.5 mV with the reported ones.[2-5]

Results

The EMF of the

$$Pt|Fe, Ln_2O_3, LnFeO_3|ZrO_2\text{-}CaO|Ni, NiO|Pt \text{ cell} \quad (II)$$
$$(Ln=Y, Gd \text{ and } Sm)$$

was reproducible at 1200—1400 K. The results are given in Fig. 2 and the first column of Table 1.

From the EMF data of the cell (II), the free energy change, ΔG°_1, of the reaction:

$$Fe + (3/2)NiO + (1/2)Ln_2O_3 \longrightarrow (3/2)Ni + LnFeO_3 \quad (1)$$

was calculated. The results are shown in the second

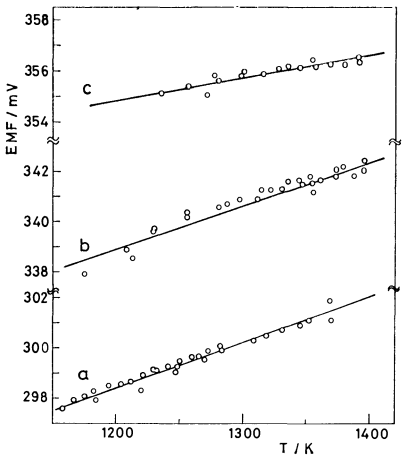

Fig. 2. EMF of cell (II).
a: $YFeO_3$, b: $GdFeO_3$, c: $SmFeO_3$.

Table 1. The EMF data and the derived Gibbs free energy changes

Ln	EMF[a] / mV	ΔG_1°[b] / cal	ΔG_2° / cal
Y	$277.1+0.0178T$ (± 0.2)	$(-19170\pm 40)-(1.23\pm 0.04)T$	$-6250-0.31T$
Gd	$318.3+0.172T$ (± 0.4)	$(-22000\pm 70)-(1.19\pm 0.07)T$	$-9105-0.27T$
Sm	$344.1+0.0089T$ (± 0.4)	$(-23800\pm 140)-(0.61\pm 0.13)T$	$-10900+0.32T$

a) The values in parentheses are square roots of invariant variances. b) Uncertainties in ΔH_1° and ΔS_1° are the standard variations.

column of Table 1, where the constant term and the temperature coefficient correspond to $\Delta H^{\circ}_{1,\,1300\mathrm{K}}$ and $\Delta S^{\circ}_{1,\,1300\mathrm{K}}$ respectively. The standard deviations of these values were also calculated.

The oxygen partial pressure at the test electrode was the lowest for Reaction (1) of $SmFeO_3$. It was $10^{-17.5}$ atm at 1200 K and $10^{-13.6}$ atm at 1400 K. According to Tretyakov and Muan,[6] the electronic transport number of the calcia-stabilized zirconia electrolyte, t_e, is $10^{-4.5}$ at these temperatures and oxygen partial pressures. Etsell and Flengas[7] have reported that the t_e value is still as low as 10^{-3} at these oxygen partial pressures. Thus, the systematic error due to the electronic conduction is negligibly small.

The values of ΔG°_2, the free energy change of the reaction

$$(1/2)Fe_2O_3 + (1/2)Ln_2O_3 \longrightarrow LnFeO_3 \qquad (2)$$

were calculated from ΔG_1°. In this calculation, the equation reported by Charette and Flengas[2] was used for the free energy of the formation of NiO. An approximation was made in the calculation of the free energy of the formation of Fe_2O_3 by using this equation:

$$\Delta G^{\circ}_{f.Fe_2O_3.1200-1400\mathrm{K}} = \Delta H^{\circ}_{f.1300\mathrm{K}} - T\cdot\Delta S^{\circ}_{f.1300\mathrm{K}}$$
$$= -193373 + 59.05T \text{ (cal/mol)}$$

The values of $\Delta H_f^{\circ}{}'_{1300\mathrm{K}}$ and $\Delta S_f^{\circ}{}'_{1300\mathrm{K}}$ were taken from the JANAF Thermochemical Tables.[8] The calculated values of ΔG_2° are given in the third column of Table 1. As may easily be seen, the absolute values of ΔS°_2 are very small, as is to be expected from Neumann-Kopp's rule on the ΔC_p of a solid-state reaction.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48 (3), 1041—1042 (1975)

Formation of Hydrogen Gas with an Electrochemical Photo-cell

Akira FUJISHIMA, Koichi KOHAYAKAWA, and Kenichi HONDA*

Department of Applied Chemistry, Kanagawa University, Rokkakubashi, Yokohama 221
**Institute of Industrial Science, The University of Tokyo, Roppongi, Tokyo 106*

(Received September 19, 1974)

Synopsis. In an electrochemical photo-cell the use of a basic electrolyte solution in the TiO_2 electrode compartment and an acidic one in the Pt cathode compartment can produce a high yield of hydrogen gas.

In a previous paper[1] we reported on an electrochemical photo-cell which consists of a titanium dioxide single crystal semiconductor as an anode, platinum black as a cathode and water as the electrochemically active species. The cell works only under irradiation on the TiO_2 electrode, generating oxygen gas at the surface of the semiconductor and hydrogen on the platinum cathode (Fig. 1). Since the forbidden gap width of TiO_2 is 3.0 eV, the effective wavelength of the irradiated light is restricted to 413 nm or less. The photo-cell produces hydrogen, which can be a source of a "clean energy", through the decomposition of water by means of solar energy.

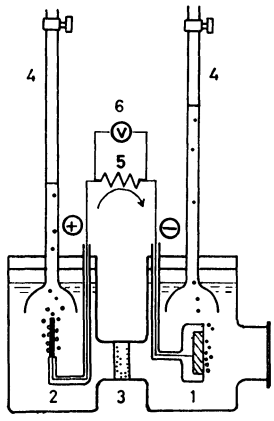

Fig. 1. Schematic diagram of electrochemical photo-cell.
1: TiO_2 electrode, 2: Platinum electrode, 3: Diaphragm (agar salt bridge), 4: Gas burette, 5: External resistance, 6: Voltmeter.

In order to increase the electro-motive force of the cell (and consequently the amount of hydrogen generated), the potential for hydrogen evolution at the cathode should be made more positive, and that for oxygen evolution at the anode more negative. The former can be attained by increasing the proton concentration, the latter by increasing the pH value of the solution, as supported by the fact that the flatband potential of TiO_2 electrode varies linearly with the pH of the solution, with the slope of *ca.* -60 mV/ΔpH.[2] The use of an alkaline solution in the TiO_2 electrode compartment and an acidic solution in the Pt cathode compartment thus brings about a higher e.m.f. of the photo-cell.

Since the potential difference at the semiconductor-electrolyte interface falls normally within the space charge region at the surface of the semiconductor, the increase in the e.m.f. leads to an enhancement of the separation efficiency for electron-hole pairs created by the irradiation in the space charge region. Under irradiation of monochromatic light (380 nm), a quantum efficiency as high as 0.3 or more is attained when the pH value of the anode compartment is higher and that of the cathode compartment is lower; it does not exceed 0.01 in the case of a common neutral electrolyte (*e.g.*, KCl) solution.

In the present study, a wafer of single crystal TiO_2, 1.5 mm in thickness and 1.0 cm^2 in area, treated under a reducing atmosphere before use, was employed. Its donor density calculated from the slope of the Mott-Schottky plot[3] was *ca.* 2.5×10^{17} cm^{-3}. The (001) face of the crystal was exposed to the electrolyte solution. A 500 W xenon lamp was used as a light source. With the use of a colored glass filter (Toshiba Kasei VV40 filter), the number of the incident quanta per second per square centimeter at the surface of the TiO_2 electrode was measured by means of the chemical actinometry using a potassium ferrioxalate system,[4] and found to be *ca.* 2×10^{17}. A platinum black electrode having the surface area of 1.0 cm^2 served as a cathode.

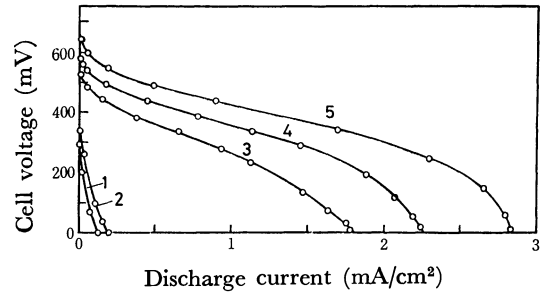

Fig. 2. Relation between the cell voltage and the discharge current.

TiO_2 anode compartment	Pt cathode compartment
1: 1 M NaOH,	1 M NaOH
2: 1 M NaOH,	1 M Na_2SO_4
3: 1 M NaOH,	0.005 M H_2SO_4
4: 1 M NaOH,	0.05 M H_2SO_4
5: 1 M NaOH,	0.5 M H_2SO_4

Figure 2 shows the relations between the cell voltage and the discharge current under irradiation, as a function of the composition of the anodic and cathodic electrolyte solutions. The curves were obtained by adjusting the external resistance. The maximum efficiency was attained by a combination of strong basic and strong acidic solutions (curve 5) as expected, the open-circuited cell voltage being *ca.* 0.64 V. The amounts of hydrogen and oxygen evolved were proportional to the intensity of light and the surface area

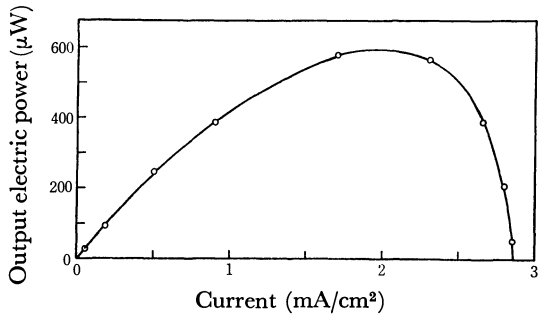

Fig. 3. Relation between the electric power output at the external resistance and the cell current.
The solutions are 1 M NaOH in the TiO_2 anode compartment and 0.5 M H_2SO_4 in the platinum black cathode compartment, respectively. The number of quanta per second per square centimeter: 2×10^{17}.

of the TiO_2 electrode, when the cross section of the incident light flux was sufficiently large as compared with the surface area of TiO_2. The rate of generation of hydrogen amounted to *ca.* 1.1 ml/hr when the cell was short-circuited, indicating the current efficiency of about 100%.

Figure 3 shows the relationship between the cell current and the output electric power at the external resistance (calculated from curve 5, Fig. 2). The apparent over-all internal resistance of the cell is estimated to be about 140 Ω from the slope of curve 5. The maximum output electric power was obtained using an external resistance of 140 Ω, as predicted by a simple theory. The quantity appearing on the abscissa in Fig. 3, *i.e.*, the current density, can be interpreted as representing the amount of hydrogen evolved, since these two quantities are proportional to each other. We see that a fairly large amount of hydrogen is obtained when the maximum output power is attained.

The fact that, when the acidic and basic solutions are used in each compartment, the electro-motive force arising from the concentration difference of hydrogen ions is involved in the cell voltage should be taken into consideration. The electro-motive force is estimated to be *ca.* 0.77 V for a pH difference of 13. In view of the theoretical decomposition voltage of water of *ca.* 1.23 V and the practical one of more than 1.6 V and the heat of combustion of hydrogen (68 kcal/mol), the observed results support the effectiveness of the combined utilization of acid-base electrolyte solutions. The liquid junction potential was actually lower than 0.05 V since a salt bridge consisting of agar containing KCl was used. Use of an ion-exchange membrane of low resistance and long durability could increase the efficiency of hydrogen evolution.

Since the electrode reactions are $4OH^- + 4p^+ \rightarrow O_2 + 2H_2O$ at the TiO_2 electrode, and $4H^+ + 4e^- \rightarrow 2H_2$ at the Pt electrode, after a long run the solution in the TiO_2 compartment will become less alkaline, and that in the Pt compartment less acid.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48 (3), 1043—1044 (1975)

The Dimerization of the Phenoselenazine and Benzo[c]-phenoselenazine Cation-radicals

Yoshio MATSUNAGA and Tomio TANAKA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received October 7, 1974)

Synopsis. The equilibrium constants and the heats of dimerization and the monomer and dimer spectra were determined for the phenoselenazine and benzo[c]phenoselenazine cation-radicals in aqueous sulfuric acid (1:1 by volume).

In connection with our work on the phenoselenazine-iodine complex,[1] attempts were made to measure the ESR absorption spectrum of the phenoselenazine cation-radical produced in sulfuric acid at various dilutions and temperatures, but all without success. During the course of such attempts, however, a reversible color change from brown to pink occurred upon warming, suggesting that the cation-radical is in the monomer-dimer equilibrium. As the monomer and dimer spectra are important tools for speculating on the mode of intermolecular interaction in solid ion-radical salts,[2] we analyzed the temperature- and concentration-dependences of the solution spectrum.

The phenoselenazine and its semiquinoid bromide employed here were prepared in our previous work.[1] The preparation of benzo[c]phenoselenazine was carried out by a method analogous to that for phenoselenazine reported by Müller *et al.*[3] The phenoselenazine bromide was dissolved in aqueous sulfuric acid (1:1 by volume). The absorption spectra of eight solutions, ranging from 5.05×10^{-5} to 6.12×10^{-4} mol/l, were recorded on a Beckman DK 2A spectrophotometer at 20, 35, and 50 °C with the aid of a temperature-regulated cell holder. As the composition of the oxidation product of benzo[c]phenoselenazine with bromine did not agree with the calculated one, the compound was directly dissolved in concentrated sulfuric acid. Then, one volume of the solution was slowly diluted, avoiding excessive heating, with one volume of water. For this radical, we prepared fifteen solutions, the concentrations of which were in the range from 1.27×10^{-5} to 1.64×10^{-3} mol/l. The spectra were then examined at 20, 35, 50, and 65 °C. The spectral change in the phenoselenazine cation-radical was found to be slightly irreversible if the solution was heated to 65 °C.

Upon heating, the intensities at 400, 475, and 733 nm in the spectrum of the phenoselenazine radical become weaker and those at 433 and 513 nm become stronger. The locations of the six isosbestic points observed are as follows: 358, 411, 438, 493, 559, and 868 nm. We assumed that the observed spectral change can be interpreted in terms of the monomer-dimer equilibrium; that is, $2(A^+)\rightleftarrows(A_2)^{2+}$. This formula does not exclude the possibility of the presence of an anionic species in the dimer. Since the absorption bands assignable to the monomer and dimer overlap considerably, the values of the true extinction coefficient of the monomer, ε_M, and that of the dimer, ε_D, were determined by the extrapolation procedure described by Boyd and Phillips.[4] The monomer band at 513 nm and the dimer band at 733 nm were chosen for this purpose. The best sets of values of ε_M and ε_D were as follows:

$\varepsilon_M = 9.50\times10^3$, $\varepsilon_D = 5.55\times10^3$ at 513 nm and

$\varepsilon_M = 0.75\times10^3$, $\varepsilon_D = 11.0\times10^3$ at 733 nm.

The average equilibrium constants evaluated from the data at the monomer and dimer bands were $K(20\ ^\circ\mathrm{C}) = 3.7\times10^3$, $K(35\ ^\circ\mathrm{C}) = 1.6\times10^3$, and $K(50\ ^\circ\mathrm{C}) = 0.72\times10^3$ l/mol. From the temperature dependence of K, the heat of dimerization of the phenoselenazine cation-radical was estimated as −9.9 kcal/mol.

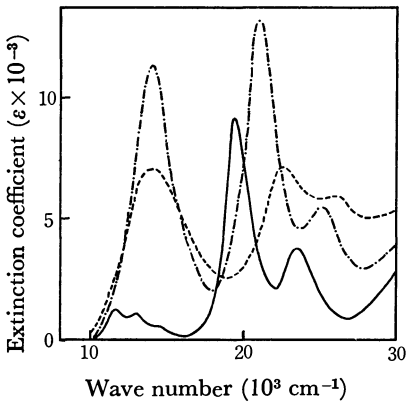

Fig. 1. Absorption spectra of the monomer (——) and dimer (– – –) of phenoselenazine cation-radical and reflection spectrum of the semiquinoid bromide (——).

The monomer and dimer spectra were constructed by plotting the measured apparent extinction coefficient, ε, at about thirty wavelengths *versus* the fraction of the stoichiometric concentration existing as a monomer calculated from the above-mentioned equilibrium constants for each concentration. They are presented in Fig. 1, along with the spectrum of the solid semiquinoid bromide, as measured by the diffuse-reflectance method. The similarity between the dimer spectrum and the solid-state spectrum provides strong evidence that the intermolecular interaction in the solid bromide is predominantly pair-by-pair.

Although phenothiazine bromide dissolved in aqueous sulfuric acid shows a spectrum essentially the same as the monomer spectrum given in Fig. 1, the dimerization has been demonstrated by Kagiya *et al.* at temperatures as low as −70 °C in an ethanol–ether–sulfuric acid solution.[5] The enthalpy change estimated by them is about −5 kcal/mol. There seems to be appreciably more shift of the equilibrium towards the dimer in the phenoselenazine cation-radical as compared with

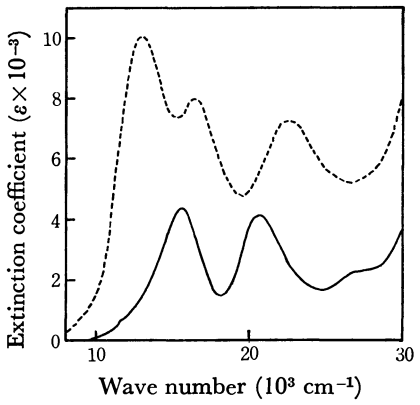

Fig. 2. Absorption spectra of the monomer (——) and dimer (– – –) of benzo[*c*]phenoselenazine cation-radical.

the sulfur-analogue. A similar marked difference in the dimerization behavior between the cation-radical of phenoxathiin and that of phenoxaselenine, as judged from the spectral and magnetic properties, has been reported by Hillebrand *et al.*[6]

Upon the introduction of an extra benzene nucleus into phenoselenazine, the temperature-dependence of the spectrum of the cation-radical becomes less pronounced. The extrapolation procedure could be applied only to the dimer band appearing at 788 nm. We obtained the following values; $\varepsilon_M = 1.25 \times 10^3$, $\varepsilon_D = 9.95 \times 10^3$, $K(20\ ^\circ\mathrm{C}) = 9.9 \times 10^4$, $K(35\ ^\circ\mathrm{C}) = 3.4 \times 10^4$, $K(50\ ^\circ\mathrm{C}) = 1.3 \times 10^4$, and $K(65\ ^\circ\mathrm{C}) = 0.48 \times 10^4$ l/mol. The heat of dimerization of -13.3 kcal/mol estimated for this cation-radical is about 30% higher than that of the phenoselenazine cation-radical; that is, the heat is approximately proportional to the size of the molecules within this pair. For such a comparison, it may be more appropriate to use the heat of the dimerization of the phenoselenazine cation-radical, evaluated only on the basis of the data taken at the dimer band. The required value is a little larger than the aforementioned value—that is, -10.7 kcal/mol. The constructed spectra of the monomeric and dimeric benzo[*c*]phenoselenazine cation-radical are presented in Fig. 2. The difficulty in analyzing the spectrum of this radical apparently arises not only from the large equilibrium constant but also from the overlap of the monomer and dimer spectra.

We attempted to extend our study to the dibenzo[*c*,*h*]phenoselenazine cation-radical; however, the dilution of a concentrated sulfuric acid solution in the desired range of concentration with an equal volume of water resulted in the formation of a dark green precipitate, and the recording of the spectrum was not possible.

The authors wish to express their thanks to Mr. Yukio Suzuki for providing them with the results of his preliminary spectral measurements of the phenoselenazine cation-radical.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48 (3), 1045—1046 (1975)

An Electron Paramagnetic Resonance Study of Low-Spin Five-coordinate Cobalt(II) Complexes[1)]

Yuzo NISHIDA and Sigeo KIDA

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received August 13, 1974)

Synopsis. EPR spectra were measured for the five-coordinate cobalt(II) complexes, $[CoCldpe_2]SnCl_3$ and $[CoCldpe_2]SnCl_3 \cdot C_6H_5Cl$, which had been determined by X-ray analyses to have a tetragonal pyramidal and trigonal bipyramidal structures, respectively. The observed g-values showed a satisfactory agreement with the previously reported prediction.[6)]

Recently, several EPR studies were reported on five-coordinate low-spin cobalt(II) complexes.[1-6)] In all those studies EPR spectra of tetragonal pyramidal complexes were interpreted on the basis of the ground state configuration $(d_{xz})^2(d_{yz})^2(d_{x^2-y^2})^2(d_{z^2})^1$, where the Z-axis conincides with the tetragonal axis and X-axis divides the planar P–Co–P bond angle. On the other hand, the ground state configuration for the trigonal bipyramidal complexes has been assumed to be $(d_{xz})^2(d_{yz})^2(d_{x^2-y^2})^2(d_{xy})^1$. On this basis Maher[2)] and Kimball *et al.*[4)] theoretically calculated $g_{//}$ and $g_\perp$ values to be 4.0 and 0, respectively. However, no EPR data to support their conclusion have yet been reported. Nishida and Shimohori investigated a series of penta-coordinated low-spin cobalt(II) complexes, $[CoXdpe]_2Y$ ($X=Cl^-$, Br^-, NCS^-, NO_3^- and $Y=ClO_4^-$, NO_3^-) and reached a different conclusion for g-values ($g_z > g_x \approx g_y > 2$) for trigonal bipyramidal complexes, assuming that the orbital degeneracy is removed by the distortion from regular trigonal symmetry, (probably due to, *e.g.*, the Jahn-Teller effect or a steric requirement of the crystal, *etc.*). On this basis they showed that the two possible geometries, *i.e.*, tetragonal pyramid and trigonal bipyramid, can be discriminated by the use of EPR data. Recently, it was demonstrated by X-ray analyses that $[CoCldpe_2]SnCl_3$ and $[CoCldpe_2]SnCl_3 \cdot C_6H_5Cl$ have tetragonal pyramidal and trigonal bipyramidal structures, respectively,[7)] where dpe denotes 1,2-bis-(diphenylphosphino)ethane. Accordingly, we have carried out an EPR study on these compounds in order to confirm the previously derived criterion for the discrimination of the geometrical isomers.[6)]

Experimental

Preparation. 1,2-Bis(diphenylphosphino)ethane(=dpe) was prepared according to Hewertson's method.[8)] The complexes, $[CoCldpe_2]SnCl_3$ and $[CoCldpe_2]SnCl_3 \cdot C_6H_5Cl$ were prepared by the method described in the literature.[7)]

EPR Measurements. EPR spectra were measured using X-band at room temperature with a JEOL ESR apparatus model JES-ME-3X, DPPH being used as a standard for magnetic field strength.

* In this model the d_{xy} and $d_{x^2-y^2}$ orbitals are not degenerate, $d_{x^2-y^2} > d_{xy}$ in energy being assumed.

Results and Discussion

Powder EPR spectra of $[CoCldpe_2]SnCl_3 \cdot C_6H_5Cl$ and $[CoCldpe_2]SnCl_3$ were shown in Figs. 1 and 2, respectively. The former shows an axial symmetry, and $g_{//}$ and $g_\perp$ were evaluated from the spectra following Sands[9)] and Kneubuhls'[10)] method. On the other hand, the latter spectrum shows a rhombic symmetry, and g_1, g_2, and g_3 were evaluated at 2.357, 2.276, and 2.003, respectively, by the same method.

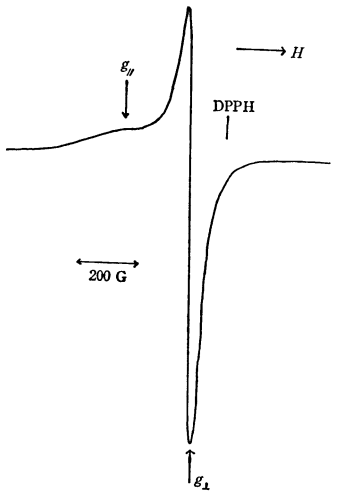

Fig. 1.

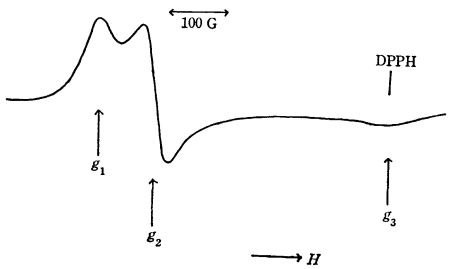

Fig. 2

As was shown in the preceeding paper,[6)] g-values for the low-spin cobalt(II) complexes of a distorted trigonal bipyramidal symmetry* were calculated in the first order as,

$$g_z = 2(1-4a_1)$$
$$g_x = 2(1-a_2)$$
$$g_y = 2(1-a_3)$$

where

$$a_1 = \zeta/\Delta\{(x^2-y^2)-(xy)\}$$

$$a_2 = \zeta/\Delta\{(x^2-y^2)-(yz)\}$$
$$a_3 = \zeta/\Delta\{(x^2-y^2)-(xz)\}$$

ζ: one electron spin-orbit coupling const.
$\Delta\{(x^2-y^2)-(xy)\}$: the energy difference between the $(d_{z^2})^2(d_{x^2-y^2})^1$ and the $(d_{z^2})^2(d_{xy})^1$ states (in terms of electron-hole formulism), and so on.

From these equations the following relation was derived for this type of complexes.

$$g_z > g_x \approx g_y > 2.0 \quad (1)$$

For the complexes of tetragonal pyramidal symmetry,

$$g_z = 2.0$$
$$g_x = 2(1-3b_1)$$
$$g_y = 2(1-3b_2)$$

where

$$b_1 = \zeta/\{\Delta(z^2)-(yz)\}$$
$$b_2 = \zeta/\{\Delta(z^2)-(xz)\}$$

$\Delta\{(z_2)-(xz)\}$: the energy difference between the $(d_{xy})^2(d_{z^2})^1$ and the $(d_{xy})^2(d_{xz})^1$ states, and so on.

From these equations the relation

$$g_x \geqq g_y > g_z \approx 2.0 \quad (2)$$

was derived.

In fact, the present EPR data** show a satisfactory agreement with the above theoretical prediction. The trigonal bipyramidal complex, $[CoCldpe_2]SnCl_3 \cdot C_6H_5Cl$ gives the g-values ($g_{//}=2.258$, $g_{\perp}=2.062$) conforming to the relation (1), and the tetragonal pyramidal one, $[CoCldpe_2]SnCl_3$, gives the g-values ($g_1=2.357$, $g_2=2.276$, $g_3=2.003$) conforming to the relation (2). This result is also quite compatible with the previous conclusion for $[CoXdpe_2]Y$.

Thus, we can conclude that the assumption on which our theoretical calculation are based[6] is valid and the two possible geometries for low-spin five-coordinate cobalt(II) complexes can be discriminated on the criterion based on the relations (1) and (2) for which numerical values are obtainable from EPR spectra.

** The effect of the intermolecular magnetic interaction on the observed g-values can be neglected in this discussion, since according to Stalick *et al.*,[7] the shortest Co–Co distance are 11.4 Å and 9.49 Å in $[CoCldpe_2]SnCl_3$ and $[CoCldpe_2]SnCl_3 \cdot C_6H_5Cl$, respectively.

Atomic Absorption Spectrophotometry of Titanium in the Iron Sulfides of NiAs Type

Kohei AMETANI

RCA Research Laboratories, Inc., Zushi-machi, Machida-shi, Tokyo 194-02

(Received August 15, 1974)

Synopsis. A method is described for the atomic absorption spectrophotometric determination of titanium in the sulfides, $Fe_{1-x}Ti_xS$ ($x \leq 0.3$), of NiAs type. Potassium sulfate was added to both sample and standard solutions to suppress the iron interference. The powder and single crystal samples were successfully analyzed using 10 mg of samples.

The atomic absorption spectrophotometry of titanium is carried out on iron ores,[1] cast iron,[2] ferric oxides,[3] steels,[2,3] and alloys[2-4] using a high temperature flame of nitrous oxide–acetylene. However, titanium forms refractory oxides in the flame and various interference effects are encountered.[3-5] Therefore, some workers described the necessity of several additives such as aluminium,[1,3] potassium chloride,[4] and organic compounds[3] to suppress the interference of foreign elements in each sample. Iron is known to be one of the interfering elements in the atomic absorption spectrophotometric analysis of titanium.[3-5] In the present work on the analyses of titanium in the iron sulfides, $Fe_{1-x}Ti_xS$ ($x \leq 0.3$), of NiAs type, the usefulness of the following reagents was examined to suppress the iron interference; hydroxylamine hydrochloride, ammonium fluoride, diammonium salt of EDTA, sodium chloride, potassium chloride, sodium sulfate, and potassium sulfate. Among these reagents, sodium or potassium sulfate was the most effective in suppressing the iron interference. Finally the results of the determination of titanium in the actual samples by a method using potassium sulfate are presented. Ten mg of samples were used for the analysis.

Experimental

Reagents. The standard solution (1 mg Ti/ml) was prepared by dissolving sponge metal (99.5% up) in hydrochloric acid. The solution was stocked as 1 M hydrochloric acid solution. The reagents to be examined as a suppressor for the iron interference were dissolved in deionized water. Reagents used were of analytical reagent grade.

Measurements of Titanium Absorption. The titanium absorption was measured in a nitrous oxide–acetylene flame using a Hitachi model 208 Atomic Absorption Spectrophotometer and a hollow cathode lamp HLA-3. Working conditions used are listed in Table 1. Figure 1 shows effects of

TABLE 1. WORKING CONDITIONS

a) Sum of the observed values for three components.

nium acetate. Reagents which increase the titanium absorption were hydroxylamine hydrochloride and ammonium fluoride. Alkali metal salts such as sodium chloride, potassium chloride, sodium sulfate, and potassium sulfate reduced the titanium absorption. However, at the higher concentration of these reagents the titanium absorption remained constant. At the lower concentration of EDTA the titanium absorption was decreased but the absorption was gradually increased with an increase of the concentration of this reagent.

To suppress the iron interference the effects of these reagents were examined by adding the reagents to the titanium solution containing iron. The concentrations of the reagents added were chosen by the value at which the titanium absorption remained constant (*cf.* Fig. 1). Ferric ions were added as chlorides. The results are shown in Fig. 2. The titanium absorption was increased in the presence of ferric ions in the solution without other reagents. The absorption was higher in hydroxylamine hydrochloride or ammonium fluoride solutions than in the other solutions examined. Though the two reagents highly enhanced the titanium absorption in the presence of ferric ions, they did not suppress the iron interference. EDTA decreased the titanium absorption linearly with an increase of ferric ion concentration. Alkali metal salts reduced the titanium absorption. However, sodium and potassium sulfates gave a constant titanium absorption over a wide range of iron concentrations. In this work, potassium sulfate was used as the suppressor for iron interference.

Analysis of Samples. The powder samples were synthesized by sintering a mixture of the respective elements with the nominal compositions shown in Table 2 at a high temperature, and the crystal structure was identified by X-ray diffraction. The single crystal samples (unknown compositions) were grown by chemical vapor transport. Ten mg of the powder or single crystal samples were dissolved in *aqua regia* containing bromine. After removal of the excess nitric acid by evaporation with hydrochloric acid, the final solution was made up to 25 ml, where the acidity was adjusted to 0.5 M hydrochloric acid and the concentration of potassium sulfate, 2000 ppm. The same adjustment was carried out for standards containing 10 to 100 ppm titanium and the atomic absorption was then measured. The results of the analyses are shown in Table 2, together with the contents of iron and sulfur obtained in separate experiments.[6] For the powder samples, the observed values are in agreement with the calculated values. All the observed values are satisfactory, as the sum of the observed values for three components is close to 100% in all cases.

The author thanks Dr. Tatsuo Takahashi of this laboratories for providing the samples.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48 (3), 1049—1050 (1975)

A New Optically Active Co(II) (salen) Type Complex Containing a Pentadentate Schiff-Base Ligand

Haruhiko Aoi and Sadao Yoshikawa

Department of Synthetic Chemistry, Faculty of Engineering, University of Tokyo. Bunkyo-ku, Tokyo 113

(Received September 19, 1974)

Synopsis. A new optically active square-pyramidal cobalt(II) complex, *N,N'*-bis(salicylaldehyde)-2-(*S*)4-*S*-methyl-4-thio-1,2-butanediiminatocobalt(II), was synthesized. The structure of this complex was examined.

The square-planar tetradentate Schiff-base complexes of cobalt such as cobaloxime, Co(salen), *etc.* have been widely studied as model compounds for coenzyme B_{12} and as oxygen carriers. Terent'ev[1] and Hipp[2] reported the conformation of *N,N'*-bis(salicylaldehyde)-(—)-propylenediiminatocobalt(II) based on analysis of the CD spectra in solution, stating that the δ conformation about the central chelate ring was preferred. It is well-known in the case of cobalamin that the spin state of Co(II) is low-spin and that the corrin ring is in-plane. Some data are available on Co(II) complexes containing a pentadentate Schiff-base ligand,[3] but in almost all cases the spin state of Co(II) was found to be high-spin. The two chelate rings composed of phenolic oxygen and the Schiff-base were not in-plane because of steric hindrance. It is therefore of interest to prepare a low-spin Co(II) complex containing a pentadentate Schiff-base ligand maintaining planarity and to examine the behavior of the atom coordinated in the apical position.

In this report we will describe the synthesis and structure of *N,N'*-bis(salicylaldehyde)-2(*S*)-4-*S*-methyl-4-thio-1,2-butanediiminatocobalt(II), Co(II)[sal$_2$-2(*S*)-SMT-BDA], [A], and its properties will be compared with those of *N,N'*-bis(salicylaldehyde)-1(*R*),2(*R*)-1,2-*trans*-cyclohexanediiminatocobalt(II), Co(II)[sal$_2$-(*R*)-CHXDA], [B], which has been discussed in the preceeding paper.[4]

Experimental

Preparation of Ligands: 2(*S*)-4-S-methyl-4-thio-1,2-butanediamine, [D], was prepared from (*S*)-methionine by the usual method. Bp/2 mmHg=81 °C; $[\alpha]_{589}^{30}=-12.3°$ (in 3% methanolic solution). NMR: (in d_4-MeOH) 1.63 (m, 2H, $-CH_2-$), 2.09 (s, 3H, $-CH_3$), 2.57 (t, 2H, $-CH_2-S$), 2.59 (d, 2H, $-CH_2-N$), 2.60 (m, 1H, $=CH-N$). *N,N'*-bis(salicylaldehyde)-2(*S*)-4-S-methyl-4-thio-1,2-butanediimine, [E], was prepared from salicylaldehyde and diamine [D] in a molar ratio of 2 : 1 in ethanol.

Co(II)[sal$_2$-2(S)-SMT-BDA], [A]: 1.56 g of anhydrous cobalt acetate and 3.01 g of ligand [E] were reacted in 40 ml of 1-propanol at 60 °C under a nitrogen atmosphere for 20 min with stirring. After concentrating the solvent to about 10 ml, 20 ml of THF was added with stirring at 60 °C. Brown needle-like crystals precipitated when cyclohexane was added. These were filtered off and washed with cyclohexane. Found: C, 57.16; H, 5.29; N, 6.71%. Calcd. for $C_{19}H_{20}N_2O_2SCo$: C, 57.14; H, 5.05; N, 7.01%. IR: (KBr) 1600 (C=N), 1525 cm^{-1} (C=C).

Co(II)[sal$_2$-2(S)-SMT-BDA]·2H$_2$O, [C]: Similar method to that of complex [A] was used but aqueous ether was added instead of cyclohexane. Found: C, 51.54; H, 5.05; N, 6.43%. Calcd for $C_{19}H_{24}N_2O_4SCo$: C, 52.41; H, 5.56; N, 6.43%. IR: (KBr) 3400 (OH), 1634 and 1603 (C=N), 1537 cm^{-1} (C=C).

Results and Discussion

The main purpose of this study was to synthesize a low-spin square-pyramidal Co(II) complex containing a pentadentate Schiff-base ligand. It is generally accepted that the values of μ_{eff} of low-spin square-planar Co(II) complexes and the low-spin octahedral Co(II) complexes fall in the range 2.1—2.9 and 1.8—1.9 B.M., respectively, while the values of μ_{eff} of high-spin five-coordinated Co(II) complexes fall in the range 4.5—4.8 B.M.[5,6]

The planarity of the ligand can be discussed in terms of the shape of the CD spectrum at the π-π^* transition

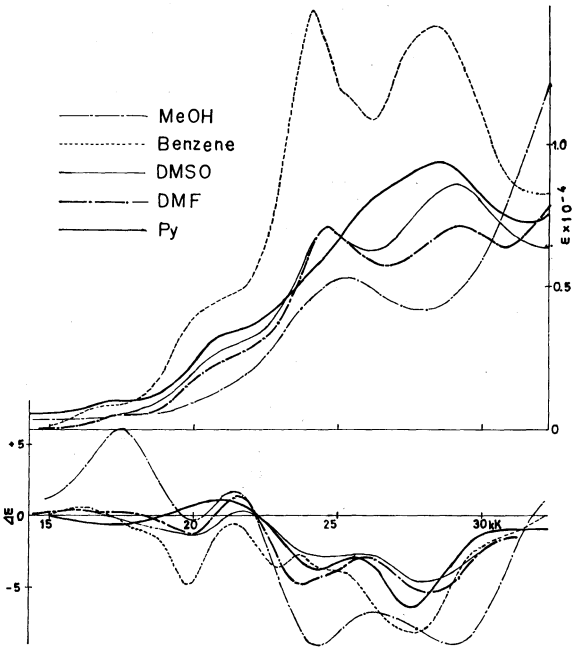

Fig. 1. The CD and absorption spectra of Co(II) [sal$_2$-2(*S*)-SMT-BDA] in various solvents.

region.[2,7,8] The π-π^* transition appears at about 28 kK and shows only one component in the cases of Co(II) and Ni(II) complexes with tetradentate Schiff-base ligands while in the corresponding Zn(II) complex the π-π^* transition contains two components with nearly equal magnitudes of positive and negative CD due to the T_d symmetry.

The magnetic moment, μ_{eff}, of complex [A] measured

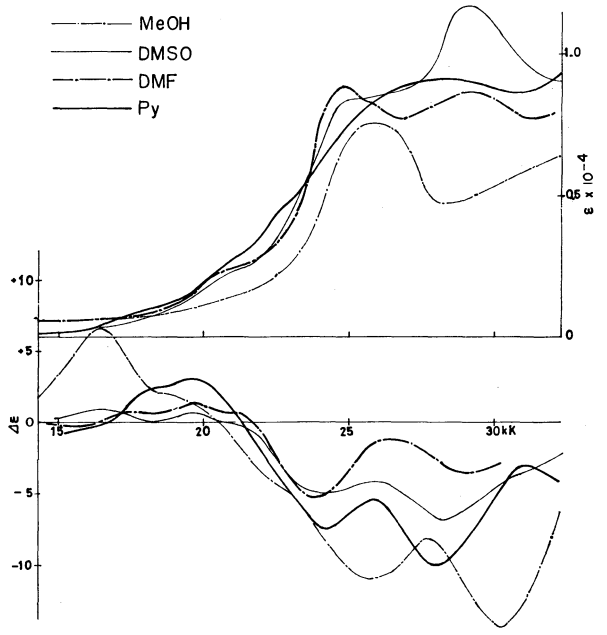

Fig. 2. The CD and absorption spectra of Co(II) [Sal_2-(*R*)-CHXDA] in various solvents.

by the method of Guoy was 1.99 B.M.; it was 2.41 B.M. in complex [B].[4] This shows that the spin state of complex [A] is low-spin, suggesting that complex [A] is square-pyramidal. The CD and associated absorption spectra of complex [A] were measured in various solvents and are given in Fig. 1. Those of complex [B] are given in Fig. 2. All the CD spectra in Fig. 1 show only one component at about 28 kK. These results suggest that the two chelate rings, composed of phenolic oxygen and Schiff-base, are coplanar in complex [A]. In complex [B] the central chelate ring is locked in the λ conformation.[4] Comparing the CD spectra of complex [A] and [B], shown in Figs. 1 and 2, the shapes of spectra are similar. Nevertheless, the CD spectra of the ligands [E] and [F][9] are almost opposite in sign, reflecting the difference of chirality of the asymmetric carbon. This would be attributed to the similarity of the central chelate ring conformation in complexes [A] and [B]. These results in the measurements of the CD spectra support the view that complex [A] is a low-spin square-pyramidal Co(II) complex. A possible structure of complex [A] is shown

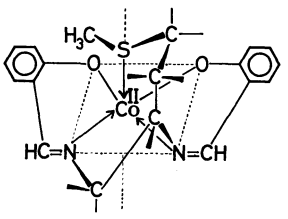

Fig. 3. The structure of Co(II) [sal_2-2(*S*)-SMT-BDA]

in Fig. 3.

A drastic change was observed in the CD spectrum of complex [A] in Py solution after dissolving complex [A] in aqueous methanol and evaporating off the solvent. This change would depend on whether or not H_2O coordinates in the *trans* position of the sulfur atom. When the *trans* position of the sulfur atom is occupied by H_2O, a Py molecule would attack at the coordinated sulfur atom, resulting in substitution of the sulfur atom. On the other hand, the Py molecule would simply interact with the vacant site in the *trans* position of the sulfur atom if no H_2O molecule was present in this position.

The complex [C], Co(II)[sal_2-2(*S*)-SMT-BDA]·$2H_2O$, was synthesized to confirm such a drastic change in the CD spectrum in Py solution. The CD spectra of complex [C] were measured in various solvents (Fig. 4). A drastic change in the CD spectrum was observed in Py solution, while similar CD spectra were seen in DMF, DMSO and methanol solutions. This drastic change also supports the view that complex [A] is a square-pyramidal Co(II) complex.

Tetracyanoethylene Complexes of Ni(0) and Co(−1) Containing Isocyanides and Nitrosyl

Katsuhiko KAWAKAMI, Kazuhiro ISHII, and Toshio TANAKA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-kami, Suita, Osaka 565

(Received September 30, 1974)

Synopsis. The magnetic equivalence of the isocyanides in $Ni(RNC)_3(TCNE)$ and $Co(NO)(RNC)_2(TCNE)$ is more likely to be due to the free rotation of TCNE in solution than to the dissociative exchange of ligands.

Many phosphine and/or carbonyl complexes of transition metals are known to react with tetracyanoethylene (TCNE) to afford complexes with a rigidly bonded TCNE.[1,2] Recently we have reported for the first time the free rotation of TCNE in its adducts with some tetrakis(isocyanide)rhodium salts.[3] On the other hand, activated olefins were found to replace one molecule of phosphine from tetrahedral tris(triphenylphosphine)-(nitrosyl)-cobalt, -rhodium, and -iridium to form a square pyramidal complex with the rigidly bonded TCNE in the basal plane.[4] In connection with these results, it seemed that it would be of interest to investigate the reactions of TCNE with tetrahedral nickel- and cobalt-isocyanide complexes.[5,6]

Here we wish to report the synthesis and some spectroscopic studies of two types of complexes, $Ni(RNC)_3(TCNE)$ and $Co(NO)(RNC)_2(TCNE)$.

Experimental

All the tetrakis(isocyanide)nickel[5] and bis(isocyanide)-(carbonyl)(nitrosyl)cobalt[6] complexes were synthesized by the literature methods, including the previously unknown 2,4,6-trimethylphenyl isocyanide complexes. The reactions were carried out under nitrogen, and the recrystallizations were done in air, unless otherwise noted.

Preparation of Tris(p-methoxyphenyl isocyanide)(tetracyanoethylene)nickel, $Ni(p\text{-}CH_3OC_6H_4NC)_3(TCNE)$ (1a). TCNE (128 mg, 1 mmol) was added to a stirred suspension of $Ni(p\text{-}CH_3OC_6H_4NC)_4$ (592 mg, 1 mmol) in petroleum ether (20 ml). The color of the suspension gradually changed from bright yellow to brown. The suspension was then stirred overnight at the ambient temperature. The resultant powder was filtered and recrystallized from CH_2Cl_2/petroleum ether to yield black crystals of **1a** (350 mg, 61%).

Other nickel complexes were prepared in similar manners. Only the $2,4,6\text{-}(CH_3)_3C_6H_2NC$ complex was recrystallized from ligroin.

Preparation of Bis(p-methoxyphenyl isocyanide)(nitrosyl)(tetracyanoethylene)cobalt, $Co(NO)(p\text{-}CH_3OC_6H_4NC)_2(TCNE)$ (2a). A reaction of $Co(NO)(CO)(p\text{-}CH_3OC_6H_4NC)_2$ (383 mg, 1 mmol) with TCNE (128 mg, 1 mmol) in a manner similar to that described for **1a** afforded a brown powder, which was then filtered and recrystallized from CH_2Cl_2/petroleum ether under nitrogen to yield brown crystals of **2a** (310 mg, 64%).

Other cobalt complexes were obtained in analogous manners; only the $p\text{-}ClC_6H_4NC$ complex was recrystallized from C_6H_6/petroleum ether under nitrogen.

The physical measurements were performed as has been described elsewhere.[3a] The analytical data and molecular weights of the complexes are collected in Table 1, and the IR and PMR data are summarized in Table 2.

Results and Discussion

The tetrakis(aryl isocyanide)nickel series reacts with an equimolar amount of TCNE to give tris(isocyanide)-(tetracyanoethylene)nickel, with the substitution of one molecule of isocyanide, as has been reported for the *t*-butyl isocyanide analog.[7] Bis(isocyanide)(carbonyl)-(nitrosyl)cobalt also reacts with TCNE to afford bis-(isocyanide)(nitrosyl)(tetracyanoethylene)cobalt, with the evolution of carbon monoxide. All the TCNE complexes of Ni and Co are dark brown or black in color and are stable in air in the solid state over an extended period of time. Some of them are, however, unstable in solution and were recrystallized under nitrogen.

TABLE 1. ANALYTICAL DATA AND MOLECULAR WEIGHTS OF COMPLEXES

a) Measured in C_6H_6 (0.03 M or less) unless otherwise noted. b) Isocyanide vibration. c) TCNE vibration. d) Measured in Nuiol mulls. e) $\nu(CO)$. f) Measured in CH_2Cl_2 (0.04 M) at 25°C. g) A_2B_2-type quartet with a coupling constant of about 9 Hz unless otherwise noted; s=singlet.

The IR spectra of the TCNE complexes show a weak ν(CN) band around 2220 cm^{-1}, which indicates TCNE π-bonded through the C=C bond.[1,7] The ν(NC) frequency of the isocyanides is always higher in the TCNE complexes than in the starting complexes about 130 and 110 cm^{-1} (the differences between the averaged values of two frequencies) for the Ni and Co complexes respectively, indicating a charge transfer from the isocyanide ligands to the TCNE moiety. Moreover, in the Co series in $Co(NO)(RNC)_2(TCNE)$ the ν(NO) bands shift to frequencies higher by about 80 cm^{-1} than those in $Co(NO)(RNC)_2(CO)$. In the PMR spectra the isocyanide protons are always shifted to lower magnetic fields upon complex formation. These results indicate that TCNE is a stronger π-acid than carbon monoxide and isocyanides.

The electronic spectrum of $Ni(p\text{-}CH_3C_6H_4NC)_4$ shows an absorption maximum at 363 nm (ε 2.3×10^4); it is probably a charge transfer band from Ni to isocyanides. On the other hand, the corresponding band of **1b** may be blue-shifted and hidden under the strong band due to the isocyanide ligands. However, a new band appears at 452 nm (ε 2×10^3); its ε value suggests that this is a charge transfer band from Ni to TCNE. This is consistent with the stronger π-acceptor capacity of TCNE than those of isocyanides.

The IR spectrum of **1a** in C_6H_6 shows two strong ν(NC) bands of the isocyanides, indicating a C_{3v} local symmetry for the three isocyanides. The PMR spectrum in CH_2Cl_2 at 25 °C displays one sharp singlet and one A_2B_2-type quartet for the CH_3O and phenyl ring protons respectively; the magnetic equivalence of the three isocyanides is consistent with either the intramolecular rotation of TCNE (averaging the anisotropic effect of TCNE) or the rapid dissociative exchange of the ligands.

The molecular-weight determination reveals the essentially monomeric nature of **1a** (Table 1). The chemical shifts of the isocyanide protons were only slightly changed (0.02 ppm) when the concentration of **1a** in CH_2Cl_2 was changed from 0.20 to 0.008 M. The temperature dependence of the chemical shifts of **1a** in CH_2Cl_2 was found to be small (0.02 ppm) over the wide temperature range between −88 and 25 °C. These results suggest only a slight dissociation of ligands, if any. The addition of one molar equivalent of free TCNE to **1a** in CH_2Cl_2 at 25 °C did not affect the PMR spectrum; this eliminates the dissociative exchange of TCNE. On the other hand, the addition of three molar equivalents of free $p\text{-}CH_3OC_6H_4NC$ to **1a** in CH_2Cl_2 at 25 °C caused changes in the chemical-shift values; the isocyanide protons appeared at the averaged field between those of the complex and the free ligand. However, at −50 °C there occurred two sets of signals which exactly correspond to the complexed and free isocyanides, as is depicted in Fig. 1. This indicates a negligible dissociative exchange of isocyanides below −50 °C on the NMR time scale. However, no signal pattern indicative of the rotation being slowed down[3] was observed as low as −115 °C in a 1:4 mixture of CH_2Cl_2 and $CHClF_2$. This is also the case with the 2,4,6-$(CH_3)_3C_6H_2NC$ derivative, which is considered to be sterically most hindered. Thus, no direct evidence for the rotation being slowed down on the NMR time scale could be obtained. However, since the possibility of the rapid dissociative exchange of the ligands has been eliminated, the magnetic equivalence of the three isocyanides is more likely to be due to the free rotation of TCNE over a very low energy barrier.[8] Similar experiments were performed for some of the other Ni and Co complexes (**1b** and **2a**); the magnetic equivalence of the isocyanides observed for these complexes is also likely to be due to the free rotation of TCNE.

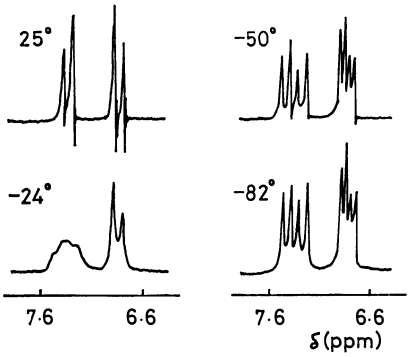

Fig. 1. Temperature-dependent PMR spectra of the phenyl ring protons of $Ni(p\text{-}CH_3OC_6H_4NC)_3$ (TCNE) (**1a**) in the presence of three molar equivalents of $p\text{-}CH_3OC_6H_4NC$ in CH_2Cl_2.

Fourier Analysis of AC Polarogaphy: Kinetic Parameters for Zn(II)-1 M $NaClO_4$ and KCl Systems

Michio HIROTA, Yoshio UMEZAWA, and Shizuo FUJIWARA
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received October 8, 1974)

Synopsis. The fundamental and second harmonic responses of the Zn(II)/Zn(Hg) electrode agreed with the theory with respect to the phase angle. Th ekinetic parameters of the systems were: $k_s=(2.8\pm0.3)\times10^{-3}$cm/s, $\alpha=0.30\pm0.05$ in 1 M $NaClO_4$ and $k_s=(3.3\pm0.3)\times10^{-3}$ cm/s, $\alpha=0.27\pm0.03$ in 1 M KCl.

Fourier transform AC polarography has the advantage of allowing the simultaneous measurement of the amplitude and phase angle for the components of the fundamental and higher harmonic AC current.[1-8] This opens a way to investigate the reaction at the electrode surface with different time scales, and it would probably be very useful for kinetic investigations.

The purpose of the present paper is to examine, taking the Zn(II) ion as an example, whether or not any discrepancy exists between the fundamental(1st) and second(2nd) harmonic responses under the same experimental conditions.

The apparatus and experimental procedures were the same as those of the previous paper.[8] The frequencies, f, of the applied AC potentials were 27.9, 55.8, 111.6, and 173.6 Hz, each with an amplitude, ΔE, of 5 mV. All the chemicals used were of analytical reagent grade, except for $Zn(ClO_4)_2\cdot6H_2O$, which was prepared by the usual method.

The actual steps of the measurements were as follows: 1) The kinetic parameters were first roughly estimated, by which the computer simulation of Procedure 2) was started. 2) Simulation was continued by varying the kinetic parameters until the calculated curve for cot ϕ *vs.* $\sqrt{w}$ at peak potential, E_p, of the 1st harmonic AC polarogram coincided with the experimental curves, where ϕ is the phase angle and ω is $2\pi f$. 3) The 2nd harmonic AC polarogram was then calculated by the use of the kinetic parameters which had just been obtained by the preceding procedure, after which the polarogram was compared with the experimental curve.

1) The standard rate constants of the electrode reaction, k_s, were calculated by means of Eq. (1);

$$\cot\phi = \frac{1}{k_s}\sqrt{\frac{\omega D}{2}},$$
$$D = D_o^{1-\alpha}\cdot D_r^{\alpha} \qquad (1)$$

where ϕ is the phase angle between the 1st harmonic AC current and the applied AC potential at the reversible half-wave potential, $E^r_{1/2}$. D_o and D_r are the diffusion coefficients of the oxidized and reduced forms respectively, and α, the transfer coefficient. By plotting cot ϕ against the frequency of the AC potential, k_s is calculated from the slope of the cot ϕ *vs.* $\sqrt{\omega}$ curve, with the intercept of 1.[14] In the present case, the cathodic peak potential, E_p^c, of the 2nd harmonic AC polarogram was used as the $E^r_{1/2}$ value, and α was roughly taken as 0.3 for both systems. These values of $E^r_{1/2}$ and α were actually the averages of the values in the literatures.[9-11,16] The observed values of k_s were $(3.5\pm0.9)\times10^{-3}$ cm/s for the Zn(II)–1 M $NaClO_4$ system and $(3.7\pm0.5)\times10^{-3}$ cm/s for the Zn(II)–1 M KCl system.

2) Simulation was performed by varying the values of k_s and α, until the calculated curve (cotϕ *vs.* $\sqrt{\omega}$) coincided with the experimental curves within the limit of experimental error, where theoretical calculation was based on the expanding-plane model.[13] The experimental values of cot ϕ used in this procedure were those obtained at E_p, where the current intensity is larger than that at $E^r_{1/2}$, which improved the precision of the phase angle. The kinetic parameters thus obtained for these systems were as follows: $k_s=(2.8\pm0.3)\times10^{-3}$ cm/s and $\alpha=0.30\pm0.05$ for Zn(II)–1 M $NaClO_4$ ($[H^+]=1$ mM), and $k_s=(3.3\pm0.3)\times10^{-3}$ cm/s and $\alpha=0.27\pm0.03$ for Zn(II)–1 M KCl($[H^+]=1$ mM). In these cases, D_o was obtained experimentally, and D_r was taken from Ref. 15.

3) Using the kinetic parameters obtained from the above procedure, the theoretical curves of the 2nd harmonic AC polarogram were described (Fig. 1). The frequency dependence of the several parameters, *i.e.*, the phase angles (Fig. 2), the ratio of I_p^c to I_p^a

same parameters as Fig. 1.

(cathodic and anodic peak currents respectively), and the separation between E_p^c and E_p^a (the anodic peak potential), were consistent with the theoretical predictions. However, the amplitude of the experimental curve was considerably (about twice) larger than that of the theoretical one in both systems. To confirm that the discrepancy was larger than the experimental error, the D_0 of Zn(II) (for the case of 1 M KCl solution) was measured by using different starting materials ($ZnCl_2$ and zinc metal). The D_0 found after four measurements was $(0.73\pm0.02)\times10^{-5}$ cm^2/s; its error gave only an error of less than 2% in the amplitude.

In conclusion, the results for the 1st and 2nd harmonic AC polarograms for the present systems agree with each other with respect to the phase angle. The kinetic parameters obtained from the phase angle of the 1st and 2nd harmonic responses are in good agreement with those previously reported.[9–11,16]

The observed amplitude, which was larger than the theoretical one, is assumed to be due to the effect of the spherical diffusion. In the present systems, the departure of the measured amplitude from the theoretical amplitudes was larger than in the cadmium system.[8] This may be qualitatively interpreted in terms of the fact that the spherical diffusion influences both the surface concentration and the deviation from the electrochemical equilibrium.[17]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48 (3), 1055—1056 (1975)

A Convenient Method for the Preparation of Aminoethyliminodiacetatocobalt(III) Complexes

Kashiro KURODA, Shuji OHTSUKA, and Noriko MATSUMOTO

Department of Chemistry, Faculty of Science, Ehime University, Matsuyama, Ehime 790

(Received October 31, 1974)

Synopsis. Sodium dinitro(aminoethyliminodiacetato)-cobaltate(III) has been obtained by the oxidation of an aqueous mixture of cobalt(II) chloride, sodium nitrite, and a reaction product between ethylenediamine and sodium monochloroacetate. Several other complexes with the tetradentate ligand have also been derived from the dinitro complex.

Schwarzenbach *et al.*[1] prepared β-aminoethyliminodiacetic acid, NH_2–CH_2–CH_2–$N<^{CH_2\text{–}COOH}_{CH_2\text{–}COOH}$ (abbreviated as aeidaH_2 in this report), and measured the formation constants with various metal ions in aqueous solutions. Chu *et al.*[2] prepared the tetradentate ligand by Schwarzenbach's method and synthesized *cis*(*O*)- and *trans*(*O*)-isomers of [Co(aeida)(en)]X (X=Cl, ClO_4). Their preparation route for the ligand requires several reaction steps, however, and so is not very convenient. It has been reported that the main product of the reaction between 1 mol of ethylenediamine and 2 mol of the monochloroacetate ion is not the aeida or the ethylenediamine-*N*,*N*′-diacetate ion (EDDA), but the ethylenediaminetetraacetate ion (EDTA) with the unreacted diamine.[3] However, we supposed that there might be some aeida in the reaction mixture and that there might be a possibility for a cobalt(III) complex with the tetradentate ligand to be separable, together with the coordination of a unidentate or a bidentate ligand. Thus, the reaction mixture was combined with cobalt(II) chloride and sodium nitrite, and the mixture was oxidized by air bubbling. As a result, sodium dinitro(aminoethyliminodiacetato)cobaltate(III) was obtained. This substance and a few complexes derived from it were identified, as will be described below.

Experimental

Sodium Dinitro(aminoethyliminodiacetato)cobaltate(III), Na[Co(aeida)(NO_2)$_2$]. Ethylenediamine (6.0 g) was placed in a 150 ml flask furnished with a reflux condenser and a dropping funnel, and the flask was set in an oil bath at 110 °C. A sodium monochloroacetate solution, which had been prepared by mixing monochloroacetic acid (18.9 g in 25 ml) with sodium hydroxide (8.0 g in 25 ml) below 20 °C, was added, drop by drop, from the funnel into the flask, taking about 2 hr. A sodium hydroxide solution (8.0 g in 25 ml) was then added, taking about 30 min. After this addition, the heating was continued for a further 2 hr. The product solution was then adjusted to be slightly alkaline by the addition of hydrochloric acid, and was combined with a solution of cobalt(II) chloride hexahydrate (24 g in 50 ml). While vigorous air bubbling into the mixture was started, a sodium nitrite solution (14 g in 25 ml) was added, drop by drop, from the inlet of the air stream. The solution, dark violet at the early period of the oxidation, gradually turned dark brown; at the same time, bright brown crystals began to come out. The air bubbling was continued for 5 hr. After the product had been placed in a refrigerator overnight, the crystals were collected and then recrystallized from 50 ml of warm water. The purified crystals were washed with methanol and ether. Yield, 7.5 g. Found: C, 20.76; H, 2.95; N, 15.99%. Calcd for Na[Co(aeida)(NO_2)$_2$]=$CoC_6H_{10}O_8N_4Na$ (348.09): C, 20.70; H, 2.90; N, 16.10%.

trans(O)-*Aminoethyliminodiacetato(ethylenediamine)cobalt (III) Perchlorate,* trans(O)-[*Co(aeida)(en)*]ClO_4. In an evaporating dish, 1.0 g of the dinitro complex was mixed with 10 ml of acetic acid and 2 ml of water. The dish was covered with a watch-glass and was heated on a boiling-water bath until the solid had been completely dissolved. Nitric oxides were evolved during the dissolution, and a red-violet solution was formed. Then the solution was concentrated with the aid of an air stream to obtain a tarry residue. After it had then been dissolved in 5 ml of water, the solution was concentrated again to the tarry state; the odor of acetic acid thereupon vanished. The product was dissolved in 5 ml of water again, and 1.0 g of 20%-ethylenediamine solution was added. The heating of the mixture on the bath for 30 min, followed by cooling and the addition of 1 ml of 6 M $HClO_4$, produced a red precipitate. The precipitate was recrystallized from 20 ml of warm water with the addition of a few drops of 6 M $HClO_4$. Yield, 0.4 g. Found: C, 24.32; H, 4.65; N, 14.10%. Calcd for [Co(aeida)(en)]ClO_4=$CoC_8H_{18}O_8N_4Cl$ (392.64): C, 24.47; H, 4.62; N, 14.27%.

trans(O)-*Aminoethyliminodiacetato(trimethylenediamine)cobalt-(III) Perchlorate,* trans(O)-[*Co(aeida)(tn)*]ClO_4. This complex was isolated by the use of trimethylenediamine instead of ethylenediamine in the above preparation. Yield, 0.4 g. Found: C, 26.50; H, 5.02; N, 13.60%. Calcd for [Co(aeida)(tn)]ClO_4=$CoC_9H_{20}O_8N_4Cl$ (406.67): C, 26.58; H, 4.96; N, 13.78%.

trans(O)-*Aminoethyliminodiacetato(diammine)cobalt(III)Perchlorate,* trans(O)-[*Co(aeida)(NH_3)$_2$*]ClO_4. One gram of the dinitro complex was treated with acetic acid and then with water, such as in the preparation of the ethylenediamine complex. Then, 5 ml of aqueous ammonia (6M) and 0.1g of active charcoal were added. After the mixture had been concentrated to dryness at ~60 °C, the residue was extracted with 20 ml of warm water. The addition of 1 ml of 6M $HClO_4$ to the extract, followed by cooling, produced a red-violet precipitate. It was recrystallized from 15 ml of warm water with the addition of a few drops of 6M $HClO_4$. Yield, 0.3 g. Found: C, 19.67; H, 4.51; N, 15.11%. Calcd for [Co(aeida)(NH_3)$_2$]ClO_4=$CoC_6H_{16}O_8N_4Cl$ (366.60): C, 19.66; H, 4.40; N, 15.28%.

Discussion

Identification. Figure 1 shows the absorption spectra of the diammine- and the diamine-complexes, in which a splitting is observable in each first band. Thus, the spectra clearly indicate that their configurations are *trans*-[CoN_4O_2]. The numerical values of the

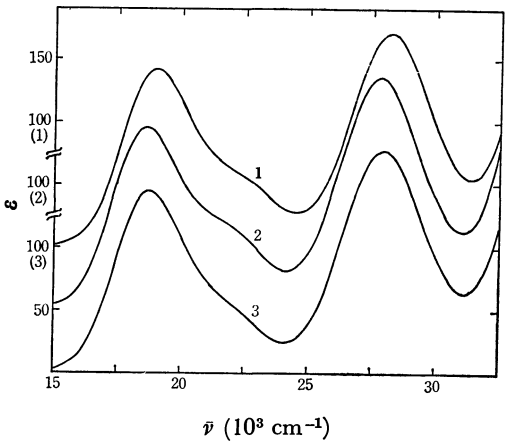

Fig. 1. Absorption spectra of some Co(III)-aeida complexes.
1: *trans*(O)-[Co(aeida)(en)]ClO_4
2: *trans*(O)-[Co(aeida)(tn)]ClO_4
3: *trans*(O)-[Co(aeida)$(NH_3)_2$]ClO_4

absorption maxima (Table 1) of our ethylenediamine complex agree satisfactorily with those of the *trans*(*O*)-isomer prepared by Chu *et al.*[2] Each of the spectra is definitely different from the spectrum of the Co(III)-EDDA complex with the corresponding ligand.[4] (An aeida-complex has the same elemental composition as the EDDA-complex with the same additional ligand.) Thus, on the basis of the absorption spectra as well as the elemental analyses, there remains no question as to the identification of the complexes.

Notes on the Preparations. Following are some notes on things observed qualitatively during the preparations:

(1) The solubility of the dinitro complex varies greatly with the temperature. The growth of the crystals from the reacting mixture is relatively slow. Thus, cooling the mixture during the later half of the air oxidation makes the preparation time shorter.

(2) In the preparations of cobalt(III) complexes with another multidentate ligand, such as trien or DTMA, a nitro complex is usually treated with hydrochloric acid to convert it into the chloro complex.[5] A similar treatment was attempted here. However, it appeared to decompose the complex itself. A large excess of acetic acid, as has been described above, is useful in expelling the nitro groups. Perchloric acid is not useful, since there is no proper means to remove the excess of the acid after the reaction.

(3) For the preparation of the diammine complex, it is necessary to add charcoal to the reacting mixture; otherwise, an aquoammine complex arises. Many other unidentate and bidentate ligands, such as SCN^-, N_3^-, phen, and dipy, also react with the product from the dinitro complex treated with acetic acid. The aquoammine complex as well as the other species in this series will be reported on elsewhere.

Ketyl Radical Formed in the Grignard Reaction of 2-Methylbenzophenone

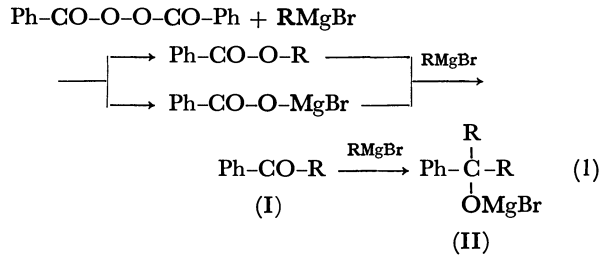
Masao Ōkubo

Department of Chemistry, Faculty of Science and Engineering, Saga University, Honshō-chō, Saga 840

(Received December 6, 1973)

Synopsis. The radical in the title reaction gave an ESR spectrum different from that of potassium-ketyl. From studies using the deuterium label technique, the reason for this difference was ascribed to the suppression of the twisting vibration caused by aggregate-formation.

The scheme for the reaction of Grignard reagents with benzoyl peroxide in tetrahydrofuran (THF) was recently established to be that shown in formula 1.[1]



In the course of a study of this reaction, a large excess of *o*-tolyl-MgBr was found to change the reaction solution from colorless to purple and an exceptionally long-lived radical species was detected.[2] As this radical is considered by the author to be related to the ketone (I, R=*o*-tolyl in formula 1), the radical produced in the Grignard reaction of 2-methylbenzophenone itself was studied in detail.

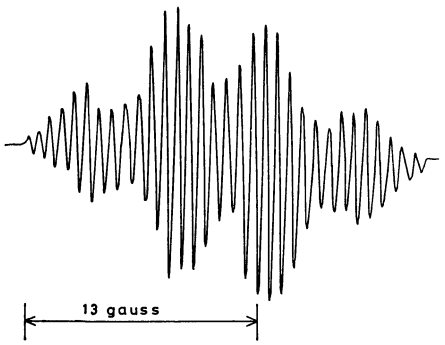


Fig. 1. ESR spectrum (A) of the radical species obtained in the reaction of 2-methylbenzophenone with *o*-tolyl-MgBr in THF.

The ESR spectrum (A) obtained in the reaction of I with *o*-tolyl-MgBr is shown in Fig. 1. As the spectrum obtained in the reaction of I with phenyl-MgBr was identical with spectrum A, the radical seemed to be a ketyl-type.[3] This radical existed even after the evacuated sample solution had been allowed to stand for several months at room temperature. This Grignard-ketyl, if that is what it is, is anomalous because of its long life[4] in comparison with the Grignard-ketyl of benzophenone which gave a measurable (by ESR) radical concentration only at temperatures lower than −20 °C.[5,6] Considering this anomaly, one might suspect that spectrum A is not that of a ketyl radical but that of triarylmethyl radical derived from the final product (II). The latter possibility, however, can be excluded by examining the calcium-ketyl of I prepared by using Ca-amalgum in THF. Spectrum B shown in Fig. 2 was obtained when the solution of Ca-ketyl was not fully diluted. Resemblance of spectrum A to B is obvious.

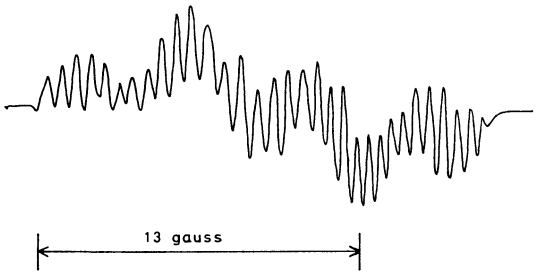

Fig. 2. ESR spectrum (B) of Ca-ketyl of 2-methylbenzophenone prepared in THF.

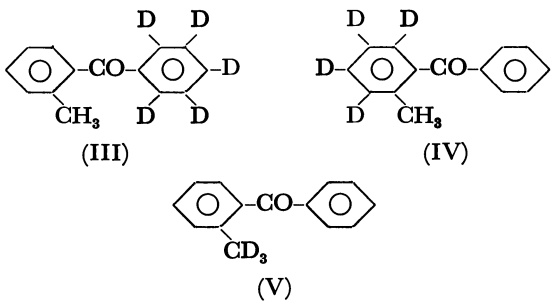
Spectrum A (total width 23.5 G) consists of four broad lines (a_1=5.86 G), each of which splits into eight lines (a_2=0.73 G). This spectrum differs from that of the potassium-ketyl of the same ketone, which is known to give a spectrum made up of only four broad lines.[7] In order to explain why the hyperfine splittings are observed in the Grignard reaction and not observed in the alkali metal reduction, the assignment of the splitting constants a_1 and a_2 is necessary. As no fruitful result is obtained if the numbers of equivalent hydrogen atoms are taken into account, the deuterium label technique was applied. When d_5-phenyl *o*-tolyl ketone (III) was treated with phenyl-MgBr, a broad single line



with the total width of 9.4 G was observed. The splitting constant a_1 is thus ascribed to the equivalent coupling of the two *ortho*- and one *para*-hydrogen atoms of the phenyl group with the free electron.[7] 2-Methyl-3,4,5,6-d_4-phenyl phenyl ketone(IV) gave four broad lines. In the case of 2-(d_3-methyl)phenyl phenyl ketone (V), spectrum C, composed of 32 lines, was observed but the relative strength of each line varied as shown in Fig. 3. The hyperfine splitting constant a_2 can thus be assigned mainly to the coupling of the nuclear

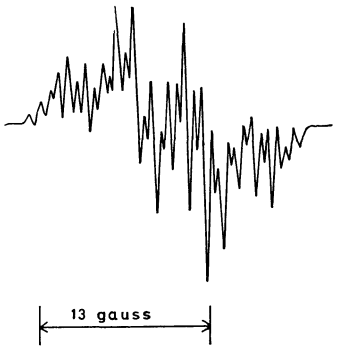


Fig. 3. ESR spectrum (C) of radical species obtained in the reaction of 2-(d_3-methyl)phenyl phenyl ketone with PhMgBr.

hydrogen atoms of the *o*-tolyl group and partly to that of the *o*-methyl hydrogen atoms with free spins.

The difference between the spectrum of the Grignard-ketyl and that of the K-ketyl can be ascribed to "aggregate-formation". The divalent calcium ion favors the formation of dimeric ketyl, which may aggregate further when the solution is less than fully diluted. During the dilution of the solution of the Grignard-ketyl in an evacuated sample tube, a portion of the deeply colored concentrated solution was observed to form a heavy layer at the bottom of the tube and some difficulty was found in obtaining a homogeneously diluted solution. This must be due to the formation of dimeric or polymeric aggregates. Resemblance of spectrum A to B suggests that the Grignard–ketyl exists in an aggregated state even in a fully diluted solution, although a description of this state cannot be given at present. The dimer- or aggregate-formation may suppress the twisting vibration of the *o*-tolyl group out of the plane of the benzoyl group, and thus the interaction of *o*-tolyl hydrogen atoms with free spins can be observed even though the spin density on the *o*-tolyl group is low. In the case of the K-ketyl, in which aggregate formation is not favored at low concentrations, the twisting vibration of the *o*-tolyl group may be rapid and the interaction of its hydrogen atoms with free spins could not be observed.

The large effect of deuterium label of the phenyl group on the total width of the Grignard-ketyl spectrum is remarkable. The spectrum width is reduced from 23.5 to 9.4 G while that of the K-ketyl is reduced from 21.7 to 18.5 G.[7] This indicates that the free spin density on the phenyl group is much higher in the Grignard-ketyl than in the K-ketyl. It is therefore concluded that the twisting angle of the *o*-tolyl group is larger in the former and the twisting vibration of the *o*-tolyl group is more rapid in the latter.

The reason for the exceptionally long life of the Grignard-ketyl is not yet clear, and further studies of Grignard-ketyls of 2-substituted benzophenones are now in progress.

Experimental

Materials. 2-Methylbenzophenone was prepared as usual. The ketone III was prepared from *o*-tolyl chloride and benzene-d_6 in CS_2 using $AlCl_3$. The ketone IV was prepared by the reaction of PhCOCl with the Grignard reagent derived from 2-methyl-3,4,5,6-d_4-phenyl bromide, which was obtained by repeated treatment of *o*-bromotoluene with 95% D_2SO_4.[9] The ketone V was prepared by the reaction of PhCOCl with the Grignard reagent derived from 2-(d_3-methyl)phenyl bromide, which was obtained from the following sequence of reactions. Anthranilic acid was converted to *o*-bromobenzoic acid by Sandmeyer reaction. By treatment of the acid with $LiAlD_4$, *o*-bromo-α,α-d_2-benzyl alcohol was obtained. The alcohol was then converted to the chloride by treatment with $SOCl_2$, and the Cl-atom was replaced by deuterium by using Zn-powder and CH_3COOD. Grignard reagents in THF were prepared as usual and transferred under N_2 to storage bottles.

ESR Measurement. Evacuated samples were prepared as previously described.[8] The molar ratio of phenyl-MgBr to ketones was 5: 1. After mixing by breaking the seal, the resulting purple solution was diluted by low-temperature-distillation in order to obtain a sufficiently resolved spectrum. A JEOL JES-ME-3X ESR spectrometer was used.

The Transisopropylation of Naphthalene[1)]

Keizo SHIMADA and Shizuo NAGAHAMA

Central Research Institute, Teijin Limited, 4-3-2 Asahigaoka, Hino, Tokyo 191

(Received June 2, 1974)

Synopsis. The transisopropylation of naphthalene with *p*-cymene and isopropylxylenes in the presence of aluminum chloride–nitromethane complex as a catalyst was studied. It was observed that the α-isomer initially formed was isomerized to the β-isomer in the reaction with isopropyl-*p*-xylene. However, when *p*-cymene or isopropyl-*o*-xylene was used, the isomer distribution was almost constant from the beginning to the end of the reaction. This was attributed to the fact that the hydride abstraction mechanism plays a role in the latter case.

In the case of the isopropylation of naphthalene, the exclusive or predominant formation of the β-isomer has been reported; this result has been explained as the isomerization of the initially formed α-isomer.[2)]

Farberov *et al.*[3)] showed that the isomeric composition depended on the alkylation conditions, especially on the temperature.

The equilibrium mixture seems to contain 95—96% of the β-isomer.[3,4)]

The isopropylation of naphthalene by transalkylation has also been reported.[5)] Several patents[6)] have claimed that the transalkylation of naphthalenes gave as product the β-isomer predominantly.

Recently, Yumoto[7)] obtained a product of transisopropylation in which the ratio of the α: β isomers was 8.4: 91.6.

One of the present authors (K. S.)[8)] has previously showed that the migration of an isopropyl group of alkylbenzene to another aromatic nucleus proceeded by two different mechanisms according to the structure of the isopropylbenzenes. That is, the transisopropylation of toluene by 1,4-dimethyl-2-isopropylbenzene in the presence of the $AlCl_3$–CH_3NO_2 catalyst gave a product which had a isomer distribution similar to that obtained by the isopropylation with isopropyl bromide. Thus, both reactions seem to proceed by means of the formation of the isopropyl cation. On the other hand, the transisopropylation of toluene with 1,2-dimethyl-4-isopropylbenzene or especially *p*-diisopropylbenzene gave a product rich in *p*-cymene.

In this case, an alkyl substituent on the *p*-position to the isopropyl group may stabilize the *tert*-carbonium ion produced by hydride abstraction from the isopropyl group, and the attack of the bulky phenyldimethyl cation on the *ortho* position of the methyl group of toluene becomes unlikely.

We wish now to report the effect of the structure of isopropylalkylbenzene as a transalkylation reagent on the isomer distribution of the isopropylnaphthalene obtained by the transisopropylation with the $AlCl_3$–CH_3NO_2 catalyst.

Experimental

Materials. The naphthalene was purified by sublimation and was 99.7% pure. The 1,4-dimethyl-2-isopropylbenzene was synthesized from *p*-xylene (purity 99.5% up) and isopropyl bromide with $AlCl_3$ and was distilled twice; 99.0% pure. The 1,3-dimethyl-5-isopropylbenzene was synthesized from m-xylene (purity 99.0% up) and isopropyl bromide as above (purity 96.7%). The 1,2-dimethyl-4-isopropylbenzene was synthesized from *o*-xylene (purity 99.0% up) and isopropyl bromide as above (purity 99.0%).

Commercial *p*-cymene and nitromethane (special grade reagent, Wako Pure Chemical Ind., Ltd.) were used. The *p*-cymene was purified by distillation and was 99.0% pure. The nitromethane was used without further purification.

Reactions. A mixture of 0.1 mol each of naphthalene and one of the isopropylbenzenes in 20 g of *n*-heptane was stirred at 50 °C. To this mixture was then added a catalyst prepared from 0.02 mol of $AlCl_3$ and 0.05 mol of nitromethane. Aliquots of samples were taken off in appropriate times, poured into ice water and ether to decompose the catalyst, washed, and dried. Finally, 0.05 mol of $AlCl_3$ was added to the reaction mixture at 20 °C and the mixture was stirred until the α- and β-isomer composition was equilibrated.

The samples were analyzed by gas chromatography, using an MBMA Golay column (45 m) at 140 °C.

Results and Discussion

1,4-Dimethyl-2-isopropylbenzene: The isomer distribution and the reaction time are shown in Table 1. The data clearly show the initial attack favorable to the α-position, followed by isomerization to the β-position.

Table 1. Isomer distribution in the isopropylation of naphthalene with 1,4-dimethyl-2-isopropylbenzene

a) Calculated from the peak area of gas chromatogram Isopropylnaphthalene/naphthalene + isopropylnaphthalene + diisopropylanphthalene

By extrapolation to the time zero, an initial isomer distribution of about 90% α- and 10% β-position was obtained. Isopropylation by isopropyl alcohol with sulfuric acid gave 80% α- and 20% β-isomer.

Thus, the attacking species of the transalkylation in this case was similar to that of the alkylation. That is, the isopropyl cation formed by proton attack on the

1,4-dimethyl-2-isopropylbenzene reacts mainly with the α-position of naphthalene.

1,2-Dimethyl-4-isopropylbenzene and p-*Cymene*: The isomer distribution and the reaction times are shown in Tables 2 and 3.

The data of the Tables 2 and 3 are quite different from those of Table 1. The ratio of α- and β-isomer was almost constant from the beginning to the end of the reaction.

This means that the attacking species must be a bulky and sterically hindered group. That is, the phenyldimethyl carbonium ion formed by hydride abstraction from the isopropyl group of 1,2-dimethyl-4-isopropylbenzene or *p*-cymene reacts with the β-position of naphthalene.

1,3-Dimethyl-5-isopropylbenzene: The results of the reaction are shown in Table 4.

The results show the two reaction mechanisms work simultaneously.

Thus, it was further confirmed that two different mechanisms, namely, the proton addition and the hydride abstraction mechanism, operated according to the structures of alkylbenzenes, in the transalkylation of such *sec*-alkyl groups as isopropyl.

The authors are indebted to Dr. Shoichi Sakajiri, Director of the Central Research Institute, Teijin Limited, for his permission to publish this article.

The Structure of Tedanin, a New Carotenoid of *Tedania digitata* (O. Schmidt)

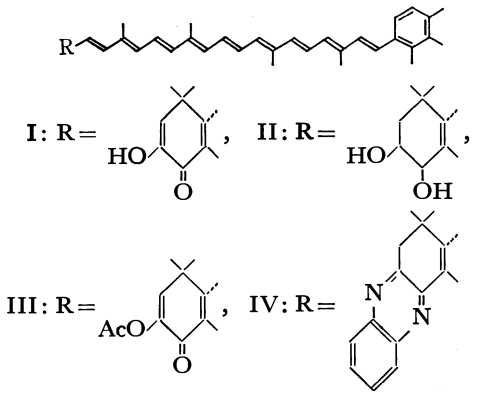
Nobuhisa OKUKADO

Department of Chemistry, Faculty of Science, Kyushu University, Higashi-ku, Fukuoka 812

(Received July 17, 1974)

Synopsis. A new carotenoid, tedanin, which was isolated as a main pigment from a sea sponge, "*Tedania digitata* (O. Schmidt)," was shown to have the (I) structure by means of spectroscopic and chemical evidence.

The carotenoids of sponges have been the subject of many investigations;[1] for instance, a novel class of carotenoids with aromatic end-groups has been discovered.[2] However, the pigments of one sea sponge, "*Tedania digitata* (O. Schmidt)," have not so far been reported. This paper will describe the isolation of a new carotenoid named tedanin from the sponge and structural studies which showed that the pigment has the structure represented by Formula (I).



Results and Discussion

Tedanin crystallizes in the form of purplish-black prisms with a mp of 188—190 °C. The molecular formula, $C_{40}H_{48}O_2$, was established by high-resolution mass spectrometry and by elemental analysis. The UV spectrum shows a single round absorption at 490 nm in benzene and one at 500 nm in pyridine, as is shown in Fig. 1. The location and the curve of the

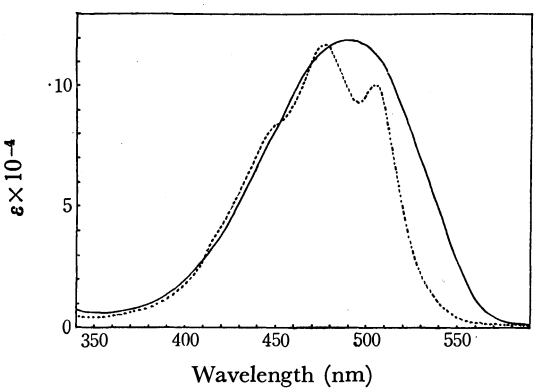


Fig. 1. Absorption spectra of tedanin (I) (——) and tetrahydrotedanin (II) (——) (benzene)

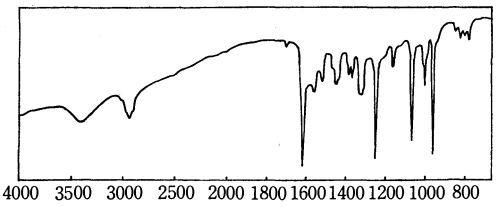

Fig. 2. IR Spectrum of tedanin (I) (KBr disk).

absorption are very similar to those of astacene.[3] Other properties, such as chromatographic behaviour, solubility, and solvent partition, also resembled those of astacene.[3] These facts seem to indicate the structural similarity of these two pigments. The IR spectrum of this pigment is shown in Fig. 2. The occurrence of peaks at 1620, 1250, 1060, 1380, and 1365 cm^{-1}, which are also present in the spectrum of astacene[4] suggests the presence of a diosphenol grouping. In addition to the ion peaks characteristic of the polyene chain of typical carotenoids [*m/e* 560(M), 468(M−92), 454(M−106), 106, and 91],[5] the mass spectrum of the pigment gives peaks at *m/e* 408(M−152), 203, 152, and 137, which are also considered to be evidence for the presence of a diosphenol end-group.[6] Furthermore, a diagnostically important peak was observed at *m/e* 133; this clearly indicates the presence of a trimethylphenyl end-group.[7] Further evidence of the presence of these end-groups was obtained from the NMR spectral study. The signals at δ 1.32(6H) and 2.11(3H) can be assigned to the 1,1-dimethyl and 5-methyl protons of the diosphenol group respectively.[8] The signals appearing at the lower field [δ 2.22(3H) and 2.31(6H)] are considered to arise from the three methyl groups attached to the aromatic nucleus, and a comparison of the chemical shifts with those of three aryl methyl groups of okenone[9] and 4′-desoxo-okenone[10] suggests that the second end-group is 2,3,4-trimethylphenyl. This was confirmed by the presence of the double doublet signal centered at δ 6.97(1H) and δ 7.27(1H) (J=7.2 Hz), which is characteristic of aromatic protons at the 5- and 6-positions of this end-group.[1c] The IR absorption at 800 cm^{-1} attributable to two adjacent aryl hydrogens is in agreement with this conclusion.

From the above evidence, the structure of tedanin can be formulated as is shown in Formula (I). The all-*trans* configuration of I was based on the absence of the *cis*-peak in the UV spectrum[11] and the presence of a sharp singlet at 960 cm^{-1} in the IR spectrum.[12]

Further evidence supporting the (I) structure comes from chemical studies. The reduction of tedanin with sodium borohydride resulted in a hypsochromic shift, accompanied by the new formation of fine structures

in the UV spectrum (Fig. 1). This is in accordance with the formation of a tetrahydro compound (II). The UV spectral data of II [λ_{max}, 496 nm (CS_2)] are very similar to those of β-renierapurpurin [λ_{max}, 497 nm (CS_2)][13] but differ from those of β-isorenieratene [λ_{max}, 487 nm (CS_2)].[13] This apparently shows that the chromophore of this reduction product (II) is not of the β,φ-carotene-type but of the β,χ-carotene-type. The acetylation of tedanin with acetic anhydride and pyridine afforded an acetate (III). Finally, the quinoxaline derivative (IV) was prepared by a reaction with *o*-phenylenediamine. The structures of these derivatives were confirmed by the fact that the mass spectra of these derivatives showed the expected molecular ion and a regular pattern of fragmentations.[14] These facts strongly support the conclusion that the structure of tedanin is 3-hydroxy-2,3-didehydro-β,χ-carotene-4-one (I).

However, it is not clear whether tedanin originally occurs in the sponge or whether it is an artifact formed by the oxidation of a ketol compound.

Experimental

All the melting points are uncorrected. The solutions were concentrated under reduced pressure below 45 °C under nitrogen. The instruments used for the measurements of the spectra were as follows. UV spectra; Hitachi, Model EPS-3T. IR spectra; Hitachi, Model 215. NMR spectra; Hitachi, Model R-22. Mass spectra; Hitachi, Model RMU-4 and JEOL, Model JMS-01SG.

Isolation of Tedanin (I). Specimens of the sponge, (80 g, dry weight), collected at Amakusa in Kumamoto Prefecture in November, 1972, were repeatedly extracted with acetone, and the pigments were transferred into benzene by the addition of water. After the evaporation of the solvent, the pigments were saponified with 10% methanolic potassium hydroxide in petroleum benzine at room temperature for 12 hr and then separated into epiphasic and hypophasic fractions by repeated partitioning between 90% methanol and petroleum benzine. The hypophasic methanol solution was then diluted with water, and the pigments were extracted again with benzene. The evaporation residue was treated with acetone, and the insoluble colorless impurities were removed repeatedly as completely as possible. The residue was finally diluted with a small quantity of petroleum benzine and left to stand in an ice-box. Repeated recrystallizations of the precipitate from methylene chloride–ethanol gave tedanin (I, 5 mg) as purplish-black prisms; mp 188—190 °C. Found: C, 85.20; H, 8.56%. Calcd for $C_{40}H_{48}O_2$: C, 85.66; H, 8.63%. UV spectra: λ_{max}, 490 nm ($\varepsilon=1.19\times10^5$)($C_6H_6$); 500 nm (pyridine). IR spectrum; Fig. 2. NMR spectrum: δ ($CDCl_3$) 1.32 (6H, s, 1,1-dimethyl); 2.00 and 2.03 (each 6H, s, chain methyl); 2.11 (3H, s, 5-methyl); 2.22 and 2.31 (3H, and 6H, respectively, s, arylmethyl); 6.03—6.90 (15H, m, olefinic protons); 6.97 and 7.27 (2H, dd($J=7.2$ Hz), aromatic protons). Mass spectrum: 560.3579 (M. Calcd for $C_{40}H_{48}O_2$, 560.3655), 408(M−92), 454 (M−106), 408(M−152), 203, 152, 137, 133, 106, 105, 92, 91, 77, 44, 28, 18.

Reduction of Tedanin to Tetrahydrotedanin (II). Tedanin (I, 1 mg) dissolved in ethanol (10 ml) was treated with sodium borohydride (40 mg) for 1 hr at room temperature. The mixture was diluted with water and extracted with benzene. The extract was washed with dilute hydrochloric acid, an aqueous sodium bicarbonate solution, and then water, dried, and evaporated. Recrystallizations of the residue from methylene chloride–ethanol gave II as red prisms (0.6 mg); mp 186 °C. UV spectra: λ_{max}, 446_{sh}, 475 ($\varepsilon=1.17\times10^5$), 506 nm ($C_6H_6$); 453_{sh}, 496, 524 nm (CS_2). Mass spectrum; 564 (M), 546, 528 472, 458, 440, 422, 408 395, 348, 329, 289, 249, 221, 133, 106, 105, 92, 91, 77, 44, 28, 18.

Acetylation of Tedanin to Tedanin Acetate (III). To a solution of tedanin (I, 1 mg) in dry pyridine (10 ml), was added acetic anhydride (1 ml). The reaction mixture was then left to stand at room temperature for 6 hr and extracted with benzene. The treatment of the extract by the usual procedure gave III as black prisms (0.65 mg); mp 172—173 °C. UV spectrum: λ_{max}, 487 nm ($\varepsilon=1.28\times10^5$)($C_6H_6$). Mass spectrum: 602 (M), 560, 510, 496, 454, 404, 362, 347, 329, 289, 133, 106, 105, 92, 91, 77, 51, 44, 28.

Preparation of Quinoxaline Derivative (IV). To a solution of tedanin (I, 1.8 mg) in glacial acetic acid (1 ml), was added *o*-phenylenediamine (15 mg). The mixture was kept at 100 °C on a water bath for 2 hr and then extracted with benzene. The treatment of the extract by the usual procedure gave IV as reddish-purple crystals (0.3 mg); mp 150—151 °C. UV spectrum: λ_{max}, 493 nm ($\varepsilon=1.16\times10^5$)($C_6H_6$). Mass spectrum: 632 (M), 617, 540, 526, 511, 434, 419, 393, 355, 343, 329, 289, 277, 275, 259, 249, 133, 105, 91, 77, 55, 41.

The author wishes to express his deep gratitude to Professor Masaru Yamaguchi for his many helpful discussions and suggestions during this work. The author also wishes to thank Dr. Michio Nakanishi of the Yoshitomi Pharmaceutical Co., Ltd., for the help he gave him in the measurement of the mass spectrum and Dr. Takaharu Hoshino of the Mukaijima Marine Station, Hiroshima University, for the identification of the sponge.

Reaction of Benzyne with *N*-Benzylideneaniline

Jyuzo NAKAYAMA, Hiroshi MIDORIKAWA, and Masayuki YOSHIDA*

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

**Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113*

(Received July 18, 1974)

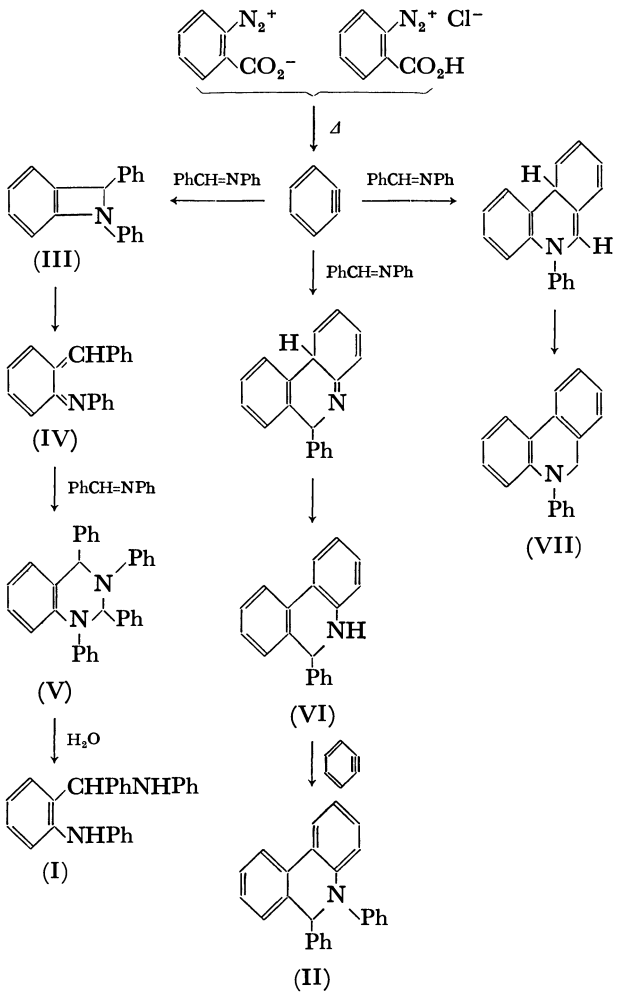
Synopsis. Benzyne, generated from benzenediazonium-2-carboxylate and 2-carboxybenzenediazonium chloride, reacted with *N*-benzylideneaniline to give *N*-(*o*-anilinobenzhydryl)aniline (I) and 5,6-dihydro-5,6-diphenylphenanthridine (II) as final products.

Although benzyne is known to undergo 1,2-cycloadditions with carbon-carbon double bonds,[1] its reactions with carbon-heteroatom double bonds are scarce and only carbonyl groups have been shown to react with benzynes.[2,3] In this paper we wish to report the first example of reaction of benzyne with an azomethine group.

Heating benzenediazonium-2-carboxylate[4] with *N*-benzylideneaniline under reflux in methylene chloride yielded *N*-(*o*-anilinobenzhydryl)aniline[5] (I, 18%[6]) and 5,6-dihydro-5,6-diphenylphenanthridine (II, 8%[6]) together with small amounts of a few unidentified products. Similarly, 2-carboxybenzenediazonium chloride[7] was decomposed with *N*-benzylideneaniline in boiling 1,2-dichloroethane in the presence of propylene oxide to afford the diamine (I, 35%[6]) and the dihydrodiphenylphenanthridine (II, 11%[6]).

In the reaction of benzyne with *N*-benzylideneaniline, the initial formation of a benzazetine (III) by a 1,2-cycloaddition of benzyne to the azomethine group of *N*-benzylideneaniline seems most probable and this benzazetine (III) is converted by ring-opening into a valence tautomer (IV), which undergoes a 1,4-cycloaddition with *N*-benzylideneaniline to yield a tetrahydroquinazoline (V). The formation of the diamine (I) from V during its isolation by chromatography is feasible because of the known susceptibility of 1,2,3,4-tetrahydroquinazolines to acid hydrolysis.[8] Evidence in support of the above reaction courses is found in the reaction of *N*-phenylbenzazetine with *N*-phenylmaleimide.[9] We have also postulated such cycloaddition and ring-opening in the formation of 2,4-diphenyl-1,3-benzodioxin from benzyne and benzaldehyde.[3] The formation of the dihydrodiphenylphenanthridine (II) may be explained in terms of a 1,4-cycloaddition of benzyne with *N*-benzylideneaniline followed by aromatization to 5,6-dihydrophenanthridine (VI) and subsequent *N*-phenylation with benzyne.[10] The last course of the *N*-phenylation was confirmed by a separate synthesis of II by heating benzenediazonium-2-carboxylate with 5,6-dihydro-6-phenylphenanthridine[11] (VI) and thus, the structure of II was confirmed.

5,6-Dihydro-5-phenylphenanthridine (VII), which might be formed by an alternative way of a 1,4-cycloaddition of benzyne with *N*-benzylidneaniline, was not observed in the reaction products. Since steric hindrance exerted in the transition states producing VI and VII seems to be the same, the selective formation



of VI may suggest that the concerted formation of two carbon-carbon bonds in the 1,4-addition is preferable to that of carbon-carbon and carbon-nitrogen bonds.

All other attempts to isolate similar products in the reaction of benzyne with substituted *N*-benzylideneaniline such as *N*-(4′-methylbenzylidene)-4-toluidine, *N*-(4′-methoxybenzylidene)-4-anisidine, and *N*-(4′-chlorobenzylidene)-4-chloroaniline have failed.

Experimental

Reaction of N-*Benzylideneaniline with Benzyne Generated from Benzenediazonium-2-carboxylate.* A suspension of benzenediazonium-2-carboxylate, prepared from 20 mmol of anthranilic acid according to the procedure described in the literature,[12] in methylene chloride (120 ml) was dried over Molecular Sieves (10 g) at 0 °C with stirring for 5 hr. To the suspension *N*-benzylideneaniline (12 mmol) was added and the mixture was heated under reflux for 1.5 hr. The dark brown reaction mixture was filtered and the filtrate, upon

evaporation of the solvent, gave a brown oily residue, which was chromatographed on silica gel (120 g). Elution with cyclohexane gave a pale yellow oil (0.48 g), which, after rechromatography, afforded 0.27 g (8%) of 5,6-dihydro-5,6-diphenylphenanthridine (II) as colorless needles and small amounts of two unidentified products (mp 146—152 °C and 128—130 °C). Elution with cyclohexane–benzene (9: 1) afforded a small amount of crystallines (mp 117—138 °C), while elution with cyclohexane–benzene (5: 1) afforded 0.38 g (18%) of *N*-(*o*-anilinobenzhydryl)aniline (I), mp 134—135 °C (lit,[5] 134—135 °C). Further elution with cyclohexane–benzene (1: 1) gave aniline and benzaldehyde.

5,6-Dihydro-5,6-diphenylphenanthridine (II) (Found: C, 90.02; H, 6.03; N, 4.30%. Calcd for $C_{25}H_{19}N$: C, 90.05; H, 5.74: H, 4.20%), mp 138—140 °C, ν_{max} (Nujol) 3070, 3040, 1592, 1496, 1438, and 1260 cm^{-1}, *m/e* 333 (M^+), δ ($CDCl_3$) 5.93 (1H, s), 6.84—7.50 (16H, m), and 7.68—7.90 (2H, m).

Chromatography of the brown oily residue over basic alumina or florisil gave similarly compounds I and II, but no tetrahydroquinazoline (V) was isolated in any experiments. The reaction carried out in the absence of Molecular Sieves yielded I and II in somewhat decreased yield along with a small amount of triphenylamine, the reaction product of benzyne with aniline, which may be formed by hydrolysis of *N*-benzylideneaniline. When the reaction was carried out in methylene chloride not strictly dried, only diphenyl- and triphenylamines were obtained, and neither I nor II was isolated.

Reaction of N-*Benzylidneaniline with Benzyne from 2-Carboxybenzenediazonium Chloride.* 2-Carboxybenzenediazonium chloride[7] (10 mmol) was heated under reflux for 1 hr with *N*-benzylideneaniline (7 mmol) in the presence of propylene oxide (1.7 ml) in 1,2-dichloroethane (100 ml). The red reaction mixture was concentrated under reduced pressure and the residue was chromatographed on silica gel. Compounds I (35%) and II (11%) were isolated in a similar way described before.

5,6-*Dihydro*-5,6-*diphenylphenanthridine (II).* Benzenediazonium-2-carboxylate, prepared from 5 mmol of anthranilic acid, was heated with 5,6-dihydro-6-phenylphenanthridine[11] (VI, 3 mmol) in methylene chloride (50 ml) under reflux for 1 hr. The brown reaction mixture was concentrated and the residue was submitted to purification by chromatography on silica gel to give 5,6-dihydro-5,6-diphenylphenanthridine (II, 35%), mp 138—140 °C, which was identical (mixed melting point) with the product obtained from benzyne and *N*-benzylideneaniline.

Steric Interaction between the 1-Methyl and 9-Hydrogen of 1,2,3,4-Tetramethyldibenzofuran[1)]

Takashi KEUMI, Yoshibumi OSHIMA, and Niichiro TOKURA*

Department of Fiber and Dyestuff, Faculty of Engineering, Fukui University, Bunkyo, Fukui 910

**Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565*

(Received July 18, 1974)

Synopsis. 1,2,3,4-Tetramethyldibenzofuran was newly synthesized and the steric interaction between the hydrogen atom at the 9-position and the methyl group at the 1-position was examined from the nuclear Overhauser effects.

Recently, we have reported that the electrophilic substitution on the 1-position of dibenzofuran was hindered sterically by the hydrogen at the 9-position.[2)] This kind of the steric hindrance has never been pointed out in the heteroaromatic compounds such as dibenzofuran, dibenzothiophene, *etc.* In this paper, we wish to report the synthesis of 1,2,3,4-tetramethyldibenzofuran (**5**) and the measurements of the intramolecular nuclear Overhauser effects (NOE) in order to confirm the steric interaction between the hydrogen at the 9-position and the substituent at the 1-position. New compound **5** was synthesized in a 54.4% total yield according to the procedures described in the experimental section. The NMR chart of this compound and the results of the NOE are shown in Fig. 1 and Table 1, respectively. The assignments of the methyl signals were made by the comparison of the spectrum of **5** with those of mono- and polymethyldibenzofurans. The proton or methyl-protons at the 1- and 9-positions of dibenzofuran are most deshielded by the induced ring currents of the outer aromatic and furan rings, followed by those at 4- and 6-positions. For example, the methyl signals of 1-, 2-, 3-, and 4-methyldibenzofurans were observed at δ 2.72, 2.50, 2.48, and 2.58 respectively.[3)]

Saturation of 1-methyl signal resulted in an enhancement of 38% of the integrated area of the multiplet of 9-hydrogen, leaving the other parts of the spectrum unaltered, whereas saturations of [2-methyl+3-methyl] and 4-methyl frequencies had no effect on the signals of the aromatic protons. Irradiation at the [2-methyl+3-methyl] frequencies gave a small increase

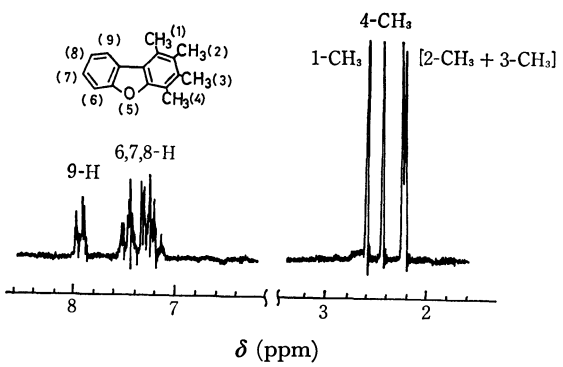

Fig. 1. NMR spectrum of 1,2,3,4-tetramethyldibenzofuran in $CDCl_3$.

TABLE 1. THE RESULTS OF THE NOE MEASUREMENTS

Irradiation protons (δ in $CDCl_3$)	Enhancements of the observed protons[a)] (%)		
	9-H	1-CH_3	6,7,8-H
1-CH_3 (2.63)	+38		—
[2-CH_3+3-CH_3] (2.26) (2.24)	+ 3	+12	—
4-CH_3 (2.46)	—	—	—

a) Average of 3 runs.

in the integrated area of the 1-methyl signals. It is clear, from these results, that the methyl group at the 1-position of dibenzofuran affects significantly the hydrogen at the 9-position in the NOE. Martin and Nouls have reported[4)] in the studies on the NOE of overcrowded aromatic hydrocarbons that the proton signals at the 5-position of phenanthrene increased in intensity by 33.5% on saturation of the methyl signal at the 4-position. The steric interaction between the 1- and 9-positions of dibenzofuran is comparable to that between the 4- and 5-positions of phenanthrene. Consequently, we should consider that not only the increase in the electronegativity of the 1-carbon by a strain effect[5)] of the fused ring and the steric hindrance by the hydrogen at the 9-position are responsible for the low reactivity[6)] of the 1-position in electrophilic substitutions of dibenzofuran derivatives.

Experimental

Measurements. NMR spectra were measured at 100 MHz on JEOL Co. Model PS-100 spectrometer using TMS as an internal standard. IR and UV spectra were measured with Hitachi EPI-S2 and EPS-2U spectrophotometers, respectively. For NOE measurements, 13% $CDCl_3$ solutions of freshly sublimed **5** were thoroughly degassed under high vacuum. These solutions were studied at 100 MHz by a frequency sweep method. The enhancements of the quotient of the integrated intensities of the observing protons with and without irradiation of the another proton signals.

Synthesis of **5**. *2-(2,3,5-Trimethylphenoxy)cyclohexanone* (**1**): A solution of α-bromocyclohexanone (prepared from 20 g of cyclohexanone and 36.4 g of *N*-bromosuccinimide in carbon tetrachloride) and sodium 2,3,5-trimethylphenoxide (prepared from 28 g of 2,3,5-trimethylphenol and 4.7 g of sodium) in benzene (200 ml) was shaken for 5 hr at room temperature. The reaction mixture was washed with water, dilute alkali, and water and the solvent was removed. Recrystallization of the residue from methanol gave 31.5 g (66.9%) of **1**. Mp 75—76 °C. IR (cm^{-1}, KBr): 1728, 1157, and

838. Found: C, 77.82; H, 8.52%. Calcd for $C_{15}H_{20}O_2$: C, 77.55; H, 8.68%.

1,3,4-Trimethyl-6,7,8,9-tetrahydrodibenzofuran (2): A mixture of **1** (20 g), polyphosphoric acid (200 ml), and phosphorus pentaoxide (100 g) was shaken at 100 °C for 3 hr, poured into ice-water, and filtered out. Recrystallization of the product from methanol gave 19.5 g (quantitatively) of **2**. Mp 95—96 °C. IR (cm^{-1}, KBr): 1450, 1215, 1100, and 860. NMR (CCl_4, δ): 6.52 (2-H, s, 1H), 2.60—2.80 (m, 4H), 2.39 (1-CH_3, s, 3H), 2.26 (4-CH_3, s, 3H), 2.22 (3-CH_3, s, 3H), and 1.70—1.90 (m, 4H). Found: C, 84.03; H, 8.54%. Calcd for $C_{15}H_{18}O$: C, 84.07; H, 8.47%.

1,3,4-Trimethyl-2-chloromethyl-6,7,8,9-tetrahydrodibenzofuran (3): **2** (5.0 g) was added to a solution of zinc chloride (0.3 g), formaldehyde (3.0 g, 37%), and concd hydrochloric acid (20 ml) with vigorous stirring. The mixture was kept at 75—80 °C for 10 hr under an introduction of hydrogen chloride, and then, it was filtered out. Recrystallization of the product from ethanol gave 5.8 g (94.8%) of **3**. Mp 131—131.5 °C. IR (cm^{-1}, KBr): 1448, 1322, 1096, and 713. NMR (CCl_4, δ): 4.68 (CH_2Cl, s, 2H), 2.60—2.88 (m, 4H), 2.56 (1-CH_3, s, 3H), 2.37 (4-CH_3, s, 3H), 2.36 (3-CH_3, s, 3H), and 1.80—2.00 (m, 4H). Found: C, 73.25; H, 7.44%. Calcd for $C_{16}H_{19}OCl$: C, 73.13; H, 7.29%.

1,2,3,4-Tetramethyl-6,7,8,9-tetrahydrodibenzofuran (4): A solution of **3** (2.0 g) in dry ether was added to a suspension of lithium aluminum hydride (0.4 g) in dry ether (20 ml) with stirring. The mixture was refluxed for 2 hr, poured into dilute hydrochloric acid, and the ether solution was evaporated to dryness. Recrystallization of the residue from ethanol gave 1.6 g (92%) of **4**. Mp 94—95 °C. IR (cm^{-1}, KBr): 1194 and 1094. NMR (CCl_4, δ): 2.60—2.90 (m, 4H), 2.40 (1-CH_3, s, 3H), 2.33 (4-CH_3, s, 3H), 2.22 (2-CH_3, s, 3H), 2.18 (3-CH_3, s, 3H), and 1.70—2.00 (m, 4H). Found: C, 84.12; H, 8.96%. Calcd for $C_{16}H_{20}O$: C, 84.16; H, 8.83%.

1,2,3,4-Tetramethyldibenzofuran (5): A mixture of **4** (5.0 g) and 5% palladium–charcoal (2.5 g) was heated at 220—230 °C for 3 hr under a slow stream of dry nitrogen, extracted with ether, and the solvent was removed. Recrystallization of the residue from ethanol gave 4.5 g (91%) of **5**. Mp 111—112 °C. IR (cm^{-1}, KBr): 1452, 1223, 1084, and 744. NMR (CCl_4, δ): 7.94 (9-H, m, 1H), 7.00—7.60 (6,7,8-H, m, 3H), 2.63 (1-CH_3, s, 3H), 2.46 (4-CH_3, s, 3H), 2.26 (2-CH_3, s, 3H), and 2.24 (3-CH_3, s, 3H). UV (cyclohexane, nm (log ε)): 311.8 (3.53), 287 (4.32), 257.6 (4.24), 228.5 (4.59), and 214.6 (4.53). Found: C, 85.52; H, 7.20%. Calcd for $C_{16}H_{16}O$: C, 85.68; H, 7.19%.

The authors are grateful to Professor A. Yoshikoshi and Mrs. R. Tanaka of the Chemical Research Institute of Non-Aqueous Solutions of Tohoku University for the measurements of NOE.

Reaction of Ethyl α,α-Dichloroacetoacetate with Aldehydes

Akira TAKEDA, Sadao TSUBOI, and Isao NAKASHIMA

Department of Synthetics Chemistry, School of Engineering, Okayama University, Tsushima, Okayama 700

(Received August 12, 1974)

Synopsis. Ethyl α,α-dichloroacetoacetate reacted with aldehydes in the presence of sodium ethoxide to give α-chloropyruvate and/or α-chloroglycidate. 2,5-Bis(1'-chloroalkylidene)-1,4-cyclohexanedione (**4**) was obtained as a by-product in a low yield.

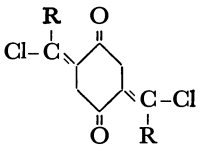
Previously, one of the present authors (A. T.) has reported the base-catalyzed condensation of dichloroacetate with aldehydes to give α-chloropyruvate (**1**) and/or α-chloroglycidate (**2**), which are useful synthetic intermediates.[1]

$$RCHO + CHCl_2CO_2R' \xrightarrow{NaOEt} \underset{\mathbf{1}}{RCH(O)C(Cl)CO_2R'} + \underset{\mathbf{2}}{R\text{-}CH(Cl)COCO_2R'}$$

As an extension of the previous work, we carried out the base-catalyzed condensation of ethyl dichloroacetoacetate (**3**) with aldehydes to give esters **1** and **2**. This reaction can be well explained by assuming the formation of enolate anion of dichloroacetate, since the ester **3** is known to undergo retro acetoacetate reaction to afford dichloroacetate in the presence of alkoxide.[2] The yields and boiling points of the products **1** and **2** are listed in Table 1.

$$\underset{\mathbf{3}}{CH_3COCCl_2CO_2Et} \xrightarrow{EtO^-} CH_3\text{-}C(=O)(OEt)\text{-}CCl_2CO_2Et \xrightarrow{-CH_3CO_2Et} \bar{C}Cl_2CO_2Et \xrightarrow{RCHO} \mathbf{1} \text{ or } \mathbf{2}$$

The identification of the products was done by comparison of spectral data with those of authentic samples.[1,3] In contrast with the reaction of dichloroacetate, the present reaction afforded a small amount of crystalline by-products, which were identified as 2,5-bis(1'-chloroalkylidene)-1,4-cyclohexanedione (**4**) or its geometrical isomers on the basis of IR, NMR, MS spectral data, and elemental analyses (see Tables 2 and 3). The mass spectra of these products as well as their analyses supported the composition of $C_8H_4Cl_2O_2R_2$.



4 (R=alkyl or aryl)

IR spectra exhibited absorptions due to conjugated C=O stretching at 1692—1705 cm^{-1} and those due to C=C stretching at 1660—1665 cm^{-1}.

Possible route of the formation of dione **4** can be explained by the following mechanism, involving the condensation of two molecules of **6**, which may be derived from the reaction of dichloroacetonyl anion (**5**) with the aldehyde.

$$\underset{\mathbf{5}}{CH_3COCCl_2CO_2Et} \longrightarrow CH_3COC\bar{C}l_2 \xrightarrow[-Cl^-]{RCHO}$$

$$\left[RCH(Cl)\text{-}C(=O)\text{-}C(Cl)(=O)\text{-}CH_3 \longrightarrow \underset{\mathbf{6}}{RCH(Cl)\text{-}C(=O)\text{-}C(=O)\text{-}CH_3} \right]$$

$$\xrightarrow{-H_2O} \left[R\text{-}CH(Cl)\text{-}C(=O)\text{-}CH=C(Cl)\text{-}C(=O) \right] \longrightarrow \mathbf{4}$$

a) NMR spectrum of this compound could not be measured, because it was almost insoluble in usual solvents such as acetone, chloroform, methanol, and dimethyl sulfoxide.

Experimental

The melting points and boiling points are uncorrected. Elemental analyses were carried out by Mr. Eiichiro Amano. We are indebted to Mr. Hiroshi Ooyama of Hokko Chemical Industry Co., Ltd. for the NMR measurements, and also to Mr. Shinichi Ninomiya for technical assistance. Ethyl α,α-dichloroacetoacetate (**3**) was obtained by the reaction of ethyl acetoacetate with sulfuryl chloride, yield 63%: bp 91.5—92 °C/13 mmHg (lit,[4] 106—108 °C/30 mmHg). Aldehydes were distilled just before use.

The following experiment is shown as a typical run.

*Reaction of **3** with 2-Methylpropanal.* To a solution of 103 g (0.52 mol) of **3** and 37.3 g (0.52 mol) of 2-methylpropanal in 104 ml of dry ether was added 40.8 g (0.6 mol) of dry, powdered sodium ethoxide in several portions at 0—5 °C. After complete addition, the mixture was allowed to warm up at room temperature and then refluxed for 2 hr. It was poured into a large excess of water. Precipitated crystals collected by filtration were washed with water and ether successively, and dried. Recrystallization of the white crystals from ethanol gave 2.8 g (3.7%) of **4b**: mp 197 °C.

The ethereal layer was washed with water several times, and dried over $MgSO_4$. After removal of the solvent, the residue was distilled to give 24.6 g (25%) of **1b**: bp 76—86 °C/6 mmHg (lit.[1] 104—106 °C/20.5 mmHg). Its IR and NMR spectra were identical with those of the authentic sample.[1]

The Cyclic Trimerization of Isocyanates by Organic Tin(II) Compounds Containing Sn-O-C Bonds

Ikuko WAKESHIMA, Hiroshi SUZUKI, and Ichiro KIJIMA

Department of Industrial Chemistry, Faculty of Engineering, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received September 4, 1974)

Synopsis. Organic tin(II) compounds containing Sn–O–C bonds were found to be effective catalysts for the cyclic trimerization of phenyl and ethyl isocyanate. The cyclic trimerization mechanism is discussed.

There have been a number of papers[1–3] describing the addition of Sn–O–C bonds of organotin(IV) oxides and alkoxides to compounds containing such activated double bonds as isocyanate, isothiocyanate, and carbodiimide. However, no similar reactions of organic tin(II) compounds have been investigated except for two reports by P. G. Harrison and J. J. Zuckerman on the reaction between phenyl isocyanate and organic tin(II) compounds.[4–5] For the purpose of investigating the reactivity of organic tin(II) compounds containing Sn–O–C bonds towards heterocumulenes, we have examined the reaction of phenyl and ethyl isocyanate with $Sn(OC_2H_4N(CH_3)_2)_2$ (A), $Sn(OC_2H_4OCH_3)_2$ (B), $Sn(OC_2H_5)_2$ (C), $Sn(OC(CH_3)=CHCOCH_3)_2$ (D), $Sn(OC(CH_3)=CHCO_2C_2H_5)_2$ (E), and $Sn(O\text{-}C_6H_4\text{-}CO_2C_2H_5)_2$ (F). The above tin(II) compounds showed different degrees of association, that is (A), (D), (E), as well as (F) are monomeric, (B) is dimer or trimer, and (C) is an associated solid.[6]

Results and Discussion

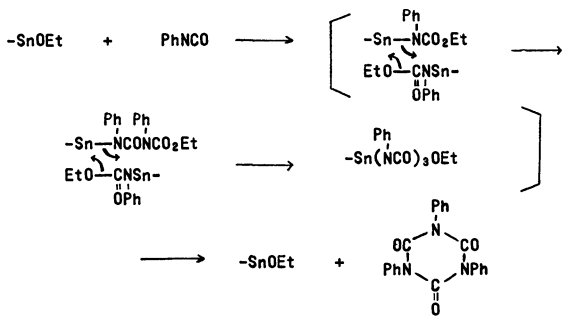
It was found that tin(II) compounds (A—F) were effective catalysts for the cyclic trimerization of phenyl isocyanate (PhNCO) and ethyl isocyanate (EtNCO), with the formation of the corresponding isocyanurates; the catalytic activity of (A) was the best, while that of (F) was least effective (Table 1).

However, similar reactions did not occur between PhNCO and tetravalent tin alkoxide, such as $Sn(OC_4H_9^t)_4$ and $n\text{-}C_4H_9Sn(OC_4H_9^t)_3$, under the same conditions; Rather, they stopped at the stage of the adduct-formation to give simply the corresponding *t*-butyl *N*-phenylcarbamatotin(IV) derivatives.

It may be concluded from these results that: i) the nucleophilicity of the oxygen atom of Sn(II)–OR bonds, which was expected from the I- and M-effects of R and the degree of association of $Sn(OR)_2$, has a marked effect on the catalytic action of Sn(II) compounds; ii) the reactivity of PhNCO toward Sn(II)–OR bonds is less than that of EtNCO; and iii) the divalent tin compounds are far better than the tetravalent tin tetraalkoxide and monoalkyltin trialkoxide as catalysts for the cyclic trimerization of isocyanates.

When a benzene solution of PhNCO and (C) in a molar ratio of 2: 1 was treated at room temperature for 40 min, the IR spectrum of the mixture showed no absorption band assigned to the NCO group. The hydrolysis products were ethyl *N*-phenylcarbamate and triphenyl isocyanurate in yields of 63 and 8% respectively. On the other hand, when the benzene solution was heated at 80—81 °C for 3 hr, the yields of the above hydrolysis products changed to 47 and 40% respectively after the hydrolysis of the reaction mixture.

Although the organotin(IV) compound-catalyzed reaction has been explained by a proposed mechanism[7] involving the successive insertion of three isocyanate units between the tin atom and the heteroatom of the attached group, followed by the elimination of the trimer from 1: 3 adducts, the change in the yields of the hydrolysis products suggests an alternative reaction route involing the four-centered intermolecular co-ordination of the divalent tin intermidiates, as is shown in the following scheme;



Scheme

This reaction route was supported by the finding that the nucleophilicity of the nitrogen atom of the *N*-phenyl urethano group in $Sn(N(Ph)CO_2C_2H_5)_2$ is more depressed than that of the *N*-ethyl urethano group in $Sn(N(Et)CO_2C_2H_5)_2$; when a mixed solution of (C) (0.1 mol)–PhNCO (0.2 mol) in benzene and (C) (0.1 mol)–EtNCO (0.2 mol) in benzene, neithere of which showed any characteristic infrared absorption band of the NCO group, was heated at 80—81 °C for 3 hr, and then hydrolyzed, ethyl *N*-phenyl-*N'*-ethylallophanate ($C_6H_5NHCON(C_2H_5)CO_2C_2H_5$) and *N*-phenyl-*N'*,*N''*-diethyl isocyanurate were obtained in yields of 51 and 6.2% respectively.

Therefore, the four-centered intermolecular co-ordination mechanism may be proposed for the reaction

Table 1. Yields of isocyanurate by the action with $Sn(OR)_2$ on R'NCO at 80 °C[a]

a) [R'NCO]: [$Sn(OR)_2$]=50: 1 (3 hrs in benzene) b) IR spectroscopy demonstrated the absence of the characteristic absorption band of NCO group within 2 hr. c) Triphenyl isocyanurate was obtained almost quantitatively by removing benzene under reduced pressure (water pump). d) R: (A); $C_2H_4N(CH_3)_2$ (B); $C_2H_4OCH_3$ (C); C_2H_5, (D); $C{=}CHCOCH_3$ (E); $C{=}CHCO_2C_2H_5$ and (F);  . e) Ref. 6.

with organotin(II) compounds containing an Sn–O–C bond, in addition to the conventional view of the successive insertion of isocyanate unites. The mechanism is based on the structural analogy of tin(II) compounds with carbene.

Experimental

Reaction Procedures.[8] *Reaction of Organic Tin(II) Compounds with PhNCO in a 1: 50 Molar Ratio*: To a suspension of C (0.4 g, 1.8 mmol) in benzene (20 ml), PhNCO (10.1 g, 90 mmol) was added, after which the mixture was heated at 80—81 °C for 3 hr. During the reaction, white crystals precipitated. After cooling, the crystals were filtered off, washed with benzene, and then recrystallized from acetone afford triphenyl isocyanurate; mp 269.2—270 °C. IR: 1710 cm^{-1} ($\nu_{C=O}$). Found: C, 70.58; H, 4.31; N, 11.55%. Calcd for $C_{21}H_{15}N_3O_3$: C, 70.58; H, 4.23; N, 11.76%.

The other organic tin(II) compounds were reacted with PhNCO similarly.

Reaction of C with EtNCO in a 1: 50 Molar Ratio. Ethyl isocyanate (7.8 g, 110 mmol) was added to a suspension of C (4.8 g, 2.3 mmol) in benzene (26 ml), and then the mixture was refluxed for 2 hr. The reaction mixture showed no characteristic absorption band ascribable to the NCO group. After the reaction mixture has been concentrated and then hydrolyzed with aqueous acetone, the insoluble parts of the hydrolyzate were separated centrifugally and concentrated again under reduced pressure. The precipitates were then filtered and recrystallized from *n*-hexane to give 7.6 g (97.4%) of white crystals; mp 94—95 °C. IR: 1680 cm^{-1} ($\nu_{C=O}$). NMR (CCl_4): δ 1.20 (3H, t, CH_3), 3.86 (2H, q, CH_2). Found: C, 50.29; H, 7.16; N, 19.59%. Calcd for $C_9H_{15}N_3O_3$: C, 50.69; H, 7.09; N, 19.71%.

Reaction of $Sn(OC_4H_9^t)_4$ with PhNCO in a 1: 50 Molar Ratio. Phenyl isocyanate (27.8 g, 231 mmol) was added, drop by drop, to a solution of $Sn(OC_4H_9^t)_4$ (1.9 g, 4.6 mmol) in benzene (55 ml), and then the mixture was refluxed for 3 hr. After the removal of solvent and the unreacted PhNCO *in vacuo*, the residue was recrystallized from benzene to give 3.4 g (83%) of tetrakis(*t*-butyl *N*-phenylcarbamato)tin(IV) as white crystals; mp 151 °C (dec). IR: 1647 cm^{-1}. NMR (C_6H_6): δ 1.45 (s, CH_3). Found: C, 60.11; H, 6.32; N, 6.38; Sn, 12.95%. Mol wt; 850. Calcd for $C_{44}H_{56}N_4O_8Sn$: C, 59.54; H, 6.36; N, 6.31; Sn, 13.37; Mol wt, 888.

The reaction of n-$C_4H_9Sn(OC_4H_9^t)_3$ with PhNCO was carried out in a similar way. The tin compound thus obtained was identified on the basis of the IR spectrum and its hydrolysis product.

Reaction of C with PhNCO in a 1: 2 Molar Ratio. *Reaction at 80—81 °C*: Phenyl isocyanate (19.8 g, 166 mmol) was added, drop by drop, to a suspension of C (17.2 g, 82.3 mmol) in benzene (69 ml) at 23—25 °C. After the disappearance of the NCO absorption band in their spectrum (40 min), the solution was refluxed for 3 hr. The white crystals thus precipitated were removed by filtration and then recrystallized from benzene to give triphenyl isocyanurate in a yield of 40%. The mother liquor was concentrated and then hydrolyzed with aqueous acetone. After the centrifugal removal of the insoluble parts, the acetone solution of the hydrolyzate was distilled *in vacuo*. *N,N'*-Diphenylurea (mp 234 °C) and ethyl *N*-phenylcarbamate (bp 140.5 °C/10.5 mmHg) were obtained in yields of 12% and 47% respectively.

Reaction at Room Temperature: After the disappearance of the NCO absorption band in the IR spectrum, the reaction mixture was hydrolyzed with aqueous acetone. Triphenyl isocyanurate, *N,N'*-diphenylurea, and ethyl *N*-phenylcarbamate were thus obtained in yields of 8%, 8%, and 63% respectively.

Similarly, the reaction of C with EtNCO in a molar ratio of 1: 2 was carried out.

Reaction of a Solution of C-PhNCO in Benzene with a Solution of C-EtNCO in Benzene. To a solution of C (15.0 g, 72 mmol) and EtNCO (10.2 g, 144 mmol) in benzene (34 ml), a solution of C (15.0 g, 72 mmol) and PhNCO (17.1 g, 144 mmol) in benzene (34 ml) was added, and then the mixture was heated at 80—85 °C for 3 hr. After the distillation of the solvent, the concentrated residue was hydrolyzed with aqueous acetone and the insoluble parts of the hydrolyzate were removed centrifugally. The vacuum distillation of the acetone solution afforded 17.3 g of ethyl *N'*-ethyl-*N*-phenylallophanate [Bp 91 °C/0.25 mmHg. IR: 1691, 1710 (sh), 1725 (sh), 1743 ($\nu_{C=O}$) and 3350 (ν_{N-H}). NMR: δ 1.15 (NCH_2CH_3), 1.20 (OCH_2CH_3), 3.83 (NCH_2), 4.08 (OCH_2), and 6.7—7.13 (C_6H_5). Found: (Calcd for $C_{12}H_{16}N_2O_3$): C, 60.54 (61.00); H, 6.80 (6.82); N, 11.88 (11.86)] and 1.58 g of *N*-phenyl-*N',N''*-diethyl isocyanurate [Mp 94.5—96.8 °C. IR: 1674 and 1697 ($\nu_{C=O}$). NMR: δ 1.26 (CH_3), 3.97 (CH_2), and 7.1—7.65 (C_6H_5). Found: (Calcd for $C_{13}H_{15}N_3O_3$): C, 59.67 (59.75); H, 5.81 (5.78); N, 16.30% (16.08%)].

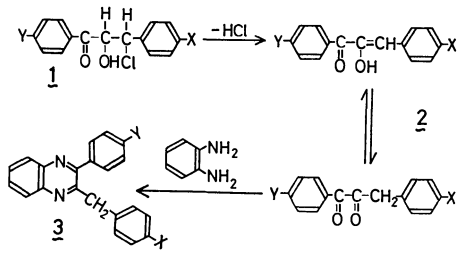
(Received September 17, 1974)

Synopsis. Dehydrochlorination of 3-chloro-2-hydroxy-1,3-diaryl-1-propanone proceeds to give 1,3-diaryl-1,2-propanedione in a high yield on heating its dioxane solution with a catalytic amount of hydrogen chloride. Kinetic studies were carried out.

α-Diketones have usually been prepared by oxidation of the corresponding ketones with selenium oxide. However, when the α-diketone to be synthesized has another methylene group at the α-position, the α-diketone produced is further oxidized to polyketones and the yield of α-diketone is, in general, not satisfactory because of the production of tarry matter.

We found a novel method for synthesis of α-diketones by chloride ion catalyzed dehydrochlorination in an acidic medium. *erythro-* and *threo*-3-Chloro-2-hydroxy-1,3-diaryl-1-propanones, (*erythro*-**1a**—**c**) and (*threo*-**1a**—**f**), underwent dehydrochlorination to give 1,3-diaryl-1,2-propanediones (**2a**—**f**) in good yields on heating their dioxane solutions containing hydrogen chloride at 70—90 °C for 20—40 hr (Scheme 1). The products (**2a**—**f**) were identified as 2-aryl-3-aroylquinoxalines (**3a**—**f**) which were produced by reaction with *o*-phenylenediamine. The yields of **3** were 80—90% (Table 1).



1—**3**: **a**, X=Y=H; **b**, X=Cl, Y=H; **c**, X=H, Y=Cl; **d**, X=CH_3, Y=H; **e**, X=H, Y=CH_3; **f**, X=H, Y=CH_3O

Scheme 1.

The significant feature of this reaction is the use of acidic medium since halide ion catalyzed dehydrohalogenation[1] is usually carried out in an aprotic solvent in the presence of amine, that is, in slightly basic medium in which carbonyl compounds are not stable enough to be isolated.

House[2] also obtained **2a**, identified as **3a**, by reaction of *erythro*-**1a** (10% yield) and *threo*-**1a** (26% yield) with sodium acetate in ethanol.* He assigned the diastereomeric configurations of *erythro-* and *threo*-**1a**, supposing that the phenyl and benzoyl groups of *erythro*-**1a** were eclipsed at the transition state for the *trans* elimination. We confirmed the diastereomeric configurations of *erythro-* and *threo*-**1a** by their NMR spectra. The reactants, *erythro*-**1b**—**c** and *threo*-**1b**—**f**, were prepared in the same manner as *erythro*-**1a**[2] and *threo*-**1a**.[3]

Some details of the kinetics of the reaction were investigated. The rate of the reaction was first order in both reactant and hydrogen chloride.** It was established that the reaction was promoted by chloride ion but not by protons, since no reactions were detectable when *p*-toluenesulfonic acid was used instead of hydrogen chloride (at 80.0 °C for 8 hr).

The kinetic results are listed in Table 2 and can be

threo-**1e**	80.0	7.89[e]	
threo-**1f**	80.0	11.4[e]	

a) °C. b) l/mol min; initial concentrations: reactant, 5.00×10^{-2} M; HCl, 5×10^{-2} M. c) $\Delta H=12.9$ kcal/mol, $\Delta S=40.8$ eu at 80.0 °C. d) $\Delta H=12.4$ kcal/mol, $\Delta S=39.9$ eu at 80.0 °C. e) $\rho=-1.3$ *vs.* σ.

summarized as follows; i) the reaction of a *threo* isomer is faster than that of the corresponding *erythro* isomer; ii) the reaction rate is enhanced by electron donating substituents (Y) on the aroyl group, whereas substituents (X) on the aryl group show little effect on the rate. From these results the reaction mechanism shown in Scheme 2 can be suggested as a plausible one.

Substituents, (X) and (Y), may not affect the equilibrium of intermediate **4** formation but the rate of C–Cl bond rupture of **4**. The formation of *erythro*-**4** may not be preferred because of eclipsing of the aryl and aroyl groups. The diastereomeric configurations of *erythro*- and *threo*-**4** may be retained, because, if they invert, the reaction rates of an *erythro* compound and the corresponding *threo* compound should become similar as the reaction proceeds but this was not the case.

Experimental

erythro-*3-Chloro-1,3-diaryl-2-hydroxy-1-propanones* (erythro-***1a-c***). *erythro*-**1a-c** was prepared by a method similar to the one described by House.[2] To a solution of 1-aroyl-2-arylethylene oxide[4] (10 g) in methanol (100 ml), cooled by ice, concentrated hydrochloric acid (100 ml) was added. After two hours' stirring, the mixture was stored in a refrigerator overnight. Precipitated crystals were filtered and recrystallized from benzene. Yields, melting points, and elemental analyses of *erythro*-**1a-c** are shown in Table 3.

threo-*3-Chloro-1,3-diaryl-2-hydroxy-1-propanones* (threo-***1a-f***). Using the same method as for *threo*-**1a**,[3] *threo*-**1b-f** was prepared from 1-aroyl-2-arylethylene oxide.[4] Yields, melting points, and elemental analyses of *threo*-**1a-f** are shown in Table 3.

NMR Spectra of erythro- *and* threo-**1a**. NMR signals of the aliphatic protons of *erythro*- and *threo*-**1a** in $CDCl_3$ were observed at $\delta=5.23$ (1H, d, $J=3.5$ Hz), 5.48 (1H, d, $J=3.5$ Hz), and 3.60 (OH, s), and 5.26 (1H, d, $J=1.8$ Hz), 5.42 (1H, d, $J=1.8$ Hz), and 3.98 (OH, s, broader than the signal of *erythro*-**1a** at 3.60). The larger coupling constant of *erythro*-**1a** than that of *threo*-**1a** supports the assignment of their diastereomeric configurations.[2]

*Products (2-Aryl-3-aroylquinoxalines (**3a-f**)).* A reactant (**1**) (*ca.* 0.5 mmol) was dissolved in 0.05 M HCl-dioxane (10 ml). The solution was heated at 80.0 °C for 20—40 hr in an ampoule and then poured into an ethanol solution of *o*-phenylenediamine (*ca.* 0.075 mmol). After standing overnight, the solution was concentrated under reduced pressure. The residue was crystallized from aqueous ethanol. Yields, melting points, and elemental analyses of products (**3**) are shown in Table 1.

Kinetics. Kinetic measurements were carried out as usual using ampoules. The acid was titrated with methanolic sodium methoxide solution.

Photochemical Reaction of Friedelin. Formation of an ε,ζ-Unsaturated Aldehyde

Hidekazu SHIRASAKI, Reiko AOYAGI, Takahiko TSUYUKI, Takeyoshi TAKAHASHI, and Robert STEVENSON*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

**Department of Chemistry, Brandeis University, Waltham, Massachusetts 02154, U.S.A.*

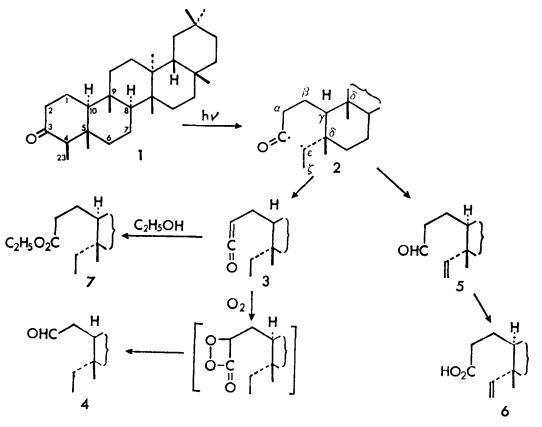
(Received September 20, 1974)

Synopsis. Friedelin (**1**) in *n*-pentane or ethanol was irradiated using a high pressure mercury lamp under a nitrogen atmosphere. From the aldehydic fraction of the photolysate, an ε,ζ-unsaturated aldehyde, 10β-(2-formylethyl)-5α-vinyl-des-*A*-friedelane (**5**) has been isolated. Upon oxidation with silver oxide, **5** afforded putranjivic acid (**6**).

Previously we reported the formation of the seco-nor saturated aldehyde (**4**), an autoxidation product of the ketene (**3**) which was formed by photoreaction of friedelin (**1**) in aprotic solvents, together with the mechanistic elucidation of the formation of **4**.[1] Attention was drawn to the fact that since there is no hydrogen atom on the δ-carbon atoms in the seco-friedelin skeleton (**2**), the usual formation of a δ,ε-unsaturated aldehyde by α-cleavage, followed by transfer of the δ-hydrogen atom through a six-membered transition state, is not feasible.

In this paper we wish to describe the formation of an ε,ζ-unsaturated aldehyde on the photolysis of friedelin (**1**). An aldehydic fraction of the photolysate of friedelin (**1**) in *n*-pentane or ethanol was reinvestigated and an unsaturated aldehyde was isolated in 2 and 0.4% yields, respectively. The unsaturated aldehyde (**5**), mp 133.5—135 °C, $[\alpha]_D$ +10° ($CHCl_3$), had a molecular formula $C_{30}H_{50}O$, determined by high resolution mass spectrometry. The PMR and IR spectra showed the presence of the groupings $-CH_2CHO$ and $-CH{=}CH_2$ (*cf.* Experimental). These data suggested that the unsaturated aldehyde (**5**) should be 10β-(2-formylethyl)-5α-vinyl-des-*A*-friedelane. This was confirmed by oxidation of **5** with silver oxide to give putranjivic acid (**6**).[2]

The formation of ε,ζ-unsaturated aldehydes is not frequently encountered.[3-5] It seems to be more likely that the ε,ζ-unsaturated aldehyde (**5**) was produced by intramolecular transfer of a hydrogen atom from a ζ-carbon atom (C-23) to the acyl radical through an eight-membered transition state,[3] rather than by intermolecular mechanisms with solvent participation. In the case of ethanol as a solvent, it would be expected that the acylalkyl biradical (**2**) undergoes a preferential hydrogen transfer reaction from C-2 to the alkyl radical through a six-membered transition state to yield the ketene (**3**), which is immediately stabilized by the reaction with ethanol yielding a seco-ester (**7**). It is therefore suggested that the acylalkyl biradical (**2**) in such circumstances undergoes a hydrogen transfer reaction *via* the eight-membered transition state to give the ε,ζ-unsaturated aldehyde (**5**).



Experimental

IR spectra were measured on a Hitachi EPI-G2 spectrometer. Mass spectra were taken on a Hitachi RMU-6-Tokugata mass spectrometer operating at 70 eV with a direct inlet system. High resolution mass spectra were taken using a Hitachi RMH-2 mass spectrometer at 70 eV. PMR spectra were measured using a Hitachi R-24 (60 MHz) spectrometer. Chemical shifts were expressed in ppm downfield from TMS as an internal standard and coupling constants in Hz. Optical rotation was measured with a JASCO DIP-SL polarimeter. Melting points were determined using a Mel-temp (Laboratory Devices) and are reported uncorrected.

Photolysis of Friedelin (1). *In* n-*Pentane*: A solution of friedelin (**1**; 1.05 g) in *n*-pentane (850 ml) was irradiated with a high pressure mercury lamp (100 W) under a nitrogen atmosphere for 9 hr at room temperature. After the irradiation, dry oxygen was passed through the solution in the dark for 14 hr at room temperature.

A part (250 ml) of the solution, on evaporation of the solvent under reduced pressure, afforded a residue (346 mg), which was separated on a silica gel (300 g) column and eluted with the following solvents (each fraction 200 ml): frs 1—7, light petroleum; frs 8—10, light petroleum–benzene (10:1); frs 11—16, light petroleum–benzene (5:1); frs 17—35, light petroleum–benzene (3:1). From fractions 27 and 28, the seco-nor aldehyde (**4**; 9 mg) was obtained and was shown to be identical with an authentic specimen.[1] Fractions 31 to 34, on evaporation, gave white crystals (6 mg; 2% yield from **1**). Mp 133.5—135 °C (from light petroleum); $[\alpha]_D$ +10° (*c*, 0.78; $CHCl_3$); MW (by high resolution mass spectrometry) 426.3887. Calcd for $C_{30}H_{50}O$: 426.3859; IR (Nujol) 2700, 1725, 1630, 1005, and 910 cm^{-1}; PMR ($CDCl_3$) δ 2.15—2.60 (2H, m, $-C\underline{H}_2-CHO$), ABX type signals due to vinyl protons $\left[H_X\rangle C{=}C\langle {H_A \atop H_B} \right]$ δ_A 4.92 (J_{AX}=18 Hz, J_{AB}=1.6 Hz), δ_B 4.96 (J_{BX}=10 Hz, J_{AB}=1.6 Hz), and δ_X 5.71 (J_{AX}=18 Hz, J_{BX}=10 Hz)], and δ 9.65 (1H, t, J=2.5 Hz,

$-CH_2-C\underline{H}O$); Mass *m/e* 426 (M^+, 8%*), *m/e* 411 [$(M-15)^+$, 12%], *m/e* 301 [$(M-C_8H_{13}O)^+$, a fragment ion due to fissions of C_5–C_6 and C_9–C_{10}, 8%], *m/e* 273 (24%), *m/e* 218 (32%), 205 (90%), and 109 (100%).

In Ethanol: Friedelin (**1**; 500 mg) in ethanol (750 ml) was irradiated for 30 hr by the same procedure as above. The reaction products, after removal of the solvent, were chromatographed on a silica gel column. The ethyl ester (**7**) was eluted with light petroleum–benzene (5:1) (66% yield from **1**) and then the unsaturated seco aldehyde (**5**; 0.4% yield from **1**) was eluted with the same eluent. This was purified by repetitive chromatography on silica gel.

Oxidation of 10β-(2-Formylethyl)-5α-vinyl-des-A-friedelane (5). To a solution of the unsaturated aldehyde (**5**; 25 mg) in ethanol (10 ml), silver nitrate (50 mg) in water (1 ml) and 0.05 M sodium hydroxide solution (20 ml) were added in turn, and the reaction mixture was stirred overnight. Usual work-up and extraction with ether afforded a residue, which was chromatographed on silica gel (50 g) and eluted with benzene–ether (10:1, each fraction 30 ml). Fractions 7 and 8, on evaporation of the solvents, afforded 8 mg (31% yield from **5**) of crystals, which was identified by direct comparison (IR, tlc (SiO_2–$AgNO_3$), and Mass) with the authentic putranjivic acid (**6**), prepared by the photoxidation of friedelin (**1**).[2e] MW (by high resolution mass spectrometry) 442.3816. Calcd for $C_{30}H_{50}O_2$: 442.3808.

* Relative intensities of peaks above *m/e* 100.

A Novel Reduction of the *O*-(3,5-Dinitrobenzoyl)-*N*,*N*-(aroylaryl)hydroxylamines by the Cyanide Ion in Dipolar Aprotic Solvents

Shigeru OAE and Tadamitsu SAKURAI*

Department of Chemistry, University of Tsukuba, Sakuramura, Niihari-gun, Ibaraki 300-31

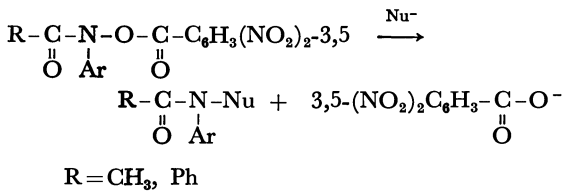
**Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558*

(Received September 20, 1974)

Synopsis. The reaction of *O*-(3,5-dinitrobenzoyl)-*N*,*N*-(aroylaryl)hydroxylamines with the cyanide ion in dipolar aprotic solvents was found to afford the corresponding reduction products, *i.e.*, *N*-aroylarylamines, in good yields *via* decarboxylation. The mechanism of this novel reduction was discussed.

In the preceding paper we have shown that *N*,*N*-dibenzyl-*O*-(*p*-nitrobenzoyl)hydroxylamine is a good model compound for studying both nucleophilic substitution and elimination reactions on the trivalent nitrogen atom.[1)]

As an extension of the earlier study, we have now prepared *O*-(3,5-dinitrobenzoyl)-*N*,*N*-(aroylaryl)hydroxylamines and allowed them to react with various nucleophiles in dimethyl sulfoxide (DMSO), expecting that the reaction would proceed *via* nucleophilic substitution on the nitrogen atom as follows:

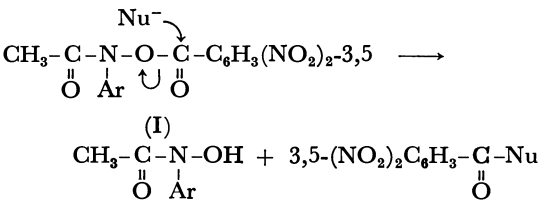


R = CH_3, Ph

Results and Discussion

The reaction of *O*-(3,5-dinitrobenzoyl)-*N*,*N*-acetyl-(*p*-chlorophenyl)hydroxylamine (I) with nucleophiles in DMSO or DMF at room temperature was found to give products which appear to be formed by the attack of the nucleophile upon the carbonyl-carbon of the reactant, as is shown below, except for the reaction with cyanide ion, as is indicated in Table 1. When the cyanide ion was allowed to react with I, an unexpected reduction product was obtained in a substantial yield, while no substitution product was detected.

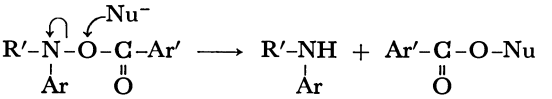
Thus, the effects of substituent on the yields of the reduction products and on the course of the reaction were investigated in order to clarify the mechanism of



Ar = *p*-ClC_6H_4

this novel reduction by the cyanide ion. The results are listed in Table 2. An inspection of the data in Table 2 clearly indicates that the novel reduction occurred only when the leaving group was 3,5-dinitrobenzoyloxy group, since no hydroxylamine (V) with *p*-nitrobenzoyloxy group as the leaving group gave the reduction product in the reaction. Moreover, the yield of the reduction tends to increase with the increase in the electron-withdrawing ability of the substituent which is attached directly to the nitrogen atom.

One mechanism to explain the product distribution of the reaction with the cyanide ion may involve the



R′ = CH_3CO (II), PhCO (III), *p*-$CH_3C_6H_4SO_2$ (IV); Ar = Ph

R′ = CH_3CO; Ar = *p*-ClC_6H_4 (I); Ar′ = $-C_6H_3(NO_2)_2$-3,5

nucleophilic substitution on the oxygen atom which has been observed in the reactions of peroxides with nucleophiles.[2)] This mechanism, however, seems un-

Table 1. Reaction of I with various nucleophiles at room temperature

likely because the reduction product of (IV) was obtained in a high yield in spite of the large steric and electronic repulsions between the sulfonyl oxygen and charged nucleophiles, serving to suppress the reduction.

A more probable mechanism is that the reduction proceeds *via* the decarboxylation of a Meisenheimer-type complex formed as an intermediate as in the displacement reaction of polynitroaromatics.[3] This mechanism explains the observation that the reduction proceeds more readily when the electron-withdrawing power of the R′ substituents increases. Another strong support for this mechanism is that carbon dioxide was trapped as barium carbonate by bubbling through an aqueous solution of barium hydroxide, with nitrogen gas as a carrier gas, in the reaction of hydroxylamine (III) with the cyanide ion in DMSO at room temperature, though the yield of carbon dioxide thus evolved was relatively low (*ca.* 10%).

$$\text{R′–N(Ar)–O–C(=O)–Ar′} \xrightarrow[CN^-]{} [\text{Meisenheimer Complex}] \xrightarrow[-CO_2]{} \text{R′–NH(Ar)} + \text{Amorphous Solid}$$

R′=CH_3CO (II), PhCO (III), *p*-$CH_3C_6H_4SO_2$ (IV); Ar=Ph

R′=CH_3CO; Ar=*p*-ClC_6H_4 (I); Ar′=$-C_6H_3(NO_2)_2$-3,5

It has been recently established that the species more readily formed in the interaction of aromatic polynitro compounds with the cyanide ion in a dipolar aprotic solvent than in alcoholic or ketonic solvents, may be formulated as Meisenheimer complexes on the basis of their UV, IR, and NMR spectra.[4] Therefore, the intermediate whose strong absorption band appeared at λ_{max}=576 nm may safely be ascribed to the Meisenheimer-type complex formed by the interaction of (III) with sodium cyanide in DMF.

Table 3. Physical properties of I, II, III, IV, and V

a) The melting points could not be precisely determined because thermal rearrangement occurred before melting.

Experimental

Materials. The *O*-(3,5-dinitrobenzoyl)-*N*,*N*-(aroylaryl)-hydroxylamines used were prepared from 3,5-dinitrobenzoyl chloride and the corresponding *N*,*N*-aroylarylhydroxylamines under the usual Schotten-Bauman conditions. The *O*-(*p*-nitrobenzoyl)-*N*,*N*-acetyl-(*p*-chlorophenyl)hydroxylamine was synthesized similarly. The mp and the IR spectrum of these hydroxylamines are shown in Table 3.

General Procedure for the Reaction of I, II, III, IV and V with Nucleophiles. A small excess of a nucleophile (1.1—1.7 mM) was added to 6 ml of a DMSO solution of I—V (0.9—1.6 mM) in a reaction vessel, after which the whole solution was stirred with a magnetic stirrer at room temperature for 25—48 hr. After the reaction, the contents were poured into a large excess of water, and then the products were extracted with $CHCl_3$. The $CHCl_3$ solution was washed with water several times and dried over Na_2SO_4. The subsequent evaporation of $CHCl_3$ afforded a residue, which was then subjected to column chromatography through silica gel, using CH_2Cl_2 as the eluent. The water solution was acidified slightly with a dil-HCl aqueous solution, and the aqueous solution was extracted with $CHCl_3$. The evaporation of $CHCl_3$ gave the crude *p*-nitro- and 3,5-dinitrobenzoic acids respectively. The structures of the products isolated were determined by comparison with authentic samples.

A Novel Method for the Synthesis of Cytidine Diphosphate-Choline

Takashi KURIHARA, Isamu YAMAMOTO, and Tsujiaki HATA*

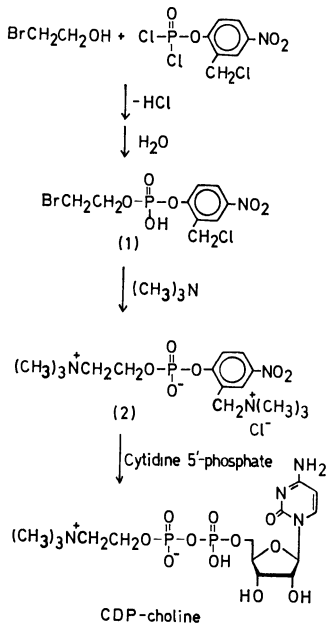
Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received November 18, 1974)

Synopsis. Cytidine diphosphate choline was synthesized by the reaction of cytidine 5′-phosphate with 2-bromoethyl 2′-(chloromethyl)-4′-nitrophenyl phosphate in the presence of trimethylamine.

Derivatives of cytidine 5′-phosphate are known to participate in the biosynthesis of phospholipids. Cytidine diphosphate choline (CDP-choline) is one of the important intermediates for the enzymatic incorporation of choline phosphate into lecithin. Although several methods for the synthesis of CDP-choline are described in the literature,[1] most synthetic methods give many by-products that are difficult to remove. An important consideration in the synthesis of CDP-choline is the method of introduction of the choline residue. Sanno and Tanaka synthesized CDP-choline with a 35% yield by the ring-opening reaction of ethyleneimine with cytidine 5′-diphosphate followed by methylation.[1b]

In this paper, we wish to report a novel method for the synthesis of CDP-choline using 2-bromoethyl 2′-(chloromethyl)-4′-nitrophenyl phosphate (**1**) as a precursor for choline phosphate as shown in Scheme 1.



Scheme 1.

In this method, the 2-(chloromethyl)-4-nitrophenoxy group is activated and the choline residue is formed by attack of trimethylamine together with the corresponding ammonium derivative (**2**), which in turn reacts with cytidine 5′-phosphate to afford CDP-choline.[2]

In addition, it should be noted that the intermediate (**2**) reacts selectively with the phosphate, leaving the amino group on the cytosine residue and the hydroxyl groups on the sugar moiety of the cytidine 5′-phosphate. Further, it was found that P^1-(2-bromoethyl) P^2-cytidine 5′-pyrophosphate and unreacted cytidine 5′-phosphate were only detected as the by-products which were easily separated from CDP-choline.

Experimental

Methods. For paper chromatography, the descending technique using Toyo Roshi No. 51 and No. 51A papers was employed. The solvent system was ethanol–1 M ammonium acetate (7: 3 v/v). Paper electrophoresis was carried out with an apparatus similar to that described by Markham and Smith.[3] The buffer solution was 0.05 M phosphate (pH 8.0). The yields of the reported compounds were most frequently estimated spectrophotometrically after elution of spots from paper chromatograms run. The preparation of 2-(chloromethyl)-4-nitrophenyl phosphorodichloridate has been described previously.[4] Commercial 2-bromoethanol was purified by distillation. Cytidine 5′-phosphate was purchased from Yamasa Shoyu co. A dry solution of trimethylamine in dimethylformamide (DMF) was prepared as follows: Gaseous trimethylamine generated from the commercially available aqueous solution by adding sodium hydroxide was passed through a soda-lime tube and bubbled into dry DMF.

Preparation of 2-Bromoethyl 2′-(Chloromethyl)-4′-nitrophenyl Phosphate (1). A mixture of 2-bromoethanol (62.4 mg, 0.5 mmol) and pyridine (39.6 mg, 0.5 mmol) was added to a solution of 2-(chloromethyl)-4-nitrophenyl phosphorodichloridate (1.52 g, 0.5 mmol) in 10 ml of tetrahydrofuran (THF) cooled to 0 °C for 2 hr. Then, it was allowed to stand at room temperature for 7 hr. The mixture was poured into an aqueous solution containing pyridine (39.6 mg, 0.5 mmol) and stirred for 30 min. After removal of THF under reduced pressure, the aqueous solution was washed with three 40 ml portions of chloroform and then with two 20 ml portions of chloroform. The chloroform extracts were combined and washed with water (5 ml) and the aqueous solution was washed again with chloroform. All of the chloroform extracts were combined and finally dried over sodium sulfate. After evaporation of chloroform, 2-bromoethyl 2′-(chloromethyl)-4′-nitrophenyl phosphate (1.66 g, 89%) was obtained as a pale yellowish oil which was homogeneous on a paper chromatogram.

Synthesis of CDP-choline. Compound **1** (0.5 mmol) was dissolved in 7 ml of DMF saturated with dry trimethylamine and containing a catalytic amount of sodium iodide. The solution was stirred at room temperature in a pressure bottle for 3 hr and then heated at 55 °C for 1 hr. After evaporation of the DMF under reduced pressure, further anhydrous trimethylamine in DMF was added and evaporation was repeated. A hot (75 °C) solution of the 4-morpholine *N,N′*-dicyclohexylcarboxamidinium salt of cytidine

* To whom correspondence should be addressed.

5′-phosphate (0.1 mmol) in dry DMF (5 ml) was added to the residue. The mixture was heated at 95 °C for 10 hr. After addition of water, the precipitate was removed. The aqueous solution was concentrated and chromatographed on a DEAE cellulose column. First, CDP-choline was eluted with a linear gradient of triethylammonium bicarbonate solution from 0 to 0.1 M. The eluate was concentrated. CDP-choline was obtained in 54% yield based on cytidine 5′-phosphate. It was homogeneous on a paper chromatogram. The CDP-choline was characterized by its electrophoretic mobility (0.25 at pH 8.0) relative to cytidine 5′-phosphate and by phosphorus analysis (phosphorus: cytidine=2.00: 1.00).

The authors wish to heartily thank Professor Teruaki Mukaiyama for his encouragement and comments throughout the investigation and to Dr. Yoshitaka Mushika for his kind advice given during the course fo this experiment.

Catalytic Function of Metal Salts on the Reduction of Pyridine-2-carbaldehyde by 1-Benzyl-1,4-dihydronicotinamide

Masamitsu SHIRAI, Taizo CHISHINA, and Makoto TANAKA

Department of Applied Chemistry, Faculty of Engineering, University of Osaka Prefecture, Sakai, Osaka 591

(Received December 12, 1974)

Synopsis. A catalytic function of metal salts on the reduction of pyridine-2-carbaldehyde by 1-benzyl-1,4-dihydronicotinamide was discussed kinetically. The reduction rate was affected not only by the nature of metal cation but by that of counter anion.

Because of a biochemical significance the reactions of 1,4-dihydronicotinamide derivatives, as a model for the reduced nicotinamide-adenine dinucleotide, have been studied by many workers.[1] Although it was known that zinc ion was essential for the activity of alcohol dehydrogenase,[2] only few investigations were reported about the catalytic function of metal ions for the reactions to which 1,4-dihydronicotinamide derivatives participated. Sigman *et al.*[3] reported that zinc ion efficiently catalyzed the reduction of 1,10-phenanthroline-2-carbaldehyde to 1,10-phenanthrolin-2-ylmethanol by 1-propyl-1,4-dihydronicotinamide. Shinkai *et al.*[4] presented that pyridoxal derivatives were reduced by 1,4-dihydropyridine derivatives and that the reductions were facilitated by metal ions. In the present study the reduction of pyridinecarbaldehyde (2-, 3-, 4-) by 1-benzyl-1,4-dihydronicotinamide(NBNH)[5] was attempted and the catalytic function of some metal salts (metal cations and their counter anions) was discussed.

Results and Discussion

Pyridine-2-carbaldehyde(2-PCHO) was found to be reduced to 2-(hydroxylmethyl)pyridine by NBNH in the presence of $Zn(OAc)_2$. The reaction rate was evaluated kinetically. 3-PCHO was not reduced and 4-PCHO was reduced with difficulty, the pseudo first-order rate constant(k) of which was twenty eight times smaller than that of 2-PCHO. This implies that a direct activation of carbonyl group by Zn^{2+} which was fixed in the neighborhood of the carbonyl group by coordination with the nitrogen atom of pyridine ring is an important factor for the reduction of PCHO, though the reaction mechanism is not obvious. Suggestive evidences for the direct activation were obtained from the UV and NMR spectra of methanolic solution of PCHO–$Zn(OAc)_2$ mixture. The UV spectrum of the mixture for 2-PCHO showed a new absorption peak at 390 nm, while that of 3- and 4-PCHO did not show any appreciable change. The difference in $\Delta\tau$ for the

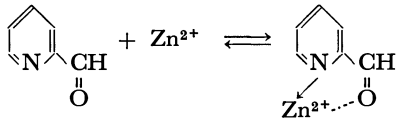

TABLE 1. PSEUDO FIRST-ORDER RATE CONSTANTS CATALYZED BY BIVALENT METAL CATIONS

k[b] $\times 10^5$ s^{-1}	7.31	2.23	2.06	10.10

a) Counter anion is OAc^-. b) At 29 °C in methanol, $[NBNH]=7.0\times10^{-5}$ M.

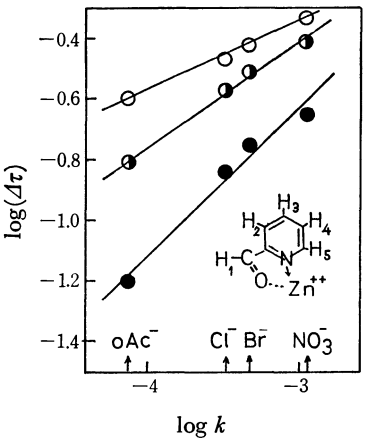

Fig. 1. Relation between log k and log ($\Delta\tau$) at 29 °C in methanol.
In pseudo first-order rate constants measurement, $[Zn^{2+}]=7.45\times10^{-3}$ M, $[2\text{-PCHO}]=3.50\times10^{-2}$ M, $[NBNH]=7.01\times10^{-5}$ M.
In NMR spectra measurement, $[Zn^{2+}]=0.25$ M, [2-PCHO]=0.50 M, $\Delta\tau=\tau$ (none)—τ (added Zn^{2+} salts)
—●—: H_2, —○—: H_3, —◑—: H_4

ring protons among the three isomers did not give any useful information but the magnitude of the diminution of aldehyde proton peak was in the order, 2-PCHO> 4-PCHO>3-PCHO≃0.

The reduction of 2-PCHO was catalyzed by other bivalent metal salts than $Zn(OAc)_2$, such as $Pb(OAc)_2$, $Cd(OAc)_2$, and $Cu(OAc)_2$, each of which was unreactive to NBNH. As shown in Table 1, the k values for these salts as catalyst decreased in the order, $Cu^{2+}>Zn^{2+}>Pb^{2+}>Cd^{2+}$, agreeing with the order of the stability constants of the complexes between pyridine-2-carboxylic acid and the corresponding metal ions.[6] Interestingly the k values were altered by change of the counter ions of Zn^{2+}, decreasing in the order, $NO_3^->Br^->Cl^->OAc^-$. The $\Delta\tau$ in the NMR spectra of the 2-PCHO–zinc salts mixture was varied by change of the counter anion. A good linear relationship, as shown in Fig. 1, was observed between log($\Delta\tau$) and

log k. This shows that the catalytic function of metal salts for the reduction of 2-PCHO by NBNH results from their strong coordination to the substrate and that the coordination strength depends not only on the nature of metal cation but on that of counter anion. Salicylaldehyde, thiophene-2-carbaldehyde and furfural were not reduced by NBNH in the presence of $Zn(OAc)_2$. This suggests the coordination of Zn^{2+} to oxygen atom or sulfur atom is too weak to fix the Zn^{2+} in the proximity of the carbonyl group.

Experimental

Kinetic Procedures. Reaction was started by mixing methanol solutions of 2-PCHO, metal salt and NBNH in a quartz cell which was placed in a water jacket maintained at a working temperature. The rate was determined spectrophotometrically by following the decrease in the absorbance at 355 nm due to NBNH. To eliminate an increment of the absorbance due to 2-PCHO–metal ion complexes which showed a weak absorbance at 355 nm, differential spectra were taken by employing a solution of 2-PCHO–metal ion mixture as a reference. An obvious isosbestic point was observed at 310 nm. Under the condition where aldehyde and metal ion were present in great excess with respect to NBNH, the rate of disappearance of NBNH depended on first order of its concentration. The pseudo first-order rate constant (k) was obtained from the slope of the plot of log [(NBNH)] against time. Metal salts were used as hydrate except $ZnCl_2$ and $ZnBr_2$; $Zn(OAc)_2 \cdot 2H_2O$, $Pb(OAc)_2 \cdot 3H_2O$, $Cd(OAc)_2 \cdot 2H_2O$, $Cu(OAc)_2 \cdot H_2O$, and $Zn(NO_3)_2 \cdot 6H_2O$.

Products Analysis. 2-PCHO (5.0 g; 0.047 mol), NBNH (1.5 g; 0.070 mol) and $Zn(OAc)_2$ (6.6 g; 0.023 mol) were dissolved into methanol (100 ml) and the solution was allowed to stand for two days at 40 °C. The methanol was removed by vaccum distillation from the reaction mixture. After dissolving the residue in water, enough amount of EDTA tetra sodium salt was added to chelate the all zinc ion and filtered. The filtrate was extracted with ether. The ether solution was dried over sodium sulfate and then the ether was evaporated. The gas chromatographic analysis (Apiezone grease L-30, 150 °C: retension time 2.45 min) and the picrate (mp 158 °C, lit.[7] 159 °C) confirmed the formation of 2-(hydroxymethyl)pyridine. A part of the aqueous filtrate was passed through an anionic resin (Amberlite IRA-400). The eluted solution showed the same UV spectrum as that of an authentic 1-benzyl-3-carbamoylpyridinium chloride (λ_{max} 265 nm in H_2O).

Fundamental Studies of Solvent Dyeing with Tetrachloroethylene. II. The Diffusion of 1,4-Diaminoanthraquinone in Nylon 6

Zenzo MORITA, Koji UCHIMURA,* and Hiromi MOTOMURA

Department of Textiles and Polymer Science, Faculty of Engineering, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184

(Received October 5, 1974)

Synopsis. The diffusion and sorption of 1,4-diaminoanthraquinone in nylon 6 were investigated using a cylindrical film-roll. The diffusion of the penetrant in nylon 6 from the aqueous dyebath was much faster than that from the tetrachlororoethylene (TCE) dyebath. The surface concentration from water was larger than that from TCE. The water added to the TCE dyebath accelerated the diffusion of the penetrant in nylon 6.

Solvent dyeing with halogenated hydrocarbons, especially tetrachloroethylene (TCE), has attracted considerable attention, and many publications on this subject have appeared in the recent literature.[1-6] In the solvent dyeing of poly(ethylene terephthalate) (PET) with disperse dyes, the diffusion from the TCE dyebath is faster than that from the aqueous one,[7] and the partition coefficient in the TCE system becomes smaller than in the aqueous system, as the solubility of dye in TCE is larger than that in water.[1]

In a previous paper, some comparisons of the diffusion of disperse dyes in PET have been made between the systems of water and of TCE.[7] The results obtained have confirmed the above facts and have shown that TCE affected the properties of PET. The glass transition temperature, T_g, of PET has been reduced and disperse dyes have been diffused into PET at lower temperatures than 80 °C.

In this paper, some comparisons will be made between the systems of water and TCE in the diffusion and sorption behavior of 1,4-diaminoanthraquinone in nylon. The effect of water added to the TCE dyebath will also be studied.

Experimental

Films. Biaxial oriented nylon 6 film (Emblem, Unitica Co., Ltd.) was used. It was cut 4 cm wide and 55 cm long, scoured with hot water, and heat-set at 95 °C in water for 24 hr. The film was wound so tightly on a glass tube (ϕ=1 cm) in the same solvent of the dyebath that there were no bubbles between the consecutive layers. The thickness of these films was measured by a thickness gage (Peacock Upright Dial Gage, Ozaki Manufacturing Co., Ltd.) to be 30.0 μm.

Chemicals. 1,4-Diaminoanthraquinone, supplied by Nippon Kayaku Co., Ltd., was crystallized by aqueous acetic acid and dried in a vacuum dryer for more than a week. The absence of impurities was checked by thin-layer chromatography. TCE of a technical grade (Toa Gosei Kagaku Kogyo Co., Ltd.) was used throughout without purification.

Diffusion and Sorption. The diffusion experiments were carried out in a 500 ml or 100 ml diffusion bottle with a reflux condenser. The dyeing conditions are shown in Table 1. Diffusion was carried out after the solution equilibrium of penetrant has been reached in the dyebath. After diffusion, the optical densities of the respective layers at the wavelength of 605 nm were measured by means of a Shimadzu MPS-50L Recording Spectrophotometer. The optical density of the penetrant on film was confirmed to obey Beer's law. The diffusion coefficient and surface concentration were calculated by the method of Sekido-Matsui from the concentration profile obtained experimentally.[8] The surface concentration was assumed to be equal to the equilibrium sorption.

Results and Discussion

The concentration profiles in the substrate are shown in Figs. 1—3. The plots are superimposed by a

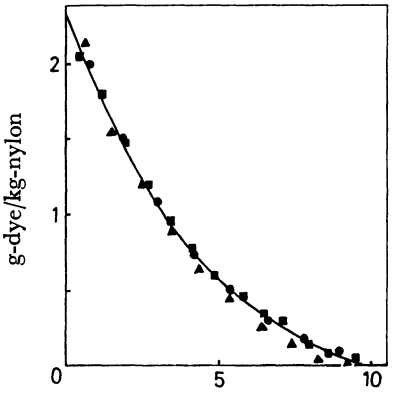

Fig. 1. Diffusion profile in nylon 6 from the water dyebath at 80 °C. (diffusion time, ■: 300 min, ▲: 180 min, ●: 120 min)

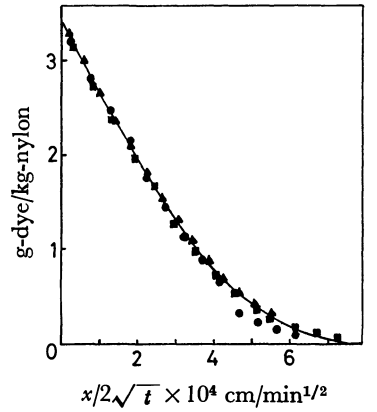

Fig. 2. Diffusion profile in nylon 6 from the 100 ml TCE+1.0 ml water dyebath at 80 °C. (diffusion time, ▲: 1050 min, ●: 720 min, ■: 600 min)

* Present address: Shikishima Spinning Co., Ltd., Higashi-ku, Osaka 541.

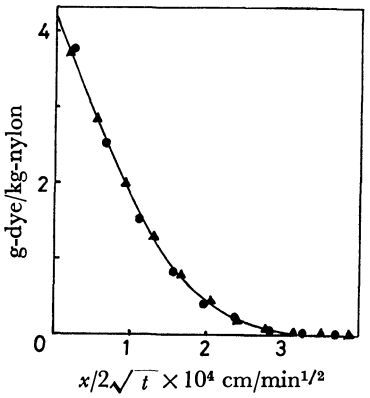

Fig. 3. Diffusion profile in nylon 6 from the 100 ml TCE+0.3 ml water dyebath at 80 °C. (diffusion time, ▲: 1260 min, ●: 900 min)

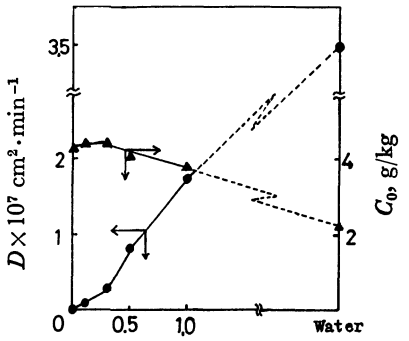

Fig. 4. The effect of water added to the TCE dyebath on the surface concentration C_0 and diffusion coefficient D in nylon 6 at 80 °C.

Boltzmann transformation ($x/2\sqrt{t}$), where x is the diffusion distance and where t is the time. These figures show that the dyeing system (nylon 6+water and/or TCE+dye) does not change during diffusion, even when more water than solubility in TCE was added, and that the diffusion obeys Fick's law. The diffusion coefficients from water were 300 times larger than those from TCE (Table 1). As the concentration in the aqueous dyebath was much smaller than that in the TCE one, the partition coefficient from the aqueous dyebath was larger than that from the TCE one.

The effect of additive water to the TCE dyebath is shown in Fig. 4. The diffusion coefficients increased with an increase in the additive water. The effect on the surface concentration was small. The solubility of water in TCE at 80 °C is estimated to be about 0.08 g in 100 ml of TCE.[9] The essential effect of such excess water is not clear.

Table 1. Diffusion in nylon 6 at 80 °C

Dyebath composition			Time of diffusion hr	Diffusion coefficient cm²/min
TCE ml	Water ml	Dye g		
0	500	0.1	2	3.79×10^{-7}
			3	3.57
			5	3.75

The Spin-Statistical Contribution in Redox Chemiluminescence Quantum Efficiency

Csaba P. Keszthelyi

Department of Chemistry, Louisiana State University, Baton Rouge, Louisiana 70803, U.S.A.

(Received June 18, 1974)

Synopsis. The theoretical upper limit of the quantum efficiency of Redox Chemiluminescence is shown to be 1.0 for both energy sufficient and energy deficient systems; whether the oxidant and reductant are generated *in situ* (as in ECL) has no effect on the chemiluminescence efficiency.

Electron transfer or redox chemiluminescence involves the conversion of chemical energy to light. The early experimental inquiries[1] were augmented by the theoretical considerations put forth by Marcus[2] and Hoytink.[3] The most common light producing sequence involves radical ions ($A^{\cdot-}$ and $D^{\cdot+}$) undergoing a homogeneous electron transfer reaction in fluid solution:

$$A^{\cdot-} + D^{\cdot+} \rightarrow A + D + h\nu. \quad (1)$$

The nature of the emitted light ($h\nu$) has allowed identification of the luminescors in many systems as $^1A^*$, $^1D^*$, $(AD)^*$ or $(A)_2^*$.[4,5] It is convenient to classify redox chemiluminescence systems as energy sufficient or energy deficient, depending on whether the enthalpy of Eq. 1 is greater or smaller than the first excited singlet energy (E_s) of the luminescor parent compound. Ways for obtaining singlet emission from an energy deficient system will be discussed further on in this paper.

An important property of all useful redox chemiluminescent systems is the quantum efficiency, Φ_{CL}, defined as the number of photons emitted per radical ion annihilation. It has recently been demonstrated that Φ_F, the fluorescence quantum efficiency determined from optical excitation, does not represent an upper limit for Φ_{CL}, because the chemiluminescence excitation reaction path may be more efficient than the optical excitation route.[6]

Recent papers dealing with redox chemiluminescors have examined their practical applicability as display devices[7-9] or a new type of laser.[10,11] While exploring practical applicability, some of the new papers have introduced a number of contradictory claims which involve erroneous interpretation of the theoretical work of Hoytink and Marcus. For example, the paper by Schwartz, Blakeley, and Robinson[8] claims that the maximum theoretical efficiency of an energy sufficient ECL system is 0.828, while that of an energy deficient (T-route) system is 0.414. This is contradicted by Pighin[9] who reported that the maximum theoretical efficiency of an energy deficient system is 6.6% (based on photons/electron). Rather than retracing the lines of thought that lead to the erroneous numbers 0.828 0.414, and 0.066, which are amply documented in the original papers themselves, we should briefly establish the correct conclusions based on the work of Marcus and Hoytink primarily.

The radical ions themselves are doublets, hence the pure spin-statistical prediction for Eq. 1 is

$$A^{\cdot-} + D^{\cdot+} \rightarrow \frac{1}{4}S + \frac{3}{4}T, \quad (2)$$

where S stands for singlet and T stands for triplet. Although it is possible to trace the quantum efficiency from Eq. 2, it would, in effect, be totally unwarranted. In the theory of Marcus the spin-statistical contribution is subject to the rate constant k for the electron transfer

$$k = \mathscr{Z}_\rho Z \exp\{-\Delta G^{\neq}/k_b T\}, \quad (3)$$

and the potential energy curves (G *vs.* Reaction Coordinate) incorporate the 'orientation polarization' factor. The activation barrier in the electron transfer step is strongly affected by the 'orientation polarization', which in turn may involve a transition state with a virtual charge distribution corresponding to $(A^{2-}\cdots D^{2+})$ for example.[2] Not only does Marcus' theory mitigate against blind reliance on the simplicistic spin-statistical approach when dealing with fluid solution media, but it would specifically make quick dissipation of ~3 eV unlikely by non-radiative means – such as required by Eq. 2 in case of an energy deficient system for 25% of the redox events; *i.e.*, producing $^1S_0$ rather than $^1S^*$ in the present notation.

Hoytink expresses the rate constants as

$$K_{singlet^*} = \frac{1}{4}K_d \exp\{-\Delta H_s^*/kT\} \quad (3a)$$

and

$$K_{triplet} = \frac{3}{4}K_d \exp\{-\Delta H_t^*/kT\} \quad (3b)$$

Hence only for the special case when the exponential terms are equal would Hoytink's work support Eq. 2. Once we emphasize the importance of specific terms that vary from system to system, we can proceed to set maximum quantum efficiency limits.

Considering Eq. 1 in some detail, we find that the over-all light production scheme involves competing reaction paths:

$$\left.\begin{aligned} A^{\cdot-} + D^{\cdot+} &\xrightarrow{k_S} {}^1S^* + {}^1S_0 \\ &\xrightarrow{k_t} {}^3T^* + {}^1S_0 \\ &\xrightarrow{k_Q} {}^1S_0 + {}^1S_0 \end{aligned}\right\} \quad (4)$$

For an energy sufficient system utilizing an efficient fluorescor parent compound, the upper limit of Φ_{CL} or Φ_{ECL} is 1.0 when $k_s \gg k_t + k_Q$. For an energy deficient system when $k_t \gg k_s + k_Q$, the number of redox events also represents the upper limit of triplets produced. In this case, corresponding to E-Type delayed fluorescence,[12] thermal activation of $^3T^*$ gives

$$^3T^* \xrightarrow[\text{activation}]{\text{thermal}} {}^1S^* \quad (5)$$

Consequently the maximum quantum efficiency of an energy deficient system is also 1.0.

We must emphasize the tenacious nature of Eq. 5 at this point; the type of thermal activation occurring in the case of eosin is not characteristic of many other systems. Also, and this is perhaps even more important, the presence of ionic species in the chemiluminescence solution (and the additional presence of a large excess of supporting electrolyte ions in an ECL system) can be expected to quench some of the triplets, hence cut the efficiency of possible thermal activation. Therefore, we should consider an alternative 'energy-doubling' process, triplet-triple annihilation or TTA:[12]

$$^3T^* + {}^3T^* \rightarrow {}^1S^* + {}^1S_0. \quad (6)$$

This would lead to the production of one excited singlet per two redox events, giving Φ_{CL} or $\Phi_{ECL}=0.5$ as the maximum value. Reliance on spin-statistics only (ignoring quintets) gives $1/4\ ^1S^*+3/4\ ^3T^*$ per TTA, a prediction which is once again unwarranted.

In closing, we should re-emphasize that various types of losses do occur in actual chemiluminescence and ECL systems. One loss that does not occur at practical concentrations of luminescor parents is electrochemical destruction of cations at the anion-generating pulse and *vice-versa* (except at the very first instant when the pulse is switched). The losses in the 'triple step' experiments of Faulkner[13] do not carry over to the typical double potential step mode of electrogeneration.

Combining the recent calculations of Measures[11] with the 20% efficient ECL system available,[10,14] one finds that laser action is not improbable in these systems; further investigations and improvements should be conducted, nevertheless, by observing the proper relationship between spin-statistics and chemiluminescence quantum efficiency.

Support of this work by the Louisiana State University Council on Research is gratefully acknowledged.

Microdetermination of Olefinic Linkage by *N*-Bromosuccinimide

Alfy Badie SAKLA,* Sadek Elsayed ABDOU, and Olfat Ahmed EL-KHADRAWY

Microanalytical Unit, Faculty of Science, University of Cairo, Giza, A. R. Egypt

(Received February 26, 1974)

Synopsis. A simple, accurate, and relatively rapid procedure for the estimation of olefinic linkage with *N*-bromosuccinimide has been presented.

Numerous methods have been developed for the determination of carbon to carbon unsaturation.[1] One of the problems is the development of a method for the determination of olefinic unsaturation, and the wide variation in reactivity of this group in different environments has resulted in the publication of some 3000 analytical methods to cover the whole range of olefinic compounds.[2] The halogenation methods are the most generally employed procedures for the determination of unsaturation in known compounds as well as mixtures. While standard bromine solution is a convenient and relatively stable reagent in macro scale analysis, yet its adaptation to the micro scale is difficult because 0.01 M bromine deteriorates rapidly.[3a]

It is now shown that *N*-bromosuccinimide (NBS) is stable, reactive, and convenient for routine microdetermination of olefinic linkage. The reaction with NBS is at least twenty five times faster than that with bromine.[4] An excess amount of a 1% aqueous solution of NBS is added to the unsaturated organic compound (2—4 mg) in glacial acetic acid at room temperature and kept for 10 min. Excess of NBS is determined titrimetrically against standard sodium thiosulphate. The results are given in Table 1 and are shown to be quite satisfactory (mean error $\pm 0.3\%$). The present procedure is simple, accurate and relatively rapid for the estimation of olefinic linkage.

It should be noted, however, that (a) none of the procedures described in the literature is applicable to all types of compounds containing the alkene function, and (b) a method yielding consistently reproducible results does not necessarily give the true unsaturation values of the substance under investigation.[3b] Estimation of tetraphenylethylene with NBS gives zero result and the starting material is recovered unchanged. This may be attributed to the absence of hydrogen atoms in the olefinic linkage. The nature of the *para*-substituent in the 1,1-diarylethylenes Ia—g has an influence on their reaction with NBS. In the presence of *para*-alkoxy groups Ia—c the corresponding 2-bromo-

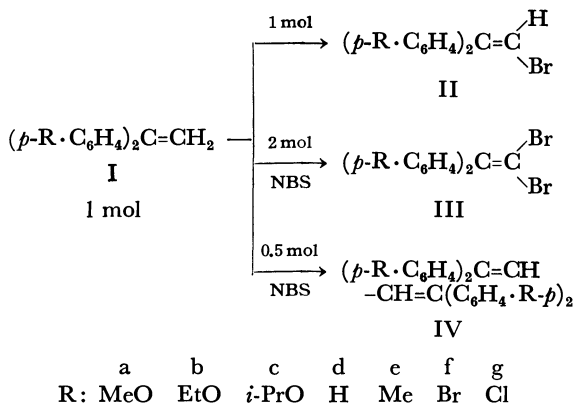
Reaction period 10 min. Solvent in all experiments, chloroform, 15 ml.

a) Found: C, 52.70; H, 4.80; Br, 35.30%. Calcd for $C_{20}H_{22}Br_2O_2$: C, 52.85; H, 4.84; Br, 35.24%.

ethylene IIa—c, 2,2-dibromoethylene IIIa—c and 1,1,4,4-tetra-arylbuta-1,3-diene IVa—c are isolated with equimolecular, dimolecular, and half-molecular quantities of NBS respectively.



The mechanism of formation of 1,1,4,4-tetra-arylbuta-1,3-dienes IVa—c is apparently the same as previously described.[5] On the other hand, the other compounds Id—g gave 2-bromoethylenes IId—g as the only product (Tables 1 and 2).

Experimental

Procedure. Introduce an exactly weighed amount (2—4 mg) of the olefinic compound in a 50 ml Erlenmeyer flask charged with 4 ml of glacial acetic acid. Stirr until the organic compound is dissolved. Add accurately 1 ml of a 1% (w/v) aqueous solution of *N*-bromosuccinimide. The flask is stoppered, shaken and left in the dark for 10 min. Add 4 ml of 10% potassium iodide and titrate the liberated iodine with standard sodium thiosulphate solution (0.02 N) to the starch end-point.

The olefinic linkage is determined by the following equation:

$$\% \text{ C=C} = \frac{(a-b)(\text{normality of } Na_2S_2O_3)(24.02)(100)}{(\text{weight of sample in mg})(2)}$$

a = ml of $Na_2S_2O_3$ for blank, and

b = ml of $Na_2S_2O_3$ for sample.

Reactions of 1,1-Diarylethylenes Ia—g with NBS: This is exemplified by the following:

A solution of 1,1-bis(*p*-methoxyphenyl) ethylene[6] (Ia, 2.4 g, 0.01 mol) in chloroform (15 ml) and NBS (1.78 g, 0.01 mol) in the same solvent (15 ml) was heated to boiling for 10 min. The residue obtained after removal of the solvent was washed with water and then crystallised from 95% ethanol to give 2-bromo-1,1-bis(*p*-methoxyphenyl)ethylene IIa (3.15 g) with mp and mixed[6] mp 84 °C.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48 (3), 1087—1088 (1975)

Magneto-chemistry and Infrared Spectra of Ammonia and Primary Aliphatic Amine Complexes of Copper(II) Chromate

Babu Ram S. SENGAR* and Gopal NARAIN**

Department of Chemistry, University of Sagar, Sagar (M.P.), India

(Received April 1, 1974)

Synopsis. Complexes of divalent copper of the type $CuCrO_4 \cdot 4Am$ and $CuCrO_4 \cdot 2Am \cdot 2H_2O$ with Am=ammonia or primary aliphatic amine, have been prepared and characterized. All the compounds reported are paramagnetic and values of μ_{eff} in the range 1.77—1.86 B.M. The assignment of the vibrational bands of the ligands and their shifts in frequency on co-ordination with copper(II) ion are discussed.

Many complexes of copper(II) have been described in literature and in particular complexes with ammonia and primary aliphatic amines. Relatively, very little work has been done on copper(II)chromate.[1] So far, most studies have been concerned with synthesis of copper(II) chromate–ammonia complexes and apart from few isolated examples, there have been no reports of magnetic data or absorption spectra. In the present communication, we report the results of an investigation into preparation, characterization, magnetic properties and infrared spectra of several complexes of copper(II)chromate with ammonia and primary aliphatic amines.

Experimental

The complexes were prepared by the following two methods:

(a) Shaking Method. About 5 g of copper(II) chromate was suspended in 40 ml of acetone with calculated quantity of liquor ammonia in a 250 ml conical flask. The contents were shaken for about two days. The complex formed was filtered, washed with acetone and dried over P_4O_{10}.

(b) Vapor Method. About 5 g of copper(II) chromate was placed in a calcium chloride tube fitted with a glass wool plug at the bottom. This tube was fitted in a conical flask containing the anhydrous primary aliphatic amine, thereby exposing the solid to vapors for about thirty hours. The complex formed was dried over P_4O_{10}.

1. Tetraaminecopper(II) Chromate. Prepared by Method a. The complex is green in color. Found: Cu, 25.59; N, 22.58; H, 6.88%. Calcd for $H_{16}O_4CrN_4Cu$: Cu, 25.23; N, 22.25; H, 6.40%.

2. Tetramethylaminecopper(II) Chromate. Prepared by Method b. Green. Found: Cu, 21.00; N, 18.42; C, 16.10; H, 6.14%. Calcd for $C_4H_{20}O_4CrN_4Cu$: Cu, 20.92; N, 18.44; C, 15.82; H, 6.58%.

3. Tetraethylaminecopper(II) Chromate. Prepared by Method b. Green. Found: Cu, 17.62; N, 15.40; C, 26.68; H, 7.49%. Calcd for $C_8H_{28}O_4CrN_4Cu$: Cu, 17.67; N, 15.58; C, 26.70; H, 7.78%.

4. Diaquodi-n-propylaminecopper(II) Chromate. Prepared by Method b. Green. Found: Cu, 18.98; N, 8.35; C, 21.86; H, 6.19%. Calcd for $C_6H_{22}O_6CrN_2Cu$: Cu, 19.06; N, 8.39; C, 21.59; H, 6.59%.

5. Diaquodi-n-butylaminecopper(II) Chromate. Prepared by Method b. Green. Found: Cu, 17.52; N, 7.61; C,

26.33; H, 6.88%. Calcd for $C_8H_{26}O_6CrN_2Cu$: Cu, 17.58; N, 7.74; C, 26.56; H, 7.19%.

6. Diaquodi-n-amylaminecopper(II) Chromate. Prepared by Method b. Green. Found: Cu, 16.27; N, 7.16; C, 31.20; H, 7.32%. Calcd for $C_{10}H_{30}O_6CrN_2Cu$: Cu, 16.31; N, 7.19; C, 30.81; H, 7.70%.

Magnetic Measurements. The absolute values of magnetic moments of the compounds were measured at room temperature (304 K) using Gouy's method. (Table 1). The infrared spectra were obtained on a Infracord Model 137 spectrophotometer with the samples mounted as KBr disks. (Table 1, Fig. 1.)

Results and Discussion

The copper(II) chromate complexes possess general molecular formulae $[Cu(Am)_4]CrO_4$ and $[Cu(Am)_2(H_2O)]CrO_4$, where Am in the former represents either ammonia, methylamine or ethylamine and in the latter either *n*-propylamine, *n*-butylamine or *n*-amylamine.

All the complexes have been found to be paramagnetic and the value of effective magnetic moment is between 1.77—1.86 B.M. The four co-ordinate planar copper(II) complexes should have a value close to spin-only value of 1.73 B.M.[2] The magnetic moments of tetrahedral copper(II) complexes are expected to be around 2.2 B.M.[3] The tetrahedral arrangement of ligands has been found to be extremely rare for all copper(II) complexes, as a perfectly tetrahedral complex is orbitally triply degenerate and hence unstable.[4]

The ν(NH) in all complexes is observed in the range 3205—3368 cm^{-1}, whereas in ammonia and free aliphatic amines the band is observed at 3414 and 3400 cm^{-1}, respectively. The ν(NH) shifts to a lower value on co-ordination due to drainage of electrons from the nitrogen atom, thereby weakening N–H bond and resulting in a highly covalent metal–nitrogen bond.[5] The magnitude of the negative shift decreases as the molecular weight of the amine increases, which indicates that covalency of metal–nitrogen bond and stability of complexes decrease in the above order.[6] The position of all other bands are affected by co-ordination when compared with free amines.[7–9]

The O–H stretching band near 3485 cm^{-1} has been observed in all aquo complexes. There is a decrease in O–H stretching frequency due to co-ordination of water molecule with metal atom.[10–12] In addition to ν(OH), a characteristic band of co-ordinated water at 795 cm^{-1} in all aquo complexes has been observed.[13–15]

The $\nu\delta$(Cr–O) band in all complexes has been observed near 884 cm^{-1} indicating the presence of ionic chromate.[16]

We thank Professor S. S. Nigam for his keen interest and help throughout this research.

Amperometric Titration of Lead with Potassium Dithiotrihydroxymethyl Aminomethane and Its Determination in Presence of Mercury and Silver

G. S. DESHMUKH, H. CHAUDHURI, and H. S. MAHANTI*
Analytical Chemistry Division, Banaras Hindu University, Varanasi, India

(Received April 2, 1974)

Synopsis. Amperometric titration of lead with potassium dithiotrihydroxymethyl aminomethane at −0.2 V (*vs.* SCE) in ammoniacal ammonium tartrate–potassium nitrate base electrolyte (pH 8.0) has been carried out with a dropping mercury electrode. Lead has also been estimated in binary solutions with silver and mercury. The accuracy of the procedure is comparable to that obtained with classical methods.

Electrometric determination of lead by precipitating with sulphate ion was first introduced by Majer.[1] Later Kolthoff and Pan[2] titrated lead with dichromate amperometrically. Lead estimation with EDTA was carried out by Tanaka *et al.*[3] The use of mercaptobenzothiazole in the amperometric estimation of lead was reported by Cihalik *et al.*[4] Diethyldithiocarbamate[5] was also reported as a successful reagent in amperometric titration for lead.

Potassium dithiotrihydroxymethyl aminomethane has now been used as a precipitating agent in the amperometric determination of lead, which has also been estimated in presence of mercury and silver. This reagent with the structural formula, $(CH_2OH)_3$ C–NH–C(SK)=S, having two sulphur and one nitrogen which can act as donors, forms insoluble complexes with metal ions. Polarographic characteristics of this compound revealed an anodic wave at dropping mercury electrode extending over a wide span of potential (−0.7 V *vs.* SCE) in ammoniacal ammonium tartrate and potassium nitrate base electrolyte (pH 7.0—10.5). The diffusion current was found to be proportional to the concentration. Two methods have been developed for the amperometric titrations. The first is based on the measurement of the anodic current of excess titrating agent after complete precipitation of lead. In the second procedure dealing with the analysis of binary mixtures, the applied potential was so chosen that one of the two components is reduced at that potential. This also being the oxidation potential of the titrant, the current readings include the cathodic current of the reducible ion as well as the anodic current of the reagent. With the addition of the reagent, the ion reducible at the applied potential is preferentially precipitated and the cathodic current is decreased. When whole of the metal ion is precipitated, the current is reduced to residual current value, and the second component starts getting precipitated. The current remained steady during this stage, and after the complete precipitation of the second cation the anodic current of the excess reagent begins to increase.

* Present address: National Institute of Foundry and Forge Technology, Hatia, Ranchi-3, India.

Solutions. Stock solutions of various metal ions were prepared from E. Merck's guaranteed reagents and standardized by gravimetric procedures.[6] All other reagents used were of AnalaR variety. The preparation and standardization[7] of potassium dithiotrihydroxymethyl aminomethane were carried out as follows: 200 ml of saturated solution of trihydroxymethyl aminomethane was taken in a beaker and 5 g of KOH was added. The beaker was cooled in ice, and then 10 ml of carbon disulphide was added, and stirred thoroughly with magnetic stirrer for 16 hr. The excess carbon disulphide was then removed by thorough shaking with double distilled pure benzene and the liquid was separated using a separating funnel. It was then evaporated little by heating on water bath and cooled in ice. Highly hygroscopic crystalline solid was separated. An aqueous solution of the reagent was standardized with potassium ferricyanide in alkaline medium in presence of osmium tetroxide as catalyst by amperometric titration at a potential of +0.2 V (*vs.* SCE) using rotating platinum micro-electrode.

Apparatus. A Fisher Electropode in conjunction with dropping mercury electrode and saturated calomel electrode was used for the titration. The pH measurements were made with a line operated Beckmann Zeromatic pH meter.

Experimental

The appropriate operative conditions for quantitative estimation of lead were established by trial experiments and it was observed that reproducible results were obtained in a base electrolyte consisting of ammoniacal ammonium tartrate and potassium nitrate (overall concentration 0.05—0.25 M) and pH range 7.0—9.0. In the actual procedure an aliquot of lead solution was taken in a titration cell containing 0.1 M base electrolyte. The pH of the solution was adjusted to 8.0 by adding ammonia. Pure nitrogen was passed into the solution to remove oxygen. A potential of −0.2 V (*vs.* SCE) was applied, the galvanometer reading was noted initially and after each addition of the titrant. After complete precipitation of lead, excess reagent gave the anodic

diffusion current of its own resulting in a regular rise in the current. The end point was located graphically (Fig. 1, Curve A). The results of estimations are given in Table 1.

For the determination of lead+silver and lead+mercury in a binary mixture, the titrations were carried out in ammoniacal ammonium tartrate and potassium nitrate base electrolyte of pH 8.0 at an applied potential of −0.2 V (*vs.* SCE). At this potential silver or mercury had its cathodic current while lead remained unreduced. During the titration the current decreased with the precipitation of silver or mercury and remained constant with the commencement of lead precipitation and increased with the anodic diffusion current of the excess reagent. The end points were located graphically (Fig. 1, Curve B), the first point of intersection gave the end point for silver or mercury and second point of intersection gave the end point for lead. The results of these titrations are given in Table 2.

Sincere thanks of the authors are due to Council of Scientific and Industrial Research, Government of India for research grants.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48 (3), 1091—1092 (1975)

Synthesis of α,β-Ethylenic Sulfones

M. SESHAPATHI RAO NAIDU and D. Bhaskar REDDY

Department of Chemistry, Post-Graduate Centre, Sri Venkateswara University, Anantapur 515003, India

(Received June 24, 1974)

Synopsis. A series of new α,β-ethylenic sulfones were prepared by the condensation of *p*-chlorophenylsulfonylacetic acid with various aryl aldehydes. The UV and IR spectra of all these compounds were recorded. Their IR spectra exhibited medium to strong bands in the region 1000—975 cm^{-1}, characteristic of *trans* ethylenic compounds.

The preparation of α,β-ethylenic sulfones by several routes has been reported.[1–5] For our current investigation on aryl cyclopropyl sulfones we were interested in preparing a series of unsaturated sulfones as intermediates. A number of new α,β-ethylenic sulfones prepared (see Table 1) by a slightly improved procedure of Baliah and Seshapathirao[1] are reported in this paper. Aromatic aldehydes were condensed with *p*-chlorophenylsulfonylacetic acid in glacial acetic acid solution in the presence of catalytic amounts of benzylamine. The synthetic utility of this procedure appears to be more elegant and convenient under simpler experimental conditions, affording fairly high yields of the unsaturated sulfones.

The UV spectra of all these unsaturated sulfones exhibited a long wavelength band around 245—320 nm, a second band around 220—236 nm and a third band with high intensity at 200 nm region.

The IR spectra of most of these sulfones showed a band in the region 1680—1620 cm^{-1} (ν C=C) and a strong band in the region 1000—975 cm^{-1} (δ CH out-of-plane) characteristic of *trans* ethylenic compounds.[4] In case of compounds containing polynuclear and heterocyclic substituents this band has

shifted to around 960 cm^{-1}.[5] These compounds also exhibited bands in the region 1295—1275 cm^{-1} [6] (δ CH in-plane). From the spectral data it may be concluded that all these compounds are *trans* isomers. They have also showed very strong peaks in the regions 1320—1300 and 1160—1120 cm^{-1} which are characteristic of sulfone groups.[7,8]

Experimental

All melting points were determined on a Mel-Temp apparatus and are uncorrected. The elemental analyses were performed by Dr. R. D. MacDonald, Australian Microanalytical Service. UV absorption measurements were determined in 95% ethanol with a Beckmann model DU-2 Ultraviolet Spectrophotometer and IR spectra were recorded on a Perkin-Elmer model 700 in nujol mulls. *p*-Chlorophenylsulfonylacetic acid[9] and 9-anthraldehyde[10] were prepared by published procedures and other aldehydes were obtained from commercial sources.

General Procedure. A solution of *p*-chlorophenylsulfonylacetic acid (0.01 mol) in acetic acid (6 ml) was mixed with an aryl aldehyde (0.01 mol) and benzylamine (0.2 ml), and refluxed for 90 min. The reaction mixture was cooled, treated with dry ether (50 ml) and any product separated was collected by filtration. The filtrate was diluted with more ether and washed successively with a saturated solution of $NaHCO_3$ (15 ml), $NaHSO_3$ (15 ml), dilute HCl (20 ml) and a finally with water. Evaporation of the dried etherial layer yielded in many cases a solid product. However, in some instances a syrupy substance separated was solidified on treatment with a small amount of methanol or 2-propanol. The relevant data on the compounds synthesized are given in Tables 1 and 2.

The Carbon-13 Nuclear Magnetic Resonance Spectra of Isomers of the Tris(*l*-propylenediamine)cobalt(III) Ion

Masaaki KOJIMA and Kazuo YAMASAKI

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received August 22, 1974)

Synopsis. The proton-decoupled carbon-13 NMR spectra were measured for the *mer*-$\Lambda(ob)$, *facial*-$\Lambda(ob)$, and *facial*-$\Delta(lel)$[Co(*l*-pn)$_3$]$^{3+}$ ions using the Fourier transform technique. There was a clear difference between the Λ and Δ configurations. However, no appreciable difference was observed between the *mer* and *facial* isomers of $\Lambda(ob)$-[Co(*l*-pn)$_3$]$^{3+}$.

Since the proton NMR spectra of tris(diamine)-cobalt(III) complexes are broad as a result of the spin-spin coupling of protons with ^{59}Co (I=7/2, 100% natural abundance), ^{59}Co decoupling is necessary to get a sufficient resolution for accurate analysis and to detect, for instance, the *mer* and *facial* isomers of the $\Delta(lel)$-[Co(*l*-pn)$_3$]$^{3+}$ ion.[1] We have separated the *mer* and *facial* isomers of $\Lambda(ob)$-[Co(*l*-pn)$_3$]$^{3+}$ by column chromatography on SP-Sephadex (Fig. 1) and measured the 100 MHz PMR spectra in DMSO-d_6; the spectra were similar for these two isomers except for the amine-proton signals.[2]

As recent developments in the carbon-13 NMR technique have made valuable contributions to the analysis of conformations[3] and to the determination of stereochemical structures,[4] this method has been applied to these isomers. Figure 2 shows an illustrative example of the 22.63 MHz ^{13}C-NMR spectra, including the assignment of the signals. Table 1 gives the results, together with that of *facial*-$\Delta(lel)$-[Co(*l*-pn)$_3$]Br$_3$. As the uncertainty of peak positions is about 0.1 ppm, there is a clear difference between the δ-positions of the Λ and Δ isomers. The *facial* isomer has a three-fold axis of rotation and its chelate rings are equivalent, whereas the chelate rings of the *mer* isomer are non-equivalent (*cf.* Fig. 1). Consequently, three signals can be expected for each carbon atom of the latter. The spectrum obtained, however, showed only one signal for the *mer* isomer as well as for the *facial* isomer (Fig. 2). Therefore, neither the ^{13}C-NMR nor the 100 MHz PMR technique is effective in distinguishing the *mer* isomer from the *facial* isomer of $\Lambda(ob)$-[Co(*l*-pn)$_3$]$^{3+}$. The cobalt-59 NMR spectra, however, showed a difference in chemical shift in the *mer-facial* isomerism.[5]

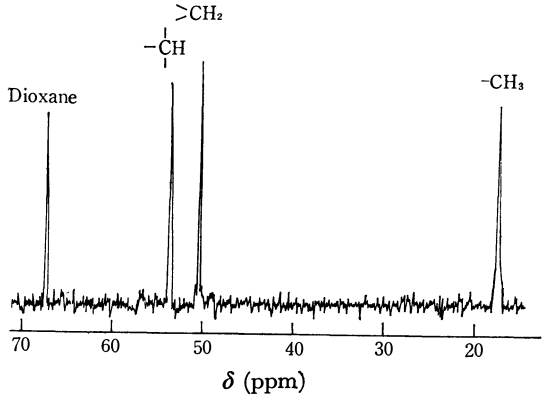

Fig. 2. ^{13}C-NMR spectrum of *mer*-$\Lambda(ob)$-[Co(*l*-pn)$_3$]Cl$_3$·4H$_2$O.

Table 1. ^{13}C-NMR Chemical shifts of the isomers of [Co(*l*-pn)$_3$]$^{3+}$ (in δ ppm)

Complex	$-CH_3$	$>CH_2$	$-\overset{\vert}{C}H$
mer-$\Lambda(ob)$-[Co(*l*-pn)$_3$]Cl$_3$·4H$_2$O	17.5	50.4	53.7
facial-$\Lambda(ob)$-[Co(*l*-pn)$_3$]Cl$_3$·3H$_2$O	17.6	50.2	53.7
facial-$\Delta(lel)$-[Co(*l*-pn)$_3$]Br$_3$	17.8	50.7	55.0

Experimental

Measurement of the ^{13}C-NMR Spectra. The proton-decoupled 22.63 MHz ^{13}C-NMR spectra were obtained by means of a Bruker WH 90 spectrometer, using the Fourier transform technique, which allows the measurement of samples with ^{13}C in natural abundance (1.1%). The solvent was D_2O, and the spectra were run at an ambient temperature. Dioxane (δ=67.40) served as an internal standard; the δ-values are given relative to TMS.

The ^{13}C-NMR spectra were measured by Dr. Sven Bagger and Prof. Woldbye, Chemistry Department A, The Technical University of Denmark. We wish to express our deep gratitude for their kindness.

A Novel Route to Menthyldiphenylphosphine

Masato TANAKA and Ikuei OGATA

National Chemical Laboratory for Industry (Tokyo Kogyo Shikensyo), Hon-machi, Shibuya-ku, Tokyo 151

(Received September 2, 1974)

Synopsis. As evidence of a novel, configurationally-stable Grignard reagent, menthyldiphenylphosphine (MDPP) has been obtained by the reaction of diphenylphosphinous chloride with the Grignard reagent derived from menthyl chloride.

During the past several years, a variety of optically active phosphines have been used in asymmetric syntheses by homogeneous phosphine–transition metal complex catalysts. Neomenthyldiphenylphosphine (NMDPP) and menthyldiphenylphosphine (MDPP) have also been examined as chiral ligands in asymmetric hydrogenation,[1] hydroformylation,[2] and hydrosilylation.[3]

Since it has been believed that the preparation of a Grignard reagent from an optically active halide where halogen is attached to the asymmetric carbon results in significant racemization,[4] MDPP has been prepared according to the same procedure as was used in the case of NMDPP by

$$NaP(C_6H_5)_2 + \text{Neomenthyl chloride} \longrightarrow (\text{Menthyl})P(C_6H_5)_2$$

the reaction of sodium diphenylphosphide with neomenthyl chloride, whose preparation is fairly difficult.[5] The present authors, however, have found, as a rare example, that MDPP can be easily prepared by the reaction of diphenylphosphinous chloride with a Grignard reagent derived from menthyl chloride:

$$\text{Menthyl chloride} + Mg \longrightarrow \xrightarrow{P(C_6H_5)_2Cl} (\text{Menthyl})P(C_6H_5)_2$$

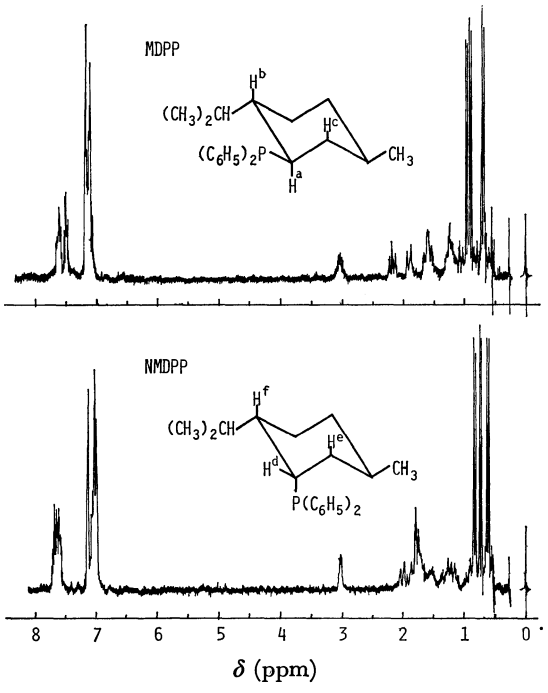

Fig. 1. The PMR spectra of MDPP and NMDPP at 220 MHz (benzene-d_6 solution).

The PMR spectra of the MDPP thus prepared is distinctly different from that of NMDPP, as is shown in Fig. 1; this indicates that MDPP is not contaminated by NMDPP. MDPP has an axial α-hydrogen (H^a) and two axial β-hydrogens (H^b and H^c) in the most stable conformation, and therefore MDPP exhibits an α-hydrogen multiplet with relatively large coupling constants. On the other hand, NMDPP has an α-hydrogen in the equatorial position, coupling and so the constant between H^d and H^e, and that between H^d and H^f, are much smaller.

The new route also offers a convenient way to prepare dimenthylphosphines and possibly even trimenthylphosphine.

Experimental

Neomenthyldiphenylphosphine was prepared by the method outlined in the literature.[1] The PMR spectra were recorded on a Varian HR-220 NMR spectrometer.

Menthyldiphenylphosphine. Menthyl chloride was prepared according to the method reported by Smith and Wright,[6] $[\alpha]_D$ −45.0° (neat). Magnesium (3.4 g, 0.14 mol) and 35 ml of dry tetrahydrofuran were placed in a 200 ml flask, and the mixture was treated with ethyl bromide (0.5 ml). Then, a solution of 20 ml of menthyl chloride (0.11 mol) in 40 ml of tetrahydrofuran was added, portion by portion, over a period of 4 hr at 50 °C, followed by reflux for 30 min. To the filtrate of the mixture, a 20 g portion of diphenylphosphinous chloride (0.091 mol) was added at 0 °C over a 10 min period. The resultant mixture was refluxed for 20 min, hydrolyzed by the cautious addition of 50 ml of water, and then extracted with hexane–ether. The organic layer was washed with water, dried over calcium sulfate, and concentrated. Through an agitated pot-still molecular distillation under $4—5\times10^{-4}$ mmHg, a fraction boiling at 110—120 °C (bath temperature) was collected, yield; 15 g (51%). A viscous oily substance solidified in several days and was then recrystallized from methanol to give large colorless needles; mp 52.9—54.0 °C (under nitrogen, corrected), $[\alpha]_D$ −93.5° (*c* 1.56, CH_2Cl_2).

Found: C, 81.60; H, 8.75%. Calcd for $C_{22}H_{29}P$: C, 81.44; H, 9.01%.

Syntheses of Trinuclear Ruthenium(III) Complexes with Dichloroacetato Ligands

Masao MUKAIDA, Mitsumasa KUSAKARI, Tadashi TOGANO, Toshihiro ISOMAE, Terunosuke NOMURA, and Tatsujiro ISHIMORI*

Department of Chemistry, Sophia University, Chiyoda, Tokyo 102

**Department of Chemistry, Rikkyo (St. Paul's) University, Ikebukuro, Tokyo 171*

(Received August 13, 1974)

Synopsis. Trinuclear ruthenium(III) complexes were prepared by the reaction of the dinuclear ruthenium(II, III) acetato complex with dichloroacetic acid. On the basis of chemical and thermal analyses, and on the basis of observations of the magnetic properties, the conductivities, the molecular weight, the alkalimetry, the infrared spectra and the electronic spectra, the complexes prepared here were formulated as $[Ru_3O(CHCl_2COO)_6(CH_3OH)_3](CHCl_2COO)$ and $[Ru_3O(CHCl_2COO)_6(OH)(H_2O)_2]$.

Some years ago, tetra-μ-monocarboxylato-chlorodiruthenium(II, III) complexes, $[Ru_2(RCOO)_4Cl]$ (R= H, CH_3, C_2H_5, *n*-C_3H_7, *n*-C_4H_9, C_6H_5), were prepared.[1,2] The structure of the butyrato complex was determined to have $[Ru_2(C_4H_9COO)]^+$ units linked into chains by Ru–Cl–Ru bridges.[3] Trinuclear acetato ruthenium(III) complexes, $[Ru_3O(CH_3COO)_6X_3]^{n+}$ (X=H_2O, py, CH_3OH, *n*=0 or 1), which contain an oxygen-centred structure, have recently been prepared.[4,5] Monochloro- and trichloroacetato ruthenium complexes have also been prepared.[2] However, no ruthenium complex with dichloroacetato ligands has yet been reported. This paper will describe the preparation and the properties of two dichloroacetato ruthenium complexes, $[Ru_3O(CHCl_2COO)_6(CH_3OH)_3](CHCl_2COO)$ and $[Ru_3O(CHCl_2COO)_6(OH)(H_2O)_2]$. The complexes prepared here were thought to have a skeletal structure similar to those of μ_3-oxo-trinuclear metal (Fe, Cr, Ru) acetato complexes.

Experimental

Preparation of $[Ru_3O(CHCl_2COO)_6(CH_3OH)_3](CHCl_2COO)$, *(1).* To a solution of tetra-μ-acetato-chlorodiruthenium(II, III) (1500 mg) in a mixture of CH_3OH (150 ml) and H_2O (150 ml), was added dichloroacetic acid (60 ml), after which the solution was left standing at room temperature.

After one or two weeks, the solution separated into two layers. The under layer (dark green) was transferred to a beaker, after which it was again kept standing for about a month. The dark green crystals thus obtained were filtered, washed with petroleum ether, and dried *in vacuo*, giving 350 mg. The crystals were recrystallized from CH_3OH. Found: Ru, 23.2; C, 15.34; H, 1.46%. Calcd for $[Ru_3O(CHCl_2COO)_6(CH_3OH)_3](CHCl_2COO)$: Ru, 23.1; C, 15.55; H, 1.45%.

The same complex was also obtained when tetra-μ-acetato-nitratodiruthenium(II, III) was used as the starting material in place of tetra-μ-acetato-chlorodiruthenium (II,III).

Preparation of $[Ru_3O(CHCl_2COO)_6(OH)(H_2O)_2]$, *(2).* The preparation was very similar to that described above, except that ethanol was used as the reaction solvent in place of methanol. Attempted recrystallization from methanol and ethanol were unsuccessful. Found: C, 12.54; H, 1.13; Cl, 37.12; H_2O, 3.3%. Calcd for $[Ru_3O(CHCl_2COO)_6(OH)(H_2O)_2]$: C, 12.64; H, 0.97; Cl, 37.32; H_2O, 3.16%.

The binuclear acetato ruthenium complexes used as the starting materials in these syntheses were prepared by methods described previously.[2]

Results and Discussion

The compositions were consistent with the formulae given in Table 1. The presence of two molecules of the coordinating water in **2** were determined by DTA and TG measurements. No endothermic peak due to the deaquation was found for **1**. The trimeric structure of the complexes was indicated by the molecular-weight measurement of **1** (Table 1). X-Ray single crystal photographs of **1** showed that the cell volume of the complex was about 4200×10^{-24} cm^3. The density calculated using the assumption of four molecules per cell was 2.07 g·cm^{-3} while the observed density was 2.03 g·cm^{-3} (by the flotation method in CCl_4 and CH_2I_2).

The unipositive cation assumed for **1** was supported by the absorbing behavior toward cation-exchange resin(Dowex 50W-X 8) in a methanolic solution, although the molar conductivities observed were quite small compared to those found for ordinary complexes of 1 : 1-type electrolytes. In the titration of a methanolic solution of **1** with a sodium hydroxide solution, two infliction points were observed, as is shown in Fig. 1. This is probably due to the ligand substitution between the coordinated methanol in **1** and the hydroxide ion.

Table 1. CHEMICAL FORMULAE AND THEIR PROPERTIES

	Complex	Λ_M in 10^{-3} M S cm^2	M.W.[c]	μ_{eff}[d] (B.M.)	λ nm[a] (ε)
1,	$[Ru_3O(CHCl_2COO)_6(CH_3OH)_3](CHCl_2COO)$	16[a]	1455[a]	2.16 (293 K)	715—690 (*ca.* 1570) 610—600 sh —420 sh
		12[b]	1366[b]		
2,	$[Ru_3O(CHCl_2COO)_6(OH)(H_2O)_2]$	20[a]		2.04 (298 K)	730—700 (*ca.* 2950) 630—600 sh —420 sh

a) in CH_3OH. b) in DMF. c) by vaper pressure osmometry. d) by Gouy method.

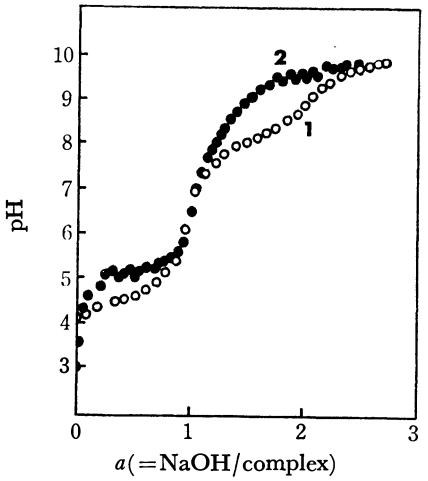

Fig. 1. pH titration curves for **1** and **2** in methanolic solution.
Complexes: 3×10^{-4} M.

On the other hand, **2** in a methanolic solution was absorbed by anion-exchange resin(Dowex 1-X 4), and only one infliction point was observed in its pH titration curve. This behavior seem to be evidence for the proton-dissociation of the aqua ligand in **2**:

$$[Ru_3O(CHCl_2COO)_6(OH)(H_2O)_2] \text{ (in solid)} \longrightarrow$$
$$[Ru_3O(CHCl_2COO)_6(OH)_2(H_2O)]^- + H^+ \text{ (in } CH_3OH)$$

The presence of methanol in **1** was ascertained by infrared spectroscopy. The IR spectra of the two complexes were almost identical except for the bands in the 1000 cm^{-1} region. In this region, two absorption bands at 996 and 968 cm^{-1} were observed for **1**, while only one absorption band, at 967 cm^{-1}, was found for **2**. The band at 996 cm^{-1} in **1** can be assigned to the methyl rocking vibration.

It has been reported that the observations of the electronic absorption spectra can serve as a guide for the characterization of μ_3-oxo-trinuclear acetato ruthenium complexes.[5] The electronic absorption spectra and the effective magnetic moments of **1** and **2** were similar to those of the complexes mentioned above.[5] The observed magnetic moments may also suggest an oxygen-centred structure in which marked spin-spin interaction occurs *via* the central oxygen atom in the Ru_3O unit.[6]

In the present study, **1** and **2** were obtained under the same reaction conditions. It is interesting to note that the formation of these species depends on the kind of alcohol used as a solvent in the syntheses. As has been noted in the Experimental section, attempts to recrystallize **2** from ethanol were unsuccessful. However, when **2** was treated by a mixture of methanol and water containing dichloroacetic acid, a crystalline material, which is thought to be $[Ru_3O(CHCl_2COO)_6(H_2O)(CH_3OH)_2](CHCl_2COO)$ on the basis of its composition and infrared spectrum, was obtained. This finding indicates a fairly strong coordinating nature of methanol in the complexes.

Epoxide Rearrangement II.† Isomerization of 1-Methylcyclohexene Oxide over Solid Acids and Bases

Kazushi ARATA, Susumu AKUTAGAWA,* and Kozo TANABE**

Department of Chemistry, Hokkaido University of Education, Hachiman-cho, Hakodate 040
**Central Research Laboratory, Takasago Perfumery Co., Kamata 5, Ota-ku, Tokyo 144*
***Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060*

(Received October 26, 1974)

The reaction of 1-methylcyclohexene oxide over solid acids and bases at 108 °C was found to give five main products, 2-methylcyclohexanone (III), 1-methylcyclohexanol (IV), 2-methyl-2-cyclohexene-1-one (V), 2-methylenecyclohexanol (VIa), and 2-methyl-2-cyclohexene-1-ol (VIb), with a small amount of 1-methylcyclohexene (I) and unidentified compound (II). The ketone (III) was formed predominantly over zeolite, SiO_2–Al_2O_3, H_2SO_4/SiO_2, $AlCl_3$, and BBr_3, while the allyl alcohol (VI) was given by Al_2O_3 and TiO_2. HCl/SiO_2 and solid H_3PO_4 calcined at 400—900°C gave both products, III and VI, in the same amounts, though the latter calcined at 200—300 °C formed almost 100% ketone. Solid lithium perchlorate was surprisingly active for the formation of ketone, but other metal perchlorates and lithium salts were quite inactive. Alkaline earth metal oxides and $NaOH/SiO_2$ were almost inactive. The catalytic activity and selectivity as well as the reaction path and mechanism are briefly discussed mainly in connection with acid-base property of solid catalysts.

Since Cope and Tiffany[1] observed an unusual base-catalyzed rearrangement of cyclooctatetraene oxide, much work has been done on the rearrangements of both cycloalkene oxide and open-chain oxide with strong bases, usually lithium dialkylamide.[2-6] The isomerization reactions of various epoxides with Lewis acid catalysts such as BF_3,[7,8] $ZnBr_2$,[9] $MgCl_2$,[10] and solid acid catalyst, Al_2O_3[11,12] have also been investigated.

Recently, Imanaka *et al.*[13,14] have studied the activity and selectivity of several solid acids and bases for the isomerization of propylene oxide. However, no work has been reported on the isomerization of epoxides other than propylene oxide and ethylethylene oxide[15,16] over solid acids or bases.

Cyclohexene oxide, one of the simplest cycloalkene oxides, seems suitable to study the selectivity and activity of solid acid or base catalysts and the effect of ring structure on the reaction. However, the reaction rate was extremely slow even over SiO_2–Al_2O_3. Thus, 1-methylcyclohexene oxide was chosen, because the reaction rate was much faster due to the electronic effect of methyl group and the selectivity for the formation of allyl alcohol with exo- or endo-double bond can be investigated.

In the present work, the activity and selectivity of several solid acids and bases and some salt catalysts for the isomerization of 1-methylcyclohexene oxide have been studied in a heterogeneous solid-liquid system.

Experimental

Catalysts and Materials. 1-Methylcyclohexene oxide, supplied from Takasago Perfumery Co., was fractionally distilled to purify to more than 98% and toluene, a guaranteed reagent, used as a solvent was redistilled over sodium metal.

The zeolite H-F9 was prepared from zeolite F-9, supplied from Tekkosha Co., by a conventional ion-exchange method using NH_4Cl and by calcining at 500° C. Al_2O_3 was KAT6 of Nishio Chemical Co. and SiO_2–Al_2O_3 was N631(L) (Al_2O_3; 15 wt. %) of Nikki Chemical Co. Both catalysts were calcined at 500 °C. H_2SO_4/SiO_2 was prepared as follows: 10 g of granular silica gel (White, Kanto Chemical Co.) was immersed in 12 ml of 0.5 M H_2SO_4, evaporated, dried and then calcined at 150 °C. HCl/SiO_2 was prepared by the same method. TiO_2 was prepared by the hydrolysis of titanium tetrachloride with 28% ammonia water at pH=9.4, followed by washing the precipitate, drying at 110 °C for 14 hr and calcining at 500 °C for 3 hr. ZnO was prepared by the hydrolysis of zinc nitrate with 28% ammonia water similarly as in the case of TiO_2.

Anhydrous $AlCl_3$ and BBr_3 were guaranteed reagents of Wako Pure Chemical Co. Solid phosphoric acid was N501 of Nikki Chemical Co. $LiClO_4 \cdot 3H_2O$, a guaranteed reagent of Nakarai Chemical Co., was used without any pretreatment. $LiClO_4$, $KClO_4$, LiCl, and $LiNO_3$, guaranteed reagents of Nakarai Chemicals Co., and $NaClO_4$ and Li_3PO_4, reagents of Wako Pure Chemical Co., were dried at 120 °C for 3 days. $NaOH/SiO_2$ was prepared by following the procedure of Malinowski and Czczepanska[17]: 10 g of granular silica gel was immersed in 12 ml of 1 M NaOH, dried and calcined at 500 °C. CaO and MgO were prepared by calcining their hydroxides in air at 550 °C or by calcining further the oxide *in vacuo* (10^{-4}—10^{-5} mmHg) in quartz tubes at 600 °C for 2 hr and at 640 °C for 3 hr, respectively. All the catalysts prepared were stored in sealed ampoules.

Procedure and Analysis of Products. In general, the reaction was carried out in the presence of toluene as a solvent at 108 °C for 2 hr. A mixture of 0.5 ml of the epoxide, 2.5 ml of toluene, and about 0.3 g of catalyst below 100 mesh was stirred in a reaction vessel by a magnetic stirrer, At appropriate time intervals, a small amount of the sample was taken out by a 1 ml syringe, separated from catalyst and analyzed by a gas chromatograph with a hydrogen-flame detector using a 3 m column of polyethylene glycol 20 M on celite 545 SK (150 °C; N_2, 0.9 kg/cm²). For the separation of two allyl alcohols, a 45 m capillary column of Ucon LB-550-X (100 °C; N_2, 1.2 kg/cm²) was used. The yields of products were calculated from VPC peak areas (uncorrected).

In the experiment where $AlCl_3$ was used as a catalyst, 0.5 g of the catalyst was added into a mixture containing 0.5 ml of the epoxide and 2.5 ml of toluene with vigorous stirring at room temperature and the reaction was continued for 15 min. Then, the reaction mixture was poured into

† Part I: K. Arata and K. Tanabe, *Chem. Lett.*, **1974**, 923.

50 ml of 5% hydrochloric acid. The organic layer was separated, washed with water twice and then dried over anhydrous calcium chloride. In the case of BBr_3, 0.3 ml of BBr_3 was poured into the same reaction mixture cooled in ice and the reaction was continued for 10 min. The subsequent procedure was the same as in the case of $AlCl_3$.

The reactions catalyzed by MgO and CaO calcined *in vacuo* were carried out by the procedure of Ohnishi and Tanabe.[18] The catalyst prepared *in vacuo* was introduced into an evacuated and sealed reaction vessel through a breakable joint to prevent the contact with air. Then, the reaction was followed by the general procedure.

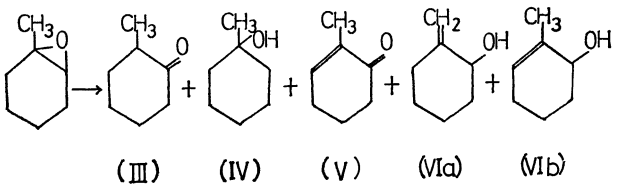
The main reaction products, III–VI, were isolated by a column chromatograph on silica gel eluted with petroleum ether-diethyl ether (1 : 1) and analyzed by NMR and IR. Compound III was easily identified as 2-methylcyclohexanone by its IR spectrum and by glc comparison with the authentic sample; IR (neat): 2940, 2860, 1710, 1445, 1370—1330, 1310, 1210, 1120, 860, 810, and 720 cm^{-1}. Compound IV was identified as 1-methylcyclohexanol by IR and NMR; IR (neat): 3400—3200, 2950—2850, 1450, 1370, 1320, 1050, 1020, and 380 cm^{-1}; NMR (δ): 3.4 (s, 1H, OH), 1.7—1.1 (m, 10H, CH_2) and 1.0 ppm (s, 3H, CH_3). Compound V was recognized as 2-methyl-2-cyclohexene-1-one by its IR and by glc comparison with the authentic sample; IR (neat): 3500—3300, 2594, 2586, 2660, 1450, 1360, 1180, 1110, 1020, and 900 cm^{-1}. Compound VI was revealed to be a mixture of two allylic alcohols by its glc analysis with a capillary Golay column, IR, and NMR; IR (neat): 3180, 990 cm^{-1} assigned to hydroxyl group and 890 cm^{-1} to methylene group; NMR (δ): 5.1—5.3 ppm assigned to olefinic protons. The mixture is considered to consist of 2-methyl-2-cyclohexene-1-ol and 2-methylenecyclohexanol in view of mechanistic considerations. The hydrogenated compound of VI was identical in glc, IR and NMR spectra to those of the synthesized and hydrogenated compound of 2-methyl-2-cyclohexene-1-ol and identified to be 2-methyl-cyclohexanol. Both allylic alcohols were synthesized as follows in order to identify compound VI in glc.

(1) *2-Methyl-2-cyclohexene-1-ol.* 1-Methylcyclohexene (1.0 g) was oxidized with $Hg(OCOCH_3)_2$ (3.2 g) in 10 ml CH_3COOH at 80 °C for 2 hr to form 1-acetoxy-2-methyl-2-cyclohexene (0.90 g): bp 85 °C/15 mmHg, which was hydrolyzed with NaOH–CH_3OH to yield its allyl alcohol (0.5 g): bp 90 °C/18 mmHg; IR (neat); 3180, 990 cm^{-1} (-OH); NMR (δ): 5.4 (t, 1H, C=CH), 4.1 (s, 1H, OH), 3.8 (t, 1H, CHOH), and 1.7 ppm (s, 3H, $C=CCH_3$), which were identical with the literature values.[19] This sample showed the second peak of compound VI in glc.

(2) *2-Methylenecyclohexanol.* Methylenecyclohexane (0.5 g) synthesized by Wittig reaction from cyclohexanone, $(C_6H_5)_3PCH_3Br$ and BuLi[20] was oxidized with SeO_2 (1.1 g) in 8 ml AcOH and 2 ml Ac_2O at 60 °C for 2 hr, followed by the saponification with aqueous NaOH to give its allyl alcohol (75 mg); IR (neat): 3170, 995 cm^{-1} (-OH) and 890 cm^{-1} ($CH_2=C$); NMR (δ): 5.3 (s, 2H, $CH_2=C$), 4.1 (s, 1H, OH), and 3.8 ppm (t, 1H, CHOH), which were identical with the literature values.[21] This sample gave the first peak of compound VI in glc.

Results and Discussion

The reaction of 1-methylcyclohexene oxide over solid acids and bases gave five main products, 2-methylcyclohexanone (III), 1-methylcyclohexanol (IV), 2-methyl-2-cyclohexene-1-one (V), 2-methylenecyclohexanol (VIa), and 2-methyl-2-cyclohexene-1-ol (VIb), with a small amount of 1-methylcyclohexene (I) and unidentified compound (II).



II was possibly the dehydrated diene-compound of VI, because cyclohexene oxide also rearranged under the same reaction conditions with extended periods to yield a small amount of cyclohexene and 1,3-cyclohexadiene, presumably formed by the dehydration of cyclohexenol. Their RRT (Relative Retention Time) in GLC was quite close to that between I and II.[22]

The relation between the yields of the products and reaction time is shown in Fig. 1, where the catalyst was solid H_3PO_4 calcined at 900 °C. The yields of III and VI increased almost parallel with each other during the course of reaction. The similar time-variation of the products was also observed in the case of TiO_2. This suggests that they are not intermediate species for each other. Since other products, IV and V, are presumably formed by hydrogenation and dehydrogenation of the starting epoxide, respectively, these two materials can not be intermediate species for III or VI formation. Consequently, it seems likely that ketone and allyl alcohol are formed by different mechanisms. However, there is a report implying the possibility of the carbonyl compound formation from the corresponding allyl alcohol on the base-induced conversion of epoxides.[5] This possibility seems to be very small, judging from the product distribution during the course of reaction in the present work.

Table 1 shows the catalytic activity and selectivity of several solid acid catalysts in 2 hr at 108 °C, and those of solid H_3PO_4 calcined at different temperatures are given in Table 2. The products are mainly divided into two categories, ketone (III) and allyl alcohol (VI). The former was formed predominantly

over zeolite, SiO_2–Al_2O_3, H_2SO_4/SiO_2, $AlCl_3$, BBr_3 and solid H_3PO_4 calcined at 200 and 300 °C, while the latter was given by Al_2O_3 and TiO_2. HCl/SiO_2 and solid H_3PO_4 calcined at 400 and 900 °C gave both products in the same amounts, though their catalytic activities were not high. It is especially interesting that SiO_2–Al_2O_3, H_2SO_4/SiO_2 and low-temperature calcined solid H_3PO_4, which are known to have strong acid sites,[23,24] formed almost 100% ketone, whereas Al_2O_3 and TiO_2 gave more than 80% of allyl alcohol.

$AlCl_3$ and BBr_3, which are typical Lewis acid catalysts, showed the almost similar selectivity for ketone to those of H_2SO_4/SiO_2 and solid H_3PO_4 calcined at low temperature, which are Brönsted acids. Accordingly, it is considered that the selectivity does not depend on the type of acid sites, Brönsted and Lewis acids. BBr_3 produced a large amount of the unidentified compound (II) and many products other than those listed in the table, probably owing to its very high acid strength.[25]

A number of authors have reported that ketone is formed from epoxides with various acid catalysts; for example, from *p*-menthene and *d*-limonene oxide with $ZnBr_2$,[26] 2,3-butene oxide with BF_3-etherate,[27] *d*-limonene oxide with CH_3COOH,[28] propylene oxide over zeolite.[29] Our observations also substantiate the ketone formation with acid catalysts.

The pronounced activity of Al_2O_3 for the allyl alcohol formation was quite similar to Nigam and Levi's results,[30] where limonene and α-pinene oxides isomerized to the corresponding α, β-unsaturated alcohols, the yields being increased in order of acidic< neutral<basic alumina. Okamoto *et al.* have investigated the isomerization of propylene oxide over SiO_2–MgO catalysts using a pulse reactor and concluded that allyl alcohol was formed by acid-base bifunctional catalysts, where the oxygen of the epoxide was adsorbed on an acidic site and β-hydrogen on a basic site and that even very weak acid site was favorable for its formation.[14] Taking into account both observations, our results of Al_2O_3 could be explained by the bifunctional mechanism. The same mechanism seems to operate over TiO_2, since it has basic sites[31] as well as acidic sites.[32] The catalytic activities of solid H_3PO_4 calcined at various temperatures correlate well with their acidities, which are 4.5 mmol/g for 250 °C, 1.6 for 400, and 0.4 for 980 at $pK_a = 1.5$.[24] The formation of allyl alcohol over the catalyst calcined at high temperature suggests that basic sites appear on the surface and the reaction takes place by acid-base bifunctional mechanism,

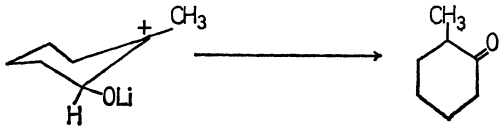
In allyl alcohol formation, VIa generally exceeded VIb. This seems to be caused by the competition between primary and secondary proton abstraction. The preference for primary proton abstraction is due to the more enhanced acidity of primary hydrogen by the electronic effect and the preferred geometry, *i.e.*, less strain of cyclohexane ring containing the exo-double bond. The similar observations were demonstrated by Rickborn and Thummel,[5,6] in which the relative rates of proton abstraction were in order of primary>secondary> tertiary in the rearrangement of both cycloalkene and open-chain oxides catalyzed by a strong base, lithium diethylamide. Only in the case of HCl/SiO_2, VIb exceeded VIa against the above rule. This is probably due to the absence of appropriate basic sites on the catalyst.

Table 3 shows the catalytic activity and selectivity of solid metal perchlorates, lithium salts and solid base catalysts. Solid lithium perchlorate was surprisingly active for the formation of ketone, but other metal perchlorates and lithium salts were quite inactive. The high polarisability of lithium cation, the smallest cation of alkali metals, combined with perchlorate ion in which negative charge is dispersed seems to be necessary as the active sites for the rearrangement. Another reason for the high activity of $LiClO_4$ is considered to be the partial dissolution of the catalyst or its complex with the epoxide. Rickborn and Gerkin[33] reported that lithium perchlorate partially dissolved in benzene solution of epoxides gave rise to the rapid rearrangement. They obtained 80% of 2-methyl-cyclohexanone from 1-methylcyclohexene oxide over $LiClO_4$ in agreement with our findings. They also found that 1,2-dimethylcyclohexene oxide gave 91—98% of 1-acetyl-1-methylcyclopentane and 2—9% of 2,2-dimethylcyclohexanone,[33] which were formed with the same amount in the $HClO_4$-catalyzed pinacolone rearrangement.[34] In both reactions, the product formation can be best interpreted by assuming a planar carbonium ion intermediate. Thus, the cyclohexanone products from 1-methyl- and 1,2-dimethylcyclohexene oxide are considered to be formed by a process which allows the development of a planar carbonium ion at the cleaved tertiary center.



Sodium-silica gel, calcium and magnesium oxides calcined in air, which have basic characters,[17,35] were almost inactive for this reaction. The alkaline earth metal oxides calcined *in vacuo*, which were found recently to show strong basic character and high catalytic activity for the isomerizations of 1-butene to 2-butenes and α-pinene to β-pinene,[18,36,37] were not active at all at the mild reaction condition in the present work. However, a small amount of ketone was formed over these basic catalysts calcined in air. The formation of ketone may be due to the weak interaction between the alkaline earth metals as soft acids and the oxygen atom of the reactant as reported by Matsumoto *et al.*[38] Since MgO was active for the isomerization of propylene oxide at 260—270 °C in a gas phase,[14] the experiment at more severe condition is being planned in order to clarify the activity difference for different epoxides.

Optically-active Vibrations and Effective Charges of Calcite and Magnesite[1)]

Akio YAMAMOTO, Yuji SHIRO*, and Hiromu MURATA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

** Shinonome Branch School, Faculty of Education, Hiroshima University, Shinonome-3-chome, Hiroshima 734*

(Received December 10, 1973)

A rigid-ion model analysis was made for the optically-active crystal vibrations of calcite ($CaCO_3$) and magnesite ($MgCO_3$) with reference to the previous vibrational treatments. The effects of the effective charge distribution on the TO–LO splittings of the lattice modes were examined on the proposed distribution model, and the effective charges have been found: $Z_{Ca}=1.21$, $Z_C=0.20$, and $Z_O=-0.47$ in calcite, and $Z_{Mg}=1.28$, $Z_C=0.21$, and $Z_O=-0.50$ in magnesite, all in electron units. The force fields and effective charges determined in the present study reproduce satisfactorily the observed transverse and longitudinal frequencies of the optically-active lattice vibrations.

The vibrational spectra of calcite and magnesite have been studied by many investigators[2–14)] in connection with those of the isomorphic crystals with the calcite structure. In this work, our attention will be confined to the optically-active vibrations of calcite and magnesite; the vibrations will be analyzed on the basis of the rigid-ion model.[15)] In the rigid-ion formulation, account is taken only of the long-range Coulomb interactions of vibrationally-induced dipoles as those of rigid point dipoles; any contribution originating in the distortion of the electronic distribution is implicitly neglected. The model has been extensively applied to the vibrational analysis of relatively simple crystals[16,17)] and has been found to give less good results for the explanation of phonon-dispersion relations[18)] than the more elaborate models.[19,20)] We will, however, apply the model to the vibrational analysis of the calcite-type crystals, since only a small number of unknown parameters are introduced in taking the Coulomb interactions, and since a fairly good agreement can be obtained at least between the calculated and observed optically-active vibration frequencies.[21)]

Method of Calculation

Crystal Structure. Calcium carbonate and magnesium carbonate crystallize in a calcite structure. The primitive unit cell is trigonal, and two formula units are present in it. The space group is $D_{3d}{}^6$–$R\bar{3}c$, and the cell constants[22)] of calcite and magnesite are $a_{rh}=6.375$ Å and $\alpha=46°5'$, and $a_{rh}=5.675$ Å and $\alpha=48°11'$ respectively. In the calcite-type lattices, each metal atom is coordinated by six oxygen atoms of different carbonate groups, and each such atom is bound to two metal atoms, as is illustrated in Fig. 1.

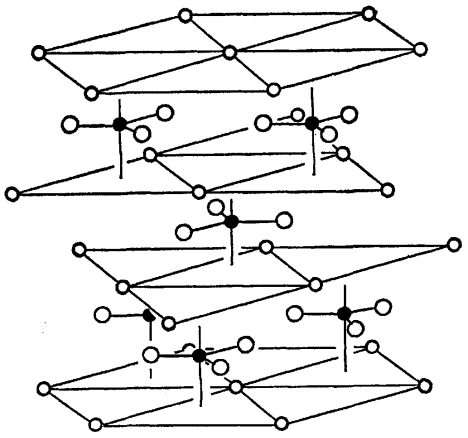

Fig. 1. Crystal structure.
○, Ca or Mg; ●, C; ○, O.

Normal Coordinate Treatment. A dynamical matrix is composed of two constituents:[15)]

$$\boldsymbol{D} = \boldsymbol{D}^s + \boldsymbol{D}^c,$$

where $\boldsymbol{D}^s$ and $\boldsymbol{D}^c$ are the short-range non-Coulomb and the long-range Coulomb interaction parts respectively; $\boldsymbol{D}^c=\boldsymbol{ZCZ}$, where $\boldsymbol{C}$ represents the long-range Coulomb interactions and $\boldsymbol{Z}$ is a diagonal matrix, the elements of which are effective charges.

Short-range Part: An application of the *GF*-matrix method[23)] to the analysis of optically-active crystal vibrations was previously reported by Shimanouchi *et al.*[24)] In the present study, a modified Urey-Bradley force field[25)] was applied to the intramolecular vibrations of carbonate groups, the correction terms of which were the bond interaction term, p, and the angle interaction term, n. On the other hand, a central force field was used for the lattice vibrations,

where only the pairs that lie within 3.5 Å were taken into consideration as effective short-range terms. As is shown in Fig. 2, there are six kinds of pairs in these crystals; the interatomic distances are given in Table 1.

Long-range Coulomb Part: In ionic crystals, the long-range Coulomb interactions are considered to play an important role in the splitting of a longitudinal mode frequency, ν_l, from the transverse ν_t. The Coulomb interaction part, $\boldsymbol{D}^c$, was calculated with the expression established by Born and Huang,[15] where the magnitude of the wave vector must be set at zero for the optically-active vibrations. In the Born and Huang expression, the $\boldsymbol{Q}$ term is a tensor of the second rank, the elements of which are called "the dipole lattice sum." The evaluation of the sum has been discussed in several places;[15,26,27] the actual calculations were performed by the use of the computer program PEG0.[28]

In contrast with simple crystals, some additional charge parameters must be introduced into these crystals, since the distribution of the effective charges in the unit cell is not known in advance. As is shown in Fig. 3, we have assumed the charge distribution on the carbonate groups under electrically neutral conditions.

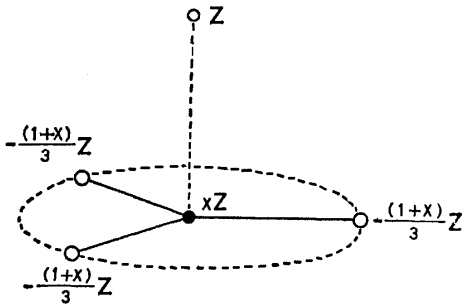

Fig. 3. Charge distribution.
○, O; ○, Ca or Mg; ●, C; Z, magnitude of effective charge in electron units; x, charge distribution parameter.

In the same manner as with short-range force constants,[29] one of the Coulomb parameters, *i.e.*, Z, can be refined by the least-squares method, since the Coulomb part has a common factor, Z^2, for a fixed distribution parameter, x.

The actual calculations were carried out on the TOSBAC 3400 TOPS 14 electronic computer at the Computing Center of Hiroshima University.

a) Observed frequencies are taken from Refs. 4, 5, and 11. ν_t, transverse frequency; ν_l, longitudinal frequency.

Results and Discussion

In calcite and magnesite, only the E_u and A_{2u} modes are infrared-active. The non-zero dipole moment is induced parallel to the z axis in the A_{2u} modes and normal to the axis in the E_u modes. When the wave vector $\mathbf{y}\rightarrow\mathbf{0}//z$, the A_{2u} modes are identified as the longitudinal modes, and the E_u, as the transverse. On the other hand, when $\mathbf{y}\rightarrow\mathbf{0}\perp z$, the E_u modes are longitudinal and the rest transverse.

Intramolecular Vibration. The intramolecular vibration modes have the following irreducible representations:[3]

$$\Gamma_n = A_{1g} + A_{1u} + A_{2g} + A_{2u} + 2E_g + 2E_u.$$

The observed[4,5,11] and calculated vibrational frequencies are compared in Table 2. It is shown that the interactions between the induced dipoles and the macroscopic field appear to exert little effect on the intramolecular modes. Since an out-of-plane angle deformation mode is accompanied by translational motions along the direction perpendicular to the tightly binding plane, the interactions may be fairly well approximated by the present model as compared with those of the other intramolecular modes. In an in-plane vibrational mode, however, the vibrational motions in the tightly binding regions should be actually followed by an intense electronic polarization originating in the distortion of the electronic distribution. Therefore, the polarization due to the electronic interactions between tightly binding atoms is likely to contribute predominantly to the total polarization rather than that due to the long-range electrostatic interactions between rigid dipoles in the above regions. It may be concluded that the rigid-ion approximation is not suitable for the interpretation of the dynamical properties of tightly-bonded systems, *e.g.*, the in-plane intramolecular vibration modes in these crystals. These subjects have been in part discussed by Decius *et al.*,[30-34] by Ishigame *et al.*,[35] and by Donoghue *et al.*[36] No quantitative explanation of the experimental results seems to have been made, though their discussions are quite suggestive. Further study based on some elaborate models will, therefore, be essential in order to obtain a satisfactory agreement with these experimental results.

Lattice Vibration. It can be shown from the factor-group theory[3] that the optical lattice modes are: $2A_{2g}+2E_g+A_{1u}+2A_{2u}+3E_u$. The observed[11] and calculated vibration frequencies are listed in Table 2, showing that the calculated frequencies for the lattice modes are in good agreement with the observed frequencies. The reason for this may be that the lattice vibration is considered to be essentially concerned with the relative motions of weakly interacting groups; therefore, the dynamical properties of these systems can be fairly well approximated by the rigid-ion model.

An introduction of the Coulomb interaction terms will change some vibrational modes from the corresponding non-Coulomb interaction modes; it has been found in some critical cases[37] that the changes are so serious that even the vibrational assignments of the fundamental bands must be modified from those determined from the non-Coulomb point of view. By examining the calculated eigenvectors carefully, it is found that there is not such a significant change in TO modes as in the above critical cases. Small changes, however, are noticeable in the LO modes, especially in the "polar" modes, which give rise to a large polarization. For instance, two polar modes, the modes which have high LO frequencies about 400 cm^{-1} in the A_{2u} and E_u symmetry, are seen to become more translational along the macroscopic field than the corresponding TO modes through additional interactions with the field.

Normal coordinate treatments have been made for calcite[38-41] on the basis of the short-range interaction models. In addition to these treatments, the long-range Coulomb interactions have been introduced by two groups of workers. First, both the interactions between the vibrationally-induced dipoles and the influence of the electronic distortion have been taken into account in the shell model by Plihal and Schaack.[42] They regarded a carbonate group as one bulky ion whose charge is located at the center of the group; they analyzed the optically-active vibrations of the three minerals of the calcite structure. Their rigid-ion model corresponds essentially to the present distribution model with $x=-1$; however, the results on these crystals were not given in their paper. If one assumes this charge distribution, any influence of the long-range interactions appears in the translational lattice modes; consequently, the Z-dependency of the lattice vibration is monotonic. In spite of their rather crude approximation, the calculated frequencies are in fair accord with the experimental results. Recently, phonon-dispersion relations were calculated for calcite by Plihal[43] by using the same model; however, the results have not been compared in detail with the observed results. Secondly, a rigid-ion model analysis was made for calcite by Onomichi.[44] He took, for the sake of simplicity, only four short-range force constants into consideration; therefore, the agreement with his observed values was seen to be less good. The effective charges attributed to the constituent atoms are read as $Z_{Ca}=1.86$, $Z_O=0.074$, and $Z_C=-2.08$ respectively in electron units; a positive value, though relatively small, was given on the most electrically-negative oxygen atom. The present authors have allowed only a negative charge on oxygen atoms from the chemical point of view.

Force Constants and Effective Charges. The short-range force constants and the effective charges are shown in Table 3. In the present study, account is taken separately of the long-range Coulomb interactions, and all of the short-range force constants need not have positive values; therefore, the physical meaning of the force constants is considered to be different from that in the previous short-range force models.

In performing the optimization procedures, some force constants were changed appreciably with the distribution models; however, the magnitude term, Z, was found to fall mostly into the range from 1.0 to 1.3, regardless of the distribution. Though the calculated TO–LO splittings seem to depend critically on the Z

term rather than on the x term, the x-dependency of the calculated splittings changes slightly from model to model[21] through the oxygen-oxygen interactions.

A careful comparizon of the calculated and found frequencies has given a fairly good agreement for $x=1/6$, though the lattice-mode frequencies are not so sensitive to the distribution parameter, x, in the range from −1.0 to 0.75 as to the Z parameter. Those distribution models which have values of x larger than unity were seen to give poorer results. The effective charge of the cation in magnesite is larger than that in calcite; the order of magnitude is consistent with the expectation based on the experimental TO–LO separations, and also with that of the effective charges determined for oxide crystals.[45]

In general, effective charges which interpret the sums of the observed TO–LO splittings may, in principle, be estimated for each infrared-active symmetry species by this relation:[17]

$$\sum\omega_l^2 - \sum\omega_t^2 = \mathrm{Trace}\{\boldsymbol{D}_l - \boldsymbol{D}_t\},$$

where ω and $\boldsymbol{D}$ are the circular frequency of the vibration and the dynamical matrix respectively, where the subscripts l and t specify longitudinal and transverse properties respectively, and where the summations are extended over the infrared-active modes. All the charges obtained by using the relation are, however, considered not to be reasonable: for instance, when the frequencies are distributed separately with wide gaps, the TO–LO splittings of the lower frequency modes are essentially neglected in the course of calculation. In these crystals, the charges which may explain appropriately the observed TO–LO separations of the modes around 1400 cm^{-1} were calculated to be extraordinary values about 5 in electron units; with these values, it is quite difficult to explain the TO–LO splittings of the lattice modes. The reason may be that the intense electronic polarization can hardly be reproduced by the point-dipole approximation, as has been mentioned above. However, its utility can best be appreciated by reference to the limitations of the rigid-ion model. Since the contribution of the lattice modes can be estimated fairly well, appropriate change parameters can be obtained when the lattice-mode frequencies are used.

A recent neutron inelastic scattering study will now be discussed briefly. Cowley and Pant[46] performed a simple shell-model analysis of the phonon-dispersion relations for the lowest-ten external branches and for the wave vectors along the optic axis; they obtained the following effective charges: $Z_{Ca}=2.3$, $Z_C=0.27$, and $Z_O=-0.87$, all in electron units. The value of Z_{Ca} is the largest of all the values[42,44] reported thus far. It is not clear at present whether the discrepancy among them depends on the electronic polarizability or on the choice of parameters. Since the intramolecular modes of vibration are influenced by the electronic polarizability [30–34] as well as the lattice modes, the effects of the Coulomb interactions must be estimated so as to reproduce simultaneously both types of vibration. Special attention should also be given to the fact that the two vibrational frequencies of the optically-inactive modes were determined to be 309 cm^{-1} and 172 cm^{-1}.

The charge distribution on molecules or groups has been estimated from the cohesive energies of crystals[47] or from the electronegativities[48,49] of constituent atoms. Those obtained are, however, considered to be static by nature; consequently, they need not always coincide with the present dynamically-effective charges. Even in these studies, the resulting distributions are seen to differ considerably with either investigators or methods.

The authors wish to express their thanks to Mr. Masaru Ohsaku of Hiroshima University for his kind and useful suggestions, and also to Mr. Tamaki Utida of Hiroshima University for permitting them the use of his computer program PEG0 and his helpful discussion.

Electron Scavenging Study on the Photobleaching of Trapped Electrons in 3-Methylhexane Matrices at 77 K

Koichi OKA, Hideo YAMAZAKI, and Yoshihiko HATANO

Laboratory of Physical Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received December 11, 1973)

The effect of addition of sulfur hexafluoride as an electron scavenger on quantum efficiency was investigated for the decay of trapped electrons in 3-methylhexane matrices at 77 K during photobleaching in the wavelength range 700—1900 nm. Since the quantum efficiency for the decay of trapped electrons in pure matrices is independent of the initial concentration, almost all the recombination of liberated electrons with the cations is geminate. The increase in quantum efficiency for the decay of trapped electrons by the addition of the electron scavenger SF_6 was analyzed quantitatively. The quantum efficiency for the photoliberation of trapped electrons from the trapping sites may be about unity. The liberated electrons in the absence of the electron scavenger are retrapped or neutralized. The ratio of the former process to the latter at a wavelength greater than 1500 nm is much larger than that at a shorter wavelength. The wavelength dependence of the ratios of the electron scavenging process to these processes has also been discussed.

The trapped electrons (e_t^-) produced by γ-irradiation in organic glasses at low temperature in the dark decay with infrared illumination (photobleaching)[1-4] or in the course of annealing (thermal bleaching).[5-7] The recombination-luminescence[8,9] and electric conductivity[10-12] have been measured during the course of bleaching. There are two states for electrons in glassy matrices, trapped electrons e_t^- and mobile electrons e_m^-, the former being stable and observable by optical absorption measurement or ESR, and the latter undergoing rapid retrapping or neutralization and not observable by the usual methods. Neutralization is either geminate or random. The decay of e_t^- might be due to either kind. The part of e_t^- geminately neutralized can not contribute to electric conductivity. The presence of electron scavengers suppresses the formation of e_t^-,[13] and increases the decay rate of e_t^- during the course of photobleaching.[1] More quantitative analysis of the photobleaching of e_t^- in 3-methylhexane glass (3MHX) and the effect of the addition of SF_6 as an electron scavenger have been carried out in order to estimate the quantum efficiency of the photoliberation of e_t^- from the trapping sites. The wavelength dependence of the fate of the photoliberated electrons has been examined in both the absence and presence of SF_6. The fate has been discussed in terms of the competition between the retrapping, neutralization and scavenging processes.

Experimental

3MHX (pure grade, Aldrich Chemical Co.) was purified by passing through an activated silica gel column. It was degassed by the freeze-pump method and trap-to-trap distillation, and stored on sodium-potassium alloy for more than a day before use. SF_6 (Matheson Co.) was used without purification.

In a mercury-free vacuum system, a constant volume (0.35 ml at room temperature) of 3 MHX was measured with a capillary of 2 mm diameter. The amounts of gaseous material added were determined by means of an oil manometer with a flask of a constant volume. The Ostwald absorption coefficient of SF_6 in liquid 3MHX at room temperature was about 1.3 and was used to determine the concentration of the solute in 3MHX glass at 77 K. The sample was sealed in a Suprasil quartz ESR tube (diameter 5 mm, volume 0.4 ml) and irradiated for 2.5—30 min with ^{60}Co γ-rays at 77 K in the dark at the dose rate $(1.0—5.4)\times 10^5$ r/hr. An aluminum foil was used to intercept the light emitted from Pyrex glass of a Dewar vessel during the course of γ-irradiation. After γ-irradiation, the ESR spectra of the samples were immediately measured in the dark with a JEP-1 X-band ESR spectrometer (JEOL) with field modulation 100 kHz. During repeated measurements by forward and backward scanning of the magnetic field, bleaching experiments were performed with monochromatic infrared light from a light source of QR-50 photospectrometer (Shimadzu). Actinometry was carried out with a photometer of thermocouple (JASCO) corrected by total light-intensity of a tungsten lamp (30 W; efficiency of the light emission 60%).

Results

The trapped electrons in γ-irradiated 3MHX matrices at 77 K were measured by ESR. The signal intensity of e_t^- decreased during the course of photo bleaching by infrared light, but not that of 3-methylhexyl radical. At a small microwave power of ESR, the saturation factor of the signal of e_t^- was almost constant during the course of photobleaching. The effect of photobleaching on the ESR signal intensity

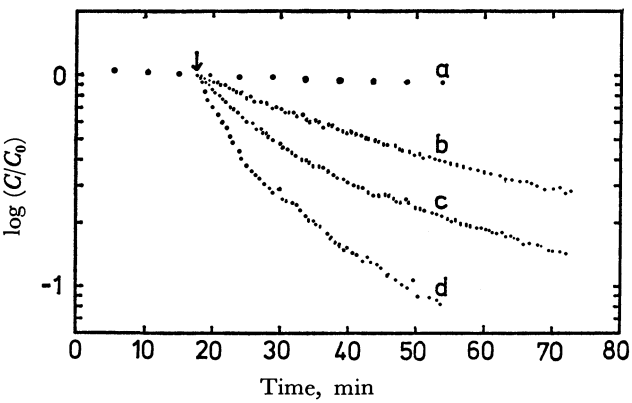

Fig. 1. The decay plots of log (C/C_0) against time in 3MHX after γ-irradiation: a) natural decay in the dark (dose$=1.1\times 10^{19}$ eV/g), and the decay due to photobleaching at $\lambda=1500$ nm after elapse of the time indicated by arrow. The slit of the monochrometer was opened to various widths, namely b) 0.2, c) 0.3, d) 0.5 mm (dose$=2.8\times 10^{18}$ eV/g).

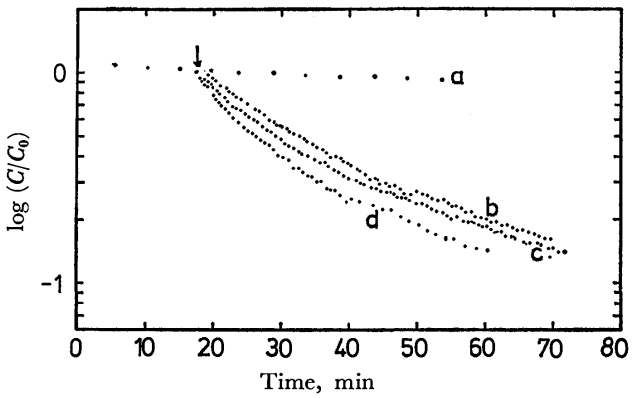

Fig. 2. The decay plots of log (C/C_0) against time after γ-irradiation: a) natural decay in the dark (γ-irradiation dose 1.1×10^{19} eV/g), and the decay due to photobleaching at $\lambda=1500$ nm with slit width 0.3 mm, in which the samples were γ-irradiated to various doses, namely b) 5.6, c) 2.8, d) 1.4 (10^{18} eV/g). The arrow on the curve indicates the starting point of infrared irradiation.

of e_t^- is given by C/C_0, the ratio of the concentration of e_t^- after and before photobleaching. Semilogarithmic plots of the decay of C/C_0 in the dark or under illumination of infrared light at $\lambda=1500$ nm are given in Fig. 1. The natural decay in the dark is negligibly small as compared with the decay due to photobleaching. At each slit width, the time necessary for C/C_0 to decay to the same value is roughly proportional to the light intensities which are proportional to the square of the slit width. At a fixed light intensity the decay rate decreased slightly with increasing doses of γ-irradiation (Fig. 2). This might be due to the nonuniformity of light intensity in a sample tube. The intensity of the light flux near the inlet of the light path is larger than that near the outlet because of the light absorption of e_t^-. Thus, the quantum efficiency for the decay of e_t^- during photobleaching Φ is given by[14]

$$-\frac{\mathrm{d}\log C}{\mathrm{d}t}=I\varepsilon\Phi\bar{Q} \qquad (1)$$

where I is light intensity, ε the extinction coefficient of e_t^- and $\bar{Q}$ the correction term attributed to the nonuniformity of light intensity in a sample tube. Assuming that the light flux is parallel in the cylindrical sample tube, $\bar{Q}$ is given as a function of D:

$$\bar{Q}=\frac{2}{\pi D\ln 10}\int_{-1}^{1}[1-\exp\{(-\ln 10)\,D\sqrt{1-y^2}\}]\mathrm{d}y \qquad (2)$$

where D $(=2\varepsilon CR)$ is the optical density of e_t^-, and R the radius of the cylinder. The value of $\bar{Q}$ approaches unity for a small value of D, namely for a small value of C or ε. The values $\varepsilon=3.0\times10^4$ l mol^{-1} cm^{-1} at 1700 nm, which is assumed to be equal to that in 3-methylpentane glass,[15] and $G(e_t^-)=0.9$,[16] are used for the calculation of Φ. An appropriate coefficient is necessary for the right term of Eq. 1.

If Φ is constant during the course of photobleaching, the plots of log (C/C_0) against time are nearly on a straight line. Actually, however, the slope or the value $(-\mathrm{d}\log C/\mathrm{d}t)$ decreases with increasing time

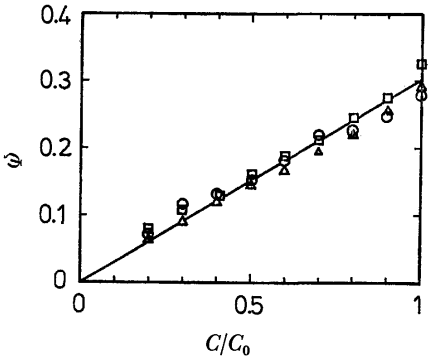

Fig. 3. Relation between Φ and C/C_0 at $\lambda=1500$ nm with slit width 0.3 mm in 3 MHX. Samples were γ-irradiated to various doses (10^{18} eV/g): ○ 1.4, △ 2.8, □ 5.6.

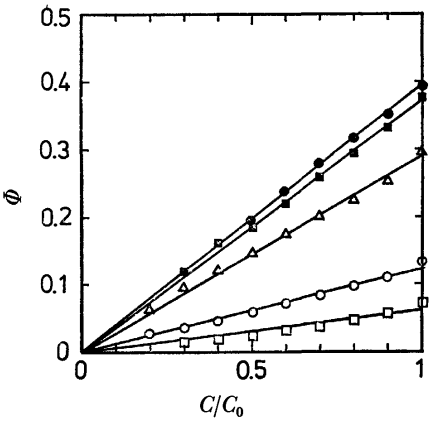

Fig. 4. Relation between Φ and C/C_0 at various wavelengths: ● 700, ■ 1300, △ 1500, ○ 1700, □ 1900 nm. This relation is also dose-independent as in Fig. 3.

(Fig. 1). The quantum efficiency for the decay of e_t^- calculated from the slopes by means of Eq. 1 decreases steadily with decreasing C/C_0. The values of Φ calculated from three series of measurements at different light intensities are almost the same for the same value of C/C_0. This shows that the main part of the primary act is a one-photon process.[17]

The efficiency Φ at 1500 nm is independent of γ-irradiation doses (Fig. 3). Also at $\lambda=1300$ nm, Φ is independent of γ-irradiation doses of $(0.28—5.7)\times10^{18}$ eV/g within 10% error. The dose-independence of γ-irradiation may support the validity of the correction term $\bar{Q}$. The relation between Φ and C/C_0 at various wavelengths is shown in Fig. 4. The plots are approximately on straight lines through origin, and represented approximately by

$$\Phi=\Phi_0(\lambda)C/C_0 \qquad (3)$$

where $\Phi_0(\lambda)$ is the initial quantum efficiency for the photobleaching at the wavelength λ, obtained from the value of Φ at $C/C_0=1$ (Fig. 4) and shown in Fig.9 as a function of the wavelength. The value of $\Phi_0(\lambda)$ is about 0.4 at 700—1300 nm. It decreases with increasing wavelength above 1300 nm. From Eqs.1 and 3 we obtain

$$-\frac{\mathrm{d}C/\mathrm{d}t}{C}=(\ln 10)I\varepsilon\bar{Q}\Phi_0\frac{C}{C_0} \qquad (4)$$

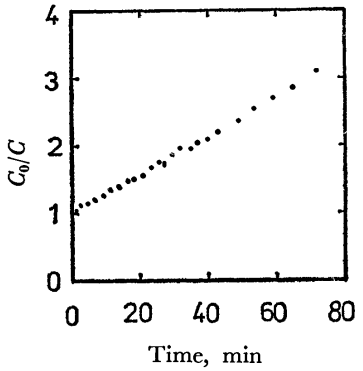

Fig. 5. Relation between C_0/C and time during photobleaching of e_t^- at $\lambda=700$ nm with slit width 1 mm (dose$=2.9\times10^{18}$ eV/g).

Since $\bar{Q}$ is regarded to be constant when either the concentration of e_t^- or the value ε is small, the solution of Eq. 4 is approximately given by

$$\frac{C_0}{C}=\Phi_0\left\{(\ln 10)I\varepsilon\bar{Q}t+\frac{1}{\Phi_0}\right\} \tag{5}$$

Substituting this into Eq. 3, we get

$$\Phi(t)=\left\{(\ln 10)I\varepsilon\bar{Q}t+\frac{1}{\Phi_0}\right\}^{-1} \tag{6}$$

The relation between C_0/C and time at wavelength 700 nm for small values of ε (Fig. 5) is in line with Eq. 5.

Since the time scale in the decay plots is influenced by both the light intensity and concentration of e_t^- (Figs. 1 and 2), we introduce a new variable T ($=\int(\ln 10)\,I\varepsilon\bar{Q}\,dt$). This is nearly proportional to t and experimentally approximated as

$$T=\sum_{j=1}^{n}(\ln 10)I\varepsilon\langle\bar{Q}\rangle_j\Delta t_j \tag{7}$$

where $C/C_0=1-j/10$ at t_j (j: integer), $\Delta t_j=t_j-t_{j-1}$, $\langle\bar{Q}\rangle_j$ is an average of $\bar{Q}$ between t_{j-1} and t_j. The exact solution of Eq. 4 is

$$\Phi(T)=\frac{1}{T+1/\Phi_0(\lambda)} \tag{8}$$

Thus the introduction of T gives a simple solution useful for the analysis of the results particularly in the presence of SF_6.

In the semilogarithmic decay plots (Fig. 6) of e_t^- in 3MHX containing SF_6, the γ-irradiation doses are controlled in order to obtain the same initial concentration of e_t^-. Although the natural decay of e_t^- in the dark is accelerated by the addition of SF_6, the slope is less than 5% of that of the photobleaching even at the highest concentration of SF_6. During photobleaching, the decay time at the same value of C/C_0 decreases with increasing concentration of SF_6, the decay curve becoming almost linear at high concentrations. Figure 7 shows Φ calculated from the slopes (Fig. 6) by means of Eq. 1. The efficiency is enhanced by the addition of SF_6. The decrement of Φ with decreasing C/C_0 is smaller in the presence than that in the absence of SF_6. At the same concentration of SF_6, Φ is smaller for high γ-irradiation

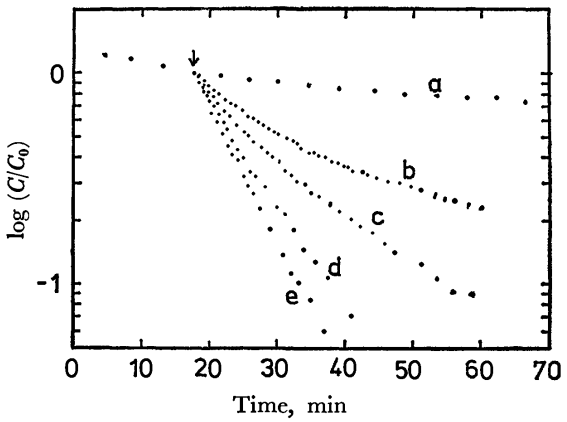

Fig. 6. The decay plots of log (C/C_0) against time in the dark and the decay due to photobleaching in the presence of SF_6 at $\lambda=900$ nm with slit width 0.7 mm: a) natural decay in the dark, $[SF_6]=9.7\times10^{-4}$ mol/l, irradiation dose$=5.6\times10^{18}$ eV/g, and the decay due to photobleaching, b) $[SF_6]=0$ mol/l, dose$=2.9\times10^{18}$ eV/g; c) $[SF_6]=1.7\times10^{-4}$ mol/l, dose$=2.1\times10^{18}$ eV/g; d) $[SF_6]=5.2\times10^{-4}$ mol/l, dose$=3.4\times10^{18}$ eV/g; e) $[SF_6]=9.7\times10^{-4}$ mol/l, dose$=7.7\times10^{18}$ eV/g. The initial concentrations of e_t^- (10^{-5} mol/l) are: a) 1.4; b) 3.8; c)d)e) 1.9. The arrow on the curve indicates the starting point of infrared irradiation.

doses than that for the lower doses.

The effect of the addition of SF_6 on the relation between Φ and T is shown in Fig. 8. The samples were γ-irradiated in the two series of doses at various concentrations of SF_6. Efficiency Φ decreases gradually with increasing T calculated by means of Eq. 7. In pure matrices the plots almost fit the solid line given by Eq. 8. The initial concentration of e_t^- is 3.8×10^{-5} mol/l in the series of high γ-irradiation doses, and 1.9×10^{-5} mol/l in the series of low γ-irradiation doses. At each concentration of SF_6, Φ observed in the series of high irradiation doses is smaller than that of the low irradiation doses. The dose dependence of γ-irradiation in the presence of SF_6 (Figs. 7 and 8) suggests that SF_6 decomposes and produces less reactive molecules than SF_6 in electron scavenging reactions.

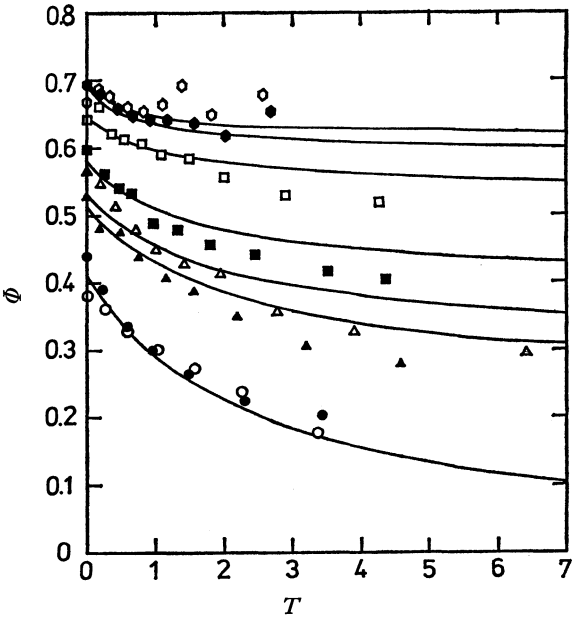

Fig. 8. Relation between Φ and T at $\lambda=1100$ nm in 3MHX containing various concentrations of SF_6 for various doses of γ-irradiation: ○● $[SF]_6=0$ mol/l, doses=1.4, 2.9×10^{18} eV/g; △▲ $[SF_6]=1.75\times10^{-4}$ mol/l, doses=2.3, 4.5×10^{18} eV/g; □■ $[SF_6]=5.2\times10^{-4}$ mol/l, doses=3.4, 6.9×10^{18} eV/g; ○● $[SF_6]=9.7\times10^{-4}$ mol/l, doses=7.7, 15.5×10^{18} eV/g. The initial concentration of e_t^- for the curves obtained by ○△□ and ○ is 1.9×10^{-5} mol/l, and for those by ●▲■ and ● 3.9×10^{-5} mol/l. The solid lines are the theoretical curves given by Eq. 13 when σ is 1, and b is selected to fit the experimental plots.

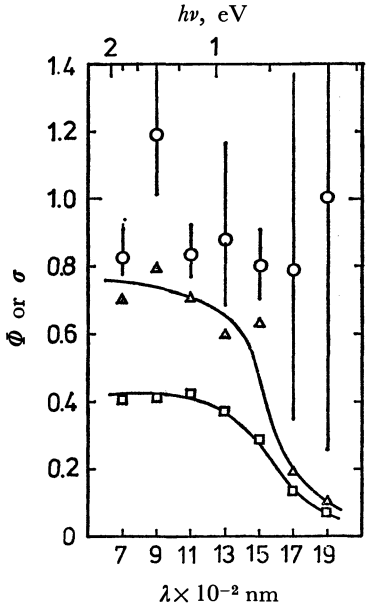

Fig. 9. Wavelength dependence of Φ or σ in the absence and presence of SF_6: □ Φ_0 in pure matrices, △ the initial value of Φ in the presence of SF_6 (9.7×10^{-4} mol/l); ○ σ obtained from the plots of Eq. 14.

The initial quantum efficiency for the decay of e_t^- is enhanced by the addition of SF_6 in the wavelength range 700—1900 nm (Fig. 9). At 700—900 nm, Φ becomes about 0.7 and can approach unity with increasing concentration of SF_6. At a wavelength greater than 1700 nm, the effect of the addition of SF_6 on the enhancement of Φ becomes less severe than that at shorter wavelength. It is difficult to know experimentally whether Φ approaches unity or not, since the ESR signal of e_t^- could not be observed at a high concentration of SF_6.

Discussion

The trapped electrons absorb the light in the infrared region and are liberated from the trapping sites in the following process.

$$e_t^- + h\nu \xrightarrow{\sigma} e_m^- \qquad (A)$$

where σ is the quantum efficiency of the primary photoliberation. Photo-liberated electrons or mobile electrons e_m^- move in matrices preceding neutralization with cations or preceding the retrapping into trapping sites (T.S.).

$$e_m^- + RH^+ \longrightarrow RH \qquad (B)$$

$$e_m^- + T.S. \xrightarrow{k_t} e_t^- \qquad (C)$$

Since the right term of Eq. 5 is independent of the initial concentration of e_t^-, the decay of e_t^- during photobleaching is a pseudo-second order process. The linear relation between C_0/C and time (Fig. 5) agrees with what is expected from Eq. 5. Since Φ_0 is not influenced by the change of initial concentration of e_t^-, the main part of the neutralization of e_t^- is geminate. The pseudo-second order processes depend probably on the probability distribution of the separation between e^-_t and cations. The main part of ion-pair separation should be smaller than the average ion-pair separation 230—600 Å, calculated from γ-irradiation doses assuming uniform distribution.

The relation between Φ and C, classified according to the type of neutralization, is given as a function of T in Table 1. The empirical relation of (2) represented by Eqs. 3 and 5 is applicable only to the non-polar hydrocarbon matrices.[1] Φ could be obtained as a function of C from the following factors characterizing the movement of electrons, *viz.*, the distribution of ion-pair separation, the range of Coulombic force of the parent cations and the mobility of e_m^-. The attractive force between electrons and cations pre-

Table 1. Φ as a function of C/C_0, and C as a function of T

2	geminate (intermediate attraction)	$\alpha C/C_0$	$(1+\alpha T)^{-1}$
3	geminate (weak attraction)	$\alpha C/C_0-\beta$; $C/C_0>\beta/\alpha$	$\left\{\frac{\alpha}{\beta}-\frac{\alpha-\beta}{\beta}\exp(-\beta T)\right\}^{-1}$
		0; $C/C_0<\beta/\alpha$	
4	random	αC	$(1+C_0\alpha T)^{-1}$

a) Classified according to the type of neutralization (see Appendix). b) α, β and m are constants.

scribed by the above factors might decrease in the order given. In (1) most of e_m^- is geminately neutralized and most of e_t^- can be easily photobleached. In (3), for a small concentration of ions, e_m^- escapes from a cation and cannot be neutralized randomly. In (4) random neutralization takes place because of uniform distribution of electrons and cations, the decay processes being of real-second order. The neutralization of e_m^- in a 2-methyltetrahydrofuran[3] glass is in an intermediate state between (3) and (4). (2) is distinguished from (4) by the role of C_0 in the equations. Experimentally the effect of γ-doses on Φ can differentiate the two types.

Diminution of Φ with the progress of photobleaching suggests that the neutralization process (B) decreases gradually as compared with the retrapping process (C). Since the rate of the geminate neutralization process is proportional to the probability density of e_m^- in the vicinity of the cations, and the position of e_t^- changes with repetition of photoliberation and reprapping, the gradual decrease of the role of recombination process may be caused by the gradual decrease of the probability density. A theoretical consideration is possible by means of prescribed diffusion approximation for an extended form[18] of the Smoluchowski equation.[19] In this approximation the rate of process (B) is given by KW, where K is a constant and W is the probability density of e_m^- in the vicinity of cations. The rate of process (C) is given by k_tS_t, where k_t is the rate constant and S_t is the concentration of the trapping sites. For the competition between (B) and (C), the quantum efficiency for the decay of e_t^- is given by

$$\Phi=\frac{\sigma KW(T)}{KW(T)+k_tS_t} \tag{9}$$

where $W(T)$ is a function of T, since the distribution of ion-pair separation changes with the progress of photobleaching. From Eqs. 8 and 9, we get

$$KW(T)=\frac{KW(0)}{(\sigma KW(0)/k_tS_t)T+1} \tag{10}$$

and

$$\frac{k_tS_t}{KW(0)}=\frac{\sigma}{\Phi_0}-1 \tag{11}$$

where k_t, K, σ, and Φ_0 are functions of λ.

In the presence of SF_6, the electron scavenging reaction competes with processes (B) and (C):

$$e_m^- + SF_6 \xrightarrow{k_s} SF_6^- \tag{D}$$

Since process (D) interrupts process (C), the value of Φ for a very large concentration of SF_6 might give the quantum efficiency σ. However, σ cannot be obtained by this method, since e_t^- is not formed at a very high concentration of SF_6. Efficiency Φ in the presence of SF_6 is given by

$$\Phi=\frac{\sigma(KW(T)+k_s[SF_6])}{KW(T)+k_tS_t+k_s[SF_6]} \tag{12}$$

Assuming that $KW(T)$ is given by Eq. 10 used in the case of pure 3MHX matrices, the following equations are obtained from Eqs. 10, 11 and 12:

$$\Phi(T)=\frac{(1-b/\sigma)^2}{T+1/\Phi_0-b/\sigma^2}+b \tag{13}$$

$$\frac{1}{b}=\frac{1}{\sigma}(1+k_tS_t/k_s[SF_6]) \tag{14}$$

The solid lines in Fig. 8 are given by Eq. 13 for the values of b selected to fit the plots at $\sigma=1$. Although the experimental data are scattered, the intercept of a straight line in plots of $1/b$ against $1/[SF_6]$ gives σ (Fig. 9). When σ is smaller than unity,

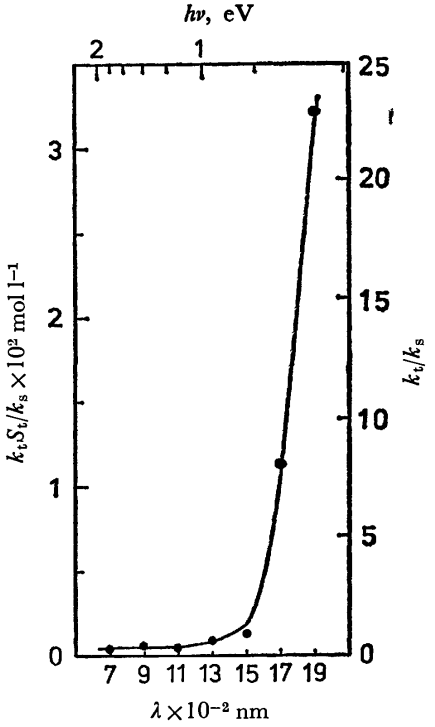

Fig. 10. Wavelength dependence of k_tS_t/k_s or k_t/k_s observed from the plots of Eq. 14 assuming that S_t is 1.4×10^{-3} mol/l.

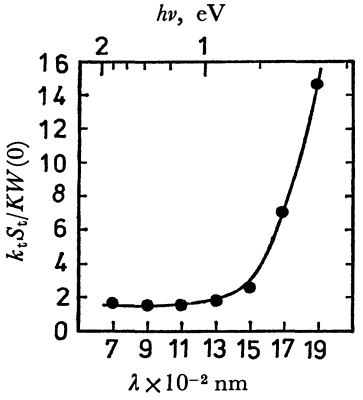

Fig. 11. Wavelength dependence of $k_tS_t/KW(0)$ estimated by means of Eq. 11.

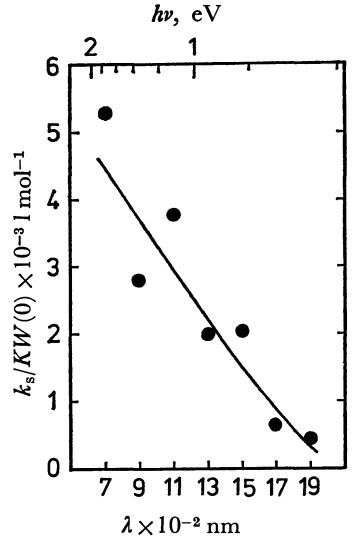

Fig. 12. Wavelength dependence $k_s/KW(0)$ calculated by means of Eq. 11 and the slope of the plots of Eq. 14.

Eq. 13 deviates from the plots to a greater extent than that at $\sigma=1$. Thus, σ might be about unity for wavelengths in the range 700—1900 nm.

Figure 10 shows the wavelength dependence of k_tS_t/k_s obtained from the slope of the straight line in the plots $1/b$ *vs.* $1/[SF_6]$. The minimum value of S_t is 1.4×10^{-3} mol/l which is estimated from the dose effect of γ-irradiation of the formation of e_t^-. The value of k_t/k_s is calculated by using this value of S_t. At a wavelength greater than 1500 nm, k_t/k_s becomes greater than that at a shorter wavelength. The value of $k_tS_t/KW(0)$ obtained from Eq. 11 becomes great at a wavelength greater than 1500 nm (Fig. 11). The value of $k_s/KW(0)$, calculated from the values of k_tS_t/k_s and $k_tS_t/KW(0)$, decreases gradually with increasing wavelength (Fig. 12). Because of a strong resemblance between Figs. 10 and 11, k_t increases markedly at a wavelength greater than 1500 nm. This wavelength dependence of k_t might show a relation between the translational energy of e_m^- and the track length of e_m^- from photoliberation to retrapping. The wavelength dependence of $k_s/KW(0)$ may be caused by the diffusion of e_m^- which separates electrons from cations.

The authors are gratefull to Professor Shoji Shida for his helpfull discussion.

Appendix

Calculation of Φ from the Decay Plot. During photobleaching, the concentration of e_t^-, C, decreases with time t. The rate of decay in a rectangular cell is given by

$$-\frac{dC}{dt}=\frac{I\Phi}{l}\{1-\exp(-\alpha lC)\} \tag{15}$$

where I is a light flux, $\alpha(=\varepsilon\ln 10)$ the extinction coefficient of e_t^-, Φ the quantum efficiency for the decay of e_t^- during photobleaching, and l the length of the cell. With the progress of photobleaching, the value of C at the inlet of light flux in the sample becomes smaller than that at the outlet, and the concentration becomes nonuniform. Equation 15 can be applied to this nonuniform sample by substituting the average concentration of e_t^- into C. The solution is found to be

$$\ln(\exp\alpha lC-1)=-I\int_{t_n}^{t}\Phi\alpha dt+\ln(\exp\alpha lC_n-1) \tag{16}$$

where C_n is the concentration of e_t^- at time t_n. Under conditions of a small αlC and a constant value of Φ, C is approximately given by exponential function:

$$C=C_n\exp\{-I\Phi\alpha(t-t_n)\} \tag{17}$$

For a large αlC, Eq. 16 is reduced to

$$C=-I\Phi(t-t_n)/l+C_n \tag{18}$$

At time t_n, Eq. 15 is given by

$$\left[\frac{d\ln C}{dt}\right]_{t_n}=-\frac{I\Phi\{1-\exp(-\alpha lC_n)\}}{lC_n} \tag{19}$$

which can be transformed into

$$\left[\frac{d\log C}{dt}\right]_{t_n}=-\varepsilon I\Phi Q \tag{20}$$

and

$$Q=\frac{1-\exp(-\alpha lC_n)}{\alpha lC_n} \tag{21}$$

In the case of a cylindrical tube, the parallel light flux is transmitted in the direction at right angle to the axis of the cylinder, and the length of light path is $l=2R\sqrt{1-y^2}$, where R is a radius of the cylinder. The effective Q is an averaged value such as

$$\bar{Q}=\int_{-1}^{1}Q\frac{2\sqrt{1-y^2}}{\pi}dy$$
$$=\frac{2}{\pi D\ln 10}\int_{-1}^{1}[1-\exp\{-D(\ln 10)\sqrt{1-y^2}\}]dy \tag{22}$$

where $D(=2\varepsilon C_nR)$ is the optical density of e_t^-.

Classification of the Geminate Reactions The experimental relation between Φ and C/C_0 can be classified as shown in Fig. 13. A speculative case given by curve (1) is expressed by

$$\Phi=\alpha(C/C_0)^{1/m},\quad m>1 \tag{23}$$

where the quantum efficiency of photobleaching is almost constant at the beginning of the photobleaching. Curve (1) corresponds to the photobleaching process of the trapped electrons, in narrow spatial distribution, in strong Coulombic field of parent ions and in weak diffusional movement. Curve (2) is given by

$$\Phi=\alpha(C/C_0) \tag{24}$$

The quantum efficiency of photobleaching is proportional to the value of C/C_0 as shown in Fig. 3. Curve (2) is observed

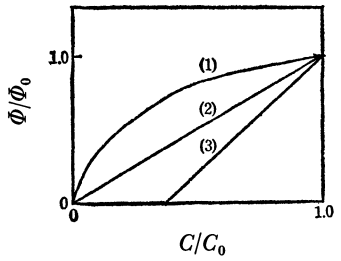

Fig. 13. Relation between Φ/Φ_0 and C/C_0 for the various types of geminate reaction: curve (1) strong attraction; curve (2) intermediate attraction; curve (3) weak attraction.

in the photobleaching process of the trapped electrons in nonpolar materices. Curve (3) can be written as

$$\Phi = \alpha(C/C_0) - \beta, \qquad C/C_0 > \beta/\alpha \qquad (25)$$
$$\Phi = 0, \qquad C/C_0 < \beta/\alpha$$

The quantum efficiency of photobleaching decreases with decreasing value of C/C_0 and becomes zero at a finite value of C/C_0. Therefore, as in the case of the neutralization in 2-methyltetrahydrofuran glass[3], it is difficult to observe a complete photobleaching. The functions in the last column of Table 1 can be obtained by integrating Eqs. 23—25.

Some Remarks on the Reaction Mechanism and Kinetic Rate Constants for the Pentacyanocobaltate(II)-catalyzed Hydrogenation of Olefins Using the Iterative Simulation Technique

Katsutoshi OHKUBO, Kohji TSUCHIHASHI, Hiromichi IKEBE, and Hiroyuki SAKAMOTO

Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860

(Received March 11, 1974)

The reaction mechanism and kinetic-rate constants of the pentacyanocobaltate(II)-catalyzed hydrogenation of olefins were investigated. The present study with an iterative simulation technique supported the $Co(CN)_5^{3-}+H_2 \rightarrow Co(CN)_5H^{3-}+H\cdot$ and $Co(CN)_5^{3-}+H\cdot \rightarrow Co(CN)_5H^{3-}$ reactions for the uptake of H_2 by the cobaltate(II) during the initial stage of the reaction. An examination was also made of the stationary-state approximation used for the kinetic analysis of the reaction.

It is well known that pentacyanocobaltate(II) takes part in the reductive cleavage of covalent molecules:

$$2Co(CN)_5^{3-} + X\text{–}Y \rightarrow Co(CN)_5X^{3-} + Co(CN)_5Y^{3-} \quad (1)$$

where X–Y means such molecules as H_2,[1–5] H_2O,[2] Br,[6] I_2[6] H_2O_2,[7] $HONH_2$[8] ICN,[8] and organic halides.[9–11]

In the hydrogenation of olefins (denoted as A) with $Co(CN)_5^{3-}$, the molecular hydrogen has been considered, on the basis of the kinetic investigations,[4,12] to participate in the formation of hydropentacyanocobaltate(III), $Co(CN)_5H^{3-}$, through Reaction (2):

$$2Co(CN)_5^{3-} + H_2 \xrightarrow{k_1} 2Co(CN)_5H^{3-} \quad (2)$$

Reaction (2) is followed by:

$$Co(CN)_5H^{3-} + A \xrightarrow{k_2} Co(CN)_5^{3-} + AH\cdot \quad (3)$$

$$Co(CN)_5H^{3-} + AH\cdot \xrightarrow{k_3} Co(CN)_5^{3-} + HAH \quad (4)$$

where AH· and HAH denote a momentarily living radical intermediate and a saturated hydrocarbon respectively.

Although the mechanism expressed by Reactions (2—4) (named Mechanism I) has hitherto been accepted as the most plausible one for the $Co(CN)_5^{3-}$-catalyzed hydrogenation of olefins, the following mechanism (named Mechanism II) can also be considered in view of the fact that the uptake of H_2 by $Co(CN)_5^{3-}$ is between first- and second-order in cobalt from 0 to 25 °C[13] and that $Co(CN)_5^{3-}$ takes part in the reductive cleavage of such X–Y as organic halides by the two-step reaction ($Co(CN)_5^{3-}+X\text{–}Y \rightarrow Co(CN)_5X^{3-}+Y\cdot$ and $Co(CN)_5^{3-}+Y\cdot \rightarrow Co(CN)_5Y^{3-}$):

$$Co(CN)_5^{3-} + H_2 \xrightarrow{k_1} Co(CN)_5H^{3-} + H\cdot \quad (5)$$

$$Co(CN)_5^{3-} + H\cdot \xrightarrow{k_2} Co(CN)_5H^{3-} \quad (6)$$

$$Co(CN)_5H^{3-} + A \xrightarrow{k_3} Co(CN)_5^{3-} + AH\cdot \quad (7)$$

$$Co(CN)_5H^{3-} + AH\cdot \xrightarrow{k_4} Co(CN)_5^{3-} + HAH \quad (8)$$

Reactions (5, 6) indicate a first-order dependence on cobalt for the formation of $Co(CN)_5H^{3-}$, which corresponds to $[Co^{II}(CN)_5(\cdot H)]^{3-}$ rather than $[Co^{III}(CN)_5(:H)]^{3-}$.[14]

In Reaction (6), the highest singly-occupied d_{z^2} Co-orbital (at -11.01 eV)[15] of $Co(CN)_5^{3-}$ seems to play an important role in the reaction with the H radical.

In this paper, we will discuss the reaction mechanism and rate constants for the $Co(CN)_5^{3-}$-catalyzed hydrogenation of olefins on the basis of Mechanisms I and II, using an iterative simulation technique involving least-squares error analysis.

Computation Method

The rate constants in systems of nonlinear differential equations such as those derived from Reactions (2—4) or (5—8) can be estimated by means of such numerical integration methods as the Runge-Kutta integration,[16] the Marquardt method,[17] and Taylor's series expansions.[18] These methods, however, require very dense data, much computation time, and highly developed mathematical techniques to estimate the rate constants directly. Therefore, we will use an iterative simulation technique combined with the least-squares error analysis in the present paper. Here, we will briefly describe the present technique.

The differential equations (rate equations) can be simply expressed on the basis of the law of mass action as:

$$d(C_s)/dt = f(k_i, (C_r))$$

where (C_s) and (C_r) denote the concentrations of C_s (s=species number) and C_r (r=species number) respectively, and where $f(k_i, (C_r))$ means a function made by the rate constants, k_i ($i=1-3$ or $1-4$ for Mechanism I or II respectively) and (C_r). The reaction increments of (C_s), $D(C_s)$, are shown with a very short time interval, Δt[19]:

$$D(C_s) = f(k_i, (C_r))\Delta t \quad (10)$$

The concentrations of C_s at the reaction time of t, $(C_s)_{t,\mathrm{calcd}}$, are evaluated by means of the trapezoidal average method:[20]

$$(C_s)_{t,\mathrm{calcd}} = (C_s)_0 + \sum^{n} D(C_s)_{\mathrm{av}}\Delta t \quad (n\Delta t = t) \quad (11)$$

where $(C_s)_0$ and $D(C_s)_{\mathrm{av}}$ indicate the initial concentrations and the average increments of C_s respectively.

In the evaluation of the $(C_s)_{t,\mathrm{calcd}}$ values, the rate constants, k_i, are inserted into Eq. (11) in accordance with our previous technique:[17,19]

$$k_i = \min k_i + \sum^{m} 10^{(\gamma-\beta)} \min k_i,\ \gamma = \mathrm{gauss}\left[\frac{m-1}{9\alpha}\right] \quad (12)$$

$$(m=1,2,\cdots\cdots;\ \beta=0,1,2,\cdots\cdots;\ \alpha=10)$$

where the notations have the same meanings as those in previous papers.[19,21]

in order to check the reliability of the selected best set of k_i. We will simulate the time-dependence of the hydrogen absorption in both the mechanisms with the following different initial specifications: $(Co(CN)_5^{3-})_0=0.005$ M and $(A)_0=0.20$ M. The simulation results are shown in Fig. 1. As can be seen from Fig. 1, the predicted $(H_2)_{t,absd}$ curves for Mechanism II accord more satisfactorily with the observed $(H_2)_{t,absd}$ curves than those for Mechanism I.

It is of interest here to notice the time conversions of the concentrations of species participating in Mechanism II. From the time conversions of the species shown in Fig. 2, we can observe that the concentrations of the H and AH radicals ($(H\cdot)/(AH\cdot)\simeq 10$) seem to be relatively high despite their momentary lives, in comparison with those of $Co(CN)_5H^{3-}$ and HAH; the $(H\cdot)$ and $(AH\cdot)$ values are almost constant at $t\gtrsim 10$ min. Under these conditions, it seems that the stationary-state approximation can be used for the concentrations of both the intermediates. Then, we will test the stationary-state approximation in order to estimate the rate constants in Mechanism II. From the rate equations (differential equations) derived from Eqs. (5—8) and (16a, b), the rate of H_2 absorption, $R_{t,calcd}$, can be expressed by the following kinetic relationships:

$$R_{t,calcd} = d(H_2)_{t,absd}/dt = ae^{-2at}((Co(CN)_5^{3-})_0-b/a) - k_1(H_2)be^{-2at}/a+k_1(H_2)(A)(Co(CN)_5^{3-})_0/a \quad (17)$$

$$(H_2)_{t,absd} = (1-e^{-2at})((Co(CN)_5^{3-})_0-b/a)/2 + k_1k_3(H_2)(A)(Co(CN)_5^{3-})_0t/a + k_1(H_2)b(e^{-2at}-1)/2a^2 + k_1(H_2)/2k_2+k_3(A)/2k_4 \quad (18)$$

where $a=k_1(H_2)+k_3(A)$ and $b=k_3(A)(Co(CN)_5^{3-})_0$.

Let us estimate the k_1 and k_3 values in Eq. (17) by means of the present technique under the following condition:

$$F' = \text{minimize}\sum_{p=1}^{p}\varepsilon_p' = \text{minimize}|R_{t,calad}-R_{t,given}|^2 \quad (19)$$

where $R_{t,calcd}$ and $R_{t,given}$ indicate the calculated and observed rates of H_2 absorption respectively.

The above procedure gave $k_1=1.0\times10^{-3}$ and $k_3=1.0\times10^{-1}$ M^{-1} s^{-1} as the best set of rate constants, appreciably different from those ($k_1=1.2\times10^{-3}$ and $k_3=2.4\times10^{-3}$ M^{-1} s^{-1}) shown in Table 1. The computer simulations with the sets of both k_1 and k_3 values obtained by means of Eq. (17) indicate that the former set of rate constants gives a more precise fit to the $R_{t,given}$ values than the latter one. However this is not a surprising phenomenon for the following reasons: (a) strictly speaking, the concentration of neither radical intermediate is constant; (b) the stationary-state approximation which neglects the rate constants of k_2 and k_4 (not extremely large rate constants) may bring about the apparent difference between the k_3 values mentioned above, and (c) the $R_{t,calcd}$-value evaluation by means of Eq. (17), derived from the stationary-state approximation with only the set of k_1 and k_3 values for Mechanism II (see Table 1), cannot give an accurate time-conversion of the H_2 absorption rate. This discussion is reasonable if we notice that the $(H_2)_{t,absd}$ values obtained from the present simulation with $k_1=1.0\times10^{-3}$, $k_2=1.0$, $k_3=1.0\times10^{-1}$, and $k_4=1.0\times10^2$ M^{-1} s^{-1} are very small compared with the observed values. Furthermore, Eq. (18) brings about somewhat large $(H_2)_{t,absd}$ values under $k_1=1.0\times10^{-3}$, $k_3=1.0\times10^{-1}$, and $k_4=1.0\times10^2$ M^{-1} s^{-1} (Eq. (18) excludes k_2), while the simulation with the best set of k_i ($i=1$—4) values for Mechanism II indicates satisfactorily precise fits to the experimental results. It may be deduced, therefore, that the kinetic analysis by means of the present iterative simulation technique, which does not include any stationary-state approximation, gives more reliable information about the unknown rate constants in elementary reactions.

Table 1. The best sets of rate constants and the least-squares error for Mechanisms I and II

Mechanism I	Mechanism II
$k_1=1.3\times10^{-1}$ M^{-1} s^{-1}	$k_1=1.2\times10^{-3}$ M^{-1} s^{-1}
$k_2=9.0\times10^{-4}$	$k_2=1.0$
$k_3=1.0\times10^2$	$k_3=2.4\times10^{-3}$
	$k_4=1.0\times10^2$
$\varepsilon_p=7.121\times10^{-11}-2.837\times10^{-7}$ M^2	$\varepsilon_p=6.713\times10^{-12}-2.360\times10^{-8}$ M^2
$F=1.466\times10^{-6}$ M^2	$F=1.345\times10^{-7}$ M^2

In conclusion, we have demonstrated that, in the $Co(CN)_5^{3-}$-catalyzed hydrogenation of olefins, the two-step reaction of the complex and molecular hydrogen may play an important role in the formation of hydropentacyanocobaltate(III), especially during the initial reaction state.

The calculations were carried out on a FACOM 230—60 computer at the Data Processing Center of Kyushu University.

Electronic Structures of Excited States of Benzoquinolines[1)]

Hiroyuki YAMAGUCHI, Teruki IKEDA, and Hiroaki MAMETSUKA
Department of Chemistry, Kumamoto University, Kumamoto 860

(Received May 2, 1974)

Measurements of the dipole moments and acidity constants in the lowest excited singlet states for benzo[*c*]quinoline, benzo[*f*]quinoline, and benzo[*h*]quinoline have been carried out by spectrophotometry. The electronic structures of excited states have been calculated by using the semi-empirical SCF–π–MO CI method, which allows for a bond order-bond length relationship at each iteration. The experimentally-determined dipole moments and acidity constants can not be correlated to the calculated electronic structures of the Franck-Condon states, but they can be correlated to the calculated structures of the equilibrium states for the lowest excited singlet states of three isomeric benzoquinolines.

Many phenomena occurring in the electronically-excited states of molecules, such as photochemical reactions, are dependent on the changes in the electronic structures. Electronic excitation in molecules leads to a new electron density distribution and, consequently, to changes in the dipole moment and in the reactivity. For example, aminonaphthalenes, which are weak bases in the ground state, lose their basic properties in the lowest excited-singlet state and become weak acids, dissociating in alkaline solutions.[2)] Furthermore, some unusual photochemical reactions of aromatic substitution seem to correlate with the electron-density distribution in the excited states.[3,4)] Numerous quantitative data are already known on the protolytic equilibria[5)] and on the dipole moments[6)] of molecules in their excited states. A comparison of the two sets of experimental data has, however, been done only exceptionally from the point of view of the electron-density distribution in the excited molecules.[7)]

It is the purpose of this paper to determine experimentally the acidity constants and dipole moments in the lowest excited singlet states of benzo[*c*]quinoline (I), benzo[*f*]quinoline (II), and benzo[*h*]quinoline (III) and to investigate the possible correlation between the experimental results and the theoretical π-electron indices.

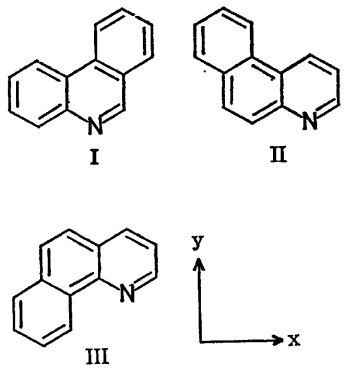

Fig. 1. Numbering of benzoquinolines and choice of axes.

Experimental

Materials. Substance I was obtained from the Dōjindō Chemicals Co. It was purified by recrystallization from light petroleum and by subsequent sublimation *in vacuo*.[8)] II and III were purchased from the Tokyo Kasei Co. According to the procedure described by Kanda and Shimada,[9)] the purification was done in the same way for both compounds. The solvents used were carefully purified according to the descriptions in Ref. 10.

Measurements. The dielectric constants were determined with a home-made resonance-method apparatus which used the electric circuit reported by Nakagawa.[11)] A dielectric-constant-measurement cell with cylindrical platinum electrodes was used. The refractive indices were measured by means of a Pulfrich refractometer. The static dielectric constant (ε) and the refractive index (n_D) at the sodium D line of the solvents agreed with the values cited in Ref. 10. The densities of the solutions were measured by the use of a pycnometer[12)] for volatile liquids.

The absorption spectra were measured with a Hitachi EPS-3T spectrophotometer. The fluorescence spectra were recorded on a Shimadzu RF-502 spectrophotometer. The wave numbers of the emission-band maxima were determined from the emission spectra, as corrected for the spectral sensitivity of the instrument. The concentration of I, II, and III was kept less than 10^{-5} mol/l for all solutions prepared, so that the system was free from any undesired concentration quenching. The measurements were made on deaerated samples at 20 °C.

Calculation

The method used in predicting the energetically most favorable nuclear arrangement for an electronically-excited state of a conjugated molecule, which is assumed to be planar, is a modified version[13)] of the semi-empirical SCF MO CI method used in combination with the variable bond-length technique, which has proved to be quite successful in predicting the ground-state electronic structures of a variety of conjugated molecules.[14)]

Assuming a certain nuclear arrangement for a conjugated molecule, we carry out the SCF MO CI calculation in the framework of the Pariser-Parr-Pople approximation.[15,16)] Using the wave function for an excited state obtained after the inclusion of the configuration mixing all the singly-excited states, we then calculate the bond length for the excited state by the aid of a suitable bond order-bond length relationship (*vide infra*). The new nuclear arrangement is taken as the geometrical structure for the next SCF MO calculation, and the process is repeated until the bond lengths for the excited state converge.

The one-center repulsion integrals were found from the corresponding valence-state ionization potentials, (W), and electron affinities, (E), by the Pariser-Parr method,[15)] the W and E being determined from the

spectroscopic data using the promotion energies of Hinze and Jaffé.[17] The two-center repulsion integrals were estimated by using the Mataga-Nishimoto method.[18]

Resonance integrals were included only between nearest neighbors. These resonance integrals were estimated by using the Wolfsberg-Helmholtz overlap approximation:[19]

$$\beta_{\mu\nu} = -0.5K_{\mu\nu}(W_\mu + W_\nu)S_{\mu\nu} \quad (1)$$

where the overlap integral, S, was calculated from Roothaan's formulas[20] using the effective nuclear charges of 3.25 and 3.90 for carbon and nitrogen respectively.

Only the nearest-neighbor two-center integrals were allowed to change, using a bond distance calculated by the aid of this relationship:

$$r_{\mu\nu} = \alpha - 0.186p_{\mu\nu} \quad (2)$$

where p is the π-bond order. The nonbonded distances were calculated assuming the ring to be regular and were kept constant for the sake of simplicity.

The values of K in Eq. (1) and α in Eq. (2) were determined as follows.

C–N Bond. The best value of K for the C–N bond was determined from the β value so adjusted that the theoretical excitation energies and intensities of the reference molecule, *s*-triazine,[21,22] which were calculated using a bond distance obtained by the X-ray technique[23] in the framework of the SCF MO CI method, might reproduce the experimental excitation energies and intensities of this molecule. We thus obtained $K=0.97$. From the bond order of the C–N bond that was calculated by using the best value of K obtained by means of the SCF MO CI method, the bond order-bond length relationship for this bond was determined. This procedure yielded $\alpha=1.459$ Å.

C–C Bond. The value of α which had been proposed by Nakajima and Katagiri,[24] was used. The value of K for this bond was determined from the value so adjusted as to reproduce the experimental excitation energies of such reference molecules as butadiene and naphthalene.[25–27] We thus obtained $K=0.85$.

Using these values for K and α, we calculated the transition energies and intensities of pyridine and pyrazine. The calculated transition energies and intensities of these molecules are in good agreement with the experimental values.[28,29]

The dipole moments of the ground and excited states for I, II, and III are calculated by using the moment due to the C–N localized bonds, 1.77 D,[30] and the C–H moment, 0.4 D.[31]

Results and Discussion

Ground-state Dipole Moments, $\vec{\mu}_0$. The dipole moment, $\vec{\mu}_0$, of I has already been measured in benzene solutions.[8] The dipole moments, $\vec{\mu}_0$, of II and III were measured in carbon tetrachrolide by the use of the ordinary Halverstadt-Kumler method.[32] The molecular refractions, $[R_L]_D$, were obtained from this expression: $[R_L]_D=M[r_2+(r_{12}-r_2)/\omega_1]$. Here, ω_1 is the weight fraction of the solute, whose molecular weight is M, and r_2 and r_{12} are the specific refractions of the solvent and the solution respectively. These results are summarized and compared with the calculated results in Table 1. The predicted values agree well with the experimental values.

Table 1. Ground-state dipole moments $\vec{\mu}_0$ and molecular refractions $[R_L]_D$ of benzoquinolines

Molecule	$[R_L]_D$ (cm^3)	μ_0 (D)[a]	
		Calcd	Obsd
I	60.82[b]	2.74 (75°)	2.39[b]
II	60.51[c]	2.52 (93°)	2.19[c]
III	60.32[c]	2.28 (91°)	1.81[c]

a) Numbers in parenthesis represents the angle that the dipole moment makes with X-axis in the counter-clockwise sense in the coordinate system of Fig. 1. b) Measured in benzene. See Ref. 8. c) Measured in carbon tetrachloride.

Excited-state Dipole Moments, $\vec{\mu}_1$. The difference between the dipole moments in the lowest singlet excited state ($\vec{\mu}_1$) and the ground state ($\vec{\mu}_0$), $|\Delta\vec{\mu}_1| = |\vec{\mu}_1-\vec{\mu}_0|$, can be estimated by measuring the wave numbers of the band maxima of the fluorescence (ν_f^m) and the absorption (ν_a^m) spectra in various solvents and by using the following equation:[33]

$$\nu_a^m - \nu_f^m = \text{Const.} + F(\varepsilon, n_D)\delta$$
$$F(\varepsilon, n_D) = \frac{\varepsilon-1}{\varepsilon+2} - \frac{n_D^2+1}{n_D^2+2} \quad (3)$$
$$\delta = \frac{2|\Delta\vec{\mu}_1|^2}{a^3hc}$$

where a is the cavity radius in Onsager's theory[34] of the reaction field.

The observed $(\nu_a^m-\nu_f^m)$ *versus* $F(\varepsilon,n_D)$ relations are shown in Figs. 2, 3, and 4. The straight lines in the figures were obtained by the least-squares method. The $\Delta\vec{\mu}_1$ values for I, II, and III were determined by using the slopes (A) of these lines.

These results are summarized and compared with the theoretical results in Table 2. Table 2 shows that the difference between the dipole moments for the equilibrium state of the lowest singlet excited state ($\vec{\mu}_E$) and for the ground state ($\vec{\mu}_0$), $|\Delta\vec{\mu}_E| = |\vec{\mu}_E-\vec{\mu}_0|$, is in better agreement with the experimental $|\Delta\vec{\mu}_1|$ value than the difference between the dipole moments for the Franck-Condon state of the lowest excited state ($\vec{\mu}_F$) and for the ground state, $|\Delta\vec{\mu}_F| = |\vec{\mu}_F-\vec{\mu}_0|$. This agreement of the experimental and computed results on the dipole moments indicates a good approximation of the electronic structures for the equilibrium states of the lowest singlet excited states.

Excited Singlet-state Acidity Constants. The pK_a values in the ground states (S_0) were previously meas-

a) Numbers in parenthesis represent the angle that the dipole moment makes with the positive X-axis in the counterclockwise sense in the coordinate system of Fig. 1. b) Estimated from the apparent molal volume ϕ_v. The ϕ_v is defined by the relation, $\phi_v = 1000(d_2 - d_{12})/(m_1 d_2 d_{12}) + M_1/d_{12}$, where d_2 and d_{12} are the densities of the solvent and the solution of molality m_1 of the solute having molecular weight M_1, respectively. c) Estimated from the tabulated data of Ref. 8. d) Measured in carbon tetrachloride.

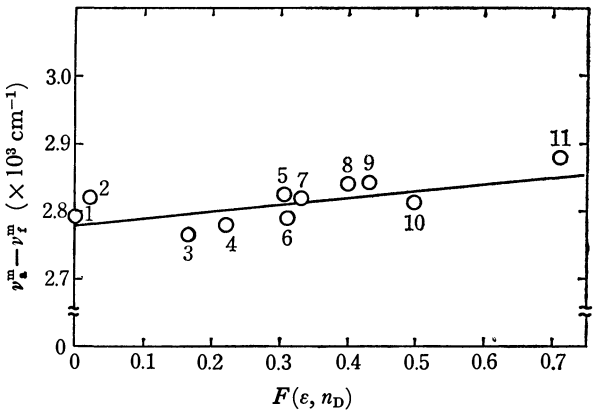

Fig. 2. The plot of $(\bar{\nu}_a^m - \bar{\nu}_f^m)$ against $F(\varepsilon, n_D)$ for benzo[*c*]quinoline. Here numbers denote the solvents as (1): cyclohexane, (2): carbon tetrachloride, (3): *n*-butyl ether; (4): anisole, (5): isoamyl acetate, (6): ethyl ether, (7): *n*-butyl acetate, (8): ethyl acetate, (9): methyl acetate, (10): benzonitrile, (11): acetonitrile.

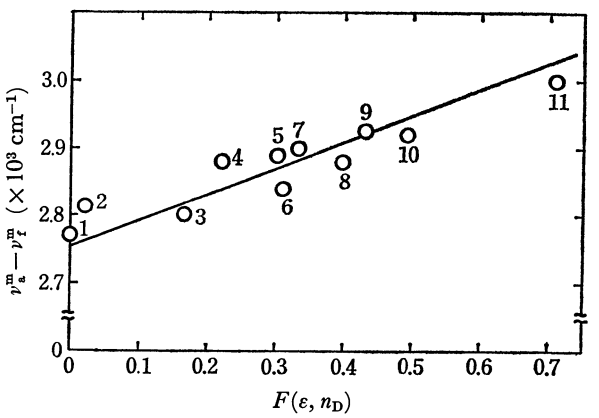

Fig. 3. The plot of $(\bar{\nu}_a^m - \bar{\nu}_f^m)$ against $F(\varepsilon, n_D)$ for benzo[*f*]quinoline. The numbers are the same as described in Fig. 2.

ured at 20 °C in an aqueous ethanol solution (50 vol. percent ethanol solution).[35)] The pK_a (S_1) values were estimated by means of the Förster cycle, as in the following relation:[2)]

$$pK_a(S_0) - pK_a(S_1) = \frac{\Delta E_{HB} - \Delta E_B}{2.303\,RT} \qquad (4)$$

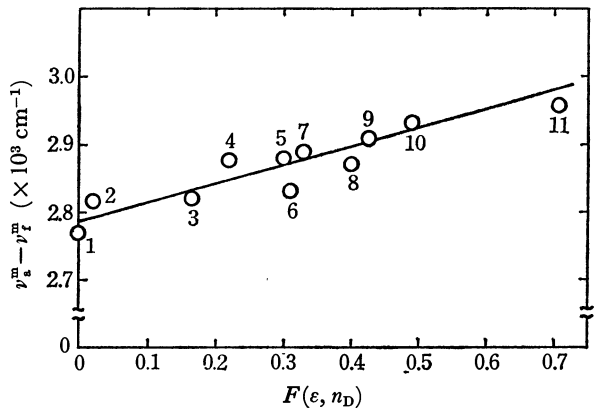

Fig. 4. The plot of $(\bar{\nu}_a^m - \bar{\nu}_f^m)$ against $F(\varepsilon, n_D)$ for benzo[*h*]quinoline. The numbers are the same as described in Fig. 2.

where ΔE_{HB} and ΔE_B are the energy differences between the ground and excited states of the protonated and unprotonated molecules respectively. The p$K_a(S_0)$ and p$K_a(S_1)$ denote the pK_a values in S_0 and the excited state (S_1) respectively. R and T are the gas constant and the absolute temperature respectively. In the present work, the energy difference between the S_0 and S_1 states was evaluated by means of the absorption and fluorescence spectra.

The absorption and fluorescence spectra of I, II, and III and of their conjugated acids were measured at 20 °C in an aqueous ethanol solution (50 vol. percent ethanol solution) for the unprotonated molecules (B) and in an aqueous ethanol solution with sulfuric acid added for the protonated molecules (BH^+). In Table 3, the p$K_a(S_1)$ values obtained by the application of the Förster cycle are collected, along with the pK_a (S_0) values.

It has been shown that there is a good correlation between the pK_a value of heterocyclic molecules containing a nitrogen atom and the electron density (q_N) of the atom.[36)] In a series of molecules where the molecular skeleton changes, the relation between pK_a and q_N is much less direct. Besides q_N, the interactions with all the π-electron charges, located at various distances from the reactive center, also influence the pK_a values.[37,38)] A large q_N value may be compensated for by the influence of positive charges located on neighboring carbon atoms. For the ground

Table 4. Calculated electron densities (q_N) and interaction terms ($\sum_p Q_p(l_N l_N|pp)$) (eV) of various states

Molecule	S_0 state		S_1 state			
			Frack-Condon		Equilibrium	
	q_N	$\sum_p Q_p(l_N l_N\|pp)$	q_N	$\sum_p Q_p(l_N l_N\|pp)$	q_N	$\sum_p Q_p(l_N l_N\|pp)$
I	1.234	−1.71	1.285	−2.28	1.262	−2.01
II	1.238	−1.73	1.280	−2.27	1.260	−2.05
III	1.237	−1.70	1.288	−2.33	1.263	−2.07

state, Nakajima and Pullman[37] have proposed this relationship between the pK_a values and the interactions:

$$pK_a \propto \sum_p Q_p(l_N l_N|pp) + \text{Const.} \quad (5)$$

In Eq. (5), Q_p is the formal charge on the p atom and $(l_N l_N|pp)$ is the Coulomb repulsion integral between the lone-pair electrons of the nitrogen atom and the π-electron on the p atom. The $(l_N l_N|pp)$ integral was calculated from Roothaan's formulas[20] using the effective nuclear charges of 3.25 and 3.90 for carbon and nitrogen respectively.

The calculated q_N and $\sum_p Q_p(l_N l_N|pp)$ values for the S_0 and S_1 states are listed in Table 4. From Tables 3 and 4, no relationship can be found between the q_N and the variation in the pK_a values of both the states. In the S_0 state and the equilibrium state of the S_1 state, however, it seems that there is a good correlation between the pK_a value and the first term in Eq. (5) for both the states. Such a correlation can not be found in the Franck-Condon state of the S_1 state.

One of the present authors (H.Y.) especially wishes to thank Professor Takeshi Nakajima of Tohoku University for his helpful discussions and encouragement. Throughout this work, a FACOM 230—60 computer of the Kyushu University Computer Center was used. The investigation was supported in part by a Scientific Research Grant from the Ministry of Education.

a) 65—100 mesh

magnesium iodide and the successive-ignition-loss method. On analysing active hydrogen by means of Zerewitinoff's method, 0.2—0.5 g of a finely divided solid sample was evacuated in a small ampoule at elevated temperatures for 4 hr, sealed off *in vacuo*, and allowed to react with methylmagnesium iodide at 25 °C after breaking the ampoule in a *n*-butylether solution containing the Grignard reagent. The amount of methane gas evolved was measured by means of a gas burette. In the measurement of water content by means of the successive-ignition-loss method, the amount of water vapor expelled by heating at successively elevated temperatures was measured volumetrically; the water content in a sample treated at a certain temperature was obtained by summing up the amounts of water vapor expelled at temperatures higher than that indicated.

Measurement of Surface Area and Porosity. The adsorption-desorption isotherms of nitrogen were determined for each sample at the temperature of liquid nitrogen. The specific surface area was computed by applying the BET method to the nitrogen adsorption isotherm in the relative pressure range 0.05—0.30, in which the cross-sectional area of a nitrogen molecule was assumed to be 16.2 Å^2.

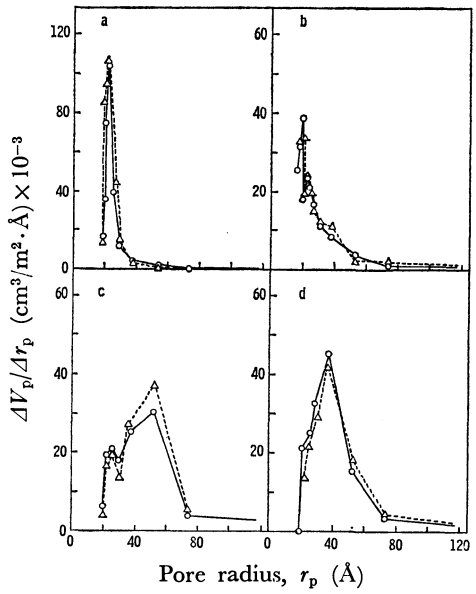

Fig. 2. Pore size distribution curve of porous silica glass (a), silica gel (b), alumina (c), and silica-alumina (d). Solid and broken lines indicate the values on the sample trated at 100° and 800 °C respectively.

The adsorption isotherms of nitrogen and the calculated specific surface area are shown in Fig. 1 and Table 1, respectively.

The porosity of the samples was calculated by applying the Kelvin equation to the desorption branch in the nitrogen isotherms,[18] where a correction for the thickness of the adsorbed layer on the walls was carried out by the method used by Clanston and Inkley.[19] The pore size distribution curves thus calculated for four samples except for Aerosil are illustrated in Fig. 2; the latter sample may be considered to have no pores in the sense of "transitional" range of Dubinin[18] because of the absence of hysteresis (Fig. 1). In Fig. 2 it can be seen that porous silica glass and silica gel have considerably small pores, both distribution curves exhibiting peaks at radii 22 and 19 Å, respectively; the latter has a broader distribution of pores than the former. The pores in alumina and silica-alumina are larger than those in the two kinds of silicas stated above, the distribution curves representing peaks at 53 and 37 Å, respectively. The pore volume can be calculated by assuming the saturated value in nitrogen adsorption isotherms of Type IV to correspond to the amount of nitrogen condensed in the pores (Table 1).

Results and Discussion

Reaction Rate of Methylmagnesium Iodide. One molecule of methylmagnesium iodide reacts with one hydroxyl group or physisorbed water molecule to liberate one molecule of methane gas.[16] The amount of methane gas evolved from one gram of metal oxides is plotted against time (Fig. 3). We see that the evolution of methane gas is rapid in the case of Aerosil, and stops in *ca.* 20 min (Fig. 3a). The reaction is extremely slow on the surface of porous silica glass, being completed after 17 hr (Fig. 3b). The results for two kinds of porous silica glass samples having different particle sizes (65—100 and 270<mesh) are essentially the same. In the case of silica gel, the rate of reaction is as slow as that on porous silica glass (Fig. 3c). In alumina and silica-alumina (SA-50), the liberation of methane gas proceeds at a

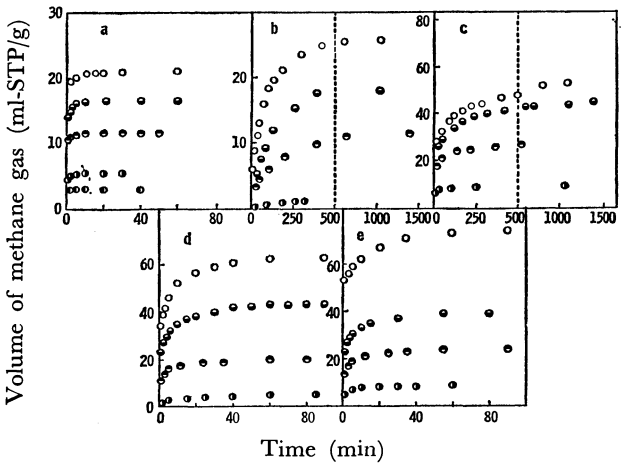

Fig. 3. Reaction of CH_3MgI with active hydrogen on Aerosil-200 (a), porous silica glass (65—100 mesh) (b), silica gel (c), alumina (d), silica-alumina (SA-50) (e); pretreatment temperature, ○: 100°, ◒: 300°, ◓: 500°, ◑: 800°, ◐: 1000 °C.

moderate rate, and ends in *ca.* 60 min (Figs. 3d and e).

A comparison of Figs. 1, 2 and 3 shows that the reaction rate of methylmagnesium iodide is closely related to the pore size distribution of metal oxides. In Aerosil samples, in which no hysteresis appears in the adsorption isotherm, the reaction is completed very rapidly (20 min), while in those having small pores the completion for the reaction requires a longer time. It takes about 60 min on alumina and silica-alumina having a peak at radii 53 and 37 Å, respectively, and about 1000 min on porous silica glass and silica gel having a peak at radii 22 and 19 Å, respectively. We can thus conclude that the rate of reaction of methylmagnesium iodide with active hydrogen on metal oxides is determined by the diffusion of the reagent into pores. The time required for the completion of the reaction gives a measure for the porosity of powders.

Dependence of Water Content upon the Nature and Origin of Samples. The water content obtained from the extreme value of methane gas evolved (Fig. 3) is plotted against pretreatment temperature (Figs. 4 and 5), along with those obtained from the successive-ignition-loss method. Figures 4 and 5 show that the values of water content measured by the two methods on each sample are in fairly good agreement with each other, as in other examples.[16] This indicates that the two methods tested here give mutually reliable data on surface water content in spite of their difference, even when the samples have pores of transitional sizes; a prolonged reaction time is required for the measurement by methylmagnesium iodide. It should be noted that the water contents in three kinds of silica are in fairly good agreement with each other, in spite of large differences in their origin and also in surface properties such as area and porosity. The

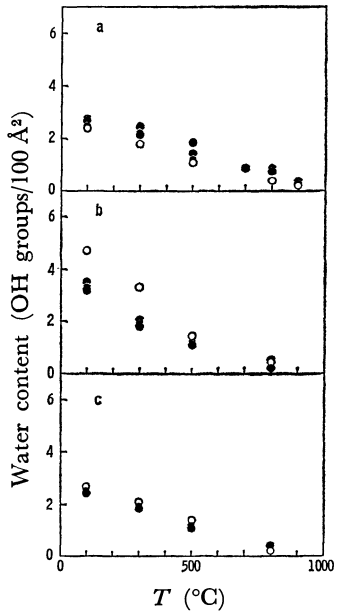

Fig. 4. Water content on Aerosil (a), porous silica glass (65–100 mesh) (b), silica gel (c), measured by the active hydrogen analysis (●) and the successive-ignition-loss method (○).

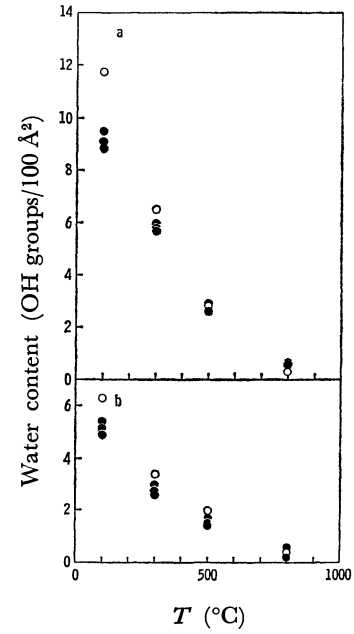

Fig. 5. Water content on alumina (a) and silica-alumina (SA-50) (b), measured by the active hydrogen analysis (●) and the successive-ignition-loss method (○).

water content in three kinds of 100 °-treated silica is *ca.* 3 OH/100 Å² (Fig. 4) which is much smaller than the values in the other oxides, but approximate to values estimated theoretically.[20]

A discrepancy between the two methods appears on porous silica glass treated at relatively lower temperatures: the successive-ignition-loss method gives a larger value. This might be due to the existence of extremely small pores which impede the diffusion of methylmagnesium iodide molecules, but permit the passage of condensed water molecules on outgassing. A similar discrepancy in the values of water content is observed on alumina and silica-alumina, when treated at lower temperatures (Figs. 5a and b). The same interpretation will also hold in these samples from the existence of pores of critical size. It can be expected that alumina and silica-alumina are easily hydrated to form aluminum atoms coordinated with water molecules or structural hydroxyl groups in the surface layer because of the well-known hydrophilic nature of aluminum ion. The latter situation will bring about a fairly large amount of observed water content on alumina as seen in Fig. 5a and also from previous results.[14,15]

It should be noted that the two methods give reliable values of water content in the process of heating the samples, especially in a range of smaller value of water content such as <2 OH/100 Å². From the fact that water evolution from the metal oxide surface at higher temperatures arises from the condensation dehydration of surface hydroxyls, it can be inferred that isolated surface hydroxyl groups which might remain on metal oxides at elevated temperatures can migrate to meet with each other on the surface, and that the migration occurs in the form of active hydrogens rather than hydroxyl groups themselves.

The Absorption and Fluorescence Spectra of 2-Methyl-1-aceanthrenone and Its Cation. A Comparison with 9-Anthracenecarboxaldehyde

Satoshi HIRAYAMA

Faculty of Textile Science, Kyoto Technical University, Matsugasaki, Sakyo-ku, Kyoto 606

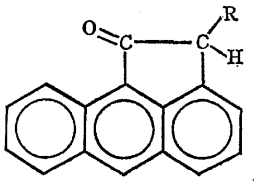
(Received June 15, 1974)

The fluorescence and absorption spectra of 2-methyl-1-aceanthrenone (I) and its cation were investigated. The spectra showed well-defined vibrational structures in a wide variety of solvents, but not in ethyl alcohol and acetic acid. The existence of the ^1L_b absorption band on the shorter-wavelength side of the ^1L_a band was strongly supported by the different solvent effects of these bands. In non-polar solvents, (I) formed a strongly fluorescent, 1 : 1, hydrogen-bonded complex with a trichloroacetic acid molecule. The formation constant in *n*-hexane was determined spectrophotometrically as $3.1 \times 10^2\ M^{-1}$ at 20 °C. In acidic solutions, pK_a and pK_a^*, were determined as -5.1 and 1.3 for the ground and first excited singlet states respectively. These values are the same as the corresponding values of 9-anthracenecarboxaldehyde (9-CHO-A), reflecting a marked resemblance in the electronic nature of the carbonyl groups of the two compounds. The broad absorption spectra of 9-CHO-A, in contrast to the highly structured spectra of (I), are due to a feasible torsional motion of the carbonyl group of the former compound.

The photochemical and photophysical processes of the carbonyl derivatives of anthracene have long attracted our attention, and several new features have been revealed by the present author and his co-workers.[1-4]

In spectroscopic studies of the carbonyl derivatives, an unavoidable complexity is met in elucidating the electronic nature of the excited states, because all these compounds have $n\rightarrow\pi^*$ states in addition to $\pi\rightarrow\pi^*$ states in the energy region attainable by usual photo-excitation. Before any detailed discussion of the photochemical and photophysical behavior of these compounds, threfore, it is necessary not only to determine the energy levels of four states—$S_{1\pi\pi^*}$, $S_{n\pi^*}$, $T_{1\pi\pi^*}$, and $T_{n\pi^*}$—at least, but also to elucidate the principal pathways of the internal conversion and intersystem crossing processes between any two states chosen from these states and the ground state. Actually, however, it is quite rare for all the above-mentioned matters to be made sufficiently clear. In this sense, 9-anthracenecarboxaldehyde (9-CHO-A) is a typical compound; its unusual photochemical reactivity has long been the subject of dispute, but no unambiguous conclusion has yet been obtained as to its reactive excited state. Several investigators, including Yang,[5-8] have proposed that the reactive excited states are the upper triplet $n\rightarrow\pi^*$ and/or the singlet $n\rightarrow\pi^*$ states. On the contrary, Suppan recently asserted that the reactive excited state was the lowest excited singlet $\pi\rightarrow\pi^*$ state.[9] The reason for this discrepancy can be ascribed to the shortage of useful spectroscopic data because of the broadness of the absorption and fluorescence spectra of 9-CHO-A.

A few studies of the molecular structure of 9-CHO-A have revealed that the angle between the anthracene ring and the plane containing the aldehyde group is approximately 25 °,[10] whereas for the other 9-carbonyl derivatives of anthracene this angle is believed to be close to 90 ° as a result of the large steric effect of the peri hydrogen atom.[11] Therefore, except for a characteristic non-fluorescent property common to these carbonyl derivatives,[1,2,12] they hardly differ from the 9-alkyl substituted anthracenes in UV absorption spectrum. Thus, the unusual photochemical reactivity and the broadness in the absorption and fluorescence spectra of 9-CHO-A may be supposed to arise from the approximate co-planarity of the anthracene ring and the plane of the aldehyde group.



(I): R=CH_3

(II): R=H

In 2-methyl-1-aceanthrenone (I) and 1-aceanthrenone (II), which are the main photo-products of 9-α-bromopropionylanthracene[13] and 9-ω-bromoacetylanthracene[4] respectively, it is quite evident that the planes of the carbonyl groups lie on the same plane as the anthracene ring. Considering the approximate co-planarity seen in both (I) and 9-CHO-A, we may expect a very similar behavior of these two compounds in various points. Therefore, detailed investigations of the spectroscopic properties and photochemical reactions of (I) or (II) should aid in clarifying the unusual photochemistry of 9-CHO-A.

The intention of this paper is to report for the first time on the fluorescence and absorption spectra of (I) and its cation and to discuss the results in comparison with the spectroscopic properties of 9-CHO-A as reported by Schulman and Young.[14]

Experimental

Materials. Compound (I) was obtained as the main product of the photolysis of 9-α-bromopropionylanthracene.[13] It was purified by column chromatography and then sublimated twice *in vacuo*. Obviously, (I) and (II) are quite similar in their structural and spectroscopic properties. (I) was employed in this paper simply because it was readily available.

9-CHO-A was prepared according to the well-known method[15] and was recrystallized from acetic acid and purified by sublimation *in vacuo*.

Among the solvents used for the spectroscopic measurements, *n*-hexane and cyclohexane were of a spectro grade (Nakarai Chem. Co., Ltd.). The other solvents (guaranteed

grade) were either distilled before use on a 1-ft Widmar column or were used as received. Tetrahydrofuran, *n*-hexane, and methylenedichloride employed to study the effect of a small amount of oxygen or moisture on the spectra were distilled from a Widmar column and then dried over sodium-potassium amalgam. All these solvents were transferred into an optical cell *in vacuo*. Sulfuric acid (s.g. 1.86) and trichloroacetic acid obtained from the Nakarai Chem. Co., Ltd., were used without further purification. Deionized and distilled water was used.

Optical Measurements. The absorption spectra at room temperature were taken on a Hitachi 124 Spectrophotometer. The fluorescence and excitation spectra were recorded on a Shimadzu Corrected Spectrofluorophotometer, RF 502. To produce corrected spectra, the time- and wavelength-dependent variation in the irradiation-source intensity was corrected automatically by using a rhodamine B quantum counter, while the response of the monochromator-photomultiplier combination was calibrated by means of the manufacturer's electrical compensator. The correctness of the calibration was checked with a dilute standard solution of quinie bisulfate (5×10^{-5} M in 0.5 M sulfuric acid). To record the fluorescence spectra at 77 K, a Dewar vessel and a sample cell made for ordinary ESR measurements at 77 K were used after a slight modification; the Dewar vessel was set in the cell holder of the spectrofluorophotometer, RF 502. Therefore the fluorescence spectra obtained thus at 77 K were uncorrected. The absorption spectra at low temperatures were taken by using a modified Beckman-type spectrophotometer equipped with an EMI 9558 QB photomultiplier. Constant low temperatures were obtained by circulating cold nitrogen gas.

Determination of the Acid Dissociation Constants. The acid dissociation constant, pK_a^*, of the first excited singlet state of (I) was determined by an approximate procedure, *i.e.*, by the fluorimetric pH titration in water-sulfuric acid mixed solvents and buffer solutions.[16] Sørensen's buffer solutions were used, and the pH measurements were made on a Takeda Riken pH-meter, Model HG-2. Sample solutions were prepared by adding a buffer or an acid solution to each 1.0 ml ethanol solution of (I) (*ca.* 10^{-4} M) in a 50 ml volumetric flask. The fluorescence intensities were measured at the wavelength where the fluorescence intensity of the neutral molecule reaches its maximum value.

The acid dissociation constant, pK_a, of the ground state of (I) was determined spectrophotometrically according to the method of Davis and Geissman.[17] The corrected Hammett acidity scale of Jorgenson and Hartter[18] was adopted here. To prepare the sample solutions, the solvent was removed from the 1.0 ml ethanol solution of (I) (*ca.* 1.2×10^{-2} M) in a 25 ml volumetric flask, and then an acidic solution of a known H_0 was poured into the flask until the volume reached 25 ml. The H_0 values were determined by weighing each solvent before mixing. Since, above $H_0=-5.3$, (I) became insoluble in water–sulfuric acid mixed solvents, a small amount of ethanol (2% by volume) was added. All the measurements were carried out at 20 °C.

Results

Neutral Molecule. In Fig. 1 are shown the absorption and fluorescence spectra of (I) observed at room temperature in *n*-hexane and ethanol. The fluorescence yield in *n*-hexane is so low that the spectrum in *n*-hexane is enlarged approximately 44 times. In relation to the photochemistry of 9-ω-bromoacetylanthracene, the absorption spectra of (II) in cyclohexane and ethanol have already been reported.[4] They are very similar to those of (I). In Fig. 2 the fluorescence and excitation spectra of (I) in EPA (5 : 5 : 2 by volume) at 77 K are shown. The fluorescence intensity is rather weak and does not increase very much when the temperature is lowered to 77 K.

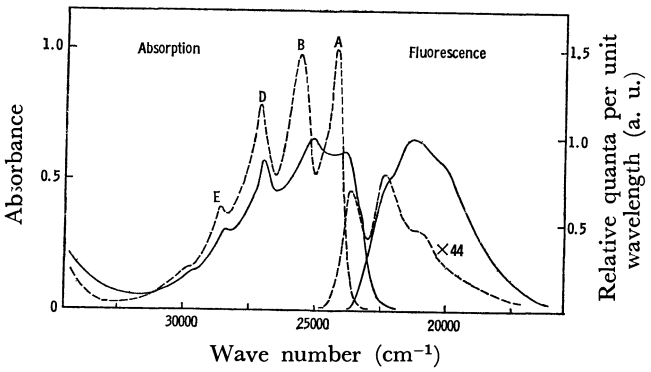


Fig. 1. Absorption and fluorescence spectra of (I) at room temperature.
——: ethanol (8.3×10^{-5} M),
----: *n*-hexane (1.0×10^{-4} M).
The fluorescence spectra were observed at the concentration of *ca.* 5×10^{-5} M in both media. The fluorescence intensity in *n*-hexane is enlarged approximately 44 times. The symbols A to E denote the vibrational band maxima (see also Table 1).

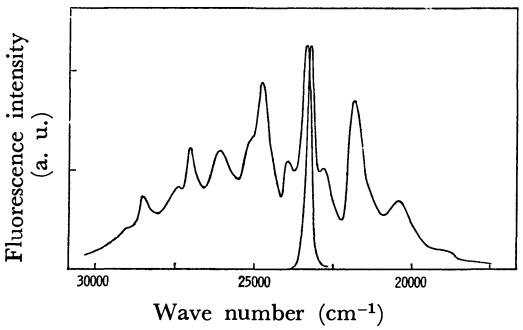

Fig. 2. Fluorescence and excitation spectra of (I) (*ca.* 5×10^{-5} M) in EPA at 77 K.
The excitation spectrum accords well with the absorption spectrum observed at 77 K in the same medium. Comparing the fluorescence and excitation spectra, the existence of the ^1L_b band with sharp band maxima at 351 and 369 nm is evident.

The absorption spectrum of 9-CHO-A in *n*-hexane is shown in Fig. 3 for the sake of comparison. Practically, 9-CHO-A is non-fluorescent in this solvent. The absorption spectrum of 9-CHO-A is inherently broad and does not differ much in a wide variety of solvents.[3] Its fluorescence spectrum at 77 K is also less structured than that of (I), and the fluorescence intensity varies little with the temperature. In contrast, the shape and the position of the absorption spectrum of (I) depend greatly on the solvents. The wave numbers of the absorption band maxima observed for (I) in various solvents are collected in Table 1 (see also Fig. 1). In such polar solvents as dimethylformamide and methylenedichloride, the red shifts were so large that the new absorption maxima (Band

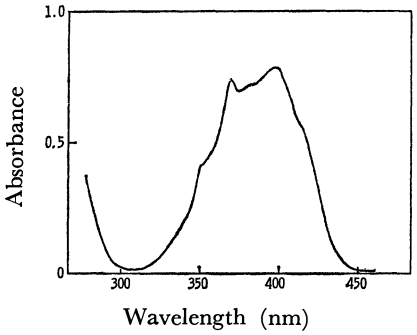
a) Absorption maxima for the hydrogen-bonded complex.



Eig. 3. Absorption spectrum of 9-CHO-A (1.2×10^{-4} M) in *n*-hexane.
The spectrum should be compared with that of (I) shown in Fig. 1. The shoulder observed at around 420 nm is attributed to the 0-0 band.

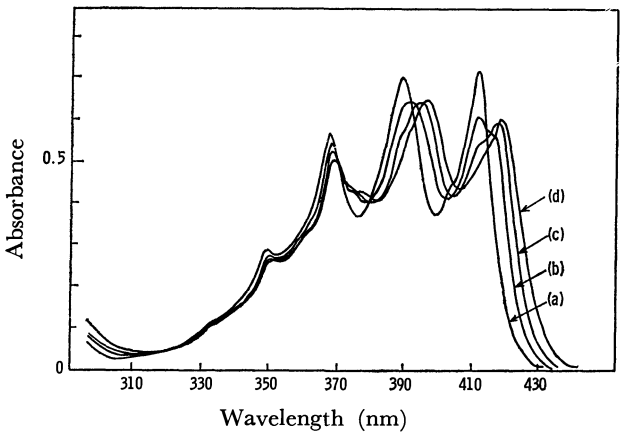


Fig. 4. Absorption spectrum change upon the addition of methylenedichloride to a *n*-hexane solution of (I). The concentrations of the additive by volume are; (a) 0%, (b) 9.1%, (c) 23.1%, (d) 50%. The concentration of (I) is the same (7.2×10^{-5} M) for (a) to (d).

C) appeared clearly between Bands B and D. Despite the large solvent effect in these solvents, the absorption spectra are highly structured and the band widths of A, B, and C are comparable to those obtained in non-polar solvents. It should also be noted that, in any of the solvents studied here, the band widths of D and E are narrower than those of A, B, and C.

On the basis of the different solvent effects on the two band groups, the A, B, and C absorption bands are considered to originate from a different electronic transition from that of the D and E bands. The former band group showed a larger red shift in polar solvents than did the latter band group. Furthermore, the energy separations between B and D, and between D and E, are not the same, so these bands are not considered to belong to the same vibrational manifold of the same excited singlet state. The A, B, and C bands could be assigned to the vibrational manifold of the ^1L_a band, and D and E, to that of ^1L_b. The fact that the fluorescence spectrum shown in Fig. 2 lacks the vibrational progression (corresponding to the bands at 28,490 and 27,100 cm^{-1}) seen in the excitation spectrum also supports this.

As an example of a large solvent effect on the absorption spectrum of (I), the absorption spectrum change in *n*-hexane–methylenedichloride mixed solvents is shown in Fig. 4. Although no clear isosbestic points can be seen, the spectrum changes as if (I) and methylenedichloride form a certain complex; two clear absorption peaks can be recognized at around 410 nm even at a high concentration of methylenedichloride. The fluorescence intensity was observed to increase as the fraction of methylenedichloride increased. In general, the fluorescence yield was larger in polar solvents than in non-polar solvents; *i.e.*, (I) showed a so-called fluorescence activation. Dissolved oxygen and moisture did not affect the fluorescence yield appreciably, as evidenced by a comparison of the fluorescence intensities observed in dry and degassed and aerated solvents.

Figure 5 shows the absorption spectrum change when a small amount of trichloroacetic acid is added to a *n*-hexane solution of (I). In this case, clear isosbestic points are seen at 415, 395.5, 377.5, 371, 355.5, and 352.5 nm, indicating the formation of a hydrogen-bonded complex. The detailed analysis of the spectra showed it to be a 1 : 1 complex with the formation constant of 3.1×10^2 M^{-1} at 20 °C.

Figure 6 shows how the fluorescence spectrum and its intensity change upon the addition of trichloroacetic acid. Compared with the fluorescence spectra shown in Fig. 1, the fluorescence spectra in Fig. 6

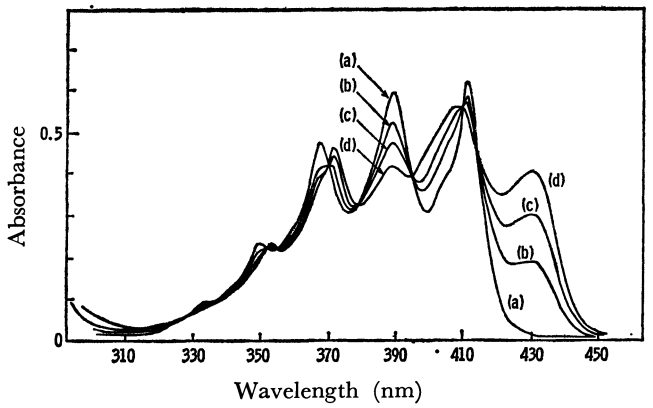

Fig. 5. Absorption spectrum change upon the addition of a small amount of trichloroacetic acid to a *n*-hexane solution of (I).
The concentrations of the additive are;
(a) 0 M, (b) 2.4×10^{-3} M, (c) 6.6×10^{-3} M,
(d) 4.4×10^{-2} M.
The isosbestic points are seen at 415, 395.5, 377.5, 371, 355.5, and 352.5 nm, indicating the formation of the 1 : 1 hydrogen-bonded complex.

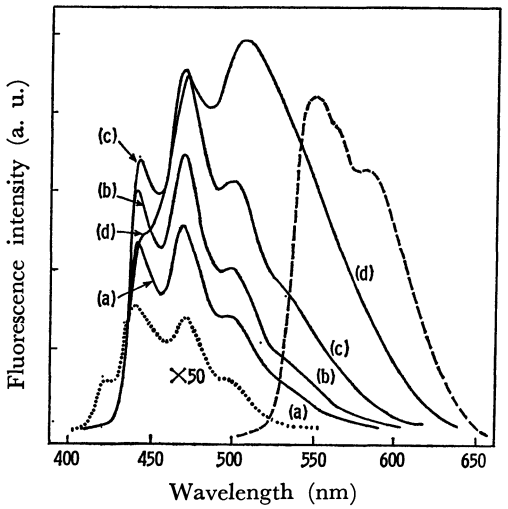

Fig. 6. Fluorescence spectra observed for the 1 : 1 hydrogen-bonded complex of (I).
The spectra denoted by (b) to (d) were observed for the solutions showing the absorption spectra represented by Fig. 5(b) to (d) respectively. The spectrum (a) was observed for the 1.2×10^{-3} M solution of trichloroacetic acid.
The excitation wavelength was 370±10 nm. The fluorescence at the longer wavelength is emitted from the cation. In a much more concentrated solution of trichloroacetic acid (*ca.* 0.5 M), the fluorescence band maximum lies at 532 nm. The broken line represents the fluorescnece spectrum of the cation in conc. sulfuric acid.
In a very dilute solution of trichloroacetic acid (*ca.* 10^{-6} M), fluorescences from the two species (hydrogen-bonded and non-hydrogen-bonded molecules) can be observed as shown by the dotted line.

differ in their position, intensity, and vibrational structure. Thus, the fluorescence spectrum observed in *n*-hexane with a small amount of trichloroacetic acid can be attributed to the hydrogen-bonded molecule. A further increase in the concentration of trichloroacetic acid greatly shifted the fluorescence spectra to the red and caused the loss of a vibrational structure. A comparison with the fluorescence spectrum observed in sulfuric acid (broken line in Fig. 6) revealed that the fluorescence in a concentrated trichloroacetic acid solution was due to a fluorescence from the cation of (I).

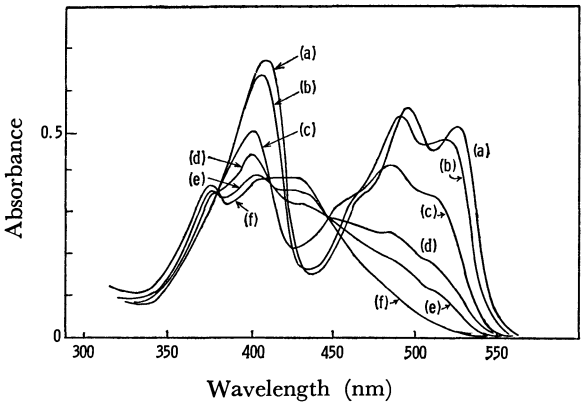

Fig. 7. Absorption spectra of (I) (5.7×10^{-5} M) in acidic solutions.
(a) conc. sulfuric acid, (b) $H_0=-7.74$,
(c) $H_0=-5.32$, (d) $H_0=-4.45$, (e) $H_0=-4.23$,
(f) $H_0=-4.03$.
In the $H_0\geqq-5.0$ range rather good isosbestic points are seen at 379 and 441 nm.

Although 9-CHO-A behaved in a way analogous to (I) upon the addition of trichloroacetic acid, the observed spectra lacked a clear vibrational structure. Consequently, the spectroscopic discrimination of the existence of a non-hydrogen-bonded state and a hydrogen-bonded state is not so feasible as in the case of (I).

Cation. Figure 7 shows the absorption spectra of (I) observed in water-sulfuric acid mixed solvents. The cation formed in sulfuric acid emitted a fluorescence with a band maximum at 550 nm. Although the cation, which naturally showed no ESR signal, was comparatively stable, it could not be set aside for a long time. The absorption at around 520 nm gradually became broader, indicating a decomposition of (I).

Schulman and Young[14] have reported on the absorption and fluorescence spectra of 9-CHO-A under similar conditions; they obtained the values of the acid dissociation constants, pK_a and pK_a^*, as −5.1 and 1.3 for the ground and the lowest excited singlet states respectively. The cations of (I) and 9-CHO-A resemble each other in their absorption spectra, though the latter cation absorbs at wavelengths a little longer. Compared with the absorption spectra observed at high H_0 values, the bands at 410 nm and in the range from 450 to 550 nm in sulfuric acid are assigned to the ^1L_b band and the ^1L_a band respectively. It should be noted here that the ^1L_b band of the cation of (I) is structureless and is as broad as that of the cation of 9-CHO-A.

pK_a and pK_a^*. An approximate value of pK_a^*[16] was obtained by observing the fluorescence intensities of the neutral molecule at 495 nm (excitation: 420±10 nm) at various pH's. The fluorescence inten-

sity *vs.* pH curve gave 1.3 as the approximate value of pK_a^*. Since the fluorescence intensity depends on the kind of buffer solution used, the error in pK_a^* determination may be considerable.

The value of pK_a was determined spectrophotometrically according to the method of Davis and Geissman.[17] The difference in the absorbances at the wavelengths of the absorption peaks of the cation and the neutral molecule were plotted against H_0. The inflection point of this curve gave the value of pK_a as -5.1. As may be seen in Fig. 7, in a strict sense no isosbestic point was observed when H_0 was varied over a wide range; hence, the obtained value of pK_a may again have an appreciable error. In the $H_0 \geqq -5.0$ range, however, rather good isosbestic points were observed at 379 and 441 nm.

The obtained values of pK_a^* and pK_a are in good agreement with those of 9-CHO-A determined by Schulman and Young,[14] indicating a close similarity of the electronic natures of the two carbonyl groups.

Using the equation based on the Förster cycle: $pK_a^* = pK_a + (0.625/T)\,(\bar{\lambda}_N^{-1} - \bar{\lambda}_C^{-1})$, the difference $\Delta pK = pK_a^* - pK_a$ was calculated as 6.7; it showed good agreement with the experimental value of 6.4. The terms in the parentheses are the 0–0 frequencies (in cm^{-1}) estimated from the mean of the positions of the wavelengths of the absorption and fluorescence maxima for the neutral molecule and the cation respectively.

Photolysis of (I). Neither the photochemical reduction of (I) in isopropanol, dimethylaniline, and triethylamine nor the photocycloaddition reaction in 2-methylpentene was observed. That is, both photochemical reactions noted for 9-CHO-A[3,5-8] did not proceed. On the irradiation of (I), however, the absorbance of the p-band gradually decreased; this indicates the occurrence of photochemical reactions presumably including a photodimerization reaction.

Discussion

Similarity and Dissimilarity in the Spectroscopic Properties of (I) and 9-CHO-A. Both compounds bear a marked resemblance to each other in various properties, such as the basicity of the carbonyl groups (pK_a^* and pK_a), a large red shift of the ^1L_a band compared with those of the other 9-carbonyl derivatives of anthracene, fluorescence activation, and the ability of hydrogen-bonding. It is quite evident that the cause for this resemblance is attributable to the fact that the planes of the carbonyl groups and the anthracene ring are approximately coplanar; *i.e.*, the increased conjugation between the carbonyl groups and the anthracene ring endows these compounds with similar properties. This is also supported by the fact that it is impossible to find such a similarity among the other 9-carbonyl derivatives: 9-RCO-A (*e.g.*, R=CH_3–, CH_3CH_2–, $CH_3CH_2CH_2$–, ph–, CH_2=CH–, NH_2– CH_3O–, HO–,) where the carbonyl groups are supposed to make almost right angles with the anthracene ring at the ground states. From this resemblance between (I) and 9-CHO-A, it can also be said that the unusual spectroscopic behavior of 9-CHO-A can not necessarily be ascribed to the fact that its carbonyl group is aldehyde.

On the other hand, a distinct difference in the spectra of (I) and 9-CHO-A lies in the sharpness and the vibrational structure of the absorption and fluorescence bands. Schulman and Young[14] have attributed the lack of a vibrational structure in the absorption spectrum of 9-CHO-A to the loss of vibrational quantization in ^1L_a band. To explain the loss of quantization, they assumed that, since the $^1L_a \leftarrow {}^1A$ transition bore a CT character to some extent, the solvent-relaxation process and the functional rehybridization (the rotation of the aldehyde group) had to occur during the electronic transition, particularly in polar fluid solvents. In comparison with the absorption spectra of (I), however, we see that Schulman's proposal has several difficulties. First, (i) it is questionable whether the rotation of the carbonyl group of 9-CHO-A competes well with the electronic transition. Second, (ii) the broadening in the UV spectrum of 9-CHO-A should be strongly solvent-dependent if solvent relaxation process alters the vibrational sublevels of the Franck-Condon-excited state. On the contrary, though, the broadening is nearly insensitive to solvents. Third, (iii) if the CT character of the ^1L_a band is partly responsible for the broadening, a similar broadening should be observed for (I) and 9-CHO-A. Fourth, (iv) even if the rotation of the carbonyl group is forbidden as in (I), its absorption and fluorescence spectra are quite broad in alcohols. (This will be discussed in a later section.) Fifth, (v) the ^1L_b band of the cation of (I), for which a non-Franck-Condon electronic transition is not to be expected because of the structurally fixed carbonyl group, is also broad and vibrationally structureless, as has been observed for the cation of 9-CHO-A. Furthermore, it should be noted that the absorption spectrum of 9-CH_3OCO-A, whose substituent is supposed to rotate into a coplanar configuration at the excited state, has been reported by Werner and Hoffman[19] to retain an anthracene-like structure. Thus it seems inappropriate to interpret the spectrum broadening observed for 9-CHO-A in terms of a non-Franck-Condon transition to the ^1L_a state.

A comparison of the ^1H spectra of 9-CHO-A and (I) implies the occurrence of a torsional motion of the carbonyl group of 9-CHO-A in the ground state.[20] Therefore, in the present author's opinion, the breadth of the absorption spectrum of 9-CHO-A can be explained as follows, without introducing the concept of a non-Franck-Condon transition to the ^1L_a state. The transition energy changes as the extent of the conjugation of the substituent varies; *i.e.*, the transition energy is a function of the angle made by the carbonyl group and the anthracene ring. Hence, if the electronic transition is supposed to occur from the various ground states with respect to the angle, this will naturally lead to the spectrum broadening, which will be almost insensitive to solvents.

The sharpness of the ^1L_b bands of (I) and 9-CHO-A can also be understood when it is noted that the energy of the ^1L_b band, which is polarized to the long axis of the anthracene ring, is not appreciably affected by meso-substitution, so the transition energy does not

depend on the extent of conjugation of the carbonyl group. This is substantiated by the approximate invariance of the values of the $^1L_b \leftarrow ^1A$ transition energy observed for several 9-substituted anthracenes.[21]

Energy Levels. The electronic states of (I) are well defined. The A, B, and C bands belong to the ^1L_a band, and D and E, to the ^1L_b band, as has been described already. Since, in general, the ^1L_a band does not suffer significantly any substituent effect due to the 1- or 2-position, the large red shift of the 0–0 band of the ^1L_a band may be regarded as being due to the conjugation effect of the carbonyl group. Though the position of the 0–0 band of the ^1L_a band of 9-CHO-A is not clear, a comparison of the absorption spectra of (I) and 9-CHO-A implies that the shoulder observed at around 420 nm in Fig. 3 is due not to the $n \rightarrow \pi^*$ transition, but to the 0–0 band of the ^1L_a band. The lowest excited singlet state of (I) is undoubtedly the $\pi \rightarrow \pi^*$ state, as can be seen from Fig. 1, so the lowest excited singlet state of 9-CHO-A, which has long been in dispute, should also be the $\pi \rightarrow \pi^*$ state. Therefore, the phenomenon of fluorescence activation found for 9-CHO-A as well as for (I) should be explained by a mechanism other than the level inversion between $S_{1\pi\pi^*}$ and $S_{n\pi^*}$ states,[22] as has been suggested by the present author in a previous paper.[3] Instead, two triplet states, $T_{2\pi\pi^*}$ and more particularly, $T_{n\pi^*}$, seem to play an important role in the fluorescence activation phenomenon. However, it is impossible at present to determine the energy levels of these states experimentally. The best way to do so would be to estimate the energy levels from the spectroscopic data accumulated for various carbonyl derivatives of anthracene.[3] All we can say now, on the basis of the present results, is that the fluorescence activation process can more reasonably be explained in terms of the level inversion between $S_{1\pi\pi^*}$ and $T_{n\pi^*}$ states, which may be caused by the increased solvent polarity or by the formation of a hydrogen-bond with a solvent molecule. The fact that abnormal photo-reactivity was not found for (I) may reflect either an unsuitable energy level of the $T_{n\pi^*}$ state relative to the $T_{2\pi\pi^*}$ state (*i.e.*, the lifetime of $T_{n\pi^*}$ is too short for its state to participate in the reactions because of an efficient internal conversion to $T_{2\pi\pi^*}$) or a steric prohibition of the reactions.

Explanation of the Absorption Spectra of (I) in Alcoholic Solvents. The absorption and fluorescence spectra of (I) observed in alcoholic solvents differ much in their breadth from those in non-alcoholic polar solvents, such as dimethylformamide and acetonitrile. The non-hydrogen-bonded neutral molecule of (I) and also the hydrogen-bonded molecule show pronounced vibrational structures in both the fluorescence and absorption spectra, as is indicated in Figs. 1 and 6. The broadening observed in alcoholic solvents can not, therefore, be explained in terms of a simple solvent effect on the spectra. When the temperature was lowered to *ca.* −80 °C, the absorption band at 418 nm sharpened, became more pronounced, and shifted to 420 nm. At the same time, the new bands with peaks at 430 (shoulder), 412, and 388 nm, which correspond well with the absorption peaks observed for a hydrogen-bonded molecule, appeared. Since the band at 418 nm corresponds to the non-hydrogen-bonded molecule, the above-mentioned fact is indicative of the coexistence of at least two species. Thus, the apparent broadening in alcoholic solvents can be reasonably explained in terms of the coexistence of hydrogen-bonded and non-hydrogen-bonded molecules, which absorb light at slightly different wavelengths. A part of the broadening observed for 9-CHO-A may be attributed to such a coexistence, but an experimental proof is need. In order to confirm these things, further studies are now in progress.

20) The chemical shift of the peri hydrogen atom of (I) is 8.93 ppm (1H multiplet) in carbon disulfide, while the two-peri hydrogen atoms of 9-CHO-A show a very similar multiplet absorption (2H multiplet) at 8.75 ppm, indicating the equivalence of the two hydrogen atoms of this molecule. This equivalence can be explained only by the torsional motion of the aldehyde group.

(Received July 11, 1974)

Photoemissions from pyrene and its derivatives, 1,3,6,8-tetrachloropyrene(TClP), 1,3,6,8-tetrabromopyrene(TBrP), 1,6-dicyanopyrene(CDNP), 1,3,6,8-tetracyanopyrene(TCNP), and 1,3,6,8-tetranitropyrene (TNO_2P), were measured. Their photoelectron energy distribution curves(EDCs) were thus obtained; the peaks or shoulder appearing on the EDCs correspond to the ionization potentials of the pyrene molecule. Further, the spectral dependences of their quantum yields(SDQYs) were measured. The ionization potentials obtained from their threshold values were 5.8 eV(pyrene), 6.3 eV(TClP), 6.0 eV (TBrP), 6.3 eV(DCNP), 6.2 eV(TCNP), and 6.6 eV(TNO_2P).

Changes in photoelectron spectra have often been investigated by introducing some functional groups into the π-electron conjugated system, mostly benzene[1]; these photoelectron spectroscopic studies have been carried out in the gaseous state, but not in the solid state. However, as the material property of the solid state is our great concern, the photoemission will give us useful information on the materials in the solid state. As is well known, the photoemission from a solid material consists of three steps:

1) optical excitation process in the solid,
2) transport process in the solid, and
3) escape process from the surface

As the photoemission is a mixed phenomenon of such processes, the information obtained does not always reflect the electronic states of the materials.

The photoemission from organic molecular crystals has been measured by several workers.[2-5] Schechtman and Spicer[6] used Spicer's **k**-independent indirect-transition model[7] (disregarding photoelectron scattering in the bulk and at the surface) and succeeded in determining the energy structures of phthalocyanine and protoporphyrin. Applying a band theory to organic crystals, and also assuming that the state density of the conduction band is constant in molecular crystals, Spicer's model is effective in these materials.[8]

In this paper, we wish to present the photoelectron energy distribution curves and the spectral dependences of the quantum yields of pyrene and its derivatives.

Experimental

Samples. The samples used in this work are pyrene, 1,3,6,8- tetrachloropyrene (TClP), 1,3,6,8- tetrabromopyrene (TBrP), 1,3,6,8- tetracyanopyrene(TCNP), 1,6- dicyanopyrene(DCNP), and 1,3,6,8-tetranitropyrene(TNO_2P). The pyrene derivatives were prepared by Iwashima,[9] as has already been reported.[10]

In order to prepare the specimens for the photoemission measurement, pyrene and its derivatives were deposited onto a small copper disk (12 mm in diameter) by the sublimation method. The deposition was carried out *in vacuo* better than 10^{-5} Torr. However, the vapour pressure of pyrene was too high to deposit in such a vacuum, therefore, we were obliged to make the specimen on the cooled copper disk in a low vacuum ($\sim 10^{-4}$ Torr).

Measurements. The photoemission was measured with a half-meter Seya-Namioka-type vacuum ultraviolet monochromator. The details of the equipment attached to the monochromator were reported previously.[4] The collector of the photocell was a spherical glass one; the inside was coated with colloidal graphite, "Aquadag."

The energy distribution curves(EDCs) were obtained by recording the derivative of the photoelectron current, with respect to the retarding potential, V. Differentiation was performed by superimposing a small sinusoidal potential, ΔV (200 mV p-p, 4 Hz), upon V; the details of this have also been reported already.[5]

The quantum yield, Y, is the ratio between the number of the photoemitted electrons and the incident photons. When the quantum yield was measured, an accelerating potential was applied between the emitter and the collector enough to collect all the electrons emitted. The spectral response of the quantum yield was observed at intervals of 1 nm.

Results and Discussion

Energy Distribution Curves. Figures 1—6 are the EDCs of pyrene and its derivatives plotted as functions of the retarding potential. The numerical value beside each EDC is the energy of the incident photon. As a whole, only a few structures were found in the curves, and the dominant peaks were located at about 0 eV. These peaks grew rapidly with an increase in the incident photon energy.[11] These peaks, independent of the incident photon energy, are so-called "stationary peaks."

During the operation, the retarding potential was swept from minus voltage to plus one. The potential when the peak takes off from the base line is the stopping voltage, V_0, and the potential when the peak falls down to the base line is the saturation voltage, V_s. When the EDC has a tail, V_0 and V_s were determined by approximating the edges of the EDCs by straight lines. The EDCs of pyrene derivatives, especially TClP (Fig. 2), have long tails on the V_s side: this phenomenon is, perhaps, produced by the potential drop between the sample surface and the copper disk, since a charge-up takes place. Moreover, the V_s-value changes with the energy of the incident photons. From these effects, both values, V_0 and V_s, have some ambiguities; these values are summarized in Tables 1 and 2.

When the EDCs are rewritten against the initial energy of the emitted electrons, measured with respect to the stopping potentials, V_0, this revised EDC is appropriate for organic crystals, since it is uncertain whether these materials are conductors or insulators. That is, there is no need to consider the Fermi level

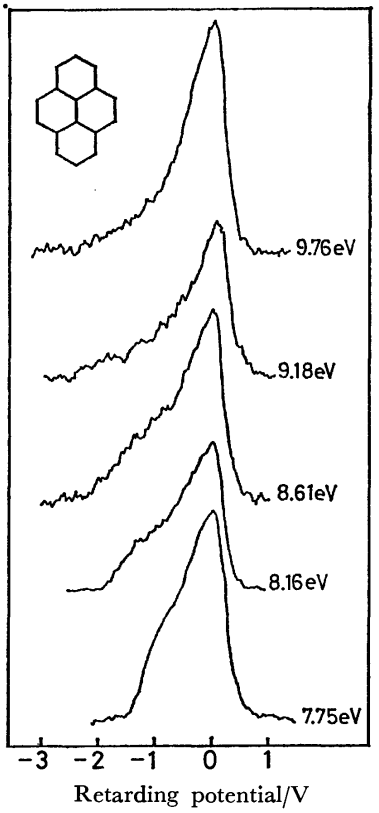

Fig. 1. Energy distribution curves of pyrene, plotted as a function of retarding potential, V, in arbitrary unit. Numerical values beside each curves (7.75 eV, 8.16 eV, 8.61 eV, 9.18 eV and 9.76 eV) are the energies of incident photon.

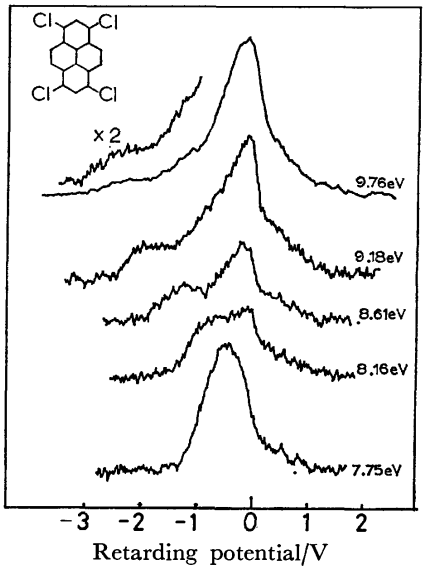

Fig. 2. Energy distribution curves of TClP. (The experimental condition is the same as Fig. 1)

in plotting.[12] Adding the threshold energy to the energy value of each peak or shoulder in EDC, which is independent of the incident photon energy in the revised plot,[13] we can find the positions of the valence bands from the vacuum levels.

In Table 3, as the peak or shoulder positions, the

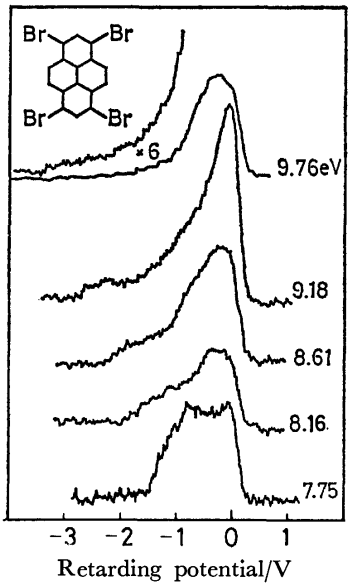

Fig. 3. Energy distribution curves of TBrP.

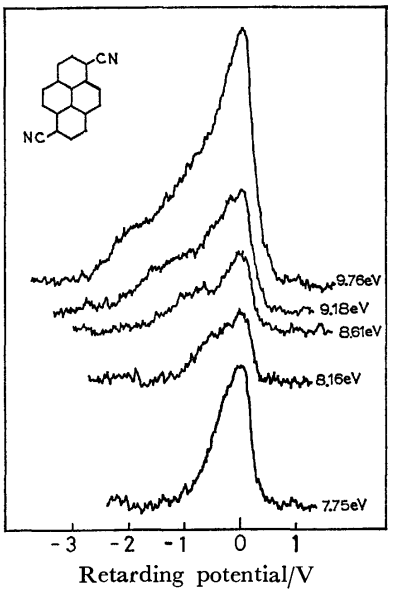

Fig. 4. Energy distribution cruves of DCNP.

energies of the optical state densities of the valence bands are listed, and the ionization potentials of pyrene in the gas phase obtained by Boschi and Schmidt[14] are also quoted. Moreover, the energy differences between the first band and the other bands are shown in Table 4.

The energy differences between the first band and the other were in good agreement with the values of Boschi's work.[14] This indicates that the locations of the first few π-bands of polycrystalline pyrene and its derivatives are similar to those of the pyrene free molecule. However, there are large differences in the shapes of their EDCs. This shape difference can be understood by considering the following several reasons:

1) The electron-attenuation lengths differ from each other; that is, the numbers of the scattering centres (π-electrons[15]) are different.

Table 1. Stoppong potentials, V_0, obtained from EDCs in V

Incident photon energy (eV)	Samples					
	Pyrene	TClP	TBrP	DCNP	TCNP	TNO_2P
7.75	−1.49	−1.25	−1.53	−1.10	−1.05	−0.82
8.16	−1.97	−1.46	−1.98	−1.46	−1.40	−1.21
8.61	−2.30	−1.91	−2.36	−1.83	−1.80	−1.81
9.18	(−2.47)	−2.43	−2.84	−2.42	−2.36	−2.38
9.76	—	−3.09	−3.42	−2.90	(−2.50)	−2.78

The values in parentheses are vague, because the determination of the onsets of the EDCs is difficult. Experimental errors were ±0.05 *V*.

Table 2. Saturation potentials, V_s, obtained from EDCs in V

Incident photon energy (eV)	Samples					
	Pyrene	TClP	TBrP	DCNP	TCNP	TNO_2P
7.75	0.42	(0.24)	0.25	0.32	0.49	0.37
8.16	0.41	(0.30)	0.25	0.38	0.50	0.38
8.61	0.34	(0.24)	0.25	0.35	0.53	0.30
9.18	0.41	(0.28)	0.23	0.42	0.59	0.36
9.76	0.42	(0.44)	0.27	0.48	0.55	0.34
Average	0.41	(0.27)	0.25	0.39	0.53	0.35

As the EDCs of TClP have long tails in V_s side, the values in this Table are the cross points of the straight parts of the EDCs and base line. Experimental errors are in ±0.05 *V*.

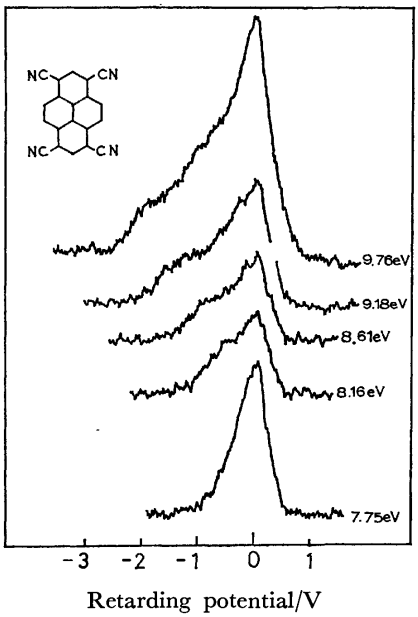

Fig. 5. Energy distribution curves of TCNP.

2) There are changes in crystal structures; that is, the escape probabilities of photoexcited electrons from the surface of the polycrystallines are different.

3) The surface cleanness differs, since their vapour pressures are not equal; that is, contamination of the surface by residual gas occurs.

4) Their electronic structures are changed by the functional groups; that is, the numbers of photo-

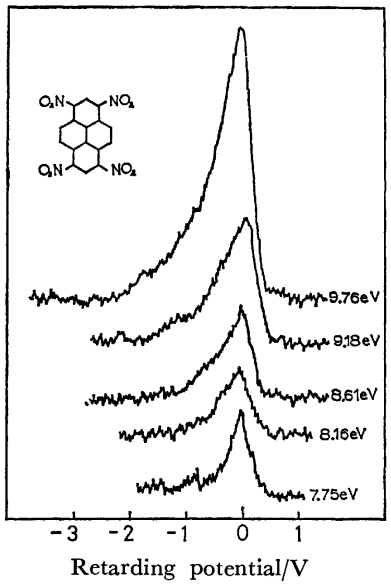

Fig. 6. Energy distribution curves of TNO_2P.

excitable electrons are affected by such functional groups.

As for the first and second reasons, no data on the electron-attenuation lengths and crystal structures of these compounds are to be found, therefore, further discussion is difficult. As for the third reason, it is known that the surface of organic compounds with high vapour pressures are fairly clean in an ordinary vacuum because of their successive sublimation. This factor is useful in comparing halogen derivatives and cyano- and nitro-derivatives. From the view point of the vapour pressure, we can expect the surface of pyrene film to be clean, since its vapour pressure is the highest among these materials. On the other hand, it is also known that a contaminated surface reduces high-energy electrons to low-energy electrons; in this case, the EDCs become structureless. As the EDCs of pyrene show less structure than those of halogenized pyrenes, contamination must take place on the pyrene film. This fact is inconsistent with self-cleaning by successive sublimation. However, practically, as the spectroscopical observation was carried out in a low vacuum and with a cooled emitter, it is feasible that the surface of pyrene film is contaminated with residual gases.

In considering the fourth reason, a well-known phenomenon, mesomeric or inductive effect, is useful. Cyano- and nitro-groups are electron-withdrawing

Table 3. Peak (shoulder) positions from vacuum level in eV

	Pyrene	TClP	TBrP	DCNP	TCNP	TNO_2P	Pyrene[a)]
1st peak	(6.5_5)	6.1_5	6.7_5	(7.3_0)	(7.2_0)	7.5_0	7.41
2nd peak	(7.3_5)	(6.8_5)	(7.6_5)	(8.3_0)	(8.0_5)	(8.5_5)	8.26
3rd peak	—	(7.4_0)	(8.3_0)	—	—	—	9.00

The values in parentheses are shoulder positions. a) Ionization potentials in gas phase in Ref. 14.

Table 4. The energy differences between the first peak and the others in eV

	Pyrene	TClP	TBrP	DCNP	TCNP	TNO_2P	Pyrene[a)]
2nd	0.8_0	0.7_0	0.9_0	1.0_0	0.8_5	1.0_5	0.85
3rd	—	1.2_5	1.5_5	—	—	—	1.59

a) gas phase pyrene

functional groups (mesomeric effect). Halogen atoms have two effects: a plus mesomeric effect and a minus inductive effect. These effects increase or decrease the electron density of the pyrene-ring system; its increase or decrease may change the number of photoexcitable electrons.

Spectral Dependence of the Quantum Yield. Figure 7 shows the spectral dependences of the quantum yields (SDQYs) of pyrene and its derivatives. As may clearly be seen, pyrene has a higher photoelectron efficiency in the whole spectral region compared to those of the others. The SDQY of pyrene is about 3×10^{-2} electrons/photon at 10 eV; it gradually decreases to 7 eV, and then falls down steeply to 7×10^{-5} electrons/photon. On the other hand, the SDQYs of the substituted pyrenes show almost the same inclinations above 9 eV. However, below 9 eV those SDQYs are classified into three groups. One group (A) consists of halogen-substituted pyrenes; Group B consists of cyano-substituted pyrenes, and Group C is nitro-substituted. The SDQYs of Group A resemble those of pyrene except for the absolute value of the quantum yield; the decrease in the absolute quantum yield can be understood in terms of a deepening of the threshold energies upon the introduction of halogen atoms. The SDQYs of Groups B and C are monotonously decreasing curves, and their inclinations are steeper than those of pyrene and Group A. The quantum yield of Group C is smaller than those of Group B. These results support the fourth reason described at the EDC shape differences. Cyano- and nitro-groups induce a decrease in the cross section (the number of photoexcitable π-electrons in the pyrene-ring system) of photoemission largely by withdrawing the electrons from the pyrene-ring system. The effect of halogen atoms is not so large comparatively.

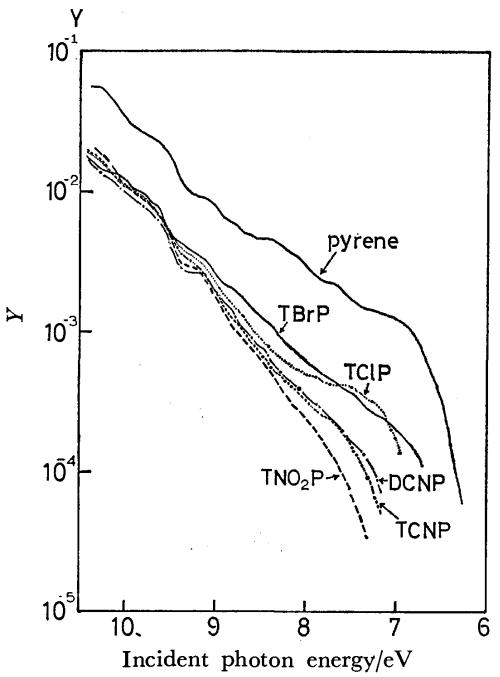

Fig. 7. Spectral dependences of quantum yields, Y, of pyrene and its derivatives, plotted as a function of incident photon energy.

Threshold Energy. To determine the ionization potential of these aromatic crystals, the threshold energy, E_{th}, is estimated by the following methods.

1) From the EDCs, with the values of V_0 and V_s, using this relations:

$$E_{th} = h\nu - V_s + V_0$$

where $h\nu$ is the incident photon energy.

2) From the SDQYs, as used by Lyons and Morris,[16] E_{th} is determined as the lowest detectable current photon energy, usually the order of $10^{-7}\sim10^{-8}$ electrons/photon as the quantum yield.

3) From the relation between the quantum yield and the incident photon energy near the threshold energy region as:

$$Y \propto (h\nu - E_{th})^3$$

In our measurments, however, there were some cases where the methods described above could not be used. The second method was especially invalid, because the lowest detectable quantum yields were in the order of $10^{-4}\sim10^{-5}$ electrons/photon, far from the order of $10^{-7}\sim10^{-8}$. The first method has some ambiguities when it is difficult to determine V_s and V_0. Moreover, as high-energy electrons often lose their energy, the determination of V_0 excited with a high-energy photon is difficult. Therefore, in this work, we adopted V_s and V_0 from the EDCs excited with 7.75 eV photons.

In the halogen-substituted pyrenes, the third method was not used, because we could not find any linear relation between $Y^{1/3}$ and $(h\nu - E_{th})$.[17] The cube-root plots of the other compounds are shown in Fig. 8.

The threshold energies obtained from the first and third methods are listed in Table 5. Batley and Lyons[18] reported the threshold energy of 1,6-diamino-

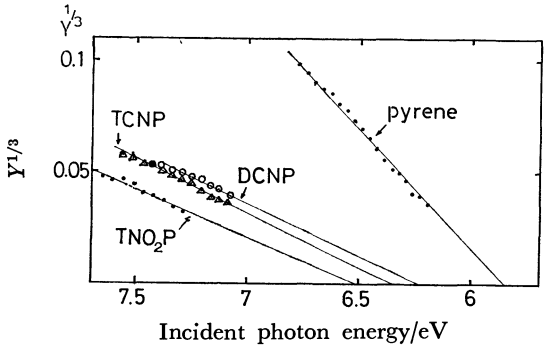

Fig. 8. Cube root of quantum yield plotted as a function of incident photon energy.

pyrene as 4.71 eV. This value is smaller than that of pyrene by more than 1 eV. As the amino group is electron-donating, the E_{th} of the amino derivative becomes small, because an electron is easily emitted from the pyrene-ring system. As for the cyano- and nitro-groups, on the other hand, the E_{th} of such substituted pyrene becomes large, because these groups are electron-withdrawing.

The authors wish to thank to Professor Satoshi Iwashima for his preparation of the materials used in this experiment.

The Analysis of the Molecular Vibration by the Molecular Orbital Method. I. Application to HCN

Tomoo MIYAZAKI, Masaru IKEDA, and Masayuki SHIBATA

Department of Applied Chemistry, Faculty of Science and Engineering, Waseda University, Nishi-Ohkubo, Shinjuku-ku, Tokyo 160

(Received July 24, 1974)

The approximate self-consistent molecular orbital method has been applied to the analysis of the vibrational spectrum of HCN. The frequencies of the fundamental, overtone, and combination bands in the region from about 700 to 12000 cm^{-1} have been calculated, and their absolute infrared absorption intensities have been estimated, the variational method being used in this calculation. Also, the frequencies and absorption intensities of hot bands, referring to the bending vibration, have been calculated. In comparison with the experimental results, the calculated frequencies were not always appropriate. However, it was found that these results are effective in the analysis of the molecular vibration if the calculated frequencies are discussed along with their infrared absorption intensities.

There have been reports in which the force constant and $\partial\mu_i/\partial S_j$ have been calculated on the basis of the results of molecular orbital calculations, where μ_i is the component of the molecular dipole moment and where S_i is an appropriate vibrational coordinate.[1-18] However, these results are not always desirable in comparison with the values from the experimental results. The main reason for the undesirable results is that the following requirement is hard to put into practice: the semi-empirical molecular orbital method adopted in the estimation of those values has to lead simultaneously to many appropriate values for the molecular constants, such as the bond length, the bond angle, the force constant, the dipole moment, and its derivative $(\partial\mu_i/\partial S_j)$. For example, the CNDO/2 method[1] proposed by Pople *et al.* can obtain reasonable values for the moleculr geometry, the dipole moment, and its derivative, but the calculated stretching force constant tends to be larger than that generally found. The MINDO/2' method[20] proposed by Dewar *et al.* leads to appropriate values for the molecular geometry and the stretching force constant, but adequate values for the bending force constant and the dipole-moment derivative with the bending coordinate cannot be obtained.

In previous papers,[14,15] the present authors discussed the abnormal infrared absorption intensity of the C–H stretching vibration band in chloroform on the basis of the dipole-moment derivative and the potential function calculated from the CNDO/2 method. In these calculations, the mechanical and electrical anharmonicities were considered and the variational method was used to estimate the energy and wave function of the vibrating system. At that time, some substantial modification for the potential function had to be made, although there was a problem to be solved in the method of modification.

In this work, the frequencies of the fundamental, overtone, and combination bands in the vibrational spectrum of HCN in the region from about 700 to 12000 cm^{-1} have been calculated by the use of the potential function obtained by the MINDO/2' method. Moreover, their absolute infrared absorption intensities have been estimated from the dipole-moment derivative calculated by the CNDO/2 method. Also, the frequencies and absorption intensities of the hot bands, referring to the bending vibration, have been calculated. In comparison with the experimental results, the calculated frequencies were not always appropriate. However, it was found that these results are effective in the analysis of the molecular vibration if the calculated frequencies are discussed along with their infrared absorption intensities. Furthermore, the effect of the different level of approximation for the bending coordinate on the calculated results was discussed.

Methods of Calculation

The Potential Energy Function. The total energies of the molecule required to determine the potential energy function for the molecular vibration have been calculated by the MINDO/2' method. In this calculation, the values of the parameters, B_{AB}, in the following approximate equation for the resonance integral, $\beta_{\mu\nu}$, were slightly modified:

$$\beta_{\mu\nu} = B_{AB}(I_\mu + I_\nu)S_{\mu\nu} \quad (1)$$

where I_μ and I_ν are the valence-state ionization potentials of the atomic orbitals, χ_μ and χ_ν, where $S_{\mu\nu}$ is the corresponding overlap integral, and where B_{AB} is a parameter characteristic of the A—B atom pair. The values of B_{CH} and B_{CN} were taken to be 0.3021 and 0.3522 respectively (the original values in the MINDO/2' method: $B_{CH}=0.2823$ and $B_{CN}=0.3453$). The calculated bond lengths of HCN, which is a linear structure, were 1.0445 Å and 1.1739 Å for r_{CH} and r_{CN} respectively (the observed values: $r_{CH}=1.06317$ Å and $r_{CN}=1.15535$ Å). According to the method of least-squares, the potential energy function, V, was obtained by fitting the increase in the total energy calculated for the distorted molecule to the 5th-order function with respect to the internal coordinates, R_i (the 6th order for the bending coordinate), but the 5th-order terms were omitted in the succeeding calculations.

$$V(R) = \sum_{i\leq j} K_{ij}R_iR_j + \sum_{i\leq j\leq k} K_{ijk}R_iR_jR_k + \sum_{i\leq j\leq k\leq l} K_{ijkl}R_iR_jR_kR_l. \quad (2)$$

For the HCN molecule, the internal coordinates are two bond-stretching coordinates, $R_1=\Delta r_{CH}$ and $R_2=$

Δr_{CN}, and two bending coordinates perpendicular to each other, $R_3=\Delta\theta_{(y)}$ and $R_4=\Delta\theta_{(z)}$. Generally, doubly degenerate vibrations, such as the bending coordinates in HCN, are treated as superpositions of these vibrations by the introduction of the polar coordinates. In this work, such a general treatment was avoided because the treatment was inconvenient in calculating collectively, by the variational method, the frequencies of all the vibrations in the molecule in view of the mechanical anharmonicity. In this calculation, the superposed system was described by a product of the wave functions of the doubly degenerate vibrations.

The calculations of the energy-increase arising from the bending deformation were performed for the different cases by the following methods, I and II. In these calculations, it was prescribed that we employ the B matrix, generally used, which is derived from the approximate linear-relation between the internal and the Cartesian coordinates. In Method I, the molecule was distorted according to the rectilinear bending deformation. The conformation of the distorted HCN molecule required to calculate the cross terms between bending and stretching vibrations was decided by the Δr_{CH}, Δr_{CN}, and $\Delta\theta$ values, which are related with one another as is shown in Fig. 1. In

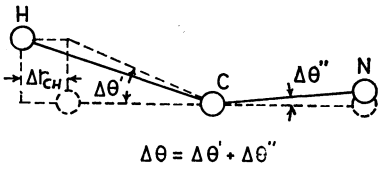

Fig. 1. Conformation of the distorted HCN referring to the C-H stretching and the rectilinear bending coordinates.

Method II, the molecule was distorted according to the curvilinear bending coordinate indicated in the potential surface of HCN, illustrated by Suzuki *et al.*[22] In this treatment, the conformation of the distorted HCN can be determined without trouble by Method I. Finally, the potential energy function represented by the internal coordinates was transformed to a function with the normal coordinates by the use of the L_R matrix elements:

$$V(Q)=\sum_i\frac{1}{2}\lambda_{ii}Q_i^2+\sum_{i\leq j\leq k}g_{ijk}Q_iQ_jQ_k+\sum_{i\leq j\leq k\leq l}h_{ijkl}Q_iQ_jQ_kQ_l. \quad (3)$$

The variational Treatment. The variational method has been used to calculate the energy levels of vibrations in view of the mechanical anharmonicities.

The total wave function, Ψ^{total}, for the molecular vibration is described as a linear combination of ψ's, each of which is written as a product of the harmonic oscillator wave functions, φ's, of all the vibrations in the molecule:

$$\Psi^{\text{total}}=\sum_i C_i\psi_i, \quad (4)$$

$$\psi_i=\varphi_l^{\,1}\varphi_m^{\,2}\varphi_n^{\,3}\varphi_o^{\,4}, \quad l,m,n, \text{ and } o=0,1,2,3\cdots\cdots \quad (5)$$

where $\varphi_n^{\,k}$ indicates the n-th harmonic oscillator wave function, referring to the normal coordinate, Q_k (here, n is the principal quantum number of the vibration), and ψ_i is decided by the variety of the combination of the quantum numbers, l, m, n, and o.

The variational treatment of the coefficient, C_i, leads to this equation:

$$\sum_{j=0}^{k}C_j(H_{ij}-E\delta_{ij})=0, \qquad i=0,1,2,3,\cdots\cdots k, \quad (6)$$

$$H_{ij}=\langle\psi_i|\hat{T}+\hat{V}|\psi_j\rangle, \quad (7)$$

where δ_{ij} is the Kronecker delta symbol, $\hat{T}$ is the operator of the kinetic energy, $-\frac{h^2}{8\pi^2}\sum_k\frac{\partial^2}{\partial Q_k^{\,2}}$ and $\hat{V}$ is the operator referring to the potential function (3) with the normal coordinates. The energy, E, is the root of the secular equation:

$$|H_{ij}-E\delta_{ij}|=0.$$

Generally, the accuracy of the wave function improved by this treatment is restricted by the maximum values of the quantum numbers, l,m,n, and o. The upper limits of the quantum numbers are determined by the ability of the computer and the other restrictions. On the other hand, in order to obtain the improved wave function in the quantum numbers from 0 to 3, we have to consider the harmonic wave functions in the quantum numbers from 0 to 10 for each vibration in Eq. (5) at least. Therefore, we divided the variational treatment into the following two steps.

The First Step: The wave function of a specified normal vibration (k) was modified in view of the principal terms of the mechanical anharmonicity, without cross terms. In this treatment, the modified wave function, Φ^k, was described by a linear combination of harmonic oscillator wave functions, φ^k's, as follows:

$$\Phi^k=\sum_i C_i^k\varphi_i^k, \qquad i=0 \text{ to } 11. \quad (8)$$

The operator, $\hat{H}'$ (k), used in this calculation was as follows:

$$\hat{H}'(k)=-\frac{h^2}{8\pi^2}\frac{\partial^2}{\partial Q_k^{\,2}}+\frac{1}{2}\lambda_{kk}Q_k^{\,2}+g_{kkk}Q_k^{\,3}+h_{kkkk}Q_k^{\,4}. \quad (9)$$

The wave function and their energies can be obtained from the appropriate set of the secular equation and the equation corresponding to Eq. (6).

The Second Step: The total wave function, Ψ^{total}, was described as a linear combination of ψ's, each of which was written as a product the wave functions, Φ's, obtained from the first-step treatment:

$$\Psi^{\text{total}}=\sum_i C_i\psi_i, \quad (10)$$

$$\psi_i=\Phi_l^{\,1}\Phi_m^{\,2}\Phi_n^{\,3}\Phi_o^{\,4}, \qquad l,m,n, \text{ and } o=0 \text{ to } 4. \quad (11)$$

The variety of combinations in ψ_i was restricted by the condition that $l+m+n+o\leqslant 4$. The calculations in the subsequent treatment were the same as those described above.

The Dipole Moment and its Expansion. It is desirable for the dipole moment of molecule to be calculated according to the method used to determine

the potential function. However, the values of the dipole-moment derivative with the bending coordinate obtained from the MINDO/2' method which was used to determine the potential function were not desirable in calculating the infrared absorption intensity; the detailed reasons why will be indicated later (see "Discussion"). Therefore, in this work, the component of the dipole moment was expanded by the normal coordinates on the basis of the results of the CNDO/2 calculations for the molecule which was distorted according to the L_x matrix elements, the values of equilibrium distances calculated by the MINDO/2' method being employed. The function of the dipolemoment component, μ_x, was obtained as the 5th-order expansion with the normal coordinates, but the 4th- and 5th-order terms were omitted in the calculation of the absorption intensities:

$$\mu_x = \mu_x{}^0 + \sum_i M_i Q_i + \sum_{i\leq j} M_{ij} Q_i Q_j + \sum_{i\leq j\leq k} M_{ijk} Q_i Q_j Q_k. \quad (12)$$

The Absolute Infrared Absorption Intensity. The method of the calculation of the absolute infrared absorption intensity in [$cm^2 s^{-1}$ $molecule^{-1}$] units was described in detail in a previous paper.[15] Practically, though, there is a difference in the integrals involving the cross terms in comparison with the previous calculation. The equation required to calculate the absolute absorption intensity, A, is as follows:

$$A_{v+n\leftarrow v} = \frac{8\pi^3}{3ch}\left(\frac{N_v}{N_t} - \frac{N_{v+n}}{N_t}\right)\nu_{v+n,v} \sum_{i=x,y,z} |(\mu_i)_v{}^{v+n}|^2, \quad (13)$$

$$N_v = N_0 \exp\left(-(E_v - E_0)\right)/kT, \quad (14)$$

$$N_t = N_0 \sum_{v=0}^{\infty} \exp(-(E_v - E_0))/kT, \quad (15)$$

$$(\mu_i)_v{}^{v+n} = \langle \Psi_v{}^{\text{total}} | \hat{\mu}_i | \Psi_{v+n}{}^{\text{total}} \rangle, \quad (16)$$

where N_0 and N_v are the numbers of the molecules per unit volume in the E_0 and E_v states of the total energies respectively; N_t is the total number of molecules, c is the velocity of light, h is Planck's constant, k is Boltzmann's constant, $\hat{\mu}_i$ is the operator corresponding to the function of the dipole-moment component with the normal coordinates (12), and $\nu_{v+n,v}$ is the transition energy in [s^{-1}] units between the E_v and E_{v+n} states of total energies. In this calculation, the absolute temperature, T, was taken to be 300 K. The absorption intensities of the hot bands, referring to the bending vibration, were also calculated.

Results and Discussion

In this work, trial calculations were performed by the use of several semi-empirical molecular orbital methods, such as the CNDO/2'[11] CNDO/BW,[19] and MINDO/2'[20] methods. We expected that any method would serve the purpose of determining the frequencies and intensities for the infrared absorption bands of HCN. Unfortunately, not every method answered to our expectations.* Elaborate parametrizations in any method would be able to satisfy our requirements, but such treatment is intricate and tedious, for universal validity is required for the values of parameters. For this reason, the MINDO/2' and CNDO/2 methods were used to calculate the total energy and the dipole moment of HCN respectively. *However, it should be emphasized that this treatment is an expediency.* The parameters in the MINDO/2' method were slightly modified in order to obtain agreement between the calculated frequencies and observed ones.

The coefficients of the potential function, $V(R)$, as calculated from Methods I and II, are indicated in Table 1; the values obtained by others[22] are also included. The large values of the cross terms between the stretching and the bending vibrations were obtained by Method I. In view of the level of approximation of the B matrix used in this work, the

* The force constants, k's, calculated by means of the CNDO/2 method were larger than those generally found:

$k_{11}=2K_{11}=12.861$ mdyn/Å, $k_{22}=2K_{22}=41.434$ mdyn/Å,
$k_{12}=K_{12}=0.42583$ mdyn/Å, $k_{33}=k_{44}=2K_{33}=2K_{44}=0.57394$ mdyn·Å/rad².

These values of the force constants led to undesirable results for the calculated frequencies of the absorption bands.

On the other hand, the coefficients, M's, of the $\mu_i(Q)$ function calculated from the MINDO/2' method were as follows:

$$\mu_x(Q): \quad M_{33}=M_{44}=68.969\times10^{20} \text{ esu}/(g\cdot c),$$
$$\mu_y(Q),\ \mu_z(Q): \begin{cases} M_3=M_4=10.020\times10 \text{ esu}/\sqrt{g} \\ M_{333}=M_{444}=-117.43\times10^{40} \text{ esu}/(\sqrt{g^3}c^2). \end{cases}$$

These values led to abnormal absorption intensities of the bending vibration; the intensities of the fundamentals, $A(0001)$ and $A(0010)$, are weak, and the intensity of the first overtone, $A((0002)+(0020))$, is much stronger than that of the former:

$A(0001)=A(0010)=57.379\times10^{-10}$ cm^2 s^{-1} $molecule^{-1}$,
$A((0002)+(0020))=504.38\times10^{-10}$ cm^2 s^{-1} $molecule^{-1}$.

treatment in Method I may be considered to be more reasonable than that in Method II. However, the final result from Method I was undesirable in comparison with the observed values. Therefore, we are especially interested in the treatment of Method II, which brings better results. The results calculated by Method II are mainly indicated in Tables 2 to 5.

The variational treatment was divided into two steps because of the technical counterplan. However, this treatment was effective in obtaining additional information. For example, we thus learned that the wave functions of molecular vibration can be specified in view of the principal terms of anharmonicity, without cross terms, as is indicated in Tables 3,4, and 5.** It is recognized that the mechanical anharmonicity of the C–H vibration is as large as that generally found. Moreover, the effects of cross terms in anharmonicity on the frequencies of the absorption bands can be confirmed. The coefficients of the function of the dipole-moment component with the normal coordinates are indicated in Table 2. In Table 6, the final results involving the frequencies and the absorption intensities of the vibrational spectrum of HCN are indicated, and the principal and additional modes of vibration are clarified. It should be noted that the representation of the vibrational mode is indicated by the quantum number of the energy level of vibration, considering the principal terms of anharmonicity without cross terms. The frequencies and the absorption intensities of the hot bands, referring to the bending vibration, are listed in Table 7. In Tables 6 and 7, the calculated frequencies and the intensities of the absorption bands are not always appropriate. However, it was found that the calculated intensities are effective in clarifying the assignment of the observed absorption bands. In comparison with the results in the references,[21,22] we can make the following statements: the absorption intensities of (1011), (1002)—(1020), (1111), and (1102)—(1120) are equal to zero, and the order of intensities of (0300), (1200), and (2002)+(2020) is 10^{-11} degree in [$cm^2\ s^{-1}$ $molecule^{-1}$] units. The absorption intensity of the degenerate hot band {(0111), (0102)−(0120)} is larger than the intensity of (0102)+(0120), and also {(0211), (0202)—(0220)} is larger than (0202)+(0220).

The results presented above show that the molecular orbital calculations are effective in the analysis of the vibrational specturm if the absorption intensities are slso calculated.

The authors would like to acknowledge the continuing encouragement of Professor K. Higasi. In their calculation, they were helped by the "University Contribution" of UNIVAC Japan, Ltd.

** There remains a further question as to the number of harmonic wave-functions used in Eq. (8). Therefore, the wave numbers, $\tilde{\nu}$, and the absorption intensities, A, were calculated under different restrictions. The results calculated on the basis of the condition ($i=0$ to 13) are as follows:

$\tilde{\nu}$		$A\times10^{10}$
704.92	(0001)	1065.7
1410.76	(0002) + (0020)	70.400
2114.40	(0003)	4.537
2137.04	(0100)	485.26
2853.91	(0004) + (0040)	0.006
3280.05	(1000)	144.58
4267.12	(0200)	0.816
6395.59	(0300)	0.360
6523.88	(2000)	13.911
8654.41	(0400)	0.063
9751.18	(3000)	0.390
12974.26	(4000)	0.013

($\tilde{\nu}$: cm^{-1}, A: $cm^2\,s^{-1}$ $molecule^{-1}$)

In comparison with the values shown in Table 6, there is no difference in the absorption intensity and the difference in the wave numbers is not a serious problem in this work.

An ESR study of the Role of CoO and NiO in Al_2O_3–MoO_3–CoO (or NiO) Desulfurization Catalysts

Hisashi UEDA and Naoyuki TODO

National Chemical Laboratory for Industry, Mita, Meguro-ku, Tokyo 153

(Received July 25, 1974)

The ESR spectra from the catalyst/perylene/purified-benzene system were studied. The surface equilibria, $Co^{3+}+P \rightleftharpoons Co^{2+}+P^+$, $Ni^{3+}+P \rightleftharpoons Ni^{2+}+P^+$, and $Mo^{6+}+P \rightleftharpoons Mo^{5+}+P^+$, have been established, with the equilibrium constants at 20°C, 3.3×10^{15}, 3.0×10^{14}, and 6.8×10^{9} respectively. In Al_2O_3–MoO_3–CoO, $Mo^{6+}+Co^{2+} \rightleftharpoons Mo^{5+}+Co^{3+}$, is attained; the equilibrium constant obtained was 2.0×10^{-6}, and the corresponding value for $Mo^{6+}+Ni^{2+} \rightleftharpoons Mo^{5+}+Ni^{3+}$ was 2.3×10^{-5}. These results indicate that the roles of NiO and CoO in these catalysts are essentially the same. It has been found that the supporting order was important when CoO and MoO_3 were supported together, but unimportant when NiO and MoO_3 were supported together. Considering the known fact that CoO is a more efficient Co-catalyst of MoO_3 than NiO at lower supported concentrations (less than 2%), it has been concluded that CoO is incorporated in the alumina-carrier surface less stereospecifically, but more effectively, than NiO.

Numerous papers have been written on Al_2O_3–MoO_3–CoO–type catalysts, including several reviews.[1] In only a few papers, however, have the catalytic roles of MoO_3, CoO, and alumina as the carrier been cosidered, particularly in the form of a discussion of the reaction mechanism.[2] This is probably because of the fact that, when handling this type of catalyst, the researchers are more concerned with the practical usefulness, high activity, or long life of the catalyst. The present authors have been studying this catalyst by means of the ESR method in an attempt to get some knowledge about the catalytic reaction mechanism. As one way of approaching this problem, the surface concentrations of the paramagnetic species have been observed.[3]

In the present paper, the surface concentrations of the paramagnetic species formed in the oxide catalysts, if they are in contact with a dehydrated and degassed perylene/benzene solution, were measured by a quantitative ESR method.[4] Particular attention had been paid to the roles which CoO and NiO play in the catalysis reaction.

The present authors have always thought it most desirable to make measurements of the properties of a catalyst under the circumstances in which the catalyst is actually used. In some of our past papers, a few such efforts have been described.[3] Comparisons of the concentrations of the paramagnetic species to be formed in the catalyst studied in the present work at, say, 400 °C and 100 atm of H_2 are very desirable, too. However, before trying such rather difficult experiments, it will be helpful to try some less difficult experiments and to find a few of the essential differences between the effects of cobalt and nickel, if possible. For this reason, the following experiments were carried out.

Experimental

Purity of the Carrier. It is often advisable to use as simple a system as possible to find the mutual interactions between the components being considered in the system. Accordingly it is better to use the purest available γ-alumina carrier in order to study the roles of the supported transition metal ions than to use a commercial-grade one. However, when some time-consuming experimental data, such as those of catalyst-activity measurements, have already been obtained using a certain commercially available carrier, a comparison between those data and the ESR results is possible by using the same commercial carrier in the sample preparation for the ESR measurements. It is for this reason that a commercial γ-alumina carrier (Shokubai Kasei Co.) was used in the experiments in this work. The ESR spectrum of the carrier used and of a relatively pure one (Baikowski A 125 AS-2; Fe 20 ppm, Si 18 ppm, Cr 8 ppm, V and Mn 3 ppm, *etc.*) are both shown in Fig. 1. It should be noted that some "built-in acid points" due to impurities already exist on the carrier surface, even when nothing is supported. The surface area of the carrier used was 200 m^2/g.

Supporting Method and Analysis. MoO_3 was supported on alumina by immersing the carrier in a solution of ammonium molybdate (impregnation method). It was then

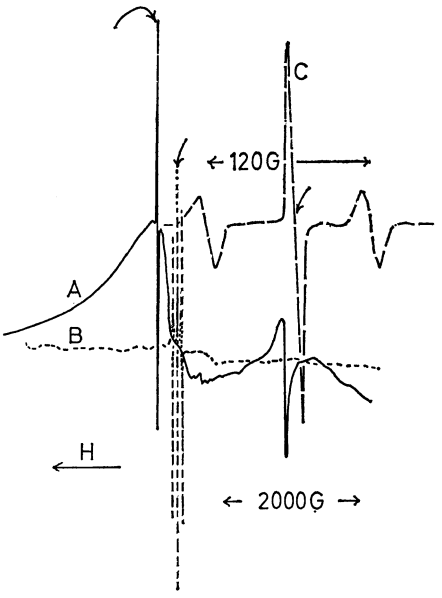

Fig. 1. ESR of the alumina carrier used. The right end of each spectrum is for 500 G, and the left end is for 5500 G of static magnetic field. The pointed arrows indicate $g=2.003$.
The modulation width used was 10 G. A: the γ-alumina used (Shokubai Kasei Co.). B: γ-alumina of Baikowski (France). The amplification of signal is 10 times of A. C: The central part of B, the amplication 1.6 times of A.

agitated for one hour at 40 °C, dried by means of a centrifuge, heated at 100 °C in an air bath, and then calcined at 550 °C for one hour. The mixed oxide thus prepared was denoted Al_2O_3–MoO_3. If a second ingredient (CoO or NiO) was supported, Al_2O_3–MoO_3 was then immersed in a solution of cobalt (or nickel) nitrate, dried, and calcined in the same way. This mixed oxide was denoted Al_2O_3–MoO_3–CoO (or NiO). If only CoO (or NiO) was supported, the supporting process for MoO_3 in the above processes was omitted. This was denoted Al_2O_3–CoO (or NiO). In the past works, the supporting order was always from MoO_3 to CoO (or NiO). In the present work, the reverse supporting order was also attempted. In this preparation, MoO_3 was supported on Al_2O_3–CoO or Al_2O_3–NiO. This was denoted Al_2O_3–CoO–MoO_3 (or Al_2O_3–NiO–MoO_3).

The analysis of the mixed oxides was done as follows: 1 g of the mixed oxide sample was heated to 130 °C with 10 ml of 1 : 1 H_2SO_4. After dissolution has been completed, it was cooled and diluted to 100 ml. The Co and Ni were analysed by means of an X-ray fluorescence analyser. The Mo was analysed by reducing all the Mo ions to Mo^{3+} and was then titrated with a $KMnO_4$ solution.

Preparation of the Sample and Measurements of ESR. By the same procedure as in a previous paper,[4] sample systems composed of oxide/perylene/purified-benzene were prepared and measurements were made after 10 min. The benzene pretreatment of the oxide was included.

Results

Figure 2 shows the concentrations of the perylene cation with the 9-line hyperfine structure, denoted as Pn^+, and those of the perylene cation without a hyperfine structure, denoted as Ps^+ (which has been denoted as P^+O^{*2-} in previous papers)[4,5] obtained by the use of Al_2O_3–CoO. The same values for Al_2O_3–NiO are shown in Fig. 3. In Fig. 3, the concentrations of Pn^+ and Ps^+ decrease when a relatively small amount of NiO is supported, probably because of some surface reactions between Ni^{3+} and the impurities. In Fig. 4, the concentrations of Pn^+, Ps^+, and Mo^{5+} obtained by Al_2O_3–MoO_3 are shown. In Figs.

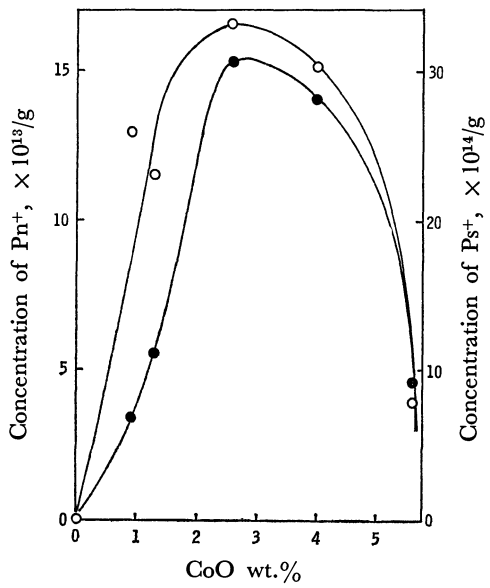

Fig. 2. P^+ concentrations obtained from Al_2O_3-CoO. ○ is for Pn^+ (left scale), and ● is Ps^+ (right scale).

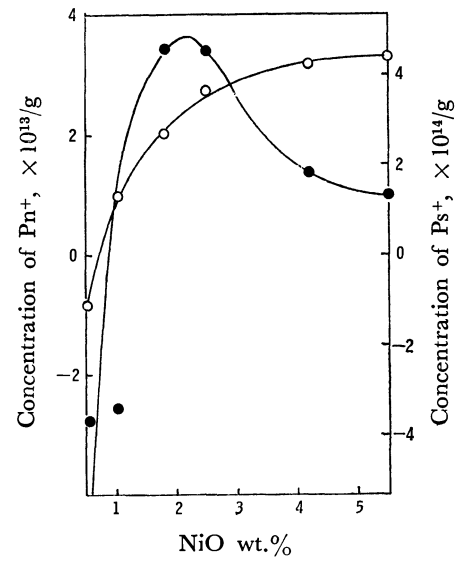

Fig. 3. P^+ concentions obtained from Al_2O_3-NiO. ○ is for Pn^+ (left scale), and ● is for Ps^+ (right scale).

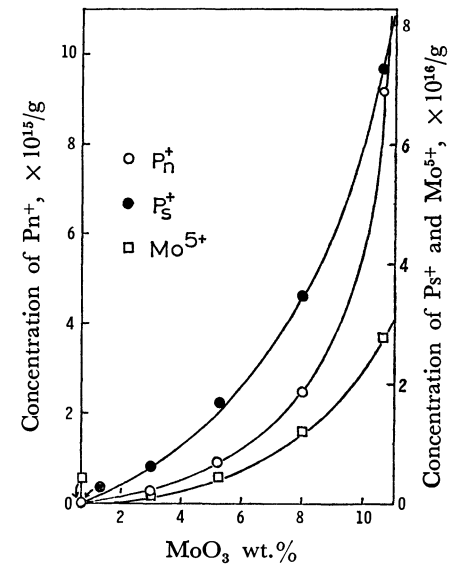

Fig. 4. P^+ and Mo^{5+} concentrations from Al_2O-MoO_3. ○ is for Pn^+ (left scale), ● is Ps^+ (right scale), and □ is for Mo^{5+} (right scale).

2 and 4, the concenrations of Pn^+ and Ps^+ formed on the unsupported carrier have been subtracted from the concentrations observed by supported catalysts; therefore, the curves pass the original point. In Table 1, the concentrations of Pn^+, Ps^+, and Mo^{5+} obtained by the use of Al_2O_3–MoO_3–CoO are shown. Table 2 is for Al_2O_3–MoO_3–NiO. In Fig. 5 the decay curves of the Pn^+ concentration obtained by the carrier and singly supported catalysts are shown. In Fig. 6, the decay curves of Pn^+ concentrations obtained by doubly supported catalysts are shown. In Fig. 7 the formation curves of the Mo^{5+} concentration obtained by doubly supported catalysts are shown.

Discussion

Surface Reaction Constants and the Role of CoO and NiO,

Table 1. Concentration of Pn^+, Ps^+, and Mo^{5+} in Al_2O_3-MoO_3-CoO ($\times 10^{13}$/g)

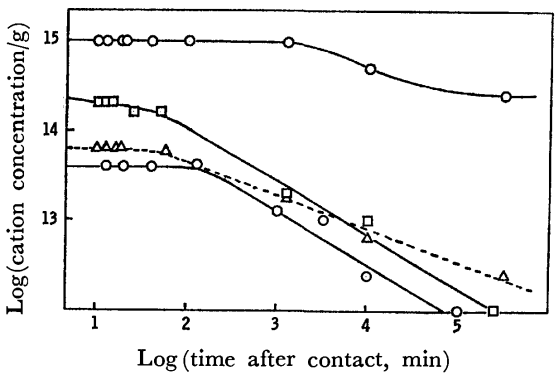

Fig. 5. Decay curves of Pn^+. ○ (bottom ones) are for Al_2O_3. △ (dotted line) are for Al_2O_3-NiO (98.2—1.8%), □ are for Al_2O_3-CoO (97.4—2.6%), and ○ (top ones) are for Al_2O_3-MoO_3 (94.8—5.2%).

As has already been discussed in previous papers, surface concentration equilibria are attained among surface redox species on an oxide surface;[5]

$$Co^{3+} + P \rightleftharpoons Co^{2+} + P^+ \quad (1)$$

$$Ni^{3+} + P \rightleftharpoons Ni^{2+} + P^+ \quad (2)$$

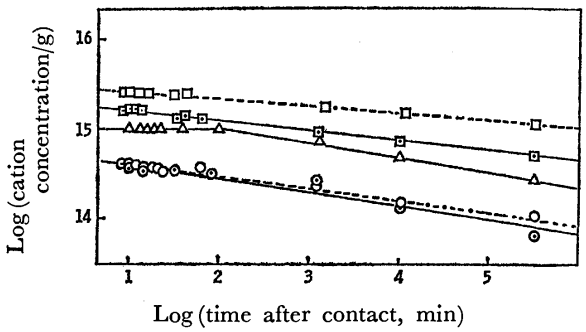

Fig. 6. Decay curves of Pn^+. △ are for Al_2O_3-MoO_3 (94.8—5.2%).
⊡ are for Al_2O_3-MoO_3-CoO (92.9—5.1—2.0%),
□ are for Al_2O_3-CoO-MoO_3 (92.8—1.9—5.3%),
⊙ are for Al_2O_3-MoO_3-NiO (93.5—5.2—1.3%),
and ○ are for Al_2O_3-NiO-MoO_3 (92.3—2.0—5.7%).

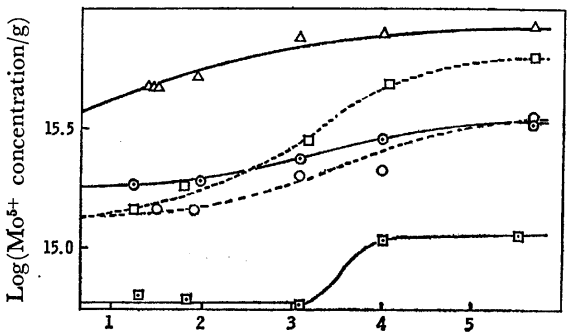

Fig. 7. Formation of Mo^{5+}. Symbols are the same as in Fig. 6.

The formation of P^+ (here, P^+ denotes both Pn^+ and Ps^+; therefore, $[P^+]=[Ps^+]+[Pn^+]$), as is shown in Figs. 2, 3, and 5, proves the existence of Co^{3+} and Ni^{3+} on the oxide surface. It is reasonable to use the activity coefficients, f_c, f_n, and f_m, for Co^{2+}, Ni^{2+}, and Mo^{6+} because it can easily be assumed that not all the metal ions supported on the oxide surface are actively working in the surface reactions. Actually, the activity of a catalyst depends not only on the amount of supported salts, but also on the method of preparation. Therefore, f_c = (concentration of active Co^{2+})/(concentration of total Co^{2+} supported). In an extreme case, in which only one Co^{2+} ion is supported on a 200 m^2 surface area (*i.e.*, one gram carrier), the Co^{2+} ion should be 100% active; in other words, $f_c = 1.0$. Therefore,

$$\frac{f_c \cdot [Co^{2+}] \cdot [P^+]}{[Co^{3+}] \cdot [P]} = K_1 \quad (3)$$

Let K be equal to the following value;

$$K = \frac{[Co^{2+}] \cdot [P^+]}{[P]} = \frac{K_1 \cdot [Co^{3+}]}{f_c} \quad (4)$$

If $[Co^{3+}] \rightarrow 1$ (ion/g catalyst) is considered, $[Co^{2+}]$ should also be close to 1 (ion/g catalyst), or $f_c \rightarrow 1.0$. Therefore, the limiting value of K_1 is K. The values of K are plotted against $[Co^{2+}]$ in Fig. 8-A. The value of K for $[Co^{2+}] \rightarrow 0$ gives $K_1 = 3.3 \times 10^{15}$ for CoO. For NiO, K_1 of 3.0×10^{14} is obtained from Fig. 8-B.

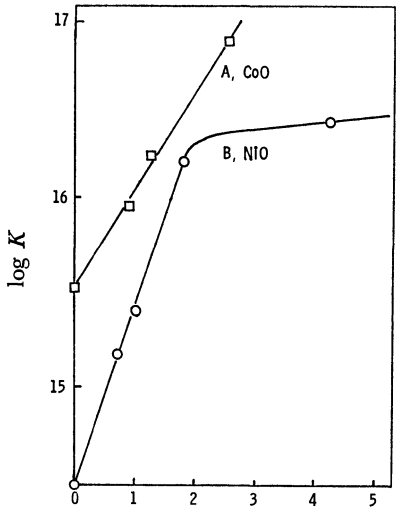

Fig. 8. Log K plotted against CoO (A) or NiO (B) concentration.

In the mixed oxide, Al_2O_3–MoO_3–CoO, there are those equilibria:

$$Mo^{6+} + Co^{2+} \rightleftharpoons Mo^{5+} + Co^{3+} \; ; \; K_r \qquad (5)$$

$$Mo^{6+} + P \rightleftharpoons Mo^{5+} + P^{+} \; ; \; K_f \qquad (6)$$

The constants are:

$$K_r = \frac{[Co^{3+}]\cdot[Mo^{5+}]}{f_c\cdot[Co^{2+}]\cdot f_m\cdot[Mo^{6+}]}, \quad K_f = \frac{[Mo^{5+}]\cdot[P^{+}]}{f_m\cdot[Mo^{6+}]\cdot[P]}.$$

Then, $K_f = K_1\cdot K_r$. At the limit of $[Mo^{6+}]\rightarrow 1$ (ion/g catalyst), $f_m \rightarrow 1.0$. Then, in the same way as in (4), the value of K_r is obtained as the limiting value of K' at $[Mo^{6+}]\rightarrow 0$:

$$K' = \frac{[Mo^{5+}]\cdot[P^{+}]}{[P]} \rightarrow K_f \text{ (when } [Mo^{6+}] \rightarrow 1).$$

From Fig. 9, 9.93×10^{9} (for Al_2O_3–MoO_3–CoO), 5.62×10^{9} (for Al_2O_3–MoO_3–NiO), and 6.31×10^{9} (for Al_2O_3–MoO_3) are obtained as the K_f values. The average value of these three values is 6.82×10^{9}. The K_r values calculated from K_f and K_1 are 2.06×10^{-6} for Al_2O_3–MoO_3–CoO, and 2.27×10^{-5} for Al_2O_3–MoO_3–NiO.

From (4), $f_c = (K/K_1)\cdot[Co^{3+}]$. Under the condition $[Co^{3+}]\simeq 1$, meaning that Co^{3+} has almost completely reacted, f_c values of 0.37,0.20,0.05, and 0.05 are obtained for 0.88, 1.27, 2.58, and 5.61% of CoO supported in Al_2O_3–CoO. In the same way, f_n values of 0.20, 0.12, 0.02, and 0.01 are obtained for 0.67, 1.02, 1.87, and 4.16% of NiO supported in Al_2O_3–NiO. f_m is obtained as $[P^{+}]$/(total $[Mo^{6+}]$ supported); the values are 2.8×10^{-5}, 8.4×10^{-5}, and 1.8×10^{-4} for 0.67, 5.22, and 10.65% of MoO_3 supported in Al_2O_3–MoO_3. The effective Mo^{6+} concentrations, $f_m\cdot[Mo^{6+}]$, are 7.8×10^{14}, 1.8×10^{16}, and 8.0×10^{16} (ion/g oxide). The $[Co^{3+}]$ value in Al_2O_3–MoO_3–CoO (CoO 1.5%, MoO_3 10.5%) was estimated by these values; it is 2.5×10^{14} (ion/g oxide), some 1 ppm of the total Co^{2+} supported concentration.

In the present catalyst, it has been established that MoO_3 plays the main role, while CoO plays the auxiliary

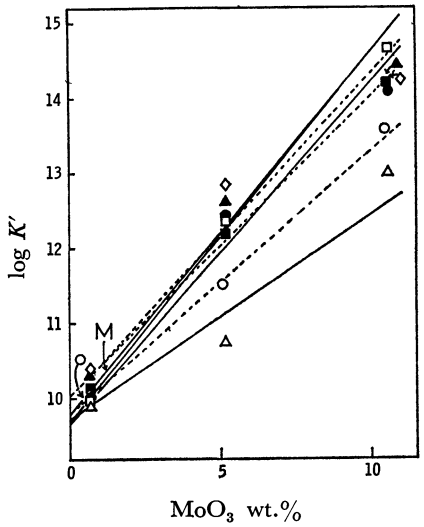

Fig. 9. Log K' plotted against MoO_3 concentration. The seven lines were obtained by, from top to bottom (viewed at 10% position), ◇, (marked M at left) Al_2O_3–MoO_3. □, NiO (0.2—0.6%). ▲, CoO (0.4—0.9%). ●, NiO (1.0—1.8%). ■, CoO (1.5—2.5%). ○, CoO (3.6—5.6%), and △, NiO (2.6—4.2%).

part. The following three results obtained by our study make possible a theoretical interpretation for those facts: (1) In the Mo^{6+}–Mo^{5+} equilibrium, the higher oxidation state is relatively more stable than the lower oxidation state; therefore, it is more suitable to activate the hydrocarbon substrate. In the Co^{2+}–Co^{3+} equilibrium, the lower oxidation state is more stable than the higher oxidation state; therefore, it does not activate the hydrocarbon. However, it oxidizes Mo^{5+} to Mo^{6+}. (2) The K_1 values are far larger than K_f; therefore, the recovery of the lower oxidation state (*e.g.*, the reversely directed reaction (5) with respect to the Mo ions) after the activation reactions, (1), (2) or (6), proceeds more easily with $Mo^{5+}\rightarrow Mo^{6+}$ than with $Co^{2+}\rightarrow Co^{3+}$. (3) There is another point which should be considered for a complete understanding of this problem — the rate constants of the following reactions:[3] $H^{+}+Co^{2+}\rightarrow H+Co^{3+}$ and $H^{+}+Mo^{5+}\rightarrow H+Mo^{6+}$. These constants must be compared in future studies.

The carrier effects have been studied with the desulfurization catalysts, and it has shown that the γ-alumina carrier used in this type of catalyst stabilizes the metal ions supported on it.[3] For this reason, it is not unreasonable to assume the existence of the higher oxidation state of Co and Ni ions at elevated temperatures and under high pressures of H_2, though this point, too, must be confirmed by future studies.

Some Results Related to the Stereochemistry of the Catalysts.

In Eq. (1) through (5), the sum of $[Pn^{+}]$ and $[Ps^{+}]$, or $[P^{+}]$, have been used instead of any one of these two components. This has been done because both species are to be counted as cations.[3,5,6] If the $[Pn^{+}]/[Ps^{+}]$ ratio is written as r, this value depends on the solvent used.[4] In Table 3 the r values are shown. It will be found that, in Al_2O_3–CoO and Al_2O_3–NiO,

TABLE 3. $[Pn^+]/[Ps^+]$, OR r-VALUE

the less the amount of the support, the higher the r value. In contrast, in Al_2O_3–MoO_3, the more the amount of the support, the higher the r value. In doubly supported Al_2O_3–MoO_3–CoO and Al_2O_3–MoO_3–NiO, no clear-cut tendency is found. However, the general tendency is the same as that in singly supported cases. These results can be understood if it is assumed that the supporting sites of Co^{2+} (or Ni^{2+}) and of Mo^{6+} are different. The assumption here agrees quite well with the conclusions of past literature that effective CoO and NiO are supported at the octahedral sites in the β-phase, while MoO_3 is supported at the tetrahedral sites in the δ-phase.[7,8] It has been shown that an analysis of the P^+ spectrum may give some knowledge about the stereochemistry of the catalyst surface.

Since the effective MoO_3 and the effective CoO (or NiO) seem to be occupying different surface sites, the catalyst prepared by the use of the reverse supporting order may have a different nature compared with the one made by the use of a normal supporting order. Such differences will be found in Figs. 6 (Pn^+ concentrations) and 7 (Mo^{5+} concentrations). In Fig. 7, the rates of the formation of Mo^{5+} before and after approximately 3×10^3 min. (the middle points of the curves) are different. Though each catalyst surface should be handled as one integrated system of Al^{3+}–Mo^{6+}–Co^{2+}–O^{2-}–*etc.* in the equilibrium state ($t=10^5$ min or more), in the initial period (t, less than 10^3 min.) the more reactive Co^{3+} may be receiving an electron from a perylene molecule faster than Mo^{6+}, thus making the initial part of the lowest curve (⊡) parallel to the time axis. It seems that this reactivity of Co^{3+} is faster for Al_2O_3–MoO_3–CoO than for Al_2O_3–CoO–MoO_3 (□). However, the equilibrium Mo^{5+} concentration must be estimated by the use of Eq. (5), not Eq. (6). The K_r value in (5) for Al_2O_3–CoO–MoO_3 is some 10 times larger than that for Al_2O_3–MoO_3–CoO. This difference may be explained as follows. If Mo^{5+} in the tetrahedral coordination is more efficiently oxidized by Co^{3+} than that in the octahedral coordination, and if a relatively larger portion of Co^{2+} ions is distributed to tetrahedral sites when CoO is supported prior to MoO_3 (Al_2O_3–CoO–MoO_3), and if, therefore, a relatively larger portion of Mo^{6+} is in this case coordinated to octahedral sites, the rsults in Fig. 7 may be interpreted by saying that the number of the combination sites, Mo^{6+} (tetrahedral)–Co^{2+}(octahedral), is smaller in Al_2O_3–CoO–MoO_3 than in Al_2O_3–MoO_3–CoO, although the overall compositions of the oxides are almost equal.

In the cases of Al_2O_3–MoO_3–NiO and Al_2O_3–NiO–MoO_3, the curves in Figs. 6 and 7 are quite similar. This may be interpreted by means of a hypothesis that Ni^{2+} is incorporated into the carrier more stereospecifically, but less effectively (for example, the number of Ni^{2+} ions in one NiO colony on the carrier surface is different from the number of Co^{2+} ions in one CoO colony), than Co^{2+} is. The ratios of the catalyst activity *vs.* the CoO and NiO content in the Al_2O_3–MoO_3–CoO (or NiO) curves are different.[9] CoO is quite efficient at 1%, and the activity reaches its maximum value at 2%, while NiO is quite inefficient at 1%, but the activity increases until the NiO content reaches 4% or more. These results show that the supporting order can be used to get information on the stereochemical interactions between the support and the carrier surface.

ESR as an Analysing Method of a Solid Catalytic Reaction System.

There are several advantages of the ESR method when it is used to analyse catalytic reaction systems. In this section, only its sensitivity will be considered as an advantage. If only 1% of CoO is supported on Al_2O_3, some 4×10^{13}/g of Pn^+ and 2×10^{15}/g of Ps^+ are formed. If all the Co^{3+} had been converted to either Pn^+ or Ps^+, $[Co^{3+}]$ should have been 2×10^{15}/g. As the $[Co^{2+}]$ supported is 8×10^{19}/g, the abundance of Co^{3+} ions in the supported cobalt salt is only 25 ppm. If only those Co^{3+} ions which produce Pn^+ are considered, their abundance is only 0.5 ppm in supported cobalt salt. No method other than ESR can detect such a very small quantity. For example, by magnetic susceptibility measurements, the contribution of $\mu(Co^{3+})$ to the observed average μ value at 25 ppm is completely negligible; this then leads to the wrong conclusion that Co^{3+} does not participate in the catalytic reactions.[10] Though their concentrations are quite small, Co^{3+} and Ni^{3+} play important roles in the dynamic reaction process of desulfurization. The detection of such dilute but reactive species can be done only either by a fast detection of a created transient state or by a trapping method. In the present application, those transient species have been transformed to Pn^+ and Ps^+ and have been measured as semistable paramagnetic species.

The authors wish to thank Mr. K. Ogawa of their Institute and Mr. K. Fujita of Kanagawa University for their cooperation in the preparation and analysis of the oxide catalysts.

On the Stable Molecular-shapes of C_mH_{m-4} Cata-condensed Nonalternant Hydrocarbons

Azumao TOYOTA

Department of Chemistry, Faculty of General Education, Yamagata University, Koshirakawa, Yamagata 990

(Received July 31, 1974)

The energetically most favorable molecular-symmetry groups and geometrical structures of C_mH_{m-4} cata-condensed nonalternant hydrocarbons were examined systematically on the basis of the symmetry rule and the semiempirical SCF MO method. The first excitation energies in the fully-symmetrical nuclear arrangements were found to decrease with increasing the number of carbon atoms, showing a tendency to converge to a certain limiting value, *ca.* 0.8 eV. Molecules larger than a certain critical size ($m\sim10$) were predicted to suffer the second-order Jahn-Teller distortion, exhibiting a double-bond fixation in the peripheral carbon skeleton. Using the most stable geometrical structures obtained, the electronic spectra of these molecules were calculated. Furthermore, the predictions of the stable molecular-shapes in the lowest excited singlet states were briefly mentioned.

Recently, we have developed the symmetry rule[1-3] for predicting the stable molecular shapes of conjugated hydrocarbons.[4,5] This rule is based on the pseudo, or the second-order Jahn-Teller effect,[6,7] which is due to the stabilization, occuring when a certain bond distortion mixes two electronic states nearly degenerate in the fully-symmetrical nuclear arrangement. On the basis of this rule, we examined systematically, in a previous paper,[8] the problem of the molecular-symmetry reduction in C_mH_{m-2} cata-condensed nonalternant hydrocarbons. As a result, we found that there is a good correlation between the molecular-symmetry reduction and the number of carbon atoms(m): in the $4n$ π-electron systems the first excitation energies in the fully-symmetrical nuclear arrangements were predicted to be significantly smaller than a certain critical value, and the molecular-symmetry reduction accompanied by a marked double-bond fixation in the peripheral carbon skeleton to occur. On the other hand, in the $4n+2$ π-electron systems, such energies were found to be considerably large for small members and to decrease rapidly with the number of carbon atoms, resulting in the molecular-symmetry reduction for members larger than a certain critical molecular size($m=14$).

The purpose of this paper is to examine further the possibility of a relationship between the number of carbon atoms and the molecular-symmetry reduction in C_mH_{m-4} cata-condensed nonalternant hydrocarbons considered as formed by the introduction of two cross-links between the carbon atoms of like parity of C_mH_m cyclic polyenes. Moreover, we investigate the second-order Jahn-Teller effects on the bond-length distributions and the excitation energies of these nonalternant hydrocarbons.

Theoretical

The method employed for predicting the energetically most favorable molecular-symmetry groups of conjugated hydrocarbons is the symmetry rule based on the second-order Jahn-Teller theorem.[7] We outline this rule briefly. Let us start by assuming for a conjugated molecule a fully-symmetrical nuclear arrangement as the unperturbed configuration. We assume that in the unperturbed nuclear configuration all the symmetrical bond distortions have taken place until the first-order energy equilibrium is reached. The unperturbed electronic wave functions ψ_0, ψ_1,$\cdots$, ψ_n,$\cdots$ and the corresponding eigenvalues E_0, E_1,$\cdots$, E_n,$\cdots$ are assumed to be known. We now distort the nuclei from the symmetrical first-order nuclear arrangement by means of the ith normal coordinate of nuclear motion Q_i. On the basis of the same approximation as used previously,[1] the energy of the ground state after deformation may be written as

$$E(Q_i) = E_0 + \frac{1}{2}\left\{k - 2\sum_n{}' \frac{|\langle\psi_n|(\partial H_\pi/\partial Q_i)_0|\psi_0\rangle|^2}{(E_n-E_0)}\right\}Q_i^2$$

where k and H_π represent the force constant for an sp^2 hybridized C–C σ-bond and the Hamiltonian for π-electrons, respectively.

According to the above equation, the force constant associated with the normal vibration Q_i should be regarded as $\{k-2\sum_n{}'|\langle\psi_n|(\partial H_\pi/\partial Q_i)_0|\psi_0\rangle|^2/(E_n-E_0)\}$ and can be negative if a given matrix element $\langle\psi_n|(\partial H_\pi/\partial Q_i)_0|\psi_0\rangle$ is nonvanishing and the associated energy gap E_n-E_0 is sufficiently small. If the force constant, *i.e.*, the curvature of $E(Q_i)$ with respect to Q_i, is negative, the energy should be lowered by the nuclear deformation Q_i, and a pseudo Jahn-Teller distortion from the symmetrical nuclear arrangement would occur spontaneously.

In order to estimate the value of the force constant, we have to take into account the infinite sum over the excited states in the above equation. However, to derive the symmetry rule we made the following drastic approximation: from the viewpoint of energy gap law, the infinite sum over the excited states is replaced by one term corresponding to the lowest excited state. In spite of the very crude approximation, Pearson and we have shown that this is justified in a variety of small molecules, complex ions and conjugated hydrocarbons.[1-5]

The symmetry rules[1] for predicting the stable molecular shapes in the closed-shell ground states are as follows: the symmetry of the nuclear displacement with the smallest force constant is identical with that of the lowest excited state, ψ_1. If the energy gap E_1-E_0 is smaller than the critical value, *ca.* 1.2 eV, the molecule would be distorted into a less symmetrical nuclear configuration. The most favorable type of bond distortion is predicted by examining the distribution of the transition density ρ_{01} over the molecular

skeleton. When the excited state is represented by a one-electron transition between molecular orbitals ϕ_i and ϕ_j, the transition density ρ_{01} between the ground and the lowest excited state is given by $\sqrt{2}\,\phi_i\phi_j$.[6]

Eigenvalues and wavefunctions for the fully-symmetrical nuclear arrangements are calculated using the self-consistent configuration interaction formalism of the Pariser-Parr-Pople method.[9-11]

Results and Discussion

Ground-state Molecular-symmetry Groups and Geometries. The symmetries and the energies of the lowest excited singlet states of C_mH_{m-4} cata-condensed nonalternant hydrocarbons (Fig. 1) obtained by assuming the fully-symmetrical nuclear arrangements are listed in Table 1. The first excitation energies for the fully-symmetrical nuclear arrangement of C_mH_{m-4} systems are shown in Fig. 2, in which those of C_mH_{m-2} systems are also shown by the open circles. It is seen that the dependence of the energy gap on the number of carbon atoms is remarkably different between C_mH_{m-2} systems. That is, in the former systems there is no such a sharp distinction of the energy gap dependence between $4n$ and $4n+2$ π-electron systems as that observed in the latter systems: the energy gaps are intermediate of those for the $4n$ and $4n+2$ π-electron systems of C_mH_{m-2}, decreasing as the number of car-

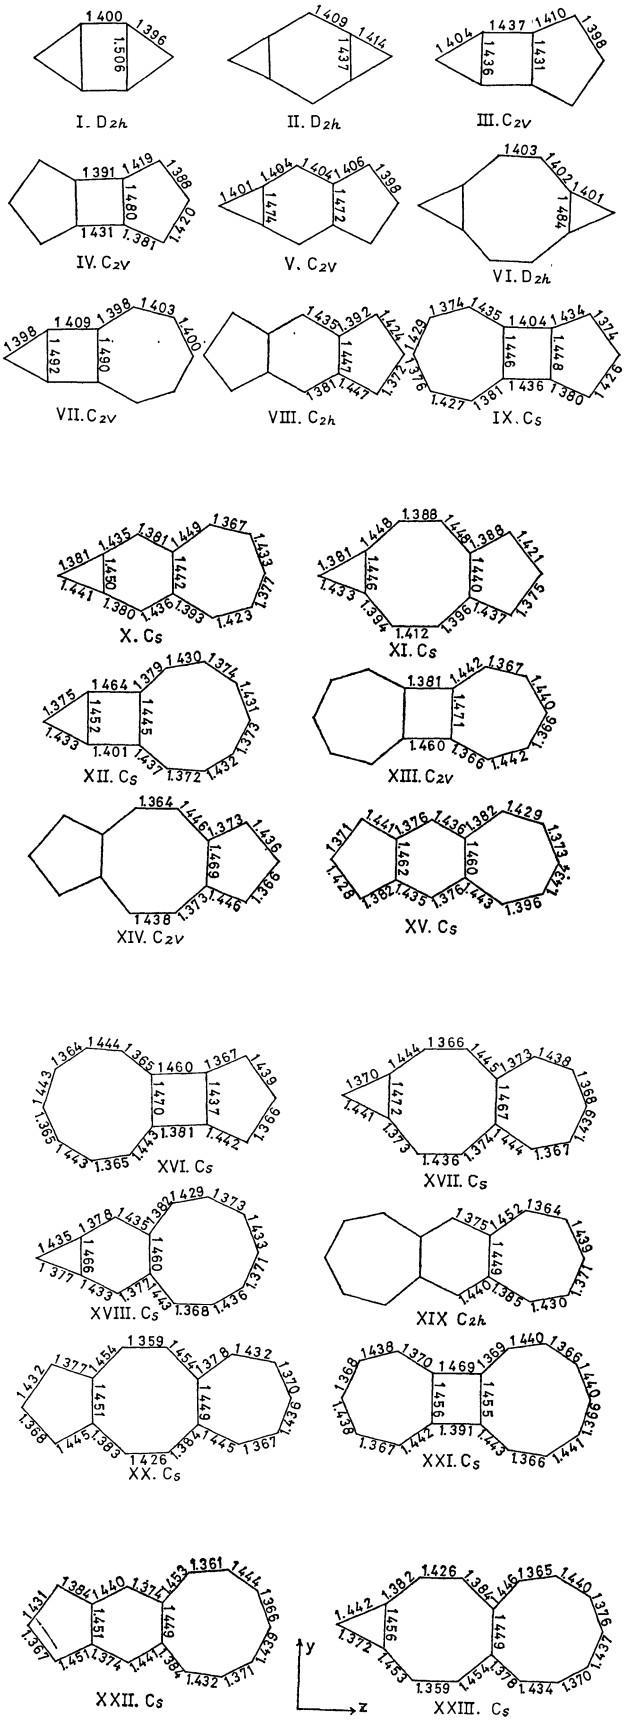

Fig. 1. Predicted stable molecular-symmetry groups and equilibrium bond lengths (in Å unit) and choice of axes.

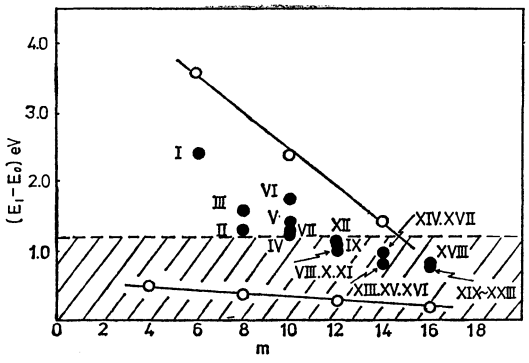

Fig. 2. Dependence of the first excitation energies for the fully-symmetrical nuclear configurations on the number of carbon atoms (m) in C_mH_{m-4} systems. Open circles mean values in C_mH_{m-2} systems.

bon atoms increases, and showing a tendency to converge to a certain limiting value, *ca.* 0.8 eV. This may be explained qualitatively by considering the orbital energy changes due to the introduction of cross-link into the unperturbed cyclic polyene. In the Hückel MO description, the energy change of the ith molecular orbital may be evaluated using the first-order perturbation theory:

$$\delta\varepsilon_i = \sum_{\mu\nu} 2C_{\mu i}C_{\nu i}\beta$$

where C_μ and C_ν are atomic-orbital coefficients for atoms μ and ν between which a cross-link is introduced. As an illustration, we show in Fig. 3 the correlation of the Hückel molecular orbitals of benzene(C_6H_6) with those of C_6H_4 and C_6H_2 (I) and in Fig. 4 that of molecular orbitals of cyclic polyene(C_8H_8) with those of C_8H_6 and C_8H_4(III). That energy gaps E_1–E_0 for C_mH_{m-4} are smaller than those for C_mH_{m-2} systems with $4n+2$ π-electrons is due to the fact that the separation between the highest occupied and the lowest vacant molecular orbitals becomes smaller by increasing the number of the cross-link between the like parity of carbon atoms of cyclic polyene. On the other hand, energy gaps for C_mH_{m-4} larger than those for C_mH_{m-2} systems with $4n$ π-electrons is ascribable to the fact that the separation between the highest occupied and the lowest vacant orbitals becomes larger by increasing the number of the cross-link, in contrast to the case of the above mentioned $4n+2$ π-electron systems.

The problem of the molecular-symmetry reduction can now be discussed on the basis of the symmetry rules and Table 1. The dashed line in Fig. 2 represents the critical value for the molecular-symmetry reduction, and in the hatched area the molecule should distort into a less symmetrical nuclear configuration.

As to the smallest member of C_mH_{m-4} systems, *i.e.*, I(m=6), the lowest excited state is of B_{2u} symmetry and the energy gap is considerably larger than the critical value. We may predict that this molecule undergoes no molecular-symmetry resuction to C_{2v} from D_{2h}. It is, however, of interest to note that the type of the nuclear displacement with the smallest force constant is that of bond-length alternation in the peripheral carbon skeleton. A similar situation

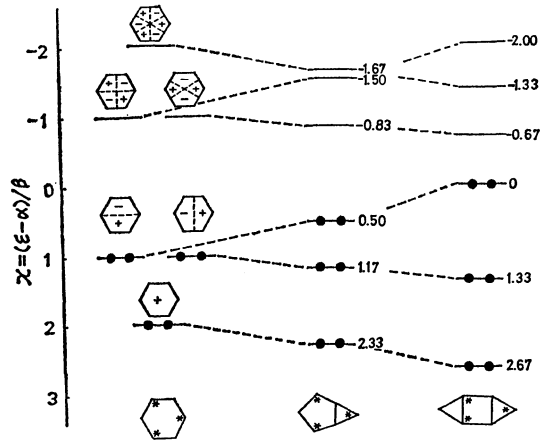

Fig. 3. Correlation of molecular orbitals of benzene (C_6H_6) with those of C_6H_4 and C_6H_2(I).

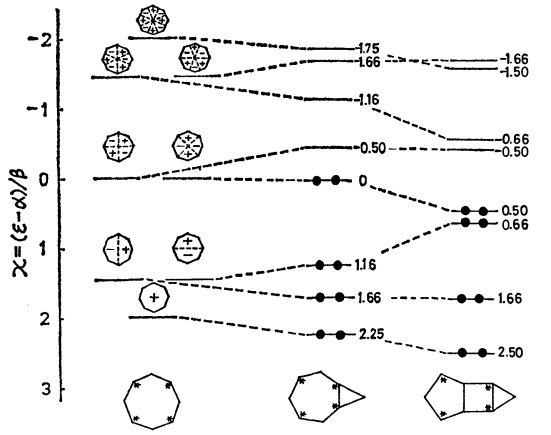

Fig. 4. Correlation of molecular orbitals of cyclic polyene (C_8H_8) with those of C_8H_6 and C_8H_4(III).

is also seen in the unperturbed cyclic polyene, benzene.

As for molecules (m=8), II and III, the energy gaps are relatively larger than the critical value and the symmetries of the lowest excited states are B_{3g} and B_2, respectively. From the view-point of energy gap law, there is no possibility for the molecular-symmetry reduction to occur in both molecules.

In case of m=10 (IV—VII), the energy gaps are predicted to be slightly large as compared with the critical value, and all these molecules, except bowtine (IV), do not suffer the second-order Jahn-Teller distortion.

Of the molecules with 12 carbon atoms, only *s*-indacene (VIII) has been synthesized by Hafner's group.[12] It is of interest to note that in these valence isomers the energy gaps are nearly the same, *i.e.*, about 1.0 eV, which are smaller than the critical value. Thus, these molecules may undergo the second-order bond distortions, reducing their ground-state molecular-symmetry groups to C_{2h}(VIII) and C_s (IX—XII) from D_{2h} and C_{2v}, respectively.

In case of m=14 (XIII—XVIII), the energy gaps are smaller than the critical value, so that these molecules are predicted to lower their ground-state molecular-symmetry groups to C_{2v}(XIII and XIV) and C_s (XV—XVIII) from D_{2h} and C_{2v}, respectively, by

a) For molecules which belong to the point group C_{2h}, the z axis is taken to be perpendicular to the molecular plane. b) The spectrum of a hexacarbometoxydihydroxy derivative; E. LeGoff and R. B. LaCount: *Tetrahedron Lett.*, **1964**, 1161.

the interaction of the ground-state with the lowest excited state through the unsymmetrical C–C stretching vibration.

Finally, in case of m=16 (XIX—XXIII) all the valence isomers have almost the same energy gaps, *i.e.*, about 0.8 eV, and it is predicted that these molecules undergo the second-order Jahn-Teller distortion, and their molecular-symmetry groups are reduced to C_{2v} (XIX) and C_s (XX—XXIII) from D_{2h} and C_{2v}, respectively.

The ground-state molecular-shapes for the energetically most favorable nuclear arrangements are predicted from the distribution of the two-center components of transition densities between the ground and the lowest excited singlet states, some of which are shown in Fig. 5.

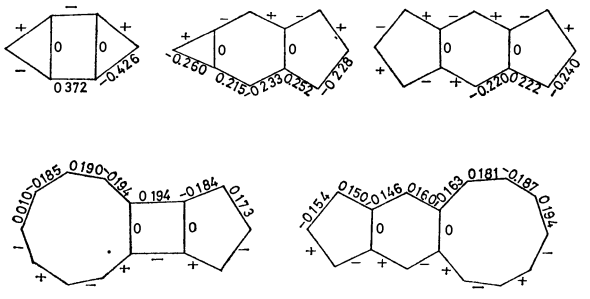

Fig. 5. Distribution of two-center components of transition densities (ρ_{01}).

In order to obtain the information on the actual magnitude of distortions or the equilibrium nuclear configurations with respect to C–C bond lengths at which the real molecule will settle, we performed the calculation using the variable bond-length SCF MO method, taking into account the distorted structures as a starting geometry.[11,13]

Results of SCF MO calculations show that almost all molecules undergo the second-order Jahn-Teller distortion, as predicted from the symmetry rule.

As to the distribution of C–C bond length, it should be noted that the second-order double-bond fixation, *i.e.*, the bond-length alternation in the peripheral carbon skeleton, is the common phenomenon in these cata-condensed nonalternant hydrocarbons (Fig. 1).

Stabilization Energies. Figure 6 shows the correlation of stabilization energies with the energy gaps calculated assuming the fully-symmetrical nuclear arrangements. We define the stabilization energy ΔE_s as the difference in total energy between the fully-symmetrical and the reduced molecular geometries. The total energy is assumed to be the sum of π-bond

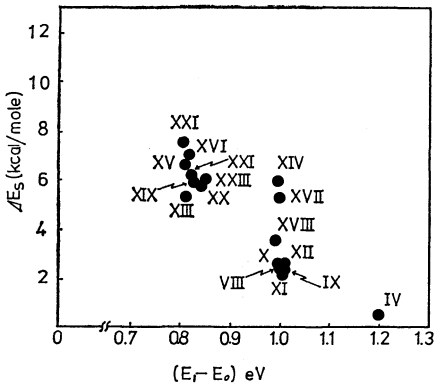

Fig. 6. Correlation of stabilization energies ΔE_s with energy gaps(E_1-E_0).

and σ-bond energies, the latter being calculated using harmonic oscillator model with the force constant equal 714 kcal mol^{-1} Å^{-2}.[14] As is seen in this figure, there is a fairly good correlation between ΔE_s and the energy gaps E_1–E_0. Particularly, it is noticed that in the valence isomers with 12 carbon atoms, the ΔE_s are almost the same.

Electronic Spectra. We calculated the excitation energies using the bond-lengths for the energetically favorable equilibrium configuration. The employed method is based on the semiempirical Pariser-Parr-Pople SCF MO CI method, and the configuration mixing of 28 singly excited states is included.

It is shown that the lowest excitation energies for the reduced molecular geometries are larger than those for the fully-symmetrical ones, and are almost constant (1.4—1.6 eV) from molecule to molecule. On the other hand, the next lowest excited states would not be remarkably changed by the molecular-symmetry reduction, lying in the region about 2.2 eV (compare Table 1 with Table 2).

Excited-state Molecular-symmetry Groups. In connection with the ground-state molecular-symmetry groups, we briefly mention the stable molecular shapes in the first excited singlet states. The criterion for the molecular-symmetry reduction in an excited state is that the energy gap E_2–E_1 is less than the critical value, *ca.* 0.6 eV.[1] From this criterion and Table 1 we may predict that all the molecules examined do not reduce their molecular-symmetry groups in the first excited singlet states. That is, the stable molecular shapes in the excited states belong to their fully-symmetrical nuclear arrangements.

Conclusion

On the basis of the symmetry rule and the semiempirical SCF MO method, the problem of the molecular-symmetry reduction in C_mH_{m-4} cata-condensed non-alternant hydrocarbons was systematically examined. It was revealed that there is a fairly good correlation between the molecular-symmetry reduction and the number of carbon atoms: that is, the molecular-symmetry reduction should set in about $m\sim10$. In these systems, there is no such a sharp distinction of molecular-symmetry reduction between $4n$ and $4n+2$ π-electron systems as that seen in C_mH_{m-2} systems. The predicted types of the energetically most favorable bond distortion, determined by examining the two-center components of transition densities, are in good agreement with the results of variable bond-length SCF MO calculations. The obtained stable molecular shapes are found to correspond to one of the Kekulé-like structures. It is concluded that such phenomena in these non-alternant hydrocarbons arise from the fact that the type of the symmetry of the lowest excited state in the fully-symmetrical nuclear arrangement is that of bond-length alternation in the peripheral carbon skeleton, and that the lowest excited state is very close to the ground state.

The auther is very grateful to Professor T. Nakajima of Tohoku University for reading the manuscript and helpful discussions.

The numerical calculation was carried out at Tohoku university with a NEAC 2200—700 computer.

The Crystal and Molecular Structure of Nagilactone A Diacetate[1)]

Ken HIROTSU, Taiichi HIGUCHI, Akira SHIMADA,† Yuji HAYASHI, and Takeo SAKAN

Department of Chemistry, Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received August 14, 1974)

The title compound crystallizes in the orthorhombic space group $P2_12_12_1$, with cell dimensions of $a=10.43$, $b=15.45$, $c=13.65$ Å, and $Z=4$. The structure was determined by direct methods from photographic data, and was refined by the least-squares method to a final R of 0.098 for 2581 reflections. Rings A and B are subject to steric strains resulting from the formation of a lactone ring. This is reflected in the abnormal values for some bond lengths, angles, and dihedral angles.

Nagilactones were the first reported compounds of novel tricyclic nor- or bisnor-diterpenoid constituents which originate in *Podocarpus* plants. Since four nagilactones, A, B, C, and D, were isolated from *P. nagi* zoll. et Moritzi in 1968,[2)] more than twenty components have been found in various *Podocarpus* species as important biologically active principles: plant-growth regulators,[3)] anti-termite substances,[4)] and insect toxins for house-fly larvae.[5)] Although the structures of all the lactones have been assigned and correlated on the basis of chemical or spectral evidence, it has become increasingly important to determine the exact structure of any congener in this group of compounds by means of X-ray crystallography. This article will report the details of the X-ray analysis of nagilactone A diacetate. The present results completely support the structure as assigned in the preliminary communication.[1)]

Experimental

Nagilactone A diacetate crystallizes from chloroform as colorless prisms. All the data were obtained from a specimen with dimensions of $0.2\times0.3\times0.4$ mm, cut from the above crystal.

Crystal Data. $C_{23}H_{28}O_8$, $M=432.5$, orthorhombic, $a=10.43(1)$, $b=15.45(1)$, $c=13.65(1)$ Å, $U=2200$ Å^3, $D_c=1.32$ g·cm^{-3} $Z=4$, $F(000)=920$, $\mu=$(Cu-$K\alpha$, $\lambda=1.542$ Å)$=6.9$ cm^{-1}; space group $P2_12_12_1(D_2^4)$; systematic absences: $h\,0\,0$ when $h\neq2n$, $0\,k\,0$ when $k\neq2n$, and $0\,0\,l$ when $l\neq2n$.

Crystallographic Measurements. The unit-cell dimensions were evaluated from zero-layer Weissenberg photographs, the spacings of the reflections being calibrated with superimposed Al powder lines. The intensity data for the $0\,k\,l$~$10\,k\,l$ and $h\,0\,l$~$h\,3\,l$ layers were recorded by equi-inclination Weissenberg photography using Cu-$K\alpha$ radiation. The intensities were estimated visually and corrected for spot shape and for Lorentz and polarization factors. No correction was applied for absorption and extinction. The resulting data were correlated and reduced to structure-factor amplitudes using the method of Hamilton, Rollet, and Sparks.[6)] A total of 2581 independent structure factors were obtained; 292 were too weak to be measured.

Structure Determination and Refinement. The normalized structure factors, E's, were calculated with a scale factor and a mean isotropic temperature factor derived from a Wilson plot.[7)] The structure was solved by direct phase-determining methods.[8)] Using 600 reflections with $E>1.21$, the $\sum_2$ relations were listed. Four zonal reflections (Table 1), having large $|E|$ values and appearing in many $\sum_2$ interactions, were chosen to define the origin and the enantiomorph. In addition, three symbolic phases (A, B, and C) were assigned. The starting set, together with the final refined values of A and B, is listed in Table 1. The manual symbolic addition procedure indicated that $B=\pi/2$ and $C=-\pi/2$, or that $B=-\pi/2$ and $C=\pi/2$. No information was obtained for the A symbol. In order to apply the tangent formula,[9)] the numerical phases from 0 ° to 315 °, in steps of 45 °, were assigned to the A symbol. Tangent refinement was carried out for each of the 16 possible phase combinations. The values of R_{Karle}[8)] ranged from 0.25 to 0.33, and those of Z,[10)] from 5602 to 7710. A reasonable structure was obtained from an E-map calculated with the phases in the most consistent set ($R_{Karle}=0.25$ and $Z=7710$). All the atoms, except for C(16) and C(17) of the isopropyl group, were located. Three cycles of block-diagonal least-squares refinement of the positions and isotropic thermal parameters for these 29 atoms reduced the R from 0.402 to 0.243. The two remaining carbon atoms were located in a difference synthesis. A further five cycles including all the non-hydrogen atoms reduced the R to 0.135. In the anisotropic least-squares calculations, the following weighting scheme was used:

$$w = 0.1 \quad \text{for } |F_o|\leq2.0$$
$$w = 1.0 \quad \text{for } 2.0<|F_o|\leq12.0$$
$$w = (12.0/F_o)^2 \quad \text{for } |F_o|>12.0.$$

Seven rounds of least-squares with block-diagonal approximation brought the refinement to convergence at 0.112. The hydrogen atoms, except for those bonded to C(22),

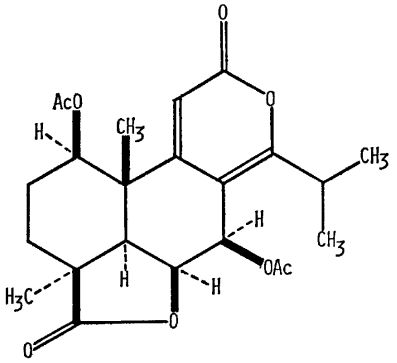
a) in the form $\exp[-(\beta_{11}h^2+\beta_{22}k^2+\beta_{33}l^2+\beta_{12}hk+\beta_{13}hl+\beta_{23}kl)]$.

C(16), C(17), C(24), and C(20), appeared in a difference map.

The inclusion of these in a structure-factor calculation, with each assigned an isotropic temperature factor of 4.0 Å^2, followed by six cycles, gave an R value of 0.098. The atomic scattering factors were taken from Ref. 11. At the end of the refinement, an analysis of the distribution of $\langle W\Delta^2 \rangle$ against $|F_o|$ and $\sin\theta$ confirmed that the weighting scheme was adequate. The final positional and thermal parameters for the atoms are listed in Table 2. The final structure factors are given in Table 3.*

Results and Discussion

A perspective view of the molecule, together with the numbering scheme, is shown in Fig. 1. The molecular structure of nagilactone A diacetate derived from X-ray analysis, as shown in (I), was consistent with that previously proposed on the basis of the chemical and spectroscopic data.[5]



(I)

The A/B ring junction is *trans*, and H(5)/H(6) and H(6)/H(7) are *cis*. The O(30) atom at the 7-position is *cis* to C(20) at the 10-position and the γ-lactone ring. O(28) is in an equatorial position.

The equations of the least-squares planes and the deviations of individual atoms from these planes are given in Table 4. The torsional angles are shown in Fig. 2.

Ring A adopts a distorted chair conformation. The deviations from the least-squares plane (Plane I of Table 4) range from 0.096 Å (C(3)) to 0.324 Å (C(10)). For a closer examination of the chair, several planes consisting of four atoms and the deviations of the atoms from them are given in Table 4. These results and the torsional angles indicate that a flattening of the chair conformation occurs at C(3) and C(4), while puckering occurs at C(1) and C(10). The distortion of Ring A from a chair conformation may be mainly attributed to the formation of a lactone ring and to the 1,3-diaxial steric strains between C(20) and C(19), and between C(20) and O(26). In spite of the deformation, the C(20)···C(19) and C(20)···O(26) distances (3.028 Å and 2.934 Å respectively) are still shorter than the sum of the van der Waals radii, although these are larger from those expected from the dreiding molecular models.

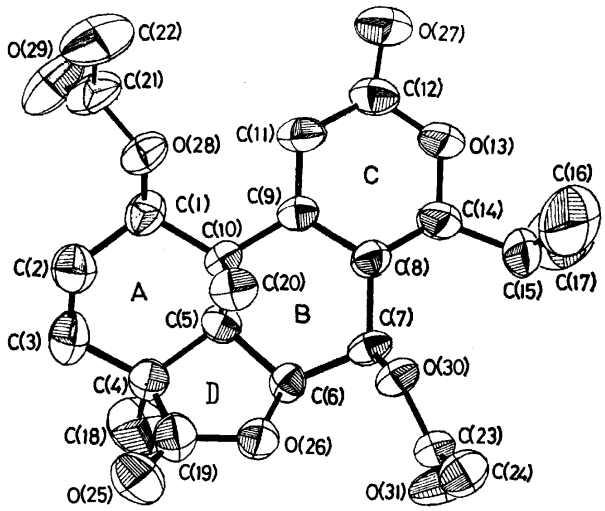


Fig. 1. Molecular structure and atomic numbering in nagilactone A diacetate. The thermal ellipsoids are scaled to include 50% probability.

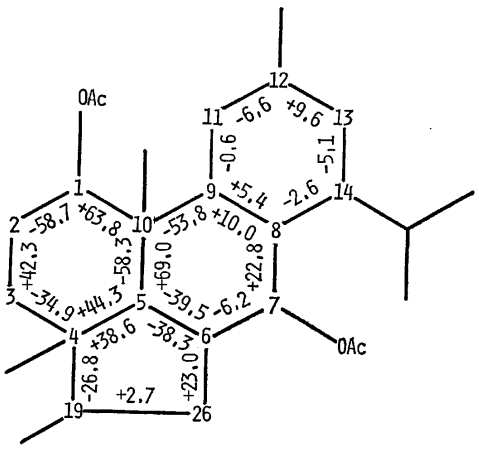

Fig. 2. Ring torsional angles in nagilactone A diacetate.

In Ring B, C(7), C(8), C(9) and C(10) are coplanar within 0.047 Å, with C(5) and C(6) deviating by 1.113 Å and 0.736 Å respectively in the same direction from this plane (Plane V). Upon the ABD ring fusion, Ring B adopts a conformation distorted from the energetically preferred half-chair form.[12] Ring C (α-pyrone ring) is nearly planar, although the deviations from Plane VI show a slight bending of the α-pyrone ring along the C(8)···C(12) vector. C(7) and O(27) deviate from Plane VI by +0.263 Å and +0.136 Å respectively in the same direction as C(12) and C(8), while C(10) and C(15) deviate by −0.093 Å and −0.090 Å respectively in the opposite direction.

In Ring D (γ-lactone ring), the C·C(O)·O·C moiety is planar with C(5), by 0.626 Å out of the plane.

The bond lengths and angles, together with their estimated standard deviations, are listed in Table 5. The mean C(sp^3)–C(sp^3) bond is 1.546 Å; however, there are a number of significant departures from

* Table 3 has been submitted to, and is kept by, the office of the Chemical Society of Japan, 1–5 Kanda-Surugadai, Chiyoda-ku, Tokyo 113. (Document No. 7509).

Table 4. Least-squares planes and deviations

The atoms indicated with asterisks were included in the calculation of the least-squares planes.

Plane I	$-0.8956x - 0.1300y - 0.4254z = 1.2292$
Plane II	$-0.8957x + 0.1506y - 0.4145z = 1.7385$

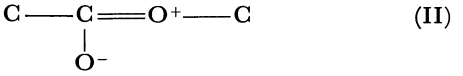
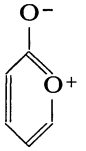
this mean. The C(2)–C(3) bond length (1.478 Å) is shorter by 6σ than the average value of the other C–C distances of Ring A. The lengthening of the C(5)–C(10) bond (1.580 Å) may be due to intramolecular steric strains between C(20) and C(19) and between C(20) and O(26). The same type of bond lengthening has been found in the crystal structures of levopimaric acid,[13] mebadonin,[14] and prerotundifuran.[15]

In Ring D, C(19)–O(26) [1.380 Å] is short and C(6)–O(26) [1.467 Å] long. Differences between C(sp^2)–O and C(sp^3)–O single-bond lengths in lactone groups have been found in many other structures.[16] A similar trend is found between C(21)–O(28) and C(1)–O(28), and between C(23)–O(30) and C(7)–O(30). The geometry observed in the C·C(O)·O·C moiety of Ring D or OAc may be ascribed to the contribution from the resonance form (II):

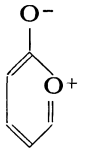


(II)

In Ring C (α-pyrone ring), the two C–O lengths (C(12)–O(13) and C(14)–O(13)) indicate a contribution from two resonance forms (IIIa and IIIb):



(IIIa)



(IIIb)

The slight shortening of C(12)–O(13) is probably due to the larger electronegativity of the C(12) bonded to O(27) than that of C(14).

The C(8)–C(9), C(11)–C(12), C(12)–O(13), and C(14)–O(13) bond lengths show that considerable delocalization occurs in Ring C.

Most of the bond angles around the C(sp^3) atoms in Rings A and B deviate greatly from the tetrahedral angle as a result of the formation of the γ-lactone ring and the 1,3-diaxial interactions. The values range from 100.1° (C(4)–C(5)–C(6)) to 117.0° (C(2)–C(3)–C(4)). The C(4)–C(19)–O(25)=131.5° bond angle is largest for those around the C(19) atom of Ring D. The same trend was observed in the bond angles around the C(12) atom of the α-pyrone ring; C(11)–C(12)–O(27) is largest.

The shorter intermolecular contacts (less than 4.0 Å) are given in Table 6. The packing of nagilactone A diacetate molecules in the crystal structure is illustrated in Fig. 3. The mean plane of the four-ring nucleus is roughly parallel to the crystallographic bc plane. The intermolecular contacts correspond to van der Waals interactions.

Computer Programs

All the calculations were performed on a FACOM 270/30 computer at the Computer Center of Osaka City University using the following programs: RSLC-3,[17] RSSFR-3,[17] HBLS-IV,[17] SCALE (film factor, Lp and layer scaling),[18] TECS (stereoscopic drawing

X-Ray Photoelectron Spectroscopic Studies of Catalysts — Supported Cobalt Catalysts —

Yasuaki OKAMOTO, Hajime NAKANO, Toshinobu IMANAKA, and Shiichiro TERANISHI

Department of Chemical Engineering, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received August 24, 1974)

XPS techniques were used to clarify the state of supported cobalt catalysts. In order to characterize Co^{2+} and Co^{3+}, the spin-orbit splitting of the 2p level, which is considered to be affected by the exchange interaction between the unpaired 3d electrons and 2p electrons, was found to be very useful. The interaction between catalyst and support was investigated. The state of supported cobalt was determined: Co_2O_3 on SiO_2, Co_2O_3+ $CoAl_2O_4$ on γ-Al_2O_3, and $LaCoO_3$ on La_2O_3. The order of the strength of the chemical interaction between cobalt and support is as follows:

$$La_2O_3 > \gamma\text{-}Al_2O_3 > SiO_2.$$

This fact was also confirmed by reduction experiments.

Recently, X-ray photoelectron spectroscopy (XPS or ESCA) techniques have been used in the studies of catalysts by many workers.[1-8] The advantage of XPS over the other techniques is that, in principle, it is capable of determining different valencies of supported metal on the surface layer simultaneously and of detecting the presence of any interaction between catalyst and support.

From XPS measurements for catalysts, we can obtain three important pieces of information–that is, information about the binding energy, the satellite, and the relative intensity of each level. On the basis of the binding energy of some inner level of an atom concerned (chemical shift), we can obtain information about the charge density of the atom and, therefore, the valence state of the atom. However, atoms with the same formal charge have different binding energies according to different circumstances, and, in some cases (for example, Ni compounds[9]), we cannot determine the valence states of the atom by the chemical shift alone.

The origins of satellite peaks have been investigated from the physical point of view by many workers.[10,11] According to their results, the paramagnetic species of some first transition-metal compounds show satellites on some levels; the satellites on the 2p-level are conidered to originate from shake-up processes (3d→4s transition), while the 3s-satellites are concluded to result from multiplet splittings by means of exchange interaction with 3d-unpaired electrons. However, the diamagnetic compounds show no such satellites. On the basis of these results, we can determine the magnetic properties of metal complexes or supported metal catalysts. The information about satellites is very useful in order to elucidate the valence state of the metal ion, especially in cases where it is difficult to determine its state by means of the binding energy alone.

From the relative intensities of the peaks for different level, we can obtain information about the surface composition of a catalyst or the surface coverage of the catalyst.[8]

According to the ESR spectra of supported cobalt catalysts,[12] it seems to be difficult to study the valence state of the supported cobalt because of the large spin-orbital interactions. Only very broad and ambiguous signals are obtained by ESR measurements for supported cobalt catalysts, and the cobaltic species are ESR-inactive. Moreover, only the bulk state of a catalyst is given by ESR and other techniques. Therefore, it seems that it would be interesting to investigate these catalysts by means of the XPS technique in order to characterize the surface state of the supported cobalt catalysts.

In this paper, on the basis of the results obtained by XPS measurements, the surface properties of the cobalt catalysts will be discussed. Moreover, we found that the energy differences between the $2p_{1/2}$ and $2p_{3/2}$ subshells of some first-transition metals are sensitive to the magnetic properties of the metal ion, and also that, in some cases, such information is more useful in the study of elucidating the valence state (magnetic properties) of the metal ion than the satellite is. We also studied the interaction between cobalt and support in order to ascertain the role of the support.

Experimental

Materials. The cobalt catalysts were prepared by a conventional impregnation technique using cobaltous nitrate. After drying at 100 °C, the catalysts were calcined at various temperatures for 5 hr in air. The supports examined were γ-Al_2O_3, SiO_2, and La_2O_3; and their surface areas were 235, 390, and 2 m^2/g respectively. The compounds used in this study were all supplied by Nakarai Chemical, Ltd., and Wako Pure Chemical, Ltd., except for the cobaltic compounds and $Co(CN)_2$, which were prepared and characterized according to published methods.[13] The CoO was obtained by the reduction of Co_2O_3 with H_2 or CO *in situ*.

Procedure. The photoelectron spectra were measured on a Hitachi 507 photoelectron spectrometer using AlKα or MgKα radiation. Powdered samples were held on a sample holder made of copper metal. The binding energies were corrected by using the value of 285.0 eV for the Cls level resulting from the contaminated carbon. The reproducibilities of the values thus obtained were within $\pm$0.2 eV; the energy differences were determined with an accuracy of $\pm$0.1 eV.

The reduction of the cobalt catalysts was carried out *in situ* using hydrogen with a pressure of 10 mmHg.

Results and Discussion

Spin-orbit Splitting of the 2p Level. There have been only a few reports of X-ray photoelectron spec-

troscopic measurements of cobalt compounds.[14] The binding energies of the cobalt compounds examined are listed in Table 1. The chemical shift is generally used to distinguish the oxidation states of the atom. However, as is shown in Table 1, the binding energies of the cobaltous compounds (Co^{2+}) examined are distributed between 782.1 eV for CoF_2 and 780.3 eV for $CoBr_2$, while those of cobaltic compounds (Co^{3+}) are distributed between 781.7 eV for $K_3Co(CN)_6$ and 779.4 eV for Co_2O_3, according to their chemical environments. Therefore, from the binding energy alone, we cannot clarify the oxidation state of these cobalt compounds. In the case of copper compounds, cuprous and cupric compounds can be distinguished by the chemical shift alone, as has been reported by Frost *et al.*,[15] whereas, in the case of cobalt compounds, as has been reported for nickel compounds,[9] the chemical shift is not a useful measure for discriminating the valence states.

The photoelectron spectra of the 2p level for some representative cobalt compounds are shown in Fig. 1. In some cases of a first-transition metal, it is well known that paramagnetic compounds show satellite(s) on the 2p level as a result of a shake-up process, while diamagnetic compounds do not. According to our systematic studies of cobalt compounds, all the cobaltous compounds except $Co(CN)_2$ have intense satellites, as is shown in Fig. 1, but none of the cobaltic compounds examined, cobalt metal, or $Co(CN)_2$ showed any such strong satellite. According to the intensity of the satellite, we classified the spectra into 4 types(A–D), as is shown in Fig. 1. The intensity ratio of the satellite and its main peak ($2p_{3/2}$) is >0.8 for Type A, >0.6 for Type B, ~0.1 for Type C, and ~0 for Type D. In Table 1, the satellite splittings and types are summarized for the cobalt compounds studied. Negative relations were observed between the satellite splittings and the binding energies for both

the $2p_{1/2}$ and $2p_{3/2}$ subshells of cobaltous compounds, as has been reported by Frost *et al.*[15] for cupric compounds. That is, when the covalency becomes smaller or the electronegativities of ligands become larger, the satellite splittings become smaller. These facts can be explained in terms of a shake-up process under the influence of the chemical environment, as has been indicated by Frost and his co-workers.[15] Therefore, the information about satellites may be used in conjunction with binding energy to predict the relative degree of covalency between the ligand and the central ion.

In the case of $Co(CN)_2$, the electronic configuration of this compound is a low-spin state; that is, $Co(CN)_2$ has one unpaired electron and the magnetic moment (μ_{eff}) of this compound is 3.11.[16] The other cobaltous compounds examined have high-spin configurations ($\mu_{eff} \fallingdotseq 5.2$). Moreover, the unpaired spin must be distributed over cyano ligands because of their large nephelauxetic effect. Therefore, $Co(CN)_2$ may behave like diamagnetic compounds in the XPS study of 2p satellites, since the spin density of the cobalt ion in $Co(CN)_2$ is low. The cobalt complex $[(NH_3)_5Co(O_2)Co(NH_3)_5]\ Cl_5$ is paramagnetic; it contains Co^{3+} and Co^{4+} and has one unpaired electron.[17] However, this compound also behaves in a diamagnetic manner for the 2p satellite, for the same reason as $Co(CN)_2$. However, an ambiguous weak satellite can be observed on the 3s level for both compounds; this indicates that the compounds are paramagnetic, as estimated from the magnetic properties.[16] It is considered that the different behavior of 2p and 3s satellites is a result of their different interaction strengths with 3d unpaired electrons.

Cobaltous compounds cannot be distinguished from cobaltic compounds by the chemical shift alone, but they can be discriminated by the satellite structure (magnetic properties). Since the chemical shift reflects the over-all electron density, and since the satellite structure shows the electronic configuration of the 3d level, it may be considered that the electron densities of the central metal ions, which are, of course, affected by the electronegativities of the ligands, are similar for cobaltous and cobaltic compounds, but that the electron configurations of the 3d levels for these compounds are influenced only very slightly by the ligands. It is estimated that the electrons of level higher than 3d (4s, 4p electrons) are responsible to a considerable degree for the bonding to the surrounding ligands.

From the XPS measurments, Co_2O_3 and Co_3O_4, which contains both Co^{2+} and Co^{3+}, could not be distinguished by chemical shift or satellite. This suggests that the surface layer of Co_3O_4 is similar to that of Co_2O_3.

As has been discussed above, the chemical shift and satellite peaks give information about the oxidation state and the chemical environment of a metal ion or a catalyst surface. However, in the studies of supported catalysts, the spectra obtained are usually weak, especially when the concentration of the catalytic components is low. Therefore, the information about the satellite is sometimes ambiguous, and it becomes difficult to characterize the catalyst.

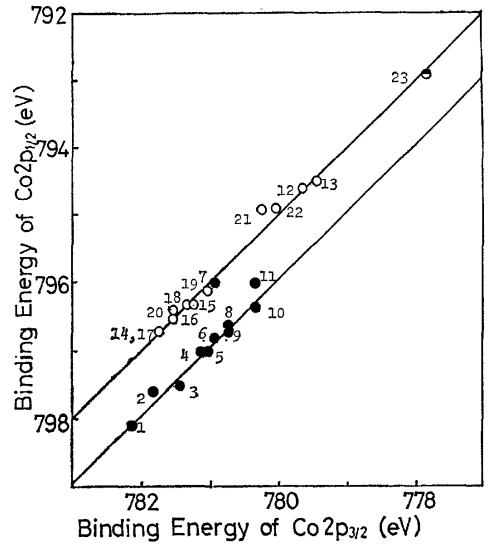

Fig. 2. Correlations of the binding energies of $Co2p_{3/2}$ and those of $Co2p_{1/2}$ for cobalt compounds. See Table 1 for a listing of the compounds

Table 2. ΔE values for Ni, Cr, and Cu compounds observed

Metal	ΔE (eV)	Compounds
Ni	17.6	Ni^{2+} compounds[1]
	17.2	Ni-metal
Cr	9.2	Cr^{6+} compounds
	9.7	Cr^{3+} compounds
	9.1	Cr-metal
Cu	20.1	Cu^{2+} compounds
	20.0	Cu^{+} compounds, Cu-metal

1) Paramagnetic compounds.

The spin-orbit splittings of the 2p level (ΔE) of the cobalt compounds examined are shown in Table 1. The relation between the binding energies of the $2p_{1/2}$ subshells and those of the $2p_{3/2}$ subshells is shown in Fig. 2. It is interesting that two different linear corelations are obtained for the cobaltous and cobaltic compounds. It is clear from Fig. 2 that, for cobaltous compounds, $\Delta E = 16.0$ eV, while for cobaltic compounds, $Co(CN)_2$, and cobalt metal, $\Delta E = 15.0$ eV. Hence, we can distinguish the oxidation states of the cobalt compounds by means of the value of ΔE. Recently, such correlations between the oxidation state and ΔE have been reported for several cobalt compounds by Frost *et al.*[14] The ΔE values for nickel, chromium, and copper compounds are shown in Table 2.

On the basis of these results, it seems to be established that the ΔE values for paramagnetic compounds are larger than those for diamagnetic compounds or metal, and that the energy difference in ΔE between paramagnetic and diamagnetic (or metal) compounds depends on the number of the unpaired electrons of the paramagnetic compounds. These results suggest that the origin of the change in ΔE is as follows. In the case of a paramagnetic 3d transition metal, the

satellite peaks of the 3s level are generally observed and the origin of the satellite is considered to be due to the exchange interaction between the 3s electron and the 3d unpaired electrons.[10] According to Basch,[10] the satellite splitting due to the exchange interaction is given as follows:

$$\Delta\varepsilon_\mu = \sum(N_t^\alpha - N_t^\beta)K_{\mu t} \quad (1)$$

where $\Delta\varepsilon_\mu$ is a satellite splitting of the μ-level, where N_t^α and N_t^β are the numbers of α and β spins respectively in the t-level, and where $K_{\mu t}$ is the exchange integral between t- and μ-levels. Such an effect of unpaired spins in the 3d band has been clearly observed on the 3s and 3p levels,[18] but for the 2p-level no such clear evidence of multiplet splitting has been found because of the smaller value of $K_{2p,3d}$ relative to $K_{3s,3d}$. According to the UHF calculations by Moskowitz *et al.*,[19] which predict a 3s-level splitting of 5.2 eV (compared to the 4.0 eV observed), the exchange splitting of the 2p level of NiF_6^{4-} is calculated to be about 2 eV. Therefore, the expected splitting of less than 2 eV would be difficult to observe with non-monochromatized X-ray sources, which give spectra with band widths at half height, typically about 2.5 eV. Recently, however, Frost *et al.*[15] reported that the widths of the main peaks of the 2p level from the cuprous compounds are narrower than that of cupric. These facts can be considered to be indirect evidence in favor of such splitting.

If we consider the case in which one unpaired electron exists in the 3d level and the orbital angular momentum, l, of the electron is spherically averaged (its state is expressed by $^2S_{1/2}$), for the sake of simplicity, the hole state of $2p_{1/2}$ and $2p_{3/2}$ subshells, after the emission of photoelectrons (whose states are expressed by $^2P_{1/2}$ and $^2P_{3/2}$ respectively), is split by exchange interaction with the 3d unpaired electron into two terms[20]:

$$^2S_{1/2}{}^2P_{1/2} \rightarrow {}^3P_0 \text{ and } {}^3P_1$$

$$^2S_{1/2}{}^2P_{3/2} \rightarrow {}^3P_2 \text{ and } {}^1P_1$$

In Fig. 3, some schematic spectra are shown. From Eq. (1), the energy differences between $^3P_0$ and $^3P_1$, or between $^3P_2$ and $^1P_1$ are given. The energy diagram of the sp configuration in an intermediate coupling[20] must be inverted in our case, since the hole states are involved in the XPS. From Fig. 3, we can expect a larger ΔE value for a paramagnetic compound than for a diamagnetic one. In real systems, the conditions are much more complicated, but the ΔE value for a paramagnetic compound may be expected to be larger than that for a diamagnetic compound. As has been discussed above, the change in ΔE is considered to be due to the multiplet splitting of the 2p level and to be indirect evidence for exchange interaction between the 2p and 3d levels. The dependence of the difference in the ΔE values between paramagnetic and diamagnetic compounds upon the number of unpaired spins can be explained by Eq. (1)

If the spin-orbit splitting of the 2p level is considered to be due to the multiplet splitting by the exchange

	5.0	500	779.7	15.0
	5.0	1000	779.6	15.0
	10.0	500	780.2	15.0
SiO_2	10.0	500	779.1	15.3

interaction with 3d unpaired electrons, the widths of the 2p-level spectra for paramagnetic cobaltous compounds must be broader than those for diamagnetic cobaltic compounds. In fact, the full widths at half height are about 3.4 eV and 2.9 eV for cobaltous and cobaltic compounds respectively. These facts support the multiplet splitting mechanism.

Consequently, in the study of catalysts with XPS, we can also use the ΔE value as a useful piece of information for elucidating the oxidation state of a catalyst component as well as the binding energy and the satellite.

Supported Cobalt Catalysts. The cobalt catalysts supported on γ-Al_2O_3, SiO_2, and La_2O_3 were also investigated. The catalysts examined are shown in Table 3; their binding energies of the $2p_{3/2}$ subshell and the ΔE values are also listed. In the case of cobalt catalysts, the ΔE values fall between 15.0 and 16.0 eV. This fact indicates the coexistence of Co^{2+} and Co^{3+} on the surface of cobalt catalysts.

In Fig. 4, the spectra of the 2p level for the supported cobalt (5 wt%) on γ-Al_2O_3 (a) are shown. As with the cobalt-alumina catalysts, after drying at 100°C the oxidation state of a large proportion of the cobalt is considered to be Co^{2+}, as expected, on the basis of the satellite and ΔE value, listed in Table

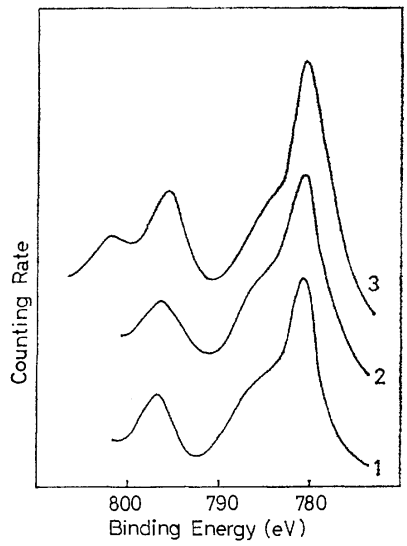

Fig. 4a. XPS spectra of Co2p level for cobalt supported (5 wt%) on γ-Al_2O_3, 1) after drying at 100 °C, 2) after calcination at 500 °C for 5 hr, 3) after calcination at 1000 °C for 5 hr.

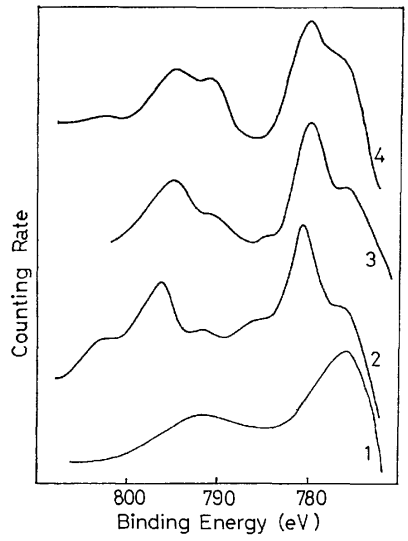

Fig. 4b. XPS spectra of Co2p level for cobalt supported (5 wt%) on La_2O_3, 1) back ground spectrum of La_2O_3, 2) after drying at 100 °C, 3) after calcined at 500 °C for 5 hr, 4) calcined at 1000 °C for 2 hr.

3. After the catalysts were calcined in air at 500 °C or 1000 °C, only very small chemical shifts for the $2p_{3/2}$ sublevel are observed, but ΔE changes 0.5 eV among these catalysts. In the case of the catalyst calcined at 500 °C, a weak satellite is observed (Fig. 4a) and the spin-orbit splitting is about 15.6 eV. Therefore, both Co^{2+} and Co^{3+} exist in comparable amounts on the 500 °C-calcined catalyst. However, with regard to the cobalt-alumina catalyst calcined at 1000 °C, it is considered that a large proportion of the cobalt is Co^{3+}, while only a small amount of Co^{2+} is present. This is confirmed by the ambiguous satellite peak for this catalyst shown in Fig. 4a. It may be concluded from Table 3 that the Co^{3+} content

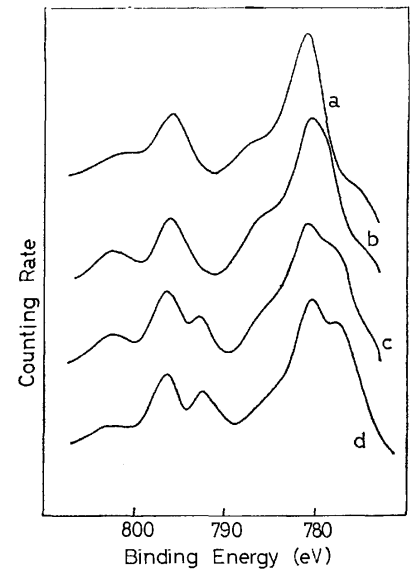

Fig. 5. XPS spectra of Co2p level for cobalt-alumina catalyst (10 wt%) reduced by H_2 (10 mmHg) at 400 °C.
a) after calcination at 500 °C for 5 hr, b) 20 min reduction, c) 80 min reduction, d) 250 min reduction

becomes larger with calcination at higher temperatures and with an increase in the amount of supported cobalt. It may be of interest to mention here that all the Co–Al_2O_3 catalysts calcined above 800 °C were blue in color, revealing the presence of Co^{2+} ions in a tetrahedral surrounding of O^{2-} ions,[21] and that X-ray diffraction analysis of this catalyst suggests the presence of $CoAl_2O_4$. Contrary to these results, a large proportion of the cobalt is Co^{3+}, as is shown by XPS measurements. The discrepancy between these results is considered to be due to different types of information about the catalyst; that is, the information about the surface layer is obtained by XPS (<20Å), about the much thicker layer, by means of the visible spectra ($<1\,\mu$), and about the "bulk" of the catalyst, by X-ray diffraction analysis. Comparing the chemical shift data in Tables 1 and 3, it is considered that the state of cobalt over γ-alumina calcined at 100°C is more covalent than that of cobaltous oxide. Moreover, after calcination at 500 °C or 1000 °C, the binding energies of $Co2p_{3/2}$ for these catalyst do not fall between those for CoO and Co_2O_3. These facts indicate an interaction (chemical or physical) between cobalt and γ-alumina, even after drying at 100 °C.

Such an interaction is supported by such reduction experiments as are shown in Fig. 5. After calcination at 500 °C (a), the cobalt-alumina catalyst (10 wt%) contains mainly Co^{3+}, as is to be expected from its spectrum (weak satellite) and ΔE value (15.1 eV). However, after a 20-min reduction at 400 °C (b), the main peak of the $2p_{3/2}$ subshell becomes broader, the satellite intensity becomes larger relative to the main peak, and the ΔE value increases to 15.5 eV. That is, the appearance of Co^{2+} can be expected. After further reduction (80 min) at 400 °C (c), a metal peak ap-

pears as a shoulder at about 778.1 eV. The higher binding energy peak of the $2p_{3/2}$ subshell with an ambiguous satellite is considered to be that of Co^{2+}, probably due to $CoAl_2O_4$, judging from the ΔE value (15.8 eV). No further intense change in the spectrum was observed even after a 250-min reduction at the same temperature (d). However, in the case of unsupported Co_2O_3, a peak due to CoO appeared after a 10-min reduction at 400 °C and a metal peak appeared clearly after a 15-min reduction at the same temperature. The spectrum of a pure metal was obtained after only a 40-min reduction. These facts indicate a strong interaction between cobalt and γ-Al_2O_3.

In the case of silica gel, it is considered that Co_2O_3 is formed on the surface; it is then easily reduced to cobalt metal as Co_2O_3. Therefore, no specific interaction between cobalt and silica gel is found.

As regards the cobalt catalysts supported on La_2O_3, a cobaltic compound can be expected after calcination over 500 °C. Comparing the chemical shifts of cobaltic compounds in Table 1, the chemical environment of cobaltic compounds on La_2O_3 is considered to be similar to that of Co_2O_3. It is clear from Fig. 4b the intensity of the cobalt 2p level, compared to the background peak of La_2O_3, becomes weaker with the calcination temperature; this indicates that the cobalt ion diffuses into La_2O_3 or that new compounds of cobalt and La_2O_3 are formed. In the cases of alumina and silica gel, no such intense change in the intensity of the cobalt peaks was observed upon treatment. On the basis of the X-ray diffraction studies, it is found that $LaCoO_3$ is formed. To confirm this conclusion, reduction experiments were carried out. After a 1-hr reduction, Co^{2+} appeared (ΔE=15.5 eV); no metal peak was observed clearly until after a 2-hr reduction at 400 °C. Therefore, cobalt on La_2O_3 is the most difficult to reduce among the cobalts on all the supports examined. These facts confirm that the new compound ($LaCoO_3$) is formed on the catalyst surface.

Summarizing these results, it is determined that the states of supported cobalt are; Co_2O_3 on SiO_2, Co_2O_3+$CoAl_2O_4$ on γ-Al_2O_3, and $LaCoO_3$ on La_2O_3. Consequently, it is concluded that the chemical interaction between support and cobalt catalyst decreases as follows:

$$La_2O_3 > \gamma\text{-}Al_2O_3 > SiO_2$$

Studies of the Catalytic Properties of Synthetic Zeolite A. IV.[1,2] The Thermal Stability of Silver-exchanged Zeolite A

Shigemi MATSUMOTO,* Masahiro NITTA, Kiyoshi OGAWA, and Kazuo AOMURA

Faculty of Engineering, Hokkaido University, Sapporo 060

(Received September 11, 1974)

The effects of the degree of exchange and the dehydration upon the structural stability of silver-exchanged forms of the synthetic zeolite Linde 4A have been investigated by means of DTA, X-ray diffraction, and adsorption studies. The relative intensity of the X-ray powder diffraction decreased with an increase in the extent of Ag^+-exchange, though it indicated no accurate information on the crystallinity. An exotherm on the DTA curves which shifted to a lower temperature with the degree of exchange became an indication of the collapse of the structure; this was in good agreement with the specific surface area of the sample heated at a higher temperature. From these results, the silver-exchanged zeolite A was concluded to be thermally unstable and to lose its crystal structure at a lower temperature than the original sodium form. It is also proposed that the comparison of the X-ray powder diffraction intensity is not suitable as a method for judging the crystallinity of zeolites A.

In the previous papers of this series,[3,4] the instability of silver-exchanged zeolites A [(Ag^{ex}, Na)-A and (Ag^{ex}, Ca)-A]** was pointed out on the basis of the low intensities of the X-ray diffraction patterns and on the basis of their catalytic properties, which are quite different from those of other cation-exchanged forms. No study of the thermal stability of Ag^{ex}-A is found in the literature except that of the reduction of silver ions in zeolite. Earlier studies of zeolite A reported that the instability of zeolite A was observed in ion-exchanges involving H^+, Ba^{2+}, Zn^{2+}, Ni^{2+}, Co^{2+}, Cu^{2+} and Fe^{3+} by means of X-ray study, and that Ag^{ex}-A was stable.[5,6] However, the influence of the degrees of exchange and dehydration (heat-treatment) on the structural stability has not been systematically investigated; also, there are many ambiguous statements in the method for determining the crystallinity of cation-exchanged zeolite in the reports.

The object of this investigation was to study the thermal stability of (Ag^{ex}, Na)-A in relation to the degree of exchange. The propriety of the method for determining the crystallinity will also be discussed in relation to DTA, X-ray-diffraction, and adsorptive studies.

Experimental

Materials. The original sodium-form of zeolite A was Linde Molecular Sieves 4A (Na–A) powder. The ion exchange was carried out at 85±1 °C with a 0.1 M solution of $AgNO_3$, according to a method described before.[4] Precautions were taken to shied it from bright light during operations as much as possible, since silver-exchanged zeolite was somewhat unstable to light. The higher exchanged sample was colored only a slight gray. The (Ag^{ex}, Na)-A samples, after having been dried at 120 °C for 10 hr, were all kept over saturated NH_4Cl solutions for at least 2 weeks at room temperature to maintain the moisture content constant. The degree of exchange was determined by a method described before.[4]

X-Ray Diffraction. The X-ray powder diffraction patterns were obtained on a scintillation counter spectrometer (Rigaku-Denki Geiger flex D-9C unit) with a pen recorder, using filtered Cu $K\alpha$ radiation. The hydrated and the dehydrated samples were exposed to air while their spectra were measured. Visual comparisons of the peak intensities of certain planes were made. The (311), (321), and (322, 410) planes were chosen, as they have suitable intensities in the original Na-A.

DTA. The differential thermal analysis was performed in air using a Rigaku-Denki 8001 DTA unit, in which the temperature was raised at the rate of 10 °C/min up to 1000 °C. The α-alumina was used as the reference material.

Specific Surface Area. The specific surface areas of the samples, which were activated at various temperatures for 3 hr, were measured by a standard volumetric method, using oxygen as an adsorbate, at −196 °C. The samples were activated in two different atmospheres, *i.e.*, *in vacuo* and in air.

Results and Discussion

First, the crystallinity of Ag^{ex}-A was estimated from the X-ray diffraction patterns. The sum of the peak intensities of the (311), (321), and (322, 410) planes of Ag^{ex}-A was compared with that of the other cation forms. As is shown in Table 1, all but Ag^{ex}-A have almost the same intensity. This shows that, after ion exchange, all the hydrated samples except Ag^{ex}-A retain their primary crystal structure, as has been reported in the literature.[5,6] In many studies of zeolites, the crystallinity has thus been determined by comparing the intensities of selected X-ray powder reflections.[7]

TABLE 1. RELATIVE X-RAY CRYSTALLINITY OF HYDRATED ZEOLITES A

a) Arbitrary unit. b) After heated for 3 hr *in vacuo*. c) After heated for 3 hr in air. d) 250 °C. e) 700 °C. f) $Na^{ex}_{0.54}$ $Ag^{ex}_{0.46}$-A reexchanged from uncalcined $Ag^{ex}_{0.99}$ $Na_{0.01}$-A.

The trouble is that the pattern of Ag^{ex}-A was very weak. As is shown in Table 2, the relative X-ray crystallinity of (Ag^{ex}, Na)-A decreased with an increase in the extent of Ag^+ exchanged; this trend was found also in the samples calcined at higher temperatures (up to 600 °C). This generally implies that ion exchange of Na-A with Ag^+ destroys the crystal structure, and it is contrary to Barrer's report.[6] However, in spite of the low intensities of all the peaks every major peak of the Na-A pattern ($5<2\theta<35°$) was present in the pattern of Ag^{ex}-A. We felt, therefore, that the low intensity of Ag^{ex}-A was a result of interference based on the high scattering power of silver for X-rays. This suspicion was verified by the fact that, when a sample of Ag^{ex}-A, which had never been dehydrated above 120 °C, was re-exchanged with an $NaNO_3$ solution, the Na^{reex}-A showed its peak intensity close to the original Na-A (See Table 2). It may, therefore, be concluded that the silver-exchange

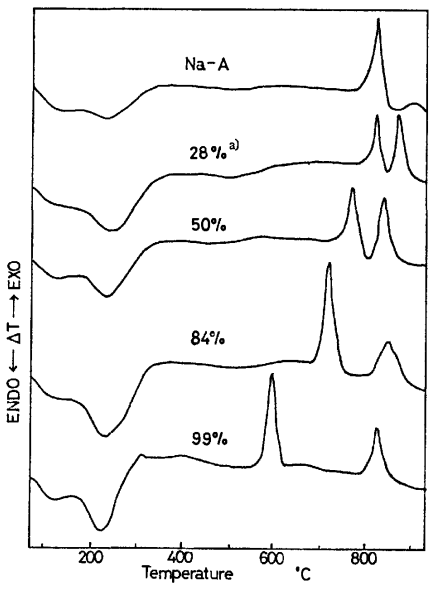

Fig. 1. DTA curves for (Ag^{ex}, Na)-A
a) The degree of exchange, $Ag^+/(Na^+ + Ag^+)$

of Na-A does not cause the crystal to collapse and that Ag^{ex}-A may be stable thermally up to 600 °C. The most important point is that a conventional X-ray powder diffraction study (*i.e.*, a comparison of the peak intensity) of cation-exchanged zeolites A does not give accurate information on the crystallinity. A similar conclusion may also be drawn from recent reports on the stability of Ba^{ex}-A.[8,9]

Then, more detailed information on the stability of Ag^{ex}-A was obtained by a thermographic method. The DTA results on (Ag^{ex}, Na)-A are shown in Fig. 1. A pronounced endothermal effect (130—230 °C) and two high-temperature exothermal effects (600—910 °C) were observed in all the samples. The endothermal effect corresponds to the removal of water from the zeolite.[10] The beginning of the first high-temperature exotherm, which is due to the loss of the structure, shifted from 780 to 560 °C with an increase in the extent of silver. In fact, the additional X-ray measurement revealed that the zeolite structure of $Ag^{ex}_{0.99}Na_{0.01}$-A is maintained until the beginning of the first exoeffect (~600 °C) and that, at 700 °C, the structure converts to the amorphous phase. This exoeffect may be considered to be due to the following reaction, caused by dehydration from structural hydroxyl groups:

$$\underset{\text{I}}{Ag(H_2O)_n\text{-Zeolite}} \overset{\Delta}{\rightleftarrows} \underset{\text{II}}{\{Ag(OH)_m\text{-Z}+AgO_x\text{-Z}+\underset{\text{IV}}{\text{H-Z}}\}}$$

$$\overset{\Delta}{\rightleftarrows} \underset{\text{III}}{AgO_x\text{-Z} + \text{amorphous phase}}$$

That is to say, the dissociation of coordinated water molecules by the polarizing power of Ag^+ and by heating releases protons, thus forming the structural hydroxyls (IV). The dehydration of IV at a higher temperature destroys the lattice structure. Since the polarizing power of Ag^+ is larger than that of Na^+, the dissociation of the protons and the hydroxyl dehydration may be promoted at lower temperatures with an increase in the extent of Ag^+ in zeolite. The process of the dehydration of IV appears on the first exotherm. This trend was in good agreement with the results obtained from the X-ray study and with the below-mentioned specific surface area.

The other exotherm appears at 850—910 °C. It is known that, at 800 °C, zeolite A recrystallizes to a β-crystobalite-type structure. The latter exoeffect, therefore, may indicate this. From these results, it may be concluded that the thermal stability of Ag^{ex}-A is lower then that of Na-A.

The specific surface area of (Ag^{ex}, Na)-A was determined from the oxygen adsorption for samples calcined at various temperatures in different atmospheres. The stability of (Ag^{ex}, Na)-A to the degree of exchange and to heat-treatment is shown in Table 3. The Ag^{ex}-A calcined at 200 °C did not adsorb oxygen. This is because of the residual water molecules coordinated strongly to Ag^+; the evidence is supported by the endotherm being sharp and larger than that of Na-A in Fig. 1. It seems that the loss of the crystallinity is slightly greater in the case of air calcination

TABLE 3. THE SPECIFIC SURFACE AREA OF (Ag^{ex}, Na)-A

% Exchanged	Specific surface area, m^2/g, Calcination temp. *in vacuo*				
	200 °C	250 °C	300 °C	400 °C	600 °C

			631[a]		36[a,b]
28	*	664	686		
38			638		
50			653		
57			661	527	
84			451		
99	*	669	403	361	71.2[a]
			326[a]	308[a]	<10[a,b]

a) Recalcined at 250 °C for 30 min *in vacuo* after calcined for 3 hr in air. b) 750 °C. * Impossible to measure.

above 300 °C was smaller than that at 250 °C. This effect increases with the extent of silver exchange. We estimate that a degradation of the structure occurred to some degree, resulting in a partial obstruction of the zeolite pores to the oxygen adsorbate. Below 600 °C, however, this structural change is too samll to appear on the DTA curves. The specific surface area of Na-A calcined at 600 °C in air was still about 35% of the value at 250 °C, whereas $Ag^{ex}_{0.99}Na_{0.01}$-A calcined at 600 °C in air retained only about 10% of its original crystallinity. The latter change is very large, and it appears on the DTA curve (see the 99% value in Fig. 1).

The results in Table 3 (column of 300 °C) suggest that Ag^+ enters into sites unfavorable to maintaining the structure when the degree of exchange exceeds about 57%, since the specific surface area suddenly decreases at 84%. Zeolite A has three kinds of cation sites.[11] Details on the site selectivity of Ag^+ have been reported by Nitta *et al.*[12]

On the other hand, it is known that the Ag^+-exchanged zeolites are relatively reducible, easily in the dehydrated state. It was first pointed out by Habgood[13] that the reduced Ag^{ex}-X has a partial loss of crystallinity with the appearance of metallic silver. Huang[14] reported also that Ag^{ex}-X and Ag^{ex}-Y were reduced after treatment with CO at 350 °C. In the present case, Ag^{ex}-A exchanged highly has colored only a slight gray in the hydrated state. This may indicate a slight reduction of Ag^+ by light or CO in air during drying at 120 °C. However, it is considered that the reduction resulting in a collapse of the structure did not occur, because the specific surface area was retained almost the same as in Na-A and because the X-ray diffraction pattern, though low in intensity, was unchanged. Giordano[15] also reported, from the results of DTA, that the collapse of the structure for Ag^{ex}-A calcined at 400 °C and reduced by hydrogen at 250 °C was negligible.

Furthermore, with regard to the color of Ag^{ex}-A, the sample was a white color and a slight grayish white color; it first turned a deep yellow-red color on dehydration *in vacuo* and in air at elevated temperatures. It changed to a bright yellow while cooling in air and ultimately back to the original white at room temperature. This color change occurred reversibly. Therefore, it is due to the alteration of the ligands of Ag^+ on dehydration, as has been described above. A study[16] of the UV spectra of Cu^{ex}-Y at different hydration levels has revealed that, in the below reaction, the absorption band corresponding to VI appears in a longer wavelength region compared with that of V:

$$\underset{\text{V}}{Cu(H_2O)_6} \overset{\Delta}{\rightleftarrows} CuO_3(OH)_3 \overset{\Delta}{\rightleftarrows} \underset{\text{VI}}{CuO_6}$$

In the present case, three distinct complexes exist at several degrees of hydration; *i.e.*, the I, II and III described above correspond to them. According to the spectrochemical series, the absorption spectrum of Ag^+ in II should shift to a wavelength longer than that of I (*i.e.*, from the ultraviolet to the visible region); probably that of III would also shift to a longer wavelength region. Consequently, the Ag^{ex}-A changes from colorless to yellow-red when it is dehydrated at elevated temperatures.

We wish to thank Professor Jiro Ishii of Tokai University for his help in the X-ray measurment, Mr. Takeshi Tsuchida of Hokkaido University for his help in DTA analysis, and Dr. Takao Yotsuyanagi of Hokkaido University for his valuable discussion on the color of metal ion.

The Quenching of the Cadmium Resonance Radiation at 326.1 nm by Ammonia and the Emission from the Complex between Excited Cadmium Atoms and Ammonia in the Presence of Argon

Shunzo YAMAMOTO, Shigeru TSUNASHIMA, and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received October 3, 1974)

The pressure dependences of the emission intensities at 326.1 and 432 nm in the cadmium-photosensitized reaction of ammonia have been measured. In order to interpret the nonlinear Stern-Volmer plots for the quenching of the 326.1 nm resonance line, the following reactions have to be taken into account in the reaction scheme: $Cd^*+NH_3 \rightleftharpoons CdNH_3{}^*{}_v$, $CdNH_3{}^*{}_v+M \rightarrow CdNH_3{}^*+M$. The pressure dependence of the emission from the $CdNH_3{}^*$ complex (at 432 nm) was also well explained in terms of a reaction scheme involving the above reactions.

It is well known that excited mercury atoms form complexes with some molecules (NH_3, H_2O, *etc.*) and that these complexes fluoresce.[1-3] Since the electronic character of cadmium atoms is similar to that of mercury atoms except for the amount of energy involved, the complexes of excited cadmium atoms with some molecules are expected to fluoresce. Recently, two groups, including one in our laboratory,[4,5] have reported a cadmium-photosensitized emission of ammonia at the wavelength of 432 nm; this emission has been attributed to that from the complex between excited cadmium atoms and ammonia. In a short communication,[4] Morten *et al.* assigned the emitting complex to that formed between $Cd(^3P_0)$ atoms and ammonia, by analogy with the Hg–NH_3 system.

As was mentioned in a previous paper,[6] the absorption intensity at 326.1 nm ($5^3P_1 \leftarrow 5^1S_0$) is dependent upon the pressure of foreign gases through the pressure broadening of the absorption line. In a previous study[5] of the cadmium-photosensitized luminescence of ammonia, however, this effect was not taken into account. The present paper will report the results of a study of the cadmium-photosensitized luminescence and of the quenching for the 326.1 nm resonance line under the conditions of the ammonia being diluted with argon and the total pressure being kept constant in order to minimize the effect of the pressure broadening. These results will reveal a somewhat detailed mechanism of the complex-formation between the excited cadmium atoms and ammonia.

Experimental

The apparatus and procedure were almost the same as those previous described.[5] The reaction cell and the cadmium resonance lamp were kept in an electric furnace at 220±1 °C. The vapor pressure of cadmium at 220 °C is 1.04×10^{-3} Torr. The lamp was operated by an alternating current (50 Hz).[6]

The cadmium metal used was high-purity cadmium (99.9999%) manufactured by the Osaka Asahi Metal Co. Pure-grade ammonia (Takachiho Shoji Co.) was used after degassing at the temperature of liquid nitrogen. Pure-grade argon purchased from the Takachiho Shoji Co. was used after repeated adsorption and desorption on a molecular sieve at the temperature of liquid nitrogen.

Results

When the empty cell was illuminated by means of the cadmium lamp, line spectra were observed at 326, 340, 347, 361, 468, 480, and 509 nm. In the presence of the cadmium vapor in the cell at 220 °C, the intensity of the 326.1-nm emission increased, but those of the other lines remained unchanged. When argon was added, the intensity of the 326.1-nm emission increased with the increase in the pressure, as is shown in Fig. 1. This increase has been attributed to the increase in the absorption of the exciting light on the basis of the pressure broadening of the absorption line.[6]

When an ammonia–argon mixture was added, the intensity of the emission at 326.1 nm decreased with the increase in the partial pressure of ammonia, while the total pressure was kept constant, and a new band emission was observed at 432 nm. The position and the profile of the new band emission at 432 nm were independent both of the total pressure examined and of the pressure ratio of ammonia to argon, while the intensity changed with the increase in the partial pressure of ammonia, as is shown in Fig. 2. As the intensity of the 432-nm emission decreased with the increase in the irradiation time, the emission intensities shown in Fig. 2 were obtained by extrapolation to zero irradiation time.

The Stern-Volmer plots for the quenching of the 326.1-nm resonance line are shown in Fig. 3, where $I^0_{326.1}$ and $I_{326.1}$ are the emission intensities at 326.1 nm in the absence and in the presence of ammonia

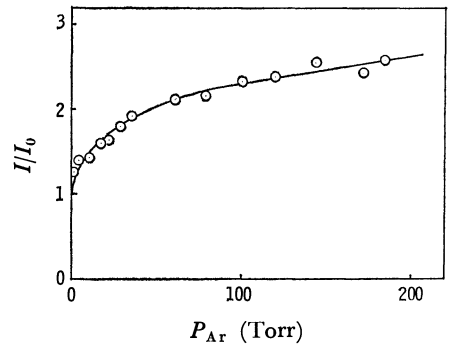

Fig. 1. The intensity of the resonance radiation at 326.1 nm as a function of the pressure of argon.

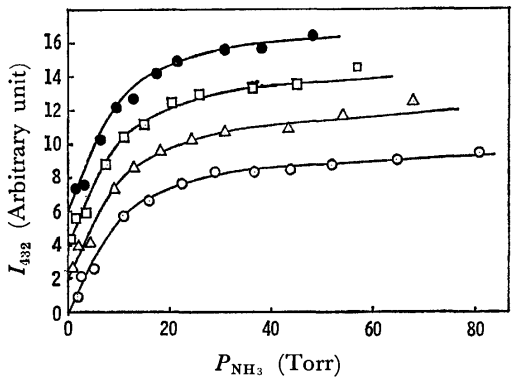

Fig. 2. The emission intensity at 432 nm as a function of the partial pressure of ammonia. The total pressures are 208 (○), 175 (△), 147 (□), and 123 (●) in Torr. Solid lines show the values calculated according to Eq. (2). The plots are displaced upwards by 2 units of I_{432} for clarity in the above order of the total pressure.

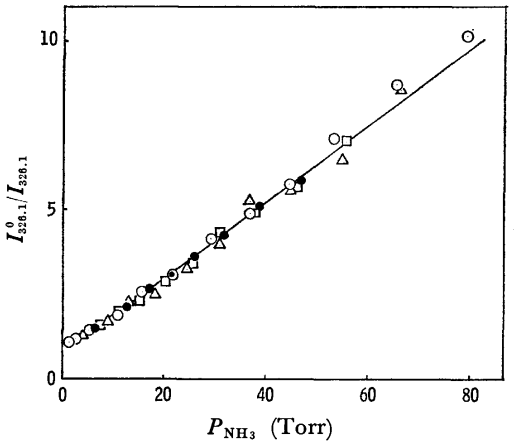

Fig. 3. Stern-Volmer plots for the quenching of the resonance radiation at 326.1 nm by ammonia diluted with argon. The total pressures are 208 (○), 175 (△), 147 (□), and 123 (●) in Torr. Solid line shows the values calculated according to Eq. (1).

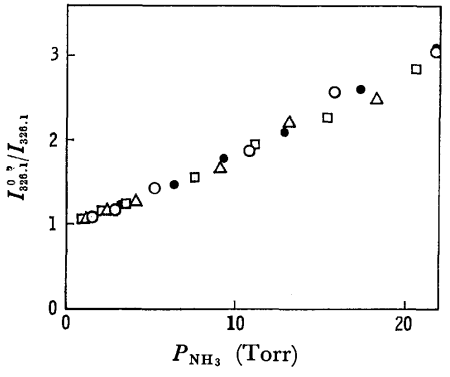

Fig. 4. Stern-Volmer plots in the low pressure region. The total pressures are 208 (○), 175 (△), 147 (□), and 123 (●) in Torr.

respectively. On the assumption that 100 Torr carbon dioxide quenches the $Cd(^3P_1)$ atoms completely,[6] the scattered light intensity at 326.1 nm was estimated to be less than 0.2% of $I^0_{326.1}$; hereafter, it was neglected. The emission intensity at 326.1 nm hardly changed with the irradiation time. As is shown in Fig. 3, the plots obtained at various total pressures lie on one curve, and no total pressure dependence can be seen. The intercept of the Stern-Volmer plots at zero pressure of ammonia obtained in the previous paper[5] was less than unity, but that in Fig. 3 was equal to unity. This discrepancy can be attributed to the neglect of the effect of the pressure broadening in the previous study. The plots obtained with ammonia were previously regarded as lying on a straight line; however, the plots shown in Fig. 3 deviate from a straight line, especially in the low-pressure region. The deviation is observed more clearly in Fig. 4. This finding forced us to modify the reaction scheme previously proposed.[5]

Discussion

The energy difference between the 5^3P_1 and 5^3P_0 states of cadmium atoms is only 1.6 kcal/mol. In the presence of foreign gases, for example, 5 Torr of Ar or 0.1 Torr of ammonia,[7] the equilibrium between the two electronic states is readily established. Consequently, we cannot discriminate the reactions of two states. Morten *et al.* used the phase-shift technique to observe the emission at 432 nm and said that the emitting species is produced by the reaction between the 5^3P_0 state of cadmium atoms and ammonia; however, if the equilibration reaction between 5^3P_1 and 5^3P_0 states is very fast, their assignment is not necessarily unique. In the following treatment, therefore, we will consider both $Cd(^3P_1)$ and $Cd(^3P_0)$ as precursors of the emitting species and will use the symbol Cd* to express either $Cd(^3P_1)$ or $Cd(^3P_0)$.

Quenching of the 326.1-nm Resonance Line. As was mentioned in the "Results" section, the Stern-Volmer plots for the quenching of the 326.1-nm resonance line by ammonia do not lie on a straight line. In order to explain such Stern-Volmer plots, the following reaction mechanism was considered:

$Cd + h\nu \longrightarrow Cd(^3P_1)$	I_a
$Cd(^3P_1) \longrightarrow Cd + h\nu$	k_0
$Cd(^3P_1) + M \rightleftharpoons Cd(^3P_0) + M$	k_1, k_{-1}
$Cd(^3P_1) + NH_3 \longrightarrow$ products	k_2
$Cd(^3P_0) + NH_3 \longrightarrow$ products	k_3
$Cd^* + NH_3 \rightleftharpoons CdNH_3^*{}_v$	k_4, k_{-4}
$CdNH_3^*{}_v + NH_3 \longrightarrow CdNH_3^* + NH_3$	k_5
$CdNH_3^*{}_v + Ar \longrightarrow CdNH_3^* + Ar$	k_5'
$CdNH_3^* \longrightarrow Cd + NH_3 + h\nu'$	k_6
$CdNH_3^* + NH_3 \longrightarrow Cd + 2NH_3$	k_7
$CdNH_3^* + Ar \longrightarrow Cd + NH_3 + Ar$	k_7'

Here, M stands for Ar or NH_3. $CdNH_3^*{}_v$ and $CdNH_3^*$ represent, respectively, an unstabilized and a stabilized complex between the triplet cadmium and ammonia. In this mechanism, it is assumed that the unstabilized complex does not fluoresce, because the profile of the emission band is independent of the pressures of ammonia and argon.

A steady-state treatment on the assumptions that the equilibration reaction between the 5^3P_1 and 5^3P_0 states is very fast and that either the $^3P_1$ or the $^3P_0$ state is the precursor of the emitting species gives the following relation:

$$\frac{I^0_{326.1}}{I_{326.1}} = 1 + a[NH_3] + \frac{b[NH_3]}{1+\dfrac{1}{c+d[NH_3]}} \quad (1)$$

Here, $I^0_{326.0}$ and $I_{326.1}$ are the emission intensities at 326.1 nm in the absence and in the presence of ammonia respectively. a, b, c, and d are constants depending only on the total pressure. When Cd* = Cd($^3P_1$), then

$$a = \frac{1}{k_0}\left(k_2+\frac{k_1}{k_{-1}}k_3\right), \quad b = \frac{k_4}{k_0}, \quad c = \frac{k_5'}{k_{-4}}[M],$$

and

$$d = \frac{k_5-k_5'}{k_{-4}}$$

In the case of Cd* = Cd($^3P_0$), a, c, and d are expressed in the same manner as above, while

$$b = \frac{k_1}{k_{-1}}\frac{k_4}{k_0}.$$

At the temperature of 220 °C, the equilibrium constant between $^3P_1$ and $^3P_0$ states is 1.68 ($=1/3 \exp(1.6/RT)=K=k_1/k_{-1}$).

According to Eq. (1), the $I^0_{326.1}/I_{326.1}$ ratio should have a linear dependence on the pressure of ammonia in the high-pressure region and a second-order dependence in the low-pressure region. These tendencies agree with the observations. By applying Eq. (1) to the observed values, the constants, a, b, c, and d, could be obtained by trial and error. The results are summarized in Table 1. The solid line in Fig. 3 was

Table 1. The constants involved in Eq. (1)

a = 0.010 ± 0.002	Torr^{-1}
b = 0.103 ± 0.002	Torr^{-1}
c/[M] = 0.0024	Torr^{-1}
d = 0.30	Torr^{-1}

drawn by introducing these values into Eq. (1). The c term is so small that the $I^0_{326.1}/I_{326.1}$ ratios calculated are scarcely dependent at all on the total pressure.

The Pressure Dependence of the Emission at 432 nm. The steady-state treatment of the above mechanism gives the following relation for the intensity of the emission at 432 nm:

$$\frac{I_{326.1}[NH_3]}{I_e} = (e+f[NH_3])\left(1+\frac{g}{h+[NH_3]}\right) \quad (2)$$

Here, I_e represents the total emission intensity arising from the stabilized complex. Since the emission profile was the same at all pressures and compositions examined, the observed emission intensity at 432 nm (I_{432}) should be proportional to the total emission intensity; *i.e.*, $I_e=\alpha I_{432}$. The proportional factor, α, depends on the geometry of the apparatus, the slit width, and the sensitivity of the photomultiplier used. e, f, g, and h are constants depending only on the total pressure; when Cd* = Cd($^3P_1$),

$$e = \frac{k_0}{k_4}+\frac{k_0}{k_4}\frac{k_7'}{k_6}[M], \quad f = \frac{k_0}{k_4}\frac{k_7-k_7'}{k_6},$$

$$g = \frac{k_{-4}}{k_5-k_5'}, \quad \text{and} \quad h = \frac{k_5'}{k_5-k_5'}[M].$$

In the case of Cd* = Cd($^3P_0$), k_4 should be replaced by $(k_1/k_{-1})k_4$. These constants have been evaluated by the method given in the Appendix and are listed in Table 2. The solid lines in Fig. 2 were drawn

Table 2. The constants involved in Eq. (2)

[M] (Torr)	αe (Torr)	αf	g (Torr)	h/[M]
208	2.17	0	3.20	0.0072
175	1.99	0	3.23	0.0072
147	1.87	0	2.78	0.0072
123	1.74	0	2.52	0.0072

by substituting the values in Table 2 into Eq. (2). The agreement between the calculated values and the observed ones is good at all the pressures examined.

The lifetime (τ_0) of Cd($^3P_1$) has been reported to be 2.39×10^{-6} s.[8] As was mentioned in a previous paper,[6] the effective lifetime is independent of the pressure of foreign gases in the range we are studying. Therefore, k_0 may be set equal to $1/\tau_0$. On the other hand, several ratios of the rate constants can be evaluated from the relationships between the constants, a, b, c, d, e, f, g, and h, and the total pressure ([M]). The results are summarized in Table 3. A comparison of

Table 3. Several rate constants and ratios between the rate constants

$k_2 + 1.68\,k_3 = (2.1\pm0.4)\times10^{-13}$ cm^3 molecule^{-1} s^{-1}
k_4 (or $1.68\,k_4$) $= (2.2\pm0.4)\times10^{-12}$ cm^3 molecule^{-1} s^{-1}
$k_5/k_{-4} = 0.336\pm0.012$ Torr^{-1}
$k_5/k_5' = 139$
$k_7/k_6 = (4.9\pm0.2)\times10^{-3}$ Torr^{-1}
$k_7/k_7' = 1$

k_4 with $(k_2+1.68\,k_3)$ indicates that the cross section for the quenching of the excited cadmium atoms through the formation of the complex is about 10 times that for the quenching through other processes, such as the abstraction of the hydrogen atom. The half-quenching pressure of ammonia is calculated to be 12.6 Torr. This value is less than a half that reported previously (29.8 Torr).[5] The latter value, however, was obtained while paying no attention to the pressure broadening of the absorption line. Therefore, the value obtained here should be more reliable.

On the basis of the data obtained by using a flash technique, Callear and McGurk[3] proposed two types of the formation of the emitting complex in the system of Hg and NH_3:

$$Hg^* + NH_3 \longrightarrow HgNH_3^* \qquad k_b$$

$$Hg^* + NH_3 + M \longrightarrow HgNH_3^* + M \qquad k_t$$

The lifetime of Hg*, therefore, was expressed as follows:

$$\tau^{-1} = \tau_M^{-1} + k_b[NH_3] + k_t[NH_3][M]$$

where τ_M is the lifetime of Hg* in the absence of foreign gases. Morten *et al.*[4] assumed a similar mechanism for the formation of the emitting cadmium complex

and estimated that $k_b=(1.7\pm0.3)\times10^{-12}$ cm^3 molecule^{-1} s^{-1} at 560 K. In our treatment, the lifetime of Cd($^3P_1$) may be expressed in this form:

$$\tau^{-1}=\tau_M^{-1}\left(1+a[NH_3]+\frac{b[NH_3]}{1+\frac{1}{c+d[NH_3]}}\right)$$

As is shown in Table 1, we obtained d=0.3 Torr^{-1}. The experiment of Morten *et al.* was carried out at more than a few Torr of NH_3. Therefore, the k_b value obtained by Morten *et al.* may be compared with the value of $(a+b)/\tau_M$. The calculated value is 2.4×10^{-12} cm^3 molecule^{-1} s^{-1} at 493 K. It may be said that these two values are in good agreement.

By assuming the cross section of 9 Å^2 for Reaction (5), which corresponds to $k_5=2.36\times10^{-10}$ cm^3 molecule^{-1} s^{-1} at 220 °C, the lifetime of the unstabilized complex was calculated to be 7.4×10^{-8} s. This is the shortest possible lifetime of the unstabilized complex. Therefore, if other molecules which are more complex than ammonia can form emitting species, and if the back reaction is not important, we shall not be able to observe the second order pressure dependence of the Stern-Volmer plots in the low-pressure region, as was observed in the present case of ammonia.

The ratio of $k_5'/k_5=0.0072$ shows that the stabilization of the unstabilized complex by ammonia is about 140 times as efficient as that by argon. On the other hand, $k_7'/k_7=1$ suggests that the efficiency of the deactivation of the stabilized complex is almost the same for both quenchers. Morten *et al.* estimated the lifetime of the emitting complex to be $(4.9\pm0.2)\times10^{-7}$ s. This suggests that Reactions (7) and (7′) are extremely inefficient.

Appendix

At the pressure of ammonia high enough for $1+\frac{g}{h+[NH_3]}\approx1$, Eq. (2) can be reduced to this form:

$$\frac{I_{326.1}[NH_3]}{I_{432}}=\alpha e+\alpha f[NH_3] \quad (3)$$

The left-hand side of Eq. (3) is plotted against the pressure of ammonia, and the constants, αe and αf, are evaluated from the intercept and the slope of the straight line obtained in the high-pressure region.

Equation (2) can be rewritten as follows:

$$\frac{I_{326.1}[NH_3]}{I_{432}}\frac{1}{\alpha(e+f[NH_3])}=1+\frac{g}{h+[NH_3]} \quad (4)$$

The left-hand side of Eq. (4) can be calculated by using the values of αe and αf obtained above. The g and h constants are determined by using the method of curve-matching. Then, according to Eq. (2), the αe and αf constants can be determined in turn by using the values of g and h just obtained. These constants should be equal to the values obtained above. We, therefore, used the circulating procedure until a self-consistent set of constants was obtained. The final values are listed in Table 2.

Solution Properties of Phycocyanin. II. Studies of the Molecular Shape and Size by Using the Shell Model**

Akira KOTERA*, Takahide SAITO, Naomichi ISO, Haruo MIZUNO, and Nobuo TAKI*

Department of Food Science and Technology, Tokyo University of Fisheries, Konan, Minato-ku, Tokyo 108

(Received October 5, 1974)

The number-average molecular weight and intrinsic viscosity of phycocyanin, isolated from *Porphyra tenera*, have been determined by osmotic pressure and viscosity measurements at various values of pH and ionic strength. The molecular shape and size for phycocyanin aggregates were also discussed by comparing the experimental values of sedimentation coefficient and intrinsic viscosity with the calculated results obtained by using the shell model theory. It is shown that the aggregate of phycocyanin at pH 5.4 is a hexamer of molecular weight 256000 and the structure consists of six juxtaposed monomers. The monomer is a prolate ellipsoid of 35 Å in diameter and 105 Å length. This structure for the hexamer is consistent with the model proposed by Jennings. At pH 6.8, it is shown that the number-average molecular weight of phycocyanin depends on the ionic strength in solution.

In a previous paper,[1] we studied the dissociation-association equilibrium of phycocyanin, isolated from red algae, *Porphyra tenera*, by sedimentation transportation measurements at pH 6.8 and 5.4 and ionic strengths of 0.1 and 0.2. The sedimentation velocity data indicated that the predominant phycocyanin aggregate was a trimer at pH 6.8 and a hexamer at pH 5.4. Moreover, the dissociation-association system of phycocyanin was presumed to be trimer⇌monomer at pH 6.8 and hexamer⇌monomer at pH 5.4.

Berns and Edwards[2] observed phycocyanin aggregates with an electron microscope. They suggested that the higher aggregate of phycocyanin consisted of six globular particles, and, also, that the shape of the hexagonal aggregate was that of an oblate or prolate ellipsoid with an axial ratio of approximately 4 : 1. Scott and Berns[3] performed diffusion and viscometric measurements on phycocyanin solutions, and proposed a round structure with a central hole for the phycocyanin aggregate. Jennings[4] discussed the size and shape of the phycocyanin aggregate on basis of an amino acid composition analysis reported by Berns *et al.*[5] and proposed that the hexamer was an aggregate of six monomers, in juxtaposition, with their major axes parallel so as to form a ring structure, as shown in Fig. 1. Although some investigators proposed a trimer for the lower aggregate of phycocyanin, the shape and size of this aggregate have not been discussed.

Bloomfield *et al.*[6,7] reported a method of estimating the size and conformation of macromolecules in terms of the number of equivalent spherical subunits. In this procedure, the complex structures are replaced by a surface shell consisting of many small spheres, and hence this approximation for a macromolecular complex structure is called the "shell model." Bloomfield *et al.*[7] studied the size of phycocyanin using their theory and proposed that the phycocyanin monomer was a single sphere having a 26 Å radius or a linear array of three spheres, each having an 18 Å radius.

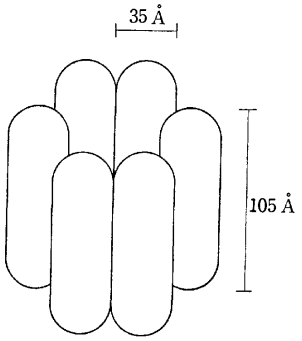

Fig. 1. Schematic model of the phycocyanin hexamer proposed by Jennings[4].

Tsuda[8,9] presented an expression for the intrinsic viscosity of macromolecules based on Kirkwood's approximation for the frictional coefficient. It was found that the experimental results obtained from the measurements of sedimentation coefficient and intrinsic viscosity for many biological macromolecules, such as fibrinogen, hemoglobin and hemocyanin, can be reasonably explained by the shell model.[7,8]

In this paper, the molecular weight and the intrinsic viscosity were measured in phycocyanin solutions under several sets of conditions, that is, pH 6.8 and 5.4, and ionic strength (μ) 0.01, 0.1 and 0.2. The molecular size and shape of this protein were discussed by using the theory of the frictional coefficient of the multi-subunit structure reported by Bloomfield *et al.*[7] and Tsuda.[8,9]

Experimental and Calculation

Treatment of Phycocyanin. The phycocyanin used in this study was obtained from dried *Porphyra tenera* by repeated precipitation with ammonium sulfate, and the process for sample preparation and the concentration determination of the protein solution were described in detail in part I.[1].

Osmotic Pressure Measurements. Osmotic pressure measurements of phycocyanin were conducted in buffer solution at 25.0 °C with a Model 502 High Speed Membrane Osmometer. Phosphate (pH 6.8, μ 0.01, 0.1 and 0.2) and acetate (pH 5.4, μ 0.1 and 0.2) buffer solutions were used in these determinations. The membrane was Gel-cellophane #600 supplied by Tokyo Cellophane, and was conditioned by the

"subsequent transfer method" from water to buffer solution. Prior to use, the membrane was equilibrated overnight in the appropriate buffer solutions. The number-average molecular weight and the second virial coefficient were obtained by the usual method.

Viscosity Measurements. Viscosity measurements were made in the buffer solution at 25.0 °C, under the following conditions: pH 6.8 and 5.4; μ 0.1 and 0.2. An Ubbelohde dilution type viscometer was used for the measurements. Kinetic energy corrections were not made. The intrinsic viscosity was obtained by using Huggins' equation.

Results and Discussion

The osmotic pressure data are shown in Fig. 2, plotted as π/c *versus* c. As shown in this figure, the concentration dependence of π/c was small for all systems. Therefore, the second virial coefficients of all systems were considered to be nearly zero. The values of π/c at pH 5.4 show the same value irrespective of the ionic strength (0.1 or 0.2), while the π/c values at pH 6.8 increased with decreasing ionic strength of the solution.

The number-average molecular weight at pH 5.4 was 256000. At pH 6.8, the number-average molecular weights were 228000 for μ 0.2, 172000 for μ 0.1 and 154000 for μ 0.01.

We consider that the change in the molecular weight of phycocyanin with the variation of ionic strength at pH 6.8 arises from the difference in the dissociation-association reaction of the protein. In the previous paper, it was shown that the sedimentation coefficient of phycocyanin did not change markedly with changing ionic strength.[1] The results seem to be a consequence of measuring the sedimentation coefficient at too low concentration. As pointed out previously,[1] the dissociation-association equilibrium for phycocyanin at low concentration was trimer$\rightleftarrows$monomer, and the predominant species was a trimer. However, the results from the present study suggest that various aggregates, having different molecular weights, coexist in higher concentration regions. At pH 5.4, the phycocyanin molecule seems to be relatively stable in solution.

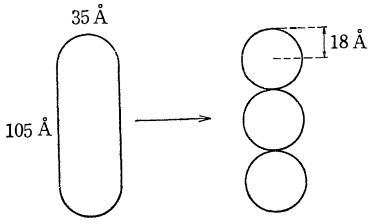

Fig. 3. Monomer model proposed by Jennings[4] treatment according to the shell model.

Figure 3 shows the model of the phycocyanin monomer for the calculation of theoretical values of sedimentation coefficient and intrinsic viscosity. This model is the same one as that proposed by Jennings[4]. The monomer structure was assumed to be an array of three identical spheres of radius of 18 Å as shown in Fig. 3. Also the molecular weight of the monomer was estimated to be 42000. This value was about 1/6 of 256000, which was the molecular weight of hexamer obtained from an osmotic pressure measurements.

Viscosity data for phycocyanin in various buffer solutions at 25.0 °C are shown in Fig. 4. All plots of η_{sp}/c against c under various conditions (pH 6.8, μ 0.2, and pH 5.4, μ 0.1 and 0.2) displayed an increase with decrease in concentration in lower concentration regions. This viscosity behavior is generally found for polyelectrolyte solutions. The viscosity characteristic for phycocyanin may be attributed to the charge effects on the protein molecule. Intrinsic viscosities of phycocyanin reported in this paper were determined by linear extrapolation of plots of η_{sp}/c against c in a higher concentration range to infinite dilution. From this extrapolation the values of $[\eta]$ for phycocyanin aggregates were found to be 3.92 ml/g at pH 5.4 and 4.32 ml/g at pH 6.8.

According to the shell model theory, the translational frictional coefficient, f, of a molecule composed of n identical spherical subunits, may be expressed by following equation[8] which is derived from the Kirkwood theory for irreversible processes in solutions of macromolecules.[10]

$$f = \frac{6\pi\eta_0 n^2 r}{n + r\sum_i \sum_{j(\neq i)} R_{ij}^{-1}} \tag{1}$$

where r is the radius of the sphere, η_0 the solvent viscosity and R_{ij} the distance between the i-th and j-th subunit.

In a fluid medium, the rate of sedimentation for solute depends on the translational frictional coefficient, f. Therefore, the sedimentation constant, s_0, is a function of the frictional coefficient and may be expressed by Eq. (2):

$$s_0 = \frac{M(1-\bar{v}\rho)}{fN_A} \tag{2}$$

where M is the molecular weight, $\bar{v}$ the partial specific volume of solute, ρ the density of solvent and N_A Avogadro's number.

On the other hand, the intrinsic viscosity of a macro-

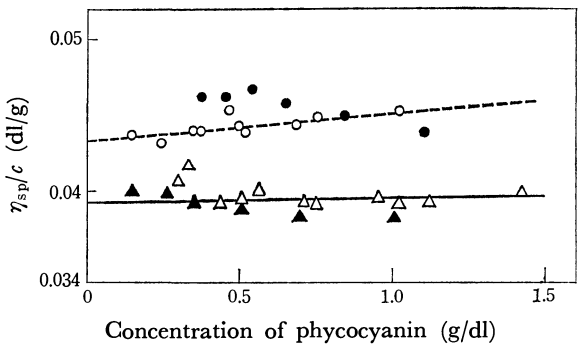

Fig. 4. Plots of η_{sp}/c *versus* concentration of phycocyanin in four different buffer solutions at 25.0 °C. ○, phosphate buffer, pH 6.8 and $\mu=0.1$; ●, phosphate buffer, pH 6.8 and $\mu=0.2$; △, acetate buffer, pH 5.4 and $\mu=0.1$; ▲, acetate buffer, pH 5.4 and $\mu=0.2$.

molecule is related to the rotational frictional property. A general expression for intrinsic viscosity of a complex structure composed of different subunits is

$$[\eta] = \left(\frac{4\pi}{3}\right)\left(\frac{N_A}{M}\right)B \tag{3}$$

where B is a parameter related to the molecular shape and size of a complex macromolecule and its form is given by Eqs. (29)—(33) of Ref. 8.

The intrinsic viscosity and sedimentation constant for various model structures of phycocyanin aggregate were calculated by a computer using Eqs (1), (2) and (3). In these calculations, the monomer structure was assumed to be an array of three identical spheres with a radius of 18 Å, and the monomer molecular weight of 42000, estimated from the osmotic pressure measurements, was used.

For the monomer model the intrinsic viscosity was calculated to be 4.2 ml/g, and the sedimentation constant to be 3.5×10^{-13} s, respectively. The s_0-value of 3.5×10^{-13} s agrees with the experimental value (3.2×10^{-13} s) obtained by Hattori *et al.*[11] Therefore, the shape of the phycocyanin monomer may be a prolate spheroid with an axial ratio of approximately 3 : 1. Since the experimental value of $[\eta]$ for the monomer has not yet been reported, the calculated value of the intrinsic viscosity cannot be compared with the experimental value.

The values of $[\eta]$ and of s_0 for Jennings' model and other assumed hexameric structure of phycocyanin were calculated by the shell theory. An $[\eta]$ value of 4.08 ml/g and an s_0-value of 11.8×10^{-13} s were calculated for Jennings' model. These values are in reasonable agreement with the exprimental values ($[\eta]=$ 3.92 ml/g and $s_0=10.8\times10^{-13}$ s[1]) obtained at pH 5.4. Therefore, the aggregate of the protein seems to be a hexamer at pH 5.4. The hexamer of phycocyanin can be considered to be an aggregate of six prolate monomers. The prolate monomers are associated side by side with their major axes parallel to the hollow core of the hexamer. Such a structure for hexamer would have an axial ratio close to unity.

From the results of osmotic pressure measurements at pH 6.8, it might be supposed that the aggregate at this pH value is a tetramer. However, the results of the calculations of $[\eta]$ and s_0 for some tetrameric models of phycocyanin aggregate eliminated this possibility.

TABLE 1. CALCULATED VALUES OF INTRINSIC VISCOSITY AND SEDIMENTATION COEFFICIENT FOR THE ASSUMED MODEL OF THE PHYCOCYANIN TRIMER

At pH 6.8 the experimental value of $[\eta]$ is 3.92 ml/g and s_0 is 6.4s.

Model	$[\eta]$ (ml/g)	s_0 (S)
Fig. 5-a	4.47	7.16
Fig. 5-b	3.65	7.74

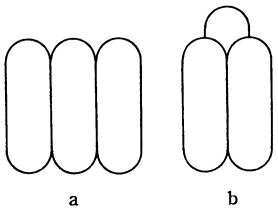

Fig. 5. Schematic models of phycocyanin trimer.

Table 1 shows the results of the calculations for some trimer models depicted in Figs. 5-a and 5-b. As is evident from Table 1, the calculated value of $[\eta]$ for the assumed structure of trimer, shows a remarkable deviation from the experimental value although it satisfactorily explains the sedimentation behavior.

From these results, it seems to be impossible to represent the trimer by a self-consistent model for both the sedimentation constant and the intrinsic viscosity. However, it should be remembered that the sedimentation constant measurements were carried out at concentrations below 0.5 g/dl. On the other hand, both the intrinsic viscosity and the osmotic pressure were measured at higher concentration. The existence of higher order aggregate cannot be neglected in the higher concentration regions at pH 6.8. It seems that the values of intrinsic viscosity and number-average molecular weight obtained in this study are averages for a mixture of trimer and higher order aggregates (probably hexamers).

The weight fraction for each species in the mixture can be calculated from the number-average molecular weight, assuming a hexamer⇄trimer equilibrium for the mixture. The results indicate the weight fraction of trimer is 0.46 and of hexamer, 0.54. By considering the intrinsic viscosity of the mixture as the weight average value, the value of $[\eta]$ for the mixture was calculated from the intrinsic viscosity estimated for trimer and hexamer. The calculated value (4.26 ml/g) of $[\eta]$ for the mixture agrees well with the experimental value (4.32 ml/g). Agreement between calculated and exprimental values suggests that the coexistence of higher order aggregates in higher concentration regions cannot be neglected.

Scheraga and Mandelkern[12] derived the following equation for a revolutional ellipsoid:

$$s_0[\eta]^{1/3} = \frac{M^{2/3}(1-\bar{v}\rho)\beta}{N_A\eta_0} \tag{4}$$

where η_0 is the viscosity of the solvent. They indicated that the quantity β is a function of the axial ratio of the ellipsoid, and has a value of $2.12—2.20 \times 10^6$ for the prolate ellipsoild when the axial ratio is less than 5.

The β values for the various aggregates of phycocyanin were calculated using Eq. (4). In the calculation of β for the monomer, an intrinsic viscosity value of 4.20 ml/g was used, which was obtained by computation with the shell model as shown in Fig. 3. The β values for the monomer, the trimer and the hexamer of phycocyanin are 2.00×10^6, 1.95×10^6 and 2.05×10^6, respectively. The results agree with the theoretical value for a prolate ellipsoid having an axial ratio lower than 5.

From the β-values obtained, the geometrical structures for phycocyanin aggregates used in this study seem to be consistent; that is, the monomer model is that as shown in Fig. 3, the trimer model that is Fig. 5-a or 5-b, and the hexamer model that in Fig. 1.

Conclusion

We conclude that the aggregate of phycocyanin at pH 5.4 is a hexamer. From an analysis of the sedimentation constant and intrinsic viscosity by the shell model, we proposed that the hexamer structurally consists of an aggregate of six juxtaposed monomers, whose major axes are parallel to each other forming a closed ring structure. Each monomer is represented by a prolate ellipsoid with axial lengths of 35 Å and 105 Å. This structure for the phycocyanin hexamer is identical to that proposed by Jennings.

The phycocyanin aggregates at pH 6.8 in higher concentration regions are considered to be composed of various aggregates with different structures. Therefore, a definite structural description of the phycocyanin aggregates at pH 6.8 cannot be given.

It has shown from the values of β that the aggregates of phycocyanin, that is, monomer, trimer and hexamer, are prolate ellipsoids with an axial ratio less than 5.

The authors wish to express their gratitude to Dr. K. Tsuda and Dr. T. Sakai, of the Research Institute for Polymers and Textiles, for their interest and helpful discussions of the problems. They also wish to express their gratitude to Dr. Y. Matsumoto, of the Industrial Research Institute of Kanagawa Prefecture, for providing facilities for the osmotic pressure measurements and for his valuable assistance in the osmometry.

Effects of Anionic and Cationic Surfactants on the Ion Flotation of Cu^{2+}

Koichi KOBAYASHI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Tokyo 158

(Received October 16, 1974)

The effects of several anionic surfactants—sodium α-sulfolaurate, sodium laurate, sodium dodecylsulfate, and cationic surfactants, dodecylpyridinium chloride, and dodecyltrimethylammonium chloride—on the bubble flotation of Cu^{2+} ions were studied. Sodium α-sulfolaurate was found to be most effective for the flotation of Cu^{2+} ions. The flotation rate (percent removed) increased sharply from zero at about pH 6, and a rate larger than 95% was attained in the pH region of about 7 to 11. Cationic surfactants alone could float Cu^{2+} ions only slightly. They floated most of the Cu^{2+} ions upon the addition of bentonite, however. A flotation rate of about 90% was attained in the pH region larger than about 6. This was explained by the Cu^{2+} ions being removed as polynuclear species, which combined directly with an anionic surfactant or a cationic surfactant with the aid of bentonite.

The foam separations of soluble and suspended matters in water have drawn increasing attention in connection with industrial waste water,[1,2] sewage treatment,[1,2] the removal of trace amounts of radioactive substance from solutions[3] and the concentration of rare elements from sea water.[4,5] The techniques of ion flotation involve the removal of surface inactive ions from aqueous solutions with the aid of bubbles and can be divided into several processes differing in detail, such as adsorption flotation, precipitation flotation, and adsorbing-particle flotation.[6] The adsorption flotation consists of the flotation of ions in a solution by adsorption on ascending bubbles. In the precipitation flotation, ions in the solution are precipitated by the addition of proper substances or by controling the pH, and the precipitates formed are floated by adding a surfactant. The adsorbing-particle flotation consists of the adsorption of ions from a solution on adsorbent particles like bentonite or a synthetic ion-exchanger; the ions are subsequently floated by the addition of a suitable surfactant. The adsorption flotation requires a stoichiometric or greater concentration of surfactants, while in the case of precipitation flotation relatively small amounts of surfactants are sufficient. A preliminary experiment showed that the adsorbing-particle flotation was the most efficient among these methods of flotation.[7]

The ion-adsorption flotation was first introduced by Sebba,[8] and the ion-precipitation flotation, by Baarson and Ray.[9] Rubin *et al.*[10] compared the effects of several variables on these processes. Recently a number of studies of ion adsorption and precipitation flotations from theoretical points of view have been reported,[11,12] but much remains unsolved.

The present work has been undertaken in order to study the flotation of Cu^{2+} ions by a number of surfactants from the surface-chemical point of view, under varying conditions of pH, gas-flow rate, time, and concentrations of the surfactants and Cu^{2+} ions.

Experimental

Materials. The cupric sulfate used was a reagent-grade $CuSO_4 \cdot 5H_2O$; it was recrystallized from distilled water, and stock solutions of 2×10^{-3} and 1×10^{-3} mol/l concentrations were prepared.

The surfactants used included sodium *n*-dodecylsulfate (SDS), sodium *n*-dodecylbenzenesulfate (DBS), sodium laurate (LNa), and sodium α-sulfolaurate (α-SLNa) as anionic surfactants, and *n*-dodecylpyridinium chloride (DPC) and *n*-dodecyltrimethylammonium chloride (DTAC) as cationic surfactants.

The SDS was synthesized from dodecanol and chlorosulfonic acid, and the product was purified by extraction with ethyl ether and recrystallization from ethanol.[13] Pure-grade DBS was supplied by the Kao Soap Co., Ltd., and was dried over phosphorus pentoxide. A reagent-grade LNa, a product of the Tokyo Kasei Industrial Co., Ltd., was recrystallized from ethanol with water. The α-SLNa, a product of the Kao Soap Co., Ltd., was recrystallized from ethanol with a little water. The DPC and DTAC, products of the Tokyo Kasei Industrial Co., Ltd., were recrystallized from acetone and ethanol respectively; the latter was washed with ether and dried. These surfactants were kept in a desiccator. The aqueous solutions were prepared before use.

The bentonite powders used as ion-exchange adsorbents were obtained from the Wako Pure Chemical Co., Ltd.; the fraction passing through a 350-mesh sieve was collected, and a suspension of 0.01 g/l concentration was made and used after shaking before each experiment. The pH of the solution was controlled by using sulfuric acid and sodium hydroxide of an extra pure grade. The water used was triply distilled; it was found to be free from Cu^{2+} ions by the use of an atomic absorption spectrometer.

Apparatus and Procedure. The apparatus used is shown in Fig. 1. Nitrogen gas from a nitrogen cylinder, A; successively passing through a gas filter, B; a manostat, C; an empty chamber, D, and a humidifier, E, saturated with water, was introduced into a flotation cell, G, at a constant rate of flow controlled with a calibrated capillary flow meter, F. The flow rate of the nitrogen gas was measured by

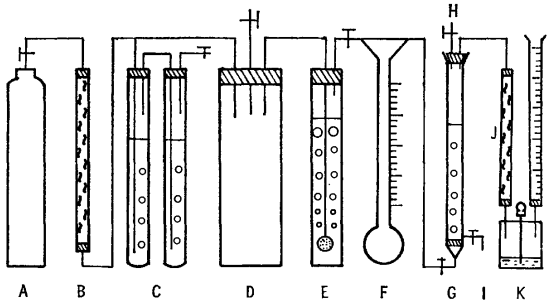

Fig. 1. Apparatus for ion flotation.
A: N_2 gas cylinder, B: glass filter, C: manostat, D: empty chamber, E: humidifier, F: capillary flow meter, G: flotation cell (No. 4), H: inlet, I: outlet J: glass filter, K: soap film flow meter.

means of a soap-film flow meter, K; after the gas has been filtered through a glass wool filter, J. The flotation cell used was a glass column, 32.0 cm long and 1.0 cm in inner diameter, equipped with a sintered glass plate with a porosity of No. 4.

The sample liquid was introduced into the cell from an inlet, H, and the residual solution after flotation was withdrawn from an outlet, I, for the measurements of the Cu^{2+}-ion concentration and the pH. The concentration of the Cu^{2+} ions was measured by using an atomic absorption spectrometer (Techtron Pty., Ltd., Model-AA-100). The absorbance was measured at 3248 Å. A glass electrode pH meter (Toadenpa Co., Ltd., HM-5A) was used to measure the pH. For the measurement of the flotation, 2 ml of a stock solution of 1×10^{-3} or 2×10^{-3} mol/l Cu^{2+} ions, a small amount of a sodium hydroxide or sulfuric acid solution to adjust the pH to a desired value, 2 ml of a bentonite suspension in the case of a cationic surfactant, and 2 ml of a surfactant solution were introduced successively into a 20-ml measuring flask; the total volume was then made 20 ml with water. About 10 ml of the sample solution thus prepared was used to measure the initial pH (pH_i). Ten ml of the remaining solution was transferred to the flotation cell, the gas flow was started, and flotation was carried out as has been described above. The gas-flow rate was kept at 10 ml/min for all the experiments except for the study of the effect of the gas-flow rate. The gas-flow time was kept at 2 or 7 min unless otherwise stated. After the flotation, about 7 ml of the solution was taken out of the flotation cell for the measurements of the final pH (pH_f) and the Cu^{2+}-ion concentration (C_f). The measurements of the flotation were carried out at a room temperature of about 25 °C.

Results and Discussion

The flotation rate, $F(\%)$, of Cu^{2+} ions is conventionally expressed by:

$$F = (1-C_f/C_i)\times100$$

where C_i denotes the initial concentration of Cu^{2+} ions.

All the experiments were run under the conditions of bubble flotation—namely, flotation using only ascending bubbles, without the aid of foam formation. Since the solution was made uniform in concentration by bubbling, and since most of the solution after flotation was used for the determination of the Cu^{2+}-ion concentration, the F measured substantially expresses the total percentage of Cu^{2+} ions removed from the solution.

(1) *Flotation of Cu^{2+} Ions by Anionic Surfactants. Relation between the Volume of the Flow Gas and the Flotation Rate*: Figure 2 shows the flotation rate as a function of the total volume of the gas flow at various rates for the Cu^{2+}-α-SLNa system. The figure shows that the flotation rate is simply a function of the volume of the gas flow and is independent of the flow rate. This is in accord with Rubin's view[14] that the flotation rate depends only on the volume of the gas flow. In the present case, F of nearly 100% is obtained, at least after 10 ml of nitrogen gas has flowed. Accordingly, all subsequent experiments were run at a gas-flow rate of 10 ml/min and a gas-flow time of 2 or 7 min.

Relation between the pH and the Flotation Rate. Figure 3 shows the effect of the pH on the flotation rate for the 2×10^{-4} mol/l Cu^{2+} and 1×10^{-5} mol/l SDS systems. As may be seen in this figure, the flotation rate increases sharply at about pH 6 and reaches its maximum at a pH value from 7 to 8 for the gas-flow times of both 2 and 7 min. An F of about 80% is obtained at the gas-flow time of 7 min. Beyond a 1×10^{-5} mol/l SDS concentration, the condition of bubble flotation changes to that of froth flotation, which was not studied since excessive foaming results in a large hold-up of the solution, thus preventing effective bubble flotation.

Figures 4 and 5 show the F *vs.* the gas-flow time and the F *vs.* surfactant concentration curves respectively for the Cu^{2+}-α-SLNa system. It may be seen in Fig. 3 that, at a 1×10^{-5}mol/l SDS concentration, the flotation rate increases with the gas-flow time. A similar effect may be expected for the Cu^{2+}-α-SLNa system, considering the same rate of flotation for the 1×10^{-5} mol/l α-SLNa concentration and the gas-flow time of 7 min. At a 4×10^{-4} mol/l α-SLNa concentration, the rate increases and shows a flat maximum of F of 98% extending from pH 7 to 11, independent of the gas-flow time, while for the SDS system the increase in the SDS concentration from 1×10^{-5} to 1×10^{-4} mol/l results in both an excessive foaming and hold-up of the solution, as has been mentioned above.

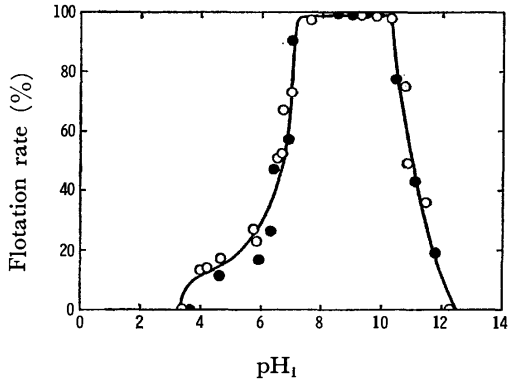

Fig. 4. Flotation rate *vs.* initial pH for Cu^{2+}–α-SLNa system.
Cu^{2+}: 2×10^{-4} mol/l, α-SLNa: 4×10^{-4} mol/l, gas-flow time: ●; 2 min, ○; 7 min.

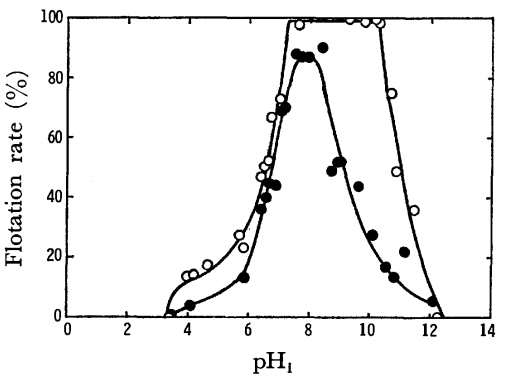

Fig. 5. Flotation rate *vs.* initial pH for Cu^{2+}–α-SLNa system.
Cu^{2+}: 2×10^{-4} mol/l, α-SLNa: ○; 4×10^{-4} mol/l, ●; 1×10^{-5} mol/l, gas-flow time: 7 min.

This may indicate that α-SLNa is superior to SDS as the additive for Cu^{2+} flotation, and confirms the view that the introduction of a carboxylic group into alkylsulfate increases the flotation efficiency.[15]

Figure 6 shows the pH dependence of the flotation rate for the Cu^{2+}–LNa system. The behavior is similar to that of the Cu^{2+}–α-SLNa system, showing a broad maximum, but a somewhat lower *F* value than that of the Cu^{2+}–α-SLNa system. Figure 7 shows the *F vs.* pH curve for the Cu^{2+}–DBS system. The rate of flotation, like that of Cu^{2+}–LNa system, shows a sharp increase at pH 6. On a further increase in the pH, a plateau or a minimum appears after a slight maximum, and then marked maxima at pH 10 appear, showing an *F* of 96% for DBS at the concentration of 2×10^{-5} mol/l. The system of 1×10^{-4} mol/l DBS exhibits stable foam formation, and so it was not studied. The Cu^{2+}–DBS system is seen to be intermediate in behavior between the Cu^{2+}–SDS and Cu^{2+}–α-SLNa systems.

Mechanism of Flotation of Cu^{2+} Ions by Means of an Anionic Surfactant. When we compare Figs. 3, 4 and 6, the cooperative effect of sulfate and carboxylic groups is evident. It may be explained by the fact that the presence of carboxylic groups is effective for the bubble flotation by combining with Cu^{2+} ions, while the coexistence of sulfonic groups enhances the

flotation rate by increasing the solubility of the collector, as has previously been reported.[11]

As has been mentioned above, Figs. 3—7 show sharp rises in the *F vs.* pH curves at pH 6, which correspond to the beginning of copper-hydroxide precipitation. This might indicate that the sublate consists mainly of a polynuclear hydroxide-surfactant complex, the process being called the precipitation flotation of the first type.[16] Figure 8 shows the effect of the concentration of α-SLNa on the rate of the

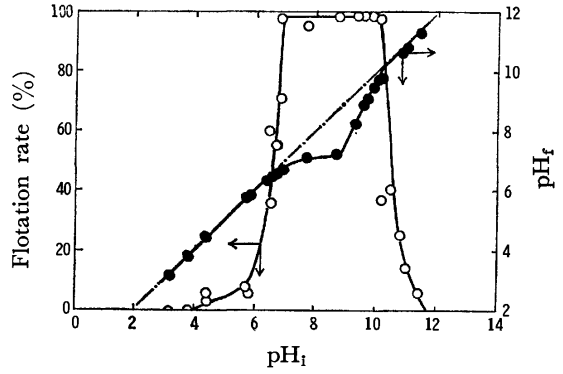

Fig. 9. Initial pH *vs.* final pH and flotation rate for Cu^{2+}-α-SLNa system.

flotation of the 2×10^{-4} mol/l Cu^{2+} solution. It may be seen in this figure that F of nearly 100% is obtained at the surfactant concentration of about 1×10^{-4} mol/l, which is equivalent to one-fourth of the Cu^{2+} ion concentration of this solution. It may be suggested that one surfactant molecule combines with at least four Cu^{2+} ions for a 100% flotation. It may similarly be estimated that the SDS/Cu^{2+} ratio is lower than 1/40 for the Cu^{2+}–SDS system. These

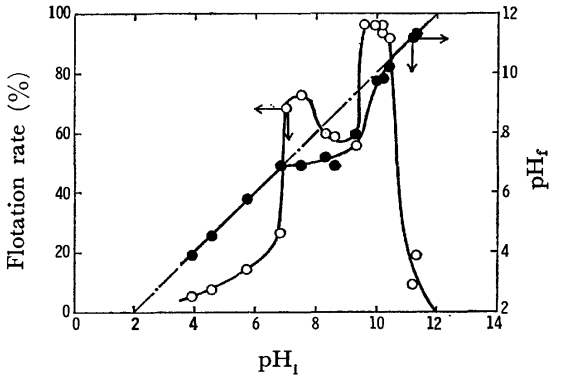

Fig. 12. Initial pH *vs.* final pH and flotation rate for Cu^{2+}-DBS system.
Cu^{2+}: 1×10^{-4} mol/l, DBS: 2×10^{-5} mol/l, gas-flow time: 7 min.

small collector/colligend ratios may be considered to be specific for the precipitation flotation of the first type as compared with the case of ion-adsorption flotation, where the surfactants combine with Cu^{2+} ions at a stoichiometric or greater ratio.[17] This also confirms that the precipitation flotation is the dominant factor in the present case.

In Figs. 9, 10, 11 and 12, the values of pH$_f$ and F are plotted against the pH$_i$ for the flotation of Cu^{2+} by α-SLNa, LNa, SDS, and DBS respectively. As may be seen in these figures, the plateau appears in the pH$_f$ *vs.* pH$_i$ curve in the vicinity of pH 8. This may be explained by the liberation of hydrogen ions due to the formation of polynuclear species,[11,18] according, for instance, to

$$n\mathrm{Cu^{2+}} + (n-1)\mathrm{H_2O} \rightarrow {}^{+}\mathrm{Cu(OCu)}_{n-2}\mathrm{OCu^{+}} + 2(n-1)\mathrm{H^{+}}$$

This may also explain the fact that large amounts of Cu^{2+} ions are removed by a small amount of a surfactant. The decrease in the flotation rate on the alkaline side is due to the competition between OH^- and surfactant anions for polynuclear Cu^{2+} ions; therefore, the pH region of the decreasing branch and the shape of the maximum of the F *vs.* pH curve depend on the nature of the acid groups.

It is also confirmed that the plateau region of the pH$_f$ *vs.* pH$_i$ curve and the maximum region of the F *vs.* pH$_i$ curve coincide with each other as a whole; this again indicates the formation of a polynuclear Cu^{2+}-surfactant complex, as has been mentioned above. The decrease in the flotation rate of Cu^{2+} ions below pH 6 can be explained by the competition between H^+ and Cu^{2+} ions for the anionic surfactant.

Now, in the case of α-SLNa system, the question arises as to whether the polynuclear Cu^{2+} ion attaches to the carboxylic or the sulfonic group of the surfactant molecule. It may be expected, from the similarity of the F *vs.* pH$_i$ curve of α-SLNa to that of the LNa curve (Fig. 6), and from a consideration of the solubility product, that the combination between the Cu^{2+} ion and the carboxylic-acid group is preferred, although Davis and Sebba have reported that the Sr^{2+} ions reacted preferentially with sulfonic groups.[15] The exact determination requires further study.

the plots of the flotation rate *vs.* the amount of bentonite for DTAC at various pH values. Figure 14 shows the flotation rate *vs.* the pH curve for DPC with and without the addition of bentonite. Figures 15 and 16 show the relationship between the flotation rate and the surfactant concentration for DPC and DTAC respectively at various pH values.

Relation between the pH and the Flotation Rate. As may be seen in Figs. 13 to 16, the flotation rate remains almost zero for the systems of both DPC and DTAC up to pH 6, above which point it increases much as in the cases of anionic surfactants; a maximum appears in the pH region from 7 to 10 or more. The flotation rate generally decreases in a sufficiently high pH region. In the case of Cu^{2+}-ion flotation by bentonite and a cationic surfactant, bentonite enhances the flotation by the adsorption of Cu^{2+} ions, followed by coagulation and flotation, since a system lacking bentonite markedly decreases the flotation rate, as will be discussed later. Thus, this flotation is classified as an ion-adsorbing particle flotation.[6] Bentonite, being considered as an macromolecular anion, acts as a bridge between the cationic Cu^{2+} ions and the cationic surfactant. The region of large F extends to a higher pH region for the Cu^{2+}–bentonite–cationic surfactant system (Fig. 16) than for the Cu^{2+}–anionic surfactant system (Fig. 5) because, in the former system, the multiple points of attachment are supplied by bentonite for the polynuclear Cu^{2+} ions and the cationic surfactant, while in the latter system the anionic surfactant offers for less site for the polynuclear Cu^{2+} ions. This results is not only an extension of the pH region to a higher value, but also a larger flotation rate of the Cu^{2+}–bentonite–cationic surfactant complex than that of the Cu^{2+}–anionic surfactant. At a sufficiently high pH, OH^- ions compete with bentonite for both cationic surfactant and Cu^{2+} ions in the case of a dilute surfactant or a surfactant of a relatively weak base, and a general tendency for F to decrease is expected, as can be seen for DPC in Figs. 14 and 15 and for DTAC in Fig. 16. A marked decrease in F above pH 10 in the case of the Cu^{2+}–bentonite–DPC system was found to be a result of the weaker basic nature of DPC than of DTAC, as confirmed by the potentiometric titration. At pH values lower than 6, the flotation rate is practically zero for Cu^{2+}–bentonite–cationic surfactant systems; this is a result of the strong adsorption of H^+ on bentonite, which prevents the adsorption of the cationic surfactant and Cu^{2+} ions.

Effect of Bentonite. As may be seen in Fig. 13, an increase in the bentonite concentration from 0.001

to 0.01% increases the flotation rate for the DTAC system. This is a result of the decrease in liquid hold-up by the suppression of foaming and the maintenance of the condition of bubble flotation. The system lacking bentonite strongly foams, so it could not be studied by the bubble-flotation system. Therefore, bentonite acts not only as a bridge between Cu^{2+} ions and bubbles, but also as an inhibitor of foaming caused by the surfactant, thus making effective bubble flotation possible. The complete removal of bentonite, however, exhibited some residual flotation rate, as is shown in Fig. 14 for the Cu^{2+}–DPC system. This may be due to some Cu^{2+} ions being adsorbed on the cationic foam, even in the absence of bentonite, perhaps by a nonspecific interaction between the polynuclear Cu^{2+} ions and the cationic surfactant.

Effect of the Concentration of the Surfactant. As may be seen in Figs. 15 and 16, the flotation rate increases with an increase in the concentration of the surfactant, and reaches a maximum, showing F values of 90% for the 1×10^{-4} mol/l DPC system and 98% for the 1×10^{-4} mol/l DTAC system. Under these conditions, the solutions after flotation look quite transparent and seem free from suspended matter. Therefore, the concentration of the 1×10^{-4} mol/l cationic surfactant is just sufficient for the flotation of both 1×10^{-4} mol/l Cu^{2+} and 001% of bentonite under the present conditions of measurement. The incomplete flotation shown in Figs. 15 and 16 can also be interpreted as resulting from the surfactant being insufficient to float the bentonite. It shoud be noted, however, that the decrease in the surfactant to 1/10 of the optimum concentration only reduces the flotation rate to more than half the optimum value.

It has been reported that the base-exchange capacity of clay mineral ranges from 70 to 150 m eq./100 g.[19] Using the values of 70 m eq./100 g clay, 1×10^{-4} mol/l Cu^{2+}, 0.01% bentonite, and 2×10^{-4} mol/l surfactant, 1000 g of a solution contains 0.07 meq. of exchange sites due to bentonite, 0.2 m eq. of Cu^{2+}, and 0.2 meq. of the surfactant. Therefore, a nearly complete flotation of Cu^{2+} requires a Cu^{2+} polynuclear structure of far less effective equivalence and only a partial adsorption of the surfactant on a limited area on the bentonite surface. The details of such a structure will be reported elsewhere.

The author wishes to thank Professor Tsunetaka Sasaki for his valuable advice and continual encouragement, and also the Ministry of Education for the financial support given to Professor Sasaki.

The Role of the Promoting Mode in Nonradiative Transitions in Large Molecules

Yuichi FUJIMURA and Takeshi NAKAJIMA
Department of Chemistry, Tohoku University, Sendai 980
(Received November 26, 1973)

A rate expression for the intramolecular nonradiative transition where a promoting mode acts also as an accepting mode at the same time has been derived within the statistical limit. The dependence of the nonradiative transition rate on the shift of the equilibrium point of the promoting mode in the relevant electronic states, Δ_p, has been examined for two cases, i) excited ⇝ ground states and ii) excited ⇝ excited states, in aromatic hydrocarbons which satisfy the above condition.

In recent years, there have been many theoretical and experimental discussions[1-18] regarding the nature of the intramolecular nonradiative transitions in large molecules. Many theoretical discussions have been made of electronic relaxation processes in which vibrational modes are explicitly classified as promoting, accepting, and irrelevant modes for the nonradiative transitions: further, the promoting modes have been distinguished from the accepting modes.

The promoting modes for the internal conversions are determined from the symmetry consideration in the coupling matrix element between the relevant electronic states.[19] On the other hand, for the intersystem crossings where two kinds of perturbing operators, *i.e.*, the spin-orbit and nuclear kinetic energy operators, may act, the identification of the promoting modes is dependent on the coupling mechanism; when the zero order spin-orbit interaction does not vanish by symmetry, the rate for the intersystem crossing is irrelevent to the promoting modes, while when the higher order spin-orbit vibronic interaction has to be included, the promoting modes will play an essential role in the intersystem crossing. Various mechanisms have been proposed,[20-24] but no one has been able to uniquely identify the promoting mode for the intersystem crossing. We shall confine our investigation to the role of the promoting mode for the internal conversion of large molecules.

Considering the simple model of the non-displaced and non-distorted harmonic potential-energy surfaces for the promoting mode, Lin[1] and Freed and Jortner[7] have demonstrated the propensity rule for the promoting mode—that is, it must gain or lose one quantum of the vibrational energy in the electronic transition. The propensity rule for the promoting mode leads to the concept of an effective energy gap which differs, as a result of increase or decrease by one quantum of the vibrational energy of the promoting mode, from the electronic energy gap between the relevant electronic states. The applicability of the propensity rule is, however, restricted to the electronic relaxation between electronic states with different irreducible representations of the point groups of a molecule in the weak coupling cases. When we consider the nonradiative transitions between the electronic states with the same irreducible representation of the point group of a molecule, the propensity rule should be altered because the promoting mode will act as an accepting mode at the same time. The physical situation in this category will involve, for example, the internal conversion from the first excited singlet state ($^1A_1$) to the ground state of phenanthrene.[25,26]

A similar problem was considered by Fong and Wassam.[27] Their formalism was based on the time-correlation function proposed by Kubo.[28] They thought that the situation will be encountered in the nonradiative transition, S_1 ⇝ T_1, of benzene in the solid state, where the D_{6h} symmetry is retained in the first excited singlet state and where, on the other hand, the symmetry in the lowest triplet state has a lower value than D_{6h}. However, the application of the formalism of Fong and Wassam to the S_1 ⇝ T_1 transition of benzene in the solid state was criticized by Nitzan and Jortner[29] because the symmetry reduction in the lowest triplet state might be due to the crystal-field effect.

In the present paper, we will derive a rate expression for the nonradiative transition, considering that the promoting mode acts also as an accepting mode in the weak coupling case; the results will be compared with those of the case in which the promoting and accepting modes act independently. The present formalism will be primarily based on the treatment by Lin[1] and Englman and Jortner[6] in the framework of the weak coupling case in large molecules. The interference effect between promoting modes will be neglected. As a simple case in which there is no displacement for the promoting mode between the relevant electronic states, the expression contains the same results as those derived by Freed and Jortner.[7] The steepest-descent method will be used to determine the most probable path for the nonradiative transition (the highest frequency mode belonging to the displaced potential surfaces) and to examine the contribution of the second-highest frequency mode to the partitioning of the excess energy. Nonradiative transitions between the excited states of such aromatic hydrocarbons as naphthalene having dimensions larger than benzene will be treated, where the shift of the origin of the highest mode ($\hbar\omega_{C-H}\approx 3000\ cm^{-1}$) may be considered to be smaller than that of the second-highest ($\hbar\omega_{C-C}\approx 1500\ cm^{-1}$) by about one order.

Theory

The nonradiative transition rate from an electronic state, s, to a lower electronic state, t, with a quasicontinuum vibronic manifold is given by the time-dependent perturbation theory as:

$$W(\mathrm{s} \rightsquigarrow \mathrm{t}) = \frac{2\pi}{\hbar}\sum_{lm} P_{sl}|\langle tm|V|sl\rangle|^2\delta(E_{tm}-E_{sl}) \quad (1)$$

where l and m refer to vibrational states belonging to s and t electronic states respectively and where E_{sl} and E_{tm} refer to the energies of the initial and final states respectively. P_{sl} is the Boltzmann weighting factor for the initial vibronic states:

$$P_{sl} = \exp(-\beta E_{sl})/\sum_{l}\exp(-\beta E_{sl}) \tag{2}$$

where $\beta = 1/k_B T$.

There has been a fair amount of discussion concerning the choice of the zero-order basis set for describing the nonradiative transition in an isolated molecule.[30-35] We shall take Born-Oppenheimer states as the zero-order set in the present treatment. In the adiabatic representation, the electronic wave function, Φ_s, and the vibrational wave function, Ξ_{sl}, satisfy the following equations:

$$H_0(r, Q)\Phi_s(r, Q) = E_s(Q)\Phi_s(r, Q), \tag{3}$$

and:

$$[T(Q)+E_s(Q)]\Xi_{sl}(Q) = E_{sl}\Xi_{sl}(Q) \tag{4}$$

where

$$H_0(r, Q) = T(r) + U(r, Q), \tag{5}$$

and where r and Q denote the coordinate of the electrons and the vibrational coordinates respectively. $T(r)$, $T(Q)$, and $U(r,Q)$ denote the kinetic energy of the electrons, the kinetic energy of the nuclei, and the electrostatic potential energy respectively. The adiabatic wave function, $\Psi_{sl}(r,Q)$, is given by the product of the electronic wavefunction, $\Phi_s(r,Q)$, and the vibrational wave function, $\Xi_{sl}(Q)$:

$$\Psi_{sl}(r, Q) = \Phi_s(r, Q)\Xi_{sl}(Q). \tag{6}$$

The perturbation, V, for the nonradiative transition is the nuclear kinetic energy, $T(Q)$. Then, the matrix element in Eq. (1) can be expressed in the following way:

$$\langle tm|V|sl\rangle = -\hbar^2\sum_p\frac{1}{M_p}\left\langle\Phi_t(r, Q)\Xi_{tm}(Q)\left|\frac{\partial\Phi_s(r, Q)}{\partial Q_p}\frac{\partial}{\partial Q_p}\Xi_{sl}(Q)\right.\right\rangle - \frac{\hbar^2}{2}\sum_p\frac{1}{M_p}\left\langle\Phi_t(r, Q)\Xi_{tm}(Q)\left|\frac{\partial^2\Phi_s(r, Q)}{\partial Q_p{}^2}\Xi_{sl}(Q)\right.\right\rangle \tag{7}$$

where the subscript, p, denotes the promoting mode which induces the nonradiative transition between relevant electronic states. We assume the potential energy surfaces to be harmonic and displaced.

In the present treatment, Eq. (1) will be evaluated within the so-called Condon approximation, which is based on the assumption that the first derivative of the initial electronic state varies slowly with the nuclear coordinates. We assume that the nonradiative transition is induced by a promoting mode, q_p.[36] We utilize the time-integral representation of the δ-function in Eq. (1). Performing the summation over the vibrational quanta, m_i and l_i, for the i-th mode in Eq. (1) by the aid of the Slater sum rule, and integrating Eq. (1) over the normal coordinates, we obtain:

$$W(s \rightsquigarrow t) = \omega_p{}^2|V_{st}{}^p|^2\int_{-\infty}^{\infty}dt\exp\left[-\frac{i\Delta Et}{\hbar}\right]\Delta_p\prod_i^{N'}\Omega_i \tag{8}$$

where:

$$V_{st}{}^p = \frac{\left\langle\Phi_t\left|\left(\frac{\partial U}{\partial q_p}\right)\right|\Phi_s\right\rangle}{\Delta E_{st}} \tag{9}$$

$$\Omega_i = \exp\left[-\frac{2n_i+1}{2}\Delta_i{}^2+\frac{n_i+1}{2}\Delta_i{}^2\exp(i\omega_i t) + \frac{n_i}{2}\Delta_i{}^2\exp(-i\omega_i t)\right] \tag{10}$$

and:

$$\Delta_p = \frac{\Omega_p}{2}\left[(n_p+1)\exp(i\omega_p t)+n_p\exp(-i\omega_p t) + \frac{\Delta_p{}^2}{2}\{2n_p+1-(n_p+1)\exp(i\omega_p t)-n_p\exp(-i\omega_p t)\}^2\right] \tag{11}$$

ΔE_{st} in Eq. (9) is the virtual energy-separation between zero-order electronic states, s and t. The n_i notation, in Eqs. (10) and (11) represents the average number of the excited vibrations with the frequency of ω_i at thermal equilibrium: that is,

$$n_i = [\exp(\beta\hbar\omega_i)-1]^{-1} \tag{12}$$

and $\Delta_i = (\mu_i\omega_i/\hbar)^{1/2}(Q_i{}^{t(0)} - Q_i{}^{s(0)})$, the reduced displacement of the equilibrium position of the i-th normal coordinate in the two electronic states. In deriving Eq. (8), the Herzberg-Teller expansion was utilized in order to obtain the approximate adiabatic electronic wave functions. The prime in Eq. (8) means the exclusion of the promoting mode in the Ω_i product. The inclusion of the Ω_p appearing in Δ_p in the Ω_i product leads to the following equation:

$$W(s \rightsquigarrow t) = \frac{\omega_p{}^2}{2}|V_{st}{}^p|^2\exp(-\eta)\int_{-\infty}^{\infty}dt\left[(n_p+1)\exp(i\omega_p t) + n_p\exp(-i\omega_p t)+\frac{\Delta_p{}^2}{2}\{2n_p+1-(n_p+1)\exp(i\omega_p t) - n_p\exp(-i\omega_p t)\}^2\right]\exp\left[-\frac{i\Delta Et}{\hbar}+\eta_+(t)+\eta_-(t)\right] \tag{13}$$

where

$$\eta = \eta_+(0)+\eta_-(0) = \sum_i\left(n_i+\frac{1}{2}\right)\Delta_i{}^2 \tag{14}$$

$$\eta_+(t) = \frac{1}{2}\sum_i(n_i+1)\Delta_i{}^2\exp(i\omega_i t) \tag{15}$$

and

$$\eta_-(t) = \frac{1}{2}\sum_i n_i\Delta_i{}^2\exp(-i\omega_i t) \tag{16}$$

We have derived the rate expression for the nonradiative transition using the harmonic displaced potential-surface model in the form of the Fourier transformation. Let us, for the sake of simplicity, consider the nonradiative transitions within the low-temperature limit; then we have

$$W(s \rightsquigarrow t) = \frac{\omega_p{}^2}{2}|V_{st}{}^p|^2\exp\left(-\sum_i\frac{\Delta_i{}^2}{2}\right)\int_{-\infty}^{\infty}dt\left[\exp\left\{-\frac{i(\Delta E-\hbar\omega_p)t}{\hbar} + \sum_i\frac{\Delta_i{}^2}{2}\exp(i\omega_i t)\right\}+\frac{\Delta_p{}^2}{2}\{1-\exp(i\omega_p t)\}^2 \times\exp\left\{-\frac{i\Delta Et}{\hbar}+\sum_i\frac{\Delta_i{}^2}{2}\exp(i\omega_i t)\right\}\right] \tag{17}$$

We are interested in the nonradiative transitions of large molecules within the statistical limit. The time integration of the nonradiative transition rate in Eq. (13) can be carried out by the steepest-descent method, which has frequently been applied to the evaluation of the nonradiative transition rates in large molecules on the assumption that the highest frequency mode with the displaced potential acts as an accepting mode. The modes with the displaced potential surface between relevant electronic states in the case of the weak coupling of large molecules such as aromatic hydrocarbons are identified as follows: (1) totally symmetric C–H stretching modes, and (2) totally symmetric C–C skeletal stretching modes. The other vibrational modes do not lead to the shifts of the adiabatic potentials when the vibronic coupling, such as the Jahn-Teller coupling and the pseudo-Jahn-Teller coupling, may be neglected. This assumption may be justified in benzene, which has a relatively low second-high frequency mode (the C–C skeletal stretching mode with $\sim$1000 cm^{-1}) compared with the highest frequency mode (the C–H stretching mode with $\sim$3000 cm^{-1}), and in the case of the nonradiative transitions between the excited and ground states of other aromatic hydrocarbons, where the reduced displacements of the accepting modes are considered to be of the same order. In this case, we have $\exp(i\omega_{C-H}t)=X^3$ if $X=\exp(i\omega_{C-C}t)$ and the coefficients of X and X^3 are of the same order in the time integration of the nonradiative transition rate; therefore the highest frequency terms, $\exp(i\omega_{C-H}t)$, makes the main contribution to the determination of the saddle point. However, this assumption may lead to a drastic error in evaluating the rates of the nonradiative transitions between the excited states of the aromatic hydrocarbons larger than benzene, where the frequency of the highest-frequency mode remains constant (3000 cm^{-1}); on the other hand, that of the next highest frequency mode increases (the C–C stretching: $\sim$1500 cm^{-1}) compared with that of benzene, and the reduced displacement of the latter may be considered to be larger than that of the former by about one order. From the above point of view, we shall use the steepest-descent method, taking into account the fact that both the C–H stretching (3000 cm^{-1}) and C–C stretching (1500 cm^{-1}) modes act as accepting modes. Utilizing the steepest-descent method, we obtain this final expression for W(s ⇝ t) at low temperature:

$$W(\mathrm{s} \rightsquigarrow \mathrm{t}) = \frac{\omega_p^2}{2}|V_{st}^p|^2 \exp\left(-\sum_i \frac{\Delta_i^2}{2}\right)\left[(1-\Delta_p^2)I(\hbar\omega_p) + \frac{\Delta_p^2}{2}\{I(0)+I(2\hbar\omega_p)\}\right] \quad (18)$$

where

$$I(\varepsilon) = \hbar(2\pi)^{1/2} \times \exp\left\{-\frac{(\Delta E-\varepsilon)}{\hbar\omega_p}\log A(\varepsilon) + \frac{\Delta_H^2}{2}A^2(\varepsilon) + \frac{\Delta_p^2}{2}A(\varepsilon)\right\} \times \left\{2(\hbar\omega_p)^2\Delta_H^2A^2(\varepsilon) + \frac{1}{2}(\hbar\omega_p)^2\Delta_p^2A(\varepsilon)\right\}^{-1/2} \quad (19)$$

and where

$$A(\varepsilon) = \frac{\Delta_p^2}{4\Delta_H^2}\left[-1+\left\{1+\frac{16\Delta_H^4(\Delta E-\varepsilon)}{\hbar\omega_p\Delta_p^4}\right\}^{1/2}\right] \quad (20)$$

The Δ_p and Δ_H which appear in Eqs. (18), (19), and (20) denote the reduced displacements of the C–C stretching mode with the ω_p frequency and the C–H stretching mode with the ω_H frequency respectively.

Discussion

Assuming that the promoting mode is independent of the accepting modes, Englman and Jortner[6] and Freed and Jortner[7] have derived the rate expression for the nonradiative transitions in large molecules using the displaced potential-surface model for the accepting modes. Their results imply that in the case of weak coupling, the nonradiative decay is characterized by the exponential dependence on the effective gap, $\Delta E-\hbar\omega_p$, in the low-temperature range (energy-gap law). It should be noted that Eq. (18) reduces to the expression derived by Freed and Jortner when there is no displacement for the promoting mode. Equation (18) reveals that, when $\Delta_p \neq 0$, the nonradiative decay occurs through Processes 1, 2, and 3, whose energy gaps are ΔE, $\Delta E-\hbar\omega_p$, and $\Delta E-2\hbar\omega_p$ respectively.

Considering the simple model systems for the nonradiative transitions, we have examined the dependence of the nonradiative transition rate, W(s ⇝ t), on the reduced displacement for the promoting mode, Δ_p, in the low-temperature range. Regrettably, the exact electronic wave function is not known at present, so we cannot obtain a reliable value of V_{st}^p by direct computation. We will instead calculate the $R=W(\Delta_p \neq 0)/W(\Delta_p=0)$ ratio, since by using it V_{st}^p need not be determined. The present information concerning the potential surfaces of aromatic hydrocarbons is insufficient for us to determine the magnitude of displacement required to evaluate the nonradiative transition rates, but at least it can be seen that the modes with the nonvanishing reduced displacements belong to the totally symmetric C–C skeletal stretching and the totally symmetric C–H stretching modes in the case of weak coupling, the magnitudes of the reduced displacements for the C–C stretching modes being of the same order between any electronic states considered. Recently, we proposed a semi-empirical method for evaluating the reduced displacements of the skeletal stretching modes in aromatic hydrocarbons; we found that the magnitudes of the reduced displacements for the C–C stretching modes are of the same order between any π–π^* electronic states considered.[37] For the reduced displacements of the C–H stretching modes in aromatic hydrocarbons, we expect the Δ_H between π–π^* excited states to be smaller than the Δ_H between π–π^* excited and ground states, as the change in the C–H bonds is considered to be smaller between π–π^* excited states, especially when lower π–π^* excited states are involved. In fact, Burland and Robinson[3] have reported that the Δ_H between the first excited-singlet and the lowest-triplet states in benzene is smaller by about one order than the Δ_H between the first excited singlet and ground states. In the absence of more detailed information concerning the value of Δ_H for other molecular systems, we suppose that the Δ_H between the excited states is also smaller

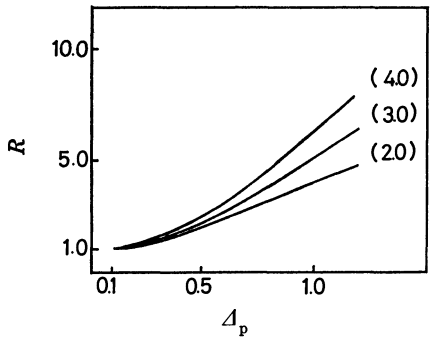

Fig. 1. Variation of R as a function of Δ_p in the excited ⟿ ground state nonradiative transition. Numbers in parentheses denote the energy gap, ΔE in eV.

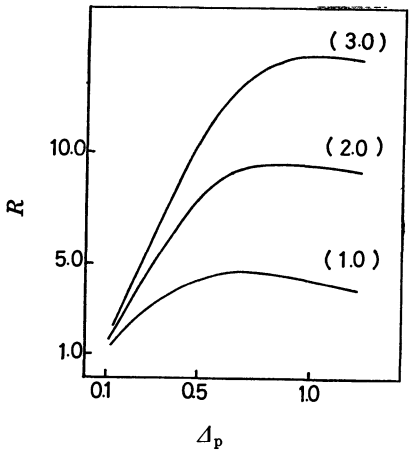

Fig. 2. Variation of R as a function of Δ_p in the excited ⟿ excited state nonradiative transition.

by one order than the Δ_H between excited and ground states in the present calculations. For the present models, two cases will be examined: i) excited ⟿ ground states, and ii) excited ⟿ excited states.

i) *Excited ⟿ Ground States.* From the analysis of the absorption spectra of aromatic hydrocarbons, Byrne *et al.*[38] have concluded that the values of Δ_H are in the range of 0.18—0.42 and that Δ_H is independent of the dimensions of the molecules. For the present calculations, the value of $\Delta_H=0.3$ will be taken. In Fig. 1, R is plotted as a function of Δ_p in the range of 0.1—1.2. Figure 1 shows that the ratio, R, of the nonradiative transition between the excited and ground states within the statistical limit increases only by a factor of 2 in the vicinity of $\Delta_p=0.5$. Using the steepest-descent condition, $\partial F(t)/\partial(it)|_{it=\tau}=0$, where $F(t)$ and $it=\tau$ are the exponent in the time integration of the nonradiative transition rate and the saddle point obtained respectively, we can then determine the partitioning of the excess electronic energy into the vibrational modes involved. Considering the nonradiative transition, whose energy gap is 24000 cm^{-1} and whose reduced displacement Δ_p is 0.5, 90% of the excess energy goes into the C–H stretching mode through Process 2 with $\Delta E-\hbar\omega_p$. From the above results it seems that the existence of an effective accepting mode (the C–H stretching mode) will be enough to explain the characteristics of nonradiative transition rates when the Δ_p and Δ_H are of the same order. In this case, the ratio, R, of the nonradiative transition rates in the low-temperature limit is expressed as a function of Δ_p as following:

$$R = K\Delta_p^2 + 1,$$

where

$$K = \frac{1}{2}\left(1-\frac{\hbar\omega_p}{\Delta E}\right)^{1/2}(\zeta\Delta E)^{-\frac{\Delta E}{\hbar\omega_H}}\{\zeta(\Delta E-\hbar\omega_p)\}^{\frac{\Delta E-\hbar\omega_p}{\hbar\omega_H}} \times \exp\left(\frac{\hbar\omega_p}{\hbar\omega_H}\right)+\frac{1}{2}\left(\frac{\Delta E-\hbar\omega_p}{\Delta E-2\hbar\omega_p}\right)^{1/2} \times \{\zeta(\Delta E-2\hbar\omega_p)\}^{-\frac{\Delta E-2\hbar\omega_p}{\hbar\omega_H}}\{\zeta(\Delta E-\hbar\omega_p)\}^{\frac{\Delta E-\hbar\omega_p}{\hbar\omega_H}} \times \exp\left(-\frac{\hbar\omega_p}{\hbar\omega_H}\right)-1. \quad (21)$$

K is independent of Δ_p, since $\zeta=\left(\sum_i\frac{\hbar\omega_i\Delta_i^2}{2}\right)^{-1}$ includes the parameters of the C–H stretching mode only. The role of the promoting mode is only to reduce the excess energy by zero, one, and two quanta of vibrations for Processes 1, 2, and 3 respectively.

ii) *Excited ⟿ Excited States.* As has been stated above, we suppose that the Δ_H between lower π–π^* excited states is smaller by one order than the Δ_H between the excited and ground states. A variation in Δ_H by a numerical factor does not contribute significantly to the present results. Then, for the sake of simplicity, the $\Delta_H=3\times10^{-2}$ value is taken regardless of the relevant π–π^* excited states. Figure 2 indicates that the ratio of the nonradiative transition rates increases from a factor of 3 to one order in the Δ_p range of 0.3—0.5; this may be considered to be a case of weak coupling, and the magnitude of the ratio may be dependent on the energy gap. Let us consider the distribution of the excess electronic energy into the vibrational modes. The distribution is strongly dependent on the Δ_p: a rough estimation shows that, contrary to the nonradiative transition to the ground state, 60, 70, and 90% of the excess energy, $\Delta E=$ 16000 cm^{-1}, go into the C–C stretching modes through Process 2 when $\Delta_p=0.3$, 0.5, and 0.8 respectively. The promoting mode may, then, act as the accepting mode in this case. This fact also indicates that we cannot exclude the second-highest frequency mode with a displaced potential from the accepting modes when we study the nature of the nonradiative transition between excited states in such large molecules as aromatic hydrocarbons.

Fong and Wassam[27] suggested that, as a consequence of the removal of the zero displacement for the promoting modes, the most important point is the effective diminution of the energy gap by the $\Delta v=2$ process in the event of a small configuration change corresponding to a case of weak coupling. The present result obtained by numerical analysis indicates that the above suggestion by Fong and Wassam is justified in the case of nonradiative transitions between excited states in the aromatic hydrocarbons.

In the present treatment we have derived the nonradiative transition rate, neglecting the interference effect between promoting modes. As has been stated

by Freed and Jortner[7], the interference effect can be expected between two modes, p and p', if the following conditions are satisfied: $\Delta_p \neq 0$, $\Delta_{p'} \neq 0$, $V_{st}^{p} \neq 0$ and $V_{st}^{p'} \neq 0$. In a subsequent paper, the interference effect between promoting modes will be described in detail.

Substitution and Hydrogen Bonding Effects on Fluorescence and Intersystem Crossing in Naphthaldehydes and Their Derivatives

Michio KITAMURA and Hiroaki BABA

Division of Chemistry, Research Institute of Applied Electricity, Hokkaido University, Sapporo 060

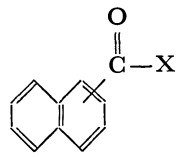
(Received December 20, 1974)

Absorption and fluorescence spectra, fluorescence and phosphorescence quantum yields and lifetimes of 1- and 2-naphthaldehyde and their derivatives have been measured in rigid glass solution at 77 K. Naphthaldehydes and acetonaphthones are non-fluorescent, whereas naphthoyl chlorides and methyl naphthoates are fluorescent. Upon formation of a hydrogen bond with ethyl alcohol, 2-naphthaldehyde and 2-acetonaphthone become fluorescent, and 1-naphthoyl chloride increases in fluorescence quantum yield by a factor of about 65. The rate constants for intersystem crossing in these three molecules decrease by about two orders of magnitudes as a result of hydrogen bonding. The decrease of the rate constants is attributed to elevation of the (n, π^*) level and the resulting change in its position relative to the (π, π^*) level. The experimental results are discussed in relation to the current theories of radiationless transition, and are found to conform to the theory in which both spin-orbit coupling and nuclear kinetic-energy operators are treated as the perturbation causing intersystem crossing.

Molecules possessing low-lying (n, π^*) states, such as aromatic carbonyls and nitrogen heterocyclics, are in general non-fluorescent or only very weakly fluorescent but strongly phosphorescent.[1,2] These phenomena have been extensively discussed by taking into account the relative positions of (n, π^*) and (π, π^*) levels and their role in intersystem crossing.[3-9]

Recently, Henry and Siebrand formulated a general rate expression for intersystem crossing by treating both spin-orbit coupling and nuclear kinetic-energy operators as the perturbation which causes the nonradiative transition.[10] The rate expression of these authors is very different from that of Lin[11] and Bixon and Jortner.[12] As has been noted by Azumi,[13] these two types of theories may predict different fluorescence characteristics for molecules with (n, π^*) states. At the present stage of the theory of intersystem crossing, therefore, a systematic study on the fluorescence characteristics of molecules of this kind is desirable to clarify the nature of the perturbation for the intersystem crossing.

In the present study, the absorption spectra and fluorescence characteristics of the simplest carbonyl substituted naphthalenes, 1- and 2-naphthaldehyde (1-, 2-NA), and their respective three derivatives have been examined in detail at 77 K with particular regard to substitution and hydrogen bonding effects. The derivatives used are as follows: acetonaphthones (1-, 2-AN), naphthoyl chlorides (1-, 2-NC), and methyl naphthoates (1-, 2-MN). On the basis of rate constants estimated for intersystem crossing and other pertinent results obtained, the mechanism of the intersystem crossing in these molecules is discussed in relation to the current theories mentioned above.



1-, 2-NA: X=H
1-, 2-AN: X=CH_3
1-, 2-NC: X=Cl
1-, 2-MN: X=OCH_3

Experimental

1-Substituted compounds were purified by distillation under reduced pressure, and 2-substituted compounds were recrystallized twice from *n*-hexane. Isopentane and methylcyclohexane were purified by chromatography using a column of silica gel. Spectro-grade ethyl alcohol (EtOH) was refluxed for five hours over calcium oxide and distilled. A mixture of isopentane and methylcyclohexane (4 : 1 by volume, abbreviated to PM hereafter) was used as solvent.

Absorption and fluorescence spectra, quantum yields and lifetimes were obtained at 77 K by the same methods as described in previous papers.[7,14] The correction of fluorescence and excitation spectra was made by the relative method.[7]

Sample solutions for quantum yield and lifetime measurements were degassed by freeze-thaw cycles. Unusual absorption and emission bands, probably due to aggregated species, appeared at concentrations higher than $(6—7)\times10^{-5}$ M. For this reason, concentrations of the sample solutions were chosen as $\sim5\times10^{-5}$ M for 1-substituted compounds and $\sim3\times10^{-5}$ M for 2-substituted compounds.

Results and Discussion

Substitution Effects on Fluorescence Characteristics and Positions of (n, π^*) Levels. The fluorescence quantum yields (Φ_F) and observed fluorescence lifetimes (τ_F) of 1- and 2-NA and their derivatives in PM at 77 K are shown in column (a) of Table 1. NA and AN do not fluoresce. The chloro or methoxy

a) Fluorescence emission could not be detected by the spectrofluorometer used in this study; Φ_F is estimated to be $<10^{-5}$. b) Obtained for a sample solution without degassing. (1- and 2-NC react with EtOH during degassing.) c) Calculated from absorption spectra. d) Calculated by the relation, $k_F=\Phi_F/\tau_F$. e) Calculated by the relation, $k_{ISC}=k_F\times(1-\Phi_F)/\Phi_F$.

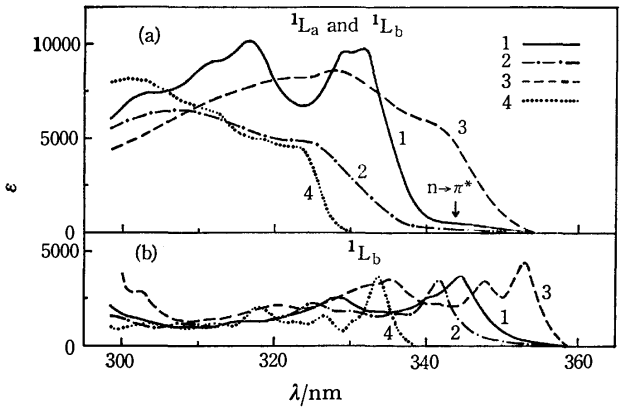

Fig. 2. Absorption spectra of 1-naphthaldehyde series (a) and 2-naphthaldehyde series (b) in PM at 77 K. The Platt notation is used for designation of electronic transitions. (1) NA; (2) AN; (3) NC; (4) MN.

substitution increases the fluorescence yield in that order in both 1- and 2-compounds. The fluorescence spectra of NC and MN in PM at 77 K are shown in Fig. 1. The fluorescence spectra of 1-MN and 2-MN are very similar to those of 1- and 2-naphthoic acid monomers, respectively.[14]

As is well known, the n→π* absorption band of saturated carbonyl compounds such as acetaldehyde is shifted to the blue by an electron-donating substituent.[15,16] The magnitude of the blue shift increases with increasing electron-donating power of the substituent, *i.e.*, in the order CH_3, Cl, and OCH_3. Roughly speaking, the fluorescence quantum yield of the molecules in Table 1 increases in the same order.

Absorption spectra of 1- and 2-NA and their derivatives in PM at 77 K are shown in Figs. 2(a) and (b). The n→π* bands of these molecules cannot easily be distinguished from π→π* bands. Absorption spectra of 1-NA and 1-AN in Fig. 2(a) show a weak band as a long tail in the region from 340 to 350 nm. It was found that this band was shifted to the blue on addition of a small amount of EtOH (~0.1%, v/v). The weak band is therefore most likely an n→π* band, which is known to be blue-shifted by hydrogen

Table 2. Phosphorescence lifetimes and yields and energies of $T_1(\pi,\pi^*)$ levels for naphthaldehyde series in PM at 77 K

Compound	τ_P (s)	Φ_P	$\nu_P(0\text{-}0)$ (cm^{-1})
1-Naphthaldehyde	0.048	0.01	19610
1-Acetonaphthone	0.093	0.01	19610
1-Naphthoyl chloride	0.25	0.04	19490

2-Acetonaphthone	0.84	0.03	20700
2-Naphthoyl chloride	0.94	0.07	20410
Methyl 2-naphthoate	2.18	0.02	20660

bond formation.[17,18] The S_1 state in these molecules is then an (n, π*) state at 77 K, as well as at 20 °C.[19] On the other hand, absorption spectra of 1-NC and 1-MN do not show such an n→π* band. For 2-NA and 2-AN in Fig. 2(b), the π→π* (^1L_b) band is situated at longer wavelengths than that of the corresponding 1-substituted compounds, and consequently the n→π* band is not clearly resolved. However, an n→π* transition is likely to contribute to the tail which appears at the longest wavelength portion of the absorption spectra of these molecules. On close inspection, it is found that such a tail is absent in 2-NC and 2-MN. On the assumption that the location of the (n, π*) level is not greatly affected by the position of the substituent (1- or 2-position of the naphthalene nucleus), and on the basis of the spectral shape described above, the S_1 state at 77 K of 2-NA and 2-AN can be assigned to an (n, π*) state, in agreement with the assignment at 20 °C.[19] The S_1 state at 77 K of 1-, 2-NC and 1-, 2-MN can be assigned to a (π, π*) state from the substitution effect and spectral shape mentioned above.

When the phosphorescent triplet state (T_1) in a molecule possessing (n, π*) states is of the (π, π*) type, the radiative lifetime of T_1 is known to increase with the elevation of the (n, π*) levels.[20] Accordingly, the position of a ^{1}(n, π*) level relative to the T_1 (π, π*)

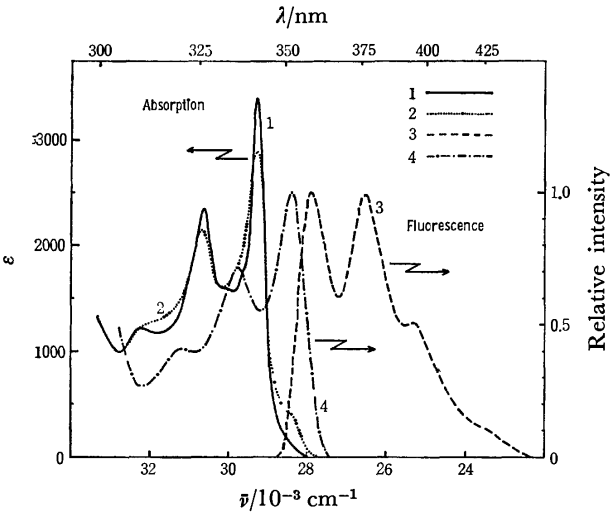

Fig. 3. Absorption, fluorescence, and excitation spectra of 2-acetonaphthone at 77 K. (1) absorption spectrum, [EtOH]=0; (2) absorption spectrum, [EtOH]= 0.05% (v/v); (3) fluorescence spectrum, [EtOH]= 0.05% (v/v); (4) excitation spectrum, [EtOH]=0.05 % (v/v).

level may be inferred from the data on the phosphorescence lifetimes. Observed phosphorescence lifetimes (τ_P) and quantum yields (Φ_P) are shown in Table 2, together with the energies of the $T_1(\pi, \pi^*)$ levels expressed by the frequency of the 0—0 band of phosphorescence ν_p (0—0). For 1- or 2-substituted compounds, the T_1 energies and the phosphorescence quantum yields are fairly constant regardless of the substituent, so that the lifetime data would reflect to some extent the differences in position of the $^1(n, \pi^*)$ levels. It may then be said from Table 2 that the $^1(n, \pi^*)$ levels are located at higher energies in the order NA, AN, NC, and MN. This is consistent with the results obtained from the absorption-spectral data.

Hydrogen Bonding Effects on Fluorescence and Intersystem Crossing. Figure 3 shows changes in the absorption spectrum of 2-AN in PM due to addition of a very small amount of EtOH (0.05%, v/v). The band intensity at 341.5 nm slightly decreases with the addition of EtOH, and at the same time a new, weak band grows at about 350 nm. These spectral changes may safely be attributed to the formation of a hydrogen bond between 2-AN and EtOH.

Although 2-AN in PM is not fluorescent, the addition of EtOH drastically changes its emission characteristics, making 2-AN fluorescent owing to the hydrogen bond. The fluorescence and excitation spectra of the hydrogen(H)-bonded 2-AN are also shown in Fig. 3. The longest wavelength band at 351 nm in the fluorescence excitation spectrum corresponds to the absorption band at about 350 nm of the H-bonded 2-AN.

As described before, the S_1 state of 2-AN in PM is of an (n, π^*) type. Since in general an $n\rightarrow\pi^*$ transition shifts to the blue by about 1000—2000 cm^{-1} as a result of hydrogen bond formation,[18] the 350 nm absorption band of the H-bonded 2-AN cannot be assigned to the $n\rightarrow\pi^*$ transition. The overall shape of the excitation spectrum resembles that of the absorption spectrum due to the ^1L_b transition in the free molecule. From these facts, the excitation spectrum, or the corresponding absorption spectrum including the 350 nm band, can be assigned to the ^1L_b transition in the H-bonded 2-AN. Thus, when 2-AN forms a hydrogen bond with EtOH, the S_1 state must change from an (n, π^*) to a (π, π^*) state.

Changes in absorption and fluorescence characteristics of 2-NA by hydrogen bond formation are similar to those of 2-AN described above. On the other hand, hydrogen bonding does not induce fluorescence in 1-NA and 1-AN. The fluorescence quantum yields and observed fluorescence lifetimes of the molecules forming hydrogen bonds with EtOH at 77 K are shown in column (b) of Table 1. It can be seen that the fluorescence quantum yields of the H-bonded 2-NA and 2-AN are at least 1000 times higher than those of the corresponding free molecules, whereas the yields of 2-NC, 1-MN, and 2-MN, which show relatively strong fluorescence in PM, are not affected significantly by hydrogen bonding. The fluorescence quantum yield of 1-NC increases by a factor of about 65 on hydrogen bond formation. Changes in fluorescence characteristics similar to those observed in 2-NA, 2-AN, and 1-NC have been reported for other molecules possessing (n, π^*) states such as pyrene-3-aldehyde,[21] acridine, quinoline, and isoquinoline.[22,23]

To explain the changes in fluorescence characteristics by hydrogen bonding, radiative rate constants for fluorescence (k_F) and rate constants for intersystem crossing (k_{ISC}) were estimated from the intensities of $S_0\rightarrow S_1$ absorption transitions and the fluorescence quantum yields and lifetimes; the results are shown in Table 1. The values of k_F for molecules with the S_1 state of (n, π^*) type were tentatively estimated from the intensity of the $n\rightarrow\pi^*$ absorption of benzaldehyde, since the $n\rightarrow\pi^*$ transition in these molecules is hardly separated from the neighboring transition (see Fig. 2).

In the estimates of k_{ISC} values the rate constants for the internal conversion $S_1 \rightsquigarrow S_0$ processes (k_{FQ}) were tentatively neglected, as usually done.[24] This procedure is supported by the fact that efficient intersystem crossing is considered to take place in non-fluorescent carbonyls.[1,2] For example, the quantum yield of intersystem crossing (Φ_{ISC}) of 2-AN, which gives no fluorescence in PM, has been reported to be 0.84 in benzene at room temperature.[25] However, even in the non-fluorescent molecules such as NA and AN the phosphorescence emission was relatively weak ($\Phi_P \approx 10^{-2}$). To confirm the validity of our procedure, we measured triplet–triplet absorption at 77 K. All the molecules showed at least the same absorption intensity as naphthalene. The Φ_{ISC} value for naphthalene has been reported to be 0.25[26] in a mixture of 30% *n*-butanol and 70% isopentane at 77 K, and 0.40[25] in benzene at room temperature. Thus, in the naphthaldehyde series studied, even if internal conversion from S_1 to S_0 should occur, k_{FQ} would be of comparable magnitude to k_{ISC} at the greatest. We may therefore reasonably neglect k_{FQ} in the following discussion, where we are concerned with the order of magnitude of k_{ISC}. As the detection limit of the

spectrofluorometer used in this study was 10^{-5} in quantum yield, the k_{ISC} values for non-fluorescent molecules were estimated by assuming Φ_F to be smaller than 10^{-5}.

To begin with, 2-NA and 2-AN will be discussed in comparison with 1-NA and 1-AN. As is seen in Table 1, the k_{ISC} values for 2-NA and 2-AN decrease with hydrogen bonding by about two orders of magnitude, while those for 1-NA and 1-AN remain unchanged. For the 2-substituted compounds, the energy separation between $S_1(n, \pi^*)$ and $S_2(\pi, \pi^*)$ (^1L_b) states is $\sim$400 cm^{-1} (see Fig. 2(b)). The (n, π^*) states in aromatic carbonyls have singlet–triplet intervals of about 2000 cm^{-1}.[27,28] This implies that the $S_2(\pi, \pi^*)$—$T_j(n, \pi^*)$ energy gaps in 2-NA and 2-AN are $\sim$2400 cm^{-1}. The $^1A \rightarrow {}^1L_b$ transition shifts to the red by about 800 cm^{-1} with hydrogen bond formation (see Fig. 3), while the $n \rightarrow \pi^*$ transition to the blue, as described before. The estimated k_{ISC} values and relatively small $S_2(\pi, \pi^*)$—$T_j(n, \pi^*)$ energy gaps suggest that in 2-NA and 2-AN a reversal of the S_1 state from the (n, π^*) to the (π, π^*) type and elevation of the $T_j(n, \pi^*)$ level above the resulting $S_1(\pi, \pi^*)$ level are likely to occur simultaneously as a result of hydrogen bonding. On the other hand, in 1-NA and 1-AN the energy separation between $S_1(n, \pi^*)$ and $S_2(\pi, \pi^*)$ (^1L_b) states is $\sim$1500 cm^{-1} (see Fig. 2(a)), and hence the $S_2(\pi, \pi^*)$—$T_j(n, \pi^*)$ energy gaps are $\sim$3500 cm^{-1}. In this case, the magnitude of the red shift due to hydrogen bonding of the ^1L_b transition is difficult to obtain because of the broadness of absorption bands. It is generally known that the red shifts of the $^1A \rightarrow {}^1L_b$ transitions due to hydrogen bonding are smaller in 1-substituted naphthalenes such as 1-naphthol than in the corresponding 2-substituted ones.[29,30] Thus, the elevation of the $T_j(n, \pi^*)$ level above the ^1L_b level is not likely to occur in the case of 1-NA and 1-AN.

The relative positions of the energy levels for both the free and H-bonded molecules of 1-NA and 1-AN and for the free molecules of 2-NA and 2-AN are schematically represented by Fig. 4(a), while those for the H-bonded 2-NA and 2-AN by Fig. 4(b). In the former group of molecules, the efficient spin-orbit coupling between $^1(n, \pi^*)$ and $^3(\pi, \pi^*)$ states should result in the fast rate of intersystem crossing.[3]

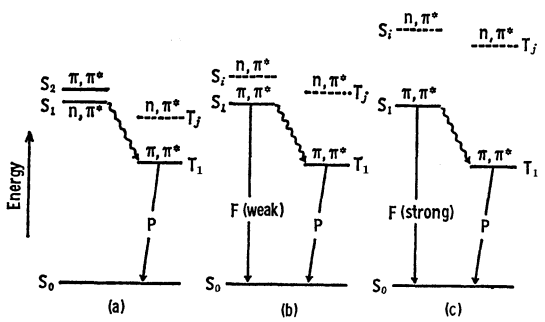

Fig. 4. Electronic energy level diagrams showing differences in fluorescence and intersystem-crossing characteristics among naphthaldehyde series. Broken lines represent the energy levels which are assumed to exist.

However, in the H-bonded 2-NA and 2-AN, the spin-orbit interaction between the singlet and triplet (π, π^*) states is vanishingly small,[3] so that the rate of the direct intersystem crossing $^1(\pi, \pi^*) \rightsquigarrow {}^3(\pi, \pi^*)$ would be low enough for fluorescence emission to compete with the intersystem crossing.

Next, the case of 1- and 2-MN will be discussed. According to the substitution effects described before, the $^1(n, \pi^*)$ state of these molecules is probably situated at a relatively high level, as shown in Fig. 4(c). Further elevation of the (n, π^*) level by hydrogen bonding will not greatly affect the intersystem crossing, and leave the fluorescence characteristics essentially unchanged.

Finally, the case of 1-NC and 2-NC will be considered. The fluorescence characteristics of 1-NC are changed by hydrogen bonding as in the case of 2-NA and 2-AN, while those of 2-NC are not changed significantly as in the case of MN. The S_1 states of the free and H-bonded NC are of (π, π^*) type, as previously mentioned. Although the definite positions of (n, π^*) levels are not known, the experimental data for 1-NC and 2-NC suggest that the $T_j(n, \pi^*)$ level should be higher than the $S_1(\pi, \pi^*)$ level. It follows from Fig. 2 that the $S_1(\pi, \pi^*)$ level of 1-NC is higher than that of 2-NC. This implies that the magnitudes of energy separations between $T_j(n, \pi^*)$ and $S_1(\pi, \pi^*)$ levels for 1- and 2-NC are different from each other, provided the (n, π^*) levels of these molecules are situated at approximately the same position. We assume that the $T_j(n, \pi^*)$ level of 1-NC in PM lies closely above the $S_1(\pi, \pi^*)$ level, as shown in Fig. 4(b). The free molecule of 1-NC will then show weak fluorescence. When 1-NC forms a hydrogen bond with EtOH, the $^3(n, \pi^*)$ level rises and the fluorescence intensity increases. From the fact that the energy separation between $T_j(n, \pi^*)$ and $S_1(\pi, \pi^*)$ levels is larger in 2-NC than in 1-NC, the relative positions of the energy levels for 2-NC are thought to be similar to Fig. 4(c). Further elevation of the (n, π^*) level of 2-NC by hydrogen bonding would not change greatly the fluorescence characteristics, as has been shown for MN.

On the Mechanism of Intersystem Crossing. Three different rate expressions have been theoretically derived so far for intersystem crossing. El-Sayed[3] first obtained a rate expression, based on the theory of Robinson and Frosch,[31] by considering the spin-orbit coupling operator (H_{SO}) as the perturbation (H') which causes the non-radiative transition. Lin[11] and Bixon and Jortner[12] independently formulated an expression by treating the nuclear kinetic-energy operator (T_N) alone as the perturbation. On the other hand, Henry and Siebrand[10] and Lawetz, Orlandi, and Siebrand[32] recently formulated a rate expression by including both H_{SO} and T_N in the perturbation.

The matrix element, H'_{mn}, in the expressions by El-Sayed and Siebrand *et al.* involves the first-order term $\langle {}^3\Psi_m | H_{SO} | {}^1\Psi_n \rangle$. Here, $^1\Psi_n$ and $^3\Psi_m$ stand for pure-spin Born-Oppenheimer wave functions of singlet and triplet states, respectively; they are written as products of an electronic wavefunction (Φ) and

a vibrational wavefunction (Λ), *i.e.*, ${}^1\Phi_n \cdot \Lambda_n$ and ${}^3\Phi_m \cdot \Lambda_m$ respectively. Such a first-order term does not appear in the formulation by Lin *et al.* As is well known, the electronic matrix element of H_{SO} between ${}^{1,3}(n, \pi^*)$ and ${}^{3,1}(\pi, \pi^*)$ states, *e.g.*, $\langle {}^3\Phi(\pi, \pi^*)|H_{SO}|{}^1\Phi(n, \pi^*)\rangle$, is far larger than that between ${}^1(\pi, \pi^*)$ and ${}^3(\pi, \pi^*)$ states, $\langle {}^3\Phi(\pi, \pi^*)|H_{SO}|{}^1\Phi(\pi, \pi^*)\rangle$. According to the theory of El-Sayed or Siebrand *et al.*, therefore, in molecules possessing (n, π^*) states, the rate of intersystem crossing depends strongly on whether or not ${}^3(\pi, \pi^*)$ and ${}^3(n, \pi^*)$ levels are located below $S_1(n, \pi^*)$ and $S_1(\pi, \pi^*)$, respectively, and the fluorescence characteristics are expected to be changed drastically by a reversal of the relative positions of (n, π^*) and (π, π^*) levels. On the other hand, the theory by Lin *et al.* does not predict such changes in fluorescence, as noted recently by Azumi.[13,33]

As has been mentioned, the fluorescence characteristics and intersystem crossing rates in the naphthaldehyde series, particularly in 2-NA and 2-AN, vary markedly, depending upon the relative positions of (n, π^*) and (π, π^*) levels. In other words, the experimental results suggest that the intersystem crossing is caused by the perturbation including H_{SO}.

The experimental results show also that there is a distinct difference in fluorescent behavior between molecules related to Fig. 4(b) and those to 4(c) (cf. Table 1). In either case the $S_1(\pi, \pi^*)$ and $T_j(n, \pi^*)$ states are arranged in the same order of energy, so that the above-mentioned difference cannot be explained in terms of the theory including only H_{SO} in the perturbation.

The matrix element H'_{mn} in the rate expression by Siebrand *et al.* involves second-order terms such as

$$\sum_i [\langle {}^3\Psi_m|H_{SO}|{}^1\Psi_i\rangle\langle {}^1\Psi_i|T_N|{}^1\Psi_n\rangle/(E_i - E_n)]$$

and

$$\sum_i [\langle {}^3\Psi_m|T_N|{}^3\Psi_i\rangle\langle {}^3\Psi_i|H_{SO}|{}^1\Psi_n\rangle/(E_i - E_n)]$$

where the subscript i refers to intermediate states, and E_i and E_n represent the energies of ${}^{1,3}\Psi_j$ and ${}^1\Psi_n$, respectively. Similar terms appear also in the rate expression by Lin *et al.* From these second-order terms it follows that an increase in energy difference between initial and intermediate states (see Figs. 4(b) and (c)) may lead to a distinct change in the intersystem crossing rate and hence in the fluorescence characteristics, in agreement with the experiment.

Thus, the present experimental results are best explained in terms of the theory in which both H_{SO} and T_N are treated as the perturbation causing intersystem crossing.

We wish to thank Professor Pill-Soon Song for his valuable discussions. We are also indebted to Mr. Masahisa Fujita for carrying out the lifetime measurement and to Mr. Yohji Achiba for obtaining triplet-triplet absorption spectra.

Diffusion and Adsorption of a Model Cationic Dye, *m*-Nitrobenzylamine, in Polyacrylonitrile

Zenzo MORITA,* T. M. Abul HOSSAIN, and Toshiro IIJIMA

Department of Polymer Science, Faculty of Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received January 8, 1975)

A model cationic dye, *m*-nitrobenzylamine (NBA), was synthesized, and the diffusion and adsorption behavior in polyacrylonitrile was investigated by the cylindrical film roll method. pK_a of NBA was determined spectroscopically to be 9.2 at 25 °C. The diffusion was concentration dependent and was described by the chemical potential gradient model. The temperature dependence of the diffusion coefficients above T_g, which was found to be 65 °C from the inflection point of Arrhenius plot, could be described by WLF equation, where C_1^g and C_2^g are 1.64 and 17.09 (deg.) at pH 4.2, and 2.41 and 33.11 (deg.) at pH 6.8, respectively. Adsorption isotherm of NBA was obtained at 95 °C and pH 1.5, 4.2 and 6.8. The adsorption of NBA, bis(*m*-nitrobenzyl)amine and Malachite Green at pH 4.2 and those of NBA and bis(*m*-nitrobenzyl)amine at pH 6.8 were more or less the same. It is concluded that the adsorption of cationic compounds on polyacrylonitrile is virtually dependent upon the ion exchange mechanism. But the presence of sodium chloride in the dye bath did not change the adsorption of NBA at pH 4.2 and 95 °C. The surface concentration of NBA was gradually increased with rise of temperature at pH 1.5, 4.2 and 6.8.

In previous papers, the diffusions of Malachite Green, a model cationic dye, *i.e.*, bis(*m*-nitrobenzyl)-amine and some model disperse dyes in polyacrylonitrile were investigated in detail.[1–4] The model cationic penetrant was synthesized to give a general view of dyeing of polyacrylonitrile. A comparison was made between the diffusion behavior of Malachite Green and bis(*m*-nitrobenzyl)amine. In both the cases the profiles as cationic penetrants were shown to be non-Fickian. It should be noted that the experimental concentration profiles of Malachite Green at pH 4.2 was described by chemical potential gradient model without any modification. But in the case of bis(*m*-nitrobenzyl)amine, the Fickian and non-Fickian diffusions were observed because it behaved simultaneously as both ionic and non-ionic penetrants. In this connection, a cationic compound having higher pK_a value than that of bis(*m*-nitrobenzyl)amine may be much better model penetrant.

Temperature dependence of diffusion and surface concentration was investigated with Malachite Green but no experiment with the variation of pH except at pH 4.2 was possible. On the other hand, diffusion and surface concentration experiments with variation of pH were carried out with bis(*m*-nitrobenzyl)amine only at 95 °C. The results obtained in both the cases of Malachite Green and bis(*m*-nitrobenzyl)amine differed in some aspects from those of the former workers in this field.[5–9] Besides different opinion and experimental data, new aspects of kinetics and equilibria in polyacrylonitrile were also revealed which need further verification and confirmation by experiments and discussion. Thermal properties, *i.e.*, glass transition temperature and the value of constants in the WLF equation were found to vary widely from the value of original WLF equation and that of Rosenbaum.[7] Again surface concentration, instead of decreasing, increased with rise of temperature. Different assumptions were made to explain the data. It is therefore desirable that in order to establish the generality of the conclusions, confirmatory experiments should be done with a better model compound, which may provide a comprehensive description of dyeing of polyacrylonitrile. With this purpose the present paper is aimed at synthesizing a suitable compound, *m*-nitrobenzylamine, to carry out the experiments of diffusion and equilibrium adsorption. Wide range of temperature and pH are taken to study the diffusion and thermal properties of polymer.

Experimental

Polymer: The polymer was the same polyacrylonitrile film that was prepared in the previous papers.[3] *Penetrant:* The penetrant, *m*-nitrobenzylamine hydrochloride, was synthesized by Gabriel method[10] with some modifications. The *m*-nitrobenzylamine produced was extracted by ether, dry potassium hydroxide was added to the extracted solution and kept overnight to absorb water in solution. It was then filtered. The ether was removed by distillation and finally completely by vacuum. Yellowish *m*-nitrobenzylamine was obtained in liquid state which was dissolved in benzene and then dry HCl gas was passed through, white precipitate of *m*-nitrobenzylamine hydrochloride was obtained instantaneously, which on crystallization from water gave the product (mp 228.5–229.0 °C). Found: N, 15.0; Cl, 18.8%. Calcd for $C_7H_9N_2O_2Cl$: N, 14.9; Cl, 18.8%. pK_a was determined spectroscopically and found to be 9.2 in water at 25 °C. pH of the solution was adjusted by HCl and CH_3COONa keeping ionic strength constant (I=0.1). *Diffusion and Adsorption:* The diffusion experiments were carried out with the concentration of 0.05 g/50 ml bath at pH 1.5, 4.2 and 6.8 with HCl–CH_3COONa buffer (I=0.1) over the temperature range between 55 and 95 °C. The equilibrium adsorption experiments were carried out at 95 °C and pH 1.5, 4.2 and 6.8 in 50 ml diffusion bath. Three different concentrations of 0.05 g/50 ml, 0.1 g/50 ml and 0.2 g/50 ml were taken. The values of equilibrium adsorption C_s were obtained from the surface concentration of respective diffusion experiment. The absorption spectra of solution and dyed film were measured by a Shimadzu SV-50A recording spectrophotometer.

* Present address: Department of Textiles and Polymer Science, Faculty of Engineering, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184.

Results and Discussion

Diffusion. At pH 1.5 due to the low surface concentration the suitable concentration/distance curve for calculation of diffusion coefficient was not obtained. The distribution profiles C/C_s *vs.* $x/2\sqrt{t}$ of *m*-nitrobenzylamine in polyacrylonitrile at 95 °C and pH 4.2 is shown in Fig. 1, where C is the concentration, C_s, the surface concentration, x, the distance, and t, the diffusion time. Diffusion coefficients in respective cases were calculated by Matano's method. D *vs.* C/C_s $(=\theta)$ plots were shown in Fig. 2. The concentration dependence of diffusion coefficients in both the cases was well described by the chemical potential gradient model as in the case of Malachite Green.[1]

The diffusion coefficients and surface concentrations for different temperatures from 55 to 95 °C were shown in Arrhenius plots of log D_0 *vs.* $1/T$ (Fig. 3). The results shown the inflection points in both pH 4.2 and 6.8 at 65 °C which may be assigned as the glass transition temperature of polyacrylonitrile during diffusion with *m*-nitrobenzylamine just as in the case of Malachite Green and model disperse dye penetrants.[1-4] The transition point during diffusion with Malachite Green in the same polymer was 80 °C. The difference may be explained by the larger size of the penetrant, which requires much energy than that required for a small size molecule like *m*-nitrobenzylamine. The occurence of the transition point at the same temperature for pH 4.2 and 6.8 was shown in Fig. 3. The ionic character of the penetrant is not changed at pH 4.2 and 6.8 due to high pK_a $(=9.2)$ but the ionic character of the polymer is changed. At pH 4.2 sulfonate end group completely and weak acidic groups, carboxyl end group, partly are ionized in polyacrylonitrile, while at pH 6.8 the weak acidic groups including strong sulfonate end groups are all completely ionized. It was already shown in previous paper with bis(*m*-nitrobenzyl)amine, from the dependence of the surface concentrations on the pH of the dye bath.[4] Thus pH of dye bath was found to be meant for the availability of the acidic groups in polymer to cationic penetrant. The appearence of the transition point in both the cases of pH 4.2 and 6.8 at the same temperature may be explained in the

○: pH 6.8, △: pH 4.2, □: pH 1.5

way that below T_g in both pH 4.2 and 6.8 only sulfonate end groups of polymer are concerned in diffusion. In Fig. 4 the variation of surface concentration with temperature is found to be of same pattern as in the case of Malachite Green above T_g.[1] A little difference is observed in the pattern below T_g where in the case of Malachite Green, the surface concentrations are almost constant, but in the case of *m*-nitrobenzylamine gradual increase with rise of temperature which is similar in shape as in the case of *m*-nitroaniline.[3]

As in the case of Malachite Green the diffusion behavior above T_g was applied to the general form of WLF equation. The constants C_1^g and C_2^g were calculated by least square method and found to be 1.64, 17.09 (deg.) for pH 4.2 and 2.41, 33.11 (deg) for pH 6.8, respectively.

The good fit of WLF equation with diffusion behavior above T_g in both pH 4.2 and 6.8, confirms the fact that the diffusion in polyacrylonitrile is governed by the segmental motion of the polymer, which sets in at T_g. The result is in agreement with those of Rosenbaum[7-9] and in previous papers.[1-4] The physical significance of the constants C_1^g and C_2^g of WLF equation from diffusion experiments with those of Malachite Green and *m*-nitrobenzylamine is not yet clear. As mentioned in the previous papers that the constant C_1^g is directly related with fractional free volume f_g at T_g, and C_2^g with f_g as well as $\Delta\alpha$, the difference of thermal expansion coefficient above and below T_g.[3] The different values of C_1^g and C_2^g for different penetrants in the same polymer may be reasonable, but the proper explanation and theoretical treatment has not yet been made.

Equilibrium. Surface concentration from the diffusion experiments carried out at 95 °C and pH 1.5, 4.2 and 6.8, were used for adsorption isotherm plot. The plot of C_s *vs.* dye bath concentration was shown in Fig. 5. The reciprocal plots, by Eq. (1), which were all straight lines were in Fig. 6.

$$\frac{[D]_\phi}{[D]_o} = K_L([S]_\phi - [D]_\phi) \qquad (1)$$

In Eq. (1), $[D]_\phi$ and $[D]_o$ denote the dye concentration on fiber and that in the dyebath, K_L, Langmuir constant, and $[S]_\phi$, the site content in the fiber.

It was found that same results were obtained for different cationic penetrants. So it may be concluded that the adsorption of cationic penetrants is adequately described by Langmuir isotherm, which may be superimposed by constant partition isotherm or Freundlich isotherm dependent upon penetrant as in the case of bis(*m*-nitrobenzyl)amine. It is found from the results of Malachite Green, bis(*m*-nitrobenzyl)amine and *m*-nitrobenzylamine at pH 4.2 and 6.8 that the uptake of these three compounds at pH 4.2 and those of bis(*m*-nitrobenzyl)amine and *m*-nitrobenzylamine at pH 6.8 are more or less the same.[1-4] As regards to the dyeing of polyacrylonitrile especially with cationic dye, important aspect is the ion exchange phenomenon. Rosenbaum showed the increase of equilibrium uptake which shows virtually no ion exhange mechanism in polyacrylonitrile dyeing.[11]

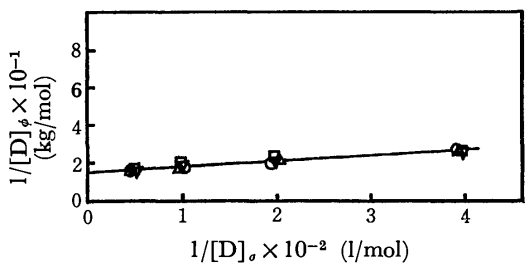

Fig. 7. Adsorption isotherm of *m*-nitrobenzylamine at 95 °C and pH 4.2 in the presence of NaCl.
○: 0 g, △: 0.4 g/l, ▽: 2.5 g/l, □: 4.0 g/l

In the series of these experiments, however, it is concluded that the adsorption of cationic compounds on polyacrylonitrile is nearly equal to the anionic site in the polymer available at that pH. No adsorption more than the anionic site in the polymer could be observed except the case such as bis(*m*-nitrobenzyl)-amine where the non-ionic species coexisted in the dyebath and were also adsorbed by the substrate.

On the other hand Sand, Glenz *et al.*, and Harwood *et al.* showed the decrease of the uptake by the addition of salt in the dye bath.[5,12,13] In this paper, an attempt was made to study the problem by the addition of sodium chloride in the bath. As is shown in Fig. 7, no change of equilibrium was detected. The adsorption of cationic compounds will be due to the salt formation or ion exchange and non-ionic

interaction of ionic species also due to the non-ionic adsorption of non-ionic species. The addition of salt will influence the salt formation and increase the non-ionic interaction and the formation of non-ionic species in the dyebath. In the series of these experiments, the salt addition was considered to bring about no influence on the salt formation and no change of the non-ionic species.

Laser Photochemistry. II.* Determination of the ORD and CD Spectra of Some Chromium(III) β-Diketonates

Hayami YONEDA, Ushio SAKAGUCHI, and Yoshiaki NAKASHIMA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received October 17, 1974)

An argon ion laser has been used to partially photoresolve the following tris(β-diketonato)chromium(III) complexes; $Cr(acac)_3$, $Cr(3\text{-X-acac})_3$ (X=Cl^-, Br^-, I^-, and NO_2^-), $Cr(tfac)_3$, and $Cr(bzac)_3$, where the abbreviations are acac=acetylacetonate ion, 3-X-acac=γ-substituted acetylacetonate ion, tfac=trifluoroacetylacetonate ion, and bzac=benzoylacetonate ion. From the wavelength dependence of the steady state resolution yield, the method of photoresolution has been confirmed to allow the determination of the ORD and CD spectra of optically pure enantiomers. The ORD and CD spectra of the above-mentioned compounds are given.

Induction of optical activity into chemical systems without resort to any asymmetric chemical agent is a rather interesting but less investigated phenomenon. Only scattered examples have been known to date in which the effect of circularly polarized light (CPL) on chemical systems or reactions has been studied. The photochemistry with CPL has recently been reviewed by Buchardt.[1] We may tentatively classify this field of research into three categories; "asymmetric photodecomposition" where the optical activity is introduced transiently by irradiating the light of circular polarization but is lost on long illumination due to photodecomposition, "total asymmetric synthesis" wherein optically inactive materials are allowed to react under the influence of CPL to produce optically active material(s), followed by the fading out of optical activity because of photodecomposition, and "partial photoresolution" which is similar in nature to the first category but different in that the material photoresolved does not lose its optical activity, except due to thermal racemization, even on long illumination. If we limit ourselves to metal compounds, a reported example of the first category may be, to our knowledge, only on potassium tris(oxalato)cobaltate(III).[2] No example of asymmetric synthesis appears to be reported for metal complexes. Partial photoresolution has been effected successfully on $[Cr(ox)_3]^{3-}$,**[4,3] $Cr(acac)_3$,[5] and $[Cr(ox)(phen)_2]^+$, $[Cr(ox)_2(phen)]^-$, $[Cr(bipy)_3]^{3+}$[6] and several other cobalt(III) and chromium(III) complexes.[7,8] A slight modification of this method has been utilized by Kane-Maguire *et al.*[9] to achieve a partial resolution of $[Cr(phen)_3]^{3+}$ using an analogue of the Pfeiffer effect.

It is reported here that partial photoresolution of tris(β-diketonate)chromium(III) complexes can be made successfully by using the beam of an argon ion laser. This method of resolution is quite important in that it allows the otherwise impossible determination of the optical rotatory dispersion (ORD) and circular dichroism (CD) spectra of optically pure enantiomers.

* Part I: H. Yoneda, Y. Nakashima, and U. Sakaguchi, *Chem. Lett.*, **1973**, 1343.

** The following abbreviations are used in this paper; ox=oxalate ion, phen=phenanthroline, bipy=bipyridyl, oxine=8-hydroxyquinolinate ion, dbzm=dibenzoylmethanate ion, TTA=thenoyltrifluoroacetonate ion, FTA=furoyltrifluoroacetonate ion, and DTC=diethyldithiocarbamate ion.

Experimental

Material. $Cr(acac)_3$, $Cr(tfac)_3$, and $Cr(bzac)_3$ have been prepared by well established methods.[10-12] The identity of the complexes has been confirmed by chemical analysis. $Cr(tfac)_3$, Found: C, 35.22; H, 2.42%. Calcd for $CrC_{15}H_{12}O_6F_9$: C, 35.24; H, 2.37%. $Cr(bzac)_3$, Found: C, 67.81; H, 5.19%. Calcd for $CrC_{30}H_{27}O_6$: C, 67.28; H, 5.08%. The γ-substituted acetylacetonates have been prepared from chromium acetylacetonate after the method of Collman and coworkers.[13] $Cr(3\text{-I-acac})_3$, Found: C, 25.43; H, 2.67%. Calcd for $CrC_{15}H_{18}O_6I_3$: C, 24.78; H, 2.50%. $Cr(3\text{-Br-acac})_3$ has been obtained as chloroform solvate. Found: C, 27.77; H, 2.66%. Calcd for $CrC_{16}H_{19}O_6Br_3Cl_3$: C, 27.24; H, 2.71%. $Cr(3\text{-NO}_2\text{-acac})_3$, Found: C, 36.74; H, 3.79; N, 8.34%. Calcd for $CrC_{15}H_{18}O_{12}N_3$: C, 37.20; H, 3.79; N, 8.68%.

Solvents are of special grade, purchased from Katayama Chemical Co., and used without further purification.

Apparatus and Measurements. The experimental arrangement used in this work is essentially similar to that reported in the literature.[3] The light source is a NEC GLG-2023 argon ion laser operating at either 514.5, 501.7, 496.5, 488.0, 476.5, or 457.9 nm(in single mode). The light of linear polarization emitted from the laser is passed through a quartz quarter-wave plate matched for the wavelength of the irradiating light to produce CPL. The light of circular polarization is then incident on a 1 cm quartz cell containing the solution to be illuminated. The diameter of the beam is approximately 8 mm. The ellipticity of CPL has been confirmed to be small enough to be neglected from measurement of the light intensity passing through a linear polarizer situated beyond the quarter-wave plate. An approximate value of the light intensity incident on the sample solution is monitored by measuring the current induced in a photovoltaic CdS cell, which is precalibrated.

The ORD and CD spectra have been recorded on a JASCO Model ORD/UV-5 spectrometer with a CD attachment. Some CD spectra have been measured also on a JASCO Model J-2 spectrometer. The process of photoresolution has been traced by checking at suitable time intervals the optical rotation of the sample solution with the aid of a Union Giken PM-71 digital polarimeter. Absorption spectra are taken on a Shimadzu double beam spectrophotometer Model UV-200.

Unless otherwise stated, all solutions have been made to 5.0×10^{-3} mol/l in benzene and irradiated at room temperature.

Principles

The principle of photoresolution is the preferential isomerization of one enantiomer over the other, which

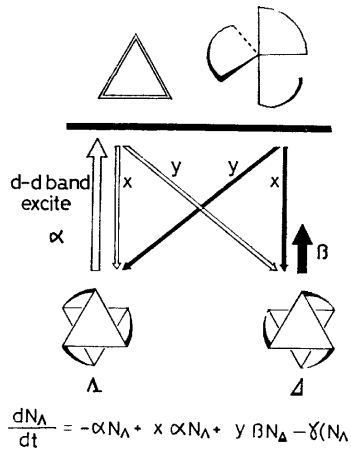

Fig. 1. Schematic illustration of a possible mechanism of photoresolution.

is a mere consequence of the differential absorptivities of the two enantiomers in a CPL (circular dichroism). Thus, the efficiency of photoresolution is expected to be a function of the asymmetric factor g.

We consider a racemic mixture of some metal complex. If right-CPL, whose intensity is I_0, is incident on the system, the complex absorbs the power ΔI. According to the Lambert-Beer's law

$$\Delta I = I_0[1-10^{-(\varepsilon_\Delta c_\Delta + \varepsilon_\Lambda c_\Lambda)d}] \tag{1}$$

where ε_Δ and c_Δ are the absorption coefficient and the concentration of the Δ-isomer and d the length of the optical path.

Note that the wavelength of the CPL corresponds to the electronic excitation of the metal compounds. Thus, absorption of the light by metal racemate induces some form of electronic excitation; metal d–d transition and/or charge transfer excitation, *etc.* (see Fig. 1). In Fig. 1 the horizontal bar is assumed to represent some excited state wherein the structure of the complex may be trigonally twisted or bond-ruptured. The transition probabilities from the excited Δ-isomer to the ground state Δ- and Λ-isomers are denoted by x and y, respectively. By symmetry the probabilities from the excited Λ-isomer to the ground state Λ- and Δ-molecules should be x and y. The values of x and y are related to the quantum yield for photoresolution and may be determined by the mechanisms of electronic relaxation and/or vibrational relaxation. Irrespective of these relaxation mechanisms, the following identity holds.

$$x + y = 1 \tag{2}$$

The change with time in the number of Λ-molecule will be governed by the kinetic equation.

$$\frac{dN_\Lambda}{dt} = -\alpha N_\Lambda + x\alpha N_\Lambda + y\beta N_\Delta \tag{3}$$

Similarly, for Δ-molecules

$$\frac{dN_\Delta}{dt} = -\beta N_\Delta + x\beta N_\Delta + y\alpha N_\Lambda \tag{4}$$

αN_Λ and βN_Δ are the numbers of Λ and Δ isomers excited by the CPL and are defined by

$$\alpha N_\Lambda = \frac{\Delta I}{h\nu}\frac{\varepsilon_\Lambda c_\Lambda}{\varepsilon_\Delta c_\Delta + \varepsilon_\Lambda c_\Lambda} \tag{5}$$

$$\beta N_\Delta = \frac{\Delta I}{h\nu}\frac{\varepsilon_\Delta c_\Delta}{\varepsilon_\Delta c_\Delta + \varepsilon_\Lambda c_\Lambda} \tag{6}$$

Since the difference between ε_Δ and ε_Λ are small as compared with ε and the best yield attainable by this method is rather low (see below), we can safely regard the coefficients α and β as the time-independent constants. To this approximation the rate of photoresolution is given by $y(\alpha+\beta)$. The photostationary state (PSS) is defined by the condition $dN_\Delta/dt=0$ and $dN_\Lambda/dt=0$. This condition leads us to the ratio of N_Λ to N_Δ as given by

$$\frac{N_\Lambda}{N_\Delta} = \frac{\beta}{\alpha} \tag{7}$$

From Eqs. (5) and (6), we obtain

$$\frac{N_\Lambda}{N_\Delta} = \frac{\varepsilon_\Delta}{\varepsilon_\Lambda} \tag{8}$$

Equation (8) holds exactly irrespective of the approximation made above. Therefore the yield of partial photoresolution is expressed in terms of the asymmetric factor g as follows.

$$\frac{N^\Lambda - N^\Delta}{N_\Lambda + N_\Delta} = \frac{g}{2} \tag{9}$$

where $g=(\varepsilon_\Delta-\varepsilon_\Lambda)/\varepsilon$. Thus, it is readily seen that the sample solution partially photoresolved will show the optical rotation at PSS

$$\theta_{PSS} = (g/2)\,\theta \tag{10}$$

and the CD proportional to

$$(g/2)\ (g\varepsilon c_0 d) \tag{11}$$

Here, θ and $(g\varepsilon c_0 d)$ are the optical rotation and the CD values, both at the wavelength used for the resolution, and expected for the optically pure enantiomer whose concentration is c_0. Note that the yield does not depend on the individual values of x and y and is determined only by the asymmetric factor g. Equations (10) and (11) hold also for the irradiation of the left-CPL, if we replace $(g/2)$ by $-(g/2)$ in both equations.

The effect of thermal racemization can be taken into account by introducing a term $-\gamma(N_\Delta - N_\Lambda)$, γ being the rate of thermal racemization. In this situation, the PSS should render the (N_Λ/N_Δ) value as given by

$$\frac{N_\Lambda}{N_\Delta} = \frac{\beta+2\gamma}{\alpha+2\gamma} \tag{12}$$

This equation indicates that as thermal racemization becomes faster, the optical activity of the sample solution at PSS are expected to decrease. The effect has really been observed and reported in some cases.[3,4]

Results and Discussion

Wavelength Dependence. Stevenson[5] has investigated the wavelength dependence of the kinetic behavior of the photoresolution process of $Cr(acac)_3$ but the effect of wavelength on the PSS yield has not been stated explicitly. Norden[4] and Stevenson and Ver-

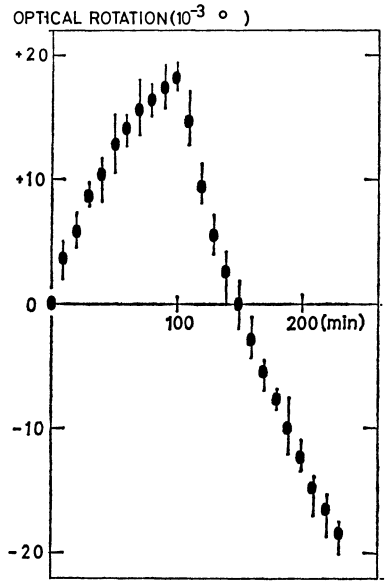

Fig. 2. The time-evolution of the optical rotation of $Cr(acac)_3$ accompanying the photoresolution.

dieck[3] have attained an apparent PSS for $[Cr(ox)_3]^{3-}$. However, it can readily be seen that the process of photoresolution is competitive with thermal or dark racemization, resulting in the optical activity much lower than that expected from Eqs. (10) and (11).

Fay *et al.*[14] have separated $Cr(acac)_3$ partially into its optical antipodes by passing through a chromatographic column containing D(+)-lactose. The first- and the second-eluted fractions have been slowly recrystallized from benzene–hexane, which gave rise to racemic crystals and resulted in an approximately tenfold enhancement in the optical rotation of the solution left uncrystallized. Molecular rotations after this partial recrystallization treatment are reported to amount to +3600° and −5240° for the first- and the second-elutions, respectively. These methods cannot, however, lead to a complete resolution and the ORD and CD curves given by them do not correspond to the optically pure enantiomers.

To ascertain whether or not the optical activity at PSS is in actuality coincident with that given by Eqs. (10) and (11), we examined the wavelength dependence of the PSS yield using $Cr(acac)_3$ as an example. A necessary prerequisite to this experiment is that the rate of thermal racemization is much smaller than that of photoresolution. For this compound, the thermal racemization rate is reported at $k=0.134\times10^{-5}$ s^{-1} (96.1 °C) so that we can neglect its effect completely. Figure 2 shows the time-evolution of the optical rotation of $Cr(acac)_3$ accompanying the photoresoution. Irradiating wavelength is 514.5 nm and the incident power is approximately 150 mW. At time $t=100$ min, the sense of the circular polarization is inverted by rotating the quarter-wave plate through 90 °. The fact that no measurable photodecomposition has occured is confirmed spectrophotometrically. This plot clearly shows that the process of photoresolution is reversible. When the light intensity incident on the sample solution is approximately 200 mW, the PSS can be reached in 3 to 4 hr. In this experiment, $Cr(acac)_3$ has been partially resolved by irradiating

CPL at four different wavelengths, 514.5, 501.7, 496.5, and 488.0 nm. The ORD and CD spectra of the optically pure enantiomer have been calculated by using Eqs. (10) and (11). If these equations are correct, these four CD spectra should coincide with each other. As seen from Table 1, the $\Delta\varepsilon$ values at the CD peak position (530 nm) are equal well within experimental uncertainties. This method of justification appears to be somewhat round-about indeed but inevitable since no other method for determining ORD and CD curves has been available at present.[15]

ORD and CD Spectra. As mentioned previously, the optical resolution with CPL has one distinctive advantage over other chemical methods of resolution in that it enables one to determine the ORD and CD spectra of the optically pure enantiomers. This is especially the case with those complexes which have no formal charge. The ORD and CD spectra and the asymmetric factor g of the optically pure $(-)_{589}$-Cr(acac)$_3$ are depicted in Fig. 3. Spectra of the other complexes are given in Figs. 4—6. Numerical values for all the compounds investigated in this work are summarized in Table 2. Cr(acac)$_3$ has been partially resolved by Stevenson[5] using a high pressure mercury lamp in more than 200 hr. Our results for this complex are in good agreement with those given by him. All the asymmetric factors listed in Table 2 fall in the range from 5.7 to 9.7×10^{-2} around the wavelength of 514.5 nm. These values correspond to the photoresolution efficiency of 2.85 to 4.85%.

Interesting is the case with Cr(bzac)$_3$, where the compound has been dissolved in chlorobenzene and

photoresolution examined. However, no optical activity was detected at room temperature even on long irradiation (5 to 8 hr at 514.5 nm). Thus, experiments have been made at elevated temperatures and the PSS has been achieved in less than 3 hr at about 70 °C. This result, along with the fact that all the complexes photoresolved in this work and so far racemize thermally, suggests that photoresolution can be effected, if possible at all, on those compounds which racemize thermally and in addition at some adequate rates.

We have tried in vain to photoresolve some complexes of chromium(III). These include $Cr(dbzm)_3$, $Cr(TTA)_3$, $Cr(FTA)_3$, $Cr(oxine)_3$, and $Cr(DTC)_3$. The first three compounds seem to have precluded the resolution for kinetic reasons mentioned just above because it is unrealistic that the asymmetric factors for these compounds differ greatly from that of $Cr(acac)_3$.

Metal Complexes Containing Six-membered Chelate Rings. IV. The Preparation and Structure of Dichlorocobalt(III) Complexes with Tetramines Derived from 2,4-Pentanediamine[1)]

Fujio MIZUKAMI*

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received May 7, 1974)

The tetramine ligands, 4,6-dimethyl-3,7-diaza-1,9-nonanediamine (2,3″, 2-tet), 6,8-dimethyl-2,5,9,12-tetraazatridecane (*N,N′*-Me_2-2,3″, 2-tet), and 4,9-dimethyl-5,8-diaza-2,11-dodecanediamine (3″,2,3″-tet), were prepared by using *RR*- and *RS*-2,4-pentanediamine as the starting material. Six kinds of *trans*-dichloro cobalt(III) complexes with these ligands were prepared and characterized. Among these complexes, three kinds of optically active complexes were obtained. The *RR*-2,4-pentanediamine and *RS*-2,4-pentanediamine parts in these complexes were considered to take a λ-skew-boat and a chair conformation respectively on the basis of molecular models, PMR, and the absorption and CD spectra.

Many cobalt(III) complexes with tetramine containing one or two β-diamine parts have been prepared in recent years.[2-9)] In these complexes, the most probable conformations for the β-diamine part have been considered to be the chair and skew-boat (or twist) conformations. Actually, two isomers in the *trans*-dichloro (3, 7-diaza-1,9-nonanediamine) cobalt(III) complex, *trans*-$[CoCl_2(2,3,2\text{-tet})]^+$, have been isolated.[2-4)] One has been assigned to the *meso* structure, in which the six-membered chelate ring takes a chair form. The other has been assigned to the racemic structure, giving a skew-boat conformation. It is considered that the *meso* isomer is thermodynamically more stable than the racemic isomer, since the latter isomerizes to the former in a methanolic solution.

On the other hand, the *trans*-dichloro(4,7-diaza-1, 10-decanediamine)cobalt(III) complex, *trans*-$[CoCl_2(3, 2, 3\text{-tet})]^+$, which has also previously been isolated, is of only one kind and has been assigned a structure in which both the six-membered chelate rings take the chair conformation and both the secondary nitrogen atoms give the same configuration.[5-8)]

Previously, we have reported that, in the cobalt(III) complexes containing 2,4-pentanediamine (2,4-ptn), *RR*-, *SS*- and *RS*-2,4-pentanediamine give the λ- and δ-skew-boat and chair conformations respectively in six-membered chelate rings.[10,11)] Accordingly, it seemed that it would be interesting to prepare cobalt(III) complexes containing tetramines derived from 2,4-pentanediamines. Thus, in the present study, seven tetramines, *R*(4),*R*(6)- and *R*(4),*S*(6)-4,6-dimethyl-3,7-diaza-1,9-nonanediamine (*RR*-2,3″,2-tet and *RS*-2,3″, 2-tet), *R*(6),*S*(8)-6,8-dimethyl-2,5,9,12-tetraazatridecane (*N,N′*-Me_2-*RS*-2,3″,2-tet) and *R*(2),*R*(4),*R*(9), *R*(11), *R*(2),*S*(4),*S*(9),*R*(11)-, *S*(2),*R*(4),*R*(9),*S*(11)-, and *R*(2),*S*(4),*R*(9),*S*(11)-4,9-dimethyl-5,8-diaza-2,11-dodecanediamine (*RRRR*-, *RSSR*-, *SRRS*-, and *RSRS*-3″,2,3″-tet), were prepared.

This paper will deal with the preparation and structure of cobalt(III) complexes containing these tetramines on the basis of molecular models, PMR, and the absorption and CD spectra.

Experimental

Preparation of Ligands. The 4,6-dimethyl-3,7-diaza-1,9-nonanediamine (2,3″,2-tet) and 6,8-dimethyl-2,5,9,12-tetraazatridecane (*N,N′*-Me_2-2,3″,2-tet) were synthesized by a method similar to that used for *C*-substituted triethylenetetramine by Goto, Saburi and Yoshikawa.[12)] The 4,9-dimethyl-5,8-diaza-2,11-dodecanediamine (3″,2,3″-tet) was synthesized according to a method similar to that used for 4,7-diaza-1,10-decanediamine (3,2,3-tet) by Hamilton and Alexander.[2)] Thus, these ligands were prepared from 2,4-pentanediamines as shown in Schemes I, II, and III.

Scheme I (Method I)

$$2ClCH_2COCl + NH_2CH(CH_3)CH_2CH(CH_3)NH_2 \xrightarrow{NaOH}$$
$$ClCH_2CONHCH(CH_3)CH_2CH(CH_3)NHCOCH_2Cl \xrightarrow{NH_3\ aq.}$$
$$NH_2CH_2CONHCH(CH_3)CH_2CH(CH_3)NHCONH_2\cdot 2HCl \xrightarrow{LiAlH_4}$$
$$NH_2CH_2CH_2NHCH(CH_3)CH_2CH(CH_3)NHCH_2CH_2NH_2$$
(2,3″,2-tet)

Scheme II (Method II)

$$2ClCH_2COCl + NH_2CH(CH_3)CH_2CH(CH_3)NH_2 \xrightarrow{NaOH}$$
$$ClCH_2CONHCH(CH_3)CH_2CH(CH_3)NHCOCH_2Cl \xrightarrow{CH_3NH_2\ aq.}$$
$$CH_3NHCH_2CONHCH(CH_3)CH_2CH(CH_3)NHCOCH_2\text{-}NHCH_3\cdot 2HCl \xrightarrow{LiAlH_4}$$
$$CH_3NHCH_2CH_2NHCH(CH_3)CH_2CH(CH_3)\text{-}NHCH_2CH_2NHCH_3$$
(*N,N′*-Me_2-2,3″,2-tet)

Scheme III (Method III)

$$2NH_2CH(CH_3)CH_2CH(CH_3)NH_2 + BrCH_2CH_2Br \xrightarrow{C_2H_5ONa}$$
$$NH_2CH(CH_3)CH_2CH(CH_3)NHCH_2CH_2NHCH(CH_3)\text{-}CH_2CH(CH_3)NH_2$$
(3″,2,3″-tet)

The optically active (*RR* and *SS*) and *meso* (*RS*) 2,4-pentanediamine (2,4-ptn) used as the starting materials in the preparation of the tetramines were synthesized according to a method reported previously.[10,13-15)]

R(4),R(6)-*4,6-Dimethyl-3,7-diaza-1,9-nonanediamine* (RR-*2, 3″,2-tet*): To 120 ml of a vigorously stirred aqueous

sodium hydroxide solution (5 M NaOH), cooled in an ice-salt bath, was added 13.7 g of *RR*-2,4-pentanediamine (0.135 mol). A solution of chloroacetyl chloride (32 g, 0.28 mol) in 100 ml of benzene was then added dropwise over a period of 30 min. The solution was stirred and cooled throughout the addition. The reaction mixture was then allowed to stand at room temperature for another 3 hr. The resulting precipitate, *N,N'*-bis(chloroacetyl)-*RR*-2,4-pentanediamine, was filtered, washed with cold water, and dried under a vacuum. The product was purified by recrystallization from ethanol; yield, 25.3 g (74%); $[\alpha]_D^{28}$ +6.11. Found: C, 42.05; H, 6.46; N, 11.01%. Calcd for $C_9H_{16}N_2O_2Cl_2$: C, 42.37; H, 6.32; N, 10.98%.

The *N,N'*-bis(chloroacetyl)-*RR*-2,4-pentanediamine (11.2 g) and 100 g of ammonium carbonate were dissolved in 500 ml of a 28% ammonium hydroxyide solution. The solution was allowed to stand for 10 days and then evaporated to dryness at 60 °C on a rotary evaporator. The product, 4,6-dimethyl-3,7-diaza-1,9-diaminononane-2,8-dione dihydrochloride, which was a pale yellow oil, was dried in a vacumm desiccator over phosphorous pentoxide and used in the next step without further purification.

The product obtained above (14 g) was dissolved in 200 ml of dry tetrahydrofuran (THF). The solution was then placed into a 500-ml, four-necked, round-bottomed flask equipped with a mechanical stirrer, a dropping funnel, and a reflux condenser with a soda lime tube. To the vigorously stirred solution was added 11 g of lithium aluminum hydride in small portions while the vessel was kept in an ice-cold bath. After the addition was complete, the mixture was allowed to stand at room temperature for another 30 min and then refluxed overnight. The reaction mixture was cooled in an ice-cold bath and carefully quenched by the dropwise addition of 30 ml of water. The white precipitate was filtered off. The filtered solid was then washed twice with 200 ml of boiling THF. The combined filtrate and washing were evaporated on a rotary evaporator. The oily residue, the crude *R*(4),*R*(6)-dimethyl-3,7-diaza-1,9-nonanediamine (*RR*-2,3″,2-tet), was used in the synthesis of the cobalt(III) complex without further purification. However, the cobalt(III) complex of this tetramine gave very satisfactory analytical results as stated in the preparation of complexes. Therefore, the oily residue is the desired product (*RR*-2,3″,2-tet).

R(4),S(6)-*Dimethyl-3,7-diaza-1,9-nonanediamine* (RS-*2,3″,2-tet*): *N,N'*-Bis(chloroacetyl)-*RS*-2,4-pentanediamine was prepared from *RS*-2,4-pentanediamine and chloroacetyl chloride by a method similar to that used for the corresponding *RR*-2,3″,2-tet described above. Found: C, 42.46; H, 6.34; N, 10.98%. Calcd for $C_9H_{16}N_2O_2Cl$: C, 42.37; H, 6.32; N, 10.98%.

The remainder of the procedure used to obtain *RS*-2,3″,2-tet is identical with the method for the corresponding *RR*-2,3″,2-tet described above. The elemental analysis of *RS*-2,3″,2-tet was achieved by the formation of the cobalt(III) complex as well as the *RR*-2,3″,2-tet described above.

R(6), S(8)-*6,8-Dimethyl-2,5,9,12-tetraazatridecane* (N,N'-Me_2-RS-*2,3″,2*-tet): According to Method II, *N,N'*-bis-(chloroacetyl)-*RS*-2,4-pentanediamine (11.2 g) wasdissolved in an aqueous solution of 30% methylamine. The solution was allowed to stand for 10 days and then evaporated to dryness on a rotary evaporator. The product, *R*(6), *S*(8)-6,8-dimethyl-2,5,9,12-tetraazatridecane-4,10-dione, was used in the next step without further purification. The remainder of the procedure was identical with that of the method for the corresponding *RR*-2,3″,2-tet described above. The elemental analysis of *N,N'*-Me_2-*RS*-2,3″,2-tet was achieved by the formation of the cobalt(III) complex as well as the *RR*-2,3″,2-tet described above.

R(2),S(4),S(9),R(11)-, S(2),R(4),R(9),S(11)-, *and* R-(2), S(4),R(9),S(11)-*4,9-Dimethyl-5,8-diaza-2,11-dodecanediamine* (RSSR-, SRRS-, *and* RSRS-*3″,2,3″-tet*): The procedure reported by Hamilton and Alexander[3] was modified. To a vigorously stirred solution of *RS*-2,4-pentanediamine (26.7 g) in 100 ml of ethanol was added 10 g of 1,2-dibromoethane in small portions. The solution was stirred and the temperature kept at about 50 °C in a water bath throughout the addition. The reaction mixture was stirred at 50 °C for another 1.5 hr and then refluxed for 12 hr. The reaction mixture was subsequently cooled to room temperature. To the vigorously stirred solution was added 2.5 g of metallic sodium in small portions. The reaction mixture was stirred at 50 °C for another 2 hr and cooled to 0 °C. After filtration, the ethanol was removed by distillation. The product, a mixture of *RSSR*-, *SRRS*- and *RSRS*-3″,2,3″-tet, was then collected by vacuum distillation at 140—160 °C (3 mmHg). Found: C, 63.15; H, 13.18; N, 23.71%. Calcd for $C_{12}H_{30}N_4$: C, 62.56; H, 13.13; N, 24.32%. A mixture of *RSSR*-, *SRRS*-, and *RSRS*-3″,2,3″-tet was separated by complexing with cobalt(III) ions as described below.

R(2),R(4),R(9),R(11)-*4,9-Dimethyl-5,8-diaza-2,11-dodecanediamine* (RRRR-*3″,2,3″-tet*): This was prepared from *RR*-2,4-pentanediamine and 1,2-dibromoethane by a method similar to that used for the corresponding *RSSR*-, *SRRS*-, and *RSRS*-3″,2,3″-tet described above. The rotation of *RRRR*-3″,2,3″-tet in water showed a plus sign at the Na D line. This tetramine gave only an approximate coincidence between the found and calculated analytical results, but its cobalt(III) complex gave very satisfactory analytical results.

Preparation of Cobalt(III) Complexes. $(+)_{600}$-trans-[$CoCl_2$(RR-*2,3″,2-tet*)]ClO_4: The ligand, *RR*-2,3″,2-tet (1 g), was added to 60 ml of an aqueous solution containing 1.2 g of cobalt(II) chloride hexahydrate and the solution was aerated with carbon dioxide-free air for 10 hr at room temperature. The solution was then filtered off, and the insoluble material was washed with a small amount of water. The filtrate and the washing were combined. To the solution was added 20 ml of concd HCl. The solution was warmed at 60 °C for 30 min to give a green solution. This solution was concentrated to 50 ml at 50 °C on a water bath and cooled to room temperature. To the solution was added 15 ml of 60% perchloric acid. The solution was allowed to stand overnight in a refrigerator. The green crystals were then filtered off, washed with a small amount of cold ethanol and ether, and air-dried. Yield: 60%. Found: C, 25.87; H, 5.92; N, 13.09%. Calcd for $C_9H_{24}N_4Cl_3CoO_4$: C, 25.89; H, 5.79; N, 13.42%.

trans-[$CoCl_2$(RS-*2,3″,2-tet*)]ClO_4, trans-[$CoCl_2$(*N,N'*-Me_2-RS-*2,3″,2-tet*)]ClO_4: These complexes were prepared from $CoCl_2 \cdot 6H_2O$ and *RS*-2,3″,2-tet or *N,N'*-Me_2-*RS*-2,3″,2-tet by a method similar to that used for the corresponding *RR*-2,3″,2-tet complex described above. *trans*-[$CoCl_2$(*RS*-2,3″,2-tet)]ClO_4 is soluble in water, but *trans*-[$CoCl_2$(*N,N'*-Me_2-*RS*-2,3″,2-tet)]ClO_4 is only slightly soluble. The yields of the former and the latter: 50% and 80% respectively. Found: C, 25.92 H, 6.03; N, 13.15%. Calcd for $C_9H_{24}N_4Cl_3CoO_4$: C, 25.89; H, 5.79; N, 13.42%. Found: C, 29.48; H, 6.70; N, 12.52%. Calcd for $C_{11}H_{28}N_4Cl_3CoO_4$: C, 29.64; H, 6.33; N, 12.57%.

trans-[$CoCl_2$(RSSR- *and* SRRS-3″,2,3″-*tet*)]$Cl \cdot H_2O$: A mixed tetramine containing a racemic pair (*RSSR* and *SRRS*) and *meso* (*RSRS*) 3″,2,3″-tet (11 g) was dissolved in 120 ml of water. To the solution was added 11.4 g of $CoCl_2 \cdot 6H_2O$. The solution was aerated with carbon dioxide-free air for

14 hr at room temperature. The deposited green powder was filtered off and washed with a small amount of water. The filtrate and the washing were then combined. To this solution was added 100 ml of concd HCl. The resulting green precipitate was filtered off and washed with a small amount of cold water. The powder and the precipitate were combined and recrystallized from water by adding concd HCl. Yield: 7.6 g. Found: C, 34.50; H, 7.96; N, 13.55%. Calcd for $C_{12}H_{32}N_4Cl_3CoO$: C, 34.84; H, 7.80; N, 13.54%.

trans-[*CoCl*$_2$(RSRS-*3″,2,3″-tet*)]*ClO*$_4$: To the blue filtrate from which the green crystals of *trans*-[$CoCl_2$(*RSSR*- and *SRRS*-3″,2,3″-tet)]Cl·H_2O had been removed, was added 60 ml of 60% perchloric acid. The solution was then concentrated on a water bath at 60 °C to yield green crystals, though the color of the solution remained blue. The green crystals were recrystallized from hot methanol. Yield 8 g. Found C, 31.58; H, 6.56; N, 11.89%. Calcd for $C_{12}H_{30}N_4Cl_3CoO_4$: C, 31.35; H, 6.58; N, 12.19%.

This complex showed a green color in the methanol solution, but a blue-violet in a concd HCl solution. This shows that the complex takes the *trans* (Cl–Cl) configuration in the methanol and the *cis* (Cl–Cl) configuration in the concd HCl solution.

cis-[*CoCl*$_2$(RSRS-*3″,2,3″-tet*)]*Cl*: The blue filtrate from which the green crystals of *trans*-[$CoCl_2$(*RSSR*- and *SRRS*-3″,2,3″-tet)]Cl·H_2O had been removed was concentrated on a water bath at 60 °C. The deposited blue-violet powder was filtered off and dried over sodium hydroxide under reduced pressure. The complex was recrystallized from concd HCl by evaporating on a water bath at 60 °C. Found: C, 36.00; H, 7.85; N, 13.84%. Calcd for $C_{12}H_{30}N_4Cl_3Co$: C, 36.43; H, 7.64; N, 14.16%.

This complex showed a blue-violet color (*cis* (Cl–Cl)) in a concd HCl solution, but a green color (*trans* (Cl–Cl)) in the methanol solution.

$(+)_{600}$-trans-[*CoCl*$_2$(RSSR-*3″,2,3″-tet*)]*Cl*·*H*$_2$*O*: The *trans*-[$CoCl_2$(*RSSR*- and *SRRS*-3″,2,3″-tet)]Cl·H_2O complex (5 g) was dissolved in 100 ml of water. To the solution was added 2.4 g of potassium oxalate monohydrate, and the solution was warmed at 70 °C for 4 hr. The reaction mixture was evaporated to dryness at 60 °C under reduced pressure. The residue was dissolved in 95% ethanol, and the potassium chloride was removed by filtration. The product was crystallized by gradually evaporating the filtrate. This product was assigned to *cisβ*-[Co(ox)(*RSSR*- and *SRRS*-3″,2,3″-tet)]Cl·H_2O, because its PMR spectrum showed four kinds of methyl signals.

The *cisβ*-[Co(ox)(*RSSR*- and *SRRS*-3″,2,3″-tet)]Cl·H_2O complex (3.1 g) was dissolved in 200 ml of water at 60 °C. To the solution was added a solution of sodium hydrogen dibenzoyl-*d*-tartrate (3.3 g) in 200 ml of hot water. The solution was stirred at 60 °C for 6 hr. The solution was subsequently cooled to room temperature, and the deposited powder was filtered off. The filtrate was concentrated to 250 ml, and the precipitated second powder was filtered off. To the second filtrate was added an appropriate amount of concd HCl slowly. The solution was stirred throughout the addition. The deposited white precipitate was filtered off. The third filtrate was evaporated in a vacuum desiccator over potassium hydroxide, and the resulting red crystals were filtered off. Red crystals were recrystallized fractionally from water until the CD spectra exhibited a constant curve.

This optically pure complex of oxalatotetramine was dissolved in concd HCl and warmed at 70 °C for 3 hr. The resulting green crystals were filtered off, washed with a small amount of cold water and ethanol, and air-dried. It was found that the optically active complex of oxalatotetramine was almost quantitatively converted to the $(+)_{600}$-*trans*-dichloro complex by this procedure. Found: C, 34.84; H, 7.62; N, 13.14%. Calcd for $C_{12}H_{32}N_4Cl_3CoO$: C, 34.84; H, 7.80; N, 13.54%.

The $(+)_{600}$-*trans*[$CoCl_2$(*RSSR*-3″,2,3″-tet)]Cl·H_2O complex was also obtained by the optical resolution of *trans*-[$CoCl_2$(*RSSR*- and *SRRS*-3″,2,3″-tet)]Cl·H_2O in water using sodium hydrogen dibenzoyl-*d*-tartrate as the resolving agent. This procedure was not very good, however, because the *trans*-[$CoCl_2$(*RSSR*- and *SRRS*-3″,2,3″-tet)]$^+$ aquated slowly in water.

$(-)_{600}$-trans-[*CoCl*$_2$(*RRRR-3″,2,3″-tet*)]*ClO*$_4$·*H*$_2$*O*: This complex was prepared from $CoCl_2$·$6H_2O$ and *RRRR*-3″,2,3″-tet by a method similar to that used for the corresponding *RR*-2,3″,2-tet described above. *trans*-[$CoCl_2$(*RRRR*-3″,2,3″-tet)]ClO_4·H_2O aquated slowly in water at room temperature, as did the other *trans*-2,3″,2-tet and 3″,2,3″-tet complexes of cobalt(III) except for *trans*-[($CoCl_2$(*RSRS*-3″,2,3″-tet)]ClO_4. Found: C, 30.61; H, 6.78; N, 12.15%. Calcd for $C_{12}H_{32}N_4Cl_3CoO_5$: C, 30.17, H, 6.75; N, 11.73%.

Measurements. The visible and ultraviolet absorption spectra were recorded with a Hitachi 124 recording spectrophotometer. The CD curves were recorded with Model ORD/UV-5 spectrophotometer of the Japan Spectroscopic Co., with a CD attachment. The spectra of the *trans*-dichloro complexes were recorded in a methanol solution, while the spectrum of the *cis*-dichloro complex was recorded in a concd HCl solution. The PMR spectra were obtained with Varian T-60 and HA-100 spectrophotometers, using Na-TMS as the internal standard. The perchlorate salts of three *trans*-dichloro complexes, *trans*-[$CoCl_2$(*RR*-2,3″,2-tet)]ClO_4, *trans*-[$CoCl_2$(*RS*-2,3″,2-tet)]ClO_4, and *trans*-[$CoCl_2$(*N,N′*-Me_2-*RS*-2,3″,2-tet)]ClO_4, were converted into chloride salts by the use of an anion exchanger, Dowex 1-X4, because the perchlorate salts were not sufficiently soluble in D_2O. The PMR spectra of the corresponding *RSSR*-, *SRRS*-, and *RSRS*-3″,2,3″-tet complexes could not be obtained, because these complexes were not sufficiently soluble in D_2O. All the measurements were made at room temperature.

Results and Discussion

Geometrical Isomers of Complexes and Configurations of Ligands. Three topological isomers are possible for the dichlorotetramine complexes of cobalt(III). However, it is rare that all three isomers are prepared by the usual air-oxidation procedure. In fact, the *trans* isomer is preferentially produced in the 2,3,2-tet and 3,2,3-tet complexes of cobalt(III).[2,3] While, on the contrary, the main products are *cis*-dichloro isomers (*cisα*, *cisβ*) in the triethylenetetramine complexes of cobalt(III).[18–20] This difference may be roughly attributed to the reaction rate, the solubility, and the steric factor of the complexes.

In the present study, dichlorotetramine cobalt(III) complexes were prepared by using the usual air-oxidation procedure. The green dichloro isomers only could be isolated from the reaction solution when any of the five tetramines (*RR*-2,3″,2-tet, *RS*-2,3″,2-tet, *N,N′*-Me_2-*RS*-2,3″,2-tet, *RRRR*-3″,2,3″-tet, and a racemic pair of *RSSR*- and *SRRS*-3″,2,3″-tet) was employed as a ligand. In the case of the [$CoCl_2$-(*RSRS*-3″,2,3″-tet)]$^+$ complexes, however, the blue-violet salt of [$CoCl_2$(*RSRS*-3″,2,3″-tet)]Cl and the green salt of [$CoCl_2$(*RSRS*-3″,2,3″-tet)]ClO_4 could be

isolated from the reaction solution as described in detail in Experimental. The six green complexes and the blue-violet complex prepared here were assigned to the *trans*(Cl–Cl) and *cis*(Cl–Cl) structures respectively from their characteristic color and absorption spectra, as shown in Figs. 5—7 and Table 1.

The configurational assignments of the asymmetric carbon atoms in the ligands of *RR*-2,3″,2-tet, *RS*-2,3″, 2-tet, *N*,*N*′-Me_2-*RS*-2,3″,2-tet, and *RRRR*-3″,2,3″-tet were confirmed unequivocally from the preparative processes of these tetramines described in Experimental.

However, when *RS*-2,4-pentanediamine was employed as the starting material in Method III, the products of the reaction contained three isomers of 3″,2,3″-tet, *meso* (*RSRS*), and a pair of racemic (*RSSR* and *SRRS*) tetramines. These three isomers were separated, resolved, and characterized on the basis of the following considerations. The molecular models indicate that *RSRS*-3″,2,3″-tet and racemic (*RSSR* and *SRRS*) 3″,2,3″-tet tend to form *cis*-[$CoCl_2$(*RSRS*-3″, 2,3″-tet)]$^+$ and *trans*-[$CoCl_2$(*RSSR*- and *SRRS*-3″,2,3″-tet)]$^+$ complexes respectively by the steric regulation of the ligands. In the first stage, a mixture of *meso* and racemic tetramine was separated by complexing with the cobalt(III) ion as follows (see Experimental). The green chloride salt was obtained in the step of air-oxidation, and then from its filtrate blue-violet chloride and green perchlorate salts were obtained. The first green chloride could be resolved into the optically active form ($(+)_{600}$-*trans*-isomer). This complex may be assigned to *trans*-[$CoCl_2$(*RSSR*- and *SRRS*-3″,2,3″-tet)]$Cl\cdot H_2O$. The blue-violet chloride salt may be assigned to *cis*-[$CoCl_2$(*RSRS*-3″,2,3″-tet)]Cl on the basis of a molecular-model study. This *cis*-dichloro complex was converted to *trans*-dichloro complex in the methanolic solution. The absorption spectrum of this *trans*-dichloro complex is in accord with that of the secondarily obtained green perchlorate salt, which was converted to the *cis*-dichloro form in concentrated hydrochloric acid. The green perchlorate salt may be *trans*-[$CoCl_2$(*RSRS*-3″,2,3″-tet)]ClO_4.

In the second stage, the configuration of the tetramine ligand in $(+)_{600}$-*trans*-dichloro complex was determined. The molecular models indicate that the most stable forms among the possible isomers in [Co (ox) (*RSSR*-3″,2,3″-tet)]$^+$ and [Co(ox) (*SRRS*-3″,2,3″-tet)]$^+$ are the *Λ-cisβ* and *Λ-cisβ* isomer respectively. The oxalatotetramine complex prepared from the

(a) *trans*-$[CoCl_2(RS\text{-}2,3'',2\text{-tet})]Cl$,
(b) *trans*-$[CoCl_2(RR\text{-}2,3'',2\text{-tet})]Cl$,
(c) *trans*-$[CoCl_2(N,N'\text{-}Me_2\text{-}RS\text{-}2,3'',2\text{-tet})]Cl$,
(d) *trans*-$[CoCl_2(RRRR\text{-}3'',2,3''\text{-tet})]Cl$, in diluted DCl.

$(+)_{600}$-*trans*-dichloro complex was optically active ($\Delta\varepsilon=+0.53$ at 17730 cm^{-1} and $\Delta\varepsilon=-2.09$ at 19920 cm^{-1}) and gave more than three kinds of methyl signals in the PMR spectrum in D_2O. These facts seem to indicate that the oxalatotetramine complex takes *Δ-cisβ* configuration.[16] The details of this compound will be reported later.[17] This oxalatotetramine complex of cobalt(III) was almost quantitatively coverted to the *trans*-dichlorotetramine complex of cobalt(III) by warming in a concd HCl solution. The absorption and CD spectra of the resulting *trans*-dichloro complex was cosistent with those of the $(+)_{600}$-*trans*-isomer used as the starting material. Therefore, it seems that the $(+)_{600}$-$[CoCl_2(3'',2,3''\text{-tet})]^+$ complex can be assigned to *trans*-$[CoCl_2(RSSR\text{-}3'',2,3''\text{-tet})]^+$.

Conformation and Structure. As stated previously,[1,10,11] *RR*-, *SS*-, and *RS*-2,4-pentanediamine are expected to give *λ*- and *δ*-skew-boat and chair conformations respectively in six-membered chelate rings. Also, it is generally understood that substituting groups on carbon atoms in puckered chelate rings always tend to take equatorial positions. When the tetramines prepared here coordinate to the cobalt(III) ion, each of the three chelate rings in the tetramine complexes of cobalt(III) can be expected to have a specific conformation because of the steric regulation coming from the methyl groups on the α-carbon atoms as *C*-substituted triethylenetetramine cobalt(III) complexes.[12,20–22]

For the above reasons, the pentanediamine part of *RR*-2,3″,2-tet is expected to give a *λ*-skew-boat conformation in the complex of *trans*-$[CoCl_2(RR\text{-}2,3'',2\text{-tet})]^+$. Then, both of the five-membered chelate rings seem to take the *δ-gauche* conformation, and both of secondary nitrogen atoms seem to take the *S*-configuration as shown in Fig. 1-b. Accordingly, the two methyl groups are equivalent to each other, because this presumed structure has the C_2 symmetry. The molecular models indicate that the structure shown in Fig. 1-b (C_2) is formed without any great steric hindrance and involves a smaller steric interaction among the chelate rings than the other possible structure. This most probable structure was confirmed by the fact that the PMR spectrum of *trans*-$[CoCl_2(RR\text{-}2,3'',2\text{-tet})]^+$ gave only one sharp doublet of the methyl signal at 1.4 ppm as shown in Fig. 2-b.

From a similar consideration, *trans*-$[CoCl_2(RS\text{-}2,3'',2\text{-tet})]^+$ seems to take the *trans-N(S),N(R)*-[(*δ-gauche*) (chair) (*λ-gauche*)] structure as shown in Fig. 1-a. As shown in Fig. 2-a, the PMR spectrum of *trans*-$[CoCl_2(RS\text{-}2,3'',2\text{-tet})]^+$ gave a doublet of the methyl signal at 1.5 ppm, in accord with the above assignment.

The structural consideration of *trans*-$[CoCl_2(N,N'\text{-}Me_2\text{-}RS\text{-}2,3'',2\text{-tet})]^+$ gives three probable structure. In the first structure, all the methyl groups take equatorial positions and the six-membered chelate ring gives a chair conformation. In the second (an enantiomeric pair of Fig. 1-c), one *N*-methyl and two *C*-methyl groups exist in equatorial positions, while the other *N*-methyl group exists in an axial position. In this structure, the six-membered chelate ring gives a chair conformation. In the third structure (an enantiomeric pair of Fig. 1-b), the six-membered chelate ring forms a skew-boat conformation in which one *C*-methyl group takes an equatorial position and

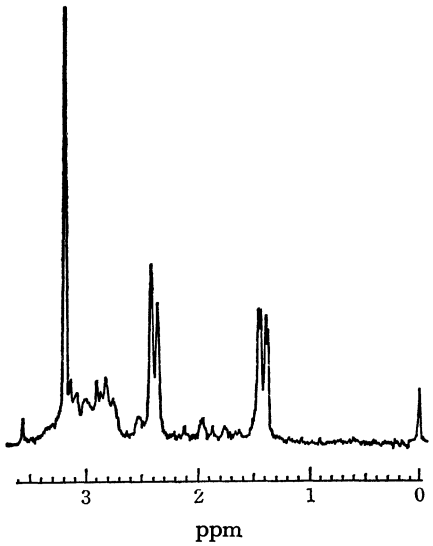

Fig. 3. PMR spectrum (100 MHz) of *trans*-[$CoCl_2$-(*N*,*N'*-Me_2-*RS*-2,3″,2-tet)]Cl in 3—4 M DCl.

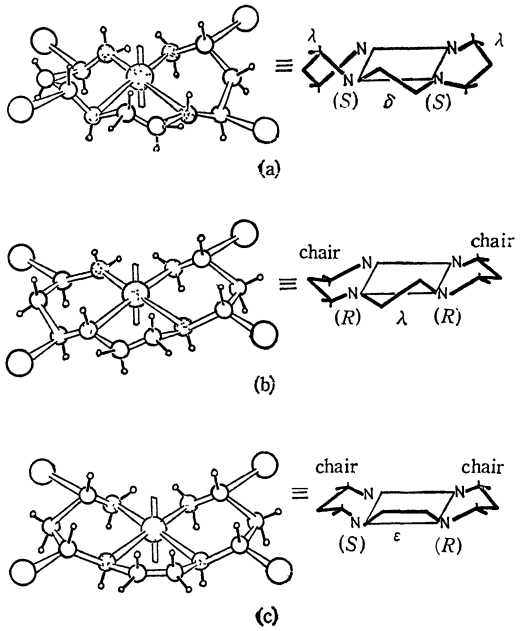

Fig. 4. Schematic structures of *trans*-[$CoCl_2$(3″,2,3″-tet)]$^+$.
(a) *trans*-[$CoCl_2$(*RRRR*-3″,2,3″-tet)]$^+$
(b) *trans*-[$CoCl_2$(*RSSR*-3″,2,3″-tet)]$^+$
(c) *trans*-[$CoCl_2$(*RSRS*-3″,2,3″-tet)]$^+$

the other *C*-methyl group is orientated in an axial position. In addition, two *N*-methyl groups take equatorial positions in this third structure. The first structure does not seem to be formed because of the great steric hindrance among the two *N*-methyl groups in equatorial positions. The structure of *trans*-[$CoCl_2$-(*N*,*N'*-Me_2-*RS*-2,3″,2-tet)]$^+$ is probably the second or the third.

The PMR spectra of the *trans*-[$CoCl_2$(*N*,*N'*-Me_2-*RS*-2,3″,2-tet)]$^+$ complex are shown in Fig. 2-c (60 MHz) and Fig. 3 (100 MHz). The two kinds of doublets at 1.4 ppm can probably be assigned to the two *C*-methyl groups. The broad doublet at 2.4 ppm, in which two kinds of doublets seem to overlap, is probably to be assigned to the *N*-methyl groups. The sharp singlet at 3.2 ppm may be assigned to the signal of amino protons, because the intensity of the signal depends upon the concentration of DCl. However, it is difficult to assign the detailed structure of *trans*-[$CoCl_2$(*N*,*N'*-Me_2-*RS*-2,3″,2-tet)]$^+$, because all four methyl groups are nonequivalent to each other in such a structure as shown in Fig. 1-c or Fig. 1-d. All attempts at the optical resolution of *trans*-[$CoCl_2$ (*N*,*N'*-Me_2-*RS*-2,3″,2-tet)]$^+$ have been unsuccessful so far.

Both six-membered chelate rings in *trans*-[$CoCl_2$-(*RRRR*-3″,2,3″-tet)]$^+$ seem to take a λ-skew-boat conformation in which each of the two α-carbon atoms has an equatorial methyl group. In this case, the central five-membered chelate ring and both secondary nitrogen atoms unequivocally take the *δ-gauche* and *S*-configurations respectively. In this presumed structure (C_2 symmetry), the two methyl groups near the five-membered chelate ring are equivalent to one another, and the two methyl groups far away are also equivalent to one another as shown in Fig. 4-a. Actually, the PMR spectrum of *trans*-[$CoCl_2$(*RRRR*-3″,2,3″-tet)]$^+$ gave two doublets of a methyl signal at 1.40 ppm and 1.45 ppm respectively as shown in Fig. 2-d. Accordingly, it seems that the structure of *trans*-[$CoCl_2$(*RRRR*-3″,2,3″-tet)]$^+$ can be assigned to *trans*-*N*(*S*), *N*(*S*)-[(λ-skew-boat) (*δ-gauche*) (λ-skew-boat)] as shown in Fig. 4-a.

The most probable structrue for *trans*-[$CoCl_2$(*RSSR*-3″,2,3″-tet)]$^+$ seems to be the *trans*-*N*(*R*), *N*(*R*)-[(chair) (*λ-gauche*) (chair)] structure as shown in Fig. 4-b. Studies with molecular models disclose that this assumed structure has a more strain-free and complete puckered conformation than the other possible structure. Also, it has been considered that the skeletal structure shown in Fig. 4-b is the most stable form in *trans*-[CoX_2(3,2,3-tet)]$^+$ (X=Cl, Br, NO_2)[5–9] and its analogs.[23,24] The PMR spectrum of *trans*-[$CoCl_2$-(*RSSR*-3″,2,3″-tet)]Cl·H_2O could not be obtained, because this complex was not sufficiently soluble in D_2O.

As the *RS*-2,4-pentanediamine parts of *RSRS*-3″,2,3″-tet tend to take chair conformations in a six-membered chelate ring, the most probable structure for the complex of *trans*-[$CoCl_2$(*RSRS*-3″,2,3″-tet)]$^+$ may be the form shown in Fig. 4-c. This structure, in which the central five-membered chelate ring takes an envelope conformation, has great strain in the bond angles of the two secondary nitrogen atoms, and it seems to be quite unstable compared with the structures of the other *trans*-dichlorotetramine complexes prepared here. Also, it was clear from the change in the absorption spectra that *trans*-[$CoCl_2$-(*RSRS*-3″,2,3″-tet)]ClO_4 rapidly aquated with a steric change in water and dilute hydrochloric acid, whereas the other *trans*-dichlorotetramine complexes prepared here aquated very slowly, retaining their configurations, and did not aquate in dilute hydrochloric acid. This may be related to the structural considerations presented above.

It is difficult to assign the structure of *cis*-[$CoCl_2$-

(·····) *trans*-[$CoCl_2$(*RS*-2,3″,2-tet)]ClO_4,
(—·—) *trans*-[$CoCl_2$(*N*,*N*′-Me_2-*RS*-2,3″,2-tet)]ClO_4 in CH_3OH.

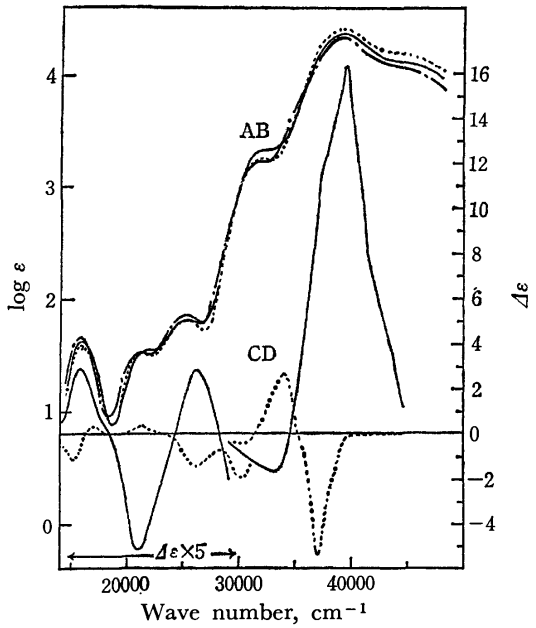

Fig. 6. Absorption (AB) and CD spectra of
(——) *trans*-[$CoCl_2$(*RRRR*-3″,2,3″-tet)]$ClO_4 \cdot H_2O$,
(·····) *trans*-[$CoCl_2$(*RSSR*-3″,2,3″-tet)]$Cl \cdot H_2O$,
(—·—) *trans*-[$CoCl_2$(*RSRS*-3″,2,3″-tet)]ClO_4 in CH_3OH.

(*RSRS*-3″,2,3″-tet)]$^+$ in detail at present. This complex readily aquated in water and smoothly isomerized to the *trans*-dichloro form in methanol. In addition, the complex of *cis*-[$CoCl_2$(*RSRS*-3″,2,3″-tet)]Cl was not sufficiently soluble in water and hydrochloric acid. Because of the above facts, the PMR spectrum of this complex could not be obtained.

Absorption Spectra. The absorption spectra of the complexes prepared here are shown in Figs. 5—7 and Table 1. The absorption spectra of *trans*-[$CoCl_2$(*RR*-2,3″,2-tet)]$^+$ and *trans*-[$CoCl_2$(*RS*-2,3″,2-tet)]$^+$ are almost identical with each other. However, the first, the second, and the charge-transfer bands of *trans*-[$CoCl_2$(*N*,*N*′-Me_2-RS-2,3″,2-tet)]$^+$ are shifted to longer wavelength than those of *trans*-[$CoCl_2$(*RR*-2,3″,2-tet)]$^+$ and *trans*-[$CoCl_2$(*RS*-2,3″,2-tet)]$^+$ (Fig. 5 and Table 1). Such a relationship is in accord with the phenomenon that the absorption bands of *trans*-[$CoCl_2$(*N*,*N*′-Me_2-en)$_2$]$^+$,[25] *trans*-[$CoCl_2$(*N*-Me-pn)$_2$]$^+$,[26] and *trans*-[$CoCl_2$(*N*,*N*′-Me_2-pn)$_2$]$^+$,[27] are shifted to longer wavelength than those of *trans*-[$CoCl_2en_2$]$^+$ and *trans*-[$CoCl_2pn_2$]$^+$ respectively.

As shown in Fig. 6, the absorption bands of *trans*-[$CoCl_2$(*RSRS*-3″,2,3″-tet)]$^+$ are shifted to longer wavelength than those of *trans*-[$CoCl_2$(*RRRR*-3″,2,3″-tet)]$^+$ and *trans*-[$CoCl_2$(*RSSR*-3″,2,3″-tet)]$^+$, which are almost identical with each other. It is difficult to discuss this result in detail at present. However, it seems to be related to the steric interaction among chelate rings and to strain in the bond angles of the secondary nitrogen atoms.

Figure 7 shows the absorption spectrum of *cis*-[$CoCl_2$(*RSRS*-3″,2,3″-tet)]$^+$ in a 12 M HCl solution. It is apparent from this spectrum that the blue-violet complex of [$CoCl_2$(*RSRS*-3″,2,3″-tet)]$^+$ takes the *cis*-

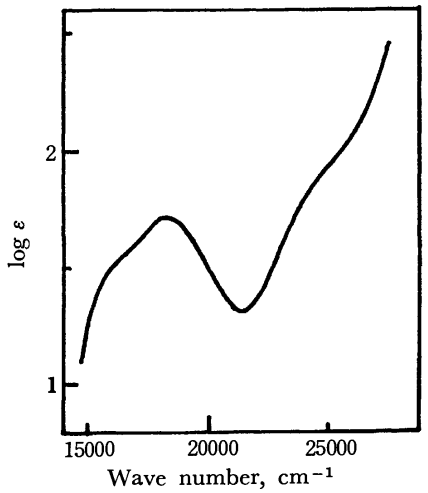

Fig. 7. Absorption spectrum of *cis*-[$CoCl_2$(*RSRS*-3″,2,3″-tet)]Cl in 12 M HCl.

dichloro configuration.

As shown in Figs. 5, and 6 and Table 1, the absorption bands of six *trans*-dichloro complexes are shifted from lower to higher wave numbers with a decrease in the number of the six-membered chelate ring or the secondary nitrogen atom, *i.e.*, in this order: *trans*-[$CoCl_2$(*N*,*N*′-Me_2-*RS*-2,3″,2-tet)]$^+$ ≃ *trans*-[$CoCl_2$(*RSRS*-3″,2,3″-tet)]$^+$ < *trans*-[$CoCl_2$(*RSSR*-3″,2,3″-tet)]$^+$ ≃ *trans*-[$CoCl_2$(*RRRR*-3″,2,3″-tet)]$^+$ < *trans*-[$CoCl_2$(*RR*-2,3″,2-tet)]$^+$ ≃ *trans*-[$CoCl_2$(*RS*-2,3″,2-tet)]$^+$. Also, a similar relationship holds between the *trans*-dichloro bisdiamine complexes of cobalt(III). The absorption bands of *trans*-[$CoCl_2$(diamine)$_2$]$^+$ are shifted to higher wave numbers in this sequence: *trans*-[$CoCl_2$(*N*,*N*′-Me_2-en)$_2$]$^+$ [25] ≃ *trans*-[$CoCl_2$(*N*,*N*′-Me_2-pn)$_2$]$^+$ [27] < *trans*-

$[CoCl_2tn_2]^+$[28] $\simeq$ *trans*-$[CoCl_2(2,4\text{-ptn})_2]^+$[11] $<$ *trans*-$[CoCl_2en_2]^+ \simeq$ *trans*-$[CoCl_2pn_2]^+$.

The above results show that the absorption bands are shifted to lower wave numbers in the order of *N*-nonsubstituted α-diamine, *N*-nonsubstituted β-diamine, and *N*-substituted α-diamine chelate in such *trans*-dichloro complexes of cobalt(III).

CD Spectra. The CD spectrum of *trans*-$[CoCl_2(RR\text{-}2,3'',2\text{-tet})]^+$ is shown in Fig. 5 and Table 1. The CD spectrum of *trans*-$[CoCl_2(RR\text{-}2,3'',2\text{-tet})]^+$ is very similar to the spectra of *trans*-*N*(*R*),*N*(*R*)-$[CoCl_2(2,3,2\text{-tet})]^+$[5-7] and *trans*-$[CoCl_2(SS\text{-diMe-}2,3,2\text{-tet})]^+$[29], which are assigned to the trans-[(*δ-gauche*)(λ-skew-boat)(*δ-gauche*)] structure. Such a similarity between the CD spectra of the three complexes strongly suggests that *trans*-$[CoCl_2(RR\text{-}2,3'',2\text{-tet})]^+$ should be assigned to the *trans*-*N*(*S*),*N*(*S*)-[(*δ-gauche*)(λ-skew-boat)(*δ-gauche*)] structure shown in Fig. 1-b.

As shown in Fig. 6 and Table 1, *trans*-$[CoCl_2(RRRR\text{-}3'',2,3''\text{-tet})]^+$ gives a CD curve very similar to that of *trans*-$[CoCl_2(RR\text{-}2,4\text{-ptn})_2]^+$.[11] Also, the spectrum of *trans*-$[CoCl_2(RR\text{-}2,3'',2\text{-tet})]^+$ in the region of about 16000 to 45000 cm^{-1} resembles that of *trans*-$[CoCl_2(RRRR\text{-}3'',2,3''\text{-tet})]^+$.

Figure 6 shows the CD spectrum of *trans*-$[CoCl_2(RSSR\text{-}3'',2,3''\text{-tet})]^+$, which is assigned to the *trans*-*N*(*R*), *N*(*R*)-[(chair)(λ-*gauche*)(chair)] structure (Fig. 4-b). This spectrum is appreciably different from the CD spectra of $(-)_{589}$-*trans*-$[CoCl_2(3,2,3\text{-tet})]^+$,[5-8] and *trans*-$[CoCl_2(R\text{-appn})]^+$,[23,24] which are very similar to each other. However, the backbones of 3,2,3-tet and *R*-appn[30] in these two complexes are identified as taking the same configuration as the backbone of *RSSR*-3″,2,3″-tet in *trans*-$[CoCl_2(RSSR\text{-}3'',2,3''\text{-tet})]^+$. Such a difference in CD spectra may be elucidated as follows: the two terminal, six-membered chelate rings in $(-)_{589}$-*trans*-$[CoCl_2(3,2,3\text{-tet})]^+$ and *trans*-$[CoCl_2(R\text{-appn})]^+$ are flexible, and it is conceivable that a conformational equilibrium exists where the terminal rings flip from the nonchiral to the chiral, skew-boat conformations. On the other hand, such a flipping in *trans*-$[CoCl_2(RSSR\text{-}3'',2,3''\text{-tet})]^+$ is not likely because of the preference of the methyl groups for an equatorial orientation.

The author wishes to thank Drs. Shigenobu Yano and Masahiko Saburi for their helpful suggestions. He also wishes to thank the Ministry of Education for a Grant-in-Aid.

Valence States of Arsenic and Antimony in Sea Water

Shiro GOHDA

Department of Nuclear Reactor Engineering, Faculty of Science and Technology, Kinki University, Kowakae, Higashiosaka 577

(Received June 14, 1974)

A simple and convenient chemical procedure for the determination of As(III), As(V), Sb(III) and Sb(V) by thermal neutron activation analysis is proposed and applied to the study of the valence state of As and Sb in sea water. Immediately after sampling, As(III) and Sb(III) were separated from As(V) and Sb(V) by extracting their diethyldithiocarbamates with chloroform, and then back-extracted into diluted nitric acid. As(V) and Sb(V) in the aqueous phase were collected by thionalide cocrystallization. They were then irradiated for 30 min at a neutron flux of 2×10^{13} n/(cm^2·s), and treated in the same manner as described in the previous report.[6] The As and Sb were determined by gamma-ray spectrometry. Sea water has been found to contain 1.56—2.45 μg As/l and 0.37—0.60 μg Sb/l. 80—97% of arsenic and 70—94% of antimony existed as the pentavelent species, only 5—20% as the trivalent species, and the remainder was probably included in suspended matter.

Because arsenic and antimony exist in aqueous solution in two chemical forms, a trivalent and a pentavalent species, it is an interesting problem to investigate the valence state of these elements in sea water. A few reports have been published on the state of arsenic in sea water. Arsenate seems to be much more stable,[1] and Armstrong and Harvey,[2] Gorgy and his cowarkers,[3] Sugawara and Kanamori,[4] Johnson and Pilson[5] studied on the valence state of arsenic in sea water. These studies were useful for the separation and the determination of trivalent and pentavalent arsenic, although their procedures were very complicated. The valence state depends strongly upon the condition of the aqueous solution, and it changes considerably as aqueous conditions change. Accordingly the separation of trivalent and pentavalent species must be done as quickly as possible, because the valence state may be changed during the storage of the sea water sample.

There is no report on the valence state of antimony in sea water.

In a previous report,[6] we proposed a procedure for the neutron activation analysis of arsenic, copper, and antimony in sea water, but the valence states of arsenic and antimony cannot be determined by that method. In the present research, a rapid, simple and convenient procedure for the determination of valence states of arsenic and antimony in sea water was developed. This procedure was based on solvent extraction followed by the neutron activation. Trivalent species were separated from pentavalent species by extraction into chloroform as the diethyldithiocarbamate chelates, and arsenic and antimony in both states were separately collected by thionalide cocrystallization. After neutron irradiation, antimony was precipitated as oxinate and arsenic was coprecipitated with ferric hydroxide, and then the ^{76}As and ^{122}Sb activities were measured. By this procedure, the valence states of micro amounts of arsenic and antimony in aqueous solution can be precisely determined. Some coastal sea water samples were analyzed by this method.

Experimental

Materials. Sodium diethyldithiocarbamate (Na-DDTC): Reagent grade Na-DDTC was used without further purification. To 1 l of sea water 0.3 g of this reagent was added directly.

Thionalide solution, 2% (w/v): 2 g of thionalide (thioglycollic-β-aminonaphthalide) was dissolved in acetone and diluted to 100 ml with acetone. The solution was freshly prepared before use.

Oxine solution, 2% (w/v): 2 g of 8-quinolinol was dissolved in 7 ml of glacial acetic acid and diluted to 100 ml with water.

Sulfuric acid, 3M : Arsenic free sulfuric acid was diluted with water.

Radioisotopes, ^{74}As and ^{124}Sb, were purchased from the Radiochemical Centre, Amersham, England. It was confirmed that the isotopes could not be extracted with DDTC-chloroform, that is, they were the pentavalent species. The trivalent species were obtained by reduction with ascorbic acid.

Apparatus. Gamma-ray spectra were obtained with a well-type 3″×3″ NaI(Tl) scintillation detector connected to a Hitachi RAH-403 400 channel pulse-height analyzer. The activities measurements were measured with a 2″×2″ NaI(Tl) detector and a Hitachi RC-2 scaler.

Extraction Procedure of Arsenic and Antimony Diethyldithiocarbamates. For separation of trivalent species of arsenic and antimony from pentavalent species in sea water, the extraction of arsenic-DDTC and antimony-DDTC chelates using radioactive tracers was studied. Na-DDTC was added to the sea water containing ^{76}As, ^{122}Sb, and ^{124}Sb in trivalent or pentavalent states and 2 μg of the carrier. After the pH was adjusted, the resulting solution was shaken with chloroform. Two milliliters of samples were pipetted from the organic and the aqueous layers, and the activities were measured.

Analytical Procedure. From the experimental results presented below, the following analytical procedure is recommended.

Immediately after the collection of sea water samples, 1 l of sea water was filtered through a 0.45 μm pore-size Millipore filter. After 0.3 g of Na-DDTC was added to the filtered sample, trivalent arsenic and trivalent antimony were extracted as DDTC chelates at pH 2.5—4.0 by shaking successively with 200 ml and 50 ml of chloroform, and then stripped by shaking the organic phase with 50 ml of 3 M nitric acid. After the solution was heated to boil out the dissolved chloroform and diluted to 1 l with redistilled water, the trivalent species were collected by thionalide cocrystallization: after 8 ml of 2% thionalide acetone solution was added to the cooled solution with vigorous stirring, the solutions were boiled for about 30 minutes and then allowed to stand overnight at room temperature. The precipitates were filtered with Millipore filters (pore-size: 0.45 μm) and

washed with redistilled water.

After the extraction the aqueous phase was acidified to 0.15 M with sulfuric acid, and pentavalent species remaining in the solution were also collected by the thionalide cocrystallization.

Millipore filters employed for the filtration of sea water samples, the filters including the thionalide precipitates, and the standards were separately packed in polyethylene capsules (8 mm long × 12 mm in diameter), which were placed in a polyethylene rabbit tube, and irradiated for 30 minutes at a thermal neutron flux of 2×10^{13} n/(cm^2·s) in the Kyoto University Reactor.

After cooling for a few hours, the irradiated samples were treated as reported previously.[6]

The oxinates and the ferric hydroxide precipitates were used for the gamma-ray spectrometry of ^{76}As and ^{122}Sb. For the hydroxide precipitate, the 0.55 MeV gamma-ray photopeak following the decay of ^{76}As was counted. For the oxinates precipitate, the decay of the 0.57 MeV photopeak of ^{122}Sb was followed, after ^{64}Cu (0.51 MeV annihilation gamma-rays) had decayed.

Results and Discussion

Redox Behavior of Arsenic in Salt Solution and Sea Water. Oxidation of arsenic(III) was measured by determining arsenic(V) by the molybdenum blue method, and reduction of arsenic(V) was followed by DDTC extraction using the radioactive isotope, ^{74}As(V). The rate of oxidation of arsenic(III) in 0.1 M sodium perchlorate, 0.1 M sodium chloride, and 0.025 M sodium sulfate solutions is shown in Fig. 1. When sodium arsenite (containing 5 mg of arsenic(III)) was dissolved in 1 l of these solutions, the pH of which had been previously adjusted to 8.0—8.5 with sodium hydroxide solution, 20—30% of arsenic(III) was immediately oxidized to arsenic(V). Then the oxidation proceeded slowly and 50—60% of arsenic existed as the pentavalent species after 400 hours standing. Aeration accelerated oxidation.

The oxidation-reduction of arsenic in sea water and artificial sea water are shown in Fig. 2. In artificial sea water, the effect of aeration was not appreciable, and after 400 hours, about 50% of arsenic(III) was oxidized to arsenic(V). The effect of aeration was significant in sea water; about 50% of the arsenic(III), which was added as sodium arsenite (containing 5 mg of arsenic) to sea water (1 l), was oxidized after 400 hours of aeration, but only about 20% was oxidized without aeration.

Curves 3—6 in Fig. 2 show the behavior of arsenic(V) added to sea water. The reduction of arsenic(V) to arsenic(III) may be caused by the decomposition of organic matter in the samples. In sea water which contains very small amounts of organic substances, reduction was not observed even after standing for 400 hrs (as shown by curve 6), and the same result was obtained in artificial sea water or the salt solutions described above.

In the case of antimony, decisive results could not be obtained because of hydrolysis of the element.

As the above results show, the trivalent species and pentavalent species must be separated immediately after the collection of the water samples.

Extraction Conditions for Arsenic and Antimony Diethyldithiocarbamates. The extraction conditions for arsenic and antimony diethyldithiocarbamates were studied, and following results were obtained.

1) Effect of pH Value: The effect of pH was investigated, using 1 ml of 1% Na-DDTC solution per 20 ml of sea water. Figure 3 shows that the optimum pH region is 2.5—5.0 for the separation of the trivalent species from the pentavalent species. Because the pH value shifts to a higher value during the extraction, the initial pH must be controlled in the range between 2.5 and 4.0.

2) *Effect of Na–DDTC Concentration*: The effect of the amount of Na–DDTC was also studied by adding various amount of the reagent to 1 l of sea water containing the tracers and 2 μg of the carriers. More than 99% of the trivalent species could be extracted by adding 0.1 g or more of Na–DDTC per 1 l, and therefore, in subsequent experiments, 0.3 g of Na–DDTC was employed per 1 l of sea water.

3) *Effect of Nitric Acid Concentration on Back Extraction*: The back extraction of trivalent arsenic and antimony was effected by shaking the organic phase with an equal volume of nitric acid. As shown in Fig. 4, trivalent arsenic and antimony could be readily stripped into 3 M nitric acid. Sulfuric and hydrochloric acids were less effective.

In the practical procedure, 250 ml of chloroform was used for the extraction from 1 l of sea water sample, and at least 50 ml of 3 M nitric acid was needed for the back extraction. The more than 98.8% recovery could be attained.

Under these extracting and stripping conditions, copper, which is cocrystallized with thionalide, was quantitatively extracted, but incompletely stripped (see Fig. 4).

TABLE 2. RESULTS OF ARSENIC AND ANTIMONY DETERMINATIONS ON SPIKED SAMPLES

Sea water sample taken (litter)	As and Sb added (μg)	As(III) found (μg)	As(V) found (μg)	Sb(III) found (μg)	Sb(V) found (μg)
1	0	0.22[a)]	1.49[a)]	0.06[a)]	0.38[a)]
1	As(III) 0.5 + As(V) 1.0 + Sb(III) 0.5 + Sb(V) 0.5	0.74 (0.24)	2.51 (1.51)	0.55 (0.05)	0.90 (0.40)
1	As(III) 0.5 + Sb(III) 0.3	0.76 (0.26)	1.53	0.39 (0.09)	0.35
1	As(V) 1.0 + Sb(V) 0.5	0.20	2.45 (1.45)	0.08	0.85 (0.35)

a) The values are the amounts of the elements in the original samples of sea water (μg/l). The values in brackets are differences between the value in original sample of sea water and the analytical value.

4) *Effect of the Amount of Thionalide*: In previous research, arsenic and antimony could be quantitatively cocrystallized with thionalide from diluted sulfuric acid solution.[6] Since nitric acid was used for the back extraction of the trivalent arsenic and antimony, in the present experiments, the thionalide was cocrystallized from diluted nitric acid solution. Recovery of more than 98% was attained by adding 8 ml or more of 2% thionalide acetone solution to 1 l of 0.03—0.2 M nitric acid solution.

Analysis of As(III), As(V), Sb(III), and Sb(V) in Sea Water. The above procedure was recommended and applied to the determination of arsenic(III), arsenic(V), antimony(III), and antimony(V) in sea water samples. Surface sea water samples were collected from 5 stations, offshore from Shirahama and Uragami, Wakayama Prefecture, and from Kojima, Osaka Prefecture.

The analytical results are shown in Table 1. As shown in Table 1, the total contents of arsenic and antimony were in the range of 1.43—2.45 μg As/l and 0.16—0.60 μg Sb/l, and these values were in good agreement with the values found in previous studies[6] and with the data recently reported,[4,7,8-11] From 80 to 93% of the dissolved arsenic and from 74 to 94% of the dissolved antimony existed as arsenate and antimonate. This result also agrees with the results of Sugawara *et al.*[4,7] The result for antimony cannot be compared with others, because no report has been published on the valence state. Overall recovery in the pre- and post-irradiation procedure was over 98%.

In order to examine the accuracy of the proposed procedure for the determination of arsenic (III), (V) and antimony(III), (V), definite amounts of arsenic (III), (V) and antimony(III), (V) ions were added to sea water samples and the entire procedure for the determination of these elements was applied to the samples. The results of this spiking analysis are shown in Table 2. From these results, the relative error for the trivalent and pentavalent species of these elements was estimated to be less than ±10 percent and ±5 percent respectively. In this case, the concentrations of trivalent species were about one tenth of the concentrations of pentavalent species, and the analytical result for the former includes a comparatively large relative error. The blank value for arsenic was 0.01—0.03 μg and for antimony 0.005—0.01 μg.

The author wishes to express his sincere thanks to Professor Tsunenobu Shigematsu, Institute for Chemical Research, Kyoto University, Professor Yasuharu Nishikawa, Faculty of Science and Technology, Kinki University, and Professor Masayuki Tabushi, Tōhoku Women's college, for their kind advice and suggestions throughout this work. The author is deeply indebted to the Hot Laboratory groups of Kyoto University for their help in the irradiation operation, and is also indebted to Professor Shiro Okabe, Faculty of Oceanography, Tokai University, for his kind help in the sampling of sea water.

Analysis of a Magnesium-containing β-Eucryptite Solid Solution by the Lattice Constant Method and Its Application[1,2]

Masaaki IWATSUKI, Norio TSUKADA, and Tsutomu FUKASAWA

Department of Applied Chemistry, Faculty of Engineering, Yamanashi University, Takeda, Kofu 400

(Received August 30, 1974)

An X-ray diffraction method has been developed for the determination of the composition of a magnesium-containing β-eucryptite solid solution which consists of a pseudo-ternary system, SiO_2–$Mg_{1/2}AlO_2$–$LiAlO_2$. Standard samples of the solid solution within the range of 60—75 mol% SiO_2 and 0—15 mol% $Mg_{1/2}AlO_2$ were prepared from high-purity materials by the "glass-crystallization" technique. The diffraction angles of the (206) and (212) planes were measured from the center of gravity of the profile recorded on a chart by a counter diffractometer. After having been corrected for various systematic errors, both angles were used for the calculation of the lattice constants. It was found that $Mg_{1/2}AlO_2$ and $LiAlO_2$ contributed similarly to a_0, but in a different way to c_0. The composition of the solid solution in a commercial glass-ceramic could be determined from the correlation between the composition and the lattice constants. The standard deviation of the determination from one measurement was about 0.2—0.4 mol%, and the time required for analysis was about 30 min.

Low-thermal-expansion glass-ceramics contain a β-spodumene solid solution ($Li_2O \cdot Al_2O_3 \cdot nSiO_2$, $n>3$) or a β-eucryptite solid solution ($Li_2O \cdot Al_2O_3 \cdot nSiO_2$, $n \geq 2$), and their properties, such as the thermal expansion, depend not only on the content, but also on the composition of the solid solution. Therefore, the determination of the composition of the solid solution in the glass-ceramics is very important for the quality control and the study of the glass-ceramics; it is possible, however, only by the X-ray diffration method, as has been described in our previous papers.[1,3] The application of this method to a β-spodumene solid solution and a β-eucryptite solid solution has already been reported by us.[1,3] A magnesium-containing β-eucryptite solid solution consists of Li_2O, MgO, Al_2O_3, and SiO_2, and the number of moles of Li_2O plus that of MgO is equal to that of Al_2O_3. Therefore, the solid solution can be expressed as a pseudo-ternary system, SiO_2–$Mg_{1/2}AlO_2$–$LiAlO_2$. Since the solid solution is a hexagonal crystal, it is expected that the composition can be determined by measurements of the lattice constants, a_0 and c_0, if the three components contribute to a_0 and c_0 in any different manner. In the present paper, the analysis of a magnesium-containing β-eucryptite solid solution in glass-ceramics will be described on the basis of measurements of the two lattice constants.

Experimental

Apparatus. A Rigaku X-ray diffractometer with a proportional counter was used for this study. The glass samples were prepared by the use of an electric furnace with a silicon carbide heating element. A nichrome wire furnace was used for the crystallization of the glass. A Nippon Jarrell-Ash atomic-absorption and flame-emission spectrophotometer, AA-500, was used to check the lithium contents in the prepared samples.

Preparation of Standard Samples. Standard samples of the magnesium-containing β-eucryptite solid solution were prepared from lithium carbonate of a guaranteed reagent grade (min. 99.0%, Kanto Chemicals) and high-purity magnesium oxide (99.9% nominal, High Purity Chemical Laboratory), aluminum oxide (99.9—99.99% nominal, Iwatani & Co.), and silicon dioxide (min. 99.8%, Nissan Rare Elements). The magnesium oxide was heated in a platinum dish for 1.5 hr by means of a Mecker burner to dehydrate it. The aluminum oxide and silicon dioxide were similarly heated for 1 hr. The raw materials were weighed out by the amounts calculated for the intended compositions of the solid solution within the range of 60—75 mol% SiO_2 and 0—15 mol% $Mg_{1/2}AlO_2$ (the residual was $LiAlO_2$). The lithium carbonate was weighed out by the 3% excess of the calculated amount, considering a partial loss of lithium due to evaporation.[1] The materials weighed were mixed in an agate mortar for about 30 min, loaded into a platinum crucible, and heated at 1430 °C for 3 hr in the electric furnace. The melt was quenched in water, together with the crucible. The resultant glass was dried in an electric drying oven and subsequently powdered in an alumina mortar. The glass powder (48—200 mesh) was placed in a platinum crucible and then kept at a constant temperature in the range of 670 to 900 °C for 2—96 hr. When a glass or β-spodumene solid solution which is stable at higher temperatures was found by means of the X-ray diffraction method, a different condition of heat-treatment was used to obtain a sample containing the β-eucryptite solid solution only. In order to check the lithium content of the prepared sample, the sample was decomposed with hydrofluoric acid, perchloric acid, and nitric acid, and the lithium content was determined by flame photometry.

Measurement of Interplanar Spacings. Since the concentrations of any two components of the solid solution vary independently, at least two diffraction lines must be measured. The lines must not overlap with any other line. In addition, it is preferable for the lines to satisfy the following requirements: (1) one of these lines be that from a plane nearly perpendicular to the c axis, and the other be that from a plain nearly parallel to the c axis, because the analysis is based on the different contributions of the three components of the solid solution to a_0 and c_0 ; (2) the diffraction angles of the lines shift as much as possible with the change in the composition; (3) the intensities of lines be as high as possible. From these requirements, the (212) and (206) lines were selected as the best lines; and each line was measured three times under the conditions shown in Table 1. In order to compensate for any slight misalignment of the goniometer, (311) and (400) lines of a high-purity, sintered silicon plate (an external standard) were measured under the same conditions before and after the measurements of the lines of the solid solution. The internal standard technique was not adopted, because the diffraction lines of any internal standard and those of the solid solution were liable to overlap.

The diffraction profiles obtained by the use of the Cu$K\alpha_1$ ($\lambda=1.54051$Å) and $K\alpha_2$ ($\lambda=1.54433$Å) radiations overlapped in part. The profiles of thirteen samples of the solid solution

were separated into α_1- and α_2-components on the charts on the basis of the intensity ratio and the degree of the α_1-α_2 angular separation. The diffraction angle obtained from the center of gravity of the triangle approximating the α_1-component was compared with the $K\bar{\alpha}$-diffraction angle obtained in a similar way from the intact profile. The difference agreed, within the limits of experimental error, with the angular separation calculated from the wavelengths of Cu$K\alpha_1$ and $K\bar{\alpha}$ (λ=1.54178 Å). For economy of time, therefore, the interplanar spacings of the other samples of the solid solution were obtained by the latter method, *i.e.*, by $K\bar{\alpha}$ angle measurements. Each profile of the (400) and (311) lines of the silicon standard was measured about ten times, and separated into α_1- and α_2-components. The difference was calculated between the angle obtained from the center of gravity of the triangle approximating the α_1-component and that obtained from the midpoint of the width at two-thirds of the maximum intensity of the intact profile. The reproducibility of the difference was good. Consequently, the diffraction angles of the silicon standard were obtained from the midpoint of the two-thirds-width of the intact profile, and corrected for the above difference.

The diffraction angles thus obtained still include the systematic errors due to the diffraction at the inner parts of specimens, the use of flat specimens, and the divergence of the primary beam perpendicular to the plane of Bragg

a) Although the samples of these compositions were not prepared, these samples will be also discussed in the study by the use of the diffraction data from the preceding paper.[1]

focusing. These errors were compensated for on the basis of the equation given by Willson and Pike.[4]

Results and Discussion

Magnesium-containing β-Eucryptite Solid Solution. Table 2 shows the conditions of crystallization and the results of the analysis of lithium. The intended and analyzed Li_2O contents agreed well, and no impurity was detected by the X-ray diffraction method. These results indicate that the prepared samples were pure enough for this study. The crystallization required higher temperatures as the content of SiO_2 or $Mg_{1/2}AlO_2$ increased.

Correlation between the Composition and the Lattice Constants. The interplanar spacings and lattice constants of the solid solution are shown in Table 3. The relation between the composition and lattice constants is shown in Fig. 1. The results can be summarized as follows: (1) when $LiAlO_2$ or $Mg_{1/2}AlO_2$ was substituted for SiO_2, a_0 increased markedly; (2) when $LiAlO_2$ was substituted for SiO_2, c_0 hardly changed at all, or even decreased somewhat, in the low-lithium region, and increased in the high-lithium region; (3) when $Mg_{1/2}AlO_2$ was substituted for SiO_2, c_0 decreased markedly except in the high-lithium region.

a) The data obtained from the preceding paper.[1]

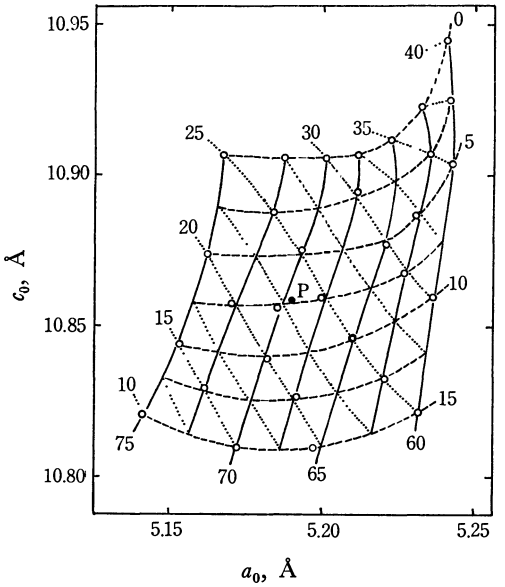

Fig. 1. Correlation between composition and lattice constants of the solid solution.
——: Line on which mol% of SiO_2 is equal.
----: Line on which mol% of $Mg_{1/2}AlO_2$ is equal.
·····: Line on which mol% of $LiAlO_2$ is equal.
Numbers in the figure indicate mol% of each component.
P: The solid solution in the glass-ceramic described in the text.

These facts may be explained as follows on the basis of the crystal structure of the solid solution. The crystal structure was determined by Chi-Tang Li[5] for the composition of 66.7 mol% SiO_2 and 33.3 mol% $LiAlO_2$. The solid solution consists of the SiO_4 and AlO_4 tetrahedra arranged along a hexagonal screw axis parallel to the c axis in double helical fashon, and of the lithium and magnesium ions on the interstitial sites along the hexagonal screw axis. The lithium or magnesium ion compensates for the deficiency in the positive charge due to the substitution of an aluminum ion for a silicon ion, and is coordinated by four oxygen ions. This LiO_4 or MgO_4 tetrahedron shares two edges with the two opposite $Al(Si)O_4$ tetrahedra. The shared edges are the shortest for both the $Li(Mg)O_4$ and $Al(Si)O_4$ tetrahedra; they have a slope of about 45° to the c axis. Two of the unshared edges of the $Al(Si)O_4$ tetrahedron lie on the $(00l)$ planes, while the others have a slope of about 45° to the c axis.[5] When $LiAlO_2$ or $Mg_{1/2}AlO_2$ is substituted for SiO_2, the lithium or magnesium ion wedges itself in the hexagonal screw. The shortest distance between a lithium (or magnesium) ion and an aluminum (or silicon) ion lies on a $(00l)$ plane and is very short (about 2.58 Å for the composition of 75 mol% SiO_2 and 25 mol% $LiAlO_2$). Therefore, the screw may be compelled to widen by the repulsive force between

Table 4. Comparison of lattice constants of magnesium-containing β-eucryptite solid solution with data of several other authors

a) Obtained from Fig. 1 for the composition.

the lithium (or magnesium) ion and the aluminum (or silicon) ion, and hence a_0 increases. On the contrary, the effect of the Li(Mg)–Al(Si) repulsive force on c_0 may be small, because the shortest Li(Mg)–Al(Si) distance lies on a (00l) plane, and the next shortest distance is relatively long and has a large slope to the c axis. Since the Li–Li distance along the c axis is long in the low-lithium region, the Li–Li repulsive force may be weak. In the high-lithium region, the distance is short; hence, the repulsive force may be strong enough to increase the c_0. Since the magnesium ion has a stronger polarizing power than the lithium ion, the Mg–O bond is stronger and more covalent than the Li–O bond. Therefore, the edges of the $Al(Si)O_4$ tetrahedra shared by the MgO_4 tetrahedra may be shorter than those of the $Al(Si)O_4$ tetrahedra shared by the LiO_4 tetrahedra. As can be seen from the orientation of the $Al(Si)O_4$ tetrahedra described above, this effect may decrease c_0 of the magnesium-containing solid solution. However, it may not decrease a_0, because the unshared edges may be elongated and counteract the contraction of the shared edges. Since the Mg–O bond is more covalent than the Li–O bond, the effective charge of the magnesium ion may be relatively small. Moreover, the number of the magnesium ions introduced is half of that of the lithium ions. Therefore, the Mg–Mg repulsive force along the c axis may be smaller than the Li–Li repulsive force. Consequently, the c_0-decreasing effect may overcome the c_0-increasing effect; hence, c_0 may be decreased by introducing magnesium ions. In the high-lithium region, though, c_0 is hardly decreased at all by introducing magnesium ions, because the Li–Li repulsive force may increase considerably.

In any case, the data indicate that the composition of the solid solution can be determined by the measurements of a_0 and c_0, because the contributions of the three components to a_0 and c_0 were markedly different.

Application to a Glass-Ceramic Sample. In the preceding paper, it was found that slightly different values of the SiO_2 content of a β-eucryptite solid solution in a glass-ceramic were obtained depending on the diffraction line used. This phenomenon was presumed to result from the partial substitution of the magnesium ion for the lithium ion. Therefore, the present method was applied to this glass-ceramic sample. The P point (a_0=5.190 Å, c_0=10.858 Å) in Fig. 1 shows the solid solution in the sample. The concentration between adjacent lines of Fig. 1 can be considered to be approximately proportional to the distance from each line. Therefore, the composition could be obtained as follows: 69.5 mol% SiO_2, 7.3 mol% $Mg_{1/2}AlO_2$, and 23.2 mol% $LiAlO_2$.

Comparison with the Data of Several Other Authors. Table 4 compares the lattice constants of the solid solution with the data reported by several other authors.[6,7] Two of Ray and Muchow's data agreed well with ours, but one disagreed. When we compare the disagreeing datum with the tendency of the composition *vs.* lattice constant curves of their paper,[6] it seems that their value is too low. Petzoldt used lower diffraction angles for the measurement of the lattice constants, and so that precision of his measurement was only ±0.005 Å for a_0.[7] In addition, the authors of both papers did not consider the possibility of the evaporation of lithium during the sample preparation. In this study, the evaporation of lithium was taken into account, and higher diffraction angles were used and corrected for the systematic errors. The standard deviation of the data was 0.0005 Å for a_0. Moreover, a large number of data were accumulated. Therefore, it seems that the data of the present paper are more reliable.

Error in the Determination. The precision of the present method was as follows. The standard deviations of 2θ, a_0, and c_0 on one measurement were about 0.01°, 0.0008 Å, and 0.0025 Å respectively. The corresponding standard deviations of the analytical values of each component varied somewhat depending on the composition region. For example, in the neighborhood of the composition of 70 mol% SiO_2, 7.5 mol% $Mg_{1/2}AlO_2$, and 22.5 mol% $LiAlO_2$, the standard deviations of SiO_2, $Mg_{1/2}AlO_2$, and $LiAlO_2$ were 0.20, 0.39, and 0.28 mol% respectively. For the weight percentage, the standard deviations of SiO_2, MgO, Li_2O, and Al_2O_3 were 0.19, 0.13, 0.07, and 0.39 wt% respectively. For the purpose of obtaining the absolute composition by the use of Fig. 1, the errors of the equi-concentration lines in the figure must also be taken into account. These errors consist of the deviations of the compositions and the errors of the lattice constants of the standard samples. Since the lattice constants were obtained from the average of three measurements, the variances of the lattice constants were one-third of those described above.

The systematic errors of the lattice constants were compensated for; hence, they are negligible here. The deviation of the composition in Fig. 1 could be estimated as follows from the errors of weighing in sample preparation, the variations of impurities of the raw materials, and the permitted differences between the intended and determined lithium contents: SiO_2 0.3 mol% or less, $Mg_{1/2}AlO_2$ 0.1 mol% or less, and $LiAlO_2$ 0.4 mol% or less as the standard deviations. Then the errors of the equi-concentration lines were calculated: SiO_2 0.32 mol% or less, $Mg_{1/2}AlO_2$ 0.25 mol% or less, and $LiAlO_2$ 0.43 mol% or less as the standard deviations. Consequently, the absolute composition of the solid solution can be obtained by the use of Fig. 1 with the following maximum errors from one measurement in the neighborhood of the above composition: SiO_2 0.38 mol%, $Mg_{1/2}AlO_2$ 0.46 mol%, $LiAlO_2$ 0.51 mol%; SiO_2 0.37 wt%, MgO 0.15 wt%, Li_2O 0.12 wt%, and Al_2O_3 0.56 wt%.

The correlation between the lattice constants and the composition has been exclusively discussed for general use. The correlation between the composition and interplanar spacings or diffraction angles of (206) and (212), however, can also be used; its use is recommended for routine work because of the simplicity of calculation. The time required for analysis was about 30 min by the use of a desk electronic computer.

We wish to thank Mr. Masanao Arakawa for supplying us with high-purity aluminum oxide and silicon dioxide, and Mr. Hiroyuki Watanabe for carrying out some of the experiments.

Molecular Complexes of Arenetricarbonylchromium, -molybdenum and -wolfram

Hiroshi KOBAYASHI, Mitaka KOBAYASHI, and Youkoh KAIZU

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received December 9, 1974)

Arenetricarbonylchromium forms a charge-transfer complex with 1,3,5-trinitrobenzene (1,3,5-TNB), while arenetricarbonylmolybdenum and -wolfram do not form a charge-transfer complex with 1,3,5-TNB. On the other hand, arenetricarbonylchromium, -molybdenum and -wolfram form a charge-transfer complex with tetracyanoethylene (TCNE). Since the intramolecular charge transfer from coordinated arene to carbonyls increases in the molybdenum and wolfram derivatives, 1,3,5-trinitrobenzene cannot form a molecular complex accepting an electronic charge of the coordinated arene. In the case of TCNE, however, a molecular complex is formed by an inner-sphere charge-transfer interaction between the acceptor and the central metal atom. Thus the stability of the TCNE molecular complexes is dependent upon the charge density of the central metal atom and also the steric effects due to the functional groups in coordinated arenes. The ionization potentials of the molybdenum and wolfram derivatives observed for their TCNE molecular complexes are almost equal but higher than those of the corresponding chromium derivatives, whereas the highest stability is obtained for the molybdenum derivatives.

Arenetricarbonylchromium forms charge-transfer complexes with electron acceptors such as 1,3,5-trinitrobenzene (1,3,5-TNB) and tetracyanoethylene (TCNE) rather than with electron donors.[1] Nevertheless, the effects of tricarbonylchromium group to the chemical properties of π-coordinated benzene ring are more likely those of an electron-withdrawing group. In fact, benzoic acid tricarbonylchromium is a stronger acid than benzoic acid and anilinetricarbonylchromium is a weaker base than aniline.[2,3] Furthermore arenetricarbonylchromium exhibits a higher susceptibility to nucleophilic substitutions while it is less susceptible to electrophilic substitutions.[2,4,5]

The ionization potential of arenetricarbonylchromium was determined from the charge-transfer transition energies in the molecular complexes with 1,3,5-TNB[1,6] and with TCNE.[1]

1,3,5-TNB forms a molecular complex with arenetricarbonylchromium by a charge-transfer interaction toward the π-coordinated benzene ring in "face-to-face" stack of the counter benzene rings as revealed by an X-ray study on the molecular complex of anisoletricarbonylchromium and 1,3,5-TNB.[7] The ionization potentials of arenetricarbonylchromium obtained from the charge-transfer transition energies in the 1,3,5-TNB molecular complexes can well reproduce the ionization potentials measured directly by electron impact technique.[8] The ionization potentials of arenetricarbonylchromium obtained from the charge-transfer transition energies in the TCNE molecular complexes increase with a decrease in the ionization potential of coordinated arene. This is opposite to the corresponding shift of the ionization potentials observed for the 1,3,5-TNB molecular complexes. The stability of the TCNE complexes increases with a decrease in the ionization potential of arenetricarbonylchromium obtained for the TCNE complexes. This indicates that TCNE forms a charge-transfer molecular complex with arenetricarbonylchromium in a structure different from the 1,3,5-TNB molecular complex. In a previous paper,[1] an inner-sphere charge-transfer interaction of TCNE with the central chromium atom of arenetricarbonylchromium was proposed. In this paper, we present further evidences of the inner-sphere charge-transfer interaction of TCNE with arenetricarbonylchromium, -molybdenum and -wolfram.

Experimental

Materials. Arenetricarbonylchromium,[2] -molybdenum,[9,10] and -wolfram[9,11] were prepared according to the methods described in the literature by refluxing hexacarbonylchromium (High Pressure Chem. Co., Pennsylvania, U.S.A.), hexacarbonylmolybdenum (High Pressure Chem. Co., Pennsylvania, U.S.A.), or hexacarbonylwolfram (Research Organic/Inorganic Chem. Corp., California, U.S.A.) with the corresponding benzene derivatives under dry nitrogen atmosphere. For the preparation of arenetricarbonylwolfram, diglyme was used as solvent. For the preparation of arenetricarbonylmolybdenum, however, the use of diglyme usually results in poor yield and thus hexacarbonylmolybdenum was refluxed directly in the corresponding arenes. The refluxed mixtures were filtered, and then the filtrate was condensed by vacuum distillation. In the case of arenetricarbonylmolybdenum, the condensed solution was filtered and the complex was precipitated by adding *n*-pentane, the precipitate being then washed with isopentane. Arenetricarbonylchromium and -wolfram were obtained as residue by condensation of the filtrates of the refluxed mixtures. Arenetricarbonylchromium was purified by recrystallization of the residue from petroleum ether. Raw arenetricarbonylwolfram was dissolved in a small amount of benzene and then filtered. By adding *n*-pentane to the filtrate, arenetricarbonylwolfram was precipitated, and then the precipitate was washed with isopentane. The complexes were identified by elemental analysis (Table 1).

Diglyme, petroleum ether, *n*-pentane, isopentane and benzene derivatives used for the preparations were dried and distilled by the usual methods.[12]

N,N,N',N'-Tetramethyl-*p*-phenylenediamine (TMPD) dihydrochloride (Tokyo Kasei Co.) was neutralized with NaOH and the free amine thus obtained was purified by vacuum distillation. 1,3,5-TNB (Tokyo Kasei Co.) was recrystallized from dil HNO_3 and then from ethanol. TCNE (Tokyo Kasei Co.) was recrystallized from chlorobenzene.

Measurements of Absorption Spectra and Determinations of the Complex Formation Constants. Absorption spectra were recorded on a Shimadzu automatic recording spectrophotometer Model MPS-50. The cell compartment was thermostatted at a constant temperature (25 °C).

The solvent 1,2-dichloroethane (Wako Pure Chem. Co.) was dried and purified by the usual procedure.[12]

The equilibrium constant K of a 1 : 1 molecular-complex formation between electron donor D and electron acceptor A is given by

$$K = \frac{[D\cdot A]}{([D]_0-[D\cdot A])([A]_0-[D\cdot A])},$$

where $[\ ]_0$ denotes the initial concentrations, and $[D\cdot A]$ is the concentration of molecular complex D·A. Measurements were carried out at a wave number in the charge-transfer band of D·A where the molar absorption coefficients of D and A (ε_D and ε_A) are negligibly small. Assuming Beer's law, $[D\cdot A]$ is rewritten in terms of the observed absorbance $E=\varepsilon_C\cdot[D\cdot A]\cdot l$, where ε_C is the molar absorption coefficient of D·A and l is the optical path length. Thus it follows that

$$[D]_0[A]_0\, l/E = \{[D]_0+[A]_0-E/\varepsilon_c\cdot l\}\cdot 1/\varepsilon_c+1/K\varepsilon_c .$$

Measurements were carried out at 25 °C for various sets of the initial concentrations of D and A. K and ε_C were then evaluated according to the method described by Rose and Drago,[13] and Lang.[14] Plots of $[D]_0[A]_0 l/E$ against $\{[D]_0+[A]_0-E/\varepsilon_C\cdot l\}$ give a straight line for a self-consistent value of ε_C obtained by iterative calculations.

Infrared Absorption Spectra. Infrared absorption spectra of arenetricarbonylchromium, -molybdenum, and -wolfram in 1,2-dichloroethane were taken on a Hitachi spectrophotometer Model EPI-G3.

NMR spectra. NMR spectra of arene metal tricarbonyls in 1,2-dichloroethane were recorded on a 100 MHz Japan Electron Optics Laboratory spectrometer Model JNM 4H-100. Tetramethylsilane was used as an internal standard.

He Photoelectron Spectra. He (584 Å) photoelectron spectra were measured on a JASCO PE-1 photoelectron spectrometer.

Results and Discussion

Arenetricarbonylchromium, -molybdenum and -wolfram do not form a molecular complex with electron donors such as TMPD. On the other hand arenetricarbonylchromium forms molecular complexes with electron acceptors such as TCNE and 1,3,5-TNB. In fact the molecular complexes of 1,3,5-TNB have been isolated.[1,15,16] Although we have not succeeded so far in the isolation of the molecular complexes of TCNE, the charge-transfer absorption band indicates the molecular-complex formation between TCNE and arenetricarbonylchromium.

Arenetricarbonylmolybdenum and -wolfram do not form a molecular complex with 1,3,5-TNB. Neither a complex could be isolated nor a significant spectroscopic evidence of molecular-complex formation was detected. However, arenetricarbonylmolybdenum and -wolfram evidently form a charge-transfer molecular complex with TCNE. Figures 1, 2 and 3 present the charge-transfer absorption bands of toluenetricarbonylchromium (toluene $Cr(CO)_3$)–TCNE, toluene $Mo(CO)_3$–TCNE and toluene $W(CO)_3$–TCNE systems in 1,2-dichloroethane.

The absorption measurements were carried out at 25 °C in the charge-transfer band for various sets of the initial concentrations of TCNE and arenetricarbonylchromium, -molybdenum or -wolfram. From the values thus obtained, K and ε_C were evaluated. Table 2 shows K and ε_C obtained in the present work for various 1 : 1 molecular complexes of arenetricarbonylchromium, -molybdenum, and -wolfram with TCNE.

The ionization potentials of arenetricarbonylchromium, -molybdenum and -wolfram were evaluated from the charge-transfer transition energies in the molecular complexes with TCNE using an empirical relationship[17]

$$h\nu_{CT} = (I_p-6.10) + 0.54/(I_p-6.10),$$

where $h\nu_{CT}$ is the charge-transfer transition energy in eV and I_p is the ionization potential in eV of arenetricarbonylchromium, -molybdenum or -wolfram. The results are summarized in Table 3.

The ionization potentials determined by using the empirical relationship are in good agreement with the values directly observed for some chromium derivatives by photoelectron spectroscopy as shown in Fig. 5. The spectra are discussed later. The ionization potential of toluene is 8.90 eV[18] while the ionization potentials of toluene $Cr(CO)_3$, toluene $Mo(CO)_3$ and toluene $W(CO)_3$ are 7.40 eV, 8.13 eV and 8.14 eV,

respectively. The ionization potential of arenes varies with their substituents, while the ionization potential of arene metal tricarbonyls is rather independent of the substituents. The ionization potentials of the molybdenum and wolfram derivatives are almost equal but higher than those of the corresponding chromium derivatives.

a) Quantitative values were not obtained for 1,3,5-$C_6H_3(CH_3)_3W(CO)_3$.

The stretching frequencies of coordinated carbonyl ($\tilde{\nu}_{CO}$) of arenetricarbonylchromium, -molybdenum and -wolfram in 1,2-$C_2H_4Cl_2$ are also presented in Table 3. An increase in the number of methyl groups in the coordinated arene gives rise to a decrease in the CO-stretching frequency, which indicates an enhancement of the back-donation of metal $d\pi$ electron toward coordinated carbonyl groups. For the same arene, the CO-stretching frequency shows a shift toward lower frequency in the order W>Mo>Cr. The NMR signals of methyl-proton presented in Table 4 also support an enhanced charge-transfer from coordinated arene to carbonyl groups in the order W>Mo>Cr.

Table 3. The charge-transfer excitation energies ($h\nu_{CT}$) in the TCNE molecular complexes, and the ionization potentials (I_p) and CO-stretching frequencies ($\bar{\nu}_{CO}$) of the arenetricarbonyl-chromium, -molybdenum and -wolfram

a) Center of gravity of the multiplet. b) Ref. 19. In Ref. 19, the NMR peaks in deuterochloroform were given. c) Ref. 20. In Ref. 20, no details of the observation were presented. However the plots given in a graph of the chemical shifts of protons in the complexes are in good agreement with those observed in the present work.

An upfield shift of phenyl-proton observed in the coordinated arenes arises from a quenching of the ring current upon the formation of molecular orbitals between the central metal atom and its coordinated arene. This effect is enhanced in the order Cr> W>Mo. Such an upfield shift has been observed also in the ^{13}C NMR of ring carbons of the corresponding mesitylene metal tricarbonyls.[21]

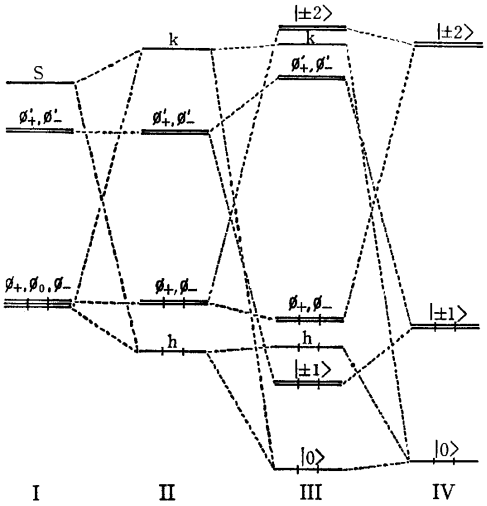

Fig. 4. The energy levels of the arene metal tricarbonyls (schematic).
I: The outer orbitals of the central metal.
II: The ϕ_0 and s orbitals are hybridized.
III: The molecular orbitals formed (Each molecular orbital is characterized by its predominant component).
IV: The π-orbitals of arene.

Since an increase in the charge density on carbonyl groups in arenetricarbonylmolybdenum and -wolfram causes no enhancement of the molecular-complex formation with electron acceptor, the molecular-complex formation cannot be attributed to a charge-transfer interaction between the carbonyl groups and the acceptor. Arenetricarbonylchromium forms a molecular complex with 1,3,5-TNB in "face-to-face" stack of the counter benzene rings, and thus an increase in the intramolecular charge migration from arene to carbonyl groups in arenetricarbonylmolybdenum and -wolfram inhibits the formation of the 1,3,5-TNB molecular complexes.

An increase in the number of methyl groups in coordinated arene promotes the intramolecular charge migration. However, the ionization potential of arene metal tricarbonyls in the TCNE molecular complexes is almost independent of the methyl substitutions. This indicates that the molecular orbital involved in an intermolecular charge transfer arising from the formation of TCNE molecular complexes is different from the molecular orbital participating in the intramolecular charge migration from coordinated arene to carbonyl groups.

The antibonding molecular orbitals predominantly localized on metal d orbitals are given by

$$\phi_+ = -\frac{1}{\sqrt{3}}\{\sqrt{2}|d_{-2}> + |d_{+1}>\}$$

$$\phi_- = \frac{1}{\sqrt{3}}\{\sqrt{2}|d_{+2}> - |d_{-1}>\}$$

$$\phi_0 = |d_0>$$

$$\phi_+' = -\frac{1}{\sqrt{3}}\{|d_{-2}> - \sqrt{2}|d_{+1}>\}$$

$$\phi_-' = \frac{1}{\sqrt{3}}\{|d_{+2}> + \sqrt{2}|d_{-1}>\},$$

where $|d_0>$, $|d_{\pm1}>$ and $|d_{\pm2}>$ are the basis set for C_3 symmetry axis. By the ligand field of carbonyl groups, ϕ_+, ϕ_- and ϕ_0 are stabilized by $2\varepsilon_\pi$ for π back-donation while ϕ_+' and ϕ_-' are destabilized by $\varepsilon_\sigma 3/2$ for σ donation. Thus a splitting between (ϕ_+, ϕ_-, ϕ_0) and (ϕ_+', ϕ_-') is $(3/2\varepsilon_\sigma + 2\varepsilon_\pi)$, which is approximately a half of the ligand field splitting in the corresponding metal hexacarbonyl. The molecular orbitals formed in the arene metal tricarbonyl are shown in a schematic fashion as in Fig. 4.

The top filled degenerate molecularo rbital pair of benzene is $|\pm1>$ and the lowest vacant degenerate molecular orbital pair is $|\pm2>$. Thus $|d_{\pm1}>$ can accept an electronic charge from $|\pm1>$, and $|d_{\pm2}>$ can donate an electronic charge into $|\pm2>$. Since the overlap $<d_{\pm1}|\pm1>$ is greater than $<d_{\pm2}|\pm2>$, a charge transfer from $|\pm1>$ toward $|d_{\pm1}>$ is predominant. 1,3,5-TNB can accept a $d\pi$-electronic charge in the $|\pm2>$ orbital of the coordinated arene

(The values for toluene and dimethylaniline were directly observed by Turner and his coworkers[25] and the value for mesitylene was determined by Watanabe.[26])

in the chromium derivatives. The methyl-proton signal exhibits an upfield shift in the chromium and molybdenum derivatives while it shows a downfield shift in the wolfram derivatives. This indicates that a charge transfer from $|\pm1>$ to $|d_{\pm1}>$ is exclusive in the wolfram derivatives while the charge transfer from $|d_{\pm2}>$ to $|\pm2>$ cannot be eliminated in the chromium and molybdenum derivatives. The resultant intramolecular charge migration from coordinated arene to carbonyl groups is enhanced in the order W>Mo>Cr as revealed by the CO-stretching frequency. Since an electronic charge in $|\pm1>$ of the coordinated arene is transferred into $|d_{\pm1}>$ of the central metal, the coordinated arene displays chemical properties which the corresponding free arene can exhibit only when substituted by more electron-withdrawing groups. The orbital ϕ_0 is not directly participating in the intramolecular charge migration, and thus less depends upon methyl substitutions in the coordinated arene. The energy of ϕ_0, however, is stabilized as a result of the countercurrent intramolecular charge transfers in the case of the chromium and molybdenum derivatives while destabilized for a one-way intramolecular charge transfer from arene to metal in the case of the wolfram derivatives. In fact, the observed ionization potentials of arene metal tricarbonyls in their TCNE molecular complexes were 7.4 eV, 8.1 eV and 8.1 eV for chromium, molybdenum and wolfram, respectively (Table 3), while the $d\pi$-ionization potentials of CrI and MoI are estimated as 3.97 eV and 4.92 eV and are lower than 8.46 eV of WI.[22]

The oxidation state of the central metal atom in the arene metal tricarbonyls is zero, and thus the energy of 4s orbital should be comparable to that of 3d orbital.[23] Although the σ bond formation between metal and carbonyl groups raises the energy of 4s orbital, a participation of 4s orbital in the outer-shell electronic structure of arene metal tricarbonyl could be sizable.[24] A mixing between ϕ_0 and 4s gives rise to an extra stabilization of the occupied counterpart orbital, which extends in a space between coordinated arene and carbonyl groups. TCNE accepts an electronic charge of this occupied hybrid orbital upon molecular-complex formation.

Figure 5 shows the He (584 Å) photoelectron spectra of toluene $Cr(CO)_3$, mesitylene $Cr(CO)_3$, and dimethylaniline $Cr(CO)_3$. The lowest ionization is attributed to an electron detachment from the filled molecular orbital predominantly localized on the metal d orbitals. A splitting of d orbitals $\phi_\pm$ and ϕ_0 was observed, although a more resolved splitting of d orbitals in some other transition-metal sandwich complexes was recently reported.[27,28] The spectrum also indicates that the top filled orbitals of the coordinated arene are more stabilized than those of the corresponding free arene.

Methyl substitutions in the coordinated arenes do not change the ionization potentials of arene metal tricarbonyls, whereas the substitutions reduce the stability of the molecular complexes with TCNE. This might be due to a steric hindrance of the methyl groups introduced to the coordinated arene. The

molecular complexes with TCNE are the most stabilized in the molybdenum derivatives, although the intramolecular charge migration increases in the order W>Mo>Cr and the ionization potentials of the molybdenum and wolfram derivatives are almost equal. This should arise from a high charge density on the molybdenum occupied hybrid orbital.

The authors would like to thank Mr. Yoshio Niwa, National Chemical Laboratory for Industry, for the measurements of He (584 Å) photoelectron spectra.

Mechanism of Racemization of Octahedral Silicon(IV) Complexes with Various β-Diketones in Organic Solvents

Tomoaki INOUE,* Junnosuke FUJITA,** and Kazuo SAITO

Chemistry Department, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received December 10, 1974)

Silicon(IV) complexes of 4 kinds of β-diketonate have been resolved and their racemization has been kinetically studied in 1,1,2,2-tetrachloroethane (TCE) and acetonitrile (AN) at 30 to 80 °C. Ultra-violet absorption spectroscopy and isotopic exchange studies with labelled ligands verified intra-molecular mechanism. A similar rate formula to that for the tris(acetylacetonato)silicon(IV)[1] was obtained: $k_0=k_1+k_2$[acid or base]. Increase in basicity of the ligand decreases the rate. Introduction of methyl group on the central carbon of the six-membered chelate ring markedly enhanced the racemization. It seems as if the intermediate species with a unidentate ligand tends to take *trans* form around the C=C axis and retards the recombination, giving rise to bigger k values. Mechanism of acid and base catalysis was also discussed.

In a previous paper we gave the results of kinetics of racemization of tris(acetylacetonato)silicon(IV) [Si(acac)$_3$]$^+$ in 1,1,2,2-tetrachloroethane (TCE) and acetonitrile (AN), and postulated an intra-molecular mechanism through an intermediate with a unidentate ligand.[1] This paper deals with further results of kinetic studies of racemization of some tris(β-diketonato)silicon(IV), with aims of examining the influence of substituents on the chelate rings upon the rate, and of verifying the proposed reaction mechanism.

The ligands are acetylacetone homologues with ethyl and phenyl on α-carbon and methyl on the central carbon. The names and abbreviated symbols are given in Table 1.

Experimental

Materials. *The ligands*: Hdprm, Hdbm and Hmedprm were obtained by the Claisen condensation of the corresponding ketones and esters.[2] Hacac was methylated with methyl iodide in the presence of potassium carbonate and acetone to give Hmeacac.[3] All the products were identified by boiling point measurement, elementary analysis and UV and PMR spectrometry.

The complexes: Dilthey's method was employed for the synthesis of the tris-type complexes. They were obtained in the form of hydrogendichlorides (2 g), which were dissolved in water (30 ml) and converted into perchlorates by adding sodium perchlorate monohydrate (*e.g.* 2 g). The product was dried, dissolved in chloroform (*e.g.* 5 ml) and treated with diethyl ether (60 ml) to precipitate the anhydrous perchlorate, which was filtered off and dried. The conversion yield was *ca.* 80%. The dprm$^-$ and medprm$^-$ complexes are new compounds. Anal. [Si(dprm)$_3$]ClO$_4$: Found: C, 49.6 and H, 6.53; Calcd for $C_{21}H_{33}O_{10}ClSi$, C, 49.6 and H, 6.53%. [Si(medprm)$_3$]ClO$_4$: Found: C, 51.7 and H, 7.07%; Calcd for $C_{24}H_{39}O_{10}ClSi$: C, 52.6 and H, 7.16%.

Resolution: All the tris-type complexes were resolved for the first time. Dibenzoyl-*d*-tartrate used for [Si(acac)$_3$]$^+$[4] is the best agent. The racemic hydrogendichloride (2 g) in a mixture of 80 ml of water and 160 ml of AN was treated with the reagent (0.6 g) in 20 ml of water and 0.1 M soldium hydroxide solution (3.8 ml). Gradual addition of water (200 to 250 ml) gave colorless precipitate of the diastereoisomer (or jelly precipitate for meacac$^-$ and medprm$^-$ complexes). Addition of sodium perchlorate monohydrate (*ca.* 3 g) to the filtrate gave crystalline (+)$_D$-enantiomer of the complex (1 g), which was dissolved in AN (35 ml) and recrystallized by adding diethyl ether (25 ml), to give anhydrous perchlorate.

All the (+)$_D$-enantiomers gave plus and minus CD peaks from longer to shorter wavelength in the π–π^* transition region and assigned to Λ configuration.[5] The CD peaks are at 306, 400, 324 and 325 nm and the $\Delta\varepsilon$ values of the perchlorates were 30 to 70, 50 to 70, 20 to 30 and 5 to 10, for dprm$^-$, dbm$^-$, meacac$^-$ and medprm$^-$ complexes respectively. The percentage of resolution seems to be *ca.* 10%.

Other reagents: The Hdbm-^{14}C was prepared by Mr. Matsuzawa.[6] Labelled Hmeacac was synthesized from Hacac and methyl iodide-^{14}C similarly to the unlabelled ligand. Acetonitrile (AN) was dehydrated with diphosphoruspentoxide and distilled with potassium carbonate. The water content was *ca.* 3×10^{-3} M. TCE was dehydrated with calcium sulfate and distilled. The water content was 5×10^{-3} M. Mono- and trichloroacetic acid were sublimed *in vacuo*. Pyridine was dehydrated with calcium sulfate and distilled *in vacuo*. The water content was less than 0.01 M.

Procedure for kinetic runs and the measurements are the same as those in Ref. 1.

Results and Discussion

All the complexes are stable in TCE and AN under the given conditions. The absorption spectrum did not change during the measurements, regardless of the concentration of dissolved water and the excessive ligand, and of the presence of acid or base. Hence the change in CD strength or the rotatory power is exclusively due to the racemization of the resolved species. The rate of decrease in rotatory power obeys first order rate law and is expressed by first order rate constant, k_0 which is expressed by Eq. (1)

$$k_0 = 1/2t(\ln[\alpha_0/\alpha_t]) \quad (1)$$

where t is the lapse of time in seconds, and α_0 and α_t are the rotations at Na-D line or 405 nm or CD strength at the plus CD peak in near UV region at time zero and t, respectively. The k_0 values were independent of the complex concentration for 0.001 to 0.02 M in TCE and AN.

The ligand isotopic exchange rate was studied with [Si(dbm)$_3$]$^+$ and Hdbm-^{14}C, and [Si(meacac)$_3$]$^+$ and

	AN	2.4×10^{-5}	24±1	−7
$[Si(dbm)_3]^+$	TCE	1.1×10^{-6}	32±1	14
	AN	5.5×10^{-5}	25±1	−1
$[Si(meacac)_3]^+$	TCE	2.0×10^{-4}	34±1	30
	AN	1.8×10^{-3}	28±1	14
$[Si(medprm)_3]^+$	TCE	4.4×10^{-5}	28±1	9
	AN	4.9×10^{-4}	25±1	3

Figs. 1 and 2 show the dependence of the rate constants upon the concentrations of water and free ligand in TCE and AN. It is clear that these concentrations do not affect the rate.

The racemization rate increases in the presence of mono- and trichloroacetic acid in TCE and of pyridine in AN. The influence is exemplified in Figs. 3 and 4. The diagrams are straight lines with intercepts, and k_0 is expressed by Eq. (2).

$$k_0 = k_1 + k_2[\text{acid or base}] \quad (2)$$

The k_1 *path.* Table 2 summerizes the rate constants k_1 and the activation parameters obtained from the experiments at 30 to 80 °C. The basic feature of the kinetics of racemization of the present Si(IV) complexes is very similar to that of previously reported $[Si(acac)_3]^+$ [1]. We postulated an intramolecular mechanism involving an intermediate with a unidentate acetylacetonate ligand and considered the break of the first Si–O bond as the rate-determining step. The present data in Table 2 seem to give support for the proposed mechanism.

If the break of the Si–O bond were the rate-determining step, the k values would decrease and the $\Delta H^{\neq}$ values increase as basicity of the ligand increases. The basicity of the ligands is best indicated by the pK values of their enol forms in the given solvents. However, only limited information is available concerning the pK values of various β-diketones in enol form. These values (pK_e) in water at 20 °C[7] are given in Table 1.

So far as the complexes with acac$^-$, dprm$^-$ and dbm$^-$ (hydrogen atom on the R′ position) are concerned, the k_1 values in TCE decrease slightly with increase in pK_e values, and the activation parameters

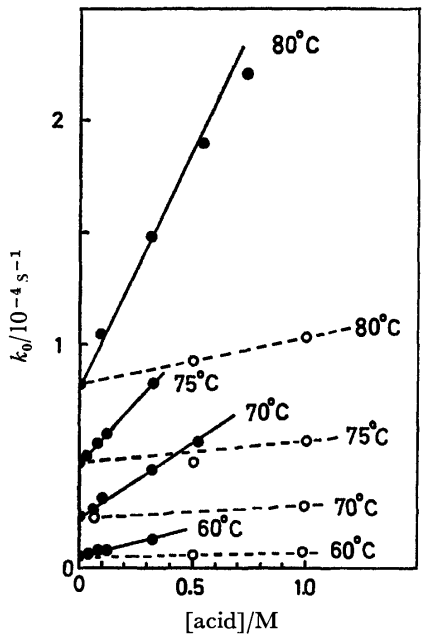

Fig. 3. Influence of acid concentration upon the racemization rate of [Si(dbm)$_3$]$^+$ in TCE.
Open marks with broken lines, $CH_2ClCOOH$; full marks with solid lines, CCl_3COOH.

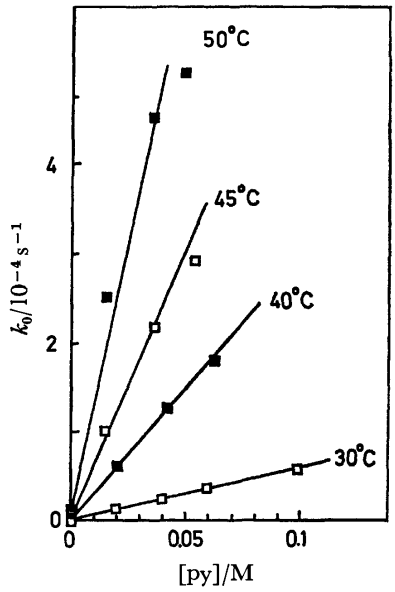

Fig. 4. Influence of concentration of pyridine on the racemization rate of [Si(dprm)$_3$]$^+$ in AN.

are similar to one another. On the other hand, the complexes with meacac$^-$ and medprm$^-$ (methyl on the R′ position) give much greater k_1 values than the corresponding complexes with hydrogen on R′. The pK_e value of Hmeacac is significantly larger than that of Hacac, and the big k_1 value should be interpreted otherwise.

Whenever alkyl groups are introduced on the R′ position of β-diketones, the keto-enol tautomeric equilibrium is shifted in favor of the keto form,[7] and the enol tautomer tends to take *trans* form around the C=C double bond axis.[8] This fact was also observed by PMR spectroscopy for Hmeacac,[9] and the conversion rate from *cis* to *trans* was reckoned to be very big.[10]

If the β-diketonate anion in the form of unidentate ligand in the intermediate state could be compared to the enol tautomer of the protonated ligand, the unidentate meacac$^-$ and medprm$^-$ ligand would tend to take *trans* form as shown in Fig. 5. Such a rearrangement would decrease the probability of the recombination of the ligand, to facilitate the racemization. When the k_1 value is written as Eq. (3) on the assumption of a stationary state,

$$k_1 = k_a(k_b/[k_{-a}+k_b])(k_c/[k_{-b}+k_c]) \quad (3)$$

the ligands with methyl on R′ would decrease the k_{-a} value to increase k_1. Comparison of $\Delta H^{\neq}$ and $\Delta S^{\neq}$ values between Hacac and Hmeacac complexes clearly shows that the labilization comes from the entropy contribution. The latter has bigger $\Delta H^{\neq}$ than the former, reflecting the bigger pK_e value of the ligand. (Comparison between dprm$^-$ and medprm$^-$ complexes is not useful, because pK_e value of the latter ligand is not known.) Thus we conclude that the present data gave concrete support for the reaction mechanism proposed before.

Either Si–O or C–O bond can be broken at the rate-determining step. Pinnavaia, Collins and Howe studied the NMR spectra of various alkyldimethylsilyl ether of Hacac in enol form and found a very rapid intramolecular rearrangement in *cis*-R(CH$_3$)$_2$Si(acac), which interchanges the allylic and acetyl methyl groups on the acac moiety.[11] The Arrhenius activation energy for the interchange was measured at −36 to +38 °C to be 13.8±0.5 kcal per mol. These are tetrahedral silicon(IV) compounds and the results may reflect the ease of homolytic cleavage of Si–O bond. Hence they should not be directly applied to our octahedral silicon(IV). Nevertheless we tend to consider that Si–O bond would be broken at the rate-determining step, although nothing decisive could be stated at the present stage.

In AN the racemization is faster than in TCE, and

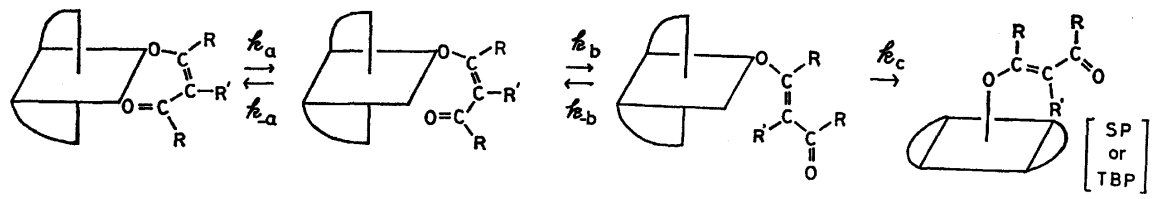

Fig. 5. Plausible racemization mechanism.

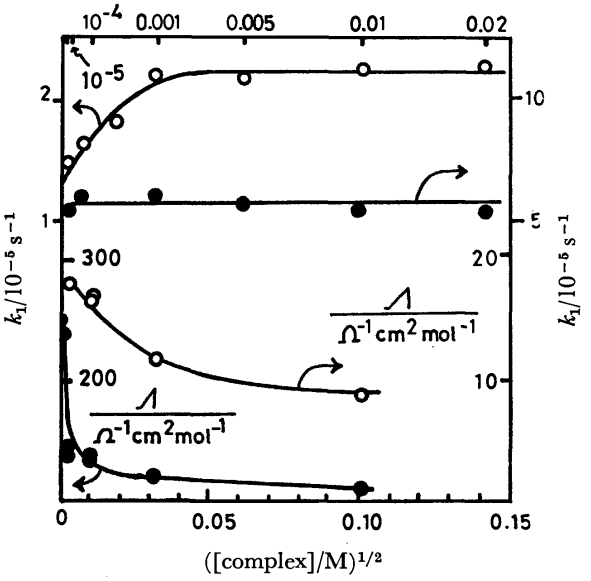

Fig. 6. Dependence of the molar conductivity and the racemization rate constant on the complex concentration of $[Si(dbm)_3]ClO_4$.
Upper: Rate constant k_1 in TCE(○) at 70° and in AN(●) at 50 °C. Lower: conductivity in TCE(○) and in AN(●) at 20 °C.

the $\Delta H^{\neq}$ values are smaller by *ca.* 6 kcal per mole. This fact indicates that the break of Si–O bond is facilitated in AN with dielectric constant 37.5. In a similar racemization of $[Ge(acac)_3]^+$ in various organic solvents,[12] we have proposed solvent-assisted dissociation of Ge–O bond, on the basis of a good correlation between Gutmann's donor number and the rate constant. Such a contribution cannot be excluded in the present racemization. However, silicon(IV) has a smaller octahedral ionic radius (0.47 Å) than germanium(IV) (0.53 Å), and the approach of a solvent molecule to Si(IV) would be more difficult than to Ge(IV). Hence solvent-assisted bond break seems less feasible for the present silicon(IV) complexes. Increase in racemization rate accompanied by the introduction of methyl on R′ could be similarly interpreted to that in TCE.

When the complex concentration was less than 0.001 M, the k_1 value decreased with decrease in concentration, as exemplified in Fig. 6. The decrease in molar conductivity with increase in complex concentration in TCE and AN is also illustrated in Fig. 6. The complexes seem to be present almost perfectly as ion pairs in more than 10^{-4} and 10^{-3} M solution in TCE and AN, respectively. The change in k_1 must reflect the state of the complexes. The constant values in more than 10^{-3} M solutions must be those of ion pairs. (The data in Tables 2 and 3 are so, too.) The racemization must proceed mostly in the form of ion pairs.

The k_2 *path.* The second order rate constants and activation parameters are shown in Table 3. Increase in racemization rate in the presence of acid was seen only in TCE. This effect must be due to the proton catalysis.[1] The absence of acid catalysis in AN may be due to hydrogen bond formation between the acid and AN.[13] Difference in $\Delta H^{\neq}$ values between k_1 and k_2 path is larger in most complexes in Table 2 than that in $[Si(acac)_3]^+$. We postulated in our previous paper that the protons are attached to the coordinated oxygen atom and facilitate the break of Si–O bond at the rate-determining step.[1] Ligands of the complexes in Table 2 are more basic than $acac^-$ and are subject to proton catalysis more remarkably. The stronger acid, trichloroacetic gives bigger influence than the weaker acid monochloroacetic does. Introduction of methyl on R′ increases the rate, and this fact can be interpreted by Eq. (3). Since the complexes are almost entirely in the form of ion pairs in the solutions used for the present study, interaction of protons with the complexes is not electrostatically implausible.

Base catalysis is only seen in AN. The absence of such an effect in TCE would be due to the hydrogen bond formation between pyridine and TCE.[14] The dbm^- complex did not give k_2 path up to 0.05 M pyridine for 0.001 to 0.02 M complex. Pyridine can

attack the Si(IV) ion as well as the ligand as a nucleophile. However, the $\Delta H^{\ddagger}$ values for the k_1 and k_2 paths in AN do not differ much. Hence pyridine seems to occupy the vacant coordination site of the intermediate with a unidentate ligand, to decrease the k_{-a} of Eq. (3). The dbm^- ligand is bulky and may hinder the approach of pyridine to the vacant site.

The authors thank the Ministry of Education for Grand-in-aid.

(Received December 25, 1974)

Replacement of the coordinated *trans*-2-butene in *trans*(*N*,olefin)[PtCl(L-pro)(*S,S-trans*-2-butene)] (L-pro= L-prolinate anion) by various olefins in acetone has been studied at −20 to +23 °C. The rate is proportional to concentrations of the complex and the olefin nucleophile. No solvent path is observed. The second order rate constant k_2 (10^{-4} to 10^{-1} M^{-1} s^{-1} at 8.0 °C) can be the measure of each substitution. The $\Delta H^{\neq}$ is around 10 kcal/mol, and $\Delta S^{\neq}$ ranges from −25 to −46 cal/mol K. Substitution of *cis*-2-butene for the asymmetrically coordinated *trans*-2-butene-^{3}H gives equal k_2's on the measurement of CD strength and on that of isotopic exchange. Similar substitution of *trans*-2-butene gives significantly larger k_2 on isotopic exchange than that on CD measurement, indicating sterically selective substitution with retention of configuration. Substitution of ethylene derivatives with various groups on the carbon atoms gives different k_2's depending on the kind of substituents. The steric interaction between the olefin nucleophile and the coordinated ligands seems to be a very important factor in determining the ease of substitution.

In a previous paper we reported the inversion of coordinated olefins in the diastereoisomer *trans*(*N*, olefin) [PtCl(L-pro)(*S,S-trans*-2-butene)] (L-pro=L-prolinate anion) and its 2-methyl-2-butene analogue, and proposed an S_N2 mechanism involving nucleophilic attack of added olefin molecules.[1] We have attempted to verify the mechanism by use of various olefin nucleophiles including *cis*- and *trans*-substituted ethylene derivatives. On comparing the rates of olefin exchange measured by CD spectroscopy and by isotopic exchange technique with *trans*-2-butene-^{3}H, a novel stereoselectivity was detected in the substitution of *trans*-2-butene for the coordinated *S,S*- and *R,R-trans*-2-butene-^{3}H in the complex in acetone. This paper deals with the verification, and the discussion on mechanism of stereoselectivity with reference to the steric interaction between the incoming olefin molecule and the coordinated ligands.

Experimental

Materials. *trans*(*N*,olefin)[(L-pro)(*S,S-trans*-2-butene)] was prepared as in Ref. 2. *trans*-(*N*,olefin)[PtCl(L-pro)(*S,S*- or *R,R-trans*-2-butene-^{3}H)]: *trans*-2-Buene-^{3}H was synthesized by the known method,[3] slightly modified to suit for a radiochemical synthesis. Lithium aluminum hydride (1.08 g) containing lithium aluminum tritide (5 mCi, 1.66 mg, New England Nuclear Co.) suspended in diethyleneglycoldiethyl ether was added to a slight excess of *trans*-1,4-dibromo-2-butene in the same solvent in a current of nitrogen. The product, *trans*-2-butene-^{3}H was trapped in dry ice-acetone (Chemical yield 0.8 g, radiochemical yield 16%). The ligand was added to *trans*(*N*,olefin)[PtCl(L-pro)(ethylene)] in acetone. The product was resolved[2] to give *trans*(N,olefin)-[PtCl(L-pro)(*S,S*- or *R,R-trans*-2-butene-^{3}H)]. The purity of the final product (*ca.* 2×10^{-2} μCi/mg) was examined by UV absorption spectrum.

Other Reagents: Extra pure grade *trans*-2-butene and *cis*-2-butene were used without further purification. The purity was checked by gas chromatography. Chemical grade *trans*-1,4-dichloro-2-butene, *cis*-2-butene-1,4-diol, and *cis*- and *trans*-1,2-dichloroethylene were distilled under a reduced pressure. Maleic and fumaric acid were recrystallized from acetone. *cis*-1,4-Dichloro-2-butene[4] and *trans*-1,4-dibromo-2-butene[5] were synthesized by the ordinary method.

Procedure. *Kinetic Runs for Loss of Optical Activity*: The complex solution in acetone was cooled, and a certain amount of cooled olefin solution in acetone added with a pipet. The solution was transferred into the cell box of the spectrometer which had been thermostated at the reaction temperatures (8.0, 17.0 and 23.6±0.3 °C). The $\Delta\varepsilon$ value at 370 nm was continuously recorded. The concentrations of the complex and the olefins at the measured temperature were calculated by taking the density of acetone at the given temperatures into consideration.

Kinetic Runs for Isotopic Exchange and Accompanied Loss of Optical Activity: The reaction mixture was similarly prepared and dispensed into 5—9 small glass-stoppered test tubes. They were kept in a thermostat at 8.0 or −20.0 (±0.3) °C, and taken out one by one at appropriate time intervals. The reaction was quenched by immersing the tubes in liquid nitrogen. Free olefin and acetone were evaporated off *in*

vacuo at dry ice-acetone temperature and room temperature, respectively. The residue was dissolved in ethanol and its absorption spectrum, CD strength and β-activity were measured. The decrease in CD strength with time obeyed first order rate law as shown in Fig. 1.

Calculation of the Exchange Constant: In our experiments the complex concentration was very small as compared with the olefin solution. Hence McKay formula can be simplified, and the isotopic exchange constant was approximated by the first order kinetic formula Eq. (1) (Fig. 1)

$$k_{0(\mathrm{iso})} = -\ln(1-F)/t \qquad (1)$$

where F is the fraction of reaction expressed by $(x_t-x_\infty)/(x_0-x_\infty)$, x's being the specific counting rate of the recovered complex.

Apparatus. Circular dichroism was measured with a JASCO Model ORD/UV-5 Spectrometer with CD attachment. Absorption spectra were recorded with a Hitachi 323 Spectrometer. β-Activity of ^3H was recorded with a Nuclear-Chicago Unilux II-A liquid scintillation counter. A Komatsu-Yamato Coolnics and Haake KT 33 thermostat were used.

Results

Isotopic Exchange. The reaction mixtures gave equal absorption spectra throughout given kinetic runs, and the recovered complexes gave almost identical absorption spectrum with the original complex in ethanol. The CD strength at 370 nm in ethanol and the β-activity of the recovered complexes decreased as the reaction vessels were kept longer in the thermostat. All the data of isotopic exchange obeyed the kinetic law of Eq. (1). Hence the $k_{0(\mathrm{iso})}$ is the first order rate constant with respect to the complex concentration. The k_0 values are proportional to the concentration of added olefins (Fig. 2) and Eq. (2) is given in the range 0.05 to 0.3 M.

$$k_{0(\mathrm{iso})} = k_{2(\mathrm{iso})}[\mathrm{olefin}] \qquad (2)$$

The CD strength of the recovered complex also obeyed first order rate law with respect to the complex concentration and the rate constant $k_{0(\mathrm{cd})}$ is the first order rate constant. When the olefin concentration of the reaction mixture was changed, Eq. (3) was substantiated.

$$k_{0(\mathrm{cd})} = k_{2(\mathrm{cd})}[\mathrm{olefin}] \qquad (3)$$

The k_2's are second order rate constants, and tabulated in Table 1.

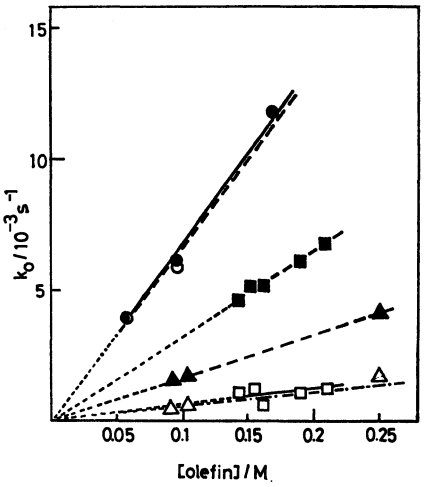

Fig. 2. Dependence of the rate constant k_0 upon the olefin concentration in acetone.
Open marks by CD measurement ($k_{0(\mathrm{cd})}$) and full marks by isotopic exchange ($k_{0(\mathrm{iso})}$). —○— and --●-- substitution of *cis*-2-butene for *S,S-trans*-2-butene at −20 °C; —□— and --■-- substitution of *trans*-2-butene for *S,S-trans*-2-butene at 8.0 °C; —△— and —▲— substitution for *R,R-trans*-2-butene at 8.0 °C. (The free *trans*-2-butene contained 1.0% *cis*-2-butene, and the individual plots were corrected for the contribution of the *cis*-isomer.)

Substitution. When those olefins in Table 3 were added to the *trans*(*N*,olefin)[PtCl(L-pro)(*S,S-trans*-2-butene)] in acetone, the UV absorption changed little, whereas the CD strength at 370 nm decreased. The final CD pattern was almost equal to that of *trans*(*N*,olefin)[PtCl(L-pro)(ethylene)], which gives only the vicinal effect of coordinated L-prolinate. The rate of decrease in CD strength obeyed first order rate law with respect to the complex concentration, and the rate constant $k_{0(\mathrm{cd})}$ was proportional to the olefin concentration. Second order rate constants $k_{2(\mathrm{cd})}$ can be calculated as in Eq. (3). They are listed in Table 3 together with the activation parameters obtained by the measurements at 8.0, 17.0 and 23.6 (±0.3 °C).

Discussion

Replacement of olefins in *trans*(*N*,olefin)[PtCl(L-pro)(olefin)] complexes by other olefins gave little change in the visible and UV absorption spectrum. Throughout the present isotopic exchange and CD measurements, the absorption spectra of the reaction mixtures and the recovered species gave little change. The geometrical isomers *trans*(*O*,olefin)[PtCl(L-pro)(olefin)] give different absorption patterns in UV region. Hence we can conclude that the essential structure of the complex remained unchanged throughout the present experiments, and only substitution of olefins for the coordinated olefin has taken place.

Nature of the decrease in CD strength. The substitution reaction of Eq. (4) with *cis*-2-butene

[PtCl(L-pro)(*S,S-trans*-2-butene)] + *cis*-2-butene
$\rightleftharpoons$ [PtCl(L-pro)(*cis*-2-butene)] + *trans*-2-butene (4)

gave equal $k_{2(\mathrm{iso})}$ and $k_{2(\mathrm{cd})}$ (Table 1). Hence the

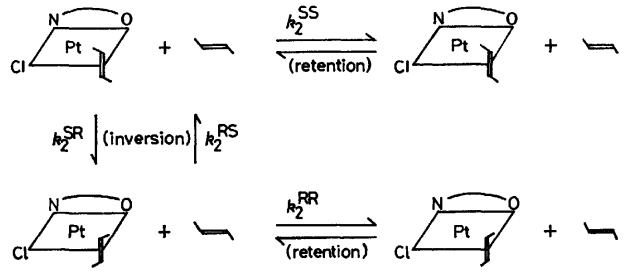

Fig. 3. Individual routes of the substitution of *trans*-2-butene for *S,S*- and *R,R-trans*-2-butene in the complex. Arcs represent L-prolinate. (*cf.* the note for Fig. 4).

decrease in CD strength at 370 nm should be exclusively due to the intermolecular substitution. Our proposal in Ref. 1 is thus verified. It is also made clear that there is no local proton exchange between free and coordinated olefin molecules.

Stereoselectivity. In the reaction between *trans*-2-butene and *trans*(*N*,olefin)[PtCl(L-pro)(*S,S-trans*-2-butene)], $k_{2(\mathrm{iso})}$ is significantly bigger than $k_{2(\mathrm{cd})}$. The former includes substitutions both with retention and with inversion of configuration of coordinated olefin, and the latter does only substitution with inversion of configuration. The same is true for the replacement of coordinated *R,R-trans*-2-butene. Hence the reactions are summerized as shown in Fig. 3. When the second order rate constants of individual routes of substitution between free *trans*-2-butene and coordinated *S,S*- and *R,R-trans*-2-butene are named as in Fig. 3, the following relationships are given between the individual k_2's and the observed k_2's. (The subscripts *SS* and *RR* denote the configuration of *trans*-2-butene in the original complexes.)

$$k_{2(\mathrm{iso})SS} = k_2{}^{SS} + k_2{}^{SR} \quad (5)$$

$$k_{2(\mathrm{iso})RR} = k_2{}^{RR} + k_2{}^{RS} \quad (6)$$

$$k_{2(\mathrm{cd})SS} = k_2{}^{SR} + k_2{}^{RS} \quad (7)$$

$$k_{2(\mathrm{cd})RR} = k_2{}^{RS} + k_2{}^{SR} \quad (8)$$

When the ratio of $k_2{}^{SR}$ and $k_2{}^{RS}$ is defined as Eq. (9),

$$K_{(SR)} = k_2{}^{SR}/k_2{}^{RS} \quad (9)$$

the $K_{(SR)}$ should be related to the CD strength due to the coordinated olefin in the equilibrated solution. The CD pattern of the reaction mixtures at infinite time is practically identical with that of non-prochiral olefin complexes such as *trans*(*N*,olefin)[PtCl(L-pro)(ethylene)], and $K_{(SR)}$ can be approximated to be unity. Hence Eq. (10) is substantiated.

$$k_{2(\mathrm{cd})SS} = 2k_2{}^{SR} = 2k_2{}^{RS} = k_{2(\mathrm{cd})RR} \quad (10)$$

Table 2 gives the rate constants calculated in accordance with Eqs. (5) to (8). The $k_2{}^{SR}$ and $k_2{}^{RS}$ values obtained by use of diastereoisomers of *trans*(*N*,olefin)[PtCl(L-pro)(*S,S*- or *R,R-trans*-2-butene)] as substrate coincide with each other, indicating equal probability of inversion. The ease of substitution reaction with retention of configuration seems to differ from each other so that $k_2{}^{SS}$ is *ca.* twice as big as $k_2{}^{RR}$. The ratio of second order rate constants with retention and with inversion of configuration are *ca.* 10 and 5, respectively for the complexes with *S,S*- and *R,R*- *trans*-2-butene ligand.

This fact indicates that both diastereoisomers are

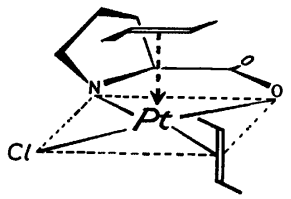

Fig. 4. Probable nucleophilic attack of *trans*-2-butene towards the complex.
The coordinated *trans*-2-butene was claimed to be rotating around the bond axis between Pt(II) and C=C[6]; the ligand is so illustrated as to make the configuration clear.

subject to olefin exchange more easily with retention of configuration than with inversion of configuration. Such a stereoselectivity is of a novel kind, and the present result is the first example. The reason why such a stereoselectivity is observed cannot be made clear at the present stage. The kinetic formulae have no term for the solvent path, and solvent molecules do not seem to give significant contribution. Difference in affinities between *trans*-2-butene nucleophile and the diastereoisomers is quite unlikely, and some kind of steric effect between the nucleophile and the coordinated ligands should be responsible. The $\Delta H^{\ddagger}$ values for $k_2{}^{SS}$ and $k_2{}^{SR}$ are 8.2 and 9.1 kcal mol^{-1} and the $\Delta S^{\ddagger}$ values are −38 and −40 cal mol^{-1} K^{-1}, respectively. These figures are only approximate, because measurements were made at two temperatures.

Figure 4 shows the possible mode of approach of the olefin nucleophile to the complex. (It was claimed that the coordinated olefin is rotating at a high rate around the metal–(C=C) axis[6]; the figure was so drawn as to make the configuration of the ligand clearer.)

Substitution. Whenever a large excess of olefin is added to the *trans*(*N*,olefin)[PtCl(L-pro)(*S,S-trans*-2-butene)] solution in acetone, the coordinated olefin is replaced by the added olefin and only a negligible amount of the original complex remains after a certain lapse of time. The CD pattern of the reaction mixture at infinite time is almost identical with that of [PtCl(L-pro)(ethylene)], and no other reaction than substitution of the olefin is feasible. The substitution

of the olefins listed in Table 3 obeyed Eq. (3) and the $k_{2(cd)}$ and the activation parameters are given there.

Electronic Effect: When the k_2 values are compared with one another for either the *cis* or the *trans* olefins with one substituent on each of ethylenic carbon, an overall decrease in rate is seen in the following squence.

$-CH_3 \simeq -CH_2Cl \simeq -CH_2OH \simeq -CH_2Br > -COOH > -Cl$

Introduction of electro-nagative substituents on ethylenic carbon decreases the rate significantly. More electro-negative chlorine (3.25) decreases the rate to a greater extent than less electro-negative carboxyl[7] (2.60)(*cf.* methyl 2.50) does. Increase in electronegativity of the substituent should bring about decrease of electron density in the bonding orbital of the ethylene moiety, and thus decrease of the σ-bond strength between platinum(II) and olefin. Our previous proposal that strength of the σ-metal–ligand bond would be responsible in determining the substitution rate of olefins[1], has thus found further experimental support.

Substitution of chlorine, bromine and hydroxyl for the methyl protons of 2-butene does not give big change in k_2's. The order of k_2 change is different for the *cis*-olefins and the *trans*-olefins. The significance of k_2 can be different for the two kinds of geometrically isomeric olefin nucleophiles (see below), and no further discussion will be made at the present stage.

Steric Effect: An overall trend is seen in Table 3 that the *cis*-isomers give larger k_2 values than the *trans*-isomers do. It is also seen that increase in number of methyl groups on ethylenic carbons decreases the k_2 quite remarkably. These factors should be ascribed to some kind of steric effect at the rate-determining step.

Since the *trans*-isomers and 2-methyl-2-butene are prochiral and can bring forward stereo-selectivity as mentioned above, the $k_{2(cd)}$ value of their substitution reckons the rate of substitution with inversion of configuration. On the other hand, the *cis*-isomers, styrene and 2,3-dimethyl-2-butene are not prochiral and their k_2 values represent the real rate of substitution. Hence the k_2 values for these two series of olefins should not be directly compared. However, the ratio of k_2's for substitution with retention and those with inversion of configuration is not extremely big; *i.e.* it is *ca.* 10 for *trans*-2-butene (Table 2). Hence such comparisons should not be very unfair so far as the discussion remains qualitative.

The olefin nucleophiles in Table 3 (except those with very electro-negative groups on ethylenic carbons) could be classified into three groups according to the k_2 values. The *cis*-isomers and styrene give the biggest k_2's, 2,3-dimethyl-2-butene gives the smallest k_2, and others, *i.e.* the *trans*-isomers and 2-methyl-2-butene, give intermediate values. Members of each group seem to have common feature in their structures. The first group has substituent only on one side of the C=C bond axis and has two protons on the other side. The third group has at least one proton on one side of the axis, and 2,3-dimethyl-2-butene has no proton on either side. If the nucleophilic attack of the olefin molecule were visualized as shown in Fig. 4, the assemblage around the C=C bond axis would be responsible in determining the ease of approach to the substrate. It seems as if the number of vacant site (*i.e.* with proton) on one side of the C=C bond axis were an important factor in determining the ease of approach.

The $\Delta H^{\ddagger}$ values in Table 3 do not give useful information, because they are more or less similar to one other, when experimental errors are taken into consideration. The $\Delta S^{\ddagger}$ values do not differ very significantly from one another but could be reckoned to reflect the steric factor to some extent.

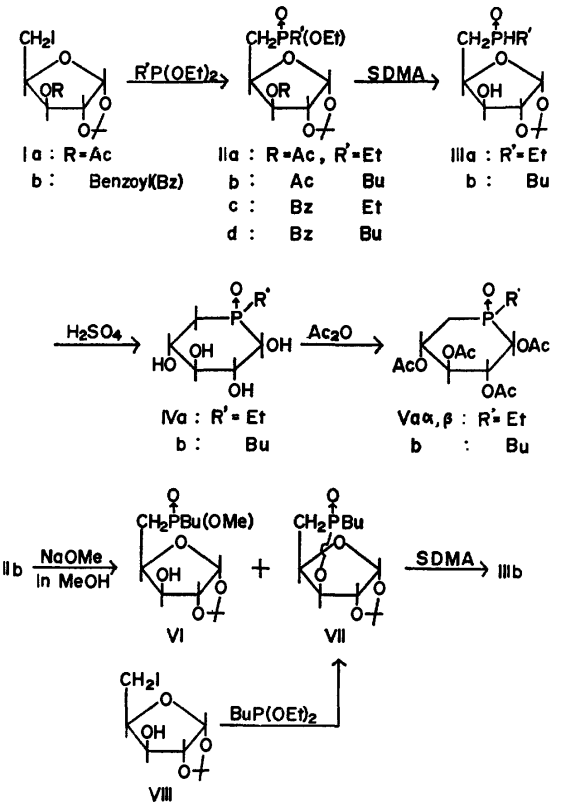
(Received February 22, 1974)

The reactions of diethyl ethylphosphonite with 3-*O*-acetyl-5-deoxy-5-iodo-1,2-*O*-isorpopylidine-α-D-xylofuranose (Ia) or 3-*O*-benzoyl-5-deoxy-5-iodo-1,2-*O*-isopropylidene-α-D-xylofuranose(Ib) afforded IIa or IIc, respectively. Similarly, using diethyl butylphosphonite in place of diethyl ethylphosphonite, IIb and IId were obtained. Treatment of IIb with methanolic sodium methoxide gave 5-deoxy-1,2-*O*-isopropylidene-5-(methoxybutylphosphinyl)-α-D-xylofuranose together with a small amount of 5-(3-*O*-cyclo-butylphosphinate)-5-deoxy-1,2-*O*-isopropylidene-α-D-xylofuranose(VII). Compound VII was also obtained from the reaction of 5-deoxy-5-iodo-1,2-*O*-isopropylidene-α-D-xylofuranose(VIII) and diethyl butylphosphonite. The reaction of IIa or IIc with sodium dihydrobis(2-methoxyethoxy)aluminate gave 5-deoxy-5-(ethylphosphinyl)-1,2-*O*-isopropylidene-α-D-xylofuranose(IIIa). Similarly, 5-(butylphosphinyl)-5-deoxy-1,2-*O*-isopropylidene-α-D-xylofuranose(IIIb) was obtained from IIb, IId, VI, and VII. Hydrolysis of IIIa and IIIb with sulfuric acid gave 5-deoxy-5-(ethylphosphinyl)-(IVa) and 5-(butylphosphinyl)-5-deoxy-D-xylopyranose(IVb), respectively. Acetylation of IVa and IVb with acetic anhydride in pyridine gave the corresponding *O*-acetates Va and Vb.

Recently, we reported the synthesis of 3-*O*-benzyl-5-deoxy-5-(ethylphosphinyl)-D-xylopyranose,[3] 5-(alkylphosphinyl)-5-deoxy-3-*O*-methyl-D-xylopyranose (alkyl; ethyl, butyl)[4] and 5-deoxy-5-(ethylphosphinyl)-D-ribopyranose,[1] sugar analoges having a phosphorus atom in the hemiacetal ring. In this paper we wish to report the syntheses of 5-deoxy-5-(ethylphosphinyl)-D-xylopyranose(IVa) and 5-(butylphosphinyl)-5-deoxy-D-xylopyranose(IVb).

Results and Discussion

In the present experiments, 3-*O*-acety-5-deoxy-5-iodo-1,2-*O*-isopropylidene-α-D-xylofuranose(Ia) and 3-*O*-benzoyl-5-deoxy-5-iodo-1,2-*O*-isopropylidene-α-D-xylofuranose(Ib) were used as the starting materials. The Michaelis-Arbuzov reaction[5] of Ia or Ib with diethyl ethylphosphonite gave, almost quantitatively, 3-*O*-acetyl-(IIa) or 3-*O*-benzoyl-5-deoxy-5-(ethoxyethylphosphinyl)-1,2-*O*-isopropylidene-α-D-xylofuranose(IIc), respectively. Similarly, the reaction of Ia or Ib with diethyl butylphosphonite gave 3-*O*-acetyl-(IIb) or 3-*O*-benzoyl-5-deoxy-5-(ethoxybutylphosphinyl)-1,2-*O*-isopropylidene-α-D-xylofuranose (IId), respectively. Reduction of IIa(IIc) or IIb(IId) with 3.3 molar equivalents of sodium dihydrobis(2-methoxyethoxy)aluminate(SDMA) in tetrahydrofuran (THF) gave, almost quantitatively,** syrupy 5-deoxy-5-(ethylphosphinyl)-(IIIa)or5-(butylphosphinyl)-5-deoxy-1,2-*O*-isopropylidene-α-D-xylofuranose(IIIb), respectively. The PMR spectrum of IIIa(IIIb) in chloroform-*d* showed a characteristic J_{P-H} value[6] of 469 Hz at δ 6.90 (470 Hz at δ 5.90); the signal disappeared on deuteration. The IR spectrum (KBr) of IIIa(IIIb) showed absorption due to a P–H group at 2350 cm^{-1} (2350 cm^{-1})[7] and absorption due to a P=O group at 1220 cm^{-1} (1220 cm^{-1}).[8] Compound IIIb was also obtained by hydrolysis of IIb and subsequent reduction. Treatment of IIb with sodium methoxide in methanol gave, in good yield, syrupy 5-deoxy-1,2-*O*-isopropylidene-5-(methoxybutylphosphinyl)-α-D-xylofuranose(VI) together with a small amount of crystalline 5-(3-*O*-cyclo-butylphosphinate)-5-deoxy-1,2-*O*-isopropylidne-α-D-xylofuranose(VII). The PMR spectrum of VI on chloroform-*d* showed P–OCH_3 (J_{P-H} = 10.5 Hz) at δ 3.56 and OH at δ 4.79 (disappearing on deuteration). The PMR spectrum of VII showed an H-3 proton signal at δ 5.18 which was at lower field than that of VI (δ 4.00). No P–OCH_3 (or P–OC_2H_5) and OH signals were found. On reduction with SDMA, VI and VII both gave IIIb in good yield. Compound VII was also obtained, almost quantitatively, by heating 5-deoxy-5-iodo-1,2-*O*-



* To whom correspondence should be addressed.

** Treatment of IId with lithium aluminum hydride[3] gave IIIb in lower yield.

isopropylidene-α-D-xylofuranose(VIII) in diethyl butylphosphonite.

Hydrolysis of IIIa or IIIb with dilute sulfuric acid (1—2%) for two hr at 80—100 °C afforded, in good yield, a hygroscopic solid, 5-deoxy-5-(ethylphosphinyl)-(IVa) or 5-(butylphosphinyl)-5-deoxy-D-xylopyranose (IVb), respectively. Study of their PMR (DMSO-d_6) and IR(KBr) spectra showed that IVa(IVb) had four OH groups and no P–H group. Acetylation of IVa with acetic anhydride in pyridine gave two kinds of crystalline 1,2,3,4-tetra-*O*-acetyl-5-deoxy-(ethylphosphinyl)-D-xylopyranose: one(Vaβ) had mp 232—234.5 °C, $[\alpha]_D^{18}$ −22° and the other(Vaα) had mp 176—178 °C, $[\alpha]_D^{18}$ +26°. The PMR spectra of Vaα and Vaβ showed four acetyl groups and no P–H group. Acetylation of IVb gave only one crystalline tetra-*O*-acetate(Vb), mp 156.5—158.5 °C, $[\alpha]_D^{19}$ +28°. The PMR spectrum of Vb showed four acetyl groups and no P–H group. Attempts to analyze the conformations of Vaα and Vaβ by 100 MHz PMR have been so faru nsuccessful.

Experimental

Melting points were determined by a Yanagimoto micro melting point apparatus. Infrared spectra were measured on a Hitachi EPI-G2 grating spectrophotometer. Proton magnetic resonance spectra were taken at 60 MHz on a Hitachi-Perkin-Elmer R-20 spectrometer, with tetramethylsilane as an internal standard. Optical rotations (sodium D line) were measured with a Hitachi PO-B polarimeter using a 0.5-dm cell. Thin-layer chromatography (tlc) was carried out on microscope slides coated with silica gel[9] in ethyl acetate–petroleum ether (A) (1 : 1 v/v), (B) (1 : 2 v/v), and (C) (1 : 4 v/v): the spots were visualized with sulfuric acid–ethanol solution.

Materials. *3-O-Acetyl-5-deoxy-5-iodo-1,2-O-isopropylidene-α-D-xylofuranose(Ia)* was prepared in 91% yield by conventional acetylation of 5-deoxy-5-iodo-1,2-*O*-isopropylidene-α-D-xylofuranose(IX)[10]. Mp 65—66 °C, $[\alpha]_D^{16.5}$ −49° (*c* 2.3, $CHCl_3$);

Found: C, 35.11; H, 4.46%. Calcd for $C_{10}H_{15}IO_5$: C, 35.11, H, 4.42%.

3-O-Benxoyl-5-deoxy-5-iodo-1,2-O-isopropylidene-α-D-xylofuranose(Ib) was prepared in 86% yield by conventional benzoylation of IX. Mp 46—48 °C, $[\alpha]_D^{16}$ −40° (*c* 10, CH_3OH);

Found: C, 44.53; H, 4.20%. Calcd for $C_{15}H_{17}IO_5$: C, 44.68; H, 4.25%.

3-O-Acetyl-5-(ethoxyethylphosphinyl)-1,2-O-isopropylidene-α-D-xylofuranose(IIa). A solution of Ia(5 g) in diethyl ethylphosphonite (10 ml) was heated under a nitrogen atmosphere for 10 hr at 140—150 °C, while the phosphonite (2 ml) was added several times. The excess phosphonite was distilled off *in vacuo* and the residue was dissolved in chloroform; the solution was washed with water, dried (sodium sulfate), and evaporated *in vacuo* to give a syrup of IIa (4.8 g, 98%); R_f: 0.25 (Solvent B); $[\alpha]_D^{20}$ −9.1° (*c* 1.3, $CHCl_3$); IR (KBr): 124 cm^{-1} (P=O); PMR ($CDCl_3$): δ 0.80—2.16 (16H, m, H-5,5′, P-C_2H_5, O-C-CH_3, $C(CH_3)_2$), 2.19 (3H, s, $COCH_3$), 4.01 (2H, q, $POCH_2$–), 4.47 (1H, d, overlapping with H-4, H-2), 5.10 (1H, d, $J_{3,4}$=3.0 Hz, H-3), 5.81(1H, d, $J_{1,2}$=4.0 Hz, H-1).

*3-O-Acetyl-5-(ethoxybutylphosphinyl)-1,2-O-isopropylidene-α-D-xylofuranose(IIb).**** 98%; R_f 0.20 (solvent B); $[\alpha]_D^{20}$ −9.1° (*c* 13, $CHCl_3$); IR (KBr) 1240 cm^{-1} (P=O); PMR ($CDCl_3$): δ 0.69—2.65 (20H, m, H-5,5′, P-C_4H_9, O-C-CH_3, $C(CH_3)_2$, 2.04 (3H, s, $COCH_3$), 3.99 (2H, m, $POCH_2$–), 4.42 (1H, d, overlapping with H-4, H-2), 5.04 (1H, d, $J_{3,4}$=3.0 Hz, H-3), 5.75 (1H, d, $J_{1,2}$=4.0 Hz, H-1).

*3-O-Benzoyl-5-deoxy-5-(ethoxyethylphosphinyl)-1,2-O-isopropylidene-α-D-xylofuranose(IIc).**** 96%; R_f: 0.20 (Solvent B); $[\alpha]_D^{21}$ −13° (*c* 4.3, $CHCl_3$); IR (KBr): 1240 cm^{-1} (P=O); PMR ($CDCl_3$): δ 0.74—2.40 (16H, m, H-5,5′, P-C_2H_5, O-C-CH_3, $C(CH_3)_2$), 4.00 (2H, m, $POCH_2$–), 4.64 (1H, d, overlapping with H-4, H-2), 5.41 (1H, d, $J_{3,4}$=3.0 Hz, H-3), 5.96 (1H, $J_{1,2}$=4.0 Hz, H-1), 7.22–8.20 (5H, *m*, COC_6H_5).

*3-O-Benzoyl-5-deoxy-5-(ethoxybutylphosphinyl)-1,2-O-isopropylidene-α-D-xylofuranose(IId).**** 98%; R_f: 0.20 (Solvent B); $[\alpha]_D^{13}$ −7.5° (*c* 14, $CHCl_3$); IR (KBr): 1240 cm^{-1} (P=O); PMR ($CDCl_3$): δ 0.63—2.23 (20H, m, H-5,5′, P-C_4H_9, O-C-CH_3, $C(CH_3)_2$, 3.94 (2H, m, $POCH_2$–), 4.54 (1H, d, overlapping with H-4, H-2), 5.28 (1H, d, $J_{3,4}$=3.0 Hz, H-3), 5.80 (1H, d, $J_{1,2}$=4.0 Hz, H-1), 7.20—8.10 (5H, m, COC_6H_5).

5-Deoxy-5-(ethylphosphinyl)-1,2-O-isopropylidene-α-D-xylofuranose (IIIa). To a solution of IIa (0.2 g) (IIb) in tetrahydrofuran (THF) (200 ml) was added THF (100 ml) containing a 70% benzene solution (6.0 g) of sodium dihydrobis(2-methoxyethoxy)alminate (SDMA) under a nitrogen atmosphere in an ice-salt bath. After stirring for 1 hr at room temperature, the reaction mixture was neutralized with THF containing hydrochloric acid and filtered; the filtrate was dried (sodium sulfate) and evaporated, to give a syrup of IIIa (1.4 g, 94%). An analytical crystalline sample was obtained by silica-gel column chromatography (Solvent A and methanol); R_f: 0.1 (Solvent A); mp 120—121 °C, $[\alpha]_D^{17}$ −12.4° (*c* 2.6, $CHCl_3$); IR (KBr): 2350 cm^{-1} (P–H), 1220 cm^{-1} (P=O); PMR ($CDCl_3$): δ 0.73—2.58 (13H, m, H-5,5′, P-C_2H_5), $C(CH_3)_2$, 4.12 (1H, d, H-3), 4.53 (1H, d, overlapping with H-4, H-2), 5.15 (1H, broad s, disappearing on deuteration, OH), 5.86 (1H, d, $J_{1,2}$=4.0 Hz, H-1), 6.90 (1H, m, disappearing on deuteration, J_{P-H}=468 Hz, P–H).

Found: C, 47.67; H, 8.04%. Calcd for $C_{10}H_{19}O_5P$: C, 47.98; H, 8.00%.

5-(Butylphosphinyl)-5-deoxy-1,2-O-isopropylidene-α-D-xylofuranose(IIIb). Compound IIb (2.5 g) was treated as described above to give a syrup of IIIb (1.8 g, 94%). R_f: 0.10 (Solvent A); $[\alpha]_D^{16.5}$ −17.3° (*c* 4.4, $CHCl_3$), IR (KBr): 2350 cm^{-1} (P–H), 1220 cm^{-1} (P=O); PMR ($CDCl_3$): δ 0.70—2.55 (17H, m, H-5,5′, P-C_4H_9, $C(CH_3)_2$), 4.18 (1H, d, H-3), 4.56 (1H, d, overlapping with H-4, H-2), 4.95 (1H, broad s, disappearing on deuteration, OH), 5.90 (1H, d, $J_{1,2}$=4.0 Hz, H-1), 6.90 (1H, m, diasppearing on deuteration, J_{P-H}=470 Hz, P–H).

5-Deoxy-1,2-O-isopropylidene-5-(methoxybutylphosphinyl)-α-D-xylofuranose(VI) and 5-(3-O-cyclo-butylphosphinate)-5-deoxy-1,2-O-isopropylidene-α-D-xylofuranose(VII). To a solution of IIb (2.1 g) in methanol (20 ml) was added a small amount of sodium methoxide and the solution stood for two days at room temperature. The solution was neutralized with Amberlite IRC-50 (H^+) ion-exchange resin and evaporated *in vacuo* to give a syrup (VI) containing a solid (VII) (1.5 g, 94% as VI) (VI : VII=5 : 1 from the PMR spectrum). The solid (VII) was collected and recrystallized from ethyl acetate. (VI), R_f: 0.30 (Solvent A), $[\alpha]_D^{16}$ −20° (*c* 2.5, $CHCl_3$); PMR ($CDCl_3$): δ 0.61—2.30 (17H, m, H-5,5′, P-C_4H_9, $C(CH_3)_2$), 3.56 (3H, d, J_{P-H}=10.5 Hz, P-OCH_3), 4.00 (1H,

*** These compounds were prepared by treatment of the corresponding sugars with the phosphonites.

d, H-3), 4.40 (1H, d, overlapping with H-4, H-2), 4.75 (1H, broad s, disappearing on deuteration, OH), 5.73 (1H, d, $J_{1,2}$=4.0 Hz, H-1). (VII), R_f, 0.35 (Solvent A); mp 221.5—222 °C; $[\alpha]_D^{14}$ +32° (*c* 2.3, CH_3OH); PMR ($CDCl_3$): δ 0.80—2.63 (17H, m, H-5,5′, P-C_4H_9, $C(CH_3)_2$); 4.58 (1H, m, H-4), 4.79 (1H, d, H-2), 5.18 (1H, *m*, 1H, m, H-3), 6.02 (1H, d, $J_{1,2}$=4.0 Hz, H-1).

Found: C, 52.19; H, 7.71%. Calcd for $C_{12}H_{21}O_5P$: C, 52.17; H, 7.66%.

The reduction of VI and VII with 1.2 molar equivalents of SDMA gave, almost quantitatively, IIIb.

Compound VII from 5-deoxy-5-iodo-1,2-O-isopropylidene-α-D-xylofuranose (VIII). A solution of VIII (1.4 g) in diethyl butylphosphonite (3 ml) was heated under a nitrogen atmosphere for 2 hr at 130—140 °C; the resulting precipitates were collected by filtration and the filtrate was evaporated *in vacuo*. The conbined precipitates were recrystallized from ethyl acetate to give pure crystalline VII (1.2 g, 93%).

5-Deoxy-5-(ethylphosphinyl)-D-xylopyranose (IVa). A solution of IIIa (1.0 g) and concentrated sulfuric acid (0.5 ml) in water (50 ml) containing a small amount of THF was heated under a stream of nitrogen for 2 hr at 100 °C. The hot solution was neutralized with barium carbonate, followed by filtration and evaporation to give a hygroscopic solid of IVa (0.8 g, 95%); R_f: 0.10 (Solvent C); $[\alpha]_D^{16.5}$ +5.8° (*c* 6.8, H_2O); IR (KBr): 1240 cm^{-1} (P=O); PMR (DMSO-d_6): δ 0.5—2.4 (7H, m, H-5,5′, P-C_2H_5), 3.0—4.5 (7H, m, four of them disappearing on deuteration).

5-(Butylphosphinyl)-5-deoxy-D-xylopyranose (IVb). Compound IIIb (0.9 g) was treated as described above to give a hygroscopic solid, IVb (0.7 g, 91%; R_f: 0.10 (Solvent C); $[\alpha]_D^{16.5}$ +11° (*c* 5.5, CH_3OH); IR (KBr): 1240 cm^{-1} (P=O); PMR (DMSO-d_6): δ 0.5—2.0 (11H, m, H-5,5′, P-C_4H_9), 4.6—5.3 (5H, m, four of them disappearing on deuteration).

1,2,3,4-Tetra-O-acetyl-5-deoxy-5-(ethylphosphinyl)-D-xylopyranose (Va). Treatment of IVa (1.4 g) with acetic anhydride (4.5 ml) in pyridine (20 ml) in the usual way gave a syrupy mixture of Vaα and Vaβ (2.2 g, 88%, $[\alpha]_D^{14.5}$ +20.9° (*c* 2.2, $CHCl_3$)). The syrup was crystallized by standing for several days in a refrigerator. Recrystallization from ethanol gave colorless crystals (Vaβ, 0.06 g), mp 232—234.5 °C, $[\alpha]_D^{18}$ −22° (*c* 1.6, $CHCl_3$). The ethanolic mother solution was evaporated *in vacuo*: recrystallization of the precipitates from ethanol-*n*-hexane gave colorless crystals (Vaα, 0.21 g), mp 176—178 °C, $[\alpha]_D^{18}$ +26° (*c* 1.4, $CHCl_3$).

Vaβ; PMR ($CDCl_3$): δ 0.80—2.82 (7H, m, H-5,5′, P-C_2H_5), 1.95, 1.98, 2.10 (12H, s, 1,2,3,4-$COCH_3$), 5.00-5.75 (4H, m, H-1,2,3,4).

Found: C, 47.32; H, 6.53%. Calcd for $C_{15}H_{23}O_9P$: C, 47.62; H, 6.13%.

Vaβ; PMR ($CDCl_3$): δ 1.00—2.76 (7H, m, H-5,5′, P-C_2H_5), 1.95, 2.00, 2.06 (12H, s, 1,2,3,4-$COCH_3$), 5.04—5.76 (4H, m, H-1,2,3,4).

1,2,3,4-Tetra-O-acetyl-5-(butylphosphinyl)-5-deoxy-D-xylopyranose (Vb). Compound IVb (0.7 g) was treated as described above to give a syrup of Vb (1.0 g, 84%, $[\alpha]_D^{14.5}$ +20.3 ° (*c* 3.5, $CHCl_3$)). Crystals were obtained from the syrup by standing for several days in a refrigerator. Recrystallization from ethanol-*n*-hexane gave colorless crystals (Vb, 0.2 g); mp 156.5—158.5 °C; $[\alpha]_D^{19}$ +28° (*c* 1.4, $CHCl_3$); PMR ($CDCl_3$): δ 1.00—2.76 (11H, m, H-5,5′, P-C_4H_9), 1.96, 2.02, 2.17 (12H, s, 1,2,3,4-$COCH_3$), 5.17—5.93 (4H, m, H-1,2,3,4).

Found: C, 49.80; 6.85%. Calcd for $C_{17}H_{27}O_9P$: C, 50.25; H, 6.70%.

Conformations of Sequential Polypeptides of L-Leucine and Glycine in Solution

Takayoshi Iio and Sho Takahashi*

Department of Physics, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

**Institute for Chemical Research, Kyoto University, Uji, Kyoto-fu 611*

(Received May 7, 1974)

With the aid of optical rotatory dispersion, circular dichroism, and infrared spectra, the conformations of the sequential polypeptides of L-leucine and glycine, $(Leu_3Gly)_n$, $(Leu_2Gly)_n$, $(LeuGly)_n$, and $(LeuGly_2)_n$, were studied and compared with the conformation of poly-L-leucine. It was shown that the polymers $(Leu)_n$, $(Leu_3Gly)_n$, $(Leu_2Gly)_n$, and $(LeuGly)_n$ could be α-helical in solution, but $(LeuGly_2)_n$ was not. The order of the stability of the α-helix of these polymers was found to be: $(Leu)_n > (Leu_3Gly)_n \sim (Leu_2Gly)_n > (LeuGly)_n > (LeuGly_2)_n$. This was attributed to interactions between side chains of L-leucines which were regularly arranged on the α-helix.

Poly-L-alanine is known to assume the very stable α-helix conformation in solution[1], on the other hand, glycine destabilizes the α-helix when it is incorporated in a polypeptide chain which otherwise might be α-helical[2]. By studying the sequential polypeptides of L-alanine and glycine we concluded that, although the short range interactions between a side chain and the atoms of the backbone of the same amino acid residue were important, the interactions between the neighboring residues could not be neglected in explaining the stability of the α-helix of the polymers, which was in the order: Ala > $(Ala_2Gly)_n$ > $(Ala_3Gly)_n$ > $(AlaGly_2)_n$ and was not proportional to the alanine content.

Poly-L-leucine also forms the very stable α-helix in water.[4] Because the side chain of leucine is much larger than that of alanine, it is desirable to study the conformational stability of sequential polypeptides of L-leucine and glycine. In this paper we report a conformational study of sequential polypeptides of L-leucine and glycine in solution.

Experimental

Polymers. The sequential polypeptides, poly(L-leucyl$_3$-glycine) (intrinsic viscosity in dichloroacetic acid at 25 °C, $[\eta]=0.158$ dl/g), poly(L-leucyl$_2$glycine)($[\eta]=0.191$), poly(L-leucylglycine) ($[\eta]=0.151$), and poly(L-leucylglycylglycine) ($[\eta]=0.262$), were obtained from the *p*-nitrophenylesters of L-leucyl$_3$glycine, L-leucyl$_2$glycine, (L-leucylglycyl)$_2$, and L-leucylglycylglycine, respectively.[5] Poly-L-leucine ($[\eta]=1.86$ in 80% trifluoroacetic acid/20% chloroform) was prepared via the usual N-carboxyanhydride method by Dr. A. Warashina of the Faculty of Science, Nagoya University. These polymers are abbreviated: $(L_3G)_n$, $(L_2G)_n$, $(LG)_n$, and $(L)_n$, respectively. The fairly large values of the intrinsic viscosity in solvents favoring the random coil conformation should be noted as they indicated that the degrees of polymerization of these polymers were high enough for conformational studies.[6]

Solution Studies. The plymers could only be dissolved in dichloroacetic acid (DCA) or in trifluoroacetic acid (TFA), so their solutions were prepared by dissolving vacuum-dried polymer in TFA and then adding TFA and chloroform or 2,2,2-trifluoroethanol (TFE) to give a solution of the required solvent ratio.

Optical rotatory dispersion (ORD) spectra over the 280—500 nm wavelength range were measured with a JASCO ORD/UV 5 spectrometer using a 1 cm cell. The solution concentrations were in the range 0.8—1.1 g/100 ml.

Circular dichroism (CD) spectra below 250 nm were measured with the same apparatus using a 0.2 cm cell. The concentration of the solution was 0.035 g/100 ml. All measurements were performed at 24 °C. To calculate [m'], the reduced mean residue rotation in degree cm^2/dmol, and [θ], molar ellipticity in the same units, from the observed rotation angle, χ^{ORD} and χ^{CD}, Eqs. (1) and (2) were used.

$$[m'] = \frac{n^2+2}{3} \cdot \frac{M}{c} \cdot \frac{\chi^{ORD}}{l} \quad (1)$$

$$[\theta] = \frac{45 \ln 10}{\pi} \cdot \frac{M}{c} \cdot \frac{\chi^{CD}}{l} \quad (2)$$

where the refractive index of the composite solvent, n, was calculated from the Lorentz-Lorenz equation using the refractive index of each pure solvent, c is the concentration of a polymer in grams per 100 ml, l is the path length in decimeters, and M is the mean residue molecular weight of polymer. ORD parameters, a_0 and b_0, were obtained by plotting the values of the optical rotation in terms of the Moffitt-Yang equation (3)[7] with a value of $\lambda_0=212$ nm.

$$[m'] = \frac{a_0\lambda_0^2}{\lambda^2-\lambda_0^2} + \frac{b_0\lambda_0^4}{(\lambda^2-\lambda_0^2)^2} \quad (3)$$

Infrared (IR) spectra were recorded with a JASCO IR-G spectrophotometer. The concentration of the solution ranged from 3 to 5 g/100 ml. Films of each polymer were prepared from TFA solution by casting the solution (polymer concentration about 5 g/100 ml) on a KBr plate and by drying the film under a vacuum at 40 °C.

Results

ORD Measurements. a_0 and b_0 values as a function of solvent composition were obtained from ORD spectra measured in a TFA–$CHCl_3$ system. These values are plotted in Fig. 1, which shows that $(L)_n$ had a random coil conformation in TFA, a random coil favoring solvent, and changed to an α-helix when the content of $CHCl_3$, a helix favoring solvent, increased.[1] The values of b_0 for $(LG)_n$ and $(LG_2)_n$ were low and did not change appreciably with solvent composition, indicating that the glycyl residues in these polymers inhibited the transition from the random coil to the helix. Polymers $(L_3G)_n$ and $(L_2G)_n$ showed a transition, but in these cases the helical content, which was considered to reflect the stability of the helix, was reduced. The magnitude of b_0 is slightly larger for $(L_2G)_n$ than for $(L_3G)_n$ throughout the whole range of TFA concentration. The

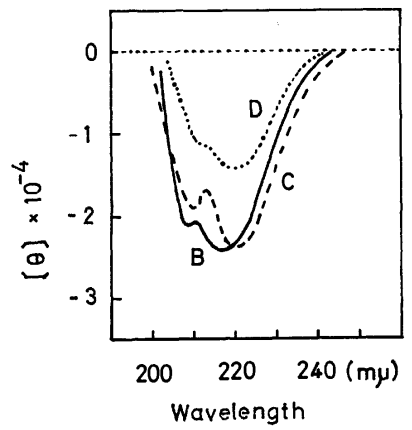

Fig. 2. CD spectra of the polymers in 96.8%TFE/3.2% TFA (v/v).
Letter symbols are the same as used in Fig. 1.

increase in b_0 in each case is accompanied by the corresponding increase in the value of a_0.

CD Measurements. The CD spectra in the far ultraviolet region for $(L_3G)_n$, $(L_2G)_n$, and $(LG)_n$ in 96.8% TFE/3.2% TFA are shown in Fig. 2. The polymers $(L)_n$ and $(LG_2)_n$ did not dissolve in such a solvent having such a large amount of TFE which was required if the solution was to be transparent in the far-ultraviolet region.

The polymer $(L_3G)_n$ exhibited two minima at 209 and 218 nm in the CD spectrum, and $(L_2G)_n$ exhibited minima at 210 and 222 nm. These bands are characteristic of the α-helix.[9] Though the magnitude of the molar ellipticity was reduced, polymer $(LG)_n$ also exhibited a spectrum characteristic of an α-helix. The value of the molar ellipticity of the band near 220 nm was −24000 for $(L_3G)_n$, −23000 for $(L_2G)_n$, and −14000 for $(LG)_n$ (a molar ellipticity of −32000 was reported for a complete α-helix in the 220 nm region[9]). From these observations, we can conclude that an α-helix exists in the polymers $(L_3G)_n$, $(L_2G)_n$, and also exists in $(LG)_n$ in solutions which contain a large amount of a helix-favoring solvent.

IR Measurements. IR spectra of the polymers in 70% $CHCl_3$/30% TFA solutions are shown in Fig. 3. All the polymers exhibited the amide I band at 1650 cm^{-1} and the amide II band around 1540 cm^{-1}, these were considered to originate from either the α-helical or the randomly coiled conformation of the polypeptide chain.[10] In addition to these bands, we observed a strong band around 1620 cm^{-1}. The peak of this band shifted from 1610 cm^{-1} as the glycine content of the polymer increased from $(L)_n$ to $(LG_2)_n$. Although the absorption band near 1630 cm^{-1} had been generally attributed to the β-structure,[10] however, in this case, the band at 1610—1635 cm^{-1} was not ascribed to the β-structure for the following reasons:

(i) The IR spectra of $(L)_n$ in TFA–$CHCl_3$ systems containing different amounts of TFA are shown in Fig. 4. As may be seen in Fig. 1, the b_0 value of $(L)_n$ showed that $(L)_n$ changed from the random coil to the α-helix as the TFA content decreased from 80% to 40%. The randomly coiled conformation of $(L)_n$ in 80% TFA has also been confirmed by NMR spectra.[8] In contrast, in the IR spectra, $(L)_n$ exhibited a band at 1610 cm^{-1} in addition to the amide

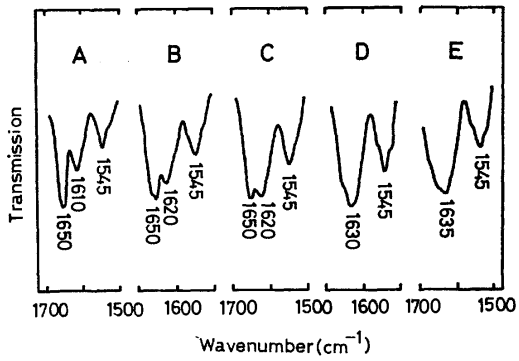

Fig. 3. IR spectra of the polymers in 70% $CHCl_3$/30% TFA (v/v).
Letter symbols, see Fig. 1.

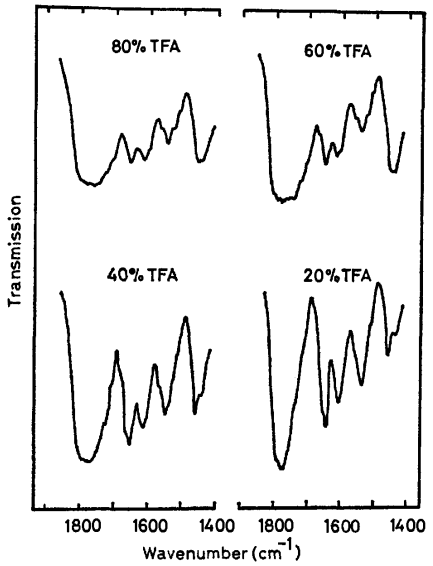

Fig. 4. IR spectra of $(L)_n$ in TFA-$CHCl_3$.

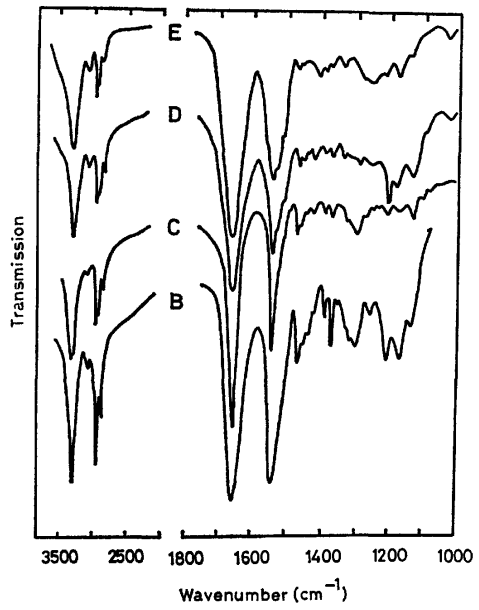

Fig. 5. IR spectra of films of the sequential polypeptides. All films were prepared from TFA solutions. Letter symbols, see Fig. 1.

I band at 1650 cm^{-1} and the amide II band at 1545 cm^{-1} for all TFA concentrations between 80 and 20%.

(ii) As was pointed out in the previous section, $(L_2G)_n$ and $(L_3G)_n$ exhibited CD spectra characteristic of the α-helix in a TFA–TFE system. However, IR spectra of the polymers in 50% TFA/50% TFE were the same as those in 70% TFA/30% $CHCl_3$: they showed the band at 1620 cm^{-1} in addition to the usual amide I band at 1650 cm^{-1} and the amide II band at 1545 cm^{-1}.

(iii) In general, the polypeptide chains cast in film have been considered to have the same conformation as they might be assumed to have in a solvent such as $CHCl_3$. IR spectra of the sequential polypeptides cast in films from TFA solutions did not exhibit the band near 1620 cm^{-1}, they exhibited only the amide I band at 1650—1660 cm^{-1} and the amide II band at 1545 cm^{-1} (Fig. 5). The 1610 cm^{-1} band was observed in a film of $(L)_n$ if the film was incompletely dried: this band disappeared as TFA was completely removed (Fig. 6).

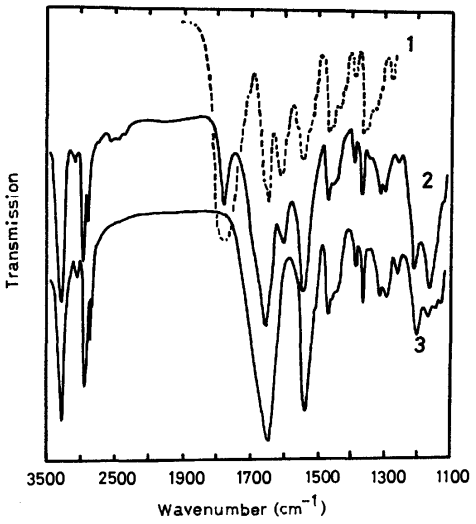

Fig. 6. IR spectra of $(L)_n$. 1: solution (80% $CHCl_3$/20% TFA (v/v)), 2: film from TFA solution (incompletely dried), 3: film from TFA solution (completely dried).

All these results strongly suggest that the band near 1620 cm^{-1} which was observed in solutions containing TFA should not be attributed to the β-structure of the polypeptide chain but to interactions between the polymer and the solvent TFA. Recently, Nagayama[11a] attributed the band at 1610 cm^{-1} to solvation of TFA with the polypeptide chain, and Combelas *et al.*[11b] also gave the same conclusion.

Discussion

Our experimental results showed that the sequential polypeptides except for $(LG_2)_n$ were α-helical in solution, although each polymer had a different helicity. The helical content, f_α, was calculated from Eq. (4) for each of the polymers,

$$f_\alpha = \frac{(-455)-(-60)}{b_0 - b_0^{TFA}}, \quad (4)$$

where we assumed that the b_0 values of $(L)_n$ were −455 at 100% helix and −60 at 100% random coil, and that all the sequential polypeptides had random coils in 100% TFA, although the b_0 value obtained with 100% TFA solution for each sequential polypeptide (b_0^{TFA}) was not zero. The results are shown in Fig. 7.

$(L)_n$ changed from a random coil to an α-helix when the $CHCl_3$ content increased from 25% to 55%, the midpoint of the transition was at 40% $CHCl_3$. On the other hand, polymers $(L_2G)_n$ and $(L_3G)_n$ showed a transition at a $CHCl_3$ content higher than 40%. For $CHCl_3$ contents between 40% and 90%, the helicity of $(L_2G)_n$ was slightly higher than that of $(L_3G)_n$. When the $CHCl_3$ content reached 90%, the helix content of $(L_2G)_n$ was the same as that of

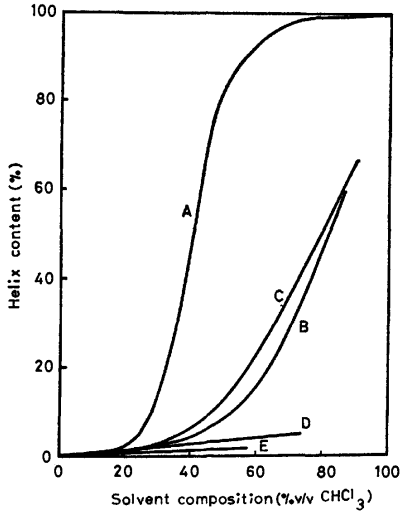

Fig. 7. Variation of the helix content (in %) of the polymers with solvent compositions. Helix content is calculated from equation (4). Letter symbols, see Fig. 1.

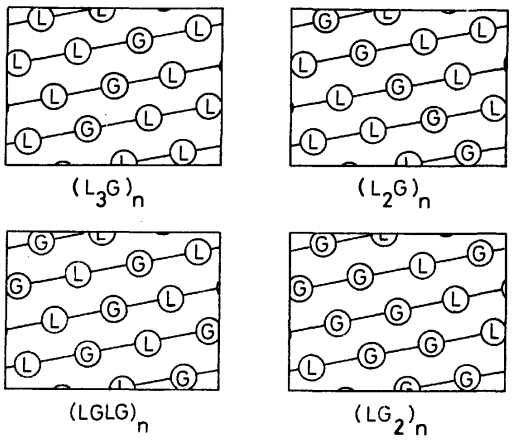

Fig. 8. Radial projection showing the distribution of the residues on the α-helix. L: leucine, G: glycine.

$(L_3G)_n$, 67%. The helix content of $(L_3G)_n$ may be higher than that of $(L_2G)_n$ when the $CHCl_3$ content is higher than 90%: this expectation was supported by CD spectra although the solvent system (TFA–TFE) was different from that used in the ORD studies (TFA–$CHCl_3$). Analysis of the CD spectra (Fig. 2) gave helical contents of 75% for $(L_3G)_n$ and 72% for $(L_2G)_n$. On the other hand $(LG)_n$ and $(LG_2)_n$ were hardly α-helical in TFA–$CHCl_3$, although $(LG)_n$ was partially α-helical in 96.8% TFE/3.2% TFA as shown by CD spectra.

These observations show us that the presence of a glycyl residue in an amino acid sequence has an important effect on the conformation of these polypeptides, causing a marked reduction in the stability of the α-helix. The magnitude of this reduction depends not only on the glycine content but also on the residue sequence, as the stability of the α-helix decreased in the order: $(L)_n > (L_3G)_n \sim (L_2G)_n > (LG)_n > (LG_2)_n$. In spite of the helicity of (L_2G) being slightly higher than that of $(L_3G)_n$, $(L_3G)_n$ and $(L_2G)_n$ were conservatively considered to have nearly equal helical stability, noting that the degree of polymerization of $(L_2G)_n$ might be slightly higher than that of $(L_3G)_n$ since the former polymer had a higher intrinsic viscosity in DCA than the latter and that the stability of the α-helix might depend on chain length.[12]

A schematic representation of α-helices, showing the radial projection of the distribution of amino acid residues onto the surface of the α-helix, is presented in Fig. 8 for each of the polymers. Each residue position corresponds to the location of an α-carbon of an amino acid, not of a side chain. The successive residues were numbered 1, 2, 3, *etc.* in the $-CO-C_\alpha-NH-$ direction from the C-terminal of the chain.

The α-helix is stabilized by the hydrogen bond between the NH group of the i-th residue and the CO group of the $(i+4)$th residue.[13] In addition to the hydrogen bond, non-covalent interaction between aliphatic side chains is the other important factor stabilizing the α-helix in solution.[14] For instance, non-covalent interaction between the i-th and the $(i+3)$th residues has been taken into account to explain the remarkable stability of the α-helix of poly-L-alanine in water.[15] In $(L)_n$, the interaction becomes more larger than in poly-L-alanine since leucine has a large aliphatic side chain. This has been actually confirmed in conformational studies on $(L)_n$ in water by Ostroy *et al.*[4a]

By considering a molecular model, we can see that two types of non-covalent interaction, one between the i-th and the $(i+3)$th residues and the other between the i-th and the $(i+4)$th residues, are possible in $(L)_n$. The magnitude of the energy of the non-covalent interaction should depend on the distance between the residues—the shorter distance would produce the larger interaction energy. We estimated the interatomic distances between the atoms of L-leucyl residues in the α-helix with the aid of a molecular model and deduced the following conclusion: the interaction between the i-th and the $(i+3)$th residues was the most effective, followed by the one between the i-th and the $(i+4)$th residues. Such interactions are not expected with polyglycine. The energy of the hydrogen bond would not be affected so much with a change in the side chain of an amino acid, provided that only amino acids which could form the α-helix were considered. However, the energy associated with the interaction between lyophobic side chains would depend significantly on the nature of side chains, and the larger the energy of the interaction, the more stable the α-helix would be. In this respect, eight kinds of side chain–side chain interaction are conceivable in the sequential polypeptides of L-leucine (L) and glycine (G) (see Fig. 8): $L(i)-L(i+3)$, $L(i)-G(i+3)$, $G(i)-G(i+3)$, $G(i)-L(i+3)$, $L(i)-L(i+4)$, $L(i)-G(i+4)$, $G(i)-G(i+4)$, $G(i)-L(i+4)$. It was concluded from examination of a molecular model that only three kinds of interaction were significant with the order of the interaction energy being $L(i)-L(i+3) > L(i)-G(i+3) > L(i)-L(i+4)$. If we assume a value of 1.0 for the energy of interaction for $L(i)-L(i+3)$, 0.4 for $L(i)-G(i+3)$, and 0.1 for $L(i)-L(i+4)$, then we could

calculate the average interaction energy per residue for each of the polymers to be 1.1 for $(L)_n$, 0.7 for $(L_3G)_n$, 0.7 for $(L_2G)_n$, 0.3 for $(LG)_n$, and 0.3 for $(LG_2)_n$. This order of the interaction energies is in good agreement with the experimentally observed stabilities of the α-helix in the polymers.

Similar studies on the influence of glycine on the stability of the α-helix of other sequential polypeptides have been reported by us[3] and by Fraser *et al.*[2] Our previous study showed that the stabilities of the α-helix of sequential polypeptides containing L-alanine (A) and glycine were in the order: $(A)_n > (A_2G)_n > (A_3G)_n > (AG_2)_n$. In this case a small amount of the α-helix was observed for $(AG_2)_n$. Fraser *et al.* reported that the stabilities of the α-helix of their sequential polypeptides of γ-ethyl-L-glutamic acid (E) and glycine were in the order: $(E)_n > (E_5G)_n > (E_4G)_n > (E_3G)_n > (E_2G)_n > (EG)_n$.[2] These two results and our present results on $(L_xG_y)_n$ apparently contradict each other. The contradiction may, however, be eliminated if we consider that the nature and magnitudes of interaction between side chains of polypeptides are different in three series of sequential polypeptides. As discussed in the previous paper[3], the order of the α-helical stability of the polymers $(A_xG_y)_n$ was explained by interactions between the i-th L-alanyl residue and $(i+3)$th residue. Recently, Brack and Spach reported that the α-helical stability of their sequential polypeptides of L-alanine and glycine in solution were in the order: $(A)_n > (A_2G)_n > (A_2G_2)_n > (AG)_n > (A_3G_3)_n > (A_2G_3)_n > (AG_2)_n > (AG_3)_n$.[16] This order can be explained by our calculation with the exception of $(AG_2)_n$. For the polymers $(E_xG_y)_n$, interactions between the i-th and the $(i+3)$th residues and between the i-th and the $(i+4)$th residues are equally important because the γ-ethyl-L-glutamic acid side chain is long enough to make the contribution of the $(i+3)$th and the $(i+4)$th residues on the i-th residue equal. If we assumed a value of 1.0 for the interaction energy for $E(i)-E(i+3)$ and $E(i)-E(i+4)$, and 0.4 for $E(i)-G(i+3)$ and for $E(i)-G(i+4)$, we could calculate the average energy of the interaction to be 2.0 for $(E)_n$, 1.5 for $(E_5G)_n$, 1.4 for $(E_4G)_n$, 1.35 for $(E_3G)_n$, 1.1 for $(E_2G)_n$, and 0.7 for $(EG)_n$. This order of the interaction energy is in good agreement with their experimental results.

We wish to thank Professor F. Oosawa of Nagoya University and Professor T. Ooi of Kyoto University for their encouragement and discussions. We are greatly indebted to Dr. A. Warashina for his kind gift of poly-L-leucine. Thanks are also due to Professor K. Yamasaki of Nagoya University who kindly made available an ORD–CD spectrometer for the experiment.

Liquid-phase Oxidation Catalyzed by Cu(II)-Cl. II. Chloride Ion Transfer during the Oxidation of Cyclohexene

Sei-ichiro IMAMURA, Takafumi OTANI, and Hiroshi TERANISHI

Department of Chemistry, Kyoto Institute of Technology, Sakyoku, Matsugasaki, Kyoto 606

(Received June 11, 1974)

Cyclohexene was oxidized in glacial acetic acid with a Cu(II)-Cl catalyst. In addition to the main oxidation products, 3-cyclohexenyl chloride, 3-cyclohexenyl acetate, 2-chlorocyclohexanol-(1), cyclohexene oxide, and hydrogen chloride were produced. The mechanism of the formation of these compounds was investigated in detail: the deactivation of the catalyst was explained by chloride ion transfer.

Previously it has been reported that, in the liquid-phase oxidation of cyclohexene in glacial acetic acid, the catalytic activity of cupric chloride was greatly increased by the addition of various alkali chlorides which formed complexes with copper.[1] As the reaction proceeded, however, the catalyst was deactivated owing to the consumption of chloride ion, but the mechanism of this deactivation could not be elucidated fully.

In this work, we have attempted to analyze the reaction products in detail in order to explain the consumption of chloride ion during the reaction.

Experimental

3-Cyclohexenyl acetate was obtained from cyclohexenol and acetyl chloride.[2] 2-Chlorocyclohexanol-(1) was prepared by the reaction of cyclohexene with hypochloric acid[3] and trans-dichlorocyclohexane by the reaction of cyclohexene with molecular chlorine.[4] Anhydrous cupric acetate was obtained by dehydration of cupric acetate monohydrate. G. R. grade commercial *t*-butyl hydroperoxide (*t*-butyl HPO) and cyclohexene oxide were used without further purification. Other reagents were obtained and purified as described previously.[1]

The oxidation apparatus used was the same as in the previous work.[1] It was confirmed that the reactions were not controlled by the diffusion of oxygen into the liquid phase. *t*-Butyl HPO was decomposed under a nitrogen atmosphere.

The reaction products were analyzed with a Hitachi 063 Gas Chromatograph equipped with a flame ionization detector, a Hitachi 215 Infrared Spectrophotometer, and a Hitachi RMU-6L Mass Spectrometer. The conditions for the operation of the gas chromatograph were as follows: (1) Column packing—Ethylhexyl sebacate/Chromosorb 101 (5 : 1); Carrier gas–N_2 (30 ml/min); Column temperature—80~100 °C, and (2) Column packing—Ethylhexyl sebacate (2 m); Carrier gas–N_2 (30 ml/min); Column temperature—115 °C.

Results and Discussion

Accumulation of By-products during the Oxidation of Cyclohexene. The main products were cyclohexenyl hydroperoxide (cyclohexenyl HPO), cyclohexenol, and cyclohexenone, which were analyzed as described previously.[1] In addition, 3-cyclohexenyl chloride, 3-cyclohexenyl acetate, 2-chlorocyclohexanol-(1), cyclohexene oxide, and a trace amount of trans-dichlorocyclohexane were detected in this work. However, cyclohexene oxide was detected only in the later stages of the oxidation. Fig. 1 shows the amounts of 2-chlorocyclohexanol-(1), 3-cyclohexenyl acetate, and 3-cyclohexenyl chloride formed together with the amount of oxygen absorbed. These curves all show a maximum when the rate of oxidation begins to decrease.[5] The amounts of main products formed after twenty minutes were 0.037 mol/l of cyclohexenyl HPO, 0.071 mol/l of cyclohexenone, and 0.015 mol/l of cyclohexenol. Table 1 shows the yield of 3-cyclohexenyl chloride plus 2-chlorocyclohexanol-(1) after various reaction times. From the table it may be seen that almost all the chloride ion added was transferred to organic chlorine compounds after forty to sixty minutes. Chloride ion forms complexes with cupric acetate in glacial acetic acid and increases its

activity in the oxidation of hydrocarbons.[1,6]

$$Cu(OAc)_2 \xrightarrow{Cl^-} Cu(OAc)Cl \xrightarrow{Cl^-} CuCl_2 \xrightarrow{Cl^-} \cdots\cdots$$

From this and the results shown in Fig. 1 and Table 1, we concluded that chloride ion transfer occurred to form these organic chlorine compounds and an inactive cupric acetate. This is the reverse of the reaction shown above. In the following sections we discuss the mechanisms of the formation of these by-products.

Formation of 3-Cyclohexenyl Acetate 3-Cyclohexenyl acetate may be formed in one of the following three possible ways. The first is an esterification of cyclohexenol, one of the oxidation products, with acetic acid.

$$ROH + AcOH \rightarrow ROAc \quad (1)$$

R: cyclohexenyl-

The second is a chloride ion transfer oxidation of cyclohexenyl radical, an intermediate radical in the oxidation of cyclohexene, by the catalyst. This is followed by acetolysis of the resulting 3-cyclohexenyl cyloride. The chloride ion transfer to cyclohexenyl radical would occur and compete with attack by oxygen, the rate constant of which is close to the diffusion controlled limit.[7]

$$R\cdot + Cu(II)Cl_x(OAc)_y \rightarrow RCl + Cu(I)_{x-1}(OAc)_y \quad (2)$$

$$RCl + AcOH \rightarrow ROAc \quad (3)$$

The third is a direct acetate ion transfer oxidation of cyclohexenyl radical.

$$R\cdot + Cu(II)Cl_x(OAc)_y \rightarrow ROAc + Cu(I)_x(OAc)_{y-1} \quad (4)$$

To investigate the possibility of the first two mechanisms, cyclohexenol and 3-cyclohexenyl chloride were refluxed in glacial acetic acid at 60 °C. For cyclohexenol (initial concentration of 0.29 mol/l), only about 2% of 3-cyclohexenyl acetate was produced after sixty minutes. The yield of cyclohexenol in the oxidation after a reaction time of twenty minutes was about 0.014 mol/l, therefore the quantity of 3-cyclohexenyl acetate formed by esterification of cyclohexenol would be calculated to be less than $0.014\times 0.02=0.00028$ mol/l. Actually the yield of 3-cyclohexenyl acetate was 0.015 mol/l after twenty minutes (see Fig. 1), so the esterification of 3-cyclohexenol can be excluded. The result for 3-cyclohexenyl chloride is shown in Fig. 2. This figure shows that the yield of 3-cyclohexenyl acetate reaches about 20% after sixty minutes. However, as shown in Fig. 1, 3-cyclohexenyl acetate accumulated from the beginning of the reaction and in almost the same amount as 3-cyclohexenyl chloride. From the results shown in Figs. 1 and 2, it seems that the formation of 3-cyclohexenyl acetate by the acetolysis of 3-cyclohexenyl chloride, although it does occur, is not the main but

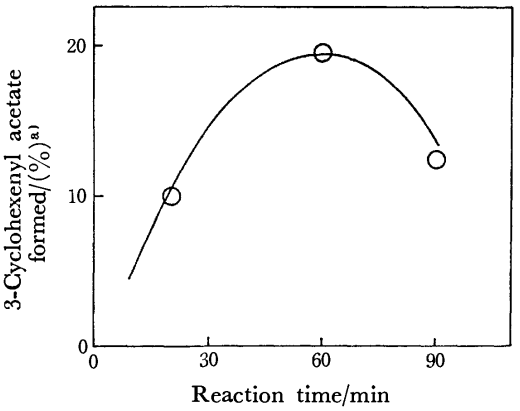

Fig. 2. Formation of 3-cyclohexenyl acetate from 3-cyclohexenyl chloride in glacial acetic acid at 60 °C.

the side route.

Next the effect of cupric acetate on the cyclohexenyl radical in the oxidation of cyclohexene was investigated. As cupric acetate in the absence of lithium chloride was inactive in initiating the oxidation, azobisisobutyronitrile was added. Figure 3 shows that the shapes of the two oxidation curves which correspond to the reaction with and without cupric acetate are almost the same. Moreover, in the presence of cupric acetate, more than 95% of cyclohexenyl HPO was obtained, showing an inactivity of cupric acetate in decomposing the HPO. Though a trace amount of 3-cyclohexenyl acetate (less than 1.4% based on oxygen absorbed) was produced after a reaction time of ninety minutes, the yield was too low compared with that obtained in the oxidation. From these results, it appears that cupric acetate itself is inactive and does not interact with cyclohexenyl radical. However, it does not mean that the active cupric acetate-chloride ion complex, $Cu(II)Cl_x(OAc)_y$, does not transfer acetate ion. As stated earlier, because 3-cyclohexenyl acetate and 3-cyclohexenyl chloride seem to be formed in a competitive process, it is preferable to assume that 3-cyclohexenyl acetate is formed by the acetate ion transfer oxidation of cyclohexenyl radical by the active catalyst system (Eq. (4)). However, this cannot be proved using the present experimental technique.

Formation of 2-Chlorocyclohexanol-(1). We assumed that 2-cyclohexanol-(1) was formed by the chlorination of the olefinic bond of cyclohexenol or cyclohexenone with Cu(II)–Cl–HPO.[8] So these compounds were treated with cupric acetate-lithium chloride-*t*-butyl HPO and the results are shown in Table 2. Other oxidation products, together with cyclohexene, were also treated in a similar manner. As water was assumed to be produced in the oxidation, the effect of addition of it was also discussed. From the table it may be seen that chlorination of cyclohexenol or cyclohexenone did not occur. It is also seen that other compounds are not intermediates for 2-chlorocyclohexanol-(1).

Next we investigated the reaction of cyclohexene oxide, which was formed in a later stage of the oxidation, with the catalyst. From Fig. 4, we can see that cyclohexene oxide reacted rapidly with the catalyst to produce 2-chlorocyclohexanol-(1) almost quantitatively (based on lithium chloride added) after twenty minutes. This indicates that chloride ion transfer from the catalyst to cyclohexene oxide is the main route leading to 2-chlorocyclohexanol-(1). As the chlorination shown above proceeded rapidly, cyclohexene oxide could not be detected in the early stages of the oxidation when the catalyst still had active chloride ion.

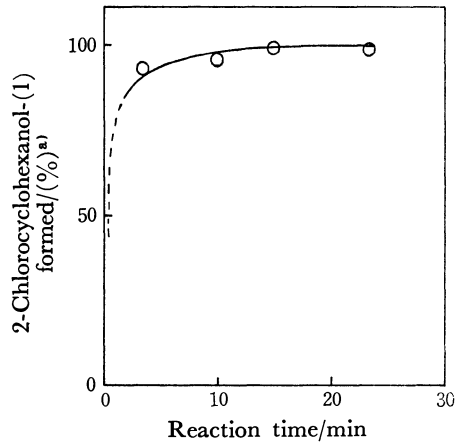

Fig. 4. Reaction of cyclohexene oxide with Cu(II)-Cl in glacial acetic acid at 60 °C.
$[Cu(OAc)_2]=8.6\times10^{-3}$ M; $[LiCl]=8.2\times10^{-2}$ M;
[Cyclohexene oxide]=0.11 M
a) Based on LiCl

Formation of Hydrogen Chloride. As shown in Fig. 1 and Table 1, the total quantity of chloride ion in the chlorinated products had a maximum value during the reaction, that is, in the later stages of the reaction it became less than that added initially as lithium chloride. As no other chlorinated products were detected, it was assumed that chloride ion was transferred to hydrogen chloride. Therefore cyclohexene was oxidized by Cu(II)–Cl (Cu : Cl=1 : 50) and the gaseous products were analyzed. As was expected, a considerable amount of hydrogen chloride, which was not measured, was detected by the gas chromatograph in the later stages of the oxidation.[9]

Mechanism of Chloride Ion Transfer. From the results obtained so far, the mechanism of the chloride ion transfer from the catalyst can be summarized as follows.

$$Cu(OAc)_2 + Cl^- \rightarrow CuCl_x(OAc)_y \quad (5)$$

$$RH \rightarrow R\cdot \xrightarrow{O_2} ROO\cdot \quad (6)$$

$$ROO\cdot + RH \rightarrow ROOH + R\cdot \quad (7)$$

$$ROOH + CuCl_x(OAc)_y \rightarrow \text{radicals} \quad (8)$$

$$ROO\cdot + RH \rightarrow \text{Cyclohexene oxide} + RO\cdot \quad (9)$$

$$\text{Cyclohexene oxide} + CuCl_x(OAc)_y \xrightarrow{H^+} \text{2-Chlorocyclohexanol-(1)} + CuCl_{x-1}(OAc)_y \quad (10)$$

$$R\cdot + CuCl_x(OAc)_y \rightarrow RCl + CuCl_{x-1}(OAc)_y \quad (2)$$

$$RCl + AcOH \rightarrow ROAc + HCl \quad (3)$$

$$R\cdot + CuCl_x(OAc)_y \rightarrow ROAc + CuCl_x(OAc)_{y-1} \quad (4)$$

In the first step cupric acetate forms complexes with chloride ion. (Eq. (5)) Equations (6) and (7) are the propagation steps. In Eq. (8) cyclohexenyl HPO is decomposed by the catalyst and the active radicals are formed. Cyclohexene oxide would be produced by the reaction of cyclohexenylperoxy radical with cyclohexene (Eq. (9)),followed by chloride ion transfer to give 2-chlorocyclohexanol-(1). (Eq. (10)) In Eq. (2) the ligand transfer oxidation of cyclohexenyl radical occurs and 3-cyclohexenyl chloride is formed. A part of the 3-cyclohexenyl chloride formed suffers an acetolysis by acetic acid to give 3-cyclohexenyl acetate. (Eq. (3)) Hydrogen chloride produced in this process partly diffuses into the gas phase and partly remains in the liquid phase to form complexes with copper again. The acetate ion transfer oxidation of cyclohexenyl radical (Eq. (4)) should occur as the main route for the formation of 3-cyclohexenyl acetate, although this could not be confirmed in this work.

The deactivation of the catalyst occurs by the chloride ion transfer as shown by Eqs. (2) and (10) to form inactive cupric acetate. The direct chlorination of the olefinic bonds of cyclohexene or its oxidation products[8] does not proceed owing to the presence of cyclohexene oxide or cyclohexenyl radical which reacts with the catalyst more rapidly than those compounds.

The authors wish to thank Dr. Masaaki Teramoto for his helpful advice and discussions. 3-Cyclohexenyl chloride was kindly provided by Dr. Akira Oku of our department of the Kyoto Institute of Technology.

Furan Derivatives. I. On the Methods of Synthesizing Some Naphtho[1,8-*bc*]furans

Takaaki HORAGUCHI, Takahachi SHIMIZU, and Tsuneo SUZUKI

Department of Chemistry, Faculty of Science, Niigata University, Igarashi, Niigata 950-21

(Received June 14, 1974)

Two kinds of methods of synthesizing naphtho[1,8-*bc*]furans (VIa–VId) are described. In the first method, naphtho[1,8-*bc*]furans (VIa–VId) were obtained by the decarboxylation of IIa–IId, which had previously been prepared from Ia–Id and ethyl bromoacetate. The yields of IIa–IId from Ia–Id were 45, 43, 49, and 46% respectively. In the second method, VIa–VId were obtained by heating Va–Vd with acetic anhydride and sodium acetate. The yields of VIa–VId were 34, 46, 46, and 70% respectively.

In previous papers,[1-3] we have reported on the syntheses of phenanthro[4,5-*bcd*]furans. In the course of the syntheses, naphtho[1,8-*bc*]furan derivatives (Xa–Xc) played an important part as the intermediate products, and the syntheses of the compounds Xa–Xc were attempted in the ways of A and B.

Attempts using Method B were all unsuccessful, however, resulting, for example, in the formation of the lactone (IX) rather than the expected naphtho-[1,8-*bc*]furan (Xb). However, the syntheses of simple naphtho[1,8-*bc*]furans such as VI, which have no propionic acid residues, may be possible by this method. By Method A, naphtho[1,8-*bc*]furans (IIe—IIg) were obtained in relatively low yields (*ca.* 40%). One of the causes of the low yields may be the steric hindrance of the propionic acid residues, and it seems that Compounds Ia—Id, which have no propionic acid residues, are converted to IIa—IId in better yields. For these reasons, syntheses of naphtho[1,8-*bc*]furans (IIa—IId and VIa—VId) were attempted from Ia—Id and Va—Vd respectively using Methods A and B. Only a few articles[4-6] on naphtho[1,8-*bc*]furan derivatives have been published: for example, Royer *et al.* obtained naphtho[1,8-*bc*]furans in very poor yields by a method similar to A.

Results and Discussion

The syntheses of naphtho[1,8-*bc*]furans (IIa—IId and VIa—VId) were attempted from 8-hydroxy-1-tetralone derivatives (Ia—Id) by two kinds of methods. The first method is the same (A) as those used in the syntheses of IIe—IIg. Naphtho[1,8-*bc*]furans (IIa—IId) were obtained by the heating of Ia—Id, ethyl bromoacetate, and potassium carbonate at 120°C, followed by hydrolyses. From the reaction mixture before the hydrolyses, Compounds IIIa—IIId were also isolated. The carboxylic acids, IIa—IId, were decarboxylated with quinoline and copper to the expected naphto[1,8-*bc*]furans (VIa—VId). The yields of the reactions from tetralones (Ia—Id) to naphtho-[1,8-*bc*]furans (IIa—IId) are shown in Table 1, along with those of IIe—IIg from Ie—Ig.

Table 1 shows that the yields of IIa—IId were comparable to one another and similar to those of IIe—IIg; the effects of the substituents (R_1, R_2, and R_3) on the yields did not appear, but in the presence of the propionic acid residues a higher reaction temperature (170—180 °C) was required to prepare IIe—IIg from Ie—Ig compared with that needed in the syntheses (120 °C) of IIa—IId. The yields of IIa—IId from Ia—Id did not vary at the reaction temperature of 150 °C. In the same way (150 °C), a benzofuran derivative (XII) was obtained in a yield of 76% from 2-acetyl-*p*-cresol (XI) and ethyl bromoacetate. It seems that the low yields of IIa—IId are a result of the inhibition of the free rotations of the carbonyl groups in Ia—Id, that is, to the difficult access of the

Ic	IIc (49)	Ig	IIg (43)	—	—
Id	IId (46)	—	—	Id	IVd (71)

a) The corresponding acid was used as the starting material in place of ester.

active methylene to the carbonyl groups or, perhaps more likely, to ring strains in IIa—IId.

The acids IIa—IId showed absorptions corresponding to those of conjugated-carboxyl groups near 1680 cm^{-1} in the IR spectra and near 276 nm (ε 16000—20000) in the UV spectra. The naphtho[1,8-*bc*]furans (VIa—VId) exhibited signals due to hydrogens of the furan ring near δ 7.15 in the NMR spectra and absorptions characteristic of benzofurans near 253 nm in the UV spectra.

When phenacyl bromide was used in place of ethyl bromoacetate in the reactions from I to II, Compounds IV were obtained (Table 1). The yield (41%) of IVa was not good because of the difficulty of isolating IVa from the reaction mixture.

The second method of synthesizing naphtho[1,8-*bc*]-furans (VIa—VId) is a way (B) by which benzofurans are usually obtained.[7-10] 8-Hydroxy-1-tetralone derivatives (Ia—Id) reacted with ethyl bromoacetate to give the corresponding acids, Va—Vd, after hydrolyses.

Table 2. The yields (%) of naphtho[1,8-*bc*]furans and lactones

Starting material	Products (%)	
Va	VIa (34)	Va[a)] (37)
Vb	VIb (46)	VIIb (32)
Vc	VIc (46)	VIIc (32)
Vd	VId (70)	VIIb (19)

a) Starting material (Va) recovered in place of a lactone (VIIa) because of hydrolysis during the working up.

When the Va—Vd acids were treated with acetic anhydride and sodium acetate, two kinds of products, VIa—VId and VIIb—VIId, were obtained. The results are shown in Table 2.

The yields of VIa—VIc were low because of the formation of lactones, but the total yields of the naphtho-[1,8-*bc*]furans and lactones were good. The better

Table 3. The ultraviolet absorption maxima of naphtho[1,8-*bc*]furans (solvent: ethanol)

Compound	λ nm (ε)

Table 4. The ultraviolet absorption maxima of benzofurans (solvent: ethanol).

Compound	λ nm (ε)			
XIII[13]	281 (2800)	274 (2400)	243 (9800)	205 (21100)
XIV[12]	289 (3100)	282 (2600)	249 (9200)	209 (25000)
XV[14]	302 (3500)	293 (3900)	251 (9100)	211 (24800)
XVI[15]	292 (2800)	284 (1700)	251 (7800)	214 (30000)

yield (70%) of VId suggests that the inductive effect of the chlorine atom in Vd played an important role in the formation of the furan ring. As benzofurans are usually obtained from phenoxyacetic acid derivatives in good yields (*ca.* 80%)[7,8,10] by the same method, the generally low yields of naphtho[1,8-*bc*]furans may be due to the inhibition of the free rotations of the carbonyl groups in Va—Vd or, more likely, to ring strains in VIa—VId. For these reasons, the formation of seven-membered lactones is comparable to that of five-membered furan rings.

The VIa—VId products were identical with the compounds obtained by the decarboxylation of IIa—IId respectively. The VIIb—VIId products showed absorptions corresponding to those of lactone rings near 1765 cm^{-1} and to those of carbon-carbon double bonds near 1646 cm^{-1} in the IR spectra.

The UV absorption maxima of the naphtho[1,8-*bc*]-furans (VIa—VId) and similar benzofurans (XIII—XVI) are shown in Table 3 and Table 4 respectively. The molecular extinction coefficients (ε) and wavelengths (λ) of naphtho[1,8-*bc*]furans and benzofurans are similar to one another except that the values of ε near 280 nm of the naphtho[1,8-*bc*]furans are lower than those of benzofurans. The differences in spectra may be due to the greater strain in the naphto[1,8-*bc*]-furan rings.

The other synthetic methods and reactivities of the naphtho[1,8-*bc*]furans will be further investigated.

Experimental

All the melting points are uncorrected. The column chromatography was performed on silica gel (WACOGEL C-200). Unless otherwise stated, anhydrous sodium sulfate was employed as the drying agent. The infrared absorption spectra were determined with a JASCO Model DS 402G infrared spectrophotometer. The ultraviolet absorption spectra were determined with a Shimadzu Model UV-200 spectrophotometer. The nuclear magnetic resonance spectra were determined at 100 MHz with a JEOL Model 4H-100 NMR spectrometer, using tetramethylsilane as the internal standard.

*4,5-Dihidro-3H-naphtho[1,8-*bc*]furan-2-carboxylic Acid (IIa).* A mixture of 8-hydroxy-1-tetralone (Ia; 5.0 g),[11] ethyl bromoacetate (18.5 g), potassium carbonate (30.7 g), and ethyl methyl ketone (10 ml) was refluxed for 6 hr at 120 °C. The reaction mixture was then extracted with acetone, and the acetone was evaporated. The residue was dissolved in a small amount of ethanol and hydrolized with a 3 M potassium hydroxide solution. The alkaline solution was acidified with 6 M hydrochloric acid, and the resulting precipitates were extracted with ether. The ethereal layer was washed with water and dried, and then evaporated. When the residue was then washed with benzene, 2.8 g (45%) of IIa were obtained; mp 238 °C (decompn.). Recrystallization from tetrahydrofuran gave colorless prisms; mp 240 °C (decompn.). IR (KBr): 1675 (COOH), 778 cm^{-1} (three adjacent aromatic hydrogen atoms). UV (EtOH): λ_{max} 282^{sh} (ε 18200), 275 (20100), 229^{sh} (13700), 224 nm (14800).

Found: C, 69.28; H, 6.19%. Calcd for $C_{15}H_{16}O_4$: C, 69.22; H, 6.20%.

*Ethyl 6-Chloro-8-methoxy-4,5-dihydro-3*H*-naphtho[1,8-*bc*]furan-2-carboxylate (IIId).* Colorless needles (from ethanol; 36%); mp 117.5—119.5 °C. IR (KBr): 1704 (ester), 808 cm^{-1} (C–Cl). NMR (CD_3COCD_3): δ 6.93 (s, 1H, Ar–H), 4.40 (q, 2H, J=8 Hz, $-OCH_2-$), 4.02 (s, 3H, OCH_3), 3.00 (t, 2H, J=6 Hz, $-CH_2-$), 2.80 (t, 2H, J=6 Hz, $-CH_2-$), 1.40 (t, 3H, J=6 Hz, CH_3). UV (EtOH): λ_{max} 305 (ε 3300), 283 (19000), 276 (17800), 239 cm (25300).

Found: C, 60.88; H, 5.04%. Calcd for $C_{15}H_{15}O_4Cl$: C, 61.13; H, 5.13%.

*2-Benzoyl-8-methoxy-4,5-dihydro-3*H*-naphto[1,8-*bc*]furan (IVb).* A mixture of Ib (3.0 g), phenacyl bromide (4.6 g), potassium carbonate (7.0 g), and dioxane (10 ml) was refluxed for 8 hr at 120 °C. The reaction mixture was then extracted with ether; the ethereal layer was washed with water and dried, and then evaporated. The residue was recrystallized from ethanol to give 3.0 g (66%) of IVb as colorless needles; mp 80.5—81.5 °C. IR(KBr): 1625 (C=O), 815 (two adjacent aromatic hydrogen atoms), 702 cm^{-1} (five adjacent aromatic hydrogen atoms). UV(EtOH): λ_{max}313 (ε17000), 254 (16500), 205 nm (28700).

Found: C, 77.80; H, 5.35%. Calcd for $C_{19}H_{16}O_3$: C, 78.06; H, 5.52%.

*2-Benzoyl-3,4-dihydro-3*H*-naphtho[1,8-*bc*]furan (IVa).* Colorless needles (from ethanol; 41%); mp 51—52° C. IR (KBr): 1629 (C=O), 773 (three adjacent aromatic hydrogen atoms), 718 cm^{-1} (five adjacent aromatic hydrogen atoms). UV (EtOH): λ_{max} 320 (ε 19100), 256^{sh} (8600), 240 (11000), 205 nm (29100).

Found: C, 82.18; H, 5.20%. Calcd for $C_{18}H_{14}O_2$: C, 82.42; H, 5.38%

*2-Benzoyl-6-chloro-8-methoxy-4,5-dihydro-3*H*-naphtho[1,8-*bc*]-furan (IVd).* Colorless needles (from acetone; 71%); mp 114—115 °C. IR (KBr): 1628 (C=O), 810 (C–Cl), 720 cm^{-1} (five adjacent aromatic hydrogen atoms). UV (EtOH): λ_{max} 314 (ε19800), 257 (16500), 210 nm (32700).

Found: C, 69.73; H, 4.66%. Calcd for $C_{19}H_{15}O_3Cl$: C, 69.89; H, 4.63%.

(2-Methoxy-8-oxo-5,6,7,8-tetrahydro-1-naphthoxy) acetic Acid (Vb). A mixture of Ib (5.0 g), ethyl bromoacetate (18.5 g), potassium carbonate (30.0 g), and acetone (40 ml) was refluxed for 6 hr at 70 °C. The reaction mixture was subsequently extracted with acetone, and the acetone was evaporated. The residue was dissolved in a small amount of ethanol and hydrolyzed with a 3 M potassium hydroxide solution. The alkaline solution was acidified with 6 M hydrochloric acid, and the resulting precipitates were collected by filtration. Recrystallization from acetone gave 4.8 g (73%) of Vb as colorless needles; mp 176—178 °C. IR (KBr): 1750 (CO-OH), 1650 (C=O), 822 cm^{-1} (two adjacent aromatic hydrogen atoms). UV (EtOH): λ_{max} 325 (ε 3200), 256 (8200), 216 nm (21600).

Found: C, 62.63; H, 5.65%. Calcd for $C_{13}H_{14}O_5$: C, 62.40; H, 5.64%.

(8-Oxo-5,6,7,8-tetrahydro-1-naphthoxy) acetic Acid (Va). Colorless plates (from acetone-*n*-hexane; 22%); mp 100—102 °C. IR (KBr): 1775, 1757 (COOH), 1645 (C=O), 798 cm^{-1} (three adjacent aromatic hydrogen atoms). UV (EtOH): λ_{max} 313 (ε 3700), 254 (9000), 216 nm (18600).

Found: C, 65.35; H, 5.51%. Calcd for $C_{12}H_{12}O_4$: C, 65.45, H, 5.49%.

(4-Methoxy-8-oxo-5,6,7,8-tetrahydro-1-naphthoxy) acetic Acid (Vc). Colorless plates (from acetone; 30%); mp 152—153 °C. IR (KBr): 1776, 1758 (COOH), 1650 (C=O), 827 cm^{-1} (two adjacent aromatic hydrogen atoms). UV (EtOH): λ_{max} 348 (ε 3500), 252 (6300), 229 nm (18200).

Found: C, 62.42; H, 5.68%. Calcd for $C_{13}H_{14}O_5$: C, 62.40; H, 5.64%.

(4-Chloro-2-methoxy-8-oxo-5,6,7,8-tetrahydro-1-naphthoxy) acetic Acid (Vd). Colorless needles (from acetone; 71%); mp 148—150 °C. IR (KBr): 1755 (COOH), 1657 (C=O), 802 cm^{-1} (C–Cl). UV (EtOH): λ_{max} 325 (ε 3300), 257 (5600), 220 nm (23100).

Found: C, 55.00; H, 4.75%. Calcd for $C_{13}H_{13}O_5Cl$: C, 54.85; H, 4.60%.

Decarboxylation of IIa–IId. A mixture of IIa (1.0 g), copper powder (1.0 g), and quinoline (10 g) was heated for 45 min at 160 °C. The reaction mixture was then extracted with ether; the etheral layer was acidified with 2 M hydrochloric acid and washed with 2 M hydrochloric acid, a 1 M potassium carbonate solution, and water, dried, and then evaporated. The residue was chromatographed on silica gel and eluted with benzene. A pale yellow fraction was collected to give 650 mg (83%) of VIa as a colorless oil. Bp 68 °C at 1.5 mmHg. IR (neat): 1627 (furan), 772 (three adjacent aromatic hydrogen atoms), 750 cm^{-1} (furan H). NMR (CCl_4): δ 6.80—7.20 (m, 3H, Ar–H), 7.13 (s, 1H, furan H), 2.82 (q, 4H, J=6 Hz, $-CH_2-+-CH_2-$), 2.00 (q, 2H, J=6 Hz, $-CH_2-$).

Found: C, 83.31; H, 6.19%. Calcd for $C_{11}H_{10}O$: C, 83.52; H, 6.37%.

VIb. Colorless oil (86%); bp 102 °C at 0.7 mmHg. IR (neat): 1638 (furan), 794 cm^{-1} (two adjacent aromatic hydrogen atoms, furan H). NMR (CCl_4): δ 7.18 (s, 1H, furan H), 6.73 (d, 1H, J=8 Hz, Ar–H), 6.55, (d, 1H, J=8 Hz, Ar–H), 5.96 (s, 3H, OCH_3), 2.75 (q, 4H, J=5 Hz, $-CH_2-+-CH_2-$), 1.98 (q, 2H, J=5 Hz, $-CH_2-$).

Found: C, 76.68; H, 6.29%. Calcd for $C_{12}H_{12}O_2$: C, 76.57; H, 6.43%.

VIc. Colorless oil (80%); bp 105 °C at 1.8 mmHg. IR (neat): 775, 765 cm^{-1} (two adjacent aromatic hydrogen atoms, furan H). NMR (CCl_4): δ 7.16 (s, 1H, furan H), 7.05 (d, 1H, J=9 Hz, Ar–H), 6.64 (d, 1H, J=9 Hz, Ar—H), 5.77 (s, 3H, OCH_3), 2.75 (q, 4H, J=8 Hz, $-CH_2-+-CH_2-$), 1.98 (q, 2H, J=5 Hz, $-CH_2-$).

Found: C, 76.44; H, 6.33%. Calcd for $C_{12}H_{12}O_2$: C, 76.57; H, 6.43%.

VId. Colorless oil (78%); bp 110 °C at 0.6 mmHg. IR (neat): 1638 (furan), 805 cm^{-1} (C–Cl). NMR (CCl_4): δ 7.21 (s, 1H, furan H), 6.60 (s, 1H, Ar–H), 3.95 (s, 3H, OCH_3), 2.73 (q, 4H, J=6 Hz, $-CH_2-+-CH_2-$), 1.90 (q, 2H, J=6 Hz, $-CH_2-$).

Found: C, 64.45; H, 4.94%. Calcd for $C_{12}H_{11}O_2Cl$: C, 64.73; H, 4.98%.

*8-Methoxy-4,5-dihydro-3*H-*naphtho*[*1,8*-bc]*furan (VIb) and Lactone (VIIb).* *VIb*: A mixture of Vb (1.0 g), sodium acetate (4.6 g), and acetic anhydride (15 ml) was heated for 1 hr at 145 °C and then for 10 min at 160 °C. The reaction mixture was poured into water, and the solution was extracted with ether. The ethereal layer was washed with a 1 M potassium carbonate solution and water, dried, and then evaporated. The residue was chromatographed on silica gel and eluted with benzene. The first fraction gave 350 mg (46%) of IVb as a colorless oil.

VIIb: A latter fraction gave 250 mg (32%) of colorless crystals. Recrystallization from benzene-*n*-hexane gave VIIb as colorless needles; mp 112—114 °C. IR (KBr): 1764 (lactone), 1642 (C=C), 810 cm^{-1} (two adjacent aromatic hydrogen atoms).

Found: C, 67.14; H, 5.35%. Calcd for $C_{13}H_{12}O_4$: C, 67.24; H, 5.21%.

*6-Methoxy-4,5-dihydro-3*H-*naphto*[*1,8*-bc]*furan (VIc) and Lactone (VIIc).* *VIc*: Colorless oil (46%).

VIIc: Colorless needles from benzene-*n*-hexane (32%); mp 102—103 °C. IR (KBr): 1759 (lactone), 1650 (C=O), 804 cm^{-1} (two adjacent aromatic hydrogen atoms).

Found: C, 67.13; H, 5.11%. Calcd for $C_{13}H_{12}O_4$: C, 67.24; H, 5.21%.

*6-Chloro-8-methoxy-4,5-dihydro-3*H-*naphtho*[*1,8*-bc]*furan (VId) and Lactone (VIId).* *VId*: Colorless oil (70%).

VIId: Colorless needles from benzene-*n*-hexane (19%); mp 153.5—155 °C. IR (KBr): 1771 (lactone), 1642 (C=C), 837 cm^{-1} (C–Cl).

Found: C, 58.33; H, 3.96%. Calcd for $C_{13}H_{13}O_5Cl$: C, 58.55; H, 4.16%.

*4,5-Dihydro-3*H-*naphtho*[*1,8*-bc]*furan (VIa).* *VIa*: Colorless oil (34%).

Va: A latter fraction gave 450 mg (37%) of crystals; mp 96—98 °C. The compound was identical with Va in its infrared spectra. This suggests that the corresponding lactone should be hydrolyzed during the working-up.

3,5-Dimethylbenzofuran-2-carboxylic Acid (XII). A mixture of XI, ethyl bromoacetate (15.2 g), and potassium carbonate (12.3 g) was heated for 6 hr at 150 °C. The following procedures were done in the same way as the synthesis of IIa to give 1.9 g (76%) of XII; mp 220—222 °C (dec.). Recrystallization from acetone-tetrahydrofuran gave colorless prisms; mp 222—223 °C (decompn.) (lit,[12] mp 224—225 °C). IR (KBr): 1670 (COOH), 815 cm^{-1} (two adjacent aromatic hydrogen atoms). UV (EtOH): λ_{max} 300[sh] (ε 5600), 273 (18700), 214 nm (17600).

The authors wish to Mr. Hideo Saisu for the infrared analyses and Mr. Takao Ono for the nuclear magnetic resonance analyses.

Stereospecific Synthesis of Natural (+)Blastmycinone and Its Three (2*R*)-Diastereomers

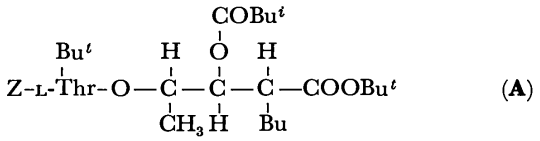
Shinpei ABURAKI, Norio KONISHI, and Mitsuhiro KINOSHITA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223

(Received June 29, 1974)

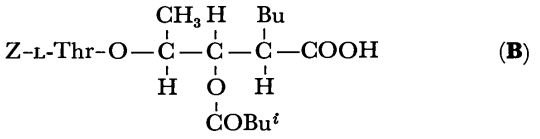
Natural (+)blastmycinone [(+)**1a**] and its three (2*R*)-diastereomers [(+)**1b**, (−)**1c**, and (−)**1d**] were synthesized through stereospecific routes *via* the corresponding (−)blastmycinolactol [(−)**2a**] and its diastereomeric hydroxylactones [(+)**2b**, (−)**2c**, and (−)**2d**] from methyl 4,6-*O*-benzylidene-3-*C*-butyl-3-deoxy-α-D-altropyranoside (**4**) prepared by the Grignard reaction of methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-mannopyranoside (**3**) with butylmagnesium chloride. By the synthesis the relative configurations of natural type of racemic blastmycinone and its all diastereomers were completely established.

Natural (+)blastmycinone[1] [(+)**1a**], obtained by saponification of antimycin A_3 (blastmycin) under mild conditions, has recently been synthesized[2] from the synthetic (−)hydroxylactone [(−)**2a**] identical with natural (−)blastmycinolactol.[1] Hydroxylactone [(−)**2a**] was prepared by lithium aluminum hydride-reduction of the optically active (+)diastereomer (**A**) of *t*-butyl 4-(*N*-benzyloxycarbonyl-*O*-*t*-butyl-L-threonyloxy)-2-butyl-3-(isovaleryloxy)pentanoate; only this is adequate for the total synthesis of natural antimycin



(**A**)

A_3.[2] The absolute configuration(2*R*,3*R*,4*S*) of the natural (+)blastmycinone [(+)**1a**] has been established on the basis of the absolute configuration of (−)blastmycinolactol [(−)**2a**] which was determined through a stereospecific synthesis of the enantiomeric blastmycinolactol [(+) **2a**].[3] The natural type of racemic blastmycinone and its diastereomers have also been synthesized and characterized by tlc and PMR.[2]* An optically active diastereomer (−)**1b** has been obtained together with the enantiomeric blastmycinone [(−)**1a**] as a byproduct in the lactonization reaction** of (2*S*,3*S*,4*R*)-4-(*N*-benzyloxycarbonyl-L-threonyloxy)-2-butyl-3-(isovaleryloxy)pentanoic acid (**B**) with trifluoroacetic anhydride in benzene.



(**B**)

A recent study by Koyama *et al.*[4] on stereoselective synthesis and relative configurations of the racemic diastereomers of blastmycinone indicates that the configuration of the diastereomer **1b** is 2,3-*cis*: 3,4-*cis*. The diastereomer (−)**1b** appears to be the 3-epimer of the enantiomeric blastmycinone (−)**1a**. However, the possibility of 4-epimerization, which may partly occur on the C-4 of compound **B** under the reaction conditions of lactonization, cannot be excluded. Confirmation of the configuration of **1b** was thus undertaken by an unambiguous method. For this purpose, we attempted a stereospecific synthesis of four optically active diastereomeric blastmycinones [(+)**1a**, (+)**1b**, (−)**1c**, and (−)**1d**], all of which have "2*R*" configuration, similar to that in the natural blastmycinone (+)**1a**, as shown in Fig. 1.

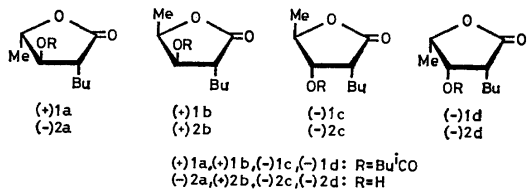


Fig. 1. Absolute configurations of diastereomeric (2*R*)blastmycinones and blastmycinolactols.

Methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-mannopyranoside[5] (**3**) was treated with excess butylmagnesium chloride in ether according to the procedure of Inch and Lewis[6] to afford methyl 4,6-*O*-benzylidene-3-*C*-butyl-3-deoxy-α-D-altropyranoside (**4**) in a 64% yield. Acetylation of **4** with acetic anhydride in pyridine gave the 2-acetate (**5**). The structures of **4** and **5** were confirmed by PMR analysis. Compounds **4** and **5** were treated with *N*-bromosuccinimide[7] in boiling carbon tetrachloride to yield methyl 4-*O*-benzoyl-6-bromo-3-*C*-butyl-3,6-dideoxy-α-D-altropyranoside (**6**) and its 2-acetate (**7**), respectively, in excellent yields.

Lithium aluminum hydride-reduction of **6** in tetrahydrofuran gave methyl 3-*C*-butyl-3,6-dideoxy-α-D-altropyranoside (**8**) in a 76% yield. Acetolysis of **8** with acetic anhydride–sulfuric acid afforded 1,2,4-tri-*O*-acetyl-3-*C*-butyl-3,6-dideoxy-D-altropyranose (**9**) as a syrupy anomeric mixture. Hydrolysis of **9** with methanolic sodium hydroxide gave a free sugar **10**, which was subjected to periodate oxidation to yield 2-*C*-butyl-2,5-dideoxy-3-*O*-formyl-D-ribofuranose (**11**) in an excellent yield. The structure of **11** was supported by its PMR spectral data ($J_{1,2}$=4.7 Hz, $J_{2,3}$=10.0 Hz, $J_{3,4}$=5.8 Hz, and δ($CDCl_3$) 8.23(s, OCHO)]. De-O-formylation of **11** with 2% hydrochloric acid in aqueous dioxane followed by oxidation with bromine–water afforded (−)(2*R*,3*S*,4*R*)-2-butyl-3,4-dihydroxypentanoic acid-1,4-lactone[(−)**2c**] in a 68% yield. Isovalerylation of (−)**2c** with isovaleric anhydride in

* Racemic blastmycinone and its diastereomers were previously designated in order of decreasing R_f-value of tlc with the solvent G (see Experimental) as **1a**, **1b**, **1c**, and **1d**.

** This reaction mainly gave the nine-membered dilactone derivative, from which the diastereomeric antimycin A_3 was synthesized.[2]

Table 1. PMR-spectra data of synthetic (2*R*)blastmycinolactols (in CD_3OD) and blastmycinones (in $CDCl_3$). Chemical shifts (δ values) and coupling constants (Hz)

Compounds:	(2*R*)Blastmycinolactols				(2*R*)Blastmycinones			
	(−)**2a**	(+)**2b**	(−)**2c**	(−)**2d**	(+)**1a**	(+)**1b**	(−)**1c**	(−)**1d**

pyridine gave (−)blastmycinone-c [(−)**1c**] in an 86% yield. The synthetic sample showed on tlc (solvent G) a single spot having the same R_f-value as that of the racemic blastmycinone-c (**1c**). The PMR spectrum of (−)**1c** was identical with that of **1c**. (Table 1)

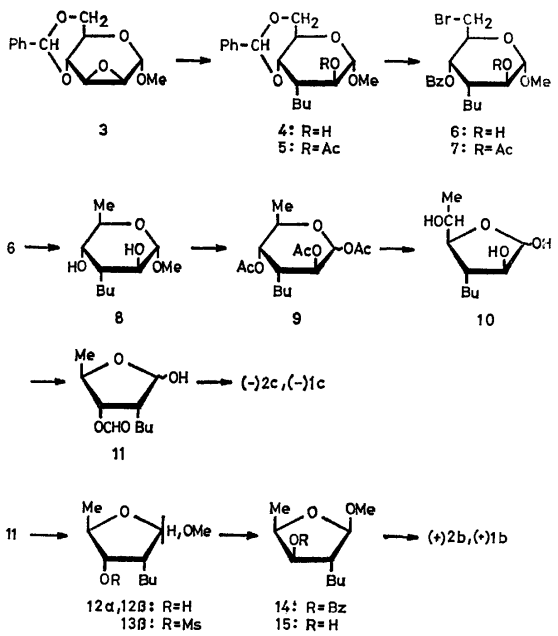

Chart 1.

The periodate-oxidation product **11** was treated with 0.5% methanolic hydrogen chloride to afford an anomeric mixture of the methyl glycoside, which was fractionated on silica gel to give α-anomer (**12**α, 30%) and β-anomer (**12**β, 50%). Treatment of the major product **12**β with methanesulfonyl chloride in pyridine gave 3-mesylate (**13**β), which was subsequently treated with sodium benzoate in dimethylsulfoxide (DMSO) at 140—145 °C for 3 hr to afford the 3-inverted-benzoate (**14**) in a 41% yield. De-O-benzoylated glycoside **15**, obtained by hydrolysis of **14** with 0.1 M methanolic sodium hydroxide, was easily converted into free sugar by treatment with 0.1 M hydrochloric acid in aqueous dioxane at room temperature. The product was then oxidized with bromine-water to afford (+)(2*R*,3*R*,4*R*)-2-butyl-3,4-dihydroxypentanoic acid-1,4-lactone [(+)**2b**] in a 62% yield based on **14**. Isovalerylation of (+)**2b** gave (+)blastmycinone-b [(+)**1b**] in an 88% yield. This showed the same R_f-value as that of the racemic blastmycinone-b (**1b**) on tlc (solvent G), its PMR spectrum also being identical with that of **1b**. (Table 1)

Compound **7** was treated with silver fluoride[8a,8b] in pyridine at room temperature to afford 5-enopyranoside (**16**, 91%) as a syrup, whose PMR spectrum showed overlapping narrow multiplets at δ 4.77—4.88 attributed to the terminal methylene protons (H-6, H-6′). Since **16** did not crystallize and showed an R_f-value close to that of **7** on tlc with all solvent systems employed, it was used without further purification for the subsequent synthesis. Hydrogenation of **16** on palladium black followed by removal of some impurities through a silica gel column gave exclusively methyl 2-*O*-acetyl-4-*O*-benzoyl-3-*C*-butyl-3,6-dideoxy-β-L-galactopyranoside (**17**) in a 70% yield. First-order analysis of the PMR spectrum of **17** revealed large ring proton coupling constants ($J_{1,2}$=8.0 and $J_{2,3}$=11.1 Hz), which suggest the preferred conformation of **17** to be 1*C* chair. Acetolysis of **17** with acetic anhydride–sulfuric acid yielded 1,2-di-*O*-acetyl-4-*O*-benzoyl-3-*C*-butyl-3,6-dideoxy-α-L-galactopyranose (**18**) which was contaminated by a small amount of its β-anomer. The protecting groups of **18** were removed with methanolic sodium hydroxide to give **19**, which was then subjected to periodate-oxidation to afford 2-*C*-butyl-2,5-dideoxy-3-*O*-formyl-L-lyxofuranose (**20**) as a semicrystalline anomeric mixture in a 98% yield based on **17**. De-O-formylation of **20** followed by oxidation with bromine–water gave the crystalline diastereomeric hydroxylactone[(−)**2d**, mp 99.0—100.5 °C] in a 51% yield. Isovalerylation of (−)**2d** afforded (−)blastmycinone-d [(−)**1d**, mp 47–48 °C] in an 86% yield, which could be characterized as blastmycinone-d by tlc and PMR.

Subsequently, the natural (+)blastmycinone [(+)**1a**] was synthesized *via* the natural (−)blastmycinolactol [(−)**2a**] as follows. Free sugar **20** was treated with 0.1 M methanolic hydrogen chloride to afford methyl 2-*C*-butyl-2,5-dideoxy-β-L-lxyofuranoside (**21**) as a major product in a 60% yield. The β-glycoside **21** was mesylated and the resulting crystalline mesylate **22** was treated with sodium benzoate in DMSO to give methyl 3-*O*-benzoyl-2-*C*-butyl-2,5-dideoxy-β-L-arabinofuranoside (**23**) in a 42% yield based on **21**, which was proved to be structurally homogeneous by PMR analysis. Debenzoylated product **24** obtained from **23** was hydrolyzed with 0.1 M hydrochloric acid and the resulting free sugar was treated with bromine-water to afford (−)**2a** (mp 49.5—50.5 °C) in an 84% yield.

This product was identical with the authentic sample of natural (−)blastmycinolactol,[2] from which the natural (+)blastmycinone [(+)**1a**] had been derived in an excellent yield.[2]

The configuration of the diastereomer **1b** was unambiguously determined from the above results, the relative configurations of all diastereomeric blastmycinones (**1a**, **1b**, **1c**, and **1d**) being completely established. Configurations [2,3-*cis*:3,4-*cis* for **1b** and 2,3-*trans*:3,4-*cis* for **1d**] proposed by Koyama *et al.*[4] should be revised to 2,3-*trans*:3,4-*cis* for **1b** and 2,3-*cis*:3,4-*cis* for **1d**. Consequently, the byproduct (−)**1b** formed during the lactonization of **B** was proved to be the 4-epimer of the enantiomeric blastmycinone [(−)**1a**].

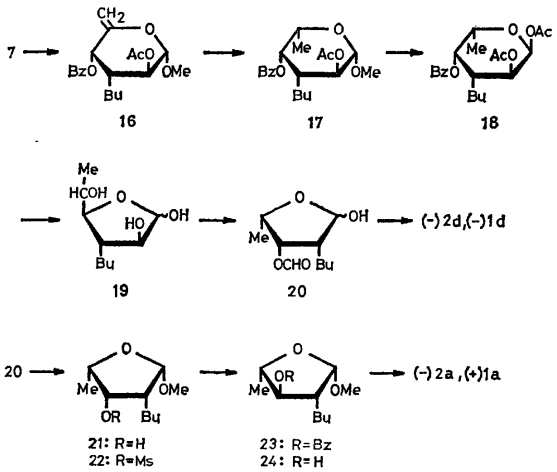

Chart 2.

Finally, we wish to describe the preferred conformations of the optically pure hydroxylactones, (−)**2a**, (+)**2b**, (−)**2c**, and (−)**2d**, in various solvents, which may closely be related to those of the corresponding diastereomeric blastmycinones, (+)**1a**, (+)**1b**, (−)**1c**, and (−)**1d**. The observed ring proton coupling constants ($J_{2,3}$, $J_{3,4}$) of these hydroxylactones in deuteromethanol (Table 1), benzene, pyridine, and deuterochloroform were approximately equal and their CD spectra in methanol measured at room temperature showed no double-humped CD curve[9] but single negative Gaussian curves corresponding to a negative Cotton effect. These evidences indicate that the hydroxylactones in solution may predominantly exist in either nonplaner E_3 or E^3 conformation which is considered to be stable conformation[10] of 1,4-lactone under the preference of co-planarity of the five atoms of lactone group (C–CO–O–C).

Legrand and Bucourt rules[11] on ring chirality allow the negative sign of the Cotton effect to be predicted for the E_3 conformations (Fig. 2) without any conflict with the established correlation between the negative sign of the Cotton effect and the absolute configuration (2*R*) at C_2 of the 1,4-lactone, which has been proposed for the aldono-1,4-lactone by Okuda *et al.*[12] and discussed by Beecham.[13] The prediction was confirmed by PMR data (Table 1) in the following way.

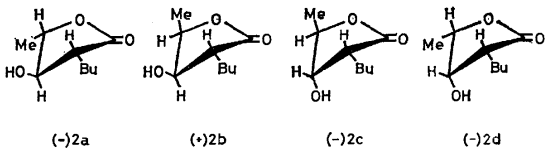

Fig. 2. Preferred conformations of diastereomeric (2*R*)blastmycinolactols.

Coupling constants ($J_{2,3}$, $J_{3,4}$) of (−)**2a** and (−)**2c** could be explained most satisfactorily on the assumption of E_3 conformation (Fig. 2) for the hydroxylactones, (−)**2a** and (−)**2c**. Calculation of the dihedral angles ($\phi_{2,3}$, $\phi_{3,4}$) of (+)**2b** carried out according to the method of Karplus[14] with the coupling constants ($J_{2,3}$, $J_{3,4}$) of (+)**2b** indicates that two conformers, (E^3 $\phi_{2,3}=128°28'$, $\phi_{3,4}=37°54'$) and E^3 ($\phi_{2,3}=48°51'$, $\phi_{3,4}=37°54'$), are possible for (+)**2b**. From a consideration of the Dreiding models, it appears that, in the E_3 conformer, the observed angle (θ *ca.* 20°) of the buckle*** of the lactone ring forces the C-4 methyl group and the C-2 hydrogen atom into a non-parallel axial orientation by which they are kept at a distance, a small 1,3-diaxial interaction between them thus being expected, while is in the E^3 conformation ($\theta \leq 65°$) the bulky C-2 butyl group closely located to the C-4 hydrogen atom which is oriented in an almost parallel axial position to the butyl group, and thus a larger 1,3-diaxial interaction should be expected. In conclusion, the E_3 conformer appears to be more favorable.

On the last hydroxylactone (−)**2d**, the calculated dihedral angles ($\phi_{2,3}=40°00'$ and $\phi_{3,4}=49°32'$) could be applied to both E_3 and E^3 conformers of the lactone. Consideration by means of the model suggests the E^3 conformer (θ *ca.* 45°) to be unfavorable, since a larger 1,3-diaxial interaction between the bulky butyl group in quasi axial position at C-2 and the quasi axial methyl group at C-4 is expected, and the interaction between the hydrogen atoms at C-2 and C-4 in the E_3 conformer might be smaller.

Experimental

Melting points were determined on a micro hot stage and are uncorrected. IR spectra were taken on a Hitachi 225 Spectrophotometer, and PMR spectra on a Varian A-60D Spectrometer using TMS as an internal standard. Optical rotations were measured with a Zeiss Photoelectric Precision Polarimeter. CD spectra were taken on a JASCO J-20 Spectropolarimeter. Tlc was carried out on Wakogel B-5 (Wako Pure Chemical Industries, Ltd.) and silica gel column chromatography on Wakogel C-200 which was activated at 110 °C for 1 hr. The following solvent systems were used: A [hexane-acetone(5 : 1)], B [*ditto*(10 : 1)], C [benzene-ethyl acetate(12 : 1)], D [*ditto*(1 : 1)], E [*ditto*(6 : 1)], F [*ditto*(50 : 1)], and G [petroleum ether-diisopropyl ether (7 : 4)]. In general, all concentrations were carried out at reduced pressure below 40 °C.

*** Extent of the buckle is represented in the angle (θ) between planes $C_{(2)}-\underset{\underset{O}{\|}}{C}_{(1)}-O-C_{(4)}$ and $C_{(2)}-C_{(3)}-C_{(4)}$.[15]

1. *Methyl 4,6-O-Benzylidene-3-C-butyl-3-deoxy-α-D-altropyranoside (4).*[3] Fresh magnesium shavings (11.1 g, 0.457 mol) were covered with dry ether (160 ml) and activated by addition of a piece of iodine. After the activation reaction had started, butyl chloride (47.9 ml, 0.460 mol) was added under stirring at room temperature for 1 hr to form butylmagnesium chloride. After standing for 12 hr, a solution of methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-mannopyranoside (**3**)[5] (8.00 g, 30.3 mmol) in dry ether (400 ml) was added to the viscous suspension. The mixture was refluxed for 9 hr under vigorous stirring, then cooled in an ice-bath, and carefully decomposed with ice-water (200 ml). The ether layer was washed with saturated aqueous NaCl, dried and evaporated to give a syrup (11.3 g), which was chromatographed on a silica gel column (1.7 kg) with solvent A to afford a homogeneous sample of **4** as a colorless oil (6.25 g, 64%): $[\alpha]_D^{18}$ +135° (*c* 1.80, chloroform); δ ($CDCl_3$) 3.41 (s, OCH_3), 4.58 (dd, H-1, $J_{1,2}=J_{1,3}=1.0$ Hz), and 5.67 (s, PhC<u>H</u>).

Found: C, 67.36; H, 7.82%. Calcd for $C_{18}H_6O_5$: C, 67.06; H, 8.13%.

2. *Methyl 2-O-Acetyl-4,6-O-benzylidene-3-C-butyl-3-deoxy-α-D-altropyranoside (5).* Acetic anhydride (1.29 ml, 13.6 mmol) was added to a solution of **4** (2.20 g, 6.82 mmol) in dry pyridine (20 ml). After standing overnight at 40 °C, the mixture was poured into cold water (45 ml) and then extracted with chloroform (30 ml×4). The combined organic layers were washed with saturated aqueous $KHSO_4$, $NaHCO_3$, and NaCl, successively. The dried solution was evaporated to give the 2-acetate **5** (2.49 g, 100%) as a pale yellow syrup. A part of this was purified through a silica gel column with solvent B to afford an analytical sample of **5**: $[\alpha]_D^{23}$ +78° (*c* 1.4, chloroform); δ ($CDCl_3$) 2.11 (s, OAc), 3.41 (s, OCH_3), 4.56 (dd, H-1, $J_{1,2}=J_{1,3}=1.0$ Hz), 5.04 (dd, H-2, $J_{2,3}=2.0$ Hz), and 5.68 (s, PhC<u>H</u>).

Found: C, 66.14; H, 7.63%. Calcd for $C_{20}H_{28}O_6$: C, 65.91; H, 7.74%.

3. *Methyl 4-O-Benzoyl-6-bromo-3-C-butyl-3,6-dideoxy-α-D-altropyranoside (6).* A mixture of **4** (2.80 g, 8.70 mmol), and *N*-bromosuccinimide (NBS) (1.86 g, 10.4 mmol) in carbon tetrachloride (100 ml) containing barium carbonate (2.42 g, 12.3 mmol) was heated for 2.5 hr under stirring at 80 °C. Solids were filtered off, and the filtrate was washed with saturated aqueous $Na_2S_2O_3$, $NaHCO_3$, and NaCl, successively. The dried solution was evaporated to give 6-bromo-4-benzoate **6** (3.49 g, 100%) as a syrup which was suitable for the next synthesis. A part of this was chromatographed on silica gel with solvent C to afford a pure sample of **6**: $[\alpha]_D^{20}$ +19° (*c* 2.02, chloroform); δ ($CDCl_3$) 3.56 (s, OCH_3), 4.66 (d, H-I, $J_{1,2}=4.7$ Hz), and 5.45 (dd, H-4, $J_{3,4}=4.0$, $J_{4,5}=5.2$ Hz).

Found: C, 53.86; H, 6.24; Br, 20.03%. Calcd for $C_{18}H_{25}O_5Br$: C, 53.87; H, 6.28; Br, 19.91%.

4. *Methyl 2-O-Acetyl-4-O-benzoyl-6-bromo-3-C-butyl-3,6-dideoxy-α-D-altropyranoside (7).* A solution of **5** (2.30 g, 6.32 mmol) in dry carbon tetrachloride (100 ml) was treated with NBS (1.35 g, 7.58 mmol) and barium carbonate (1.77 g, 8.95 mmol) in the manner described in the Expt. 3 to afford a practically pure sample of **7** (2.80 g, 100%). A part of this was purified through a silica gel column with solvent C to give a pure sample of **7** as a colorless syrup: $[\alpha]_D^{23}$ +46° (*c* 1.62, chloroform); δ ($CDCl_3$) 2.16 (s, OAc), 4.73 (d, H-1, $J_{1,2}=1.8$ Hz), 5.09 (dd, H-2, $J_{2,3}=4.4$ Hz), and 5.40 (dd, H-4, $J_{3,4}=5.1$, $J_{4,5}=8.6$ Hz)

Found: C, 54.48; H, 6.11; Br, 18.33%. Calcd for $C_{20}H_{27}O_6Br$: C, 54.18; H, 6.14; Br, 18.03%.

5. *Methyl 3-C-Butyl-3,6-dideoxy-α-D-altropyranoside (8).* A suspension of $LiAlH_4$ (2.65 g, 69.6 mmol) in dry tetrahydrofuran (THF) (100 ml) was added in one portion to a stirred and cooled solution of **6** (3.45 g, 8.60 mmol) in dry THF (140 ml). The mixture was refluxed for 1 hr under stirring. To the cooled reaction mixture was slowly added ethyl acetate and water under stirring and solids were then filtered off. The filtrate was washed with water and saturated aqueous NaCl. The dried solution was evaporated and the residue (3.0 g) was purified through a silica gel column (200 g) with solvent D to afford a homogeneous sample of **8** (1.43 g, 76%) as a colorless oil: $[\alpha]_D^{19}$ +24° (*c* 1.31, chloroform); δ ($CDCl_3$) 1.31 (d, 5-CH_3, $J=6.7$ Hz), 3.49 (s, OCH_3), 4.13 (dq, H-5, $J_{4,5}=4.2$ Hz), and 4.51 (d, H-1, $J_{1,2}=6.0$ Hz).

Found: C, 60.64; H, 10.20%. Calcd for $C_{11}H_{21}O_4$: C, 60.52; H, 10.16%.

6. *1,2,4-Tri-O-acetyl-3-C-butyl-3,6-dideoxy-D-altropyranose (9).* To a solution of **8** (1.05 g, 4.82 mmol) in acetic anhydride (25.6 ml, 270 mmol) was added concd sulfuric acid (0.226 ml, 4.24 mmol) under ice-cooling. After being kept for 30 min at room temperature, the reaction mixture was poured into cold water (150 ml) and the solution was neutralized with solid $NaHCO_3$ and then extracted with chloroform (60 ml× 3). The combined extracts were washed with saturated aqueous NaCl, dried and evaporated to give a sample of **9** (1.59 g, 100%) as a yellow syrup: δ ($CDCl_3$) 1.31 (d, 5-CH_3, $J=6.8$ Hz) and 2.1—2.2 (three OAc).

7. *3-C-Butyl-3,6-dideoxy-D-altrofuranose (10).* To a solution of **9** (1.59 g, 4.82 mmol) in methanol (15 ml) was added aqueous 1M NaOH (14 ml) under ice-cooling. After being kept standing for 50 min at room temperature, the solution was neutralized with carbon dioxide and evaporated. To the residue was added acetone. The insoluble matter was filtered off and the filtrate was evaporated to afford the syrupy free sugar **10** (980 mg, 100%) as an anomeric mixture: δ ($CDCl_3$) 1.11 (d, 5-CH_3, $J=6.8$ Hz), 5.29 (d, $J_{1,2}=3.8$ Hz) and 5.40 (s) (each anomeric H-1).

8. *2-C-Butyl-2,5-dideoxy-3-O-formyl-D-ribofuranose (11).* To a solution of **10** (948 mg, 4.64 mmol) in acetone (28 ml) was added a solution of sodium metaperiodate (3.08 g, 14.4 mmol) in water (30 ml). The mixture was stirred for 4 hr at room temperature and the precipitates formed were filtered off and washed with acetone. The combined filtrate and washings were evaporated and the residue was dissolved in chloroform. The solution was washed with saturated aqueous NaCl, dried and evaporated to afford a sample of **11** (940 mg, 100%) as a colorless syrup, which was used for the subsequent synthesis without further purification: δ ($CDCl_3$) 1.28 (d, 4-CH_3, $J=6.8$ Hz), 5.22 (dd, H-3, $J_{2,3}=10.0$ Hz, $J_{3,4}=5.8$ Hz), 5.44 (d, H-1, $J_{1,2}=4.7$ Hz), and 8.23 (s, OC<u>H</u>O).

9. *(−)(2R,3S,4R)-2-Butyl-3,4-dihydroxypentanoic Acid-1,4-Lactone[(−)2c].* A sample of **11** (50 mg, 0.25 mmol) was de-O-formylated with 2% HCl (W/V) in 50% dioxane-water (v/v) (8.8 ml) for 2 hr at room temperature. The reaction mixture was then neutralized with solid $NaHCO_3$. To the mixture containing the de-O-formylated product was added bromine (0.016 ml, 0.32 mmol) and the mixture was stirred at room temperature for 2.5 hr. The oxidation product was extracted with ethyl acetate. The extract was washed with saturated aqueous $Na_2S_2O_3$ and saturated aqueous NaCl, successively, dried and evaporated. The residue (60 mg) was purified through silica gel (6 g) with solvent E to afford a homogeneous sample of (−)**2c** (29.1 mg, 68%) as a colorless syrup: $[\alpha]_D^{17}$ −69° (*c* 0.28, methanol); $[\theta]_{215}^{MeOH}$ −6400; $\nu_{max}^{CCl_4}$ (0.002 M) 3620 (OH) and 1780 cm^{-1} (1,4-lactone).

Found: C, 62.56; H, 9.18%. Calcd for $C_9H_{16}O_3$: C, 62.76; H, 9.36%.

10. *(−)(2R,3S,4R)-2-Butyl-4-hydroxy-3-(isovaleryloxy)-pentanoic Acid-1,4-lactone [(−)blastmycinone-c][(−)**1c**].* Isovaleric anhydride (0.042 ml, 0.20 mmol) was added to a solution of (−)**2c** (18.2 mg, 0.106 mmol) in dry pyridine (0.7 ml). After being kept for 40 hr at room temperature, the reaction mixture was poured into cold water and extracted with ether. The ethereal extracts were washed with saturated aqueous NaCl, dried and evaporated. The residue (31 mg) was chromatographed on silica gel (3 g) with solvent G to afford a pure sample of (−)**1c** (23.1 mg, 86%) as a colorless oil: $[\alpha]_D^{18}$ −88° (*c* 0.97, chloroform); $\nu_{max}^{CCl_4}$ (0.1 M) 1790 (1,4-lactone) and 1742 cm^{-1} (ester); R_f 0.48 (solvent G).

Found: C, 65.66; H, 9.39%. Calcd for $C_{14}H_{24}O_4$: C, 65.59; H, 9.44%.

11. *Methyl 2-C-Butyl-2,5-dideoxy-β-D-ribofuranoside (**12β**) and Its α-Anomer (**12α**).* Periodate-oxidation product **11** (646 mg, 3.19 mmol) was treated with 0.5% methanolic HCl (32.3 ml) for 1.5 hr at room temperature. The reaction mixture was neutralized with solid $NaHCO_3$ and the insoluble matter was removed by filtration. The filtrate was evaporated and the residue (561 mg) was chromatographed on silica gel (70 g) with solvent E to fractionate α-anomer (**12α**) as a faster-moving component and the β-anomer (**12β**) as a slower migration component. α-Anomer (**12α**): colorless oil, 180 mg (30%); $[\alpha]_D^{18}$ +95° (*c* 0.86, chloroform); δ ($CDCl_3$) 1.19 (d, 4-CH_3, J=6.7 Hz), 3.39 (s, OCH_3), 3.74 (dd, H-3, $J_{2,3}$=5.2 Hz, $J_{3,4}$=0.4 Hz), 4.29 (dq, H-4), and 4.91 (d, H-1, $J_{1,2}$=3.8 Hz).

Found: C, 64.06; H, 10.50%. Calcd for $C_{10}H_{20}O_3$: C, 63.79; H, 10.71%.

β-Anomer (**12β**): colorless oil, 295 mg (50%); $[\alpha]_D^{18}$ −79° (*c* 1.26, chloroform); δ ($CDCl_3$) 1.30 (d, 4-CH_3, J=6.3 Hz), 3.45 (s, OCH_3), 4.11 (dd, H-3, $J_{2,3}$=5.7 Hz, $J_{3,4}$=2.3 Hz), 4.14 (dq, H-4), and 4.80 (d, H-1, $J_{1,2}$=4.1 Hz).

Found: C, 64.07; H, 10.50%. Calcd for $C_{10}H_{20}O_3$: C, 63.79; H, 10.71%.

12. *Methyl 2-C-Butyl-2,5-dideoxy-3-O-methanesulfonyl-β-D-ribofuranoside (**13β**).* To a solution of **12β** (120 mg, 0.64 mmol) in dry pyridine (1.2 ml) was added methanesulfonyl chloride (0.06 ml, 0.77 mmol) and the solution was kept for 2 hr at room temperature. After addition of water (15 ml), the mixture was extracted with chloroform and the extract was washed with saturated aqueous NaCl, dried and evaporated to afford 3-mesylate (**13β**) (157 mg, 93%) as a pale yellow syrup, which was used for the subsequent synthesis without further purifications, because of its instability. **13β**: δ ($CDCl_3$) 1.34 (d, 4-CH_3, J=6.7 Hz), 3.06 (s, OMs), 3.44 (s, OCH_3), 4.42 (dq, H-4, $J_{3,4}$=2.3 Hz), 4.83 (d, H-1, $J_{1,2}$=4.4 Hz), and 5.01 (dd, H-3, $J_{2,3}$=5.7 Hz).

13. *Methyl 3-O-Benzoyl-2-C-butyl-2,5-dideoxy-β-D-xylofuranoside (**14**).* A mixture of **13β** (157 mg, 0.59 mmol) and sodium benzoate (255 mg, 1.77 mmol) in dry DMSO (3.1 ml) was heated at 140—145 °C for 3 hr. After being cooled to room temperature, the solids were filtered and washed with ethyl acetate. The combined filtrate and washings were washed with water and saturated aqueous NaCl. The dried solution was evaporated and the residue (210 mg) was chromatographed on silica gel (20 g) with solvent F to afford a homogeneous sample of **14** (70 mg, 41%) as a colorless syrup: $[\alpha]_D^{18}$ −15° (*c* 0.45, chloroform); δ ($CDCl_3$) 1.32 (d, 4-CH_3, J=6.4 Hz), 3.45 (s, OCH_3), 4.52 (dq, H-4, $J_{3,4}$=5.8 Hz), 4.76 (d, H-1, $J_{1,2}$=2.3 Hz), and 5.25 (dd, H-3, $J_{2,3}$=2.7 Hz).

Found: C, 69.61; H, 8.22%. Calcd for $C_{17}H_{24}O_4$: C, 69.83; H, 8.27%.

14. *Methyl 2-C-Butyl-2,5-dideoxy-β-D-xylofuranoside (**15**).* A solution of **14** (70 mg, 0.24 mmol) in dry methanol (0.29 ml) was treated with 1M methanolic sodium methoxide (0.288 ml) for 1 hr at room temperature. The solution was neutralized with 1M HCl and evaporated to give a sample of **15** (45 mg, 100%) as a pale yellow oil: δ ($CDCl_3$) 1.34 (d, 4-CH_3, J=6.7 Hz), 3.40 (s, OCH_3), and 4.78 (s, H-1).

15. *(+)(2R,3R,4R)-2-Butyl-3,4-dihydroxypentanoic Acid-1,4-Lactone [(+)**2b**].* A sample of **15** (45 mg, 0.24 mmol) was treated with 1M HCl/50% aqueous dioxane (0.45 ml) for 1 hr at room temperature. The reaction mixture containing the free sugar was neutralized with solid $NaHCO_3$, and then treated with bromine (0.015 ml, 0.30 mmol) for 3 hr at room temperature. The reaction mixture was worked up and purified by the procedure described in Expt. 9 to afford a homogeneous sample of (+)**2b** (25.3 mg, 62%) as a colorless oil: $[\alpha]_D^{18}$ +71° (*c* 0.53, methanol); $[\theta]_{216}^{MeOH}$ −3500; $\nu_{max}^{CCl_4}$ (0.002M) 3625 (OH) and 1783 cm^{-1} (lactone).

Found: C, 62.45; H, 9.10%. Calcd for $C_9H_{16}O_3$: C, 62.76; H, 9.36%.

16. *(+)(2R,3R,4R)-2-Butyl-4-hydroxy-3-(isovaleryloxy)-pentanoic Acid-1,4-Lactone [(+)Blastmycinone-b] [(+)**1b**].* By the same procedure as in the preparation of (−)**1c**, the hydroxylactone (+)**2b** (18.5 mg) was isovalerylated to afford (+)**1b** (24.3 mg, 88%) as a colorless oil: $[\alpha]_D^{17}$ +57° (*c* 1.01, chloroform); $\nu_{max}^{CCl_4}$ (0.1 M) 1790 (1,4-lactone) and 1743 cm^{-1} (ester); R_f 0.60 (solvent G).

Found: C, 65.82; H, 9.40%. Calcd for $C_{14}H_{24}O_4$: C, 65.59; H, 9.44%.

17. *Methyl 2-O-Acetyl-4-O-benzoyl-3-C-butyl-3,6-dideoxy-α-D-arabino-hex-5-enopyranoside (**16**).* Anhydrous silver fluoride (3.40 g, 26.8 mmol) was added to a solution of **7** (2.00 g, 4.52 mmol) in dry pyridine (30 ml), and the mixture was stirred for 1.5 hr at room temperature in the dark. Addition of ether (100 ml) to the reaction mixture gave precipitates, which were filtered and washed with ether. The combined filtrate and washings were washed with saturated aqueous $KHSO_4$, $NaHCO_3$, and NaCl, successively. The dried solution was evaporated to afford a sample of **16** (1.48 g, 91%) as a yellow syrup which was used for the subsequent synthesis without further purification: δ ($CDCl_3$) 2.16 (s, OAc), 3.54 (s, OCH_3), 4.68 (d, H-1, $J_{1,2}$=4.7 Hz), 4.77–4.88 (m, 2H, H-6 and H-6'), 5.24 (dd, H-2, $J_{2,3}$=7.8 Hz), and 5.89 (d, H-4, $J_{3,4}$=3.2 Hz).

18. *Methyl 2-O-Acetyl-4-O-benzoyl-3-C-butyl-3,6-dideoxy-β-L-galactopyranoside (**17**).* To a solution of **16** (1.48 g, 4.08 mmol) in dioxane (50 ml) was added freshly prepared palladium black (*ca.* 300 mg) and the mixture was stirred vigorously for 2 hr under bubbling with hydrogen. The filtered solution was evaporated and the residue (1.60 g) was chromatographed on silica gel (160 g) with solvent B to afford a homogeneous sample of **17** (1.03 g, 70%) as a colorless syrup: $[\alpha]_D^{23}$ −89° (*c* 1.52, chloroform); δ ($CDCl_3$) 1.24 (d, 5-CH_3, J=6.4 Hz), 2.13 (s, OAc), 3.55 (s, OCH_3), 3.91 (dq, H-5, $J_{4,5}$=1.0 Hz), 4.43 (d, H-1, $J_{1,2}$=8.0 Hz), 5.11 (dd, H-2, $J_{2,3}$=11.1 Hz), and 5.44 (dd, H-4, $J_{3,4}$=2.8 Hz).

Found: C, 66.13; H, 7.66%. Calcd for $C_{20}H_{28}O_6$: C, 65.91; H, 7.74%.

19. *1,2,-Di-O-acetyl-4-O-benzoyl-3-C-butyl-3,6-dideoxy-α-L-galactopyranose (**18**).* A sample of **17** (1.00 g, 2.74 mmol) was treated with acetic anhydride (30 ml, 313 mmol) and concd. sulfuric acid (0.29 ml, 5.46 mmol) for 1 hr at room temperature. The solution was worked up by the procedure described in Expt. 6 to give a sample of **18** (1.08 g, 100%) contaminated by a small amount of its β-anomer, as a yellow syrup: δ ($CDCl_3$) 1.17 (d, 5-CH_3, J=6.6 Hz), 2.07 and

2.18 (each s, OAc), 4.37 (dq, H-5, $J_{4,5}$=0.8 Hz), 5.29 (dd, H-2, $J_{2,3}$=11.8 Hz), 5.57 (dd, H-4, $J_{3,4}$=2.3 Hz), and 6.46 (d, H-1, $J_{1,2}$=3.4 Hz) [β-anomer contaminated, 5.83 (d, H-1, $J_{1,2}$=8.2 Hz)].

20. *2-C-Butyl-2,5-dideoxy-3-O-formyl-L-lyxofuranose (**20**).* A solution of product **18** (1.00 g, 2.55 mmol) in methanol (25 ml) was treated with 1 M NaOH (16.5 ml) for 4 hr at room temperature. The solution was worked up by the procedure described in Expt. 7 to afford 3-*C*-butyl-3,6-dideoxy-L-galactofuranose (**19**) (520 mg, 100%) as a pale yellow syrup. A solution of **19** (500 mg, 2.45 mmol) in acetone (35 ml) was treated with a solution of sodium metaperiodate (1.57 g, 7.35 mmol) in water (40 ml) for 2 hr at room temperature in the dark. The reaction mixture was worked up by the procedure described in Expt. 8 to afford a semicrystalline anomeric mixture of **20** (485 mg, 98%) which was used for the subsequent synthesis without further purification: δ ($CDCl_3$) 1.28 (d, 4-CH_3, J=6.3 Hz), 4.53 (dq, H-4, $J_{3,4}$=3.0 Hz), 5.35 (dd, H-3, $J_{2,3}$=3.0 Hz), *ca.* 5.6 (1H, H-1 in α- and β-anomer), and 8.28 (s, 1H, OCHO).

21. *(−)(2R,3S,4S)-2-Butyl-3,4-dihydroxypentanoic Acid-1,4-lactone [(−)**2d**].* A crystalline sample of (−)**2d** (41.9 mg, 51%) was obtained from **20** (97 mg) by the method described in Expt. 9. Recrystallization of the sample from ethyl acetate-petroleum ether afforded an analytical sample of (−)**2d**: mp 99.5–100.5 °C; $[\alpha]_D^{17}$ −96° (*c* 0.34, methanol); $[\theta]_{214}^{MeOH}$ −5230; $\nu_{max}^{CCl_4}$ (0.002M) 3625 (OH) and 1780 cm^{-1} (lactone).

Found: C, 62.56; H, 9.24%. Calcd for $C_9H_{16}O_3$: C, 62.76; H, 9.36%.

22. *(−)(2R,3S,4S)-2-Butyl-4-hydroxy-3-(isovaleryloxy)-pentanoic Acid-1,4-Lactone [(−)Blastmycinone-d] [(−)**1d**].* The hydroxylactone (−)**2d** (14.5 mg) was isovalerylated by the procedure described in Expt. 10 to afford a crystalline (−)**1d** (18.5 mg, 86%) which was recrystallized from ethyl acetate-petroleum ether: mp 47.0—48.0 °C; $[\alpha]_D^{18}$ −89° (*c* 0.90, chloroform); $\nu_{max}^{CCl_4}$ (0.1 M) 1792 (lactone) and 1748 cm^{-1} (ester); R_f 0.33 (solvent G).

Found: C, 65.82; H, 9.42%. Calcd for $C_{14}H_{24}O_4$: C, 65.59; H, 9.44%.

23. *Methyl 2-C-butyl-2,5-dideoxy-β-L-lyxofuranoside (**21**).* The periodate oxidation product **20** (300 mg, 1.48 mmol) was treated with 0.5% methanolic hydrogen chloride (15 ml, 2.06 mmol) for 3 hr at room temperature. The solution was worked up by the same procedure as described in Expt. 11 and the product (415 mg) was fractionated on silica gel (40 g) with solvent E. The faster-moving fraction gave the α-anomer showing a positive rotation and the slower-moving fraction afforded β-anomer **21** with a negative rotation as a major product. Since both anomers separated were very unstable, no analytical samples could be obtained. (+)α-Anomer: 15.2 mg (5.5%); δ ($CDCl_3$) 1.32 (d, 4-CH_3, J=6.3 Hz), 3.39 (s, OCH_3), 4.19 (dq, H-4, $J_{3,4}$=3.7 Hz), and 4.85 (d, H-1, $J_{1,2}$=4.0 Hz). (−)β-Anomer (**21**): 167 mg (60%); δ ($CDCl_3$) 1.24 (d, 4-CH_3, J=6.5 Hz), 3.40 (s, OCH_3), 3.98 (dd, H-3, $J_{2,3}$=4.5, $J_{3,4}$=2.5 Hz), 4.19 (dq, H-4), and 4.71 (d, H-1, $J_{1,2}$=5.0 Hz).

24. *Methyl 2-C-Butyl-2,5-dideoxy-3-O-methanesulfonyl-β-L-lyxofuranoside (**22**).* A crystalline sample of **22** (219 mg) was prepared from freshly prepared **21** (155 mg) by the procedure in Expt. 12. It was recrystallized from ether-petroleum ether to afford fine needles which were also very unstable: mp 56—58 °C; δ ($CDCl_3$) 1.37 (d, 4-CH_3, J=6.3 Hz), 3.09 (s, OMs), 3.45 (s, OCH_3), 4.39 (dq, H-4, $J_{3,4}$=2.8 Hz), 4.82 (d, H-1, $J_{1,2}$=4.9 Hz), and 5.17 (dd, H-3, $J_{2,3}$=5.2 Hz).

25. *Methyl 3-O-Benzoyl-2-C-butyl-2,5-dideoxy-β-L-arabinofuranoside (**23**).* A solution of **22** (200 mg, 0.753 mmol) in DMSO (4 ml) was heated with sodium benzoate (326 mg, 2.26 mmol) at 140 °C for 1 hr and the reaction mixture was worked up by the procedure in Expt. 13 to afford a homogeneous sample of **23** (91 mg, 42%) as a colorless syrup: $[\alpha]_D^{22}$ −48° (*c* 1.67, chloroform); δ ($CDCl_3$) 1.42 (d, 4-CH_3, J=6.3 Hz), 3.44 (s, OCH_3), 4.28 (dq, H-4, $J_{3,4}$=5.9 Hz), 4.81 (d, H-1, $J_{1,2}$=1.2 Hz), and 4.88 (dd, H-3, $J_{2,3}$=3.8 Hz).

Found: C, 69.50; H, 8.13%. Calcd for $C_{17}H_{24}O_4$: C, 69.83; H, 8.27%.

26. *Methyl 2-C-Butyl-2,5-dideoxy-β-L-arabinofuranoside (**24**).* A sample of **24** (29 mg, 100%) was obtained from **23** (45 mg) by the procedure in Expt. 14: δ ($CDCl_3$) 1.32 (d, 4-CH_3, J=6.5 Hz), 3.41 (s, OCH_3), 4.06 (dq, H-4, $J_{3,4}$=5.8 Hz), and 4.74 (d, H-1, $J_{1,2}$=1.5 Hz).

27. *Natural (−)Blastmycinolactol [(−)**2a**].* A crystalline sample of (−)**2a** (22.3 mg, 84%) was obtained by treatment of **24** (29 mg) with 1 M HCl followed by bromine-oxidation by the same procedure as described in Expt. 15. Recrystallization from ether-petroleum ether afforded a pure sample of (−)**2a**: mp 49.5—50.5 °C; $[\alpha]_D^{18}$ −18° (*c* 1.09, methanol); $[\theta]_{217}^{MeOH}$ −5500; $\nu_{max}^{CCl_4}$ (0.002 M) 3635 (OH) and 1785 cm^{-1} (lactone).

Found: C, 62.60; H, 9.22%. Calcd for $C_9H_{16}O_3$: C, 62.76; H, 9.36%.

28. *Natural (+)Blastmycinone [(+)**1a**].* Isovalerylation of (−)**2a** (16.5 mg) in the same manner as described in Expt. 10 afforded (+)**1a** (21.3 mg, 86%) as a colorless oil: $[\alpha]_D^{17}$ +10° (*c* 1.20, chloroform); $\nu_{max}^{CCl_4}$ (0.1 M) 1788 (lactone) and 1745 cm^{-1} (ester); R_f 0.66 (solvent G).

Found: C, 65.72; H, 9.31%. Calcd for $C_{14}H_{24}O_4$: C, 65.59; H, 9.44%.

The authors wish to thank Prof. Sumio Umezawa, Keio University, for his interest and kind advice. Thanks are also due to Prof. Shonosuke Zen, Kitasato University, for the measurment of CD spectra and to Mr. Saburo Nakada, Keio University, for elemental analyses. Financial support by the Asahi Glass Foundation for Contribution to Industrial Technology is acknowledged.

Crystallographic Studies of Interaction between Nucleotides and Metal Ions. I. Crystal Structures of the 1 : 1 Complexes of Cobalt and Nickel with Inosine 5′-Phosphate

Katsuyuki Aoki

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received July 6, 1974)

The crystal structures of the 1 : 1 complexes of inosine 5′-phosphate with cobalt ($C_{10}H_{11}O_8N_4PCo,7H_2O$) and inosine 5′-phosphate with nickel($C_{10}H_{11}O_8N_4PNi,7H_2O$) have been determined from single-crystal X-ray data collected on an automated diffractometer. The both isomorphous crystals belong to orthorhombic system, space group $P2_12_12_1$ with four formula units in the unit cell of dimensions $a=10.859$, $b=25.987$, $c=6.845$ Å for the cobalt complex and $a=10.812$, $b=25.898$, $c=6.845$ Å for the nickel complex respectively. The structure of the cobalt complex was determined by three-dimensional Patterson and Fourier methods and that of the nickel complex was elucidated from that of the cobalt complex. Both were refined by the block-diagonal least-squares method including anisotropic temperature factors. The final R values were 0.051 and 0.075 for the cobalt and nickel complexes, respectively. All of the 25 hydrogen atoms in the case of the cobalt complex and 22 hydrogen atoms in the case of the nickel complex were found. The hypoxanthine bases related by the two-fold screw axis parallel to c are extensively overlapped at a distance of 3.42 Å for both complexes. The nucleotides have the preferred *anti* conformation about the glycoside linkage with the ribose ring showing the C(3′)-*endo* pucker. The torsion angles around the C(5′)−O(5′) bond are 161.6° (cobalt complex) and 162.0° (nickel complex). In the both complexes, therefore, the phosphate group has the extended conformation. The metals are not directly bonded to the phosphate oxygen atoms but are bonded to the nitrogen atom N(7) of the base and to five water oxygen atoms. There is extensive hydrogen bonding involving the hypoxanthine ring, the phosphate anion, the hydroxyl groups of the furanose ring and seven water molecules in the crystal.

It has now been widely recognized that metal ions have profound effects on the structure and function of nucleic acids and their constituents. They stabilize or destabilize the manifold structure of nucleic acid[1,2] and alter the coding specificity in protein synthesis.[3]

The other interesting area of metallonucleic acid chemistry includes the use of heavy metals to determine the sequence of nucleic acid biopolymers by electron microscope techniques[4,5] and to determine the structure of tRNA by X-ray method.[6] We have investigated the crystal structures of 1 : 1 metal complexes of inosine 5′-phosphate(5′-IMP) in order to obtain the fundamental and precise informations regarding interaction of transition metals with the component of nucleic acid, where inosine is present as minor base in the triplet anticodon of yeast tRNAs such as alanine tRNA, serine tRNA1, serine tRNA2 and valine tRNA.

The crystal structures of 5′-IMP containing alkali metals such as barium and sodium have been investigated by Nagashima and Iitaka,[7] and Rao and Sundaralingam.[8]

After we had completed those structure determinations it came to our attention that Clark and Orbell had reported the brief communication on the same crystal structure of the inosine 5′-phosphate–nickel complex.[9] Their data are in agreement with those obtained from our X-ray crystallographic studies.

Experimental

Violet crystals of ($C_{10}H_{11}O_8N_4PCo$, $7H_2O$) and light green crystals of ($C_{10}H_{11}O_8N_4PNi$, $7H_2O$) were prepared by adding aqueous solution of cobalt nitrate hexahydrate and nickel nitrate hexahydrate to that of disodium inosine 5′-phosphate in an equivalent mole ratio, adjusting to pH 4.5 with dilute nitric acid. They were grown from an aqueous solution by slow evaporation. The elementary analysis revealed that the ratio of inosine 5′-phosphate to metal is 1 : 1 for both complexes.

The unit-cell dimensions were determined from high-order reflexions on a Rigaku four-circle automated diffractometer.

	Crystal data	
	$C_{10}H_{11}O_8N_4PCo$, $7H_2O$(5′-IMP-Co)	$C_{10}H_{11}O_8N_4PNi$, $7H_2O$(5′-IMP-Ni)
System	Orthorhombic	Orthorhombic
a	10.859±0.005 Å	10.812±0.005 Å
b	25.987	25.898
c	6.845	6.845
U	1931.6 Å^3	1916.1 Å^3
F(000)	1100	1104
Space group	$P2_12_12_1$	$P2_12_12_1$
Number of independent non-zero reflexions used for the structure determination	1424	1500

Three-dimensional intensity data in the 2θ-range from 0 to 50° for the cobalt complex with Zr-filtered Mo$K\alpha$ radiation and 130° for the nickel complex with Ni-filtered Cu$K\alpha$ radiation were collected on a Rigaku four-circle automated diffractometer. A 2θ-ω scan technique at a rate of 2°/min for the cobalt complex and 4°/min for the nickel complex was employed for the data collection. Background counts of 10 s were measured at each beginning and end of the scan. Three standard reflections were checked at an interval of every 52 reflections and they showed fluctuations in intensity of only ±2.0% for the cobalt complex and ±2.8% for the nickel complex. The data were corrected for Lorentz and polarization effects, but no absorption corrections were made ($\mu=10.8$ cm^{-1} (Co complex for Mo $K\alpha$ radiation) and 20.9 cm^{-1} (Ni complex for Cu $K\alpha$ radiation) and approximate crystal dimensions of $0.1\times0.2\times0.3$ mm (Co complex) and $0.1\times0.1\times0.2$ mm (Ni complex)). A reflection was considered unobserved if the intensity was smaller than 3.0 times its standard deviation. On this basis, 1424 reflections out of the total of 2067 reflections (Co complex) and 1500 out of the total of 1986 reflections (Ni complex) were adopted in the subsequent refinement of the structure.

The temperature factors for the heavier atoms are of the form, $T=\exp[-(\beta_{11}h^2+\beta_{22}k^2+\beta_{33}l^2+2\beta_{12}hk+2\beta_{13}hl+2\beta_{23}kl)]$, and those for the hydrogen atoms are, $T=\exp[-B(\sin\theta/\lambda)^2]$. The hydrogen atoms H′(W3), H(W6) and H′(W6) were found on the final difference electron density map and their atomic parameters were not refined. Three hydrogen atoms bonded to W(2) and W(7) were not clearly found on the difference map.

Determination and Refinement of the Structure

The structure was established by heavy atom method. Approximate positional parameters of the cobalt atom were determined from (1/2, v, w), (u, 1/2, w) and (u, v, 1/2) Harker sections. The Fourier synthesis based on the phases of the cobalt atom revealed the complete molecular structure and seven water oxygen atoms. The refinement was carried out using the block-diagonal least-squares method. Five cycles of isotropic and five cycles of anisotropic refinement reduced R value to 0.08. The least-squares weighting was that similar to Hugehes,[10] where $\sqrt{w}=50/|F_o|$ for $|F_o|>50$, $\sqrt{w}=1.0$ for $|F_o|\leq 50$. At this stage a difference Fourier synthesis could locate 23 hydrogen atoms out of 25. Three more cycles of refinement including hydrogen atoms with isotropic thermal parameters gave final R value of 0.051. Finally, two remaining hydrogen atoms could be found from the subsequent difference Fourier synthesis. The final atomic parameters are given in Table 1 together with their standard deviations.

The structure of the nickel complex was elucidated from that of the cobalt complex. Five cycles of isotropic block-diagonal least-squares refinement using the atomic parameters of the cobalt complex as starting parameters reduced the R value to 0.134. Subsequent five cycles of anisotropic refinement decreased R to 0.088. In a difference Fourier synthesis calculated at this stage, 19 hydrogen atoms in the asymmetric unit were actually located and their positions were in accord with the stereochemistry of the molecule, and they were included in the refinement with isotropic temperature factors. Three cycles of refinement, including all atoms brought R to 0.075; an additional final cycle gave no significant changes in positional or thermal parameters. Finally, a difference Fourier synthesis was computed in order to locate the six remaining hydrogen atoms, three of which were actually located. The weighting scheme was; $\sqrt{w}=25/|F_o|$ for $|F_o|>25$, $\sqrt{w}=1.0$ for $|F_o|\leq 25$. The refined atomic parameters are given in Table 2. Complete lists of the observed and calculated structure factors are preserved by the Chemical Society of Japan.[11]

The atomic scattering factors used in the present structure determination were; for hydrogen atoms those cited as Q–1 in International Tables for X-ray Crystallography,[12] for carbon SX–6, for nitrogen SX–7, for oxygen SX–8, for phosphorus SX–70, for cobalt SX–27 and for nickel SX–28.

Discussion of the Structure

The bond lengths and bond angles of the inosine 5′-phosphate molecules along with their estimated standard deviations are listed in Table 3. In this table the values are compared with those of the inosine molecules in monosodium inosine 5′-phosphate (5′-IMP–Na),[8] inosine dihydrate (Inosine, $2H_2O$)[13] and inosine.[14] Figure 1 is a perspective view of the molecule in the cobalt complex showing the numbering

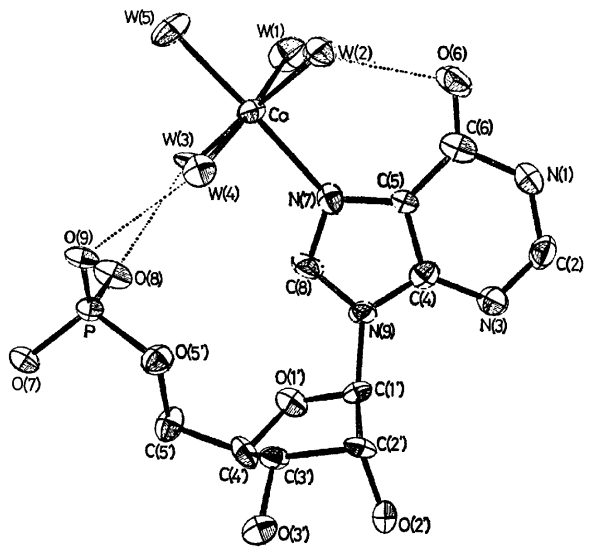

Fig. 1. Perspective view of the molecule in the cobalt complex showing the numbering system and the anisotropic thermal motion of the non-hydrogen atoms represented by 50% probability ellipsoids.

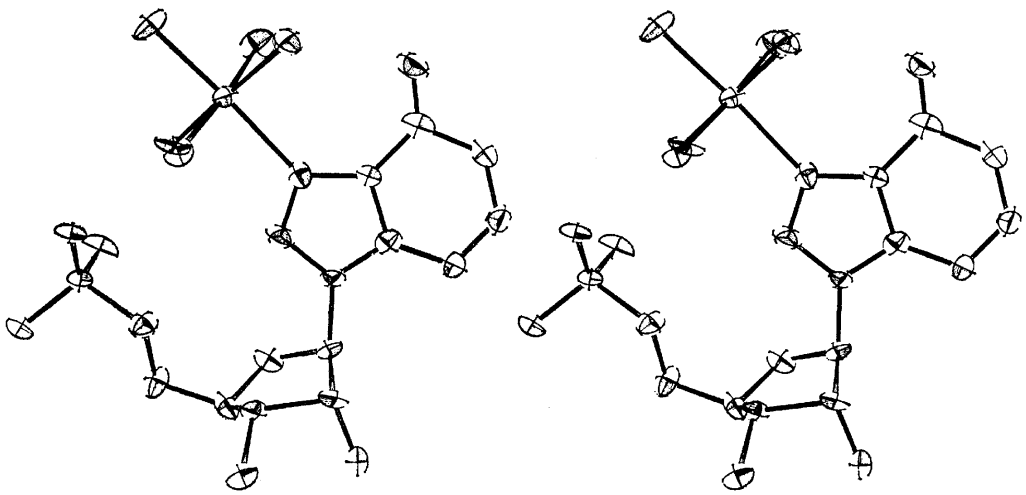

Fig. 2. Stereoscopic view of the structure of the molecule in the cobalt complex.

The atoms marked * were included in the calculations of the least-squares planes. The equation of the least-squares plane is defined by $AX+BY+CZ=D$, where X, Y and Z are the orthogonal coordinates measured in Å units along the crystallographic a, b and c axes, respectively.

ϕ_{OO}: torsion angle O(1′)-C(4′)-C(5′)-O(5′), defined by Shefter and Trueblood (1965).
ϕ_{OC}: torsion angle C(3′)-C(4′)-C(5′)-O(5′), defined by Shefter and Trueblood (1965).
ϕ_{CN}: torsion angle C(8)-N(9)-C(1′)-O(1′), defined by Sundaralingam and Jensen (1965).
ϕ_{OP}: torsion angle C(4′)-C(5′)-O(5′)-P.

system. A stereoscopic view of the structure of the molecule in the cobalt complex is also shown in Fig. 2. Aspects of the coordination and the conformation of the inosine 5′-phosphate molecule in the cobalt and nickel complexes are similar to each other.

The Hypoxanthine Ring. The bond lengths and bond angles in the both hypoxanthine rings are in over all agreement with those found in the compounds mentioned above. A common and characteristic feature of the hypoxanthine moieties is regarding angles around the C(6)–O(6) bond; the C(5)–C(6)–O(6) angle is apparently larger than the N(1)–C(6)–O(6), differences of which are distributed in the range of 6—11°. This may be due to the effect of the steric interaction between the oxygen atom O(6) and the nitrogen atom N(7).

The least-squares plane through the nine atoms of the base, excluding the substituent atom O(6), and the deviations of atoms from this plane are given in Table 4, comparing with those of the compounds mentioned above. The atoms composing the purine ring show a significant degree of puckering, which has been often found in purine and pyrimidine derivatives.

The binding of the metal to N(7) has little effect on the base geometry as shown in Tables 3 and 4.

The Ribose Ring. The bond lengths and bond angles in the ribose ring have their usual values.[15] The conformational parameters of the ribose ring for the inosine 5′-phosphate molecule are listed in Table 5, comparing with those of monosodium inosine 5′-phosphate,[8] disodium inosine 5′-phosphate (5′-IMP–2Na)[7] and barium inosine 5′-phosphate (5′-IMP–Ba).[7] An important stereochemical parameter in nucleosides and nucleotides is the glycosyl torsion angle ϕ_{CN},[15] C(8)–N(9)–C(1′)–O(1′), which describes the relative orientation of the base with respect to the sugar. Those angles are 25.4° (Co complex) and 24.0° (Ni complex), therefore, the conformation about the glycosyl bond is *anti* in both complexes.

The ribose carbon atom C(1′) is out of the base plane by 0.134 Å (Co complex) and 0.155 Å (Ni complex) and the glycosidic C(1′)–N(9) bond makes an angle of about 5.0° (Co complex) and 6.0° (Ni complex) with the base plane. As shown in Table 4, the ribose ring is puckered with C(3′) displaced by the best four-atom plane of the furanose ring by 0.560 Å (Co complex) and 0.566 Å (Ni complex) on the same side as C(5′), the conformation of the ribose ring is, therefore, C(3′)-*endo*. When refered to the three-atom plane C(1′), O(1′) and C(4′), the conformation is C(3′)-*endo*-C(2′)-*exo* for both complexes, where C(3′) and C(2′) are displaced by 0.465 and 0.122 Å (Co complex) and 0.477 and 0.151 Å (Ni complex).

Dihedral angles between the base and the ribose planes are 67.3° (Co complex) and 66.5° (Ni complex) (Table 4).

The ribose ring conformation can also be described in terms of torsion angles around the ring bonds. The conformation around the C(4′)–C(5′) bond, described by the angles ϕ_{OO},[16] O(1′)–C(4′)–C(5′)–O(5′) and ϕ_{OC},[16] C(3′)–C(4′)–C(5′)–O(5′), is *gauche-gauche* for both complexes.

The Phosphate Group. The ester linkage, C(5′)–O(5′), shows the elongated conformation as usual, the torsion angle ϕ_{OP}, C(4′)–C(5′)–O(5′)–P, being 161.6° (Co complex) and 162.0° (Ni complex).

It may be noted that both phosphorus atoms in the cobalt and nickel complexes lie approximately in the base plane; only 0.188 Å (Co complex) and 0.173 Å (Ni complex) off the base plane.

Coordination Geometry about the Metal Atom. The coordination geometries about (a) the cobalt and (b) nickel atoms are shown in Fig. 3, together with the bond lengths and bond angles within the metal coordination spheres. They are approximately octahedral with the six coordination sites occupied by the five oxygen atoms of the water molecules and the nitrogen atom N(7) of the hypoxanthine moiety, a site which is accessible and presumedly favorable in the biopolymer, and are similar to that found in the cobalt-theophylline complex.[5] Other two cases of the transition metal binding to N(7) of the purine base have been reported in the zinc–adenine[17] and the copper–9-methylhypoxanthine[18] complexes. Although in the vitamine B_{12} derivatives,[19] the analogous N(7) site of the dimethylbenzimidazole base is coordinated to the cobalt atom which is chelated to the corrine nucleus in a manner similar to that of the present complexes, it is to our knowledge the first case in the crystal structure of nucleotides that the transition metal directly bonds to the base. Bond lengths and bond angles of the cobalt complex agree in general

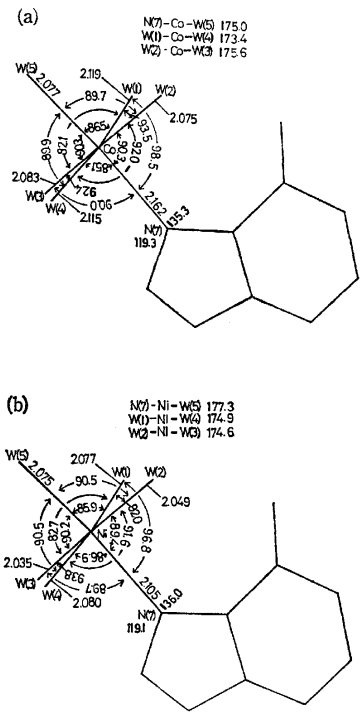

Fig. 3. The coordination geometries around (a) the cobalt atom and (b) the nickel atom. The bond lengths and angles within the metal coordination spheres are shown. The average estimated standard deviations are 0.009 Å for Metal-W bonds and 0.010 Å for Metal-N bonds and 0.4° for W-Metal-W and W-Metal-N angles and 0.8° for C-N-Metal angles.

(3) The dihedral angle between the planes, (1) and (2)	87.5°	87.6°

The atoms marked * were included in the calculations of the least-squares planes. The equation of the least-squares plane is defined by $AX+BY+CZ=D$, where X, Y and Z are the orthogonal coordinates measured in Å units along the crystallographic a, b and c axes, respectively.

a) This plane is identical with that in Table 4.

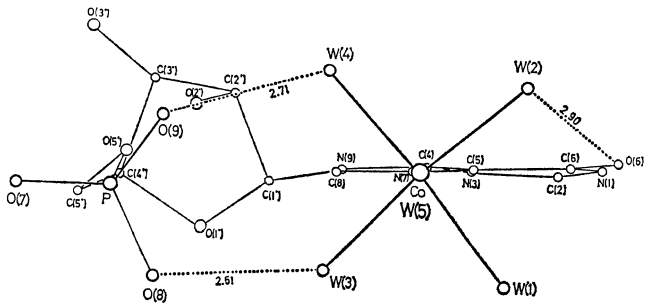

Fig. 4. A view of the cobalts complex down the W(5)–Co bond. Note the dispositions of the hypoxanthine ring system, and in particular the intramolecular hydrogen bonds from W(3) and W(4) to O(8) and O(9) of the phosphate group respectively.

with those of the nickel complex. However, each bond length in the nickel complex is smaller than the corresponding one in the cobalt complex. The metal–oxygen coordination distances range from 2.075 to 2.119 Å with an average value of 2.094 Å for the cobalt complex and from 2.035 to 2.080 Å with that of 2.063 Å for the nickel complex. The metal–nitrogen coordination distances are 2.162 Å for the cobalt complex and 2.105 Å for the nickel complex. These values of the nickel complex in the present study are in good agreement with those of the same nickel complex reported by Clark and Orbell[9]; (Ni–H_2O)average= 2.06 Å and Ni–N(7)=2.11 Å. As shown in Table 6, the cobalt and nickel atoms involving the water oxygen W(5) lie in the base plane. The cobalt and nickel atoms are also in the least-squares plane through four water oxygen atoms, W(1), W(2), W(3) and W(4), which is approximately perpendicular to the base plane.

Table 7. Bond lengths and angles involving hydrogen atoms in water molecules

Bond length	5′-IMP-Co	5′-IMP-Ni

H-W(7)-H′	121(12)	—

A notable feature of the metal coordination is that metals are not directly attached to the phosphate oxygen atoms, as is found for sodium ion in the crystal structures of disodium inosine 5′-phosphate[7] and monosodium inosine 5′-phosphate[8] and for barium ion in those of barium inosine 5′-phosphate,[7] barium uridine 5′-phosphate[16] and barium 5′-ribophosphate,[20] whereas in the structures of calcium thymidylate[21] and disodium adenosine triphosphate,[22] metal ions bond directly to the phosphate oxygen atoms.

Figure 4 is a view of the cobalt complex down to W(5)–Co bond. The hypoxanthine ring has positioned itself nearly symmetrically between the bonds Co–W(3) and Co–W(4), but asymmetrically between the bonds Co–W(1) and Co–W(2). This may be due to the intramolecular hydrogen bond from the water W(2) to the carbonyl oxygen O(6) of the base. Figure 5 is the arrangement of the molecules in the unit cell in projection down the c axis for the cobalt complex. Cobalt atom interacts indirectly with phosphate oxygens through the water molecules.

Molecular Packing and Hydrogen Bonds. In Fig. 5, the close contacts are shown by broken lines, which may represent hydrogen bonds. The positions of the molecules are denoted as following: I at x, y, z; II at

a) Some of the atoms are designated by Code No.

1/2−x, 1−y, 1/2+z; III at 1/2+x, 1/2−y, 1−z and IV at 1−x, 1/2+y, 1/2−z, with the x, y and z coordinates as given in Tables 1 and 2. The translations along the three edges of the unit cell are indicated in parentheses.

The packing of the molecules seems to be governed by the base stacking and intermolecular hydrogen bonds. Further stabilization of the structure is provided by hydrogen bonding of the complex to two water molecules of crystallization. The bond lengths and bond angles involving hydrogen atoms in water molecules are listed in Table 7. The lengths and the

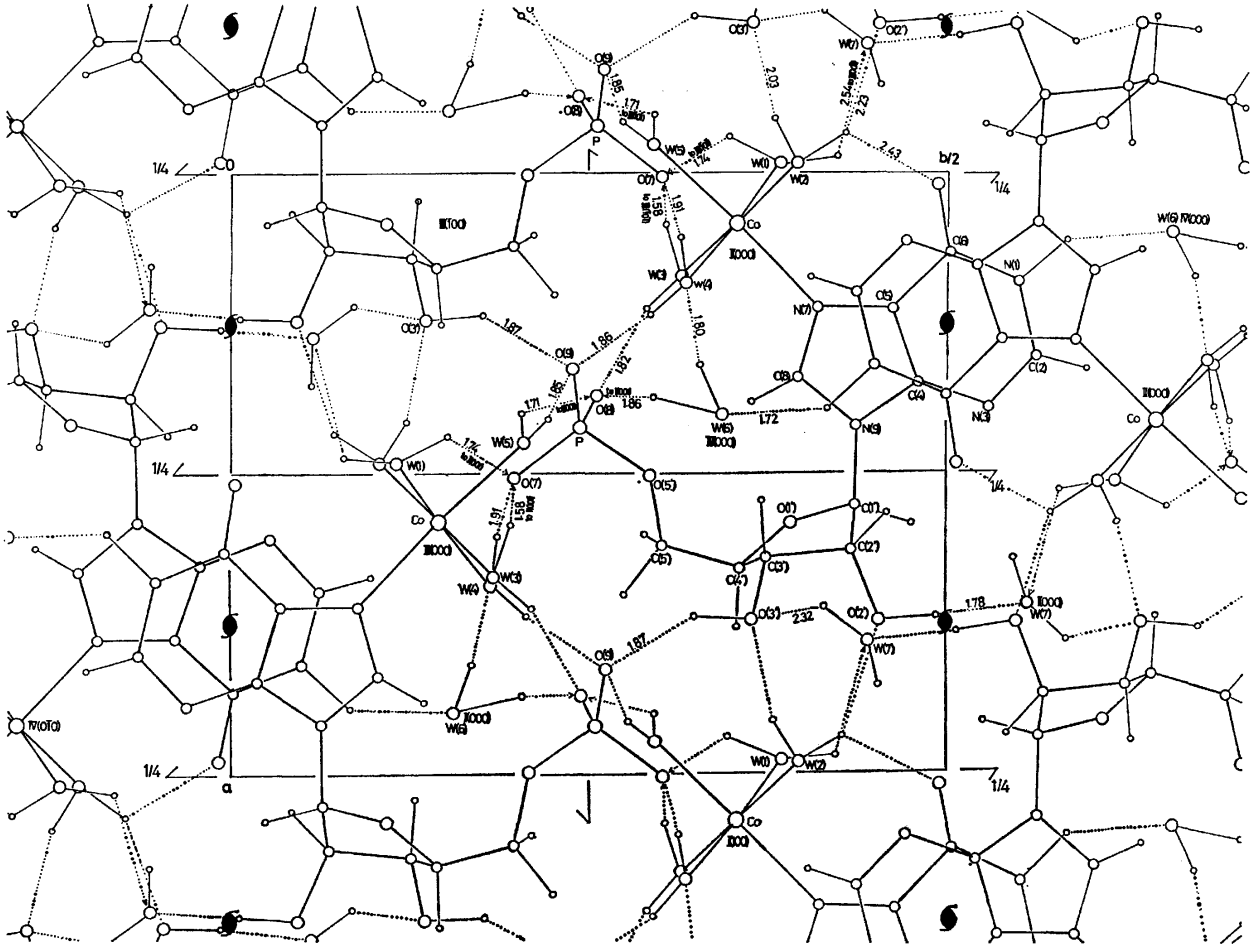

Fig. 5. Projection of the crystal structure of the cobalt complex along the c axis. Hydrogen bonds are shown by broken lines.

directions of the hydrogen bonds are summarized in Tables 8 and 9.

There is an infinite stack of relatively extensive overlapping bases about a two-fold screw axis along the c axis. Adjacent bases are rotated by 180° from each other, which favours dipole-dipole interactions. It is well known that this type of purine superposition may be an important stabilizing force in the inosine and guanosine structures.[23] The hypoxanthine rings lie in the ab plane so that they are stacked with a separation of 3.42 Å along the c axis in both complexes, this value is normal for the perpendicular distance between the base planes.

As expected, the highest concentrations of water molecules are seen around the metal and the anionic phosphate group of the nucleotide. The base, sugar and phosphate moieties are all hydrogen bonded to different degrees with the water molecules, but there is only one hydrogen bond which does not involve a water molecule, that from O(3′) to the phosphate oxygen O(9) (III(000)), and there are no interbase hydrogen bonds. The phosphate groups are running parallel to the a axis about the two-fold screw axis (at x, 1/4, 0) forming hydrogen-bonded ribons, $-(-\text{P}-\text{O}(7)\cdots\text{W}(3)\cdots\text{O}(8)-)-_n$.

The author wishes to thank Professor Y. Iitaka, the University of Tokyo, for his valuable discussion and suggestions.

Selective Dimerization of Propene to 4-Methyl-1-pentene by Potassium–Copper based Catalysts

Junzo YAMASHITA, Kiyoshi SASAKI, Takao KAWAMURA, Koichi HIGUCHI, Shotaro MIURA, and Harukichi HASHIMOTO

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Sendai 980

(Received July 9, 1974)

The dimerization of propene by potassium catalyst was carried out at 180 °C in *n*-heptane to give 4-methyl-1-pentene as a major product. The effects of the addition of metal powders, potassium alkoxides and tertiary amines were investigated. The selective production of 4-methyl-1-pentene on adding metal powders increased in the order of Cu, Ag>Mg, Co>Al, Fe, Ni, Zn. When long-chain alkoxides were added to the potassium-copper catalyst system, potassium catalyst was observed to be dispersed, the relative reaction rates increased, and the isomerization of 4-methyl-1-pentene formed was retarded. Thus, the selectivity increased more than 90% after 40% conversion of propene. The potassium-copper-aliphatic tertiary amine-catalyst system caused the yield of 4-methyl-1-pentene to increase in a similar manner to the potassium-copper-alkoxide-catalyst system and inhibited the formation of the carbonaceous substance covering the surface of the catalyst, and the selectivity was not lowered after a higher conversion of propene.

The dimerization of propene by heavier alkali metal- or alkylalkali-catalysts has been reported to give 4-methyl-1-pentene,[1] from which a stereoregular polymer with a low density and a higher melting point than polyethylene and polypropylene is obtained, whereas the dimerization catalyzed by an acid[2] or a transition metal complex[3] gives a mixture of *n*-hexenes, methylpentenes and 2,3-dimethylbutenes. In the alkali metal- or alkylalkali-catalyzed dimerization, the catalyst system is heterogeneous so that the surface area of the catalyst may have a significant effect upon the reaction. Therefore, the effect of the addition of powdered metals (inert carriers) has been studied. It has been proposed by Wilkes[1c] that organoalkali intermediates were the active species in this reaction. So we have investigated the effect of the addition of bases such as potassium alkoxides and tertiary amines upon the reaction. These bases may coordinate with the counter cation of carbanions to dissociate the insoluble organoalkali intermediates. These effects of bases have been reported in Grignard reactions in hydrocarbon solvents,[4] in reactions of organolithium compounds,[5] and in polymerization of butadiene by alfin catalyst.[6] A highly selective catalyst system which affords 4-methyl-1-pentene in more than 90% after a higher conversion of propene has been found.[7]

Results and Discussion

The Effect of Powdered Metals. Potassium was chosen as a catalyst because it is easier to handle:

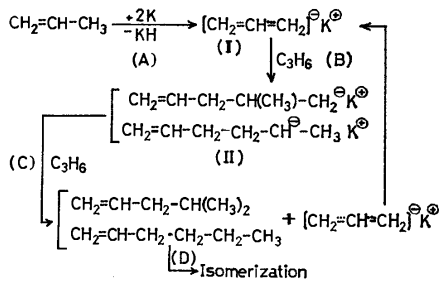

Fig. 1. Reaction scheme for propene-dimerization catalyzed by potassium.

both cesium and potassium have been reported to be effective in the formation of 4-methyl-1-pentene from propene.[1] The reaction was carried out at 180 °C under pressure with vigorous stirring (*ca.* 1000 rpm) in an autoclave equipped with a magnetic stirrer. *n*-Heptane was used as a solvent. Aromatics such as benzene, used in other reports,[1] were found to inhibit the reaction.

The scheme of the reaction has been considered to be as in Fig. 1,[1] *i.e.* allylpotassium (I) was formed in step A, followed by the addition step B and the exchange step C to yield the products. The organopotassium intermediates (I) and (II) are insoluble in the reaction medium, and probably aggregate in the course of the reaction. Since the condition of the catalyst surface may influence the reaction, the effect of adding powdered metals was investigated (Table 1). These powdered metals were expected to function as inert carriers and to increase the surface area of the molten potassium.

The selectivity was increased by added metals in the order of Cu, Ag>Mg, Co>Al, Fe, Ni, Zn. The potassium catalyst was observed to be finely dispersed when the powdered metals were added.

Curtin and Koehl reported that coating of lithium with powdered copper was effective in preparing organolithium compounds.[8] They indicated that it covered the surface of the lithium and inhibited the oxidation of the lithium. They also suggested that the chemical interaction between lithium and copper might be involved. However there has been no report which implies the formation of an alloy or other compounds between potassium and copper. No appropriate explanation for the difference of the effect of the metals can be offered at present.

The Effect of the Addition of Potassium Alkoxides. The reaction step A occurs on the surface of potassium metal. As described above, the reactivity of the catalyst could be increased by an increase in the surface area due to the added powdered metals. In addition, the dissociation of aggregated organopotassium may promote the reaction rate.[5,6] Thus, the effect of the addition of various potassium alkoxides to the potassium–copper catalyst system was investigated.

Table 1. Effect of added metal powders on the potassium catalyzed dimerization of propene[a]

a) Reaction conditions: K 2.0 g (0.05 g atom), *n*-heptane 70 ml, powdered copper 3.2 g (0.05 g atom), 180 °C, 1000 rpm. b) Yields obtained upon heating for 6 hr after the removal of unreacted propene. c) See Table 1.

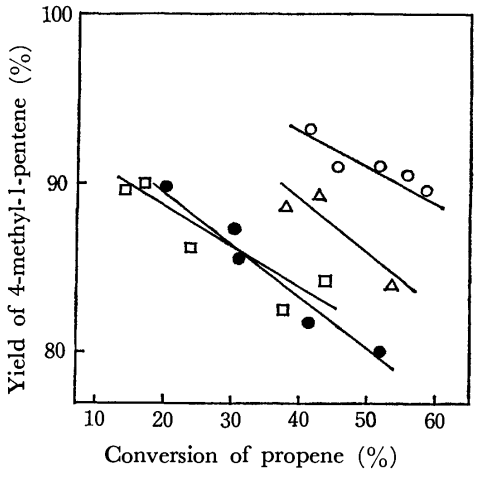

Fig. 2. Variation of the yield of 4-methyl-1-pentene *versus* propene conversion.
●: no additive △: isopropoxide
○: *n*-octyloxide □: *sec*-butoxide
See Table 3 for the other reaction conditions

Figure 2 shows the yields of 4-methyl-1-pentene against the propene conversion for this catalyst system, where the selectivity decreased as the conversion of propene increased. Intermediate organopotassium (I) or (II) in Fig. 1 can also react with primary products resulting in isomerization. So the isomerization of the terminal olefins may become significant as the reaction proceeds. It is compatible with the decreasing selectivity at a higher conversion shown in Fig. 2. Base catalyzed isomerization of methylpentenes and other olefins[9] are known to occur under milder reaction conditions.

Table 3. Effect of the addition of ROK[a]

R	Yields (%)[b] (1)	(1) + (2)	Relative[c] rate

tert-Butyl	79	89	15
n-Octyl	93	94	40
Benzyl	no reaction		

a) Reaction conditions: K 2.0 g, *n*-heptane 70 ml, powdered copper 3.2 g (0.05 g atom), ROK 0.05 mol, propene 40—60 g, 180 °C, 1000 rpm. b) Yields were calculated at 40% conversion of propene, referred to Fig. 2. See Table 1 for (1) and (2). Isomerization of (1) to the other isomers than (2) is very small. c) (Maximum pressure − minimum pressure) (atm) × 100/maximum pressure/reaction time (hr).

Without propene, isomerization of 4-methyl-1-pentene was also significant in our catalyst systems as shown in Table 2. The yields of 4-methyl-1-pentene at 40% conversion of propene and the relative reaction rates in potassium–copper–potassium alkoxide catalyst systems are shown in Table 3, where added alkoxides in the range 0.5—2.0 mol per mol of potassium produced no significant differences in the results. The long chain alkoxides, such as *n*-butoxide, *n*-octyloxide and

n-propoxide, were the most effective additives. More branched, short chain, secondary or tertiary alkoxides were less effective. It was noticed that the addition of tertiary butoxide promoted the isomerization of 4-methyl-1-pentene and that the byproducts(carbonaceous substances) covering the catalyst surface served to gradually slow down the reaction rate. This unexpected observation may be due to the instability of the butoxide under the reaction conditions or the pronounced proton transfer from the products on increase of the catalytic activity. Benzyloxide inhibited the reaction as efficiently as aromatic solvents due to the presence of the aromatic nucleus. Since the isomerization of the olefins occurs without any detectable rearrangement of the carbon skeleton in this catalyst system, the ratio of methylpentenes to *n*-hexenes should be determined at step B in Fig. 1. The total yields of methylpentenes shown in the column (1)+(2) in Table 3 were constant. This indicates that the addition of alkoxides does not affect the course of the addition reaction in step B. The added alkoxides suppressed the isomerization of 4-methyl-1-pentene formed as shown in Table 2. When longer chain alkoxides were added, the catalysts were finely dispersed. The observation suggested that the dispersing effect of the alkoxides has a significant role in the nature of the catalyst systems. When the alkoxides were added, the relative rates became considerably larger, but had no direct correlation with the selectivity. More precise studies of the role of the alkoxides are now in progress.

The Effect of the Addition of Tertiary Amines. Tertiary amines are known to coordinate to counter ions in carbanion reactions where the reactivity of carbanions increases.[5a] Thus, the effect of the addition of various tertiary amines was investigated with the results shown in Table 4 and Fig. 3. The added aliphatic tertiary amines inhibited the formation of the carbonaceous substance covering the surface of the catalyst and did not lower the selectivity at a higher conversion of propene (Fig. 3). The result has a practical importance in the preparation of 4-methyl-1-pentene. The difference between the effect of the alkoxides and tertiary amines is not yet explained. The other effects of the amines were similar to those of the alkoxides.

TABLE 4. EFFECT OF THE ADDITION OF R_3N[a]

R	Yields (%)[b] (1)	Yields (%)[b] (1)+(2)	Relative[c] rate
None	85	94	11
Ethyl[d]	87	93	21
n-Propyl[d]	86	92	15
n-Butyl[d]	90	93	15
n-Hexyl[e]	90	92	14
n-Octyl[e]	90	92	11
N-Methylpiperidine[f]	91	95	25
Pyridine[f]	no reaction

Experimental

Materials. Propene of polymerization grade was dried on a column of molecular sieve 3A. *n*-Heptane of guaranteed reagent grade was washed several times with concentrated sulfuric acid and then with water, refluxed over sodium for 20 hr., distilled and stored over sodium. Reagent grade alcohols were dried with magnesium or sodium and distilled. Reagent grade amines were dried with calcium hydride or naphthylisocyanide and distilled. Powdered Mg, Al, Fe, Co, Ni, Cu, Zn and Ag of reagent grade (*ca.* 100 mesh) were dried under vacuum and stored in a desiccator. The oxide coating of reagent grade potassium was removed under *n*-heptane and the potassium was immediately used for the reaction.

Analyses. The reaction products were analyzed at 50 °C on a Hitachi-Perkin-Elmer Model 6DH gas chromatograph using a 2 m column packed with squalane 20 wt% on Diasolid M. Their NMR spectra and relative retention times in glc analyses agreed with those of authentic samples.

Standard Procedure. *n*-Heptane (70 ml), potassium (3.9 g, 0.1 mol), powdered copper (3.2 g, 0.05 mol) and *n*-butanol (3.7 g, 0.05 mol) were placed in a 300 ml autoclave (SUS 32) equipped with a magnetic stirrer and heated at 100 °C under a nitrogen atmosphere for 3 hr to form potassium *n*-butoxide *in situ*. After purging hydrogrn gas formed during the reaction with nitrogn, propene (*ca.* 50 g) was introduced and allowed to react at 180 °C while stirring at 1000 rpm. for several hours. The autoclave was then cooled rapidly. When powdered metals alone or copper plus tertiary amines were used, potassium (2.0 g, 0.05 mol) was used without the above pretreatment.

The authors wish to thank Dr. S. Miyano for his valuable comments on the problem and to acknowledge the assistance of Mr. Y. Morimoto, S. Kushiyama and S. Omiya in obtaining some of the data. This work

was supported in part by a Grant for Scientific Research from the Ministry of Education, and was presented in part at the 20th (Tokyo 1964) and 30th (Osaka 1974) Annual Meetings of the Chemical Society of Japan.

The Reaction of Cycloalkanones with Copper(II) Halides. I. The Reaction of Cyclohexanones with Copper(II) Chloride

Kyoko NISHIZAWA* and J. Yasuo SATOH

Department of Chemistry, St. Paul's (Rikkyo) University, Nishi-Ikebukuro, Toshima-ku, Tokyo 171

(Received July 18, 1974)

The reaction of cyclohexanones with copper(II) chloride gave polychlorinated cyclohexanediones directly in fairly good yields. With methylcyclohexanones, in general the type of product depends on the number of methylene groups between the carbonyl group and the methyl-substituted carbon in the starting material. A possible mechanism for the reaction is discussed.

The reactions of organic compounds with copper(II) halides have been known to involve addition reactions with olefins[1] and substitution reactions with aromatic[2] or carbonyl compounds. Although substitution reactions with copper(II) chloride have also been reported for saturated or unsaturated ketones[3,4] and aldehydes,[5] monochloro-derivatives were obtained in all cases. Recently, the γ-chlorination of unsaturated ketones and aldehydes was reported by Dietl *et al.*[6] A report by Castro *et al.*[7] on both addition and substitution reactions has also appeared. In the above works, however, the reactions were carried out using only 3—5-fold molar amounts of copper(II) chloride, hence, they proceeded only to the stage of mono- or di-chlorination.

Previously, in synthesizing diosphenol from menthone with a 3-fold molar amount of iron(III) chloride according to the method of Asahina,[8] we found that a quinone derivative, which seemed to be a product of a further reaction, was obtained as a minor product, together with diosphenol.[9] It was also found that the reaction in a dioxane medium proceeded more slowly than in the case of an acetic acid medium; the reaction with copper(II) chloride also proceeded more slowly than in the case of iron(III) chloride. On the basis of these preliminary results, the reaction of cyclohexanones with excess copper(II) chloride in 50% dioxane was carried out in order to investigate the formation of the quinone derivative mentioned above. We reported[10] in a previous communication that, in this reaction, the corresponding polychlorinated cyclohexanediones were obtained in fairly good yields. In the present paper, we wish to describe the details of this reaction.

Experimental

All the melting points are uncorrected. Thin-layer chromatography was carried out on silica gel (Wakogel B-5), with detection done by means of iodine or an *o*-phenylenediamine-ethanol solution. Column chromatography was carried out on silica gel (Wakogel C-100). The IR spectra were measured with a Hitachi 215 grating infrared spectrophotometer by the KBr disk method, and the UV spectra, with a JASCO ORD/UV-5 spectrometer and a Hitachi 323 recording spectrophotometer in an ethanol solution. The NMR spectra were recorded in $CDCl_3$, unless otherwise noted, with TMS as the internal standard and using a Hitachi R-20A nuclear magnetic resonance spectrometer. The chemical shifts are presented in terms of the δ value. The mass spectra were obtained with a Hitachi RMU-7M mass spectrometer at 70 eV.

Materials. The 2-, 3-, and 4-methylcyclohexanone and 3,4- and 3,5-dimethylcyclohexanone were prepared from the corresponding alcohols by oxidation with sodium dichromate.[10]

Reaction of Cyclohexanones with Copper(II) Chloride. A typical procedure was as follows: the cyclohexanone (2 g) with 20—30 times as much $CuCl_2 \cdot 2H_2O$ in 50% dioxane (v/v, 200 ml) was reacted under reflux conditions for 1—4 hr. The reaction mixture was then extracted with ether, and the extract, after being washed and dried (sodium sulfate), was evaporated under reduced pressure. The residue was purified by column chromatography.

Reaction of 2-Chlorocyclohexanone with Copper(II) Chloride. In the general manner described for the cyclohexanones, 2-chlorocyclohexanone (2 g) with $CuCl_2 \cdot 2H_2O$ (77 g) was treated under reflux for 4 hr; the usual work-up subsequently gave 1.1 g (34%) of 3,6,6-trichloro-2-hydroxycyclohex-2-en-1-one (**3**); mp 119—120 °C (lit,[12] 115—116 °C).

*Reaction of 2-Hydroxy-3-methylcyclohex-2-en-1-one (**11**) with Copper(II) Chloride.* 2-Hydroxy-3-methylcyclohex-2-en-1-one (**11**) was prepared from 2-methylcyclohexanone (10 g) according to the method of Wallach.[11a] The recrystallization of the resultant product from water containing a small amount of methanol gave needles (**11**, 2.8 g; overall yield, 22%); mp 59—60 °C (lit,[11] 62—63 °C), IR; ν_{OH} 3407 cm^{-1}, $\nu_{C=O}$ 1670 cm^{-1}, and $\nu_{C=C}$ 1640 cm^{-1}, NMR; 1.92 ppm (s, 3H), 2.03—2.85 ppm (m, 6H), and 6.22 ppm (s, 1H). By the general procedure described for the cyclohexanones, 1 g of (**11**) was refluxed with $CuCl_2 \cdot 2H_2O$ (26.8 g) for 2 hr; the reaction mixture was subsequently worked up in the usual way to give 1.1 g (70%) of 6,6-dichloro-2-hydroxy-3-methylcyclohex-2-en-1-one (**4**); mp 115—116 °C.

*Reduction of 3,6,6-Trichloro-2-hydroxy-4-methylcyclohex-2-en-1-one (**7**) with $LiAlH_4$.* The trichlorocyclohexanedione (0.5 g) in ether (15 ml) was treated with $LiAlH_4$ (0.17 g) under reflux for 1.5 hr. After the usual work-up, 0.095 g (22%) of 3,6-dichloro-2-hydroxy-4-methylcyclohex-2-en-1-one (**6**) [mp 150—153 °C (subl.)] was obtained by recrystallization from CCl_4.

Results and Discussion

The products resulting from the reaction of cyclohexanone and of its methyl derivatives with a 20-fold molar amount of copper(II) chloride are shown in Table 1, and their physical constants (Table 2). The product obtained from cyclohexanone itself showed peaks due to a diosphenolic hydroxyl group (3363 cm^{-1}) and an α,β-unsaturated ketone (1678 cm^{-1} and 1640 cm^{-1}) in the IR spectrum, and the K band (λ_{max}^{EtOH} 281 nm, ε=10900) due to an α,β-unsaturated

a) Analyzed by high resolution mass spectrometry.

ketone in the UV spectrum. In the NMR spectrum, the peaks appeared at 4.51 ppm (triplet, J=6 Hz) due to $-CH(Cl)-$ and at 6.18 ppm (singlet) due to a phenolic hydroxyl group. From these data, the mp, and analysis, the product was identified as Compound **2**.

In the cases of 2- and 3-methylcyclohexanone, the same product was obtained. The IR and UV spectra had peaks due to an α-hydroxy-α,β-unsaturated ketone. In the NMR spectrum, a peak at 1.77 ppm (singlet) attributable to methyl protons was observed, but the peak due to $-CH(Cl)-$ was not observed. From

these data, the resulting product was identified as Compound **4**.

In the reaction of 4-methylcyclohexanone with copper(II) chloride, two products were obtained. One of these was obtained as crystals from the reaction mixture; the other was obtained from the mother liquor by column chromatography with hexane/ether (9/1). The IR and UV spectra of the former definitely indicated the presence of an α-hydroxy-α,β-unsaturated ketone, and the NMR spectrum showed a peak at 1.20 ppm (doublet, $J=6$ Hz) due to methyl protons and a peak at 4.34 ppm (doublet, $J=2.5$ Hz) due to -CH(Cl)-. This product was concluded to be Compound **5** on the basis of the above data. The other product also showed the presence of an α-hydroxy-α,β-unsaturated ketone in the IR and UV spectra. The NMR spectrum had a peak at 1.28 ppm (doublet, $J=6$ Hz) due to methyl protons and a peak at 4.25 ppm (double-doublet, $J=10.5$ and 1.5 Hz) due to -CH(Cl)-. Hence, this product must have the structure of **6**.

In the reaction with a 20-fold molar amount of the reagent, 2- and 3-methylcyclohexanone gave a *gem*-dichloro derivative, while cyclohexanone and 4-methylcyclohexanone did not give such a product with a *gem*-dichloro-function. It was considered that, in the cases of cyclohexanone and 4-methylcyclohexanone, their reactive carbon in the α-position with respect to the carbonyl group should make them capable of yielding the products mentioned above, just as in the cases of 2- and 3-methylcyclohexanone. Therefore, the reaction was attempted using a 30-fold molar amount of copper(II) chloride. The product resulting from cyclohexanone was identified as Compound **3**, with the *gem*-dichloro-function, from the facts that it did not show a peak due to -CH(Cl)- in the NMR spectrum and that the IR and UV spectra had peaks attributable to an α-hydroxy-α,β-unsaturated ketone. Furthermore, the product from 4-methylcyclohexanone was found to be Compound **7** inasmuch as its IR and UV spectra indicated an α-hydroxy-α,β-unsaturated ketone, while its NMR spectrum showed a peak at 1.39 ppm (doublet, $J=7$ Hz) due to methyl protons and another peak at 6.12 ppm (singlet due to a phenolic hydroxyl group.

These results indicate that, in the reaction of monomethylcyclohexanone with copper(II) chloride, in general the type of product depends on the number of methylene groups between the carbonyl group and methyl-substituted carbon in the starting material. In the case of no or only one methylene group—that is, 2- or 3-methylcyclohexanone—the product obtained in either case was a *gem*-dichloroderivative—that is, of Type B, with a vinyl methyl group. In the case of two methylene groups—that is, 4-methylcyclohexanone—the product obtained was a trichloro-derivative—that is, of Type A, with a methyl group at the 4-position.

Therefore, in order to find out whether this reaction could occur in the cases of dimethylcyclohexanones, the reactions of 3,4- and 3,5-dimethylcyclohexanone with a 20-fold molar amount of the reagent were carried out under the same conditions. Compounds **8** and **9** were thus obtained from the 3,4- and 3,5-dimethyl derivatives respectively. Consequently, it was found that a reaction like that in the case of the monomethyl derivatives also occurred in the case of such dimethylcyclohexanones. Moreover, from the fact that the product obtained was Type B in the case of 3,4-dimethylcyclohexanone, it was found that the generality that the oxygen group enters the 2-position, not the 6-position, is also applicable in this case.

Now, on the basis of these results, let us consider the pathway for the formation of Type A. It has previously been reported[3] that an α-chlorination occurs easily *via* the enol complex in the reactions of saturated ketones with copper(II) chloride. It was found that, in steroidal ketone, a *gem*-dichloro derivative was obtained together with an α-chloro derivative.** Hence, the present reaction would be initiated by an attack on the α-carbon in cyclohexanone with copper(II) chloride, followed by α,α- and/or α,α'-dichlorination.

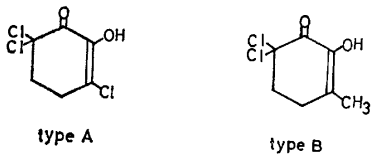

Fig. 1.

Therefore, the α-chlorination product (**a**)—namely, 2-chlorocyclohexanone—, was treated under the same conditions. It was found that oxidative chlorination occurred to give Compound **3**, just as in the case of cyclohexanone. To ascertain the intermediate product in the oxidative chlorination of cyclohexanone, the reaction with a 20-fold molar amount of the reagent was stopped after the mixture had been refluxed for only 1 hr under the same conditions. The product was isolated from the reaction mixture in the usual way and identified as Compound **1** from its spectroscopic data and from its melting point. Moreover, Compounds **2** and **3** were obtained in fairly good yields from the reaction of cyclohexanone with 20-fold molar and 30-fold molar amounts of reagents respectively, as has been mentioned before.

The foregoing results suggest that, after the α-monochlorination product (**a**) is chlorinated to give α,α,α'-trichlorinated cyclohexanone (**c**) through α,α- and/or α,α'-dichlorinated derivatives (**b**), the resulting product (**c**) is hydrolyzed to give 3-chloro-2-hydroxycyclohex-2-en-1-one (**1**). In the later stages, **1** is further chlorinated at the α-position with respect to the carbonyl group to give **3** through **2**. In the case of 4-methylcyclohexanone, the reaction proceeds according to the pathway described above, not being affected by the methyl group, for the methyl group in the methylcyclohexanone is located in a γ-position with respect to the carbonyl group. Hence, this is the pathway proposed for the formation of Type A (Fig. 2):

Next, let us consider the pathway for the formation

** Unpublished data: in the reaction of 5α-cholestan-3-one with copper(II) chloride under the same condentions, 2α-chloro- and 2,2-dichloro-5α-cholestan-3-one were obtained.

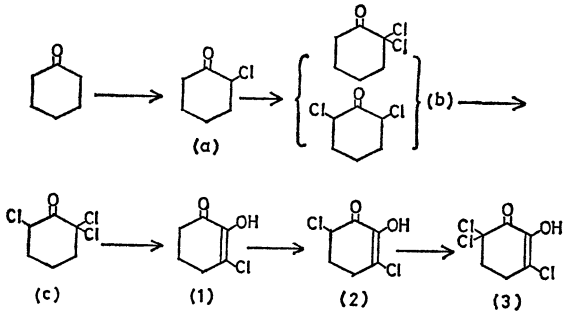

Fig. 2.

of Type B. In the cases of 2- and 3-methylcyclohexanone, the same product (**4**) was obtained. In these cases, the reaction also proceeds *via* Type (**1**), according to Fig. 2. Hence, Type (**1**) —namely, 2-hydroxy-3-methylcyclohex-2-en-1-one (**11**)—was prepared by the method of Wallach,[11a] and the product (**11**) was reacted with copper(II) chloride under the same conditions to give Compound **4**. Also, the reaction of 2-methylcyclohexanone with a 20-fold molar amount of copper(II) chloride was stopped after 15 min under the same conditions. The NMR spectrum of the reaction mixture showed that Compounds **4** and **11** had already been produced. Consequently, 2- and 3-methylcyclohexanone were each refluxed with a 10-fold molar amount of the reagent for 7 hr under the same conditions. The NMR spectra of the reaction mixtures suggested that Compound **11** was quantitatively produced in both cases. Therefore, it was found that Compound **11** was an intermediate of the reaction for the formation of Type B.

It was considered that, in these cases, the reaction also proceeded *via* the enol complex in the earlier stage. Then, in the case of 2-methylcyclohexanone, α-chlorination occurs preferentially at C_6 in the methylcyclohexanone, in contrast with the case of halogenation with molecular halogen,[11a] because the steric hindrance at C_6 is smaller than that at C_2 in the formation of the enol complex. This assumption is supported by the findings that Compound **4**, derived from the C_6-chlorination product, not from the C_2 product, was isolated in a 70% yield, and that no phenol derivative, such as would be derived from the C_2-chlorination product, could be isolated. The α-chlorinated product (**a'**) is dichlorinated at C_6, followed by hydrolysis to give **10**. The dione (**10**) is enolized in the direction of the methyl group to give Compound **11** because of the stabilization by hyperconjugation of the methyl group.

In the case of 3-methylcyclohexanone, the methyl group should have no influence on the earlier stage of the reaction, just as in the case of 4-methylcyclohexanone, because the methyl group was located in the β-position with respect to the carbonyl group in the starting material, in contrast with the 2-methylcyclohexanone. Therefore, it was considered that the pathway were: (**a''**)→(**b''**)→(**10**)→(**11**)→(**2''**)→(**4**) and/or (**a''**)→(**b''**)→(**c''**)→(**2''**)→(**4**). The former pathway, however, is more reasonable because Compound **11**, as an intermediate, was obtained from the reaction of 3-methylcyclohexanone with a 10-fold molar amount of copper(II) chloride, as has been mentioned above. Hence, the pathway for the formation of Type B may be described as follows:

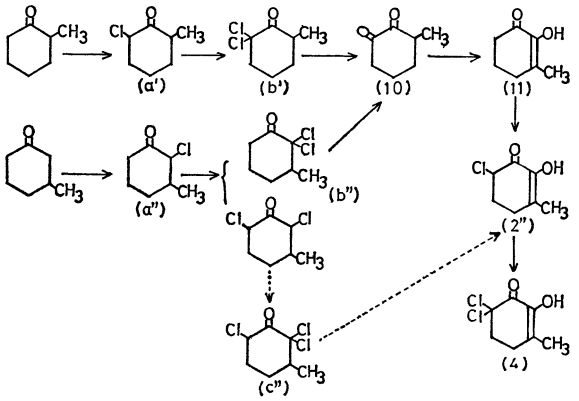

Fig. 3.

On the synthesis of the compounds obtained from the present work, there have been only a few reports. One of these is by Sucrow and Wanzlick,[12] in which 3,6,6-trichloro-2-hydroxycyclohex-2-en-1-one (**3**) was synthesized *via* Compounds **1** and **2** from cyclohexane-1,2-dione in several steps. The present work, however, has demonstrated that Compound **3** can be synthesized in one step from readily available cyclohexanone and copper(II) chloride. Thus, it can be concluded that this reaction constitutes an improved method for the synthesis of polychlorinated cyclohexanediones.

The authors wish to thank Professor A. Hagitani of Rikkyo University for his kind guidance and helpful suggestions in this work. Thanks are also due to Dr. S. Hishida, Naka Works, Hitachi Ltd., for his measurement of the high resolution mass spectra.

Vinyl Polymerization. 327.[1] Determination of the Initiating Radical Species in Polymerization with a Dimethylmercury and Copper(II)-Ion System

Minoru IMOTO, Yoshiaki NAKAMURA, and Tatsuro OUCHI

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Suita-shi, Osaka 564

(Received July 31, 1974)

Dimethylmercury was found to give a methyl radical ($\cdot CH_3$) by the reaction with Cu(II)-ion in the presence of water. Generation of $\cdot CH_3$ was proved by scavenging with 1,3,5,-triphenylverdazyl. Radical polymerization of methyl methacrylate and acrylonitrile was carried out with the system dimethylmercury/water/Cu(II)- or Fe(III)-ion.

Koton[2] found that dialkylmercury could initiated the polymerization of vinyl monomer and that the stronger the bond strength of C–Hg of dialkylmercury, the slower the rate of polymerization, *i.e.* dimethylmercury(DM-Hg) was the weakest promoter. Inoue[3] *et al.* and Razubaev[4] *et al.* carried out vinyl polymerization initiated by dibutylmercury or diisopropylmercury in the presence of various metallic salts, using appropriate organic solvents. However, the initiating mechanism remains unclarified.

We have carried out the polymerization using DM–Hg as an initiator in the presence of metallic salts, water being used instead of organic solvent. The initiating species for the polymerization was determined by reaction of DM–Hg with 1,3,5-triphenylverdazyl(TPV) and cupric chloride in benzene.

Experimental

Materials: All metallic salts, DM–Hg and methylmercury chloride (MC–Hg) of special grade were used without further purification. TPV was synthesized by Kuhn's method.[5] Methyl methacrylate(MMA), styrene(St), acrylonitrile(AN) and solvents were purified, according to the usual method.

Procedure: Polymerization was carried out in a 30 cm^3 tube. Monomer, mercury compound, metallic salt and solvent were placed in the tube which was cooled to −78 °C and thawed thrice with nitrogen and sealed under vacuum. After the tube had been shaken in a thermostat at 85 °C for 6 hr, the contents of the tube were poured into a large amount of methanol to precipitate the polymer.

Results and Discussion

Polymerization in the Presence of Metallic Salt and Water. The effects of metallic salt and water on the polymerization of MMA, AN and St are given in Table 1. It can be seen that cupric chloride and ferric chloride in groups 2 and 3 are active promoters for the polymerization of MMA and AN, the presence of water being necessary. NaCl, $NiCl_2$, $SnCl_4$, $CrCl_3$, $HgCl_2$ and the lower valency salts of iron and copper(group 4) can not be regarded as promoters in such small amount as 1.5×10^{-5} mol.

Effect of Amount of Water on Polymerization. In order to confirm the effect of water on the polymerization of MMA initiated with DM–Hg and Cu(II)-ion, polymerization was carried out, varying the amount of water and keeping the amounts of DM–Hg and MMA constant. The results are shown in Fig. 1. It was confirmed that the presence of water is indispensable.

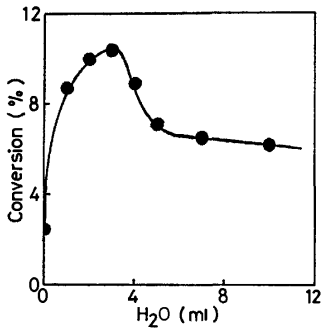

Fig. 1. Effect of the amount of water on the polymerization of MMA.
MMA 5 ml, DM-Hg 0.1 ml, Cu(II)-ion 1.5×10^{-5} mol; 85 °C, 6 hr

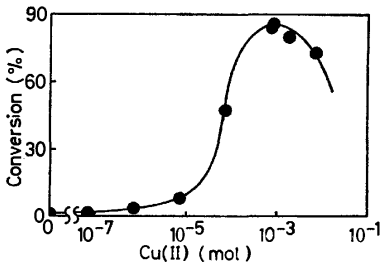

Fig. 2. Effect of the amount of Cu(II)-ion on the polymerization of MMA.
MMA 5 ml, DM-Hg 0.1 ml, H_2O 3 ml; 85 °C, 6 hr

Effect of Amount of Metallic Salt on Polymerization. Keeping the amounts of water and monomer constant and varying the amount of cupric chloride, the polymerization of MMA was carried out at 85 °C for 6 hr (Fig. 2).

Maximum conversion was attained at 1.3×10^{-3} mol of Cu(II)-ion. 0.1 ml of DM–Hg corresponds to 1.28×10^{-3} mol, *viz.*, maximum conversion was obtained when the molar quantity of DM–Hg was equal to that of Cu(II)-ion. This suggests that the initiation proceeds through the bimolecular reaction of DM–Hg with Cu(II)-ion. No formation of a complex of DM–Hg with Cu(II)-ion could be observed from its electronic spectrum.

Excess Cu(II)-ion might act as an inhibitor of the propagation by the following reaction:

$$\cdots\cdots M\cdot + CuCl_2 \rightarrow \cdots\cdots M\text{-}Cl + CuCl$$

Proof of the Radical Mechanism. In order to confirm the radical mechanism of the polymerization, the copolymerization of St and MMA was carried out (Fig. 3).

Determination of Initiating Radical Species. We have assumed that the initiating species is the methyl radical from DM–Hg. If this is the case, the methyl radical should be captured TPV and become colorless methyl-TPV.

2.56×10^{-3} mol (2 ml) of DM–Hg, 1.4×10^{-3} mol (2.16 g) of $CuCl_2\cdot2H_2O$, 9.57×10^{-4} mol (0.300 g) of TPV and 8 ml of benzene were placed in a tube, evacuated, sealed and warmed at 85 °C for 2 hr under shaking. The content turned almost colorless from a deep green. The reacted system was fractionated into three portions: Residue, Fractions I and II (Fig. 4).

Fraction I: Recrystallization of Fraction I from methanol gave pale yellow powder-like crystals (0.21 g). mp 138—139 °C, mol wt 328.6 (by VPO-method, using benzene as a solvent at 37 °C); *cf.* the values by Kuhn and Trischmarm,[5] mp of methyl-TPV 138—139 °C, mol wt of methyl-TPV 328.4.

Found: C, 76.89; H, 6.12; N, 16.99%.

Calcd for $C_{21}H_{20}N_4$: C, 76.80; H, 6.14; N, 17.06%.

The yield (0.21 g) corresponds to 6.39×10^{-4} mol of methyl-TPV, corresponding to 67% of the theoretical value. IR-spectrum of TPV showed no definite absorption of C=N at 1660 cm^{-1} by resonance of π-electrons. Fraction I had a strong absorption of νC=N at 1660 cm^{-1}.

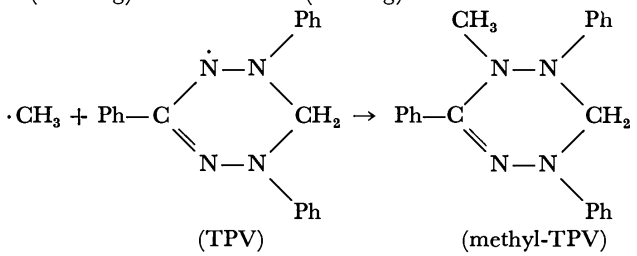
Fraction II: Fraction II gave white plate crystals. By successive recrystallization from methanol and water. Yield 2.41 g; mp 170—171 °C; mol wt 251.4 (VPO). The reported melting point of chloromethylmercury (MC–Hg) is 170 °C[6] and its mol wt 251.5. The mixed melting point of the crystals with an authentic sample was also 170—171 °C. Thus Fraction II was found to be consistent with MC–Hg.

Residue: The residue, yellow green, was washed thoroughly with benzene, methanol and water, yield 1.23 g. Its solution in dilute aqueous nitric acid gave a white precipitate of AgCl with $AgNO_3$ solution. The washed residue contained 76.36% copper.

Calcd for CuCl: Cu, 79.88%; calcd for $CuCl_2$: Cu, 41.68% Thus the residue mainly consists of cuprous chloride.

The reaction was thus concluded to proceed as follows:

$$(CH_3)_2Hg + CuCl_2 \longrightarrow \underset{\text{(MC-Hg)}}{CH_3HgCl} + CuCl + \cdot CH_3$$
$$\text{(DM-Hg)}$$



It can be concluded that the initiating species is the methyl radical.

Polymerization of MMA with MC–Hg and Cu(II)-ion. 5 ml of MMA, 1.5×10^{-5} mol of $CuCl_2\cdot2H_2O$, 0.2 g of MC–Hg and 3 ml of water were shaken under vacuum at 85 °C for 6 hr to obtain a trace of poly-MMA. MC–Hg is thus found to be unable to initiate the polymerization of MMA, even in the presence of cupric chloride and water.

A-Substituted 5β-Steroids. VII. The Polyhalogenation of 5β-Cholestan-2-one

J. Yasuo SATOH, C. Akira HORIUCHI, and Akira HAGITANI

Department of Chemistry, St. Paul's (Rikkyo) University, Nishi-Ikebukuro, Toshima-ku, Tokyo 171

(Received September 5, 1974)

The polyhalogenation of 5β-cholestan-2-one (I) in acetic acid containing hydrogen halide occurs in this positional order: $C_1 \rightarrow C_3 \rightarrow C_3$ and finally at C_1, which has the largest steric hindrance. The tetrahalogenation of the ketone (I) yields 1,1,3,3-tetrachloro-5β-cholestan-2-one (IXb), but fails to give the tetrabromo derivative; rather, it yields 1β,3,3-tribromo-5β-cholestan-2-one (Va), 1,1,3-tribromo-5β-cholest-3-en-2-one (VIIIa), and 1β,3-dibromo-5β-cholest-3-en-2-one (VIa). The conformations of the dihalo-, the trihalo-, and the tetrachloroketone derivatives are discussed in connection with the ORD, CD, IR, and NMR spectra.

Although the halogenation of most 5α-steroids[1] which possess an oxo group on each position in Ring A has been thoroughly investigated, only very little information on 5β-steroids is found in the literature, and even this concerns only the bromination of 3-oxo-5β-steroids.[2] We reported earlier that the monohalogenation of 2-oxo-5β-steroids affords the 1β-halo-2-oxo-5β-steroids[3] in good yields.

In this paper, we would like to discuss the positional order of the halogens introduced, and the conformation of the haloketones produced by the polyhalogenation of 5β-cholestan-2-one.

Results and Discussion

The dibromination of 5β-cholestan-2-one (I) in acetic acid in the presence of hydrogen bromide gave the dibromo Compound A (mp 182—185 °C) and, from the filtrate, the dibromo Compound B (mp 155—156 °C). Compound A was epimerized by treatment with hydrogen bromide in acetic acid at room temperature to the stable Compound B. These dibromo derivatives showed shifts of the carbonyl absorption (+3 and +18 cm^{-1} respectively) compared with that of the parent ketone (I) in their IR spectra. The NMR spectra also showed a multiplet at τ 5.6—5.8, with a small half-band width ($W/2$= 12 Hz) with an equatorial character, and at τ 4.20, with a large half-band width ($W/2$=20 Hz) of an axial character due to the C_3HBr. From these facts, the structures of the two dibromoketones were confirmed to be 1β,3β-dibromo-(IIIa) and 1β,3α-dibromo-5β-cholestan-2-one (IVa) respectively.

On the other hand, the dichlorination of 5β-cholestan-2-one (I) gave the dichloroketone (IVb) (mp 128—129 °C). This product was presumed to be 1β,3α-dichloro-5β-cholestan-2-one from the sign of the Cotton effect, Δ[A]*-, and the $\Delta\lambda_1$**-values (+192 and +12 nm respectively compared with 5β-cholestan-2-one) in the ORD spectrum, the shift of the C=O stretching band (1745 cm^{-1}) in the IR spectrum, and the signal (τ 4.70, $W/2$=20 Hz) due to the C_3HCl in the NMR spectrum.

Also, by tlc, it was confirmed that, when a solution of bromine was slowly added to the ketone (I) in acetic acid containing hydrogen bromide to effect dibromination, 1β-bromoketone (IIa) was formed first, and then the dibromoketones.

Thus, these results show that, as was previously reported for the monohalogenation[3] of the ketone (I), in the case of dihalogenation also the halogen enters first at the C_1β-bond, and then at the C_3β-bond. The 1β,3β-dibromo derivative thus produced is epimerized to a more stable 1β,3α-dibromo derivative.

On the basis of these data, we shall now discuss the conformation of the dihaloketones. It is considered, from the shifts in the C=O absorption (+18 for IVa and +33 cm^{-1} for IVb) compared with the ketone (I) in the IR spectra and from the pattern of the NMR spectra, that 1β,3α-dihaloketones (IV) exists as a chair conformation. This is supported by the signs of the Cotton effect, Δ[A]*-(+248 for IVa and +192 for IVb) and the $\Delta\lambda_1$**-values (+13 and +12 nm respectively) in ORD. Further, it is generally presumed that, if the A ring assumes a chair conformation, the ORD curve of 1β,3β-dibromoketone (IIIa) exhibits a negative sign of the Cotton effect, in accordance with the Octant rule.[4] However, the ORD data (Δ[A]*: +93 compared with 5β-cholestan-2-one) of this compound are unusual in view of this presumption. Hence, it is considered that this compound (IIIa) prefers a deformed conformation because of the 1 : 3-interaction between the C_1β-Br and the C_3β-Br. This was supported by showing the half-band width ($W/2$=12 Hz) due to the C_3–H and also by the shift of C=O ($\Delta\nu$: +2 cm^{-1}) compared with that of 5β-cholestan-2-one in the IR spectrum.

In order to determine the position of the third halogen in the trihalogenation of 5β-cholestan-2-one (I), the ketone (I) was treated with 3 M bromine in acetic acid. The reaction mixture was then chromatographed on silica gel. Elution with *n*-hexane–benzene (10 : 1) gave the tribromoketone (Va) (mp 157—158 °C). It was determined to be 1β,3,3-tribromo-5β-cholestan-2-one by means of its NMR spectrum, which shows a singlet at τ 4.47 and no proton signal due to the C_3HX. The second fraction, eluted with the same solvent, gave the 1β,3α-dibromo derivative (IVa), while the last fraction, eluted with the same solvent, gave the unsaturated dibromoketone (VIa), which shows absorptions at 1708 (C=O) and 1611 cm^{-1} (C=C) in its IR spectrum, as the main product. The NMR spectrum of VIa showed a singlet at τ 5.31 due to the proton at C_1, and a doublet at τ 3.12 due to the vinyl proton. Therefore, the derivative (VIa) was presumed to be 1β,3-dibromo-5β-cholest-3-en-2-one, which is formed by the elimination of hydrogen bromide from the 1β,3,3-tribromo derivative (Va). It was then demonstrated that the trichlorination of 5β-

* Molar dispersion contribution of the substituent.

** The difference (nm) between the first extremum of the derivative and that of the parent ketone.

cholestan-2-one gave 1β,3,3-trichloro-5β-cholestan-2-one (Vb).

From these results, it was concluded that the trihalogenation occurs at the C_3 position.

On the basis of the CD, ORD, and IR spectral data for Va and Vb (Δ[A]*: −57, Δ[θ]: −98, $\Delta\lambda_1$**: +14 nm, $\Delta\nu$: +42 cm^{-1} and Δ[A]*: −62, Δ[θ]: −37, $\Delta\lambda_1$**: +14 nm, $\Delta\nu$: +31 cm^{-1}), it is considered that the conformation in the A ring of the trihaloketone is a considerably distorted boat form.

In a previous paper[5], we reported that 1β-halo-5β-cholestan-2-one (II) can not change to the 1α-isomer, probably because of the 1 : 3-interaction between the C_1-equatorial bond and the C_9–C_{11} bond. Also, the steric hindrance at the C_3-position is considerably less than that at C_1, and its position has mobility. Consequently, the halogen in the 1β-haloketone rearranges to the allylic position.

In order to study the introduction of the fourth halogen at the position, which has a large steric hindrance, the ketone (I) was allowed to react with 4 M bromine in acetic acid containing hydrogen bromide at 20 °C for 48 hr. The reaction product did not give the tetrabromo derivative; rather, it yielded 1β,3,3-tribromoketone (Va) as the main product. This reaction at 85 °C for 1 hr gave 1β,3,3-tribromoketone (Va) and the unsaturated tribromoketone (VIIIa), showing absorptions at 1708 (C=O) and 1602 cm^{-1} (C=C) in its IR spectrum. The NMR spectrum of VIIIa also showed a doublet (J=3.0 Hz) due to the vinyl proton. From these data, the unsaturated ketone (VIIIa) was presumed to be 1,1,3-tribromo-5β-cholest-3-en-2-one (VIIIa).

Under the same conditions, the chlorination of the ketone(I) yielded 1,1,3,3-tetrachloro-5β-cholestan-2-one (IXb). This structure was determined from the fact that no signal due to the CHX appeared in the NMR spectrum.

From the ORD, CD, and IR spectral data, it can be considered that the conformation of IXb in the A ring preferred a form that was considerably distorted and had no eclipsed conformation between the C_1β-X bond and the C_{10}–Me bond, as in the case of the trihaloketone, no 1 : 3-interaction between the C_1α-X bond and the C_9–C_{11} bond, and no 1 : 3-interaction between the C_1–X bond and the C_3–X bond.

It is considered that this difference in the bromination and the chlorination has the following causes: in the case of the tetrabromo derivative, a possible explanation is that there is a large steric hindrance between the axial bromines at the C_1 and C_3 positions, and between the C_9–C_{11} bond and C_1–α bond, than those in the case of tetrachloro derivative. This consideration is supported by the experimental fact that the bromination of 1β,3-dibromo-5β-cholest-3-en-2-one which no longer has the 1 : 3-interaction between the axial bromine at the C_1 and C_3 positions, occurs at the C_1 position.

On the basis of these results, it was concluded that the polyhalogenation of 5β-cholestan-2-one (I) in acetic acid containing hydrogen halide occurs in this positional order: $C_1 \rightarrow C_3 \rightarrow C_3$, and finally at C_1, with the largest steric hindrance in the A ring.

Experimental

All the melting points are uncorrected. The IR, ORD, and CD spectra were measured using a Hitachi model 215 grating infrared spectrophotometer and two JASCO spectropolarimeters, models ORD/UV-5 and J-20, respectively. The NMR spectra were measured in carbon tetrachloride, with TMS as the internal standard, using a nuclear magnetic resonance spectrometer, Hitachi-Perkin Elmer R-20A.

Dibromination of 5β-Chlestan-2-one (I). I (1.0 g) in acetic acid (50 ml) was treated with bromine (0.91 g) in acetic acid (5 ml) containing a few drops of 48% hydrobromic acid at room temperature for 40 min. The reaction mixture was then taken up in ether, and the ether extracts were washed with a sodium hydrogen carbonate solution and water, dried, and evaporated. The crystallization of the residue from ethanol gave plates of IIIa (40 mg); mp 182—185 °C; IR (KBr): 1715 cm^{-1}; IR (CCl_4): 1716 cm^{-1}; ORD (c, 0.207, Di) at 21 °C: $[\alpha]_D$ +14°, $[\alpha]_{400}$ +125°, $[\alpha]_{356}$ +405° (peak), $[\alpha]_{325}$ 0° and $[\alpha]_{250}$ −935° (trough); CD (c, 0.207, Di) at 21 °C: $[\theta]_{325}$ +3465° (peak); NMR (CCl_4) τ: 5.67 (1H, s, C_1α-H) and *ca.* 5.6—5.8 (1H, m, $W/2$=12 Hz, C_3α-H). Found: C, 59.49; H, 7.93%. Calcd for $C_{27}H_{44}OBr_2$: C, 59.56; H, 8.14%.

From the mother liquor, recrystallization gave plates of IVa (360 mg); mp 155—156 °C; IR (KBr): 1730 cm^{-1}; IR (CCl_4): 1736 cm^{-1}; ORD (c, 0.190, Di) at 21 °C: $[\alpha]_D$ +105°, $[\alpha]_{400}$ +434°, $[\alpha]_{329}$ +2237° (peak), $[\alpha]_{300}$ +1868° (shoulder), $[\alpha]_{305}$ 0° and $[\alpha]_{283}$ −1947° (trough); CD (c, 0.169, Di) at 21 °C: $[\theta]_{308}$ +20610° (shoulder) and $[\theta]_{303}$ +21040° (peak); NMR (CCl_4) τ: 5.64 (1H, s, C_1α-H) and 4.20 (1H, m, $W/2$=20 Hz, C_3β-H). Found: C, 59.34; H, 8.08%. Calcd for $C_{27}H_{44}OBr_2$: C, 59.56; H, 8.14%.

Isomerization of 1β,3β-Dibromo-5β-cholestan-2-one (IIIa). IIIa (10 mg) in acetic acid (5 ml) was stirred with a few drops of 48% hydrobromic acid at room temperature for 15 hr. After the usual work-up, crystallization from ethanol afforded plates of IVa (6 mg); mp 155—156 °C.

Tribromination of 5β-Cholestan-2-one (I). I (800 mg) in acetic acid (40 ml) was treated with bromine (1.09 g) in acetic acid (4 ml) at room temperature. After 17 hr, decolorization was complete; the reaction mixture was then taken up in ether, and the ether extracts were washed with a sodium hydrogen carbonate solution and water, dried, and evaporated. The resultant oil (1.225 g) was chromatographed on silica gel (100 g). Elution with *n*-hexane-benzene (10 : 1) (400 ml) gave needles of Va (41 mg) from ethanol; mp 157—158 °C; IR (KBr): 1747 cm^{-1}; IR (CCl_4): 1756 cm^{-1}; ORD (c, 0.150, Di) at 19.5 °C: $[\alpha]_D$ +33°, $[\alpha]_{400}$ +87°, $[\alpha]_{373}$ 0°, $[\alpha]_{370}$ −6.7° (trough), $[\alpha]_{367}$ 0°, $[\alpha]_{324}$ +1223° (peak), $[\alpha]_{299}$ 0° and $[\alpha]_{281}$ −588° (trough); CD (c, 0.111, Di) at 22 °C: $[\theta]_{347}$ −2328° (trough), $[\theta]_{330}$ 0° and $[\theta]_{303}$ +5611° (peak); NMR (CCl_4) τ: 5.68 (1H, s, C_1α-H). Found: C, 52.03; H, 6.90%. Calcd for $C_{27}H_{43}OBr_3$: C, 52.03; H, 6.95%.

The next fraction, eluted by the same solvent (300 ml), on crystallization from ethanol gave needles of IVa (134 mg), while the last fraction, eluted with the same solvent (370 ml) and with benzene (400 ml), on crystallization from ethanol gave needles of VIa (287 mg); mp 186—189 °C; IR (KBr): 1695 and 1610 cm^{-1}; ORD (c, 0.220, Di) at 25 °C: $[\alpha]_D$ −20°, $[\alpha]_{400}$ −89°, $[\alpha]_{360}$ −282° (shoulder), $[\alpha]_{350}$ −341° (trough), $[\alpha]_{335}$ −150° (shoulder), $[\alpha]_{329}$ 0° and $[\alpha]_{280}$ +1592° (peak); CD (c, 0.164, Di) at 25 °C: $[\theta]_{338}$ −2330° (shoulder), $[\theta]_{328}$ −3174° (trough), $[\theta]_{320}$ −2667° (peak), $[\theta]_{316}$ −2755° (trough), $[\theta]_{290}$ 0° and $[\theta]_{264}$ +13070° (peak); λ^{D1}_{max} 260 nm (ε 4,900); NMR (CCl_4) τ: 5.31 (1H, s, C_1α-H) and 3.12

(1H, d, J=3.0 Hz, C_4-H). Found: C, 60.08; H, 7.77%. Calcd for $C_{27}H_{42}OBr_2$: C, 59.79; H, 7.80%.

Tetrabromination of 5β-Cholestan-2-one (I) at Room Temperature. A solution of I (800 mg) in acetic acid (40 ml) was treated with bromine (1.452 g) according to the procedure described for the tribromination of I. After the usual work-up, the resultant oil, on crystallization from ethanol, gave needles of Va (451 mg); mp 157—159 °C. After the crystallization filtrate had been evaporated *in vacuo*, the resultant oil (602 mg) was chromatographed on silica gel (80 g). Elution with *n*-hexane-benzene (9 : 1) (1350 ml) gave needles of Va (81 mg) from ethanol; mp 154—157 °C. The second fraction, eluted with the same solvent (800 ml), on crystallization from ethanol gave IVa (42 mg); the third fraction, eluted with *n*-hexane-benzene (5 : 1) (1750 ml), on crystallization from ethanol gave VIa (124 mg) (mp 186—189 °C).

Bromination of 1β,3-Dibromo-5β-cholest-3-en-2-one (VIa). The bromination of VIa was carried out using the technique described for the synthesis of the 1β-bromoketone.[3] After the usual work-up, the resultant oil was chromatographed on silica gel (10 g). Elution with *n*-hexane-benzene (1 : 10) (330 ml) and with benzene (300 ml) gave needles of VIIIa (19 mg) from ethanol; mp 84—86 °C; IR (KBr): 1708 and 1605 cm^{-1}; ORD (*c*, 0.169 Di) at 25 °C: $[\alpha]_D$ −44°, $[\alpha]_{400}$ −288°, $[\alpha]_{340}$ −616° (shoulder), $[\alpha]_{294}$ −2272° (trough), $[\alpha]_{284}$ 0° and $[\alpha]_{250}$ +7558° (peak); CD (c, 0.182, Di) at 25 °C: $[\theta]_{443}$ +469° (peak), $[\theta]_{394}$ 0°, $[\theta]_{347}$ −2203° (trough), $[\theta]_{320}$ 0°, $[\theta]_{303}$ +2711° (peak), $[\theta]_{294}$ 0° and $[\theta]_{269}$ −12200° (trough); λ_{max}^{Di} 266 nm (ε 3,800); NMR (CCl_4) τ: 3.22 (1H, d, J=3.0 Hz, C_4-H). Found: C, 52.43; H, 6.76 %. Calcd for $C_{27}H_{41}OBr_3$: C, 52.19; H, 6.65%.

Tetrabromination of 5β-Chlestan-2-one (I) at 85 °C. I (500 mg) in acetic acid (25 ml) was treated with bromine (908 mg) in the presence of 48% hydrobromic acid at 85 °C for 1 hr. After the usual work-up, the resultant oil (532 mg) was chromatographed on silica gel (100 g). Elution with *n*-hexane-benzene (10 : 1) (550 ml) gave needles of Va (77 mg) from ethanol (mp 154—157 °C). The next fraction, eluted with *n*-hexane-benzene (5 : 1) (600 ml), on crystallization from ethanol gave needles of VIIIa (98 mg) (mp 84—86 °C); the last fraction, eluted with *n*-hexane-benzene (3 : 1) (3200 ml), on crystallization from ethanol gave VIa (147 mg) (mp 186—189 °C).

Dichlorination of 5β-Cholestan-2-one (I). A mixture of I (2.0 g), chlorine gas (855 mg) in chloroform (10 ml), and acetic acid was carried out according to the procedure described for the synthesis of the 1β-chloroketone.[3] After the usual work-up, the resultant oil was chromatographed on silica gel (100 g). Elution with *n*-hexane gave plates of IVb (343 mg) from ethanol; mp 128—129 °C; IR (KBr): 1740 cm^{-1}; IR (CCl_4): 1737 cm^{-1}; ORD (*c*, 0.203, Di) at 26 °C: $[\alpha]_D$ +103°, $[\alpha]_{400}$ +370°, $[\alpha]_{328}$ +2069° (peak), $[\alpha]_{318}$ +1601° (shoulder), $[\alpha]_{304}$ 0°, $[\alpha]_{280}$ −1675° (trough); CD (*c*, 0.203, Di) at 26 °C: $[\theta]_{309}$ +12070° (peak), $[\theta]_{305}$ +11850° (trough) and $[\theta]_{302}$ +12070° (peak); NMR (CCl_4) τ: 5.65 (1H, s, $C_1\alpha$-H) and 4.20 (1H, m, $W/2$=20 Hz, $C_3\beta$-H). Found: C, 71.04; H, 9.36%. Calcd for $C_{27}H_{44}OCl_2$: C, 71.19; H, 9.73%. The next fraction, eluted with the same solvent (1300 ml), on crystallization from ethanol-acetone gave 1β-chloro-5β-cholestan-2-one (IIb) (253 mg) (mp 116—118 °C).[3]

Trichlorination of 5β-Chlestan-2-one (I). The trichlorination of I (800 mg) was carried out using the technique described for the synthesis of the 1β-chloroketone.[3] The resultant oil (1.01 g) was chromatographed on silica gel (100 g). From the first elution with *n*-hexane (2450 ml) and with *n*-hexane-benzene (5 : 1) (450 ml), Vb was obtained as needles (389 mg); mp 142—145 °C; IR (KBr): 1745 cm^{-1}; IR (CCl_4): 1745 cm^{-1}; ORD (*c*, 0.219, Di) at 19.5 °C: $[\alpha]_D$ −9.1°, $[\alpha]_{400}$ −37°, $[\alpha]_{330}$ −624° (trough), $[\alpha]_{322}$ −452° (peak), $[\alpha]_{318}$ −485° (trough), $[\alpha]_{310}$ 0° and $[\alpha]_{275}$ +1050° (peak); CD (*c*, 0.219, Di) at 19.5 °C: $[\theta]_{324}$ −2769° (trough), $[\theta]_{312}$ −5021° (trough), $[\theta]_{308}$ −4762° (peak) and $[\theta]_{302}$ −5242° (trough); NMR (CCl_4) τ: 5.68 (1H, s, $C_1\alpha$-H). Found: C, 66.02; H, 8.56%. Calcd for $C_{27}H_{43}OCl_3$: C, 66.18; H, 8.84%. The second fraction, eluted with *n*-hexane-benzene (1 : 1) (200 ml), on crystallization from ethanol gave plates of IVb (57 mg) (mp 128—129 °C).

Tetrachlorination of 5β-Cholestan-2-one (I). I (2.5 g) and concd hydrochloric acid (0.3 ml) in acetic acid (100 ml) were treated with chlorine gas in chloroform (10 ml) at 85 °C for 20 hr. After the usual work-up, the resultant oil (3.0 g) was chromatographed on silica gel (100 g); further treatment with *n*-hexane (500 ml) eluted a yellow oil, which, on crystallization from ethanol, gave needles of IXb (810 mg); mp 104—105 °C; IR (KBr): 1766 cm^{-1}; IR (CCl_4): 1765 cm^{-1}: ORD (*c*, 0.242, Di) at 19.5 °C: $[\alpha]_D$ +87°, $[\alpha]_{400}$ +253°, $[\alpha]_{332}$ +636° (peak), $[\alpha]_{304}$ 0° and $[\alpha]_{289}$ −178° (trough); CD (*c*, 0.242, Di) at 19.5 °C: $[\theta]_{311}$ 3537° (peak). Found: C, 61.66; H, 7.99%. Calcd for $C_{27}H_{42}OCl_4$: C, 61.84; H, 8.07%. The next fraction, eluted with the same solvent (2500 ml) and with *n*-hexane-benzene (7 : 3) (350 ml), on crystallization from ethanol gave needles of 1β,3-dichloro-5β-cholest-3-en-2-one (VIb) (56 mg); mp 147—149 °C; IR (KBr): 1700 and 1615 cm^{-1}; ORD (*c*, 0.096, Di) at 19.5 °C: $[\alpha]_D$ +41°, $[\alpha]_{460}$ 0°, $[\alpha]_{400}$ −131°, $[\alpha]_{364}$ −386° (shoulder), $[\alpha]_{360}$ −438° (trough), $[\alpha]_{353}$ −399° (peak), $[\alpha]_{345}$ −522° (trough), $[\alpha]_{335}$ −256° (peak), $[\alpha]_{322}$ −282° (trough), $[\alpha]_{324}$ 0°, $[\alpha]_{307}$ +418° (shoulder) and $[\alpha]_{274}$ +522° (peak); CD (*c*, 0.096, Di) at 19.5 °C: $[\theta]_{335}$ −2625° (shoulder), $[\theta]_{324}$ −3515° (trough), $[\theta]_{317}$ −2929° (peak) and $[\theta]_{313}$ −3046° (trough); λ_{max}^{Di} 251 nm (ε 6,700); NMR (CCl_4) τ: 5.48 (1H, s, $C_1\alpha$-H) and 3.40 (1H, d, J=2.5 Hz, C_4-H). Found: C, 70.63; H, 9.33%. Calcd for $C_{27}H_{42}OCl_2$: C, 71.50; H, 9.33%.

The authors are indebted to Mr. Takashi Takakuwa, Applied Research Laboratory of the Japan Spectroscopic Co., Ltd., for the measurement of the ORD and CD spectra, and to Mr. Tohru Miyasaka for collaboration in the experimental work.

The Effects of Substituents and Solvents on the Structure of Fluorenyl and Cyclopentadienyl Salts

Masao TOMOI, Toshio YONEYAMA, and Hiroshi KAKIUCHI

Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Yokohama 233

(Received September 14, 1974)

The electronic spectra of 9-(ω-methoxyalkyl) and 9-(ω-dimethylaminoalkyl)fluorenyl salts of alkali cations were measured in ethereal solvents. The relative amounts of the contract ion pairs connected with the 9-substituents (R) decreased in this order: $R=(CH_3)_2N-(CH_2)_2->CH_3O-(CH_2)_2->CH_3O-(CH_2)_3->(CH_3)_2N-(CH_2)_3-\gg CH_3O-(CH_2)_4-\approx n\text{-}C_4H_9-$. This behavior was explained in terms of the formation of an intramolecular association between the hetero atoms in the substituents and the counter ions; such an association favored the formation of the contact ion pair. The interaction of magnesium fluorenide and cyclopentadienide with hexamethylphosphoramide (HMPA) was studied by means of NMR spectroscopy in ether or tetrahydrofuran. The fluorenide changed from a covalent type to a solvent-separated ion pair by the coordination of three HMPA with the magnesium. The cyclopentadienide was proposed to change from a contact ion pair to a solvent-separated ion pair by means of two-step process in which the cyclopentadienyl ions became successively separated from the magnesium ion.

It is well-known that donor solvents interact with organometallic compounds of alkali or alkaline earth metals and affect the structure or reactivity of the compounds.[1] For example, Hogen-Esch and Smid have reported that alkali fluorenides exist as two kinds of ion pairs—contact and solvent-separated ion pairs in ethereal solvents.[2] In previous papers,[3–5] it was shown that the reactivity of organo-magnesium compounds increased markedly in the presence of hexamethylphosphoramide (HMPA). Such phenomena can be explained in terms of the coordination of donor solvents with the metals of organometallic compounds. In this paper, the electronic spectra of 9-substituted fluorenyl salts of alkali cations, in which the substituents can interact with the cations, were measured in ethereal solvents in order to investigate the nature of the intramolecular association. The interaction of magnesium fluorenide and cyclopentadienide with HMPA was also studied by NMR spectroscopy.

The study of such interaction will be useful in accounting for the behavior of the anionic polymerization initiated with organometallic compounds of alkali or alkaline earth metals.

Experimental

Reagents. Six 9-substituted fluorenes were prepared by the reaction of fluorenylsodium with the corresponding alkyl halides[6,9] or by the base-catalyzed alkylation of fluorene with alcohols[7,8]: *n*-butyl-[8] (bp 127 °C/0.6 mmHg), 2-methoxyethyl-(bp 143 °C/0.5 mmHg. Found: C, 85.08; H, 7.44%. Calcd for $C_{16}H_{16}O$: C, 85.71; H, 7.14%), 3-methoxypropyl- (bp 135 °C/0.2 mmHg. Found: C, 84.90; H, 7.62%. Calcd for $C_{17}H_{18}O$: C, 85.71; H, 7.56%), 4-methoxybutyl- (bp 169 °C/1.5 mmHg. Found: C,85.00; H, 7.99%. Calcd for $C_{18}H_{20}O$: C, 85.71; H, 7.94%), 2-dimethylaminoethyl-[9] (bp 137 °C/0.5 mmHg), 3-dimethylaminopropyl-fluorene[9] (bp 154 °C/0.5 mmHg). The structure of these fluorenes was also confirmed by means of NMR spectroscopy. The tetrahydrofuran (THF), dimethoxyethane (DME), and *n*-hexane were refluxed and distilled over metallic sodium under a nitrogen atomosphere. The HMPA was refluxed and distilled over calcium hydride *in vacuo*.

The substituted fluorenyl salts of lithium, sodium, and potassium ions were prepared by the reaction of the corresponding fluorenes with *n*-butyllithium, sodium hydride or amide, and metallic potassium respectively. The magnesium fluorenide was prepared by the reaction of fluorene with diethylmagnesium in the presence of HMPA.[4] The dicyclopentadienylmagnesium was prepared from magnesium turnings and cyclopentadiene at about 500 °C.[10]

Spectroscopic Measurements. The samples for spectral measurements were prepared under a nitrogen atmosphere. The electronic spectra of the fluorenyl salts were recorded at room temperature by means of a Shimadzu UV-200 spectrophotometer, using 0.2-cm optical cells provided with a 0.18-cm spacer. The NMR spectra of the organo-magnesium-HMPA systems were taken on a JNM C-60H spectrometer, using benzene or tetramethylsilane as the internal standard.

Results and Discussion

Electronic Spectra of 9-Substituted Fluorenyl Salts of Alkali Cations. Figures 1 and 2 show the spectra of 9-substituted fluorenyllithiums in THF at room temperature. The peaks near 360 and 380 nm could be assigned to contact and solvent-separated ion pairs

(·—·): 9-(2-dimethylaminoethyl)fluorenyllithium.

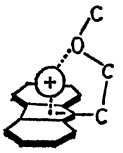
respectively, by analogy with the results obtained by Chan and Smid.[11] The methoxyethyl and dimethylaminoethyl derivatives were found to yield higher fractions of contact ion pairs, while the other derivatives gave much higher fractions of solvent-separated ion pairs. Figure 3 shows the spectra of the methoxyethyl and dimethylaminoethyl derivatives with the lithium counter-ion in DME at room temperature. The former was predominantly present as a solvent-separated ion pair, while the latter was predominantly present as a contact ion pair. In a *n*-hexane–THF (1 : 1) mixture, the methoxypropyl derivative gave a higher fraction of a contact ion pair, while the *n*-butyl, methoxybutyl, and dimethylaminopropyl derivatives gave higher fractions of solvent-separated ion pairs. Consequently, the relative amounts of the contact ion pairs of the lithium salts due to the 9-substituents (R) decreased in the following order: R= $(CH_3)_2N-(CH_2)_2- > CH_3O-(CH_2)_2- > CH_3O-(CH_2)_3- > (CH_3)_2N-(CH_2)_3- \gg CH_3O-(CH_2)_4- \approx n\text{-}C_4H_9-$. A similar order was observed for the sodium and potassium salts.

Such an effect of substituents suggests that a special interaction between the counter ions and the oxygen or nitrogen of the substituents may take place because of the favorable position of the hetero atoms with respect to the cations. In the case of the methoxyethyl and dimethylaminoethyl derivatives, the hetero atom exists at a position where a five-membered ring can be formed by the intramolecular coordination of the atom with the counter ion. For example, the structure of a contact ion pair for the methoxyethyl derivative could be represented as in Formula (I): In this



(I)

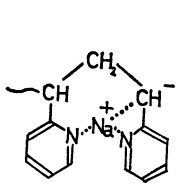
formula, the counter ion was assumed to be located over the aromatic ring, by analogy with the results on fluorenyllithium in THF.[12] In contrast, the X-ray analysis of fluorenyllithium as a tertiary amine complex has shown the lithium ion to be located above the plane, but outside the perimeter of the ring.[13] The intramolecular association as is shown in Formula (I) is, in any event, considered to take place easily and to favor the formation of a contact ion pair.

The observed order also shows that the formation of a contact ion pair becomes easier with a decrease in the size (n) of a ring, which is formed by intramolecular association— *i.e.*, in the order of $n=5>6>7$. Kuhn and Wires[14] have measured the equilibrium constant for the equilibrium between intramolecularly hydrogen bonded conformations and nonbonded conformations in the monomethyl ethers of ethylene glycol, propane-1,3-diol, and butane-1,4-diol: the constant became smaller with an increase in the number of carbon atoms between two oxygen atoms. The observed order for the fluorenyl salts is in good agreement with this order. This finding supports the presence of an intramolecular association such as has been described above.

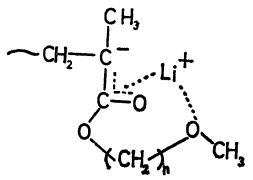
The coordinating power of aliphatic nitrogen donors is generally stronger than that of aliphatic oxygen donors.[15] The difference between the dimethylaminoethyl and methoxyethyl derivatives, therefore, can be explained in terms of that in the coordinating power of the hetero atoms. However, the dimethylaminopropyl derivative gave fewer contact ion pairs than the methoxypropyl one. The formation of an intramolecular bonding must result in conformational changes, and thereby increase the repulsive interactions among atoms, groups, and bonds in the ring formed. Such interactions, which reduce the formation of a contact ion pair, may be stronger in the former derivative, which has two methyl groups, than in the latter, which has only one.

All the salts yielded higher fractions of solvent-separated ion pairs in ethereal solvents containing a small amount of HMPA. This fact suggests that the solvating power of HMPA is stronger than the intramolecular coordinating power of the hetero atoms.

Such an intramolecular solvation has also been proposed to account for the behavior of the anionic polymerizations of 2-vinylpyridine[16] and ω-methoxyalkyl methacrylate.[17]



(II)



(III)

In the case of 2-vinylpyridine, (II), the nitrogens of both the ultimate and penultimate units have been considered to contribute to the coordination of the counter cation. Such a penultimate unit effect seems reasonable in view of the similarity of structure between (II) and 9-(3-dimethylaminopropyl)fluorenyl salt, in which six-membered rings formed by intramolecular coordination.

Ito *et al.*[17] have proposed that, in the case of the methacrylate, (III), the interaction of the methoxy oxygen in the substituent (R′) with the counter ion decreases with an increase in the number of carbon atoms between the oxygen and ester oxygen, so that the syndiotacticities of the polymers obtained in toluene increase in this order: $R'=CH_3O-(CH_2)_2- > CH_3O(CH_2)_3- > CH_3O-(CH_2)_4-$. This order is in agreement with that of the ease of formation of contact ion pairs for 9-(ω-methoxyalkyl)fluorenyl salts. Therefore, it is reasonable that the intramolecular association shown as Formula (III) is present in the propagation step of the anionic polymerization of these methacrylates.

Intraction of Magnesium Fluorenide with HMPA. Figure 4 shows the NMR spectrum of the magnesium fluorenide prepared by the reaction of fluorene with equimolar quantities of diethylmagnesium (Et_2Mg) at $[HMPA]/[Et_2Mg]=3$. This spectrum indicates that the fluorenide consists of equimolar amounts of fluorenyl and ethyl groups. The chemical shift of methylene protons, δ_{CH_2}, in the fluorenide was −1.10, while the δ_{CH_2} for Et_2Mg was −0.88 at $[HMPA]/[Et_2Mg]=3$.[4] This fact indicates that the diamagnetic anisotropy induced by the aromatic ring strongly shields the ethyl protones. The fluorenyl part of the NMR spectrum of the fluorenide was similar to that of fluorenyllithium in THF.[18,19] Consequently, the metalation results in the formation of ethylfluorenylmagnesium (Fl^-Mg^+Et) as follows:

$$\text{Fluorene}+Et_2Mg \xrightarrow{\text{HMPA}} Fl^-Mg^+Et+\text{Ethane}$$

The chemical shifts of the ethyl and fluorenyl ring protons for Fl^-Mg^+Et changed as is shown in Fig. 5 on the addition of Et_2Mg to the fluorenide solution. The chemical shift of the 9-proton for the fluorenide, δ_9, changed markedly with the molar ratio of HMPA to magnesium, [HMPA]/[Mg]. This fact indicates that the nature of the carbon–magnesium bond of the fluorenide is highly dependent on the [HMPA]/[Mg] ratio. The chemical shifts of the 9-proton for alkali fluorenides are between ~5.8 and ~6.0, and they are not appreciably affected by the variation in the counter ion and the solvent.[18,19] This behavior must correspond to the fact that the carbon–alkali bonds of alkali fluorenides are essentially ionic.[1d] On the other hand, the large shift in δ_9 (from ~4.9 to ~5.8) suggests that the carbon–magnesium bond of the magnesium fluorenide is essentially covalent in the absence of HMPA (see below) and that the bond changes to an ionic type in the presence of HMPA. The charge formed on the 9-carbon delocalizes over the aromatic ring; hence, the peaks due to the ring protons and 9-proton must shift upfield and downfield respectively. The fact that the values of δ_9 become approximately constant at $[HMPA]/[Mg] \geq \sim 3$ suggests that the ionic species are formed by the coordination of three HMPA molecules to the magnesium. Figure 6 shows the variation in the chemical shift of the methyl protons for HMPA with the [HMPA]/[Mg] ratio. The chemical shift was approximately constant (~2.0) at $[HMPA]/[Mg] < \sim 3$, and then it

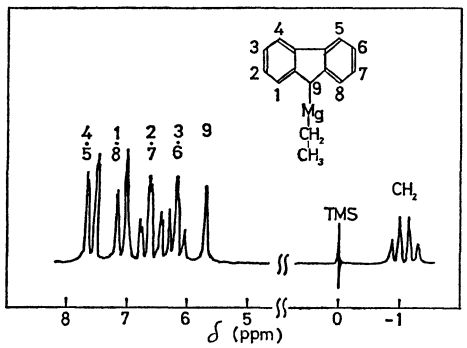


Fig. 4. NMR spectrum of magnesium fluorenide.
Solvent: ether, [HMPA]/[Mg]=3.
Peaks of ether, HMPA, and methyl group in Fl^-Mg^+-Et are not written in the figure.

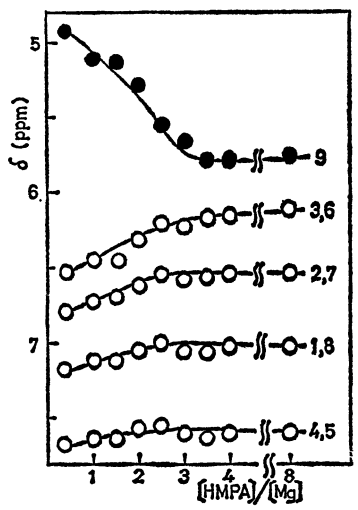

Fig. 5. Variation of chemical shifts for fluorenyl ring protons with [HMPA]/[Mg] ratio.
Numbers in the figure denote positions of the protons.

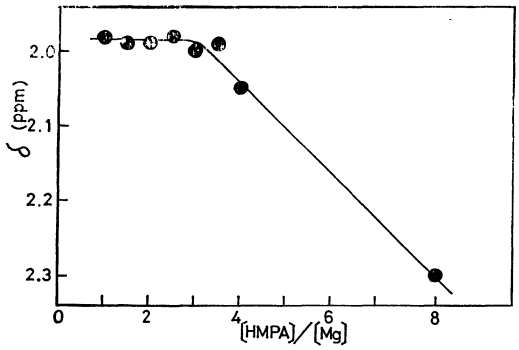

Fig. 6. Variation of chemical shift for HMPA with [HMPA]/[Mg] ratio.

shifted downfield with a further increase in the [HMPA]/[Mg] ratio, while the chemical shift for free HMPA was ~2.5. Those facts indicate that the diamagnetic anisotropy induced by the aromatic ring strongly shields the methyl protons of the HMPA coordinated with the magnesium; they also support the above concept of the formation of the ionic species.

This ionic species was confirmed to be a solvent-separated ion pair by a study of its electronic spectrum. However, the spectra of the magnesium fluorenide–HMPA systems, even at [HMPA]/[Mg]<3, had no peak near 340 nm, where the contact ion pair of the fluorenide is considered to have a characteristic peak by analogy with the results of barium and strontium fluorenides (347 and 344 nm respectively).[20,21] This finding suggests that magnesium fluorenide of a covalent type may change to a solvent-separated ion pair directly, not *via* a contact ion pair.

In the case of the interaction of HMPA with Et_2Mg, the species coordinated by two HMPA molecules was predominantly formed at [HMPA]/[Mg]>2, and the ionic species with the coordination of three HMPA was considered to be formed only slightly.[4] This behavior is in contrast to that in the case of the fluorenide. Such a difference can be explained in terms of that in the stabilities of the carbanions formed. That is to say, the fluorenyl anion, in which there is a resonance stabilization, must be formed more easily than the ethyl anion, in which there is no resonance stabilization.

Interaction of Dicyclopentadienylmagnesium with HMPA. The NMR spectrum of dicyclopentadienylmagnesium (Cp_2Mg) had a singlet peak in THF. The shape of the spectrum, however, varied upon the addition of HMPA to the Cp_2Mg solution (Fig. 7). The signal due to Cp_2Mg shifted upfield with an increase in the [HMPA]/[Mg] ratio when the ratio was less than ~1.5. A second peak began to appear at a lower field at [HMPA]/[Mg]=~2. The upfield peak shifted upfield with a further increase in the [HMPA]/[Mg] ratio, while the intensity of the peak decreased at the same time. In contrast, the intensity of the downfield peak increased and came to be almost equal to that of the upfield peak at [HMPA]/[Mg]=~3. The peaks gradually overlapped with a further increase in the HMPA concentration, and broadened at [HMPA]/[Mg]=~6. At [HMPA]/[Mg]>6, the spectrum had again a singlet peak, one between the previous peaks. The width of this peak decreased with an increase in the [HMPA]/[Mg] ratio. A similar phenomenon was observed for the variation in the spectrum with an increase in the temperature at a constant [HMPA]/[Mg] ratio. Figure 8 shows the variation in the spectrum at [HMPA]/[Mg]=3.3. These results indicate that, in the Cp_2Mg–HMPA system, several species coexist at equilibrium, one which is dependent on the [HMPA]/[Mg] ratio and the temperature.

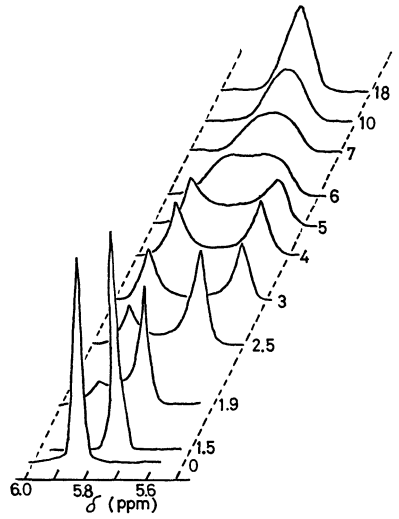

Fig. 7. Variation of NMR spectrum of Cp_2Mg with [HMPA]/[Mg] ratio.
Solvent: THF, Temp.: 22 °C.
Numbers in the figure denote values of [HMPA]/[Mg] ratio.

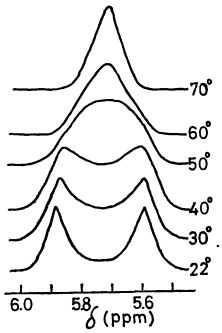

Fig. 8. Dependence of NMR spectrum of Cp_2Mg on temperature.
Solvent: THF, [HMPA]/[Mg]=3.3.

When Cp_2Mg and HMPA were mixed in ether at [HMPA]/[Mg]<~2.5, the solution separated into two layers. The spectrum of the lower portion of the solution had peaks for ether and two kinds of peaks for Cp_2Mg and HMPA (Fig. 9). The downfield peaks were assigned to free species of Cp_2Mg and HMPA, in comparison with the spectra of separate solutions of Cp_2Mg and HMPA. The upfield peaks of Cp_2Mg was found to shift upfield gradually with an increase in the HMPA concentration. The upfield peaks, therefore, were assigned to coordinated species

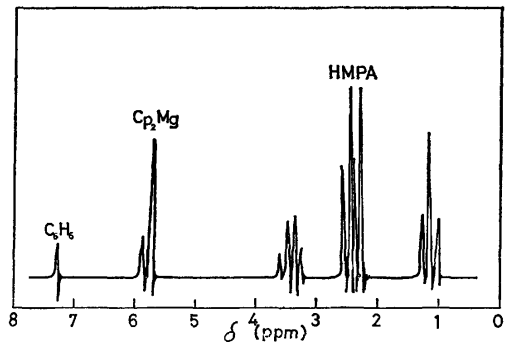

Fig. 9. NMR spectrum of Cp_2Mg in the presence of HMPA in ether.

of Cp_2Mg and HMPA. The unmber of HMPA molecules coordinated with magnesium was estimated from the intensity ratio of the upfield peaks of Cp_2Mg and HMPA; the number was ~1.6 when Cp_2Mg and HMPA were mixed at [HMPA]/[Mg]=2. This fact indicates that the upfield peak of Cp_2Mg is due to the Cp_2Mg coordinated with one or two HMPA molecules. When Cp_2Mg and HMPA were mixed in ether at 5>[HMPA]/[Hg]>~2.5, an ether-insoluble product was obtained. The precipitate, which was filtered, washed with ether, and dried under a vacuum, was found by acid-base titration to be a complex with the formula of $Cp_2Mg\cdot(HMPA)_{3.0-3.1}$. The NMR spectrum of this precipitate (THF-soluble) in THF had two kinds of peaks for Cp_2Mg, and the intensities were almost equal. This spectrum, moreover, was almost the same as that of the Cp_2Mg–HMPA mixture prepared directly in THF at [HMPA]/[Mg]=~3 (see Fig. 7). This finding suggests that the evolution of two peaks for Cp_2Mg in a THF–HMPA mixture is also due to the coordination of three HMPA molecules with the magnesium.

Consequently, the spectral change in the presence of HMPA is most likely to be due to the structural change in the Cp_2Mg ion pair, since Cp_2Mg has been considered to be an ion triplet in THF.[22] The change in the contact ion pair to the solvent-separated ion pair could be accounted for by the following scheme:

$$\underset{\text{(I)}}{\overset{\text{THF}}{\overset{\downarrow}{Cp^-, Mg^{2+}, Cp^-}\overset{\uparrow}{\text{THF}}}} + \text{HMPA} \rightleftharpoons \underset{\text{(II)}}{\overset{\text{THF}}{\overset{\downarrow}{Cp^-, Mg^{2+}, Cp^-}\overset{\uparrow}{\text{HMPA}}}} + \text{THF}$$

$$\text{(II)} + \text{HMPA} \rightleftharpoons \underset{\text{(III)}}{\overset{\text{HMPA}}{\overset{\downarrow}{Cp^-, Mg^{2+}, Cp^-}\overset{\uparrow}{\text{HMPA}}}} + \text{THF}$$

$$\text{(III)} + \text{HMPA} \rightleftharpoons Cp^-//\text{HMPA} \rightarrow \underset{\text{(IV)}}{\overset{\text{HMPA}}{\overset{\downarrow}{Mg^{2+}, Cp^-}\overset{\uparrow}{\text{HMPA}}}}$$

$$\text{(IV)} + m\text{HMPA} \rightleftharpoons \underset{\text{(V)}}{Cp^-//Mg^{2+} \leftarrow (3+m)\text{HMPA}//Cp^-}$$

It is reasonable to assume that Cp_2Mg exists as monomeric Species (I) coordinated with two THF molecules in THF, since other Grignard reagents and dialkylmagnesium compounds have been found to be monomeric in THF, even at concentrations>1 M.[23] Species (I) and also Species (II), which is coordinated by one HMPA and one THF, coexist at equilibrium at [HMPA]/[Mg]<1. When the [HMPA]/[Mg] ratio is between about unity and about two, Species (III), which is coordinated by two HMPA molecules, coexists with Species (II). The spectrum of Species (II) must have a singlet peak, since the two cyclopentadienyl rings of the species are equivalent. In the same manner, the spectrum of Species (III) must have a singlet peak different from that of Species (II) if the exchange between these species is slow. However, the fact that the chemical shift of Cp_2Mg changes continuously at [HMPA]/[Mg]<~2 suggests that the exchanges among Species (I), (II), and (III) are rapid at room temperature.

When the [HMPA]/[Mg] ratio is more than about two, Species (IV) coexists with Species (III), and the former becomes a predominant species at [HMPA]/[Mg]=~3. Species (IV), which is coordinated with three HMPA molecules, was concluded, by a comparison with the results for the magnesium fluorenide–HMPA complex (see the above section), to be an asymmetrically solvent-separated ion pair in which one of the cyclopentadienyl rings is separated from the magnesium ion. The two rings of Species (IV) are nonidentical; hence, the spectrum must have two singlet peaks if the exchange between the two rings is slow. Actually the spectral behavior at [HMPA]/[Mg]≥3 indicates that the exchange between the distinct rings is slow at room temperature on the NMR time scale, but becomes rapid with an increase in the temperature. On the basis of the spectral change with the [HMPA]/[Mg] ratio, the upfield and downfield peaks of Cp_2Mg at [HMPA]/[Mg]=~3 were assigned to the contact and the separated cyclopentadienyl rings respectively.

When the [HMPA]/[Mg] ratio is more than three, Species (IV) changes gradually to Species (V) by interaction with *m* molecules of HMPA. Species (V) is a symmetrically separated ion pair, in which two of the cyclopentadienyl rings are separated from the magnesium. This species has two identical rings; hence, the NMR spectrum must give a singlet peak. The spectral change at [HMPA]/[Mg]>3 can be explained by assuming that Species (V) is formed by the interaction of Species (IV) with three HMPA molecules; that is, the *m* in the equation is three. That is to say, the symmetrically separated ion pair of Cp_2Mg is formed by the interaction of Cp_2Mg with six HMPA molecules. Cp_2Mg was found to form a THF-insoluble complex with three octamethylpyrophosphoramide (OMPA) molecules. The coordination number of the magnesium ion is six since OMPA is a bidentate ligand. Magnesium perchlorate has also been reported to form a complex with three OMPA.[24] These results support the above concept. Such a two-step separation process has already reported in the case of fluorenylstrontium in THF when studied

by electronic spectroscopy.[21]

(Received September 19, 1974)

The polycondensation reaction of acetylferrocene and furfural was investigated in the presence of concentrated H_2SO_4 as a catalyst without solvent. Stoichiometric reaction took place with 2 mol of acetylferrocene and 5 mol of furfural. Polycondensation afforded satisfactory results when 1 mol of acetylferrocene was treated with 2—7 mol of furfural. The structural evidence for these products was derived from chemical and infrared analyses. Density, micro Vickers hardness, magnetic susceptibility, and thermal behavior of these products were measured in comparison with those of other resins.

In recent years efforts have been made to obtain polymers with properties differing from those of conventional organic polymers, the ultimate objective being polymers with better electrical and magnetic properties with abrasion resistance, thermal stability and opaqueness to certain types of radiation. Organometallic compounds have been suggested as starting materials for the synthesis of these polymers; they have been polymerized by means of various procedures.[1] The organometallic polymer is expected to have properties characteristic of both organic compounds and metals, since it contains a metal as the organometallic complex. Ferrocene ($C_{10}H_{10}Fe$) is stable against acid and base, and easily undergoes aromatic substitution reactions.[2] Synthetic studies of ferrocene polymers have been carried out in the past two decades.[3] Emphasis was placed on soluble products possessing linear chain structures. However, very few attempts have been made to synthesize crosslinked ferrocene polymers (resins).[4-7]

From ferrocene, iron atoms are released by heat treatment above 400°C and then coagulate to metallic iron.[8] In the case of ferrocene resins, iron atoms would be also released from ferrocene skeletons by heat treatment. It appears that the released iron atoms do not coagulate and are isolated in the form of atoms or ultra-fine particles above room temperature due to networks of the resins. The preparation of metal atoms was reported by Barrett *et al.*[9,10] An inert gas and vapourized metal were condensed on a Be disk at liquid helium temperature, iron atoms being frozen into an inert gas matrix. The isolated iron atoms could only be present near liquid helium temperature. Preparation of ultra-fine particles of metals and their compounds has been sought by Mulay *et al.*[11,12]

Our studies deal with the synthesis of resins containing ferrocene. Reports were given on the preparation of free iron atoms or ultra-fine particles of an iron metal by pyrolysis of the ferrocene resin.[13,14] The resin used was synthesized by polymerization of furfural (II) and a ferrocene derivative. Furfural (II) was polycondensed with acetone.[15] Acetylferrocene (I) is considered to serve as a ketone derivative of ferrocene for the polycondensation. Acetylferrocene (I) was polycondensed with various proportions of furfural (II) in the presence of concentrated sulfuric acid. The structure of the synthetic resin was elucidated by chemical and infrared spectroscopic analyses. Density, micro Vickers hardness and magnetic susceptibility were measured and thermal behavior was observed.

Experimental

Materials. Polycondensation was carried out with acetylferrocene, furfural and concentrated sulfuric acid. Ferrocene was synthesized according to the method given by Hata *et al.*[16] Acetylferrocene was prepared by reacting ferrocene with acetic anhydride in anhydrous dichloromethane.[17] It was then purified by recrystallization from *n*-hexane and sublimation *in vacuo*; mp 85—86 °C (Ref. 17, 85—86 °C). Furfural was redistilled prior to use; bp 67—68 °C/20 mmHg. Concentrated sulfuric acid (reagent grade) was used.

Preparation of Resins. Concentrated sulfuric acid which was used for the preparation of furfural-acetone resins was used as the catalyst of polycondensation.[15] Polycondensation temperature was fixed at 45 °C, since low temperature is preferable for preventing the decomposition of ferrocene skeletons by acid. Acetylferrocene was dissolved in furfural in a test tube. Concentrated sulfuric acid was added to this solution at certain wt% of acetylferrocene and furfural. The reaction mixtures were stirred and then heated at 45 °C for a certain period of time. After polycondensation, synthetic resins were dried *in vacuo* at room temperature and then heated up to 100 °C for 24 hr in order to remove volatile materials.

Elemental Analysis and Measurement of Properties. Iron determination was carried out with a Hitachi-207 atomic absorption spectrophotometer. IR spectra were measured with a Nihonbunko Jasco IR-S grating IR spectrometer using potassium bromide disks. Apparent densities were calculated from the weight and size of resins. Micro Vickers hardness was measured with an Akashi Model MVK Type D instrument with a load of 200 g. Magnetic susceptibility was recorded on a Shimadzu MB-10A magnetic balance. A helical spring microbalance was used for thermogravimetric analysis (TGA), the heating rate being 2 °C/min. Powdered samples with initial weight of 100 mg were used, the determination being performed *in vacuo* (1×10^{-3} mmHg).

Results and Discussion

Polycondensation Reaction and Resin Structure. The results are summarized in Tables 1—3. Polycondensation seems to be affected by experimental conditions. Effects of (a) amount of a catalyst and (b) the length of reaction time were investigated using a mixture of 1 mol of acetylferrocene and 5 mol of furfural. Forty-hour polycondensation data are given in Table 1 for (a),

The yields of resins were constant when more than 3% of the catalyst was used, their density being independent of the amount of the catalyst. Molar ratios of furfural to acetylferrocene (F/A) in resins could be calculated from elemental analyses of carbon, hydrogen and iron contents. The molar ratios of F/A increased with the amount of catalyst. The effects of the reaction time were investigated with 4% catalyst (Table 2). Yields of resins were approximately constant when polycondensation was continued for 40 hr or longer. The density of resins was independent of the reaction time. The molar ratios of F/A in resins increased with an increase in the reaction time. The behavior of polycondensation was considered to be influenced by the molar ratios of F/A in starting materials. The influence was investigated under experimental conditions where the catalyst was 4% and reaction time was 40 hr. In Table 3, the notation of resins shows the number of moles of furfural per mole of acetylferrocene in the starting materials. No resins were formed when the concentration of the acetylferrocene component was reduced to below 15 of F/A. Yield of resins decreased in proportion to the decrease in acetylferrocene. The density of resins was invariable for 2- to 7-Resins, but reduced rapidly for 10- to 15-Resins. The molar ratio of F/A in the resin of the 2-Resin was greater than that in the starting material. For other resins, the relation between the molar ratios of the starting material and the resin was reversed. The stoichiometry of polycondensation was thus considered to be as follows. In the case of the 2-Resin, excess acetylferrocene not capable of reacting with furfural was removed. On the other hand, furfural in the starting material of the 3-Resin was more than enough to react with acetylferrocene. The excess furfural was removed, but what remained might have become partially incorporated into resins according to the progress of polycondensation. Thus, the stoichiometry of polycondensation was decided to be a reaction of 2 mol of acetylferrocene and 5 mol of furfural (2-Resin). The mechanism of the stoichiometric reaction was estimated on the chemical reactivities of acetylferrocene and furfural. Furfural could not be subject to polycondensation without the

presence of other compounds.[15] Furfuryl alcohol has been established to be a versatile polymer precursor.[18] Thus, if furfural is converted into the form of furfuryl alcohol in the course of polycondensation process, the polycondensation reaction would successfully proceed to give resin. The initial step in polycondensation involves 1 mol of acetylferrocene and 2 mol of furfural to undergo aldol condensation and Friedel-Crafts reactions to yield oligomer (III). The oligomer was in the form of furfuryl alcohol containing four reaction points (1, 2, 3, 4); with further reactions with each other and 1 mol of furfural, it produces polymers (IV), as shown in Fig. 1. The polymer was reactive with

780	Out-of-plane bending of furan C-H	22
478	Ring metal stretching of ferrocene	19

furfural or became crosslinked with each other, after removal of hydroxy groups.

The IR spectrum of the 2-Resin, shown in Fig. 2, exhibited absorption bands at 3080, 2930, 2850, 1700, 1655, 1445, 1375, 1273, 1160, 1103, 1017, 818, 780, and 478 cm^{-1}. Assignments of all bands except for those at 1700 and 1273 cm^{-1} were referred to those of ferrocene polymers available in literature (Table 4). The 1700 cm^{-1} band corresponded to one of the absorption bands in the IR spectrum of furfural.[24] It is therefore considered to be due to a ketone conjugated with a furan ring (furyl ketone). The 1273 cm^{-1} band would be assigned to the acetylated cyclopentadienyl ring since this absorption band was observed in the IR spectrum of acetylferrocene[25] but not in that of ferrocene.[19] Rosenblum and Woodward reported that two bands near 1000 and 1100 cm^{-1} indicated the presence of unsubstituted cyclopentadienyl rings.[26] In the case of the 2-Resin, unsubstituted cyclopentadienyl rings were not contained in its structure because of the lack of the 1000 cm^{-1} band of those bands in the resin. Results of IR spectrum studies are in accord with the structure (IV) of the 2-Resin predicted here. However, its actual structure might partially deviate from structure (IV) owing to the effect of the furyl ketones and the acetylated cyclopentadienyl rings remaining in the structure. For 3-Resin to 15-Resin, the excess furfural which exceeded the stoichiometric composition in the starting material would be expected to lead to a Diels-Alder addition reaction in furyl side-groups of the polymer structure (IV)[22] and a substitution reaction with the hydroxyl groups. Thus, structures of these resins were considered to decrease in crosslinkages. Holliday suggested that the connection number is useful in describing crosslinkages and it can be derived from the density of the polymer.[27] From the relationship between density and connection number, 1.43 density was found to correspond to 2.3 (connection number). Since the maximum connection number is 2.5 for CH polymer, 2.3 shows a considerably high value of crosslinkages. Low density of 10- to 15-Resins as compared to other resins corresponded to the decrease in crosslinkages. The densities of 2- to 7-Resins were higher than those of phenolic novolac resins.[28]

Micro Vickers Hardness. Micro Vickers hardness measurements were carried out for the mechanical properties of resins. The values of hardness were approximately the same for 2-Resin to 7-Resin. The hardness of 10-Resin to 15-Resin decreased with the decrease in density. A linear relationship was obtained between hardness and density (Fig. 3). Close packed resins (2- to 7-Resins) are assumed to have high hardness characteristics. Hardness of these resins was similar to that of phenolic novolac and melamine resins.[29]

Magnetic Properties. Magnetic susceptibilities of 2-Resin, 5-Resin and 15-Resin are given in Table 5. The observed values of magnetic susceptibility were all positive and of the order of 10^{-6} irrespective of iron content. The paramagnetism should be discussed in connection with the structure of resins since the magnetic susceptibility of ferrocene has been reported

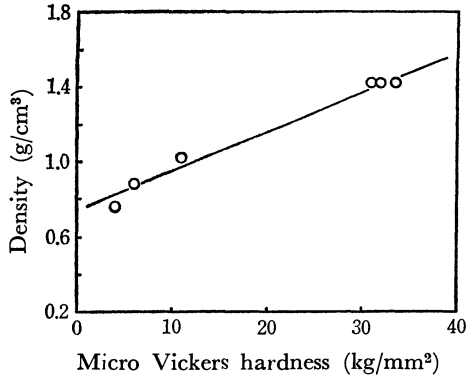

Fig. 3. Relation between density and micro Vickers hardness of resins.

Table 5. Magnetic susceptibility of the resins at 20 °C

Samples	χ_g cgs units
2-Resin	2.91×10^{-6}
5-Resin	2.74×10^{-6}
15-Resin	2.88×10^{-6}

to be $\chi_a=-99.0\times10^{-6}$ cgs units.[30] Kalimov and Shchegolev demonstrated that the products can be converted from paramagnetic into diamagnetic with the use of paramagnetic ferrocene polymers[31] described by Nesmeyanov *et al.*[32] Since the present specimens could not be purified because of insolubility, the paramagnetism does not seem to arise from the structure of the resins; instead, it might be related to magnetic contaminants. However, it is evident that no ferromagnetic iron compounds are contained in the resins.

Thermal Behavior. Structural changes of resins were investigated by means of IR spectroscopy. IR spectra of heat-treated 2-Resin (200 and 300 °C) do not differ from those of 2-Resin (Fig. 2). From the IR spectrum of 2-Resin heat-treated at 400 °C, we see that the structure was decomposed on heating at 400 °C. This structural change corresponded to carbonization of resins, since carbonization of organic compounds starts near 400 °C.[33] Thermal behavior was investigated by means of a thermobalance. The thermograms of resins, heated up to 800 °C, are shown in Fig. 4. The weight losses were remarkable above 300 °C for 2- to 7-Resins and above 100 °C for 10- to 15-Resins. Residues at the end of thermogravimetric analysis are given in Table 6. The reduced residues are derived by subtraction of the amounts of iron from the residues. The residues of 2- to 7-Resins differ from each other, but no difference is seen in their reduced residues. In the case of 10- to 15-Resins, no such difference was observed in the reduced residue. Thermograms and reduced residues of 2- to 7-Resins are similar to those of phenolic novolac resins.[34] We see that the thermal behavior of the resins was not affected by the presence of iron. It is known that the residues of organic polymers heat-treated above 600 °C increase with the formation of crosslinkages.[35] A decrease in reduced residues of 10- to 15-Resins as

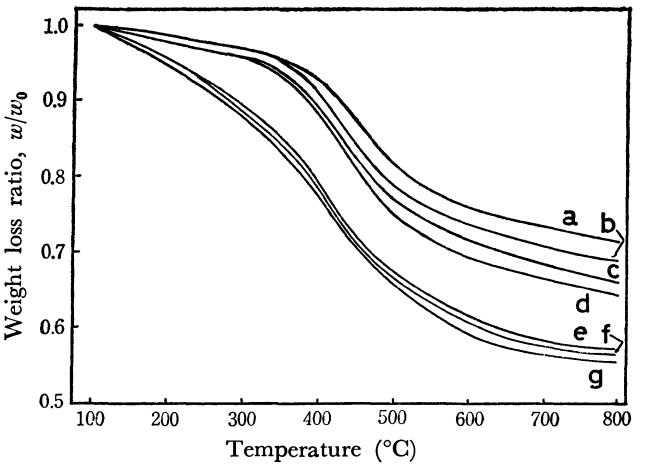

Fig. 4. Thermograms for resins; (a) 2-Resin, (b) 3-Resin, (c) 5-Resin, (d) 7-Resin, (e) 10-Resin, (f) 12-Resin, (g) 15-Resin.

Table 6. Residue and reduced residue of the resins heat-treated at 800 °C

Samples	Residue (wt%)	Fe in residue (wt%)	Reduced residue[a] (wt%)
2-Resin	71.4	19.1	52.3
3-Resin	69.0	16.9	52.1
5-Resin	66.0	13.8	52.2
7-Resin	64.3	13.0	51.3
10-Resin	57.3	12.1	45.2
12-Resin	56.4	11.5	44.9
15-Resin	55.4	9.40	46.0

a) Reduced residue=Residue-Amounts of Fe.

compared with 2- to 7-Resins is considered to correspond to the decrease in crosslinkages. Thermograms of 10- to 15-Resins show that the decrease of their reduced residues mainly results from the weight loss at low temperatures (100—300 °C).

The authors would like to thank Dr. T. Hirai, Tohoku University, for valuable suggestions. Thanks are also due to Mr. T. Shoji and Mrs. H. Arai, Tohoku University, for their assistance in iron and CH analyses.

Photosensitized Polar Addition of Acetic Acid to 4-Homoadamantene: The Behavior of the 4-Homoadamantyl Cation*

Ryohei YAMAGUCHI and Mituyosi KAWANISI

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received October 3, 1974)

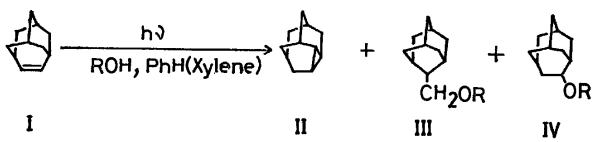
The photosensitized polar addition of acetic acid to 4-homoadamantene (I) gave 2,4-dehydrohomoadamantene (II), 2-adamantylmethyl acetate (IIIa), and 4-homoadamantyl acetate (IVa). The same treatment of I in pivalic acid gave analogous products, II, 2-adamantylmethyl pivalate (IIIb), and 4-homoadamantyl pivalate (IVb). It was shown that II and III were derived from the 4-homoadamantyl cation (V). On the other hand, the diazotization of 4-homoadamantylamine (XV) in the presence of acetic acid gave I, II, and IVa, whereas it has been reported that a buffered acetolysis of 4-homoadamantyl tosylate (XIV) gave I and IVa, but not II. The formation of II may be explained by assuming a different energy state of V of different origin; it proves a vibrationally excited nature of V generated in the photosensitized polar addition reaction.

The photochemical incorporation of protic solvents into 6- and 7-membered cycloalkenes in the presence of BTX (aromatic hydrocarbon sensitizer) has been extensively investigated.[1] We ourselves have reported that the chemically reactive species in the reaction of photosensitized polar addition to *cis*-cyclooctene was *trans*-cyclooctane[2] and that a carbocation was the intermediate in the photosensitized polar addition to bicyclo[3.3.1]non-2-ene system, a bridged cyclooctene, since a novel intramolecular hydride shift was observed.[3]

On the other hand, the behavior of carbocations of cage compounds has attracted considerable attention in the field of carbocation chemistry.[4] The behavior of the 4-homoadamantyl cation (V) has been studied in three different ways—solvolysis of 4-homoadamantyl tosylate (XIV),[5,6] the treatment of 4-homoadamantene (I) with Lewis acid,[7] and the treatment of I or 4-homoadamantanol (VIII) with concentrated sulfuric acid in the presence of pentane.[8] In this paper, we wish to report on the behavior of V, which is generated by the photosensitized polar addition of acetic acid to I[9] and by diazotization of 4-homoadamantylamine (XV).

Results and Discussion

A solution of I in acetic acid containing benzene or xylene as a sensitizer was irradiated in a quartz vessel by means of a medium-pressure mercury arc; three products were detected by glc analysis: 2,4-dehydrohomoadamantane(II), 2-adamantylmethyl acetate (IIIa), and 4-homoadamantyl acetate (IVa).[10] A similar reaction of I in pivalic acid gave II, 2-adamantylmethyl pivalate (IIIb), and 4-homoadamantyl pivalate (IVb). The results are summarized in Table 1.



Formula 1.

Table 1. Irradiation of I in protic solvents[a]

	R	Conversion[b] (%)	Products ratio[b] II(%)	III(%)	IV(%)
a	Ac	62	40	8	52
b	*t*-BuCO	46	63	9	28

a) Irradiated at room temperature for 7 day.
b) Determined by glc (PEG 20 M, 160 °C).

The structures of the products were confirmed by comparison with the corresponding authentic samples. No product other than II, III, and IV was detected by glc or NMR analyses. The ratio of II in the reaction with pivalic acid was larger than that in the reaction with acetic acid, probably because of the bulkiness of pivalic acid.

The following observations confirm that the presence of a proton source is indispensable for the isomerization of I into II. (a) When the irradiation of I in an xylene or benzene solution was effected without a proton source—*i.e.*, acetic acid or pivalic acid, no isomerization of I into II was observed. (b) The irradiation of I in xylene containing a small amount of methanesulfonic acid as a proton source did induce the isomerization of I into II. (c) When I was irradiated in AcOD containing xylene, the resulting II contained one deuterium (41% d_1 by mass spectroscopic analysis). The above observations, as well as the diazotization of XV (*vide infra*), prove that II is produced *via* 4-homoadamantyl cation (V).

In order to ascertain that III was produced from V by rearrangement, the photochemical reaction was effected in AcOD. The resulting deuterated compound (III-d_1) was reduced by lithium aluminum hydride to give deuterated 2-adamantylmethanol (IX-d_1). The mass spectra of IX-d_1 and an authentic

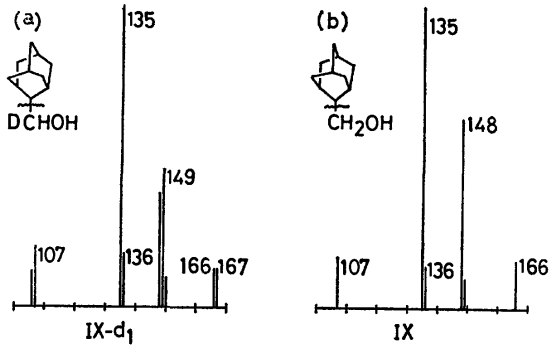


Fig. 1. Mass spectra of IX-d_1 and IX

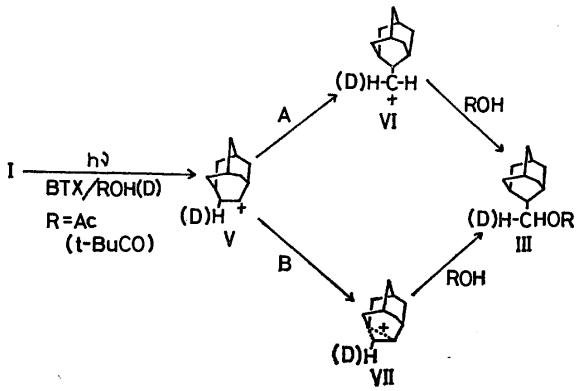
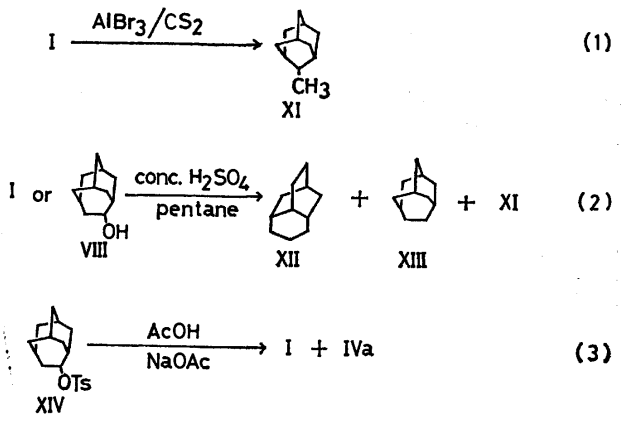
2-adamantylmethanol (IX) are depicted in Fig. 1.

As is shown in Fig. 1a, IX-d_1 contains one deuterium (49% d_1). The base peak at *m/e* 135 in Fig. 1b is characteristic of the adamantyl skeleton. The fact that the intensity of the peak at *m/e* 136 in Fig. 1a is almost the same as that in Fig. 1b implies that deuterium is not located on the adamantyl skeleton, but on the α-carbon atom. These results shows that V must rearrange into the 2-adamantylmethyl cation (VI) through a simple Wagner-Meerwein rearrangement (Path A) or into a non-classical cation (VII) (Path B), which subsequently gives III due to the nucleophilic trapping of the solvent (Scheme 1). In our experiments it is still not clear which pathway (A or B) the rearrangement proceeds through, although we feel that Path B is more likely because a simple primary carbocation appears to be energetically inaccessible under usual reaction conditions.[7,11,18b]



Scheme 1.

It has been proposed that a photosensitized polar addition of protic solvents to 6—8 membered cycloalkenes proceeds through the following sequences:[1-3] (i) the BTX sensitized photo-induced *cis-trans* isomerization of olefins,[12] (ii) protonation to the strained *trans*-olefins producing cycloalkyl cations, and (iii) nucleophilic trapping by the protic solvents, deprotonation to other olefins (*i.e.*, exocyclic olefins), and the regeneration of the starting olefins. Since I is regarded as a bridged cycloheptane, it is highly probable that the present reaction proceeds through the same sequences.[13] Consequently, the corresponding cycloalkyl cation is the 4-homoadamantyl cation (V).



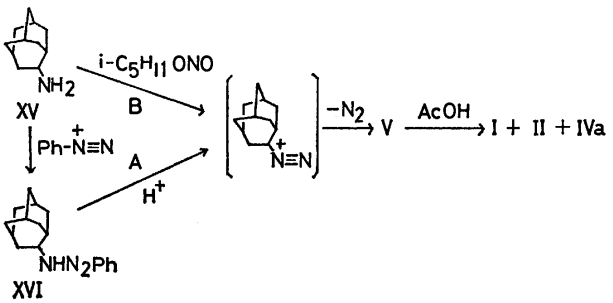
Scheme 2.

As to the behavior of V, there have been several reports, as has been mentioned above. The treatment of I with Lewis acid gave a single product, 2-methyladamantane (XI)[7] (Scheme 2, Eq. 1), while the reaction of I or 4-homoadamantanol (VIII) with concentrated sulfuric acid in the presence of pentane gave 4-homoisotwistane (XII), homoadamantane (XIII), and XI[8] (Scheme 2, Eq. 2). Furthermore, the buffered acetolysis of 4-homoadamantyl tosylate (XIV) gave I and IVa[5,6] (Scheme 2, Eq. 3).

The photochemical reaction and the buffered acetolysis are kinetically controlled,[15] while the adamantane rearrangement (Scheme 2, Eqs. 1 and 2) is thermodynamically controlled. However, differences were observed in the reaction products between the photochemical reaction and the acetolysis. These differences can be explained by assuming a vibrationally excited nature of V generated in the photosensitized polar addition reaction.[16] In order to support this assumption, we have examined the diazotization of 4-homoadamantylamine (XV), since it has been suggested that a "hot" ("highly energetic" or "poorly solvated") carbocation is formed from the diazonium ion and that it is different from the "normal carbocation" formed during solvolysis.[17]

The diazotization of XV was effected in two different ways. A compound, 3-(4-homoadamantyl)-1-phenyltriazene (XVI), was prepared from XV by a conventional method and decomposed with acetic acid (Method A), and isopentyl nitrite was used in the direct diazotization of XV (Method B). The results are summarized in Table 2.

The products, I, II, and IVa, were identical with the respective authentic samples in glc retention time, mass, and IR spectra. Every reaction mixture contained I, II, and IVa, but IIIa could not be detected by glc analysis. On the other hand, as has been mentioned above, it has been reported that no II was



Formula 2.

Table 2. Diazotizations of XV

Method	Sovent	AcOH	Temp.	Time (hr)	Products ratio (%)[a]		
					I	II	IVa
A	AcOH	excess	room temp.	1	31	20	49
A	PhH	1 eq.	room temp.	12	35	37	28
B	AcOH	excess	room temp.	72	7	14	79
B	PhH	1 eq.	reflux	12	26	39	35

a) Determined by glc (PEG 20 M, 160 °C).

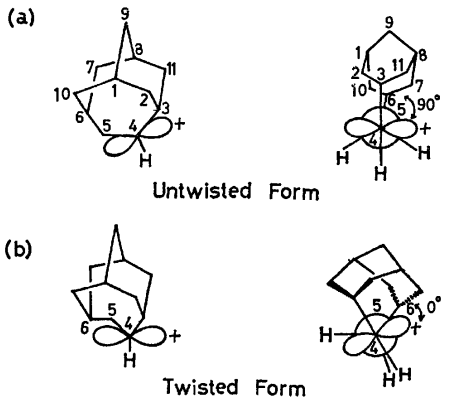


Fig. 2. Conformations of V.

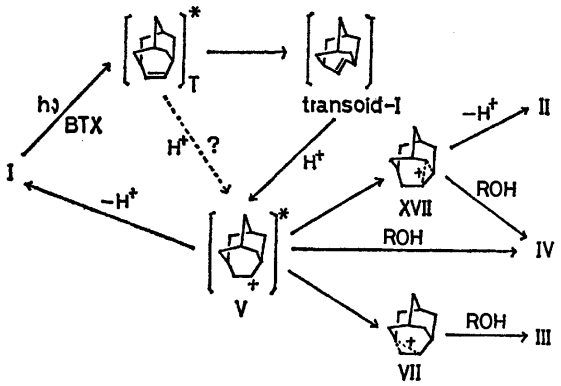
produced in the solvolysis.[5,6] The possibility that II would be formed in the acetolysis and would subsequently react with acetic acid, thus giving I and IVa, can be ruled out, since II was stable under the acetolysis conditions (70 °C for 3 hr[6]). Thus, the formation of II should be due to the "hot," *i.e.*, vibrationally excited, nature of V. Therefore, V must have the enhanced nature of the non-classical cation (XVII), which is nicely deprotonated to give II (Scheme 3).



Scheme 3.

Although III was produced in the photochemical reaction, no III was detected in the diazotization or in the acetolysis[5,6] (Scheme 2, Eq. 3). Under thermodynamic controlled conditions, as are shown in Scheme 2, Eqs. 1 and 2,[7,8] the formation of XI is not surprising, because the homoadamantyl skeleton is known to be about 10 kcal/mol more strained than the adamantyl skeleton.[18] Therefore, III should be thermodynamically more stable than IV.[19] However, the photochemical reaction, the diazotization, and the buffered acetolysis[5,6] should be kinetically controlled. The cation (V) generated in the solvolysis must be in the ground state and, therefore, would not have enough energy to produce II. On the other hand, the cation (V) generated in the diazotization as well as the photochemical reaction would have enough energy to produce II. Although the reason why III is produced only in the case of the photochemical reaction is still not clear, in this rearrangement not only a energetic factor but also a stereochemical one would be operative.[20]

In summary, the total pathway of the photosensitized polar addition of protic solvents to I can be depicted as is shown in Scheme 3. Additionally, it should be noted that no 1,2-hydride shift in V forming a 3-homoadamantyl cation is observed in any of the three different ways so far as the product analysis is concerned.

Experimental

All the temperatures are uncorrected. The IR spectra were obtained on a Shimadzu IR-27 spectrometer. The mass spectra were taken by using a Hitachi RMS-4 mass spectrometer. The NMR spectra were obtained on a Varian EM-360 spectrometer, TMS being chosen as the internal standard. The microanalyses were performed in the Kyoto University Elemental Analysis Center.

Photosensitized Polar Addition of Acetic Acid to I. In an analytical-scale experiment, a solution of I (50 mg, 0.34 mmol) in 5 ml of glacial acetic acid containing 1 ml of benzene (xylene) was irradiated by means of a 300 W medium-pressure mercury lamp under nitrogen for 7 days. The reaction mixture was then poured onto water, neutralized by sodium hydrogen carbonate, and extracted by CH_2Cl_2. The organic layer was washed with aq. $NaHCO_3$ and water, and dried (Na_2SO_4). The solvent was removed, and the residue was analyzed by glc (PEG 20 M, 160 °C). Each product was isolated by preparative glc and was identical with the corresponding authentic sample (II, IIIa, and IVa) in glc retention time and in IR and NMR spectra.

In a preparative-scale run, a solution of I (1.00 g, 6.75 mmol) in 45 ml of glacial acetic acid containing 5 ml of xylene was irradiated by means of a 300 W medium-pressure mercury lamp under nitrogen for 30 days. The usual work-up (see above) gave a crude oil, from which xylene was quickly removed under reduced pressure, but the high subliming property of II prevented the complete removal of the xylene. The glc analysis showed the complete disappearance of I. The residue (2.0 g) was chromatographed on silica gel (200 g). The eluting solvent was gradually changed from *n*-hexane to a mixture of *n*-hexane and ether (95 : 5). The eluent of *n*-hexane gave pure II (216 mg, 21.6%). The eluent of *n*-hexane with ether gave pure IIIa (25 mg, 1.8%), a mixture of IIIa and IVa (303 mg, 21.6%), and pure IVa (360 mg, 25.7%).

A solution of I (500 mg; 3.4 mmol) in 10 ml of AcOD containing 3 ml of xylene was irradiated for 14 days. The usual work-up and chromatography on silica gel gave a mixture of I and II (185 mg, I : II=1 : 2.5 by glc analysis) and a mixture of III-d_1 and IV-d_1 (278 mg, 6 : 1 by glc analysis). The preparative glc gave pure I and pure II, which contained 12% d_1 and 41% d_1 respectively, as determined by mass spectrometry. The mixture of III-d_1 and IV-d_1 (150 mg) was treated with $LiAlH_4$ (75 mg) in refluxed ether for 10 hr, the subsequent usual work-up gave a crude solid (140 mg) which contained IX-d_1 and VIII-d_1 (*ca.* 1 : 6 by glc analysis). The preparative glc gave pure VIII-d_1 and pure IX-d_1, which contained 45% d_1 and 49% d_1 respectively, as determined by mass spectrometry.

The products, II, IIIa, and IVa, were shown by control experiments to be stable under the present photochemical reaction conditions.

Photosensitized Polar Addition of Pivalic Acid to I. A mixture of I (50 mg; 0.34 mmol), 2.5 ml of pivalic acid, and 2.5 ml of benzene was irradiated by means of a 300 W medium-pressure mercury lamp under nitrogen for 7 days.

The usual work-up gave a crude oil, which was then analyzed by glc (PEG 20 M, 160 °C). Each product, when isolated by preparative glc, was found to be identical with the corresponding authentic sample (II, IIIb, and IVb) in glc retention time and in IR and NMR spectra.

The authentic samples were prepared as follows:

2,4-Dehydrohomoadamantane (II)[21] and 4-homoadamantyl acetate (IVa)[5] were synthesized by the reported method.

4-Homoadamantyl Pivalate (IVb). To a solution of 4-homoadamantanol (VIII) (166 mg; 1.0 mmol) in 1 ml of pyridine, we added pivaloyl chloride[22] (180 mg; 1.5 mmol) in an ice-water bath. The reaction mixture was stirred at room temperature for 24 hr and then poured onto aq. HCl (5%) and extracted with CH_2Cl_2. The CH_2Cl_2 solution was washed successively with 5% aqueous HCl, aqueous $NaHCO_3$, and water, and then dried (Na_2SO_4). The subsequent removal of the solvent gave a crude oil, which was chromatographed on silica gel. The eluent of *n*-hexane with ether (5%) gave pure IVb (204 mg, 81.6%); bp 140 °C/40 mmHg (bath temp.); IR (neat) 2980, 1750, 1160, cm^{-1}; NMR δ (CCl_4) 1.13 (s, 9H), 1.30—2.30 (complex m, 16H), 4.93 (m, 1H). Found: C, 76.49; H, 10.55%. Calcd for $C_{16}H_{26}O_2$: C, 76.75; H, 10.14%.

2-Adamantylmethanol (IX).[23] This compound was prepared by the reported methods. Adamantane-2-carboaldehyde[24] was synthesized by the treatment of adamantyleneoxirane[25,26] with BF_3-etherate.[26] The aldehyde was oxidized by Jones' reagent to give adamantane-2-carboxylic acid,[24,26] which was then reduced with $LiAlH_4$ to furnish IX.[23]

2-Adamantylmethyl Acetate (IIIa). To a solution of IX (50 mg; 0.30 mmol) in 1 ml of pyridine, we added 0.5 ml of acetic anhydride, after which the reaction mixture was stirred for 19 hr at room temperature. The usual work-up gave crude IIIa (60 mg, 96%); bp 135 °C/40 mmHg (bath temp.); IR (neat) 2930, 1750, 1455, 1370, 1220, 1035 cm^{-1}; NMR δ(CCl_4) 1.87 (broad s, 15H), 2.00 (s, 3H), 4.17 (d, 2H, J=7.5 Hz). Found: C, 75.09; H, 9.75%. Calcd for $C_{13}H_{20}O_2$: C, 74.96; H, 9.68%.

2-Adamantylmethyl Pivalate (IIIb). To a solution of IX (50 mg; 0.30 mmol) in 0.5 ml of pyridine, we added pivaloyl chloride (60 mg; 0.5 mmol) in an ice-water bath. The reaction mixture was then stirred at room temperature for 19 hr, after which the usual work-up gave a crude oil, which was subsequently chromatographed on silica gel. The eluent of *n*-hexane with ether (5%) gave pure IIIb (64 mg, 85%); bp 135 °C/30 mmHg (bath temp.); IR (neat) 2940, 1745, 1480, 1460, 1290, 1150 cm^{-1}; NMR δ (CCl_4) 1.17 (s, 9H), 1.83 (broad s, 15H), 4.14 (d, 2H, J= 7.5 Hz). Found: C, 77.02; H, 10.85%. Calcd for $C_{16}H_{26}O_2$: C, 76.75; H, 1047%.

Diazotization of 4-Homoadamantylamine (XV). The amine was synthesized by a previously reported method.[27] Some typical examples will be described.

Diazotization by Isopentyl Nitrite: A solution of XV (80 mg; 0.48 mmol) and isopentyl nitrite (65 mg; 0.55 mmol) in 5 ml of glacial acetic acid was stirred at room temperature for 72 hr. The reaction mixture was then poured onto water, neutralized with $NaHCO_3$, and extracted with CH_2Cl_2. The CH_2Cl_2 solution was washed with aq. $NaHCO_3$ and water, and dried (Na_2SO_4). After the removal of the solvent, the residue was analyzed by glc (PEG 20 M, 160 °C). Each product, when isolated by preparative glc, was found to be identical with the corresponding authentic sample (I, II, and IVa) in glc retention time and in mass and IR spectra.

Diazotization via XVI: The triazene (XVI) was synthesized by the usual method.[28] Since XVI could not be isolated, the crude XVI was used immediately after its preparation. To the crude XVI (100 mg) we added glacial acetic acid (4.5 ml); nitrogen evolved. The reaction mixture was then stirred at room temperature for 1 hr and poured onto water. The solution was neutralized with $NaHCO_3$ and extracted with CH_2Cl_2. The extract was washed with aqueous $NaHCO_3$ and water, and dried (Na_2SO_4). After the removal of the solvent the residue was analyzed by glc (PEG 20 M, 160 °C). Each product, when isolated by preparative glc, was found to be identical with the corresponding authentic sample (I, II, and IVa) in glc retention time and in mass and IR spectra.

Stability of II under the Buffered Solvolysis Conditions. A mixture of II (50 mg; 0.34 mmol), NaOAc (60 mg; 0.73 mmol), and 1 ml of glacial acetic acid was heated at 70 °C for 3 hr.[6] No change was observed by glc analysis.

The authors are indebted to Mr. S. Arimatsu for the preliminary studies.

8) K. M. Majerski and Z. Majerski, *Tetrahedron Lett.*, **1972**, 4915

9) A preliminary account on this subject has been reported: R. Yamaguchi, S. Arimatsu, and M. Kawanisi, *Chem. Lett.*, **1973**, 121.

10) In a preliminary report[9] we assigned an incorrect structure, 3-homoadamantyl acetate, to the second product. Subsequent detailed studies confirmed the structure of the product to be IIIa instead of 3-homoadamantyl acetate. It is exactly the same as the structure of IIIb.

11) Another reason why Path B would be favored is as follows: The classical cation (VI) would be likely deprotonated to give methyleneadamantane,[29] which would be stable under the present photochemical reaction conditions. However, this compound was not detected by either glc or NMR analyses.

12) Recently evidence has been presented for the ground state *trans*-isomers as chemically reactive intermediates in the photo-induced polar addition of protic solvents to 7- and 8-membered cycloalkenones; R. Noyori and M. Kato, This Bulletin, **47**, 1460 (1974).

13) Scheleyer *et al.* have suggested that the C_4–C_5 ethylene bridge in homoadamantane system is so flexible that the dihedral angle can change from 0 to *ca.* 30°.[14] Therefore, it is not improbable to assume for geometrical reasons that considerably twisted *transoid*-4-homoadamantene is a chemically reactive intermediate.

14) E. M. Engler, L. Chang, and P. v. R. Schleyer, *Tetrahedron Lett.*, **1972**, 2525; T. M. Corrie, E. M. Engler, R. C. Bingham, and P. v. R. Schleyer, *ibid.*, **1972**, 3039.

15) Control experiments showed that the products, II, III, and IV, are stable under the present photochemical reaction conditions.

16) As to the nature of the carbocation generated in a photosensitized polar addition reaction, Kropp and Krauss described as follows: Caution must be urged against carrying the analogy too close to ground state chemistry, since the carbonium ion will, at least initially, have much more vibrational energy and probably a different geometry than an analogous carbonium ion generated by the simple protonation of a ground state *cis*-olefin; P. J. Kropp and H. J. Krauss, *J. Amer. Chem. Soc.*, **89**, 5199 (1967).

17) L. Friedman, "Carbonium Ions," Vol. II, G. A. Olah and P. v. R. Schleyer, ed., Wiley-Interscience, New York (1970), p. 655.

18) a) R. C. Fort, Jr. and P. v. R. Schleyer, *Advan. Alicycl. Chem.*, **1**, 283 (1966). b) J. Janjatovic, D. Skare, and Z. Majerski, *J. Org. Chem.*, **39**, 651 (1974).

19) It has been reported that 3-homoadamantyl acetate was converted into 1-adamantylmethyl acetate by treatment with *p*-toluenesulfonic acid in refluxed acetic acid (J. E. Nordlander, S. P. Jindal, P. v. R. Schleyer, R. C. Fort, Jr., J. J. Harper, and R. D. Nicholas, *J. Amer. Chem. Soc.*, **88**, 4475 (1966)). We have examined the similar treatment of IVa; we thus obtained IIIa and an additional acetate, the structure of which has not yet been determined. However, this result does not contradict our present discussion.

20) An important factor in skeletal rearrangement, especially under kinetically controlled conditions, may be the degree of overlap of the vacant orbital of the carbocation center and the C–C bond, which migrates. At this point, for the anticipated most stable geometry of V, which has an untwisted ethylene bridge (C_4–C_5), it would be unfavorable for V to being converted into VII (or VI), because the sp^2-vacant orbital at C_4 is orthogonal to the C_5–C_6 bond, which migrates (Fig. 2a). The more twisted the ethylene bridge is (Fig. 2b), the more favorable would be the rearrangement, because the overlap of the sp^2-vacant orbital at C_4 and C_5–C_6 bond increases. Since the geometry of V generated in the photochemical reaction would probably be a twisted one (Fig. 2b), at least initially,[16] the conversion of V into VII (or VI) would occur, while the geometry of the V generated in the solvolysis as well as in the diazotization would be an untwisted one (Fig. 2a).

* Throughout this paper we have adopted trivial nomenclature for simplicity. The IUPAC names for I, II, and IV are tricyclo[4.3.1.$1^{3,8}$]undec-4-ene, tetracyclo[5.3.1.$0^{3,5}$-$0^{4,9}$]undecane, and tricyclo[4.3.1.$1^{3,8}$]undec-4-yl acetate (pivalate), respectively.

Formation of 9,9′:9′,9″-Terfluorenyl Isomers Using Metalated Fluorenes as Synthetic Intermediates

Masahiro MINABE and Kazuo SUZUKI

Department of Industrial Chemistry, Faculty of Technology, Utsunomiya University, Ishii-cho, Utsunomiya 321–31

(Received October 7, 1974)

Rotational isomers of 9,9′: 9′,9″-terfluorenyl were obtained by the addition of 9-lithiofluorene to 9,9′-bifluorenylidene (III). 2,7-Dibromo- (VI) and 2,7,2″,7″-tetrabromo-9,9′: 9′,9″-terfluorenyl (VIII) resulted from similar reactions of the corresponding bromo-derivatives. 9-Lithio-9,9′-bifluorenyl was treated with 9-bromo-9,9′-bifluorenyl to give 9,9′-bis(9,9′-bifluorenyl) (X), 9,9′: 9′,9″-terfluorenyl isomers (mp 293 °C (dec) (I) and mp 257 °C (dec) (II)), 9,9′-bifluorenyl (IX), III, and fluorenone. The isomerization of I by metallic potassium gave the other rotamer II, which decomposed into its components, IX, III, and fluorene (IV).

The formation of the stereoisomeric 9,9′: 9′,9″-terfluorenyl, mp 293 °C (dec) (I) and mp 257 °C (dec) (II), has been reported in the previous paper of this series.[1] The conformations of I and II were proposed to be *s-cis,s-cis* and *s-cis,s-trans*, respectively.[2] Both rotamers were produced simultaneously by the Michael reaction[3] of 9,9′-bifluorenylidene (III)[4] with fluorene (IV), by the reaction[5] of 9-bromofluorene with methanolic potassium hydroxide in acetone, and by the reaction[6] of 9-lithiofluorene with 9-bromo-9,9′-bifluorenyl.[7]

The present investigation was undertaken in order to discover additional synthetic routes which gave 9,9′: 9′,9″-terfluorenyls through 9-lithiofluorenyl derivatives or other alkali metal compounds as active intermediates.

Results and Discussion

A possible route for the formation of both I and II was achieved by addition of 9-lithiofluorene to III in dry benzene. Similarly, 9-lithiofluorene was treated with 2,7-dibromo-9,9′-bifluorenylidene (V)[8] to yield 2,7-dibromo-9,9′: 9′,9″-terfluorenyl (VI)[8] as the main product, accompanied by a trace amount of 2′,7′-dibromo-9,9′: 9′,9″-terfluorenyl (VII).[8] 2,7,2″7″-Tetrabromo-9,9′: 9′,9″-terfluorenyl (VIII)[8] was obtained by the reaction of 2,7-dibromo-9-lithiofluorene with V.

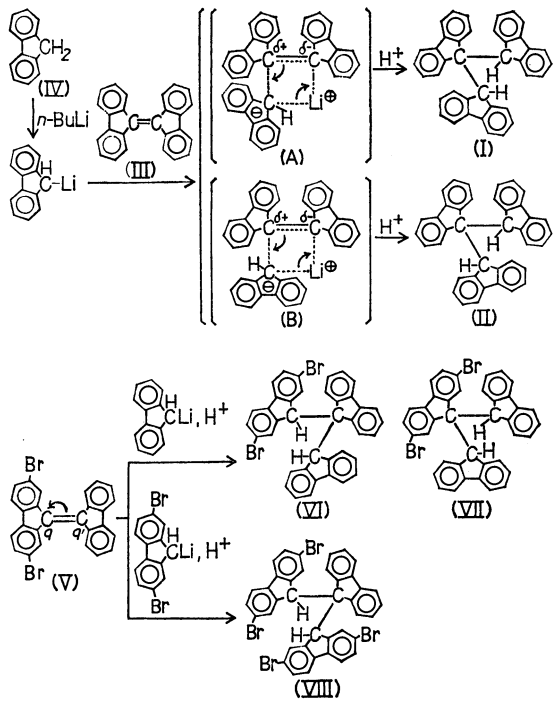

Fig. 1.

The formation of I and II by the reaction of 9-lithiofluorene with III could be expected to proceed through the four-center transition states (A) and (B), as shown in Fig. 1. The 9′-carbon is more electropositive than the 9-carbon in such a highly-polarized unsymmetrical ethylenic linkage as V owing to the electro-withdrawing effect of the two bromine atoms. This effect is brought out in the reaction of 9-lithiofluorene with V which gives a major product VI and a trace amount of VII.

The reaction of 9-lithio-9,9′-bifluorenyl with 9-bromo-9,9′-bifluorenyl yielded I, II, III, 9,9′-bifluorenyl (IX), 9,9′-bis(9,9′-bifluorenyl) (X),[9] and fluorenone. When 9-bromo-9,9′-bifluorenyl was treated with a half mole equivalent of *n*-butyl lithium and the reaction mixture was immediately refluxed in xylene, 9-*n*-butyl-9,9′: 9′,9″-terfluorenyl (XI) was also isolated.

The formation of I and II can be attributed to the reaction of 9-bromo-9,9′-bifluorenyl with 9-lithiofluorene which may be generated by the metal-halogen interconversion reaction between 9-bromo-9,9′-bifluorenyl and *n*-butyl lithium.

It has been reported by Nasielski *et al.*[9] that X was obtained by photo-reduction of III, however, no data on melting point, elementary analysis, molecular weight, *etc.*, were reported.

The structures of X and XI were confirmed from their mass spectral fragmentation patterns. The parent peak of X is small at *m/e* 658. The fragmentary ions *m/e* 493 (9,9′: 9′,9″-terfluorenyl cation, strong), 329 (9,9′-bifluorenyl cation, base peak), 328 (9,9′-bifluorenylidene ion, strong), and 165 (9-fluorenyl cation) originate from the simple cleavage of $C_{9-9'}$, $C_{9''-9'''}$, and/or $C_{9'-9''}$ bonds of the parent ion, X.

The mass spectrum of XI was as follows: the parent peak was small at *m/e* 550, and the fragment peaks were at *m/e* 493, 385 (9-*n*-butyl-9,9′-bifluorenyl cation, weak), 329, 328 (strong), 221 (9-*n*-butyl-9-fluorenyl cation, base peak), 191 (9-vinyl-9-fluorenyl cation), 179 (9-methyl-9-fluorenyl cation and/or 9,10-dihydrophenanthryl cation, strong), and 165 (very strong). The peaks at *m/e* 493, 329, 328, and 165 were identical with those of X.

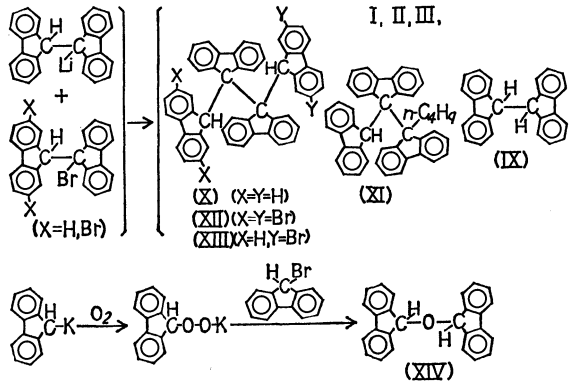

Fig. 2.

The IR spectrum of X closely resembled those of I and II.

An analogous reaction between 9-lithio-9,9′-bifluorenyl with 2,7,9′-tribromo-9,9′-bifluorenyl[10] yielded 9,9′-bis(2′,7′-dibromo-9,9′-bifluorenyl)(XII), 9-(2,7-dibromo-9-fluorenyl)-9,9′: 9′,9″-terfluorenyl (XIII), X, II, V, IX, III, 2,7-dibromofluorenone, and fluorenone. The IR spectra of XII and XIII were very similar to those of I, II, VIII, and X.

An attempt to synthesize X by the reaction of I, metallic potassium, and 9-bromofluorene was unsuccessful; however, isomeric II, IX, III, and di(9-fluorenyl) ether (XIV)[11] were isolated. Compound XIV was obtained by the reaction between 9-bromofluorene and metallic potassium, accompanied by II, IX, and III. The formation of II may result from the reaction of intermediate 9-potassio-9,9′-bifluorenyl with 9-bromofluorene.[6] The occurrence of XIV can be explained by the reaction of 9-bromofluorene with 9-fluorenylpotassium peroxide which could be formed by action of metallic potassium and 9-bromofluorene in the presence of contaminating oxygen in the nitrogen, as Fig. 2 shows.

I isomerized into II by reaction with metallic potassium; II was broken down into its components, IX, IV, and III by the same reaction.

These findings are analogous to the reaction[12] of I (or II) with lithium aluminum hydride, therefore, the isomerization presumably proceeds *via* intermediary 9-potassio-9,9′: 9′,9″-terfluorenyl.

Experimental

All the melting points are uncorrected.

The compounds were confirmed by mixed-melting-point determinations and by comparison of their IR spectra with those of authentic samples.

Mass, NMR, and IR spectra were recorded using Hitachi RMU-6E, JEOL JNM-C60-HL, and JASCO IR-G spectrometers.

All reactions were carried out under an atmosphere of dry nitrogen.

Reaction of 9-Lithiofluorene with 9,9-Bifluorenylidene (III): 9-Lithiofluorene was prepared in the usual way[13] by the reactions of *n*-butyl bromide (3.3 g in 20 ml of ether) with lithium chips (0.31 g) in ether (20 ml), and of the resulting mixture with IV (5.0 g) in benzene (45 ml). A solution of 6.56 g of III in 60 ml of benzene was added dropwise into the 9-lithiofluorene solution at 0 °C for 20 min, and the mixture was boiled.

After standing at room temperature, the reaction mixture was treated with 5% aqueous ammonium chloride, and the organic layer was dried over calcium chloride, and evaporated to dryness under reduced pressure.

The residue was purified by means of fractional recrystallization, alumina column chromatography, and vacuum sublimation: 1.25 g (13%) of I, mp 291—293 °C (dec) (benzene), 1.05 g (11%) of II, mp 255—257 °C (dec) (ethyl acetate), 0.20 g (2%) of fluorenone, mp 82—83 °C (ethanol), 2.13 g (32%) of III, mp 181—183 °C (cyclohexane), and 1.85 g (37%) of IV, mp 111—113 °C (ethanol), were isolated.

Reaction of 9-Lithiofluorene with 2,7-Dibromo-9,9′-bifluorenylidene (V): To the 9-lithiofluorene solution obtained from 2.3 g of IV in 25 ml of benzene, 6.7 g of V in benzene was added during a period of 35 min below 10 °C.

The reaction mixture was then worked-up as usual, the crude product afforded 6.55 g (73%) of VI, mp 285—286 °C (dec) (ethyl acetate), a trace amount of VII, mp 302—303 °C (dec) (benzene), and 0.12 g (2%) of V, mp 244—245 °C (ethyl acetate).

Reaction of 2,7-Dibromo-9-lithiofluorene[14] *with V*: 2,7-Dibromofluorene (4.5 g) was metalated to the corresponding 9-lithio-compound in the usual way, and then allowed to react with V (6.7 g) in benzene.

After the usual treatment, 2.34 g (21%) of VIII, mp 313—314 °C (dec) (benzene), a trace amount of 2,7-dibromofluorenone, mp 201—202 °C, 1.46 g (32%) of 2,7-dibromofluorene, mp 162—163 °C, and 3.29 g (49%) of V, mp 244—245 °C, were obtained.

Reaction of 9-Lithio-9,9′-bifluorenyl with 9-Bromo-9,9′-bifluorenyl. a): A solution of 4.1 g (10 mmol) of 9-bromo-9,9′-bifluorenyl in 70 ml of xylene was added dropwise to the *n*-butyl lithium solution obtained from 12.5 mmol of *n*-butyl bromide and 0.025 g. atom of lithium chips, while being stirred at 0—2 °C for 45 min, and the mixture was heated gradually to 135 °C. After cooling, 3.3 g (8 mmol) of 9-bromo-9,9′-bifluorenyl in 60 ml of xylene was added dropwise to the resulting solution at 5—10 °C for 30 min. The mixture was stirred for 24 hr at room temperature, and then was maintained at a boil for 30 min.

The resulting mixture was treated in the usual manner, and the residual part was chromatographed on alumina in benzene. Further elution and subsequent evaporation gave 0.016 g of X, mp 313—314 °C (dec) (pyridine). Found: C, 94.92; H, 5.06%. Calcd for $C_{52}H_{34}$: C, 94.80; H, 5.20%. Mass: *m/e* 658 (M^+), 493, 329, 328, and 165.

In addition, 0.13 g of I, mp 292—293 °C (dec) (ethyl acetate), 0.42 g of II, mp 256—257 °C (dec) (ethyl acetate), 0.10 g of IX, mp 244—245 °C (ethyl acetate), and 0.36 g of III, mp 182—183.5 °C (ethanol), were obtained from the benzene mother liquor.

By extraction with ethanol from the lower band on the column, 1.05 g of 9-hydroxy-9,9′-bifluorenyl, mp 193—195 °C (benzene), was isolated. Fluorenone (0.65 g), mp 82—83 °C (ethanol), was obtained from the upper yellow band.

b): To an *n*-butyl lithium solution (prepared from 0.08 g of lithium chips and 0.78 g (5.7 m mol) of *n*-butyl bromide in ether) was added slowly 4.1 g (10 m mol) of 9-bromo-9,9′-bifluorenyl in 45 ml of xylene at 3—7 °C, and then refluxed at 135 °C for 1 hr.

The solution was treated in the usual way, affording 0.43 g of X, mp 313—314 °C (dec) (pyridine), 0.08 g of XI, mp 280—281 °C (dec) (benzene), 0.01 g of I, mp 292—293 °C (dec) (benzene), 0.022 g of II, mp 256—257 °C (dec) (benzene), 0.86 g of III, mp 184—186 °C (cyclohexane), 0.01 g

of IX, mp 244—245 °C (ethyl acetate), and 0.45 g of 9-hydroxy-9,9′-bifluorenyl, mp 193—195 °C (benzene). Found for XI: C, 93.85; H, 6.04%. Calcd for $C_{43}H_{34}$: C, 93.82; H, 6.18%. Mass: *m/e* 550 (M^+), 493, 385, 329, 328, 221, 191, 179, and 165.

The mother liquor was concentrated to dryness under reduced pressure, and the residue was steam distilled to give 0.021 g of oily products. The oil was confirmed to consist of fluorenone and a small amount (*ca.* 1%) of IV by comparing of their retention times on a gas chromatogram with those of authentic samples.

Reaction of 9-Lithio-9,9′-bifluorenyl with 2,7,9′-Tribromo-9,9′-bifluorenyl: A xylene (200 ml) solution containing 4.54 g of 2,7,9′-tribromo-9,9′-bifluorenyl was added to 9-lithio-9,9′-bifluorenyl (prepared from 4.09 g of 9-bromo-9,9′-bifluorenyl) solution while being stirred for 45 min at room temperature. The mixture was then continuously stirred for a period of 23 hr, and followed by refluxing for another 1 hr.

The reaction mixture was worked-up as usual and the following compounds were obtained: 0.70 g of XII, mp 295—296 °C (dec) (pyridine), 0.08 g of XIII, mp 292—294 °C (dec) (pyridine), 0.04 g of X, mp 313—314 °C (dec) (pyridine), 0.24 g of II, mp 254—256 °C (dec) (ethyl acetate), 1.36 g of V, mp 241—242 °C (ethyl acetate), 0.16 g of IX, mp 242—244 °C (ethyl acetate), 0.31 g of III, mp 183—185 °C (ethyl acetate), 0.03 g of 2,7-dibromofluorenone, mp 198—200 °C (ethanol), 0.23 g of fluorenone, mp 80—83 °C (ethanol), and 0.03 g of 9-hydroxy-9,9′-bifluorenyl, mp 193—194 °C (benzene). Found for XII: C, 64.29; H, 3.17%. Calcd for $C_{52}H_{30}Br_4$: C, 64.10; H, 3.10%. Found for XIII: C, 76.11; H, 3.89%. Calcd for $C_{52}H_{32}Br_2$: C, 76.48; H, 3.95%.

Reaction of 9,9′: 9′,9″-Terfluorenyls with Potassium Metal and 9-Bromofluorene. a): A solution of 1.0 g of I and 0.1 g of potassium chips in 60 ml of tetrahydrofuran (THF) was refluxed for 3 hr. 9-Bromofluorene (1.25 g) in THF (20 ml) was added dropwise to the resulting mixture while it was stirred for 50 min at 5—10 °C. Then the reaction mixture was stirred for 13 hr at room temperature and refluxed briefly.

The mixture was decomposed with 10 ml of ethanol, then with dilute hydrochloric acid, and extracted with benzene. The organic layer was concentrated to give 0.66 g of I, mp 291—293 °C (dec) (ethyl acetate), 0.17 g of II, mp 255—257 °C (dec) (ethyl acetate), 0.04 g of IX, mp 243—245 °C (ethyl acetate), and 0.03 g of XIV, mp 227—228 °C (benzene).

Found for XIV: C, 90.24; H, 5.41%. Calcd for $C_{26}H_{18}O$: C, 90.15; H, 5.24%. Mass: *m/e* 346 (M^+), 181, 165, and 152. NMR (in 99% C_6D_6): δ 5.74 (2H, s) and 6.97—7.49 (16H, m) ppm.

The benzene mother liquor was chromatographed on an alumina column: 0.06 g of III, mp 183—184 °C (ethanol), and 0.03 g of fluorenone, mp 82—84 °C (ethanol), were separated.

b): II (1.0 g) was treated as in (a) to give 0.74 g of II, mp 255—257 °C (dec) (ethyl acetate), 0.03 g of IX, mp 243—245 °C (ethyl acetate), 0.06 g of XIV, mp 227—228 °C (benzene), 0.014 g of III, mp 181—183 °C (ethanol) and 0.15 g of fluorenone, mp 82—85 °C (ethanol).

Reaction of 9-Bromofluorene with Metallic Potassium: A mixture of 4.9 g of 9-bromofluorene and 0.78 g of potassium chips in 50 ml of THF was stirred at room temperature for 20 hr.

The reaction mixture was treated as usual and 0.57 g of II, mp 255—257 °C (dec) (ethyl acetate), 0.22 g of IX, mp 242—244 °C (ethyl acetate), 0.20 g of XIV, mp 226—228 °C (benzene), and 0.47 g of III, mp 184—186 °C (ethyl acetate), were isolated.

Reaction of I with Potassium: A solution of 1.0 g of I and 0.2 g of potassium chips in 70 ml of THF was refluxed for 3.5 hr.

After cooling, the resulting mixture was then worked-up as usual, and afforded 0.32 g of II, mp 256—257 °C (dec) (ethyl acetate). The mother liquor was evaporated to dryness under reduced pressure and sublimed *in vacuo* at 120 °C to give 0.10 g of IV, mp 111—113 °C (ethanol).

The residue from the sublimation gave 0.32 g of IX, mp 242—243 °C (ethyl acetate), and 0.03 g of III, mp 183—185 °C (ethyl acetate).

Reaction of II with Potassium: A solution of 1.0 g of II and 0.2 g of potassium chips in 70 ml of THF was refluxed for 20 hr and the mixture was treated as usual: 0.24 g of II, mp 256—257 °C (dec) (ethyl acetate), 0.35 g of IX, mp 242—243 °C (ethyl acetate), 0.02 g of III, mp 183—185 °C (ethanol), and 0.24 g of IV, mp 111—112.5 °C (ethanol), were obtained.

This work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, which is acknowledged. The authors are grateful to Dr. Elizabeth K. Weisburger of the National Institutes of Health, U.S.A., for reading their manuscript.

14) As we have already reported[8], the formation of 2,7-dibromo-9-lithiofluorene was confirmed as 2,7-dibromofluorene-9-carboxylic acid. However a misprint shows the melting point of the carboxylic acid as 208—209 °C instead of the correct value, 258—259 °C (dec).

Multifunctional Hydrolytic Catalyses. III. Catalytic Hydrolysis of *p*-Nitrophenyl Acetate by Imidazole-4-carbohydroxamic Acids[1)]

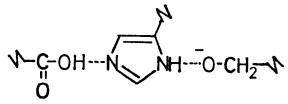
Toyoki KUNITAKE and Seiji HORIE

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka 812

(Received November 5, 1974)

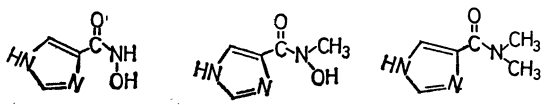
Imidazole-4-carbohydroxamic acids (I) and its *N*-methylhydroxamic acid derivative (II) were synthesized from imidazolecarboxylic acid and hydroxylamines, and the catalytic hydrolysis of *p*-nitrophenyl acetate was studied. The reaction was analyzed by the pseudo-first-order kinetics and the burst kinetics. The hydrolysis proceeds *via* the formation and the subsequent decomposition of the acetyl hydroxamate intermediate. The acylation rate with these catalysts were comparable to those observed with other simple hydroxamic acids. On the other hand, the deacylation of the acetyl intermediate of II was greater than expected and increased with pH. This suggests that the intramolecular imidazole group (neutral and/or anionic species) assists deacylation, thus increasing the overall efficiency of catalysis.

Multifunctional catalysis is one of the major characteristics of the enzyme reaction. A typical example is the charge relay system which is present at the active site of several serine proteases.[2)] This system is composed of a series of hydrogen bonding connecting the aspartyl carboxylate, histidyl imidazole and seryl hydroxyl groups, and acylation by specific ester and amide substrates occurs at the seryl hydroxyl group. Therefore, a combination of the imidazole function and a good oxygen nucleophile like the hydroxamate anion would be considered as a model charge relay system.



charge relay system

The present paper is an account of our initial efforts toward preparations of such catalysts in small-molecule systems. The catalyst compounds employed are imidazole-4-carbohydroxamic acid (I) and its *N*-methyl derivative (II). Similar attempts by using polymer catalysts have been described elsewhere.[3,4)]



I II III

Experimental

Melting points are uncorrected. UV-visible spectroscopic measurements were made with a Hitachi 124 spectrophotometer. NMR spectra were obtained with a Varian A 60 instrument.

Materials. *p*-Nitrophenyl acetate was prepared by reaction of *p*-nitrophenol with acetic anhydride and recrystallized from cyclohexane, mp 78 °C (lit[5)], 81—82 °C).

Imidazole-4-carboxylic acid was prepared essentially by the procedure of Pyman[6)] by oxidation of 4-hydroxymethylimidazole[7)] with concentrated nitric acid ($d=1.38$) at 80 °C for 3 hr. After the reaction was over, solvent was removed *in vacuo*. Water was removed completely as an azeotrope with benzene. The remaining colorless granules were dissolved in a smallest amount of water, and the solution was neutralized to pH 6 by slow addition of a cold saturated aqueous solution of Na_2CO_3. Colorless precipitates were recrystallized repeatedly from hot water. Mp 285—287 °C (dec) (lit[6)] mp 281 °C (dec)).

According to the procedure of Wegner and Weidenhagen,[8)] imidazole-4-carboxylic acid was converted by PCl_5 to the corresponding acid chloride. The pale yellow, hygroscopic solid was used as such for the subsequent experiment.

N,N-*Dimethylimidazole-4-carboxamide (III).* The acid chloride was prepared from 1.0 g (0.0089 mol) of imidazolecarboxylic acid and 1.78 g (0.0089 mol) of PCl_5. Dimethylamine hydrochloride (1.4 g, 0.0178 mol) was mixed with 3.6 g (0.036 mol) of triethylamine in 30 m*l* of DMF. Triethylamine hydrochloride was filtered and the solution was added to the solid acid chloride with cooling. After standing overnight, precipitates were filtered and the solvent removed *in vacuo*. The dark brown, viscous residue was carefully dissolved in concentrated hydrochloric acid and, then solvent was removed *in vacuo* from the resulting solution. The white solid formed was recrystallized from a mixture of ethanol and ethyl acetate and from ethanol to give pale yellow needles: yield 30—40%, mp 196—198 °C. IR and NMR spectra were consistent with the structure. Found: C, 39.05; H, 5.98; N, 22.81%. Calcd for $C_6H_9N_3O\cdot 1/2H_2O$: C, 39.12; H, 5.96; N, 22.76%.

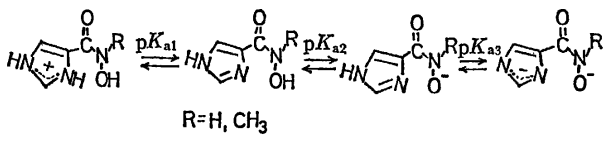
Imidazole-4-carbohydroxamic Acid (I). Hydroxylamine hydrochloride (10.0 g, 0.144 mol) was reacted with 29 g (0.287 mol) of triethylamine in DMF, and triethylamine hydrochloride was filtered. The solution was added to the solid acid chloride which had been prepared from 2.8 g (0.025 mol) of imidazolecarboxylic acid. After standing overnight, triethylamine hydrochloride was filtered and the solvent removed *in vacuo*. The pale red residue was dissolved in hydrochloric acid and the solvent evaporated to dryness. Recrystallization from 1 : 2 H_2O-CH_3OH gave 1.5 g (40% yield) of colorless needles. Mp 202—206 °C. IR: 3420 cm^{-1} (ν_{NH}, hydroxamic acid), 1650 cm^{-1} ($\nu_{C=O}$, hydroxamic acid). Found: C, 26.57; H, 4.35; N, 23.18%. Calcd for $C_4H_5N_3O_2\cdot HCl\cdot H_2O$; C, 26.44; H, 4.41; N, 23.14%.

N-*Methylimidazole-4-carbohydroxamic Acid (II).* *N*-Methylhydroxylamine hydrochloride (4.0 g, 0.042 mol) which was obtained by zinc reduction of nitromethane was mixed with 8.0 g (0.080 mol) of triethylamine in dry DMF, and triethylamine hydrochloride formed was filtered. The DMF solution was added to the acid chloride which had been prepared from 2.24 g (0.020 mol) of imidazolecarboxylic acid. The work-up was the same as that described above. Pale yellow crystals were obtained as the hydrochloride in 40% yield and recrystallized from methanol or from methanol-acetonitrile: mp 196—197 °C (dec). IR: hydroxamic acid, 3220 cm^{-1} (ν_{OH}), 1640 cm^{-1} ($\nu_{C=O}$); imidazole, 3080, 2800, 860 cm^{-1}. Found: C, 33.85; H, 4.50; N, 23.58%. Calcd for $C_5H_7N_3O_2\cdot HCl$: C, 33.80; H, 4.51; N, 23.66%.

Rate Measurements. The rate of reaction of hydroxamic acids with PNPA was determined by following the formation of the *p*-nitrophenolate anion at 401 nm. A 1-cm cell was employed for the hydrolysis of PNPA at low concentrations. On the other hand, when high PNPA concentrations were used in order to observe the burst kinetics, a 0.9-cm spacer was inserted into the 1-cm cell.

Results

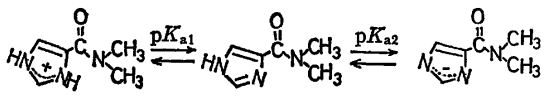
pK_a *Determination.* Imidazolecarbohydroxamic acids I and II possess the following three dissociation processes:



(1)

The pK_a values for the first two processes can be readily determined by the potentiometric titration. The titration was carried out by using a Toa pH stat system, using a jacketed titration vessel. Water was circulated from a constant temperature bath and 0.1 N alkali was added in 0.05-m*l* portions from an autoburet. The pK_{a3} value was difficult to determine by this method.

Two dissociation processes are present for imidazole derivative III, and its pK_{a1} was determined by the potentiometric titration.



(2)

The pK_a values for the dissociation of the imidazole proton were difficult to determine by the potentiometric titration, because they are above 10.

The UV titration can be employed for the pK_a determination by using the characteristic absorption of each species.[9]

$$pK_a = pH + \log\frac{OD_I - OD}{OD - OD_M} \quad (3)$$

where OD_I: absorbance of the ionic species at a given wavelength, OD_M: absorbance of the neutral species and OD: absorbance of species mixtures. The above equation is transformed to

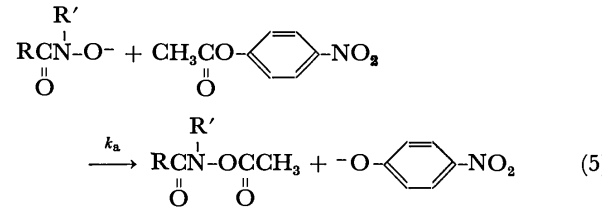
$$OD = OD_I - \frac{1}{K_a}[H^+](OD - OD_M) \quad (4)$$

The hydroxamate anion possesses a characteristic UV absorption maximum at *ca.* 270 nm. In the case of hydroxamic acid I, UV spectra showed a complex variation with pH and an attempt to determine pK_a was unsuccessful. An anionic species in which proton on the hydroxamic acid nitrogen is dissociated may exist at higher pH's, in addition to those shown in Eq. (1).

The dissociation behavior of hydroxamic acid II is simpler than that of I. Assuming that only the monoanionic species exist at pH 12, OD_I (300 nm) = 0.740 and OD_M (300 nm) = 0.009 were obtained at pH 12 and pH 2, respectively (30 °C, 28.9 v/v% EtOH–H_2O, [I] = 1.13×10^{-4} M). The OD values were determined in the pH range of 8.3 to 9.3, and pK_{a2} was obtained from those data, using Eq. (3). The pK_{a3} value was not obtainable by this method.

The determination of the pK_{a2} value of III from Eq. (3) was not possible, because the accurate determination of OD_I was difficult. Eq. (4) is useful in this case. Thus, OD (280 nm) was measured at pH 10 to 13, and plotted against $[H^+](OD - OD_M)$ (OD_M = 0.005, [III] = 2.06×10^{-4} M). A good linear relationship was obtained (correlation coefficient = 0.9998), and OD_I and pK_a were determined to be 0.300 and 12.09, respectively. These results are summarized in Table 1.

Reaction of I with PNPA. The hydroxamate anion reacts with PNPA quite readily to yield acetyl hydroxamate and *p*-nitrophenol.[10-13]



(5)

The reaction can be followed very readily by the release of the *p*-nitrophenolate anion. Since PNPA hydrolyzes spontaneously, the overall rate v is composed of the catalytic and spontaneous terms.

$$v_{total} = v_{cat} + v_{spont} \quad (6)$$

When hydroxamic acid I (1.98×10^{-4} M) was reacted with an excess of PNPA (3.86×10^{-3} M) at 30 °C, pH 8.92, *p*-nitrophenol (2.28×10^{-4} M) was released within one minute and further release was not observed, apart from the spontaneous hydrolysis. The amount of *p*-nitrophenol released approximately corresponded to that of the hydroxamic acid. This means that the acetyl transfer occurred quantitatively according to Eq. (1), and that the acetyl hydroxamate formed is too stable to regenerate hydroxamic acid.

The acetylation reaction was further investigated under the pseudo-first-order condition ([HA] ≫ [PNPA]), and $k_{a,obs}$ was determined by

$$k_{total} = k_{a,obs}[HA]_0 + k_{spont} \quad (7)$$

$$\log\frac{OD_\infty}{OD_\infty - OD_t} = \frac{k_{total}\cdot t}{2.303} \quad (8)$$

Table 1. pK_a values[a]

Compound	pK_{a1}	pK_{a2}	pK_{a3}
I	3.52	9.43	>12[c]
II	4.50	8.90, 8.81[b]	>12[c]
III	4.30	12.1[b]	—
Benzohydroxamic acid	9.36	—	—

a) Determined by the potentiometric titration. 30 °C, aqueous ethanol (ethanol content: 20—30 v/v%). b) Determined by UV titration. The pK_{a2} value of II from the UV titration is less reliable than that obtained by the potentiometric titration and, therefore, not used for the calculation of rate data. c) Estimated from potentiometric titration.

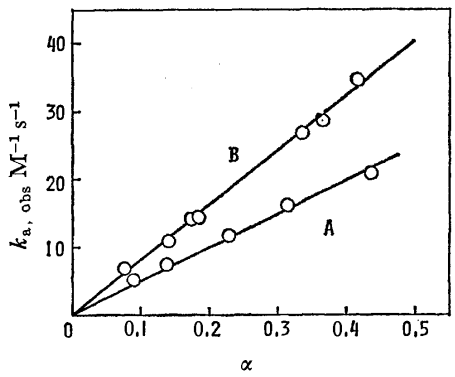


Fig. 1. Dependence of the rate constant of reaction between PNPA and hydroxamic acid upon the degree of dissociation of hydroxamic acids (α).

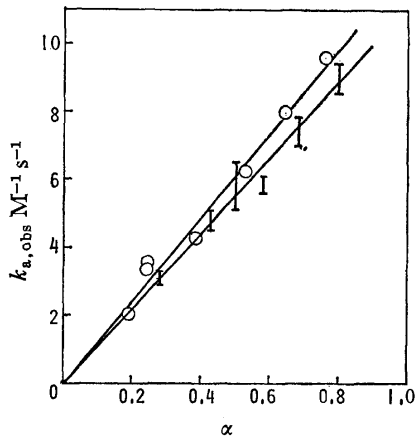

Fig. 2. Dependence of the rate constant of acylation of II by PNPA upon the degree of dissociation of the hydroxamic acid group (α).
Reaction condition: 30 °C, 28.9 vol%EtOH-H_2O, 0.1 M KCl, 0.15 M Barbital buffer.
The circle is the rate constant determined under the pseudo first-order condition. The vertical line indicates the range of $k_{a,obs}$ estimated from the burst kinetics (see Table 2).

where OD_∞ is the absorbance of *p*-nitrophenol at the infinite reaction time and OD_t is the absorbance at time *t*.

The reaction was carried out in the pH range of 8.3 to 9.3, and $k_{a,obs}$ was determined by using Eqs. (7) and (8). Figure 1 shows the relationship of $k_{a,obs}$ thus obtained and α (degree of dissociation of hydroxamic acid). A linear relationship was obtained (correlation coefficient=0.9987). Similar results were obtained for the reaction of benzohydroxamic acid and PNPA.

The k_a values (true second-order rate constant) determined from the slope of Fig. 1 were 80.4 and 50.0 M^{-1} s^{-1} for I and benzohydroxamic acid, respectively.

Reaction of II with PNPA. In the first place, the reaction of PNPA was carried out with large excesses of hydroxamic acid II: *i.e.*, under the pseudo-first-order condition. And $k_{a,obs}$ was determined by the use of Eqs. (7) and (8). The $k_{a,obs}$ value showed a linear dependence on α, as shown in Fig. 2. The true second-order rate constant k_a was determined to be 12.1 M^{-1} s^{-1} from the slope by the least squares method (correlation coefficient=0.9996).

Subsequently, when the reaction was carried out in the presence of large excesses of PNPA relative to II, typical burst reactions were observed: the initial rapid release of *p*-nitrophenol followed by the slower, steady release. This result suggests that the acetyl hydroxamate formed is hydrolyzed to a measurable degree and that the hydroxamate anion is regenerated.

The burst kinetics were analyzed according to the procedure of Bender *et al.*[14] The nucleophilic catalysis of the ester hydrolysis is expressed by

$$\begin{array}{c} C + S \xrightarrow{k_a} CS' \xrightarrow{k_d} C + P_2 \\ + \\ P_1 \end{array} \qquad (9)$$

where C, S and CS′ denote catalyst, ester substrate and acyl intermediate, respectively.

The formation of *p*-nitrophenol (P_1) is given by

$$[P_1] = At + B(1-e^{-bt}) \qquad (10)$$

where $A=a-(a/b)k_a[S]_0$, $B=(a/b^2)\cdot k_a\cdot[S]_0$, $a=k_a[C]_0-[S]_0$, and $b=k_a[S]_0+k_d$.

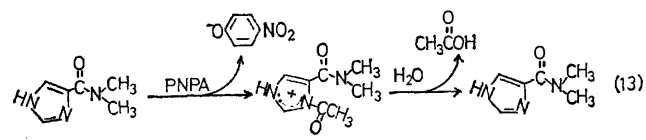
The rate constants may be determined by more than one method. However, the slope of the linear portion was rather small in the present system, and the following equations were employed for calculating rate constants in order to minimize the arithmetic erorr.

$$k_a = \frac{b}{[S]_0}\sqrt{\frac{B}{[C]_0}} \qquad (11)$$

$$k_d = b - k_a[S]_0 \qquad (12)$$

Since determination of the k_a and k_d values can sometimes involve large errors, the reaction was carried out many times at a given pH, and the undoubtedly erroneous data were discarded. The approximate agreement of the k_a values thus determined with those determined under the pseudo-first-order condition was a measure of the reliability of data. The resulting k_a and k_d values are summarized in Table 2. The k_a value for the hydroxamate anion was determined from the slope of $k_{a,obs}$ *vs.* α (Fig. 2) by the least-squares method to be 11.1 M^{-1} s^{-1}.

Reaction of III with PNPA. The hydrolysis of PNPA is catalyzed by imidazole compound III.



Supposedly, the formation of the acetylimidazole intermediate is rate-limiting, and the decomposition of acetylimidazoles is fast. The reaction was conducted under the pseudo-first-order condition ([III]≫

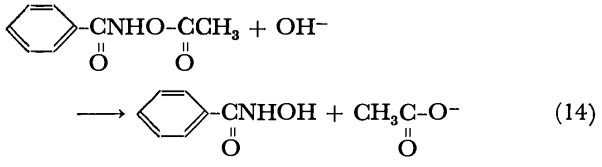
9.68	82.0	55.7	5.89

a) 30 °C, 0.1 M KCl, 0.15 M Barbital, 28.9 v/v% EtOH-H_2O, $[III]=4.46\times10^{-3}$ M, $[PNPA]=1.20\times10^{-4}$ M. b) Phosphate buffer, 0.15 M. c) Obtained at pH 9.04.

[PNPA]). The release of *p*-nitrophenol was quite slow, and, therefore, the rate constants (k_{total} and k_{spont}) were determined from the initial portion of the first-order plot. The results are summarized in Table 3. The $k_{a,obs}$ value increases rapidly above pH 9.

Hydrolysis of O-Acetyl Benzohydroxamate. O-acetyl benzohydroxamate was dissolved in aqueous alkali (pH 12) and the solution kept at 30 °C. Figure 3 shows the change of the UV spectra with time. An isosbetic point is found at 265 nm. After 24 hr, the spectrum became identical with that of the benzohydroxamate anion. The final concentration of the anion was calculated to be 3.38×10^{-5} M by using $\varepsilon=5150$ at $\lambda_{max}=268$ nm. The initial concentration of *O*-acetyl benzohydroxamate was 3.16×10^{-5} M.

These UV results imply that the following hydrolysis occurred.



(14)

The half-life of the hydrolysis was estimated to be approximately 4 hr from the UV spectral change. The corresponding rate constant was *ca.* 10^{-5} s^{-1} at pH 12. The k_a value of acetyl isobutyro-*N*-methylhydroxamate is estimated to be 0.24 s^{-1} at pH 12.[13] The difference amounts to more than 10^4 fold.

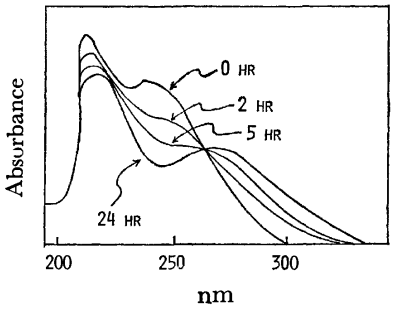


Fig. 3. Spectral change of aqueous acetyl benzohydroxamate.
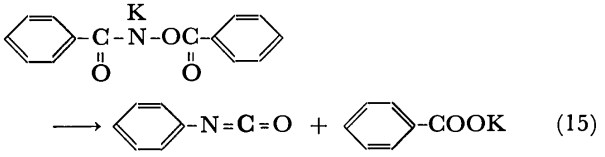
pH 12, 30 °C.
Acetyl benzohydroxamate; 3.16×10^{-5} M.

The smooth hydrolysis observed for *O*-acetyl benzohydroxamate is not necessarily consistent with the literature. Dougherty and Jones[15] reported the occurrence of the Lossen rearrangement along with hydrolysis, and Hauser *et al.*[16,17] made a kinetic study for potassium *N,O*-dibenzoylhydroxylamine derivatives in 0.1 N aqueous ammonia.



(15)

In contrast, the exclusive hydrolysis was observed in the present study. It is possible that the *O*-acetyl derivative is less prone to rearrange than the *O*-benzoyl counterpart.

Discussion

The object of the present study is two-fold. The hydroxamate anion is a very good nucleophile toward esters. However, the hydrolysis of acyl hydroxamate intermediates is very slow under ordinary reaction conditions, and the use of hydroxamic acids as catalyst for ester hydrolysis is limited. It was hoped that introduction of the neighboring imidazole group would facilitate the deacylation process. Secondly, the combination of a good oxygen nucleophile and the

Table 4. Rate constants of acetylation[a]

Hydroxamic acid	pK_a of hydroxamic acid group	k_a $M^{-1}s^{-1}$

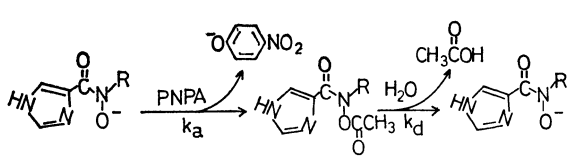
The vertical line indicate the range of $k_{d,obs}$ estimated from the burst kinetics (see Table 2).

imidazole function resembles the charge relay system found at the active site of serine esterases, and an examination of this combination as a model enzyme system is important.

The powerful nucleophilicity of the hydroxamic acids employed are readily seen from the rate data of Table 4. The k_a value of hydroxamic acid I is greater than that of benzohydroxamic acid by 60%. This may be a reflection of the pK_a difference between the two hydroxamic acids (ΔpK_a=0.07), in consistence with a good Brønsted relationship (β=0.72) found by Dessolin *et al.*[11] for ring-substituted benzohydroxamic acids.

The smaller k_a value for II relative to that of I is not unexpected. The nucleophilic reactivity of *N*-alkylhydroxamic acids is several times lower than that of the corresponding *N*-unsubstituted hydroxamic acids, and the reason for this difference has been discussed previously.[12,18] The observed difference in nucleophilicity between I and II is a reasonable one, when compared with other examples.

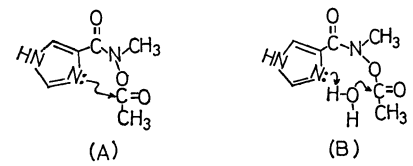
The deacylation reaction of the acetyl derivative of I was very slow. In fact, the occurrence of deacylation could not be detected in the burst kinetics at pH 8 to 9. On the other hand, the deacylation step was clearly observed in the burst kinetics of the *N*-methylhydroxamic acid II.



(16)

Figure 4 shows the pH dependence of the apparent rate constant of deacylation. The observed rate of deacylation is estimated to be much greater than those of simple hydroxamic acids. For example, $k_{d,obs}$ was 2.8×10^{-5} s^{-1} at pH 9 for acetyl *N*-phenylisobutyrohydroxamic acid.[13] The corresponding rate constant for acetylated II is 1×10^{-3} s^{-1}. This difference of almost 40 fold may suggest that deacylation is assisted by the intramolecular imidazole group, as we had conceived.

The intramolecular imidazole group can assist the hydrolysis of the acetyl intermediate by nucleophillic catalysis (A) and/or by general-base catalysis (B).



(A) (B)

In general, the general-base mechanism will be of greater significance compared with the nucleophilic mechanism in the hydrolysis of esters whose leaving groups are stronger bases than the imidazole catalyst.[19] The pK_a values of II are 8.9 for the hydroxamic acid group and 4.5 for the imidazole group. Therefore, the pK_a difference is 4.4, and the general-base mechanism B may be the preferred course of deacylation in the pH region where the neutral imidazole species plays a greater role. However, the anionic imidazole species (p$K_a\cong$12.5) is more important above pH 8 (see below) and the intramolecular attack of this species appears to be difinitely nucleophilic.

Bruice and Schmir found in the hydrolysis of PNPA with a large number of imidazole derivatives that imidazoles with values of pK_{a1} of 4.0 or lower owed their catalytic activity partially or primarily to the presence of their anionic species.[20] The increase of $k_{d,obs}$ at higher pH's (Figure 4) suggests the increasing involvement of the anionic imidazole group in the deacylation process. Unfortunately, the pK_{a3} value of II was not possible to determine by titration, and the efficiencies of intramolecular catalysis of the neutral and anionic imidazole species cannot be compared directly. However, pK_{a3} for II in 28.9% EtOH-H_2O may be estimated to be *ca.* 12.5 on the basis of the pK_a data shown in Table 1, by considering the difference of pK_a of the first and second deprotonations of III and the solvent change.

The following Brønsted rules have been reported for the nucleophilic attack of the neutral and anionic imidazole species.[20]

$$\log k_N = 0.8\ pK_{a1} - 4.30 \quad (17)$$

$$\log k_A = 0.15\ pK_{a2} + 1.35 \quad (18)$$

where k_N and k_A are rate constants for neutral and anionic imidazoles, respectively.

By substituting pK_a values (pK_{a1}=4.50, pK_{a2}=12.5), the relative rate constant (k_A/k_N) becomes *ca.* 10^4. The fraction of the anionic imidazole is about 10^{-3} at pH 9.5, the rest being the neutral species. Therefore, the anionic imidazole species is ten times more effective than the neutral species in the deacylation at pH 9.5. On the other hand, the anionic imidazole fraction is 4×10^{-5} at pH 8, and the contribution of the anionic imidazole species toward deacylation can be considered negligible below pH 8.

Quite the same conclusion is obtained for the reaction of PNPA with imidazole-4-carboxamide (III).

This reaction is a model reaction of deacylation of the acyl intermediate (compare Eqs. (13) and (16)).

As shown in Fig. 4, the $k_{a,obs}$ value does not change from pH 7 to 8.5 and then increases with pH rather rapidly. This increase is again considered to be a reflection of the involvement of the anionic imidazole species. The parallel tendency observed in Fig. 4 is not unexpected, since the pK_a values for the imidazole proton are very close in these imidazole compounds.

In conclusion, it was shown that a bifunctional catalyst containing the hydroxamate and imidazole functions, II, was effective in the hydrolysis of PNPA. The neighboring imidazole group appears to assist the decomposition of the acetyl hydroxamate intermediate. Unfortunately, the acceleration of deacylation is not remarkable. This may be attributed to the lower nucleophilicity of the imidazole group and/or to the possibly unfavorable arrangement of the two functional groups. Hopefully, superior hydrolytic catalyst systems will evolve from the study of compounds possessing various arrangements of the hydroxamate and imidazole functions.

The authors wish to express their appreciation to Mr. Y. Okahata and Miss R. Ando for their cooperation during the course of this study.

Infrared Spectra and Structure of Substituted Unsaturated Carbonyl Compounds. XIX. Four Component Conformational Equilibria in β-Ketoaldehyde *Trans* Enol Ethers

Janusz DABROWSKI and Michal TENCER
Institute of Organic Chemistry, Polish Academy of Sciences, 00-961 Warsaw, Poland

(Received January 7, 1974)

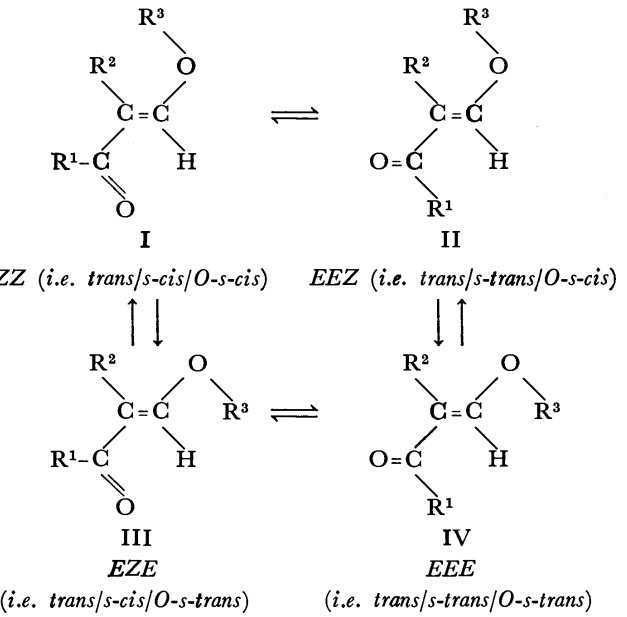
Acylic aliphatic *trans* β-alkoxy-α,β-unsaturated ketones, $R^1COCR^2{=}CHOR^3$, have been shown to exhibit restricted rotation around both the C_{sp^2}–C_{sp^2} and C_{sp^2}–O single bonds. The conformational equilibria between the *EZZ*, *EEZ*, *EZE* and *EEE* rotamers, estimated from comparison of the IR band intensities, are dependent on the steric requirements of the alkyl substituents. The sequence of the $\nu_{C=O}$ and $\nu_{C=C}$ vibrational frequences is $\nu_{C=O}$(*s-cis/O-s-trans*)>$\nu_{C=O}$(*s-cis/O-s-cis*)>$\nu_{C=O}$(*s-trans/O-s-trans*)>$\nu_{C=O}$(*s-trans/O-s-cis*)>$\nu_{C=C}$(*s-trans/O-s-trans*)>$\nu_{C=C}$(*s-trans/O-s-cis*)>$\nu_{C=C}$(*s-cis/O-s-trans*)>$\nu_{C=C}$(*s-cis/O-s-cis*). The wave number differences $\Delta\nu_{C=C}^{C=O}=\nu_{C=O}-\nu_{C=C}$ enable to classify the particular compounds according to their conformation in that $\Delta\nu_{C=C}^{C=O}$(*s-cis/O-s-trans*)=75—85 cm^{-1}, $\Delta\nu_{C=C}^{C=O}$(*s-cis/O-s-cis*)=80—100 cm^{-1}, $\Delta\nu_{C=C}^{C=O}$(*s-trans/O-s-trans*)=20—30 cm^{-1} and $\Delta\nu_{C=C}^{C=O}$(*s-trans/O-s-cis*)=35—50 cm^{-1}.

In studies on the rotational isomerism in α,β-unsaturated carbonyl compounds comparatively little attention has been paid to their β-alkoxy derivatives. Eistert *et al.*[1] were able to isolate the *cis* and *trans* methyl enol ethers of acetyloacetone. Their structure was subsequently confirmed by Awang[2] in his nuclear Overhauser effect and solvent shift ("ASIS") studies. In the same paper[2] a choice was made between the possible conformers resulting from restricted rotation around the C_{sp^2}–C_{sp^2} single bond, *i.e. s-cis* and *s-trans* rotational isomers. In many cases because of its unfavourable time scale NMR spectroscopy is unsuitable for detecting the individual rotamers and Awang's results must be considered only as an approximation. Therefore, it was of interest to us to study by means of IR spectroscopy a series of β-ketoaldehyde enol ethers capable of existing in these rotational forms. This technique has proved helpful in numerous investigations on rapid rotational equilibria.[3-9] In the dissertation by Giza[10] several spectra of β-alkoxy-α,β-unsaturated ketones were published but the resolution was obviously too low to reveal the band splittings observed in our work.

A further reason for the present study was the possibility of the simultaneous occurence of another restricted rotation, *viz.* that around the C_{sp^2}–O bond; the latter type of isomerism has been observed[11-13] in simple vinyl ethers.

Results and Discussion

As follows from the Introduction, in general, eight stereoisomeric forms are to be expected for β-alkoxy-α,β-unsaturated ketones having formula $R^1COCR^2{=}CHOR^3$. In our study their number is reduced to four however, as in all cases, due to thermodynamic considerations, only the *trans* (*E*) geometrical isomers were obtained. Four isomers are possible because of restricted rotation around the C_{sp^2}–C_{sp^2} and C_{sp^2}–O single bonds:



Since two IR bands, *viz.*, $\nu_{C=O}$ and $\nu_{C=C}$* are to be expected in the double bond stretching region for each of the isomers, their total number should amount to eight if all the isomers I—IV were present at equilibrium. Such is the case in the spectra of the methyl ketones (R^1=Me) **1**, **5**, and **6**. However, in all other cases investigated the number of bands was less, which can be explained either by the absence of some of these isomers or by coincidence of some of their bands.

The experimental data for the solutions in tetrachloroethylene are presented in Table 1.

In order to illustrate the relationship between band intensities and the bulkiness of the substituents R^1, R^2 and R^3 the IR spectra of the appropriate compounds are compared in Figures 1, 2, 4, and 5. The estimation of the populations of the rotamers are based on the reasonable assumption of approximately constant absorbances of the given absorptions for all the compounds investigated.

Let us consider first, for simplicity, the ketones for which the $\nu_{C=O}$ band is split into two components only, *i.e.* those other than **1**, **5**, and **6**. As can be seen from Fig. 1 presenting compounds with constant R^3=Me one band in the $\nu_{C=O}$ region (band B) and two bands

* Although it is obvious that the vibrations of the C=O and C=C groups are strongly coupled, nevertheless the bands, for simplicity, will be called $\nu_{C=O}$ and $\nu_{C=C}$.

a) The spectra of all solutions were obtained in a standard cell of thickness 0.1 mm. b) In both the *s-cis* and *s-trans* isomers, if present, except for compound **10**. c) The variable temperature measurements showed some preference of the *s-trans* rotamer. d) Checked by the variable temperature study. e) Weak absorption of a probably non-planar form.

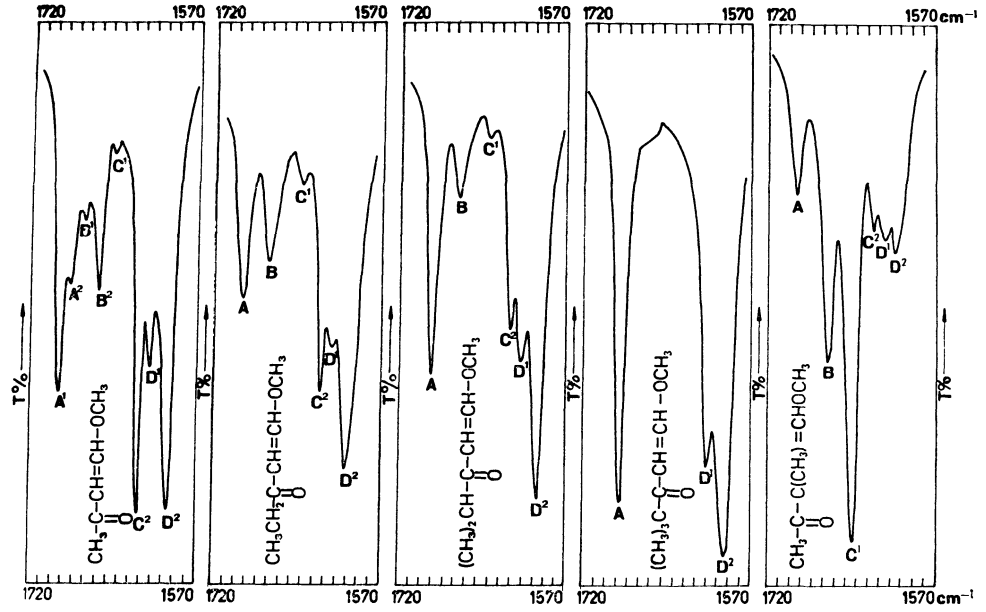

Fig. 1. Infrared spectra of compounds **1**, **2**, **3**, **4**, and **10** in tetrachloroethylene. Cell thicknesses and concentrations are given in Table 1.

in the $\nu_{C=C}$ region (bands C^1 and C^2) decrease in intensity with increasing size of the substituent R^1 in going from compound **2** to **3** and **4** while another $\nu_{C=O}$ band (band A) and two $\nu_{C=C}$ bands (D^1 and D^2) increase in the same sequence. On the basis of published data concerning other α,β-unsaturated systems[3–9] these intensity changes can be attributed to the shift of the equilibrium towards the *s-cis* rotamer due to growing steric interactions between R^1 and the β-hydrogen atom in the *s-trans* rotamer. Therefore, the decreasing bands B, C^1 and C^2 are assigned here to the $\nu_{C=O}$ and $\nu_{C=C}$ vibrations of the *s-trans* rotamers II and/or IV, and the increasing bands A, D^1 and D^2 are ascribed to the *s-cis* rotamers I and/or III. As shown further in the text (see the next page) the splittings of the bands C and D result from restricted rotation around the C_{sp^2}–O bond. This rotation is also responsible for the splitting of the bands A and B in the spectrum of the methyl ketone **1**.** Taking this splitting into account the band intensities of **1** fit very well to the sequence **1**, **2**, **3** and **4**.

A similar regularity occurs when comparing compounds **6**, **7** and **8**.

Solvent-induced intensity changes are in agreement with these assignments: when passing from hexane to tetrachloroethylene and particularly to the more polar tetrahydrofuran solutions an enhancement of the bands

** The IR spectrum of **1** has been published,[14] but no splitting of bands A, B, C and D was reported.

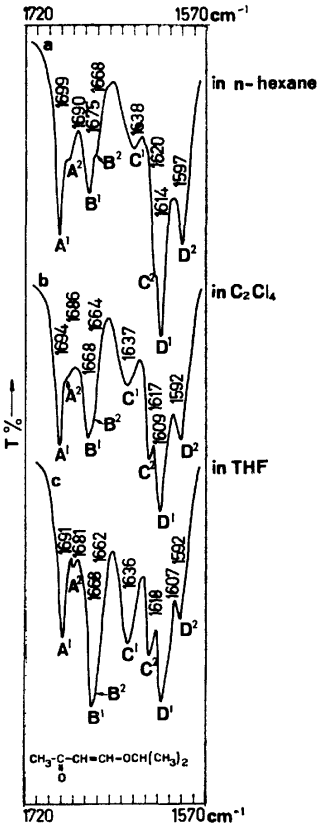

Fig. 2. Infrared spectra of compound **6**. (a) in *n*-hexane (b) in tetrachloroethylene (c) in tetrahydrofuran. Concentrations 0.13 M, cell thicknesses 0.1 mm.

B and C of the more polar *s-trans* form is observed (*e. g.* for **6**; Fig. 2).

The results concerning the *t*-butyl ketones **4**, **8** and **9** are remarkable in that a residual absorption near wave number characteristic of the *s-trans* form is still observed in spite of extremely high strain energy in this form. It seems likely that a twisted form is involved.

If R^2 is larger than hydrogen its non-bonded interactions with R^1 in the *s-cis* rotamers I and III increase dramatically[15] resulting in an equilibrium shift towards the *s-trans* rotamers II and IV as clearly seen from the relative intensities of the bands B and C^1+C^2 *vs.* A and D^1+D^2 (*e.g.* for compound **10**, see Fig. 1).

As already mentioned on the foregoing page, we believe that the splitting of bands A, B, C and D into two components is a consequence of the restricted rotation around the C_{sp^2}–O bond. This assumption finds convincing support in the intensity changes occuring on varying the steric requirements of the substituent R^3 and, in part, of R^2 and R^1. Like other rotational equilibria, the *O-s-cis*⇌*O-s-trans* equilibrium is dependent on electronic and steric factors. The latter can be estimated by comparing the corresponding interatomic distances in these two rotamers. Although it is virtually impossible to exactly calculate these distances, the approximation sufficient for the present purposes can be made by adopting the parameters obtained experimentally by Cahill, Gold and Owen[11b] for the *O-s-cis* isomer of the methyl vinyl

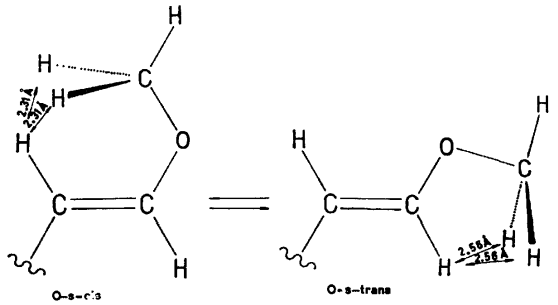

Fig. 3. H–H interatomic distances in *O-s-cis* and *O-s-trans* conformers of methyl enol ethers.

ether. In our analysis equal bond lengths and angles were taken for both the *O-s-cis* and *O-s-trans* conformations and no allowance was made for their distortion (*i.e.* optimalization was not attempted). The interatomic H–H distances were calculated for the most probable orientation of the methyl group. The strain differences thus deduced are undoubtedly even more pronounced for larger R^3 groups.

As can be seen from Fig. 3, the interatomic distance between the methyl hydrogens and the nearest vinylic hydrogen is considerably less in the *O-s-cis* rotamer. Nevertheless, this rotamer prevails in the methyl vinyl ether,[11] obviously due to electronic factors.[12]

Let us consider now the splitting of band D in compounds **4**, **8** and **9** having invariable R^1=*t*-Bu (see Fig. 4).

In the spectrum of the *O*-methyl derivative **4** the much more intense $\nu_{C=C}$ band D^2 can safely be ascribed to the energetically favoured rotamer, as proved by its diminution on raising the temperature. As follows from the above scheme, replacing of R=Me by a bulkier group should shift the equilibrium towards the *O-s-*

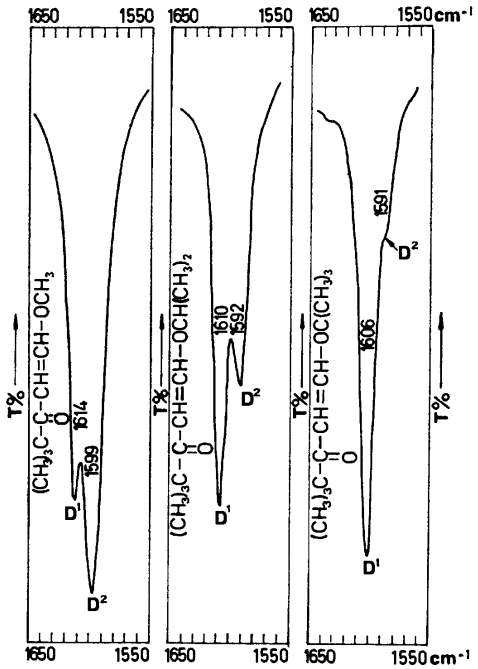

Fig. 4. Infrared spectra of compounds: **4** (concn 0.14 M) **8** (concn 0.12 M) and **9** (concn 0.11 M) in *n*-hexane. Cell thicknesses 0.1 mm.

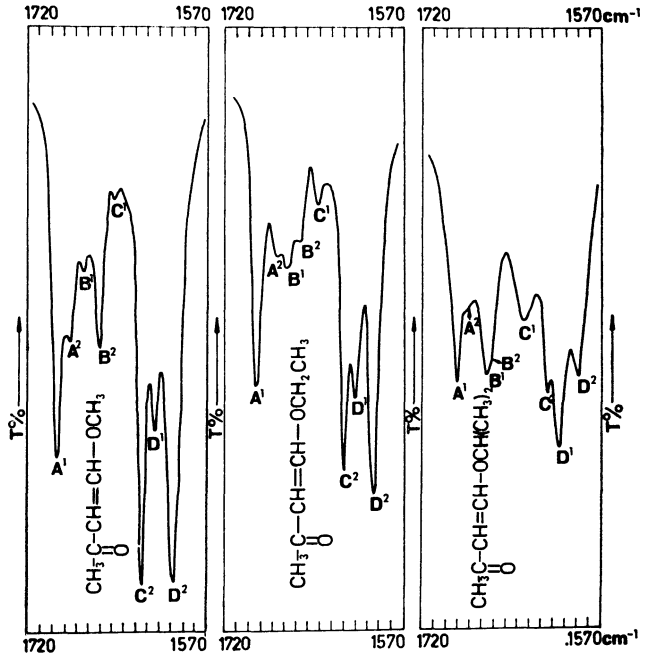

Fig. 5. Infrared spectra of compounds **1**, **5** and **6** in tetrachloroethylene. Concentrations and cell thicknesses are given in Table 1.

trans rotamer, assuming the electronic factor to be constant. Accordingly, the D^1 band which dramatically increases in the series **4**, **8**, **9** is ascribed here to this rotamer. Band D^2 which corresponds thus to the *O-s-cis* rotamer disappears almost completely when R^3=*t*-Bu, due to extremely high strain in this form.

Similar splittings and intensity changes due to the restricted rotation around the C_{sp^2}–O bond are always observed with band C (if present) and also with bands A and B, provided R^1=Me. In the latter case, the high frequency components of all the bands under consideration, *i.e.* A^1, B^1, C^1, and D^1, increase on the expense of the A^2, B^2, C^2, and D^2 ones along with increasing steric requirements of the R^3 group (see Fig. 5). Therefore, the index "1" is assigned to all bands of the *O-s-trans* rotamers and the bands of the *O-s-cis* ones are indexed "2". It should be noted that band A^1 of the *O-s-trans* rotamer has a very high absorbance as seen from its higher intensity *vs.* that of band A^2 in cases of prevailing *O-s-cis* conformation in **1**. The assignment of bands A^1 and A^2 is conclusively supported here by the enhancement of the former on the expense of the latter on going to higher temperature.
