hydrate are so different that the interactions between the resonant nucleus and the surrounding atoms are quite different. This must be clarified by the assignment of the Br atoms. Therefore, we observed the Zeeman effect on ^{81}Br NQR. The results are shown in Fig. 2. Each resonance line gives two zero-splitting patterns, indicating that the monohydrate crystal belongs to a monoclinic or a higher symmetric system. The Br atom was assigned on the basis of the angles between the IBr_2^- ions, assuming that the principal z axis of the Br atom is parallel to the linear ion. The angles thus obtained are listed in Table 2. The X-ray analysis indicates that the angles between the chemically equivalent ions are 17.66° for the ions with Br(1) and 35.92° for those with Br(2). Therefore, the Br atoms contributing to the lower and higher resonance lines were assigned to Br(1) and Br(2) respectively.

Fortunately, the I atoms could be assigned from the intensities of the resonance lines on the single crystal. The principal z axis of the I atom is considered to be parallel to the linear IBr_2^- ion, that is, parallel to that of the Br atom. The Zeeman analysis indicates that the angles between the principal z axis of the Br atoms and the rf coil axis are about 90° for Br(1) and about 45° for Br(2). Therefore, the strong resonance line is assigned to the I atoms bonded to Br(1), and the weak line, to those bonded to Br(2). The observed intensity ratio of the higher resonance line to the lower was nearly 2 : 1, indicating that the former line is due to I(1) and the latter to I(2).

The resonance frequency of Br(1) is considerably lower than that of Br(2). Therefore, Br(1) seems to be strongly affected by the intermolecular interaction. This is obvious from the temperature dependence of the resonance frequency shown in Fig. 3. The intermolecular interactions which affect the Br atoms include the OH···Br hydrogen bonding and the Br···I interaction. The hydrogen bondings at both Br atoms are considered to affect the nuclei to almost the same

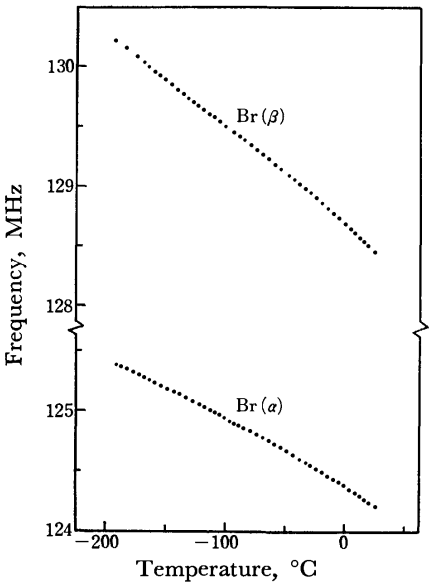

Fig. 3. Temperature dependences of ^{81}Br NQR frequencies in $KIBr_2 \cdot H_2O$.

Table 3. ^{81}Br NQR parameters of $KIBr_2 \cdot H_2O$ at 300 K

Resonance line	ν(MHz)	η(%)	e^2Qq/h(MHz)
$^{81}Br(\alpha)$	124.17	0.5±0.3	248.34
$^{81}Br(\beta)$	128.41	3.4±1.1	256.77

extent, because the X-ray analysis[10] indicates that the O···Br(1) and O···Br(2) distances are 3.60 Å and 3.64 Å respectively. On the other hand, the I(1)···Br(2) distance is 4.23 Å and the I(2)···Br(1) distance is 3.87 Å, which is about 0.2 Å less than the sum of the van der Waals radii. Therefore, the difference in the resonance frequencies between Br(1) and Br(2) is mainly to be ascribed to the I···Br interaction. In this case, the I(2)···Br(1) interaction is considered to be formed by the charge transfer from I to Br. The charge from the lone-pair orbital of I(2) enters the bonding orbital of Br(1), and the quadrupole coupling constant of Br(1) decreases and that of I(2) increases.

The asymmetry parameters of the electric field gradient are obtained from the zero-splitting loci; they are listed in Table 3. The asymmetry parameters of both Br atoms are so small that the electric field gradients are almost axially symmetric. This may be seen from the fact that the IBr_2^- ions are symmetric and the Br–I bond has little double-bond character.

The charge on the Br atom can be obtained from the quadrupole coupling constant. All the asymmetry parameters of Br in $KIBr_2 \cdot H_2O$ and those of I in the trihalide ions are so small (up to 4%)[5] that they can be neglected. Furthermore, s hybridization does not seem to participate in the halogen-halogen bond. Using the Townes-Dailey method,[11] the following equations are obtained for the terminal and the central halogen atoms.

For a terminal atom:

$$\frac{(e^2Qq)_{obsd}}{(e^2Qq)_{atom}} = 1 - i = 2 - N_z \qquad (1)$$

Table 4. Electron populations and charge distributions in linear trihalide ions

Compound	N_z		$Q_x(e)$		Total charge (e)
	Terminal	Central	Terminal	Central	
$KIBr_2 \cdot H_2O$	1.61	0.78	−0.61	0.22	−1.00
	1.60	0.82	−0.60	0.18	−1.02
$KIBr_2$	1.60	0.80	−0.60	0.20	−1.00
$KICl_2 \cdot H_2O$	1.66	0.70	−0.66	0.30	−1.02
$KICl_2$	1.65	0.71	−0.65	0.29	−1.01

For a central atom:

$$\frac{(e^2Qq)_{obsd}}{(e^2Qq)_{atom}} = (1-i) + 2i(1+\varepsilon) = 1 + (1-N_z)(1+2\varepsilon), \quad (2)$$

where $(e^2Qq)_{obsd}$ is the observed quadrupole coupling constant and $(e^2Qq)_{atom}$ is that due to one p_z electron, *i.e.*, 643.03 MHz for ^{81}Br and 2292.71 MHz for ^{127}I.[12,13] ε is a correction factor for a positively charged resonant atom and 0.12 for ^{127}I.[11] N_z is the electron number of the p_z orbital. Using the N_z values obtained from Eqs. 1 and 2, the charges, Q_x, on the halogen atoms are readily calculated by means of the following relation: $Q_x = 1 - N_z$. The values thus obtained are listed in Table 4, in which the values for the ICl_2^- ions are given for purposes of comparison. Since no resonance lines except those in $KIBr_2 \cdot H_2O$ are assigned, the charges on the halogen atoms were calculated for the averaged resonance frequency. The charges of the terminal and central halogen atoms in the ICl_2^- ions are larger than those in the IBr_2^- ions. This can be explained by the difference in electronegativity between Br and Cl. In any case, the calculated total charges are equal to the theoretical value, $-e$. Therefore, the approximation used in the present work is reasonable.

(Received January 20, 1977)

Temperature and concentration dependences of the delayed luminescence observed in the naphthalene (guest)–biphenyl (host) mixed crystal system have been studied. The presence of the temperature-independent delayed fluorescence (TIDF) and its significance in the evaluation of activation energy have also been confirmed in this system as in the case of the benzo[*f*]quinoline–biphenyl system previously reported, and the generality of the existence of TIDF as well as its significance in relation to activation energy has been suggested. In addition, some remarks have been made on the nature of TIDF and the decay behavior.

We have observed TIDF of benzo[*f*]quinoline in biphenyl host in the low temperature region from 90 K down to liquid helium temperature and showed that subtraction of this temperature-independent contribution (I_{TIDF}) from the observed total delayed fluorescence intensity ($(I_{DF})_{total}$) above 90 K gave straight-line fits of both $\log I_{DF}/I_P^2$ and $\log I_{DF}$ *vs.* $1/T$ plots, where I_{DF} and I_P stand for the delayed fluorescence (DF) and phosphorescence (P) intensities, respectively, in good agreement with the usual temperature-dependent model.[1-3] Moreover, it has been shown that the decay behavior of TIDF may be responsible for the unusual decay behavior of DF around 77 K, the decay of which deviates considerably from exponentiality in the lower temperature region where the exponential behavior is expected from the usual temperature-dependent model.[2] The investigation on the temperature and concentration dependences of both the intensity and the decay of the delayed luminescence (P and DF) of naphthalene in biphenyl host has been made in order to examine the existence and its significance of TIDF as found in the benzo[*f*]quinoline–biphenyl system. Incidentally, Misra[4] reported an observation of TIDF in the same system. In the present work, therefore, we will mainly discuss whether this temperature-independent portion of DF plays an important role for the anomaly of DF observed in the lower temperature region in the naphthalene–biphenyl system. Benzo[*f*]quinoline has overlapping phosphorescence and triplet-triplet absorption bands,[5] whereas it is not the case in naphthalene.[6] Since this type of overlapping might be significant in the triplet-triplet annihilation,[7] it seems interesting to choose naphthalene as another guest to be compared with benzo[*f*]quinoline.

Experimental

Chemicals were obtained from Tokyo Kasei Kogyo Co., Ltd. Biphenyl was recrystallized twice from ethanol, and was further purified by the method of repeated zone refining and abstraction of the non-emissive portions of the specimen. Naphthalene of the UP grade (zone refined, number of passes: 23) was used without further purification. The polycrystalline samples used were prepared from the melts between two fused-silica plates which were mounted in a brass block holder. Concentration of the samples studied ranges from 10^{-2} to 10^{-4} mol/mol. All apparatus and techniques were identical to those already described.[2]

Results and Discussion

Spectra. As shown in Fig. 1, the normal and delayed fluorescence spectra obtained at 77 K with a guest concentration of 1.0×10^{-3} mol/mol are in good correspondence with each other in any of the mixed crystal samples, giving a confirmation that the observed DF is genuine. The temperature dependence of the delayed luminescence was studied for bands b, c, and d in Fig. 1. The phosphorescence spectrum obtained at 77 K from the mixed crystals is given in Fig. 2, where "a" stands for the 0,0-band of P. The delayed luminescence spectrum of the naphthalene–biphenyl mixed crystals has been reported, particularly by Misra and McGlynn.[8] Comparing our observed spectrum with theirs, the naphthalene guest is identified to be the emitting species.

Temperature Dependence of Intensity. The results of the temperature dependence of the delayed luminescence with a guest concentration of 1.0×10^{-2} mol/mol in the

(a): Phosphorescence intensity observed at 475 nm, *i.e.*, the 0,0-band shown in Fig. 2; (b) and (c): delayed fluorescence intensities observed at 318 nm (the 0,0-band) and the corresponding band shown in Fig. 1, respectively. No correction was made for the spectral response of the apparatus.

temperature region above 77 K are shown in Fig. 3. The results on DF observed at band d are not shown in the figure because it is similar to those of bands b and c as far as the temperature dependence is concerned. The results obtained with the guest concentrations of 1.0×10^{-3} and 1.0×10^{-4} mol/mol were also similar to those obtained with the guest concentration of 1.0×10^{-2} mol/mol just mentioned above. As can be seen in Fig. 3, the DF intensities observed at bands b and c remain constant at least in the temperature range of 77—110 K. This thermal behavior is quite similar to that in the benzo[*f*]quinoline–biphenyl system[2] except that T_{max} (the temperature at which maximum intensity of DF occurs) shifts to the higher temperature. These suggest that I_{DF} below 77 K may be independent of temperature. This system has very weak delayed luminescence at temperatures below 77 K, which we were not able to study quantitatively even by use of an NF LI-572B auto lock-in amplifier, partly because of the use of glass dewars. Incidentally, Misra[4] has reported that I_{DF} observed in the same system remains fairly constant in the temperature range from 6 to 77 K, 77 K being the highest temperature in their study. On the other hand, we also observed TIDF in the range of 77—105 K. Combining these results obtained in the different temperature regions, it may be concluded that TIDF exists over a wide range of temperature in this system just as in the case of the benzo[*f*]quinoline–biphenyl system. Hence, the important features of TIDF may be investigated in the region above 77 K. In this system, a rather peculiar temperature dependence of I_{DF}, as was already pointed out by Misra and McGlynn,[8] was found in the lower temperature region where an exponential temperature dependence is expected. This peculiarity may be correlated to the DF decay behavior at the same lower temperature region[2] and we emphasize that this peculiarity is due to the existence of TIDF over a wide range of temperature.

Evaluation of Activation Energy from Intensity Analyses. We have emphasized in the previous papers[1,2] that the peculiarity of DF in the lower temperature region can be understood well in accodance with the kinetic model if we take into consideration the temperature-independent portion of DF in a process of estimation of I_{DF}. We use the following three Arrhenius plots[2,9] in order to estimate the activation energy ΔE from the intensity analyses:

(1) In the higher temperature region, $\log I_P$ *vs.* $1/T$ (plot (1))
(2) in the lower temperature region, $\log I_{DF}$ *vs.* $1/T$ (plot (2))
(3) in the whole temperature region, $\log I_{DF}/I_P^2$ *vs.* $1/T$ (plot (3)).

In Fig. 4 are shown plots (1) and (2) obtained with three different concentrations, together with the plot obtained using corrected values of I_{DF}, *i.e.*, $[(I_{DF})_{total}-I_{TIDF}]$. Among the plots, only the latter one gave good fits to straight lines in all the concentrations studied. Figure 5 shows the results obtained with plot (3) in the three different concentrations. Here also, only the plot obtained with the corrected values of I_{DF} gave a straight line over the whole temperature range. In the naphthalene–biphenyl system, however, the effect of the correction is found to be smaller than that in the benzo[*f*]quinoline–biphenyl system, reflecting the fact that the temperature-independent fraction is much smaller, as can be seen in Fig. 3. The slopes of the straight-line portions shown in Figs. 4 and 5 give the activation energies listed in Table 1, which are comparable with the spectroscopic value[8] of 1940 cm^{-1}. Misra and McGlynn[8] obtained the ac-

See text. c) See Fig. 1. d) See text. e) Only the corrected plot gives a good fit to a straight line. See text. f) $(I_{DF})_m$ denotes the maximum I_{DF} at T_{max}.

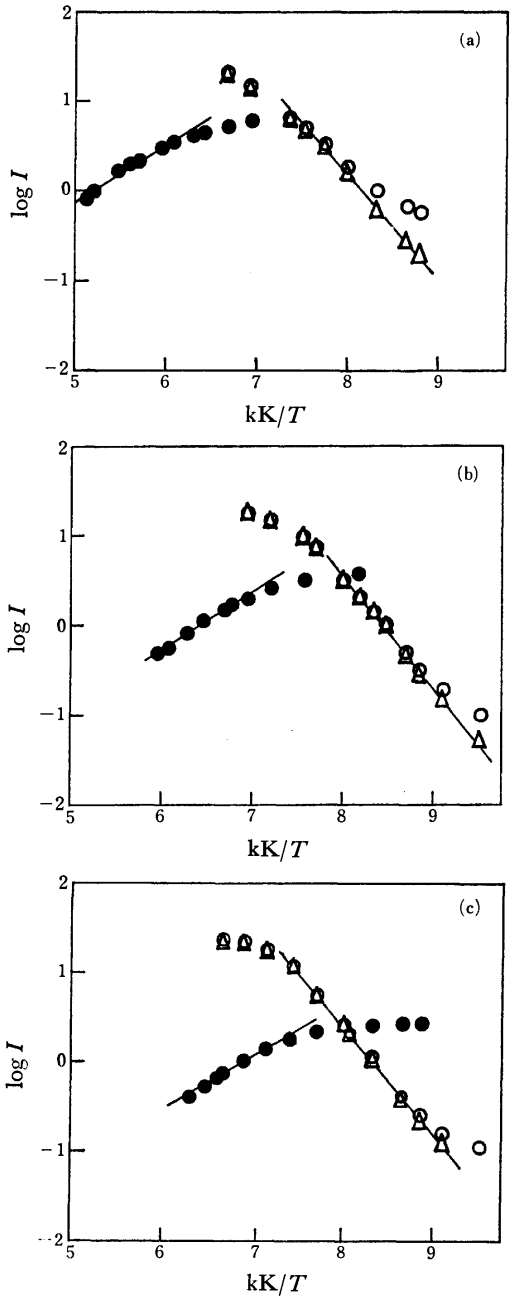

Fig. 4. Plots of log $(I_{DF})_{total}$ (○), log $[(I_{DF})_{total}-I_{TIDF}]$ (△), and log I_P (●) *vs.* $1/T$ with I_{DF} at band c shown in Fig. 1. Concn: (a) 1.0×10^{-2}, (b) 1.0×10^{-3}, (c) 1.0×10^{-4} mol/mol.

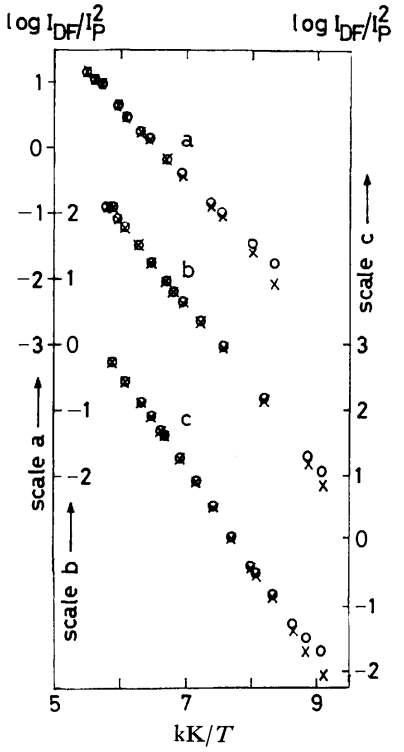

Fig. 5. Plots of log $(I_{DF})_{total}/I_P^2$ (○) and log $[(I_{DF})_{total}-I_{TIDF}]/I_P^2$ (×) *vs.* $1/T$ with I_{DF} at band c. Concn: (a) 1.0×10^{-2}, (b) 1.0×10^{-3}, (c) 1.0×10^{-4} mol/mol.

tivation energy of 1760 cm^{-1} from the "uncorrected" part of plot (3) and 175 K for T_{max}. Our uncorrected results are in good agreement with theirs. We would like to emphasize here that, according to our results, the existence of shallow traps in host crystal lattices suggested by Misra and McGlynn[8] as an interpretation of DF in the lower temperature region is in doubt and that it should be re-interpreted as due to the existence of TIDF as has been detailed on the benzo-[*f*]quinoline-biphenyl system.[1,2] The activation energies obtained from plot (3) with a very low guest concentration of 10^{-4} mol/mol seem too large to fall within the experimental error in either of the spectroscopic value or the other thermal activation energies. As was already suggested in the previous paper,[2] this may be due to an influence of a very weak trap-DF observed at such a very low concentration. Judging from the thermal values obtained from the other sources (*i.e.*, plots (1) and (2)) and from the discussion in the previous

paper,[2] it may be concluded that the thermal activation energy is independent of concentration.

Decay Behavior. We have observed exponential or nearly exponential decays of DF of naphthalene in biphenyl host crystals in the temperature range of 120—130 K,[3] just as have been reported by Hirota[9] and by McGlynn *et al.*[8,10,11] in the vicinity of the so-called characteristic temperature (*i.e.*, the temperature at which deviations from exponential decay behavior of P begin to occur). These experimental observations indeed seem to be in accordance with our suggestion[2] that when the contribution of TIDF is negligible and the decay of temperature-dependent DF remains exponential, the exponential decay behavior of DF to be observed will be expected at least in the vicinity of the characteristic temperature. Detailed results on the decay behavior will be presented elsewhere.

Some Remarks on the Nature of TIDF. In the last column of Table 1 are given the ratios of I_{TIDF} to I_{DF} at T_{max}, that is, $I_{TIDF}/(I_{DF})_m$. For naphthalene in biphenyl host, Misra obtained a value of 0.12 for the above ratio from the temperature dependence of I_{DF},[4] while our values are lower by one order as listed in Table 1. These ratios seem to exhibit the concentration dependence, as have already been suggested by us, and are much smaller than those obtained in the benzo[*f*]quinoline–biphenyl system.[1,2] In any event, considering the fact that we have observed TIDF, it may be concluded that the overlap of the P and T-T absorption bands is not necessarily significant for the occurrence of TIDF. Recently, Gondo *et al.*[12] have suggested, on the sound basis of the results on the concentration depolarization in P and normal fluorescence of some aromatic compounds in ethanol glass at 77 K, that formation of the molecular complexes might be responsible for the energy transfer observed in the benzophenone-naphthalene-in-rigid-glass system by Terenin and Ermolaev.[13] Namely, the experimental results that the triplet-triplet energy transfer is inefficient and is of the short range phenomenon,[12] and that TIDF has been observed at the low concentrations of the order of 10^{-4} mol/mol, suggest that the formation of molecular aggregates in mixed crystals may be responsible for the existence of TIDF.[2,14]

Similar TIDF has also been observed for naphthalenes and phenanthrenes in biphenyl host crystals,[4,9] for perprotobenzene in perdeuterobenzene host crystals,[15] and in the crystalline 1,2,4,5-tetracyanobenzene–biphenyl complex,[16] as well as for the naphthalene– and benzo[*f*]quinoline–biphenyl systems. Very recently, in the benzo[*h*]quinoline–biphenyl system, TIDF has also been observed and the above-mentioned correction has been carried out successfully.[17] Therefore, it may be allowed to state that the existence of TIDF in organic mixed crystals is a general phenomenon and the correction should be carried out in those systems where TIDF is observed.

Construction of a ^{3}He Calorimeter and Heat Capacity Measurement of the 1965 Calorimetry Conference Copper Standard between 0.4 and 20 K

Naoto Arai, Michio Sorai, Hiroshi Suga, and Syûzô Seki

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received January 21, 1977)

Construction of an isoperibol-type calorimeter with a ^{3}He cryostat is described. A system of charcoal-adsorption-pump is adopted. A Ge-thermometer used in the heat capacity measurements is calibrated in the temperature range from 0.4 to 1.5 K against the magnetic susceptibility of chromium potassium alum. The precision and the accuracy of the calorimeter is ascertained by the heat capacity measurement of the 1965 Calorimetry Conference Copper Standard (T-8.6) in the temperature range from 0.420 to 19.46 K. The deviation of the experimental points from the "copper reference equation" is within the experimental error of $\pm 2.5\%$ between 0.4 and 0.9 K, $\pm 1.5\%$ between 0.9 and 1.5 K, $\pm 1.2\%$ between 1.5 and 4 K, and $\pm 0.6\%$ between 4 and 20 K. The highest deviation of absolute value of the present heat capacity data of copper is 1.86% smaller than the "selected values (Furukawa *et al.*)" around 6 K. This difference may be primarily attributable to the NBS-65 temperature scale adopted in the present experiment.

In the field of magnetism, weak interactions among the magnetic moments are unambiguously interpreted based on the heat capacity measurements at extremely low temperatures where the lattice contribution is negligibly small. In the temperature region below 1 K, there are known considerable number of inorganic and metallic substances on which magnetic heat capacity measurements are performed. However, precise heat capacity measurements of organometallic and complex compounds are very scanty because these compounds are usually obtained as a polycrystalline form. In this work we constructed a calorimeter capable of measuring precisely the heat capacity of polycrystalline sample in the temperature range from 0.4 to 20 K. Two kinds of calorimeter cell suitable for this purpose were also designed.

The calorimeter constructed here is an isoperibol ^{3}He evaporation-type. To attain temperature significantly below 1 K there are two possible ways for evaporation; one is to pump out ^{3}He vapor by use of a diffusion pump or a rotary pump[1,2] and the other is to use a charcoal adsorption pump.[3,4] The latter is superior to the former due to the following three reasons. (i) The evaporation rate by an adsorption pump is much larger than that by an oil diffusion pump because it is possible to connect an adsorption pump to a ^{3}He pot *via* the extremely short pumping line which is everywhere near 1 K. (ii) In case of an adsorption pump one can avoid the heat generation arising from mechanical vibration of a rotary pump. Mechanical vibration causes very large temperature drift of a calorimeter cell at very low temperatures. (iii) A gas handling system using an adsorption pump is much simpler and securer than that consisting of a rotary pump. Based on our design Oxford Instrument Co., Ltd. constructed a part of the evaporation system of the present ^{3}He cryostat. In the present investigation a charcoal adsorption pump is adopted to avoid mechanical vibrations. A germanium resistance thermometer used here was calibrated against the magnetic temperature scale derived from the magnetic susceptibility of chromium potassium alum. For this end, an a.c. Hartshorn mutual inductance bridge and a coil assembly were constructed. The working principle of the ^{3}He cryostat and the calibration of Ge-thermometer will be described rather in detail.

Any physical quantity can exhibit its exact meaning only when the precision and the accuracy are critically evaluated. A convenient method of their estimation is to compare particular physical quantity with a well-established "standard" value. As to the low temperature calorimetry, heat capacity of high purity copper has been recommended as the calorimetry standard since last decade or so. At the 19th Annual Calorimetry Conference (U. S. A.), it was recommended to use a specially prepared and characterized copper sample for this purpose. In response to this recommendation, standard samples were prepared by Osborne *et al.*, and these samples are now available from Argonne National Laboratory.[5]

To estimate the precision and the accuracy for the present low temperature calorimetry, we measured the heat capacity of the 1965 Calorimetry Conference Copper Standard (Argonne Designation "T-8.6") in the temperature range from 0.4 to 20 K. The results and comparison with those by other investigators will be described below.

Experimental

1. Construction of Apparatus. The calorimeter consists of four major parts, namely a ^{3}He cryostat of isoperibol type, calorimeter cell, temperature measuring circuit, and energy measuring circuit.

1.1 ^{3}He Cryostat: The cryostat consists of three precooling steps and the innermost ^{3}He refrigerant system. The three precoolants are liquid N_2 and liquid ^{4}He at 4.2 and 1.2 K, respectively. The liquid containers for these coolants are designated hereafter as the N_2 reservoir, the ^{4}He main bath and 1.2 K pot, respectively. In order to minimize a heat evolution caused by mechanical vibration due to both a rotary pump used for a vacuum system and the laboratory building, the metal frame supporting the cryostat has been installed on rubber-dampers "Rubloc" and suitable bellows are inserted into the pipings, which cut off the vibration conducted from the building.

Figure 1 illustrates a schematic drawing of the main part of the ^{3}He evaporation cryostat. In this figure the drawing of a part of the dewar vessel and the N_2 reservoir is omitted. A gold-plated copper vacuum jacket (G) immersed in the ^{4}He main bath (C) houses the 1.2 K pot (K), a charcoal adsorption pump (N), a ^{3}He evaporator or the ^{3}He pot (P)

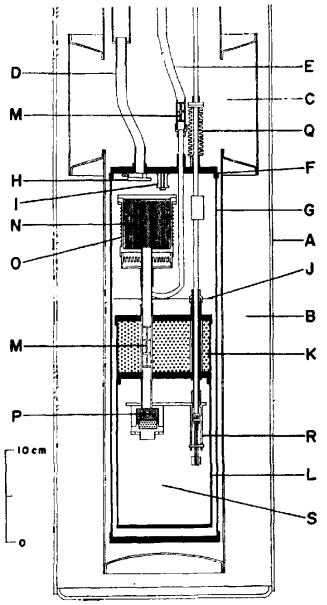

Fig. 1. Schematic drawing of the main part of ^{3}He evaporation-type cryostat (0.4—20 K): (A) aluminium jacket (liquid N_2 temperature), (B) vacuum space, (C) ^{4}He main bath, (D) vacuum pumping tube, (E) ^{3}He filling tube, (F) Wood's alloy joint, (G) gold-plated copper vacuum jacket, (H) radiation shield, (I) thermal anchor for leads, (J) radiation shield, (K) 1.2 K pot, (L) 1.2 K shield, (M) flow-impedance, (N) charcoal adsorption pump, (O) heater, (P) ^{3}He evaporator, (Q) bellows, (R) mechanical thermal switch, (S) experimental space.

and a mechanical thermal switch (R). The 1.2 K pot (inner volume of 400 cm^3) is filled with the liquid ^{4}He in the main bath *via* a needle valve. The 1.2 K pot is pumped down slowly to 1.2 K. The charcoal adsorption pump is heated to about 30 K by use of a heater (O) wound around it. The ^{3}He gas admitted through a flow-impedance (M) from an external storage tank is liquefied by passing it through a tube which is in thermal contact with the 1.2 K pot. The liquid ^{3}He drops into the ^{3}He pot. Then the heater is switched off and at the same time a compartment attached to the bottom of the adsorption pump is filled with liquid ^{4}He *via* a needle valve. The adsorption pump is cooled down to 4.2 K and the ^{3}He evaporator reaches rapidly its lowest temperature (0.26 K). The lowest temperature is sustained for more than ten hours in the heat capacity measurements.

The mechanical thermal switch has the gold-plated copper jaws, which are anchored to the ^{3}He evaporator by the copper braids. A stainless steel frame for sample mounting, which is not drawn in Fig. 1, is set in an experimental space (S) and supports a calorimeter cell with fine nylon threads. All the leads between the hermetic seals at the top of the cryostat at room temperature and the tag located under the 1.2 K pot are 46 S.W.G. enamelled copper and are thermally anchored at the 4.2 K spot (I) and at the 1.2 K pot, respectively.

Figure 2 is a sketch of the experimental space inside the 1.2 K shield. Here, a calorimeter cell is already mounted.

1.2 Calorimeter Cells: Tow kinds of calorimeter cells were constructed for the heat capacity measurements of polycrystalline specimen in the low temperature region. One is to use a small amount of ^{3}He gas as a heat exchanger, while the other is to use an organic material (Apiezon-N grease) forming a glassy state for good thermal contact. For convenience, these two cells are designated hereafter the calorimeter cell-type 1 and -type 2, respectively.

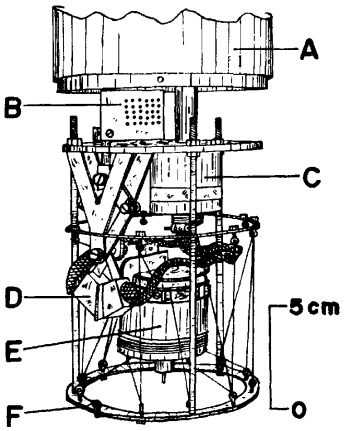

Fig. 2. Sketch of experimental space. The 1.2 K shield is dismantled and a calorimeter cell of type-1 is mounted: (A) 1.2 K pot, (B) tag for leads, (C) ^{3}He evaporator, (D) mechanical thermal switch, (E) calorimeter cell, (F) sample mounting frame.

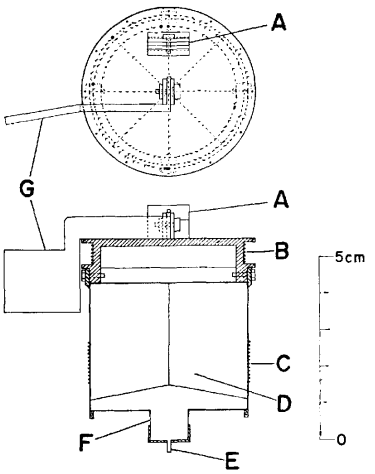

Fig. 3. Schematic diagram of calorimeter cell-type 1: (A) germanium thermometer holder, (B) leads for germanium thermometer, (C) heater, (D) eight vertical radial vanes, (E) ^{3}He gas filling tube, (F) sample filling tube, (G) clamping post.

1.2.1 Calorimeter Cell-Type 1: The calorimeter cell-type 1 (Fig. 3) consists of two parts: the upper part made of gold-plated copper is equipped with a clamping post (G) and a germanium thermometer holder (A), while the lower part is a sample container made of 20 carat gold which has a cylindrical form with the dimension of 4.2 cm in diameter, 3.5 cm in height and *ca.* 42 cm^3 of capacity. Both parts are connected mechanically. This device is necessary to protect the Ge-thermometer from contamination and mechanical vibration when the sample is loaded. Eight vertical radial vanes (D) in the cell makes the thermal equilibration within the cell easier and to the same end a small amount of ^{3}He gas (*ca.* 2 kPa at room temperature) is also sealed. The heater (C) is formed of a strain-free manganin wire of about 1.5 kΩ (49 S.W.G.) wound non-inductively. The heater is wound directly on to the periphery of the cell for assurance of good thermal contact at very low temperatures. For improvement of electric insulation and thermal contact between

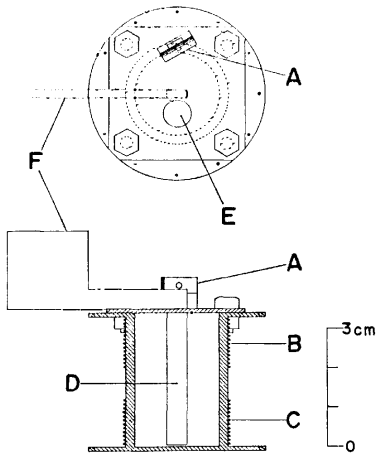

Fig. 4. Schematic diagram of calorimeter cell-type 2: (A) germanium thermometer holder, (B) thermometer leads, (C) heater, (D) copper stirring rod, (E) evacuating hole, (F) clamping post.

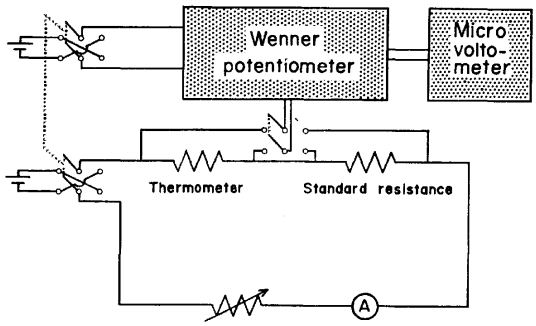

Fig. 5. Block-diagram of temperature measuring circuit.

the cell and the heater, the manganin wire is coated with GE7031 varnish. Thermal contact between the Ge-thermometer and the holder is increased by use of a small quantity of Apiezon-N grease between them. A part of the leads is thermally anchored to the upper part of the cell by means of GE7031 varnish. The cell is fixed to the sample mounting frame by fine nylon threads. The clamping post is adjusted to locate symmetrically between the jaws of the mechanical thermal switch (see Fig. 2).

1.2.2 Calorimeter Cell-Type 2: Figure 4 shows the calorimeter cell-type 2. In this case a polycrystalline sample is mixed with Apiezon-N grease. Heat transfer within the cell is promoted by a copper stirring rod (D) attached to one end of the clamping post. The cell is a copper cylinder of 2.5 cm in diameter, 3.5 cm in length and *ca.* 12 cm^3 of capacity. The clamping post (F), the thermometer holder (A) and so on are similar to those of the type 1.

1.3 Temperature Measuring Circuit: The measurement of temperature is achieved by the potential drops across both a germanium resistance thermometer (CryoCal, Inc., type CR100) and a standard resistor (1 kΩ, Shimadzu Electrical Measuring Instruments Co., Ltd.) arranged in series with it (see Fig. 5). These measurements are made by use of a Wenner-type potentiometer (Leeds & Northrup Co.). The degree of imbalance of the potentiometer is monitored by a d.c. micro voltmeter (Ohkura Electric Co., model AM-1001). The electric current used for the resistance measurements of the Ge-thermometer is selected to be 3.6—46 μA in the temperature range from 0.9 to 20 K, while below 0.9 K 1 μA or less is used so that the self-heating effect can be

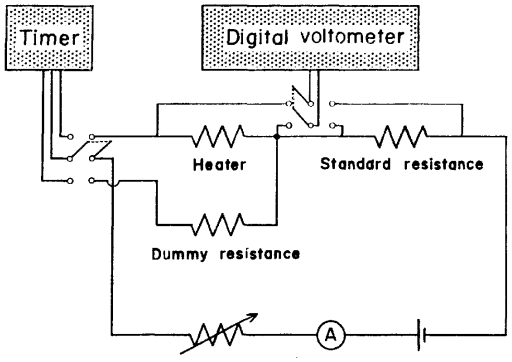

Fig. 6. Block-diagram of heating circuit.

minimized. The thermal electromotive force generated in the circuit is compensated by the reversion of the electric current. The apparent temperature difference caused by the current reversion were, *e.g.*, 0.6 mK at 0.61 K and 1.0 mK at 1.3 K. The standard resistor and an unsaturated-type standard cell (Epply Laboratory, Inc.) necessary for the potentiometer are kept at constant temperature.

1.4 Heating Circuit: Figure 6 shows the heating circuit. The heater current is supplied from a bank of low discharge lead storage batteries. The circuit is arranged to give a continuously variable current from 20 μA to 3.7 mA. The electric current flowing through the heater is determined by the potential drop across a standard resistor (1 kΩ). The heating element consists of a 49 S.W.G. manganin wire whose resistance is *ca.* 1.5 kΩ at room temperature. The d.c. voltages across the heater and the standard resistor are displayed on an integrating digital voltmeter (Takeda Riken Industry Co., Ltd., model TR-6515D, 5 digits). A dummy resistor having a similar resistance to the heater is placed in parallel to the heater. This dummy circuit enables the batteries to supply a stable current for a long period. The duration of the heating period is determined by an electronic counter (Takeda Riken Industry Co., Ltd., model TR-5104/04F, 6 digits).

2. Calibration of Ge-thermometer between 0.4 and 1.5 K. The germanium resistance thermometer (CryoCal, Inc., type CR100) used for the present heat capacity measurements has been already calibrated in the temperature range from 1.5 to 20 K at CryoCal, Inc. The temperature scale between 1.5 and 2.0 K is based on the helium-4 vapor pressure scale of 1958 (T_{58}). The 2.25 to 13 K readings are traceable to the National Bureau of Standards Provisional Scale 2—20 (1965) through a secondary standard. The temperature scale between 14 and 20 K is based on the International Practical Temperature Scale of 1968 (T_{68}) through a secondary standard.

Then the calibration below 1.5 K is made against the magnetic temperature scale derived from our measurement of magnetic susceptibility for chromium potassium alum. For this end, an a.c. Hartshorn mutual inductance bridge and a coil assembly for it were constructed. The oscillator is a commercially available audio-frequency signal generator (General Radio Co., type 1301-A). The frequency used here is 100 Hz. The inductive unbalance of the measuring secondary coil can be resolved into two components; the first component corresponds to the real part of the magnetic susceptibility of the paramagnetic salt and can be compensated by a variable mutual inductor (H. Tinsley & Co., Ltd., type 4229). The second component corresponds to the imaginary part of the susceptibility and can be compensated by taking off a small voltage from a potentiometer. The null balance of the circuit is attained by visual observation on the oscil-

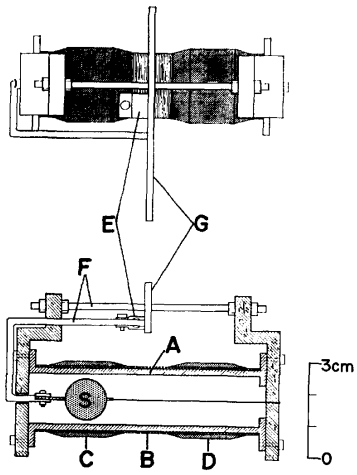

Fig. 7. Schematic diagram of the coil assembly: (S) paramagnetic salt, (A) nylon bobbin, (B) primary coil, (C) measuring secondary coil, (D) compensating secondary coil, (E) germanium thermometer holder, (F) copper rod, (G) clamping post.

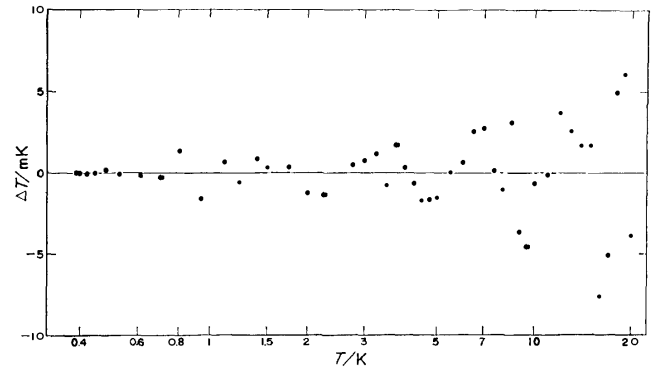

Fig. 8. Deviation plot for the germanium thermometer. $\Delta T = T_{\text{calcd}} - T_{\text{obsd}}$, where T_{obsd} is the calibrated temperature and T_{calcd} is the temperature calculated from the observed resistance R and the polynomial of the form given by Eq. 1.

lograph.

In the coil assembly (see Fig. 7), the Nb–Ti superconducting wire is wound on a nylon bobbin as a primary coil. The use of superconducting wire prevents the heat evolution due to Joule-effect in the primary coil at low temperatures. The measuring and the compensating secondary coils (copper wire) are wound directly onto the primary coil in opposite directions so that the mutual inductance due to the empty coil may be reduced to a conveniently small value. A single crystal of chromium potassium alum (*ca.* 2 g) is mounted in the bobbin.

The calibration procedure is as follows; in the first place, the magnetic susceptibility of the specimen was measured in the range from 1.5 to 7.0 K by use of the temperature scale of the Ge-thermometer. Based on these measurements we determined the Curie constant, the geometry factor of the salt, and the constant mutual inductance characteristic of the present apparatus. By assuming that these factors would not change below 1.5 K the Ge-thermometer was calibrated against the magnetic susceptibility in this temperature region. At each temperature the readings of the mutual inductor and the resistance of the thermometer were recorded over a period of 15—30 min. Twenty-seven sets of the experimental points were determined in the range between *ca.* 0.4 and 7 K. During the calibration the temperature of the coil assembly was controlled by both the mechanical thermal switch and the heater.

The calibration data, together with those above 1.5 K, were fitted to the following polynomial by using the method of least squares in the fractional deviations with equal weight:

$$\ln R = \sum_{i=0}^{13} A_i (\ln T)^i. \qquad (1)$$

This polynomial with fourteen parameters can reproduce the calibration points within ±2 mK below 6 K, within ±5 mK between 6 and 15 K, and within ±8 mK between 15 and 20 K (see Fig. 8).

The main source of experimental errors lies in the inaccuracy of the measurement of the mutual inductance. Its readings have an uncertainty of ±0.1 μH owing to the small current in the primary coil. On the other hand, the lowest range of the mutual inductor showed different values of the reading taken in the clockwise and the counterclockwise directions. This may be caused by the external electromagnetic coupling around the mutual inductor.

The validity of temperature calibration will be discussed later in connection with the heat capacity data of the 1965 Calorimetry Conference Copper Standard.

3. Heat Capacity Measurement of Standard Copper Sample. To evaluate the precision and the accuracy for the present low temperature calorimetry, we measured the heat capacity of the 1965 Calorimetry Conference Copper Standard (Argonne Designation "T-8.6")[5] in the temperature range from 0.4 to 20 K. The purity of the present copper sample is guaranteed to be better than 99.999%.

3.1 Preparation of Standard Copper Sample: The standard copper sample employed for the present purpose was the 1965 Calorimetry Conference Copper Standard (T-8.6), which was prepared in Argonne National Laboratory by vacuum casting 99.999+% High Purity Copper (American Smelting and Refining Co.) into rods. The sample has a cylindrical form of 5.3 cm in height and 3.1 cm in diameter. It was cleaned first with nitric acid and then with hydrochloric acid, rinsed with distilled water and dried *in vacuo*. After the surface treatments was over it was annealed in H_2 atmosphere for 2 h at 670 K, in ^{4}He atmosphere for 4.5 h at 720 K, and cooled *in vacuo* overnight in a Pyrex vessel. The final mass of the sample was 376.605 g (≙5.92649 mol).

For the heat capacity measurement the sample was mounted in a sample holder (Fig. 9). The sample holder consists of two flat copper disks (B) and (C); the upper one (B) is equipped with a clamping post (D) and a germanium thermometer holder (A). The sample (E) was interposed mechanically between these two disks. The calibrated germanium thermometer was inserted into the thermometer holder. Small amount of Apiezon-N grease was used for the attainment of good thermal contact between each part. A heater consists of a manganin wire (49 S.W.G.) with about 1.5 kΩ, which was wound directly onto the periphery of the sample rod and glued with GE7031 varnish. The sample holder was tightly hung in the calorimeter mounting frame in the cryostat by fine nylon threads. The clamping post was adjusted to locate centrally between the pair of jaws of the mechanical thermal switch. The weight of the sample holder and other addenda was 84.333 g.

3.2 Heat Capacity Measurement of Standard Copper Sample: The heat capacity measurement was made by an impulse method. The principle of this method is to measure a tem-

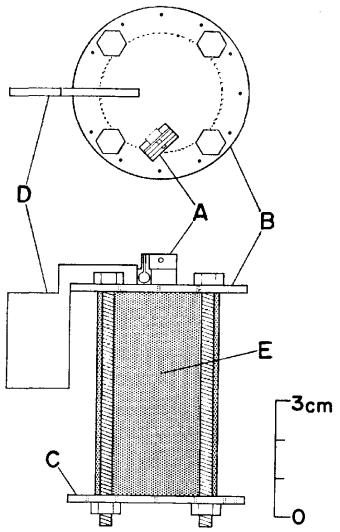

Fig. 9. Schematic diagram of the sample holder for standard copper: (A) germanium thermometer holder, (B) upper disk, (C) lower disk, (D) clamping post, (E) copper sample.

perature increment ΔT after a known quantity of heat ΔQ is introduced to a sample at a temperature T. The average heat capacity C_{av} in the temperature interval between T and $T+\Delta T$ may be given by $C_{av}=\Delta Q/\Delta T$. On the other hand, the true heat capacity (C) is defined as $C=\lim_{\Delta T\to 0}(\Delta Q/\Delta T)=dQ/dT$. When the ΔT is small enough, C_{av} approximates well to C and can be regarded as the true heat capacity at the average temperature T_{av} ($=T+\Delta T/2$). However, in the temperature region where the heat capacity is largely varied with temperature, the curvature correction should be made.

The temperature drift was monitored over a period of *ca.* 8 min and the attainment of thermal equilibrium in the sample was confirmed. The heat leak into the sample was estimated to be 20 nW at 0.45 K and −21 nW at 0.68 K. On the other hand, a breaking-off operation of the thermal switch brought about a temperature rise of 50 mK from the realized lowest temperature (*ca.* 0.32 K). This heat evolution is caused by the friction between the clamping post and the jaws of the thermal switch.

The heat capacity of the copper plus addenda was first measured in the temperature range from 0.391 to 20.02 K. Then the auxiliary measurement of the heat capacity of addenda was made between 0.456 and 19.18 K. The same amount of Apiezon-N grease was used for both sets of measurements. The ratio of the heat capacity of the addenda to the total amounts to about 20% at 0.42 K and becomes smaller with increasing temperature.

Results and Discussion

The experimental heat capacities, average temperatures and temperature increments are given in Table 1. The curvature correction has been applied for the determination of the heat capacity over the whole temperature region investigated. The experimental values below 2.0 K are compared in Fig. 10 with the results of previous measurements on copper in this temperature region. The open triangle and square represent the individual experimental points of previous measurements,[5,9] while a solid line is a smoothed curve calculated as an average of the data obtained by other two groups.[6-8] The present data (solid circle) agree well with these previous results except for several points around 1.0 K, which are scattered within ±2%. It may be mainly caused by rather small temperature increments in the present heat capacity measurement in this temperature region. On the whole, however, the calibration accuracy of the present thermometer below 1.5 K seems to be satisfactory.

The heat capacities of copper were fitted to the following equation proposed by Barron and Morrison[10] for the heat capacity of metallic solids,

$$C_p=\sum_{i=1}^{n}A_iT^{2i-1}, \qquad (2)$$

by using the method of least squares weighted with $1/C_p^2$, so that the sum of squares of the fractional deviations of the observed C_p values from the calculated ones may be minimized. Here, the first term propor-

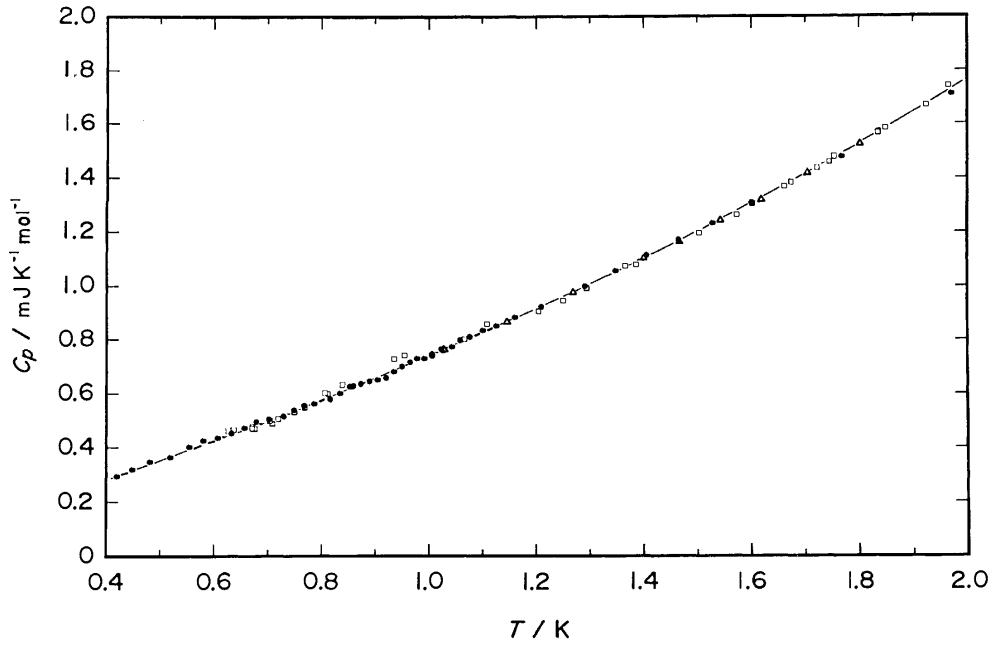

Fig. 10. Heat capacity of copper below 2.0 K: solid curve, Martin,[6,7] and Gmelin and Gobrecht;[8] □, Hurley and Gerstein;[9] △, Osborne *et al.*;[5] ●, present work.

tional to T is the "electronic heat capacity" due to conduction electrons and the remaining higher terms such as T^3, T^5 and so on correspond to the contributions from lattice heat capacity. Osborne *et al.*[5] designated the polynomial as "the copper reference equation" and used it for the purpose of interlaboratory comparison of heat capacity measurements. For the calculation the higher terms greater than $n=6$ were truncated. The "best fit" values of the coefficients were determined to be

$$A_1/\text{mJ K}^{-2}\,\text{mol}^{-1} = 0.69783,$$
$$A_2/\text{mJ K}^{-4}\,\text{mol}^{-1} = 0.45586 \times 10^{-1},$$
$$A_3/\text{mJ K}^{-6}\,\text{mol}^{-1} = 0.26336 \times 10^{-4},$$
$$A_4/\text{mJ K}^{-8}\,\text{mol}^{-1} = -0.39043 \times 10^{-7},$$
$$A_5/\text{mJ K}^{-10}\,\text{mol}^{-1} = 0.16039 \times 10^{-9},$$

and

$$A_6/\text{mJ K}^{-12}\,\text{mol}^{-1} = -0.15882 \times 10^{-12}.$$

The percentage deviations of the present results from the polynomial are shown in Fig. 11. The deviation of the experimental points is within the experimental error of ±0.6% above 4 K, ±1.2% between 4 and 1.5 K, ±1.5% in the range from 1.5 to 0.9 K, and ±2.5% below 0.9 K. As described above, the rather large scatter between 0.9 and 1.5 K may attributable to the small temperature increment in the heat capacity measurement, while the systematic deviation between 1.5 and 4 K may be caused by the discrepancy between the NBS-65 and the T_{58} scales. This problem will be discussed below together with the effect of both temperature scales upon the heat capacity values of copper.

A_1 is the coefficient of electronic heat capacity. The coefficient A_2 corresponds to $12\pi^4R/5[\theta_D(0)]^3$ and thus yields the Debye characteristic temperature $\theta_D(0)$ at 0 K, where R is the gas constant. In Table 2, both

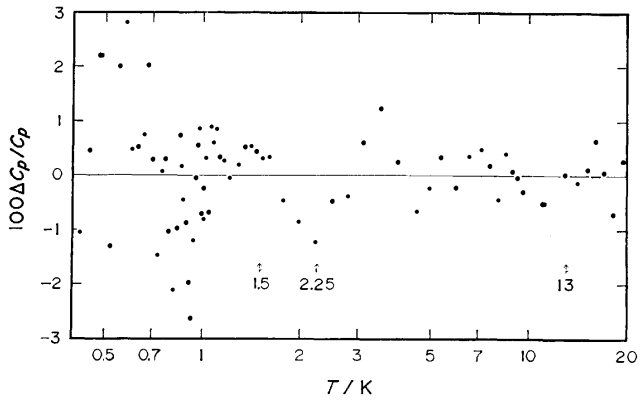

Fig. 11. Percentage deviations of the experimental C_p values from the calculated values, C_p(calcd), by the aid of the copper reference equation; $\Delta C_p = C_p - C_p$(calcd).

values are compared with those reported in recent years by a number of workers.[5-9,11-15] Almost all the measurements have been made by using thermometers calibrated against the T_{58} scale, except for the case of Bloom *et al.*[14] They have used the thermometer based on a combination of the T_{58} and the NBS-65 acoustic scales, as is in our case. The present value of $\theta_D(0)$ is slightly larger than the previous results. The difference may be primarily attributed to the temperature scale above 1.5 K because the data below 1.5 K coincide well with the reported values (see Fig. 10). In the present case, the calibration of the germanium thermometer between 1.5 and 2.0 K is based on the helium-4 vapor pressure scale of 1958 and that between 2.25 and 13 K on the National Bureau of Standards Provisional Scale 2—20 (1965). The temperature scale between 14 and 20 K is based on the International Practical Temperature Scale of 1968. The NBS-65 scale was determined on the assumption that the speed of sound

in helium gas is proportional to the square root of thermodynamic temperature. The NBS-65 scale is known to be higher than the T_{58} scale.[11,16] Therefore, in order to investigate more critically the dependence of the heat capacity of copper on both temperature scales, we should convert the present data based on the NBS-65 scale into those based on the T_{58} scale in the temperature range between 1 and 5 K.

To do this, we estimated the relationship between the T_{58} and the $T_{NBS\text{-}65}$ scales by use of the numerical values listed in reference (11) and obtained the following equation;

$$T_{58} = -0.1534\times10^{-2} + 0.9982\ (T_{NBS\text{-}65}) - 0.5340\times10^{-4}\ (T_{NBS\text{-}65})^2. \quad (3)$$

For examination of the dependence of heat capacity on the two different temperature scales, two sets of values concerning A_1 and $\theta_D(0)$ were calculated by use of the heat capacity data in the range from 1 to 5 K. Firstly, the data due to the $T_{NBS\text{-}65}$ scale were fitted to the equation,

$$C_p = A_1T + A_2T^3, \quad (4)$$

by the method of least squares with a weight of $1/C_p^2$ and A_1 and $\theta_D(0)$ were determined. Secondly, the heat capacity data recalculated based on the T_{58} scale (Eq. 3) were also fitted to Eq. 4. Two sets of the parameters A_1 and $\theta_D(0)$ are given in Table 2. The corrected values show evidently a tendency to approach the reported values. The $T_{NBS\text{-}65}$ scale itself is smoother than the T_{58} scale as previously described, but it is, for the moment, realized by use of only the acoustic thermometer in U. S. National Bureau of Standards. The present germanium thermometer has been calibrated above 2.25 K not directly against the $T_{NBS\text{-}65}$ scale but through a secondary thermometer possessed by CryoCal Co. It is, therefore, plausible to consider that the extra errors have been included in the process of calibration. Another possible reason for the deviation of the heat capacity of copper may be caused by different qualities of copper from sample to sample, because the original data for the evaluation of the standard values[11] include heat capacity measurements on a variety of coppers other than the calorimetry standard copper. At any rate, the temperature scales at low temperatures are hoped to be unified internationally as soon as possible.

By use of this calorimeter, we have measured the heat capacity of a five-coordinated ferromagnet, Fe-$[S_2CN(C_2H_5)_2]_2Cl$, in the temperature range from 0.4 to 20 K. The detailed results will be published in due course.[17]

This work was partially supported by Grant-in-Aid for Fundamental Scientific Research from the Ministry of Education. The authors thank Dr. Darrell W. Osborne for providing them the 1965 Calorimetry Conference Copper. Experimental assistance by Mr. Masanori Yoshikawa is also gratefully acknowledged.

Structural Studies of Asymmetric Hydrogenation. II*. The Crystal Structure of Methyl(R(+)-α-methylbenzylamine)-bis(dimethylglyoximato)cobalt(III) Benzene Solvate

Yuji Ohashi and Yoshio Sasada

Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received January 28, 1977)

The structure of methyl(R(+)-α-methylbenzylamine)bis(dimethylglyoximato)cobalt(III) benzene solvate has been determined by X-ray crystal analysis. The crystal is orthorhombic; space group, $P2_12_12_1$; $Z=4$ with $a=14.074(1)$, $b=14.390(1)$, and $c=12.202(1)$ Å. The structure was deduced by the heavy-atom method and refined by the block-diagonal least-squares method to a final R value of 0.063 for 1413 observed reflections. The symmetry of the bis(dimethylglyoximato)cobalt moiety has been lowered from D_{2h} to C_{2h} as a result of the steric repulsion from optically active amine. It is proposed that this deformation is a factor inducing the asymmetry in the hydrogenation catalyzed by the complex of bis(dimethylglyoximato)cobalt and the active amine.

It has recently been shown that the complexes of bis(dimethylglyoximato)cobalt (abbreviated to Co(dmg)$_2$ or cobaloxime) and optically active amine catalyze the asymmetric hydrogenation of olefins with the CH_2=CXY formula, where X and Y are nucleophilic and electrophilic substituents respectively.[2-7] The hydrogenation proceeds according to the scheme shown in Fig. 1. We explored the mechanism of inducing the asymmetry by analyzing the structures I, II, and III. In the first place, the title complex was chosen because it is the simplest crystallized complex of the methylcobaloxime and the asymmetric amine. The methyl group does not seem bulky enough to change the structural features of the Co(dmg)$_2$ moiety, and it can be expected that the effect of the optically active amine on the structure of Co(dmg)$_2$ will be revealed.

Experimental

Dark red crystals of the title complex were obtained from a benzene solution. They are unstable in the air. The unit-cell dimensions were determined from zero-layer Weissenberg photographs, using Co$K\alpha$ radiation about the a and c axes. Spacing of 80 high-angle reflections ($\theta \geqq 70°$), calibrated with superposed silicon powder lines, were subjected to the least-squares treatment. The crystal data are summarized in Table 1.

Using a crystal with dimensions of $0.3\times0.2\times0.3$ mm, coated with nail enamel, the intensities for the layers from $hk0$ to $hk15$ and $0kl$ were collected on a Hilger-Watts linear diffractometer with Mo$K\alpha$ radiation. The balanced Y/Zr filter pair was used. Out of 3190 independent reflections ($3° \leqq 2\theta \leqq 55°$), 1418 were observed, those of $I<2.5\,\sigma(I)$ being regarded as unobserved. Only 65 reflections between 50° and 55°(2θ) had non-zero intensities. The usual Lorentz and polarization, but no absorption, corrections were made.

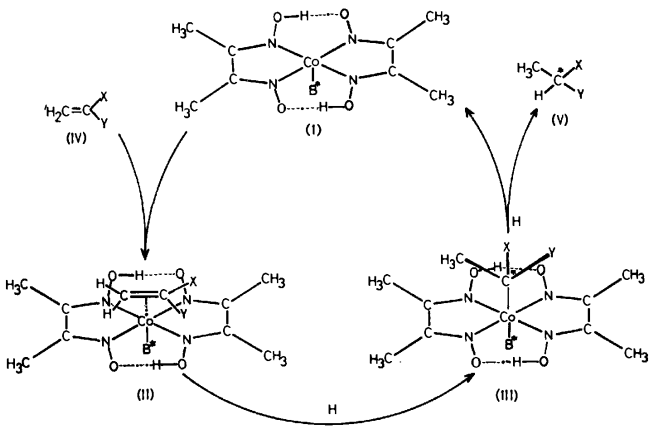

Fig. 1. The reaction path of the asymmetric hydrogenation, where B* is the optically active amine; (I) the catalyzer, (II) the π-complex, (III) the σ-complex, (IV) the substrate, and (V) the product.

* Part I of this series[1] deals with the crystal structure of β-cyanoethyl(D(−)-*erythro*-1,2-diphenyl-2-hydroxyethylamine)bis(dimethylglyoximato)cobalt(III).

Structure Determination

The positions of the cobalt and the six coordinated atoms were obtained from the three-dimensional Patterson function. The other atoms were revealed on the first Fourier map phased with those seven atoms.

The structure was refined by the block-diagonal least-squares methods. After several cycles of the refinement, the five strongest reflections were excluded because they seemed to be affected by secondary extinction. All the hydrogen atoms were found on the three-dimensional difference Fourier map. The final refinement was performed including these hydrogen atoms, with isotropic temperature factors which were assumed to be equal to those of the directly bonded atoms. The weighting

Table 1. Crystal data

Formula	$C_{17}H_{28}N_5O_4Co\cdot C_6H_6$
F. W.	503.5
Crystal system	Orthorhombic
a	14.074(1) Å
b	14.390(1)
c	12.202(1)
Volume of a unit-cell	2471.3 Å^3
Systematic absences	$h00$, h odd
	$0k0$, k odd
	$00l$, l odd
Space group	$P2_12_12_1$
Z	4
Density measured	1.353 g/cm^3
Density calculated	1.353 g/cm^3
μ(Mo$K\alpha$)	7.57 cm^{-1}

Table 2. Fractional atomic coordinates ($\times 10^4$) and thermal parameters ($\times 10^5$) for the non-hydrogen atoms

The anisotropic thermal parameters are of this form:

$$T=\exp\left[-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{13}hl+B_{23}kl)\right].$$

The estimated standard deviations are in parentheses.

scheme of $w=(13.8/|F_o|)^2$ if $|F_o|>13.8$, $w=1.0$ if $13.8\geqq|F_o|\geqq4.6$, and $w=0.2$ if $|F_o|<4.6$ was employed. The final R became 0.063 for 1413 observed reflections. At the final stage, no peaks higher than 0.03 e Å^{-3}, except for the peaks of 0.05 e Å^{-3} around the cobalt atom, were observed on the difference map. The atomic scattering factors were taken from International Tables for X-Ray Crystallography.[8] The final atomic parameters and their standard deviations are given in Table 2 for non-hydrogen atoms and in Table 3 for hydrogen

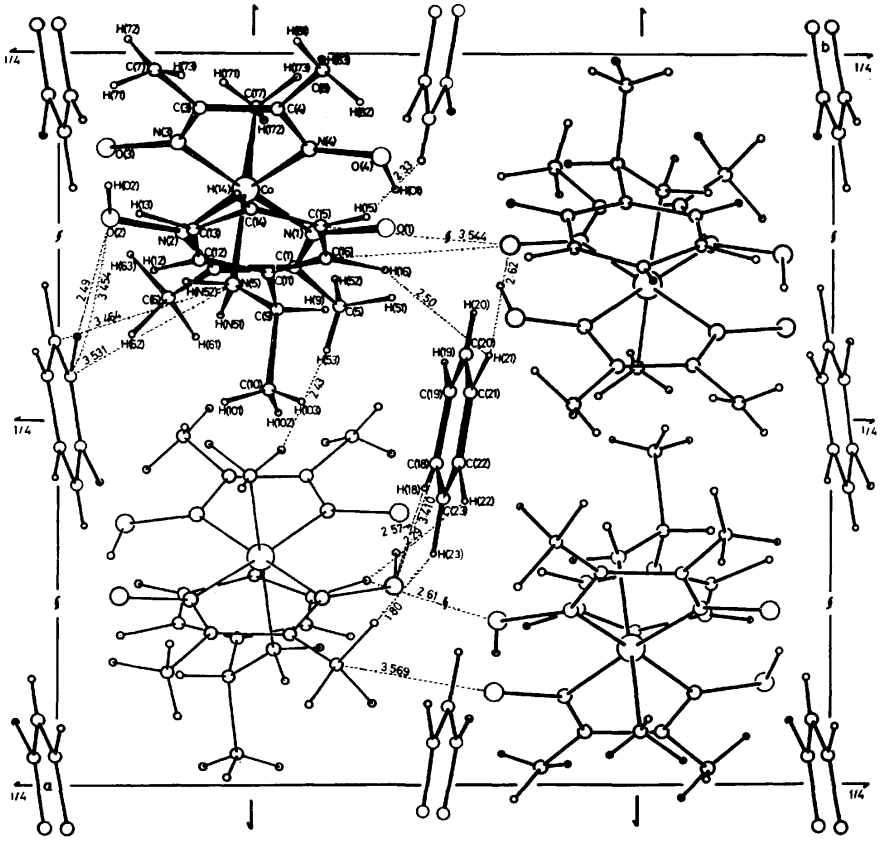

Fig. 2. Projection of the structure along the c axis and the interatomic distances between the Co-complexes and between the Co-complex and benzene. Along the c axis the contacts, 3.775 Å for C(14)···C(6), 2.77 Å for C(15)···H(52), and 2.30 Å for H(15)··· H(52), are observed.

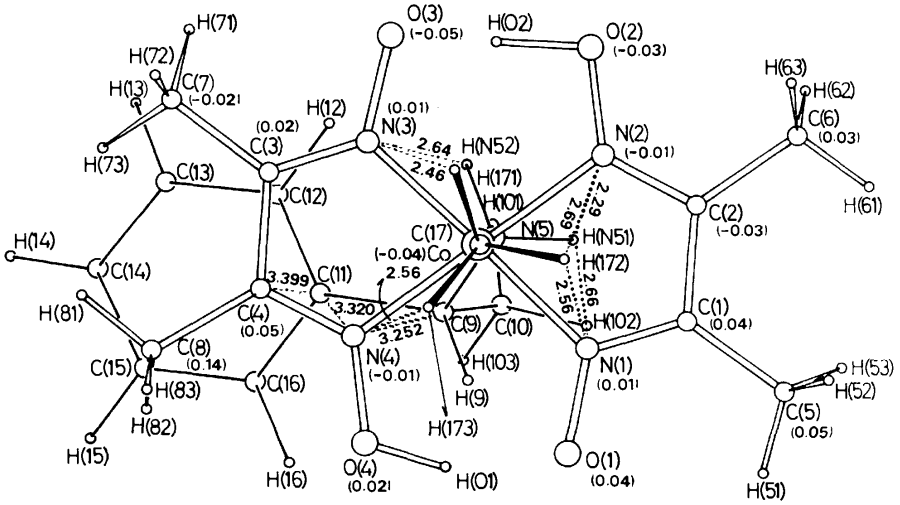

Fig. 3. Projection of the complex to the mean plane of four nitrogen atoms of $Co(dmg)_2$ and the short contacts between non-bonded atoms (l/Å), their threshold values being 3.400 Å for distances between the non-hydrogen atoms and 2.70 Å for those including hydrogen atoms. The deviations of the non-hydrogen atoms of $Co(dmg)_2$ from the plane are in parentheses.

atoms. A list of the observed and calculated structure factors is kept in the office of the Chemical Society of Japan (Document No. 7711).

The computation was done on the HITAC 8800 computer at the University of Tokyo and on the HITAC 8700 computer at Tokyo Institute of Technology. The programs, PROC for the data reduction and TLSU for the determination of the cell dimensions, were used. The other programs used were those in the UNICS Program System[9] with some modification.

Description of the Structure

The crystal structure viewed along the c axis is shown in Fig. 2, in which the short interatomic distances are also given. There are no unusual short contacts between the Co-complexes, or between the Co-complex and the benzene molecule. The mean plane of the

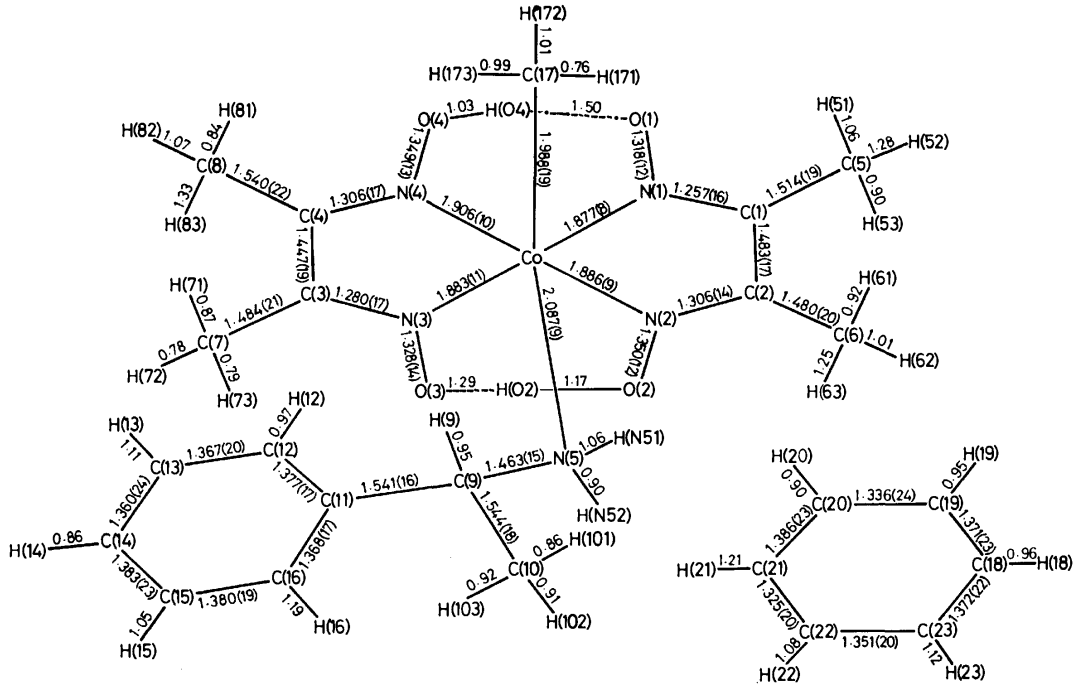

Fig. 4. Bond distances (l/Å). Their standard deviations are in parentheses, while those involving hydrogen atoms are 0.11—0.15 Å and are omitted for clarity.

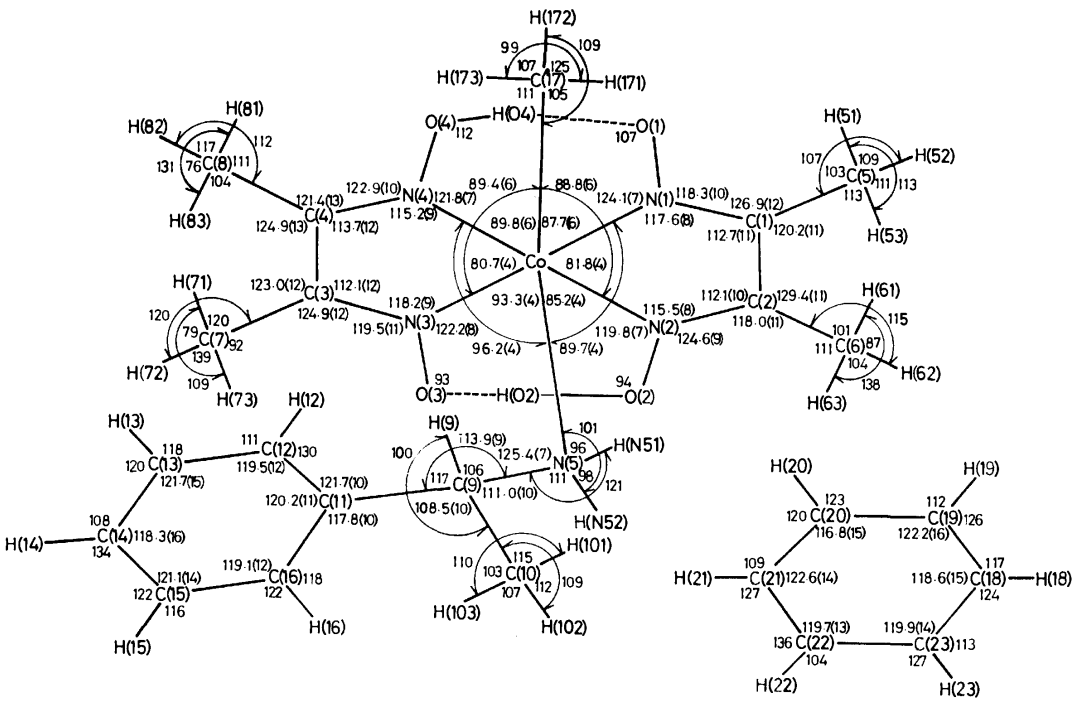

Fig. 5. Bond angles (ϕ/°). Their standard deviations are in parentheses, while those involving hydrogen atoms are 6—14° and are omitted for clarity.

benzene ring is about at right angles to that of $Co(dmg)_2$ and to that of the phenyl ring of α-methylbenzylamine (abbreviated as mba).

The four nitrogen atoms in $Co(dmg)_2$ are coplanar within the limits of 0.01 Å, and the equation of the best plane is given by:

$$-0.8157X + 0.0781Y - 0.5731Z + 2.6438 = 0,$$

where X, Y, and Z are the coordinates (in Å units) referred to the crystal axes. The deviations of the atoms from the plane and the distances between the non-bonded atoms in the complex are shown in Fig. 3. The C(8) atom over the phenyl ring is significantly out of the best plane, probably to avoid the short contact with the phenyl ring. The cobalt atom is slightly displaced from the plane toward mba. The short contact, N(4)···C(9), which is also observed in the complex reported in Part I (abbreviated as β-cne(dphyea)cobaloxime), seems to represent a fairly strong steric repulsion. The Co–N(5) bond makes an angle of 84° with the average plane.

The bond distances and angles are shown in Figs. 4 and 5 respectively. The $Co(dmg)_2$ moieties of aquomethylcobaloxime,[10,11] methylpyridinecobaloxime,[12] and methyl(3-*N*-methylimidazolyl)cobaloxime[12] have the D_{2h} symmetry. Bigotto *et al.*[12] have suggested, on the basis of all the reported structures of the alkylcobaloxime complexes, that the standard values for Co–N, N–O, N–C, and C–CH_3 are 1.879, 1.343, 1.297, and 1.500 Å respectively. In the present complex, however, the bonds of Co–N, N–O, and N–C around N(2) and N(4) are longer than the standard lengths, whereas those around N(1) and N(3) are shorter except for Co–N(3). The hydrogen atoms, H(O1) and H(O2), do not exist at the mid-point of O···O, but come close to O(2) and O(4) respectively. The three angles of Co–N–O, Co–N–C and O–N–C around N(1) are in fair agreement with the corresponding angles of N(3), but are distinct from those of N(2), which, on the other hand, are close to those of N(4). These dimensions indicate that $Co(dmg)_2$ has a two-fold axis perpendicular to its plane and that the symmetry is approximately C_{2h}.

The Co–C distance coincides with those of the related methyl–Co(III) complexes.[10–14]

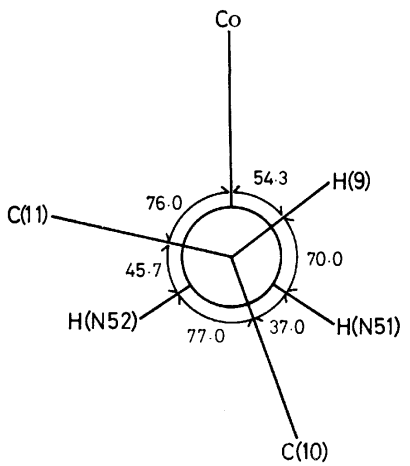

Fig. 6. Newman projection of mba along C(9)–N(5) with the angles (ϕ/°) between the projected bonds.

The values of Co–N(5) and Co–N(5)–C(9) (2.087 Å and 125.4°) are nearly equal to those in β-cne(dphyea)-cobaloxime (2.08 Å and 126°), but significantly greater than the corresponding distance and angle of 2.001 Å and 119.5° in bis(aniline)cobaloxime chloride.[15] This is probably because of the steric repulsion between Co-$(dmg)_2$ and the pheny ring of mba; the 'trans-influence' suggested by Brückner and Randaccio[16] would also be included. The conformation of mba is a staggered form as shown in Fig. 6. The N(5)–C(9) length of 1.463 Å is close to the usual C–N(amine) distance (1.472±0.005 Å),[17] and the C(9)–C(11) value of 1.541 Å is slightly longer than the usual C–C(aromatic) bond (1.505±0.005 Å).[17] The phenyl ring is planar within an error of 0.02 Å, and makes an angle of 10° with the $Co(dmg)_2$ plane. The deviation of C(9) from the phenyl ring plane is 0.04 Å, C(9)–C(11) making an angle of 2.2° with the plane.

Discussion

A fairly strong steric repulsion between $Co(dmg)_2$ and the axial ligand of the asymmetric amine was observed in the present complex. The $Co(dmg)_2$ moiety is deformed significantly, and its symmetry changes from D_{2h} to C_{2h} as a result of the repulsion. In order to explore the reaction mechanism, it is necessary to examine whether or not such a deformation can exist in the solution.

In conformation analysis to solve the problem, we made some simplifying assumptions which will not lead to any serious errors:

(1) The structure of $Co(dmg)_2$ has the D_{2h} symmetry and the dimensions suggested by Bigotto *et al.*;[12]

(2) the dimensions and the conformation of mba are the same as those in the crystal, because the conformation around N(5)–C(9) is a stable staggered form and the rotation around C(9)–C(11) is prevented by the $Co(dmg)_2$ plane when the amine enters into coordination;

(3) the bond of Co–N(5) is perpendicular to the $Co(dmg)_2$ plane and has the same length as that in the crystal;

(4) the formulae and the parameters for the van der Waals energy are those proposed by Giglio,[18] because his parameters were deduced from the crystal of dimethylglyoxime;

(5) the parameters of the methyl groups of $Co(dmg)_2$ are the same as those of the nitrogen atom, because the methyl groups probably rotate freely around the C–CH_3 bonds.[19]

On such simplifications, the van der Waals energy was calculated by changing the rotation angle, ϕ, around Co–N(5), as shown in Fig. 7. The minimum energy was obtained at the angle of −13°, which is in good agreement with the observed dihedral angle of N(4)–Co–N(5)–C(9), −17.6°, in the crystal. The N(4)···C(9) distance in the structure of the miniumm energy was 2.239 Å, which is shorter than that of the crystalline state. To avoid such short contact, N(5) should be driven toward N(2) and Co–N(4) should be lengthened, as observed in the crystal. It is reasonable to assume

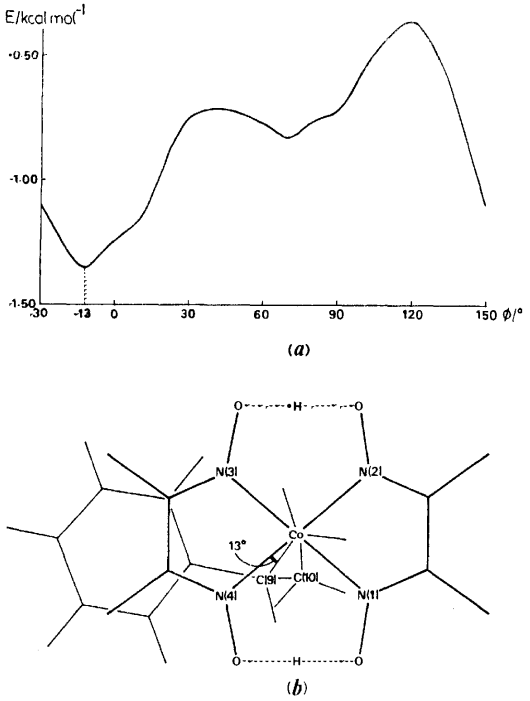

Fig. 7. (a) The variation of van der Waals energy, E, with the rotation angle, ϕ, around Co–N(5), $Co(dmg)_2$ being fixed. The axial ligand of mba is rotated clockwise from the position in which the dihedral angle of N(4)–Co–N(5)–C(9) is zero. (b) The conformation with the minimum energy.

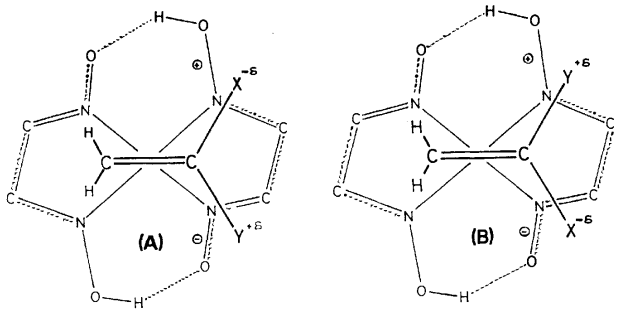

Fig. 8. Two possible ways in which the substrate approaches the active site of the catalyzer.

that such an elongation of Co–N(4) causes the change of the π-electron distribution and the geometry of dmg from D_{2h} to C_{2h}. The negative charge in dmg is localized on the shorter bonds.

The hydrogenation proceeds when the substrate has the nucleophilic and electrophilic substituents adjacent to the C=C double bond.[2] These observations suggest that the electrostatic force controls the way in which the substrate comes close to the active site of the catalyzer. As shown in Fig. 8, the mode of approaching, (A), is more favorable than (B) in view of the electrostatic interaction, so that one configuration of the asymmetric carbon in the intermediate σ-complex (termed (III) in Fig. 1) should be preferable to the other. We propose that this is a factor for inducing the asymmetry in the hydrogenation. Besides the factor proposed above, some others, for example, the van der Waals force, probably affect the overall optical yield in the step of π-bond formation and in the following steps illustrated in Fig. 1. We intend to examine those factors and correlate the optical yield to each factor in further studies of this series.

The authors are grateful to Dr. Yoshiaki Ohgo and Professor Juji Yoshimura for kindly supplying the specimens and for their valuable discussions.

Ultrasonic Study of Aqueous Solutions of Amines

Sadakatsu NISHIKAWA, Unpei OTANI, and Mitsuo MASHIMA

Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjo-machi, Saga 840

(Received January 31, 1977)

Ultrasonic absorptions in aqueous solutions of allylamine have been measured in the frequency range from 8.5 to 220 MHz at 20 °C. Only a single relaxational absorption has been observed in the concentration range from 0.0562 to 4.00 M; this absorption has been attributed to the proton-transfer reaction. The rate constants and the standard volume change due to the reaction have been determined, and the results are compared with those for aqueous solutions of other amines previously published. It has been elucidated from the ultrasonic absorption data that the presence of the intermediate in the proton-transfer reaction is required in order to analyze the ultrasonic absorption mechanisms quantitatively. The hydrophobic effect in the aqueous solutions of amines has also been discussed.

Ultrasonic absorptions in aqueous solutions of amines are characterized by two kinds of relaxation processes. One is the phenonemon associated with the Peak Sound Absorption Concentration, which is observed in relatively concentrated solutions. Barfield and Schneider,[1] and Andreae *et al.*[2] have attributed the phenomenon to the solute-solvent interactions. However, on the basis of ultrasonic studies in aqueous solutions of several amines, the present authors[3,4] have concluded that the phenomenon is, rather, due to the aggregation reaction of amine molecules not ionized.

The other is the relaxation phenomenon due to the proton-transfer reaction. Maass *et al.*[5,6] have reported the kinetic data of the proton-transfer reaction for various amines; also there have been several discussions for the role of the perturbation of the proton-transfer equilibria of the basic residues of proteins in aqueous solutions.[7,8]

The present authors intend to investigate the correlations between these two kinds of phenomena in ultrasonic absorptions. In this paper the experimental results in an aqueous solution of allylamine will be reported, and the results will be compared with those for other amines.

Experimental

The ultrasonic absorption measurements were made at the odd harmonics of 0.5, 5, and 20 MHz x-cut quartz transducers by using the pulse technique. The frequency range was from 8.5 to 220 MHz. The sound velocity was measured by a sing-around method operated at 1.92 MHz. The major mechanical features of the apparatus have been shown elsewhere.[9] The values of pH were determined by means of Hitachi-Horiba F-5 pH-meter. A saturated solution of $Ca(OH)_2$ was used as the standard reference of the electrode of the pH-meter. All the measurement were made in a dry nitrogen gas atmosphere in order to prevent the contamination of air, for the aqueous solutions of amines are highly basic. The allylamine was distilled once from a commercial product of a G. R. grade. The purity was confirmed by the gas-chromatographic method to be more than 99.9%. NaOH and HCl (guaranteed reagent) were used to obtain the desirable hydroxide concentrations. The measurement cells were immersed in a water bath mantained at a constant temperature within ±0.002 °C. All the measurements were made at 20 °C.

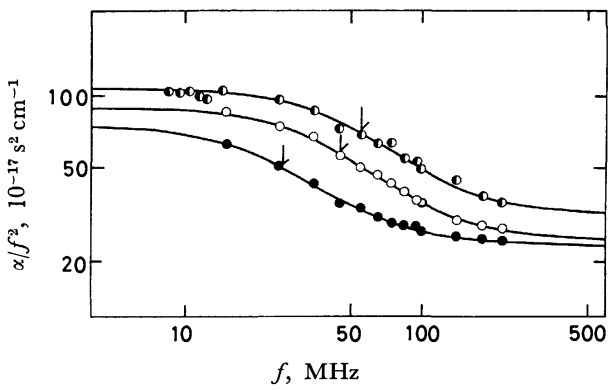

Fig. 1. Representative ultrasonic absorption spectra in aqueous solutions of allylamine at 20 °C. The arrow shows the relaxation frequency. ◐: 2.86 M, ○: 0.435 M, ●: 0.0562 M.

Results

The sound absorption caused by a single relaxation process can generally be expressed by

$$\alpha/f^2 = A/[1+(f/f_r)^2] + B, \quad (1)$$

where α is the sound absorption coefficient; f, the frequency; f_r, the relaxation frequency; and A and B, the constants. Figure 1 shows some representative ultrasonic absorption spectra in an aqueous solution of allylamine. The spectra in the concentration range up to 4.00 M are all characteristic of a single relaxation process; the ultrasonic parameters, A, B, and f_r, were determined so as to obtain the best fit of the experimental data to Eq. 1. The parameters are listed in Table 1, along with the values of the density, the pH, and the activity coefficient of the solutions used. The activity coefficients were calculated by means of Daviss' equation, $-\log\gamma = 0.5[(\sqrt{I}/(1+\sqrt{I})) - 0.3I]$, where I is the ionic strength. The relaxation frequencies and the excess absorptions increase continuously with the solute concentrations, and finally both of them reach their constant values. From these facts it is expected that only a single relaxation process is observed in the frequency range measured. The excess absorption is observed even in relatively dilute solution; thus, the perturbation of the following equilibrium will be considered as the excess absorption mechanism:

$$R\text{-}NH_3^+ + OH^- \underset{k_b}{\overset{k_f}{\rightleftharpoons}} R\text{-}NH_2 + H_2O, \quad (2)$$

where k_f and k_b are the forward and backward rate

constants respectively. The concentration dependences of the relaxation frequency and the maximum excess absorption per wavelength, μ_{max}, for the above mechanism can be written as follows:

$$2\pi f_r = 2k_f\gamma^2[OH^-] + k_b, \quad (3)$$

and

$$\mu_{max} = Af_r c/2 = \pi\rho c^2(\Delta V)^2\Gamma_c/2RT, \quad (4)$$

where

$$\Gamma_c = (1/[OH^-] + 1/[R\text{-}NH_3^+] + 1/[R\text{-}NH_2])^{-1}, \quad (5)$$

and where γ is the activity coefficient; ρ, the density; c, the sound velocity; ΔV, the standard volume change associated with the reaction. The relaxation frequencies are plotted in Fig. 2 as functions of $\gamma^2[OH^-]$; the straight line drawn provides the rate constants from the slope and intercept, which are determined by using the least-mean square method. For determining the rate constants, the experimental values in the concentration range below 0.749 M were used because in the concentrated solutions the Daviss equation might not hold and another reaction, such as molecular aggregation with hydrogen-bonding, might affect the reaction of Eq. 2. The standard volume change is determined by Eqs. 4 and 5. The obtained values are listed in Table 2 along with the results of other amines. The equilibrium constants obtained by the $K=k_b/k_f$ relation are abnormally larger than the dissociation constants in the literature, as may be seen in Table 2. The dissociation constant, K_b, was calculated from the pH dependence on the analytical concentration by the equation, $K_b=\gamma^2[OH^-]/(C_o-[OH^-])$; we obtained the value of 3.75×10^{-5} M[10] for K_b which was in agreement with that in the literature (see Table 2).

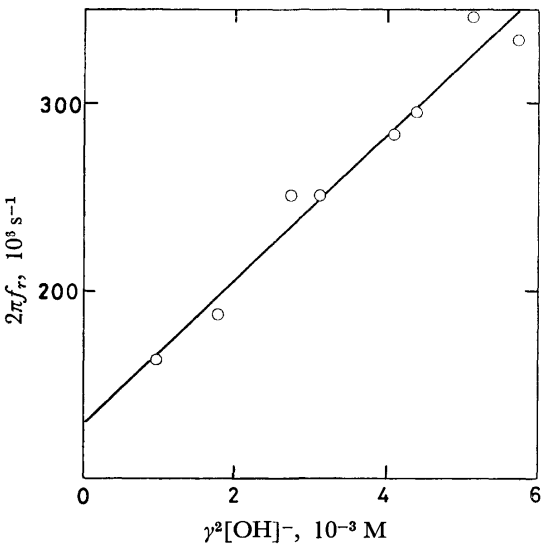

Fig. 2. The plots of $2\pi f_r$ *vs.* $\gamma^2[OH^-]$ in aqueous solutions of allylamine at 20 °C.

In order to ascertain the excess absorption mechanism associated with the reaction expressed by Eq. 2, the pH dependence of the absorption at a constant concentration of allylamine has been investigated by adding small amounts of NaOH or HCl. However, the relaxation frequencies obtained did not agree with those calculated by means of Eq. 3; also the pH dependence of μ_{max} was not in accordance with the theory. These facts indicate the presence of another equilibrium in the aqueous solutions of amines.

Discussion

The investigations of a number of proton-transfer reactions of compounds containing the $-NH_2$ group have been performed and the kinetics have been rationalized in terms of the following mechanism:[7,8,13]

$$R\text{-}NH_3^+ + OH^- \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} R\text{-}NH_3^+\cdots OH^- \underset{k_{32}}{\overset{k_{23}}{\rightleftharpoons}} R\text{-}NH_2 + H_2O. \quad (6)$$

If the second step is faster than the first one, we get the following relations for each process:

$$2\pi f_{r1} = k_{12}\gamma^2([R\text{-}NH_3^+] + [OH^-]) + k_{21}(1+K_{23}^{-1})^{-1}, \quad (7)$$

TABLE 2. RATE CONSTANTS AND STANDARD VOLUME CHANGE OF PROTON-TRANSFER REACTIONS IN AQUEOUS SOLUTIONS OF AMINES

Solute	k_f (10^{10} M s^{-1})	k_b (10^7 s^{-1})	$K(k_b/k_f)$ (10^{-3} M^{-1})	ΔV (cm^3 mol^{-1})	K_b[a] (10^{-4} M^{-1})	Ref.
Propylamine	2.5	3.7	1.5	21	3.73	5)

Allylamine	1.9	13	6.8	29	0.368	This work
Butylamine	4.1	12	2.9	32	4.44	16)
Pentylamine	3.0	7.5	2.5	25	4.94	4)
Octylamine	1.0	7.6	7.6	32	4.5	17)

a) The dissociation constants, K_b, are taken from Refs. 10 and 11.

TABLE 3. REEXAMINED RATE AND EQUILIBRIUM CONSTANTS OF PROTON-TRANSFER REACTIONS

Solute	k_{12} (10^{10} M s^{-1})	k_{21} (10^7 s^{-1})	K_{12} (10^3 M)	K_{23}
Propylamine	2.5	4.7	0.53	4.0
Allylamine	1.9	13	0.15	190
Butylamine	4.1	14	0.30	6.5
Pentylamine	3.0	8.8	0.33	5.1
Octylamine	1.0	8.1	0.12	17

$$2\pi f_{r2} = k_{23} + k_{32}, \tag{8}$$

where f_{r1} and f_{r2} are the relaxation frequencies associated with the first and second step respectively, and where $K_{23}=k_{23}/k_{32}$. Comparing Eq. 3 with Eq. 7, the rate constants obtained from the plots of $2\pi f_r$ *vs.* γ^2-[OH$^-$] may easily be written as follows:

$$k_f = k_{12}, \quad k_b = k_{21}(1+K_{23}^{-1})^{-1}. \tag{9}$$

The dissociation constant, K_b, which is determined by the static method, may be expressed by the following equation, considering the detailed equilibrium of Eq. 6:

$$K_b^{-1} = K_{12} + K_{12}K_{23}, \tag{10}$$

where $K_{12}=k_{12}/k_{21}$. The following relation is derived from Eqs. 9 and 10:

$$K_{23} = k_b K_b^{-1}/k_f. \tag{11}$$

The values of the rate constants, k_{12} and k_{21}, and the equilibrium constants, K_{12} and K_{23}, as calculated from Eqs. 9 and 11, are listed in Table 3. The absorption data in aqueous solutions of other amines reported previously[4,16,17] were reexamined by using the above treatment; these results are also listed in Table 3. The values of K_{23} are larger than unity, which reflects the fact that the intermediate of the hydrolysis of amines is not very stable.

Debye[14] has derived an expression for the diffusion-controlled rate of the reactions of ions in solutions and Eigen[15] has considered the reverse process of dissociation to form ions. The rate constant, k_{12}, of the first step in Eq. 6 is reasonable for the diffusion-controlled reaction, because the rate constant determined agrees very closely with the results obtained experimentally and theoretically for other compounds.[4,7] However, the rate constant of the reverse process is too low because its order should be 10^{10} s^{-1} according to Eigen's theory;[7] the similar discrepancies have also been found by Applegate *et al.*[7] for some aminoacids and polypeptides.

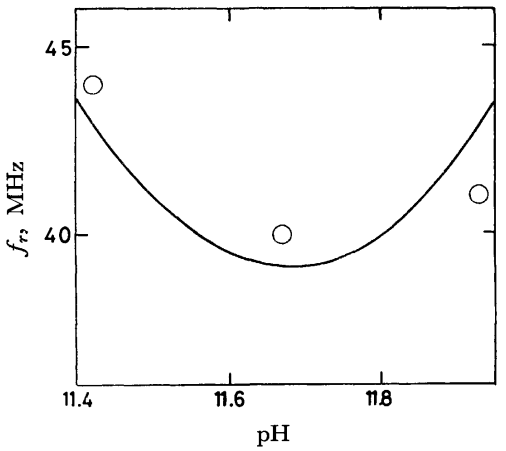

Fig. 3. The pH dependence of the relaxation frequency associated with the proton-transfer reaction. The solid curve is the theoretical value.

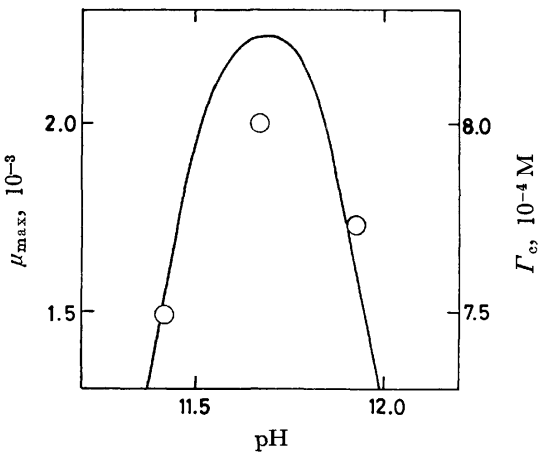

Fig. 4. The pH dependence of μ_{max} and Γ_c. The solid curve is the calculated value of Γ_c.

Though the pH dependences of f_r and μ_{max} are difficult to be interpreted only in terms of the process of Eq. 2, the introduction of the intermediate expressed by Eq. 6 allows us to analyze the dependences quantitatively. Figure 3 shows the pH dependences of the relaxation frequencies. The solid line represents the relaxation frequencies calculated by Eq. 7, where the analytical concentration has to be written as $C_0=[R\text{-}NH_3^+]+[R\text{-}NH_3^+\cdots OH^-]+[R\text{-}NH_2]$. The pH dependence of μ_{max} is also shown in Fig. 4, along with that of Γ_c

which is nearly dependent on μ_{max} (see Eqs. 4 and 5). Though the contribution from the fast process to the slow one for μ_{max} should be taken into account, the effects were very small. As may be seen in Fig. 4, the tendency of the pH dependence of μ_{max} is similar to that of Γ_c. These facts confirm that the excess absorption mechanism in the aqueous solution of allylamine is due to the perturbation of the equilibrium of Eq. 6.

In aqueous solutions of allylamine, only one kind of excess absorption is found in the frequency range investigated here; the character of the excess absorption is similar to that obtained for propylamine.[4] However, another excess absorption in aqueous solutions of butyl,[3] pentyl,[4] and octylamine[18] has been observed in addition to that due to the proton-transfer reaction. The cause of the latter excess absorption has quantitatively interpreted by the molecular aggregation theory,[4,18] and this excess absorption may be the main cause of the phenomenon associated with the Peak Sound Absorption Concentration. These results lead us to predict that the characteristic ultrasonic absorption due to the molecular aggregation reaction is associated with the hydrophobicity in amine molecules; that is, the aggregate may be formed by hydrophobic effects. With decrease in the hydrophobic effects, the excess absorption disappears in the frequency range measured except for the absorption due to the proton-transfer reaction.

The background absorption, B, in Eq. 1 increases with the analytical concentration. This means that the other excess absorption, *e. g.*, that due to the aggregation reaction with hydrogen-bondings, may exist in the higher-frequency range. However, this is beyond the scope of this paper.

In conclusion, the present ultrasonic study has revealed that the excess absorption mechanism in aqueous solutions of allylamine is attributable to the hydrolysis which proceeds through an intermediate, and the excess absorption associated with the Peak Sound Absorption Concentration has not been observed.

The Effective π-Electron Hamiltonian for the Excited State. The Effect of Σ-Π Interaction*

Izumi MAKI, Kazuo KITAURA, and Kichisuke NISHIMOTO

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received February 2, 1977)

The effective π-electron Hamiltonian for the excited molecule has been derived from the singly excited configuration interaction method (SECI) considering Σ-Π interaction. In this paper, the zero-differential overlap (ZDO) approximation has been employed. Then, in SECI scheme, π-π^* and σ-σ^* configurations interact through the exchange type MO-integrals over π- and σ-MO's. As the result, only the excited singlet states are modified by Σ-Π interaction. So that the triplet states remain unchanged by this type of interaction.

When the ZDO approximation is employed, the effective electron interaction over AO's, $\tilde{\gamma}_{\mu\nu}$, can be derived. It is found that $\tilde{\gamma}_{\mu\nu}$'s are represented approximately in terms of topological matrix, so named 'bond index matrix'.

Semiempirical LCAO-SCF-MO method for the π-electron systems, namely P-P-P method,[1] has been succeeded for both the ground and excited states. However, there are still some problems left behind. For the calculations of the excitation energies, there is no good formula of the electron repulsion integrals for both the triplet and singlet states. It is generally known that Nishimoto-Mataga approximation[2] gives good results for the calculation of the excited singlet states but not good for the triplet states. On the other hand, Ohno-Klopman[3] and P-P[4] approximations calculate the satisfactory energy separation between the first singlet state and triplet state, but not good for the excited singlet states. These problems seem to be mainly caused by the difference in the Σ-Π interaction at the singlet and triplet states and also that in the electron correlation between each state. In this paper, we treat only the former problem. Concerning the Σ-Π interaction, there are some approaches based on MO techniques,[5] one approach is the MO-CI method considering all valence electrons, such as CNDO approximation.[6] However, CNDO method is suitable for the calculations of the ground state properties, but not appropriate for the excited state. In order to improve this point, Bene and Jaffe introduced a σ-π separation parameter and obtained good results of n-π^* and π-π^* excitation energies.[7] Recently, Lipari and Duke modified CNDO/2 by introducing empirical formula for the electron repulsion integrals and using different bonding parameters.[8]

In this paper, we analyze the Σ-Π interaction explicitly from the standpoint of the π-electron approximation. We also derive the effective π-electron interaction at the excited state considering its effect and derive the effective electron repulsion integrals, $\tilde{\gamma}_{\mu\nu}$.

Theoretical

The Effective π-Electron Hamiltonian for the Excited State. We are concerning with a closed system in the ground state and assume that the Hartree-Fock orbitals are already obtained. We use the following notation; i, j, k, l,···for the occupied molecular orbitals and α, β, γ, δ,···for the unoccupied ones.

Singly excited configuration interaction (SECI) method is our starting point.[9] The excited state is expressed as follows;

$$\Phi = \sum_{i\alpha} C_{i\alpha} |{}^{\alpha}_{i}>, \tag{1}$$

where, $|{}^{\alpha}_{i}>$ represents the singly excited configuration associated with the excitation of an electron from i to α $C_{i\alpha}$'s are coefficients to be determined by the variation method. The variation of the expectation value of the total Hamiltonian $\boldsymbol{H}$ leads to the following seqular equation,

$$[\boldsymbol{H} - \boldsymbol{E}\boldsymbol{I}]\boldsymbol{C} = 0, \tag{2}$$

where, $\boldsymbol{H}$ is Hamiltonian matrix represented by singly excited configurations. $\boldsymbol{C}$ is the coefficient vector. For the Simplicity, we use the ZDO approximation in this paper. Then configurations $|{}^{\pi}_{\pi}>$ and $|{}^{\sigma}_{\sigma}>$ do not interact with $|{}^{\sigma}_{\pi}>$ or $|{}^{\pi}_{\sigma}>$. So that the matrix can be divided into two mutually independent groups; one is made from $|{}^{\pi}_{\pi}>$ and $|{}^{\sigma}_{\sigma}>$ and another is made from $|{}^{\sigma}_{\pi}>$ and $|{}^{\pi}_{\sigma}>$. As we are interested in the π-π^* excited state, hereafter we treat only the former group. In order to get the effective π-electron Hamiltonian for the excited state, we divide the configurations into two subgroups. One is a subgroup containing $|{}^{\pi}_{\pi}>$ and another is one containing $|{}^{\sigma}_{\sigma}>$. Then Eq. 2 is written as follows;

$$[\boldsymbol{H}^{\Pi\Pi} - \boldsymbol{E}\boldsymbol{I}]\boldsymbol{C}^{\Pi} + \boldsymbol{H}^{\Pi\Sigma}\boldsymbol{C}^{\Sigma} = 0, \tag{3-a}$$

$$\boldsymbol{H}^{\Sigma\Pi}\boldsymbol{C}^{\Pi} + [\boldsymbol{H}^{\Sigma\Sigma} - \boldsymbol{E}\boldsymbol{I}]\boldsymbol{C}^{\Sigma} = 0, \tag{3-b}$$

where, $\boldsymbol{H}^{\Pi\Pi}$, $\boldsymbol{H}^{\Sigma\Sigma}$, and $\boldsymbol{H}^{\Sigma\Pi}$ mean the submatrices with elements $<{}^{\pi}_{\pi}|\boldsymbol{H}|{}^{\pi}_{\pi}>$, $<{}^{\sigma}_{\sigma}|\boldsymbol{H}|{}^{\sigma}_{\sigma}>$ and $<{}^{\sigma}_{\sigma}|\boldsymbol{H}|{}^{\pi}_{\pi}>$, respectively. $\boldsymbol{C}^{\Pi}$ and $\boldsymbol{C}^{\Sigma}$ are coefficient vectors corresponding to π-π^* and σ-σ^* subspaces, respectively. If the matrix $[\boldsymbol{H}^{\Sigma\Sigma} - \boldsymbol{E}\boldsymbol{I}]^{-1}$ has no singularities at π-π^* excitation energies, $\boldsymbol{C}^{\Sigma}$ can be given as follows from Eq. 3-b,

$$\boldsymbol{C}^{\Sigma} = -[\boldsymbol{H}^{\Sigma\Sigma} - \boldsymbol{E}\boldsymbol{I}]^{-1}\boldsymbol{H}^{\Sigma\Pi}\boldsymbol{C}^{\Pi}. \tag{4}$$

Substituting this equation into Eq. 3-a, we obtain the equation containing only $\boldsymbol{C}^{\Pi}$ explicitly.

$$[\boldsymbol{H}^{\Pi\Pi} - \boldsymbol{H}^{\Pi\Sigma}(\boldsymbol{H}^{\Sigma\Sigma} - \boldsymbol{E}\boldsymbol{I})^{-1}\boldsymbol{H}^{\Sigma\Pi} - \boldsymbol{E}\boldsymbol{I}]\boldsymbol{C}^{\Pi} = 0, \tag{5}$$

or;

$$|\boldsymbol{H}^{\Pi\Pi} - \boldsymbol{H}^{\Pi\Sigma}(\boldsymbol{H}^{\Sigma\Sigma} - \boldsymbol{E}\boldsymbol{I})^{-1}\boldsymbol{H}^{\Sigma\Pi} - \boldsymbol{E}\boldsymbol{I}| = 0. \tag{6}$$

* A preliminary report of this work was presented at the Oji International Seminar on Theories and *Ab Initio* Computations of Molecular Electronic Structure, Hokkaido, September 1976

When we write,

$$\tilde{\boldsymbol{H}}^{\Pi\Pi} = \boldsymbol{H}^{\Pi\Pi} - \boldsymbol{H}^{\Pi\Sigma}[\boldsymbol{H}^{\Sigma\Sigma} - \boldsymbol{EI}]^{-1}\boldsymbol{H}^{\Sigma\Pi}, \tag{7}$$

then, the eigenvalue problem to be solved becomes as follows;

$$|\tilde{\boldsymbol{H}}^{\Pi\Pi} - \boldsymbol{EI}| = 0. \tag{8}$$

Thus, $\tilde{\boldsymbol{H}}^{\Pi\Pi}$ represents the matrix associated with the effective π-electron Hamiltonian of the excited state, $\tilde{\boldsymbol{H}}(\pi)$. And $\tilde{\boldsymbol{H}}(\pi)$ can be expressed in the operator form, referring to the partitioning technique proposed by Löwdin,[10]

$$\tilde{\boldsymbol{H}}(\pi) = \boldsymbol{H} - \boldsymbol{VP}\frac{1}{\boldsymbol{H}-\boldsymbol{E}}\boldsymbol{PV}. \tag{9}$$

Where, $\tilde{\boldsymbol{H}}(\pi)$ is defined only in the subspace spanned by π-π^* configurations and V means the operator associated with the electron repulsions. As we use the Hartree-Fock basis, Σ-Π interaction appears through the electron repulsions. $\boldsymbol{P}$ in Eq. 9 represents the projection operator defined by Eq. 10, which picks up σ-σ^* configurations.

$$\boldsymbol{P} = \sum_{\sigma\sigma^*} |{}^{\sigma^*}_{\sigma}><{}^{\sigma^*}_{\sigma}|. \tag{10}$$

Thus the matrix elements associated with $\tilde{\boldsymbol{H}}(\pi)$ coincide with Eq. 7. Referring to Eq. 9, the effective π-electron interaction $\tilde{\boldsymbol{V}}(\pi)$ can be defined as follows;

$$\tilde{\boldsymbol{V}}(\pi) = \boldsymbol{V} - \boldsymbol{VP}\frac{1}{\boldsymbol{H}-\boldsymbol{E}}\boldsymbol{PV}. \tag{11-a}$$

$$\tilde{\boldsymbol{V}}(\pi) = \sum_{\xi\eta}\tilde{v}_{\xi\eta} \tag{11-b}$$

$$\boldsymbol{V}(\pi) = \sum_{\xi\eta} v_{\xi\eta}, \tag{11-c}$$

$v_{\xi\eta}$ means potential between ξ and η electrons and $\tilde{v}_{\xi\eta}$ is corresponding modified potential which is not given in the explicit form.

As σ-MO may be considered to be approximately localized in the particular bond, the off-diagonal matrix elements of $\boldsymbol{H}^{\Sigma\Sigma}$ in Eq. 5 may be negligibly small. So, the matrix element, $<{}^{\alpha}_{i}|\tilde{\boldsymbol{H}}|{}^{\beta}_{j}>$, becomes as follows;

For the singlet state,

$$\langle {}^{\alpha}_{i}|\tilde{\boldsymbol{H}}|{}^{\beta}_{j}\rangle = (\varepsilon_\alpha - \varepsilon_i)\delta_{ij}\delta_{\alpha\beta} - V_{i\alpha j\beta} + 2V_{ij\alpha\beta} - 4\sum_{k\gamma} V_{ik\alpha\gamma}V_{kj\gamma\beta}\, e_{k\gamma}, \tag{12-a}$$

$$e_{k\gamma} = [(\boldsymbol{H}^{\Sigma\Sigma} - \boldsymbol{EI})^{-1}]_{k\gamma,k\gamma}.$$

For the triplet state,

$$\langle {}^{\alpha}_{i}|\tilde{\boldsymbol{H}}|{}^{\beta}_{j}\rangle = (\varepsilon_\alpha - \varepsilon_i)\delta_{ij}\delta_{\alpha\beta} - V_{i\alpha j\beta}, \tag{12-b}$$

$$V_{i\alpha j\beta} = \iint i^*(1)\alpha^*(2)\; v_{12}\, j(1)\beta(2)\; d\tau_1 d\tau_2.$$

Where, i, j, α, and β are used for the π-MO's and k, l, γ, and δ are for the σ-MO's. Comparing Eqs.12-a and 12-b, it is seen that π-π^* configurations interact with σ-σ^* ones only in the excited singlet state, but not in the triplet state.[11] The matrix elements of the effective interaction of the excited singlet state can be divided into two parts,

Exchange type interaction

$$\tilde{V}_{ij\alpha\beta} = V_{ij\alpha\beta} - \frac{1}{2}\sum_{k\gamma} 4V_{ik\alpha\gamma}V_{kj\gamma\beta}\, e_{k\gamma}. \tag{13-a}$$

Coulomb type interaction

$$\tilde{V}_{i\alpha j\beta} = V_{i\alpha j\beta} \tag{13-b}$$

From Eqs. 13-a and 13-b, it is seen that only the exchange type interaction between π-electrons is modified by Σ-Π interaction. From the standpoint of the π-electron approximation, it means that π-electron excitation makes σ-field polarize and π-electrons in the excited state interact each other through the polarized σ-field, in addition to direct coulomb potential. Such kind of interaction appears only on exchange interaction between π-electrons. So that only the exchange type integrals over MO's are modified.

In the present study, $\boldsymbol{E}$ in the inverse matrix is treated as a parameter so that the calculated excitation energies agree with those of experiments.

Using the LCAO approximation as,

$$\psi = \sum_t d_{it}\phi_t,$$

the effective π-electron repulsion integral, $\tilde{\gamma}_{\mu\nu}$, can be written as,

$$\tilde{\gamma}_{\mu\nu} = \gamma_{\mu\nu} + \frac{1}{2}\sum_{rs}\gamma_{\mu r}\Pi_{rs}\gamma_{s\nu}, \tag{15}$$

where,

$$\Pi_{rs} = -4\sum_{k\gamma} d_{kr}d_{\gamma r}d_{ks}d_{\gamma s}e_{k\gamma}, \tag{16}$$

$\tilde{\gamma}_{\mu\nu}$ and $\gamma_{\mu\nu}$ are defined as follows,

$$\tilde{\gamma}_{\mu\nu} = \iint \phi^*_\mu(1)\phi^*_\nu(2)\; \tilde{v}_{12}\phi_\nu(1)\phi_\mu(2)\; d\tau_1 d\tau_2,$$

$$\gamma_{\mu\nu} = \iint \phi^*_\mu(1)\phi^*_\nu(2)\; v_{12}\phi_\nu(1)\phi_\mu(2)\; d\tau_1 d\tau_2,$$

where, μ and ν are used for the π-AO's and r and s for the σ-AO's. Π_{rs} represents the mutual polarizability associated with σ-electrons. Therefore, the second term of Eq.15 indicates the effect of the polarized σ-field on the π-electron-electron interaction. It is interesting to note that the formula of $\tilde{\gamma}_{\mu\nu}$ is similar to that of Little's which was derived by the RPA method.[12]

An Improvement of P-P-P Method Including σ-Electrons as the Field. Following the result mentioned above, P-P-P method can be improved from the standpoint of Σ-Π interaction, including the σ-electron as the field.

Employing the avaraged energy parameter $1/\tilde{e}$ instead of $e_{k\gamma}$ in Eq.16, $\tilde{\gamma}_{\mu\nu}$ of Eq. 15 can be written as follows;

$$\tilde{\gamma}_{\mu\nu} = \gamma_{\mu\nu} + \Delta_{\mu\nu}, \tag{17-a}$$

$$\Delta_{\mu\nu} = \frac{1}{2\tilde{e}}\sum_r\sum_s \gamma_{\mu r}Q_{rs}\gamma_{s\nu}, \tag{17-b}$$

$$Q_{rs} = -4\sum_{k\gamma} d_{kr}d_{\gamma r}d_{ks}d_{\gamma s}. \tag{17-c}$$

It is convenient to divide the correction term, $\Delta_{\mu\nu}$, into two terms,

$$\Delta_{\mu\nu} = \Delta^1_{\mu\nu} + \Delta^2_{\mu\nu}.$$

When r and s belong to the same atom A, the contribution is collected into the term $\Delta^1_{\mu\nu}$. On the other hand, if r and s belong to the different atoms, respectively, we collect the contribution into the term $\Delta^2_{\mu\nu}$. Using the bond order P_{rs} and the virtual bond order P^*_{rs} defined by

$$P_{rs} = 2\sum_{k}^{\text{occ.}} d_{kr}d_{ks}, \tag{18-a}$$

$$P^{*}_{rs} = 2\sum_{r}^{\text{unocc.}} d_{\gamma r}d_{\gamma s} = 2\delta_{rs} - P_{rs}. \tag{18-b}$$

$\Delta^{1}_{\mu\nu}$ and $\Delta^{2}_{\mu\nu}$ can be written as follows;

$$\Delta^{1}_{\mu\nu} = \frac{-1}{2\tilde{e}}\sum_{A}[\sum_{r}^{A}\gamma_{\mu r}(2P_{rr}-P^{2}_{rr})\gamma_{r\nu} - \sum_{\substack{r\\(r\neq s)}}^{A}\sum_{s}^{A}\gamma_{\mu r}P^{2}_{rs}\gamma_{s\nu}], \tag{19}$$

$$\Delta^{2}_{\mu\nu} = \frac{1}{2\tilde{e}}\sum_{B}\sum_{C}\sum_{r}^{B}\sum_{s}^{C}\gamma_{\mu r}P^{2}_{rs}\gamma_{s\nu}. \tag{20}$$

When CNDO scheme is adopted, the electron repulsion integrals, $\gamma_{\mu\nu}$'s depend only on the nature of atoms A, B, and C. Therefore, after the summation over r and s for each atom, Eqs. 19 and 20 become as follows:

$$\Delta^{1}_{\mu\nu} = \frac{-1}{2\tilde{e}}\sum_{A}\gamma_{\mu A}[\sum_{\substack{r,s\\(s\neq r)}}^{A}(2P_{rr}-P^{2}_{rr}-P^{2}_{rs})]\gamma_{A\nu}, \tag{21}$$

$$\Delta^{2}_{\mu\nu} = \frac{1}{2\tilde{e}}\sum_{B}\sum_{C}\gamma_{\mu B}(\sum_{r}^{B}\sum_{s}^{C}P^{2}_{rs})\gamma_{C\nu}. \tag{22}$$

The terms, $\sum(2P_{rr}-P^{2}_{rr}-P^{2}_{rs})$ in Eq. 21 and $\sum_{rs}(P^{2}_{rs})$ in Eq. 22 correspond to the bond index proposed by Wiberg.[13] These terms are easily understood by the concept of hybrid orbitals. The hibrid orbital, X^{A}_{h}, is constructed from the adequate unitary transformation of the basis AO's, ϕ_{p}'s, which are s, p_x, p_y, and p_z; $X^{A}_{h}=\sum_{p}d_{hp}\phi_{p}$. Where, X^{A}_{h} means a hybrid orbital of the atom A. The bonding orbital ϕ and antibonding orbital ϕ^{*} associated with nonpolar σ-bond between atoms A and B can be approximately written in terms of the hybrid orbitals X^{A}_{h} and $X^{B}_{h'}$;

$$\phi = \frac{1}{\sqrt{2}}(X^{A}_{h}+X^{B}_{h'}), \qquad \phi^{*} = \frac{1}{\sqrt{2}}(X^{A}_{h}-X^{B}_{h'}).$$

A lone pair orbital of the atom A can be approximately written as $\phi=X^{A}_{h}$. The values of Eqs. 21 and 22 are invariant to the unitary transformation, so that we can express approximately,

$$\sum_{rs}^{A}(2P_{rr}-P^{2}_{rr}-P^{2}_{rs}) = \sum_{h}^{A}(2P_{hh}-P^{2}_{hh}), \tag{23}$$

$$\sum_{r}^{B}\sum_{s}^{C}(P^{2}_{rs}) = \sum_{h}^{B}\sum_{h'}^{C}(P^{2}_{hh'}). \tag{24}$$

When X_h and $X_{h'}$, belong to the same atom, P_{hh} is equal to 1.0, except for the lone pair orbital. If X_h represents a lone pair orbital, P_{hh} becomes 2.0. If there exists a nonpolar σ-bond between B and C, $P_{hh'}$ becomes 1.0. Otherwise, $P_{hh'}$ is equal to zero. Therefore, the following simple relations are visualized.

$$\sum_{\substack{r,s\\(s\neq r)}}^{A}(2P_{rr}-P^{2}_{rr}-P^{2}_{rs}) = \boxed{\text{Number of valence electrons of the atom A}} - \boxed{\text{Number of lone pair electrons of the atom A}} - \boxed{\text{Number of } \pi\text{-electrons of the atom A}} = N_A\,[\text{Number of } \sigma\text{-bond of the atom A}] \tag{25}$$

$$\sum_{r}^{B}\sum_{s}^{C}(P^{2}_{rs}) = \begin{cases}1 & \begin{pmatrix}\text{If there exists } \sigma\text{-bond between atoms}\\ \text{B and C}\end{pmatrix}\\ 0 & \text{(Otherwise)}\end{cases}$$

$$B = \begin{pmatrix} -1 & 0 & 0 & 0 & 1 & 0\\ 0 & -1 & 0 & 0 & 1 & 0\\ 0 & 0 & -1 & 0 & 0 & 1\\ 0 & 0 & 0 & -1 & 0 & 1\\ 1 & 1 & 0 & 0 & -3 & 1\\ 0 & 0 & 1 & 1 & 1 & -3 \end{pmatrix}$$

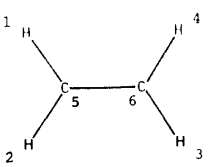

Fig. 1. The bond index matrix for ethylene and the numbering of the atoms.

Combining Eqs.21 and 22, the following relation is obtained.

$$\Delta_{\mu\nu} = \frac{1}{2\tilde{e}}[\sum_{A}(-N_A)\gamma_{\mu A}\gamma_{A\nu} + \sum_{B-C}^{\text{Bond}}\gamma_{\mu B}\gamma_{C\nu}], \tag{27}$$

where, the summation, $\sum_{B-C}^{\text{bond}}$, runs over all the σ-bonding atomic pairs.

Using Eq. 27, the effective electron repulsion integrals given by Eq. 15 can be rewritten by the matrix representation introducing a new matrix $\boldsymbol{B}$, as follows;

$$\tilde{\boldsymbol{\gamma}}^{\Pi} = \boldsymbol{\gamma}^{\Pi} + \boldsymbol{\Delta}^{\Pi}, \tag{28-a}$$

$$\boldsymbol{\Delta}^{\Pi} = \frac{1}{2\tilde{e}}\boldsymbol{\gamma}^{\Pi\Sigma}\boldsymbol{B}\boldsymbol{\gamma}^{\Sigma\Pi}, \tag{28-b}$$

$$\boldsymbol{\gamma}^{\Pi\Sigma} = (\boldsymbol{\gamma}^{\Sigma\Pi})^{+}. \tag{28-c}$$

$\tilde{\boldsymbol{\gamma}}^{\Pi}$, $\boldsymbol{\gamma}^{\Pi}$, and $\boldsymbol{\Delta}^{\Pi}$ are $N\times N$ square matrices and $\boldsymbol{\gamma}^{\Sigma\Pi}$, $N\times M$ rectangular matrix and $\boldsymbol{B}$, $M\times M$ square matrix. Here N and M are number of π-AO's and that of atoms, respectively. The value of the diagonal term of the matrix $\boldsymbol{B}$ is equal to $(-N_A)$. The value of the off-diagonal term is equal to $P_{hh'}$, namely 0 or 1. This matrix is named bond index matrix and is easily made from the structural formula of the molecule. As an example, $\boldsymbol{B}$ matrix of ethylene is shown in Fig. 1. This matrix reflects bonding relations of atoms in the molecule. So that the correction terms, $\Delta_{\mu\nu}$, depend on the topological nature of the molecule.

From these results we conclude that the most important effect of Σ-Π interaction on the π-electron-electron interactions depends on the topology and conformation of the molecule. Using Eqs. 28-a and 28-b, we can take into account the effect of σ-electrons explicitly in the π-electron approximation.

Calculational Procedure. π-π^{*} Excitation energies are calculated, considering Σ-Π interaction by the method mentioned above. According to the present theory, all valence electrons are taken into account, however, only the SCF-MO-CI calculation based on P-P-P scheme is needed, because σ-electrons are treated as it forms a field.

The calculational procedure is summarized as follows. First of all, we carry out the usual P-P-P calculation for the ground state. Secondly, we evaluate the effective $\tilde{\gamma}_{\mu\nu}$, using Eq. 28-a and an appropriate bare $\gamma_{\mu\nu}$. Lastly, we perform the SECI calculation, in which we use $\tilde{\gamma}_{\mu\nu}$ instead of $\gamma_{\mu\nu}$, only in the evaluation of the exchange type integrals over MO's in CI matrix elements.

In the present calculation, Ohno-Klopman formula[3] is applied for the standard (or bare) electron repulsion integrals,

$$\gamma_{\mu\nu} = \frac{14.40}{\sqrt{(R_{\mu\nu}^2 + a_{\mu\nu}^2)}} \text{(eV)},$$

where $R_{\mu\nu}$ is the interatomic distance between μth and νth atoms.

One center repulsion integrals, $\gamma_{\mu\mu}$, are evaluated by the approximation suggested by Pariser and Parr,[14]

$$\gamma_{\mu\mu} = I_\mu - A_\mu,$$

where A_μ and I_μ are the valence state electron affinity and the valence state ionization potential of the μth atom, respectively. These values are found in the work of Hinze and Jaffé.[15] Two center core integrals $\beta_{\mu\nu}$ are approximated by the formula given by Nishimoto and Forster,[16]

$$\beta_{\mu\nu} = A_0 + A_1 P_{\mu\nu}$$

where, $P_{\mu\nu}$'s are bond order which depend on each iteration. Standard values of parameters for A_0 and A_1 are summarized by Younkin *et al.*[17]

In order to estimate the correction term $\Delta_{\mu\nu}$ in Eq. 27, the electron repulsion integrals between π and σ AO's are required, which does not come out in the usual π-electron theory. For the calculation of these integrals we employ the same approximations as used for the π-electrons, namely, Pariser-Parr prescription for the one center electron repulsion integrals and Ohno-Klopman formula for the two center ones. Iwata[18] have pointed out that Pariser-Parr approximation for the one center electron repulsion integral includes Σ-Π interaction. Therefore, in this paper, we did not apply the present method to one center electron repulsion integrals.

We use 13.0 eV as the value of the averaged energy parameter $\bar{e}$ to reproduce the lower excitation energies of benzene. We consider whether the approximation $\bar{e}$ and the value of 13.0 eV are reasonable or not by the following manner: The mutual polarizability of σ-cores, Π_{rs}, is written by the atomic suffix as follows,

$$\Pi_{AB} = \sum_r^A \sum_s^B \Pi_{rs},$$

and Π_{AB} is related to the matrix element of the bond index matrix B_{AB} by

$$\Pi_{AB} = \frac{1}{2\bar{e}} B_{AB}.$$

In Tables 1 and 2, the calculated values of Π_{AB} and $(B_{AB}/2\bar{e})$ are listed, respectively. The atom-atom mutual polarizabilities associated with σ-electrons of ethylene are calculated by CNDO/2. From these Tables, it is found that the present approximation is reasonable and the parametrized value, 13.0 eV, is also admittable in spite of the drastic approximation was introduced. There are small discrepancies among the values in these Tables, which are caused by the approximation of averaging e_{kr} and neglecting the off-diagonal terms of the inverse matrix in Eq. 7.

Results and Discussion

In Tables 3—6, the calculated excitation energies of polyacenes are summarized. As seen from these Tables, the agreement between calculations and experiments is satisfactory.

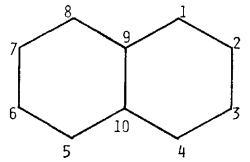

Fig. 2. The numbering of the atoms of naphthalene.

It is seen from Table 3, $^1B_{2u}$ excited state of benzene is unchanged by the Σ-Π interaction. The $^1B_{2u}$ excited state is much improved compared to that of Ohno's.

It is also found from Tables 4—6 that Σ-Π interaction has an effect of increasing the excitation energies of $^1B_{2u}$($^1B_{1u}$ in benzene) states which are polarized to the direction of molecular short axis. On the other hand, the excitation energies of $^1B_{3u}$($^1B_{2u}$ in benzene) states which are polarized to the direction of molecular long axis, remain unchanged or slightly decrease. These very interesting effect of Σ-Π interaction can be understood from the point of view of the polarization of the σ-framework caused by π-π^* excitation. It should be noted that the calculated excitation energies of the singlet state by the present method are similar to the Nishimoto-Mataga's.

In Table 7, the correction terms, $\Delta_{\mu\nu}$, of naphthalene are given. From this Table, it is found that the magnitude of $\Delta_{\mu\nu}$ depends considerably on the interatomic distance and also on the relative atomic sites in the molecule. Moreover, it can be generally said that the correction is larger at the inner part than at the outer part in the molecule.

We will apply the present theory to linear polyenes, aromatic derivatives, heterocycles and interaction of two aromatic systems connected by aliphatic chain in our next papers.

Electrical Conductivity of Single Crystals of *N*-Methylphenazinium-TCNQ and Rb-TCNQ

Genshiro Fujii, Ichimin Shirotani, and Hiroshi Nagano

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received February 5, 1977)

Temperature and pressure dependence of the electrical conductivity of NMP(I)-, NMP(II)-, Rb(I)- and Rb(II)-TCNQ single crystals was studied. NMP(I)-TCNQ showing diffuse streaks was found to have a semiconductive behavior at atmospheric pressure and no conductive maximum appeared at low temperatures. Moreover the metallic behavior was not shown even at 100 kbar. The crystal structure of NMP(II)-TCNQ is not similar to that of NMP(I)-TCNQ. The difference of physical properties of two phases is discussed. The anomalous electrical behavior in the pressure range from 1 bar to 40 kbar was observed for Rb(I)-TCNQ. The resistivity of Rb(II)-TCNQ decreased monotonously with increasing pressure. The magnitude of their activation energies was 0.15 eV for Rb(I) salt and 0.11 eV for Rb(II) salt at 100 kbar. The insulator to metal transition could not be observed at least up to 100 kbar.

Physical properties of TCNQ (tetracyanoquinodimethane) salts which are quasi one-dimensional conductors have been a subject of considerable interest in recent years. NMP (*N*-Methylphenazininum)-TCNQ and Rb-TCNQ are polymorphic having two crystalline forms at room temperature. One is a triclinic phase (NMP(I)-TCNQ, Rb(II)-TCNQ) and the other is a monoclinic phase (NMP(II)-TCNQ, Rb(I)-TCNQ).

The crystal structure of NMP(I)-TCNQ consists of linear chains of $TCNQ^-$ anions and parallel chains of NMP^+ cations.[1,2] The crystals of this phase are one of the most highly conductive ion-radical salts. The electrical,[3-5] magnetic,[6] and optical[7,8] properties have been intensively studied. The conduction mechanism in NMP(I)-TCNQ crystal has been particularly discussed by many authors.

The monoclinic phase of NMP(II)-TCNQ shows semiconductive behavior; $\rho \approx 10^4\ \Omega$ cm at room temperature with an activation energy of 0.4 eV.[9] NMP^+ cations and $TCNQ^-$ anions alternate in columns parallel to the c axis.[10] The columnar structure of NMP(II)-TCNQ is remarkably different from that of NMP(I)-TCNQ.

Rb(I)-TCNQ has monoclinic symmetry and the $TCNQ^-$ anions are stacked face to face to form columns of diadic units of a $TCNQ^-$. Within a column, two different intermolecular spacings, 3.159 and 3.484 Å, appear alternately.[11]

The X-ray study of Rb(II)-TCNQ shows a triclinic structure consisting of linear chains of identical TCNQ molecules stacked face to face and equally separated from one another.[12] This columnar structure is very similar to that found in the crystal of NMP(I)-TCNQ. However, the electronic structure of Rb(II)-TCNQ is remarkably different from that of NMP(I)-TCNQ. The differences of the physical properties in both Rb-TCNQ have already been discussed in previous papers.[13-15]

In this paper, we present some findings on the temperature and pressure dependence of electrical conductivity in single crystals of NMP- and Rb-TCNQ and discuss the conduction mechanism for these salts.

Experimental

Preparation of Single Crystals. The acetonitrile solvent (Donin Yaku Kagaku, Spectro Grade) was refluxed over P_2O_5 and fractionally distilled. TCNQ (Tokyo Kasei Company) was recrystallized twice from pure acetonitrile and sublimed three times at 120 °C and 10^{-5} Torr. Only brilliant yellow orange TCNQ crystals from the center zone were collected for usage. NMP-TCNQ was prepared by treatment of *N*-methylphenazinium methyl sulfate in hot alcohol with a boiling solution of Li-TCNQ in ethanol.[16] Li-TCNQ was prepared by the reaction of TCNQ and anhydrous LiI provided by Hashimoto.[17] The phenazine provided by Anzai was purified by zone refining and sublimation.

Black needle single crystals of NMP(I)-TCNQ were grown from saturated acetonitrile solutions by fast recrystallization. The largest crystal obtained was $0.6 \times 0.08 \times 5$ mm^3. Single crystals prepared by us showed the diffuse streaks along the c* direction.[2] Crystals of NMP(II)-TCNQ were grown from dilute acetonitrile solutions by very slow recrystallization.

The preparation of Rb-TCNQ has been reported in detail previously.[13]

Electrical Measurements. DC four-probe resistance measurements were made on single crystals of NMP-TCNQ and Rb-TCNQ along the needle axis parallel to the TCNQ stacks. The gold wires (0.02 mm diameter) were used for electrical lead wires. Electrical contact with the crystals was made by wetting the electrical lead wires with a silver paste paint. Using this arrangement, the crystals could be thermally cycled without damage. The sample holder, in which the sample was already placed, was mounted in a vacuum can of a temperature-variable cryostat. The temperature, which was controlled by helium exchange gas and a heater, was determined by means of a copper-constantan thermocouple.

Measurements of electrical resistance as a function of pressure were made using a clamped-type high-pressure anvils-apparatus as previously described.[18]

Optical measurements have been made by the same manner as described previously.[13]

Results and Discussion

NMP(I)-TCNQ. Fritchie's average structure of NMP(I)-TCNQ shows that NMP^+ cation is located at the position (1/2, 1/2, 1/2) in unit cell, taking either of the two possible orientations of the methyl groups as equally probable[1]. On the basis of this structure, Bloch *et al.*[5] have tried to apply the theory of hopping in disordered systems to the conductivity of NMP(I)-TCNQ. The hopping theory for one dimensional disordered system predicts $\ln\sigma(T) = \ln\sigma_0 - (T_0/T)^{1/2}$. They have found that the temperature dependence of the conductivity could be approximately fitted by $\ln\sigma \approx$

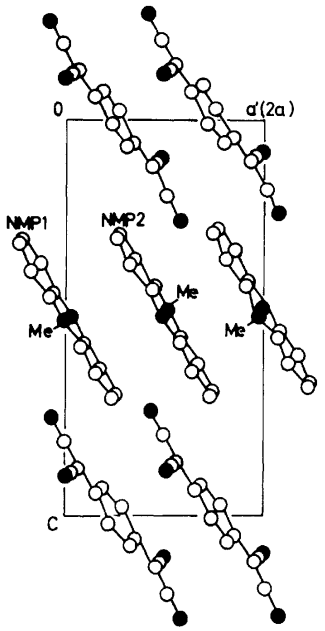

Fig. 1 (a). Crystal structure of NMP(I)–TCNQ showing diffuse streaks along b axis.[2]

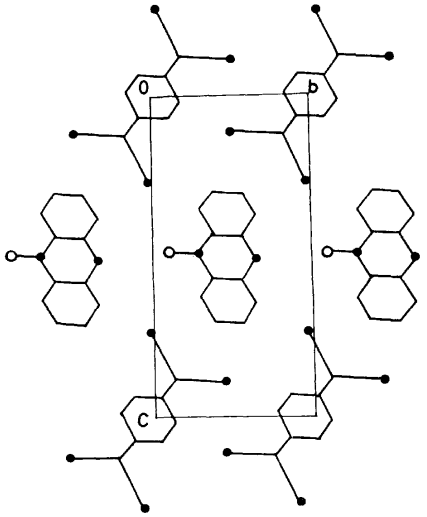

Fig. 1 (b). Crystal structure of NMP(I)–TCNQ showing diffuse streaks along a axis.[2]

$(T_0/T)^{1/2}$. On the other hand, Coleman *et al.*[4] have emphasized that the electronic and magnetic properties can be quantitatively described in terms of the one-dimensional Mott-Hubbard model. The temperature dependence of the conductivity of high purity single crystals has revealed that the plot of $\ln(\sigma/\sigma_0)$ *vs.* $1/T$ shows straight-line; this is not consistent with the analysis of Bloch *et al.*

Recently, Kobayashi[2] has studied an X-ray analysis of high purity single crystal of NMP(I)–TCNQ prepared by us. The X-ray diffraction patterns of this crystal show diffuse streaks along the c* direction. The analysis of the intensities of these streaks reveals that the orientation of NMP^+ cation is one-dimensionally disordered along the c axis as is shown in Fig. 1. The structure obtained indicates that the potential exerted on an electron moving in a column of TCNQ is not random, but can be expressed by a periodic function.

a) Ref. 1. b) Ref. 9. c) Ref. 11. d) Ref. 12. e) Ref. 10. f) Ref. 4. g) Ref. 13. h) Present work.

The temperature and pressure dependence of the conductivity of single crystals of NMP(I)–TCNQ showing the diffuse streaks were studied. The conductivity data are presented in Fig. 2, where $\log(\sigma/\sigma_{300})$ is plotted as a function of T^{-1}. The room temperature conductivity was 130 Ω^{-1} cm^{-1}. The activation energy was 0.06 eV as shown in Table 1. No conductivity maximum appeared. This behavior is not consistent with the data reported by Coleman *et al.*[4]

Morosin[19] has pointed out that the single crystals supplied by Heeger did not show diffuse streaks. The conductivity of those crystals indicates a metallic state above 200 K with a continuous transition to an insulator below 200 K.[3,4] Morosin has conjectured that Kobayashi's observation on NMP(I)–TCNQ arose from the disordered regions formed between the twin boundaries of two different phases of NMP–TCNQ. If single crystals are grown from saturated acetonitrile solution by fast recrystallization, crystals of the triclinic phase (NMP(I)–TCNQ) are only found. Crystals prepared by us showed diffuse streaks. Therefore, Kobayashi's observation does not arise from the twin

boundaries of two phases, but is the intrinsic property of NMP(I)-TCNQ. There is an apparent difference in the columnar structure of NMP^+ between Heeger's crystals and ours. This inconsistency may be due to the difference of the method of sample preparation.

As is shown in Fig. 1, the positive potential exerting on an electron moving in a column of TCNQ can be expressed by the periodic function. Therefore, the corresponding energy band has not to be a half-filled band, but a filled band.[2] It seems to be reasonable that the

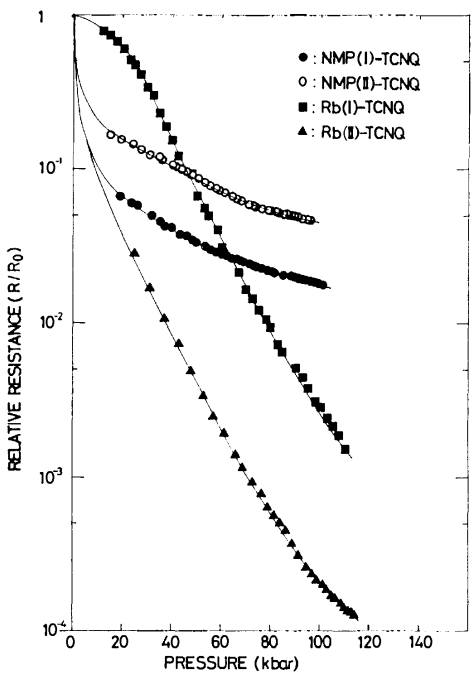

Fig. 5. Pressure dependence of relative resistance for NMP- and Rb-TCNQ.
●: NMP(I)-TCNQ, ○: NMP(II)-TCNQ, ■: Rb(I)-TCNQ, ▲: Rb(II)-TCNQ.

electrical behavior in NMP(I)-TCNQ showing diffuse streaks is semiconductive.

The pressure effect on electrical resistivity of this single crystals was measured along the conductive axis up to 100 kbar at room temperature. The result is shown in Fig. 3. The electrical resistivity decreased with increasing pressure. The resistivity at 100 kbar was 1.38×10^{-4} Ωcm. Figure 4 exhibits the pressure dependence of the activation energies of the TCNQ salts. The activation energy of NMP(I)-TCNQ rapidly decreased up to 20 kbar. It was 0.02 eV at 100 kbar. NMP(I)-TCNQ showing diffuse streaks did not show the metallic behavior even at 100 kbar.

NMP(II)-TCNQ. This compound crystallizes in space group $P2_1/n$ with $a=10.558$, $b=25.952$, $c=7.0872$ Å, $\alpha=90.68°$, and $z=4$.[10] The anion and cation alternate in the column parallel to the c axis with slightly unequal interplanar spacings. This structure does not resemble that of NMP(I)-TCNQ. Coleman *et al.*[9] have already studied the temperature dependence of the electrical conductivity for NMP(II)-TCNQ; this monoclinic phase is semiconductive with a room temperature conductivity of 7.67×10^{-5} Ω^{-1} cm^{-1} and an energy gap of 0.81 ± 0.02 eV.

Recently the absorption spectra of two crystalline forms have been studied by Tanaka *et al.*[8] Their absorption spectra are very different. The lowest energy transition in NMP(I)-TCNQ appears along the a axis at 5500 cm^{-1}. This band is assigned to an intermolecular transition between TCNQ molecules. On the other hand, the CT band in NMP(II)-TCNQ is observed at near 8000 cm^{-1}. This band corresponds to a charge transfer of an electron from the NMP molecule to TCNQ. The large difference between electrical and optical properties of such two-phase salts indicates

a crucial role of crystal structure of an organic salt. Mulliken[20] discussed the effect of pressure on electronic state of D^+A^- complexes and predicted a red shift and an increase of absorption intensity of a CT band and a decreased resistivity with increasing pressure. The majority of D^+A^- complexes show a decrease in resistivity with increasing pressure.[21,22] As shown in Figs. 3 and 4 the electrical resistivity and the activation energy in NMP(II)–TCNQ single crystals rapidly droped in the low pressure region and above 30 kbar decreased monotonously with increasing pressure. Figure 5 exhibits the ratio of the resistance, $\log R/R_0$, for both NMP–TCNQ. Above 30 kbar the rate of the pressure change of resistivity for the NMP(I) salt is approximately equal to that for the NMP(II) salt.

The values of their activation energies (ΔE_{I} and ΔE_{II}) decrease in the rate of

$$(\partial \Delta E_{\mathrm{I}}/\partial P)_T = -3.5\times10^{-4}\ \mathrm{eV/kbar}$$
$$(\partial \Delta E_{\mathrm{II}}/\partial P)_T = -4.4\times10^{-4}\ \mathrm{eV/kbar}.$$

These values are nearly equal, though the crystal structures of both NMP–TCNQ are significantly different. This may have arisen from the comparable compressibility between the two phases. Similar electrical behavior was found for both Rb–TCNQ salts, as discussed in the next section.

We suggest that the electrical behavior of these salts above 30 kbar may mainly be due to the increase of interchain interactions.

Rb(I)- and Rb(II)-TCNQ. Phase transitions and electrical and optical properties in both Rb salts have been already studied.[13] The relation between those properties and crystal structures have been discussed in the previous paper.[14] The electrical resistance of powdered Rb–TCNQ has been measured up to 500 kbar at room temperature.[15] The lowest resistivity for the Rb(I) salt is 1 Ωcm at 135 kbar, while that for the Rb(II) salt is 0.06 Ωcm at 170 kbar.

Figure 6 shows the effect of pressure on the resistance of single crystals of Rb(I)- and Rb(II)–TCNQ. The positive slope of the electrical resistance in the pressure range from 1 bar to 40 kbar was observed for the Rb(I) salt. Since the pressure induced phase transition in Rb(I)–TCNQ has been found at about 3.5 kbar,[13] this positive slope may be due to the appearance of a high pressure phase at quasi hydrostatic pressure. The activation energy was 0.15 eV at 100 kbar. A phase transition to a metallic state was not observed.

The resistivity of Rb(II)–TCNQ decreased monotonically with increasing pressure. The resistivity along the conductive axis was 1.5×10^{-2} Ωcm and the activation energy was 0.11 eV at 100 kbar. The compressibility of Rb(II)–TCNQ has not been measured, but it is probably comparable to that of aromatic crystals. From the relation between the pressure and the volume for molecular solid given by Samara and Drickamer,[23] the average intermolecular distance at 100 kbar was estimated to be about 90% of that at atmospheric pressure. Therefore, we can estimate the interplanar spacings between TCNQ molecules in the Rb(II) salt around at 100 kbar to be shorter than that in metallic TCNQ salts at 1 bar.[21] However, metallic behavior could not be observed in Rb(II)–TCNQ at 100 kbar

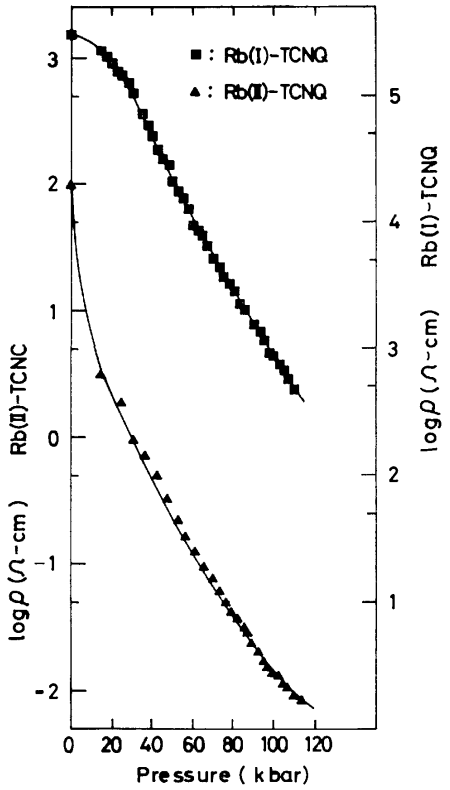

Fig. 6. Pressure dependence of electrical resistivity for Rb–TCNQ.
■: Rb(I)–TCNQ, ▲: Rb(II)–TCNQ.

The large difference in the conductivity of Rb(II)- and NMP(I)–TCNQ at atmospheric pressure has been mainly explained by two models. LeBlanc[25] suggested that the excitonic polarizability of the cation is the more important determinant of the variation in conductivities. On the other hand, Torrance *et al.*[7] proposed the new model in which the large conductivity of NMP(I)–TCNQ is attributed to incomplete charge transfer from the aromatic cation to TCNQ.

Figure 7 shows the effect of pressure on the absorption spectra of NMP(I)–TCNQ at room temperature. The absorption spectrum of NMP(I)–TCNQ is similar to that of complex salts such as Q- and Ad–$TCNQ_2$. The absorption bands have been assigned by Torrance *et al.*[7] and Tanaka *et al.*[8]

The pressure induced absorption band observed at around $20\times10^3\ \mathrm{cm^{-1}}$ for NMP(I)–TCNQ has also been found many complex salts.[26] Oohashi and Sakata[27] have suggested that the new band at high pressure may be assigned to the 8→9′ CT transition from $TCNQ^-$ to $TCNQ^0$. This shows that there may be neutral TCNQ molecules in NMP(I)–TCNQ. The incomplete charge transfer from NMP to TCNQ has been discussed by Butler *et al.*[28] and Kwak *et al.*[29] Ukei[30] has observed new weak X-ray diffuse streaks in addition to Kobayashi's observation. These diffuse lines can be interpreted in terms of a Kohn anomaly. From the observed superperiod the degree of charge transfer is estimated. The characteristic electrical and optical behavior in NMP(I)–TCNQ arises from the incomplete charge transfer from NMP to TCNQ.

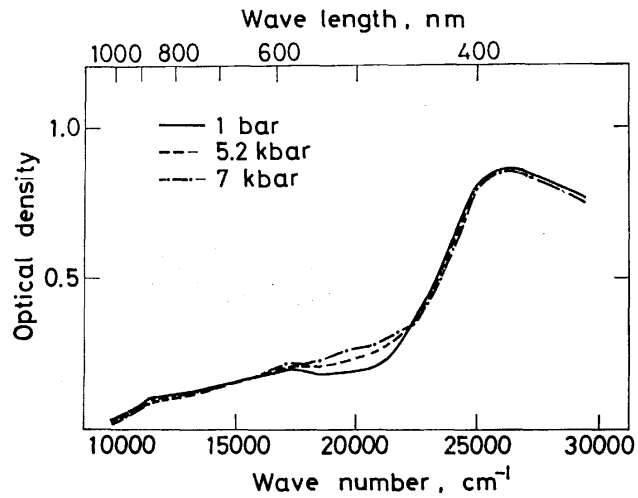

Fig. 7. Effect of pressure on the absorption spectra for NMP(I)-TCNQ.
——: 1 bar, ----: 5.2 kbar, ——: 7 kbar.

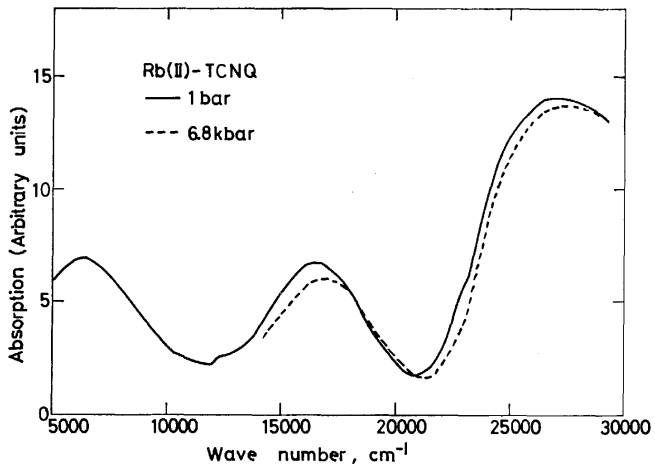

Fig. 8. Pressure effect on absorption spectra for Rb(II)-TCNQ.
——: 1 bar, ----: 6.8 kbar.

Figure 8 illustrates the pressure effect on absorption spectra of Rb(II)-TCNQ at room temperature. The absorption bands in the visible region are the locally excited (LE) bands within the $TCNQ^-$ anion. These exhibit the spectral blue shift with increasing pressure. The rate of pressure shift was $+67\ cm^{-1}$/kbar for $26.2 \times 10^3 cm^{-1}$ band and $+62\ cm^{-1}$/kbar for $16.1 \times 10^3\ cm^{-1}$ band. The near-infrared band at around $5.5 \times 10^3\ cm^{-1}$ is assigned to the charge transfer band between $TCNQ^-$ anions. The pressure effect on the CT band could not be observed because of interference by the pressure-transmitting fluid. The absorption spectrum of Rb(II)-TCNQ is markedly different from that of NMP(I)-TCNQ.

Rb(II)-TCNQ is fully charge transferred from Rb to TCNQ. Torrance *et al.*[8] have pointed out that in the case of complete charge transfer the lower Hubbard band was full; such a compound was a Mott insulator. Though NMP- and Rb-TCNQ are 1 : 1 simple salts, their electronic structures are essentially different. The conductivity along the conductive axis for the Rb(II) salt at 100 kbar is smaller than that of the NMP(I) salt at 1 bar, and the Rb(II) salt does not indicate the metallic behavior at 100 kbar though we can expect the interplanar distance between TCNQ molecules in the Rb(II) salt at 100 kbar to be shorter than 3.26 Å in NMP(I)-TCNQ at 1 bar. These results indicate that the electrical conductivity depends not only on the molecular distance between TCNQ molecule but also to a good extent on the electronic structure of TCNQ salts.

The authors wish to thank Dr. Y. Oda, Mr. H. Mukaida and Mr. K. Masuda in our institute for their kind help throughout this work. Their thanks are also due to Dr. S. Hashimoto, Kyoto University of Education and Dr. H. Anzai, Electrotechnical Laboratory for providing the materials.

(Received February 5, 1977)

The behavior of electronically excited chloranil interacting with the titled vinyl compounds and solvents has been studied by means of the nanosecond laser photolysis technique. Semiquinone radicals and/or chloranil anions have been detected as transients except in the system containing styrene. Careful observation and analysis of the kinetic behavior of the transient absorptions reveal that these transients are brought about by the interaction of excited triplet state of chloranil with vinyl monomers and/or solvents. The logarithms of the quenching rate constants and rate constants of the formation of transients are linearly related to the ionization potentials of the vinyl monomers and solvents used. The mechanisms of the triplet quenching and transient formation can reasonably be interpreted by taking the relaxed triplet-state complex with a charge-transfer character into account as the precursor leading to the production of semiquinone radicals, chloranil anions, and other intermediate compounds.

Several investigations of the behavior of the chloranil (CA) molecule, as a representative quinone, have been performed with reference to electron donor–acceptor (EDA) complex formations,[1] photochemical reactions,[2] electronic states,[3] and electrical conductivities.[4] Among these, the photopolymerization mechanism in which the excited state of CA plays an important role is one of the most interesting. Mikawa and his co-workers[5,6] have reported, in their studies concerning the photosensitized polymerization mechanism of *N*-vinylcarbazole (VCZ) by CA, that electron transfer occurs from VCZ to excited CA, producing the CA anion (CA^-) and the VCZ cation, and that VCZ cations behave differently depending as the polarity of the solvents used; in a polar solvent such as acetone cyclodimerization occurs,[5,6] but in a nonpolar solvent such as benzene catonic polymerization occurs without any induction period.[6] In contrast to their studies, we have confirmed[7] that acrylonitrile (AN), methyl methacrylate (MMA), and styrene (ST) react with excited CA and that radical polymerization occurs after a well-defined induction period, during which addition compounds between CA and the vinyl monomers used are produced both in polar and in nonpolar solvents. The difference in the polymerization mechanisms between the two series of systems mentioned above seems to be originally attributable to a difference in the ionization potentials of the vinyl monomers. Mikawa and his co-workers used vinyl monomers with relatively small ionization potential values, while we used vinyl monomers with relatively large ionization potentials. It is well known that, because of their strong electron-accepting and hydrogen-abstracting properties, CA molecules in the excited states interact with various electron and/or hydrogen donors, even with some solvents as well, to produce semiquinone anions and/or radicals.[9–14] Furthermore, the presence of the excited triplet state EDA complex has been suggested by Tsubomura and his co-workers,[10] who used a microsecond flach-photolysis technique in a fluid solution of CA–benzene and CA–acetone systems.

Since the excited CA behaves, as has been mentioned above, in very different ways as systems studied vary, very careful experiments should be performed to determine the photosensitized polymerization mechanisms, with special attention paid to the interaction between the excited CA and the vinyl monomers in both the presence and absence of solvents.

In this work, as a part of our studies of the polymerization mechanisms photosensitized by CA, nanosecond ruby laser photolysis has been carried out, with special attention paid to the detection of transients, tracing their origins, and making sure of the kinetic behavior of the transients produced by the interactions between excited CA and AN, MMA, ST, and tetrachlorohydroquinone in the presence and absence of dichloroethane, trichlorotrifluoroethane, and acetonitrile as solvents. The interactions of excited CA with dichloroethane, trichlorotrifluoroethane, and acetonitrile have also been studied in order to obtain further knowledge.

Experimental

Apparatus and Measurements. The nanosecond laser photolysis apparatus used in the present study is shown schematically in Fig. 1. A giant pulse of 694 nm, with an output of *ca.* 2 J, was generated with a ruby laser (JEOL, JLS-R3A) Q-switched by a rotating prism and passed through an ADP frequency doubler to obtain a second harmonic for excitation. After the elimination of an undoubled fundamental pulse with a 10-mm cell containing a saturated cupric sulfate solution, the doubled laser pulse of a 23 ns half-duration, with a wavelength of 347 nm, was supplied into a sample in a 10-mm quartz cell mounted on a cell holder. The output energy of this laser pulse was measured with a thermopile (TRG, Model 107) combined with a recorder (Hitachi, Model 056) through a microvolt meter (Ohkura Electric Co., AM-1001). The power of the pulse through the sample cell was also measured with the same thermopile each time photolysis was done. In each measurement, the spectra of the transients were easily corrected to the same laser intensity by this way after confirmation of the absorption arising through the one-photon process. Since the laser intensity effect on the absorption intensities of transients should be checked beforehand, a small part of the exciting pulse, which was reflected with a beam splitter placed between the solution filter and the sample cell, was simultaneously monitored by means of a photomultiplier, PM-1 (HTV, 1P28) with a high response. Glass plates were employed to reduce the intensity of the exciting pulse. A xenon flash of *ca.* 600 μs half-width from a stroboscope (SUNPACK, Model 107) was used as an analysis flash for the detection of the transients; its peak

was synchronized electronically with the laser pulse. After crossing through the sample cell at right angles with respect to the laser beam, this analyzing light was collected by a lens and focussed onto the slit of a grating monochromator which was a part of a Hitachi UV-VIS spectrophotometer (model 139). An appropriate combination of glass filters at the front of the cell was used not only to remove the second-order stray light, but also to prevent the sample solution from being illuminated undesirably. The exit light from the monochromator was received by a photomultiplier tube, PM-2 (HTV, R446), loaded with a 75Ω resistor. The output signal from this tube was displayed on a 200 MHz oscilloscope (Iwatsu, SS-6200) which was triggered externally by the pulse from a photodiode (EG & G, SGD-100A) monitoring the laser pulse scattered from the ADP crystal. The rise and decay profile of a single sweep of the signal was photographed on X-ray films. Further, a third photomultiplier tube, PM-3 (HTV, 1P28), was used to correct the intensity fluctuation of the analysis lamp. The response of the photomultiplier which was exposed to the analyzing flash, attenuated by half-transparent papers, was guided into the second channel of the oscilloscope; thus, a reference signal to the signal corresponding to a 100% transmittance of the analyzing light was obtained. Operation using the chopped-sweep function of the oscilloscope made it possible to photograph this reference signal and the decay of the transient absorption simultaneously. Then decay patterns of the long-life transients could be analyzed accurately, even in a time region where the intensity of the analyzing flash was no longer 'steady.' In addition, air conditioning was needed to obtain a constant output of second harmonics, because the best matched axis of the ADP crystal to the fundamental laser beam was quite sensitive to room temperature. The variation in the temperature in an operating room was controlled in the range of ±1.0 °C during laser photolysis. Thus, the nanosecond time resolution was obtained by the use of this instrumental system and the transient spectra, and the rise and/or decay curves could be followed up quantitatively over the time range from the starting time of laser oscillation to *ca.* 200 μs.

When samples were photolyzed at the temperature of liquid nitrogen, the cell holder was replaced by a quartz vessel with three flat windows at right angles with each other. In the present study, all the experiments, except for the system of CA and MMA in EPA (ethylether : isopentane : ethanol=5 : 5 : 2 in volume), were carried out at room temperature.

The EDA complex formation in the ground state between CA and the vinyl compounds was examined by measurements of the absorption spectra using Hitachi 124 and 139 spectrophotometers. To describe the results briefly in this section, spectroscopic evidence for complexing in 1,2-dichloroethane was not observed in the CA–AN system. On the other hand, in the CA–MMA system a new broad band appeared around 315 nm as a shoulder of the falling branch of the intense π-π^* transition of uncomplexed CA, which has a maximum at 292 nm, and in the CA–ST system a band having its maximum at 420 nm was remarkably observed. Both of the latter bands can be reasonably interpreted as charge-transfer (CT) bands by the aid of the Benesi-Hildebrand equation, the Ketelaar equation, and the linear relation of CT-band energies against the ionization potentials of the donors.

Materials. The chloranil (Tokyo Kasei, G. R. grade) was purified by a recommended method,[15] *i.e.*, recrystallized twice from benzene and chromatographed on freshly baked calcium carbonate, using purified benzene as the eluant in order to eliminate any acidic impurities. After one more recrystallization, a vacuum sublimation was undertaken just before use. The acrylonitrile (Wako, G. R. grade) was washed with 5% NaOHaq, phosphoric acid, and distilled water, three times each. After drying over potassium carbonate, it was fractionally distilled twice in an atmosphere of nitrogen under reduced pressure. Methyl methacrylate (Wako, G. R. grade) was purified by the method described elsewhere.[16a] The styrene (Wako, Practical grade) was treated with 5% NaOHaq, washed with distilled water, dried over calcium chloride and barium oxide, and purified twice by fractional distillation in a nitrogen atmosphere under reduced pressure. These vinyl monomers were passed through a short column of molecular sieves *(Zeolite)* and silica gel immediately before use. The tetrachlorohydroquinone (CA-H_2) (Tokyo Kasei, C. P. grade) was purified as follows. The faint pink substance which was obtained by two recrystallizations from glacial acetic acid and successive washing with hot water was treated with an aqueous solution of sodium sulfite in order to reduce, chemically, a little amount of contaminated CA to the corresponding hydroquinone. The precipitates which were obtained by adding an adequate amount of hydrochloric acid to the aqueous solution were washed throughly with ethanolic water and dried. The raw product was sublimed under a vacuum. A pure white material was thus obtained; it was found by usual analytic methods, to be tetrachlorohydroquinone. The benzophenone, which was used as a standard to estimate the extinction coefficient of the triplet chloranil, CA(T), was purified by the method described elsewhere.[16b] The 1,2-dichloroethane (DCE), acetonitrile, trichlorotrifluoroethane, ethyl ether, and isopentane used as solvents were purified by ordinary methods,[17] while the ethanol (Kanto Chemical Co., G. R. grade) was used without further purification. The solutions subject to laser photolysis were deaerated carefully by the freeze-pump-thaw cycle method. The concentration of CA in the solution was controlled in the range of $(1—3)\times10^{-3}$ mol dm^{-3}.

Results and Discussion

Identification of Transients. CA–DCE System:

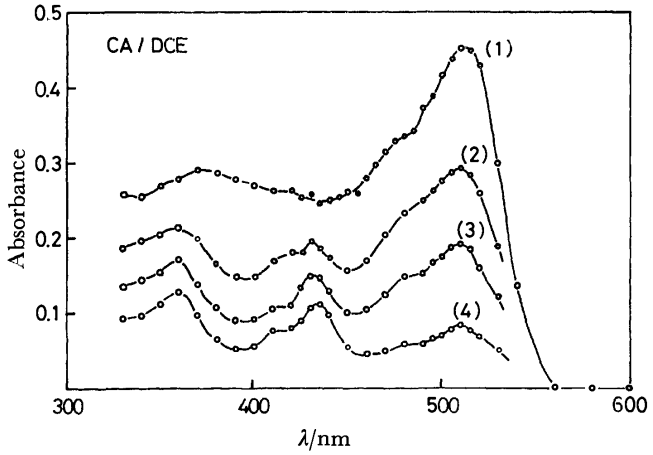

Fig. 2. Time resolved transient spectra for CA–DCE system: $[CA]=2\times10^{-3}$ mol dm^{-3}. The delay time from the laser pulsing, (1) 0, (2) 2, (3) 4, (4) 8 μs.

Figure 2 shows the time-resolved spectra after laser excitation for the system of CA alone in DCE. Observed bands with maxima at 510 and 370 nm in the spectrum immediately after pulsing closely resemble those of CA(T) in several solvents illustrated in Fig. 1 of Ref. 10 and discussed in Ref. 9. From an examination of the exponential decay of the 510 nm band, its lifetime was determined to be 5.6 μs in the deaerated solution and 0.45 μs in the aerated solution. These values are nearly equal to those for other solvent systems previously reported.[9a,9c] This is other evidence that this band belongs to CA(T). According to the investigation by the authors of Ref. 10, the 370 nm band is also attributable to CA(T). From the standpoint of these authors, we may also regard this band as belonging to CA(T), although, in our case, the band around 370 nm behaves, after a lapse of time, in the somewhat complicated manner to be described below. With the lapse of time, the spectrum is gradually replaced by another with band maxima at 430 and 360 nm. As regards these two bands, we obtained the following information: (a) Both of these bands had a relatively long life, and they decayed with similar time profiles. (b) Both the shape of the 430 nm band and the position of the 360 nm band closely resemble those studied in Ref. 10, which were attributed to semiquinone radicals. (c) Our experiments, performed by replacing the DCE by trichlorotrifluoroethane (with no hydrogen atom), revealed the non-existence of these bands. Using the microsecond-flash-photolysis technique, in which the irradiation of light over a broader range of wavelengths than in the case of nanosecond-laser photolysis is not avoided, Tsubomura and his co-workers[10] have reported the appearance of the bands attributable to the semiquinone radicals produced by the chlorine atom transfer to CA(T) from the Diflon S3 used as a solvent. This seems to indicate that the quite high excess vibrational energy in the lowest excited electronic state might be required for the abstraction of a 'heavy' chlorine atom in this system. An inspection of this information allows us to consider these two bands as belonging to semiquinone radicals of CA, CAH·, which have been produced by hydrogen-atom abstraction from the solvent.

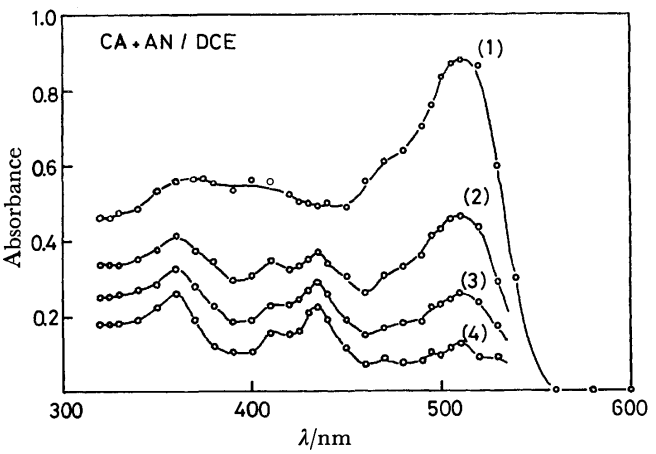

Fig. 3. Time resolved transient spectra for CA–AN–DCE system: $[CA]=2\times10^{-3}$ mol dm^{-3}, $[AN]=0.76$ mol dm^{-3}. The delay time from the laser pulsing, (1) 0, (2) 2, (3) 4, (4) 8 μs.

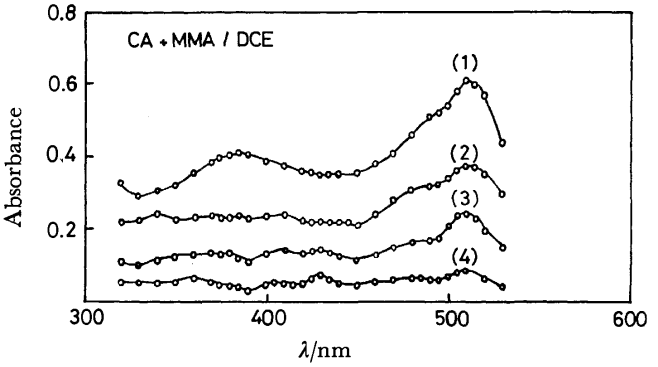

Fig. 4. Time resolved transient spectra for CA–MMA–DCE system: $[CA]=2\times10^{-3}$ mol dm^{-3}, $[MMA]=0.94$ mol dm^{-3}. The delay time from the laser pulsing, (1) 0, (2) 0.1, (3) 0.2, (4) 0.4 μs.

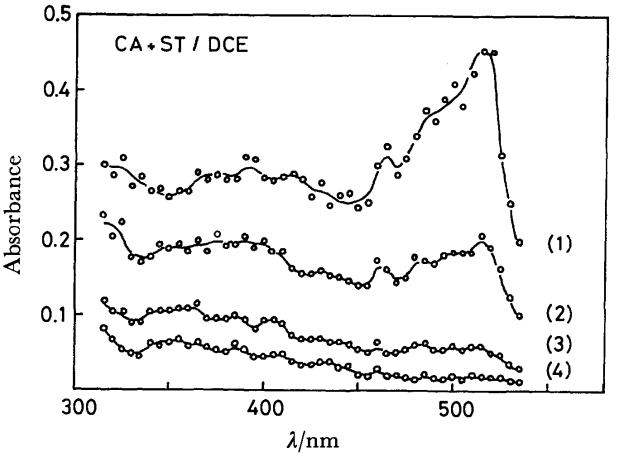

Fig. 5. Time resolved transient spectra for CA–ST–DCE system: $[CA]=1.7\times10^{-3}$ mol dm^{-3}, $[ST]=0.87\times10^{-3}$ mol dm^{-3}. The delay time from the laser pulsing, (1) 0, (2) 0.2, (3) 0.7, (4) 1.5 μs.

CA–Vinyl Monomer–DCE Systems: The transient absorption spectra changing with the lapse of time are exemplified for several systems in Fig. 3 (CA–AN–DCE), Fig. 4 (CA–MMA–DCE) and Fig. 5 (CA–ST–DCE).

The spectral features of the CA–AN–DCE system closely resemble those of the CA–DCE system (Figs. 2 and 3). In the CA–MMA–DCE system containing a high concentration of MMA the 510 nm absorption of CA(T) decays rapidly and scarcely no spectral components of CAH· remain (Fig. 4). In the CA–ST–DCE system containing a high concentration of ST ($\geq$0.1 mol dm^{-3}), no transient could be observed at all. However, in the same system containing a low concentration of ST, where ground-state EDA-complex formation is negligible, the initial spectrum rapidly disappears, keeping its spectral aspects without any bands attributable to semiquinone radicals being distinguishable (Fig. 5).

Kinetic Behavior of the 425 nm Band. The behavior of the absorption band monitored at 425 nm in the CA–DCE and CA–AN–DCE systems was followed from the time just after pulsing to *ca.* 10 μs (Fig. 7a). The decay of this absorption apparently obeyed the second-order kinetics after a rapid rise just after pulsing. The absorption intensity at the pulse end was recognized to be linearly related with the power of the laser for excitation. This means that this band arose through a one-photon process. It was observed that the 510 nm band also arose through a one-photon process. Since species bearing the 425 nm absorption in our systems are CA(T) and CAH·, it is important to check if CAH· comes from the singlet excited state of CA, CA(S) or from CA(T). This problem can be clarified by observing and analyzing the addition effect of ST, CAH_2, and MMA, as will be described below.

(a) As has previously been suggested for the CA–ST–DCE system, CA(T) is quenched rapidly, keeping its spectral features, and no observable transient like CAH· exists during the quanching process. This indicates that the initial appearance of the 425 nm band is due to CA(T). We will further discuss what would happen if CAH· is assumed to be produced in CA(S). The disappearance of CAH· might occur following self-disproportionation:[11a]

$$\text{CAH}\cdot + \text{CAH}\cdot \longrightarrow \text{CA} + \text{CAH}_2 \qquad k_d, \qquad (1)$$

and/or the conventional mechanism[19] described below, which is generally accepted for a radical polymerization with an induction period:

$$\text{CAH}\cdot\ (\text{or } \sim\text{CA}\cdot) + \text{ST} \longrightarrow \sim\text{ST}\cdot \qquad k_o, \qquad (2)$$

$$\sim\text{ST}\cdot + \text{CA} \longrightarrow \sim\text{CA}\cdot \qquad k_z, \qquad (3)$$

$$\sim\text{ST}\cdot + \text{ST} \longrightarrow \sim\text{ST}\cdot \qquad k_p. \qquad (4)$$

Here, k_d, k_o, k_z, and k_p are the rate constants of Reactions 1, 2, 3, and 4 respectively, and $k_d=1.4\times10^9$ mol^{-1} dm^3 s^{-1} (to be described in detail later), $k_p=123$ mol^{-1} dm^3 s^{-1},[18] $k_z/k_p=2040$ at 50 °C,[18] and $k_o<k_p$.[19] An inspection of the values of those rate constants and the relation between them indicates that the disappearance of CAH· would be efficiently subject to self-disproportionation, which, in turn, is very slow compared to the disappearance of CA(T) under our experimental conditions. On the assumption that CAH· would be produced from CA(S), therefore, the 425 nm band due to CAH· should remain during the spectral change in question. This contradicts the experiments and suggests that CAH· is not produced from CA(S).

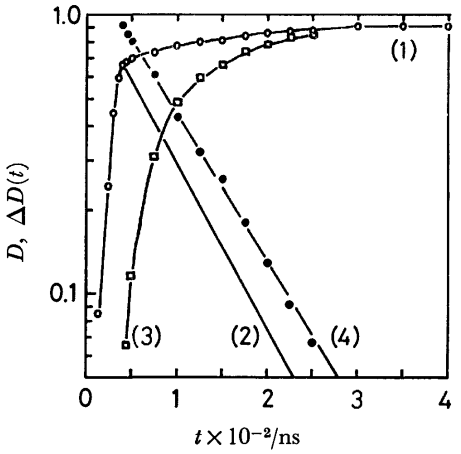

Fig. 6. Graphical analysis of the decay function of transient observed at 425 nm in CA–CAH_2–DCE system: [CA]$=2.36\times10^{-3}$ mol dm^{-3}, [CAH_2]$=2.58\times10^{-3}$ mol dm^{-3}. Curve (1): observed, (2) triplet decay, (3): CAH· rise, $D(t)=(1)-(2)$, (4): rate determining curve for CAH· formation, $\Delta D(t)=D_p-D(t)$; $D_p=0.92$.

(b) In order to clarify more distinctly the kinetic behavior of the absorption at 425 nm, we examined the addition effect of CAH_2 to the CA–DCE system. The decay profile followed up at 425 nm was analyzed kinetically for this system containing a small amount of CAH_2 (2.6×10^{-3} mol dm^{-3}), where no spectroscopic evidence exists as to a ground-state complex formation between CA and CAH_2. The analyzed results regarding the kinetic behavior of the 425 nm absorption can be reasonably explained by considering that the CA(T) which is generated at first will be quenched dynamically by CAH_2 and that the CAH· will increase through the CA(T) + CAH_2 → 2CAH· reaction. In fact, in our experiments, the increase in the 425 nm band was shown directly on the oscilloscope. Furthermore, this band was distinctly confirmed to belong to CAH· by an examination of its position and band shape as distinguished from all others in the spectrum. Figure 6 shows the results analyzed carefully. When the contribution of CA(T) to the absorbance at this wavelength, (2), is subtracted from the observed signal, (1), Curve (3) results; this curve refers to the growth of CAH· itself. Since the decay rate of the radical is much lower than that of the triplet (its decay time, $\tau_T=73$ ns in the present system), the disappearance of the former can reasonably be neglected during such a short time interval as in our experiments. Then, the subtraction of Curve (3), $D(t)$, from the peak value, D_p, of the observed curve gives Curve (4), $\Delta D(t)$, from which the time constant of CAH· formation can be obtained. By these procedures, it was quantitatively ascertained that the initial absorption at 425 nm was certainly due to CA(T) and that the rise time of CAH· ($\tau_r=83$ ns) was equal to the decay time of CA(T), within our limits of experimental accuracy. That is to say, CAH· is certainly produced *via* CA(T). Another support to this reasoning is also obtained from a comparison of the decay patterns of the 425 nm absorption between the CA–DCE and CA–CAH_2–DEC systems. Figure 7

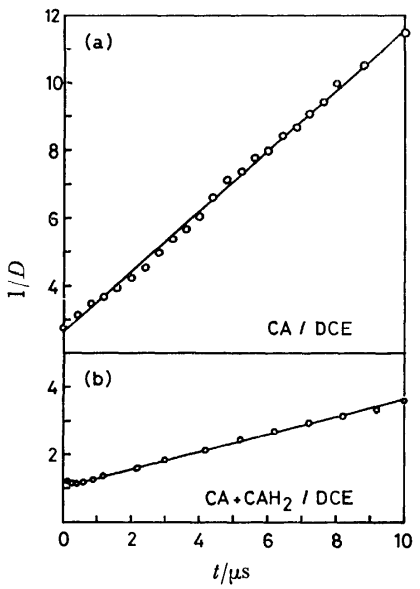

Fig. 7. Plots of second-order kinetics for the decay observed at 425 nm. a: CA–DCE, b: CA–CAH_2–DCE system.

shows the curves obtained by plotting the reciprocal of the optical density (D) against the lapse of time for these two systems. In the CA–CAH_2–DCE system (Fig. 7b), after the complete disappearance of CA(T) and the complete rising of CAH· at the initial stage of time lapse, the decay of the 425 nm band with reference to CAH· proceeds along a good straight line (Line *b*). In the CA–DCE system, there is apparently a straight line (Line *a*) following the second-order kinetics (Fig. 7a). If the transients were the same for both systems, their decay constants and, accordingly, the slopes of Line *a* and Line *b* would have to be identical. However there is a remarkable discrepancy between these two slopes, as may be seen in Fig. 7. Since Line *b* is the very realization of the kinetic behavior of CAH·, Line *a* does not embody the kinetic behavior of only CAH·. Moreover, a close inspection of Fig. 7a shows the string of circles to form a slightly S-shaped curve. We observed, further, a little more striking S-shaped curve for this system when the kinetic behavior was followed at 430 nm. This decay picture is characteristic when the absorption of a long-life transient, obeying the second-order decay kinetics, overlaps that of another transient decaying exponentially. Therefore, the observations can be understood by reasoning that, because of the superpostion of the CAH· rise and decay on the CA(T) decay, the absorption at 425 nm in the CA–DCE system apparently behaves as if the initially formed CAH· has decayed alone and smoothly with the second-order kinetics. As has been mentioned in the previous section, the 425 nm band in the CA–AN–DCE system also decayed apparently following the second-order kinetics from the time immediately after pulsing. This feature is the reflex of the same situation as that of Fig. 7a. These interpretations well correspond to those of Kemp and Porter[9b] as to the origin of the durosemiquinone radical produced by microsecond-flash photolysis in liquid paraffin.[20] Now, we can estimate the decay constant of CAH· accurately from Fig. 7b. From the slope of Line *b*, which strictly obeys the second-order kinetics, the decay constant was determined to be $2.8\times10^5\varepsilon l$ mol^{-1} dm^3 s^{-1}, where ε is the molar extinction coefficient of CAH· at 425 nm and where l is the width of the photolyzed part, which was estimated as 0.70 cm from the size of the second harmonics for excitation. The estimated value, 1.4×10^9 mol^{-1} dm^3 s^{-1}, was obtained using the reference value of ε, 7.3×10^3 mol^{-1} dm^3 cm^{-1}.[11a]

(c) In the system containing a high concentration of MMA, the absorption at 425 nm due to CA(T) early disappears exponentially, and after this rapid decay the remaining transient, CAH·, gradually decays with a long life. Although no exact analysis on the growth of CAH· was done in the DCE solvent, the above behavior and the results of kinetic analysis for CA^- and CAH· in the CA–MMA–CH_3CN system described in the next section may allows us to consider that the formation of CAH· arises from CA(T). It is noteworthy that CAH· is surely generated in this system, also through interaction between CA(T) and MMA.

Therefore, from the above discussions it can safely be concluded that the origin of CAH· in the CA–DCE system, regardless of the presence or absence of the additives (ST, CAH_2, AN, and MMA), is the triplet state of CA.

Production of the Chloranil Anion in the Polar Solvent.

The time-resolved spectra obtained by the laser photolysis for the CA–CH_3CN system are shown in Fig. 8a. CA(T), with maxima at 510 and 370 nm, decays relatively fast, and the absorption bands of maxima at 450, 430, and 360 nm become conspicuous 5 μs after flashing. These aspects closely resemble those obtained by the microsecond-flash photolysis for the same system.[10] It has already been known that CA^- has absorption bands at 448, 422, and 321 nm.[23] From this knowledge and from a comparison with the results for the CA–DCE system (Fig. 2), it is possible to deduce that, among the bands observed, the 450 nm band is brought about mainly from CA^-, the 360 nm band mainly from CAH·, and the 430 nm band from both CA^- and CAH·. On adding ST to this solution, CA(T) decayed rapidly, keeping its original aspects and without producing any transients, in the same way as in the case of the DCE solution. On the other hand, however, as may be seen in Fig. 8b, the addition of 1.0 mol dm^{-3} MMA to the solution causes a rapid decrease in CA(T) and does not prevent CA^- and CAH· from being produced and living for a relatively long time. The kinetic behavior of the band with its maximum at 450 nm was analyzed carefully in the same manner as in the CA–CAH_2–DCE system. The results revealed that CA^- grow simultaneously with the decay of CA(T). The kinetic analysis at 420 nm also led to the same result. Therefore, which one of the two species, CA^- or CAH·, is the primary transient is not proven, but it is elucidated that both of them come from CA(T).

Some observations have now established that the weak EDA complex in a polar solvent is photolyzed to produce the anion of an electron acceptor due to ionic dissociation in the first excited singlet state.[21] However, for the CA–MMA complex in acetonitrile, no

TABLE 1. QUENCHING RATE CONSTANTS FOR TRIPLET CHLORANIL BY VINYL MONOMERS AND THEIR IONIZATION POTENTIALS (I)

Quencher	I/eV	Solvent	k_q/mol^{-1} dm^3 s^{-1}
AN	10.91	DCE	3.1×10^4
MMA	9.8	DCE	5.1×10^6
		CH_3CN	6.7×10^6
ST	8.47	DCE	2.5×10^9
		CH_3CN	8.0×10^9

indication of the direct production of the anion *via* the excited singlet state has been obtained. This may be interpreted as follows. As the CT band maximum of the CA–MMA complex is located at a higher energy than its locally excited band within the CA molecule, the lowest excited singlet state of the complex is probably similar in nature to that of uncomplexed CA. Accordingly, a rapid intersystem crossing in the complex may occur, as in CA, immediately after pumping to the singlet state, this crossing being then followed by ionic dissociation.

The Mechanism of Triplet Quenching and Semiquinone Formation. As is illustrated in Figs. 3, 4, and 5, CA(T) is quenched by each of the vinyl monomers. The rate of decay at 510 nm obeyed a Stern-Volmer-type relation in the relatively low concentration range of quenchers: $1/\tau=1/\tau_0+k_q[Q]$, where τ and τ_0 are the decay times of CA(T) in the presence and absence of a quencher, Q, respectively, where [Q] is the concentration of Q, and where k_q is the quenching rate constant. The values of the rate constants are listed in Table 1. The values of k_q increase with a decrease in the ionization potentials of the quenchers, and an increase in the solvent polarity tends to enhance the quenching by vinyl monomers, especially by ST. This means that the CT interaction between CA(T) and ST is quite responsible for the quenching.

For the purpose of estimating the quantum yields of the transients, we estimated the molar extinction coefficient of CA(T) at 510 nm by comparison with that of the benzophenone triplet at 532.5 nm in benzene,[22] assuming the triplet yield of CA to be unity. The estimated value was $(7.2\pm1.3)\times10^3$ mol^{-1} dm^3 cm^{-1} in DCE, nearly equal to that of duroquinone triplet in cyclohexane or benzene.[22] Using this value and that of CAH·[11] or CA$^-$,[23] the yield, ϕ, of the CAH· or CA$^-$ formed from CA(T) can be approximately evaluated from the time-resolved spectra for the systems shown in Figs. 2, 3, 4, and 8 and for the system of CA in neat AN or MMA as well. In this estimation, the triplet yield of CA has already been assumed to be unity, and it was assumed that there was no effect of the solvent change upon the absorptivity of CA(T). Since the observed ϕ value corresponds approximately to $k_{ri}[M_i]\tau$, where k_{ri} is the second-order rate constant for the transient arising from the interactions between CA(T) and the reactant, M_i (the vinyl compound and/or solvent), where $[M_i]$ is the concentration of M_i, and where τ is the lifetime of CA(T) under the examining conditions, one can estimate k_r easily. These results

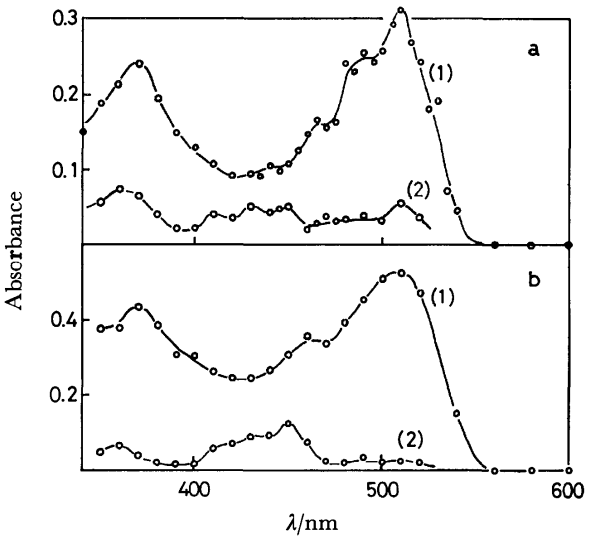

Fig. 8. Transient absorption spectra obtained by nanosecond laser photolysis for CA–CH_3CN and CA–MMA–CH_3CN systems. a: [CA]$=1.5\times10^{-3}$ mol dm^{-3}, b: [CA]$=3\times10^{-3}$ mol dm^{-3}, [MMA]$=1.0\times10^{-3}$ mol dm^{-3} in acetonitrile.

TABLE 2. YIELD OF CAH· AND CA$^-$ FOR SEVERAL SYSTEMS AND RATE CONSTANTS FOR THEIR FORMATION

Transient	System	ϕ	k_r/mol^{-1} dm^3 s^{-1}
CAH·[a]	CA-DCE	0.19	3×10^3
	CA-AN	0.20	7×10^3
	CA-MMA	0.08	4×10^5
CA$^-$ [b]	CA-CH_3CN	0.08	9×10^2
	CA-MMA-CH_3CN	0.15	9×10^5

a) The molar extinction coefficients at 435 and 420 nm in dioxane[11] were used for all our systems: $\varepsilon(435)=7.7\times10^3$ mol^{-1} dm^3 cm^{-1}, $\varepsilon(425)=7.3\times10^3$ mol^{-1} dm^3 cm^{-1}. b) $\varepsilon(450)=9.7\times10^3$ mol^{-1} dm^3 cm^{-1} [23] was used.

are summarized in Table 2, along with the corresponding ϕ values. The low yields of CAH· and CA$^-$ imply that other quanching processes are efficiently competing with their formation. One of the competing processes is the rather efficient production of an intermediate compound during the induction period of the ST or MMA polymerization photosensitized by CA.[7] That is to say, the quenching of CA(T) by vinyl monomers results mainly in the production of adducts between CA and monomers, and partly in the formation of CAH· and/or CA$^-$.

When the logarithms of the formation-rate constants (k_r) of CAH· are plotted against the ionization potentials of the reactants, a linear relationship is obtained. Plots of log k_q against the ionization potentials of the quenchers also show a linearity (Fig. 9). An inspection of these results reveals that the hydrogen transfer as well as the triplet quenching may be swayed by the CT interaction.[25] Accordingly, the existence of a triplet state complex as a precursor may be safely assumed, from which the electron transfer, the hydrogen transfer, the formation of intermediate componds for polymerization, and a return to the ground state may be thought to take place. In this connection, the next

●: log k_r, ○: log k_q.

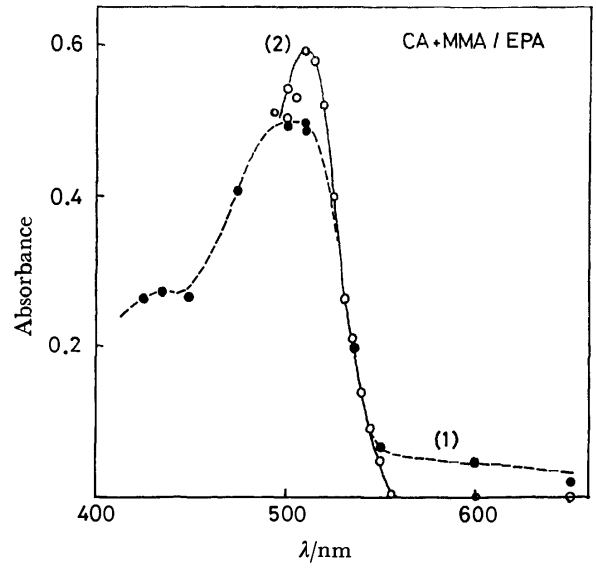

Fig. 10. Transient absorption spectra immediately after pulsing for CA–MMA–EPA and CA–MMA–DCE systems. (1): CA–MMA–EPA system at 77 K, [MMA]=0.48 mol dm^{-3}, (2): CA–MMA–DCE system at room temperature, [MMA]=0.94 mol dm^{-3}.

observation seems to supply additional support for the CT character of the triplet intermediate. The photolysis for the CA–MMA complex at 77 K in EPA, where the ground-state conformation of the complex may be almost frozen, gave a new, weak, transient absorption in the 550—650 nm region like that of the triplet EDA complex between CA(T) and benzene or between CA(T) and acetone,[10] although at room temperature such a broad band was not found, not even in a more concentrated MMA solution. These aspects are shown in Fig. 10. As the ionization potential of MMA is not very different from that of acetone, it may be possible to regard that absorption as the band arising from the CT interaction between CA(T) and MMA.

The observations and considerations described above allow us to explain the interaction mechanisms of the excited state of CA with the vinyl monomers used in the present work by assuming the following scheme:

$$CA(T) + M \rightarrow {}^3(CA^{\delta-}\cdots M^{\delta+}) \rightarrow CAH\cdot + M'\cdot$$

$$(TC) \quad \text{and/or}$$

$$\swarrow \quad \searrow \quad CA^- + M^+$$

$$CA(S_0) + M \qquad P$$

where M means the vinyl monomer; TC, the triplet complex, and P, the intermediate compound which relates to polymerization. The main features of this scheme resemble that proposed for the photoreduction of benzophenone by amines.[25,26] Whether the semiquinones appear or not may be determined by the relative efficiency of each process under the effect of surrounding solvent molecules upon the triplet-state complex. In so far as our present systems are concerned, both electron transfer and hydrogen abstraction by CA(T) should take place from a relaxed equilibrium state of the triplet intermediate after solvent reorientation is realized, because the triplet quenching is rather slow compared to the diffusion-controlled rate.

This conclusion is very interesting compared to the assumption[26] of the existence of a non-relaxed triplet-state encounter complex from which hydrogen-atom abstraction occurs, competing with the ionic dissociation, for the benzophenone-tertiary amine systems with relatively low ionization potentials.

The authors wish to thank Mr. Norihito Suzuki and Mr. Kazuo Maeda for their experimental assistance. One of the authors (H. K.) would like to acknowledge the award of a Grant-in-Aid for Scientific Research from the Ministry of Education.

(Received February 7, 1977)

Exciplex (DA)* and triple exciplex (DDA)* formation between 1,4-dicyanobenzene (DCB) and alkylnaphthalenes was investigated by steady-state and nanosecond time-resolved fluorescence spectroscopies at room temperature. Typical two-component decay of the exciplex and the fluorescence rise of the triple exciplex were observed in dioxane solutions of DCB and several alkylnaphthalenes. The results imply a significant dissociation process of (DDA)* to (DA)*. Triple exciplex formation *via* excimer (DD)* was proposed to be significant in a concentrated solution of alkylnaphthalene ($>10^{-1}$ M), while the triple exciplex was formed *via* the exciplex in a dilute solution of the electron donor.

Triple exciplex formation was reported first by Beens and Weller in the 1,4-dicyanobenzene (DCB) and naphthalene system. They reported the fluorescence lifetime of the exciplex ($\approx$30 ns) and an extraordinary rate constant (1.8×10^{8} $s^{-1}M^{-1}$) of triple exciplex formation from the exciplex.[2] Recently, Saltiel *et al.* reported triple exciplex emission in the system of 9,10-dichloroanthracene and 2,5-dimethyl-2,4-hexadiene in a polar solvent such as acetonitrile.[3] On the other hand, Grellmann and Suckow have reported triple exciplex formation in the anthracene–diethylaniline system in the temperature region of $\approx$230—180 K and discussed its intersystem crossing to the triplet state of anthracene.[4] More recently, Mimura and Itoh reported an intramolecular triple exciplex formation between two naphthyl moieties of 1,3-dinaphthylpropane (DNP) and DCB, and they suggested that the triple exciplex was not formed *via* intramolecular excimer of DNP, but *via* exciplex (DA)* formed between DCB and DNP.[5] Preliminary results of the exciplex and the triple exciplex were also reported for the DCB and alkylnaphthalene system. The dissociation process from the triple exciplex to the exciplex was so significant that this system exhibits typical two-component decay of the exciplex and fluorescence rise of the triple exciplex.[6] Although two-component decay of D*(or A*) and also fluorescence rise of (DA)* has been reported,[7] there are no reports of lifetime measurements which bear on the transformation between the exciplex, (DA)*, and the triple exciplex, (DDA)*.

This paper reports steady-state and nanosecond time-resolved fluorescence studies of the triple exciplex as well as the exciplex in several solvents of the DCB and several alkylnaphthalene systems at room temperature. Typical two-component decay of the exciplex fluorescence and the fluorescence rise of the triple exciplex were observed in the dilute solution of alkylnaphthalenes and DCB in dioxane. Concentrated solutions ($>10^{-1}$ M) of acenaphthene (AcN) and DCB in dioxane or THF exhibit fluorescence rise of the exciplex, which is not attributable to exciplex formation from DCB and AcN, but to dissociation of the triple exciplex. Since a time-dependent exciplex concentration in the system cannot show any fluorescence rise of the exciplex (see Eq. 1),[7,8] the triple exciplex formation *via* the excimer is suggested not to be negligible. This is consistent with the fact that the fluorescence quenching of alkylnaphthalene by DCB depends remarkably on the concentration of alkylnaphthalene above $\approx10^{-1}$ M. The triple exciplex formation and dissociation in the intermolecular system of alkylnaphthalene and DCB are discussed in comparison with the results of the intramolecular system of DNP and DCB mentioned above.

Experimental

Commercially available 2-methylnaphthalene (2-MN), 1,5-dimethylnaphthalene (1,5-DMN) and 2,3,6-trimethylnaphthalene (2,3,6-TMN)(Tokyo Kasei) were purified by silica gel chromatography and recrystallized from methanol (spectrograde) several times. Zone-refined acenaphthene (AcN) which was available commercially (Tokyo Kasei) was also purified in a manner similar to that described above. The fluorescence spectra were recorded with a Hitachi MPF-2A spectrophotometer with an exciting light of 310 nm. Good commercial solvents (Dotite spectrosols) were used, and chloroform was used after purification through an alumina colum (Woelm, Activity I) for removal of methanol which was present as a stabilizer. Solutions were contained in squartz cells (1 cm) equipped with graded seals, and were degassed by freeze-thaw cycles at 10^{-4}—10^{-5} Torr. Rectangular quartz cells with lightpath length 0.1 mm and 1 mm were also used for the concentrated solution. The time-resolved fluorescence spectra and the fluorescence lifetimes were determined by analyzing exponential decay curves measured by an oscilloscope (Tektronix 465), and a photomultiplier, HTV-R342 or R666, and by excitation with a coaxial N_2 gas laser which has a maximum 20-kW photon peak intensity at 3371 Å.

Results and Discussion

Steady-State Fluorescence Study. Fluorescence spectra of dioxane solutions of alkylnaphthalene, $<10^{-4}$ M, and in the presence of several concentrations of DCB at room temperature exhibit ordinary fluorescence behavior as expected for the electron donor-acceptor system. The fluorescence intensity of alkylnaphthalene decreases and the exciplex fluorescence intensity ($\lambda_{max}=$ 420—440 nm, $\tau=\approx$10—15 ns) increases when the DCB concentration increases. Apparent rate constants for exciplex formation were obtained from linear Stern-Volmer plots of the fluorescence quenching of 2-MN by DCB, and found to be 1.6×10^{10} $s^{-1}M^{-1}$ in dioxane and 2.5×10^{9} $s^{-1}M^{-1}$ in chloroform assuming negligible reversal of exciplex formation (Scheme 1).

Excitation spectra monitored at 450 nm (concentration of electron donor $<10^{-1}$ M, where fluorescence was determined from front surface of the sample cell in the concentrated solution) and the absorption spectra of dioxane solutions of 2-MN and DCB by using 1 mm and 1 cm quartz cells indicate no complex formation in the ground state. Figure 1 shows fluorescence spectra of dioxane solutions of DCB (concentration, $\approx 10^{-2}$ M) and several concentrations of 2-MN. The fluorescence of both exciplex and alkylnaphthalene are quenched with increasing 2-MN concentration up to 10^{-3} M. In highly concentrated solution of electron donor, $>\approx 10^{-1}$ M, fluorescence intensity at the longer wavelength region increases and an isoemissive point is observed at $\approx$480 nm. The fluorescence at 490 nm region may be ascribed to the triple exciplex, as mentioned in the previous paper.[5,6] In the concentrated solution ($>10^{-1}$ M) of 2-MN, however, it is difficult to determine an exact stoichiometry of the triple complex from fluorescence intensity.

The Stern-Volmer plots of the fluorescence quenching of 2-MN show a linear relationship against DCB concentration, as mentioned above. The slope of the Stern-Volmer plots increases markedly with increasing 2-MN concentration $>\approx 10^{-1}$ M, as shown in Fig. 2. On the other hand, excimer fluorescence is known to be observed for alkylnaphthalene such as [2-MN] $>\approx 10^{-1}$ M, while excimer formation is negligible in more dilute solution of alkylnaphthalene.[9] However, unless triple exciplex formation *via* the excimer is taken into account, the fluorescence quenching of 2-MN by DCB cannot depend on the concentration of 2-MN (Scheme 1). This argument is still valid even if dissociation of the long lived excimer to D* might be significant in the concentrated solution of 2-MN. Anomalous fluorescence quenching by DCB was observed for other alkylnaphthalenes such as AcN in the concentrated solutions, [AcN]$>\approx 10^{-1}$ M. Therefore, the concentration dependence of the slope of the Stern-Volmer plot shown in Fig. 2 may be attributable to the triple exciplex formation *via* the excimer. These transformations of the excited species are shown in Scheme 1. The anomalous fluorescence quenching of alkylnaphthalene evident in this steady-state fluorescence measurement agrees well with results of the time-resolved fluorescence studies in the following section.

Time-Resolved Fluorescence Study. Figure 3 shows time-resolved fluorescence spectra of a dioxane solution of DCB and 2-MN. The fluorescence spectra cen-

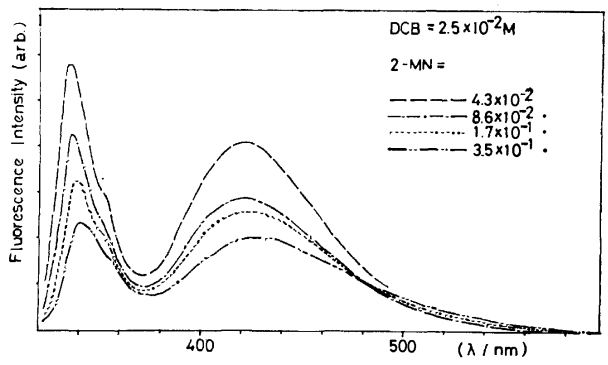

Fig. 1. Fluorescence spectra of dioxane solutions of DCB and several concentrations of 2-MN at room temperature.

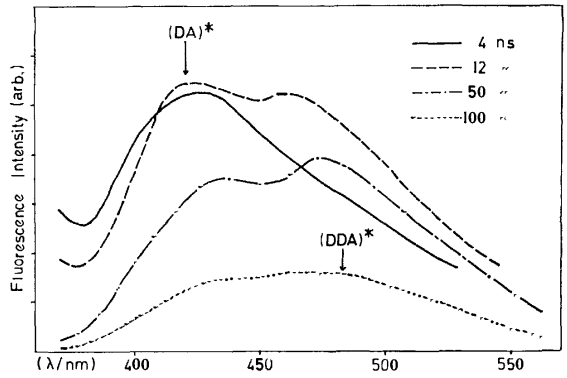

Fig. 3. Time-resolved fluorescence spectra of the intermolecular system of 2-MN (2×10^{-1}M) and DCB (2×10^{-2}M) in dioxane (extracted from the previous paper, Ref. 6).

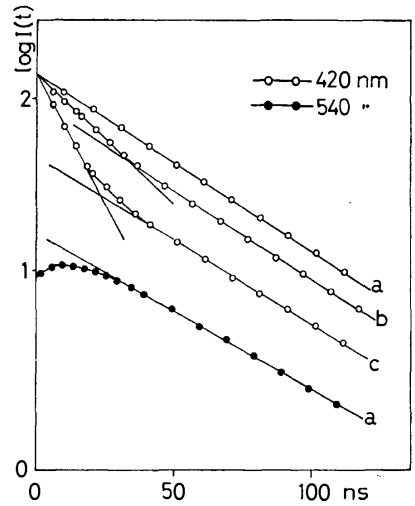

Fig. 4. Time development of the fluorescence of the exciplex, (DA),* and the triple exciplex, (DDA),* in dioxane solutions of 2-MN and DCB (2×10^{-1}M). The concentrations of 2-MN are 2.0×10^{-1}M (a), 3.5×10^{-3}M (b), and 8.8×10^{-4}M (c), respectively.

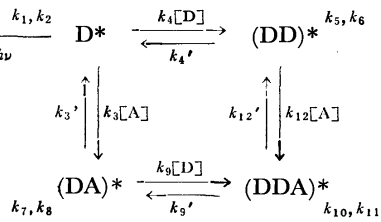
tered at 420 and 490 nm are ascribed to the exciplex and the triple exciplex, respectively. The fluorescence spectrum of the exciplex with a maximum at the 420—430 nm region was observed at 4 ns after laser pulse, while the fluorescence spectra of the exciplex as well as the triple exciplex were observed at 50—100 ns after a laser pulse. Figure 4 shows semilogarithmic plots of the fluorescence decay monitored at 420 nm in dioxane solutions of DCB and several concentrations of 2-MN. The fluorescence at 420 nm shows a single exponential decay in a high concentration of 2-MN, while the fluorescence at 420 nm exhibits a double exponential decay with decreasing concentration of 2-MN. On the other hand, fluorescence rise when the emission is monitored in the 470—580 nm region was observed from a concentrated solution of 2-MN and DCB (Fig. 4).

The photochemical interactions in the excited states are as follows:



Scheme 1.

where D and A are alkylnaphthalene and DCB, respectively. The rate constants k_1,k_5,k_7, and k_{10} are the radiative rate constants of each excited species, and k_2, k_6,k_8, and k_{11} are nonradiative rate constants. The rate constants k_3,k_4,k_9, and k_{12}, and their primed counter parts are for the association and dissociation of the excimer, the exciplex and the triple exciplex, respectively. If excimer formation is neglected in a dilute concentration of alkylnaphthalene,[2] the time dependent concentrations of the exciplex (DA)* and the triple exciplex (DDA)* are expressed by the following well known equations:[4,8]

$$[(DA)^*] = c_1 \exp(-\lambda_1 t) + c_2 \exp(-\lambda_2 t), \quad (1)$$

$$[(DDA)^*] = c_3\{\exp(-\lambda_1 t) - \exp(-\lambda_2 t)\}, \quad (2)$$

where

$$\lambda_{1,2} = 1/2[k_7+k_8+k_9[D]+k_9'+k_{10}+k_{11}+k_{12}' \mp\{(k_9'+k_{10}+k_{11}+k_{12}'-k_7-k_8-k_9[D])^2 + 4k_9k_9'[D]\}^{1/2}]. \quad (3)$$

The time lag (t_L) between a response curve of the triple exciplex fluorescence and the exciting laser pulse is given by[8]

$$t_L = \ln(\lambda_2/\lambda_1)/(\lambda_2-\lambda_1). \quad (4)$$

The value of λ_2 was obtained from t_L and decay of the triple exciplex for several concentrations of the electron donor in dioxane solution. The association rate constant (k_9) was obtained from a slope of $\lambda_1+\lambda_2$ against alkylnaphthalene concentration, and the dissociation rate constant (k'_9) was obtained from λ_2 and fluorescence lifetimes of the exciplex, $(k'_3+k_7+k_8)^{-1}$, in a very dilute solution of electron donor compared with that of DCB. The rate constant k_9 and k'_9 obtained here for the 2,3,6-TMN and DCB system are 2.1×10^9 $s^{-1}M^{-1}$ and 1.5×10^7 s^{-1}, respectively as reported in a previous paper.[5] These rate constants demonstrate a significant dissociation process of the triple exciplex to the exciplex, which are in good agreement with results obtained from the typical two-component decay of the exciplex fluorescence. However, the values of k_9 determined in the concentrated solutions of alkylnaphthalene, $>\approx10^{-1}$ M, appear to be considerably smaller than those determined in dilute solution. This is attributed to formation of the triple exciplex *via* the excimer as well as the exciplex in concentrated solutions of alkylnaphthalenes.

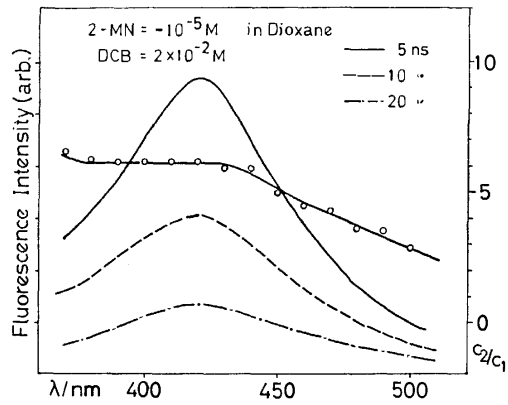


Fig. 5. Time-resolved fluorescence spectra of the intermolecular system 2-MN ($\approx10^{-5}$M) and DCB (2×10^{-2}M) in dioxane at room temperature and plots of c_2/c_1 at several wavelengths.

In order to exclude the ambiguity that the double-exponential decay curve of the exciplex may overlap the decay of the triple exciplex, ratios of c_2 and c_1, in Eq. 1, were plotted *vs.* the wavelength. The values of c_1 and c_2 were obtained by a deconvolution method from the decay curves of the exciplex. Figure 5 shows these plots and time-resolved fluorescence spectra in the dilute solution of 2-MN and DCB. The ratio of c_2/c_1 does not depend on the wavelength in the 380—440 nm region in dioxane solution. The fact implies real two-exponential decay of the exciplex fluorescence. Time-resolved fluorescence spectra in dilute solution shown in Fig. 5 reveal no significant triple exciplex but two-component decay of the exciplex fluorescence. Similar behavior of the fluorescence decay of the exciplex was observed for DCB associated with other alkylnaphthalenes. The results are summarized in Table 1.

The AcN–DCB system in a polar solvent such as THF does not exhibit triple exciplex fluorescence in either steady-state fluorescence or in time-resolved fluorescence spectra. The plots of c_2/c_1 also indicate no triple exciplex fluorescence even in 500—590 nm. Nevertheless, the double exponential decay of the exciplex fluorescence was observed at low concentration of the electron donor ($<10^{-5}$ M). A short lifetime component in the double exponential decay decreased and a long lifetime component increased with increasing AcN concentration. Furthermore, the fluorescence rise of the exciplex was observed in concentrated solutions of AcN $>\approx10^{-1}$ M. Semilogarithmic plots of these exciplex fluorescence decay for several concentrations of AcN are shown in Fig. 6.

TABLE 1. FLUORESCENCE MAXIMA OF EXCIPLEX (DA)* AND TRIPLE EXCIPLEX (DDA)*, THEIR LIFETIMES AND TIME LAGS t_L

Electron donor	Fluorescence maxima		Fluorescence lifetimes		
	(DA)* (nm)	(DDA)* (nm)	t_L [a] (ns)	(DA)* [b] (ns)	(DDA)* [a] (ns)
2-MN	425	480	6	10 (49)	56
1,5-DMN	435	490	8	6 (40)	38
2,3,6-TMN	440	510	12	8 (49)	55

Concentration of DCB is constant (2×10^{-2} M). Concentrations of electron donors are $10^{-1}\approx10^{-2}$ M (a) and $\approx10^{-4}$ M (b), respectively. Values in parentheses are long lifetime components in exciplex fluorescence decay curves.

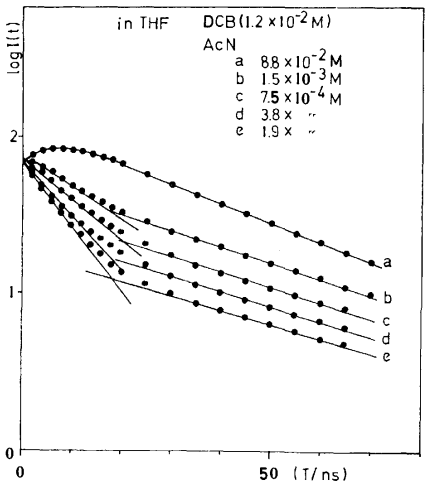

Fig. 6. Time developments of the fluorescence of the exciplex in the DCB-AcN system at room temperature.

In the dioxane solution of AcN and DCB, slope of Stern–Volmer plots of the AcN fluorescence against DCB concentration increased with increasing AcN concentration, $>\approx10^{-1}$ M, as mentioned for the 2-MN and DCB system. The experimental fact was accounted for by a postulate of significant triple exciplex formation *via* excimer and dissociation to the exciplex in high concentration of AcN, as mentioned above. This is consistent with the observation of fluorescence rise for the exciplex in a concentrated solution of AcN, as shown in Fig. 6. The excimer is implicated in the triple exciplex formation because the time dependent exciplex concentration as expressed by Eq. 1 cannot show any fluorescence rise, nor is fluorescence rise from the direct formation of exciplex between excited AcN and DCB molecules detected.

In the DCB and 1,3-dinaphthylpropane (DNP) system, the absence of concentration dependence of the fluorescence lifetimes of the excimer on the DCB concentration suggested that the intramolecular triple exciplex is not formed *via* excimer but formed *via* exciplex, as reported in the previous papers.[5,6] However, similar concentration dependence of the excimer fluorescence lifetimes was difficult to determine in the DCB and alkylnaphthalene systems. This is because the weak excimer fluorescence (lifetime $\tau=\approx35$ ns) was hardly distinguishable from the emission of the exciplex ($\tau=\approx10$ and ≈45 ns). In the concentrated solution of alkylnaphthalene where the excimer formation occurs,[9] the triple exciplex formation *via* the excimer as well as the exciplex was suggested in this paper. On the other hand, the intramolecular excimer formation is well known in symmetric DNP ($\beta\beta$- and $\alpha\alpha$-DNP).[10] Therefore, if the triple exciplex formation from the excimer and DCB is significant as mentioned above, the triple exciplex formation *via* the excimer can be also observed in the DNP and DCB system. The results of no triple exciplex formation *via* excimer in the DCB and DNP systems were ascribed to the different geometrical arrangement of two naphthyl moieties in the triple exciplex from that of the excimer. The favorable intramolecular excimer of DNP was regarded as a parallel sandwich structure of the long axis in the naphthyl moiety,[10] while two naphthyl moieties were regarded to be twisted in the molecular plane by a small angle around an axis perpendicular to the plane (a twisted model[6]). These two models cannot be transformed into each other while retaining the distance between the two aromatic moieties which is imposed by the steric requirements of the trimethylene chain. In the formation of the triple exciplex from the excimer of alkylnaphthalene and DCB which is suggested here, no steric hindrance in the transformation between a parallel sandwich model and a twisted model is anticipated.

The authors are indebted to Prof. Keitaro Yoshihara of Institute for Molecular Science, Okazaki, and Dr. Takayoshi Kobayashi of Institute of Physical and Chemical Research, Wako, for valuable discussions. The authors are also indebted to Prof. Toshihiko Okamoto for his kind encouragement and financial support.

Bimolecular Quenching of Triplet Exciton in Crystalline *p*-Dibromobenzene

Takayoshi Kobayashi and Noboru Hirota*†
The Institute of Physical and Chemical Research, Wako, Saitama, 351
**The Institute for Solid State Physics, The University of Tokyo, Minato-ku, Tokyo, 106*
(Received February 7, 1977)

The rate constants of the bimolecular quenching (γ), the hopping rate (λ), and the diffusion coefficient (D) of triplet exciton in crystalline *p*-dibromobenzene at temperatures between 160 and 77 K were obtained by analyzing the phosphorescence decay curves at high and low density excitations with the use of an N_2 laser as an exciting pulsed light source. Estimated values of γ, λ, and D at room temperature (300 K) are $(2\pm1)\times10^{-12}$ cm^3 s^{-1}, $9\pm4\times10^9$ s^{-1}, and $2\pm1\times10^{-4}$ cm^2 s^{-1}, respectively. The activation energy of the exciton hopping was obtained to be 290 ± 50 cm^{-1}. This implies that the triplet exciton in *p*-dibromobenzene crystal is described in terms of a localized exciton model.

One of the most important properties of excitons is their ability to transport electronic excitation energy without transport of charge. The diffusion constant of a triplet exciton in aromatic crystals has been obtained by several methods: *i.e.* (1) the dependence of an integrated intensity of delayed fluorescence in an aromatic crystal on the spatial distribution of excitons created by spatially inhomogeneous excitation,[1] (2) the absorption spectrum for generation of a triplet exciton by polarized light,[2] (3) surface quenching of a triplet exciton,[3] (4) diffusion of the excitons out of the tracks where they were formed by ionizing radiation,[4] (5) the magnetic field dependence of the effect of triplet excitons on the proton spin-lattice relaxation.[5] In the present paper we determined the diffusion constant of the triplet exciton by observing the phosphorescence decay curve at high and low density excitations using an intense N_2 laser light source in crystalline *p*-dibromobenzene (hereafter abbreviated to DBB). The present method of the determination of exciton migration rate has been applied to the singlet exciton in aromatic crystals[6-8] and the triplet exciton in uranyl salts.[9,10]

Experimental

The determination method of the rate constants of the bimolecular quenching and exciton migration is the same as that described in a previous paper.[8] The excitation pulsed light source is an N_2 laser (Avco Everett Model 950) with the peak power of 48 kW and the pulse width of 10 ns.

DBB was purified by repeated zone meltings. DBB single crystal in a Bridgman tube was cut in a size of $5\times4\times2$ mm^3 ($b\times c\times a$, respectively). Incident laser light was focused on the bc cleavage surface of the crystalline sample. The normal line of the surface and the incident light beam make an angle of about 45° with each other. Cooled nitrogen gas obtained from liquid nitrogen was used to control the tempetarure of the sample crystal between 97 and 160 K.

Results and Discussion

Phosphorescence Decay Curve. The phosphorescence decay curve at low density excitation observed at several temperatures between 77 and 160 K was exponential and was independent of the observing wavelength. This implies that the phosphorescence emission from the crystalline DBB sample used in the present work is not contaminated with the impurity emission. The phosphorescence intensity of DBB deviated from the exponential one at high density excitation at temperature between 77 and 160 K. The phosphorescence decay curves at low and high density excitations at 77 K are shown in Fig. 1. If the faster decay of phosphorescence at high density excitation is due to the biexcitonic quenching, the exciton concentration $n(t)$ at time t after excitation can be given by the following equation:[6,7]

$$1/n(t) = \{1/n(0) + \gamma/\alpha\}\exp(\alpha t) - \gamma/\alpha, \qquad (1)$$

where α and γ are the rate constants of monomolecular and bimolecular anihilation processes, respectively. α is obtained from the decay curve of phosphorescence at low density excitation.

The inverse of the exciton density in an arbitrary unit at high density excitation at 77 K is plotted against $\exp(\alpha t)$, the result being shown in Fig. 2. As is shown in this figure, the existence of a good linear relationship between the two quantities is consistent with the quenching mechanism given by Eq.1. Therefore the shortening of the phosphorescence decay time observed at high density excitation can be explained in terms of biexcitonic quenching. From the estimation of the initial concentration of the exciton ($n(0)$) and the intercept of the plot of $n(t)^{-1}$ *versus* $\exp(\alpha t)$, γ can be obtained. The initial concentration of the triplet exciton can be

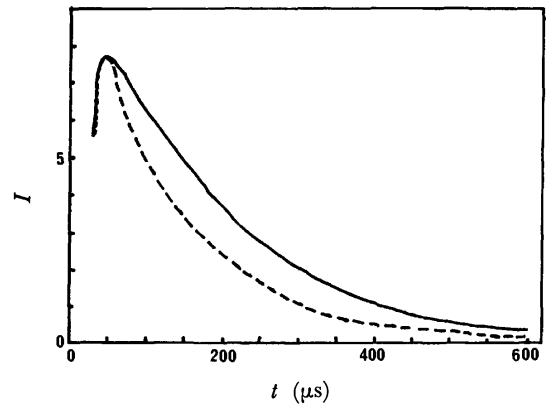

Fig. 1. Phosphorescence decay curves of crystalline DBB at 77 K at low (——) and high (----) density excitations.

† On leave from Department of Chemistry, State University of New York at Stony Brook, New York, U. S. A.; present adress Department of Chemistry, Kyoto University, Kyoto.

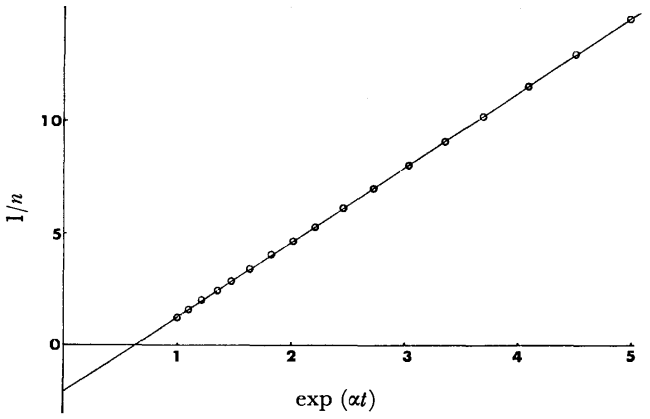

Fig. 2. The plot of $1/n$ *versus* $\exp(\alpha t)$ for the triplet exciton in crystalline DBB at 77 K at high density excitation. n is in an arbitrary unit. The initial concentration, $n(0)$, is estimated to be 1×10^{-3} M ($=6\times10^{17}$ cm^{-3}).

obtained by the $T_1\leftarrow S_0$ absorption cross section of the DBB crystal at the wavelength of the excitation laser pulse.

Estimation of the Initial Concentration of Triplet Exciton. The initial concentration of the triplet exciton, $n(0)$, is estimated by using the following equation:[8]

$$n(0) = \frac{N_0(1-e^{-1})L}{\Delta S\Delta l} = \frac{0.632N_0L}{\Delta S}\times 2.303\,\varepsilon c = \frac{1.455N_0\varepsilon cL}{\Delta S}, \quad (2)$$

where N_0 and ΔS are the number of photons irradiated and the irradiated area on the sample crystal, respectively. ε and Δl are the molar extinction coefficient and absorption depth of the $T_1\leftarrow S_0$ transition in the DBB crystal at the wavelength of the N_2 laser oscillation, respectively, and L and c are the light transmittance of lenses and dewar and the molar concentration of the DBB crystal, respectively. Crystal data[11] were used to estimate c to be 9.96 M. From the data on the $T_1\leftarrow S_0$ absorption spectrum of the DBB crystal measured by Castro and Hochstrasser,[12] molar extinction coefficients parallel to b and c axes at 337.1 nm are estimated to be 5.0 and 7.5 M^{-1} cm^{-1}, respectively. The average of the two values were used for the estimation of $n(0)$ using Eq. 2. By applying these values to Eq. 2, $n(0)$ is estimated to be *ca.* 1×10^{-3} M($=6\times10^{17}$cm^{-3}).

Estimation of γ and Hopping Rate (λ) of Triplet Exciton in DBB Crystal. From the estimated value of $n(0)$ and the intercept of the plot, γ is obtained to be $(4\pm2)\times10^{-14}$ cm^3 s^{-1} at 77 K. The relationship between the biexcitonic quenching rate constant γ and the hopping rate, λ, of the exciton is expressed by the following equation[10]:

$$\gamma = (2-A)\frac{V_0z_n}{V_{tot}z_u}\frac{\lambda\mu}{\lambda+\mu}. \quad (3)$$

Here A, z_n, and z_u are the quantum yield of the formation of a triplet exciton from a pair of two nearest neighboring excitons, the number of sites in the nearest neighbor, and the number of molecules in a unit cell of the DBB crystal with volume V_0, respectively, and

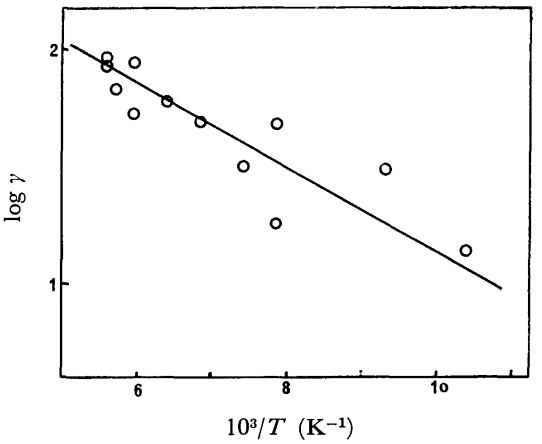

Fig. 3. The logarithmic plot of γ *versus* $1/T$ for the triplet exciton in crystalline DBB.

μ represents the rate of the quenching for a pair of two nearest neighboring excitons.

Now we consider two extreme cases: (1) The rate of bimolecular quenching is determined by that of the transition to the final higher excited state and therefore is thought to be temperature independent. In this case,

$$\gamma = (2-A)\frac{V_0z_n}{z_u}\mu. \quad (4)$$

(2) The bimolecular quenching rate is determined by the migration rate of the exciton and γ increases or decreases with the increasing temperature dependeng upon the mechanism of exciton migration. With increasing temperature the rate of the exciton migration in the hopping model (Case (b-1): $\lambda=\lambda_h$) increases, while the rate in the coherent model (Case (b-2): $\lambda=\lambda_c$) decreases. In this case,

$$\gamma = (2-A)\frac{V_0z_n}{z_u}\lambda. \quad (5)$$

The temperature dependence of γ of the triplet exciton in crystalline DBB shows that it can be described in the hopping model (Fig. 3). The activation energy of exciton hopping in DBB is obtained to be 290 ± 50 cm^{-1} from the temperature dependence of γ shown in Fig. 3.

Since it is difficult to determine A experimentally, it is tentatively assumed to be unity. The assumption makes the γ value different by factor of only 2 from that obtained by the assumption of $A=0$. The difference is smaller than the experimental error in the determination of $n(0)$ and hence of γ. The obtained value of γ is listed in Table 1 together with the data of the triplet exciton in crystalline anthracene and pyrene previously reported by Avakian and Merrifield,[13] and Ern *et al.*,[14] respectively. The values of γ and D of triplet exciton in crystalline DBB are quite similar to those in crystalline anthracene and pyrene. The similarity in the magnitude of D and hence γ of triplet exciton in anthracene, pyrene, and DBB is in contrast with the difference in the magnitude of γ of singlet exciton in crystalline anthracene ($\gamma=1.25\times10^{13}$ cm^3 s^{-1})[15] and pyrene ($\gamma=5\times10^{10}$ cm^3 s^{-1}).[16] This may be interpreted in terms of the expected smaller difference in the ex-

A Chlorine NQR Study of Trichloromethyl Derivatives. I

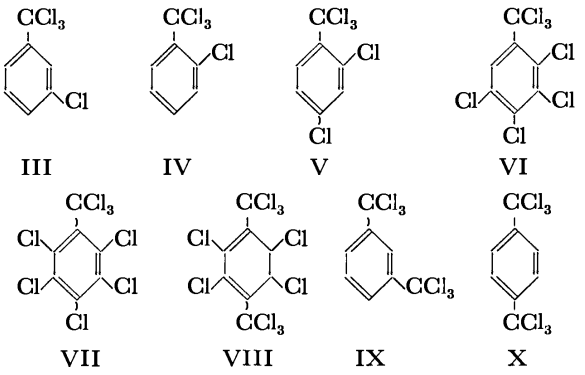
Masao HASHIMOTO

Department of Chemistry, Faculty of Science, Kobe University, Nada-ku, Kobe 657

(Received February 9, 1977)

The chlorine NQR frequencies of several benzene derivatives with $-CCl_3$ groups were measured at temperatures above 77 K. For all the compounds studied, the NQR signals of the $-CCl_3$ groups were observed to fade out; the fade-out temperatures (T_f) were in the temperature range of 130—370 K. It was found that the most important factors involved in determining the T_f value are the intramolecular steric hindrance, hyperconjugation, and intermolecular interactions. In some compounds, an increase in the NQR frequency was found to be caused by the intramolecular steric hindrance.

It is well known that the chlorine NQR signals of the trichloromethyl ($-CCl_3$) group often fade out at temperatures far below the melting point. The fade-out temperatures (T_f) reported so far for several compounds are distributed over a fairly wide temperature range.[1-7] The object of this work is to explore the role of the various factors involved in determining the T_f value. For this purpose, several tens of compounds with $-CCl_3$ group(s) were investigated; of them, a series of benzene derivatives will be discussed here. Of the benzene derivatives, trichloromethylbenzene (I)[1,7] and 1-trichloromethyl-4-chlorobenzene (II)[5] have already been studied in detail. In this work, therefore, NQR measurements were carried out for the materials shown below.



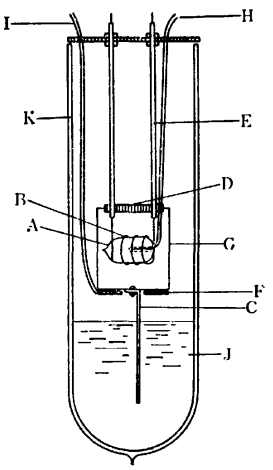


Fig. 1. Cryostat for the NQR measurement. A: Sample. B: Sample coil. C: Copper plate. D: Teflon. E: Transmission line (stainless steel pipe). F: Electric heater. G: Copper case. H: Thermocouple. I: Heater leads. J: Liquid nitrogen. K: Glass Dewar flask.

Experimental

The NQR signals of ^{35}Cl were detected by a LC-push-pull type superregenerative spectrometer.[8] For the measurement of the temperature dependence of the NQR frequency, the simple cryostat shown in Fig. 1 was employed. The temperature was controlled by changing both the amount of liquid nitrogen and the heater current. The temperature was measured with a calibrated copper-constantan thermocouple.

A commercial compound (Tokyo Kasei) of 1-trichloromethyl-3-chlorobenzene (III) was purified by vacuum distillation (3 Torr, 120 °C). Commercial reagents (Tokyo Kasei) of 1-trichloromethyl-2-chlorobenzene (IV), 1-trichloromethyl-2,4-dichlorobenzene (V), 1,3-bis(trichloromethyl)benzene (IX), and 1,4-bis(trichloromethyl)benzene (X) were purified by recrystallization from ethyl ether. The 1-trichloromethyl-2,3,4,5-tetrachlorobenzene (VI), 1-trichloromethyl-2,3,4,5,6-pentachlorobenzene (VII), and 1,4-bis(trichloromethyl)-2,3,5,6-tetrachlorobenzene (VIII) were supplied by Professor Akira Fujino, Osaka City University.

Results and Discussion

The ^{35}Cl NQR frequencies of III, IV, V, VI, VII, VIII, IX, and X were measured at temperatures above 77 K. The NQR frequencies of these compounds at 77 K are listed in Table 1. The results obtained for III, IV, IX, and X at 77 K in good agreement with the data reported by Ardalan and Lucken,[9] except for slight differences in the data for IV and IX (see footnotes of Table 1). The NQR signals corresponding to the chlorine atoms of the $-CCl_3$ group (α-chlorine atoms) of each compound were found to fade out at temperatures below the melting point of the compound. The fade-out temperatures (T_f) are summerized in Table 2, together with the melting points (T_m).

Four NQR lines were observed for V at 77 K. As judged by the value of the resonance frequency, two of them (39.733 and 39.405 MHz) are assigned to α-chlorine atoms, and, as the intensity of the line at 39.405 MHz is stronger than that at 39.733 MHz, the lower-frequency line is assigned to two equivalent α-chlorine atoms.

The NQR spectrum of VI consists of twelve lines. The number of resonance lines indicates that there are two crystallographically nonequivalent molecules in a unit cell and that each molecule has a mirror plane which coincides with the benzene ring. The most energetically favorable arrangement for the $-CCl_3$

	38.300			

a) By thermal analysis, this compound was found to form a glassy state from a supercooled liquid (T_g=166 K and T_c=201 K). For a quenched specimen, no NQR signals were observed because of the formation of the glassy state. b) The NQR frequencies corresponding to chlorine atoms attached to the benzene ring are denoted by asterisks. c) Aldaran and Lucken (A & L) reported three frequencies, 39.602, 39.158, and 35.794 MHz, at 77 K and assigned the highest one to two equivalent α-chlorine atoms.[9] The existenec of the four lines was confirmed in this work by the temperature dependence of the NQR frequencies. d) Sasikala and Murty reported three NQR frequencies, 38.76, 36.40, and 34.87 MHz, at room temperature.[10] e) A & L reported twelve frequencies, 39.481, 39.461, 39.307, 39.084, 38.987, 38.913, 38.761, 38.692, 38.640, 38.570 38.462, and 38.440 MHz, at 77 K.[9] Nine of these frequencies agreed with the present data, but the rest of them (39.307, 38.640, and 38.440 MHz) were not detected, even in spite of careful measurement. f) By thermal analysis it was found that the room-temperature modification of X is transformed into a high temperature phase at 362 K. The frequencies given in this table correspond to the room-temperature modification. A supercooled high-temperature modification gave fairly broad NQR signals at 77 K, their frequencies being 39.54, 39.42, 39.34, 39.23, and 38.82 MHz.

groups in these molecules appears to be the one in which two α-chlorine atoms are located symmetrically above and below the plane of the benzene ring, while the third one lies on it, pointing away from the ortho chlorine atom. Therefore, the two crystallographically nonequivalent molecules have the same molecular configuration. Four of the twelve lines of VI (40.093, 39.909, 39.851, and 39.709 MHz at 77 K) were found to fade out; they are assigned to the two $-CCl_3$ groups of the two crystallographically nonequivalent molecules. Since the intensities of the signals at 40.093 and 39.851 MHz are approximately twice as strong as those at 39.909 and 39.709 MHz, each of the former two lines corresponds to two equivalent α-chlorine atoms in a molecule.

Table 2. Fade-out temperatures (T_f) of the NQR signals of $-CCl_3$ groups and melting points (T_m) of several benzene derivatives

Compound	T_f/K	T_m/K
I[a]	130 and 215	265
II[b]	250	270
III	260	270
IV	260	303
V	320	323
VI	330 and 370	395
VII	260	345
VIII	300	380
IX	145—160	308
X	160—170 and 255	383

a) Ref. 7. b) Ref. 5.

Three of the eight NQR lines of VII (41.744, 41.034, and 39.794 MHz) and six of the ten NQR lines of VIII (41.649, 41.214, 41.169, 40.491, 39.689, and 39.381 MHz) are undoubtedly to be assigned to α-chlorine atoms, because of the fade-out phenomena of these lines.

Ballester *et al.* pointed out that the $-CCl_3$ group of VII is arranged in such a way that two α-chlorine atoms lie on one side, and the third one on the other side, of the plane of the benzene ring, and that the benzene ring is distorted as the result of a strong steric repulsion between the α-chlorine atom and the ortho substituent.[11] As is shown in Table 1, the $-CCl_3$ group of VII gives three NQR lines, two of them with relatively high resonance frequencies (41.744 and 41.034 MHz) as compared to the third one (39.794 MHz). The two higher frequency lines are probably to be assigned to the two α-chlorine atoms, which interact with the ortho substituents. The reason for this assignment is as follows: the steric repulsion between the chlorine atoms causes a decrease in the ionic character of the C–Cl bond in the $-CCl_3$ group, and, according to the theory of Townes-Daily,[12] the decrease in the ionic character increases the resonance frequency.

For the chlorine atoms attached to the benzene ring (olefinic chlorine atoms) of VII, the mean NQR frequency is 38.80 MHz, while that of hexachlorobenzene is 38.45 MHz.[13] The rise in the NQR frequency in VII is also to be attributed to the steric repulsion between chlorine atoms. In the case of VIII, the mean NQR frequency (38.93 MHz) of the olefinic chlorine atom is higher than that of VII, in accord with the fact that, in VIII, all of the olefinic chlorine atoms are repelled.

The fade-out phenomenon of the NQR signals of the $-CCl_3$ group is known to be due to the reorientation of the group around its three-fold axis.[14] Recently, several authors have reported both the values of the potential barriers (V_0) for the reorientation of the group and the T_f's for some compounds.[1-3,5,6] These data show that the values of V_0 and T_f vary widely from compound to compound and that the T_f value tends to rise with an increase in the V_0 value. Of the benzene derivatives studied in this work, the substances with a

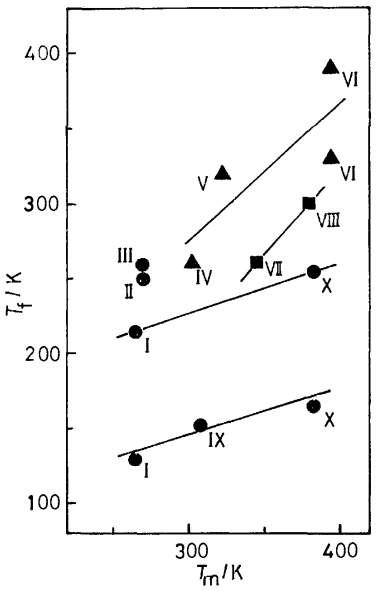

Fig. 2. Fade-out temperature (T_f) *vs.* melting point (T_m) plots of benzene derivatives.
●: Substances without ortho-substituent,
▲: substances with ortho-substituent(s),
■: perchloro-compounds.

$-CCl_3$ group with ortho substituent(s) show considerably high T_f values. Since the intramolecular steric hindrance between the $-CCl_3$ group and ortho substituent(s) raises a potential barrier for the reorientation of the $-CCl_3$ group, it seems reasonable that the substances with ortho substituent(s) show high T_f values. It is worth noting that the fade-out phenomenon was observed even for the $-CCl_3$ groups of VII and VIII, in which the groups are flanked by two ortho chlorine atoms. Moreover, despite the presence of the two ortho substituents, the T_f values of VII and VIII are comparable with those of other compounds with one ortho substituent. Therefore, the distortion of the benzene ring in VII and VIII relieves the steric hindrance, thus decreasing the value of V_0.

In the single-crystal NQR study of II, Kiichi *et al.* reported the presence of hyperconjugation between the $-CCl_3$ group and the π-systems of the benzene ring.[5] According to them, the hyperconjugation tends to lower both the NQR frequency and the magnitude of the temperature coefficient of the α-chlorine atom associated with the hyperconjugation. The $-CCl_3$ group of III gives the NQR frequencies of 39.510, 39.065, and 39.045 MHz at 77 K; their mean temperature coefficients are -3.00, -3.23, and -2.51 kHz/K respectively. The possibility of the hyperconjugation in III is suggested by the fact that the lowest frequency line exhibits the smallest absolute value of the temperature coefficient. In addition, the high T_f value of III seems to support the possibility of the hyperconjugation.[5,6]

Quite different T_f values were found for the $-CCl_3$ groups of the two crystallographically nonequivalent molecules of VI. Among the nine NQR signals of X, three signals (39.343, 39.276, and 38.716 MHz at 77 K) were observed up to 255 K, while the others faded out in the temperature region of 160—170 K. The large differences in T_f evidently indicate that, in each of these compounds, there exist two kinds of $-CCl_3$ groups with different potential barriers for the reoricntation of the group. The cause of the difference in T_f for VI is probably of intermolecular nature, because the two crystallographically nonequivalent molecules have almost the same molecular configuration.

For the benzene derivatives studied, T_f *vs.* T_m plots are shown in Fig. 2. In the series of the substances without an ortho substituent (denoted by ● in Fig. 2), T_f tends to increase with an increase in T_m.[15] The same trend can be seen for the compounds with an ortho substituent (denoted by ▲) and also for the perchloro compounds (denoted by ■). Since T_m reflects the degree of intermolecular interaction, this tendency implies that T_f (in other words, V_0) is affected not only by intramolecular interactions, but also by intermolecular ones.

The author would like to express his gratitude to Professor Ryôiti Kiriyama for his helpful discussion. The author also wishes to thank Professor Akira Fujino for the generous gift of authentic samples of 1-trichloromethyl-2,3,4,5-tetrachlorobenzene (VI), perchlorotoluene (VII), and perchloro *p*-xylene (VIII). Thanks are due to Dr. Koichi Mano for his thermal analyses.

The Microwave Spectrum of 1-Propanethiol

Osamu OHASHI, Mamoru OHNISHI, Akira TAGUI, Takeshi SAKAIZUMI, and Ichiro YAMAGUCHI

Department of Chemistry, Faculty of Science and Technology, Sophia University, Chiyoda-ku, Tokyo 102

(Received March 1, 1977)

The microwave spectra of 1-propanethiol and its deuterated species ($CH_3CH_2CH_2SD$) were measured in the frequency region from 8.5 to 35 GHz. Several a-type R-branch transitions for the ground and excited vibrational states of the normal species and for the ground state of the deuterated species were identified, and the following rotational constants in MHz were obtained: $A=23429\pm653$, $B=2345.29\pm0.03$, and $C=2250.18\pm0.03$ for the ground state of the normal species; $A=24483\pm945$, $B=2346.30\pm0.04$, and $C=2253.91\pm0.04$ for the excited state of the normal species, and $A=21758\pm461$, $B=2306.71\pm0.03$, and $C=2217.79\pm0.03$ for the ground state of the deuterated species. The spectrum assigned to the ground vibrational states has been attributed to the T–G rotational isomer, and the excited vibrational state has been ascribed to the $-CH_2-CH_2-$ torsional motion.

The chemical thermodynamic properties and rotational isomerism of 1-propanethiol have been reported by Pennington *et al.*[1] In the gas phase, the potential energy of the *trans* form, a conformer with respect to the central C–C bond, is only about 400 cal mol^{-1} lower than that of the *gauche* form.[1] The vibrational assignment and rotational isomerism of 1-propanethiol have been reported by Hayashi *et al.*[2] Taking account of the additional rotational isomerism around the C–S bond, we would expect the five possible rotational isomers, T-T, T-G, G-T, G-G, and G-G′, shown in Fig. 1, where the first symbol refers to the isomerism around the central C–C bond, and the second, to the one around the C–S bond.[2] In the gaseous and liquid states, the T-T isomer, the more stable one, and the G-T isomer have been confirmed to exist.[2]

Microwave spectroscopic studies have shown that the *gauche* form is more stable than the *trans* form for 1-fluoropropane[3] and 1-chloropropane.[4] The 1-propanol molecule has been confirmed by microwave spectroscopy to exist in both *trans* and *gauche* forms.[5] The relative intensity measurement has shown that the *gauche* form is more stable than the *trans* form by 0.29 ± 0.15 kcal mol^{-1}.[5]

The relative intensity measurement of the microwave spectral lines of ethanethiol showed that the *gauche* isomer is more stable than the *trans* isomer by 142 ± 15 cm^{-1} in their lowest vibrational states.[6]

We are interested in the rotational isomerism of 1-propanethiol, and so we examined the microwave spectra of the normal and deuterated ($CH_3CH_2CH_2SD$) species.

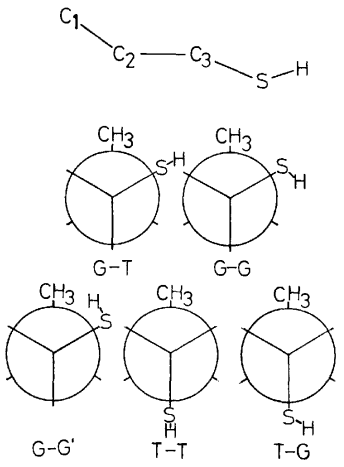

Fig. 1. Five possible rotational isomers and the numbering of carbon atoms.

Experimental

The sample of 1-propanethiol was obtained commercially (Tokyo Kasei Kogyo Co., Ltd.) and was purified by trap-to-trap distillation *in vacuo*. The deuterated species was prepared in the absorption cell by the following procedures. First, the cell was filled with D_2O vapor. It was then evacuated by means of a vacuum pump for about 20 min. At the end of this time, 1-propanethiol, purified beforehand, was admitted into the cell.

The spectrometer used was a conventional 100 kHz sinusoidal and square-wave Stark modulation type, with a phase-sensitive detector. The measurements of the transition frequencies were made with a Hewlett-Packard Model 5245 L frequency counter.

The rotational spectra were observed in the frequency region from 8.5 to 35 GHz at about −40 °C. The measurement of the relative intensity was made at about −40 °C and at room temperature. The sample was renewed about every 30 min.

Results and Discussion

Normal Species. It has been reported that 1-propanethiol exists in the T-T and G-T forms and that the T-T form is more stable than the G-T form in the gaseous and liquid states.[1,2] Consequently, the spectrum of the T-T rotational isomer was searched for at first. The moments of inertia calculated from the assumed structural parameters in Table 1 indicated that the T-T form was nearly prolate symmetric top with Ray's asymmetric parameter of −0.989. A large component of the dipole moment in this molecule was expected to lie close to the a axis. Consequently, strong a-type R-branch absorption lines were expected.

Many groups of relatively strong absorption lines were observed at intervals of about 4600 MHz. The strong

lines in a group were preliminarily assigned to the T-T isomer in the ground vibrational state and fitted to the rigid rotor Hamiltonian by the least-squares method. These assigned absorption lines are accompanied by the several satellite lines. It seems reasonable to ascribe some of these satellite lines to the excited vibrational states. One set of the absorption lines, picked up from the bushes of the satellite lines, could be fitted to the rigid rotor Hamiltonian by the least-squares method and assigned to the first excited vibrational state. The observation of the temperature dependence of the lines led to the confirmation of the assignments of the sets of lines to the ground and excited vibrational states. The other sets of satellite lines were partly observed. The observed and calculated frequencies of the transition lines, assigned to the ground and excited states, are given in Table 2 and are in good agreement. The rotational constants obtained by the least-squares fit are given in Table 3.

The $\Delta(=I_a+I_b-I_c)$ value of 12.4 amu Å^2 calculated from the rotational constants for the ground states is very different from that of 9.569 amu Å^2 predicted from the T-T model. This indicates that the molecular structure in question deviates from the T-T form which has a plane of symmetry.

Table 4 shows a comparison of the observed rotational constants, Ray's asymmetry parameters, and the values of $\Delta(I_a+I_b-I_c)$ with those calculated from the assumed structural parameters for the five possible rotational isomers. A comparison of the observed constants with the calculated ones in Table 4 reveals that the observed spectrum assigned to the ground vibrational state can reasonably be attributed to the T-G rotational isomer. Although the existence of the T-T and G-T forms has been confirmed in the gaseous and liquid states,[2] that of the T-G rotational isomer has not yet been reported. The exsitence of the T-G isomer of 1-propanethiol in the gas phase is consistent with the following facts: the *trans* form of 1-propanethiol around the central C–C bond is more stable than the *gauche* form in the gas phase[1,2] and the *gauche* isomer of ethanethiol with respect to the C–S bond is more stable than the *trans* isomer in the gaseous state.[6]

There are two possible equivalent configurations in the T-G form which can interchange with each other through thiol internal motion. The spectrum of the T-G form, therefore, can be expected to be split into doublets due to the tunneling effect of the thiol internal rotation, as is observed in the spectrum of ethanethiol.[6] Therefore, the counterpart lines of the doublets were searched for in the vicinity of the lines assigned to the rigid T-G rotor, but there was no absorption line to be assigned as a counterpart line. Consequently, the analysis of the spectrum was done assuming the rigid T-G form.

Deuterated Species. The transitions of the deuterated species were predicted from the assumed T-G model with the same structural parameters as for the normal species. The observed transition lines in Table 2 were identified by measurements of their Stark effects and fitted to the rigid rotor Hamiltonian in order to obtain the rotational constants in Table 3. Table 2 indicates that the observed and calculated transition frequencies are in good agreement. Table 4 shows that the observed Δ value of 14.44 amu Å^2 is in good agreement with the value of 14.016 amu Å^2 calculated from the T-G model.

Conformation of 1-Propanethiol. The r_s coordinates of the thiol hydrogen atom were calculated from the observed rotational constants of the normal and deuterated species in Table 3, using the expressions given by Kraitchman.[7] Table 5 shows that the r_s coordinates obtained from the observed rotational constants are in good agreement with the coordinates calculated from the T-G model. This is consistent with the result ob-

c	1.11 (13)	1.050	0

Values in parentheses denote the uncertainties estimated from the standard deviations of the rotational constants.

tained above from Table 4.

Dipole Moment. The dipole moments of the molecules were determined from the measurements of the Stark effect of the absorption lines for the ground and excited vibrational states of the normal species and for the ground state of the deuterated species. The observed Stark coefficients are listed in the third, sixth, and eighth columns in Table 6 for the ground and excited vibrational states of the normal species, and for the ground state of the deuterated species, respectively. The electric field inside the absorption cell was calibrated by observing the Stark shifts of the transitions, $1\leftarrow0$ and $2\leftarrow1$, of OCS, whose dipole moment is 0.71521 D.[8]

In the T-T form, the component of μ_c along the c principal axis should be zero due to the plane of symmetry. The T-G rotational isomer, however, has no electronic plane of symmetry, and it is expected that all three components of μ will be nonzero. Schmidt and Quade[6] have report d that, in the *gauche* isomer of ethanethiol, the inclusion of the tunneling energy in the denominator of the Stark coefficient of μ_c^2 gave the correct variation of $\Delta\nu/E^2$ for the doublet split due to the tunneling motion of the thiol hydrogen in the normal spectrum. We proceeded, however, to analyze the observed Stark coefficients without taking account of the tunneling motion of the thiol hydrogen atom, because we could not observe the doublet lines split due to the tunneling effect described above.

The least-squares fit to obtain μ_a and μ_b, assuming $\mu_c=0$, for the ground state gave the results presented in the fourth column (Calcd I) of Table 6. The calculated Stark coefficients for the M=0 components of the transitions, $3_{12}\leftarrow2_{11}$, $4_{04}\leftarrow3_{03}$, and $4_{13}\leftarrow3_{12}$, are very different from the observed ones. These deviations may be attributed to the assumption of the μ_c component being zero, since the μ_c component of the dipole moment in this molecule, if there is one, should give rise to a large effect on the Stark coefficients of these transitions. This fact indicates that the molecule in question is not in the T-T form. This result is consistent with the one deduced from the observed and calculated rotational constants.

Since the T-G isomer was likely to exist in the gaseous state, as has been described above, the observed Stark coefficients were fitted to obtain all three components of the dipole moment by the following procedures. First, since the μ_b and μ_c components have a smaller

effect on the Stark coefficients for the a-type R-branch transitions than the μ_a component, the observed Stark coefficients of the M=0 components of the transitions, $3_{03}\leftarrow 2_{02}$, $3_{12}\leftarrow 2_{11}$, $3_{13}\leftarrow 2_{12}$, and $4_{14}\leftarrow 3_{13}$, all sensitive to the μ_b and μ_c components, were fitted to obtain all three components, μ_a, μ_b, and μ_c respectively. The values of μ_b and μ_c obtained are shown in the fifth column (Calcd II) of Table 6. Next, the values of μ_b and μ_c obtained above were kept fixed, and all the observed Stark coefficients were fitted to obtain the μ_a component. The results are listed in the fifth column of Table 6. The observed and calculated Stark coefficients are in good agreement, as a whole.

The observed Stark coefficients for the excited vibrational state of the normal species and for the ground state of the deuterated species were fitted to obtain all three components, μ_a, μ_b, and μ_c, by the same procedure as was used for the ground state of the normal species. The results are given in the seventh and last columns of Table 6 respectively.

The value of the total dipole moment of 1-propanethiol in the gas phase obtained in this work, 1.69 D, is considerably larger than the value of 1.33 D determined in a benzene solution.[9] This difference may be compared with that reported for ethanethiol; the dipole moments determined by microwave spectroscopic investigation, were 1.58 and 1.61 D in the gas phase for the *trans* form and for the *gauche* form respectively,[6] and 1.39 D in a benzene solution.[10]

The values of μ_a, μ_b, and μ_c for the T-G isomer of 1-propanethiol determined in this work can be compared with the values of μ_a (1.49 D), μ_b (0.19 D), and μ_c (0.59 D) for the *gauche* isomer of ethanethiol in the gas phase.[6]

Excited Vibrational State. Our measurements of the intensities of the transition lines, $J=2\leftarrow 1$, $3\leftarrow 2$, and $4\leftarrow 3$, in the excited state relative to the lines in the ground state yielded the vibrational frequency of 136 ± 35 cm^{-1}. This value is very close to the $-CH_2-CH_2-$ torsional frequency of 130 cm^{-1} calculated using the Urey-Bradley force field.[2] Therefore, the assigned vibrational satellite can reasonably be ascribed to the excited state of the $-CH_2-CH_2-$ torsional mode.

Thermal Decomposition of Hydrogen Cyanide in Shock Waves

Kiyohiko TABAYASHI, Takayuki FUENO, Kenji TAKASA, Okitsugu KAJIMOTO, and Kazuo OKADA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received December 17, 1976)

The thermal decomposition of hydrogen cyanide diluted to 0.2, 0.5, and 1.0 mol% in argon was studied behind incident shock waves over the temperature range 2600—3600 K. The decomposition process was followed by monitoring the CN $X^2\Sigma^+$-$B^2\Sigma^+$ (0-0) absorption centered at 3883 Å. The bimolecular rate constants for the reaction HCN+Ar→H+CN+Ar were obtained from the initial slopes of absorption; $k_1=(1.26\pm0.28)\times10^{16}$ exp[$-(99.69\pm1.39)$kcal mol$^{-1}/RT$] cm^3 mol^{-1} s^{-1}. The kinetic results are well fitted by the classical collision-theory expression, $k_1=\lambda(Z/n!)(E/RT)^n\exp(-E/RT)$, with $\lambda=0.22$, $n=3.5$, and $E=D_0$(H-CN)$=118.7$ kcal/mol. The overall absorption profiles were found to be explicable on the basis of the reaction scheme involving the homorecombinations of H and CN as well as the chain reaction with H and CN as carrier species.

Precise kinetic studies of the thermal decomposition of cyano compounds in shock waves have already been reported for cyanogen (C_2N_2)[1,2] chlorocyanogen (ClCN),[3] and bromocyanogen (BrCN).[4,5] The primary step of the overall decomposition process is established to be the bimolecular reaction of these compounds with diluent gas, to give CN radicals. The rate parameters obtained for this primary process over specified temperature ranges were rationalized reasonably well in terms of the classical collision theory.[6]

In this work, we extend our absorption studies[2,5] to the decomposition of hydrogen cyanide in argon behind incident shock waves. As in the cases of ClCN[3] and BrCN,[4,5] the overall kinetics of the HCN decomposition is expected to conform to the following reaction scheme:

$$HCN + Ar \rightleftharpoons H + CN + Ar \qquad \Delta H_0^\circ = 118.7 \text{ kcal/mol}, \quad (1)$$

$$C_2N_2 + Ar \rightleftharpoons 2CN + Ar \qquad \Delta H_0^\circ = 125.5 \text{ kcal/mol}, \quad (2)$$

$$H_2 + Ar \rightleftharpoons 2H + Ar \qquad \Delta H_0^\circ = 103.3 \text{ kcal/mol}, \quad (3)$$

$$CN + HCN \rightleftharpoons C_2N_2 + H \qquad \Delta H_0^\circ = -6.9 \text{ kcal/mol}, \quad (4)$$

$$H + HCN \rightleftharpoons H_2 + CN \qquad \Delta H_0^\circ = 15.5 \text{ kcal/mol}. \quad (5)$$

(1 kcal=4.184 kJ)

Our primary purpose is to obtain accurate rate constant k_1 for the forward process of Reaction 1. Examination of the validity of the assumed mechanism (1)—(5) is also an aim of this work.

Experimental

Material. Hydrogen cyanide was generated[7] by pouring a saturated aqueous solution of sodium cyanide onto the surface of sulfuric acid and dried by passing through anhydrous calcium chloride. It was distilled over diphosphorus pentaoxide under a dry nitrogen atmosphere. The material was solidified at the temperature of Dry Ice-acetone bath and degassed several times by the freeze-thaw method. Mass spectrometric analysis of the purified sample showed no indication of impurities. Argon, from the Osaka Sanso Kogyo Corp., having a purity of 99.99% was used as a diluent gas without further purification. Reaction mixtures of 0.2, 0.5, and 1 mol% HCN in Ar were prepared at a total pressure of 600 Torr and stored in 10-l glass flasks. Mixing was allowed to proceed by diffusion for at least 12 h before use.

Procedure. Experiments were carried out in a stainless-steel cylindrical shock tube having an internal diameter of 10.4 cm. Variations in concentration of the CN radicals formed behind incident shock waves were followed by means of specific absorption spectroscopy. Details of the shock tube and associated equipments have been described previously.[2]

Shock waves were generated with hydrogen as driver gas. Mylar diaphragms of 0.1 and 0.188 mm in thickness, which corresponded to the burst driver pressures of 4 and 7.5 atm (1 atm=101325 Pa), respectively, were used. Prior to filling the test gas, the driven section was evacuated to a pressure less than 10^{-5} Torr. The leak rate was no greater than 8.5×10^{-6} Torr/min (1 Torr=(101325/760) Pa). The initial pressure, P_1, of the gas mixture was varied from 6.0 to 30 Torr to produce a given temperature condition for operation. The temperature range studied was 2600 to 3600 K.

For measuring the CN concentrations, portions of CN $X^2\Sigma^+$-$B^2\Sigma^+$ (0-0) absorption (P branch, head at 3883 Å, 1 Å=10^{-10} m) were utilized. A Rikotsusho MC-50 grating monochromator with 0.27-mm entrance and exit slits was set to isolate the spectral bandwidth 3880.6—3884.4 Å. This region encompasses the overlapping rotational lines $J=12$—44 of the ground state CN ($X^2\Sigma^+$, $v=0$).

Thermodynamic properties of the shock-heated gas immediately behind the shock front were calculated from the initial temperature and pressure in conjunction with the measured incident shock velocity. The gases were assumed to be ideal; no correction was made for the reaction heat behind the shock wave. Boundary layer effects[8] on the gas properties were estimated to be small under our experimental conditions and hence were ignored throughout. All calculations were carried out on a NEAC N-2200 digital computer.

Results

Equilibrium. The oscillographic records of the CN absorption generally showed a fast initial rise, followed by a gradual rise to a steady level. This final constancy in absorption intensity is an indication that the overall decomposition attains an equilibrium within the observation time.

Concentrations of the five species HCN, H, CN, H_2, and C_2N_2 at any given time should bear the following constraints:

$$[HCN]_0 = [HCN] + [CN] + 2[C_2N_2], \quad (6)$$

$$[HCN]_0 = [HCN] + [H] + 2[H_2], \quad (7)$$

where $[HCN]_0$ denotes the concentration of hydrogen cyanide at zero time. It follows that the concentra-

0.515	23.0	1.69	3.61	2846	4.47	0.519	0.432	0.364	2.55×10^8
0.498	8.53	1.75	3.63	3016	1.66	0.805	0.773	0.726	5.96×10^8
0.515	15.0	1.82	3.66	3235	2.96	0.877	0.858	0.820	2.38×10^9
0.498	6.45	1.92	3.69	3591	1.28	0.988	0.986	0.981	8.43×10^9
1.02	11.4	1.73	3.62	2968	2.19	0.633	0.570	0.500	6.46×10^8
1.02	6.90	1.86	3.67	3368	1.35	0.935	0.925	0.901	5.70×10^9
1.02	6.18	1.92	3.69	3570	1.22	0.975	0.971	0.961	1.05×10^{10}

tions of only three of the five species can be regarded as independent unknown quantities. Thus, the overall equilibrium can be represented by the scheme comprising the three independent local equilibria as follows:

$$\underset{(1-x_e)}{HCN} \rightleftharpoons \underset{(x_e-z_e)}{H} + \underset{(x_e-y_e)}{CN}, \quad (8)$$

$$\underset{(y_e/2)}{C_2N_2} \rightleftharpoons \underset{(x_e-y_e)}{2CN}, \quad (9)$$

$$\underset{(z_e/2)}{H_2} \rightleftharpoons \underset{(x_e-z_e)}{2H}. \quad (10)$$

The fractions of dissociation at equilibrium, x_e, y_e, and z_e, which are defined as in the above scheme, can be obtained by solving the following set of simultaneous equations:

$$K_1 = m(x_e-y_e)(x_e-z_e)P/(1-x_e)S, \quad (11)$$

$$K_2 = m(x_e-y_e)^2P/(y_e/2)S, \quad (12)$$

$$K_3 = m(x_e-z_e)^2P/(z_e/2)S. \quad (13)$$

where K_1, K_2, and K_3 are the pressure-based equilibrium constants for Reactions 8—10, respectively; m is the initial molar fraction of HCN; P is the total pressure of the shock-heated gas mixture; and S is the quantity defined by

$$S = 1 + m(x_e-y_e/2-z_e/2). \quad (14)$$

Evaluations of the equilibrium constants were based on the thermodynamic data listed in the JANAF Tables[9] except for the new values $\Delta H_f^\circ(CN)=99.5$ kcal/mol[2] and $\Delta H_f^\circ(HCN)=32.4$ kcal/mol.[10] The values of x_e, x_e-y_e, and x_e-z_e thus calculated for some representative runs are shown in Table 1.

The equilibrium concentration of CN radicals is given by

$$[CN]_e = m(x_e-y_e)[Ar]_0. \quad (15)$$

$[Ar]_0$ being the concentration of argon heated by the shock. $[CN]_e$ should be related with the observed absorbance at equilibrium by

$$\ln(I_0/I_e) = \beta_{00}lF_{ab}(T)[CN]_e, \quad (16)$$

where β_{00} is the effective absorption coefficient for CN radicals in the absorbing levels ($X^2\Sigma^+$, $v=0$, $J=12-44$); $l=10.4$ cm is the length of optical path across the tube diameter; and $F_{ab}(T)$ is the fractional population of the absorbing CN($X^2\Sigma^+$) radicals at temperature T. In the present work, $F_{ab}(T)$ is given by

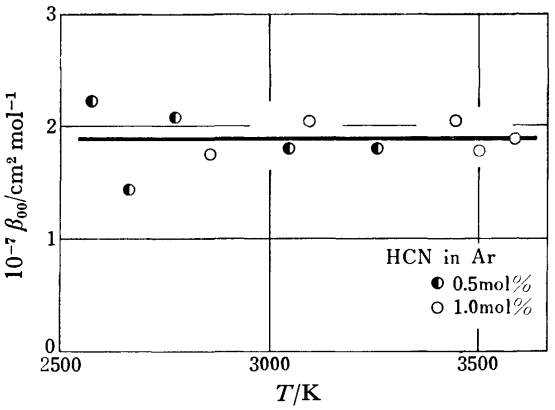

Fig. 1. Temperature variation of the CN absorption coefficient β_{00} at 3883 Å.

$$F_{ab}(T) = \frac{\sum_{J=12}^{44}(2J+1)\exp[-J(J+1)\varepsilon_{rot}/kT]}{Q_{rot}Q_{vib}}, \quad (17)$$

where ε_{rot} denotes the rotational quantum of the CN radical and where Q_{rot} and Q_{vib} respectively stand for its rotational and vibrational partition functions.

The absorption coefficient β_{00} which is related with the absorbance by Eq. 16 should by least temperature-dependent.[2] As is shown in Fig. 1, the values of β_{00} calculated from Eq. 16 for different runs were indeed nearly constant over the entire temperature range studied. The results assure that the assumption concerning the complete equilibration of Reactions 1—5 is basically correct and that the influence of CN emission on the absorbance is not significant below 3600 K. The average β_{00} value was $(1.90\pm0.12)\times10^7$ cm^2/mol.

Dissociation Kinetics. At the initial stage of reaction, disappearance of hydrogen cyanide by Reaction 1 is the only process to be considered. Thus, the bimolecular dissociation rate constants k_1 can be evaluated from the initial slopes of the CN absorption traces. Guided by Eq. 16, we may write:

$$k_1 \equiv (d[CN]/dt)_0/[HCN]_0[Ar]_0$$
$$= r_0/\beta_{00}lF_{ab}(T)[HCN]_0[Ar]_0, \quad (18)$$

where r_0 is the initial slope of the absorbance

$$r_0 = \{d\ln(I_0/I)/dt\}_0. \quad (19)$$

We set $\beta_{00}=1.90\times10^7$ cm^2/mol as has been determined

$k_1=1.26\times10^{16}\exp(-99.69\ kcal\ mol^{-1}/RT)\ cm^3\ mol^{-1}\ s^{-1}$.

in the preceding section.

Kinetic data were taken for 0.2, 0.5, and 1.0% HCN-Ar mixtures at the total pressures between 0.353 and 1.16 atm. The temperature range was limited by immeasurably small initial rise of the absorption intensities below 2600 K and by significant influence of the CN emission on the absorption trace above 3600 K. The values of k_1 obtained for representative runs are listed in Table 1, together with pertinent experimental data, *i.e.*, the initial pressure of the test gas, P_1, the measured shock velocity, U_s, the density ratio across the shock front, ρ_{21}, the reaction temperature, T_2, and the concentration of Ar behind the incident shock.

Figure 2 shows Arrhenius plots of k_1 obtained for a total of 21 experiments. A single straight line fits the plots, irrespective of the $[HCN]_0/[Ar]_0$ ratio. Least-squares treatment of the data led to the Arrhenius expression:

$$k_1 = (1.26\pm0.28)\times10^{16}\times\exp[-(99.69\pm1.39)\ kcal\ mol^{-1}/RT]\ cm^3\ mol^{-1}\ s^{-1}. \quad (20)$$

In Fig. 2, the rate constants which Roth and Just[11] have recently obtained by the H-atom resonance absorption spectroscopy are compared with our results. Their rate constants are expressed by

$$k_1^{RJ} = 5.7\times10^{16}\times\exp(-117.1\ kcal\ mol^{-1}/RT)\ cm^3\ mol^{-1}\ s^{-1}, \quad (21)$$

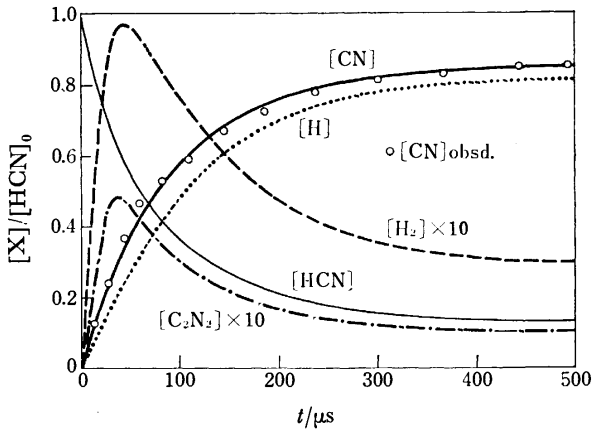

Fig. 3. Relative concentrations *vs.* particle time.
$T_2=3235$ K, $m=0.5$ mol%, $[HCN]_0=1.53\times10^{-8}$ mol/cm³, $[CN]_e=1.31\times10^{-8}$ mol/cm³.

in the temperature range 2200—2700 K. Their results are uniformly smaller than ours by a factor of *ca.* 6 in the overlapping temperature region.

Overall kinetics. The rate equations pertinent to the entire mechanism (1)—(5) were subjected to numerical (Runge-Kutta-Gill) integration on a computer. Table 2 presents the rate parameters used for computation. The rate constants k_1, k_2, and k_3 are those determined at high temperatures (~3000 K) behind shock waves.[2,12] The rate constant k_{-4} at room temperature was found to be $5.2\times10^8\ cm^3\ mol^{-1}\ s^{-1}$ in a cyanogen flow.[13] Assuming the activation energy for this reaction to be close to its endothermicity, we estimated the preexponatial factor of k_{-4} to be $8\times10^{13}\ cm^3\ mol^{-1}\ s^{-1}$. For Reaction 5, we estimated the rate parameters by analogy with other metathetic reactions of the X+XCN type.[3,5] Rate constants for the reverse reactions were all calculated from those for the forward reactions and the equilibrium constants. The time step used for integration was 0.2 μs.

The results of computation for the case of $T_2=3235$ K as an example are shown in Fig. 3. The abscissa expresses the concentrations of the various species relative to $[HCN]_0$ while the ordinate, the particle time t. The experimental concentrations of CN radicals read from the CN absorption records are indicated with open circles. The agreement between the calculated and experimental concentration profiles of CN radicals is excellent.

The computation results for other temperatures were qualitatively much the same as those shown in Fig. 3. In all cases, the concentrations of H_2 and C_2N_2 reached their maxima at a relatively early stage of reaction while those of both H and CN increased monotonously. Im-

portantly, however, these initial spikes of the H_2 and C_2N_2 concentrations were not so large as to affect the initial slope of the CN concentration curve which was calculated separately for Reaction 1 alone. The only rate constants which are adjustable for the present computations are k_{-4} and k_5. We varied these rate constants over a wide range (by a factor of 5), but the computed concentration profiles remained essentially unaltered at least in the initial 20% region of the HCN decomposition. It was also verified that Reactions 2 and 3 exert virtually no influence on the initial portion of the CN concentration profile. Evaluation of k_1 from the initial slope of absorption is thus confirmed to be perfectly legitimate.

Discussion

The apparent activation energy of 99.7 kcal/mol observed for Reaction 1 is clearly below the dissociation energy of HCN (118.7 kcal/mol). The results indicate that the internal energy of the molecule should participate in the activation process. The situation can most conveniently be represented by the Fowler-Guggenheim expression:[6]

$$k_1 = \lambda(Z/n!)(E/RT)^n \exp(-E/RT). \quad (22)$$

Under the assumption that E is equal to $D_0(\mathrm{H-CN}) = 118.7$ kcal/mol, the best fit of the temperature variation is obtained when $n=3.5$. The least-squares fit of Eq. 22 with $n=3.5$ to the experimental values of k_1 led to the expression

$$k_1 = [(1.88\pm0.26)\times 10^{12}/3.5!]T^{1/2} \times (E/RT)^{3.5} \exp(-E/RT)\ \mathrm{cm^3\ mol^{-1}\ s^{-1}}. \quad (23)$$

The value of $n=3.5$ obtained indicates that the number of the squared terms contributing to the dissociation process is 9, a nearly maximal value permissible from a classical point of view. Assuming a mean HCN–Ar collision diameter of 3.54 Å, we obtain the steric factor $\lambda=0.22$. These results do not appear unreasonable.

The results reported by Roth and Just[11] are somewhat anomalous in the sense delineated above. Their activation energy 117.1 kcal/mol for Reaction 1 is only slightly below the bond dissociation energy $D_0=118.7$ kcal/mol. If their rate constants, Eq. 21, are to be expressed in the Fowler-Guggenheim form, it is required to set $n=1$, which in itself may not be quite unreasonable. However, use of $n=1$ leads to the steric factor $\lambda=9.2$. Such an anomalously *large* λ has never been met with in the existing literature. Even when we set D_0 equal to 122.4 kcal/mol as these authors have done in their work, the results are still $n=1.5$ and $\lambda=4.0$. Perhaps, their resonance absorption technique involves some systematic errors.

It is interesting to note that, although HCN bears similarities to BrCN and ClCN in both the number of atoms and the kind of bonds involved, its activation invokes apparently more internal degrees of freedom than in the cases of its halogen homologs. More specifically, the rotational energy contributes to activation in the case of HCN only. This would not be surprising in view of the small momentum of inertia for HCN, a linear molecule which carries a hydrogen atom, an extremely light atom, at its terminal.

This work was supported in part by a Scientific Research Grant from the Ministry of Education (No. 011002).

Color and Precipitation Reactions of Lanthanoids with Chlorophosphonazo III

Tomitsugu TAKETATSU

Laboratory of Chemistry, College of General Education, Kyushu University, Ropponmatsu, Chuo-ku, Fukuoka 810

(Received August 16, 1976)

Aqueous solutions of pH 1—3 containing Chlorophosphonazo III chelates of lanthanoids give an absorption spectrum of the α-type, the spectrum showing two maximum peaks at approximately 620 and 670 nm, in the presence of an excessive amount of the reagent. However, the chelates of heavier lanthanoids give an absorption band of the β-type, which extends from 700 to 800 nm with a maximum at 745 nm, with an increase in the mole ratio of the metal against the reagent. A dark-violet precipitate forms from the solution, giving the β-type spectrum under certain experimental conditions. The combining ratio of the metal against the reagent in the precipitate is estimated to be 1:1. Since a reaction rate from the α-type to the β-type corresponds to the second order, the combining form between the metal and the reagent in the β-type chelate is assumed to be 2 : 2, *i.e.*, a dimer. The chelates of lanthanum to samarium do not give the β-type spectrum under the same conditions.

The Chlorophosphonazo III [2,7-bis(4-chloro-2-phosphonophenylazo)-1,8-dihydroxynaphthalene-3,6-disulfonic acid] reagent, which is one of the symmetrical bisazo derivatives of chromotropic acid, was used by O'Laughlin and Jensen to determine a micro-amount of the lanthanoids.[1] The determination was carried out by the measurement of the absorbance at a maximum peak near 670 nm of the absorption spectrum. The pattern of the spectrum was previously defined as α-type by the present author.[2] O'Laughlin *et al.* reported that, when the lutetium and ytterbium concentrations were increased to approximately half of the reagent concentration of 6×10^{-6}M at pH 3.0, a precipitate was formed and the solution became colorless.[1] The present author found the heavier lanthanoid chelates gave an absorption band, defined as of the β-type, which extends from 700 to 800 nm with a maximum at 745 nm, and a dark-violet precipitate is formed in the solution containing the β-type chelate under certain experimental conditions.[2]

In the present paper, the equilibrium relationship between the α-type and β-type chelates, the reaction rate of the change from the α-type to the β-type chelate, and the combining ratio of a metal against the reagent in the precipitate and the β-type chelate are investigated.

Experimental

Apparatus. All the absorption spectra were measured with a Hitachi EPS-3T automatic recording spectrophotometer. The hydrogen-ion concentration was determined by means of a Hitachi model M-4 pH meter.

Reagents. Standard aqueous solutions of lanthanoid chlorides were prepared from the respective oxides in a 99.9% purity.

Chlorophosphonazo III obtained from the Dojindo Co., Ltd., was used without further purification. The concentration was represented by multiplying the amount weighed by 0.76 because the purity of this reagent was 76%.[3]

Procedure. The absorption spectra were recorded after the prepared solutions had been allowed to stand for more than 50 h, unless otherwise indicated. Since the precipitate formed in the solution was readily dispersed by shaking, the measurement could be carried out by using the resulting solution.

The concentration of lanthanoid and phosphorus in the precipitate was estimated by the following procedure: the precipitate was obtained by adding 10 ml of a 2.4×10^{-4} M thulium, ytterbium, or lutetium chloride solution to 10 ml of a 2.4×10^{-4} M Chlorophosphonazo III solution at pH 1—2. The precipitate was then separated from the solution by centrifuging, and the supernatant was removed from the tube. An acidic solution of pH 1 containing a samll amount of magnesium chloride, used for preventing deflocculation of the precipitate, was added to the precipitate in the tube. The centrifuge tube was then shaked to disperse the precipitate into the solution. Again, the solution was removed from the precipitate by centrifuging. The dispersing and centrifuging was repeated 3—5 times. A part of the precipitate was then transferred into a conical beaker and decomposed by concentrated perchloric and nitric acids. After a clear solution had been obtained, the lanthanoid and phosphorus were determined spectrophotometrically by the O'Laughlin[1] and Lucena-Conde[4] methods respectively.

Results and Discussion

Absorption Spectra of the Lanthanoid Chelates. Figure 1 shows the absorption spectra of the aqueous

Concentration of lanthanoids: 7.50×10^{-6}M. pH 2.5.

solution of pH 1.6 containing an equimole of each lanthanoid and Chlorophosphonazo III. The spectra of the chelates of lanthanum to terbium give an similar pattern and correspond to that of the α-type. On the other hand, the chelates of dysprosium to lutetium give a maximum absorption band at 745 nm, which is characteristic of the β-type. The tendency for the conversion from the α-type into the β-type increases with an increase in the atomic number, except in the case of lutetium.

Figure 2 shows the variation in the absorbance at 745 nm for the chelates of several lanthanoids as a function of the pH. The height of the maximum peaks and the degree of the transfer of the maximum position to the lower region increase with an increase in the atomic number. The precipitate was observed in a lower pH range than each maximum position; the dotted line indicates the range. The chelates of lanthanum to gadolinium do not give the β-type spectrum in the pH range between 1.0 and 4.0.

Figure 3 shows the variation in the absorbance at 745 nm as a function of the mole ratio of each lanthanoid

to the reagent. The intensity of the absorption band first increases and then decreases with an increase in the mole ratio. The maximum values of the ratio for thulium to lutetium, for terbium to erbium, and for europium to gadolinium were observed at the mole ratios of approximately 1 : 1, 1.5 : 1, and 2 : 1 respectively. However, the absorption band of the β-type was not observed in the case of lanthanum to samarium even when the mole ratio of [metal]/[reagent] attained 15 : 1.

Reaction Rate of the Variation from the α-Type to the β-Type Chelate. Figure 4 shows the variation in the absorption spectrum of the thulium chelate from the α-type to the β-type as a function of the elapsed time. The spectrum gives the typical α-type at first, and then the pattern changes to the β-type with time. An isosbestic point is observed at approximately 700 nm. This fact suggests that an equilibrium relationship exists between the α-type and β-type chelates. The order of the reaction rate was investigated, and the following results were obtained; (i) the concentration of the β-type chelate follows Beer's law at 745 nm, and (ii) x and a, which represent the absorbance at 745 nm after t and 72 h respectively, are proportional to the reacting and initial concentration of the α-type chelate respectively. Figure 5 shows that the reaction rate for the thulium chelate is second-order, because the $1/(a-x)$ *vs.* t diagram gives a straight line.

Composition of the β-Type Chelate. Figure 6 shows the the continuous-variation plots at 745 nm for the holmium chelate. The peak at the mole fraction [Ho]/([Ho]+[reagent]) of 0.5 indicates that the combining ratio is 1 : 1. Moreover, the mole ratio of the lantha-

noid to phosphorus in the precipitate obtained from the solution of the β-type chelate was estimated by the method described above. Table 1 shows that the mole ratio of lanthanoid against phosphorus is 1 : 2; *i.e.*, the combining ratio of lanthanoid against the reagent is 1 : 1. The impurities in the Chlorophosphonazo III used were presumed to be mono- and bisazo derivatives of chromotropic acid and unreacted chromotropic acid.[5] However, it is considered that these materials do not react to lanthanoids under the present experimental conditions.

Savvin reported[6] that only one functional group in Arsenazo III, which is one of the symmetrical derivatives of chromotropic acid, participates in the 1 : 1 chelate formation with lanthanoids. It is expected that the form of the α-type chelate of Chlorophosphonazo III resembles that of the Arsenazo III chelate, because the ratio of the metal against Chlorophosphonazo III is known[1] to be 1 : 1 and the spectrum of the α-type is similar to that of the Arsenazo III chelate. Thus, it may be concluded from the results of the reaction rate that the β-type chelate is a 2 : 2 dimer. The present author previously reported[2] that the β-type chelate may be supposed to be a chained-form in which two functional groups of Chlorophosphonazo III interact with the lanthanoids. However, the recent work

shows that the β-type chelate is not the chained-form, but the 2 : 2 form.

Figure 7 shows the variation in the absorbance of the dysprosium chelate as 745 nm as a function of the concentration of the coexisting metal ions. The absorbance increases with an increase in the concentration of the coexisting metal ions, and finally the precipitate is formed. The effects of the metals on the intensity of the absorbance are in the following increasing order: sodium, potassium, and magnesium. However, it seems that anions do not contribute to the intensity. The formation of the precipitate may be explained by a coagulation of the anionic β-type chelate as a result of the influence of the coexisting cations.

The β-type spectrum was not observed in the Chlorophosphonazo III chelates of iron(III), aluminum, gallium, indium, scandium, zirconium, thorium, and uranium(VI), nor in the Arsenazo III chelates of these metals, including all of the lathanoids. On the other hand, it has been reported by several investigators that the chelate formed between a lighter lanthanoid and Carboxynitrazo[7] or Arsenazo-*p*-NO_2,[8,9] which is an unsymmetrical bisazo derivative of chromotropic acid, gives an absorption spectrum which is similar to the β-type. It is interesting to study the reason why the β-type spectrum appears considering the relationship between the positions or sorts of functional groups in the reagent and the ionic radius or coordination number of the metals.

Reactions of ^{125}I Activated by $^{125}Xe(EC)^{125}I$ Process with Methane

Masakatsu SAEKI and Enzo TACHIKAWA

Division of Chemistry, Japan Atomic Energy Research Institute, Tokai-Mura, Ibaraki 319-11

(Received September 24, 1976)

The reactions of ^{125}I obtained from the $^{125}Xe(EC)^{125}I$ process with methane have been investigated. It was confirmed that electron scavengers, such as I_2, SF_6, and O_2, play an important role. The main product is only $CH_3{}^{125}I$, the yield decreasing significantly with the concentration of Xe. By adding various additives, the yield of $CH_3{}^{125}I$ in the presence of trace amount of I_2 was assigned as follows: $8.7\pm6.7\%$ by the hot atom reaction, $35.8\pm8.0\%$ by $^{125}I^+$ in the $^1D_2$ state, and $31.5\pm2.0\%$ by $^{125}I^+$ in the ^3P states. The results are discussed in comparison with those reported on similar reactions utilizing different activation processes. Chemical sequences of the formation of $CH_3{}^{125}I$ are proposed.

Many papers have appeared on the reactions of recoil iodine from various nuclear transformations[1-12] with simple alkanes. Iodine ions in excited states always play important roles in the reactions. A number of experiments were carried out dealing with the systematics of the role of excited iodine ions.

Rack and Gordus investigated the reactions of ^{128}I obtained from the $^{127}I(n,\gamma)^{128}I$ reaction with gaseous methane, and they concluded that about 18.4% of the 54.4% organic ^{128}I is formed as a result of hot ^{128}I reactions, 11% as a result of excited iodine ions in $^3P_2$, $^3P_1$, and/or $^3P_0$ states, and 25% as a result of reactions of $I^+(^1D_2)$ ions.[3,4] Nicholas *et al.* reached a similar conclusion in the reactions of ^{130}I activated by the (n,γ) or (IT) process with methanes (CH_4 and CD_4).[5] Due to rather high yield of hot reactions, the recoils, ^{128}I and ^{130}I, however, are not necessarily suitable for a specific study of the role of excited iodine ions.

Loberg and Welch chose ^{123}Xe formed by the $^{122}Te(^3He,2n)^{123}Xe$ reaction as nuclide to give iodine, and studied the ionic reactions of $^{123}I^+$ with CH_4.[10] The nuclide, ^{123}Xe, decays in two modes, electron capture and β^+ decay.[13] In the latter mode, 14% of the ^{123}I recoils are formed initially in the I^- state.[10] This indicates that for a detailed analysis the role of the negative ion should be taken into account. The ^{125}I recoil from $^{125}Xe(EC)^{123}I$ process is preferable to other recoils for a specific investigation of iodine ions, since the nuclide, ^{125}Xe, decays only by electron capture and the resulting ^{125}I has a maximum kinetic energy of 15.6 eV.[13]

Schroth and Adloff examined the reactions of ^{125}I obtained from ^{125}Xe with methane.[6] Schleiffer and Certout also investigated the same reaction system.[11] However, they reached different conclusions.

We have studied the reactions of ^{125}I obtained from ^{125}Xe with methane in gaseous phases. The reaction yield was carefully investigated by adding various gases to the reaction system. The results are discussed in comparison with those reported from the viewpoint of the role of iodine ions in the excited state.

Experimental

Chemicals. Xenon gas with natural composition (Nippon Sanso Co., purity 99.9%) and methane (Takachiho Chem. Co., purity 99.95%) were used. Other reagents used as additives had the highest purity among those available.

Sample Preparation. Xenon gas with natural composition was introduced in a silica ampoule (18.5 ml) equipped with a breakable seal. The pressure was kept at around 700 Torr. The ampoule was irradiated in the T-pipe of a JRR-4 reactor of JAERI for 30—120 min; the neutron flux at the irradiation port was 4×10^{13} n cm^{-2} s^{-1}. After 4—12 h from the end of irradiation, the radioactive xenon mixture was purified by passing the mixture through a column packed with granular silver in order to remove ^{125}I formed in the ampoule.

Pyrex glass ampoules, with volume either 6.5 or 10.5 ml, were used as the reaction vessels. The irradiated and purified xenon gas, additive gas, when necessary, and methane were introduced into the reaction vessel by means of a vacuum line. The pressure of the reaction system was usually kept constant at 500 Torr, but it was widely varied for investigation of the dependence of the product yields on pressure. The pressure of radioactive xenon was usually kept at 20 Torr [0.04 m.f. (mole fraction)]. For the addition of excess iodine, a small amount of solid iodine was placed in an ampoule. Subsequently, air was pumped off and the radioactive xenon and methane were introduced. The samples were stored in the dark at room temperature for more than 4 days. Some samples were exposed to a 45 kCi ^{60}Co source immediately after their preparation.

Sample Processing. The reaction products were separated by means of a radio-gas chromatograph. The sample was directly injected into a radio-gas chromatograph by means of a vacuum line. A potassium hexacyanoferrate(II) 16/20 mesh precolumn of $4\phi\times100$ mm was placed in front of the separation column in order to prevent the introduction of inorganic iodides such as HI and I_2.[14] The separation column was 2.8 m D.O.P. column, Neopak 1A of 60/80 mesh coated with 15% dioctyl phthalate. In the operation, the temperature of the column was raised from room temperature to 115 °C at a rate of 8 °C min^{-1}. The effluent was collected by bubbling through a trap filled with liquid scintillator, after its activities had been continuously measured with a NaI(Tl) counter. The traps were radio-assayed with a liquid scintillation counter.

Total organic yield in the reaction system of Xe(0.04 m.f.) and CH_4 was determined to be 60.7% by the conventional solvent extraction method. This particular reaction system was chosen as a reference in determining the total organic yield in other reaction systems. In the solvent extraction method, toluene with iodine carrier (10^{-3} M) was used as an organic layer and 0.5 M Na_2SO_3 solution as an inorganic layer. The radioactivity of each layer was measured with a NaI scintillation counter and a liquid scintillation counter.

The absolute yields (AY) in other systems were determined according to the equation

$$AY(\%) = 60.7\ (A_{Xe}/A_{CH_3I})_{ref}\cdot(A_P/A_{Xe})_{sam},$$

where 60.7 is the absolute yield in the reference sample.

A_{Xe}, A_P, and A_{CH_3I} denote the activities of xenon, some product of interest and methyl iodide, respectively, in a radio-gas chromatogram (A_{CH_3I} and A_P were also measured with a liquid scintillation counter). Subscripts "ref" and "sam" denote the reference system (Xe(0.04 m.f.) and CH_4) and any other reaction systems, respectively.

Results

The vacuum line used in most of the experiments was previously utilized for sampling gases including iodine. The iodine adsorbed on the surface can not be removed completely. Thus, almost all reaction systems will have been contaminated with iodine vapor, unless otherwise stated.

The total organic yield in the reaction system, Xe (20 Torr) and CH_4(480 Torr), was 60.7±4.5%. The results based on the two different measurements, NaI and liquid scintillation counters, agree. The organic yield product in the gaseous phase was only $CH_3{}^{125}I$, unless other additives such as C_2H_6, C_2H_5Cl, and solid-I_2 were present.

When the pressure was changed from 16 to 923 Torr, the Xe/CH_4 ratio being kept at 0.10, the yield of $CH_3{}^{125}I$ remained at 54.8±4.1%. The results obtained at various temperatures are given in Table 1. The yield of $CH_3{}^{125}I$ remained unchanged, showing no temperature-effect. No wall effect was observed. Addition of 0.5 g of quartz wool (1−5 μ) inside a pyrex ampoule of similar size hardly affected the results.

The variation of $CH_3{}^{125}I$-yield with the concentration of Xe is given in Table 2. The yields decreased with an increase in the concentration of Xe, from 74.0 ±5.0% (0.011 m.f. of Xe) to 31.5±2.0% (1.0 m.f. of Xe).

The effects of additives on the reaction system of 0.04 m.f. of Xe and CH_4 containing a trace amount of I_2 are shown in Fig. 1. The yield of $CH_3{}^{125}I$ decreased monotonically with an increase in the concentration of Kr, Ar, and N_2. It was extrapolated to be 52.0±5.0 % at 1.0 m.f. of additives. When O_2 or SF_6 was chosen as an additive, the yield increased at the beginning, but decreased with a further increase in the concentrations. The extrapolated value at 1.0 m.f. of O_2 is also 52.0±5.0%, but 31.5±2.0% for the case of SF_6. With the addition of CH_3Cl, C_2H_5Cl, and C_2H_6, the yield of $CH_3{}^{125}I$ decreased with an increase in the concentrations of additives, the limiting values being 4.9± 0.8%, almost 0%, and 2.4±0.4%, respectively. A small amount of $C_2H_5{}^{125}I$ was detected in the case of C_2H_5Cl and C_2H_6 additives.

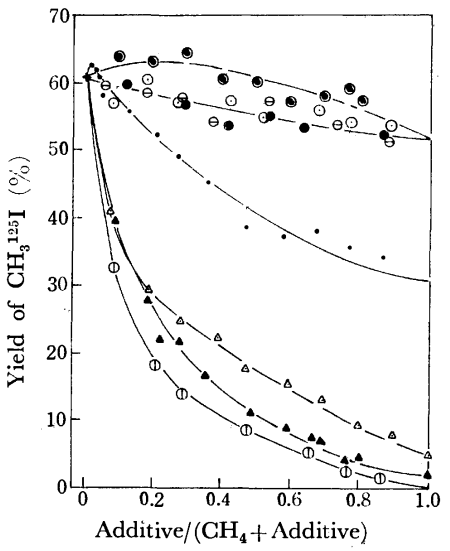

Fig. 1. Variation of the $CH_3{}^{125}I$-yield with the concentrations of various additives.
●: O_2, ⊙: Ar, ●: Kr, ⊖: N_2, ●: SF_6, △: CH_3Cl, ▲: C_2H_6, ⊕: C_2H_5Cl.

Addition of Br_2 significantly influenced the $CH_3{}^{125}I$ yield; less than 0.5 mol % of Br_2 reduced the yield below 1%. However, the addition of a macroscopic amount of I_2 has no definite effect on the $CH_3{}^{125}I$ yield (Table 1). A concomitant formation of $CH_2{}^{125}II$ scarcely occurred; the yield was less than 1%.

Some experiments with CD_4 were performed. The yield of methyl iodide, $CD_3{}^{125}I$, was 59.9±6.9% at the concentration of Xe, 0.04 m.f. The effects of pressure and Xe-concentration were similar to the case of the

reaction with CH_4.

Some samples were exposed to a ^{60}Co source of 45 kCi for 20 h within 30 min after preparation in a similar manner to that of other samples. The results are summarized in Table 3 with experimental conditions.

Discussion

Formation of $CH_3{}^{125}I$ via Energetic Process. Schroth and Adloff[6] and Schleiffer and Certout[11] studied similar reaction systems to those in the present experiments, although no reference was made to the hot atom reaction. The latter gave the extrapolated value of 55±3% at 1.0 m.f. of additives of He, Ne, Ar, and Kr.[11] This is in good agreement with our results, 52.0±5.0 %. Schleiffer and Certout maintained the concentration of Xe at 0.025 m.f. throughout their experiments.

Loberg and Welch investigated the reaction of ^{123}I from ^{123}Xe with methane and mentioned the following for the hot atom reactions: "this lack of reactivity due to kinetically hot species indicates that by the time the iodine ion has attained a charge of +1 it has come to thermal equilibrium with its surroundings."[10] However, they observed the hot atom reactions with ethane and neopentane as reactants. The ^{123}I atom from ^{123}Xe has the maximum kinetic energy of 34.4 eV as a result of the electron capture decay.[13] The excess kinetic energy corresponds to the median kinetic energies of ^{80}Br and ^{82}Br from the isomeric transition processes.[15] In the reactions of these recoil bromines with alkanes, it has been confirmed that the reactivity of methane was higher than that of other alkanes.[16,17] From the chemical similarity between bromine and iodine, the trend may be maintained also in the energetic reaction of recoil iodine. Thus, the failure of detection of energetic yield in the reaction of ^{123}I with methane[10] would not necessarily indicate the absence of the hot atom reactions.

The nuclide of ^{125}I decays only by electron capture, and the Q value of the decay is reported as 1.9 MeV.[13] From this value, the maximum recoil energy possessed by the ^{125}I atom is calculated to be 15.6 eV. The limiting yield of $CH_3{}^{125}I$ at 1.0 m.f. of additives is 52.0 ±5.0% for Kr, Ar, N_2, and O_2 (Fig. 1). The difference between the yield at 0.04 m.f. of Xe, 60.7±4.5%, and this limiting value, 52.0±5.0%, should be considered to result from hot atom reactions. Although the presence of 0.04 m.f. of Xe may influence the yield dependence on kinetic energy, its extent is considered to be unimportant, being less than 1% as referred to the results of bromine hot atom reaction.[18] Thus, the yield of hot atom reaction is assigned to be 8.7±6.7%.

Main Mechanisms of $CH_3{}^{125}I$-formation via Ionic Process. The absence of the wall effect of vessel indicates that the reactions mainly occur in gaseous phase and the reactions are not catalyzed by the wall.

The yield of $CH_3{}^{125}I$ decreased with an increase in the concentration of Xe (Table 2). The value extrapolated to zero m.f. of Xe is 76.0±6.0% and the limiting value at 1.0 m.f. of Xe is 31.5±2.0%. This reduction of the yield is due to the near resonant charge exchange between xenon and I^+ in the $^1D_2$ state, and the limiting yield, 31.5±2.0%, should be ascribed to reactions of I^+ in the ^3P states.[3,4,10,11]

Table 4. Effects of electron scavengers on the yield of $CH_3{}^{125}I$

Additive[1]	Yield of $CH_3{}^{125}I$(%)	
	By new line	By old line
no	47.8±4.8	60.7±4.5
SF_6(0.07 m.f.)	57.3±4.8	60.1±5.9
O_2 (0.30 m.f.)	59.3±4.3	64.0±6.0

1) All reaction systems contain 0.04 m.f. of Xe.

The yield of $CH_3{}^{125}I$ increases first with an increase in the concentration of O_2 and SF_6(Fig. 1). This suggests that an electron scavenger plays an important role in the mechanism of $CH_3{}^{125}I$-formation. Since I_2 is also an excellent electron scavenger, experiments were carried out with a new vacuum line in order to investigate of the effect of trace amout of I_2 in the reaction. The results are shown in Table 4. The yield obtained by the new line was significantly lower than that by the old line contaminated with iodine vapor, the yield increasing by about 10%, on addition of SF_6 or O_2 to the system.

This trend was not observed with use of the old line. We see that the presence of electron scavengers raises the yield of $CH_3{}^{125}I$. The following finding also supports the result.

Samples prepared in a similar way using the old line were exposed to a ^{60}Co source. The yield of $CH_3{}^{125}I$ in the system of CH_4±0.04 m.f. of Xe was reduced to less than 0.5% (Table 3). However, in the system containing SF_6, the yield was 38.5±1.6% under the same conditions. The trace amount of I_2 originally contained in the system would have been consumed by the reactions with radiolysis-products of CH_4 and stabilized to either HI or organic iodides. As a result, the system would be cleaned from I_2 in the early stage of the reactions. Thus, we see that $CH_3{}^{125}I$ can not be produced in the system with carrier free ^{125}I unless some other electron scavenger is present, and that the samples prepared by the new line are still contaminated by a trace amount of I_2, although the extent is much less than with the old line. (Pumps and reagents were used in common in both experiments.)

Schleiffer and Certout proposed the following reaction sequences:

$$CH_4 + {}^{125}I^+ \rightarrow CH_3{}^{125}I^+ + H \quad (1)$$

$$CH_3{}^{125}I^+ + I_2 \rightarrow CH_3{}^{125}I + I_2{}^+ \quad (2)$$

$$CH_3{}^{125}I + e^- \rightarrow CH_3 + {}^{125}I^- \quad (3)$$

The mechanism involves a neutralization process of $CH_3{}^{125}I^+$ with additives and is consistent with the results. If the neutralization of $CH_3{}^{125}I^+$ is the working process, the role of SF_6 observed in the systems exposed to ^{60}Co-source can be ascribed to the following scheme in analogy with Reaction 2:

$$CH_3{}^{125}I^+ + SF_6 \rightarrow CH_3{}^{125}I + SF_6{}^+ \quad (4)$$

However, a similarity in the effects of Xe and SF_6 on the $CH_3{}^{125}I$ yield (Fig. 1 and Table 2) predicts that the ionization potential of SF_6 is in the same range of

a) Assigned as the yield resulting from the reaction of I^+ in the $^1S_0$ state.

Xe, both being higher than that of CH_3I. This implies that Reaction 4 is unimportant. Loberg and Welch reported that the reaction to form $CH_3{}^{125}I^+$ is exothermic only with $I^+(^1D_2)$.

Reaction 3 would not be important under the low electron density as in the present case. When samples which had been stored for more than 4 days after their preparation were exposed to a ^{60}Co-source up to the total dose 6.6×10^5 R, more than 10% of $CH_3{}^{125}I$ still survived, even in the absence of an electron scavenger.

The reaction sequences proposed by Schleiffer and Certout do not seem to be able to explain our results. Let us introduce the following reaction mechanisms:

$$^{125}I^+ + CH_4 \rightarrow (CH_4{}^{125}I)^+ \quad (5)$$

$$(CH_4{}^{125}I)^+ + CH_4 \rightarrow CH_3{}^{125}I + CH_5^+ \quad (6)$$

$$(CH_4{}^{125}I)^+ + e^- \rightarrow CH_4 + {}^{125}I \quad (7)$$

$$SF_6,\ I_2,\ \text{or}\ O_2 + e^- \rightarrow SF_6^-,\ I + I^-,\ \text{or}\ O_2^- \quad (8)$$

According to the reaction sequences, $CH_3{}^{125}I$ is formed by Reactions 5 and 6. However, the formation will be interferred by Reaction 7. In the presence of SF_6, O_2, or I_2, Reaction 8 occurs in competition with Reaction 7. As a result the yield of $CH_3{}^{125}I$ would increase.

As is shown in Table 1, no temperature effect was observed within experimental error. $CH_3{}^{125}I$ will be predominantly produced by Reactions 5 and 6, and hot atom reactions. These reactions usually occur adiabatically in a very short period. The energy required for the reactions is supplied by the excitation energy of I^+ ions or the kinetic energy of recoils. This explains the fact that the yield is independent of temperature.

In the reactions of ^{123}I obtained from the decay of ^{123}Xe, Loberg and Welch stressed the importance of a molecular ion complex, AI^+, where A can be any molecule involved in the system, for the formation of $CH_3{}^{123}I$, based on the observation that the yield increased with some additives such as Kr, Ar, and Ne.[10] However, we have observed no such characteristic behavior of the yield. This suggests that the role of AI^+ is much less important in the reactions of ^{125}I as compared with those of ^{123}I.

Effects of Reactive Additives. When the additives CH_3Cl, C_2H_5Cl, and C_2H_6 were added to the reaction system, the yield of $CH_3{}^{125}I$ decreased with an increase in the concentration of additives and continuously approached the values found in the absence of CH_4, *i.e.*, 480 Torr of additive gas and 20 Torr of Xe (4.9±0.8 % for CH_3Cl, almost zero % for C_2H_5Cl, and 2.4±0.4% for C_2H_6).

The results indicate that the $CH_3{}^{125}I$-yield resulting from the reaction with CH_4 can be suppressed by any of the additives. The ionization potentials (IP) of the reagents are 11.28±0.01 eV for CH_3Cl, 10.97±0.02 eV for C_2H_5Cl, and 11.65±0.03 eV for C_2H_6.[20] Thus, the IP alone as a determining factor of the yield can not explain the efficient reduction of the yield by C_2H_6, since the I.P. of C_2H_6 is higher than that of I^+ state, 11.34 eV. Thus, an alternative reaction pathway for the reaction of $^{125}I^+$ will be present, such as the one suggested by Loberg and Welch.[10]

$$^{125}I^+(^3P_2) + C_2H_6 \rightarrow (C_2H_6{}^{125}I)^+ \rightarrow H^{125}I + C_2H_5^+ \quad (9)$$

Similarly in the presence of CH_3Cl, Reaction 10 would be important.

$$^{125}I^+(^3P_2) + CH_3Cl \rightarrow (CH_3Cl^{125}I)^+ \rightarrow {}^{125}ICl + CH_3^+ \quad (10)$$

The addition of Br_2 remarkably reduced the yield. However, when Br_2 was added to the reaction system after the completion of the reactions (after more than 4 days from the preparation of the sample), the yield was also reduced to less than 1%. This is due to the fact that Br_2 undergoes exchange with ^{125}I in $CH_3{}^{125}I$ as follows:

$$Br_2 + CH_3{}^{125}I \rightarrow CH_3Br + {}^{125}IBr \quad (11)$$

Comparison of the Results. The present results as well as previous ones are summarized in Table 5. A general trend exists in the reactivities of excited iodine. Hot yields show a remarkable dependence on the initial kinetic energies possessed by the recoil iodines, decreasing in the order $(n,\gamma)>(IT)\geq(EC)$. The maximum kinetic energies imparted to the recoils are 194 eV for ^{128}I and 177 eV for ^{139}I from the (n,γ) process[21] and 15.6 eV for ^{125}I from the (EC) process.[13] From these values and experimental findings, the kinetic energy for ^{130}I from the (IT) process is assumed to be *ca.* 20 eV when $CH_3{}^{130m}I$ is used as an iodine source.

In contrast, the thermal ionic yield was the highest for ^{125}I obtained from the (EC) process. It can be

concluded that the population of the iodine ion in each excited state depends on the decay mode of precursors. We found that the population of $^{125}I^+(^1D_2)$ is slightly higher than that of $^{125}I^+$ in the ^3P states. This is in line with the results by Schleiffer and Certout[12] and by Loberg and Welch[10] in the presence of a macroscopic amount of I_2. However, Schroth and Adloff[6] and Schleiffer and Certout[12] reported lower yields for ^3P states than ours. This discrepancy may be due to the amount of I_2 in the reaction system. In the former cases, they examined the system with saturated vapor pressure of I_2. We see from the results by Loberg and Welch[10] that the presence of a macroscopic amount of I_2 would protect I^+ in the $^1D_2$ state.

As regards the reactant-isotope-effect between CH_4 and CD_4, the present results, together with those reported by Nicholas *et al.*[5] provide no positive evidence, indicating that the effect, if it exists at all, should be very small. In the reactions of ^{80}Br obtained from $^{79}Br(n,\gamma)^{80}Br$ process with methane the large reactivity-isotope-effect was observed in the hot yields.[18,22] However, it has been confirmed that the isotope effect is not present in the yield due to ionic processes.[23,24] In the present system, over 80% of $CH_3{}^{125}I$ is formed by the reaction of I^+ in the excited states. Thus, the expected isotope effect in hot reactions might have been overlooked because of large fluctuations in experimental conditions.

Kinetics of the Oxidation of Formate by Iodine in the Water–Methanol and the Water–Ethanol Mixed Solvents

Katumitu HAYAKAWA and Makoto SATO

Department of Chemistry, Faculty of Science, Kagoshima University, Koorimoto, Kagoshima 890

(Received December 9, 1976)

The kinetics of the iodine–formate reaction gives an identical rate equation in several water–alcohol mixed solvents: rate$=k[HCOO^-]\,[I_3^-]/(a[I^-]+1)$. The values of $k/M^{-1}\,s^{-1}$ and $10^{-3}\,a/M^{-1}$ are 5.5 and 16 in ethanol at 35 °C, 3.6 and 12 in methanol at 30 °C, and 0.06 and 0.7 in water at 30 °C, respectively. The values of a are comparable to the formation constants of I_3^- in the water–alcohol mixtures. The rate-determining step is the reaction between an iodine molecule and a formate ion. The activation parameters, $\Delta H^*/kJ\,mol^{-1}$ and $\Delta S^*/J\,K^{-1}\,mol^{-1}$, are 71 and −1 in the 0.95 mole fraction of methanol, 60 and −32 in the 0.92 mole fraction of ethanol, and 75 and −20 in water, respectively. The entropy term contributes to the acceleration by alcohol in the water–methanol mixtures, whereas both the entropy term and the enthalpy term contribute to the acceleration in the water–ethanol mixtures. These effects of the mixed solvents suggest that the specific interactions of the solvent molecule with the reactants and the activated complex, such as a specific solvation or a hydrogen bond, play an important role in the rate-determining step.

The iodine–formate reaction 1 is remarkably accelerated by the addition of dimetyl sulfoxide(DMSO) to water:[1]

$$I_3^- + HCOO^- \longrightarrow 3I^- + H^+ + CO_2 \qquad (1)$$

According to the electron-transfer theory,[2] changes in dielectric properties are expected to affect the reorganization of a solvent molecule around the reactants and the activated complex. The water–alcohol solvent mixtures exhibit pronounced structural and dielectric changes at different component ratios.[3] In the present paper, we will deal with the kinetics of Reaction 1 and will determine the activation parameters in the water–methanol and water–ethanol mixed solvents. The dependence of the rate and the activation parameters on the changes in such bulk properties as the dielectric property will be discussed quantitatively. The changes in the microscopic properties around the reactants and the activated complex, such as the specific solvation or the hydrogen bond, play an important role in the rate-determining step in Reaction 1.

Experimental

Reagents. The iodine, potassium iodide, sodium formate, methanol, and ethanol were obtained commercially. The ethanol was of Wako's super special grade, while the other substances were of a guaranteed grade. The iodine was purified by sublimation, and the solutions were prepared by dissolving the iodine in the potassium iodide solution in each measurement. The potassium iodide and sodium formate were dried at 120 °C overnight. The sodium perchlorate was obtained from BDH Chemicals, Ltd. It was recrystallized from water and used as a control of the ionic strength of the solutions. The pH of the aqueous solution was controlled using a phosphate buffer. In the water–alcohol mixed solvents, the pH and ionic strength of the solution were uncontrolled.

Measurements. The reaction was followed by measuring the absorbance at 350 nm at different times, using a Hitachi 101 spectrophotometer with quartz cells in a thermostated holder. When high iodide concentrations are employed, the iodine is completely converted into the triiodide ion. The ion is the only species which absorbs appreciably at 350 nm. Independent experiments showed that Beer's law was obeyed in water–alcohol mixed solvents. The reaction was also followed by measuring the concentration of total iodine in the aqueous solution by iodometry. Both methods give the same rate constant.

When mixtures of iodine and potassium iodide in several mixed solvents were left standing for 25 h, the absorbance of the solutions changed slightly (below 5%). The change was neglected compared with the rate of the reaction of iodine with formate. Irradiation with light of 350 nm had no effect on the rate.

Results and Discussion

Kinetics and the Mechanism. The rate depended on the concentrations of iodine, iodide, and formate, and in the aqueous solution it was independent of the pH at 4—9 and of the ionic strength below 0.6 M, as is shown in Table 1.

In all the kinetic runs, the initial concentrations of iodide and of formate were chosen to be much greater than the initial total iodine concentration. Under these conditions, the reaction was found to be a first-order reaction of the triiodide ion. The apparent first-order rate constant, k_{app}, is proportional to the formate concentration (Fig. 1). Figure 2 shows that the plot of $1/k'$ *vs.* $[I^-]$, where $k'=k_{app}/[HCOO^-]$, gives a straight line with an intercept. Thus, the following rate law describes the kinetics in the present solvents:

$$\text{Rate} = -d[I_3^-]/dt = k[I_3^-][HCOO^-]/(a[I^-]+1). \qquad (2)$$

Table 2 shows the kinetic parameters, k and a, in the various solvents.

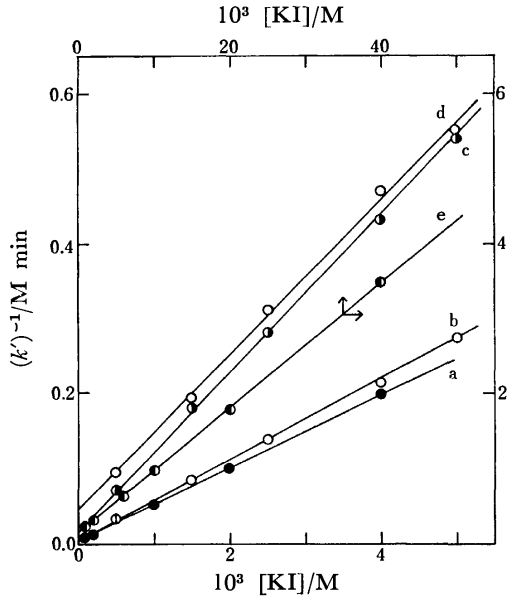

Fig. 2. Dependence of $k'(=k_{app}/[HCOO^-])$ on the iodide concentration in various solvents: a. EtOH, b. MeOH, c. EtOH-H_2O, d. MeOH-H_2O, e. H_2O.

The rate equation is derived from the following mechanism:[1]

$$I_3^- \underset{k_{3-}}{\overset{k_{3+}}{\rightleftharpoons}} I_2 + I^-, \quad (3)$$

$$I_2 + HCOO^- \xrightarrow{k_4} \text{Products}. \quad (4)$$

When k_4, k_{3+}, and k_{3-} are the rate constants of the respective reactions,

$$-d[I_2]/dt = k_4[I_2][HCOO^-] - k_{3+}[I_3^-] + k_{3-}[I_2][I^-], \quad (5)$$

$$-d[I_3^-]/dt = k_{3+}[I_3^-] - k_{3-}[I_2][I^-] = d[I_2]/dt + k_4[I_2][HCOO^-]. \quad (6)$$

Assuming that Reaction 4 is slow and Reaction 3 is in pseudo-equilibrium,

$$[I_2] = [I_3^-]/(K_f[I^-]), \quad (7)$$

where K_f is the formation constant of I_3^-.

$$\frac{d[I_2]}{dt} = \frac{1}{K_f[I^-]}\left(\frac{d[I_3^-]}{dt} - \frac{[I_3^-]}{[I^-]}\frac{d[I^-]}{dt}\right) \approx \frac{1}{K_f[I^-]}\frac{d[I_3^-]}{dt}, \quad (8)$$

because $[I_3^-]/[I^-] \ll 1$ and $|d[I^-]/dt| \leqslant |3d[I_3^-]/dt|$. When Eqs. 7 and 8 are substituted into Eq. 6,

$$-d[I_3^-]/dt = k_4[I_3^-][HCOO^-]/(K_f[I^-]+1). \quad (9)$$

Thus, the experimental kinetic parameters, k and a, equal k_4 and K_f respectively. The fourth column in Table 2 shows the K_f values obtained by the spectrophotometric method.[4] The finding that K_f is comparable to a supports the mechanism proposed in the present study. The mechanism involving the iodine atom[5,6] is eliminated because the rate must be proportional to the root of the iodine concentration in the mechanism. The effects of the pH and the water content of the solvent on the rate eliminate the mechanism involving hypoiodous acid.[7] The fact that the rate was independent of the ionic strength of the solution indicates that the rate-determining step involves a non-ionic species[8-12] and supports the mechanism proposed in the present study.

The slow step involves an iodine attack on the formate anion, although one can only speculate about the nature of the following intermediate. Hiller and Krueger[1] proposed a rate-determining step involving a transfer of a hydride ion from carbon to iodine, as is shown in Eq. 10, because $DCOO^-$ has a considerable effect on the rate $(k(HCOO^-)/k(DCOO^-)=3.8$ in water and 2.2 in DMSO).

$$I_2 + HCOO^- \longrightarrow I_2H^- + CO_2 \quad \text{(slow)}, \quad (10)$$

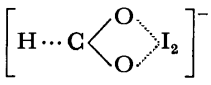
$$I_2H^- \longrightarrow 2I^- + H^+ \quad \text{(fast)}. \qquad (11)$$

In order to estimate the srtucture of the activated complex, the MO's energy and the formal charge for $HCOO^-$ were calculated by means of the CNDO method. The calculation indicated that the energy level of the highest occupied orbital of $HCOO^-$ (−2.26 eV) is higher than that of the lowest vacant orbital in I_2 (−7.0 eV[13]). It seems that the iodine molecule is an electrophilic reagent in the reaction with the formate ion.[14] The formal charge and the frontier electron density[15] of $HCOO^-$ shown in Table 3 suggest

Table 3. The formal charge and the frontier electron density in the $HCOO^-$ ion

Atom	Formal charge	Frontier electron density
H	+0.20	0.0
C	−0.27	0.0
O	−0.47	1.0

that an iodine molecule attacks the O-atom in $HCOO^-$. The kinetic isotope data[1] suggest that the H–C bond is loosened or severed by the attack of the iodine molecule. Thus, the activated complex may be proposed to be **1**, in which the C–H bond is greater than those in a formate ion.



1

Table 2 shows that the rate in alcohol is much faster than that in water. The dependence of the rate on the solvents is, clearly, not caused by the change in the mechanism in the water–alcohol mixed solvents.

The Activation Parameters in the Mixed Solvents. The apparent first-order rate constants were determined at various temperatures in mixed solvents of various alcohol contents. The rate constant, k, was calculated using the formation constant of the triiodide ion, K_f, which was determined by the spectrophotometric method.[4] Table 4 shows the values of k, ΔH^*, ΔS^*, and the relative thermodynamic functions of activation, $\Delta(\Delta H^*)$ and $\Delta(-T\Delta S^*)$. The small maximum in ΔH^* appears near the 0.1 mole fraction of methanol, and the entropy term contributes to the acceleration by alcohol in the water-methanol system, whereas the maximum in ΔH^* disappears and both the entropy term and the enthalpy term contribute to the acceleration in the water–ethanol system.

For the reaction between an ion and a neutral molecule, the rate constant is given by Eq. 12:[16]

$$\ln k = \ln k_0 + (Az^2/2RT\varepsilon_r)(r^{-1} - r_*^{-1}), \qquad (12)$$

where $A = N_A e^2/4\pi\varepsilon_0$. In Eq. 12, ε_r is a relative permittivity; r and r_*, the respective radii of the ion and the activated complex; z, a charge of the ion, and the others, the usual constants. Since $r_* > r$, the rate constant increases with a decrease in the permittivity of the solution. When r and r_* are independent of the temperature of reaction, the activation energy is given by:

$$E_a = E_0 - (Az^2/2)(r^{-1} - r_*^{-1})(1 - bT)/\varepsilon_r, \qquad (13)$$

where b is given by $\varepsilon_r = c\exp(-bT)$ and where $E_0 = -R\mathrm{d}(\ln k_0)/\mathrm{d}(1/T)$. When b is calculated by means of the data of Albright and Gosting[17] and Akerlöf,[18] $(1-bT)/\varepsilon_r$ is negative and decreases with an increase in the alcohol contents. Thus, Eq. 13 indicates that E_a increases with an increase in the alcohol content. This prediction does not agree with the present results.

The changes in the solvation properties also have an important influence on the rate. Laidler and Eyring[19] and Scatchard[20] recognized the possible importance of specific solvation as a determining factor in the behavior of the rate constant. Hyne[21] ascribed the appearance of the maximum or the minimum in an activation energy to a specific solvation. According to him, the maximum appears as a result of the specific solvation

a) $\Delta(\Delta H^*) = \Delta H^* - \Delta H^*(\text{in } H_2O)$. b) $\Delta(-T\Delta S^*) = -T\Delta S^* + T\Delta S^*(\text{in } H_2O)$.

when the reactant is an ionic species and when the transition state is a "dipole," which means also a charge-delocalized species. In the transition state, **1**, the negative charge must undergo delocalization preliminary to the electron transfer. A consideration of the transition state, **1**, as a "dipole" seems, therefore, a valid approximation. Then, the appearance of a maximum in ΔH^* can be expected. The small maximum in ΔH^* is possibly to be ascribed to the specific solvation in the water-methanol system. Though the relative permittivity suggests a larger maximum in the water–ethanol system than that in the water–methanol system,[21] the experimental results indicate that the maximum disappears in the former system.

Water forms a strong hydrogen bond to the O-atom in $HCOO^-$ and interferes with the approach of the iodine molecule to the ion. Since alcohol has a weak hydrogen-bonding property, the rate may be faster in alcohol than in water. Though DMSO has a greater permittivity than alcohols, it does not form a hydrogen bond, so the rate constant in DMSO is the largest among them.[1]

Hiller and Krueger observed that the ion-pairing of formate lowers the rate.[1] Since the ion-pair association constant increases with a decrease in the permittivity of a solvent, the ion-pairing effect lowers the rate with an increase in the alcohol content. This is not consistent with the present results.

Thus, the specific interactions of the solvent molecule with the reactants and the activated complex, such as the specific solvation or the hydrogen bond, possibly play an important role in the rate-determining step of Reaction 1.

Crystal and Molecular Structure of a Chelating Ylide Complex of Palladium : [(Benzoylmethylene)diphenyl-2-(diphenylphosphino)-ethylphosphorane]dichloropalladium(II) Toluene Solvate

Hirofumi Takahashi, Yoshinao Oosawa, Akiko Kobayashi, Taro Saito, and Yukiyoshi Sasaki*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received December 13, 1976)

The crystal structure of the title compound was solved by single-crystal X-ray diffraction techniques. Crystals are monoclinic, space group $P2_1/c$, with cell dimensions $a=13.39(5)$, $b=16.88(1)$, $c=19.85(6)$ Å, $\beta=123.54(1)°$, $Z=4$. The final R was 0.065. The ylide ligand coordinates to palladium through the ylide carbon Pd–C, 2.115(15) Å and phosphine phosphorus Pd–P, 2.230(8)Å forming a six-membered chelate ring. The chelating ligand together with two chlorine atoms forms a square-planar geometry around the palladium. The Pd–Cl distances are discussed in terms of *trans*-influence of the ylide carbon.

We have reported syntheses of chelating ylide ligands derived from 1,2-bis(diphenylphosphino)ethane and bis-(diphenylphosphino)methane and their palladium(II) and platinum(II) complexes.[1-4] The coordination of the ylide carbon to the metal has been inferred from infrared, ^1H and ^{31}P NMR spectra.[4] The present X-ray structure determination of one of the ylide complexes, [(benzoylmethylene)diphenyl-2-(diphenylphosphino)ethylphosphorane]dichloropalladium(II) (formulated as $[PdCl_2(bdep)]$† in this paper), has confirmed that the ylide carbon and phosphine phosphorus coordinate to palladium. This paper describes the details of the X-ray study, the preliminary results of which have been published.[5]

Experimental

The chelating ylide ligand and its complex, $[PdCl_2(bdep)]$, were prepared as described in an earlier report.[4]

Preparation of the Crystal. $[PdCl_2(bdep)]$ (0.1 g) was dissolved in nitromethane (7 ml), and toluene (15 ml) was added to the solution. The solution was kept at 20 °C for three days. Yellow crystals were filtered, washed with diethyl ether, and dried *in vacuo*. A ^1H NMR spectrum and elemental analyses indicated that the crystals contained a toluene molecule per palladium atom as a crystallization solvent. A single crystal with dimensions *ca.* $0.25\times0.25\times0.10$ mm was used for measurement of diffraction intensities.

Crystal Data. $C_{34}H_{30}Cl_2P_2Pd\cdot C_7H_8$, $M=786.0$, monoclinic, $a=13.39(5)$, $b=16.88(1)$, $c=19.85(6)$ Å, $\beta=123.54(1)°$, $V=3740$ Å^3, $Z=4$, $D_m=1.42$ and $D_x=1.40$ g/cm^3, $\mu=7.47$ cm^{-1} (Mo-$K\alpha$). Space group $P2_1/c$ from systematic absences,, $h0l$, $l=2n+1$ and $0k0$, $k=2n+1$.

Intensity data were recorded on a Rigaku automated four-circle diffractometer, by use of graphite-monochromatized Mo-$K\alpha$ radiation. By the $\omega-2\theta$ scan technique, diffraction intensities were measured up to $2\theta=55°$ and 2652 independent reflections ($|F_o|\geq3\sigma$) were used for the structure analysis. Intensities were corrected for Lorentz and polarization effects but not for absorption and extinction.

Determination of the Structure. The position of the palladium atom was deduced from a three-dimensional Patterson map, and the positions of non-hydrogen atoms including carbon atoms of toluene were determined by the usual heavy-atom method. The structure was refined by block-diagonal least-squares, first with isotropic and then with anisotropic temperature factors. Of the 38 hydrogen atoms, 23 atoms were located from a difference Fourier map, and were refined with isotropic temperature factors. After inclusion of the rest of the hydrogen atoms whose positions were obtained by calculation, the final R value was reduced to 0.065.

Atomic scattering factors were taken from ref. 6. A weighting scheme adopted was $w=1.0$ for $|F_o|\geq36.19$ on an absolute scale and $w=0.5$ otherwise was employed. The calculation was performed on a HITAC 8800/8700 computer at the Computer Center of the University of Tokyo using a local version of UNICS programs.[7]**

Final positional and thermal parameters are given in Table 1, with their estimated standard deviations.

Results and Discussion

Molecular Structure. Final positional and thermal parameters are given in Table 1, with their estimated standard deviations. The molecular structure with the numbering scheme of atoms and a stereoview are

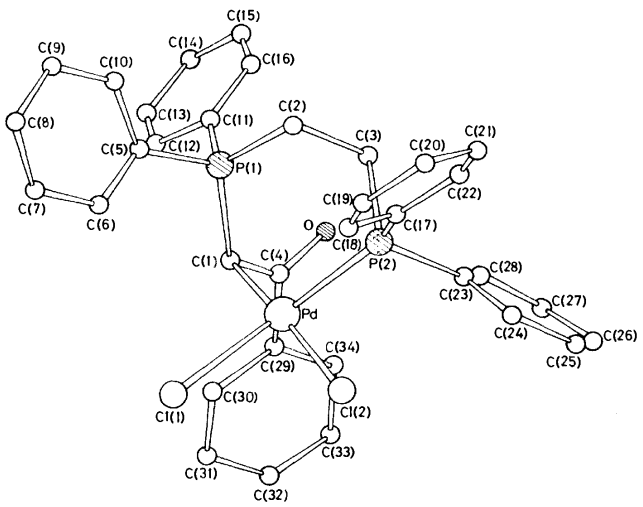

Fig. 1. Molecular structure of $[PdCl_2(bdep)]$ and numbering scheme of non-hydrogen atoms.

† bdep = C_6H_5–C(=O)–C$^-$–H–P$^+$–$(CH_2)_2$–P–$(C_6H_5)_2$, with $(C_6H_5)_2$ on P

** Observed and calculated structure factors are held by the office of the Chemical Society of Japan as Document No. 7710.

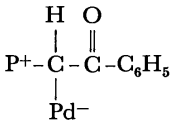
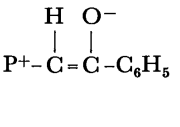
illustrated in Figs. 1 and 2, respectively. Bond lengths and bond angles are listed in Tables 2 and 3. The results show that [$PdCl_2$(bdep)] is an ylide complex in which the ylide carbon coordinates to palladium with Pd-C bond length of 2.115(15) Å. This value is slightly larger than the metal-ylide carbon bond lengths (1.91—2.10 Å) determined by X-ray diffraction for some other ylide complexes.[8-10] Although the ylide methine hydrogen atom could not be located, the bond angles around the ylide carbon ∠Pd-C(1)-P(1) (115.1 (6)°), ∠Pd-C(1)-C(4) (102.9(9)°), and ∠P(1)-C(1)-C(4) (111.2(12)°), suggest that the C(1) carbon orbital is nearly sp^3 hybrid. This provides another example of the conversion of sp^2 hybridized ylide carbon to sp^3 state on coordination to the metal.[8,11] The phosphine P also is coordinated to palladium with the Pd-P(2) bond length of 2.230(8) Å, and a six-membered chelate ring is formed. The five atoms, Pd, C(1), P(2), Cl(1), and Cl(2), are approximately coplanar and the coordination around the palladium has square-planar geometry with the angles, ∠C(1)-Pd-P(2) (86.2(1)°), ∠C(1)-Pd-Cl(1) (87.3(4)°), ∠Cl(1)-Pd-Cl(2) (90.8 (1)°), and ∠Cl(2)-Pd-P(2) (96.2(4)°).

The bond lengths of the ylide system in the present complexes, P(1)-C(1) (1.795(12) Å), C(4)-O (1.225(21) Å, and C(4)-C(1) (1.486(27) Å), indicate that the complex presumably takes the betaine structure (I) in contrast with the significant contribution of the betaine structure (II) in the free ligand which can be inferred from the lower ν(CO) frequency in an infrared spectrum.[4] The X-ray structure determination of a benzoyl stabilized ylide, benzoylchlorotriphenylphosphorane, has shown that the main contribution in the bonding is the betaine structure (II).[12]



(I)



(II)

It seems significant to compare the properties of ylides as ligands with those of phosphines, because both ylides (C ligands) and phosphines (P ligands) coordinate to the metal in similar fashion formally. Bdep which has both ylide and phosphine parts in a molecule appears to be a suitable ligand for the comparison of such properties as trans-influence (or -effect) simulta-

neously. Chlorine atoms in $[PdCl_2(bdep)]$ are bonded to palladium with bond lengths of Pd–Cl(1) (2.390(8) Å) and Pd–Cl(2) (2.340(8) Å). The Pd-Cl(2) which is trans to the ylide C is somewhat shorter than the other Pd–Cl(1) which is *trans* to the phosphine P. Since longer bond length of the bond *trans* to a ligand can be regarded as an indication of larger *trans*-influence of the ligand,[13] it is likely that the *trans*-influecne of the ylide C is comparable with, but slightly smaller than, that of the phosphine P in bdep.

Crystal Structure. The crystal structure projected along b axis is shown in Fig. 3. Toluene molecules are packed in voids formed by $[PdCl_2(bdep)]$ molecules, but the molecular interaction seems to be rather loose judging from the intermolecular contacts which are larger than 4 Å.

Stereoselectivity in Mixed Ligand Copper(II) Complexes with Electrostatic Ligand-Ligand Interactions. Application to Optical Resolution of α-Amino Acids with a Charged Side Chain

Osamu YAMAUCHI, Takeshi SAKURAI, and Akitsugu NAKAHARA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received January 14, 1977)

Optical resolution of DL-aspartic acid and DL-glutamic acid (abbreviated as DL-A) has been achieved *via* formation of ternary copper(II) complexes composed of a DL-A and L-arginine, L-lysine, or L-ornithine (L-B). For every pair of ligands DL-A and L-B, a neutralized solution containing $Cu(ClO_4)_2$, DL-A, and L-B in the molar ratio of 1 : 2 : 1 gave the mixed ligand complex abounding in [Cu(D-A)(L-B)] as crystals, from which incorporated A was isolated through a Dowex CCR-2 column after treating with H_2S. In a very similar manner D-enantiomer-rich B was obtained from DL-B by using an L-A. The optical purities of the resolved amino acids were as high as 90 and 70% for aspartic acid and glutamic acid, respectively, and 40—50% for the basic amino acids. The finding shows that the electrostatic ligand-ligand interactions in the mixed ligand complexes give rise to geometric isomerism around copper(II) and hence preferential formation and crystallization of the *meso* complexes, [Cu(L-A)(D-B)] and [Cu(D-A)(L-B)], probably with a *cis* configuration.

Stereoselectivity has been reported recently for kinetically labile transition metal complexes containing simple amino acids[1,2] and *N*-carboxymethyl[3] and *N*-benzyl[4] derivatives of amino acids, and in most cases the selectivity has been attributed to the steric hindrance arising from two bulky ligands coordinated around a metal ion. In our previous studies electrostatic ligand-ligand interactions between the oppositely charged groups in the side chains of coordinated amino acids and related compounds have been inferred from the CD (circular dichroism) spectral magnitude enhancements in the d-d region, and interpreted as one of the driving forces leading to the formation of mixed ligand copper(II) complexes.[5,6] Because of the steric requirements for such interactions around the central atom, they were expected to give rise to geometric isomerism in the ternary copper(II) complexes, Cu(A)(B), where A refers to the ionized form of aspartic acid (Asp) or glutamic acid (Glu) and B to the protonated form of arginine (Arg), lysine (Lys), or ornithine (Orn).[7] In fact,the infrared spectra of the isolated complexes indicated the existence of the geometric isomerism,[6a] and molecular models suggested a *trans* structure (**1**) for Cu(L-A)(L-B) and a *cis* structure (**2**) for Cu(D-A)(L-B).

The stereoselectivity attributable to steric interactions between the side chains of the ligands in the coordination sphere has been applied to optical resolution of amino acids with a bulky side chain by ligand-exchange chromatography in the presence of copper(II) and other metal ions.[8] Since the selectivity is purely due to steric hindrance, resolvable amino acids have been confined to those having a bulky group, such as proline, valine, and leucine.

On the other hand, the stereoselectivity due to the electrostatic ligand-ligand interactions suggested the possibility of optical resolution of amino acids with a charged side chain, such as aspartic acid, glutamic acid, arginine, and lysine, which have been excluded from the resolution based on the bulkiness of the side chains. We reported in a previous communication[9] that racemic aspartic acid and glutamic acid could be resolved into enantiomers by using copper(II) and an optically active basic amino acid, L-B, and now we have investigated the stereoselectivity in detail to explore a novel approach to optical resolution of the enantiomers of the mentioned amino acids *via* formation of mixed ligand copper(II) complexes.

Experimental

Materials. D-Arginine hydrochloride and D-lysine hydrochloride were obtained from Fluka AG and D-ornithine hydrochloride from Sigma Chemical Co. All other amino acids were purchased from Nakarai Chemicals Ltd. Their purity was checked by the specific rotations, $[\alpha]_{589}^{20}$ (in 3M HCl; $c=1$), which were +25.7° (L-Asp), −24.9° (D-Asp), +31.9° (L-Glu), −30.9° (D-Glu), +22.8° (L-Arg·HCl), −21.7° (D-Arg·HCl), +20.8° (L-Lys·HCl), −20.5° (D-Lys·HCl), +22.9° (L-Orn·HCl), and −22.5° (D-Orn·HCl). All the materials used were of reagent grade or of highest grade available.

Measurements. Absorption spectra of the complexes were measured with a Union Giken SM-401 High-Sensitivity recording spectrophotometer and CD spectra with a JASCO MOE-1 spectropolarimeter in a 1-cm or a 2-cm quartz cell. The spectral measurements were made in the range 400—800 nm at a constant copper(II) concentration of 5.0×10^{-3} M in water at room temperature. The pH values (7.5—8.5) of the solutions were roughly adjusted with aqueous sodium hydroxide and dilute perchloric acid and finally determined immediately after the spectroscopic measurements. Optical rotations of amino acids were measured on a Yanagimoto OR-10 polarimeter at 589 nm in a 5-cm quartz cell at 20 ±0.1 °C. Infrared spectra of the isolated mixed ligand copper(II) complexes were obtained in the range 4000—650 cm^{-1} with a Hitachi 215 grating infrared spectrophotometer with the KBr disk method.

Optical Resolution of Racemic Aspartic Acid and Glutamic Acid. For every pair of DL-A and L-B, optical resolution of an

acidic amino acid was performed by essentially the same method as typically described for the Cu(II)–DL-Asp–L-Arg system. Copper(II) perchlorate hexahydrate (3.70 g, 10 mmol), DL-aspartic acid (2.66 g, 20 mmol), and L-arginine hydrochloride (2.10 g, 10 mmol) were dissolved in *ca.* 50 ml of water, and the pH of the resulting solution was adjusted to *ca.* 7 with aqueous sodium hydroxide. After stirring for 1 h at room temperature, the reaction mixture was concentrated *in vacuo* to a small volume at temperatures below 50 °C. Addition of ethanol to the residue gave [Cu(asp)(L-argH)]·$2H_2O$ as blue crystals (0.68 g, 1.7 mmol; 17% based on the amount of copper(II) used). Found: C, 29.29; H, 5.51; N, 17.27%. Calcd for $C_{10}H_{19}N_5O_6Cu \cdot 2H_2O$: C, 29.66; H, 5.73; N, 17.30%.

After copper(II) had been removed by treating an aqueous solution of the isolated complex with hydrogen sulfide, the incorporated aspartic acid was separated from L-arginine through a 1×100 cm column of Dowex CCR-2 (mesh 20—50) in the H^+ form by eluting with water. Isolated aspartic acid was recrystallized from aqueous ethanol to give a salt-free product (0.16 g, 1.2 mmol; 12% based on the half amount of DL-aspartic acid used). The specific rotation of −22.9° (in 3M HCl; $c=1$) demonstrates that D-aspartic acid was preferentially incorporated into the ternary complex. Its optical purity (89%) was substantiated by an estimation made from the CD curve of the isolated ternary complex in aqueous solution (pH 8.0) according to the method described below.

In order to determine the optical purities of the acidic amino acids incorporated into [Cu(asp)(L-lysH)], [Cu(asp)(L-ornH)], and [Cu(glu)(L-ornH)], the first crops, which were nearly pure, were recrystallized once from aqueous ethanol.

Optical Resolution of Racemic Arginine, Lysine, and Ornithine. According to a procedure very similar to that described above, racemic basic amino acids were resolved into enantiomers by using a different Cu(II) : L-A : DL-B molar ratio of 1 : 1 : 1.5 to avoid precipitation of less soluble binary complexes $Cu(B)_2$. The amino acids B incorporated into Cu(L-A)(B) were separated from L-A through a 1×100 cm column of Amberlite IR-45 in the Cl^- form by eluting with water and obtained as hydrochlorides.

Determination of Optical Purity by CD Spectral Curves. The optical purities of the incorporated amino acids were also determined by the CD calibration curves, which were based on either the magnitude or the maximum wavelength and set up for the Cu(A)(L-B) and Cu(L-A)(B) systems with five different enantiomer contents of A and B, respectively, at the molar ratio of 1 : 1 : 1. The measurements were made at selected pH values where the complex formation was nearly complete. The enantiomer contents of the Cu(glu)(L-B) and Cu(L-A)(B) systems were found to be linearly correlated with the CD magnitudes ($\Delta\varepsilon$) at fixed wavelengths around 600 nm. Because the magnitudes for the Cu(asp)-(L-B) systems changed only slightly at different L- or D-Asp contents, the calibration curves were made by plotting the enantiomer contents against the maximum wavelengths that shifted with the contents.

Results and Discussion

Stereoselective Incorporation of Amino Acids into Ternary Complexes. Yields and optical purities of the acidic and the basic amino acids obtained *via* the ternary complex formation are summarized in Tables 1 and 2. The specific rotations clearly indicated that the D-enantiomers of the racemic amino acids used were preferentially incorporated into the ternary copper(II) complexes each containing an L-A or an L-B. Another line of evidence supporting the incorporation of the D-enantiomers is given by the optical purities of A and B estimated directly from the CD spectra of the complexes in the d-d region according to the calibration curves, such as are shown in Figs. 1 and 2. The optical purities determined by the two methods are in reasonable agreement with each other, and the differences between the correspoding values may be due to the inaccuracies pertaining to the calibration curves based on the CD spectra. The IR spectra of the isolated complexes, [Cu(A)(L-B)], showed the patterns that were more closely related to [Cu(D-A)(L-B)] than to [Cu(L-A)(L-B)], further substantiating that the *meso* complexes were preferentially obtained as crystals under the conditions employed.

It is interesting to note that, whereas X-ray structure analyses[10,11] have revealed that some bis(amino acidato)-

copper(II) complexes assume a *cis* structure while others assume a *trans* one, every possible combination of A and B invariably gives as the main product a *meso* complex probably with a *cis* structure.[6a]

Factors Affecting the Optical Resolution. Probably owing to the electrostatic ligand-ligand interactions, the protonated ternary copper(II) complexes containing L-histidine and a basic amino acid, such as L-arginine and L-lysine, have been reported to have slightly higher stability constants than those containing D-histidine in place of L-histidine.[2b,2c] Although equilibrium constants are a reliable source of information about the species distribution and hence the stereoselectivity in solution, it seems difficult to detect the selectivity in solution in the present cases, because the electrostatic ligand-ligand interactions are seriously affected by the ionic strength of the solution, whose influence has been found to be reflected in the CD magnitudes of the

ternary systems.[5,6] A preliminary potentiometric study showed that the enantiomeric pairs of the ternary systems give almost identical titration curves at the ionic strength of 0.1(KNO_3). Accordingly, it may be unrealistic to expect large stability differences between the enantiomeric species present in the reaction media. No significant difference was observed between the CD spectra in the d-d region of 1 : 1 : 1 and 1 : 2 : 1 mixtures of Cu(II), DL-A, and L-B, which indicates that there exists no remarkable preference of *cis*-[Cu(D-A)(L-B)] over *trans*-[Cu(L-A)(L-B)] in solution and that the two isomers are approximately equally present. In contrast to this, the ternary complex isolated from a 1 : 1 : 1 mixture of Cu(II), L-Glu, and DL-Orn had incorporated D-Orn with 17% enantiomeric excess. These findings suggest that the solubility factor rather than the stability factor plays an important role in the optical resolution *via* complex formation.

In conclusion, the electrostatic interactions between the ligands within a complex molecule serve as an essential force fixing the structure of the complex in a particular configuration, and the resulting *cis-trans* isomerism makes optical resolution of racemic ligands feasible under favorable conditions.

This work was supported in part by a grant from the Ministry of Education, which is gratefully acknowledged. We also wish to thank Miss Teruko Kuroe for elemental analysis.

Preparation and Stereochemistry of *trans*-Dianionocobalt(III) Complexes with (*S*)-2-(Methylaminomethyl)pyrrolidine

Taku KITAMURA, Yoshiko SATO, Masahiko SABURI, and Sadao YOSHIKAWA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received January 22, 1977)

trans-Dinitro and dichloro cobalt(III) complexes containing (*S*)-2-(methylaminomethyl)pyrrolidine (*N*-Me-ampr) were prepared. Their stereochemistry differs a great deal from that of other *N*-methylated 1,2-diamines. The *N*-Me-ampr complexes prefer the *trans,cis* instead of the *trans,trans* configuration, the axial *N*-methyl groups being fairly stabilized. In the case of the dinitro complex, only one isomer which has the axial *N*-methyl groups, was isolated, but in the case of the *trans*-dichloro complex two diastereomers (*trans,cis(RR)* and *trans,cis(SS)*) were obtained. These dichloro isomers were slowly converted into an equilibrium mixture in methanol. The CD spectral data of the equilibrium mixture show that the *trans,cis(RR)* is more stable than the *trans,cis(SS)* isomer ($-\Delta G=0.4$ kcal/mol).

Substituents introduced into polyamine ligands have been seen to regulate the configuration of their metal complexes. For example, the dianionobis(diamine)cobalt (III) complexes (diamine=*N*-substituted 1,2-diamine) sterospecifically adopt the *trans* configuration with respect to the unidentate anionic ligands, and the *N*-substituents take *trans* position to each other. Thus the structures of these complexes are not *trans,cis* but *trans, trans* configuration.[1] The *C*- and *N*-substituents in the chelate rings generally prefer the equatorial position[2] and cnsequently the chelate rings are fixed to the δ or λ gauche conformation.

(*S*)-2-(Methylaminomethyl)pyrrolidine (*N*-Me-ampr) has some characteristics differing from other *C*- and *N*-substituted diamines. The absolute configuration of the asymmetric carbon in the five membered chelate ring is *S* and the gauche chelate conformation should be fixed to δ.[3] The asymmetric nitrogen in the pyrrolidine ring is considered to coordinate with the *S* configration.[4] On the other hand, the absolute configuration of the asymmetric nitrogen center with the *N*-methyl groups is capable of having either the *S* or the *R* configuration, corresponding to the axial or the equatorial *N*-methyl groups, respectively.

For the cobalt(III) complexes of the type $[CoX_2(N\text{-Me-ampr})_2]^+$ (X=Cl^- or NO_2^-), we have observed some stereochemical features differing from the complexes of other *N*-methyl diamines. First, the *N*-Me-ampr complexes have the *trans,cis* configuration instead of the *trans,trans*. Second, the axial *N*-methyl groups are fairly stabilized. Third, equilibrium between the isomer having the axial and that having the equatorial *N*-methyl groups is influenced by the kind of apical anionic ligands.

Experimental

trans,cis(SS)-[*Co(NO$_2$)$_2$(N-Me-ampr)$_2$]ClO$_4$*. *Air Oxidation Method*: To an aqueous solution of $CoCl_2\cdot 6H_2O$ (1.19 g in 10 cm^3 of water) was added a solution of *N*-Me-ampr (1.14 g in 5 cm^3 of water containing 0.41 cm^3 of concentrated hydrochloric acid), and $NaNO_2$ (0.69 g) then being added quickly. The resulting solution was vigorously aerated in an ice cold bath for 20 min, and then for 2 h at room temperature. The solution was warmed and evaporated to half its volume at 60 °C on a water bath. Yellow crystals appeared on addition of large excess of $NaClO_4$. The crystals were filtered off and washed with a small volume of cold water, and ethanol and then ether, and air dried. The compound was recrystallized from a small volume of hot water. Yield; 0.5 g. Found: C, 30.13; H, 5.59; N, 17.42%. Calcd for $C_{12}H_{28}N_6O_8ClCo$: C, 30.00; H, 6.06; N, 17.13%.

Derivation from Sodium Hexanitrocobaltate (Na$_3$[Co(NO$_2$)$_6$]): A solution of $Na_3[Co(NO_2)_6]$ (4.04 g in 30 cm^3 of water) was mixed with *N*-Me-ampr (2.28 g), warmed on a water bath at 70 °C for 15 min and then filtered. Yellow crystals appeared on addition of an excess of $NaClO_4$ (3 g) to the filtrate, and the mixture was warmed on a water bath at 60 °C for about 5 min. After being stored in a refrigerator overnight, the precipitate was filtered off, washed with a small volume of cold water and ethanol, and dried under reduced pressure. The compound was recrystallized from a small volume of water. Yield; 3.15 g. Found: C, 30.24; H, 5.89; N, 17.56%. Calcd for $C_{12}H_{28}N_6O_8ClCo$: C, 30.00; H, 6.06; N, 17.13%.

The visible absorption, CD and ^{1}H NMR spectral data indicate that the dinitro complexes prepared by two methods are identical.

trans,cis(SS)-[*CoCl(NO$_2$)(N-Me-ampr)$_2$]ClO$_4$*. A solution of *trans,cis(SS)*-$[Co(NO_2)_2(N\text{-Me-ampr})_2]ClO_4$ (2.0 g) in concentrated hydrochloric acid (4 cm^3) was warmed at 40 °C on a water bath for 1 h. Excess $LiClO_4$ (0.5 g) was added and the solution was cooled to room temperature. Red crystals were filtered off and washed with a small volume of cold water and ethanol and dried under reduced pressure. The product was recrystallized from methanol. Yield; 1.6 g. Found: C, 30.54; H, 6.14; N, 14.35%. Calcd for $C_{12}H_{28}N_5O_6Cl_2Co$: C, 30.78; H, 6.03; N, 14.96%.

trans,cis(SS)-[*CoCl$_2$(N-Me-ampr)$_2$]ClO$_4$*. *trans,cis(SS)*-$[CoCl(NO_2)(N\text{-Me-ampr})_2]ClO_4$ (0.4 g) was dissolved in hydrochloric acid (10 cm^3) and the solution was heated on a water bath at 80 °C until the color of the solution turned from red to deep green. Green crystals formed by the addition of perchloric acid (60% 3 cm^3), were filtered off, washed with a small volume of cold water, ethanol and ether, and air dried. The product was recrystallized from methanol. Yield; 0.3 g. Found: C, 31.41; H, 6.15; N, 12.45%. Calcd for $C_{12}H_{28}N_4O_4Cl_3Co$: C, 31.49, H; 6.17; N, 12.24%.

trans,cis(RR)-[*CoCl$_2$(N-Me-ampr)$_2$]ClO$_4$*. To an aqueous solution of $CoCl_2\cdot 6H_2O$ (2.39 g in 15 cm^3 of water) was added *N*-Me-ampr (2.28 g in 10 cm^3 of water) and the resulting solution was aerated for 5 h with carbon dioxide free air. After concentrated hydrochloric acid (15 cm^3) had been added, the solution was heated on a boiling water bath and concentrated to about half of its original volume. Green crystalline powder of the *trans*-dichloro complex was formed by the addition of perchloric acid (60% 10 cm^3), was filtered off, washed with a small amount of ethanol and ether, and air dried.

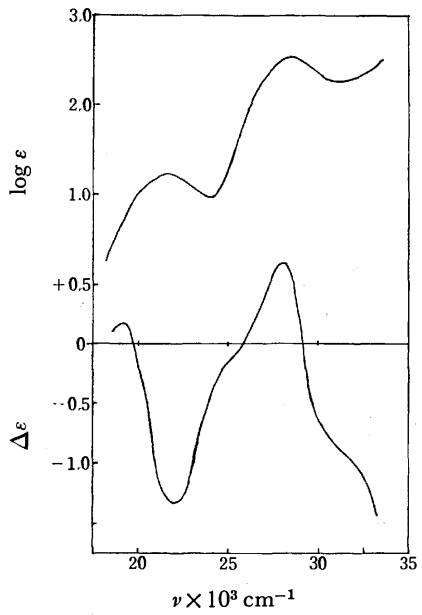

Fig. 1. Absorption (upper) and CD spectra (lower) of *trans*-$[Co(NO_2)_2(N\text{-Me-ampr})_2]ClO_4$.

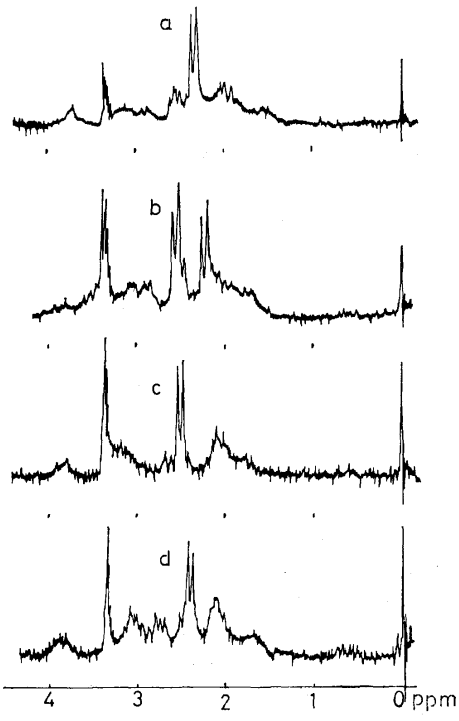

Fig. 2. ^1H NMR spectra of *N*-Me-ampr complexes. a) *trans*-$[Co(NO_2)_2(N\text{-Me-ampr})_2]ClO_4$, b) *trans,cis*-$[CoCl(NO_2)(N\text{-Me-ampr})_2]ClO_4$, c) *trans,cis(SS)*-$[CoCl_2(N\text{-Me-ampr})_2]ClO_4$, d) *trans,cis(RR)*-$[CoCl_2(N\text{-Me-ampr})_2]ClO_4$.

This product was found to be a mixture of two isomers of *trans,cis(SS)* and *trans,cis(RR)* on the basis of ^1H NMR and CD spectral data. The pure *trans,cis(RR)* isomer was obtained by repeated recrystallization from methanol (less soluble part). Yield; 2.0 g. Found: C, 30.93; H, 6.06; N, 12.49%. Calcd for $C_{12}H_{28}N_4O_4Cl_3Co$: C, 31.49; H, 6.17; N, 12.24%.

Results and Discussion

trans-$[Co(NO_2)_2(N\text{-Me-ampr})_2]ClO_4$ was prepared by two methods (usual air oxidation and a reaction of diamine with $[Co(NO_2)_6]^{3-}$ ion). The absorption, circular dichroism (CD) and ^1H NMR spectra of the products obtained by the two methods were identical with each other, indicating the identity of the complexes. The absorption spectrum (Fig. 1) shows two absorption maxima at 465 nm (ε=189.7) and 354 nm (ε=3720), indicating that the complex has *trans* configuration with regard to the nitrite ions.[1,5] In the ^1H NMR spectrum of this complex (in CD_3OD), one doublet assignable to the *N*-methyl groups was observed at 2.36 ppm, indicating that the two *N*-Me-ampr are chemically equivalent (Fig. 2). Since the CD spectrum of *N*-Me-ampr complex (Fig. 1) differs a great deal from the other complexes of *N*-substituted diamines with fixed δ conformations, the vicinal contribution from the asymmetric nitrogens would affect the CD pattern.

Four possible structures of the *trans*-$[Co(NO_2)_2(N\text{-Me-ampr})_2]^+$ ion, with equivalent *N*-Me-ampr, are shown in Fig. 3. Two forms (a,b) have the *trans,trans* configuration and the others (c,d) the *trans,cis* configuration. The structures of this type were assigned by converting them into chloronitro complexes in hydrochloric acid.[5] When the dinitro isomer has the *trans,trans* configuration, the chloronitro complex should be composed of two diastereomers, the yields of which would differ. In such diastereomers, however, both chelate rings are situated in identical chemical environment. Consequently, the ^1H NMR spectra of the *trans,trans* isomers would show two kinds of *N*-methyl signals with different intensities. On the other hand, the *trans,cis* isomer should give rise to only one isomer of chloronitro complex. However, the two chelate rings are affected by distinct circumstances of anionic ligands, which will result in two *N*-methyl resonances with equal intensities.

The ^1H NMR spectrum of the $[CoCl(NO_2)(N\text{-Me-ampr})_2]^+$ ion (in CD_3OD) showed two *N*-methyl doublets at 2.24 ppm and 2.58 ppm (Fig. 2). The intensities of these methyl signals could be regraded as practically equal. The spectral pattern did not change after

repeated recrystallization from methanol or 1M HCl solution. This indicates that the chloronitro complex adopts the *trans,cis* configuration, though the absolute configuration of the *N*-methyl centers, either the *RR* or the *SS*, can not be determined from the ^{1}H NMR data. The orientation of the *N*-methyl group was clarified by examining the CD curves of dichloro complexes.

The *trans,cis*-$[Co(NO_2)_2(N\text{-Me-ampr})_2]^+$ ion was converted into the *trans,cis*-$[CoCl_2(N\text{-Me-ampr})_2]^+$ ion in hydrochloric acid, where no stereochemical change including the inversion of the *N*-methyl centers should occur. The ^{1}H NMR spectrum of the dichloro complex has a single doublet at 2.51 ppm assignable to the *N*-methyl resonances, as expected (Fig. 2). The *trans*-dichloro complex prepared by the usual air oxidation showed a CD curve differing a great deal from that of the *trans,cis*-dichloro complex derived from the *trans,cis*-dinitro complex (Fig. 4). This indicates that the *trans*-(Cl)-$[CoCl_2(N\text{-Me-ampr})_2]^+$ ion exist in at least two isomeric forms. The ^{1}H NMR spectrum of the dichloro complex prepared by air oxidation showed only one doublet at 2.45 ppm assignable to the *N*-methyl groups (Fig. 2), which shows that the *N*-Me-ampr chelates are situated in equivalent circumstances.

Two isomers of the *trans*-dichloro complex show mutarotation in methanol solution, and the CD spectra of both isomers converge to the same curve. This suggests that these complexes isomerize and give rise to the same equilibrium mixture. The configurational rearrangement from *trans,cis* to *trans,trans* and *vice versa* seems to be unlikely. However, it is possible that the inversion of asymmetric nitrogen of *N*-methyl group takes place to contribute to the mutarotation. We thus conclude that the *trans*-dichloro complex prepared from air oxidation also has the *trans,cis* configuration. One of the dichloro isomers should adopt the *RR* configuration and the other the *SS* configuration with respect to the *N*-methyl centers (Fig. 3).

The CD spectrum is considered to arise from the configurational, the conformational and the vicinal effects[6]. In the case of *trans*-dianiono complexes, only the latter two effects should be taken into consideration. It is assumed that the contribution from the δ conformations and asymmetric *S*-nitrogens in pyrrolidine rings are equal for both of the *trans*-dichloro isomers, and that the vicinal contributions from the *S* and the *R* methylated nitrogens are opposite in sign and have approximately equal intensities. Half of the subtract of the CD of *trans,cis(SS)* from that of the *trans,cis(RR)* would be regarded as the vicinal contribution of *R* nitrogens. The half of the CD curve obtained by subtracting the curve of the former dichloro isomer (from dinitro complex) from that of the latter (by air oxidation) are given in Fig. 4 ($1/2$*(trans,cis(RR)—trans,cis(SS))* or *vice versa*). The vicinal contribution of the *R* nitrogens is known to have a positive and a negative Cotton effect dominating the E_g and the A_{2g} (D_{4h}) components, respectively, in the first d-d transition region[6]. From a positive (E_g) and a negative (A_{2g}) maxima in the subtracted CD curve (Fig. 4), it is considered that the absolute configuration of *N*-methyl centers in the dichloro complex obtained by air oxidation is *R* (equatorially disposed

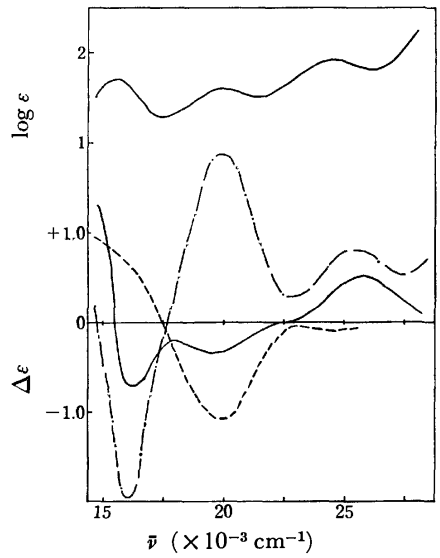

Fig. 4. Absorption (upper) and CD (lower) curves of *traas*-dichloro isomers of *N*-Me-ampr complexes *SS* (——) and *RR*(——), and the differential CD spectrum ($1/2\times(RR-SS)$) (——).

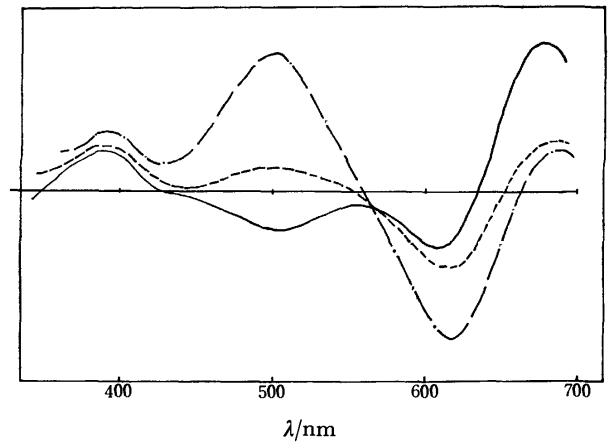

Fig. 5. CD spectra of *trans*-dichloro isomers and the equilibrium mixture (——).

N-methyl groups), and that of the dichloro complex prepared from the dinitro complex as well as the parent dinitro complex is *S* (axial *N*-methyl groups).

From CD spectral data of an equilibrium mixture, the free energy difference between the axial and the equatorial *N*-methyl groups is calculated to be *ca.* 0.4 kcal/mol (axial(*S*): equatorial (*R*)=1 : 2)(Fig. 5). In *trans*-dianiono complexes *N*-methyl groups in the axial orientation are known to interact with the apical ligands more strongly than those in the equatorial orientation. DeHayes and Busch calculated the free energy difference between the axial and the equatorial *N*-methyl groups to be 0.49 kcal/mol from conformational analysis.[7] However, the experimental data obtained so far show that the equatorial *N*-methyl groups are far more profitable than the axial ones in octahedral Co(III) complexes.

The stereochemistry of *N*-Me-ampr complexes is quite different from that of other *N*-methyl substituted diamines. The *N*-Me-ampr complexes prefer the *trans,cis*

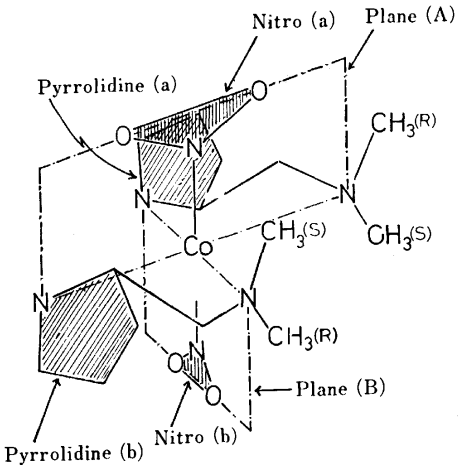

Fig. 6. Illustrative structure of *trans,cis(SS)*-$[Co(NO_2)_2$-(*N*-Me-ampr)$_2]^+$ ion.

rather than the *trans,trans* configuration. The *N*-methyl groups orientate to the axial position more easily than other *N*-methylated diamine complexes. In the *trans*-dinitro complex, the *N*-methyl groups adopt stereospecifically axial positions, and in the *trans*-dichloro complex, two isomers arise due to the difference of the absolute configuration of asymmetric nitrogen centers (axial and equatorial *N*-methyl groups).

The predominance of the axial *N*-methyl groups in the *trans*-dinitro complexes in comparison with the *trans*-dichloro complexes indicates that the orientation of *N*-methyl groups is affected by the kind of apical ligand. The characteristic orientation of the *N*-methyl groups would be attributed to the geometry of apical ligands as well as the steric interaction among the pyrrolidine rings, the apical ligands and the *N*-methyl groups. A possible structure of *trans,cis*-$[Co(NO_2)_2$(*N*-Me-ampr)$_2]^+$ is illustrated in Fig. 6. The triangular nitro groups[8] result in rotational isomers around the NO_2^-–Co–NO_2^- axis. When the nitro group (a) is situated on the plane (A) (Fig. 6), the steric repulsion between nitro group (a) and pyrrolidine ring (a) can be reduced, and another nitro group (b) will locate on the plane (B) for the same reason. The equatorial methyl groups will produce more strict steric repulsions than the axial ones. This may be the reason why the *N*-methyl groups prefer to axial position in the dinitro complex.

Since the chloride ion has spherical symmetry, the *trans*-dichloro complexes has no rotamer around the Cl^-–Co–Cl^- axis. The orientation of *N*-methyl groups depends only on stereochemical interactions between the Cl^- and the *N*-methyl groups. The equatorial *N*-methyl groups in the *trans*-dichloro complex are stabilized to a great extent than the axial ones as well as other *N*-methylated diamine complexes. However, the reason why the axial *N*-methyl group is more stabilized than other *N*-methyl derivatives is not clear.

According to the conformational analysis of some *C*- and/or *N*-methyl substituted diamine complexes,[7] the axial *N*- and *C*-methyl groups flatten the chelate ring conformations. It was demonstrated by X-ray crystal structure analysis[9] that a remarkable flattening of the chelate rings takes place in the *cis*-$[Co(NO_2)_2(ampr)_2]^+$, (ampr=(*S*)-2-(aminomethyl)pyrrolidine) relative to ethylenediamine chelate rings. The averaged dihedral angle of N–C–C–N moieties in the ampr complex was 46°, that for ethylenediamine chelate 55°. It is possible that the asymmetric *S*-nitrogen in the pyrrolidine rings of *N*-Me-ampr complexes would also flatten the chelate rings, reducing the energy difference between the axial and the equatorial *N*-methyl groups.

^{13}C NMR Spectroscopy. Substituent Effects in the Ethyl *trans*-2-Substituted Cyclopropanecarboxylates

Yoshiaki KUSUYAMA and Yoshitsugu IKEDA

Department of Chemistry, Faculty of Education, Wakayama University, Masagocho, Wakayama 640

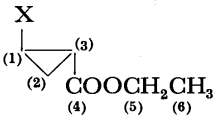
(Received August 14, 1976)

^{13}CFT NMR spectra have been obtained for ethyl *trans*-2-substituted cyclopropanecarboxylates. The chemical shifts have been compared with those of saturated and unsaturated compounds and with substituent constants. The chemical shifts of the methylene carbon of the ethyl group have been correlated linearly with σ_m.

A substantial body of evidence supporting resonance interactions between the cyclopropane ring and the p-orbital of substituents has been obtained from spectroscopic measurements and chemical reactions.[1] However, there has been little work suggesting such interactions based on ^{13}C NMR spectroscopy, which is a useful source of information on the nature of chemical bonds.[2] This paper will describe some characteristic results for the ^{13}C chemical shifts of ethyl *trans*-2-substituted cyclopropanecarboxylates. It is hoped that the effects of the substituents at the 2-position of the ring on the chemical shifts of ^{13}C of the ethyl group will provide a convenient tool for estimating the transmitting ability of the polar effect through a cyclopropane ring.

Results and Discussion

Proton-decoupled natural-abundance ^{13}CFT NMR spectra were obtained at 25.15 MHz at 30 °C. The samples were run as a 1.5±0.1 M solution in $CDCl_3$ containing tetramethylsilane as an internal reference. The signals have been assigned on the basis of the peak intensities and the chemical shifts reported in the literature.[3-5] The assignments of the ^{13}C resonances of the ethyl cyclopropanecarboxylates investigated in this work are shown in Table 1.



Ring carbons are strongly affected by the substituents. The screening at the carbons of the α and β positions relative to the substituents is influenced by several factors (inductive, steric, magnetic anisotropy, *etc.*) contributed by the substituents. One of the most common methods to interpret the substituent effects is a comparison with other similarly substituted compounds.

The best agreement of the cyclopropyl α-carbon shieldings of the monosubstituted cyclopropanes *vs.* the shieldings of substituted methanes was found by Weiner and Malinowski.[3] In addition to their results, a very high correlation of $C_{(1)}$ chemical shifts with the chemical shifts of substituted methanes[2a,3,6] or those of the α-position of 1-substituted pentanes[2a,2b] was obtained by others (slope, 0.80; Fig. 1.). Spiesecke and Schneider[6,7] reported that the chemical shifts of ^{13}C, to which substituents were attached, were correlated by the electronegativity (Ex) of the substituents. In Table 2, the relations of the relative substituent-induced chemical shifts of α-carbons to substituents(C_α-scs) and Ex[8] are

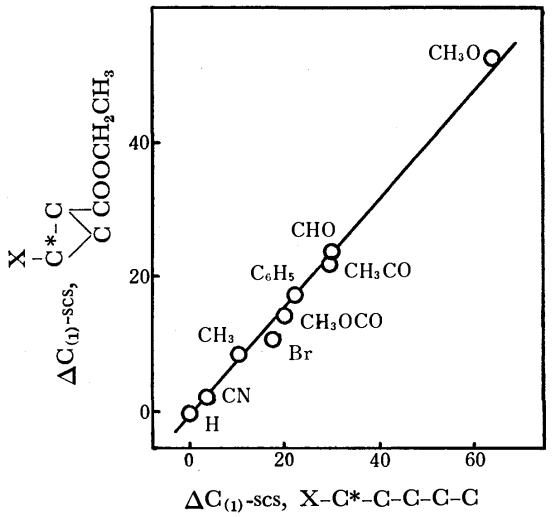


Fig. 1. Comparison of relative substituent-induced ^{13}C chemical shifts of the substituted carbons ($\Delta C_{(1)}$-scs) in 1-substituted pentanes and ethyl *trans*-2-substituted cyclopropanecarboxylates.

summarized. The electronegativity of the group substituents, OCH_3, NH_2, and CH_3, was assumed to be that of the first atom in the group. Good correlations of C_α-scs with Ex were obtained except for the X-vinyl derivative. In the case of the X-vinyl derivative, neighbor-anisotropy may contribute considerably.[2,7] In all five series, bromine deviated from the correlation line because of the contribution of the heavy-atom effect.[2b,9,10] The ($C_{(\alpha)}$-scs *vs.* C_{X-Me}-scs) slopes were parallel to the ($C_{(\alpha)}$-scs *vs.* Ex) slopes. Thus, the electronegativity of the substituents is the most important factor in the ^{13}C chemical shifts of α-carbons.[6] It may be though that the hydridization of α-carbons is a result of the susceptibility of the electronegativity.

The chemical shifts of $C_{(3)}$ were slightly larger than those of $C_{(2)}$. There is a good linear relation between the shifts of $C_{(3)}$ and those of the β-carbons of 1-substituted pentanes for the methyl, bromo, and methoxyl groups,[11] while the cyano, formyl, methylcarbonyl, and acetyl groups are scattered (Fig. 2). Also the chemical shifts of $C_{(3)}$ can not be correlated by those of the β-carbons of substituted ethylenes.[2,12]

For the β-carbons to the substituents in the unsaturated frameworks, the substituent effects exhibit a much wider range of shifts than those observed in saturated frameworks.[2] The chemical shitfs may be indicated by the kinds of canonical resonance structures:

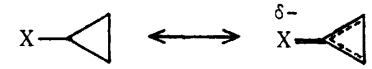
$$X\text{-}C{=}C \leftrightarrow \overset{\delta-}{X}{=}C\text{-}\overset{\delta+}{C} \leftrightarrow \overset{\delta+}{X}{=}C\text{-}\overset{\delta-}{C}. \quad (1)$$

The cyclopropane ring exhibits a considerable degree of π-bond character and interacts with the p-orbitals of the substituents, especially releasing electrons to substituents:[1,2]



(2)

The cyano, formyl, methoxycarbonyl, and acetyl groups are electron-attracting groups by means of their resonance and decrease the electron densities of $C_{(2)}$ and $C_{(3)}$, as is shown in (2). Accordingly, $C_{(2)}$ and $C_{(3)}$ shift downfield from those expected from the shift of the saturated frameworks. It may be thought that the interaction is responsible for the appreciable differences between the observed values and the predicted values (Table 3.) which were calculated by the simple additive rule.[5] The shift differences in $C_{(2)}$ is largest in the three ring carbons except for the $C_{(1)}$ of the bromo derivative, to which the heavy halogen atom effect may contribute.[2] In order to estimate semiquantitatively

the contribution of the ionic canonical form in (2), the differences (Δ_R) in the chemical shifts between $C_{(3)}$ (ethyl *trans*-2-substituted cyclopropanecarboxylate) and $C_{(\beta)}$ (1-substituted pentane) were calculated (Table 4). For unsaturated frameworks, the substituent effects may be designated as follows:

$$\Delta\delta = \Delta\delta_{saturated} + \Delta_R. \quad (3)$$

A linear correlation was obtained between Δ_R and σ_R^- for the electron-attracting groups by means of the resonance (slope, 15.97; r: correlation coefficient, 0.980). On the basis of these results, it seemed reasonable to assume that the resonance interaction of a cyclopropane with electron-attracting substituents plays an important role in the chemical shifts of $C_{(2)}$ and $C_{(3)}$.

The most striking result in the present investigation is a measurable chemical shift of $C_{(5)}$. In general, chemical shifts of the carbon of the δ position to substituents are correlated by a Hammett-type equation because of the absence of steric interaction between the substituents and δ-carbon. The present chemical shifts of $C_{(5)}$ are correlated with σ_m (slope, 2.07; r=0.985), and a more excellent correlation was obtained with σ_m° (slope, 2.17; r=0.994)[13] although σ_m and σ_m° were obtained from the reaction in hydroxylic solvents, and solvent-variable substituent constants are included in the calculations.

$$\Delta\delta_{(C5)} = 2.07\sigma_m,$$
$$\Delta\delta_{(C5)} = 2.17\sigma_m^\circ.$$

It is noteworthy that σ_m and σ_m° include considerable contributions of the resonance effects.[1,14]

$$\sigma_m = \sigma_I + 0.33\sigma_R,$$
$$\Delta\delta_{(C5)} = 2.1\sigma_I + 0.72\sigma_R.$$

On the basis of this correlation of $^{13}C_{(5)}$ chemical shifts, it seemed reasonable to assume that the cyclopropane ring can transmit the resonance effect, although its influence is rather small. The pK_a values of *trans*-2-substituted cyclopropanecarboxylic acids in water or in 50% aqueous alcohol were correlated by σ_m:[15]

$$\Delta pK_a = 1.99\sigma_m = 0.96\Delta\delta(C_{(5)}) \text{ (in water)}$$
$$\Delta pK_a = 2.92\sigma_m = 1.41\Delta\delta(C_{(5)}) \text{ (in 50\% alcohol)}$$

Thus, the relative acidities of carboxylic acids may be estimated by means of the ^{13}C chemical shifts of alkoxyl carbons of appropriate esters, in which substituents are sufficiently remote from the carboxyl group.

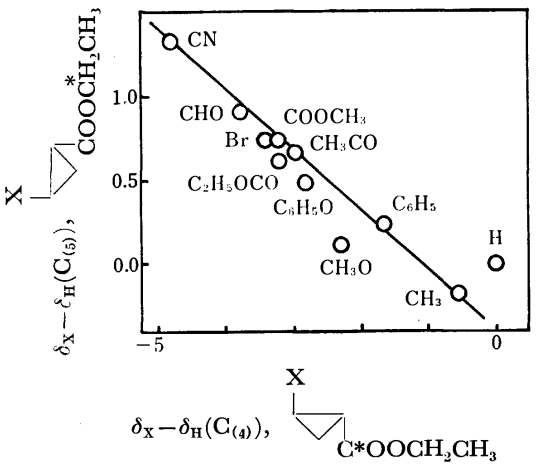

Fig. 3. Correlation between the ^{13}C chemical shifts of carbonyl carbons and those of alkoxy carbons in ethyl *trans*-2-substituted cyclopropanecarboxylates.

A linear correlation was observed between the ^{13}C chemical shifts of $C_{(4)}$ and those of $C_{(5)}$ (Fig. 3). The unsaturated compound, however, deviated from the correlation line. The direction of the chemical shifts of $C_{(4)}$ is reversed in terms of the substituent electronic properties. A "reverse" correlation has previously been reported for the chemical shifts of carboxyl carbons in the substituted benzoic acids[16] and benzocaine hydrochlorides[17] and of cyanide carbons in the substituted benzonitriles.[18] It appears that the large charge separation in the carboxyl group is responsible for the reversal in this direction of the substituent effects.

The $C_{(6)}$, which is most remote from the site of substitution, is practically not influenced at all by the substituent and has a chemical shift equal to 14.2±0.1 ppm from tetramethylsilane. This carbon seems too distant from the substituent for any substituent effect to be detected.

Experimental

^{13}C NMR Spectra. The ^{13}CFT NMR spectra were obtained at 25.15 MHz on a JEOL-JNM-PFT-100 apparatus at 30 °C. Samples were dissolved in $CDCl_3$ containing tetramethylsilane as the internal reference. The concentrations were 1.5±0.1 M. The measurement conditions were as follows: puls width, 15 μs(90°); repetition time, 2.5 s; frequency range, 6.25 KHz; data points, 8192. The accuracy is at least ±0.06 ppm.

Materials. The materials were identified on the basis of spectroscopic and gas-chromatographic measurement and elemental analysis. The NMR spectra were measured on a JEOL-JNM-C-60HL(60 MHz) spectrometer, with tetrameth-

ylsilane employed as the internal standard. Two geometrical isomers of ethyl 2-substituted cyclopropanecarboxylates were isolated by fractional distillation and/or by GLC. For the 2-phenyl derivative, the *trans*-isomer in a mixture of the two isomers was hydrolyzed to *trans*-2-phenylcyclopropanecarboxylic acid, which was then converted to the appropriate ethyl ester by the usual method.[19] The GLC analyses were carried out on a Yanaco GCG-550T, using a 1-m column of Silicone DC 550 or Silicone XF 1150. The *trans*-isomer always showed the shorter retention time. The separation of the two isomers were carried out on a Yanaco G80 apparatus equipped with AP11. The structure assignments for the geometrical isomers were made by means of the ^1H NMR spectra using shift reagents based on a generalization[20] that the tendency of the shift of the signal of the *cis* proton to ethoxycarbonyl is larger than that of the shift of the *trans* protons.

The ethyl 2-phenyl-, methoxy-, ethoxy-, phenoxy-, cyano-, and ethoxycarbonyl-cyclopropanecarboxylates were prepared by the reaction of ethyl diazoacetate with the appropriate alkene.[15] Ethyl *trans*-2-methylcyclopropanecarboxylate was obtained by the ethanolysis of the appropriate acid chloride,[21] itself prepared by the chlorination of *trans*-2-methylcyclopropanecarboxylic acid[21,22] with thionyl chloride. The ethyl 2-bromocyclopropanecarboxylate was synthesized by a Hunsdicker reaction[23,24] of silver *trans*-2-ethoxycarbonylcyclopropanecarboxylate using bromine. The *trans*-2-ethoxycarbonylcyclopropanecarboxylic acid[24] was chlorinated by thionyl chloride to *trans*-2-ethoxycarbonylcyclopropanecarbonyl chloride. The methanolysis of *trans*-2-ethoxycarbonylcyclopropanecarbonyl chloride afforded methyl ethyl cyclopropane-1,2-dicarboxylate. Ethyl 2-formyl- and 2-cyanocyclopropanecarboxylates were obtained by the reaction of ethyl (dimethylsulfuranylidene) acetate with acrolein and acrylonitrile respectively.[25] The boiling points of the ethyl *trans*-2-substituted cyclopropanecarboxylates are summarized in Table 5.

The authors wish to thank Professor Teijiro Yonezawa and Mr. Toshiro Inubushi (Kyoto Univ.) for their ^{13}CFT NMR measurements.

α,β-Unsaturated Carboxylic Acid Derivatives. XII. A Convenient Synthesis of Oxazole-4-carboxylic and 3,3-Dibromo-2,2-diamino Acids[1]

Chung-gi SHIN,* Yoshiaki SATO, Hidetoshi SUGIYAMA, Katsumi NANJO, and Juji YOSHIMURA**

Laboratory of Organic Chemistry, Faculty of Technology, Kanagawa University, Rokkakubashi, Kanagawa-ku, Yokohama 221

***Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Ōkayama, Meguro-ku, Tokyo 152*

(Received November 16, 1976)

Treatment of *t*-butyl 2-acetylamino-3-bromo-2-alkenoate with triethylamine gave *t*-butyl 5-alkyl-2-methyloxazole-4-carboxylate by dehydrobromination, but no reaction occurred with primary amines. While treatment of *t*-butyl 2-acetylimino-3,3-dibromoalkanoate with hydroxylamine or several aliphatic and aromatic primary amines gave addition products, *t*-butyl 2-acetylamino-3,3-dibromo-2-(hydroxyamino)- and 2-(substituted amino)-alkanoate, respectively, in fairly good yields.

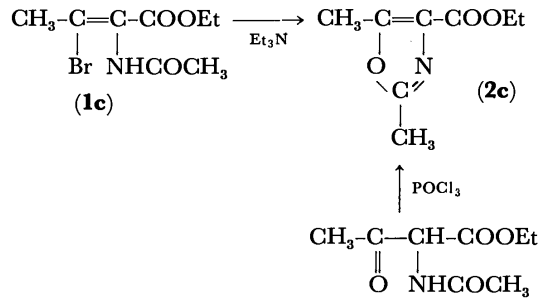
Previously, Shin *et al.* have reported on the facile synthesis of *t*-butyl 2-(*N*-bromoacetylamino)-2-alkenoate by the reaction of *t*-butyl 2-acetylamino-2-alkenoate with *N*-bromosuccinimide (NBS), and its bromine migration into *t*-butyl 2-acetylamino-3-bromo-2-alkenoate (**1**).[2] Repeated bromination of **1** and its migration gave *t*-butyl 2-acetylimino-3,3-dibromoalkanoate (**4**), to which water or several kinds of alcohol were added readily to give the corresponding 2-hydroxy- and alkoxy derivatives.[1]

Recently, it has been described that the same addition reaction of aliphatic primary and some secondary amines to methyl 2-acylamino-3,3-dichloroacrylate gave a mixture of methyl 2-acylamino-2-(substituted amino)-3,3-dichloropropanoate and oxazole derivatives.[3,4] However, not only has the suppositional imino-form intermediate, methyl 2-acylimino-3,3-dichloropropanoate, not been isolated, but also there was no evidence for the presence of the intermediate.

In order to ascertain and extend the above addition reaction, the reaction of **4** with several aliphatic and aromatic primary amines and that of **1** with triethylamine was carried out and these resulted in the convenient synthesis of 3,3-dibromo-2,2-diamino acid derivatives and oxazole-4-carboxylic acids, respectively.[5]

Results and Discussion

*Reaction of **1** with Triethylamine.* When a solution of **1a,b** (**a**; R=CH_3, **b**; R=C_2H_5) and triethylamine in benzene was refluxed for 2.5 h, a colorless syrup, which gradually crystallized during distillation under reduced pressure, was obtained in a *ca.* 40% yield. The colorless crystals isolated were determined to be *t*-butyl 5-alkyl-2-methyloxazole-4-carboxylate (**2a, b**) from elemental analysis and spectroscopic data. A similar treatment of ethyl 2-acetylamino-3-bromo-2-butenoate (**1c**), derived from the reaction of ethyl 2-acetylamino-2-butenoate with NBS, also gave ethyl 2,5-dimethyloxazole-4-carboxylate (**2c**). An independent preparation of **2c**, by the reaction of ethyl 2-acetylamino-3-oxobutanoate with phosphoryl chloride,[6] demonstrated the structure unambiguously.



Although the assignment of the proper configuration (*E*-, *Z*-) was not successful in this work, the geometric isomer of **1** was subjected to the cyclization reaction (Table 1). Moreover, **2a** was converted into colorless, crystalline, 2,5-dimethyloxazole-4-carboxylic acid (**3a**) in a 57% yield, by treatment with hydrogen chloride in chloroform at room temperature. On the other hand, it was found that conversion of **1** into **2** by ammonia or benzylamine did not occur.

The yields, physical properties, and spectral data of **2** and **3** are summarized in Table 1.

*Reaction of **4** with Several Amines.* The compound **4a,b** (**a**; R=CH_3, **b**; R=C_2H_5) used was prepared according to the method previously reported.[1] Treatment of **4** with excess gaseous ammonia in ether with stirring below 10 °C gave only *t*-butyl 2-acetylamino-2-amino-3,3-dibromoalkanoate (**5**) as colorless crystals in a *ca.* 70% yield. The subsequent acylation of **5** with acetic anhydride and benzoyl chloride in pyridine at room temperature or below, respectively, gave *t*-butyl 2,2-diacetylamino- and 2-acetylamino-2-benzoylamino-3,3-dibromoalkanoates (**12** and **13**), which could not be obtained independently from the direct addition of the acid amide to **4**. Furthermore, a similar addition reaction of almost equimolar **4** and alkylamines (benzylamine and phenylhydrazine) or arylamines (aniline, ethyl *p*-aminobenzoate, 2-aminopyridine and 2-aminothiazole) in ethanol below 10 °C or at room temperature also gave *t*-butyl 2-acetylamino-2-(substituted amino)-3,3-dibromoalkanoates (**6**—**11**) as colorless crystals in *ca.* 85% yields, without the accompaniment of the expected oxazoline derivatives (**19** and **20**).

From the above results, it was found that the amino group added readily and dominatly to the carbon-nitrogen double bond in **4**, even in the presence of ethanol.

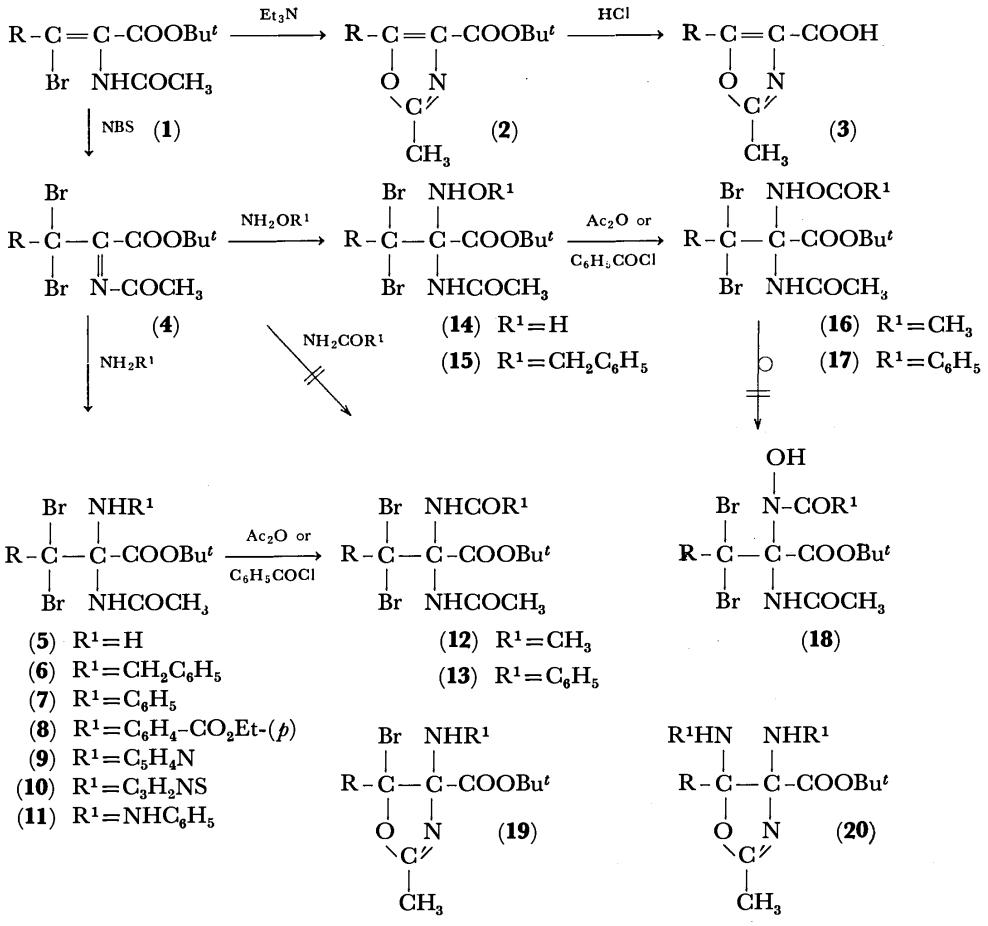

Scheme 1.

Moreover, the reaction of **4** with hydroxylamine in ethanol below 10 °C gave the expected *t*-butyl 2-acetylamino-3,3-dibromo-2-(hydroxyamino)alkanoate (**14**) in an unstable crystalline state. The structure of **14** was assigned, on the basis of the appearance of the hydroxyl group absorption band at 3360—3370 cm^{-1} in the IR spectrum and the subsequent acylation of **14**. The acylation of **14** with acetic anhydride and benzoyl chloride in pyridine gave *t*-butyl 2-acetylamino-2-acetoxyamino- and 2-benzoyloxyamino-3,3-dibromoalkanoates (**16** and **17**) as colorless crystals in *ca.* 87% yields. Compounds **16** and **17** showed no coloration with methanolic ferric chloride, indicating the absence of hydroxamic acid structures. However, migration of the acyl group on an oxygen in **16** or **17** to a nitrogen atom, as reported an earlier paper,[7] was not observed. Moreover, a similar treatment of **4** with *O*-benzylhydroxylamine gave *t*-butyl 2-acetylamino-2-benzyloxyamino-3,3-dibromoalkanoate (**15**). In this work, however, the conversion of **15** into **14** was unsuccessful. Although reactions of **4** with other primary amines, for example, butylamine, cyclohexylamine and 2-aminoethanol, occurred, the un-

TABLE 2. *t*-BUTYL 3,3-DIBROMO-2-(SUBSTITUTED AMINO)-2-ACETAMIDO-2-ALKANOATES $\left(\begin{array}{c} Br \quad NH\text{-}R^1 \\ | \quad | \\ R\text{-}C\text{-}C\text{-}COOBu^t \\ | \quad | \\ Br \quad NHCOCH_3 \end{array}\right)$

stable crystalline products obtained could not be confirmed.

The yields, physical properties, and spectral data of **5**—**17** are summarized in Table 2.

Experimental

All boiling and melting points are uncorrected. The IR spectra were recorded with a Hitachi EPI-G3 Spectrometer.

The NMR spectra were measured using a JNM-PS-100 Spectrometer (Japan Electron Optics Laboratory Co., Ltd.) with tetramethylsilane as the internal standard.

Materials. The *E*- and *Z*-isomers of **1a,b** were prepared by the method recently reported.[2] Similarly, **1c** was also obtained by the reaction of ethyl 2-acetylamino-2-butenoate (0.0304 mol) and NBS (0.0335 mol) in carbon tetrachloride (30 ml). Colorless needles from dibutyl ether, yield 55%, mp 108—109 °C. IR (KBr): 3245 (NH), 1720 (COO), 1660 and 1520 (NHCO) cm^{-1}. NMR (δ): 2.34, 2.55 (two s, $COCH_3$), 2.04, 2.07 (two s, CH_3–C=), 7.47, 8.20 (two broad s, NH), contributing to the mixture of the *E*- and *Z*-isomers of **1c**. From the intensity of the amide proton, **1c** was found to be composed of the *E*- and *Z*-isomers in a ratio of 1 : 1. Found: C, 38.52; H, 4.81; N, 5.60%. Calcd for $C_8H_{12}NO_3Br$: C, 38.40; H, 4.80; N, 5.60%.

*Preparation of **2a,b,c**.* A solution of **1a,b,c** (0.0036 mol) and triethylamine (0.0072 mol) in dry benzene (20 ml) was refluxed for 2.5 h. The triethylamine hydrobromide separated out was filtered off, and then the benzene solution was washed three times with water (30 ml). The benzene layer was dried over anhydrous magnesium sulfate and then evaporated under reduced pressure to give a colorless syrup. The residual syrup was distilled under reduced pressure to give crystals of *t*-butyl 2,5-dimethyloxazole-4-carboxylate (**2a**) and *t*-butyl 5-ethyl-2-methyloxazole-4-carboxylate (**2b**) or a syrup (**2c**).

*Preparation of **3a**.* A solution of **2a** (0.0177 mol) in dry chloroform (10 ml) was saturated with dry hydrogen chloride with cooling. After standing overnight at room temperature, colorless crystals gradually separated out from the resulting brown solution. The crystalline product was collected and washed with chloroform and then recrystallized from ethanol to give colorless needles (**3a**).

*Preparation of **5a**.* When a solution of **4a** (1.54 g, 0.0043 mol) in ether (10 ml) was saturated with gaseous ammonia with stirring below 10 °C, a colorless crystalline product precipitated immediately. The crystals were identified to be *t*-butyl 2-acetylamino-2-amino-3,3-dibromobutanoate.

In an analogous manner, *t*-butyl 2-acetylamino-2-amino-3,3-dibromopentanoate (**5b**) was obtained from the reaction of **4b** with ammonia.

*Preparation of **6a**.* A solution of **4a** (0.0043 mol) and benzylamine (0.48 g, 0.0045 mol) in ethanol (10 ml) was stirred below 10 °C. A small quantity of water added to the resulting solution and a similar work up gave *t*-butyl 2-acetylamino-2-benzylamino-3,3-dibromobutanoate.

*Preparation of **7a**.* A solution of **4a** (0.0043 mol) and aniline (0.42 g, 0.0045 mol) in ethanol (10 ml) was stirred below 10 °C and worked up similarly to give *t*-butyl 2-acetylamino-2-anilino-3,3-dibromobutanoate.

In an analogous manner, *t*-butyl 2-acetylamino-2-anilino-3,3-dibromopentanoate (**7b**) was obtained from **4b** and aniline.

*Preparation of **8a**.* *t*-Butyl 2-acetylamino-2-(4-ethoxycarbonylanilino)-3,3-dibromobutanoate was prepared from **4a** (0.0043 mol) and ethyl *p*-aminobenzoate (0.75 g, 0.0045 mol) in a manner similar to the preparation of **6a**.

*Preparation of **9a**.* In a similar manner, *t*-butyl 2-acetylamino-2-(2-pyridylamino)-3,3-dibromobutanoate was synthesized from **4a** and 2-aminopyridine (0.0045 mol).

*Preparation of **8b**.* Into a solution of ethyl *p*-aminobenzoate (0.71 g, 0.0043 mol) in benzene (30 ml), **4b** (1.51 g, 0.0041 mol) was added with stirring at room temperature. After stirring for 5 h, the resulting solution was washed successively once with 3M-hydrochloric acid and once with water. The benzene layer was dried over anhydrous magnesium sulfate and then evaporated under reduced pressure to give crystals of *t*-butyl 2-acetylamino-2-(4-ethoxycarbonylanilino)-3,3-dibromopentanoate.

*Preparation of **9b**.* *t*-Butyl 2-acetylamino-2-(2-pyridylamino)-3,3-dibromopentanoate was obtained from **4b** and 2-aminopyridine in the manner described above.

*Preparation of **10a**.* Into a solution of 2-aminothiazole (0.45 g, 0.0045 mol) in benzene (30 ml), **4a** (0.0043 mol) was added with stirring at room temperature. After stirring for 24 h, the crystalline product separated out was collected and washed with ethanol. The crystals were identified to be *t*-butyl 2-acetylamino-2-(2-thiazolylamino)-3,3-dibromobutanoate.

In an analogous manner, *t*-butyl 2-acetylamino-2-(2-thiazolylamino)-3,3-dibromopentanoate (**10b**) was obtained from **4b** and 2-aminothiazole, after stirring for 4 days.

*Preaparation of **11a**.* A solution of **4a** (0.0043 mol) and phenylhydrazine (0.49 g, 0.0045 mol) in ethanol (10 ml) was stirred below 10 °C, and a similar work up gave *t*-butyl 2-acetylamino-2-phenylhydrazino-3,3-dibromobutanoate.

In an analogous manner, *t*-butyl 2-acetylamino-2-phenylhydrazino-3,3-dibromopentanoate (**11b**) was obtained from **4b** and phenylhydrazine.

*Preparation of **14a**.* Into a solution of **4a** (0.0043 mol) in ethanol (10 ml), a solution of hydroxylamine (made from hydroxylamine hydrochloride (0.33 g, 0.0047 mol) and sodium hydrogencarbonate (0.4 g, 0.0047 mol) in water (3 ml)) was added dropwise with stirring below 10 °C. The reaction was immediately completed and a colorless crystalline product was separated out by adding water (10 ml) to the resulting solution. The crystals were collected and washed with a small quantity of petroleum ether, and identified as *t*-butyl 2-acetylamino-3,3-dibromo-2-hydroxyaminobutanoate.

In an analogous manner, *t*-butyl 2-acetylamino-3,3-dibromo-2-hydroxyaminopentanoate (**14b**) was obtained from **4b** and hydroxylamine.

*Preparation of **15a**.* A solution of **4a** (0.0043 mol) and *O*-benzylhydroxylamine (made from *O*-benzylhydroxylamine hydrochloride (0.72 g, 0.0045 mol) and sodium ethoxide (made from sodium (0.1 g, 0.0045 mol) and ethanol (5 ml)) in ethanol (50 ml) was similarly worked up to give a residual yellowish syrup. After adding benzene (50 ml) to the residue, the benzene solution was washed once with water and dried over anhydrous magnesium sulfate, and then evaporated under reduced pressure to give *t*-butyl 2-acetylamino-2-benzyloxyamino-3,3-dibromobutanoate.

In an analogous manner, *t*-butyl 2-acetylamino-2-benzyloxyamino-3,3-dibromopentanoate (**15b**) was obtained from **4b** and *O*-benzylhydroxylamine.

*Preparation of **12a**, **12b**, **16a**, and **16b**.* The acetylation of **5a**, **5b**, **14a**, and **14b** was carried out by the usual procedure using acetic anhydride and pyridine at room temperature, giving the acetoxyamino compounds, **12a**, **12b**, **16a**, and **16b**, respectively.

*Preparation of **13b**.* A solution of **5a** (3 g, 0.008 mol) and benzoyl chloride (1.24 g, 0.0088 mol) in pyridine (20 ml) was stirred below 10 °C for 3 h, and a similar work up gave *t*-butyl 2-acetylamino-2-benzoylamino-3,3-dibromobutanoate.

*Preparation of **17a** and **17b**.* Similarly, **14a** and **14b** were treated with benzoyl chloride below 10 °C in pyridine, giving the benzoyloxyamino compounds, **17a** and **17b**, respectively.

Organic *N*-Halogen Compounds. X.[1] Preparative Studies on *N*-Benzimidoylsulfilimines

Toshio FUCHIGAMI and Keijiro ODO

Department of Electronic Chemistry, The Graduate School, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received December 6, 1976)

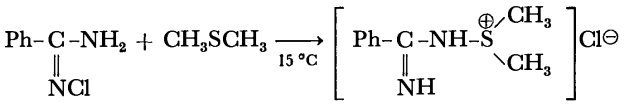
N-Chlorobenzamidine (**1**) reacted readily with dimethyl sulfide to form *N*-benzimidoylaminodimethylsulfonium chloride (**2**). Treatment of **2** with sodium hydroxide gave *N*-benzimidoyl-*S*,*S*-dimethylsulfilimine (**3**) quantitatively. The thermolysis of acyl derivatives of **3** gave rise to 1,2,4-oxadiazoles. *N*-Chloro derivative (**6**) prepared by treating **2** with sodium hypochlorite, reacted with potassium thiocyanate to form *N*-(3-phenyl-1,2,4-thiadiazolyl-5-yl)-*S*,*S*-dimethylsulfilimine (**7**).

Sulfilimines, unique in reactivity, are useful for organic synthesis. Many studies on them have been reported, but they deal with the stable *N*-sulfonyl and *N*-acysulfilimines. We wish to report the preparation of a new class of sulfilimines stabilized by an imino group together with some interesting reactions of acyl and *N*-halogen derivatives of *N*-benzimidoyl-*S*,*S*-dimethylsulfilimine, **3**.

Results and Discussion

Preparation of N-*Benzimidoylaminodimethylsulfonium Chloride (2).* *N*-Halogen compounds react readily with sulfides to form sulfonium salts.[2,3] We investigated the possible formation of such a sulfonium salt from *N*-chloroamidine and sulfide in various solvents. *N*-Chlorobenzamidine (**1**) reacted readily with dimethyl sulfide to form sulfonium chloride (**2**). Acetonitrile was found to be the most suitable solvent for the formation of **2**. When the concentration of **1** was high, the yield of **2** increased considerably. Compound **1** did not react with ethyl phenyl sulfide. The results are summarized in Table 1.

TABLE 1. PREPARATION OF SULFONIUM SALT (**2**)

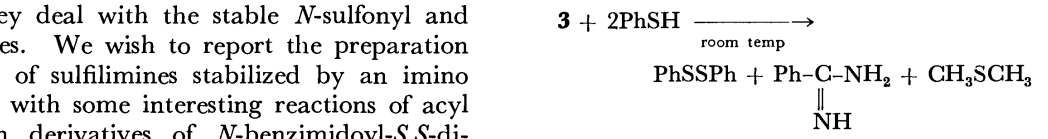


Solvent (ml)	Reaction time (h)[a]	Yield (%)
EtOEt (20)	2.0 (—)[b]	52
CH_2Cl_2 (20)	1.5 (1.0)	62
CH_3CN (20)	1.0 (0.3)	72
CH_3CN (10)	1.0 (0.3)	84

20 mmol scale.
a) Active chlorine disappeared. b) Active chlorine did not disappear.

Preparation of N-*Benzimidoyl*-S,S-*dimethylsulfilimine (3).* Treatment of **2** with aqueous sodium hydroxide gave **3** quantitatively. Treatment of **3** with dry hydrogen chloride afforded the starting material, **2**. The new sulfilimine, **3**, which could be recrystallized from chloroform–ether, melts at 67—68 °C. Sulfilimine **3** is strongly hygroscopic and soluble in common organic solvents except for hydrocarbons. It was found that **3** is quite stable under reflux in tetrahydrofurane for 3 h but decomposes evolving dimethyl sulfide under reflux in xylene for 2 h.

However, the S–N bond of **3** was found to cleave easily on being treated with benzenethiol.



Structure of 3. The structures of **2** and **3** are discussed on the basis of spectral data as follows. In the IR spectra[4] the C=N streching vibration of **2** is at 1650 cm^{-1}, that of **3** at 1510 cm^{-1}. The shift is analogous to that observed in the case of a carbonyl group attached to a ylide carbon or ylide nitrogen atom— (a).

In the UV spectra, **2** and **3** have the same λ_{max} (239 nm) but ε_{max} of **3** (11300) is by 2100 larger than that of **2**— (b).

In the NMR spectra,[5] the resonance of protons to the positively charged sulfur atom and the nitrogen atom shifts upfield by 0.3 and 3.5 ppm, respectively, in going from **2** to **3**— (c).

(a) and (c) suggest that form (**3a**) is a contributor to the sulfilimine structure. (b) and (c) suggest that the S–N bond posesses a partial double bond character due to 2p—3d orbital overlap, (**3b**).

The overall structure can be represented by (A).

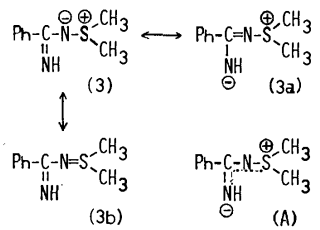


Fig. 1.

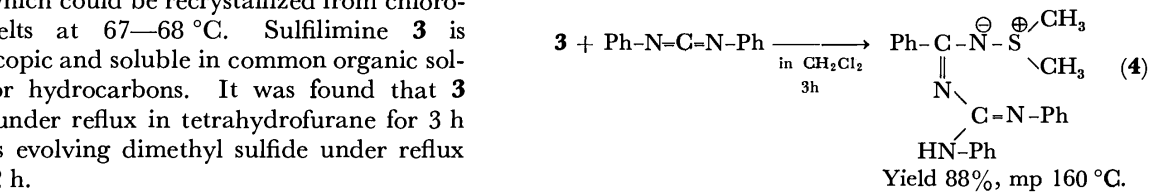
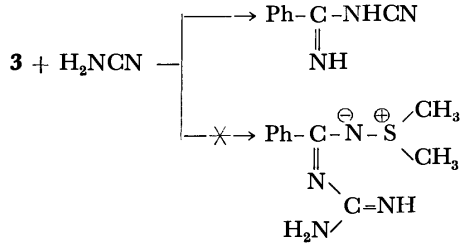
These resonance forms can contribute to the stabilization of this new type sulfilimine.

Amidino and Acyl Derivatives of 3. Addition of **3** to diphenylcarbodiimide occurred easily at low temperature to afford amidino derivative (**4**) in a good yield.



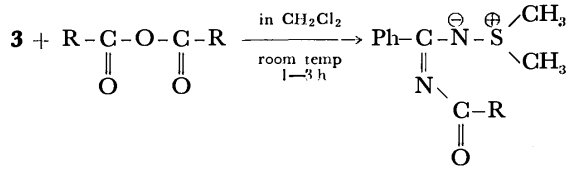
Yield 88%, mp 160 °C.

Cyanamide, which seems to be carbodiimide, did not react with **3** at room temperature, but gave *N*-cyanobenzamidine in 60% yield under reflux in tetrahydrofuran for 30 min.



Detailed mechanism has not been clarified yet. The reaction path might be similar to that proposed in the formation of cyanoamidine from amidine and cyanamide.[6]

Acyl derivatives of **3** were easily prepared by the treatment of **2** with acid anhydride.



5a: R=Ph
5b: R=*p*-$CH_3C_6H_4$
5c: R=CH_3

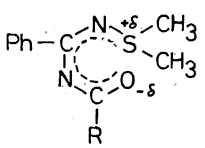
The results and physical properties of **5** are given in Table 2.

Table 2. Physical properties of **5**

Compounds	Yield (%)	Mp (°C)	IR (cm^{-1}) $\nu_{C=N}$	IR (cm^{-1}) $\nu_{C=O}$	UV λ_{max} (ε)
5a	66	188—190	1600	1570	245 (11700)
5b	54	172—173	1590	1550	251 (18600)
5c	60	114—116	1620	1600	230 (10800)

These sulfilimines have relatively high melting points and are soluble in common organic solvents except for ether and hydrocarbons.

In the IR spectra, the C=N absorption of **5** is at a shorter wavelength than that of **3**. On the other hand, the C=O absorption is at a longer wavelength than that of normal amide absorption. In view of these shifts in the IR spectra, the structure of **5** can be represented by (B).

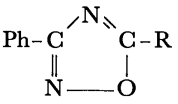


(B)

Fig. 2.

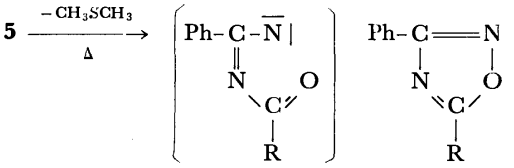
The mass spectrum of **5a** revealed that the primary fragmentation is loss of dimethyl sulfide. Thus, it was expected that 1,2,4-oxadiazole would be formed by elimination of dimethyl sulfide. In fact, heating of **5a** and **5b** without solvent in test tubes at about 200 °C gave rise to 1,2,4-oxadiazoles. However, **5c** gave no corresponding product. The structures of these products were confirmed by elemental analyses and IR spectra. The results are given in Table 3.

Table 3. Formation of 1,2,4-oxadiazoles

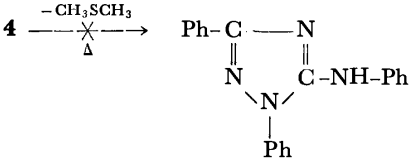


R	Reaction temp (°C)	Reaction time (min)	Yield (%)	Mp (°C)
Ph	200—210	10	70	108 (108)[18]
p-$CH_3C_6H_4$	190—200	20	63	121—122
CH_3	160	5	0	—

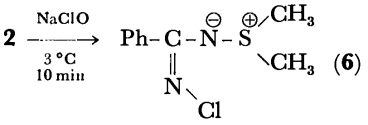
Detailed mechanism of this interesting internal ring formation has not been clarified. The thermolysis seems to proceed *via* a nitrene in view of oxadiazole formation from dimethyl diazidomalonate[7] and *N*-benzoyl-*N'*-chloroamidino compounds.[8,9]



Amidino derivative **4** was also expected to form 1,2,4-triazole by thermolysis. However, no cyclization occurred.



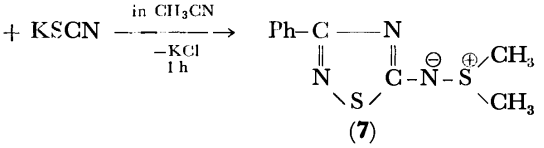
Preparation and Reaction of N-*Chloro Derivative of* **3**. Sulfilimines are stabillized by an electron-withdrawing group attached to the ylide nitrogen atom. Attempts were made to prepare *N*-halogen derivative of **3**. The *N*-chlorosulfilimine (**6**) could easily be prepared quantitatively by treatment of **2** with sodium hypochlorite at low temperature.



(**6**)

The sulfilimine **6** which can be recrystallized from chloroform–petroleum ether is relatively stable, its melting point being 98—99 °C (with decomposition).

N-Haloamidino compounds readily react with potassium salts of thiocyanic acid and Cyanoiminothiocarbonic acid to give thiadiazoles[10–12] and Δ^4-1,2,4-thiadiazolines[13–16] in good yields. We investigated the reaction of **6** with potassium thiocyanate. The ex-



(**7**)

Yield 68%, mp 168—169 °C.

othermic reaction proceeded immediately in acetonitrile to afford *N*-(3-phenyl-1,2,4-thiadiazolyl-5-yl)-*S*,*S*-dimethylsulfilimine (**7**).

The structure of **7** was determined from the following.

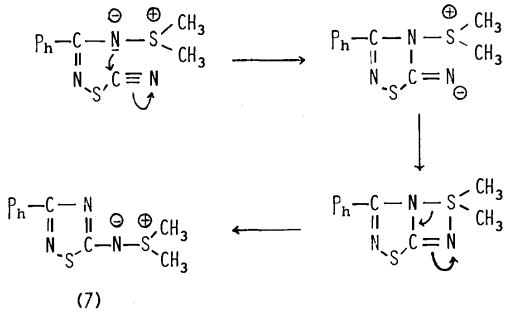
(a) No absorption of a thiocyanate group was observed in the IR spectrum.

(b) The analytical values of **7** and its picrate are in good agreement with their theoretical ones.

(c) UV and NMR data.

The formation of **7** might proceed as in the following scheme. The S–N bond was initially formed, internal ring formation being then followed by migration of the dimethylsulfonio group to yield **7**.

No such migration of a sulfonio group in sulfilimine is known.



Scheme 1.

Experimental

The melting points are uncorrected. IR spectra were taken with a Hitachi EPI-S2 spectrometer. NMR spectra were recorded at 60 MHz with a Hitachi R-24A spectrometer, and the chemical shifts were given in δ-values, TMS being used as an internal standard. Mass spectra were taken with a JEOL-D100 mass spectrometer. UV spectra were taken in methanol with a Hitachi 624 spectrometer.

N-Chlorobenzamidine (**1**) was prepared by the method[17] described previously.

N-Benzimidoylaminodimethylsulfonium Chloride (2). A solution of **1** (20 mmol) in acetonitrile (5 ml) was added drop by drop to a stirred solution of dimethyl sulfide (24 mmol) in acetonitrile (5 ml). The temperature was maintained below 15 °C during the reaction. After stirring for *ca.* 0.3 h, active chlorine disappeared and sulfonium salt precipitated. The solid was separated by filtration and washed with acetonitrile; yield, 84%; mp 183 °C. Recrystallization from ethanol gave a pure product; mp 183—183.5 °C (Found: C, 49.37; H, 5.76; N, 12.90%. Calcd for $C_9H_{13}N_2SCl$: C, 49.88; H, 6.05; N, 12.93%). Picrate: mp 152—153 °C (from water). (Found: C, 44.15; H, 3.62; N, 17.15%. Calcd for $C_{15}H_{15}N_5SO_7$: C, 44.01; H, 3.69; N, 17.11%).

The reaction when carried out in ether and dichloromethane in a similar way gave **2** in 52 and 62% yields, respectively.

N-Benzimidoyl-S,S-dimethylsulfilimine (3). 2M sodium hydroxide (50 ml) was added to a stirred solution of **2** (70 mmol) in water–chloroform (20—70 ml) at a temperature below 5 °C. After the chloroform layer was separated, residual **3** was extracted twice with 15 ml portions of chloroform. The combined extracts were dried (Na_2SO_4), filtered, and evaporated under reduced pressure. The residual needles were wahsed with ether and separated by filtration under nitrogen atmosphere; yield, quant; mp 65—67 °C. Recrystallization from chloroform–ether gave the pure sulfilimine; mp 67—68 °C. (Found; N, 15.70%. Calcd for $C_9H_{12}N_2S$: N, 15.54 %). *m/e* 180 (M^+).

*Reaction of **3** with Cyanamide.* A mixture of **3** (10 mmol) and cyanamide (10 mmol) in THF (10 ml) was refluxed for 30 min. The reddish reaction mixture was treated with active carbon and was concentrated under reduced pressure. The remaining sirup was dissolved in hot chloroform. Ether was then added. After cooling, the resulting crystals were separated from solution by filtration, and the filtrate was evaporated. The remaining oily material was crystallized from 2 M hydrochloric acid. The total yield of *N*-cyanobenzamidine was 60%; mp 141 °C (from ethanol–water; Ref. 6 mp 141—142 °C).

N-(N-Benzoylbenzimidoyl)-S,S-dimethylsulfilimine (5a). A solution of benzoic anhydride (22 mmol) in dichloromethane (8 ml) was added to a stirred solution of **3** (20 mmol) in dichloromethane (7 ml) at 20—25 °C. After completion of addition, crystals precipitated. After 1 h of continued stirring, the precipitated crystals were separated by filtration and the filtrate was concentrated. The remaining oily material was washed with 2M sodium hydroxide (10 ml) and ether to give crystals of **5a**. The total yield of **5a** was 66%; mp 188—190 °C (from chloroform–ether). (Found; C, 67.36; H, 5.70; N, 9.70%. Calcd for $C_{16}H_{16}N_2OS$: C, 67.58; H, 5.67; N, 9.85%). *m/e* 284 (M^+). NMR (DMSO-d_6): 2.91 (s, CH_3S) and 7.20—8.15 (m, $C_6H_5C{=}O$, $C_6H_5C{=}N$).

N-(N-p-Tolylbenzimidoyl)-S,S-dimethylsulfilimine (5b). This was synthesized by the same procedure. Yield, 54%; mp 172—173 °C (from chloroform–ether). (Found: C, 68.03; H, 6.13; N, 9.10%. Calcd for $C_{17}H_{18}N_2OS$: C, 68.43; H, 6.08; N, 9.39%). *m/e* 298 (M^+). NMR (DMSO-d_6): 2.87 (s, CH_3S), 2.33 (s, $CH_3C_6H_4$), and 7.13—7.96 (m, C_6H_5, $CH_3C_6H_4$).

N-(N-Acetylbenzimidoyl)-S,S-dimethylsulfilimine (5c). Acetic anhydride (17 mmol) and **3** (15 mmol) were stirred in dichloromethane (13 ml) in the presence of sodium carbonate (8.5 mmol) at room temperature for 1 h. After the reaction mixture had been poured into water, the oily layer was separated. The aqueous layer was then extracted twice with 7 ml portions of dichloromethane. After the combined extracts had been dried over sodium sulfate, the solvent was removed by concentration. The remaining oily material was crystallized from ether; yield, 60%; mp 114—116 °C (from dichloromethane–ether). (Found: C, 59.60; H, 6.01; N, 12.51%. Calcd for $C_{11}H_{14}N_2OS$: C, 59.43; H, 6.35; N, 12.60%). NMR (DMSO-d_6): 2.72 (s, CH_3S), 2.02 (s, CH_3-O), and 7.17—7.75 (m, C_6H_5). *m/e* 222 (M^+).

3,5-Diphenyl-1,2,4-oxadiazole. Sulfilimine **5a** was heated in a test tube in an oil-bath at 200—210 °C for 10 min. Evolution of dimethyl sulfide was observed. The contents of the tube were cooled, and the resulting crystals were dissolved in ether. After being treated with active carbon and concentrated to dryness, the remaining crystals were purified by washing with a small amount of aqueous ethanol. Yield, 70%; mp 108 °C (from aqueous ethanol; Ref. 18 mp 108 °C)

3-Phenyl-5-p-tolyl-1,2,4-oxadiazole. After heating **5b** at 190—200 °C for 20 min and then cooling, the contents were dissolved in ether. Treatment of the solution with active carbon and concentration under reduced pressure gave needle-like crystals. Yield, 63%; mp 121—122 °C (from ethanol–water). (Found: C, 76.15; H, 5.08; N, 11.49%. Calcd for $C_{15}H_{12}N_2O$: C, 76.25; H, 5.12; N, 11.86%). *m/e* 236 (M^+).

N-(N-Chlorobenzimidoyl)-S,S-dimethylsulfilimine (6). Sodium hypochlorite (40 mmol) was added to a stirred solution of **2** (36 mmol) in water (20 ml) and dichloromethane

(25 ml) below 3 °C. After stirring for 10 min, the oily layer was separated, and the aqueous layer was extracted with dichloromethane (10 ml). The combined extracts were dried over sodium sulfate, filtered, and concentrated under reduced pressure. The remaining oily substance was crystallized from ether. Yield, 92%; mp 98—99 °C (from chloroform–petroleum ether). (Found: C, 50.05; H, 5.26; N, 13.25%. Calcd for $C_9H_{11}N_2SCl$: C, 50.35; H, 5.16; N, 13.05%). UV: λ_{max} 217 nm (ε: 14000). *m/e* 214 (M^+).

N-*5-(Phenyl-1,2,4-thiadiazoyl)*-S,S-*dimethylsulfilimine (7)*. A solution of **6** (7 mmol) in acetonitrile (4 ml) was added to a stirred suspension of potassium thiocyanate (8 mmol) in acetonitrile (6 ml) with cooling in an ice-bath. A violent exothermic reaction took place, the solution turning yellow. After stirring at room temperature for 1 h, insoluble matter was removed by filtration. A yellowish oily substance was obtained by concentrating the filtrate under reduced pressure. The oil was crystallized from ether and the resulting crystals were collected, yield, 68%. Recrystallization twice from dichloromethane–ether gave pure **7**; mp 168—169 °C. (Found: C, 50.35; H, 4.69; N, 17.88%. Calcd for $C_{10}H_{11}N_3S_2$: C, 50.61; H, 4.67; N, 17.70%). UV: λ_{max} 248 nm (ε: 34000). NMR (DMSO-d_6): 2.88 (s, CH_3S), 7.32—8.15 (m, C$_6H_5$). *m/e* 237 (M^+). Picrate: mp 176 °C (from water). (Found: C, 40.93; H, 2.95; N, 18.06%. Calcd for $C_{16}H_{14}N_6O_7S_2$: C, 41.20; H, 3.03; N, 18.02%).

We thank Dr. E. Ichikawa of Tokyo Institute of Technology and Dr. H. Matsuyama of Tokyo Metropolitan University for their valuable discussions.

Photochemical Reactions between Dibromomaleic Anhydride and Benzo[*b*]thiophene[1]

Taku MATSUO and Satoru MIHARA

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka 812

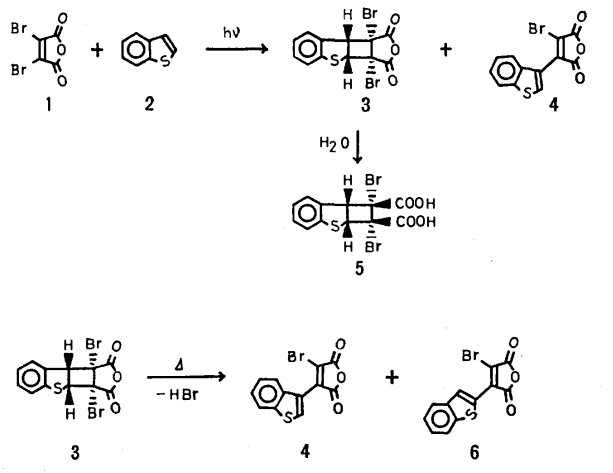
(Received December 10, 1976)

On the irradiation of dibromomaleic anhydride in the presence of benzo[*b*]thiophene, both photosubstitution and photocycloaddition are simultaneously induced. The ratio of the substituted product to the cycloadduct increased with solvent polarity, and the same Stern-Volmer plots were obtained with both of the reactions. Kinetic parameters, obtained under various concentrations of benzo[*b*]thiophene, indicate that the reactions proceed *via* a common triplet exciplex. The activation energy for the photosubstitution is higher than that for the cycloaddition by 1—2 kcal/mol, where the former reaction is considered to proceed *via* a more polar transition state than the latter.

Photochemical reaction between maleic anhydride (or maleimide) and benzene (or alkyl-substituted benzene) affords cycloaddition compounds.[2-4] Photosubstitutions are observed, when dibromomaleic anhydride (or dibromomaleimide) is irradiated in the presence of aromatic compounds such as monosubstituted benzenes,[5] phenylpyrrole,[6] and indole.[7] In the case of dibromomaleic anhydride–benzo[*b*]thiophene system, as reported in this paper, both photosubstitution and photocycloaddition proceed simultaneously. The mechanistic detail and the relationship between photosubstitution and photocycloaddition will be discussed below.

Results

Reaction Products. After irradiation of dibromomaleic anhydride (**1**) and benzo[*b*]thiophene (**2**) with a high-pressure mercury lamp, the reaction mixture was treated with silica gel column chromatography, and two crystalline materials were obtained. On the basis of the spectroscopic data, the crystalline materials were suggested to be 1-bromo-2-(3-benzo[*b*]thienyl)-maleic anhydride (**4**) and *anti*-1,2-dibromo-1,2,2a,7b-tetrahydrocyclobuta[*b*]benzo[*d*]thiophene-1,2-dicarboxylic acid (**5**). The compound **5** is a hydrolysis product of *anti*-1,2-dibromo-1,2,2a,7b-tetrahydrocyclobuta[*b*]benzo[*d*]thiophene-1,2-dicarboxylic anhydride (**3**). Thermal decomposition of **3** in acetic anhydride gave **4** (6%) and 1-bromo-2-(2-benzo[*b*]thienyl)maleic anhydride (**6**, 94%).



Scheme 1.

Quenching Studies. The variation of the quantum yields for the formation of **3** and **4** in dichloromethane solutions was studied as a function of cyclooctatetraene (COT) concentration (Fig. 1). The amounts of **3** and **4** were evaluated by the visible absorption and GLC, respectively.[8]

The Stern-Volmer plots of both **3** and **4** gave nearly the same straight lines up to Φ_0/Φ-values near 5. The quenching constant (K)[9] was found to depend on the concentration of **2**. Assuming that k_q equals the diffusion-controlled rate parameter, the lifetime of ^{3}**1**(τ_{obsd}) in various concentration of **2** can be estimated from the K-values. The correlation between the concentration of **2** and inverse of the τ_{obsd}-value was linear (Fig. 2). From the intercept, τ^0_{obsd} can be calculated to be 1×10^{-5} s. In addition to benzo[*b*]thiophene, kinetics were also investigated with phenylpyrrole, benzene and chlorobenzene, which gave substituted product by the photo-induced reaction with **1**.[5,6] The results are shown in Fig. 2. Slopes of the straight lines (k_d) in Fig. 2 and the charge transfer bands of TCNE complex for each compound are summarized in Table 1.

Quantum Yields. The reactions were carried out by the use of a modified merry-go-round irradiation apparatus. The light intensity of monochromatic light (313 nm) was monitored by the use of a photochemical reaction between **1** and phenylpyrrole.[6] The quantum yields for the formation of **4** was estimated by the ab-

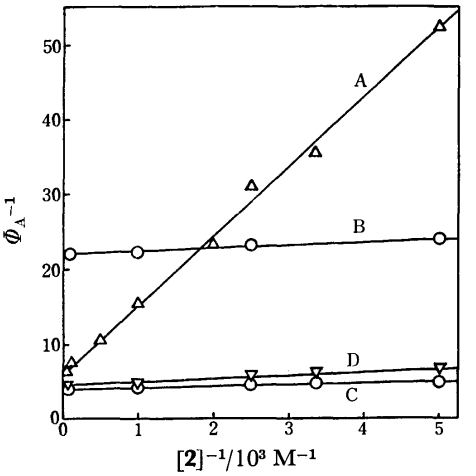

Fig. 4. Relationship between the quantum yield of **3** and the concentration of **2** in various solvents. The notations are the same as those in Fig. 3.

sorption maximum of visible spectrum. Relative yields for the formation of **3** to **4** were evaluated from the GLC peaks area of the pyrolysis products, **4** and **6**. Then the yield for the formation of **3** was calculated from that for **4** and the relative yield, **4**/**3**. The inverses of the quantum yields for the substitution and cycloaddition reactions are plotted *vs.* [**2**]$^{-1}$ in Fig. 3 and Fig. 4, respectively. Linear relationships with different slopes and intercepts were observed with various solvents. The values for Φ_A and Φ_S at the infinite concentration of **2** are given in Table 2.

Temperature Effects. The ratio of quantum yields for formations of **4** to **3** in various solvents was measured at various temperatures. The slope of the Arrhenius

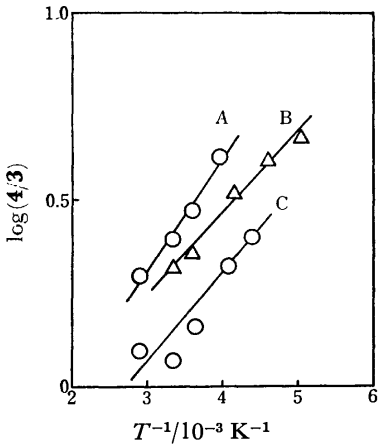

Fig. 5. Arrhenius plots of the product ratio (**4**/**3**) in various solvents. A: Carbon tetrachloride. B: Dichloromethane. C: Acetonitrile.

plots of the ratio, as shown in Fig. 5, corresponds to the difference in activation energies between photosubstitution and photocycloaddition. The difference in activation energies thus obtained also included in Table 2.

Discussion

The above experimental data clearly indicate that the cycloaddition and substitution simultaneously proceed upon the irradiation of **1** and **2**. Thermal decomposition of the cycloadduct **3** at high temperature affords substituted benzo[*b*]thiophene isomers, **4** and **6** (major product), while the formation of **6** was not noticed at all in close examination of the ^{1}H NMR spectra of the irradiated solution. In other words, the photosubstitution takes place exclusively at the 3-position of benzo[*b*]thiophene. The reactions, here investigated, may be summarized by the following scheme:

On the basis of the Stern-Volmer plots (Fig. 1), it is concluded that the triplet species is involved in the formation of both **3** and **4**. The irradiation condition for the quenching experiments is adjusted so that **1** is exculsively excited. Besides, the triplet energy of **1** (E_T=53.5 kcal/mol)[14] is located between those of **2** (E_T=68.9 kcal/mol)[15] and COT ($E_T \leq$39 kcal/mol).[16] Therefore, the active species under discussion must be ^{3}**1**.

The triplet species is quenched by the addition of various aromatic substances as shown in Fig. 2. For a given concentration of the aromatic additive, the apparent lifetime of the triplet (τ_{obsd}) decreases with the increase in the electron-donating property of the additive. Then, the presence of donor-acceptor type interaction in the excited state is indicated. Based on the intercept of the straight lines in Fig. 2, the lifetime of the triplet in the absence of aromatic additive (τ^0_{obsd}) was estimated to be 1×10^{-5} s.

In order to account for the above experimental facts, as well as a linear correlation between $[\mathbf{2}]^{-1}$ and Φ_S^{-1} (or Φ_A^{-1}) in Fig. 3 (or Fig. 4), the following reaction scheme is suggested.

	Rate	
$A \xrightarrow{h\nu} {}^1A$	I_a	(1)
${}^1A \xrightarrow{k_{d-1}} A$	$k_{d-1}[^1A]$	(2)
${}^1A \xrightarrow{k_{isc}} {}^3A$	$k_{isc}[^1A]$	(3)
${}^3A \xrightarrow{k_{d-3}} A$	$k_{d-3}[^3A]$	(4)
${}^3A + Q \xrightarrow{k_q} A + {}^3Q$	$k_q[^3A][Q]$	(5)
${}^3A + D \xrightarrow{k_r} E$	$k_r[^3A][D]$	(6)
$E \xrightarrow{k_{-r}} {}^3A + D$	$k_{-r}[E]$	(7)
$E \xrightarrow{k_{d-e}} A + D$	$k_{d-e}[E]$	(8)
$E \xrightarrow{k_A} P_A$	$k_A[E]$	(9)
$E \xrightarrow{k_S} P_S$	$k_S[E]$	(10)

$$\Phi_{A(\text{or S})}^{-1} = \frac{k_A+k_S+k_{d-e}}{\Phi_{isc}\cdot k_{A(\text{or S})}}\left(1+\frac{k_{d-3}+k_q[Q]}{k_d[D]}\right) \quad (11)$$

$$k_d = \frac{k_A+k_S+k_{d-e}}{k_A+k_S+k_{d-e}+k_{-r}}\cdot k_r \quad (12)$$

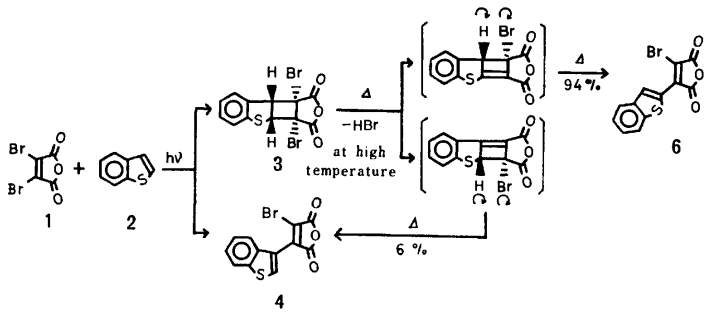
$$\frac{(\Phi_{A(\text{or S})})_0}{\Phi_{A(\text{or S})}} = 1+\frac{k_q}{k_d[D]+k_{d-3}}[Q] = 1+k_q\tau_{obsd}[Q] \quad (13)$$

$$\tau_{obsd} = \frac{1}{k_d[D]+k_{d-3}} \quad (14)$$

$$\tau^0_{obsd} = \frac{1}{k_{d-3}} \quad (15)$$

$$\tau^{-1}_{obsd} = (\tau^0_{obsd})^{-1} + k_d[D] \quad (16)$$

The role of donor-acceptor interaction is taken into consideration in the formation of the triplet exciplex (E) between the excited triplet and the aromatic additives. The relevant species **1**, **2** or other aromatic additives used in Fig. 2, the substituted product, the cyclo-



Scheme 2.

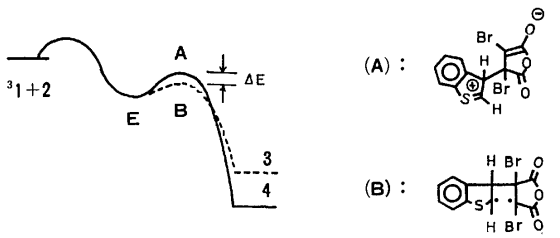


Fig. 6. Reaction diagram.

adduct, and quencher (COT) are denoted by A, D, P_S, P_A, and Q, respectively.

The linear relationships in Fig. 2 are represented by Eq. 16, while those in Figs. 3 and 4 are explained by Eq. 11. By the use of Eq. 11, the $k_d \cdot \tau^0_{obsd}$-value for dibromomaleic anhydride–benzo[*b*]thiophene system in carbon tetrachloride is evaluated to be 3.7×10^4 M^{-1} (Figs. 3 and 4). This value is in good agreement with the product between k_d (6.4×10^9 $M^{-1}\,s^{-1}$) and τ^0_{obsd} (1×10^{-5} s), which were previously obtained by the quenching experiments (Fig. 2, Table 1).

The k_d-value increases with electron-donating ability of D, as summarized in Table 1. In the case of *N*-phenylpyrrole and benzo[*b*]thiophene, the k_d-values are practically the same as k_{diff}. The large k_d-value is associated with high quantum yields ($\Phi_S + \Phi_A$). However, the variation in the k_d-value is approximately ten-times larger than that in the quantum yield. It may be that the deactivation of the triplet exciplex, as represented by Eq. 8 and k_{d-e}, becomes increasingly important as donor-acceptor interaction gets stronger.[17]

Donor-acceptor interactions are favored in polar solvents. Then, the small quantum yields of the photoproducts in acetonitrile is easily understood as due to the increased donor-acceptor interaction in the triplet exciplex in this highly polar solvent. In this connection, the quantum yields in diethyl ether are extraordinary small. Besides the polarity, donor-acceptor interaction between ^{3}A and the solvent itself should be taken into consideration, because ethers have been known to be good electron donors in the study of charge-transfer complex. The donor-acceptor interaction between ^{3}A and diethyl ether may induce quite effective deactivation of the former through radiationless transition.

The ratio of photosubstitution relative to the cycloaddition increases with the temperature and polarity of solvent (Table 2 and Fig. 5). On the basis of the above discussion, it is clear that both reactions proceed *via* the same active species (^{3}A) and the triplet exciplex (E). Since, the photosubstitution is favored in polar solvents, the electronic structure of the transition state may be closer to a polar structure (A). On the other hand, the contribution of a biradical structure (B) may be most important in the transition state of the photocycloaddition, which is at lower energy by approximately 1 kcal/mol than that of the photosubstitution as summarized in Fig. 6.

Experimental

Materials and Equipments. Dibromomaleic anhydride was prepared by the reported procedure.[18] Benzo[*b*]thiophene, COT and solvents of guaranteed grade were purified before use. The photoproducts were isolated either by sublimation or by the use of column chromatography on silica gel (Mallinckrot, silic acid 100 mesh). The IR, NMR, mass, and electronic spectra were recorded on JASCO DS-301, Varian A-60, JEOL JES-01SG, and Shimadzu UV-200 spectrometers, respectively. GLC was obtained by a Shimadzu GC-3BF gas chromatograph.

*Photoreaction between **1** and **2** in Preparative Scale.*

(A) A dioxane solution (250 ml) containing **1** (0.64 g) and **2** (0.34 g) was internally irradiated with a 400 W high-pressure mercury arc lamp (Riko-Sha UVL-400HA) equipped with pyrex jacket in a nitrogen atmosphere for 4.5 h. The pyrex jacket was filled with a filter solution (a layer (1 cm) of an aqueous solutions containing nickel sulfate (0.95 M) and potassium chromic sulfate (0.075 M)). After the solvent was completely removed under reduced pressure, **4** and **6** were isolated from the residue by sublimation (1—2 Torr, 110—150 °C). 1-Bromo-2-(3-benzo[*b*]thienyl)maleic anhydride (**4**): mp 208—209 °C; IR (KBr) 1856, 1823, and 1767 (C=O), 1244 and 1230 (COC) cm^{-1}; UV (Dioxane): λ_{max} 225 (ε 2.83×10^4), 263 (8.45×10^3), and 378 nm (1.82×10^4); Mass, *m/e* 310 (M^+), 308; NMR(Dioxane): δ 8.60 (1H, s, 2-H) and 7.3—8.1 (4H, m, 4-H—7-H); Found: C, 46.58; H, 1.64% Calcd for $C_{12}H_5OBrS$: C, 46.62; H, 1.63%. 1-Bromo-2-(2-benzo[*b*]thienyl)maleic anhydride (**6**): mp 146—147 °C; IR (KBr) 1846, 1816, and 1767 (C=O), 1267, 1252, and 1229 (COC) cm^{-1}; UV (Dioxane): λ_{max} 266 (ε 9.64×10^3) and 383 nm (5.7×10^3); Mass, *m/e* 310 (M^+) and 308; NMR(Dioxane): δ 8.14 (1H, s, 3-H), 7.3—8.1 (4H, m, 4-H—7-H). Found: C, 46.57; H, 1.68%. Calcd for $C_{12}H_5O_3BrS$: C, 46.62; H, 1.63%.

(B) A dichloromethane solution (3 ml) containing **1** (0.39 g) and **2** (0.21 g) was externally irradiated in a nitrogen atmosphere with a 400-W high pressure mercury arc lamp through a pyrex water jacket and window glass filter (2 mm) for 1 h. After the solvent was removed under reduced pressure, the residue was subjected to column chromatography. Elution with a hexane–benzene–ethyl acetate mixture afforded **4** (60 mg) and **5** (143 mg). *anti*-1,2-Dibromo-1,2,2a,7b-tetrahydrocyclobuta[*b*]benzo[*d*]thiophene-1,2-dicarboxylic acid (**5**)[19]: mp 151—153 °C; IR (KBr) 3452 and 3242 (OH), 1760, 1726, and 1712 (C=O) cm^{-1}; Mass, *m/e* 409 (M^+), 408 and 407; NMR (Acetonitrile): δ 4.93 (2H, q, 2-H and 3-H), 7.0—7.3 (4H, m, 4-H—7-H), $J_{2,3}$=8.2 Hz.

*Photoreaction between **1** and Chlorobenzene.* A chlorobenzene solution of **1** (1.3 g/200 ml) was internally irradiated with a 30-W low-pressure mercury arc lamp (Riko-Sha UVL 303-Q) in a nitrogen atmosphere for 15 h. The GLC analysis (column: Silicone DC 430 5% on Chamerite CS 60/80, oven temperature 210 °C) of the crude residue shows the formation of **7** (90% by peak area) accompanied with small amounts of other two products (10% by peak area). After the solvent and **1** were almost removed under reduced pressure, the residue was subjected to column chlomatography. Elution with benzene–hexane mixture afforded **7** (0.25 g). 1-Bromo-2-(*p*-chlorophenyl)maleic anhydride (**7**): mp 85—86 °C; IR (KBr) 1761 and 1839 (C=O), 1250, 1273 and 1293 (COC) cm^{-1}; Mass, *m/e* 290 (M^+), 288 and 286; NMR (CCl_4): δ 7.70(m). UV (CCl_4): λ_{max}, 339 nm ($\varepsilon = 1.40 \times 10^4$). Found: C, 41.84; H, 1.42%. Calcd for $C_{10}H_4O_3BrCl$: C, 41.78; H, 1.40%.

Quenching Experiment. The relative quantum yields (313 nm) in various quencher concentrations were measured by the use of rotating cylinder.[6] After the irradiation, the amount of photoproducts was determined by the use of either

the absorption spectra or GLC analysis (column: silicon OV-17 1.5% on Diasolid L; oven temperature: 215 °C).

Temperature Effects. In the experiments above room temperatures, various solutions containing **1** (1.5×10^{-2}M) and **2**(1.5×10^{-2}M) were placed in a pyrex tube and were immersed in 1 l beaker, whose temperature was controlled by a heater within ±2 °C. In the case of temperatures below 0 °C, the sample tubes were held in a pyrex dewar vessel, filled with methanol. The temperature of dewar vessel was controlled within ±3 °C by adjusting the amount of Dry Ice. Both the dewar vessel and a 400-W high pressure mercury lamp were held in a plastic tube filled with running water. Under these conditions, sample tubes were externally irradiated through the wall of either beaker or pyrex dewar vessel for about 1 h. The amount of photoproducts was evaluated either by the GLC or by the NMR spectra.

Photochemical Behavior of 1,2-Diphenylcyclobutene in Protic Solvents. Addition of Secondary Amines

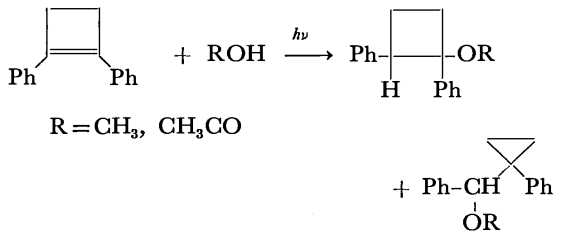
(Received December 14, 1976)

Irradiation of 1,2-diphenylcyclobutene (**1**) and diethylamine in hexane with light of longer wavelengths than 300 nm affords *N,N*-diethyl-1,2-diphenylcyclobutanamine (**2a**), 1,2-diphenylcyclobutane (**3**), and 1,1′,2,2′-tetraphenylbicyclobutyl (**4**). Upon similar irradiation, **1** and morpholine afford *N*-(1,2-diphenylcyclobutyl)morpholine **3** and **4**. A mechanism involving a charge-transfer complex is proposed on the basis of the observations that the amines quenched the olefin fluorescence at a rate close to the diffusion limit in hexane, and that when diethylamine-*N*-*d* was used as an additive the deuterium was retained in the methine groups of compounds **2a**, **3**, and **4**.

Amines interact with excited states, singlets and triplets of many molecules, including aromatic hydrocarbons and ketones. This interaction is believed to be of the charge-transfer type, which always results in deactivation of the excited state, and often in photoreactions.[1] In the photoreaction of aromatic hydrocarbons with tertiary amines an α-hydrogen atom of the amines is transferred to hydrocarbon anion radicals, resulting in reduction and addition products.[1] With primary and secondary amines an amino hydrogen atom can be transferred more easily than the α-hydrogen atom, generating a radical pair containing an aminyl radical. Only a few reports have appeared on the amino hydrogen transfer.[1-5] For example, 2-propanamine has been shown to react with 1-phenylcyclohexene, affording a mixture of the C-adduct and the N-adduct in the proportion of 58 : 37.[2] Piperidine and cyclohexanamine react with benzene to afford 1,4-addition products, 2,5-cyclohexadienamine derivatives.[3] Recently, a report was given on the photoinduced exchange of the nuclear hydrogen of benzonitrile with an amino hydrogen of diethylamine and with water in the presence of triethylamine.[4]

In an investigation of the photochemical behavior of 1,2-diphenylcyclobutene (**1**) in protic solvents,[6] it was shown that this cyclobutene is photoprotonated in methanol and acetic acid to give 1,2-diphenyl-1-methoxycyclobutane and 1-(α-methoxybenzyl)-1-phenylcyclopropane, and the corresponding acetates, respectively, and that the polar addition proceeds from the excited singlet state of the cyclobutene on the basis of quenching experiments of the olefin fluorescence.



We wish to report on an extended study of the photochemical behavior of the four-membered cyclic olefin with amines. The excited singlet state of the cyclobutene was quenched efficiently by secondary and tertiary amines, among which diethylamine and morpholine gave addition products, the corresponding cyclobutanamine derivatives.

Results and Discussion

Fluorescence quenching experiments of 1,2-diphenylcyclobutene (**1**) by amines were carried out under aerated conditions in hexane. No change was found in the fluorescence maximum and in the shape of fluorescence spectrum of **1** upon the addition of amines in various concentrations. Plots of the reciprocals of the relative fluorescence intensities against the concentrations of the amines are linear, fitting the Stern-Volmer equation,

$$I_0/I = 1 + k_q\tau_0[Q],$$

where I_0 and I denote the intensities of the fluorescence of **1** in the absence and in the presence of the quencher in the concentration [Q], respectively, k_q is the rate constant of the bimolecular quenching process, and τ_0 denotes the average lifetime of the excited singlet state of **1** in the absence of the quencher. The slopes of the Stern-Volmer plots ($k_q\tau_0$) are shown in Table 1 together with ionization potentials of the amines. Since the lifetime of the excited singlet state of **1** (τ_0)

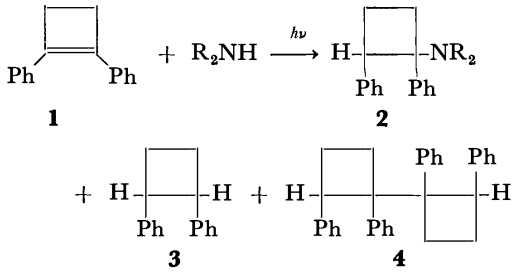
is reported to be shorter than 5 ns,[7] the quenching rate constants (k_q) of the secondary and tertiary amines can be estimated to be 10^8—10^9 M^{-1} s^{-1}, close to the diffusion limit, whereas the primary amines interact less efficiently with the cyclobutene. Plots of logarithms of the $k_q\tau_0$ values against the ionization potentials of the amines give a linear relationship (Fig. 1). These results suggest that the singlet excited **1** interacts with the ground states of amines, possibly forming exciplex intermediates.[8]

A solution of 1,2-diphenylcyclobutene (**1**, 0.01 M) in a mixture of diethylamine and hexane (1 : 4 by volume) was irradiated with light of longer wavelengths than 300 nm using a 500-W xenon lamp through a filter. The reaction mixture was separated by column chromatography on silica gel into three principal components in addition to the recovered starting material. The products isolated were *N,N*-diethyl-1,2-diphenylcyclobutanamine (**2a**), 1,2-diphenylcyclobutane (**3**), and 1,1′,2,2′-tetraphenylbicyclobutyl (**4**). These were identified mainly on the basis of their elemental analyses and spectral data. The NMR spectrum of the N-adduct, **2a**, of the amine and **1** displayed a six-proton triplet at δ 1.03 (J=7 Hz) and a four-proton quartet at δ 2.55 (J=7 Hz) attributable to the ethyl groups, and a one-proton multiplet at δ 3.7—4.2 attributable to the methine proton. Gas chromatographic analysis showed that **2a** consists of only one isomer. From the NMR spectrum the reduction product, **3**, was found to be a *ca.* 2 : 1 mixture of *cis*- and *trans*-diphenylcyclobutane. The reduction dimer, **4**, was a mixture of more than two isomers, the ratio and configuration of which have not been determined.



a : R=CH_3CH_2-
b : R_2=-$CH_2CH_2OCH_2CH_2$-

Similar irradiation of a solution of **1** (0.02 M) in a mixture of morpholine and hexane or benzene (1 : 4 by volume) afforded *N*-(1,2-diphenylcyclobutyl)morpholine (**2b**), **3**, and **4**. Small amounts of diphenylacetylene and 1,2,5,6-tetraphenyltricyclo[4.2.0.$0^{2,5}$]octane, the cleavage and dimerization products, respectively, were also obtained on irradiation in hexane.[7,9] The adduct, **2b**, displayed two four-proton triplets (δ 2.37 and 3.59, J=4.5 Hz) attributable to the ethylene groups in the morpholine moiety in the NMR spectrum. The gas chromatographic analysis showed that **2b** also consists of one isomer. The addition products, **2a** and **2b**, as well as aforementioned 1,2-diphenyl-1-methoxycyclobutane and 1,2-diphenylcyclobutyl acetate exhibited a multiplet or a broad

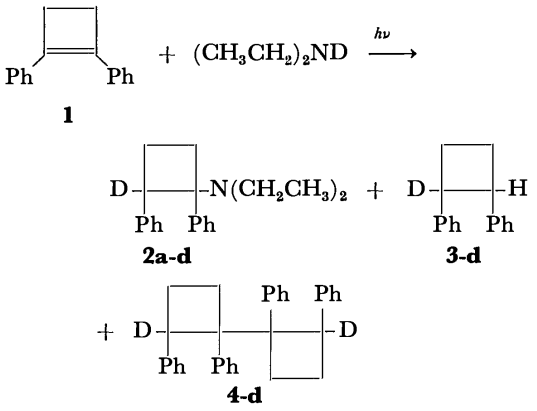
a) In a mixture of an amine and a solvent (1 : 4 by volume). b) Yield based on the diphenylcyclobutene reacted. c) *N,N*-Diethyl-1,2-diphenylcyclobutanamine-2-*d*. d) 1,2-Diphenylcyclobutane-1-*d*. e) 1,1′,2,2′-Tetraphenylbicyclobutyl-2,2′-d_2.

triplet due to the methine proton at the same region (δ 3.7—4.2) as did *cis*-1,2-diphenylcyclobutane, while *trans*-1,2-diphenylcyclobutane displayed a multiplet at a somewhat higher field (δ 3.2—3.6).[6,10] Taking into account the small effect of the β-substituents on the chemical shift of a methine proton,[11] **2a** and **2b** can be safely assigned to *cis*-configuration. The results are summarized in Table 2. Although the UV spectra of the amines extend to longer wavelengths than 300 nm, their absorbances are very small in this region, more than 99.9% of the incident light being absorbed by **1**.

In order to clarify the origin of hydrogen atoms incorporated in the products, labeling experiments were undertaken using diethylamine-*N*-*d* as the additive. A solution of 1,2-diphenylcyclobutene (**1**) in a mixture of diethylamine-*N*-*d* and hexane (1 : 4 by volume) was irradiated similarly and the products were isolated in a way similar to that described above (Table 2). The NMR spectra of the products showed that a deuterium atom is incorporated in each cyclobutane ring of the product; 1,2-diphenylcyclobutane (**3-d**) undergoes deuteration at C-1, 1,1′,2,2′-tetraphenylbicyclobutyl (**4-d**) at C-2 and C-2′, and *N*,*N*-diethyl-1,2-diphenylcyclobutanamine (**2a-d**) at C-2. From these results it might be concluded that the photoreaction proceeds



through an initial amino hydrogen transfer with the formation of diphenylcyclobutyl radicals (**7**), which in turn undergo four competing reactions: a) hydrogen atom abstraction from the solvent to afford **3**, b) dimerization affording **4**, c) recombination with the concurrently generated aminyl radicals to afford **2**, and d) disproportionation with the aminyl radicals which regenerates starting materials. The fact that only *cis*-isomer of **2** was produced supports the view that **2** arises from the combination of the diphenylcyclobutyl radical and the aminyl radical within the solvent cage in contrast to the out-of-cage formation of **3** and **4**.

The quantum yields of the reactions of **1** were measured in hexane under aerated conditions in the presence of various amounts of the amines by monitoring the decrease of the starting olefin on irradiation with 330±7-nm light. Although a linear relationship is found between the reciprocal of the quantum yield (Φ) for the decrease of the olefin and the reciprocal of the concentration of the amine, the intercept is not unity but 6.2 and 11 for diethylamine and morpholine, respectively. Since only bimolecular process need be considered upon extraporation to infinitely concentrated amine solution, these results indicate that there should be a bimolecular energy wastage step in the reaction. The following simplest mechanistic scheme accounts for all the above results.

$$\mathbf{1} + h\nu \longrightarrow \mathbf{1}^*$$

$$\mathbf{1}^* \xrightarrow{k_f} \mathbf{1} + h\nu'$$

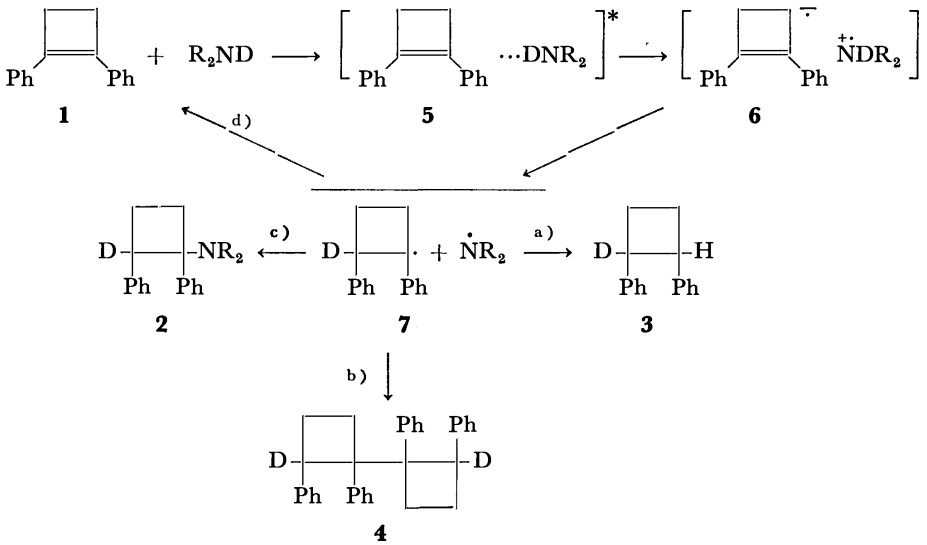
$$\mathbf{1}^* + O_2 \xrightarrow{k_o} \mathbf{1} + O_2$$

$$\mathbf{1}^* + HNR_2 \xrightarrow{k_q} [\mathbf{1}\cdots HNR_2]^*$$

$$[\mathbf{1}\cdots HNR_2]^* \xrightarrow{k_d} \mathbf{1} + HNR_2$$

$$[\mathbf{1}\cdots HNR_2]^* \xrightarrow{k_r} \mathbf{7} + \cdot NR_2 \longrightarrow \text{products},$$

where **1*** denotes the excited singlet state of **1**, and [**1**···HNR_2]* the exciplex between **1** and the amine. At infinite dilution under degassed conditions the quantum yield for the fluorescence of **1** is unity[7] and therefore intersystem crossing to the triplet state can be neglected. Furthermore, the unimolecular reactions, ring fission giving diphenylacetylene and ethylene, and dimerization, are minor perturbations under the conditions



employed, and can be neglected. Thus, by adopting the usual steady-state assumption, the quantum yield for the decrease of **1** is written as follows:

$$1/\Phi = (1+k_d/k_r)(1+1/k_q\tau_0[HNR_2]).$$

The k_d/k_r values, *i.e.*, the ratio of rates for the decay process and the amino hydrogen transfer in the charge-transfer complex, can be estimated to be 5.2 for diethylamine and 10 for morpholine, and the $k_q\tau_0$ values, the quenching constants, are evaluated to be 3.0 M^{-1} for diethylamine and 2.2 M^{-1} for morpholine. These values are in good agreement with those obtained in the fluorescence quenching experiments: 3.1 M^{-1} for diethylamine and 2.2 M^{-1} for morpholine (Table 1). These results substantiate the above mechanism.

The present results together with those reported previously[6,10] show that 1,2-diphenylcyclobutene (**1**) reacts, in its excited singlet state, not only with alcohols and acetic acid by ionic process but with secondary amines by radical process through the charge-transfer complex, to give the addition products, respectively.

Experimental

The IR and UV spectra were recorded on a Hitachi EPI-G3 grating infrared spectrophotometer and a Hitachi EPS-3 recording spectrophotometer, respectively. The NMR spectra were recorded on a JEOL C-60HL NMR spectrometer. GLPC analysis was performed on a Hitachi 163 gas chromatograph equipped with a flame ionization detector. Fluorescence intensities were determined with a Hitachi MPF-2A fluorescence spectrophotometer.

Materials. 1,2-Diphenylcyclobutene was prepared according to the method of Dodson and Zielske.[12] Amines were purified by distillation or recrystallization. Special grade hexane and benzene were distilled prior to use.

Photoreaction of 1,2-Diphenylcyclobutene with Diethylamine. A solution of 1,2-diphenylcyclobutene (400 mg) in a mixture of diethylamine (35 ml) and hexane (140 ml) was irradiated for 50 h using a 500-W xenon lamp through a Corning 0—54 filter. This procedure was repeated five times. The reaction mixtures were combined, concentrated, and subjected to chromatography on silica gel affording four components. The first white solid (trace amounts) was found to be the starting diphenylcyclobutene by GLPC analysis. The second white crystalline solid (500 mg) was deduced to be 1,2-diphenylcyclobutane by comparing its NMR spectrum with that of an authentic specimen of *cis*-1,2-diphenylcyclobutane, prepared by catalytic reduction of 1,2-diphenylcyclobutene,[12] and the reported NMR data of *cis*- and *trans*-1,2-diphenylcyclobutane.[12] The diphenylcyclobutane obtained was found to be a *ca.* 2 : 1 mixture of *cis*- and *trans*-isomers from the NMR and GLPC data. Found: C, 92.28; H, 7.55%. Calcd for $C_{16}H_{16}$: C, 92.26; H, 7.74%.

The third white crystalline solid (340 mg) was 1,1′,2,2′-tetraphenylbicyclobutyl, the structure of which was established by the spectral data and elemental analysis. The NMR spectrum of the solid showed that it consists of more than two isomers. Recrystallization from ethanol gave a single isomer; mp 143—144 °C. NMR($CDCl_3$) δ 1.7—3.0 (m, 8H, CH_2CH_2), 4.54 (t, 2H, methine H), 6.0—7.2 (m, 20H, aromatic H). Mass spectrum (*m/e*) 414 (M^+). Found: C, 92.62; H, 7.37%. Calcd for $C_{32}H_{30}$: C, 92.71; H, 7.29%.

The fourth colorless liquid (700 mg) was *N,N*-diethyl-1,2-diphenylcyclobutanamine, the structure of which was established by the spectral data and elemental analysis. The GLPC analysis showed that it consists of one isomer. NMR($CDCl_3$) δ 1.03 (t, J=7 Hz, 6H, CH_3), 1.7—2.5 (m, 4H, CH_2CH_2), 2.55 (q, J=7 Hz, 4H, CH_2), 3.7—4.2 (m, 1H, methine H), 6.6—7.3 (m, 10H, aromatic H). Mass spectrum (*m/e*) 279 (M^+). Found: C, 85.97; H, 9.24; N, 5.02%. Calcd for $C_{20}H_{25}N$: C, 85.97; H, 9.02; N, 5.01%.

Photoreaction of 1,2-Diphenylcyclobutene with Morpholine. A solution of 1,2-diphenylcyclobutene (1 g) in a mixture of morpholine (40 ml) and benzene (160 ml) was irradiated similarly for 110 h. The reaction mixture was separated similarly, affording the starting olefin (290 mg), 1,2-diphenylcyclobutane (trace amounts), 1,1′,2,2′-tetraphenylbicyclobutyl (280 mg), and *N*-(1,2-diphenylcyclobutyl)morpholine (395 mg). The structure of the last product was established by the spectral data and elemental analysis. The GLPC analysis showed that the adduct consists of one isomer. NMR($CDCl_3$) δ 1.7—2.7 (m, 4H, CH_2CH_2 of cyclobutane), 2.37 (t, J= 4.5 Hz, 4H, NCH_2), 3.59 (t, J=4.5 Hz, 4H, OCH_2), 3.90 (t, J=7.5 Hz, 1H, methine H), 6.5—7.1 (m, 10H, aromatic H). Found: C, 82.01; H, 7.85; N, 4.74%. Calcd for $C_{20}H_{23}NO$: C, 81.87; H, 7.90; N, 4.77%.

A solution of 1,2-diphenylcyclobutene (450 mg) in a mixture of morpholine (40 ml) and hexane (160 ml) was irradiated similarly for 110 h. The products separated similarly on silica gel were *N*-(1,2-diphenylcyclobutyl)morpholine (260 mg), diphenylacetylene (20 mg), 1,2-diphenylcyclobutane (25 mg), 1,1′,2,2′-tetraphenylbicyclobutyl (35 mg), and 1,2,5,6-tetraphenyltricyclo[4.2.0.$0^{2,5}$]octane (25 mg).[7,9]

Photoreaction of 1,2-Diphenylcyclobutene with Diethylamine-N-d. A solution of 1,2-diphenylcyclobutene (1.5 g) in a mixture of diethylamine-*N-d* (40 ml) and hexane (160 ml) was irradiated similarly for 150 h. The chromatographic separation of the reaction mixture gave the starting olefin (190 mg), 1,2-diphenylcyclobutane-1-*d* (160 mg), 1,1′,2,2′-tetraphenylbicyclobutyl-2,2′-d_2 (70 mg), 1,2,5,6-tetraphenyltricyclo[4.2.0.$0^{2,5}$]-octane (160 mg), and *N,N*-diethyl-1,2-diphenylcyclobutanamine-2-*d* (300 mg). The position of deuteration in each product was determined by comparing its NMR spectrum with that for the corresponding non-deuterated product.

Quantum-Yield Measurements. The exciting light for the quantum-yield measurement was furnished by a JASCO CRM-FA spectroirradiator equipped with a 2-kW xenon lamp as the light source and a grating monochromator. The light intensity was measured by potassium ferrioxalate actinometry. Hexane solutions of 1,2-diphenylcyclobutene (10^{-3} M) and amine (0—1 M) were irradiated with 330±7-nm light for 3 min. The reaction mixture was diluted 20 times with the same solvent and its UV spectrum was measured.

Intrachain Charge-Transfer Complex in Ethanol Solution on a Polysarcosine Chain Having a Terminal Electron Donor and a Terminal Electron Acceptor Groups*

Hiroaki TAKAGI, Masahiko SISIDO,† Yukio IMANISHI, and Toshinobu HIGASHIMURA

Department of Polymer Chemistry, Kyoto University, Kyoto 606

(Received December 16, 1976)

Polysarcosine having a terminal electron donating group (*p*-dimethylaminoanilide group) and a terminal electron accepting group (3,5-dinitrobenzoyl group) was synthesized. An ethanol solution of the polymer showed a distinct charge-transfer absorption band around 435 nm. With use of the extinction coefficient determined for the low-molecular-weight model compounds, the fraction of polymers forming an intrachain complex was evaluated to be about 0.08 for $\bar{n}=6$ ($\bar{n}$ is the degree of polymerization of the polysarcosine chain). The fraction decreased with rise in temperature and increase in chain length. The fraction experimentally observed was considerably larger than that estimated from the Monte Carlo calculation on polysarcosine chain, indicating that the cyclic conformations are greatly stabilized by the intrachain charge-transfer interaction. Thermodynamic parameters were determined for the intrachain complex. The chain length dependence of the parameters in ethanol was the opposite of that obtained previously in a chloroform solution. The difference was explained in terms of the difference of the conformations of polysarcosine chain in chloroform and in ethanol solutions. This was evidenced by the NMR spectra recorded in the solvents.

The intrachain reaction between a pair of terminal groups (X and Y) attached on a polymer chain is affected by the conformational properties of the connecting polymer chain in solution.[1-9] For the reaction with a moderately high activation energy, the intrachain reaction is determined by the equilibrium conformational property, *i.e.*, the probability that a pair of reactive groups approach within a short distance capable of the reaction.[2,5,8,10] The conformational equilibrium would depend not only on external factors such as temperature, solvent, *etc.*, but also on internal factors such as intrachain interactions. If a stabilizing force operates between X and Y, the fraction of cyclic conformations would increase considerably, strongly enhancing the intrachain reaction or intrachain interaction. In this respect, protein molecules are regarded as a limiting case, in which various types of intramolecular interactions operate to stabilize the three-dimensional structures in solution.

The results of a study on the hydrolysis of a *p*-nitrophenoxycarbonyl group catalyzed intramolecularly by a pyridyl group attached to the same polysarcosine chain were found to be in line with the ring-closure probability calculated by the Monte Carlo method taking no intrachain force into account.[2] This indicates that intrachain force virtually does not participate in the above system. On the other hand, when electron-donating and electron-accepting groups are attached to respective ends of a polysarcosine chain, a relatively weak intrachain charge-transfer interaction greatly increases the fraction of cyclic conformations in a chloroform solution.[3] This prompted us to investigate the above system in more detail, the present experiment being carried out with an ethanol solution. Since the conformation of polysarcosine has been found to show a marked solvent dependence,[11-13] it was expected to clarify the effct of polymer conformation upon the intrachain interaction.

* Intrachain Reaction of a Pair Reactive Groups Attached to Polymer Ends. Part IV.

Experimental

Polymer samples were synthesized by the polymerization of sarcosine *N*-carboxyanhydride (NCA) with sarcosine *p*-dimethylaminoanilide as an initiator. After complete polymerization, 3,5-dinitrobenzoyl chloride was added to incorporate an electron-accepting group into the other end of the polymer chain. The average degree of polymerization $\bar{n}$ was calculated by Eq. 1,[14] the results agreeing with those determined by vapor pressure osmometry.

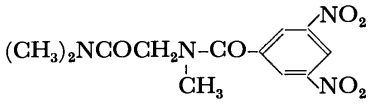
$$\bar{n} = [\text{NCA}]/[\text{initiator}] + 1 \qquad (1)$$

A Poisson type distribution of the degree of polymerization was expected.[14] This was confirmed with polysarcosines obtained with use of sarcosine dimethylamide as an initiator.[15] Details of the synthesis of other compounds and the characterization of polymer samples have been reported.[3] Ethanol used for the optical measurement was fractionally distilled from magnesium metal. 220-MHz NMR spectra were obtained with a Varian HR-220 instrument.

Results and Discussion

Intermolecualr Charge-Transfer Complex between Model Compounds. First, the nature of charge-transfer complex in an ethanol solution was examined with model compounds for the terminal electron-donating and electron-accepting groups. The absorption spectrum of the mixture of *N*-acetyl-*N'*,*N'*-dimethyl-*p*-phenylenediamine (I) and *N*-(3,5-dinitrobenzoyl)-sarcosine dimethylamide (II) in ethanol is shown in Fig. 1.

(I)



(II)

The spectrum shows a typical charge-transfer band around 430 nm, where virtually no absorption was observed for the component species. No spectral change was detected at least for five days, indicating the chemical stability of the charge-transfer complex in the ethanol solution. The plots of the absorbance

at 450, 500, and 550 nm were made as functions of the mole fraction of I, the total concentration of I and II being kept constant. The intensity was strongest at an equimolar concentration of I and II, showing that the composition of the charge-transfer complex was 1 : 1.

The association constant K_2 and the extinction coefficient ε_i at each wavelength for the complex were calculated by the non-linear least squares method.[16] 210 absorption values for 10 different pairs of concentrations and 21 different wavelengths in the range 380—580 nm were used for the calculation. The measurements were made at four temperatures and the least squares calculations were carried out independently at each temperature. The initial set of K_2 and ε_i's for the iterative calculation was obtained from the Benesi-Hildebrand plot.[17] The results are given in Table 1 and the extinction coefficients are plotted in Fig. 2 as a function of the wave number. The extinction coefficient showed virtually no temperature dependence in

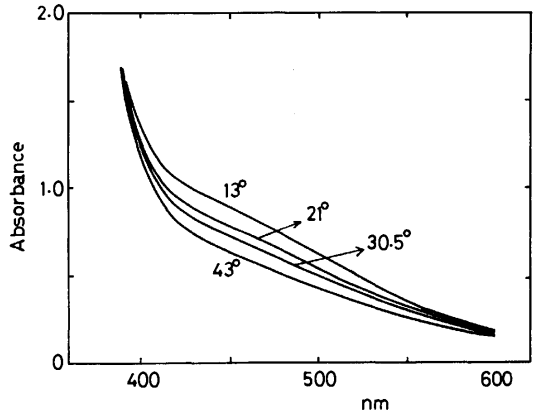

Fig. 3. Absorption spectra of the polymer sample III in ethanol solution at four different temperatures, $c_0=6.5\times1^{-3}$ M, $\bar{n}=16$, Cell length=5.0 cm.

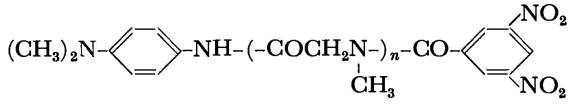
the range 13—43 °C. Figure 2 also shows the extinction coefficients in a chloroform solution. The absorption maximum lies at about 435 nm and at 455 nm in ethanol and chloroform solutions, respectively. The hypsochromic shift of the charge-transfer band caused by a strongly solvating solvent, such as alcohol, has been explained in terms of the specific solvation in the ground state of the component species.[19] The association constant determined in an ethanol solution was nearly equal to that in a chloroform solution.[3]

The plot of log K_2 against $1/T$ gave a straight line. The thermodynamic parameters ΔH_2 and ΔS_2 were evaluated (Table 1). Although the values of K_2 were almost the same in both solvents, the thermodynamic parameters in the ethanol solution were substantially different from those in the chloroform solution ($\Delta H_2 = -5.86$ kJ mol^{-1}, $\Delta S_2 = -20.4$ J mol^{-1}K^{-1}).[3]

Intrachain Charge-Transfer Complex on Polysarcosine Chain. Figure 3 shows the absorption spectrum of polysarcosine having a terminal *p*-dimethylaminoanilide group and a terminal 3,5-dinitrobenzoyl group (III). Although



(III)

the polymer concentration is too low to form a measurable amount of *inter*-molecular charge-transfer complex, the spectrum of III shows a considerable intensity

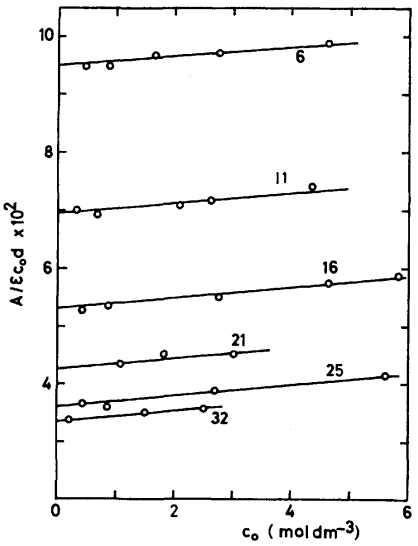


Fig. 4. Plots of $A/\varepsilon c_0 d$ against c_0 for six different degrees of polymerization at 13 °C. Solid lines were drawn with a theoretical slope evaluated according to Eq. 2.

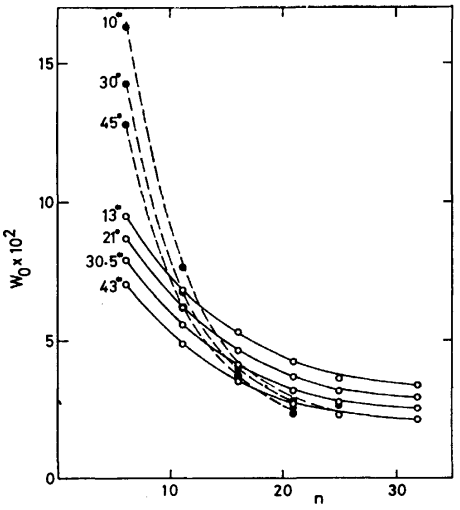

Fig. 5. Dependence of the fraction of polymers forming intraction complex upon the chain length in ethanol solution (—○—), and in chloroform solution (—●—).

around the charge-transfer band. This indicates the formation of an intrachain charge-transfer complex and its predominance over the intermolecular complex. The plot of the absorbance A at 450 nm against the polymer concentration c_0 shows an upward deviation from a straight line, indicating an increased contribution of the intermolecular complex at higher concentrations. In order to separate the contribution of the intrachain complex from that of the intermolecular one, $A/\varepsilon c_0 d$ was plotted against c_0, where ε is the extinction coefficient at 450 nm and d is the cell length (Fig. 4). The intercept gives the fraction of polymers forming intrachain complex at infinite dilution W_0, the slope being proportional to the association constant K_2 for the intermolecular complex between polymer ends (see Appendix).

$$A/\varepsilon c_0 d = W_0 + K_2(1-2W_0)(1-W_0)^2 c_0 + \cdots \quad (2)$$

In Eq. 2 the extinction coefficient for the intrachain complex and that for the intermolecular complex between polymer ends are assumed to be identical with that for the intermolecular complex between the model compounds (Table 1). Figure 4 shows typical plots for different chain lengths at 13 °C, The slope is in good agreement with the calculated value using the association constant between model compounds. This shows that the stability of intermolecular charge-transfer complex between polymer ends is almost the same as that between model compounds, irrespective of the chain length.

The plots was made for six different chain lengths and at four different temperatures, values for W_0 being obtained under various conditions. The results are plotted in Fig. 5 together with the data obtained in a chloroform solution.[3] W_0 increases with decrease in chain length and also temperature. The dependence of W_0 on the chain length is more marked in a chloroform solution, while that on temperature is more marked in an ethanol solution. The values of W_0 in either solution do not differ a great deal. They are 20—100 times as larger as those expected for "unperturbed" chains free from any interachain force. The unperturbed values have been estimated from the rate constants of intramolecularly catalyzed hydrolysis on polysarcosine chain[1] and from the Monte Carlo calculation of randomly coiled polysarcosine chain.[2] The larger values of W_0 indicate that the cyclic conformations are greatly stabilized by the intrachain force based upon the charge-transfer interaction between a pair of terminal groups.

Evaluation of the extent of the stabilization of cyclic conformations made previously[3] was applied to the present case. The free energy of the electronic stabilization in the intramolecular charge-transfer complex ΔG_e was estimated from the thermodynamic parameters of model compounds (Table 1).

$$\begin{aligned} \Delta H_e &= \Delta H_2 = -11.3 \text{ kJ mol}^{-1}, \\ \Delta S_e &= \Delta S_2 - \Delta S_b = -38.4 - (-15.1) \\ &= -23.3 \text{ J mol}^{-1}\text{K}^{-1}, \\ \Delta G_e &= \Delta H_e - T\Delta S_e = -4.23 \text{ kJ mol}^{-1} \ (30.5°\text{C}). \end{aligned} \quad (3)$$

In the second equation the entropy for the bimolecular encounter $S_b = -15.1$ J mol^{-1}K^{-1} was subtracted from the total entropy for the model compounds.[1,3] The association constant for the intrachain complex K_1 is related to W_0 as

$$K_1 = W_0/(1-W_0). \quad (4)$$

K_1 should be related to the association constant K_1^0 for the cyclization of a polymer chain which is free from intrachain interaction, according to the equation

$$K_1 = K_1^0 \exp(-\Delta G_e/RT). \quad (5)$$

The "unperturbed" value of the association constant K_1^0 was evaluated from the rate constant of intramolecularly catalyzed hydrolysis on polysarcosine chain in aqueous solution[1] (Table 2). The value of K_1 calculated by Eq. 5 is compared with that evaluated from the observed value of W_0 (Eq. 4, Table 2). Although the increase in the K_1 value by the electronic stabilization is definite, the calculated value of K_1 is still smaller than the observed one.

a) The "unperturbed" value evaluated from intramolecularly catalyzed hydrolysis on polysarcosine chain in aqueous solution at 35 °C.[1] b) Calculated by mean of Eq. 5 for 30.5 °C. c) Observed with the intrachain charge-transfer complex on polysarcosine chain in an ethanol solution at 30.5 °C.

Thermodynamic Parameters for Intrachain Complex.
The plot of log K_1 against $1/T$ is linear. Thermodynamic parameters ΔH_1 and ΔS_1 were calculated from the slope and the intercept, respectively. They consist of two terms, one associated with the conformational change for the cyclization (ΔH_c or ΔS_c) and the other for the electronic change (ΔH_e or ΔS_e).

$$\Delta H_1 = \Delta H_c + \Delta H_e, \quad \Delta S_1 = \Delta S_c + \Delta S_e. \tag{6}$$

The values of ΔH_e and ΔS_e estimated in the preceding section were used for calculating ΔH_c and $-T\Delta S_c$ (T=298 K). The results are plotted in Fig. 6 as functions of chain length. In an ethanol solution the enthalpy required for the conformational change decreases slightly and the value of $-T\Delta S_c$ increases with increasing chain length. The results are in contrast to those obtained with a chloroform solution where ΔH_c increases with increase in chain length; $-T\Delta S_c$ remaining nearly constant.[3] The latter situation has been observed also in the activation parameters for conformational change accompanied by the intramolecularly catalyzed hydrolysis on polysarcosine chain in aqueous solution.[1] However, the present result is consistent with the result obtained from the Monte Carlo calculation.[2] In the Monte Carlo calculation in which no conformational energy is taken into account, the fraction of cyclic conformations decrease with increase in chain length except for very short chains. This indicates that ΔS_c decreases with increase in chain length whereas ΔH_c is zero irrespective of the chain length.

In view of these results, the experimental finding can be interpreted as follows. In an ethanol solution ΔH_c is nearly zero irrespective of the chain length. In this case, the conformational energy can be neglected in the Monte Carlo calculation. The observed chain length dependence of ΔS_c is in reasonable accordance with the

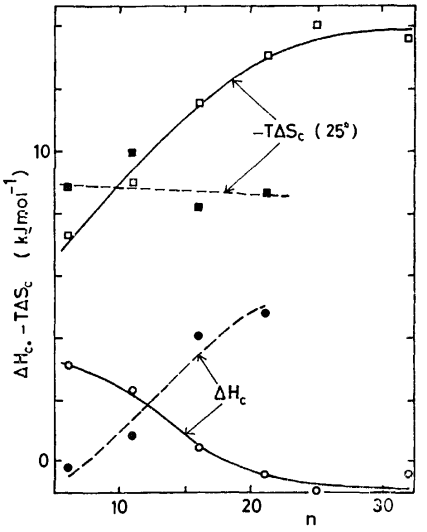

Fig. 6. Dependence of the thermodynamic parameters upon the chain length in ethanol solution (—○—, —□—) and in chloroform solution (--●--, --■--).

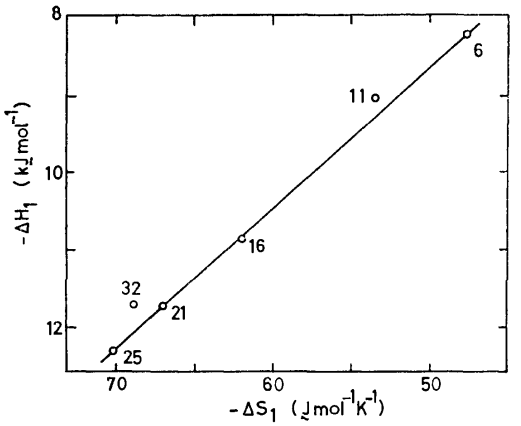

Fig. 7. Correlation between the thermodynamic parameters for the intrachain charge-transfer complex. Numbers in the Figure indicate degree of polymerization.

calculated one. On the other hand, ΔH_c in a chloroform solution or ΔH_c^* in aqueous solution increases considerably with increase in chain length and becomes the dominant factor to determine the chain length dependence of the intrachain association constant or intrachain rate constant. Thus the results of the Monte Carlo calculation, in which no conformational energy has been taken into account, cannot be compared with the experimental data obtained in these solvents. The difference in thermodynamic parameters may be accounted for by the difference in the polymer conformations in the three solvents.

Figure 7 shows the plot of ΔH_1 against ΔS_1 obtained for six different chain lengths. The plot lies on a straight line with a slope of —93 °C. This suggests that the chain length dependence of K_1 vanishes at —93 °C and K_1 increases with increase in chain length below —93 °C. However, this has not been observed because of experimental difficulties.

It is interesting to compare the present result with

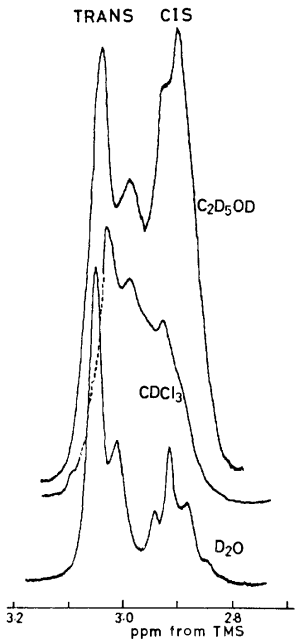

Fig. 8. Partial 220 MHz NMR spectra of polysarcosine in three different solvents. (Only the region of the main chain *N*-methyl protons is shown.) Polymer concentration=*ca.* 10 w/v%.

that obtained in the intramolecularly catalyzed hydrolysis in aqueous solution.[1] In the latter case, the conformational activation enthalpy ΔH_c^* shows a linear relation to the conformational activatioon entropy ΔS_c^*, giving an isokinetic temperature of +93 °C. The temperature should coincide with that in the present experiment (−93 °C), if the conformational properties of polysarcosine chain were the same in both ethanol and aqueous solutions. It should be emphasized that in either case, a mechanism operates to compensate the loss of conformational entropy associated with the cyclization by the decrease in conformational enthalpy, or *vice versa*. If this is the case, the isokinetic or isothermodynamic temperature can be a parameter characterizing a thermodynamic property of polymer conformations in solution. By utilizing the compensation relation, it will be possible to control the intrachain reaction proceeding on a polymer chain by varying the temperature.

Conformation of Polysarcosine Chain in Ethanol, Chloroform, and Aqueous Solution. It was suggested that the conformation of polysarcosine chain in chloroform and aqueous solutions differs a great deal from that in an ethanol solution. The conformation of polysarcosine chains in these solvents was studied by 220-MHz NMR spectroscopy. Figure 8 shows the *N*-methyl region of the NMR spectra. The absorption bands split into several peaks due to the distribution of *trans* and *cis* amide links along the main chain. A peak assignment has been made.[12] The lowest-field peak is ascribed to *trans-trans* and the second lowest to *trans-cis* dyad sequence. These two peaks in lower field correspond to a *trans* conformation. The remaining peaks in higher field correspond to a *cis* conformation. It is evident that the fraction of *cis* conformation in ethanol is considerably larger than that in the other two solvents. This relation holds for other chain lengths except for very short chains.[13]

The NMR data indicate that the conformation of polysarcosine chain in an ethanol solution differs from that in chloroform and aqueous solutions. This is in line with the result of thermodynamic parameters *i.e.*, the dependence of thermodynamic perameters on the chain length in ethanol differs from that in the other two solvents. In an ethanol solution the stability of the *cis* conformation is nearly the same as that of *trans*. Hence, virtually no conformational energy is required to attain the cyclic conformations in which *cis* bond is preferred to *trans* (Fig. 6).[13] For short polysarcosine chains ($\bar{n} \lesssim 10$), the fraction of *cis* conformation has been found to decrease with decrease in chain length.[13] The reduced stability of *cis* conformation may explain the higher conformational enthalpy observed for shorter chains. At present, however, a correspondence between NMR data and thermodynamic parameters is not clear in chloroform and aqueous solutions.

Appendix

In a solution containing X—Y-type polymers a series of linear polymers such as X—Y, X—YX—Y, *etc.* and series of cyclic polymers such as X—Y, X—YX—Y, *etc.* should be relevant to present treatment. The problem is much simplified if participation of the species beyond linear "trimer" and cyclic "dimer" is neglected at a low feed concentration of the linear "monomer" X—Y. If we denote [X—Y]=c, [X—Y]=c_1, [X—YX—Y]=c_2, and the total feed concentration of X—Y=c_0, the association constant for the intrachain complex, K_1 and that for the intermolecular complex, K_2 are expressed as

$$K_1 = c_1/c, \tag{A.1}$$

$$K_2 = c_2/c^2, \tag{A.2}$$

with

$$c_0 = c + c_1 + 2c_2. \tag{A.3}$$

The absorbance at 450 nm is expressed as

$$A = \varepsilon d(c_1 + c_2), \tag{A.4}$$

where ε is the extinction coefficient and d is the cell length. Using the above equations, A is expressed as a function of c_0 as

$$A = \varepsilon d\left\{\left(\frac{K_1}{1+K_1}\right)c_0 + K_2\left[\frac{1}{(1+K_1)^2} - \frac{2K_1}{(1+K_1)^3}\right] + \cdots\right\}, \tag{A.5}$$

where terms up to c_0^2 are retained. Equation 2 is obtained by substituting K_1 for $W_0 = K_1/(1+K_1)$.

The Structure of Ikarugamycin, an Acyltetramic Acid Antibiotic Possessing a Unique *as*-Hydrindacene Skeleton[1)]

Shosuke Ito and Yoshimasa Hirata

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

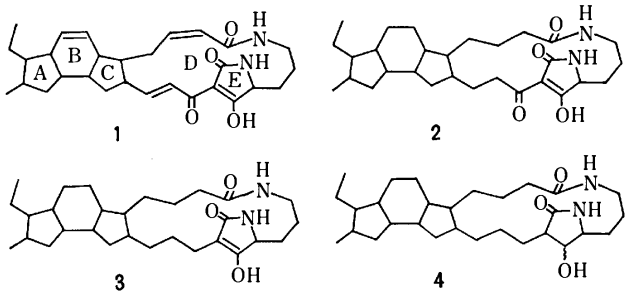
(Received December 25, 1976)

The structure and configuration of an antibiotic, ikarugamycin, have been established to be **1e** on the basis of chemical reactions, especially of oxidative degradation. It is suggested that the *as*-hydrindacene skeleton arises biogenetically *via* an intramolecular Diels-Alder reaction.

A new antibiotic, ikarugamycin ($C_{29}H_{38}N_2O_4$), possessing specific antiprotozoal activity has been isolated from the culture broth of *Streptomyces phaeochromogenes var. ikaruganensis* Sakai by Jomom *et al.*[2)] In this paper, we wish to describe evidence for assigning structure **1e** to ikarugamycin. A biogenesis of this antibiotic is also proposed.

Chromophoric Part of Ikarugamycin. On catalytic hydrogenation over PtO_2 for 1 h, ikarugamycin (**1**) absorbed 3 mol of hydrogen giving hexahydroikarugamycin (**2**), $C_{29}H_{44}N_2O_4$. The presence of three disubstituted double bonds in **1** was revealed by PMR spectrometry (Fig. 1). The double bond bearing strongly deshielded H_a and H_b protons (δ 6.96 and 6.64, respectively, in DMSO-d_6) must be trans substituted (J= 15.6 Hz). The other two pairs of olefinic protons (δ 5.6—6.2 in DMSO-d_6) should be attached to cis double bonds; although the H_d proton signal is obscured by those of the H_e and H_f protons, its counterpart, the H_c proton signal appears as a broad doublet with J= 12 Hz,[3)] and the H_e and H_f protons are observed as a broad AB quartet with J=10 Hz. The PMR spectrum of the hexahydro derivative (**2**) exhibited no signals for the olefinic protons.

The presence of an enolized β-tricarbonyl grouping in both **1** and **2** was suggested by an orange-red coloration with ferric chloride and the formation of greenish



copper complexes, as well as by the formation of an *N*-methylpyrazole derivative upon heating with methylhydrazine. Further catalytic hydrogenation of **2** over PtO_2 for 24 h resulted in conversion of one of the carbonyl groups into a methylene group[4)] giving deoxooctahydroikarugamycin (**3**), $C_{29}H_{46}N_2O_3$. The UV maximum for the compound displayed a bathochromic shift of 33 nm upon the addition of an alkali (Table 1). The PMR spectrum showed a signal at δ 10.32 attributable to an enol proton. These data, coupled with a pK_a value of 7.8 and the formation of an enol ether, as well as of an enol acetate, indicates that an enolized β-dicarbonyl group is present in **3**.

Upon reduction with $LiBH_4$, **3** was readily converted to deoxodecahydroikarugamycin (**4**), $C_{29}H_{48}N_2O_3$ (probably a mixture of epimers) which could also be formed

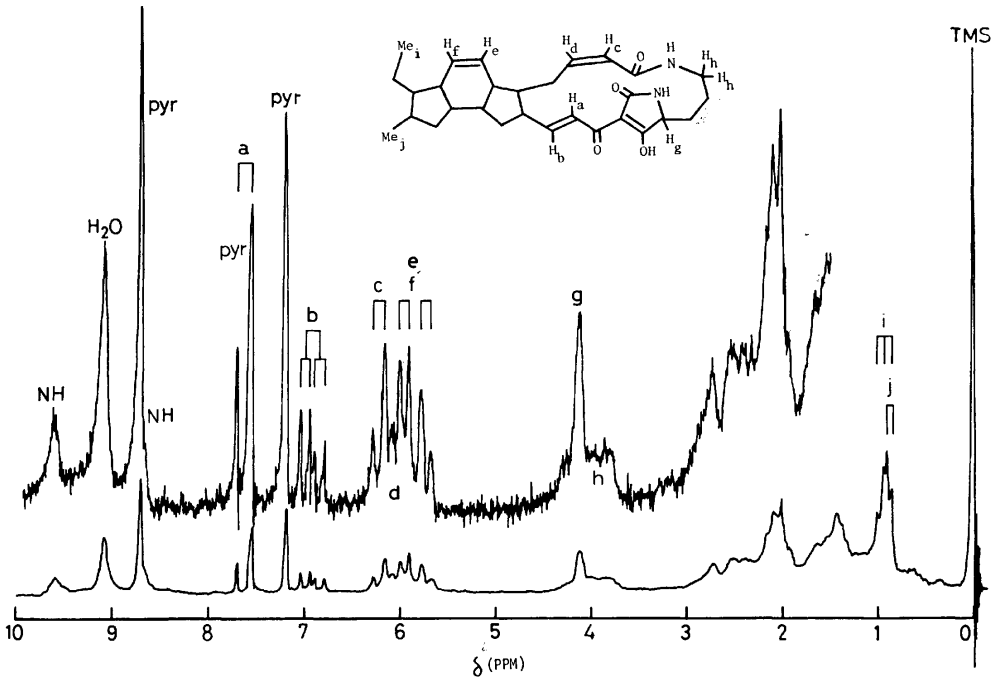


Fig. 1. The 100 MHz PMR spectrum of ikarugamycin (**1**) in pyr-d_5.

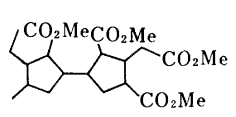
Table 1. UV spectra of ikarugamycin, its derivatives and related compounds

	λ_{max} (ε)	Solvent
Ikarugamycin (**1**)	227 (20700), 327 (17300)	MeOH
	243 (21400), 321 (13300)	0.1 M NaOH-MeOH
Hexahydroikarugamycin (**2**)	220 (5000), 280 (12400)	MeOH
	243 (10300), 279 (13600)	0.1 M NaOH-MeOH
Deoxooctahydroikarugamycin (**3**)	220 (6100), 240^{sh} (4600)	MeOH
	222 (3200), 273 (9300)	0.1 M NaOH-MeOH
Deoxodecahydroikarugamycin (**4**)	211 (910)	MeOH
Tenuazoic acid (**10**)[8]	217 (5100), 277 (12900)	EtOH
	239 (9600), 279 (12000)	0.1 M NaOH
Decahydroerythroskyrine[9]	225 (7200), 284 (12900)	EtOH
	246 (14100), 288 (14100)	0.1 M NaOH

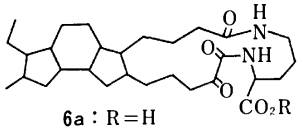
directly from **2** under more drastic conditions. That **4** no longer contains the β-dicarbonyl group is evident from its UV spectrum (Table 1) and the formation of an acetate.

In the PMR spectra of **1** to **4**, two 1H broad singlets were always observed in the range of δ 6—9, which disappeared upon the addition of deuterium oxide. This indicates the presence of two secondary amide groups in **1** to **4**, which is further supported by the IR spectrum of **4** showing, in addition to amide NH (3430 cm^{-1}) and amide II (1520 cm^{-1}) bands, two amide carbonyl bands at 1695 and 1655 cm^{-1}. All of the oxygen and nitrogen atoms present in **1** can thus be assigned to a β-tricarbonyl system in which one of the carbonyl groups is involved as an amide carbonyl group, and to an additional amide group.

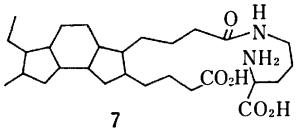
The relative position of the two amide nitrogen atoms was then established by ozonolysis of **1**. Thus, ether extraction of the oxidation mixture yielded a carboxylic acid which was isolated as bicyclic tetramethyl ester **5**, $C_{14}H_{22}$ $(CO_2Me)_4$, and the water-soluble part gave, after acid hydrolysis, L-ornithine and oxalic acid. These results led to the formulation of the chromophoric part of ikarugamycin as **1a**; in order to account for the formation of **5**, as well as the shift of a UV absorption maximum from 327 nm for **1** to 280 nm for **2** (Table 1), two double bonds should be located at the positions shown in **1a**.



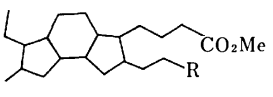
5



6a : R=H
6b : R=Me

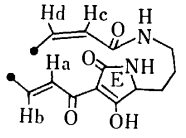


7

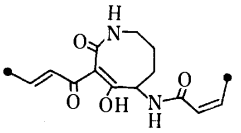


8 : R=CH_2CO_2Me
11 : R=CO_2Me

In principle, an alternative structure **1b** is also consistent with these chemical data. However, such a possibility can be ruled out by the formation of α-DNP-ornithine[5] from **3** *via* **6** and **7**. Chromic acid oxidation of **3** resulted in cleavage of the enolic double bond to give the keto acid **6a**, $C_{29}H_{46}N_2O_5$ and similarly, permanganate oxidation of the enol ether of **3** afforded the corresponding keto ester **6b**, $C_{30}H_{48}N_2O_5$. Treatment of **6a** or **6b** with alkaline hydrogen peroxide cleaved the α-keto amide group, giving an amino acid, **7**, which was characterized as its *N*-acetyl dimethyl ester. Acid hydrolysis of the DNP derivative of **7** gave α-DNP-ornithine and a carboxylic acid isolated as trimethyl dimethyl ester **8**, $C_{21}H_{36}$ $(CO_2Me)_2$. Thus, the partial structure **1a** was established for ikarugamycin. The configurations of the two double bonds were assigned on the following basis. The occurrence of the H_a proton



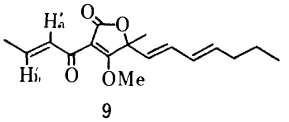
1a



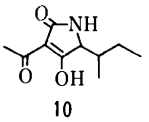
1b

at a lower field than the H_b proton is unusual for olefinic protons in a trans α,β-unsaturated carbonyl system;[6] an example of such a case is found in aspertetronin A (**9**) which gives a PMR spectrum exhibiting H_a' and H_b' protons at δ 7.32 and 7.06, respectively.[7]

Natural products having the acyltetramic acid chromophore are already known and examples include tenuazoic acid (**10**),[8] erythroskyrine,[9] *etc.*[10,11] As expected, the peculiar UV spectral behavior of hexahydroikarugamycin (**2**) closely parallels that of other acyltetramic acids (Table 1). Further chemical evidence for **1a** was provided by alkaline hydrolysis of **2**. The reaction led to cleavage of the tricarbonyl system and the amide bonds to give the carbocyclic part of **2**, a carboxylic acid isolated as dimethyl ester **11**, $C_{20}H_{34}$-$(CO_2Me)_2$.



9



10

Drastic Oxidation of Ikarugamycin, Hexahydroikarugamycin, and Deoxooctahydroikarugamycin. From the molecular formula and the functional groups (three double bonds, a diketo amide, and an amide), ikarugamycin (**1**) is a pentacyclic compound. The formation of the bicyclic tetramethyl ester **5** by ozonolysis of **1** and of the tricyclic dimethyl ester **11** by hydrolysis of **2** indicates that i) **1** possesses three carbocyclic rings, one of which contains the cis double bond not shown in **1a** and ii) two

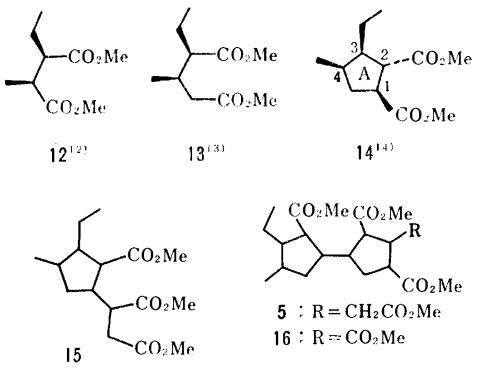


Fig. 2. Permanganate oxidation products of ikarugamycin (**1**).

side chains in the partial structure **1a** are connected with the carbocyclic part, thereby forming a large-membered lactam ring. Although there are 16 carbon atoms in **1** which are not included in **1a**, little information has so far been obtained beyond that revealed by the PMR spectrum of **1** (Fig. 1): the presence of a primary methyl (δ 0.93) and a secondary methyl (δ 0.88) groups. Since the carbon skeleton of **1** appeared to be unique, an attempt was made to obtain information on the structure of the carbocyclic part by oxidative degradations which were vigorous enough to cleave carbon–carbon single bonds. This approach was remarkably successful, as the following results show.

(a) Oxidation of Ikarugamycin (1): Prolonged oxidation of **1** with $KMnO_4$ in pyridine–water at 60 °C yielded, after esterification with diazomethane, a series of esters which was effectively isolated by preparative GLC. The products, including **5** as the major one, are listed in Fig 2 in the order of their GLC retention times. The PMR sepctrum of **14** shows a doublet (J= 7.5 Hz) at δ 0.85 due to a secondary methyl group, a triplet (J=6.7 Hz) at δ 0.89 due to a primary methyl group, a complex multiplet between δ 1.2—2.4 (6H), a triplet (J=8.0 Hz) at δ 2.79 and a multiplet (ddd, J= 8.5, 8.0, and 7.5 Hz) at δ 3.09 attributable to two methine protons on carbons bearing ester groups, and two 3H singlets at δ 3.63 and 3.64 due to two methoxyl groups. Irradiation at δ 3.09 caused the triplet at δ 2.79 to collapse to a doublet (J=8.0 Hz), indicating a vicinal arrangement of the two methoxycarbonyl groups. On the basis of these data, coupled with the concomitant formation of **13**, the diester was formulated to be **14** (not considering stereochemistry). The *r*-1, *t*-2, *c*-3, *c*-4-configuration has been unambiguously established by the synthesis of the four possible 3,4-*cis* diastereomers.[14] The trimethyl ester **15** produced a mass spectrum containing three characteristic peaks at *m/e* 169 due to the $M^+-MeO_2CCH_2\dot{C}HCO_2Me$ ion, at *m/e* 146 due to the $(MeO_2CCH_2CH_2CO_2Me)^+$ ion formed by MacLafferty rearrangement,[15] and at *m/e* 109 due to the $C_8H_{13}^+$ ion from the cyclopentane ring. This, together with the formation of **22** from **2** (see below), suggests the structure **16** for the ester.

Next, chromic acid oxidation in 3 M H_2SO_4–acetic acid at 80 °C was examined. Compared with the permanganate oxidation, the reaction led to more extensive cleavage of carbon bonds as indicated by the products (Fig. 3). The structure for **19** was suggested by the empirical formula $C_6H_8(CO_2Me)_4$ and by the formation of **17** and **18**. The relative configuration of **18** has been established by synthesis.[18]

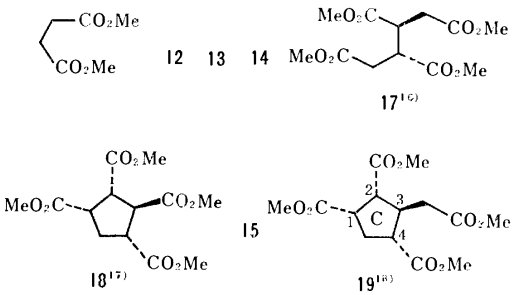

Fig. 3. Chromic acid oxidation products of ikarugamycin (**1**).

(b) Oxidation of Hexahydroikarugamycin (2) and Deoxooctahydroikarugamycin (3): As expected, chromic acid oxidation of **2** under conditions similar to those for **1** gave a completely different series of products (Fig. 4). The structures of **21** and **22** were deduced from their mass and PMR spectra (see Experimental) and were then confirmed by synthesis (of mixtures of diastreomers).[20] The mass spectrum of **23** shows two characteristic peaks at *m/e* 174 and 160 due to the $(MeO_2CCH_2CH_2CH_2CH_2CO_2Me)^+$ and $(MeO_2CCH_2CH_2CH_2CH_2CO_2Me)^+$ ions, respectively, thus indicating the structure. Its *threo* configuration was established by synthesis.[20] Structure of **24** was suggested by its mass spectrum and the formation of **20** and **23**, and was eventually confirmed by synthesis (of a mixture of diastereomers).[20]

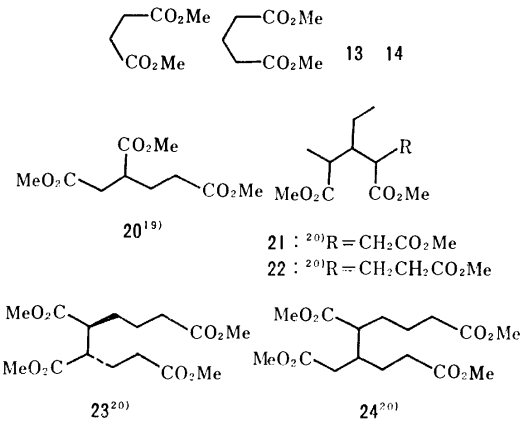

Fig. 4. Chromic acid oxidation products of hexahydroikarugamycin (**2**).

Finally, chromic acid oxidation of **3** was examined, since it should give information concerning the position of the methylene group in **3** which was derived from a carbonyl group in the β-tricarbonyl system of **2**. The oxidation afforded, in addition to all the products from **2**, the trimethyl ester **25** and the tetramethyl esters **26** and **27** (Fig. 5) which are the higher homologs of **20**, **23**, and **24**, respectively. Structure of **27** was suggested by its mass spectrum and the formation of **25** and **26**, and was then confirmed by synthesis.[20]

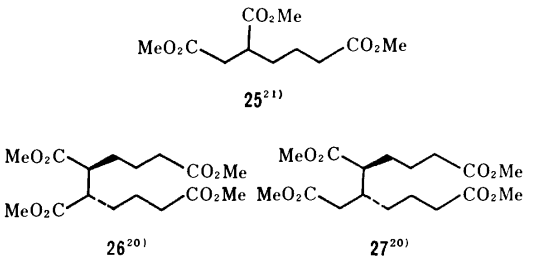

Fig. 5. Chromic acid oxidation products of deoxooctahydroikarugamycin (**3**) (in addition to the compounds shown in Fig. 4).

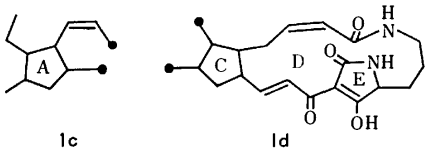
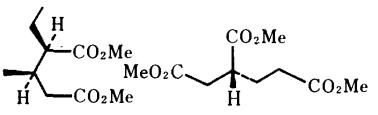
Structure of Ikarugamycin. The formation of **14** from **1** and of **22** from **2** and **3** but not from **1** can be accounted for by the partial structure **1c** for ikarugamycin. From the structural relationships among **17**, **24**, and **27**, coupled with the formation of **19** from **1**, partial structure **1a** can now be extended to **1d**. The

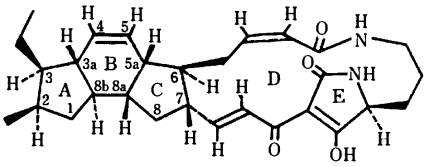


coupling patterns of the H_a–H_d protons in the PMR spectrum of **1** (Fig. 1) are fully consistent with this structure. There then remain two possibilities to explain how these two parts, **1c** and **1d**, could be connected to make up the remaining B ring. This problem was settled by the following experiment. Triester **15** was prepared by the permanganate oxidation of **1** in pyridine–deuterium oxide and was examined by mass spectrometry which showed that the succinyl residue in **15** contained only *ca.* 0.3 deuterium. This indicates that **15** was formed without decarboxylation and therefore, that the C-1 position in **14** should be connected to C-1 (not to C-2) in **19**. Consequently, ikarugamycin can now be represented by structure **1**.

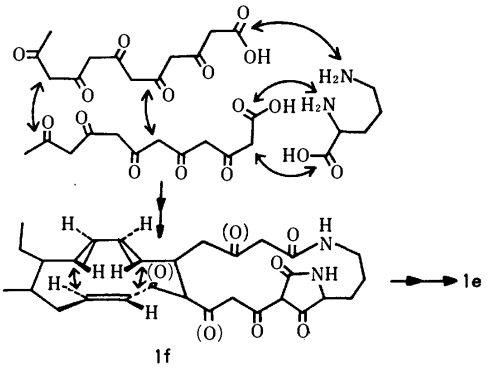
Stereostructure and Biogenesis of Ikarugamycin. In ikarugamycin there are eight consecutive asymmetric centers at the C-2, C-3, C-3a, C-8b, C-5a, C-6, and C-7 positions on rings A, B, and C, and one at the junction of rings D and E. The configuration of the latter is evident from L-ornithine. The relative configurations on rings A and C are also apparent from those of **14** and **19**, respectively. That the latter were formed without epimerization was proved by the oxidation of **1** in deuterium-containing solvents. Thus, the permanganate oxidation in pyridine–deuterium oxide yielded **14** which according to the mass spectrum consisted of d_0 (65%), d_1 (30%), and d_2 (5%) derivatives. Also, the chromic acid oxidation in 3M D_2SO_4–D_2O gave **19** consisting of d_0 (85%) and d_1 (15%) derivatives.

It has already been established that (−)-*erythro*-2-ethyl-3-methylglutarate, $[\alpha]_D$ −14.9°, has the 2*R* : 3*S* (**13a**) configuration.[13b] The natural **13** obtained by the oxidation of **1** has $[\alpha]_D$ −8.6° and, therefore, must have the absolute configuration of **13a**. The absolute configuration of trimethyl (+)-1,2,4-butanetricarboxylate, $[\alpha]_D$ +16.2°, has also been reported to be *R* (**20a**).[19b] Therefore, the absolute configuration of the natural **20** ($[\alpha]_D$ +12.6°) obtained by the oxidation of **2** and hence that of C-7 in ring C was established as shown below. From the combination of these absolute configurations, ikarugamycin can now be assigned the stereostructure **1e**.





Since, to the best of our knowledge, ikarugamycin is the first example of a natural product with an *as*-hydrindacene skeleton, its biogenesis appears to be of considerable interest. It has been proved that other natural acyltetramic acids, such as tenuazoic acid (**10**), can be biosynthesized from an amino acid (L-isoleucine in case of **10**) and a polyacetate (diacetate in case of **10**).[8b,9b,10b] It appears likely, therefore, that ikarugamycin can also be derived from L-ornithine and two hexaacetate chains as outlined in Scheme **1**. Although exactly how the unique carbon skeleton is formed remains a matter of conjecture, it is suggested that an intramolecular Diels-Alder reaction between the butadiene part and the double bond in a hypothetical intermediate such as **1f** could lead to the formation of the decahydro-*as*-indacene skeleton of ikarugamycin.



Scheme 1. A biogenesis of ikarugamycin (**1**).

Experimental

The mp values are uncorrected. The IR spectra were recorded with JASCO model IR-S and DS-402G spectrophotometers and for the UV spectra a Perkin-Elmer model 202 spectrophotometer was used. The PMR spectra were recorded on JEOL models JNM-C60H and 4H-100 spectrometers; the chemical shifts are given in ppm relative to internal TMS. The mass spectra were obtained with a Hitachi model RMU-6C mass spectrometer. Optical rotations were determined with a JASCO model ORD/UV-5 spectrophotometer

or a JASCO model DIP-SL polarimeter (for **13** and **20**) and pK_a values were determined from titration curves taken with a Radiometer model TTT1 titrater. For TLC, Merch GF_{254} or PF_{254} silica gel was used and for column chromatography, Mallinckrodt silicic acid. Gas-liguid chromatography (GLC) was carried out with a Varian Aerograph model 1828-4 chromatograph. The column used for preparative GLC was composed of 5% SE-30 on celite 545 (3 m×0.95 cm).

*Properties of Ikarugamycin (**1**).* Repeated recrystallization of crude **1** from MeOH gave colorless needles, mp 228—229 °C (dec), $[\alpha]_D^{25}+390°$ (*c* 0.19, DMF), slightly soluble in DMF, DMSO, THF, EtOH, MeOH, and pyridine. The antibiotic showed pK_a 5.6 (67% EtOH); IR ($CHCl_3$): 3450, 1700, 1665, 1642, 1580, 1510 cm^{-1}; (KBr): 3380, 3220, 1700, 1678, 1645, 1583, 1519 cm^{-1}; PMR (pyr-d_5): δ 0.88 (3H, d, J=7 Hz), 0.93 (3H, t, J=7), 3.6—4.4 (2H, m), 4.1 (1H, narrow m), 5.72 and 5.95 (each 1H, br ABq, J=10), 6.0 (1H, m), 6.20 (1H, br d, J=12), 6.94 (1H, dd, J=15.6 and 9.5), 7.62 (1H, d, J=15.6), 8.7 and 9.6 (each 1H, br s, D_2O exchangeable); (DMSO-d_6): δ 5.6—6.2 (4H, m), 6.64 (1H, dd, J=15.0 and 9.5 Hz), 6.96 (1H, J=15.0), 7.79 and 8.62 (each 1H, br s, D_2O exchangeable). Found: C, 72.67; H, 8.20; N, 5.90%; *m/e* 478.2771. Calcd for $C_{29}H_{38}N_2O_4$: C, 72.77; H, 8.00 N, 5.85%; M, 478.2731.

*Copper Complex of **1**.* A soln of **1** (50 mg) and cupric acetate (12 mg) in EtOH (30 ml) was heated under reflux for 2 h. Crystals deposited after cooling, which were recrystallized from EtOH to give yellow-green needles (21 mg), mp>280 °C. Found: C, 63.50; H, 7.65; N, 5.13%. Calcd for $(C_{29}H_{37}N_2O_4)_2Cu\cdot 4H_2O$: C, 63.86; H, 7.58; N, 5.14%.

*Hexahydroikarugamycin (**2**).* A soln of **1** (600 mg) in EtOH (200 ml) was hydrogenated in the presence of PtO_2 (100 mg) for 1 h at room temp and atmospheric pressure. It was filtered and evaporated to a small volume under reduced pressure. The solid that precipitated was recrystallized from $CHCl_3$ to give 350 mg of **2** as needles, mp 243—244 °C (dec), $[\alpha]_D^{25}+110°$ (*c* 0.44, $CHCl_3$), pK_a 5.1 (67% EtOH), IR ($CHCl_3$): 3450, 1710, 1662, 1610, 1520 cm^{-1}; PMR ($CDCl_3$): δ 5.86 and 6.0 (each 1H, br s, exchangeable with D_2O), no other signals above δ 4.0. Found: C, 71.51; H, 9.27; N, 5.82%; *m/e* 484.3303. Calcd for $C_{29}H_{44}N_2O_4$: C, 71.86; H, 9.15; N, 5.78; M, 484.3301.

*Copper Complex of **2**.* Green crystals, mp>280 °C (from EtOH). Found: C, 65.01; H, 8.74; N, 4.99. Calcd for $(C_{29}H_{43}N_2O_4)_2Cu\cdot 2H_2O$: C, 65.21; H, 8.50; N, 5.25%.

*N-Methylpyrazole Derivative of **2**.* A soln of **2** (48 mg) and *N*-methylhydrazine sulfate (20 mg) in 90% EtOH (5 ml) was heated under reflux for 30 h. The product was subjected to preparative TLC ($CHCl_3$–MeOH, 4 : 1), giving 19 mg of an oil, mass: *m/e* 494 (M^+); IR ($CHCl_3$): 3360, 1680, 1654, 1540 cm^{-1}; UV (MeOH): λ_{max} 226 nm (ε 4900); PMR ($CDCl_3$): δ 3.85 (3H, s), 4.1 (1H, m), 6.8 (1H, br s,) 8.2 (1H, br s).

*Deoxooctahydroikarugamycin (**3**).* A soln of **2** (500 mg) in EtOH (170 ml) was hydrogenated in the presence of PtO_2 (150 mg) for 24 h. It was filtered and evaporated to give an oily residue which was crystallized from MeOH, affording 350 mg of **3** as prisms, mp 155—157.5 °C, pK_a 7.8 (67% EtOH), mass: *m/e* 470 (M^+); IR ($CHCl_3$): 3470, 3250, 1775, 1705, 1665, 1510 cm^{-1}; PMR (DMSO-d_6): δ 7.09, 7.85, and 10.32 (each 1H, br s, D_2O exchangeable). Found: C, 74.12; H, 9.99; N, 6.04%. Calcd for $C_{29}H_{46}N_2O_3$: C, 74.00; H, 9.85: N, 5.95%.

*Enol Ether of **3**.* Treatment of **3** (140 mg) with diazomethane yielded, after preparative TLC, 97 mg of an oil mass: *m/e* 484 (M^+); IR ($CHCl_3$): 3450, 3300, 1677, 1652, 1515 cm^{-1}; UV (MeOH): λ_{max} 224 (ε 5300) and 242^{sh} nm (4600): PMR ($CDCl_3$): δ 3.98 (3H, s).

*Enol Acetate of **3**.* Acetylation of **3** with acetic anhydride–pyridine gave an oily enol acetate, mass: *m/e* 512 (M^+), 470, 452; IR ($CHCl_3$): 3450, 3340, 1781, 1690, 1664, 1515, 1185 cm^{-1}; UV (MeOH): λ_{max} 222 nm (ε 7000); PMR ($CDCl_3$): δ 2.29 (3H, s).

*Deoxodecahydroikarugamycin (**4**).* *(a) From **3**:* A mixture of **3** (100 mg) and $LiBH_4$ (100 mg) in THF (20 ml) was stirred for 24 h at room temp. Water and then 2M HCl were added to the ice-cooled mixture until it became a clear, neutral soln which was then extracted with $CHCl_3$. The extract was washed with water, dried, and evaporated. The residue was crystallized from MeOH to give 68 mg of **4** as needles, mp 220—222 °C, mass: *m/e* 472 (M^+), 454; IR ($CHCl_3$): 3430, 3500—3200, 1695, 1655, 1520 cm^{-1}; PMR (DMSO-d_6): δ 4.4 (1H, m), 5.0, 7.65, 7.88 (each 1H, br, exchangeable with D_2O). Found: C, 71.38; H, 10.18; N, 5.62%. Calcd for $C_{29}H_{48}N_2O_3\cdot H_2O$: C, 70.98: H, 10.27; N, 5.71%.

*(b) From **2**:* A suspension of **2** (150 mg) and $LiBH_4$ (150 mg) in dimethoxyethane (45 ml) was heated under reflux for 6 h with stirring. The work-up described in *(a)* afforded 68 mg of **4**.

*Acetate of **4**.* Acetylation of **4** gave an oily acetate, mass: *m/e* 514 (M^+), 454; IR ($CHCl_3$): 3460, 3400—3200, 1741, 1699, 1662, 1521, 1240 cm^{-1}; PMR ($CDCl_3$): δ 2.18 (3H, s), 5.53 (1H, m).

*Ozonolysis of **1**: Formation of **5**, Oxalic Acid, and* L-*Ornithine.* Through a soln of **1** (100 mg) in MeOH (70 ml) at—70 °C ozonized oxygen was passed until the soln turned pale purple. After the excess of ozone had been expelled by a nitrogen stream, the solvent was removed at room temp and to the residue 98% formic acid (10 ml) and 35% hydrogen peroxide (1 ml) were added. The mixture was stirred for 1 h at 0 °C and then 14 h at room temp. After decomposition of the excess oxidant with $NaHSO_3$ (1 g), the mixture was evaporated to dryness and the residue was dissolved in 0.5 M H_2SO_4 (10 ml) and extracted with ether; the aqueous layer was saved for further experiment (see below). The ether extract was washed with water, dried, and evaporated to leave an oil which was then treated with diazomethane. The crude ester thus obtained was purified by preparative TLC (hexane–ether, 1 : 1), giving 40 mg of the tetramethyl ester **5**, mass: *m/e* 426 (M^+), 366, 334 (base peak), 306, 246; IR (CCl_4): 1740 cm^{-1}; PMR (CCl_4): δ 0.88 (3H, t, J=6.2 Hz), 0.88 (3H, d, J=6.5), 3.57 (3H, s), 3.59 (6H, s), 3.64 (3H, s), Found: *m/e* 426.2254. Calcd for $C_{22}H_{34}O_8$: M, 426.2253.

The aqueous layer (see above) was adjusted to 1 M with respect to H_2SO_4 by the addition of concd H_2SO_4 and heated under reflux for 4 h. Continuous extraction with ether afforded a crude acid which was recrystallized from ether–CCl_4, giving 16 mg of oxalic acid dihydrate (identified by IR) as prisms. The dimethyl ester derivative, mp 51—54 °C, also had an IR spectrum identical with that of dimethyl oxalate. The aqueous layer remaining after the continuous extraction was neutralized with 0.2 M $Ba(OH)_2$ and the $BaSO_4$ precipitated was removed by filtration. The filtrate was concentrated to a small volume under reduced pressure and applied to a column (1×6 cm) of Dowex 50W-X8 (H^+ form). Elution with 1 M NH_4OH (60 ml) afforded an amino acid which was crystallized from dil HCl (pH *ca.* 4)–EtOH to give 15 mg of L-ornithine monohydrochloride (identified by IR) as prisms, mp 224—229 °C (dec), $[\alpha]_D^{25}+40°$ (*c* 0.42, 5 M HCl), lit,[22] $[\alpha]_D^{25}+37.5°$ (*c* 2, 5 M HCl). Found: C, 35.29; H, 7.88; N, 16.60%. Calcd for $C_5H_{12}N_2O_2\cdot HCl$: C, 35.61; H, 7.77; N, 16.61%.

Keto Acid ***6a.*** A suspension of **3** (94 mg) and CrO_3 (80 mg) in 3 M H_2SO_4 (10 ml) was heated at 80 °C for 2 h with stirring. Cooling of the resulting solution caused precipitation of crystals which were filtered, washed well with water, and recrystallized from MeOH–water, yielding 68 mg of microcrystals, mp 222—223 °C, IR (KBr): 3300, 2800—2300, 1745, 1725, 1665, 1617, 1545 cm^{-1}. Found: C, 67.56: H, 9.59; N, 5.32%. Calcd for $C_{29}H_{46}N_2O_5 \cdot MeOH$: C, 67.38; H, 9.43; N, 5.24%.

Keto Ester ***6b.*** To a soln of the enol ether of **3** (145 mg) in a mixture of acetone (20 ml) and water (30 ml) were added KH_2PO_4 (75 mg), $MgSO_4$ (150 mg), and $KMnO_4$ (75 mg). The mixture was stirred for 24 h at room temp and then made clear and neutral by the addition of $NaHSO_3$ powder and 2 M HCl. The soln was extracted with $CHCl_3$ and the extract washed with water, dried, and evaporated to dryness. Crystallization of the residue from MeOH–water afforded 100 mg of **6b**, mp 173—174 °C; mass: *m/e* 516 (M^+), 488; IR (KBr): 3430, 3310, 1760, 1739, 1660, 1639, 1550 cm^{-1}; PMR (pyr-d_5): δ 3.59 (3H, s), 3.63 (3H, s), 4.90 (1H, m), 8.5 and 9.7 (each 1H, br, exchangeable with D_2O). Found: C, 67.51; H, 9.25; N, 5.15%. Calcd for $C_{30}H_{48}N_2O_5 \cdot MeOH$: C, 67.85; H, 9.55; N, 5.11%.

The keto ester was also obtained by esterification (MeOH–HCl) of keto acid **6a**.

Amino Acid ***7.*** To a soln of **6a** (68 mg) in MeOH (10 ml) were added 1 M NaOH (10 ml) and 35% hydrogen peroxide (0.9 ml). After stirring for 64 h at room temp, the mixture was acidified with 6 M HCl, which caused precipitation of an amorphous powder. It weighed 64 mg, was homogeneous (R_f 0.7) on TLC in 1-butanol–acetic acid–water, 4 : 1 : 2, and became pink with ninhydrin.

N-*Acetyl Dimethyl Ester of* ***7.*** To a stirred soln of **7** (18 mg) in 1 M NaOH (1 ml) was added acetic anhydride (0.1 ml) at room temp. After a time, an additional 1 M NaOH (1 ml) was added and the mixture was extracted with $CHCl_3$. The aqueous layer was acidified with 2 M HCl, extracted with $CHCl_3$, and the extract washed with a sat NaCl soln, dried, and evaporated. The residue was then treated with diazomethane and the product was purified by preparative TLC ($CHCl_3$–MeOH, 9 : 1) to give 5 mg of an oil, mass: *m/e* 562 (M^+) ; IR ($CHCl_3$): 3460, 3300, 1739, 1673, 1513 cm^{-1}; PMR ($CDCl_3$): δ 2.04 (3H, s), 3.67 (3H, s), 3.75 (3H, s), 4.5 (1H, m), 6.0 (1H, br s), 6.50 (1H, br d, J=8 Hz).

Hydrolysis of the DNP Derivative of ***7****: Formation of* ***8*** *and 2,4-Dintrophenylornithine.* To a suspension of **7** (40 mg) in EtOH (2 ml) and water (2 ml) were added $NaHCO_3$ (0.2 g) and 2,4-dinitrofluorobenzene (0.1 ml). After stirring at 40 °C for 6 h, the EtOH was removed under reduced pressure and the aqueous residue was extracted with ether. The ether layer was washed with water, and the aqueous layers were combined, acidified with 6 M HCl, and extracted with EtOAc. The extract was washed with water and a sat NaCl aq soln. and dried. Evaporation of the solvent left an oil which was subjected to preparative TLC ($CHCl_3$–MeOH–acetic acid, 90 : 9 : 1), giving 30 mg of the DNP derivative as an amorphous powder. This was dissolved in concd HCl (3 ml) and acetic acid (3 ml) and heated to 110 °C. After 24 h, additional concd HCl (2 ml) was added and heating was continued for another 12 h. The hydrolysate was concentrated to dryness under reduced pressure and the residue, taken up in 50% MeOH, was placed on a column (1.2×2 cm) of Dowex 50W-X8 (H^+ form). Elution with 50% MeOH yielded a crude carboxylic acid which was esterified with diazomethane. Preparative TLC (hexane–ether, 2 : 1) of the crude ester yielded 3 mg of oily **8**, mass *m/e* 406 (M^+), 388 (base peak), 374, 356; IR (CCl_4): 1743 cm^{-1}; PMR (CCl_4): δ 3.61 (6H, s). Found: *m/e* 406.3074. Calcd for $C_{25}H_{42}O_4$: M, 406.3083.

The Dowex column was then eluted with 0.5 M NH_4OH (40 ml) and 1 M NH_4OH (20 ml) to afford an oil which was crystallized from dil HCl. Orange crystals (3 mg) of α-DNP-ornithine were obtained (identified by IR and paper chromatography in comparison with an authenic sample[5]). The R_f values of the α- and δ-DNP-ornithines on paper chromatography in 1-butanol saturated with water were 0.48 and 0.52, respectively.

Alkaline Hydrolysis of ***2****: Formation of* ***11.*** A soln of **2** (25 mg) in ethylene glycol (1 ml) was prepared by heating at 150 °C. To this soln, 40% NaOH (0.3 ml) was added and the mixture heated at 100 °C for 24 h. The ice-cooled mixture was acidified with dil HCl, extracted with EtOAc, and the extract was treated with diazomethanne. After decomposition of the excess diazomethane with acetic acid, the EtOAc soln was washed with water, an aq $NaHCO_3$ soln, and again with water, and then dried. Evaporation of the solvent left an oil which was purified by preparative TLC (hexane–ether, 4 : 1), giving 6 mg of dimethyl ester **11** as an oil, mass: *m/e* 392 (M^+), 374, 361, 360, 343, 319 (base peak); IR (CCl_4): 1743 cm^{-1}; PMR (CCl_4): δ 0.89 (3H, t, J=7 Hz), 0.93 (3H, d, J=7), 3.62 (6H, s). Found: *m/e* 392.2951. Calcd for $C_{24}H_{40}O_4$: M, 392.2926.

Oxidation of ***1*** *with $KMnO_4$ in Pyridine–Water.* A mixture of **1** (478 mg) and $KMnO_4$ (3.5 g) in pyridine (40 ml) and water (40 ml) was stirred at room temp overnight and then at 60 °C for 5 h. The solvents were evaporated under reduced pressure, water was added, and the evaporation repeated. To the residue were added $NaHSO_3$ powder and concd HCl until the mixture became a clear, acidic soln. The latter was continuously extracted with ether for 8 h and the extract was dried and evaporated giving a mixture of carboxylic acids which was then esterified with diazomethane. The esters (260 mg) thus obtained were partially separated by column chromatography on silica gel (5 g); elution with hexane–ether, 4 : 1 and then 1 : 1 gave 35 and 64 mg of oil, respectively. Preparative GLC of the former (column temp: 130—270 °C, 20 °C/min) afforded **12** (1.5 mg), **13** (1.0 mg), **14** (4.2 mg), and **15** (0.3 mg), and that of the latter (column temp: 270 °C) **16** (1.1 mg) and **5** (17 mg).

Dimethyl erythro-*2-Ethyl-3-methylsuccinate* ***(12)***: $[\alpha]_D^{25}$ +2.2° (*c* 0.44, $CHCl_3$); mass: *m/e* 157 (M^+−OMe), 102, 101 (base peak), 88, 87; PMR (CCl_4): δ 0.89 (3H, t, J=7.2 Hz), 1.10 (3H, d, J=7.0), 1.2—1.8 (2H, m), 2.4—2.7 (2H, m), and 3.66 (6H, s). This compound was identified by means of IR, PMR, mass spectrometry, and GLC with an authentic sample of the *erythro* isomer.[12]

Dimethyl erythro-*2-Ethyl-3-methylglutarate* ***(13)***: $[\alpha_D^{25}]$ −8.6° (*c* 0.64, $CHCl_3$), lit[13b] $[\alpha]_D^{25}$ −14.9° (*c* 1.19, $CHCl_3$); mass: *m/e* 171 (M^+−OMe), 142, 129, 102, 101 (base peak), 87, 74; PMR (CCl_4): δ 0.89 (3H, t, J=6.8 Hz), 0.93 (3H, d, J=6.3), 1.1—2.7 (6H, m), 3.61 (3H, s), and 3.62 (3H, s). This ester was identical with an authenic sample of the *erythro* isomer (IR, PMR, mass, and GLC).[13]

Dimethyl c-*3-Ethyl*-c-*4-methyl*-r-*1*,t-*2-cyclopentanedicarboxylate* ***(14)***:[14] $[\alpha]_D^{25}$ +23° (*c* 0.60, $CHCl_3$); mass: *m/e* 228 (M^+), 199, 197, 168, 109 (base peak).

Trimethyl Ester ***15***: Mass: *m/e* 314 (M^+), 169*, 146 (base peak), 109. Found: *m/e* 314.1724. Calcd for $C_{16}H_{26}O_6$: M, 314.1729.

Tetramethyl Ester ***16***: PMR (CCl_4): δ 3.58, 3.59, 3.65,

* The compositions of these peaks were established by high-resolution mass spectrometry.

and 3.67 (each 3H, s). Found: *m/e* 412.2075. Calcd for $C_{21}H_{28}O_8$: M, 412.2097.

Oxidation of **1** *with* CrO_3 *in* H_2SO_4*–Acetic Acid.* A suspension of **1** (500 mg) and CrO_3 (2.5 g) in 3 M H_2SO_4 (25 ml) and acetic acid (25 ml) was heated at 80 °C with stirring. After 16 h, the oxidation mixture was concentrated under reduced pressure, water was added, and the concentration repeated. The residue was taken up in concd NH_4OH (8 ml) and the still strongly acidic soln was continuously extracted with ether for 30 h. The crude acids (108 mg) thus obtained were first esterified with diazomethane and the resultant esters were heated under reflux in MeOH (10 ml) containing concd H_2SO_4 (1 drop) for 1 h to convert some ethyl esters formed during the ether extraction into methyl esters. The MeOH was evaporated, the residue diluted with water, and extracted with ether. The extract was washed with an aq $NaHCO_3$ soln, water, and a sat NaCl soln, and then dried. Evaporation of the solvent left a mixture of methyl esters (110 mg) which was passed through a silica gel (3 g) column. Elution with ether gave 85 mg of an oil which was subjected to preparative GLC (column temp: 200—280 °C, 4 °C/min). The products were (in the order of increasing retention time): dimethyl succinate (4.7 mg), **12** (0.5 mg), **13** (3.8 mg), **14** (1.0 mg), **17** (7.8 mg), **18** (0.2 mg), **15** (0.5 mg), and **19** (1.6 mg).

Tetramethyl meso*-1,2,3,4-Butanetetracarboxylate (17)*: Mp 74—74.5 °C (from ether hexane), lit,[16] mp 75 °C; mass: *m/e* 259 (M^+–OMe), 139 (base peak); PMR (CCl_4): δ 2.1—3.4 (6H, m), 3.66 (6H, s), and 3.69 (6H, s). Found: C, 49.65; H, 6.25%. Calcd for $C_{12}H_{18}O_8$: C, 49.48; H, 6.43%. This compound was identical with an authentic sample of the *meso* isomer (IR, PMR, mass, and GCL).[16]

Tetramethyl r*-1*, c*-2*, t*-3*, c*-4-Cyclopentanetetracarboxylate (18)*: Found: *m/e* 302.0976. Calcd for $C_{13}H_{18}O_8$: M, 302.1001. This ester was identified with an authenic sample having the configuration depicted in **18** (IR, mass, and GLC).[17]

Trimethyl t*-3-(Methoxycarbonylmethyl)-*r*-1,*c*-2,*c*-4-cyclopentanetricarboxylate (19)*:[18] Mass: *m/e* 316 (M^+), 285, 224, 165 (base peak); PMR (CCl_4): δ 2.0—3.4 (8H, m), 3.58 (3H, s), 3.60 (6H, s), and 3.63 (3H. s). Found: *m/e* 316.1160. Calcd for $C_{14}H_{20}O_8$: M, 316.1158.

Oxidation of **2** *with* CrO_3 *in* H_2SO_4. A mixture of **2** (330 mg) and CrO_3 (1.2 g) in 3 M H_2SO_4 (35 ml) was stirred at 80 °C for 8 h. The work-up described for the CrO_3 oxidation of **1** gave 93 mg of methyl esters which were separated by preparative GLC (column temp: 120—280 °C, 10 °C/min). The products were: dimeth l succinate (13.8 mg), dimethyl glutarate (3.2 mg), **13** (1.4 mg), **14** (0.3 mg), **20** (2.2 mg), **21** (0.4 mg), **22** (0.9 mg), **23** (2.9 mg), and **24** (4.2 mg).

Trimethyl 1,2,4-Butanetricarboxylate (20): $[\alpha]_D^{25}$ +12.6° (*c* 0.68, acetone), lit[19b] $[\alpha]_D^{25}$ +16.2° (*c* 13.7, acetone); mass: *m/e* 201 (M^+—OMe); PMR (CCl_4): δ 1.6—2.4 (7H, m), 3.61, 3.62, and 3.64 (each 3H, s). This compound was identified with an authetic sample.[19]

Trimethyl 3-Ethyl-1,2,4-pentanetricarboxylate (21): Mass: *m/e* 243 (M^+—OMe)*, 214 (M^+—HCO_2Me), 187 (fragmentation between C-3 and 4)*, 155 (base peak), 146 [(MeO_2-$CCH_2CH_2CO_2Me$)$^+$]*; PMR (CCl_4): δ 0.88 (3H, t, J= 7.0 Hz), 1.20 (3H, d, J=7.0), 3.69, 3.71, and 3.73 (each 3H, s). This ester exhibited a mass spectrum and GLC behavior identical to a synthetic sample (of a mixture of diastereomers).[20]

Trimethyl 4-Ethyl-1,3,5-hexanetricarboxylate (22): Mass: *m/e* 257 (M^+—OMe)*, 228 (M^+—HCO_2Me)*, 201 (fragmentation between C-4 and 5)*, 169 (base peak), 160 [(MeO_2CCH_2-$CH_2CH_2CO_2Me$)$^+$]*, 129; PMR (CCl_4): δ 0.89 (3H, t, J=7.6 Hz), 1.18 (3H, d, J=7.2), 3.68 (6H, s), 3.70 (3H, s). This ester also exhibited a mass spectrum and GLC behavior identical to a synthetic sample (of a mixture of diastereomers).[20]

Tetramethyl threo*-1,3,4,7-Heptanetetracarboxylate (23)*: Mass: *m/e* 301 (M^+—OMe)*, 174*, 160*, 59 (base peak); PMR (CCl_4): δ 1.2—2.9 (12H, m), 3.63 (6H, s), and 3.67 (6H, s). This compound was identical with a synthetic sample of the *threo* isomer (IR, PMR, mass, and GLC).[20]

Trimethyl 3-(Methoxycarbonylmethyl)-1,4,7-heptanetricarboxylate (24): Mass: *m/e* 315 (M^+–OMe)*, 174 [($MeO_2CCH_2CH_2$-$CH_2CH_2CO_2Me$)$^+$]*, 59 (base peak); PMR (CCl_4): δ 1.1—2.7 (14H, m), 3.62 (9H, s), and 3.66 (3H, s). This ester exhibited a mass spectrum and GLC behavior identical to a synthetic sample (of a mixture of the *threo* and *erythro* isomers).[20]

Oxidation of **3** *with* CrO_3 *in* H_2SO_4*–Acetic Acid.* A mixture of **3** (100 mg) and CrO_3 (600 mg) in 3M H_2SO_4 (5 ml) and acetic acid (5 ml) was stirred for 9 h at 80 °C. Work-up of the oxidation mixture gave 50 mg of a mixture of methyl esters which was separated by preparative GLC (column temp: 140—290 °C, 10 °C/min). The products were: dimethyl succinate (10 mg), dimethyl glutarate (3.2 mg), **13** (0.2 mg), **20** (1.0 mg), **25** (0.3 mg), **21** (0.1 mg), **22** (0.2 mg), **23** (0.9 mg), **24** plus **26** (2.3 mg), and **27** (0.9 mg).

Trimethyl 1,2,5-Pentanetricarboxylate (25): Mass: *m/e* 215 (M^+—OMe), 146; PMR (CCl_4): δ 1.4—1.8 (4H, m), 2.1—2.9 (5H, m), 3.65, 3.66, and 3.69 (each 3H, s), This ester was identical with an authentic sample (IR, PMR, mass, and GLC).[21]

Tetramethyl threo*-1,4,5,8-Octanetetracarboxylate (26)*: The PMR spectrum(CCl_4) of an inseparable mixture of **24** and **26** in the presence of Eu(DPM)[23] gave rise to six methoxyl signals, two of which came from **26** and the others from **24**; the intensities of the former increased upon the addition of a synthetic sample of **26**.[20]

Trimethyl threo*-5-(Methoxycarbonylmethyl)-1,4,8-octanetricarboxylate (27)*: Mass: *m/e* 329 (M^+—OMe)*, 174 [(MeO_2-$CCH_2CH_2CH_2CH_2CO_2Me$)$^+$]*; PMR (CCl_4): δ 1.1—1.9 (8H, m), 1.9—2.6 (8H, m), 3.64 (9H, s), and 3.67 (3H, s). This compound was identical with a synthetic sample of the *threo* isomer (IR, PMR, mass, and GLC).[20]

$KMnO_4$ Oxidation of **1** *in Pyridine–*D_2O. A mixture of **1** (100 mg) and $KMnO_4$ (700 mg) in pyridine (10 ml) and D_2O (10 ml) was heated at 60 °C with stirring. After 5 h, concd HCl and $NaHSO_3$ powder were added to the ice-cooled mixture until it became an acidic, clear soln. This was extracted with ether and the extract was washed with water and a sat NaCl aq soln, and dried. Evaporation of the ether left an oil which was treated with diazomethane. The esters were separated by preparative GLC (column temp: 140—290 °C, 10 °C/min). Esters **14** (0.7 mg) and **15** (0.2 mg) were obtained.

CrO_3 Oxidation of **1** *in 3 M* D_2SO_4. A mixture of **1** (100 mg) and CrO_3 (500 mg) in 3 M D_2SO_4–D_2O (10 ml) was heated at 80 °C for 12 h with stirring. The reaction mixture was then continuously extracted with ether for 10 h and a subsequent work-up gave esters which were separated by preparative GLC giving 1.1 mg of **19**.

The authers are grateful to the Fujisawa Phamaceutical Co., Ltd., for the generous gift of ikarugamycin and for the high-resolution mass spectrometry. They are also indebted to Dr. Tadao Kondo (Nagoya University) for the 100 MHz PMR measurements.

Oxidation of 2,6-Piperazinediones

Tatsuo TANAKA, Hiroaki YAMAZAKI, and Masaki OHTA

Department of Industrial Chemistry, Faculty of Engineering, Ibaraki University, Nakanarusawa-cho, Hitachi-shi, Ibaraki 316

(Received January 6, 1977)

1,4-Disubstituted 2,6-piperazinediones (**1**) are susceptible to oxidation at the methylene group in the piperazine ring, giving piperazinetetrone (**4**) on being treated with selenium dioxide in boiling dioxane. Treatment of 1,4-diphenyl-2,6-piperazinedione (**1a**) with either nitrobenzene or tosyl chloride and triethylamine in benzene gives cyclic dimer (**9**) of dehydrogenated **1a**. Cycloadduct (**10**) is obtained in the presecne of *N*-phenylmaleimide. It seems that both **9** and **10** are formed *via* labile mesoionic intermediate (**8**). Piperazinedione (**1a**) reacted with tosyl chloride, pyridine, and benzoyl chloride to give mesoionic compound (**11**) having 3-benzoyl and 5-(*p*-tolylthio) groups.

Only a few papers have appeared on the oxidation of 2,6-piperazinedione derivatives. Oxidation of piperazinediones by chromium trioxide[1] or nitric acid[2] was reported to afford piperazinetetrones. Honzl *et al.*[3] reported that the reaction of 1,4-disubstituted 2,6-piperazinedione (**1**) with phosphorus pentachloride followed by hydrolysis afforded a piperazinetetrone, while the reaction of 1,4-disubstituted 2,6-piperazinedione with arenesulfonyl chloride in pyridine yielded six-membered mesoionic compound (**2**) by dehydrogenation and substitution at positions 3 and 5. The reaction of 1,4-disubstituted 2,6-piperazinedione with chloranil afforded cycloadducts (**3**) formed by the addition of chloranil to the dehydrogenated 2,6-piperazinedione at positions 3 and 5.[4]

The peculiar behavior of 2,6-piperazinedione to form a mesoionic intermediate is similar to that of hydrogenated benzenoid aromatics which show a tendency to form aromatic systems by dehydrogenation. These results prompted us to examine the behavior of 2,6-piperazinedione towards various oxidizing reagents. The positions susceptible to oxidation are apparently 3 and 5, the anticipated reactions being the formation of piperazinetetrone (**4**) and a mesoionic intermediate (**8**). The final products of the latter reaction depend on the stability of the mesoionic intermediate and the nature of the oxidizing reagents employed. In the case the intermediate is labile, isolation of its substituted derivative, dimerization product or cycloadduct with a trapping reagent may be anticipated. The present paper deals with the reaction of 1,4-disubstituted 2,6-piperazinediones with several oxidizing reagents other than those so far reported.

Results and Discussion

Oxidation with Selenium Dioxide. Selenium dioxide is usually used for the oxidation of an active methylene or methyl group to a carbonyl group and sometimes

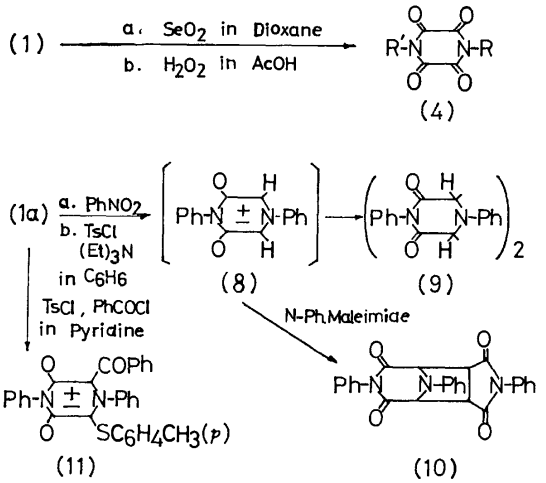

Fig. 1. Reaction scheme of 1,4-disubstituted 2,6-piperazinediones.

for the dehydrogenation of dihydroaromatics to aromatic compounds. We have found that the oxidation of 1,4-disubstituted 2,6-piperazinediones (**1**) with selenium dioxide in dioxane afforded the corresponding piperazinetetrones, (**4a**—**d**) no formation of mesoionic intermediate being observed. The yields, melting points, and IR absorptions of the products are summarized in Table 1.

When some acid anhydrides are used as the cyclization reagent in the synthesis of five-membered mesoionic heterocycles, the products isolated are frequently their stable derivatives formed by acylation of the cyclization products.[5] An attempt to isolate the labile intermediate in the form of its acetyl derivatives by using acetic anhydride instead of dioxane was unsuccessful.

In view of the current mechanism of the selenium dioxide oxidation,[6] the selective oxidation of ring methylene group to carbonyl group can be ascribed to the initial enolization which facilitates the attack of selenium dioxide. When 1,4-diphenyl- or 1-phenyl-4-benzyl-2,6-piperazinedione was oxidized with selenium dioxide in dioxane, a samll amount of the corresponding *N*,*N*′-disubstituted oxamide was isolated along with the tetrone. That these oxamides are formed by hydrolysis of the tetrones was confirmed by a separate experiment wherein the hydrolysis of 1,4-diphenylpiperazinetetrone in boiling dioxane containing a small amount of water in the presence of selenium dioxide

TABLE 1. PRODUCTS FROM THE OXIDATION OF 1,4-DISUBSTITUTED 2,6-PIPERAZINEDIONE WITH SELENIUM DIOXIDE

	Product R	Product R'	Mp (°C) (Recryst. solv.)	IR (cm^{-1})			Yield (%)	By-product (Yield %)

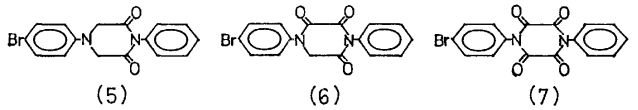
afforded *N,N'*-diphenyloxamide. The formation of the tetrone derivatives was also observed when 1,4-diphenyl-2,6-piperazinedione was oxidized with hydrogen peroxide in acetic acid.

Reaction with Bromine. Investigation of the behavior of 2,6-piperazinediones towards bromine seems to be of interest in view of the validity of bromine both as an oxidizing and brominating reagent and the polyfunctional structure of 1,4-disubstituted 2,6-piperazinedione. Among the reactions of bromine we have carried out, only one reaction gave an isolable product: the reaction of 1,4-diphenyl-2,6-piperazinedione (**1a**) with an equimolar of bromine in acetic acid at room temperature occurred immediately affording 4-(*p*-bromophenyl)-1-phenyl-2,6-piperazinedione hydrobromide which was readily hydrolyzed by water to give the free base (**5**). This shows that the *p*-position of the 4-phenyl substituent is activated by the amino nitrogen towards electrophilic substitution. Further reaction of the free base with bromine in chloroform immediately gave a precipitation, but work up of the precipitate gave mostly the starting material. From the mother liquor of the reaction, trione (**6**) was isolated in poor yield which was characterized by elemental and spectral analyses. When **5** was reacted with bromine in nitrobenzene at 100 °C, tetrone (**7**) was isolated along with the trione in a poor yield.



(5) (6) (7)

Oxidation with Nitrobenzene. A well-known reaction in which nitrobenzene plays a role of dehydrogenation to form an aromatic system is the Skraup synthesis of quinoline. The fact that 2,6-piperazinediones are readily dehydrogenated to an aromatic system led us to investigate the reaction of 2,6-piperazinediones with nitrobenzene, the formation of mesoionic intermediates being expected.

When **1a** was heated in nitrobenzene under reflux, a product isolated in poor yield was considered to be a dimer of mesoionic intermediate (**8**) on the basis of elemental and spectral analyses. The formation of this dimer (**9**) was not observed at 170—175 °C and decomposition of **1a** predominated at 210 °C. It was found that the addition of acetic anhydride to the reaction mixture loweres the reaction temperature, improving the yield of the dimer to 23%. However, the role of acetic anhydride in this reaction remains unsettled. The formation of the dimer may be ascribed to the dimerization of the 1,3-dipolar mesoionic intermediate (**8**). The proposed intermediate could successfully trapped by addition of *N*-phenylmaleimide to the reaction mixture and a cycloadduct (**10**) was obtained. **10** was isolated by the reaction of **1a** with chloranil in the presence of *N*-phenylmaleimide.[4]

Reaction of 2,6-Piperazinedione with Tosyl Chloride. Honzl *et al.* obtained mesoionic compounds (**2**) by the reaction of 2,6-piperazinedione with tosyl chloride in pyridine, though the mechanism of this reaction remains unsolved. We tried to improve the yield of the mesoionic product following their procedure[3] by varying the reaction time, reaction temperature, molar ratio of the reactants and using pyridine homologues as the solvent instead of pyridine. However, no improvement was achieved. The reaction of 2,6-piperazinedione with tosyl chloride in benzene in the presence of triethylamine gave the same dimer (**9**) as that obtained by oxidation of 2,6-piperazinedione with nitrobenzene. When the reaction was carried out in the presence of *N*-phenylmaleimide, the cycloadduct (**10**) was obtained. We then performed the reaction of 2,6-piperazinedione with tosyl chloride in pyridine in the presence of benzoyl chloride anticipating the formation of a mesoionic compound having benzoyl groups instead of *p*-tolylthio groups of compound **2**. The reaction gave mesoionic compound (**11**) with a 3-benzoyl-5-(*p*-tolylthio) substituent in 14% yield along with a small quantity of **2**, no 3,5-dibenzoyl derivative being isolated. Compound **11** could be formed neither from **1a** nor **2** by heating with benzoyl chloride in pyridine. This indicates that **11** was formed not *via* **2**, but presumably by benzoylation of mesoionic intermediate having one *p*-tolylthio group.

Experimental

All the melting points are uncorrected. The IR spectra were recorded on a JASCO IRA-2 spectrometer and NMR spectra on a JEOL H-100 spectrometer.

Materials. Commercial selenium dioxide, chloroform, nitrobenzene, triethylamine, benzoyl chloride, pyridine, and *N*-phenylmaleimide were used without further purification. Dioxane was distilled and tosyl chloride was recrystallized from benzene.

General Procedure for Oxidation with Selenium Dioxide. Selenium dioxide (10 mmol) was added to a solution of 1,4-disubstituted 2,6-piperazinedione (5 mmol) in dioxane (20 ml), and the resulting mixture was refluxed for 6 h. After being cooled, solid products were collected by filtration and subjected to continuous extraction with acetone in a Soxhlet apparatus. The extract was evaporated to dryness under reduced pressure and the residue was recrystallized from the solvents given in Table 1.

*1-Methyl-4-phenylpiperazinetetrone (**4b**).* Colorless silky crystals, mp 314—316 °C. Found: C, 56.86; H, 3.38; N, 12.21%. Calcd for $C_{11}H_8N_2O_4$: C, 56.89; H, 3.48: N, 12.07%.

*1-Benzyl-4-phenylpiperazinetetrone (**4c**).* Colorless silky crystals, mp 268—271 °C. Found: C, 66.30; H, 3.96; N, 8.93%. Calcd for $C_{17}H_{12}N_2O_4$: C, 66.22; H, 3.93; N, 9.09 %.

*1,4-Dibenzylpiperazinetetrone (**4d**).* Colorless needles, mp 263—265 °C. Found: C, 67.19; H, 4.38; N, 8.79%. Calcd for $C_{18}H_{14}N_2O_4$: C, 67.07; H, 4.39; N, 8.69%.

*4,9,11,12-Tetraphenyl-4,9,11,12-tetraazatricyclo[5.3.1.1^{2,6}]dodecane-3,5,8,10-tetrone (**9**).* *Method A*: A mixture of **1a** (3 g, 11.3 mmol), acetic anhydride (2.3 g, 22.6 mmol), and nitrobenzene (30 ml) was heated at 170—175 °C for 5 h. The mixture was concentrated under reduced pressure and cooled, and the resulting brown solid was filtered and washed with ethanol. Recrystallization of the solid from DMSO gave 0.8 g (27%) of **9**. Colorless needles, mp 420—423 °C. Found: C, 72.35; H, 4.60; N, 10.58%. Calcd for $C_{32}H_{24}N_4O_4$: C, 72.71; H, 4.58; N, 10.60%. IR (KBr): 1730, 1690 cm^{-1}. MS: *m/e* 528 (M$^+$).

Method B: Triethylamine (3 g, 30 mmol) was added to a solution of **1a** (4 g, 15 mmol) and tosyl chloride (5.7 g, 30 mmol) in benzene (55 ml), and the resulting mixture was refluxed for 27 h. The solvent was evaporated under reduced pressure to give an oil which gradually crystallized by addition of a small amount of benzene under cooling. The crystals were filtered and washed with water to give 0.4 g (10%) of crude **9**.

*4,9,11-Triphenyl-4,9,11-triazatricyclo[5.3.1.0^{2,6}]undecane-3,5,8,-10-tetrone (**10**).* *Method A*: A mixture of **1a** (1 g, 3.3 mmol), *N*-phenylmaleimide (0.65 g, 3.8 mmol), and nitrobenzene (15 ml) was refluxed for 8 h. After cooling, crystals were filtered and washed with diethyl ether. Recrystallization of the product from acetonitrile gave 0.2 g (12%) of **10** as colorless needles, mp 326—327 °C. IR (KBr): 1742, 1708, 1684 cm^{-1}. The product was identified as **10** by comparison of its IR spectrum and mixed melting point measurement with the authentic sample synthesized by the method using chloranil.[4]

Method B: Triethylamine (0.8 g, 8 mmol) was added to a solution of **1a** (1 g, 3.8 mmol), *N*-phenylmaleimide (0.65 g, 3.8 mmol), and tosyl chloride (1,5 g. 7.9 mmol) in benzene (10 ml), and the mixture was refluxed for 20 h. White crystals formed gradually during the course of heating were filtered and washed with water. The crude product was recrystallized from acetonitrile.

*Anhydro-3-benzoyl-2,6-dihydroxy-1,4-diphenyl-5-(p-tolylthio)-pyrazinium dihydroxide (**11**).* A solution of benzoyl chloride (3.2 g, 22.6 mmol) in pyridine (15 ml) was added dropwise to a solution of **1a** (3 g, 11.3 mmol) and tosyl chloride (4.3 g, 22.6 mmol) in pyridine (40 ml) under reflux over a period of 1 h. The resulting mixture was refluxed for 19 h. After cooling, the reaction mixture was poured into ice-water and the resulting dark brown solid was chromatographed on silica gel using chloroform as an eluent. The 4th fraction gave 0.73 g (13.8%) of **11** as yellow needles, mp *ca.* 240 °C. This was recrystallized from 1-propanol to give yellow needles, mp 244—245 °C. Found: C, 73.13; H, 4.58; N, 5.54%. Calcd for $C_{30}H_{22}N_2O_3S$: C, 73.45; H, 4.52; N, 5.71%. IR (KBr): 1675, 1650, 1620 cm^{-1}. NMR (τ): 2.4—3.0 (m, 19, Ar-H), 7.75 (s, 3, CH_3). MS: *m/e* 490 (M$^+$).

Mesoionic 1,4-diphenyl-3,5-di(*p*-tolylthio) derivative (**2**) was isolated from the 3rd fraction of chromatography described above as yellow needles, mp 239—241 °C.

(Received January 10, 1977)

Two new lignans, kadsurin and kadsurarin, were isolated from *Kadsura japonica* Dunal, and their structures were established. The stereostructures of the schizandrin-type lignans including their conformations were elucidated by measurements of intramolecular nuclear Overhauser effects.[1)]

The decoction of the stems of *Kadsura japonica* Dunal ("Binnan Kadsura" in Japanese) is used in Taiwan as a remedy for snake-bites and also as an antipyretic, antispasmodic and anodyne by the local people.[2)] In the course of our search for physiologically active substances of this plant, we isolated two new schizadrin-type lignans, named kadsurin (**1**) and kadsurarin (**2**). In this paper we wish to describe the isolation and structures of kadsurin and kadsurarin. The conformation of these new lignans with a cyclooctadiene system, which can adopt two possible conformers, is discussed.

The dried stems of *Kadsura japonica* Dunal were pluverized, and then extracted with a large amount of hexane. The extracts were directly chromatographed on silica gel (Kieselgel, E. Merck, Darmstadt) and eluted with hexane–EtOAc (4 : 1) to give colorless needles of kadsurin (**1**), mp 157—158 °C, in a 0.0015% yield. Further elution with hexane–EtOAc (2 : 1) afforded colorless needles of kadsurarin (**2**), mp 255—256 °C, in a 0.005% yield.

Structure of Kadsurin. Kadsurin (**1**) has a molecular formula $C_{25}H_{30}O_8$, and can be regarded as a biphenyl-type compound with two aromatic protons (δ 6.48 and 6.60) on the basis of its spectral data [ν_{max} 1615, 1600, 1585, and 1495 cm^{-1}; λ_{max} 278, 254, and 230 nm (ε, 3500, 11300, and 26300, respectively)]. The UV spectrum of this lignan in particular is almost superimposable on that of schizandrin (**3**),[3)] indicating that kadsurin is a schizandrin-type lignan. From the NMR spectral data (see the Table), kadsurin has four methoxyl groups (δ 3.65, 3.83, 3.89, and 3.92) and one methylenedioxy group (δ 5.99). All of them should be attached to the two aromatic rings, although their accurate positions are still uncertain. The presence of a partial structure [■–CH(OAc)–CH(Me)–CH(Me)–CH_2–■] can be confirmed by analysis of the NMR spectrum of kadsurin with aid of double resonance experiments: irradiation at the center of δ 1.92—2.20 (2H, complex) caused each signal at δ 0.95, 1.08, 2.67, and 5.67 to collapse to a sharp singlet. The presence of the AcO–$\underset{|}{C}$H– grouping is also confirmed by its mass and NMR spectra [*m/e* 398(M^+—AcOH); δ 1.60 and 5.67] together with the following chemical evidence. Reduction of Kadsurin (**1**) with $LiAlH_4$ (room temp, 6 h) readily afforded the corresponding hydroxy compound (**4**) (mp 134—135 °C; $C_{23}H_{28}O_7$; ν_{max} 3560 cm^{-1}) in high yields, although **1** resisted base-catalyzed hydrolysis (0.5 M KOH in MeOH–dioxane) in contrast to kadsurarin (**2**). In the NMR spectrum of **4**, the sharp singlet at δ 1.60 in **1** was not observed, but the signal at δ 5.67 in **1** shifted to δ 4.64 in a higher magnetic field. The structure including the position of each functional group and conformation of kadsurin (**1**) was clarified by measurement of intramolecular nuclear Overhauser effects (NOE), as follows.

Low intensity irradiation at δ 5.67 (AcO–$\underset{|}{C}$H–) caused a 21% increase in the integrated intensity of one of the aromatic protons (H^a), no enhancement of the signal intensity of the remaining proton (H^b) being observed. This indicates that the distance between H^a and the proton, which is attached to the carbon atom bearing the acetoxyl group, is short. It should be noted that the signal intensity of H^a was not increased by irradiation at the frequencies corresponding to the absorbance of each methoxyl group, indicating that none of them

† To whom inquiries should be addressed.

TABLE. NMR SPECTRA OF KADSURIN (**1**) AND KADSURARIN (**2**)

1	**2**
0.95(3H, d, J=7.0 Hz)	
1.08(3H, d, J=7.0 Hz)	1.23(3H, d, J=6.8 Hz)
	1.36(3H, s)
	1.40(3H, fine spritted s)
1.60(3H, s)	1.60(3H, s)
	1.85(3H, dq, J=7.5, 1.5 Hz)
	2.10(1H, br s, OH)
1.92—2.20(2H, complex)	2.16(1H, q, J=6.8 Hz)
2.67(2H, d, J=4.2 Hz)	
3.65(3H, s)	3.64(3H, s)
3.83(3H, s)	3.75(3H, s)
3.89(3H, s)	3.90(3H, s)
3.92(3H, s)	3.95(3H, s)
5.67(1H, br s)	5.68(2H, br s)
5.99(2H, br s)	5.90(2H, s)
	6.00(1H, br q, J=7.5 Hz)
6.48(1H, s)	6.43(1H, s)
6.60(1H, s)	6.60(1H, s)

can occupy the position adjacent to H^a. Thus, the remaining methylenedioxy group should be located at the position adjacent to H^a, as shown in [A]. In the next step, the measurements of NOE were focused on the signal (δ 6.60) corresponding to the aromatic proton H^b. Low intensity irradiation at δ 3.92, 2.67, and 0.95 caused 11, 13, and 9.6% enhancement, respectively, of the signal intensity of H^b. Therefore, one of four methoxyl groups (δ 3.92) should be located at a position adjacent to H^b, and one of two secondary methyl groups (δ 0.95) and H^b should be close to each other. The configuration of the remaining secondary methyl group was clarified by the following NOE measurements. Low intensity irradiation at δ 1.08 caused a 12% increase of the signal intensity of the proton attached to the carbon atom bearing the acetoxyl group (δ 5.67), no interaction between the secondary methyl group (δ 1.08) and H^a (δ 6.48) being detected. The undetermined secondary methyl group (δ 1.08) should be placed in such a space as depicted in [A]. This is also confirmed by the appearance of the NMR singlet at δ 5.67 with J value ($\approx$0 Hz), indicating that the dihedral angle between the two vicinal methine protons is almost 90°. Thus, the results can be explained only by the conformation [A] for kadsurin (**1**), and not by the other conformation [B].

Structure of Kadsurarin. Kadsurarin (**2**), whose molecular formula is $C_{30}H_{36}O_{11}$, has the same schizandrin-type chromophore as that of kadsurin (**1**) on the basis of its spectral data [ν_{max} 1620, 1585 sh and 1500 cm^{-1}; λ_{max} 280, 255, and 231 nm (ε, 3200, 10600, and 30000, respectively); δ 6.43 and 6.60]. Further analysis of its NMR spectrum indicates that kadsurarin (**2**) has the same carbon skeleton as that of **1** except for some functional groups.

Comparing the NMR spectra of **1** and **2** (see the Table), we see that the former has two secondary methyl groups (δ 0.95 and 1.08) and one methylene group

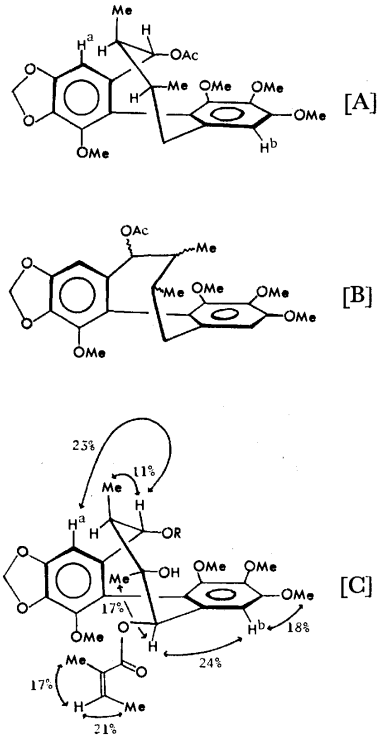

Fig. 2.

(δ 2.67), while **2** has one secondary methyl group (δ 1.27) and no methylene group. However, the latter has a tertiary methyl group (δ 1.36) on the carbon atom having a hydroxyl group, and one proton (δ 5.68)[4] attached to the carbon atom bearing an oxygen atom constituting a part of the angelate (δ 1.40, 1.85, and 6.00).

Kadsurin (**1**) is quite stable under basic conditions. However, when treated with 0.5 M KOH in MeOH–dioxane (room temp, 4.5 h), kadsurarin (**2**) was selectively converted into deacetyl kadsurarin (**5**), mp 227—228 °C ($C_{28}H_{34}O_{10}$), in high yields. In the NMR spectrum of **5**, a new singlet was observed at δ 4.84 (1H) instead of disappearance of the sharp singlet at δ 1.60 (3H) in **2** together with decrease in the integrated intensity at δ 5.68 in **2**. The easy and selective hydrolysis of the acetoxyl group in **2** is attributable to a proximity effect of the tertiary hydroxyl group, whose configuration is based on the NOE measurements of **5**. As shown in [C], the results are essentially similar to those of kadsurin (**1**) except for the following points. No interaction between the tertiary methyl group (δ 1.32) and H^b was detected. However, low intensity irradiation at δ 1.32 caused a 17% enhancement of the integrated intensity of the singlet at δ 5.66. This indicates that the configuration of the tertiary methyl group in **2** clearly differs from that of the corresponding secondary methyl group in **1**. As the first example, the stereostructures of schizandrin-type lignans were established. The stereostructure of schizandrin is still undetermined,[3] but may be similar to that of kadsurarin (**2**), as shown in **3**.

Quite recently, Ikeya *et al.* reported the isolation of gomicin D (**6**), whose stereostructure was also elucidated by means of an X-ray crystallographic analysis of the

corresponding dibromide.[5] The stereostructure of gomicin D is identical with that of kadsurarin (**2**), suggesting that the former can be produced from deacetoxykadsurin in the plant.

Experimental

All the mps are uncorrected. IR spectra were recorded on a JASCO IR-S spectrophotometer. UV spectra were taken on a Perkin-Elmer 202 spectrophotometer using MeOH as a solvent. NMR spectra were recorded on a Varian HA-100 NMR spectrometer using $CDCl_3$ as a solvent. The chemical shifts are given in ppm relative to the internal TMS, only prominent signals being cited (d, doublet; m, multiplet; q, quartet; s, singlet; t, triplet). Mass spectra were obtained on a Hitachi RMU-6D mass spectrometer, operating with an ionization energy of 70 eV. Optical rotations were measured on a JASCO ORD/UV-5 spectrometer using $CHCl_3$ as a solvent.

Isolation of Kadsurin and Kadsurarin. The dried material (2 kg) of the stems of the plant *Kadsura japonica* Dunal was pulverized and extracted with hexane (8 l) by refluxing for 3 h. The hot mixtures were filtered from the undissolved residue which was extracted again in the same way using hexane (8 l). The combined filtrates were evaporated to dryness under reduced pressure. The resulting dark green substance (20 g) was directly chromatographed on silica gel (Kieselgel, E. Merck, Darmstadt) (800 g), and eluted with hexane–EtOAc (4 : 1) to give crude crystals which were repeatedly recrystallized from EtOH to afford colorless needles (30 mg) of kadsurin (**1**); mp 157—158 °C; $[\alpha]_D^{25} = -39°$ ($c=0.13$); ν_{max} (Nujol) 1735, 1615, 1600, 1585, and 1495 cm^{-1}; *m/e* 458 (M^+) and 398 (M^+-60) ($m^*=346$) (Found: C, 65.33; H, 6.66%. Calcd for $C_{25}H_{30}O_8$: C, 65.49; H, 6.60 %). Further elution with hexane–EtOAc (2 : 1) afforded crude crystals, which were recrystallized from EtOAc to give colorless needles (100 mg) of kadsurarin (**2**); mp (dec) 255—256 °C (in a sealed tube); $[\alpha]_D^{25} = -65°$ ($c=0.10$); ν_{max} (Nujol) 3550, 1735, 1720 sh, 1643 sh, 1620 1600 1585 sh, and 1500 cm^{-1}; *m/e* 572 (M^+), 512 (M^+-60) ($m^*=458$), and 412 (Found: C, 63.49; H, 6.28%. Calcd for $C_{30}H_{36}O_{11}$: C, 62.95; H, 6.30%).

Reduction of Kadsurin with $LiAlH_4$. To a solution of kadsurin (20 mg) in tetrahydrofuran (2 ml) was added $LiAlH_4$ (10 mg) at room temperature for 6 h with stirring. After decomposition of excess reagent with ice water, the reaction mixture was diluted with 5% HCl aq solution, and then extracted with EtOAc. The extract was washed with water and then dried over anhydrous Na_2SO_4. Removal of the solvent under reduced pressure gave a white solid (17 mg), which was recrystallized from MeOH to afford colorless needles of deacetylkadsurin (**4**); mp 134—135 °C; ν_{max} (Nujol) 3560, 1620, 1595, 1575, and 1495 cm^{-1}; δ 0.95 (3H, d, $J=$ 7.0 Hz), 1.17(3H, d, $J=7.0$ Hz), 1.45 (1H, br s, OH), 1.95 (1H, q, $J=7.0$ Hz), 2.05(1H, m), 2.65(2H, d, $J=4.5$ Hz), 3.68(3H, s), 3.84 (3H, s), 3.89(3H, s), 3.90(3H, s), 4.64(1H, br.s), 5.98 (2H, s), 6.34(1H, s), and 6.60(1H, s); *m/e* 416 (M^+) and 398 (Found: *m/e* 416.1829. Calcd for $C_{23}H_{28}O_7$: *m/e* 416.1835).

Hydrolysis of Kadsurain with Methanolic KOH. To a solution of kadsurarin (23 mg) in a mixed solvent of dioxane (1 ml) and MeOH (0.5 ml) was added, with stirring, 0.5 M methanolic KOH (1 ml) at room temperature. The resulting solution was stirred at room temperature for 4.5 h, and then diluted with a large amount of water to give crystalline precipitates, which were washed with water and then dried under reduced pressure. Recrystallization from hexane–EtOAc afforded colorless needles (16 mg) of deacetylkadsurarin (**5**); mp 227—228 °C; ν_{max} (Nujol) 3500 br, 1715, 1645 sh, 1620, 1585 sh, and 1500 cm^{-1}; δ 1.32 (3H, s), 1.36 (3H, d, $J=$ 7.2 Hz), 1.39(3H, fine splitted s), 1.73(2H, br s, OH), 1.85 (3H, dq, $J=7.5$, 1.7 Hz), 1.98(1H, q, $J=7.2$ Hz), 3.73(6H, s), 3.87(3H, s), 3.90(3H, s), 4.84(1H, s), 5.66(1H, s), 5.88 (1H, d, $J=1.2$ Hz), 5.92(1H, d, $J=1.2$ Hz), 5.99(1H, qq, $J=7.5$, 1.5 Hz), 6.28(1H, s), and 6.76(1H, s), *m/e* 530 (M^+), 512 and 412 (Found: *m/e* 530.2146. Calcd for $C_{28}H_{34}O_{10}$: *m/e* 530.2152).

The authors wish to thank Drs. Masayasu Kurono and Masaaki Toda, Ono Central Research Laboratories, for measurements of high resolution mass spectra.

Studies of Unusual Amino Acids and Their Peptides. VIII. The Syntheses of an Iminohexapeptide as a Model of Bottromycin and Its Related Iminopeptides[1]

Takashi YAMADA, Toshifumi MIYAZAWA, Shigeru KUWATA, and Hiroshi WATANABE

Laboratory of Chemistry, Faculty of Science, Kōnan University, Okamoto, Higashinada-ku, Kobe 658

(Received January 17, 1977)

As a model of bottromycin, the structure of which had been proposed by Nakamura *et al.*, an iminohexapeptide, Z–Val–Val–ImPro–Gly–Phe–Phe–OMe, and its related iminopeptides were synthesized in good yields. These syntheses were achieved by the condensation of the imidates, Z–ImPro–OEt, Z–Val–ImPro–OEt·HCl, or Z–Val–Val–ImPro–OEt·HCl, with the peptide esters, Gly–Phe–OMe·HBr or Gly–Phe–Phe–OMe·HCl, in the presence of triethylamine. All of the resulting iminopeptides were isolated as the hydrobromide or the hydrochloride. The pK_a values of these iminopeptide salts were measured to be 9.75—9.3 in methanol–water; they showed that the pK_a rule of Nakamura *et al.* could not be applied in the cases of these iminopeptides.

In a previous paper,[2] we have reported on some properties and reactions of iminodipeptides and concluded that it is impossible to elongate the *C*-terminal of *N*-benzyloxycarbonyl(Z)-(iminoprolyl)glycine[3] because of the easy formation of an imidazolone derivative. This means that bottromycin (Fig. 1), the structure of which was proposed by Nakamura *et al.*,[1,4] could not be synthesized by the fragment condensation of the three already known dipeptide components; pivaloyl-*t*-leucylvaline,[5] (iminoprolyl)glycine,[2] and *β*-methylphenylalanyl-*β*-(2-thiazolyl)-*β*-alanine methyl ester.[6] Another possible route to build up bottromycin may be through the coupling of the two tripeptide components (pivaloyl-*t*-leucylvalyl(iminoproline) and glycyl-*β*-methylphenylalanyl-*β*-(2-thiazolyl)-*β*-alanine methyl ester) at the iminopeptide bond situated in the middle of this antibiotic molecule, because imidazolone formation could successfully be avoided by locating a carboxyl group (or an alkoxycarbonyl group) sufficiently apart from an imino group in the molecule—*e.g.*, the imidate (I) could be coupled with the dipeptide ester (II), affording the desired iminotripeptide (III)[2] (Scheme 1).

In order to ascertain the possibility of the latter method, as well as to reveal the properties of iminopeptides, we tried to synthesize an iminohexapeptide, Z–Val–Val–ImPro–Gly–Phe–Phe–OMe (XVII), as a model of bottromycin, and its related iminopeptides.

As the *N*-terminal fragments for this purpose, three sorts of imidates were prepared: ethyl *N*-Z-2-pyrrolidinecarboximidate (I),[2] ethyl *N*-(*N*-Z-valyl)-2-pyrrolidinecarboximidate hydrochloride (VII), and ethyl *N*-(*N*-Z-valylvalyl)-2-pyrrolidinecarboximidate hydrochloride (XI). The synthetic routes of these compounds are shown in Scheme 2. The imidates thus obtained were used for the next reaction without further purification.

As the *C*-terminal components, glycylphenylalanine methyl ester hydrobromide (II) and glycylphenylalanylphenylalanine methyl ester hydrochloride (XII) were used. Every coupling reaction was carried out by stirring a methanol solution of a free imidate, prepared from the hydrochloride just before the reaction, or an imidate hydrochloride itself, and a peptide ester salt in the presence of triethylamine at room temperature for 2 days. The products were isolated by chromatography on silica gel.

By the coupling of the imidate (I) with the dipeptide

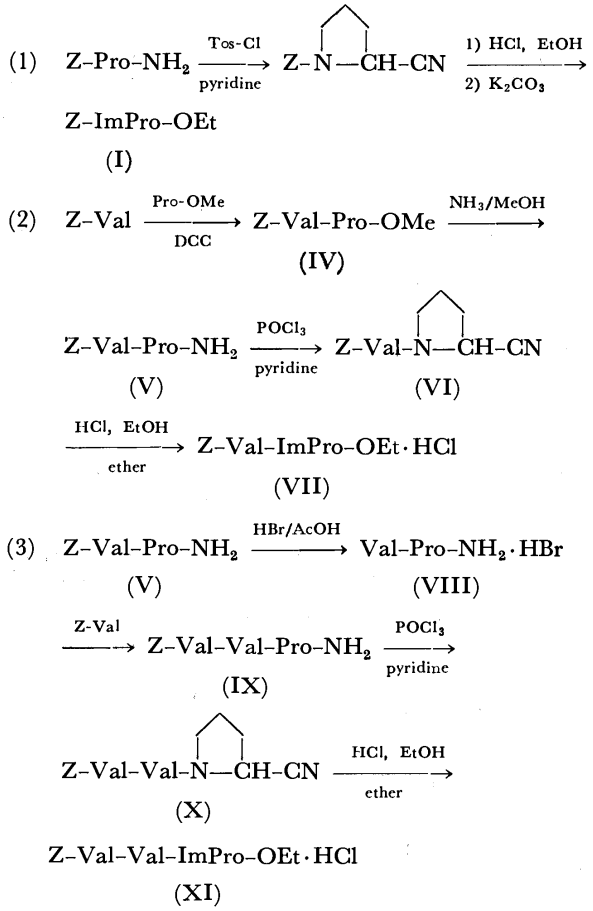
TABLE 1. SYNTHESES OF *N*-BENZYLOXYCARBONYL IMINOPEPTIDE HYDROHALIDES

Compd	Iminopeptide hydrohalides	Yield (%)	$[\alpha]_D^{20}$ (c 1, MeOH)	Molecular formula	Found (Calcd) (%) C	H	N
XIII	Z-ImPro-Gly-Phe-Phe-OMe·HCl	60	−17.0°	$C_{34}H_{39}N_5O_6 \cdot HCl \cdot H_2O$	61.26 (61.12)	6.45 (6.34)	10.11 (10.48)
XIV	Z-Val-ImPro-Gly-Phe-OMe·HBr	25[a]	−40.9°	$C_{30}H_{39}N_5O_6 \cdot HBr \cdot 2H_2O$	52.22 (52.79)	6.58 (6.50)	10.13 (10.25)
XV	Z-Val-ImPro-Gly-Phe-OMe·HCl	36[a]	−28.9°	$C_{30}H_{39}N_5O_6 \cdot HCl \cdot H_2O$	58.24 (58.10)	7.10 (6.83)	11.07 (11.29)
XVI	Z-Val-ImPro-Gly-Phe-Phe-OMe·HCl	59	−10.6°	$C_{39}H_{48}N_6O_7 \cdot HCl \cdot H_2O$	60.98 (61.05)	6.54 (6.70)	10.92 (10.95)
XVII	Z-Val-Val-ImPro-Gly-Phe-Phe-OMe·HCl	70	−35.7°	$C_{44}H_{57}N_7O_8 \cdot HCl \cdot H_2O$	61.30 (60.99)	7.35 (6.98)	10.80 (11.32)

a) Both compounds were isolated from the same reaction mixture. See Experimental part.



Scheme 2. Synthetic routes of the imidates of *N*-terminal fragments.

ester hydrobromide (II), the desired iminotripeptide derivative was obtained as a foamy solid; however, unexpectedly, it proved to be the hydrobromide instead of the free compound, as described previously.[2] This was also the case for the coupling of the imidate (I) with the tripeptide ester hydrochloride (XII), which yielded the iminotetrapeptide hydrochloride (XIII). In the coupling of the imidate hydrochloride (VII) with the ester hydrobromide (II), the resulting iminotetrapeptide derivative was found to be a mixture of the hydrobromide (XIV) and the hydrochloride (XV), which could be separated chromatographically, though two equivalents of triethylamine were used. The coupling of the dipeptide imidate (VII) with the tripeptide ester (XII) was carried out by using both the hydrochloride in the presence of triethylamine, and the iminopentapeptide derivative was obtained as the hydrochloride (XVI).

Finally, the coupling of the tripeptide imidate hydrochloride (XI) with the tripeptide ester hydrochloride (XII) was attempted under the same conditions as above; the desired model compound (XVII) could be obtained in a 70% yield as the hydrochloride. The synthetic results of these iminopeptides are summarized in Table 1. Supported by this success, we decided to couple the two tripeptide fragments at the iminopeptide bond for the total synthesis of bottromycin. The results will be published later.[7]

TABLE 2. pK_a VALUES OF IMINOPEPTIDES

	Iminopeptides	pK_a	(temp)
III	Z-ImPro-Gly-Phe-OMe·HBr	9.75[a]	(22 °C)
XIII	Z-ImPro-Gly-Phe-Phe-OMe·HCl	9.65[b]	(17 °C)
XIV	Z-Val-ImPro-Gly-Phe-OMe·HBr	9.4[a]	(18 °C)
XVI	Z-Val-ImPro-Gly-Phe-Phe-OMe·HCl	9.45[a]	(18 °C)
XVII	Z-Val-Val-ImPro-Gly-Phe-OMe·HCl	9.3[b]	(18 °C)

a) MeOH–H_2O (1 : 1). b) MeOH–H_2O (3 : 2).

The iminopeptides seemed to be more basic than triethylamine, because all the iminopeptides were isolated as salts in spite of the presence of equimolecular triethylamine, as has been seen above. Therefore, we measured the pK_a values of these iminopeptides, thereby examining the validity of the pK_a rule used by Nakamura *et al.*[4b,8] in order to elucidate the position of the imino group in the bottromycin molucule. The results are shown in Table 2. The basicities of these iminopeptides were unexpectedly found to be less than that of triethylamine (pK_a = 10.4 in MeOH–H_2O (3 : 2)) but the differences were small, so that the unusual isolation of the iminopeptide salts could be explained by also considering the volatility of triethylamine. There also exsists a tendency, though not so marked, that the more inner the iminopeptide bond comes to, the smaller the pK_a value.

It should be pointed out that the pK_a rule of Nakamura *et al.* could not be applied in the cases of our iminopeptides, because the rule predicts that every pK_a value of them is 8.1—8.4. Furthermore, it is noteworthy thet the iminohexapeptide derivative (XVII), prepared here as a model of bottromycin, has a pK_a value of 9.3, in contrast with the 8.1—8.3 value[4b] of the antibiotic.

The antimicrobial activities of these iminopeptides against several microorganisms (gram-positive bacteria containing *Mycobacterium*, a negative one, and some fungi) were examined, but no activities were observed in any.

Experimental

All the melting points are uncorrected. The optical rotations were measured by means of a Yanagimoto polarimeter, OR-10. The pK_a values were measured by means of a Hitachi-Horiba pH meter, F-7. Thin-layer chromatography (TLC) was done on Merck's Kieselgel GF_{254} (Type 60), and circular paper chromatography, on Toyo Roshi No. 2.

Z-Val-Pro-OMe (IV). Into a cold mixture of Z-Val-OH (5.03 g, 20 mmol), H-Pro-OMe·HCl (3.31 g, 20 mmol), and Et_3N (2.02 g, 20 mmol) in CH_2Cl_2 (50 ml) and dioxane (20 ml), a solution of DCC (4.32 g, 21 mmol) in CH_2Cl_2 (10 ml) was stirred below −5 °C. The mixture was stirred at 0 °C for 3 h and then at room temperature overnight. The reaction mixture, treated as usual, gave a crude dipeptide as an oil, which was chromatographed on a silica gel column with benzene–AcOEt (4 : 1) to afford a colorless oil; yield, 5.81 g (80.1%); $[\alpha]_D^{20}$ −87.7° (*c*, 1 MeOH). Found: C, 62.77; H, 7.28; N, 7.64%. Calcd for $C_{19}H_{26}N_2O_5$: C, 62.96; H, 7.23; N, 7.73%.

Z-Val-Pro-NH$_2$ (V). A solution of IV (1.631 g, 4.5 mmol) in a saturated solution of NH_3 in MeOH (21.9%) (20 ml) was allowed to stand at room temperature for 5 days. The solution was then evaporated under reduced pressure to give a syrup, which afforded white crystals when treated with AcOEt; yield, 535 mg (34.2%); mp 131—132.5 °C, $[\alpha]_D^{20}$ −81.6° (*c* 1, MeOH).

When condensed, the filtrate gave a syrup (1.060 g) which was mainly composed of the starting material. The syrup was treated again with a saturated solution of NH_3 in MeOH (20 ml) at room temperature for 15 days, affording white crystals after the treatment described above; yield, 733 mg (46.9 %), mp 131—132 °C, $[\alpha]_D^{20}$ −81.3° (*c* 1, MeOH).

All the crystals obtained were combined and recrystallized from AcOEt–petroleum ether; mp 133—134 °C, $[\alpha]_D^{20}$ −84.3° (*c* 1, MeOH). Found: C, 62.02; H, 7.38; N, 11.92%. Calcd for $C_{18}H_{25}N_3O_4$: C, 62.23; H, 7.25; N, 12.01%.

N-(Z-Val)-2-cyanopyrrolidine (VI). To a stirred solution of V (1.390 g, 4 mmol) in dry pyridine (7 ml), $POCl_3$ (0.48 ml, 5.2 mmol) in CH_2Cl_2 (0.9 ml) was added, drop by drop, below −7 °C. The resulting solution was stirred at about −10 °C for 1 h, and then treated with ice (50 g) and extracted with AcOEt. The organic layer was successively washed with 1M-HCl, water, 1M-$NaHCO_3$ and water, and dried over $MgSO_4$; yield, 1.278 g (97%); slightly yellow oil, $[\alpha]_D^{20}$ −89.0° (*c* 1, MeOH). Found: C, 65.79; H, 7.23; N, 12.64%. Calcd for $C_{18}H_{23}N_3O_3$: C, 65.63; H, 7.04; N, 12.76%.

Z-Val-ImPro-OEt·HCl (VII). This compound was prepared by bubbling dry HCl into a cold solution of VI (658 mg, 2 mmol) and absolute EtOH (120 mg, 2.6 mmol) in dry ether (10 ml) according to our previously described procedures;[2] yield, 820 mg (99.5%); a foamy solid. This imidate hydrochloride was used for the next reaction without purification.

H-Val-Pro-NH$_2$·HBr (VIII). This compound was prepared by the removal of the Z group from V (2.084 g, 6 mmol) with 25% HBr in AcOH (6 g) as usual. A crude product, a yellow syrup, was treated with MeOH–ether to give white crystals; yield, 1.632 g (92.5%); mp 214—217 °C (sublim.), $[\alpha]_D^{20}$ −45.6° (*c* 1, MeOH). Found: C, 40.71; H, 7.26, N, 14.01%. Calcd for $C_{10}H_{19}N_3O_2·HBr$: C, 40.83; H, 6.85; N, 14.28%.

Z-Val-Val-Pro-NH$_2$ (IX). Into a cold solution of Z-Val-OH (754 mg, 3 mmol) and *N*-methylmorpholine (304 mg, 3 mmol) in THF (10 ml), *i*Boc-Cl (410 mg, 3 mmol) was stirred, drop by drop, below −10 °C, after which the turbid mixture was stirred for 15 min at the same temperature. To the mixture we then added a mixture of VIII (883 mg, 3 mmol) and *N*-methylmorpholine (304 mg, 3 mmol) in DMF (10 ml) below −10 °C for 15 min, at about −5 °C for 1 h, and then at room temperature overnight. After the removal of a precipitate, the filtrate was concentrated under reduced pressure. The residual DMF solution was diluted with water (100 ml), extracted with AcOEt, washed with water, 1M-$NaHCO_3$, and water, and dried over $MgSO_4$. The solution was evaporated to a foamy solid; yield, 1.275 g (95.2%); $[\alpha]_D^{20}$ −94.5° (*c* 1, MeOH). Found: C, 61.61; H, 7.72; N, 12.45%. Calcd for $C_{23}H_{34}N_4O_5$: C, 61.86; H, 7.68; N, 12.55%.

N-(Z-Val-Val)-2-cyanopyrrolidine (X). This compound was prepared by the dehydration of IX (1.340 g, 3 mmol) with $POCl_3$ (0.36 ml, 3.9 mmol) in a mixture of dry pyridine (5 ml) and CH_2Cl_2 (0.7 ml) below −10 °C, as has been described above for the preparation of VI; yield, 1.131 g (88%); a foamy solid, $[\alpha]_D^{20}$ −103.0° (*c* 1, MeOH). Found: C, 64.26; H, 7.56; N, 13.19%. Calcd for $C_{23}H_{32}N_4O_4$: C, 64.46; H, 7.53; N, 13.08%.

Z-Val-Val-ImPro-OEt·HCl (XI). This compound was prepared by passing dry HCl into a mixture of X (900 mg, 2.1 mmol) and absolute EtOH (126 mg, 2.73 mmol) in dry ether as has been described above; yield, 1.002 g (93.4%); a foamy solid.

H-Gly-Phe-Phe-OMe·HCl (XII). This compound was prepared by the coupling of Z-Gly-ONp[9] with H-Phe-Phe-OMe in DMF according to the method of Katsoyannis *et al.*,[10] followed by the hydrogenation of the resulting Z-tripeptide ester (5.17 g, 10 mmol) over 5% palladium-carbon (1.5 g) in MeOH (200 ml) containing concentrated hydrochloric acid (0.9 ml); yield, 3.75 g (76.5% based on Z-Gly-ONp); mp 190—192.5 °C (dec), $[\alpha]_D^{20}$ +8.4° (*c* 1, MeOH). Found: C, 59.49; H, 6.28; N, 9.48%. Calcd for $C_{21}H_{25}N_3O_4·HCl$: C, 60.07; H, 6.24; N, 10.01%.

Iminopeptides. a) General Procedure: A solution of an imidate hydrochloride (1.2 mmol), a peptide ester hydrochloride (or hydrobromide) (1.0 mmol), and Et_3N (2.2 mmol) in dry MeOH (5 ml) was stirred at room temperature for 2 days. The solution was then evaporated under reduced pressure, leaving a syrup with some crystals. The syrup was taken up in AcOEt and freed from any insoluble materials by filtration. The filtrate was chromatographed on a silica gel column with MeOH–AcOEt (1 : 4), or on preparative layers of silica gel with MeOH–AcOEt (1 : 4) or $CHCl_3$–MeOH–AcOH (95 : 15 : 3), to give a foamy solid. The results are summarized in Table 1.

b) The Hydrobromide (XIV) and the Hydrochloride (XV) of Z-Val-ImPro-Gly-OMe: A solution of the imidate hydrochloride (VII) (820 mg, 2.0 mmol), the dipeptide ester hydrobromide (II)[2] (634 mg, 2.0 mmol), and Et_3N (404 mg, 4.0 mmol) in MeOH (10 ml) was stirred at room temperature

for 2 days. After the procedure described above, the resulting foamy solid was chromatographed on a silica gel column with MeOH–AcOEt (1 : 9) eluting one compound (A: 336 mg), and then with MeOH eluting the other compound (B: 430 mg); TLC: Compound A, R_f 0.37, Compound B, R_f 0.23 (MeOH–AcOEt (1 : 4)). Circular paper chromatography (1-BuOH–AcOH–H_2O (4 : 1 : 2, upper phase)) of the hydrolysates of these compounds showed both to contain 4 amino acids, and elemental analyses revealed that Compound A is iminotetrapeptide hydrobromide (XIV) and Compound B is the hydrochloride (XV).

The present work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education (14703, 1976). We are grateful to Dr. Ichiro Chibata and his co-workers, Tanabe Seiyaku Co., Ltd., for the test of the antimicrobial activity.

3) The following nomenclatures and abbreviations are used for iminopeptides and their derivatives. An amino acid containing =NH instead of =O in the carboxyl group is called an imino amino acid and abbreviated as ImAA (AA=amino acid); *e.g.*,  is called iminoproline (ImPro). Therefore,  is called (iminoprolyl)glycine (ImPro–Gly), and ethyl *N*-Z-2-pyrrolidinecarboximidate (I) may be abbreviated as Z–ImPro–OEt. Further, an iminopeptide bond means an amidino group (–C(=NH)–NH–) situated between amino acid residues. In addition, abbreviations according to the IUPAC-IUB Commission (*J. Biol. Chem.*, **247**, 977 (1972)) are used throughout. Additional abbreviations: DCC, dicyclohexylcarbodiimide; THF, tetrahydrofuran; DMF, *N*,*N*-dimethylformamide; BuOH, 1-butanol; *i*Boc–Cl, isobutyloxycarbonyl chloride; Tos–Cl, *p*-toluenesulfonyl chloride. The amino acids and their derivatives used here are all of the L-configuration.

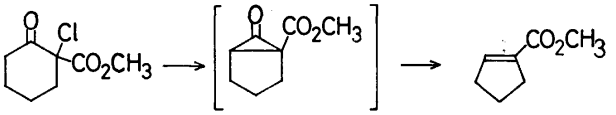
Synthesis of Methyl-substituted 1-Cyclopentene-1-carboxylates and Related Compounds*

Akira TAKEDA, Kōichi SHINHAMA, and Sadao TSUBOI
Department of Synthetic Chemistry, School of Engineering, Okayama University, Tsushima, Okayama 700
(Received January 20, 1977)

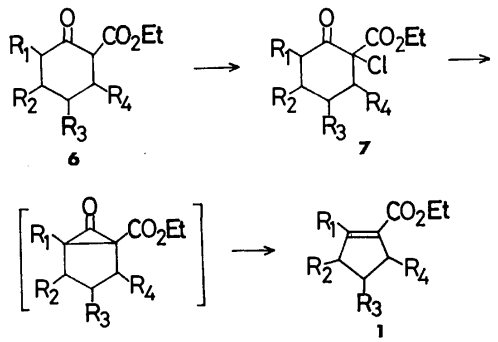
The treatment of methyl-substituted 1-chloro-2-oxo-1-cyclohexanecarboxylic esters (**7a—e**) with anhydrous Na_2CO_3 in refluxing xylene gave the corresponding methyl-substituted 1-cyclopentene-1-carboxylic esters (**1a—e**). Several intermediates important in the synthesis of natural products, such as 4,4-dimethyl-1-cyclopentene-1-carbaldehyde (**9**), 5-methyl-1-cyclopentene-1-carbaldehyde (**12**), α-(3-methyl-1-cyclopentenyl)propionic acid (**16**), and ethyl 2-methyl-3-oxo-1-cyclopentene-1-carboxylate (**17**), have been prepared starting from esters **1e**, **1d**, **1b**, and **1a**, respectively.

During the course of our work in cyclopentane monoterpene synthesis we required several methyl-substituted 1-cyclopentene-1-carboxylic esters (**1a—d**) and/or the corresponding aldehydes (**2**). The synthetic procedures of **1** as well as **2** so far reported appear to be inconvenient because they yield a mixture of structural isomers.[1,2] Recently Büchi *et al.*[3] have reported the dehydrochlorination-decarbonylation of 2-chloro-2-alkyl-1,3-cyclohexanedione to produce 2-alkyl-2-cyclopentene-1-one. The reaction was then extended to other 2-chloro-1,3-dicarbonyl compounds, such as cyclic α-chloro-β-keto aldehydes and α-chloro-β-keto esters. Thus, the dehydrochlorination-decarbonylation of methyl 1-chloro-2-oxo-1-cyclohexanecarboxylate (**3**) with sodium carbonate in hot xylene afforded methyl 1-cyclopentene-1-carboxylate (**5**).[4] Büchi has suggested that the product originates from the cyclopropanone intermediate (**4**) by thermal, nonconcerted elimination of carbon monooxide.



3 **4** **5**

We decided to investigate the dehydrochlorination-decarbonylation of four methyl-substituted 1-chloro-2-oxo-1-cyclohexanecarboxylic esters (**7a—d**) in an attempt to devise a straightforward synthesis of the desired esters **1a—d**.



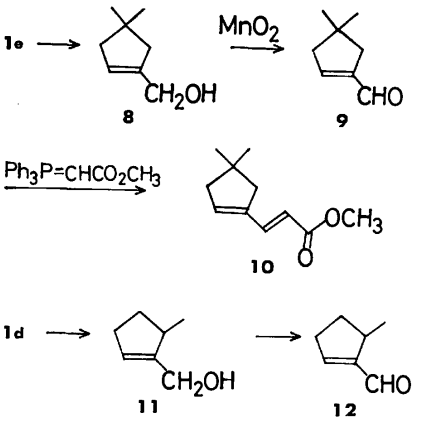
6a, 7a, 1a: $R_1=CH_3$, $R_2=R_3=R_4=H$
6b, 7b, 1b: $R_2=CH_3$, $R_1=R_3=R_4=H$
6c, 7c, 1c: $R_3=CH_3$, $R_1=R_2=R_4=H$
6d, 7d, 1d: $R_4=CH_3$, $R_1=R_2=R_3=H$

Four methyl-substituted 2-oxo-1-cyclohexanecarboxylic esters (**6a—d**) were chlorinated with *t*-butyl hypochlorite (*t*-BuOCl) under conditions similar to those in the literature[4] to give the corresponding α-chloro-β-keto esters (**7a—d**) in good yields (Table 1). The spectral data given in Table 2 support their structure. Both the IR spectra and the NMR spectra of compounds **7a—d** clearly show that they are nonenolizable β-keto esters. The NMR signals of the methyl protons of **7d** shifted to a lower field (δ 1.30) as compared with the other isomers, being affected by the neighboring chlorine atom.

These chlorides were treated with anhydrous Na_2CO_3 in refluxing xylene in the presence of glass powder until their exhaustion to give the corresponding 1-cyclopentene-1-carboxylates (**1a—d**) in 47—82% yields. The results are listed in Tables 3 and 4.

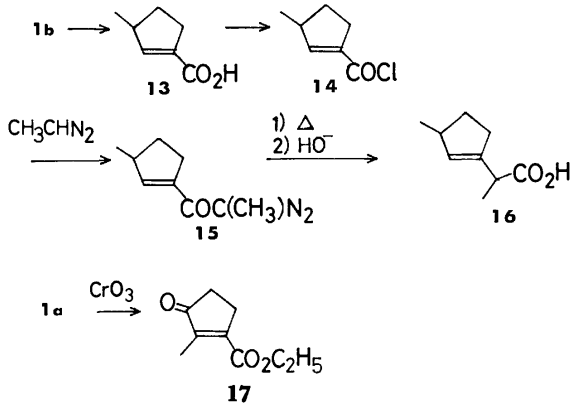
Starting from appropriate cyclopentenecarboxylates, we also prepared several intermediates such as 4,4-dimethyl-1-cyclopentene-1-carbaldehyde (**9**),[10] 5-methyl-1-cyclopentene-1-carbaldehyde (**12**),[12,13] α-(3-methyl-1-cyclopentenyl)propionic acid (**16**),[14] and ethyl 2-methyl-3-oxo-1-cyclopentene-1-carboxylate (**17**), useful for the synthesis of natural products.

The chlorination of ethyl 5,5-dimethyl-2-oxo-1-cyclohexanecarboxylate (**6e**)[11] with *t*-BuOCl gave ethyl 1-chloro-5,5-dimethyl-2-oxo-1-cyclohexanecarboxylate (**7e**) in a 79% yield. The treatment of **7e** with Na_2CO_3 afforded ethyl 4,4-dimethyl-1-cyclopentene-1-carboxylate (**1e**) in a 76% yield. The reduction of **1e** with $LiAlH_4$ gave 4,4-dimethyl-1-cyclopentenylmethanol (**8**) in a 93% yield. This alcohol was oxidized with active manganese dioxide[15] to the aldehyde **9** in a 33%

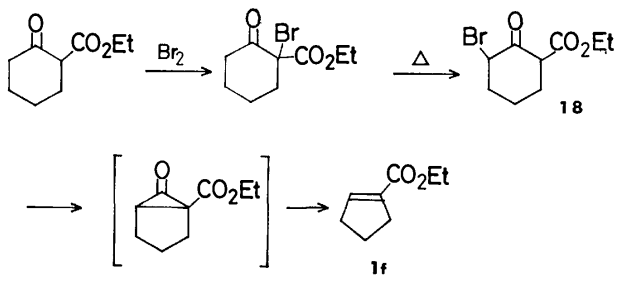


* Presented in part at the 33rd Annual Meeting of the Chemical Society of Japan, Fukuoka, October 1975.

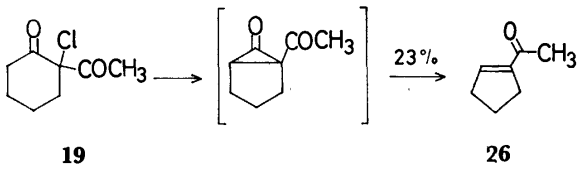
yield. Compound **9** was further converted into methyl *trans*-β-(4,4-dimethyl-1-cyclopentenyl)acrylate (**10**)[10] by the Wittig reaction with $Ph_3P{=}CHCO_2CH_3$.[16] Ethyl 5-methyl-1-cyclopentene-1-carboxylate (**1d**) was also converted into aldehyde **12** *via* 5-methyl-1-cyclopentenylmethanol (**11**) in a 35% overall yield. Ethyl 3-methyl-1-cyclopentene-1-carboxylate (**1b**) can be used as a starting material to prepare the acid **16**. The reaction of 3-methyl-1-cyclopentene-1-carbonyl chloride (**14**) with diazoethane afforded the corresponding diazo ketone (**15**). The thermal decomposition of **15** and the subsequent hydrolysis of the product gave the acid **16**. Compounds **12** and **16** are important intermediates for the synthesis of iridomyrmecin.[12-14] The oxidation of ethyl 2-methyl-1-cyclopentene-1-carboxylate (**1a**) with CrO_3 in glacial acetic acid gave 2-methyl-3-oxo-1-cyclopentene-1-carboxylate (**17**), the ester of the structural isomer of sarcomycine, in a 20% yield.[17]



Further synthetic application was carried out by the use of ethyl 3-bromo-2-oxo-1-cyclohexanecarboxylate (**18**),[18,19] 2-chloro-2-acetylcyclohexanone (**19**),[20] 2-chloro-2-acetylcyclopentanone (**22**),[21] propyl 1-chloro-2-oxo-1-cyclopentanecarboxylate (**23**), 2-chloro-2-formylcyclohexanone (**24**), and 2-chloro-2-formyl-4,4-dimethylcyclohexanone (**25**) as substrates. The treatment of the bromide **18** with Na_2CO_3 yielded ethyl 1-cyclopentene-1-carboxylate (**1f**), the same product as that from the 2-halogeno derivative, in a 61% yield. While the IR spectrum of **19** obtained by the



chlorination of 2-acetylcyclohexanone (**31**)[30] with *t*-BuOCl was identical with that of the literature,[20] the TLC analysis as well as the NMR survey indicated the presence of the 6-chloro isomer (**20**) (**19** : **20**=1 : 4). This mixture of isomers **19** and **20** was used for the next step without separation, since the both compounds should give the same Favorskii-type products, as is shown in the case of **18**. Thus, the reaction of the mixture of isomers **19** and **20** afforded 1-acetyl-1-cyclopentene (**26**) in a 23% yield.[22] The reactions of compounds **22**, **23**, **24**, and **25** failed to afford the anticipated products, instead yielding only tarry material.[21]



Studies of the synthesis of furopelargone[23] from the ester **1b**, that of photocitral[24] from the aldehyde **12**, and that of nepetalic acid[25] from the ester **1d** are now in progress.

Experimental

The melting points and boiling points are uncorrected. The elemental analyses were carried out by Mr. Eiichiro Amano of our laboratory. The analytical determinations by GLPC were performed on a Hitachi Model K-53 gas chromatograph fitted with the following columns (3 mm o.d. × 1 m) A, 10% Apiezon Grease L on Chromosorb W; B, 10% poly(neopentyl glycol succinate) on Chromosorb W; C, 10% SE-30 on Chromosorb W. The preparative isolations by GLPC were performed on a Yanagimoto Model GCG-550T gas chromatograph (3 mm o.d. ×2.25 m, 10% Apiezon Grease L on Chromosorb W). The mass spectra were obtained with a Hitachi Model RMS-4 mass spectrometer. The NMR spectra (60 MHz) were recorded with a Hitachi Model R-24 apparatus. The thin-layer chromatograms were prepared with Merck Kieselgel 60 PF_{254} (E. Merck AG, Darmstadt). The column chromatograms were prepared with Wakogel B-5F (Wako Junyaku Kogyo Co., Ltd.).

The following compounds were obtained in ways which have been described in the literature: **6a**,[5] **6b**,[6] **6c**,[7] **6d**,[8] **18**,[19] 2-acetylcyclopentanone (**21**),[28] 2-hydroxymethylenecyclohexanone (**30**),[29] and **31**.[30]

The following are typical runs. The reaction of **6b** illustrates the manner in which the chlorination of **6a**—**d** and the dehydrochlorination-decarbonylation of the chlorides **7a**—**d** were carried out.

*Ethyl 1-Chloro-4-methyl-2-oxo-1-cyclohexanecarboxylate (**7b**).* To a stirred solution of 7.4 g (0.04 mol) of ethyl 4-methyl-2-oxo-1-cyclohexanecarboxylate (**6b**)[6] dissolved in 60 ml of methanol was added 4.8 g (0.044 mol) of *t*-BuOCl[31] below 0 °C under nitrogen. After it had been stirred for an additional 1 h at the same temperature, the mixture was kept in a refrigerator for 40 h, and then allowed to stand at room temperature for 4 h. After the evaporation of methanol, the solution was distilled under reduced pressure to give 7.9 g (91%) of **7b**.

*Ethyl 3-Methyl-1-cyclopentene-1-carboxylate (**1b**).* Following the procedure reported by Büchi,[4] a flask was charged with 9.3 g (0.088 mol) of crushed, anhydrous Na_2CO_3 and 36 g of glass powder. After the content of the flask had been dried at 160 °C for 2 h *in vacuo*, it was filled up with nitrogen gas. A solution of 16 g (0.073 mol) of the chloride **7b** in 110 ml of xylene was then added to the flask, and the mixture was refluxed with stirring. The reaction was continued for 40 h until the chloride **7b** had been exhausted, as checked by GLPC. The resulting mixture was cooled and filtered. After evaporation of the solvent, it was fractionally distill-

ed under diminished pressure to give 8.9 g (79%) of the ester **1b**: bp 93—94 °C/22 Torr.

*Ethyl 5,5-Dimethyl-2-oxo-1-cyclohexanecarboxylate (**6e**).*[11] This substance was prepared from 4,4-dimethylcyclohexanone (**29**)[27] in a 24% yield by an adaptation of Snyder's method:[9] bp 90—110 °C/60 Torr [lit,[11] bp 75 °C/1Torr]; IR (neat) 1755, 1720, 1668, and 1627 cm^{-1}; NMR ($CDCl_3$) δ 0.98 (s, 6H), 1.30 (t, 3H), 2.20 (s, 2H), 2.28 (m, 4H), and 4.20 ppm (q, 2H).

*Ethyl 1-Chloro-5,5-dimethyl-2-oxo-1-cyclohexanecarboxylate (**7e**).* The ester **6e** (1.22 g, 62 mmol) was chlorinated in 15 ml of methanol with 0.85 g (7.9 mmol) of *t*-BuOCl in the manner used in the preparation of **7b**. The distillation of the residue obtained after working up as usual gave 1.12 g (79%) of the chloride **7e**: bp 115 °C (0.2 mm); IR (neat) 1730 cm^{-1}; NMR (CCl_4) δ 1.07 (s, 3H), 1.14 (s, 3H), 1.33 (t, 3H), 4.22 (q, 2H), and 1.6—3.0 ppm (m, 6H).

Found: C, 56.99; H, 7.20%. Calcd for $C_{11}H_{17}ClO_3$: C, 56.78; H, 7.36%.

*Ethyl 4,4-Dimethyl-1-cyclopentene-1-carboxylate (**1e**).* The dehydrochlorination-decarbonylation of the chloride **7e** (0.512 g, 2.1 mmol) with anhydrous Na_2CO_3 (0.256 g, 2.4 mmol) was carried out in refluxing xylene (4 ml) in the presence of glass powder (1.5 g). The reaction was continued for 28 h at the refluxing temperature until **7e** was exhausted, as checked by GLPC. The resultant mixture was cooled, filtered, and passed through a column of 10 g of dried silica gel. After the removal of xylene, using hexane as the eluant, a colorless eluate was collected with chloroform. The subsequent evaporation of chloroform afforded 267 mg (76%) of a pure ester (**1e**): IR (neat) 1725, and 1630 cm^{-1}; NMR (CCl_4) δ 1.16 (s, 6H), 1.23 (t, 3H), 2.3 (m, 3H), 2.31 (s, 2H), 4.07 (q, 2H), and 6.51 ppm (br, 1H).

*4,4-Dimethyl-1-cyclopentenylmethanol (**8**).* To a stirred suspension of $LiAlH_4$ (77 mg, 2 mmol) in 3 ml of dry ether was added dropwise the ester **1e** (267 mg, 5 mmol) dissolved in 1 ml of dry ether at −76 °C over a period of 0.5 h. After the addition had been completed, the mixture was stirred for an additional 4.5 h at −50——20 °C. To the mixture which had been allowed to warm up to room temperature was added 132 mg (1.5 mmol) of ethyl acetate to decompose the excess of $LiAlH_4$. The resulting mixture was treated with

0.35 ml of saturated aqueous ammonium chloride. The solid residue was washed with ether. The combined ethereal solution was then dried ($MgSO_4$) and evaporated to yield 175 mg (93%) of crude alcohol (**8**): IR (neat) 3360 cm^{-1}; NMR (CCl_4) δ 1.07 (s, 6H), 2.10 (s, 4H), 3.15 (br, s, 1H), 4.00 (s, 2H), and 5.41 ppm (br, s, 1H).

4,4-Dimethyl-1-cyclopentene-1-carbaldehyde (9). A mixture of 2.0 g of active manganese dioxide,[15] 175 mg (1.39 mmol) of crude alcohol **8**, and 10 ml of petroleum ether (bp 30—44 °C) was stirred for 3.5 h under nitrogen at room temperature, filtered and evaporated to give 168 mg of a crude product. Separation by column chromatography (silica gel) afforded 56 mg (33%) of pure aldehyde (**9**): IR (neat) 1678, and 1617 cm^{-1}; NMR (CCl_4) δ 1.12 (s, 6H), 2.32 (m, 4H), 6.63 (br, s, 1H), and 9.67 ppm (s, 1H).

Methyl trans-*β-(4,4-Dimethyl-1-cyclopentenyl)acrylate (10).* A solution of 56 mg (0.45 mmol) of the aldehyde **9** in 1 ml of benzene was added to 196 mg (0.59 mmol) of $Ph_3P{=}CHCO_2CH_3$,[16] after which the mixture was refluxed for 17 h. After working up,[2] 30 mg (37%) of the ester **10** was obtained. The spectral data (IR and NMR) of this product were identical with those of the literature.[10]

5-Methyl-1-cylopentenylmethanol (11). To a stirred suspension of $LiAlH_4$ (300 mg, 7.9 mmol) in 12 ml of dry ether was added dropwise ethyl 5-methyl-1-cyclopentene-1-carboxylate (**1d**) (937 mg, 6.1 mmol) dissolved in 5 ml of dry ether at −76 °C over a period of 20 minutes. The crude product which was obtained after working up in the manner used in the preparation of the alcohol **8** was subjected to vacuum distillation to yield 257 mg (38%) of pure alcohol (**11**): bp 62—64 °C (10 mm); IR (neat) 3350 cm^{-1}; NMR ($CDCl_3$) δ 1.05 (d, 3H, J=6 Hz), 1.55 (m, 2H), 2.27 (m, 2H), 2.70 (br, m, 1H), 3.60 (br, s, 1H, $-O\underline{H}$), 4.18 (s, 2H, $-C\underline{H}_2OH$), and 5.69 ppm (br, s, 1H).

Found: C, 74.76; H, 10.63%. Calcd for $C_7H_{12}O$: C, 74.95; H, 10.78%.

5-Methyl-1-cyclopentene-1-carbaldehyde (12). A mixture of 3.2 g of active manganese dioxide, 250 mg (2.2 mmol) of the alcohol **11**, and 16 ml of petroleum ether was stirred for 5.5 h under nitrogen at room temperature. The working-up was essentially the same as in the preparation of the aldehyde **9**, yielding 159 mg (65%) of the aldehyde **12**: IR (neat) 1672, and 1610 cm^{-1}; NMR ($CDCl_3$) δ 1.13 (d, 3H, J=6 Hz, $-C\underline{H}_3$), 1.65 (br, m, 2H), 2.50 (br, m, 2H), 3.00 (br, m, 1H), 6.78 (m, 1H, $=C\underline{H}-$), and 9.75 ppm (s, 1H, $-C\underline{H}O$).

3-Methyl-1-cyclopentene-1-carboxylic Acid (13). To a solution of potassium hydroxide (67 g, 1.2 mol) in 500 ml of ethanol was added 57 g (0.37 mol) of ethyl 3-methyl-1-cyclopentene-1-carboxylate (**1b**). The soultion was then refluxed for 20 h. After the evaporation of the solvent, enough dilute hydrochloric acid to acidify the mixture was added. The acidic organic layer was then extracted with ether. After being dried with $MgSO_4$, the ethereal solution was evaporated to dryness to give 47 g (quantitative) of the acid **13**: mp 34 °C (lit,[32] mp 35—36 °C); IR (Nujol) 3600—2100, 1675, and 1625 cm^{-1}; NMR (CCl_4) δ 1.11 (d, 3H, J=7 Hz), 1.3—3.1 (m, 5H), and 6.70 ppm (m, 1H).

3-Methyl-1-cyclopentene-1-carbonyl Chloride (14). This substance was prepared by treating the acid **13** (875 mg, 7 mmol) with $SOCl_2$ (1.05 g, 8.8 mmol) as usual. The subsequent removal of the excess $SOCl_2$ by evaporation gave 838 mg (84%) of the chloride **14**: bp 75—79 °C/31 Torr; IR (neat) 1752, and 1623 cm^{-1}; NMR (CCl_4) δ 1.16 (d, 3H, J=7 Hz), 1.3—3.3 (m, 5H), and 6.96 ppm (m, 1H, $=C\underline{H}-$).

α-(3-Methyl-1-cyclopentenyl)propionic Acid (16). The Arndt-Eistert reaction with diazoethane[33] was employed to prepare this compound. The chloride **14** (793 mg, 5.8 mmol) was allowed to react with 15 mmol of diazoethane in 100 ml of ether to give the diazo ketone (**15**): IR (neat) 3400, 2070, 1718, 1621, and 1550 cm^{-1}. This product was then subjected to thermal decomposition, followed by hydrolysis. The subsequent purification of the crude product with TLC [silica gel, benzene–methanol–AcOH (50 : 1 : 1), R_f=0.3] gave 156 mg of the acid **16** (18% yield from **14**): IR (neat) 3600—2400, 1700, and 1628 cm^{-1}; NMR ($CDCl_3$) δ 1.10 (d, 3H), 2.12 (d, 3H), 1.0—3.0 (br, m, 6H), 6.77 (m, 1H), and 7.44 ppm (br, s, 1H, $CO_2\underline{H}$).

Ethyl 2-Methyl-3-oxo-1-cyclopentene-1-carboxylate (17). To a stirred solution of ethyl 2-methyl-1-cyclopentene-1-carboxylate (**1a**) (1.96 g, 12.7 mmol) in 2.5 ml of glacial acetic acid was added dropwise a solution of chromium trioxide (2.0 g, 20 mmol) in aqueous acetic acid (3.8 ml of AcOH mixed with 1.1 ml of H_2O) over a 1-h period at room temperature. After the completion of the addition, the mixture was stirred for a further 54 h. The resulting mixture was treated with 70 ml of brine and then extracted with ether. The ethereal layer was washed twice with a 5% aqueous sodium hydroxide solution and dried over $MgSO_4$. After the evaporation of the solvent, the residue was subjected to column chromatography (silica gel, hexane : acetone=50 : 1 to 20 : 1), giving 615 mg of the unchanged ester and 418 mg (20%) of the ester **17**: IR (neat) 1712 and 1637 cm^{-1}; NMR (CCl_4) δ 1.33 (t, 3H, $-CO_2-C(=O)-C\underline{H}_3$), 1.99 (t, 3H, $=C(\underline{CH}_3)-$), 2.32 (m, 2H, $=C(\underline{CH}_2^-)-$), 2.65 (m, 2H, $-C(=O)-C\underline{H}_2-$), 4.25 ppm (q, 2H, $-CO_2-C\underline{H}_2-$); MS (70 eV) *m/e* (rel intensity) 168 (M^+, 31), 140 (30), 123 (33), 112 (55), 95 (25), 67 (100).

Ethyl 1-Cyclopentene-1-carboxylate (1f). A mixture of 3.27 g (13.1 mmol) of ethyl 3-bromo-2-oxo-1-cyclohexanecarboxylate (**18**),[19] 2.0 g (19 mmol) of anhydrous Na_2CO_3, and 10 g of glass powder was heated in refluxing xylene (20 ml) under an atmosphere of nitrogen for 29 h. The resulting mixture was filtered and passed through a column packed with 6 g of dry silica gel. After the elution of xylene with hexane, 1.12 g (61%) of the product **1f**, was obtained by washing out with chloroform: IR (neat) 1715 and 1630 cm^{-1} [lit,[34] IR (CCl_4) 1710 and 1620 cm^{-1}]; NMR (CCl_4) δ 1.23 (t, 3H), 1.5—2.7 (m, 6H), 4.09 (q, 2H), and 6.63 ppm (br, s, 1H).

2-Chloro-2-acetylcyclohexanone (19) and 6-Chloro-2-acetylcyclohexanone (20). *t*-BuOCl (2.15 g, 19.8 mmol) was stirred into a solution of 2-acetylcyclohexanone (**31**)[30] (2.31 g, 16.5 mmol) in absolute methanol (20 ml) under nitrogen over a 40 minute period, the temperature being kept below −20 °C. The mixture, which was then worked up as usual, yielded 1.77 g (62%) of a mixture of isomers **19** and **20**: bp 85—105 °C (0.3 Torr) [lit,[20] bp 50—51 °C/0.1 Torr]. The preparative TLC of this product (80 mg) afforded 14 mg of the chloride **19** [R_f=0.38; IR (neat) 1724 cm^{-1}; NMR (CCl_4) δ 2.29 (s, 3H, $-C(=O)-C\underline{H}_3$), 1.5—2.6 ppm (m, 8H, ring proton)], together with 54 mg of the chloride **20** [R_f=0.24; IR(neat) 1720, 1630, and 1585 cm^{-1}; NMR (CCl_4) δ 2.29 (s, 3H, $-C(=O)-C\underline{H}_3$), 1.5—2.3 (m, 7H), 4.1—4.5 (br, m, 0.6H, $-C(=O)-C\underline{H}(-)-C(=O)-$), and 15.02 ppm (s, 0.4H, $-C(-O\underline{H})=C-$)].

2-Chloro-2-acetylcyclopentanone (22). The chlorination of 2-acetylcyclopentanone (**21**)[28] with *t*-BuOCl gave this substance in an 80% yield: bp 75—80 °C (0.1 Torr) [lit,[21] bp

92—94 °C/13 Torr]; IR (neat) 1750, 1715, and 1650 cm^{-1}; NMR (CCl_4) δ 2.40 (s, 3H, $-\overset{\overset{O}{\|}}{C}-CH_3$), and 1.7—2.7 ppm (m, 6H, ring proton).

*Propyl 1-Chloro-2-oxo-1-cyclopentanecarboxylate (**23**).* The chlorination of propyl 2-oxo-1-cyclopentanecarboxylate (**27**) with *t*-BuOCl gave the chloride **23** in an 85% yield: bp 105—110 °C (0.05 Torr); IR (neat) 1755, and 1723 cm^{-1}; NMR (CCl_4) δ 0.77 (t, 3H), 1.72 (m, 2H), 2.0—3.0 (m, 6H), and 4.14 ppm (t, 2H).

*2-Chloro-2-formylcylclohexanone (**24**).* The chlorination of 2-hydroxymethylenecyclohexanone (**30**)[29] with *t*-BuOCl in chloroform gave this substance in a 70% yield: bp 50—60 °C/5 Torr; IR (neat) 1740 and 1720 cm^{-1}; NMR (CCl_4) δ 1.98 (m, 4H), 2.4—3.3 (m, 2H), and 9.55 ppm (s, 1H, $-C\underline{H}O$).

*2-Chloro-2-formyl-4,4-dimethylcyclohexanone (**25**).* The chlorination of 2-hydroxymethylene-4,4-dimethylcyclohexanone (**28**) with *t*-BuOCl in chloroform gave this substance in a 59% yield: bp 74—77 °C/5 Torr; IR (neat) 1740 and 1730 cm^{-1}; NMR (CCl_4) δ 1.08 (s, 3H, $-CH_3$), 1.28 (s, 3H, $-CH_3$), 1.5—3.0 (m, 6H, ring proton), and 9.37 ppm (s, 1H, $-C\underline{H}O$).

*1-Acetyl-1-cyclopentene (**26**). Dehydrochlorination-decarbonylation of the Chloride **19**.* The treatment of the crude chloride **19** (554 mg, 3.2 mmol) with 450 mg of anhydrous Na_2CO_3 in refluxing xylene afforded 267 mg of a crude product, which was subsequently purified by preparative TLC (silica gel, hexane : acetone = 10 : 1) to give 79 mg (23%) of the ketone: IR (neat) 1663 and 1616 cm^{-1}; NMR (CCl_4) δ 2.20 (s, 3H, $-\overset{\overset{O}{\|}}{C}-CH_3$), 1.7—2.8 (m, 6H, ring proton), and 6.52 ppm (br, s, 1H, $=C\underline{H}-$).

*Propyl 2-Oxo-1-cyclopentanecarboxylate (**27**).* This substance was prepared in a 79% yield by the Dieckmann condensation[26] of dipropyl adipate: bp 95—100 °C/7 Torr; IR (neat) 1755, 1720, 1658, and 1620 cm^{-1}; NMR (CCl_4) δ 0.95 (t, 3H), 1.65 (m, 2H), 2.14 (m, 6H), 3.00 (m, 1H), and 4.01 ppm (t, 2H).

*2-Hydroxymethylene-4,4-dimethylcyclohexanone (**28**).* This substance was prepared in a 45% yield by the formylation of 4,4-dimethylcyclohexanone (**29**)[27] in a manner similar to that used in the preparation of 2-hydroxymethylenecyclohexanone (**30**)[29]: bp 63—65 °C/10 Torr; IR (neat) 2900, 1640, and 1600 cm^{-1}: NMR (CCl_4) δ 1.00 (s, 6H), 1.45 (t, 2H), 2.10 (s, 2H), 2.42 (t, 2H), 8.50 (s, 1H, $=C\underline{H}-OH$), and 14 ppm (br, s, 1H, $=CHO\underline{H}$).

(Received January 20, 1977)

The isolation and structures of six new alkaloids [yuzurine, daphnigracine, daphnigraciline, oxodaphnigracine, oxodaphnigraciline, and epioxodaphnigraciline] are described. The structure of yuzurine, which has been elucidated by means of an X-ray crystallographic analysis of the corresponding methiodide, is in full agreement with its spectral data. The structures of the other five alkaloids, all of which were isolated from the plant *Daphniphyllum gracile* Gage collected in New Guinea, were deduced on the basis of an exhaustive comparison of their spectral data coupled with chemical evidences. Finally, a plausible biogenesis of these alkaloids with a new type of nitrogen heterocyclic skeleton is discussed.

The plant *Daphniphyllum macropodium* Miquel ("yuzuriha" in Japanese) contains a great variety of related alkaloids, which can be regarded as a triterpene alkaloid. From a structural point of view, they are divided into five types of nitrogen heterocyclic skeleton represented by daphniphyldine, secodaphniphylline, daphnilactone A, daphnilactone B, and yuzurimine.[1] However, all of them possess in common the 2-azabicyclo[3.3.1]nonane system [A], a part of which constitutes a part of the bicyclo[5.3.0]decane system. Thus, these daphniphyllum alkaloids are reasonably related to one another by bond formation or fission on the basis of our biosynthetic study indicating that they are biosynthesized from six molecules of mevalonic acid *via* a squalene-like intermediate.[2] In particular, the isolation of daphnilactones A and B strongly suggests that such compounds as [B] and [C] must be key intermediates between two main groups represented by daphniphylline and yuzurimine.[3] In connection with the above biogenetic consideration, our considerable efforts have been made to search for the biogenetically important intermediates. In the present paper, we wish to describe the novel structures of six new daphniphyllum alkaloids that have no 2-azabicyclo[3.3.1]nonane system and differ from the other structurally known alkaloids.

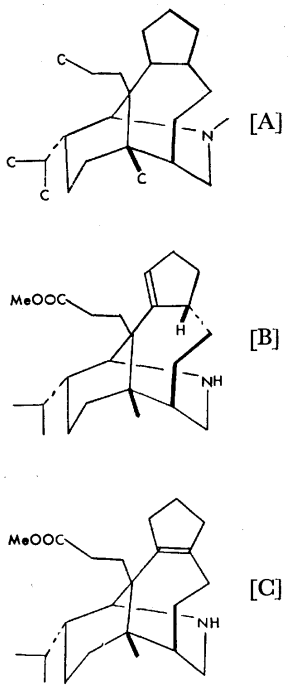

Fig. 1.

The Structure of Yuzurine. Yuzurine (**1**) has been isolated from the bark and leaves of the plant *Daphniphyllum macropodum* M. as one of the minor components, and cited as the alkaloid A_2.[4] This alkaloid is a colorless viscous liquid with a molecular formula [$C_{24}H_{37}O_4N$ (*m/e* 403 (M^+))] and characterized as the corresponding methiodide (**7**); mp 229—230 °C; $C_{25}H_{40}O_4NI$ [*m/e* 403 (M^+-MeI)]. Although this base can be regarded as one of the C_{22}-alkaloids from its molecular formula, the spectral data of **1** and **7** indicate that the carbon skeleton of yuzurine seems to be considerably different from those of the other daphniphyllum alkaloids, whose structures have been already established.

Firstly, yuzurine (**1**) has one ethyl group [δ 0.85 (3H, t, J=7.4 Hz)]. Furthermore, the NMR spectrum of the free base has two methyl singlets at δ 2.17 and 3.21 due to each one of NMe and OMe groups in addition to the presence of a methoxycarbonyl group (ν_{max} 1740 cm^{-1} and δ 3.64) and a $-CH_2-O-$ grouping [δ 3.93 (2H, s)]. In the case of the corresponding methiodide (**7**), the methyl singlet at δ 2.17 in **1** was shifted to lower magnetic field and two singlets were observed at δ 3.57 and 3.63 assignable to two methyl groups attached to the newly formed quaternary nitrogen atom. Secondly, three doublets with a geminal coupling constant (J=12—13.5 Hz) were newly observed at δ 3.35, 4.06, and 4.10 in the NMR spectrum of **7**. In addition, the NMR signal corresponding to the geminal doublet at δ 4.06, is present at δ 3.67—3.85. From these data, the methiodide (**7**) must have a partial structure $(-CH_2-\overset{\overset{Me}{|}}{\overset{+}{N}}-CH_2-)$. Finally, the complex structure of yuzurine (**1**) was elucidated by means of an X-ray crystallographic analysis of the methiodide (**7**),[5] which was subjected to Hofmann degradation to give the

original alkaloid (**1**). Further study on this quaternary base[6] has revealed that yuzurine (**1**) has the same absolute configuration as those of daphmacrine[7] and methyl homosecodaphniphyllate.[8] The structure of yuzurine so far obtained is in full agreement with its spectral and chemical data.

As described earlier, many number of alkaloids have been isolated from the plant *Daphniphyllaceae* growing in Japan.[1,3] Recently, an extensive survey was made of the occurrence of alkaloids in New Guinea plants,[9] and according to general procedures (see Experimental) the crude alkaloidal components were obtained from the plant *Daphniphyllum gracile* Gage by one of us (J. A. L). Interestingly, an analytical TLC of the crude oil so far obtained did not show any spots corresponding to daphniphylline and yuzurimine, both of which had been already isolated from the Japanese species as a main product.[10] This crude oil was further separated carefully by repeated preparetive TLC [Kieselgel PF_{254}; hexane–Et_2O–Et_2NH (10 : 10 : 1)] to give five new alkaloids, namely daphnigracine (**2**), daphnigraciline (**3**), oxodaphnigracine (**4**), oxodaphnigraciline (**5**) and in epioxodaphnigraciline (**6**) in 0.0046, 0.023, 0.0041, 0.016, and 0.019% overall yields, respectively.[11]

The Structures of Daphnigracine and Daphnigraciline. Daphnigracine is a colorless viscous liquid [**2**, $C_{24}H_{37}NO_4$; *m/e* 403 (M^+) and 385 (M^+-18)]. This alkaloid has each one of hydroxyl and methoxycarbonyl groups [ν_{max} 3450 cm^{-1}; ν_{max} 1730 cm^{-1} and δ 3.62 (3H, s)], and can be characterized as the corresponding methiodide [**8**, mp (dec) 198—199 °C; $C_{25}H_{40}O_4NI$]. Daphnigraciline [**3**, mp 76—78 °C; $C_{23}H_{35}O_4N$; *m/e* 389 (M^+) and 371 (M^+-18)] has a hydroxyl group (ν_{max} 3500 cm^{-1}) and a methoxycarbonyl group [ν_{max} 1735 cm^{-1} and δ 3.62 (3H, s)]. Similarly, treatment of **3** with MeI in acetone afforded the corresponding methiodide [**9**, mp (dec) 163—165 °C; $C_{24}H_{38}O_4NI$], in an almost quantitative yield. As shown in Tables 1 and 2, the spectral data, particularly NMR spectra, of both alkaloids are quite similar to each other except for the following points: the NMR signal due to an isopropyl group is observed at δ 0.93 in **2**, while daphnigraciline (**3**) has a methyl triplet at δ 0.94. Furthermore, when treated with Ac_2O–AcOH (1 : 1), both of the methiodides (**8** and **9**) were readily converted into the corresponding dehydration products (**10** and **11**) in high yields [**10**; mp (dec) 243—245 °C; $C_{25}H_{38}O_3NI$; *m/e* 385 (M^+—MeI); ν_{max} 1675 cm^{-1}; δ 4.44 (1H, m). **11**; mp (dec) 235—237 °C; $C_{24}H_{36}O_3NI$; *m/e* 371 (M^+—MeI); ν_{max} 1680 cm^{-1}; δ 4.39 (1H, m)]. From these data, clearly, daphnigracine and daphnigraciline must have the same carbon skeleton except for the different alkyl groups. Finally, the structures of these alkaloids were elucidated by conversion of daphnigraciline (**3**) into yuzurine (**1**), as follows.

When treated with MeOH containing one drop of AcOH (room temp, overnight), daphnigraciline (**3**) was converted into yuzurine (**1**), in a high yield, in addition to a small amount of an epimer (**12**) which was characterized as the corresponding methiodide [**13**: mp (dec) 144—146 °C; $C_{25}H_{40}O_4NI$; *m/e* 403 (M^+—MeI); ν_{max} 1730 cm^{-1} and no OH absorption band; δ 3.11 (3H, s)]. On Hofmann degradation, **13** was easily re-

converted into the starting base (**12**).

Finally, although the configuration of the hydroxyl group in a acetal moiety is not determined chemically, the NMR spectrum of **2** (or **3**) indicates that this hydroxyl group must be in an axial configuration, as discussed below. In the NMR spectrum of daphnigracine (**2**), as expected, a sharp doublet (δ 4.32) due to the geminal proton (H^A), which is in a 1,3-diaxial relationship to the hydroxyl group, is observed in lower magnetic field than the NMR signal at δ 3.89 assignable to the equatorial geminal proton (H^B) which can couple with a proton (H^C) along the 'W' path.

The Structures of Oxodaphnigracine, Oxodaphnigraciline and Epioxodaphnigraciline. The IR, UV, and NMR spectra of oxodaphnigracine (**4**: mp 116—117 °C; $C_{24}H_{35}O_5N$) and oxodaphnigraciline (**5**: mp 107—109 °C; $C_{23}H_{33}O_5N$) indicate that these two alkaloids must be quite similar to each other except for the alkyl group [δ 0.88 (6H, d, J=7.0 Hz) in **4**; δ 0.94 (3H, t, J=7.0 Hz) in **5**], as seen in the cases of daphnigracine (**2**) and daphnigraciline (**3**). In the UV spectra of **4** and **5**, particularly, the absorption maximum is observed at 253 nm, indicating the presence of an α,β-unsaturated CO group which must be included in the seven-membered ring.[12]

Epioxodaphnigraciline (**6**: mp 102—104 °C; $C_{23}H_{33}O_5N$) has the same molecular formula as that of oxodaphnigraciline (**5**), and their spectral data are also quite similar to each other. However, a remarkable difference is seen in the following points: the NMR spectrum of the former has the sharp doublet (δ 3.88) due to the geminal proton (H^A) at slightly higher magnetic field than that of **5** (δ 4.03). Therefore, the structure of epioxodaphnigraciline must be represented by **6**. Furthermore, these results are supported by the ^{13}C NMR spectra of the dehydration products (**14**, **15**, and **16**), which have been obtained on dehydration of the corresponding alkaloids **2**, **3**, and **5** (or **6**) with Ac_2O–AcOH (1 : 1).

As demonstrated in the previous paper,[13] the methyl, methylene, methine and quaternary carbon signals in the ^{13}C NMR spectra of these dehydro compounds are easily differentiated by measurements of their partially relaxed FT ^{13}C NMR spectra coupled with off-resonance experiments, and the results are summarized in Table 3. In the spectrum of **14**, nine methylene and four methine signals are observed, while ten methylene and three methine signals are found in that of **15**. In the case of **16**, nine methylene and three methine signals are found in addition to one new CO signal (δ 208.9). Furthermore, the olefinic signals at δ 138.6 and 183.3 strongly suggest that this CO group must conjugate with the tetra-substituted double bond (C_6–C_7) in **16**. In the cases of **15** and **16**, the ^{13}C NMR signals of the NMe group [δ 26.6 in **15**; δ 26.5 in **16**] appear at extraordinary high magnetic field. This may be due to complicated steric compression. The other signals of these three dehydration products show the one-to-one correspondence to one another.

From a biogenetic point of view, these new alkaloids may be produced from the plausible intermediate [B] according to a pathway (a) or (b), as shown in Scheme

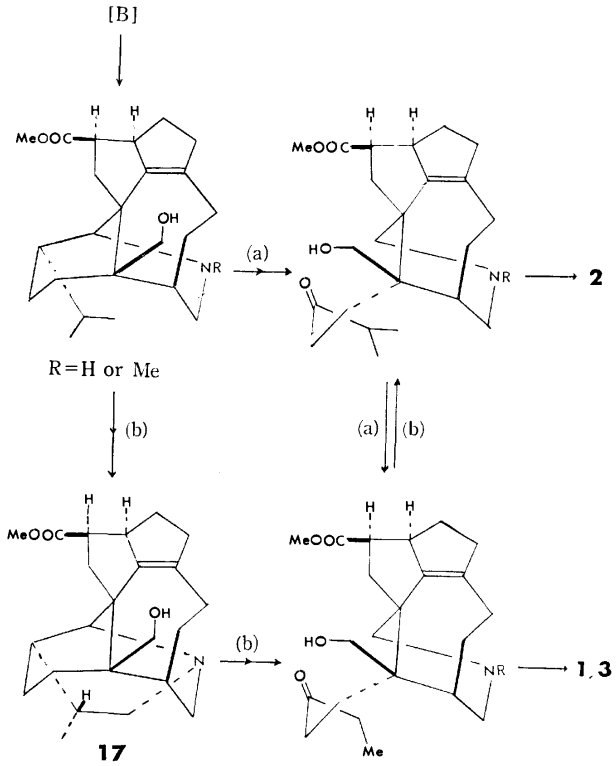
a) Assignment of chemical shifts for close-lying peaks may be reversed.



Scheme 1.

1. Of two possibilities, the isolation of daphnigracine (**2**) with an isopropyl group from the plant suggests that yuzurine (**1**) and daphnigraciline (**3**) both are not necessarily derived from yuzurimine B (**17**), but may be produced by oxidative demethylation of daphnigracine (**2**) or its precursor Biosynthetic experiments are further required to solve these problems.

Experimental

All the mps are uncorrected. IR spectra were recorded on a JASCO Model IR-S spectrophotometer. UV spectra were obtained on a Perkin Elmer 202 spectrophotometer, using MeOH as the solvent. NMR spectra were recorded on a Varian Associate AH-100 or A-60, or JEOL JNM-PS 100 NMR spectrometer, using $CDCl_3$ as the solvent, unless otherwise stated. The chemical shifts are given in ppm relative to the internal TMS, and only prominent signals are cited (d, doublet; m, multiplet; q, quartet; s, singlet; t, triplet). Mass spectra were taken on a Hitachi RMU-6C mass spectrometer, operating with an ionization energy of 70 eV.

Column chromatography was carried out on basic alumina (Nakarai Chemical Co., Ltd., *ca.* 300 mesh) or on silicic acid (Mallinckrodt, 100 mesh). Thin layer chromatography was performed on Kieselgel PF_{254} using hexane–Et_2O–Et_2NH (10 : 10 : 1) or Et_2O–Et_2NH (40 : 3), unless otherwise stated.

*Physical Properties of Yuzurine (**1**).* Isolation of this alkaloid was reported in the reference 4. Yuzurine is a colorless viscous liquid (**1**); ν_{max} (film) 1740 cm^{-1}; δ 0.85(3H, t, J=7.4 Hz), 2.17(3H, s), 3.21(3H, s), 3.64(3H, s), and 3.93 (2H, s); *m/e* 403 (M^+ for $C_{24}H_{37}O_4N$), 388, 372, 360, and 344.

*Formation of Yuzurine Methiodide (**7**).* A solution of yuzurine (40 mg) and MeI (1 ml) in acetone (2 ml) was allowed to stand at room temperature overnight, and then concentrated under reduced pressure to give pale yellow crystals (45 mg). Recrystallization from benzene–MeOH afforded pale yellow needles, which were subjected to an X-ray crystallographic analysis.[5] Its physical data are as follows: mp (dec) 229—230 °C; ν_{max} (KBr) 2700 and 1740 cm^{-1}; δ 0.87 (3H, t, J=7.0 Hz), 3.20(3H, s), 3.35(1H, br d, J=13.5 Hz,) 3.57(3H, s), 3.64(3H, s), 3.67(3H, s), 3.67—3.85(1H, superimposed on Me signals), 3.85(2H, br s), 4.06 (1H, d, J=12 Hz), and 4.10(1H, br d, J=13.5 Hz); *m/e* 403 (M^+−MeI) (Found: C, 54.51; H, 7.44; N, 2.51%. Calcd for $C_{25}H_{40}O_4NI$: C, 55.04; H, 7.39; N, 2.57%).

Hofmann Degradation of Yuzurine Methiodide. To a solution of yuzurine methiodide (80 mg) in MeOH–H_2O [(4 : 1) 5 ml] was added excess amounts of Ag_2O (*ca.* 200 mg). The reaction mixture was stirred at room temperature for 1 h, and then filtered. The filtrate was concentrated under reduced pressure to leave a crystalline residue, which was heated *in vacuo* at *ca.* 200 °C for 10 min, and then cooled. The resulting oily residue was purified by preparative TLC, using hexane–Et_2O–Et_2NH (10 : 10 : 1) to afford a colorless oil of yuzurine (47.2 mg) (analytical TLC and IR spectrum).

*Isolation of Daphnigracine (**2**), Daphnigraciline (**3**), Oxodaphnigracine (**4**), Oxodaphnigraciline (**5**), and Epioxodaphnigraciline (**6**).* The leaves of the plant *Daphniphyllum gracile* Gage growing in New Guinea were collected late in January. According to a usual procedure,[9] the air-dried leaves were milled and extracted by continuous percolation with MeOH at 40 °C. The methanolic extracts were concentrated under reduced pressure so that the temperature of the solution did not exceed 40 °C. The concentrate was diluted with water, and then acidified by addition of 1M H_2SO_4. The solution was filtered and made basic by addition of ammonia, and then extracted repeatedly with chloroform. Evaporation of the combined chloroform extracts gave the crude alkaloids as a dark brown residue. This residue was dissolved in chloroform (apart from a small amount of largely nonalkaloidal gum) and the alkaloids were extracted from the solution by repeatedly shaking with successive lots of 1M H_2SO_4. The crude alkaloids as a dark brown oil were recovered from the aqueous acidic solution by basification with ammonia followed by extraction with chloroform. Yield of the crude alkaloids from the air-dried leaves is 0.15% in weight.

The dark brown oil (556 mg) was further separated carefully by repeated preparative TLC using hexane–Et_2O–Et_2NH (10 : 10 : 1) to give five new alkaloids in the following order from the less polar to polar fractions: daphnigracine (**2**) (17.2 mg), daphnigraciline (**3**) (84.3 mg), oxodaphnigracine (**4**) (15 mg), oxodaphnigraciline (**5**) (61.4 mg) and epioxodaphnigraciline (**6**) (70.8 mg). Their physical data are shown below.

*Daphnigracine (**2**)* as a colorless viscous liquid: ν_{max} (film) 3450 and 1730 cm^{-1}: *m/e* 403 (M^+) and 385 (Found: *m/e* 403.27186. Calcd for $C_{24}H_{37}O_4N$: *m/e* 403.27224).

*Daphnigraciline (**3**):* Mp 76—78 °C (from hexane–Et_2O); ν_{max} (Nujol) 3500 and 1735 cm^{-1}; *m/e* 389 (M^+) and 371 [Found: C, 70.70; H, 9.25; N, 3.23% (*m/e* 389.25396). Calcd for $C_{23}H_{35}O_4N$: C, 70.92; H, 9.06; N, 3.60% (*m/e* 389.25659)].

*Oxodaphnigracine (**4**):* Mp 116—117 °C (from hexane–Et_2O); ν_{max} (Nujol) 3400 br, 1730, 1685, and 1650 cm^{-1}; λ_{max} 253 nm (ε, 7500); δ 0.88(6H, d, J=7.0 Hz), 2.10(3H, s), 3.60(1H, dd, J=11, 2 Hz), 3.69(3H, s), and 4.03(1H, d, J=11 Hz); *m/e* 417 (M^+) and 399 (Found: *m/e* 417.25334. Calcd for $C_{24}H_{35}O_5N$: *m/e* 417.25151).

*Oxodaphnigraciline (**5**):* Mp 107—109 °C (from hexane–Et_2O); ν_{max} (Nujol) 3380 br, 1730, 1685, and 1648 cm^{-1}; λ_{max} 253 nm (ε, 8060); δ 0.94(3H, t, J=7.0 Hz), 2.12(3H, s), 3.58(1H, dd, J=11.5, 3 Hz), 3.70(3H, s), and 4.03(1H, d, J=11.5 Hz); *m/e* 403 (M^+) and 385 (Found: *m/e* 403.23692. Calcd for $C_{23}H_{33}O_5N$: *m/e* 403.23585).

*Epioxodaphnigraciline (**6**):* Mp 102—104 °C (from hexane–Et_2O); ν_{max} (Nujol) 3400 br, 1735, 1685, and 1650 cm^{-1}; λ_{max} 252 nm (ε, 7000); δ 0.92 (3H, t, J=7.5 Hz), 2.15(3H, s), 3.61(4H, s)*, and 3.88(1H, d, J=12 Hz); *m/e* 403 (M^+) and 385 (Found: *m/e* 403.23532. Calcd for $C_{23}H_{33}O_5N$: *m/e* 403.23585).

*Formation of Daphnigraciline Methiodide (**9**).* According to the similar procedure as that of yuzurine (**1**), a solution of daphnigraciline (20 mg) in acetone (5 ml) was treated with MeI (1 ml) at room temperature overnight to give pale yellow crystals in quantitative yield:; mp (dec) 163—165 °C (from acetone–Et_2O); ν_{max} (Nujol) 3300 and 1710 cm^{-1}; *m/e* 371 (M^+−MeI−H_2O) (Found: C, 54.17; H, 7.36; N, 2.45%. Calcd for $C_{24}H_{38}O_4NI$: C, 54.23; H, 7.21; N, 2.64%).

*Formation of Daphnigracine Methiodide (**8**).* Under the same conditions as that of daphnigraciline (**3**), daphnigracine methiodide was also produced in an almost quantitative yield; mp (dec) 198—199 °C (from acetone–Et_2O); ν_{max} (Nujol) 3450 br, 3320 and 1710 cm^{-1}; *m/e* 385 (M^+−MeI−H_2O) (Found: C, 53.57; H, 7.15; N, 2.46%. Calcd for $C_{25}H_{40}O_4NI \cdot H_2O$: C, 53.28; H, 7.15; N, 2.64%).

*Dehydration of Daphnigraciline Methiodide (**9**).* A solution of **9** (15 mg) in Ac_2O–AcOH [(1 : 1) 2 ml] was allowed to stand at room temperature overnight, and then concentrated under reduced pressure at 100 °C to leave a crystalline

* One of the geminal protons (H^B) is included.

solid (13 mg). Recrystallization from acetone–Et_2O gave pale yellow needles (**11**): mp (dec) 235—237 °C; ν_{max} (Nujol) 1730 and 1680 cm^{-1}; δ 1.00(3H, t, J=7.2 Hz), 3.29 (1H, d, J=13.5 Hz), 3.54(3H, s), 3.61(3H, s), 3.62(3H, s), 3.73—3.92(2H, br), 4.02(1H, d, J=12 Hz), 4.18(1H, d, J=13.5 Hz), 4.38(1H, d, J=12 Hz), and 4.39(1H, m); *m/e* 371 (M^+—MeI), 356, 343, 340, 328, 314, 312, and 300 (Found: C, 55.99; H, 7.13; N, 2.31%. Calcd for $C_{24}H_{36}O_3NI$: C, 56.14; H, 7.07; N, 2.72%).

Dehydration of Daphnigracine Methiodide (8). Under the similar conditions as that of **9**, daphnigracine methiodide (20 mg) was treated with Ac_2O–AcOH [(1 : 1) 3 ml] to give a crystalline solid (*ca.* 20 mg), which was recrystallized from acetone–Et_2O to give pale yellow needles (**10**): mp (dec) 243—245 °C; ν_{max} (Nujol) 1730 and 1675 cm^{-1}; δ 1.01(6H, d, J=7.0 Hz), 3.30(1H, d, J=13.5 Hz), 3.57(3H, s), 3.63(3H, s), 3.65(3H, s), 3.7—3.90(2H, br), 4.02(1H, d, J=12 Hz), 4.21(1H, d, J=13.5 Hz), 4.44(1H, d, J=12 Hz), and 4.44 (1H, m); *m/e* 385 (M^+—MeI), 370, 357, 354, 342, 326, 314, and 300 (Found: C, 57.45; H, 6.83; N, 2.38%. Calcd for $C_{25}H_{38}O_3NI$: C, 56.92; H, 7.26; N, 2.66%).

Conversion of Daphnigraciline Methiodide (9) into Yuzurine Methiodide (7). Daphnigraciline methiodide (10 mg) was dissolved in MeOH (2 ml) containing one drop of AcOH. The resulting solution was allowed to stand at room temperature overnight, and then concentrated under reduced pressure on a boiling water-bath to give a pale brown solid (*ca.* 10 mg), which was crystallized from MeOH–benzene to afford pale yellow crystals of yuzurine methiodide (**7**) (mp and IR spectrum).

Conversion of the Dehydration Product (11) into Yuzurine Methiodide (7). According to the same procedure as that of daphnigraciline methiodide (**9**), **11** (10 mg) was treated with MeOH (2 ml) containing one drop of AcOH to give a crystalline solid quantitatively, which was recrystallized from MeOH–benzene to give yuzurine methiodide (**7**) (mp and IR spectrum).

Conversion of Daphnigraciline (3) into Yuzurine (1) and Epiyuzurine (12). A solution of **3** (100 mg) in MeOH (5 ml) containing AcOH (*ca.* 0.01 ml) was stirred at room temperature for 4 h, and then concentrated under reduced pressure at 100 °C to leave a slightly brown residue, which was separated by preparative TLC [hexane–Et_2O–Et_2NH (20 : 20 : 3)] to give yuzurine (75 mg) (TLC and IR spectrum) and a colorless viscous liquid of epiyuzurine (*ca.* 7 mg) which was characterized as the corresponding methiodide (**13**), mp (dec) 144—146 °C (from acetone–Et_2O); ν_{max} (Nujol) 1730 cm^{-1}; δ 0.85(3H, t, J=7.0 Hz), 3.11(3H, s), 3.42(2H, br s), 3.55(3H, s), 3.65(3H, s), 3.66 (3H, s), 3.34—3.72(1H, superimposed on Me signals), and 3.84—4.22(3H, complex); *m/e* 403 (M^+—MeI), 388, 371, 343, 340, 328, 314, 312, and 300 (Found: C, 54.59; H, 7.15; N, 2.20%. Calcd for $C_{25}H_{40}O_4NI$: C, 55.04; H, 7.39; N, 2.57%).

Dehydration of Daphnigracine (2). A solution of **2** (20 mg) in Ac_2O–AcOH [(1 : 1) 2 ml] was allowed to stand at room temperature overnight, and then concentrated to dryness under reduced pressure at 100 °C. The resulting pale brown oil was purified by preparative TLC, using hexane–Et_2O–Et_2NH (10 : 10 : 1) to afford a colorless viscous liquid (15 mg) [**14**: ν_{max} (film) 1735 and 1675 cm^{-1} (no OH absorption band) (Found: *m/e* 385.25956. Calcd for $C_{24}H_{35}O_3N$: *m/e* 385.26168) which was characterized as the corresponding methiodide (**10**).

Dehydration of Daphnigraciline (3). According to the same procedure as that of daphnigracine (**2**), treatment of **3** (20 mg) with Ac_2O–AcOH [(1 : 1) 2 ml] afforded the corresponding dehydration product (12 mg) as a colorless viscous liquid [**15**: ν_{max} (film) 1740 and 1678 cm^{-1} (no OH absorption band) (Found: *m/e* 371.24465. Calcd for $C_{23}H_{33}O_3N$: *m/e* 371.24603)]. This product was also characterized as the corresponding methiodide (**11**).

Dehydration of Oxodaphnigraciline (5). According to the same conditions as that of daphnigracine (**2**), **5** (22 mg) was treated with Ac_2O–AcOH [(1 : 1) 2 ml] to give a brown oil, which was purified by preparative TLC using Et_2O–Et_2NH (40 : 3) to afford an almost colorless viscous liquid (10 mg) [**16**: ν_{max} (film) 1735, 1690 br, and 1665 cm^{-1} (no OH absorption band); δ 1.00(3H, t, J=7.5 Hz), 2.16(3H, s), 3.55 (1H, d, J=11.5 Hz), 3.64(3H, s), 4.11(1H, dd, J=11.5, 2 Hz), and 4.36(1H, m) (Found: *m/e* 385.22619. Calcd for $C_{23}H_{31}O_4N$: *m/e* 385.2253)].

The authors wish to thank Dr. Masayasu Kurono (Ono Central Research Laboratories) for measurements of high resolution mass spectra. They are also indebted to Miss. Kikuko Kato (Analytical Center, Meijo University) for elemental analyses. This research has been supported in part by grants from the Ministry of Education, to which greatful acknowledgement is made.

Layered Compounds. XLII.[1] Syntheses and Properties of Layered Paracycloheterophanes

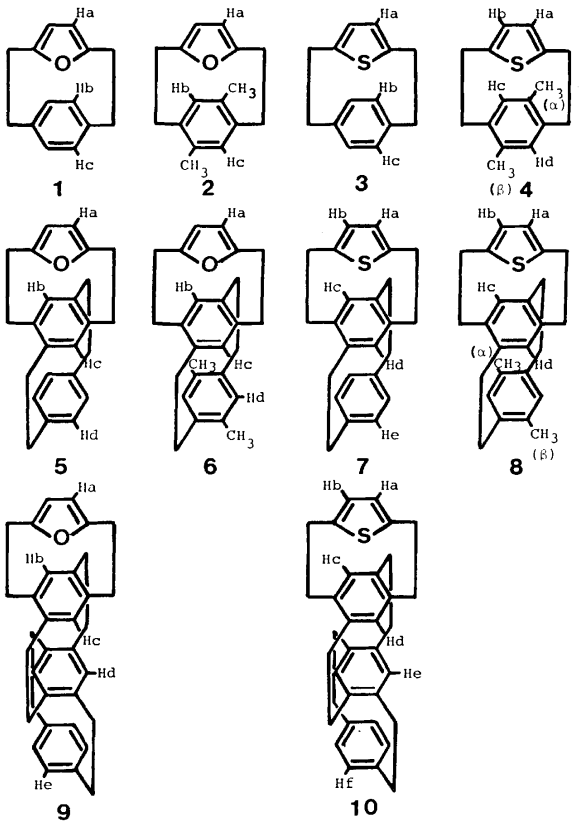
Tetsuo OTSUBO, Shigeyoshi MIZOGAMI, Norihisa OSAKA, Yoshiteru SAKATA, and Soichi MISUMI

The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka 565

(Received January 21, 1977)

A series of multilayered paracyclofuranophanes and paracyclothiophenophanes were synthesized by cross-breeding Hofmann elimination method from mixed quaternary ammonium hydroxides. Their structures and conformations were elucidated by NMR analyses. In electronic spectra, paracyclothiophenophanes exhibited stronger transannular electronic interactions than paracyclofuranophanes whose absorption curves show unexpected resemblance to those of multilayered metaparacyclophanes. Paracyclofuranophanes and [2.2](2,5)furanophane underwent addition reaction with benzyne to give 1 : 1 and 1 : 2 adducts, respectively. Their structures and properties were also studied by spectral measurements.

In recent years, multilayered compounds in which three or more aromatic rings are mutually stratified have been extensively investigated from a viewpoint of transannular π-electronic interaction.[2-4] It has become apparent that such electronic interactions among aromatic rings and the internal strain due to face-to-face benzene ring compression are mainly responsible for a number of anomalous physical and chemical properties of layered compounds, and the interaction increases with an increase of layer number. These results have prompted us to study multilayered cyclophanes containing heteroaromatic ring such as furan and thiophene, **1**—**10**, which might demonstrate much information on the transannular electronic interaction between benzene and heteroaromatic rings and on their chemical properties.



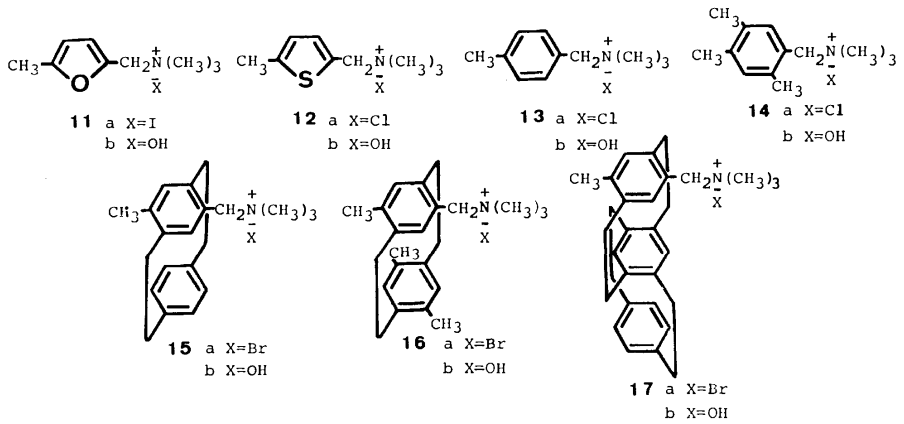
Scheme 1.

Results and Discussion

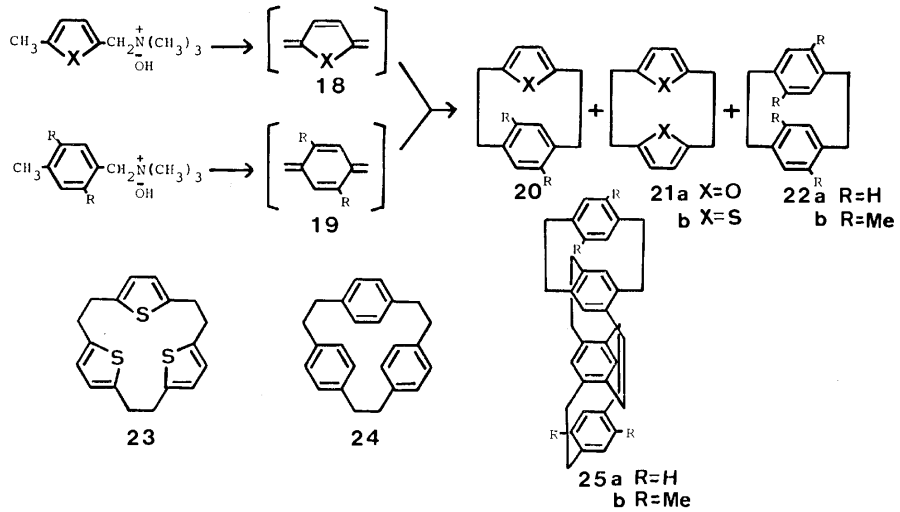
Syntheses. Although a number of synthetic methods have been recently developed for [2.2]cyclophane,[5] 1,6-Hofmann elimination method presented by Winberg *et al.*[6] is still very convenient and advantageous for the synthesis of multilayered [2.2]paracyclophane because of facile availability of the intermediary compounds.[2,3] In the present work we applied the same method for the syntheses of all paracycloheterophanes **1**—**10**. The syntheses of intermediates, quaternary ammonium salts **11**—**17**, were carried out in the same way as described in literatures.[2,3,6]

Cram and his coworkers first found out the formation of [2.2]paracyclo(2,5)furanophane **1** by the cross-breeding Hofmann degradation of 5-methylfurfuryltrimethylammonium hydroxide **11b** and *p*-methylbenzyltrimethylammonium hydroxide **13b**.[7] Similarly, we prepared [2.2]paracycloheterophanes **2**—**4** by cross-breeding reaction of the corresponding two quaternary ammonium hydroxides. A cross-breeding reaction generally produces a mixture of three main cyclophanes. For example, two intermediates, **18** and **19**, generated from pyrolysis of the corresponding quaternary ammonium hydroxides give cyclophane **20** from a cross coupling and cyclophanes **21**[6] and **22**[2,3,6] from homo-coupling. Besides them, [2.2.2](2,5)thiophenophane **23** was formed from **12** and [2.2.2]paracyclophane **24**[2] from **13** as minor products. Triple- and quadruple-layered paracycloheterophanes **5**—**10** were also synthesized by the same cross-breeding method using the corresponding multilayered quaternary ammonium salts **15**—**17**. In these cases, multilayered [2.2]paracyclophanes such as **25**[2,3] were formed as one of homo-coupling products.

The yields of cross coupling products are fairly low as compared with those of homo-coupling products and decrease with an increasing number of layers because multilayered cyclophanes and layered quinodimethane intermediates are relatively unstable. In the syntheses of layered paracyclophanes, a cross coupling product was easily separated from homo-coupling products by careful column chromatography on silica gel or alumina. However, some paracycloheterophanes were found to be very difficult to purify by means of conventional chromatography. This difficulty could be overcome by



Scheme 2.



Scheme 3.

use of silica gel coated with silver nitrate, which adsorbed heteroaromatic nucleus more strongly. In addition, use of preparative gel permeation liquid chromatography was found to be advantageous..

Structures and NMR Spectra. The NMR specrtal data of multilayered [2.2]paracycloheterophanes are summarized in Table 1. The most remarkable feature is that the chemical shifts of all the aromatic protons appear at high field as in the case of multilayered [2.2]-paracyclophanes.[8] There has been observed a certain regularity for upfield shifts of the aromatic protons, since each benzene ring is stacked in parallel at regular intervals (mean value 3.06 Å).[9] The upfield shifts of the present paracycloheterophanes are relatively small and rather irregular. This suggests that heteroaromatic rings are not stacked in the same mode as that of benzene rings. Table 1 also shows that two thiophene protons of the paracyclothiophenophanes appear nonequivalently except for **3**. In the case of 4,7-dimethyl-[2.2]paracyclophane **26**, the aromatic protons Ha at pseudo-gem position to methyl group were observed to shift considerably downfield due to the steric compression effect.[8] Similarly the nonequivalence of the thiophene protons is interpreted to arise from a downfield shift of one of the protons, which is sterically compressed by pseudo-*gem* methyl or methylene group. The steric compression effect (−0.32 ppm) of methyl group in **4** is almost same as that (−0.36 ppm) in **26**. The steric compression effect of bridged methylene is generally not observed in a series of paracyclophanes as indicated by equivalence of outer aromatic protons in **25a** or **27**.[8] The appearance of such effect on thiophene proton indicates that the proton is very close to pseudo-*gem* methylene group owing to the bulkiness of sulfur atom. On the other hand, furan series shows no steric compression effect. Thus the NMR signal

of the furan protons remains to be a singlet even at low temperature which may give rise to fixation of the furan ring. It seems reasonable to assume that the stacking modes of furan and thiophene rings are quite different from each other. In order to elucidate these structural problems, X-ray crystallographic analyses of triple-layered paracycloheterophanes **5** and **8** were very recently carried out by Kasai and his coworkers (Figs. 1 and 2).[10] Thus the furan ring is stacked at some angle on the faced benzene ring just like [2.2]metaparacyclophane.[11] The geometry is consistent with the spectral behavior described above. On the other hand, the thiophene ring is stacked in parallel on the faced benzene ring like [2.2]paracyclophane,[12] but it is slidden in such a way that the thiophene proton comes close to pseudo-*gem* methylene group as predicted by NMR analysis.

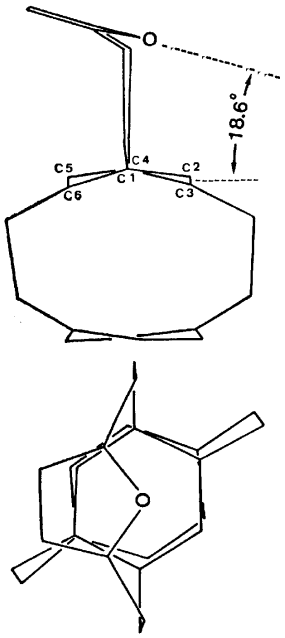

Fig. 1. Profile of triple-layered paracyclofuranophane **5**. Intramolecular non-bonded distances (Å); O···Cl, 2.860; O···C2, 2.927; O···C3, 3.054; O···C4, 2.820; O···C5, 3.011; O···C6, 3.173.

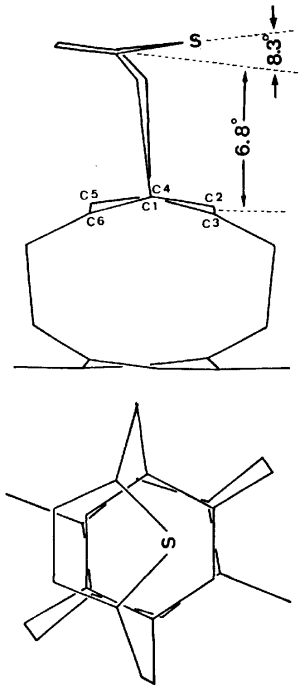

Fig. 2. Profile of dimethyl triple-layered paracyclothiophenophane **8**. Intramolecular non-bonded distances (Å); S···Cl, 3.121; S···C2, 3.049; S···C3, 3.197; S···C4, 3.122; S···C5, 3.436; S···C6, 3.597.

The structural difference between furanophane and thiophenophane is mainly due to larger bulkiness of sulfur atom relative to oxygen atom.

Another striking feature in NMR data is that aromatic protons of benzene ring faced to heteroaromatic ring appear to be nonequivalent in thiophene series and to be equivalent in furan series. These phenomena

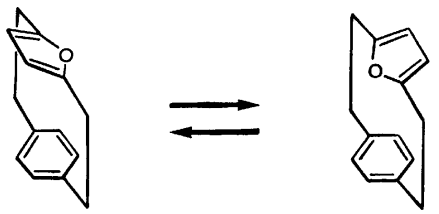

Fig. 3. Ring inversion of [2.2]paracyclofuranophane **1**.

	D_1	D_2	D_3	D_4

Fig. 4. Non-bonded distances between heteroatom and faced benzene in the transition state of the interconversion process.

can be explained to arise from the fixation of thiophene ring in the former series and the rapid interconversion of furan ring in the latter series as shown in Fig. 3.[13] We studied the dynamic behavior of a series of paracyclofuranophanes by variable temperature NMR spectroscopy. When the temperature is lowered, coalescence occurs and the aromatic protons of the faced benzene ring become nonequivalent (Table 1). Activation energy ΔG^* for the interconversion process was calculated by peak separation method according to Gutowsky and Holm[14] (Table 2). The flipping in triple- and quadruple-layered paracyclofuranophanes is appreciably easier than that in double-layered one. This can be explained in terms of the geometry of the faced benzene ring. Molecular model of **1** shows that the benzene ring is deformed into a boat shape like [2.2]paracyclophane.[12] On the other hand, as indicated by X-ray analysis of **5**, the inside benzene ring of multilayered cyclophane is deformed into a twist form which is caused by pulling up and down with two pairs of methylene bridges. Such structural changes of the faced benzene ring are considered to lower the steric barrier for the flipping of the furan ring.

The thiophene ring of paracyclothiophenophanes was, at the beginning, expected to flip at high temperature. However, they showed no change in their NMR spectra up to 150 °C but appreciable decomposition above this temperature. For understanding of the conformational behavior of furan and thiophene, it is advisable to in-

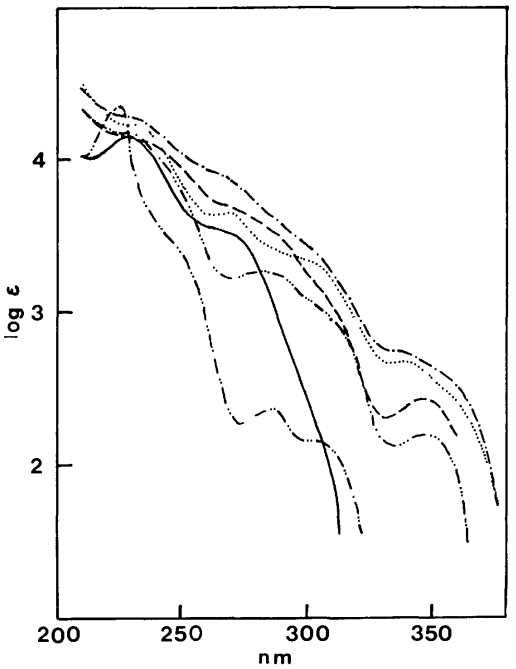

Fig. 5. Electronic spectra of multilayered paracyclothiophenophane **3** (——), **7**(----), and **10** (—·—), together with multilayered paracyclophanes **22a** (—··—), **27** (—···—), and **25a** (·····) in cyclohexane.

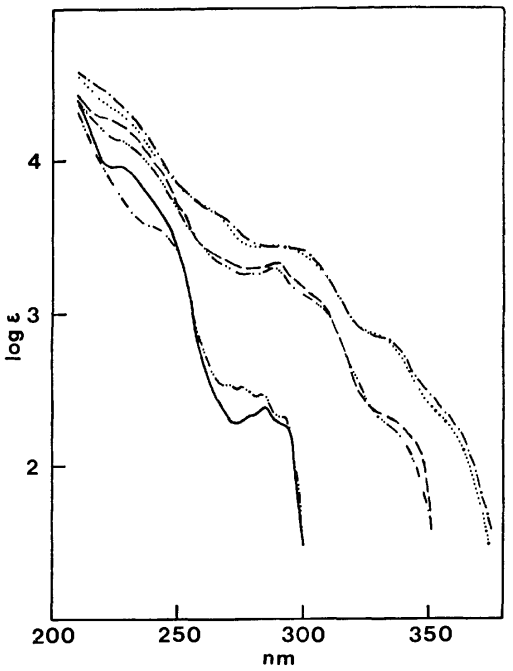

Fig. 6. Electronic spectra of multilayered paracyclofuranophanes **1** (——), **5** (----), and **9** (—·—), together with [2.2]metaparacyclophane (—··—), **28** (—···—), and **29** (·····) in cyclohexane.

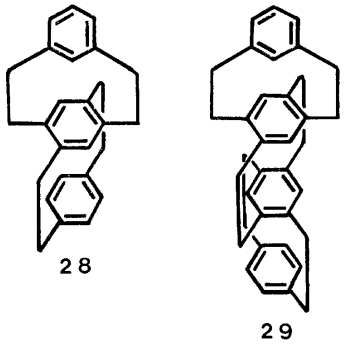
quire the non-bonded distances between heteroatom and faced benzene in the transition state where heteroaromatic ring is perpendicular to benzene ring. A minute calculation was performed on a computer using X-ray data of **5** and **8** as shown in Fig. 4.[10] The non-bonded distances for paracyclofuranophane are comparable to van der Waals distance (3.10 Å) of oxygen and benzene, supporting that the ring flipping is feasible according to temperature condition. On the other hand, the non-bonded distances for paracyclothiophenophane are much smaller than van der Waals distance (3.55 Å) of sulfur and benzene. The resulting large steric barrier inhibits the flipping process of thiophene ring.

Electronic Spectra. It is well-known that the transannular electronic interaction between two chromophores which are closely fixed with each other affects strongly the electronic spectra.[15] Multilayered [2.2]-paracyclophanes exhibited strong bathochromic and hyperchromic effects in their spectra with an increasing number of the layers, which were theoretically explained by both exciton and charge-transfer interactions.[16] As shown in Figs. 5 and 6, the present multilayered paracycloheterophanes show an analogous tendency, and the characteristic absorptions of the heteroaromatic rings disappear successively as the number of layer increases. The bathochromic shifts of the thiophene series are more significant than those of the furan series, indicating that thiophene interacts more strongly with benzene than furan. Incidentally, the absorption curves of the former show unexpected resemblance to those of multilayered paracyclophanes **25a** and **27** (Fig. 5) and the spectra of the latter to those of the corresponding multilayered metaparacyclophanes **28** and **29** (Fig. 6).[17] These spectral properties seem to be partly attributable to the stacking modes of paracyclothiophenophane similar to multilayered paracyclophane and paracyclofuranophane to multilayered metaparacyclophane. The transannular electronic interactions are also observed in the cases of [2.2](2,5)thiophenophane **21b**, [2.2.2](2,5)thiophenophane **23**, and [2.2](2,5)furanophane **21a** (Fig. 7). Thiophene or furan itself has no absorption in the ultraviolet region above 230 nm.[18] These cyclophanes clearly show bathochromic shifts or



Scheme 5.

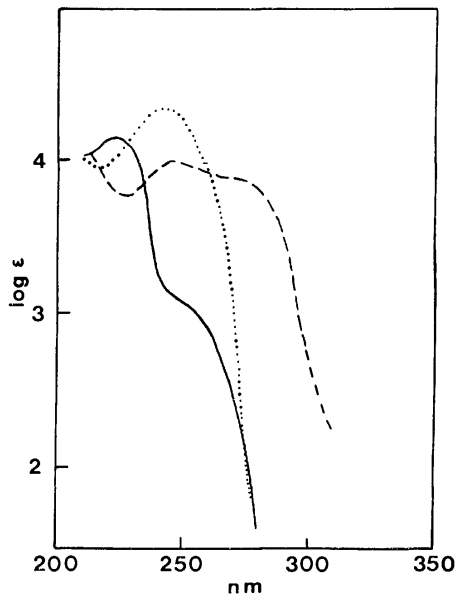


Fig. 7. Electronic spectra of heterophanes **21a** (——), **21b** (----), and **23** (·····) in cyclohexane.

appearance of new peaks in the longer wavelength. The stronger effect in **21b** relative to that in **21a** suggests that d-orbitals of sulfur atom plays significant role in the interaction.

TCNE Complexes. The transannular electronic interaction in cyclophane system is usually reflected in the increase of the π-basicity, in other words, the interaction brings a strong donor character to that system.[2,3,19] The absorption maxima of charge-transfer complexes of the present paracycloheterophanes and tetracyanoethylene (TCNE) are summarized in Table 3. As the number of layers increases, the absorption maxima shift to longer wavelength as seen in the case of multilayered [2.2]paracyclophane.[2,3] Although furan and thiophene have lower ionization potentials (9.00 and 9.10 eV, respectively) than benzene (9.52 eV), the CT bands of multilayered paracycloheterophanes with more than three layers appear at rather shorter wavelength than those of paracyclophane analogues. Evidently the electronic interaction between heteroaromatic and benzene rings is less effective than that between benzene rings. Table 3 also shows that thiophene series has stronger interaction than furan series.

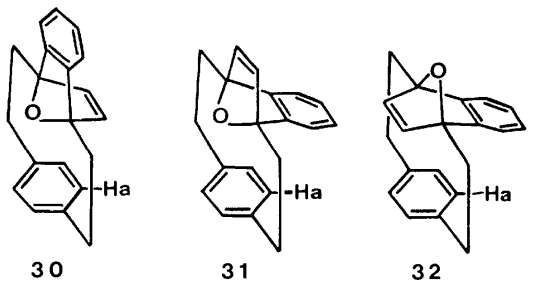
Addition Reaction with Benzyne. Layered cyclophanes offer many example of unusual addition reactions.[20] In particular, furanophanes have shown to undergo Diels-Alder reactions to give polycyclic compounds bearing unique skelton.[7,21] However, the present paracyclofuranophanes did not react with ordinary dienophiles such as maleic anhydride, dimethyl acetylenedicarboxylate, and tetracyanoethylene. When benzyne was used as a dienophile, paracyclofuranophanes **1** and **5** gave 1 : 1 adduct respectively. Three types of conformations are possible for these adducts. *e.g.*, **30**, **31**, and **32** from **1**. In the structures **31** and



30 **31** **32**

Scheme 6.

32, the NMR signals of Ha protons would shift significantly to high field due to magnetic anisortropy of the fused benzene ring. The NMR spectra of the adducts are consistent with the structures **30** and **33** (Fig. 8). Moreover, examination with molecular model indicates that the structures **31** and **32** are sterically unfavorable because there are considerable repulsion between the fused benzo group and faced benzene rings.

As shown in Fig. 9, the electronic spectra of these adducts exhibit unexpected large bathochromic and hyperchromic shifts. The CT bands of their TCNE complexes also appear at longer wavelength than predicted; **30**, λ_{max} 505 and 570(sh) nm; **33**, λ_{max} 530(sh)

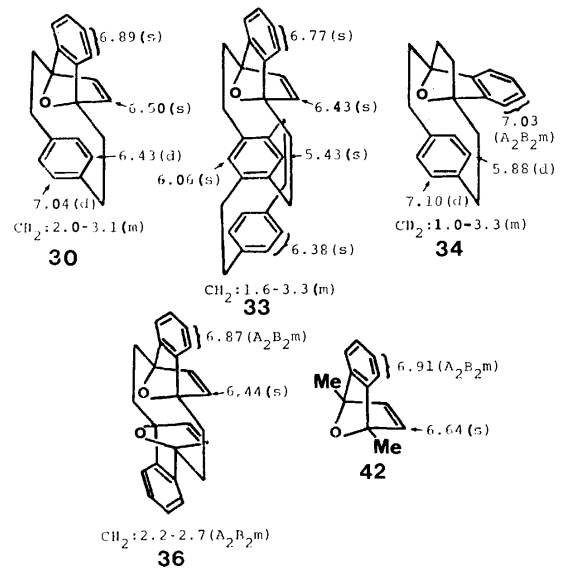


Fig. 8. NMR data of benzyne adducts (δ value in deuteriochloroform).

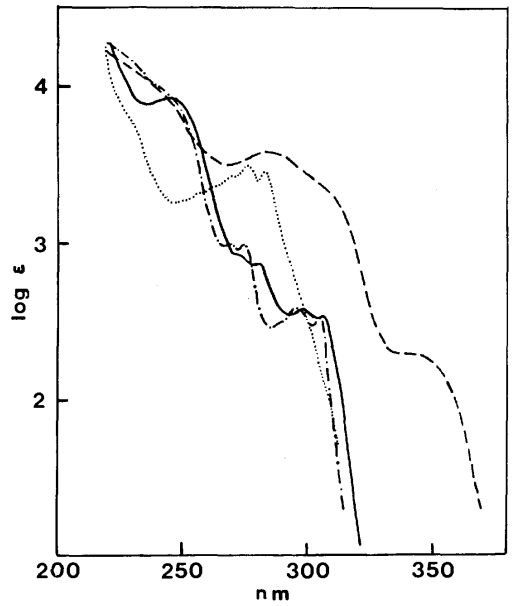

Fig. 9. Electronic spectra of benzyne adducts **30** (——), **33** (----), **34** (—·—), and **36** (·····) in tetrahydrofuran.

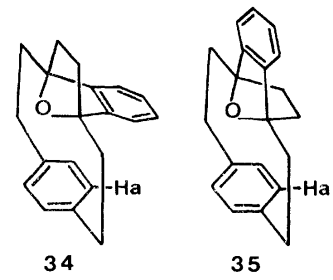
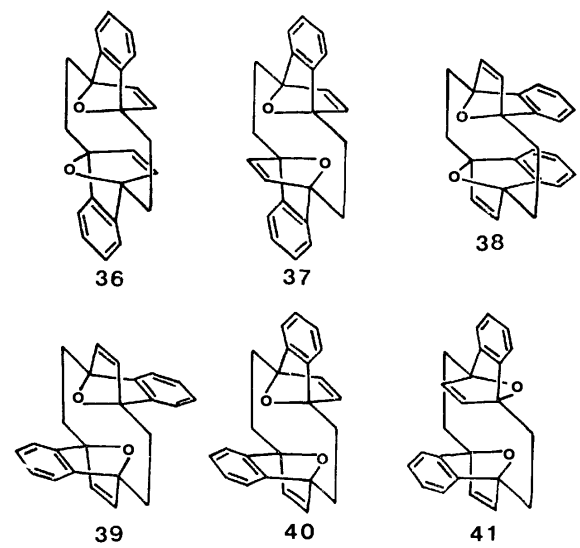
and 634 nm in dichloromethane. These data apparently indicate the presence of strong transannular electronic interaction in the adducts. A direct interaction between the two benzene rings does not seem to take place. Therefore, either olefinic group or oxygen atom is predicted to take part in the electronic interaction. In order to obtain further evidence, the olefinic group of **30** was saturated by catalytic reduction using Pd–C. Surprisingly, the hydrogenation gave dihydro compound **34** accompanied by an inversion of the conformation instead of **35** with retention. The structure of **34** is assigned by its NMR spectrum. Thus the Ha proton drastically shifts to high field compared to Ha proton of **30**, which is due to magnetic anisotropy of the fused benzo group. Probably, the conformational change



Scheme 7.

arises from an increasing steric hindrance of ethano group with Ha proton in **35**, as compared to that of fused benzo group with Ha proton in **34**. The electronic spectrum of **34** is similar to that of adduct **30** (Fig. 9) and the absorption maxima of its TCNE complex, 490 and 570 nm in CH_2Cl_2, are almost same as those of **30**. These facts suggest that there is no essential difference between the electronic interactions in **30** and **34**, and thereby oxygen atom makes considerable contribution to the interaction in both adducts **30** and **33**.

Battiste and Kapicak[22] reported that [2.2](2,5)furanophane **21a** underwent a Diels-Alder reaction with benzyne to give non-internally cyclized 1 : 1 adduct and 1 : 2 adduct, and that an *anti* structure for the latter bis-adduct would be favored over others on the basis on *anti* structure of **21a** and steric requirement of benzyne approaching. We have carried out the same addition reaction of **21a** with benzyne generated from anthranilic acid and obtained 1 : 2 adduct in 16% yield. Of six possible conformations **36**—**41** for the adduct other than sterically unfavorable structures with outmost oxygen like **32**, the structure **36** is most favorable from NMR data (Fig. 8) which show 0.2 ppm upfield shift for olefinic proton and invariable shift for aromatic proton as compared with a reference compound **42**.[23] The other structures are therefore in conflict with the NMR data. Thus, the structures **40** and **41** would not give any symmetrical NMR pattern. The olefinic proton of **37** would be expected to shift rather to downfield by a deshielding effect of closely placed



Scheme 8.

oxygen atom. In **38** or **39**, one would predict the olefinic signal to be identical to that of **42** and the aromatic signal to be different from that of **42**. The electronic spectrum of the adduct and the CT spectrum of its TCNE complex (λ_{max}, 410 and 544 nm in CH_2Cl_2) exhibit unusual transannular electronic interaction as in the case of **30** and **33**.

Experimental

Melting points are uncorrected. All solvents are of reagent grade. NMR spectra were taken with a Hitachi Perkin-Elmer R-20 spectrometer (60 MHz) using tetramethylsilane as an internal standard. MS and UV spectra were measured with a Hitachi RMU-7 spectrometer (70 eV) and a Hitachi EPS-3T spectrophotometer, respectively. A general procedure of Hofmann elimination reaction was described in detail in the experimental part of 4,7-dimethyl[2.2]paracyclo-(2,5)furanophane **2**. Chromatography was usually done with silica gel (Merck, activity II—III) of 20 to 100 times of a mixture to be separated. Silica gel coated with silver nitrate was made as follows: silica gel (100 g) was shaken sufficiently with silver nitrate (20 g) in 100 ml of distilled water, and then water was removed using a rotary evaporator. The residual silica gel coated with silver nitrate was activated on standing overnight in an oven at 110 °C and used with care to avoid exposure to light.

4,7-Dimethyl[2.2]paracyclo(2,5)furanophane **2**. 5-Methylfurfuryltrimethylammonium iodide **11a**[6] (15 g, 53 mmol) and duryltrimethylammonium chloride **14a**[3] (10 g, 44 mmol) were dissolved in 500 ml of distilled water and passed through ion exchange column packed with Dowex 1-X8 ion exchange resin which was previously converted to hydroxide form. The eluted aqueous solution of **11b** and **14b** was mixed with xylene (50 ml) and phenothiazine (50 mg). The mixture was heated with stirring in a nitrogen atmosphere, and water was removed by azeotropic distillation using a Dean-Stark type of water separator. After removal of water, reflux was continued for additional 10 h. Insoluble polymer was filtered off and washed with xylene. The filtrate and washing were combined, dried over anhyd magnesium sulfate, and evaporated. The residue was chromatographed on silica gel using petroleum ether as an eluent. There was eluted first a mixture of 4,7-dimethyl[2.2]paracyclo(2,5)furanophane **2** and 4,7,12,15-tetramethyl[2.2]paracyclophane **22b**,[2,3] and then [2.2](2,5)furanophane **21a**[6] (0.6 g). The mixture was rechromatographed on silica gel coated with silver nitrate. Elution with 1 : 1 petroleum ether–ether gave first **2** (884 mg, 9%) and then **22b** (674 mg). Recrystallization of **2** from petroleum ether afforded colorless plates, mp 63.0—64.5 °C.

MS *m/e* 226 (M^+). Found: C, 85.02; H, 8.08%. Calcd for $C_{16}H_{18}O$: C, 84.91; H, 8.01%.

[2.2]Paracyclo(2,5)thiophenophane **3**. In the same way as **2**, the cross-breeding reaction of the quaternary hydroxides derived from 5-methylthenyltrimethylammonium chloride **12a**[6] (4 g, 19 mmol) and *p*-methylbenzyltrimethylammonium chloride **13a** (9.6 g, 48 mmol) gave a mixture of the desired cyclophane **3**, [2.2]paracyclohpane **22a**, [2.2](2,5)thiophenophane **21b**, [2.2.2](2,5)thiophenophane **23**, and [2.2.2]paracyclophane **24**. After usual column chromatography on silica gel and then on silica gel coated with silver nitrate, preparative gel permeation liquid chromatography gave pure **3** (92 mg, 2.3%), colorless prisms from 1 : 1 hexane–benzene, mp 230—231 °C (sealed tube).

MS *m/e* 214 (M^+). Found: C, 78.67; H, 6.36%. Calcd for $C_{14}H_{14}S$: C, 78.48; H, 6.59%.

4,7-Dimethyl[2.2]paracyclo(2,5)thiophenophane **4**. The cross-breeding reaction of the quaternary hydroxides derived from 5-methylthenyltrimethylammonium chloride **12a** (3.0 g, 14.6 mmol) and duryltrimethylammonium chloride **14a** (2.7 g, 11.9 mmol) gave a mixture of **4**, **21b**, and **22b**. The desired cyclophane **4** was separated as in the case of **2**, 50 mg (1.7%), colorless plates from petroleum ether, mp 125.0—126.0 °C.

MS *m/e* 242 (M^+). Found: C, 79.62; H, 7.62; S, 13.06 %. Calcd for $C_{16}H_{18}S$: C, 79.29; H, 7.48; S, 13.23%.

Triple-layered Paracyclofuranophane **5**. The cross-breeding reaction of two quaternary ammonium hydroxides (derived from **11a**, 9.4 g, 33.4 mmol and **15a**, 5.0 g, 13.4 mmol) gave a mixture of **5**, **21a**, and quadruple-layered paracyclophane **25a**. The desired cyclophane **5** was separated by column chromatography on silica gel ,300 mg (6.8%), colorless plates from hexane, mp 117.0—118.0 °C.

MS *m/e* 328 (M^+). Found: C, 87.60; H, 7.16%. Calcd for $C_{24}H_{24}O$: C, 87.76; H, 7.36%.

Dimethyl Triple-layered Paracyclofuranophane **6**. In this case, anion exchange process was carried out by use of silver oxide instead of ion exchange resin. Thus, two quaternary ammonium salts **11a** (0.7 g, 2.5 mmol) and **16a** (1.0 g, 2.5 mmol) were stirred with two equivalents of fresh silver oxide in 30 ml of distilled water for a few hours. After filtration, the aqueous solution was pyrolyzed in the same way as **2**. Column chromatography of the products on silica gel using 1 : 9 benzene–hexane for elution gave first tetramethyl quadruple-layered paracyclophane **25b**, then [2.2](2,5)furanophane **21a** and finally the desired cyclophane **6** (20 mg, 2.2%), colorless prisms from petroleum ether, mp 127.0—128.0 °C.

MS *m/e* 356 (M^+). Found: C, 87.72; H, 7.87%. Calcd for $C_{26}H_{28}O$: C, 87.60; H, 7.91%.

Triple-layered Paracyclothiophenophane **7** *and [2.2.2](2,5)-Thiophenophane* **23**. The cross-breeding reaction of the quaternary hydroxides derived from two ammonium salts **12a** (7 g, 34 mmol) and **15a** (5 g, 13 mmol) and the subsequent column chromatography on silica gel with 1 : 9 benzene–hexane gave first **21b**, and then a mixture of **7** and quadruple-layered paracyclohpane **25a**. From final fraction [2.2.2](2,5)-thiophenophane was obtained as colorless crystals (348 mg, 3.1%), mp 124 °C.

MS *m/e* 330 (M^+). Found: C, 65.45; H, 5.49%. Calcd for $C_{18}H_{18}S_3$: C, 65.44; H, 5.45%.

The desired cyclophane **7** was purified by column chromatography on silica gel coated with silver nitrate, 22 mg (0.5%), colorless prisms from 1 : 3 carbon tetrachloride–acetone, mp 177 °C with dec.

MS *m/e* 344 (M^+). Found: C, 83.50; H, 6.88%. Calcd for $C_{24}H_{24}S$: C, 83.69; H, 7.02%.

Dimethyl Triple-layered Paracyclothiophenophane **8**. As usual, the desired cyclophane **8** was obtained from the cross-breeding reaction of two quaternary ammonium hydroxides (from **12a**, 4 g, 19 mmol and **16a**, 4.6 g, 11 mmol), followed by column chromatography on silica gel and then on silica gel coated with silver nitrate, yield 33 mg (0.8%), colorless plates from petroleum ether, mp 149—151.5 °C with dec.

MS *m/e* 372 (M^+). Found: C, 83.96; H, 7.73%. Calcd for $C_{26}H_{28}S$: C, 83.83; H, 7.58%.

Quadrulpe-layered Paracyclofuranophane **9**. The usual cross-breeding reaction of two quaternary ammonium hydroxides (derived from **11a**, 3.03 g, 10.8 mmol and **17a**, 3.00 g, 6.0 mmol) followed by chromatogrphy on silica gel with 1 : 9 benzene–hexane gave the desired cyclohpane **9** (56 mg, 2%), colorless plates from 1 : 3 carbon tetrachloride–acetone, mp 176—178 °C.

MS *m/e* 458 (M^+). Found: C, 88.94; H, 7.27%. Calcd for $C_{34}H_{34}O$: H, 89.04; H, 7.47%.

Quadruple-layered Paracyclothiophenophane ***10***. The cross-breeding reaction of two quaternary ammonium hydroxides (derived from **12a**, 3.5 g, 17 mmol and **17a**, 3.0 g, 6 mmol) and subsequent purification by column chromatography on silica gel with 1 : 9 benzene–hexane gave the cyclophane **10** (40 mg, 1.4%), colorless prisms from 1 : 3 carbon tetrachloride–acetone, dec 195 °C.

MS *m/e* 474 (M^+). Found: C, 85.30; H, 6.99%. Calcd for $C_{34}H_{34}S$: C, 86.04; H, 7.22%.[24]

Addition Reaction of [2.2]Paracyclo(2,5)furanophane ***1*** *with Benzyne.* Anthranilic acid (525 mg, 3.83 mmol) in 25 ml of 1,2-dimethoxyethane and isopentyl nitrite (672 mg, 5.74 mmol) in 25 ml of 1,2-dimethoxyethane were added dropwise and simultaneouly with stirring for one hour into a refluxed solution of **1** (253 mg, 1.28 mmol) in 25 ml of 1,2-dimethoxyethane. After the addition, reflux was continued for additional 30 min. Sodium hydroxide solution (1.7 M, 300 ml) was added in the cooled mixture, and the mixture was extracted with benzene. The extract was washed with water, dried over anhyd sodium sulfate, and evaporated *in vacuo*. The residue was taken up in carbon tetrachloride and subjected to column chromatography on silica gel or alumina to give the adduct **30** (85 mg, 24%), colorless plates from hexane, mp 84.5—85.5 °C.

MS *m/e* 274 (M^+). Found: C, 87.56; H, 6.43%. Calcd for $C_{20}H_{18}O$: C, 87.56; H, 6.61%.

Addition Reaction of Triple-layered Paracyclofuranophane ***5*** *with Benzyne.* In the same way as **30**, the adduct **33** was obtained from the benzyne reaction of **5** (235 mg, 0.72 mmol), yield 230 mg (79%), colorless columns from toluene, mp 245—252 °C with dec.

MS *m/e* 404 (M^+). Found: C, 89.13; H, 6.84%. Calcd for $C_{30}H_{28}O$: C, 89.07; H, 6.98%.

Addition Reaction of [2.2](2,5)Furanophane ***21a*** *with Benzyne.* [2.2](2,5)Furanophane **21a** (501 mg, 2.66 mmol) was allowed to react with anthranilic acid (1.09 g, 8.0 mmol) and isopentyl nitrite (1.61 ml, 12 mmol) in the same way as **30**. The usual purification of the crude product gave 1 : 2 adduct **36** (142 mg, 16%), colorless plates from toluene, dec 220 °C.

MS *m/e* 340 (M^+). Found: C, 84.85; H, 5.81%. Calcd for $C_{24}H_{20}O_2$: C, 84.68; H, 5.92%.

Hydrogenation of Adduct ***30***. The adduct **30** (85 mg, 0.31 mmol) was hydrogenated in the presence of a 5% Pd–C in 20 ml of tetrahydrofuran until hydrogen absorption was ceased. The mixture was filtered and the filtrate was condensed. Column chromatography of the residue on alumina gave dihydro compound **34** (58 mg, 68%), colorless plates from hexane, mp 95—96 °C.

MS *m/e* 276 (M^+). Found: C, 87.21; H, 6.97%. Calcd for $C_{20}H_{20}O$: C, 86.92; H, 7.26%.

We are grateful to Professor Nobutami Kasai and Dr. Yasushi Kai of Osaka University for their kind information of X-ray crystallographic structures of triple-layered paracycloheterophanes prior to publication and for their helpful discussions. Thanks are also due to Mr. T. Fujino for microanalyses and to Mr. Y. Takai for NMR measurements. This research is partly supported by the Grant-in-Aid of the Ministry of Education.

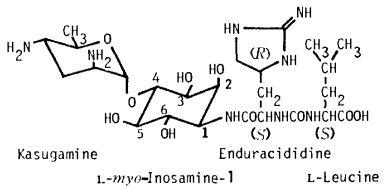
Total Synthesis of Minosaminomycin[1]

Katsuharu IINUMA, Shinichi KONDO,* Kenji MAEDA, and Hamao UMEZAWA
Institute of Microbial Chemistry, 14-23, Kamiosaki 3-chome, Shinagawa-ku, Tokyo 141
(Received January 21, 1977)

A component of the antibiotic minosaminomycin (**1**), (−)-1D-1-amino-1-deoxy-*myo*-inositol (**4**) was synthesized from D-inositol (**3**) by catalytic oxidation of an axial hydroxyl group followed by reduction of the ketoxime. Minobiosamine, 1D-1-amino-1-deoxy-4-*O*-(α-D-kasugaminyl)-*myo*-inositol (**2**), was synthesized from 2′,4′-di-*N*-acetylkasuganobiosamine (**9**) by a similar method, and separated from the two isomers of **2**. The total synthesis of **1** was accomplished by coupling 2′,4′-di-*N*-benzyloxycarbonylminobiosamine (**14**) and N^{α}-[(*S*)-1-benzyloxycarbonyl-3-methylbutylcarbamoyl]enduracididine (**15**) followed by removal of the protective groups. Compound **14** was derived from 1,2′,4′-tri-*N*-benzyloxycarbonylminobiosamine through the formation of the *cis*-1,2-carbamate. A diastereomer of **1** was also synthesized using alloenduracididine.

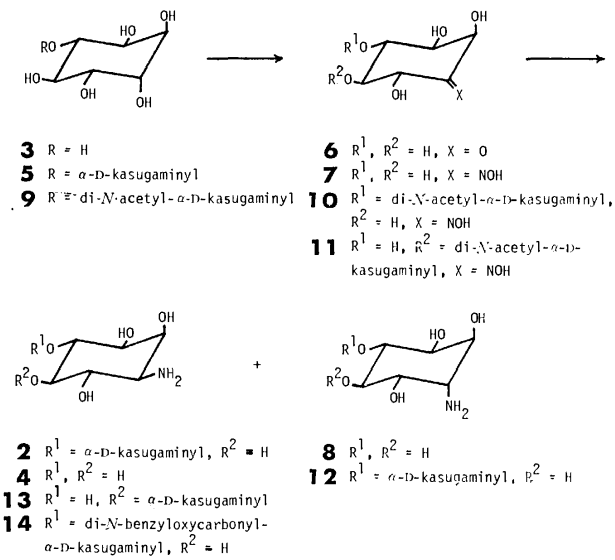
Minosaminomycin (**1**), produced by a streptomyces, inhibits the growth of mycobacteria.[2] The mechanism of action of **1** is similar to that of kasugamycin; that is, **1** inhibits the initiation of protein synthesis in a cell free system of *Escherichia coli* and exhibits stronger inhibition than kasugamycin.[3] The structure of **1** and its partial synthesis from natural minobiosamine (**2**) have been reported in a previous communication.[4] In this paper we report the synthesis of (−)-1D-1-amino-1-deoxy-*myo*-inositol (L-*myo*-inosamine-1) (**4**) from D-inositol (**3**), the synthesis of **2** from kasuganobiosamine[5] (**5**) and the total synthesis of **1**.



1

The absolute structure of the new aminocyclitol **4** determined by application of the TACu method,[2] was confirmed by the following synthesis. Catalytic oxidation of **3** with platinum black by the method of Post and Anderson[6] gave L-*myo*-inosose-1 (**6**).[7] The inosose **6** was treated with hydroxylamine to give a ketoxime (**7**) and then **7** was reduced with sodium amalgam to afford **4** in 16.5% yield from **3** by the method of Anderson and Lardy.[8] The identity of **4** with the natural material was confirmed in all respects. The synthesis of **4** also yielded the new aminocyclitol, (+)-1L-1-amino-1-deoxy-*chiro*-inositol (D-inosamine-2) (**8**) which was isolated by column chromatography on Amberlite CG-50 resin and silica gel in 12.4% yield. The structure of **8** was confirmed by the NMR spectrum of its *N*,*O*-hexaacetate in chloroform-*d*, which showed signals for an axial *O*-acetyl groups (δ 2.16), an axial *N*-acetyl and four equatorial *O*-acetyl groups (δ 2.05×3, 2.03, and 2.00)[9] and by application of the TACu method ($\Delta[M]_{TACu}$ −800°).[10]

Based on the successful synthesis of **4**, we designed a synthesis of **2** from **5** which had been synthesized in the total synthesis of kasugamycin.[11,12] Catalytic oxidation of 2′,4′-di-*N*-acetylkasuganobiosamine[5] (**9**) with platinum black followed by treatment with hydroxylamine gave a mixture of ketoximes **10** and **11**. Reduction of the mixture with sodium amalgam followed by alkaline hydrolysis with 2 M sodium hydroxide afforded a mixture of **2**, 1L-1-amino-1-deoxy-4-*O*-(α-D-kasugaminyl)-*chiro*-inositol (**12**) and 1D-1-amino-1-deoxy-5-*O*-(α-D-kasugaminyl)-*myo*-inositol (**13**) which were separated by column chromatography on Amberlite CG-50 resin in 7.9, 16.3, and 5.4% yields from **9**, respectively. The synthetic **2** was identical with the natural one in all respects. From the NMR spectra of **12** and **13** in deuterium oxide, the 1-amino group was confirmed to have an axial orientation in **12** (H-1: δ 3.76, multiplet having small coupling constants with two vicinal protons), and an equatorial orientation in **13** (H-1: δ 3.25, multiplet having a large coupling constant with one of vicinal protons). Acid hydrolysis of the *N*,*O*-heptaacetate of **12** gave **8**. The NMR spectra of the tri-*N*-acetyl-di-*O*-isopropylidene derivative (**12a**) of **12** (methyl signals of *trans*-*O*-isopropylidene: δ 1.37 and 1.39, *cis*: δ 1.32 and 1.48)[13] and the tri-*N*-acetyl-mono-*O*-isopropylidene derivative (**13a**) of **13** (methyl singals of *cis*-*O*-isopropylidene: δ 1.36 and 1.52) confirmed the structures of **12** and **13**.



3 R = H
5 R = α-D-kasugaminyl
9 R = di-*N*-acetyl-α-D-kasugaminyl

6 R^1, R^2 = H, X = O
7 R^1, R^2 = H, X = NOH
10 R^1 = di-*N*-acetyl-α-D-kasugaminyl, R^2 = H, X = NOH
11 R^1 = H, R^2 = di-*N*-acetyl-α-D-kasugaminyl, X = NOH

2 R^1 = α-D-kasugaminyl, R^2 = H
4 R^1, R^2 = H
13 R^1 = H, R^2 = α-D-kasugaminyl
14 R^1 = di-*N*-benzyloxycarbonyl-α-D-kasugaminyl, R^2 = H

8 R^1, R^2 = H
12 R^1 = α-D-kasugaminyl, R^2 = H

For the total synthesis of **1**, 2′,4′-di-*N*-benzyloxycarbonylminobiosamine[4] (**14**) was prepared from 1,2′,4′-tri-*N*-benzyloxycarbonylminobiosamine in good yield by fromation of a cyclic carbamate with sodium hydride in *N*,*N*-dimethylformamide followed by hydrolysis with 5% barium hydroxide octahydrate solution in 50%

* To whom correspondence should be addressed.

aqueous dioxane at 80 °C.[14] The structure of the cyclic carbamate was shown to be the *cis*-1,2-carbamate of **14** by the NMR spectrum of its mono-*O*-isopropylidene derivative (**14a**) which showed methyl signals for a *trans*-*O*-isopropylidene group at δ 1.38.

The total synthesis of **1** was accomplished in 21% yield by condensation of **14** with N^{α}-[(*S*)-1-benzyloxycarbonyl-3-methylbutylcarbamoyl]enduracididine (**15**) by the activated ester method using 1-hydroxybenzotriazole and dicyclohexylcarbodiimide in *N*,*N*-dimethylformamide[15] followed by catalytic hydrogenation with 5% palladium on carbon in a mixture of methanol, acetic acid and water, as described in a previous communication.[4] The ureylene compound **15** was prepared from L-leucine benzyl ester hydrochloride in 33% yield by treatment with trichloromethyl chloroformate in toluene followed by coupling with enduracididine.[16] Enduracididine found in the antibiotic enduracidin[17] has recently been synthesized from L-histidine by Shiba and coworkers.[18]

We synthesized also a diastereomer (2*R*-isomer) of **1** from alloenduracididine[16] in place of enduracididine. This isomer showed about 20% of the bacteriostatic activity of **1** by the cylinder plate method using *Mycobacterium smegmatis* ATCC 607 as the test organism.

Experimental

Melting points were determined in capillary tubes and uncorrected. IR spectra were measured in KBr pellets with a Hitachi EPI-S2 spectrometer. NMR spectra were obtained on either a Varian A60-D, HA-100D, or XL-100 spectrometer. Chemical shifts in D_2O were recorded in ppm using tetramethylsilane as an external reference. All chemical shifts in other solvents were recorded in ppm downfield from internal tetramethylsilane. Optical rotations were measured with a Carl Zeiss LEP A2 polarimeter. Mass spectra were recorded with a Hitachi RMU-6M spectrometer. In all the experiments, TLC was carried out on silica gel plates (Merck, Art. 5721) and the spots on TLC were visualized with ninhydrin, 10% sulfuric acid, Rydon-Smith,[19] and HBr–ninhydrin (sprayed with 48% hydrobromic acid and heated at 105 °C, then with ninhydrin) reagents. High-voltage paper electrophoresis was carried out with a Model LT-48A from Savant Instruments under 3500 V for 15 min using formic acid–acetic acid–water (1 : 3 : 36) as an electrolyte solution.[19]

L-myo-*Inosamine-1* (*4*) *and* D-*Inosamine-2* (*8*) *from* D-*Inositol* (*3*). According to the method of Post and Anderson,[6] an aqueous solution (70 ml) of **3** (700 mg, 3.9 mmol) was mixed with an aqueous suspension (35 ml) of platinum black prepared from 350 mg of platinum dioxide just before the reaction, and then oxygen gas was bubbled through at 45 °C for 3 h with stirring. The catalyst was removed by filtration and the filtrate was concentrated to dyrness under reduced pressure, yielding a crude powder (752 mg) of L-*myo*-inosose-1 (**6**). By the method of Anderson and Lardy,[8] to an aqueous solution (12 ml) of the crude **6** (602 mg) and hydroxylamine hydrochloride (323 mg, 4.65 mmol), an aqueous solution (6 ml) of sodium acetate (318 mg, 3.88 mmol) was added dropwise under stirring, and the ketoxime (**7**) was formed by further stirring for 2.5 h at room temperature. To the reaction mixture diluted with water (5 ml), 5% sodium amalgam (total 25 g) was added at 10-min intervals for 1 h under stirring and cooling to below 25 °C in a water bath. The pH was held between 5.5 and 6.5 by the occasional addition of acetic acid (4 ml) and the reaction mixture was continuously stirred for 2 h, After removal of mercury by decantation, the supernatant was made up to 200 ml with water and charged on a column of Amberlite CG-50 (a mixture of 70% NH_4^+ form and 30% H^+ form, 80 ml). The column was washed with water (320 ml) and the eluate with 0.15 M ammonia (800 ml) was collected in 8-ml fractions. The ninhydrin-positive fractions (Nos. 59—66) were combined and concentrated to dryness yielding a slightly yellow powder (256 mg). An aqueous solution (4 ml) of the powder was adjusted to pH 8.2 by 1 M hydrochloric acid and rechromatographed on a column of Amberlite CG-50 (NH_4^+ form, 50 ml). The column was washed with water (200 ml) and eluted with 0.05 M ammonia (500 ml). The eluate was collected in 5-ml fractions. Evaporation of the ninhydrin-positive fractions (Nos. 12—31) afforded a white crystalline powder of **8** (69 mg, 12.4% from **3**); mp 192—193 °C (dec), $[\alpha]_D^{22}$ +55.2° (*c* 0.78, water) (lit,[20] L-isomer: mp 200—205 °C (dec), $[\alpha]_D^{23}$ −64.3°), $\Delta[M]_{TACu}$ −800°.[10] MS *m/e* 180 $[(M+1)^+]$, NMR (D_2O) δ 3.86 (1H t, J=3 Hz, H-1) and 3.9—4.6 (5H), TLC (chloroform–methanol–28% ammonia–water, 1 : 4 : 2 : 1) R_f 0.41. Found: C, 39.78; H, 7.19; N, 7.59%. Calcd for $C_6H_{13}NO_5$: C, 40.22; H, 7.31; N, 7.82%.

Evaporation of other ninhydrin-positive fractions (Nos. 49—59) from the rechromatography afforded a crude powder (156 mg) of **4**. The crude powder was chromatographed on a column of silica gel (Wakogel C-200, Wako Pure Chemicals, 15 g) developed with methanol–chloroform–17% ammonia (4 : 1 : 1), affording a white crystalline powder of **4** (91 mg, 16.5% from **3**); mp 207—212 °C (dec), $[\alpha]_D^{25}$ −4.2° (*c* 2.86, water). MS *m/e* 180 $[(M+1)^+]$, NMR (D_2O) δ 3.18 (1H m, H-1), 3.6—4.3 (4H) and 4.48 (1H br, H-2), TLC (chloroform–methanol–28% ammonia–water, 1 : 4 : 2 : 1) R_f 0.35. Found: C, 38.94; H, 7.04; N, 7.91%. Calcd for $C_6H_{13}NO_5 \cdot 1/2H_2O$: C, 38.30; H, 7.50; N, 7.44%.

The hydrochloride of **4** was crystallized from a mixrute of water and ethanol as colorless needles; mp 201—203 °C (dec), $[\alpha]_D^{25}$ −8.9° (*c* 1.35, water) (lit,[2] mp 201—203 °C, $[\alpha]_D^{26}$ −9.5°). This compound was identical with natural **4** hydrochloride ($C_6H_{13}NO_5 \cdot HCl \cdot 1/2H_2O$)[2] in all respects.

N,O-*Hexaacetates of* **4** *and* **8**. Treatment of **4** (47 mg) with acetic anhydride (0.25 ml) in pyridine (0.5 ml) at room temperature for 21.5 h gave mono-*N*-acetyl-penta-*O*-acetyl-L-*myo*-inosamine-1. Crystallization from a mixture of methanol and diethyl ether afforded colorless needles (97 mg); mp 212—214 °C (dec), $[\alpha]_D^{22}$ −15° (*c* 2.92, chloroform). MS *m/e* 432 $[(M+1)^+]$, IR (KBr) 1750 and 1230 (ester C=O), 1690, and 1530 cm^{-1} (amide), NMR ($CDCl_3$) δ 1.91 (3H s, eq NAc), 1.97 (3H s, eq OAc), 2.01 (6H s, eq OAc×2), 2.04 (3H

s, eq OAc), 2.21 (3H s, ax OAc), 4.51 (1H m, H-1), 5.52 (1H t, J=3 Hz, H-2), and 5.81 (1H d, J=9 Hz, amide), TLC (chloroform–ethanol, 10 : 1) R_f 0.65. Found: C, 50.31; H, 5.66; N, 3.65%. Calcd for $C_{18}H_{25}NO_{11}$: C, 50.11; H, 5.84; N, 3.25%.

Treatment of **8** (23 mg) with acetic anhydride (0.25 ml) in pyridine (0.5 ml) at room temperature for 18 h gave mono-*N*-acetylpenta-*O*-acetyl-D-inosamine-2. Crystallization from diethyl ether afforded colorless crystals (56 mg); mp 151—152 °C (dec), $[\alpha]_D^{23}$ −1.7° (*c* 0.67, chloroform). MS *m/e* 432 [(M+1)$^+$], IR (KBr) 1755 and 1230 (ester C=O), 1650 and 1550 cm^{-1} (amide), NMR ($CDCl_3$) δ 2.00 (3H s, eq OAc), 2.03 (3H s, eq OAc or ax NAc), 2.05 (9H s, eq OAc or ax NAc×3), 2.16 (3H s, ax OAc), 4.71 (1H m, H-1), and 6.51 (1H d, J=8 Hz, amide), TLC (chloroform–ethanol, 10 : 1) R_f 0.56. Found: C, 49.99; H, 5.62; N, 4.08%. Calcd for $C_{18}H_{25}NO_{11}$: C, 50.11; H, 5.84; N, 3.25%.

*Minobiosamine (**2**) and Its Isomers (**12** and **13**) from Kasuganobiosamine (**5**).* According to the method of Suhara *et al.*[5] 2′,4′-di-*N*-acetylkasuganobiosamine (**9**) was derived from **5**. An aqueous solution (200 ml) of **9** (2.0 g, 5.1 mmol) was mixed with an aqueous suspension (100 ml) of platinum black which was prepared from 1.0 g of platinum dioxide, and then oxygen gas was bubbled through at 45 °C for 2.5 h with stirring.[6] The catalyst was removed by filtration and the filtrate was concentrated to dryness yielding a mixture (1.75 g) of oxo compounds. To an aqueous solution (30 ml) containing the mixture (1.48 g) and hydroxylamine hydrochloride (396 mg, 5.7 mmol), an aqueous solution (15 ml) of sodium acetate (390 mg, 4.75 mmol) was added dropwise under stirring at room temperature, and stirring was continued for 2 h. The reaction mixture was concentrated to dryness yielding a mixture (1.946 g) of ketoximes **10** and **11**. The ketoxime (896 mg) in water (15 ml) was reduced with 25 g of 5% sodium amalgam in the same manner as described for **7**. After removal of mercury by decantation, the supernatant was concentrated to dryness. The residue was dissolved in 2 M sodium hydroxide (40 ml) and refluxed for 15 h in an oil bath at 125 °C to remove the acetyl groups. After neutralization with acetic acid (4.8 ml), the solution was made up to 400 ml with water and charged on a column of Amberlite CG-50 (a mixture of 70% NH_4^+ form and 30% H^+ form, 150 ml). The column was washed with water (600 ml) and the eluate with 900 ml of 0.5 M ammonia was collected in 15-ml fractions. Ninhydrin-positive fractions (Nos. 27—31) were combined and concentrated to dryness yielding a white powder (271 mg). It was dissolved in 5 ml of water and rechromatographed on a column of Amberlite CG-50 (NH_4^+ form, 80 ml). The column was washed with water (160 ml) and products were eluted with 0.1 M ammonia. The eluate was collected in 4-ml fractions which were examined by TLC with chloroform–methanol–28% ammonia–water (1 : 4 : 2 : 1). The fractions (Nos. 40—47) with R_f 0.69 were combined and concentrated to dryness yielding an epimer of **2**, 1L-1-amino-1-deoxy-4-*O*-(α-D-kasugaminyl)-*chiro*-inositol (**12**), as a white powder (81 mg, 16.3% from **9**); mp 104—115 °C (dec), $[\alpha]_D^{27}$ +117° (*c* 0.3, water). MS *m/e* 308 [(M+1)$^+$], NMR (D_2O) δ 1.72 (3H d, J=6 Hz, H-6′), 2.38 (2H m, H-3′), 3.44 (1H m, H-4′), 3.76 (2H, H-1 and -2′), and 5.43 (1H br, H-1′).

The fractions (Nos. 60—79) which contained material with R_f 0.64 were combined and concentrated to dryness yielding a positional isomer of **2**, 1D-1-amino-1-deoxy-5-*O*-(α-D-kasugaminyl)-*myo*-inositol (**13**), as a white powder (27 mg, 5.4% from **9**); mp 112—128 °C (dec), $[\alpha]_D^{27}$ +76° (*c* 0.59, water). MS *m/e* 308 [(M+1)$^+$], NMR (D_2O) δ 1.71 (3H d, J=6 Hz, H-6′), 2.36 (2H m, H-3′), 3.10—3.55 (2H, H-1 and -4′), 3.71 (1H m, H-2′), and 5.46 (1H d, J=2 Hz, H-1′).

The fractions (Nos. 80—102) with R_f 0.66 by TLC were combined and concentrated to dryness affording a white powder (39 mg, 7.9% from **9**) of **2**; mp 126—128 °C (dec), $[\alpha]_D^{32}$ +82.5° (*c* 1.0, water) (lit,[4] mp 126—128 °C (dec), $[\alpha]_D^{29}$ +81°). MS *m/e* 308 [(M+1)$^+$], NMR (D_2O) δ 1.69 (3H d, J=6 Hz, H-6′), 2.24 (2H m, H-3′), 2.95—3.38 (2H m, H-1 and -4′) 3.58 (1H m, H-2′), and 5.37 (1H d, J=2 Hz, H-1′). Found: C, 44.52; H, 8.38; N, 12.45%. Calcd for $C_{12}H_{25}N_3O_6\cdot H_2O$: C, 44.29; H, 8.36; N, 12.93%.

N,O-*Heptaacetate of **2**.* Treatment of **2** (37 mg) with acetic anhydride (0.4 ml) in pyridine (0.8 ml) at room temperature for 18 h afforded the *N,O*-heptaacetate of **2**. Crystallization from a mixture of methanol and diethyl ether gave colorless needles (48 mg); mp 273—274 °C (dec), $[\alpha]_D^{25}$ +4.3° (*c* 2.55, chloroform). MS *m/e* 602 [(M+1)$^+$], IR (KBr) 1755 and 1230 (ester C=O), 1660 and 1550 cm^{-1} (amide), NMR ($CDCl_3$) δ 1.14 (3H d, J=6 Hz, H-6′), 1.75 (2H m, H-3′), 1.89 (3H s, 1-eq NAc), 1.95, 1.98, 2.01, 2.04, 2.15 (each 3H s, eq OAc×3, 2′-NAc and 4′-NAc), 2.18 (3H s, 2-ax OAc), and 6.1—6.8 (3H, amides), TLC (chloroform–ethanol, 10 : 1) R_f 0.26. Found: C, 51.52; H, 6.25; N, 6.56%. Calcd for $C_{26}H_{39}N_3O_{13}$: C, 51.91; H, 6.53; N, 6.99%. It was identical with the *N,O*-heptaacetate derived from natural **2** in all respects.

N,O-*Heptaacetates of **12** and **13**.* Compound **12** (79 mg) was treated with acetic anhydride (0.75 ml) in pyridine (1.6 ml) at room temperature for 18 h and the reaction mixture was concentrated to dryness. The residue was chromatographed on a column of silica gel (Wakogel C-200, 14 g) developed with chloroform–ethanol (10 : 1). Fractions containing the *N,O*-heptaacetate of **12** were combined and concentrated to dryness yielding a white crystalline powder (127 mg); mp 158—160 °C (dec), $[\alpha]_D^{24}$ +29° (*c* 0.74, chloroform). MS *m/e* 602 [(M+1)$^+$], NMR ($CDCl_3$) δ 1.17 (3H d, J=6 Hz, H-6′), 1.80 (2H m, H-3′), 1.97, 2.00, 2.02, 2.04, 2.05, 2.11 (each 3H s, eq OAc ×3, 1-ax NAc, 2′-NAc and 4′-NAc), 2.12 (3H s, 2-ax OAc), and 6.2—7.2 (3H, amides), TLC (chloroform–ethanol, 10 : 1) R_f 0.15.

Treatment of **13** (25 mg) with acetic anhydride (0.25 ml) in pyridine (0.5 ml) at room temperature for 18 h followed by column chromatography on silica gel (Wakogel C-200, 4.5 g) developed with chloroform–ethanol (20 : 1) gave a white crystalline powder of the *N,O*-heptaacetate of **13** (30 mg); mp 172—177 °C (dec). MS *m/e* 602 [(M+1)$^+$], NMR ($CDCl_3$) δ 1.12 (3H d, J=6 Hz, H-6′), 1.75 (2H m, H-3′), 1.89 (3H s, 1-eq NAc), 1.95, 1.97, 1.99, 2.07, 2.11 (each 3H s, eq OAc×3, 2′-NAc and 4′-NAc), 2.20 (3H s, 2-ax OAc), and 6.0—6.7 (3H, amides), TLC (chloroform–ethanol, 10 : 1) R_f 0.20.

Hydrolysis of the N,O-*Heptaacetate of **12**.* The *N,O*-heptaacetate of **12** (45 mg) was hydrolyzed with 6 M hydrochloric acid (2 ml) by refluxing in an oil bath at 100 °C for 5 h and the reaction mixture was concentrated to dryness. The residue was chromatographed on a column of Amberlite CG-50 (NH_4^+ form, 5 ml) eluted with 0.05 M ammonia (50 ml). The eluate containing **8** was concentrated to dryness yielding a white crystalline powder of **8** (11 mg, 82%).

*1L-1-Acetamido-1-deoxy-4-*O*-(di-*N*-acetyl-α-D-kasugaminyl)-2,3 : 5,6-di-*O*-isopropylidene*-chiro*-inositol (**12a**).* Compound **12** (20 mg, 0.067 mmol) was treated with acetic anhydride (0.3 ml) in methanol (0.6 ml) at room temperature for 6.5 h and the reaction mixture was concentrated to dryness yielding a slightly yellow powder (26 mg) of the tri-*N*-acetate of **12**. To a solution of this powder in dry *N,N*-dimethylformamide (0.6 ml) were added 2,2-dimethoxypropane (62 mg, 0.6 mmol) and *p*-toluenesulfonic acid monohydrate (1.4 mg

0.006 mmol). The reaction mixture was heated at 60 °C for 2 h under stirring. After neutralization with triethylamine (1.2 mg), the reaction mixture was concentrated to dryness. Purification by column chromatography on silica gel (Silic AR CC-7, Mallinckrodt, 4 g) developed with chloroform–ethanol (12 : 1) gave a white powder of **12a** (13 mg); mp 177—181 °C (dec), $[\alpha]_D^{23}$ +111° (*c* 0.73, methanol). IR (KBr) 1650 and 1545 cm^{-1} (amide), NMR (CD_3OD) δ 1.15 (3H d, J=6 Hz, H-6′), 1.32, 1.37, 1.39, 1.48 (each 3H s), 1.80 (2H m, H-3′), 1.91 (3H s, NAc), 1.99 (6H s, NAc×2), and 4.97 (1H br, H-1′), TLC (chloroform–ethanol, 1 : 1) R_f 0.81.

1-D-*1-Acetamido-1-deoxy-5-*O-*(di-*N-*acetyl-α-*D-*kasugaminyl)-2,3-*O-*isopropylidene-*myo-*inositol (**13a**).* Treatment of **13** (4.0 mg, 0.013 mmol) with acetic anhydride (0.05 ml) in methanol (0.15 ml) at room temperature for 7 h afforded a slightly yellow powder (5.0 mg) of the tri-*N*-acetate of **13**. Treatment of this powder in dry *N,N*-dimethylformamide (0.2 ml) with 2,2-dimethoxypropane (12 mg, 0.115 mmol) and *p*-toluenesulfonic acid monohydrate (0.2 mg, 0.001 mmol) at 60 °C for 2 h followed by neutralization with triethylamine (0.2 mg) and evaporation gave a crude powder. Purification by column chromatography on silica gel (Silic AR CC-7, 800 mg) developed with chloroform–ethanol (4 : 1) yielded a white crystalline powder of **13a** (2.9 mg); mp 157—162 °C (dec), $[\alpha]_D^{24}$ +64° (*c* 0.43, chloroform–ethanol (4 : 1)). IR (KBr) 1640 and 1540 cm^{-1} (amide), NMR (CD_3OD–$CDCl_3$ (1 : 1)) δ 1.16 (3H d, J=6 Hz, H-6′), 1.36, 1.52 (each 3H s), 1.85 (2H m, H-3′), 1.97, 2.02, 2.06 (each 3H s, NAc×3), and 5.01 (1H br, H-1′), TLC (chloroform–ethanol, 1 : 1) R_f 0.59.

*2′,4′-Di-*N*-benzyloxycarbonylminobiosamine (**14**).* To a solution of **2** (1.03 g, 3.35 mmol) and sodium hydrogencarbonate (1.1 g, 13 mmol) in water (15 ml), benzyloxycarbonyl chloride (1.88 g, 11 mmol) was added dropwise. The mixture was stirred for 1.5 h in an ice bath and then allowed to stand overnight at room temperature. The resulting precipitate was filtered and washed with water (30 ml) and diethyl ether (50 ml) to give a colorless powder of 1,2′,4′-tri-*N*-benzyloxycarbonylminobiosamine (2.02 g, 85%); mp 171—172 °C (dec), $[\alpha]_D^{24}$ +33° (*c* 1.0, *N,N*-dimethylformamide). IR (KBr) 1690 and 1525 cm^{-1} (amide), NMR (CD_3COCD_3) δ 1.15 (3H d, J=6 Hz, H-6′), 2.02 (2H m, H-3′), 5.06 (6H s, CH_2-ar), 5.16 (1H br, H-1′), and 7.34 (15H, ar), TLC (chloroform–methanol, 10 : 1) R_f 0.60. Found: C, 60.25; H, 6.41; N, 5.97%. Calcd for $C_{36}H_{43}N_3O_{12}$: C, 60.92; H, 6.11; N, 5.92%.

To a solution of 1,2′,4′-tri-*N*-benzyloxycarbonylminobiosamine (1.50 g, 2.1 mmol) in dry *N,N*-dimethylformamide (15 ml), 50% sodium hydride (273 mg, 5.7 mmol) was added, and the mixture was stirred for 4.5 h in an ice bath under a stream of nitrogen. After neutralization with acetic acid (0.36 ml), the solution was concentrated to dryness. A solution of the residue in ethyl acetate (50 ml) was washed with water (10 ml), dehydrated with anhydrous sodium sulfate, and evaporated to give a pale yellow oil (2.0 g). The oil was chromatographed on a column of silica gel (Silic AR CC-7, 100 g) developed with chloroform–methanol (10 : 1). Fractions containing 2′,4′-di-*N*-benzyloxycarbonylminobiosamine-1,2-carbamate were combined and concentrated to dryness yielding a white powder (970 mg, 77%); mp 115—118 °C (dec), $[\alpha]_D^{25}$ +45° (*c* 1.0, chloroform). IR (KBr) 1750 (C=O), 1690, and 1525 cm^{-1} (amide), NMR ($CDCl_3$) δ 1.14 (3H br, H-6′), 1.84 (2H m, H-3′), 4.98 (4H s, CH_2-ar ×2), and 7.22 (10H, ar), TLC (1-butanol–ethanol–chloroform–17% ammonia, 4 : 5 : 2 : 1) R_f 0.52. Found: C, 57.50; H, 6.96; N, 6.80%. Calcd for $C_{29}H_{35}N_3O_{11}$: C, 57.90; H, 6.86; N, 6.99%.

A solution containing the carbamate (914 mg, 1.52 mmol) and barium hydroxide octahydrate (765 mg, 2.34 mmol) in 50% aqueous dioxane (29 ml) was heated at 80 °C for 6 h. The reaction mixture was neutralized with carbon dioxide, and the resulting precipitates were removed by filtration. The filtrate was concentrated to give a solid (793 mg), which was chromatographed on a column of silica gel (Silic AR CC-7, 80 g) developed with 1-butanol–ethanol–chloroform–17% ammonia (8 : 10 : 4 : 1). Fractions containing **14** were combined and concentrated to dryness yielding a white powder of **14** (556 mg, 64%); mp 123—126 °C (dec), $[\alpha]_D^{24}$ +43° (*c* 1.0, *N,N*-dimethylformamide). IR (KBr) 1690 and 1520 cm^{-1} (amide), NMR (CD_3OD) δ 1.13 (3H d, J=6 Hz, H-6′), 1.88 (2H m, H-3′), 2.62 (1H m, H-1), 5.04 (5H, H-1′ and CH_2-ar), and 7.30 (10H, ar), TLC (1-butanol–ethanol–chloroform–17% ammonia, 4 : 5 : 2 : 1) R_f 0.24. Found: C, 56.77; H, 6.67; N, 7.12%. Calcd for $C_{28}H_{37}N_3O_{10}\cdot H_2O$: C, 56.65; H, 6.62; N, 7.08%.

*2′,4′-Di-*N*-benzyloxycarbonyl-5,6-*O*-isopropylideneminobiosamine-1,2-carbamate (**14a**).* To a solution of 2′,4′-di-*N*-benzyloxycarbonylminobiosamine-1,2-carbamate (17 mg, 0.029 mmol) in dry *N,N*-dimethylformamide (0.3 ml) were added 2,2-dimethoxypropane (31 mg, 0.3 mmol) and *p*-toluenesulfonic acid monohydrate (0.7 mg, 0.003 mmol). The mixture was heated at 60 °C for 2 h under stirring. After neutralization with triethylamine (0.6 mg), the reaction mixture was concentrated to dryness. Purification by column chromatography on silica gel (Silic AR CC-7, 3 g) developed with chloroform–ethanol (30 : 1) gave a white crystalline powder of **14a** (14.7 mg); mp 121—124 °C (dec), $[\alpha]_D^{23}$ +49.5° (*c* 0.85, methanol). IR (KBr) 1755 (C=O), 1700, and 1520 cm^{-1} (amide), NMR (CD_3OD) δ 1.19 (3H d, J=6 Hz, H-6′), 1.38 (6H s), 1.90 (2H m, H-3′), 4.92 (1H br, H-1′), 5.08 (4H s, CH_2-ar), and 7.32 (10H, ar), TLC (chloroform–ethanol, 10 : 1) R_f 0.50.

*Minosaminomycin (**1**).* To a solution of L-leucine benzyl ester hydrochloride (206 mg, 0.8 mmol) in dry toluene (4 ml), trichloromethyl chloroformate (336 mg, 1.7 mmol) was added. After refluxing for 4.5 h in an oil bath at 130 °C, the reaction mixture was evaporated to give a colorless oil of the isocyanate of L-leucine benzyl ester (189 mg, 95%); $n_D^{25.5}$ 1.4987, $[\alpha]_D^{26}$ −29° (*c* 1.55, toluene). IR (KBr) 2200 (N=C=O) and 1740 cm^{-1} (ester C=O), NMR ($CDCl_3$) δ 0.90 (6H d, J=5 Hz, CH_3×2), 1.4—2.0 (3H m, CH_2–CH), 4.10 (1H dd, J=7, 8 Hz, α-methine), 5.26 (2H s, CH_2-ar), and 7.42 (5H, ar).

A solution containing the isocyanate (189 mg, 0.77 mmol) and enduracididine (73 mg, 0.43 mmol) in dry dimethyl sulfoxide (4.5 ml) was stirred at room temperature for 17.5 h and then freeze dried to give a colorless oil (350 mg). Purification of the oil by column chromatography on silica gel (Silic AR CC-7, 36 g) developed with 1-butanol–ethanol–water (10 : 1 : 1) gave a white powder of N^{α}-[(*S*)-1-benzyloxycarbonyl-3-methylbutylcarbamoyl]enduracididine (**15**) (64 mg, 33% from enduracididine). To a methanolic solution (1 ml) of **15**, 0.5 M hydrochloric acid (0.28 ml) was added, and the solution was concentrated to dryness yielding a white powder (67 mg) of the monohydrochloride of **15**. To a solution containing the monohydrochloride (64 mg, 0.13 mmol) and 1-hydroxybenzotriazole[15] (22 mg, 0.16 mmol) in dry *N,N*-dimethylformamide (1.5 ml) was added a solution of **14** (77 mg, 0.13 mmol) in dry *N,N*-dimethylformamide (2 ml) and then dicyclohexylcarbodiimide (28 mg, 0.13 mmol). The mixture was stirred at 0 °C for 1 h and then at room temperature for 22.5 h. The dicyclohexylurea formed was removed by filtration and the filtrate was concentrated to dryness yielding a solid (202 mg). To remove the *N*-benzyl-

oxycarbonyl and benzyl ester groups, this solid in a mixture of methanol (3 ml), water (1 ml), and acetic acid (1 ml) was hydrogenated with 5% palladium on carbon (126 mg) under atmospheric pressure for 5 h. The catalyst was removed by filtration and the filtrate was concentrated to dryness yielding a white powder. An aqueous solution of the powder was charged on a column of Amberlite CG-50 (a mixture of 70% NH_4^+ form and 30% H^+ form, 5 ml). The column was washed with water (20 ml) and **1** was eluted with 0.15 M ammonia. Fractions containing **1** detected by high-voltage paper electrophoresis were combined and concentrated to dryness yielding a crude powder of **1** (35.8 mg). Purification by rechromatogrphy on a column of Amberlite CG-50 (NH_4^+ form, 5 ml) eluted with 0.05 M ammonia (50 ml) gave a white powder of **1** (17 mg, 21% from **15**); mp 225—260 °C (dec), $[\alpha]_D^{23}$ +28.4° (*c* 0.53, water) (lit,[2]) mp 225—260 °C (dec), $[\alpha]_D^{22}$ +30°). It was identical with natural **1** ($C_{25}H_{46}N_8O_{10}\cdot 2H_2O$) in all respects including biological activity.

2R-Isomer of 1. A diastereomer (2*R*-isomer) of **1** was synthesized using alloenduracididine with the method described for **1**. To a solution of alloenduracididine (51 mg, 0.3 mmol) in dry dimethyl sulfoxide (4 ml) was added the isocyanate of L-leucine benzyl ester (146 mg, 0.6 mmol) in dry dimethyl sulfoxide (1 ml). The mixture was stirred at room temperature for 22.5 h, and freeze-dried to give a slightly yellow oil (280 mg). The oil was chromatographed on a column of silica gel (Wokogel C-200, 28 g) developed with 1-butanol–ethanol–water (10 : 1 : 1) and a white powder (23 mg, 17% from alloenduracididine) of the 2*R*-isomer of **15** was obtained. The monohydrochloride of the 2*R*-isomer of **15** was prepared by addition of 0.5 M hydrochloric acid (0.08 ml) in a methanolic solution (0.5 ml). To a solution of the monohydrochloride in dry *N,N*-dimethylformamide (0.5 ml) was added **14** (33 mg, 0.057 mmol) in dry *N,N*-dimethylformamide (0.5 ml), 1-hydroxybenzotriazole (11.5 mg, 0.085 mmol), and dicyclohexylcarbodiimide (10.7 mg, 0.052 mmol). The mixture was stirred at 0 °C for 1 h and then at room temperature for 26.5 h. The dicyclohexylurea formed was removed by filtration and the filtrate was concentrated to give a solid (83.4 mg). This solid in a mixture (2.5 ml) of methanol, water, and acetic acid (3 : 1 : 1) was hydrogenated with 5% palladium on carbon (50 mg) under atmospheric pressure for 6.5 h. After removal of the catalyst, the solution was concentrated to dryness. The residue was purified by column chromatography with Amberlite CG-50 (a mixture of 70% NH_4^+ form and 30% H^+ form, 5 ml) eluted with 0.15 M ammonia to yield a crude powder (15.6 mg). The crude powder was rechromatographed on a column of Amberlite CG-50 (NH_4^+ form, 5 ml) eluted with 0.05 M ammonia to give a white powder (2.9 mg, 9% from the 2*R*-isomer of **15**) of the pure 2*R*-isomer of **1**; mp 195—220 °C (dec), $[\alpha]_D^{27}$ +42° (*c* 0.95, water). IR (KBr) 1660 and 1570 cm^{-1} (amide), TLC (1-butanol–ethanol–chloroform–17% ammonia, 4 : 5 : 2 : 5) R_f 0.13.

We wish to express our deep gratitude to Emeritus Professor Sumio Umezawa, Keio University, for his encouragement through the course of this work. We also wish to thank Dr. I. R. Hooper, Bristol Laboratories, for critical reading of the manuscript.

ESR Studies of *N*-(Arylthio)-*t*-butylaminyls[1]

Yozo MIURA, Hidetsugu ASADA, and Masayoshi KINOSHITA

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received January 21, 1977)

It was found that *N*-(arylthio)-*t*-butylaminyls (**2**) are easily generated by the photolysis of *N*-*t*-butylbenzenesulfenamides (**1**). The ESR spectra of **2** were split into a 1 : 1 : 1 triplet by the interaction with the nitrogen nucleus (11.70—11.89 G), and each of the triplet was further split by the ring protons ($a_{o\text{-}H}$: 0.89—1.07 G). The *g*-values of **2** lie in the range from 2.0068—2.0073. The radicals persist in benzene and it appears that they are not sensitive to the atmospheric oxygen.

A number of nitrogen-centered free radicals have so far been prepared and extensive ESR spectroscopic studies of these radicals have been undertaken.[2] In the course of ESR studies on nitrogen-centered free radicals containing sulfur atoms adjacent to the radical center, it was found that *N*-(arylthio)-*t*-butylaminyls (**2**) can easily be generated by the photolysis of *N*-*t*-butylbenzenesulfenamides (**1**). Up to the present time, some structually related radicals have been detected, *e.g.* $2\text{-}NO_2C_6H_4\dot{S}NH$,[3] $Me_3C\dot{N}SN(CMe_3)MR_n$,[4] $Ar\dot{N}S\text{-}Ar'$,[1,5,6] and $4\text{-}ClC_6H_4\dot{S}NR$.[7] The last-mentioned radical, which was detected as an intermediate radical upon the thermal decomposition of *N*-alkenyl-*N*-(2,3-dihydro-2-oxobenzoxazol-3-yl)-*p*-chlorobenzenesulfenamides, is closely related to that examined in the present experiment. However, a detailed ESR spectroscopic investigation of $R\dot{N}SAr$ has not been undertaken. In this report, an ESR spectroscopic investigation of **2** will be described.

$$t\text{-Bu-NH-S-Ar} \xrightarrow{-H\cdot} t\text{-Bu-}\dot{N}\text{-S-Ar}$$

1 **2**

Ar: **a**=C_6H_5, **b**=4-FC_6H_4, **c**=4-ClC_6H_4, **d**=4-BrC_6H_4, **e**=4-$NO_2C_6H_4$

Results and Discussion

Generation of the Radicals. One of the most conventional methods for generating the desired free radicals is hydrogen-abstruction from an appropriate precursor by a *t*-butoxyl radical. This method was first employed for the generation of **2**. In a typical procedure, after a benzene solution of **1c** and di-*t*-butyl peroxide had been degassed, it was irradiated with a high-pressure mercury lamp. From the solution, two paramagnetic species were detected. The ratio drived from the intensities of the respective ESR signals was *ca.* 1 : 2. The stronger signal was present in the form of a 1 : 1 : 1 triplet (11.75 G) with each the triplet further split into a poorly-resolved 1 : 2 : 1 triplet (0.93 G). The *g*-value of the radical was found to be 2.0071. From these results, the radical was assigned to the desired radical, *N*-(4-chlorophenylthio)-*t*-butylaminyl (**2c**). The ESR parameters are close to those reported for $4\text{-}ClC_6H_4\dot{S}NR$ (a_N: 11 G, *g*-value: 2.0073).[7] The other radical resulted in a simple 1 : 1 : 1 triplet (a_N: 14.11 G) and its *g*-value was found to be 2.0051. These ESR parameters are close to those reported for *N*-alkoxyalkylaminyls.[8] Thus, it appears likely that it is an *N*-alkoxyalkylaminyl, *N*-(*t*-butoxy)-*t*-butylaminyl.[9] In the ESR spectrum obtained by this procedure, the two signals partially overlapped. Thus, it was difficult to accurately determine the ESR parameters of **2**. For this reason, another procedure for the generation of **2** was examined. It was found that after a degassed benzene solution containing **1** alone had been irradiated with a high-pressure mercury lamp, only **2** was detected in the solution. In this case, the mechanism for the generation of **2** may be illustrated as follows:

$$\mathbf{1} \xrightarrow{h\nu} t\text{-Bu-}\dot{N}\text{H} + \text{ArS}\cdot$$

$$\downarrow \mathbf{1}$$

$$t\text{-Bu-NH}_2 + \mathbf{2}$$

A typical ESR spectrum of **2** is illustrated in Fig. 1, and the ESR parameters for **2** are listed in Table.

Although the coupling due to the *ortho* and *para* protons could be observed for all the radicals, the values of coupling constant for the ring protons of **2a** could not be accurately determined because of poor resolution. In **2b**, further coupling due to the fluorine nucleus was observed in addition to that due to the ring protons (Fig. 2).

Radical **2** was also generated by oxidation with lead dioxide and potassium carbonate. A benzene solution of **1** was stirred for 5 min in the presence of the oxidizing agents under ambient conditions and, after the oxidizing agents were removed, only **2** was detected in the solution.

On the other hand, the ESR parameters for *t*-butyl arylthio nitroxide radicals (in benzene) are 15.90—

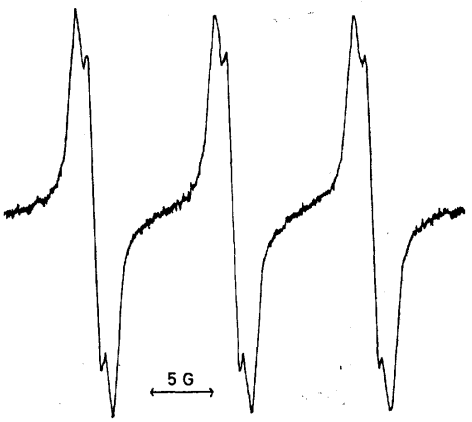

Fig. 1. Experimental ESR spectrum of *N*-(4-chlorophenylthio)-*t*-butylaminyl in benzene at room temperature.

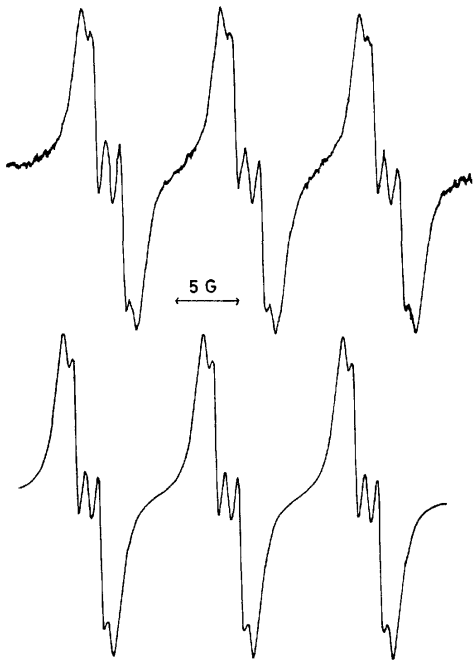

Fig. 2. Experimental ESR spectrum of *N*-(4-fluorophenylthio)-*t*-butylaminyl (**2b**) in benzene at room temperature (upper), and computer simulated, using Lorentzian line shapes and a line width of 0.96 G.

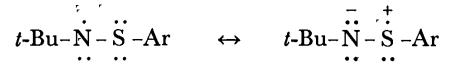
18.03 G (a_N) and 2.0066—2.0067 (*g*-value).[10,11] On the basis of these results, it is obvious that radical **2** is not the corresponding nitroxide radical.

From the ESR parameters shown in the table, it can be safely said that in **2** the unpaired electron is mainly located on the nitrogen ($2p_z$ orbital) because of the large a_N values. Considering the *g*-values, they are rather large for a nitrogen-centered free radical. This indicates that extent of delocalization of the spin onto the adjacent sulfur is not small.[12] In comparing the ESR parameters for **2** with those of the other related radicals described above, the values of a_N for **2** are somewhat smaller than those for $Me_3CNS(Me_3)MR_n$-[$a_N(\alpha)$: 12.0—12.6 G],[5] and are considerably larger than those for ArNSAr′ (8.74—9.59 G).[6] This can be explained in terms of the larger ability of the phenyl rings to delocalize an unpaired electron in comparison with the $-SN(CMe_3)MR_n$ or the *t*-butyl group.

Decay Kinetics of the Radicals. Decay kinetic investigations were performed, and the results are illustrated in Fig. 3. As can be seen from the figure, the radicals are fairly long-lived.[7] This may be explained by a) the protection by the *t*-butyl group of the radical center and b) the absence of hydrogen atoms at the β position. In addition to this explanation, it appears likely that Form II makes an important contribution to the persistence.[6]



Form I. Form II.

Moreover, decay kinetics were carried out both in the presence and absence of the atmosphere in order to examine whether or not radical **2** reacts with oxygen.

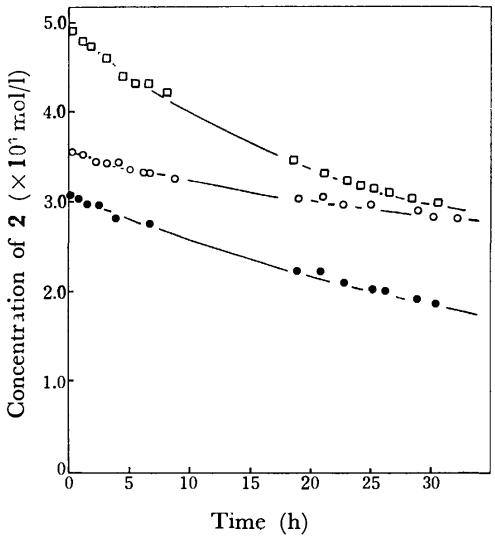


Fig. 3. Decay plots of *N*-(arylthio)-*t*-butylaminyls (**2**) in benzene at 15 °C; (□): **2a** in the absence of oxygen, (○): **2c** in the absence of oxygen, (●): **2c** in the presence of oxygen.

TABLE. ESR PARAMETERS FOR *N*-(ARYLTHIO)-*t*-BUTYLAMINYLS[a]

t-Bu-N-S-Ar	Ar	Coupling constant a_N	$a_{o\text{-H}}$	a_{other}	*g*-Value
2a	C_6H_5	11.70			2.0069
2b[b]	4-FC_6H_4	11.83	0.89	2.22 (a_F)	2.0070
2c	4-ClC_6H_5	11.75	0.93		2.0071
2d	4-BrC_6H_4	11.76	1.00		2.0072
2e	4-$NO_2C_6H_4$	11.89	1.07		2.0068

a) In benzene at room temperature (15 °C). b) The coupling constants were determined by computer simulation.

In both cases, radical **2c** decayed at about the same rate. On the other hand, the *t*-butyl arylthio nitroxide radicals,[11] which were generated by the photolysis of diaryl disulfide in the presence of 2-methyl-2-nitrosopropane, decayed comletely within 20 s after turning off of the mercury lamp used to produce the arylthiyl radicals from the diaryl disulfides. This indicates that the *t*-butyl arylthio nitroxide radicals are extremely short-lived. From these results, it appears that **2** is not sensitive to the atmospheric oxygen.

Experimental

All melting points are uncorrected. The IR spectra were obtained on a Jasco model IR-G Spectrometer. The NMR spectra were recorded on a Hitachi-Perkin-Elmer R-20 Spectrometer using TMS as an internal standard.

Materials. The benzene used for the ESR measurements was purified by the usual method.[13] Benzenethiol, 4-chlorobenzenethiol, and *t*-butylamine were obtained commercially and used without further purification. 4-Fluoro-,[14] 4-bromo-,[15] and 4-nitrobenzenethiol[16] were prepared by the reported methods.

General Procedure for Preparation of N-t-*Butylbenzenesulfen-*

amides (1). Benzenethiol was treated with chlorine gas in dry chloroform at −5 to 0 °C. After removal of chloroform, the residual oil was distilled (56—57 °C/3 Torr for benzenesulfenyl chloride, and other sulfenyl chlorides were used in the following step without distillation).

A solution of *t*-butylamine (0.050 mol) and triethylamine (0.050 mol) in dry diethyl ether (ether, 200 ml) was cooled to 0 °C. To the solution was added dropwise benzenesulfenyl chloride (0.045 mol) in dry ether (30 ml) with stirring. After the addition of the sulfenyl chloride, the reaction mixture was further stirred at 0 °C for 30 min. After the triethylamine hydrochloride had been filtered off, ether was evaporated to give crude **1**. The purification of **1** is described below for each case. The purities of the **1** prepared were examined by TLC [alumina (E. Merck GF_{254})–hexane for **1a**—**d** and benzene–hexane (1 : 1 in vol) for **1e**].

N-t-*Butylbenzenesulfenamide (1a).* After the residue had been distilled (60—62 °C/0.07 Torr), a small amount of hexane (*ca.* 1 ml) was added to the distillate and the solution was cooled to −20 °C, giving colorless prisms. The parent solution was decanted, the residual crystals were then dissolved in hexane and the resulting solution was again cooled to −20 °C. This cycle was repeated several times, and finally, the crystals were dried in a vacuum at 0 °C. Yield 45% (before recrystallization). n_D^{25}: 1.5429 (lit,[17] n_D^{25}: 1.5435)). NMR (CCl_4): δ 1.17 (s, *t*-Bu), 2.65 (bs, NH), and 6.86—7.32 (m, C_6H_5).

N-t-*Butyl-4-fluorobenzenesulfenamide (1b).* After the residue had been distilled (69—71 °C/0.07 Torr), the distillate was treated similarly to the case of **1a**. Yield 63% (based on the amount of 4-fluorobenzenethiol and before recrystallization). n_D^{20}: 1.5227. IR (liquid): 3320 cm^{-1}(NH). NMR (CCl_4): δ 1.15 (s, *t*-Bu), 2.75 (bs, NH), and 6.76—7.73 (m, C_6H_4). Found: C, 60.01; H, 6.91; N, 6.99%. Calcd for $C_{10}H_{14}FNS$: C, 60.27; H, 7.08; N, 7.03%.

N-t-*Butyl-4-chlorobenzenesulfenamide (1c).* After the residue had been distilled (94—95 °C/0.07 Torr), the distillate was recrystallized from hexane (cooled to −20 °C), giving colorless prisms with mp 44—45 °C in a 34% yield (based on the amount of 4-chlorobenzenethiol). IR (KBr): 3320 cm^{-1}(NH). NMR (CCl_4): δ 1.14 (s, *t*-Bu), 2.68 (bs, NH), and 7.02 (s, C_6H_4). Found: C, 55.37; H, 6.31; N, 6.52%. Calcd for $C_{10}H_{14}ClNS$: C, 55.66; H, 6.55; N, 6.49%.

N-t-*Butyl-4-bromobenzenesulfenamide (1d).* After the residue had been distilled (111—113 °C/0.07 Torr), the distillate was recrystallized from hexane (cooled to −20 °C), giving colorless prisms with mp 37—38 °C in a 33% yield (based on the amount of 4-bromobenzenethiol). IR (KBr): 3320 cm^{-1}(NH). NMR (CCl_4): δ 1.14 (s, *t*-Bu), 2.63 (bs, NH), and 7.05 and 7.27 (d, J=8 Hz, C_6H_4). Found: C, 46.27; H, 5.18; N, 5.43%. Calcd for $C_{10}H_{14}BrNS$: C, 46.16; H, 5.42; N, 5.38%.

N-t-*Butyl-4-nitrobenzenesulfenamide (1e).*[18] The residue obtained was recrystallized from hexane, giving yellow needles with mp 78—79 °C in an 18% yield (based on the amount of 4-nitrobenzenethiol). IR (KBr): 3300 cm^{-1}(NH). NMR (CCl_4): δ 1.12 (s, *t*-Bu), 2.34 (bs, NH), and 7.18 and 8.02 (d, J=8 Hz, C_6H_4). Found: C, 53.07; H, 5.95; N, 12.26%. Calcd for $C_{10}H_{14}N_2O_2S$: C, 53.05; H, 6.23; N, 12.38%.

Generation of N-*(Arylthio)*-t-*butylaminyls (2).* *a*) The compound **1** (20 mg) and benzene (0.20 ml) were placed in an ESR tube. The solution was degassed by three freeze-thaw cycles and the tube was then sealed. After the solution had been irradiated for 5 min from a distance of 10 cm with a 100 W high-pressure mercury lamp (JES-UV-1), the tube was set in the ESR cavity; *b*) **1** (0.10 g) in benzene (2 ml) was stirred for 5 min in the presence of lead dioxide (0.50 g) and potassium carbonate (0.50 g). After the oxidizing agents had been filtered off, 0.2 ml of the filtrate was placed in an ESR tube and the soluion was degassed as described above, and the tube was then sealed.

Decay Kinetics. When the kinetics was carried out in degassed benzene, the sample was prepared according to procedure *a*. On the other hand, when the kinetics was carried out in a system containing air, the sample was prepared as follows: after photolysis of a degassed benzene solution of **1**, the solution was exposed to the atmosphere and shaken well, and then the tube was set in the ESR cavity. The decay rates of **2** were measured at 15 °C in the dark by monitoring the intensities of ESR signal. Integration of the ESR signals was achieved using a Model JES-ID-2 Integrator, with a benzene solution of 3,4-dihydro-2,4,6-triphenyl-2*H*-1,2,4,5-tetrazin-1-yl (1,3,5-triphenylverdazyl)[19] as a standard.

The ESR spectra were recorded at 15 °C on a JES-ME-3X Spectrometer equipped with 100 kHz field modulation. Computer simulation of the spectrum was carried out using a FACOM 270-30 Computer equipped with a FACOM 6201B Plotter. The simulation was fitted by trial and error.

Layered Compounds. XLIII.[1] Syntheses and Properties of [2.2]Naphthaleno- and [2.2]Anthraceno-heterophanes

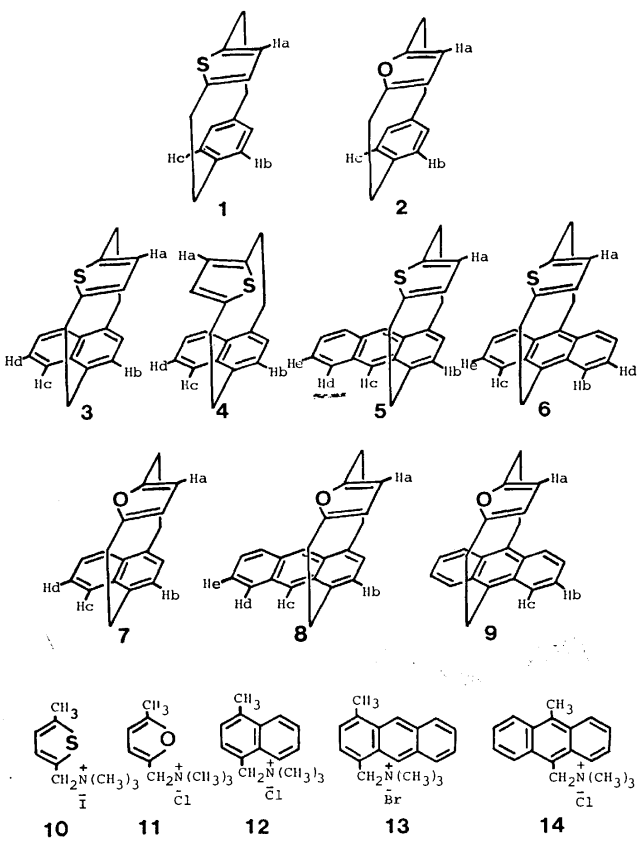
Tetsuo Otsubo, Shigeyoshi Mizogami, Norihisa Osaka, Yoshiteru Sakata, and Soichi Misumi

The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka 565

(Received January 24, 1977)

Several [2.2]naphthaleno- and [2.2]anthraceno-heterophanes were synthesized by cross-breeding Hofmann degradation of the corresponding two quaternary ammonium hydroxides. Two isomers, *anti*- and *syn*-forms, were obtained for [2.2](1,4)naphthaleno(2,5)thiophenophane, and one isomer, *anti*-form, for the [2.2](1,4)anthraceno homologue. The structures of the heterophanes were determined by variable temperature NMR analysis. Transannular π-electronic interactions between the condensed aromatic ring and the heteroaromatic ring were examined on the basis of electronic and emission spectra. The thiophene ring interacts more strongly with the condensed aromatic ring than the furan ring. For anthracenophanes, 9,10-bridged system shows more effective interaction than 1,4-bridged one.

The syntheses and properties of a series of multilayered paracycloheterophanes have been reported in the preceding paper.[1] A transannular π-electronic interaction has been observed between the benzene and the heteroaromatic ring in double-layered [2.2]paracycloheterophanes **1** and **2**, increasing with an increase in layer number of multilayered [2.2]paracycloheterophanes. The structures of the paracycloheterophanes, *i.e.*, facile flipping of the furanophane system and tight fixation of the thiophenophane system, and the addition reactions of the former series with benzyne as well as the NMR spectra and CT spectra of TCNE complexes have been reported. The present work was undertaken to study transannular electronic interaction between heteroaromatic and condensed aromatic rings. A series of naphthaleno- and anthraceno-heterophanes **3**—**9** were synthesized with expectation of marked interaction as compared with those of multilayered paracycloheterophanes.



Scheme 1.

Results and Discussion

Syntheses. Five quaternary ammonium salts **10**—**14** were prepared according to the reported methods.[2-5] All the new cyclophanes were obtained by the cross-breeding Hofmann degradation of the corresponding two quaternary ammonium hydroxides in the same method as **1** and **2**. **2** shows the flipping of the furan ring at room temperature. However, **1** exhibits tight fixation of the thiophene ring even at 150 °C due to the bulkiness of sulfur atom.[1] Thus, both conformers, *anti* **3** and *syn* **4**, of [2.2](1,4)naphthaleno(2,5)thiophenophane are expected to be separated as stable ones. Actually the two isomers **3** and **4** were obtained by the pyrolysis of mixed quaternary hydroxides, derived from **10** and **12**, in boiling xylene. The mass spectra of **3** and **4** showed an identical pattern, indicating that both are isomeric with each other. Their structures were assigned on the basis of NMR analyses. The lower yield (0.3%) of *syn*-form **4** than that (4.2%) of *anti*-form **3** is ascribed to π-π repulsion between fused benzo group and thiophene ring in *syn* form. Although *syn*-[2.2](1,4)naphthalenophane and *syn*-[2.2](1,4)anthracenophane were thermally isomerized to *anti*-form, no isomerization of **4** to **3** was observed because of its ready decomposition. In the case of [2.2](1,4)anthraceno(2,5)thiophenophane, however, only one isomer was obtained in 2.8% yield by a cross-breeding reaction of two quaternary ammonium hydroxides derived from **10** and **13** in boiling xylene. Its structure was assigned to *anti*-conformer **5** by NMR spectrum. The *syn*-isomer could not be detected either when the pyrolysis was carried out in boiling toluene (pyrolysis at lower temperature). The *syn*-conformer seems to be very unstable due to both the increasing π-π repulsion and access of the reactive part of the anthracene ring to the thiophene ring. [2.2](9,10)Anthraceno(2,5)thiophenophane **6** and [2.2](1,4)anthraceno(2,5)furanophane **8** were synthesized by similar cross-breeding reactions in 5.5% yield from **10** and **14** and in 0.8% yield from **11** and **13**, respectively. As reference compounds, [2.2](1,4)naphthaleno(2,5)furanophane **7**[6] and [2.2](9,10)-anthraceno(2,5)furanophane **9**[5] were also prepared

according to the reported methods.

Structure and NMR Spectra. The NMR spectral data of all the naphthaleno- and anthraceno-heterophanes **3**—**9** as well as [2.2]paracycloheterophanes **1** and **2** are summarized in Table 1. Heterophanes **3**—**9** show the signals of all the bridged methylene protons to be roughly divided into two groups of multiplets. Of these, the lower field multiplet is associated with the endo proton (see **15**) of methylenes attached to condensed aromatic ring for 1,4-bridged systems (**3**, **4**, **5**, **7**, and **8**) or both protons of methylenes attached to the same ring for 9,10-bridged systems (**6** and **9**). The downfield shift of these protons is explained by the large deshielding effect of the neighbouring condensed aromatic ring. Most aromatic protons show more or less upfield shifts and are reasonably assigned by considering

diamagnetic anisotropy of the opposite aromatic rings. As shown in Table 1, the magnitudes of the shifts are calculated using the chemical shifts (Fig. 1) of the aromatic protons of 2,5-dimethylfuran, 2,5-dimethylthiophene, *p*-xylene, 1,4-dimethylnaphthalene, 1,4-dimethylanthracene, and 9,10-dimethylanthracene as standards. The structural difference between **3** and **4** is unequivocally realized in the NMR spectra. The upfield shift (1.28 ppm) of thiophene proton Ha of **4** is drastic as compared with that of **1** (0.11 ppm) or **3** (0.07 ppm), suggesting that the proton is situated above the center of the opposite naphthalene ring. The naphthalene protons Hc and Hd show reasonable upfield shifts. However, Hb proton shows absorption at rather lower field. On the other hand, the shifts of Hc and Hd protons in **3** are negligible, the upfield shift (0.67 ppm) of Hb proton being marked and roughly the same as that (0.86 ppm) of Hb proton in **1**. These data are best accommodated by the *anti*-conformation for **3** and *syn*-conformation for **4**. The structure of 1,4-bridged anthracenothiophenophane **5** can be assigned to *anti*-conformation by a comparison of its NMR data with those of **3** and **4**. Thus the upfield shifts of Ha and Hb protons in **5** are identical with those of Ha and Hb in **3**, respectively. Small shielding effects on the Hc, Hd, and He protons are also explained by *anti* structure, but not by *syn* structure. The NMR pattern of 9,10-bridged anthracenothiophenophane **6** is in contrast to that of 1,4-bridged one **5**, and the chemical shifts are explained by considering both shielding effects of *anti*-form **3** and *syn*-form **4**.

A variable temperature NMR analysis of [2.2]paracyclofuranophane **2** exhibited the conformational flipping of the furan ring at room temperature and the fixation at low temperature (T_c, −39 °C).[1,7] Thus, 1,4-bridged naphthalenofuranophane **7** and anthracenofuranophane **8** are expected to show similar behavior, that is, consisting of one isomer at room temperature and two conformers, *syn* and *anti*, at low temperature. However, the NMR spectra exhibited no temperature-dependence, though the temperature was lowered to −100 °C. The upfield shifts of Hb protons of **7** and **8** are much larger than that of benzene proton of **2** at room temperature and close to that at ring fixation temperature. The furan protons Ha show no large

shielding effect due to the fused aromatic ring. These data support the view that both **7** and **8** exist exclusively in the *anti*-conformation rather than in the *syn*-conformation owing to a π-π repulsive instabilization in the latter conformation.[8] The NMR spectrum of 9,10-bridged anthracenophane **9** is characterized by a symmetrical pattern, indicating a rapid flipping of the furan ring unlike **7** and **8**.

Electronic Spectra and Emission Spectra. Figures 2, 3, and 4 show the electronic spectra of naphthaleno- and anthraceno-heterophanes together with those of the corresponding paracyclophanes **16**—**18**.[9] All the absorption curves exhibit common features of cyclophanes, *viz.*, broadening, bathochromic and hyperchromic shifts,[10] caused by the transannular electronic interaction. A comparison of Fig. 2 with Fig. 3 shows that

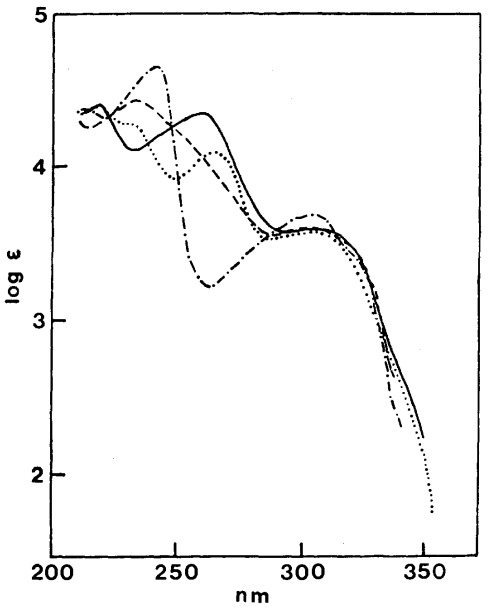

Fig. 4. Electronic spectra of **3** (——), **4** (----), **7** (—·—), and **16** (·····) in cyclohexane.

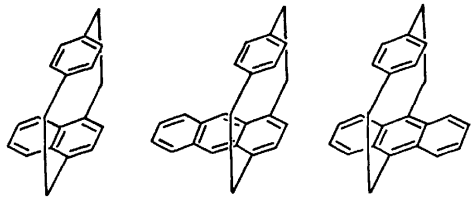

16 **17** **18**

Scheme 3.

the interactions in 9,10-bridged anthracenophanes are more effective than those in 1,4-bridged analogues. The spectra of the thiophenophane are very similar to those of the corresponding paracyclophanes as in the case of multilayered paracyclothiophenophanes,[1] indicating a strong interaction between thiophene and condensed aromatic ring. The broad long wavelength band and the short wavelength band are due to ^1L_a and ^1B_b transitions of naphthalene or anthracene. The single band between them (260 nm for *anti*-form **3**, 281 nm for *anti*-form **5**, and 292 nm for **6**) is considered to be associated with a transition of the thiophene ring, showing a considerable bathochromic shift due to the strong interaction with the condensed aromatic ring, as compared with an absorption band (230 nm) of thiophene itself.[11] On the other hand, absorption of the thiophene ring in *syn*-form **4** exhibits no such large shift, being superposed on ^1B_b band of naphthalene at 233 nm. The difference between the *anti* and *syn* forms suggests that the d-orbitals of sulfur atom play an important role in the interaction, especially for the former.

Furan shows no absorption in the long wavelength region above 220 nm[11] In the present furanophanes, the absorption due to the furan ring is submerged by band ^1B_b of the naphthalene or anthracene ring. The presence of reasonable transannular electronic interaction in the furan series is supported by the broadening and bathochromic shift of the long wavelength band (^1L_a band). However, the shift value is smaller than that of the other cyclophanes. The interaction between furan ring and condensed aromatic ring is relatively weak.

Anthracene	Cyclohexane	378, 400

a) Shoulder.

In order to obtain further informations on the interaction, emission spectra were measured (Table 2). Since the heteroaromatic ring shows about zero value of fluorescence quantum yield and, in the present cycloheterophanes, energy transfer is expected to take place transannularly from the excited state of the heteroaromatic ring to the lowest excited level of the condensed aromatic ring, only transitions $^1L_a \rightarrow {}^1A$ of the condensed aromatic rings are observed as fluorescence. Their fluorescence maxima show remarkable bathochromic shifts as compared with that of naphthalene or anthracene. The feature of the shifts agrees with that discussed on the electronic absorption spectra; the thiophenophanes and the 9,10-bridged anthracenoheterophanes show more effective interaction than the furanophanes and the 1,4-bridged analogues, respectively.

Experimental

Melting points are uncorrected. All the solvents are of reagent grade. NMR spectra were taken with a Hitachi-Perkin Elmer R-20 spectrometer (60 MHz) using tetramethyl silane as an internal standard. MS spectra were measured with a Hitachi RMU-7 spectrometer and UV spectra with a Hitachi EPS-3T spectrophotometer. Emission spectra were taken on a Hitachi MPF-2A spectrophotometer using 1×10^{-3}M degassed solution in tetrahydrofuran or EPA (5 : 5 : 2 volume ratio of ethyl ether–isopentane–ethanol) at room temperature. Emission spectra are uncorrected.

anti- *and* syn-*[2.2](1,4)Naphthaleno(2,5)thiophenophanes*, ***3*** *and* ***4***. 5-Methylthenyltrimethylammonium iodide **10** (8.2 g, 40 mmol) and (1-methyl-4-naphthylmethyl)trimethylammonium chloride **12** (5 g, 20 mmol) were dissolved in distilled water (*ca.* 300 ml) and passed through a column of strong anion exchange resin (Dowex 1-X8) which had been

converted into hydroxide form with 3M sodium hydroxide solution. The eluted solution (*ca.* 700 ml) was mixed with xylene (150 ml) and phenothiazine (100 mg), water being removed by azeotropic distillation in a nitrogen atmosphere. After complete removal of water, reflux was continued for 7 h. The insoluble polymer was filtered and washed with xylene. The filtrate and the washings were combined and concentrated. The residue was taken up in benzene and subjected to column chromatography on silica gel. Elution with 1 : 9 benzene–hexane gave successively [2.2](2,5)thiophenophane,[2] *syn*-[2.2](1,4)naphthaleno(2,5)thiophenophane **4**, *anti*-[2.2](1,4)naphthaleno(2,5)thiophenophane **3**, and a mixture of *anti*- and *syn*-[2.2](1,4)naphthalenophanes.[3] Recrystallization of **3** from 1 : 1 hexane–benzene gave colorless prisms (222 mg, 4.2%), mp 182—183 °C.

MS *m/e* 264 (M^+). Found: C, 81.90; H, 6.04%. Calcd for $C_{18}H_{16}S$: C, 81.79; H, 6.10%.

Recrystallization of **4** from 1 : 1 hexane–benzene gave colorless plates (16 mg, 0.3%), mp 142—143 °C.

MS *m/e* 264 (M^+). Found: C, 81.59; H, 6.00%. Calcd for $C_{18}H_{16}S$: C, 81.79; H, 6.10%.

[2.2](1,4)Anthraceno(2,5)thiophenophane **5**. The method described above was used for the cross-breeding reaction of the quaternary hydroxides derived from 5-methylthenyltrimethylammonium iodide **10** (6 g, 29 mmol) and (1-methyl-4-anthrylmethyl)trimethylammonium bromide **13** (5 g, 14.5 mmol). The cross coupling product **5** was separated from homo coupling products, [2.2](2,5)thiophenophane,[2] [2.2.2](2,5)-thiophenophane,[1] *anti*-[2.2](1,4)anthracenophane,[4] and *syn*-[2.2](1,4)anthracenophane and its photoisomer[12] by careful column chromatography on silica gel using 1 : 9 benzene–hexane and recrystallized from 1 : 1 benzene–hexane to give pale yellow prisms (130 mg, 2.8%), mp 195 °C with decompn.

MS *m/e* 314 (M^+). Found: C, 84.25; H, 5.59%. Calcd for $C_{22}H_{18}S$: C, 84.05; H, 5.77%.

[2.2](9,10)Anthraceno(2,5)thiophenophane **6**. The method described for **3** and **4** was used for pyrolysis of the quaternary hydroxides derived from a mixture of two ammonium salts **10** (6 g, 29 mmol) and **14** (4.5 g, 15 mmol), giving cross coupling cyclophane **6**, together with homo coupling products, [2.2](2,5)thiophenophane,[2] [2.2.2](2,5)thiophenophane,[1] and [2.2](9,10)anthracenophane.[5,13] Column chromatography on silica gel with 1 : 9 benzene–hexane and recrystallization from pentane–dichloromethane gave pure greenish yellow needles **6** (260 mg, 5.5%), dec>100 °C.

MS *m/e* 314 (M^+). Found: C, 83.80; H, 5.57%. Calcd for $C_{22}H_{18}S$: C, 84.05; H, 5.77%.

[2.2](1,4)Anthraceno(2,5)furanophane **8**. The method described for **3** and **4** was used for the pyrolytic reaction of the quaternary hydroxides derived from a mixture of two ammonium salts **11** (8 g, 28 mmol) and **14** (5 g, 14 mmol), the desired cyclophane **8** being obtained. After removal of homo coupling cyclophanes by column chromatography, recrystallization of **8** from 1 : 1 benzene–hexane gave pale yellow prisms (34 mg, 0.8%), dec>154 °C.

MS *m/e* 298 (M^+). Found: C, 88.32; H, 5.97%. Calcd for $C_{22}H_{18}O$: C, 88.56; H, 6.08%.

This research was partly supported by a Grant-in-Aid of the Ministry of Education.

New Method for the Preparation of Carboxylic Esters

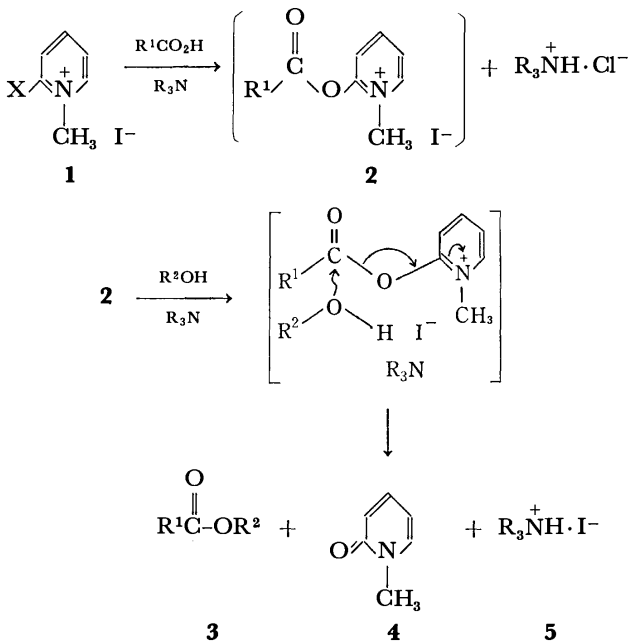
Kazuhiko SAIGO,[1] Masahiro USUI, Kazunori KIKUCHI,
Eiichiro SHIMADA, and Teruaki MUKAIYAMA
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received February 4, 1977)

Various carboxylic esters including functionalized ones are prepared in good yields from equimolar amounts of free carboxylic acids and alcohols under mild conditions by the use of 2-chloro- or 2-bromopyridinium salt, a new and efficient coupling reagent.

The ester formation is one of the most fundamental reactions in organic synthesis and a number of methods have been presented. However, relatively little work has been reported on the successful preparation of carboxylic esters by the equimolar reaction of free carboxylic acids and alcohols except when *p*-toluenesulfonyl chloride,[2] trifluoroacetic anhydride,[3] polyphosphate ester,[4] dicyclohexylcarbodiimide,[5] and graphite hydrogensulfate[6] were employed as coupling reagents.

This prompted us to develop a new and efficient coupling reagent, and 2-chloro- and 2-bromopyridinium salts were found to be efficient for the preparation of carboxylic esters from equimolar amounts of free carboxylic acids and alcohols as briefly reported in the previous communications.[7]

The work was undertaken based on the following considerations; 2-acyloxy-1-methylpyridinium iodide (**2**), an active acylating intermediate, would be produced easily and rapidly by a nucleophilic attack of the carboxylate ion on 2-chloro- or 2-bromo-1-methylpyridinium iodide (**1**) since the halogen atom at 2-position of **1** is facile to be displaced by the attack of nucleophiles. The intermediate, **2**, is in turn converted into stable molecules, *i.e.*, carboxylic esters (**3**), 1-methyl-2-pyridone (**4**) and ammonium salt (**5**) by the nucleophilic attack of alcohol to carbonyl carbon of **2** in the presence of tertiary amine, a hydrogen iodide captor.



In the first place, the effective hydrogen halide captors in the ester forming reaction were examined using equimolar amounts of phenylacetic acid and benzyl alcohol. Several runs were carried out in the presence of 2.4 molar amounts of tertiary amines, such as triethylamine, tributylamine, 2,6-lutidine, α-picoline, pyridine, and *N*,*N*-diethylaniline, by the use of 2-chloro-1-methylpyridinium iodide. Of the amines employed, triethylamine, tributylamine, and 2,6-lutidine gave good results (see Table 1). These results indicate that the basicity of tertiary amine influences on the yield of benzyl phenylacetate, namely, the yield decreases with lowering basicity of the amine.

Next, the effect of the solvent on the reaction of phenylacetic acid and benzyl alcohol was examined using 2-chloro-1-methylpyridinium iodide in the presence of tributylamine. As listed in Table 1, no remarkable solvent effect was observed, that is, benzyl phenylacetate was obtained in almost quantitative yield in all of the solvents used.

Based on these results, several equimolar reactions of free carboxylic acids and alcohols were carried out in dichloromethane by the use of 2-chloro-1-methyl-

C_2H_5	Cl	BF_4	73
C_2H_5	Br	BF_4	82

pyridinium iodide and tributylamine, and good results were obtained. 2-Bromo-1-methylpyridinium iodide was also found to be as effective as 2-chloro-1-methylpyridinium iodide in the esterification. An improvement in the yields was rarely recognized except for the case of the condensation of pivalic acid, a bulky carboxylic acid, with benzyl alcohol when the esterifications were carried out at an elevated temperature, that is, in refluxing toluene (see Table 2).

The consideration that both the counter ion and halogen atom attached to 2-position of the pyridinium salt would influence on the yield of carboxylic esters urged us to look for more effective pyridinium salt. The equimolar reaction of 3-phenylpropionic acid with benzyl alcohol was undertaken by the use of 2-halo-

$CH_3CH{=}CH{-}CH{=}CH$	$C_6H_5CH_2$		59[c]

Values in parentheses indicate the yields when the reactions were carried out in dichloromethane under refluxing for 3 h using 2-chloro-1-methylpyridinium iodide as a coupling reagent.
a) Yields determined by GLC. b) As a by-product, 4-benzyloxy-4-methyl-4-butanolide was obtained in 13% yield. c) Sorbic anhydride was obtained in 21% yield.

pyridinium iodide or tetrafluoroborate to determine the influence on the yield. As shown in Table 3, 2-bromo-1-ethylpyridinium tetrafluoroborate gave the best result.

Based on the above results, the reaction of several free carboxylic acids, including functionalized ones, with equimolar amounts of alcohols was carried out employing 2-bromo-1-ethylpyridinium tetrafluoroborate as the coupling reagent, and favorable results were obtained especially when the esterification was undertaken at room temperature (see Table 4).

In conclusion, it is noted that various carboxylic esters are conveniently prepared in good yields from equimolar amounts of free carboxylic acids and alcohols under mild conditions by the use of 2-chloro- or 2-bromo-1-methylpyridinium iodide or 2-bromo-1-ethylpyridinium tetrafluoroborate, as a coupling reagent, in the presence of tributylamine. The present method is also successfully applied to the carboxylic ester synthesis

starting from free carboxylic acids or alcohols having bulky alkyl group or having functional group sensitive toward acid or base.

Experimental

Spectra. Proton NMR were obtained on Hitachi R-24 spectrometer. Chemical shifts are reported on the δ scale relative to tetramethylsilane as an internal standard. Infrared spectra were taken using Hitachi EPI-G2 spectrophotometer. Products were identified by NMR and IR spectra and elemental analyses.

Materials. All solvents used here were distilled according to the general methods and were stored over molecular sieves or sodium metal as a drying agent. Carboxylic acids and alcohols were recrystallized or distilled before use.

2-Chloro-1-methylpyridinium Iodide. To a solution of 2-chloropyridine (10.0 g, 88 mmol) in acetone (3 ml) was added methyl iodide (15.0 g, 106 mmol) at 0 °C and the mixture was stirred for 3 days at room temperature. Precipitate appeared was filtered and washed with dry ether (50 ml). After drying under reduced pressure, 2-chloro-1-methylpyridinium iodide (18.0 g, 80%) was obtained and used for the esterification without recrystallization.

2-Bromo-1-ethylpyridinium Tetrafluoroborate. A solution of 2-bromopyridine (2.88 g, 18 mmol) was added to triethyloxonium tetrafluoroborate (4.00 g, 21 mmol) at room temperature under an argon atmosphere. The solution became clear in a few minutes and white precipitate appeared gradually. After the suspension was warmed at 50—60 °C for 1 h, the mixture was cooled with ice-water bath. The precipitate was filtered and washed with dry ether (15 ml). Drying under reduced pressure at room temperature gave 2-bromo-1-ethylpyridinium tetrafluoroborate (4.07 g, 83%) which was employed for condensation without recrystallization.

General Procedure for Carboxylic Ester Synthesis by the Use of 2-Chloro- or 2-Bromo-1-methylpyridinium Iodide. To a suspension of 2-chloro-1-methylpyridinium iodide (612 mg, 2.4 mmol) or 2-bromo-1-methylpyridinium iodide (720 mg, 2.4 mmol) in dichloromethane or toluene (2 ml) was added a solution of free carboxylic acid (2.0 mmol), alcohol (2.0 mmol), and tributylamine (888 mg, 4.8 mmol), in the solvent (2 ml) under an argon atmosphere and the mixture was stirred for 3 h under refluxing. The solution became clear in accordance to progress of the reaction. After evaporation of the solvent, the residue was separated by silica gel column chromatography to give carboxylic ester.

General Procedure Utilizing 2-Bromo-1-ethylpyridinium Tetrafluoroborate. To a solution of 2-bromo-1-ethylpyridinium tetrafluoroborate (329 mg, 1.2 mmol) in dichloromethane (2 ml) was added a mixture of free carboxylic acid (1.0 mmol), alcohol (1.0 mmol), and tributylamine (444 mg, 2.4 mmol) at room temperature under an argon atmosphere. After stirring overnight at room temperature, the solvent was evaporated and the residue was chromatographed on silica gel to give carboxylic ester. The NMR and IR spectra and elemental analysis data of products were listed in Table 5.

(Received February 8, 1977)

Isopropylidenation of 1,2-*O*-cyclohexylidene-*myo*-inositol and its 3-*O*-tosyl- and 3-*O*-benzoyl derivatives with 2,2-dimethoxypropane in *N*,*N*-dimethylformamide in the presence of acid catalyst gave the corresponding 4,5- and 5,6-*O*-isopropylidene derivatives. Selective benzoylation of 1,2-*O*-cyclohexylidene-4,5-*O*-isopropylidene-*myo*-inositol with benzoyl chloride in pyridine gave mainly the 3-*O*-benzoate, whereas with benzoic anhydride the 6-*O*-benzoate. Several unaccessible blocked inositols were prepared by displacement reaction of the protected sulfonyl derivatives with sodium benzoate.

Partially blocked *myo*-inositol is a potential intermediate for the synthesis of various kinds of inositol derivatives. In continuation to the previous paper,[1] isopropylidenation of 1,2-*O*-cyclohexylidene-*myo*-inositol (**1a**),[2] and its 3-*O*-tosyl- and 3-*O*-benzoyl derivatives (**1b**[2] and **1c**[1]) has been studied. Preparation of several unaccessible protected derivatives of *allo*-, *chiro*-, and *muco*-inositols starting from the sulfonates obtained in this studies has also been carried out.

Isopropylidenation. Treatment of **1a** with 2,2-dimethoxypropane in *N*,*N*-dimethylformamide in the presence of *p*-toluenesulfonic acid gave the 4,5-*O*-isopropylidene derivative (**2a**) as crystals in 22% yield, which was further characterized as the ditosylate and diacetate (**2b** and **2c**). The remaining syrupy product consisted mainly of the 5,6-*O*-isopropylidene derivative (**3a**) was directly tosylated or benzoylated to give the crystalline ditosylate (**3b**) or dibenzoate (**3c**) in an isolated yield of 26 or 62% based on **1a**. Positions of the isopropylidene groups in **2a** and **3a** were established by converting **2b** and **3b** into the known 1,4- and 1,6-di-*O*-tosyl-*myo*-inositol,[2] respectively.

Scheme 1.

Under the identical reaction conditions, 1,2-*O*-cyclohexylidene-3-*O*-tosyl-*myo*-inositol (**1b**) was acetonated to afford the crystalline 4,5- and 5,6-*O*-isopropylidene derivatives (**2d** and **3d**) in 18 and 19% yields, respectively. Their structures were determined by converting them into **2b** and **3b**, respectively.

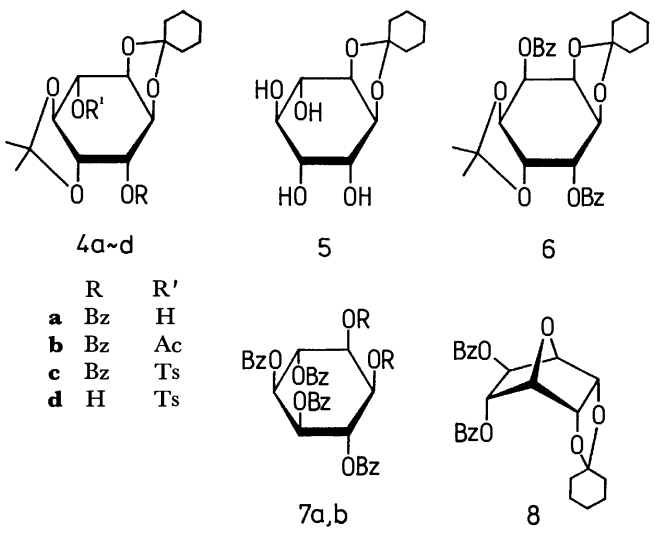
Similarly, isopropylidenation of 1-*O*-benzoyl-2,3-*O*-cyclohexylidene-*myo*-inositol (**1c**) gave, upon separation by silica gel chromatography, the 5,6-*O*-isopropylidene derivative (**2f**, 20%) as crystals, and the 4,5-*O*-isopropylidene derivative (**3f**, 43%) as a syrup. The assigned structures were confirmed on the basis of the following evidences. Acetylation of **2f** and **3f** afforded the corresponding acetates (**2g** and **3g**). In the NMR spectrum of **2g**, the signals due to two protons which attached to the carbon atoms bearing the acyloxy functions were shown not to be coupled with each other. Methylation of **3f** with methyl iodide and silver oxide in *N*,*N*-dimethylformamide gave two crystalline methyl ethers (**3h** and **3i**) in 75 and 4% yields, respectively.[3] While, the methyl ether (**2h**) derived from **2f** was different from either **3h** or **3i**. On removal of the blocking groups followed by acetylation, **3h** and **3i** were transformed into the known 4-[4] and 1-*O*-methyl-*myo*-inositol pentaacetate,[5] respectively.

Selective Benzoylation and Tosylation. Treatment of **2a** with 1.5 molar equiv of tosyl chloride in pyridine at 0—5 °C for 2 days yielded **2d** almost exclusively in 57% yield. When **2a** was treated with 1.3 molar equiv of benzoyl chloride in pyridine at −5 °C for 1.5 h, **2f** and the dibenzoate (**2i**) were obtained in 33 and 28% yields, respectively. These results indicated that the C-3 hydroxyl group being adjacent to *cis*-arranged cyclohexylidene oxygen atom is more reactive than the less hindered C-6 hydroxyl group.[6]

On the other hand, selective benzoylation of **2a** with 1.3 molar equiv of benzoic anhydride in pyridine at room temperature for 5 days gave rise to the 6-*O*-benzoate (**2j**) in 52% yield, together with **2i** (12%) and a trace of **2f**. Accordingly, in contrast to the case of acid halide, steric factor seemed to play a role in selectivity of *O*-acylation with acid anhydride.

Preparation of Blocked Inositols. Unaccessible partially protected *chiro*-inositol derivatives were obtained by nucleophilic displacement reaction of the tosylates of **2a** with a benzoate ion. Thus, **2d** was treated with an excess of sodium benzoate in boiling *N*,*N*-dimethylformamide for 120 h to give 1-*O*-benzoyl-5,6-*O*-cyclohexylidene-2,3-*O*-isopropylidene-*chiro*-inositol (**4a**) in 52% yield. On de-*O*-benzoylation followed by mild acid treatment, **4a** was converted into 1,2-*O*-cylohexylidene-*chiro*-inositol (**5**) in 95% yield, whose structure was ascertained by conversion to *chiro*-inositol.[7]

Treatment of **2b** with sodium benzoate under the



Scheme 2.

similar conditions for 50 h afforded 1-*O*-benzoyl-5,6-*O*-cyclohexylidene-2,3-*O*-isopropylidene-4-*O*-tosyl-*chiro*-inositol (**4c**) in 72% yield. When the reaction time was prolonged to 70 h, the tosyloxy group on C-6 was partially displaced with a benzoate ion giving 2,5-di-*O*-benzoyl-3,4-*O*-cyclohexylidene-1,6-*O*-isopropylidene-*allo*-inositol (**6**) in 10% yield, together with 31% yield of **4c**. The structure of **4c** was tentatively assigned by comparing the NMR spectrum with those of **4a** and its acetate (**4b**).

Additionally, the protected *muco*-inositol was prepared by the following reaction sequence. Reaction of **1b** with potassium carbonate in boiling 80% aqueous 2-methoxyethanol for 30 h followed by benzoylation gave 1,2,3,6-tetra-*O*-benzoyl-4,5-*O*-cyclohexylidene-*muco*-inositol (**7a**) in 51% yield, which was, upon de-*O*-cyclohexylidenation, converted into tetrabenzoyl-*muco*-inositol (**7b**) in 92% yield. The NMR spectrum of **7a** supported the assigned structure. Conversion of **7b** into *muco*-inositol[8] gave the final evidence.

A small amount of crystals (**8**, 1.3%) was isolated from the mother liquor from **7a** after a long storage. The elemental analysis and NMR spectrum suggested that **8** had an 1,4-anhydro ring. On lithium aluminum hydride reduction followed by benzoylation,[9] 1,4-anhydro-5,6-*O*-cyclohexylidene-3-*O*-tosyl-*chiro*-inositol[10] gave 1,4-anhydro-2,3-di-*O*-benzoyl-5,6-*O*-cyclohexylidene-*chiro*-inositol that was shown to be identical with **8**. Mechanistically, **7a** was formed by diaxial opening of the intemediate 3,4-epoxide with OH^- and **8** was obtained by the rear-side attack of the 6-hydroxyl group on C-3.

Experimental[11]

*Isopropylidenation of 1,2-O-Cyclohexylidene-*myo*-inositol (**1a**).* To a slurry of **1a** (20 g) in *N,N*-dimethylformamide (100 ml) was added 2,2-dimethoxypropane (30 ml) and *p*-toluenesulfonic acid (0.2 g), and the mixture was heated at 70—75 °C for 90 min. The cooled reaction mixture was treated with sodium hydrogencarbonate (5 g) and then evaporated to dryness. The crystalline residue was extracted with hot 2-butanone (3×50 ml) and the extracts were evaporated to give crystals that were recrystallized from 2-butanone–toluene to afford 1,2-*O*-cyclohexylidene-4,5-*O*-isopropylidene-*myo*-inositol (**2a**, 5.1 g, 22%) as needles: mp 180.5—181.5 °C.

Found: C, 60.12; H, 7.93%. Calcd for $C_{15}H_{24}O_6$: C, 59.98; H, 8.05%.

Compound **2a** (3 g) was treated with tosyl chloride (7.7 g) in pyridine (30 ml) at room temperature for 2 days. The reaction mixture was poured into ice–water and the resulting crystals were collected. Recrystallization from 2-butanone–toluene gave the ditosyl derivative (**2b**, 5.7 g, 93%): mp 192—195 °C; NMR ($CDCl_3$) δ 2.43 (s, 6, two tosyl CH_3), 3.35 (dd, 1, $J_{4,5}$=9 Hz, $J_{5,6}$=11 Hz, H-5), 4.01 (dd, 1, $J_{3,4}$=11 Hz, H-4), 4.12 (dd, 1, $J_{1,2}$=5 Hz, $J_{1,6}$=6.5 Hz, H-1), 4.41 (dd, 1, $J_{2,3}$=4 Hz, H-2), 4.80 (dd, 1, H-3), 5.38 (dd, 1, H-6).

Found: C, 57.37; H, 5.88; S, 10.47%. Calcd for $C_{29}H_{36}O_{10}S_2$: C, 57.22; H, 5.97; S, 10.53%.

Compound **2b** (0.1 g) was refluxed with 80% aqueous acetic acid (10 ml) for 2 h. After cooling, the resulting crystals were collected by filtration, washed with water, and dried to give 1,4-di-*O*-tosyl-*myo*-inositol (0.07 g, 89%): mp 199—200 °C. This compound was identified with an authentic sample[2] (mp 198—200 °C) by comparison with IR spectra.

Compound **2a** (0.2 g) was treated with acetic anhydride (5 ml) and pyridine (5 ml) at room temperature for 2 h. The mixture was poured into ice–water and the resulting crystals were collected by filtration. Recrystallization from ethanol gave the diacetyl derivative (**2c**, 0.24 g, 95%) as needles: mp 175.5—176.5 °C; NMR ($CDCl_3$)[12] δ 2.16 (s, 3) and 2.20 (s, 3) (OAc), 3.55 (dd, 1, $J_{4,5}$=11 Hz, $J_{5,6}$=9 Hz, H-5), 4.21 (dd, 1, $J_{2,3}$=5 Hz, $J_{3,4}$=6.5 Hz, H-3), 4.21 (dd, 1, $J_{1,6}$=11 Hz, H-6), 4.70 (t, 1, $J_{1,2}$=4.5 Hz, H-2), 5.20 (dd, 1, H-1), 5.38 (dd, 1, H-4).

Found: C, 59.60; H, 7.35%. Calcd for $C_{19}H_{28}O_8$: C, 59.36; H, 7.34%.

The mother liquor obtained from **2a** was concentrated and purified by passing through a short alumina column with 2-butanone as an eluent to give a syrupy product (*ca.* 16 g) consisting mainly of **3a**. A 6-g portion of the syrup was tosylated as described for **2a** to give 1,2-*O*-cyclohexylidene-5,6-*O*-isopropylidene-3,4-di-*O*-tosyl-*myo*-inositol (**3b**, 4.3 g, 25% yield based on **1a** used) as needles, after recrystallization from 2-butanone–toluene: mp 165—167 °C; NMR ($CDCl_3$) δ 2.47 (s, 6, two tosyl CH_3), 3.45 (dd, 1, $J_{4,5}$=8 Hz, $J_{5,6}$=10 Hz, H-5), 4.02 (dd, 1, $J_{1,6}$=7 Hz, H-6), 4.80 (t, 1, $J_{2,3}$=$J_{3,4}$=3 Hz, H-3), 4.99 (dd, 1, H-4).

Found: C, 57.12; H, 5.90; S, 10.92%. Calcd for $C_{29}H_{36}O_{10}S_2$: C, 57.22; H, 5.97; S, 10.53%.

Compound **3b** (50 mg) was treated with boiling 80% aqueous acetic acid followed by acetylation in the usual manner to give 1,6-di-*O*-tosyl-*myo*-inositol tetraacetate (40 mg, 84%) as crystals: mp 195—197 °C, which was identified with an authentic sample[2] (mp 196—197.5 °C) by comparison with IR spectra.

A 10-g portion of crude **3a** was treated with benzoyl chloride (30 ml) in pyridine (70 ml) at room temperature overnight. The reaction mixture was poured into ice–water and the resulting gum was extracted with chloroform (2×50 ml). The extracts were washed with aqueous sodium hydrogencarbonate and water, dried, and concentrated to leave a syrup, which was crystallized from toluene to give the dibenzoyl derivative (**3c**). Recrystallization from 2-butanone gave pure crystals (12.5 g, 62% yield besed on **1a** used): mp 199—202 °C.

Found: C, 68.43; H, 6.27%. Calcd for $C_{29}H_{32}O_8$: C, 68.49; H, 6.34%.

Isopropylidenation of 1,2-O-Cyclohexylidene-3-O-tosyl-myo-inositol (1b). To a solution of **1b**[2] (20 g) in *N,N*-dimethylformamide (100 ml) were added 2,2-dimethoxypropane (40 ml) and *p*-toluenesulfonic acid (0.2 g), and the mixture was heated at 90 °C for 15 min. After cooling, the reaction mixture was neutralized by treating with Amberlite IRA-410 (OH^-) and then concentrated to give a syrup that was crystallized from 2-butanone–toluene to give 1,2-*O*-cyclohexylidene-4,5-*O*-isopropylidene-3-*O*-tosyl-*myo*-inositol (**2d**, 4.3 g, 18%) as needles: mp 167—169 °C; NMR ($CDCl_3$) δ 2.46 (s, 3, tosyl C$\underline{H}_3$), 3.31 (dd, 1, $J_{4,5}$=10 Hz, $J_{5,6}$=10.5 Hz, H-5), 4.45 (t, 1, $J_{1,2}=J_{2,3}$=4.5 Hz, H-2), 4.89 (dd, 1, $J_{3,4}$=10 Hz, H-3).

Found: C, 58.41; H, 6.65; S, 7.19%. Calcd for $C_{22}H_{30}O_8S$: C, 58.13; H, 6.65; S, 7.05%.

Compound **2d** (0.2 g) was acetylated in the usual manner and the crude product was recrystallized from 2-butanone–methanol to give the acetyl derivative (**2e**, 0.2 g, 91%): mp 215—216 °C; NMR ($CDCl_3$) δ 2.14 (s, 3, OAc), 2.48 (s, 3, tosyl C$\underline{H}_3$), 3.40 (dd, 1, $J_{4,5}$=9 Hz, $J_{5,6}$=11 Hz, H-5), 4.12 (dd, 1, $J_{3,4}$=10.5 Hz, H-4), 4.13 (dd, 1, $J_{1,2}$=4.5 Hz, $J_{1,6}$=7 Hz, H-1), 4.46 (t, 1, $J_{2,3}$=4.5 Hz, H-2), 4.90 (dd, 1, H-3), 5.29 (dd, 1, H-6).

Found: C, 58.13; H, 6.46; S, 6.62%. Calcd for $C_{24}H_{32}O_9S$: C, 57.67; H, 6.46; S, 6.23%.

Treatment of **2d** (0.2 g) with tosyl chloride (0.25 g) in pyridine (2 ml) at room temperature for 2 days gave **2b** (0.21 g, 77%), mp 187—189 °C, after recrystallization from chloroform–ethanol, which was identified with the sample obtained before.

The mother liquor from **2d** was concentrated to leave a syrup that was crystallized from toluene giving 1,2-*O*-cyclohexylidene-5,6-*O*-isopropylidene-3-*O*-tosyl-*myo*-inositol (**3d**, 4.1 g, 19%) as crystals. It melted at 163—165 °C, solidified at 168—175 °C, and then remelted at 223—227 °C with decomposition; NMR ($CDCl_3$) δ 2.49 (s, 3, tosyl C$\underline{H}_3$), 3.43 (dd, 1, $J_{4,5}$=9 Hz, $J_{5,6}$=10 Hz, H-5), 4.71 (t, 1, $J_{2,3}=J_{3,4}$=*ca.* 4.5 Hz, H-3).

Found: C, 58.00; H, 6.61; S, 6.84%. Calcd for $C_{22}H_{30}O_8S$: C, 58.13; H, 6.65; S, 7.05%.

Compound **3d** (0.2 g) was acetylated to give, after crystallization from ethanol, the acetyl derivative (**3e**, 0.19 g, 91%) as crystals: mp 151—153 °C; NMR ($CDCl_3$) δ 2.04 (s, 3, OAc), 2.49 (s, 3, tosyl C$\underline{H}_3$), 3.52 (dd, 1, $J_{4,5}$=9 Hz, $J_{5,6}$ 10.5 Hz, H-5), 3.99 (dd, 1, $J_{1,6}$=7 Hz, H-6), 4.86 (dd, 1, $J_{2,3}$=4.5 Hz, $J_{3,4}$=5.5 Hz, H-3), 5.41 (dd, 1, H-4).

Found: C, 58.04; H, 6.51; S, 6.46%. Calcd for $C_{24}H_{32}O_9S$: C, 57.67; H, 6.46; S, 6.23%.

Tosylation of **3d** (0.2 g) in the usual manner gave **3b** (0.16 g, 52%), mp 165—167 °C, which was identical with the compound obtained before.

Isopropylidenation of 1-O-Benzoyl-2,3-O-cyclohexylidene-myo-inositol (1c). To a solution of **1c** (6 g) in *N,N*-dimethylformamide (60 ml) were added 2,2-dimethoxypropane (12 ml) and *p*-toluenesulfonic acid (0.06 g), and the mixture was heated for 5 min at 90 °C. After cooling, the reaction mixture was neutralized with 5% aqueous potassium carbonate and then poured into ice–water(300 ml). The resulting white powder was collected by filtration and dried over phosphorus pentaoxide *in vacuo* giving a gum (*ca.* 6 g). A 4-g portion of this product was chromatographed on silica gel (135 g) with 2-butanone–toluene (1 : 6, v/v) as an eluent. Two fractions were separated according to the results of TLC. The first fractions gave 1-*O*-benzoyl-2,3-*O*-cyclohexylidene-4,5-*O*-isopropylidene-*myo*-inositol (**3f**, 1.9 g, 43%) as a homogeneous syrup. The second fractions gave a syrup (0.9 g) that was crystallized from ethanol to give 1-*O*-benzoyl-2,3-*O*-cyclohexylidene-5,6-*O*-isopropylidene-*myo*-inositol (**2f**, 0.6 g, 13%) as needles: mp 172.5—173 °C; NMR ($CDCl_3$), **2f**: δ 3.57 (dd, 1, $J_{4,5}$=8.5 Hz, $J_{5,6}$=9.5 Hz, H-5), 4.76 (t, 1, $J_{1,2}=J_{2,3}$=4.5 Hz, H-2), 5.41 (dd, 1, $J_{1,6}$=10 Hz, H-3); **3f**: δ 3.57 (dd, 1, $J_{4,5}$=10 Hz, $J_{5,6}$=8.5 Hz, H-5), 4.10 (dd, $J_{1,2}$=4 Hz, $J_{2,3}$=7 Hz, H-3), 5.31 (t, 1, $J_{1,6}$=4 Hz, H-1).

Found for **2f**: C, 65.58; H, 6.89%. Calcd for $C_{22}H_{28}O_7$: C, 65.32; H, 6.99%.

Compound **2f** (0.1 g) was acetylated in the usual manner to give, after crystallization from chloroform–ethanol, the acetyl derivative (**2g**, 0.09 g, 77%): mp 219 °C (sublimation); NMR ($CDCl_3$) δ 2.15 (s, 3, OAc), 3.59 (dd, 1, $J_{4,5}$=11 Hz, $J_{5,6}$=9.5 Hz, H-5), 4.23 (dd, 1, $J_{2,3}$=4.5 Hz, $J_{3,4}$=7 Hz, H-3), 4.34(dd, 1, $J_{1,6}$=10 Hz, H-6), 4.75 (t, 1, $J_{1,2}$=4.5 Hz, H-2), 5.38 (dd, 1, H-4), 5.43 (dd, 1, H-1).

Found: C, 64.40; H, 6.67%. Calcd for $C_{24}H_{30}O_8$: C, 64.55; H, 6.79%.

Compound **3f** (0.1 g) gave the acetyl derivative (**3g**, 0.1 g, 98%) as a homogeneous syrup; NMR ($CDCl_3$) δ 2.10 (s, 3, OAc), 3.71 (dd, 1, $J_{4,5}$=10 Hz, $J_{5,6}$=8.5 Hz, H-5), 4.07 (t, 1, $J_{2,3}=J_{3,4}$=7 Hz, H-3).

Methylation of 3f. To a solution of **3f** (1.9 g) in *N,N*-dimethylformamide (19 ml) were added silver oxide (2.8 g) and methyl iodide (2.8 ml), and the mixture was stirred at room temperature for 24 h under dark. An insoluble matter was filtered off and the filtrate was evaporated to dryness. The residue was extracted with hot ethyl acetate and the extract was passed through a short alumina column. The solution was evaporated and crystallized from ethanol to give the 6-*O*-methyl derivative (**3h**, 1.5 g, 75%) as prisms: mp 129—131 °C; NMR ($CDCl_3$) δ 3.58 (s, 3, OC$\underline{H}_3$).

Found: C, 66.33; H, 7.10%. Calcd for $C_{23}H_{30}O_7$: C, 66.00; H, 7.24%.

The mother liquor from **3h** afforded, after long storage in a refrigerator, crystals that were recrystallized from ethanol to give 4-*O*-benzoyl-1,2-*O*-cyclohexylidene-5,6-*O*-isopropylidene-3-*O*-methyl-*myo*-inositol (**3i**, 0.07 g, 4%) as needles: mp 150.5—151.5 °C; NMR ($CDCl_3$) δ 3.58 (s, 3, OC$\underline{H}_3$), 3.71 (dd, 1, $J_{4,5}$=7.5 Hz, $J_{5,6}$=8.5 Hz, H-5), 5.43 (dd, $J_{3,4}$=2.5 Hz, H-4).

Found: C, 66.16; H, 7.31%. Calcd for $C_{23}H_{30}O_7$: C, 66.00; H, 7.24%.

1-O-Benzoyl-2,3-O-cyclohexylidene-5,6-O-isopropylidene-4-O-methyl-myo-inositol (2h). Methylation of **2f** (0.45 g) with silver oxide (0.45 g) and methyl iodide (0.45 g) in *N,N*-dimethylformamide (5 ml) gave, after crystallization from ethanol, **2h** (0.33 g, 70%) as needles: mp 128—129.5 °C; NMR ($CDCl_3$) δ 3.61 (s, 3, OC$\underline{H}_3$), 4.76 (t 1, $J_{1,2}=J_{2,3}$=4.5 Hz, H-2), 5.37 (dd, 1, $J_{1,6}$=11 Hz, H-1).

Found: C, 66.20; H, 7.33%. Calcd for $C_{23}H_{30}O_7$: C, 66.00; H, 7.24%.

1,2-O-Cyclohexylidene-5,6-O-isopropylidene-3-O-methyl-myo-inositol (3j). To a solution of **3i** (0.19 g) in methanol (5 ml) was added 0.1 M methanolic sodium methoxide (0.1 ml) and the mixture was allowed to stand at room temperature overnight. After having been neutralized with Amberlite IR-120 (H^+), the solution was evaporated and the crystalline residue was recrystallized from ethanol to give **3j** (0.12 g, 86%): mp 169—171 °C.

Found: C, 61.27; H, 8.14%. Calcd for $C_{16}H_{26}O_6$; C, 61.12; H, 8.35%.

Compound **3j** (0.21 g) was hydrolyzed with boiling 80% aqueous acetic acid (10 ml) for 2 h. The reaction mixture was evaporated and the product was crystallized from ethanol to give 1-*O*-methyl-*myo*-inositol (DL-bornesitol) (0.09 g, 71%)

as crystals: mp 197—198 °C (lit,[13] 198—200 °C). Acetylation gave the pentaacetyl derivative: mp 152—154 °C (lit,[4] 154—154.5 °C).

1-O-Acetyl-2,3-O-cyclohexylidene-4,5-O-isopropylidene-6-O-methyl-myo-*inositol (**3k**).* De-*O*-benzoylation of **3h** (5 g) with methanolic sodium methoxide in methanol (100 ml) gave a syrupy product, which was, without furhter purification, acetylated in the usual manner to give, after crystallization from ethanol, **3k** (3.7 g, 89%): mp 140.5—141.5 °C.

Found: C, 60.88; H, 7.75%. Calcd for $C_{18}H_{28}O_7$: C, 60.65; H, 7.93%.

Compound **3k** (0.2 g) was hydrolyzed with boiling 80% aqueous acetic acid (10 ml) and acetylated to give pentaacetyl-4-*O*-methyl-*myo*-inositol (-DL-ononitol) (0.21 g, 84%): mp 131—132 °C (lit,[5] 134—135 °C).

*Selective Tosylation of **2a**.* To a solution of **2a** (10 g) in dry pyridine (100 ml) was added tosyl chloride (9.5 g, 1.5 molar equiv) at −5 °C under stirring, and then the mixture was allowed to stand in a refrigerator for 2 days. The mixture was poured into ice-water and the precipitates were collected by filtration. The crude product (10.5 g) was recrystallized from toluene to give **2d** (8.6 g, 57%) as practically pure crystals: mp 154—155 °C.

*Selective Benzoylation of **2a**.* *a)* To a solution of **2a** (0.5 g) in dry pyridine (5 ml) was added benzoyl chloride (0.25 ml, 1.3 molar equiv) at −5 °C under stirring. After having been stood at room temperature for 1.5 h, the mixture was poured into ice-water to give 0.5 g of crude products. TLC indicated the presence of two components. Fractional crystallization from 2-butanone gave **2f** (0.22 g, 33%) and the dibenzoyl derivative (**2i**, 0.24 g, 28%): mp 230 °C; NMR ($CDCl_3$) δ 5.77 (dd, 1, $J_{4,5}$=11 Hz, $J_{5,6}$=9 Hz, H-5), 4.44 (dd, 1, $J_{2,3}$=4.5 Hz, $J_{3,4}$=6 Hz, H-3), 4.45 (dd, 1, $J_{1,6}$=10 Hz, H-6), 4.85 (t, 1, $J_{1,2}$=4.5 Hz, H-2), 5.51 (dd, 1, H-1), 5.69 (dd, 1, H-4).

Found: C, 68.56; H, 6.43%. Calcd for $C_{29}H_{32}O_8$; C, 68.49; H, 6.34%.

b) To a solution of **2a** (3 g) in dry pyridine (30 ml) was added benzoic anhydride (2.9 g, 1.3 molar equiv) and the mixture was allowed to stand at room temperature for 5 days. TLC indicated one major and one minor spots. The reaction mixture was poured into ice-water and the resulting crystals were recrystallized from 2-butanone to give **2i** (0.6 g, 12%). The mother liquor from **2i** was concentrated and crystallized from toluene to give 6-*O*-benzoyl-1,2-*O*-cyclohexylidene-4,5-*O*-isopropylidene-*myo*-inositol (**2j**, 2.1 g, 52%) as needles: mp 169—174 °C. Recrystallized sample melted at 177—178 °C: NMR ($CDCl_3$) δ 5.63 (dd, 1, $J_{1,6}$=6 Hz, $J_{5,6}$=11 Hz, H-6).

Found: C, 65.47; H, 7.00%. Calcd for $C_{22}H_{28}O_7$: C, 65.32; H, 6.99%.

The presence of a trace of **2f** was detected in crude **2j** by the NMR spectrum.

1-O-Benzoyl-5,6-O-cyclohexylidene-2,3-O-isopropylidene-chiro-*inositol (**4a**).* A mixture of **2d** (4 g) and sodium benzoate (3.8 g, 3 molar equiv) in *N,N*-dimethylformamide (100 ml) was refluxed for 120 h. After cooling, ethyl acetate (80 ml) was added to the reaction mixture and an insoluble matter was removed by filtration. The filtrate was evaporated to dryness and the residue was extracted with hot ethyl acetate (3×50 ml). The extracts were filtered through a short column of alumina and evaporated to give a syrup, which was crystallized from ethanol to give **4a** (1.8 g, 52%) as crystals: mp 176.5—177 °C.

Found: C, 65.46; H, 6.96%. Calcd for $C_{22}H_{28}O_7$: C, 65.32; H, 6.99%.

Compound **4a** (0.2 g) was acetylated in the usual manner to give, after crystallization from ethanol, the acetyl derivative (**4b**, 0.19 g, 86%) as needles: mp 166.5—167 °C; NMR ($CDCl_3$) δ 2.19 (s, 3, OAc), 5.42 (dd, 1, J=5.5 Hz, J=11 Hz, H-3), 6.07 (t, 1, J=1.5 Hz, H-6).

Found: C, 64.28; H, 6.67%. Calcd for $C_{24}H_{30}O_8$: C, 64.55; H, 6.79%.

1,2-O-Cyclohexylidene-chiro-*inositol (**5**).* Compound **4a** (3 g) was dissolved in a mixture of chloroform (60 ml) and ethanol (15 ml), and *p*-toluenesulfonic acid (0.3 g) was added at 0 °C. The mixture was allowed to stand in a refrigerator overnight. Then the mixture was diluted with methanol (60 ml) and 1 M methanolic sodium methoxide (12 ml) was added. After having been stood at room temperature, the resulting crystals were collected to give **5** (1.8 g, 95%): mp 181—183 °C. Recrystallization from ethanol–water gave pure prisms: mp 182—183 °C.

Found: C, 55.64; H, 7.73%. Calcd for $C_{12}H_{20}O_6$: C, 55.36; H, 7.76%.

Hydrolysis of **5** (0.05 g) with boiling 6 M hydrochloric acid (10 ml) for 1 h gave *chiro*-inositol (0.03 g, 81%) as crystals: mp 227—235 °C. Recrystallization from ethanol–water gave a pure sample: mp 245—247 °C (lit,[7] 253 °C).

1-O-Benzoyl-5,6-O-cyclohexylidene-2,3-O-isopropylidene-4-O-tosyl-chiro-*inositol (**4c**).* *a)* A mixture of **2b** (2.5 g) and sodium benzoate (2 g) in *N,N*-dimethylformamide (50 ml) was refluxed for 50 h. The reaction mixture was cooled to room temperature and diluted with 2-butanone (30 ml). An insoluble matter was removed by filtration and the filtrate was filtrated through a short alumina column. Evaporation gave a syrup that was crystallized from methanol to give **4c** (1.7 g, 72%): mp 141.5—144.5 °C. Recrystallization from 2-butanone–methanol gave pure product (1.4 g, 63%): mp 165.5—167 °C; NMR ($CDCl_3$) δ 2.43 (s, 3, tosyl CH_3), 4.70—5.00 (m, 1, H-4), 5.94 (broad d, 1, J=*ca.* 2 Hz, H-1).

Found: C, 62.57; H, 6.19; S, 5.92%. Calcd for $C_{29}H_{34}O_9S$: C, 62.34; H, 6.14; S, 5.74%.

b) A mixture of **2b** (2 g) and sodium benzoate (2 g) in *N,N*-dimethylformamide (70 ml) was refluxed for 70 h. The mixture was processed as described above to give crystalline mixtures. Fractional crystallization from ethanol–ethyl acetate gave **4c** (0.55 g, 31%): mp 162—165 °C, and 2,6-di-*O*-benzoyl-3,4-*O*-cyclohexylidene-1,6-*O*-isopropylidene-*allo*-inositol (**6**, 0.16 g, 10%): mp 210—212 °C; NMR ($CDCl_3$) δ 4.26 (dd, 1, J=10.5 Hz, J=2.5 Hz), 4.70 (dd, 1, J=3 Hz, J=10.5 Hz), 5.95—6.20 (m, 2, H-2 and H-5).

Found: C, 68.47; H, 6.44%. Calcd for $C_{29}H_{32}O_8$: C, 68.49; H, 6.34%.

1,2-O-Cyclohexylidene-4,5-O-isopropylidene-3-O-tosyl-chiro-*inositol (**4d**).* A solution of **4c** (2 g) in 2-butanone (20 ml) was treated with catalytic amount of methanolic sodium methoxide for 40 min at room temperature. The reaction mixture was neutralized with acetic acid and evaporated to give a white solid, which was chromatographed on silica gel (70 g) with 2-butanone–toluene (1 : 4, v/v). The major fractions were collected and crystallized from 2-butanone–toluene to give **4d** (0.5 g, 31%): mp 134—136 °C.

Found: C, 57.97; H, 6.58; S, 7.10%. Calcd for $C_{22}H_{30}O_8S$: C, 58.13; H, 6.65; S, 7.05%.

1,2,3,6-Tetra-O-benzoyl-4,5-O-cyclohexylidene-muco-*inositol (**7a**) and 1,4-Anhydro-2,3-di-O-benzoyl-5,6-O-cyclohexylidene*-chiro-*inositol (**8**).* A mixture of **1b** (10 g), anhydrous potassium carbonate (10 g) and 80% aqueous 2-methoxyethanol (200 ml) was refluxed for 3.5 h, and then evaporated to dryness. After the residue was dried by codistillation with dry toluene, it was treated with benzoyl chloride (23 ml) in pyridine (60 ml) under ice cooling. After overnight at room temperature, the reaction mixture was poured into ice-water (300 ml) and the resulting gum was extracted with chloro-

form (100 ml). The extract was washed successively with 1M hydrochloric acid, 5% aqueous sodium carbonate, and water, dried, and evaporated to give a syrup that was crystallized from chloroform–ethanol giving a mixture of **7a** and **8**. Fractional crystallization from the same solvents gave **7a** (8.3 g, 51%): mp 177—179 °C; NMR ($CDCl_3$) δ 4.58 (broad d, 2, J=4 Hz, H-4 and H-5), 5.86 (broad d, 2, J=6 Hz, H-1 and H-2), 6.14 (broad dd, 2, H-3 and H-6).

Found: C, 71.26; H, 5.39%. Calcd for $C_{40}H_{36}O_{10}$: C, 70.99; H, 5.36%.

From the mother liquor of **7a**, a small amount of **8** (0.14 g, 1.3%) was obtained as hair like needles: mp 155—157 °C; NMR ($CDCl_3$) δ 4.6—5.2 (m, 4, H-1, H-4, H-5, and H-6), 5.37 (broad t, 1, $J_{2,3}$=3.5 Hz, $J_{3,4}$=4.5 Hz, $J_{3,5}$=*ca.* 1 Hz, H-3), 6.05 (d, 1, H-2).

Found: C, 69.55; H, 5.90%. Calcd for $C_{26}H_{26}O_7$: C, 69.32; H, 5.82%.

1,2,3,6-Tetra-O-*benzoyl*-muco-*inositol (**7b**)*. A mixture of **7a** (6 g) and 80% aqueous acetic acid (50 ml) was refluxed for 1 h. After cooling, the resulting crystals were collected by filtration to give **7b** (4.9 g, 92%): mp 252—254 °C. An analytical sample melted at 256—257 °C after recrystallization from pyridine-ethanol.

Found: C, 68.24; H, 4.90%. Calcd for $C_{34}H_{28}O_{10}$: C, 68.47; H, 4.73%.

A solution of **7b** (0.5 g) in 2-methoxyethanol (10 ml) was treated with 1 M methanolic sodium methoxide (0.5 ml) at 90 °C for 10 min. The reaction mixture was diluted with water and treated with Amberlite IRA-120 (H^+) and then evaporated to give a crystalline residue that was pulverized with ethanol and collected to give crude *muco*-inositol (0.15 g, 98%): mp 190—220 °C. Recrystallization from water–ethanol gave a pure sample (0.13 g): mp 285—290 °C (lit,[8] 281—290 °C).

The authors wish to thank Mr. Toru Fukata, Mr. Shukichi Muto, and Mr. Keiji Iwata for assistance in preparative experiments.

Proton NMR Spectra and Conformations of *N*-Alkyl-*N*-benzyl- and *N*-Alkyl-*N*-(α-chlorobenzyl)carbamoyl Chlorides

Kinko KOYANO, Hiroshi SUZUKI, and Colin R. MCARTHUR*

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153

**Department of Chemistry, York University, 4700 Keele Street, Toronto, Ontario, Canada*

(Received February 12, 1977)

Rotational isomerization about the amide C–N bond of twelve *N*-alkyl-*N*-benzylcarbamoyl chlorides (C_6H_5-CHX-NR-COCl, **1**: X=H, **2**: X=Cl; R=CH_3, C_2H_5, *n*- and *i*-C_3H_7, *n*- and *t*-C_4H_9) was studied by proton NMR spectroscopy. The values of ΔG^* for the isomerization are 15.8—17.3 kcal/mol for compounds **1** and 13.3—15.9 kcal/mol for compounds **2**. Another kind of slow rotation was observed about the benzyl–nitrogen bond of **1**(R=*t*-C_4H_9) and the α-chlorobenzyl–nitrogen bond of **2**(R=CH_3) at low temperature. The chiral centers of compounds **2** produce large nonequivalences for the geminal protons of the 2-methylene group of **2**(R=*n*-C_3H_7) as well as **2**(R=*n*-C_4H_9) and for the geminal methyl protons of **2**(R=*i*-C_3H_7), reflecting some conformational preference of these compounds.

It is well established that the structure of amides can be represented by the hybrid structure I.

I

Extensive studies by NMR spectroscopy, which have been reviewed,[1,2] substantiate the assignment of a partial double bond character to the C–N bond of the amide group. This double bond character, as pointed out by Stewart and Siddall,[1] leads to the following consequences: A comparatively large barrier to the rotation about the C–N bond of the amide group, which can result in nonequivalent signals for the protons in R^1 and the corresponding ones in R^2 even if $R^1=R^2$; and subsidiary hindered rotations about other bonds as a consequence of a rigid, approximately planar framework of the amide group.

In the case of carbamoyl chlorides (I, R^3=Cl), kinetic studies of their amide C–N bond rotations have been reported, especially on dimethylcarbamoyl chloride[3-6] and also on some other derivatives.[7]

The present study examines the NMR spectra of a series of six *N*-alkyl-*N*-benzylcarbamoyl chlorides [**1**; $C_6H_5CH_2$–NR–COCl, R=CH_3 (**1-a**), C_2H_5 (**1-b**), *n*-C_3H_7 (**1-c**), *i*-C_3H_7 (**1-d**), *n*-C_4H_9 (**1-e**), *t*-C_4H_9 (**1-f**)] and of a series of six correspondingly *N*-alkylated (α-chlorobenzyl)carbamoyl chlorides (**2**; C_6H_5CHCl–NR–COCl). First, results of a kinetic study of the amide C–N bond rotations are presented. Secondly, evidence is presented that the restricted rotations about the amide C–N bond gives rise to another slow rotations about the benzyl–nitrogen bond of **1-f** and also the α-chlorobenzyl–nitrogen bond of **2-a** on NMR time scale as the temperature is lowered further. Thirdly, preference of rotational conformations about single bonds of compounds **2** is discussed in view of the nonequivalences of the 2-methylene geminal protons of **2-c** and the geminal methyl groups of **2-d**.

Experimental

The proton NMR spectra were recorded on a JEOL JNM-MH100 spectrometer operating at 100 MHz in the frequency-sweep and internal TMS-locked mode, using Iwasaki-Tsushin UC-80033 universal counter, for *ca.* 5% (w/v) degassed solution in $CDCl_3$ or in hexachloro-1,3-butadiene at various temperatures. Temperatures were calibrated with the hydroxyl shifts of methanol below room temperature and of 1,3-propanediol above room temperature.

The IR spectra were taken with a Japan Spectroscopic Co., Ltd. JASCO DS-403 grating infrared spectrometer.

N-Alkyl-N-benzylcarbamoyl Chlorides. To a stirred solution of 75 ml of a 12.5% solution of phosgene in benzene (0.15 mol of phosgene), maintained in an ice bath, was added, dropwise, a benzene solution (50 ml) of the appropriate *N*-alkylbenzylamine (0.07 mol). The reaction mixture was stirred at room temperature for an hour, and then filtered to remove amine hydrochloride. Benzene was removed from the solution by distillation to afford crude carbamoyl chloride.

*N-t-Butyl-N-benzylcarbamoyl Chloride (**1-f**)*:[10] Yield 47.1%; mp 86—87 °C (recrystd from heptane); IR (Nujol): $\nu_{C=O}$ 1753 cm^{-1}.

N-Alkyl-N-(α-chlorobenzyl)carbamoyl Chlorides. By a procedure similar to that described for *N*-methyl-*N*-(α-chlorobenzyl)carbamoyl chloride (**2-a**),[11] the appropriate *N*-alkylbenzylideneamine was treated with phosgene to give the corresponding *N*-alkyl-*N*-(α-chlorobenzyl)carbamoyl chloride.

*N-Ethyl-N-(α-chlorobenzyl)carbamoyl Chloride (**2-b**)*: Yield 74.4%; bp 96—98 °C (3×10^{-3} Torr); IR (Nujol): $\nu_{C=O}$ 1749 cm^{-1}. Found: C, 51.77; H, 4.94; Cl, 30.51; N, 6.12%. Calcd for $C_{10}H_{11}Cl_2NO$: C, 51.75; H, 4.78; Cl, 30.55; N,

6.04%.

N-*Propyl*-N-*(α-chlorobenzyl)carbamoyl Chloride (2-c)*: Yield 56.9%; bp 99 °C (3×10^{-3} Torr); IR (Nujol): $\nu_{C=O}$ 1747 cm^{-1}. Found: C, 53.74; H, 5.50; Cl, 28.71; N, 5.66%. Calcd for $C_{11}H_{13}Cl_2NO$: C, 53.68; H, 5.32; Cl, 28.81; N, 5.69%.

N-*Isopropyl*-N-*(α-chlorobenzyl)carbamoyl Chloride (2-d)*: Yield 89%, mp 49—51 °C (recrystd from diethyl ether); IR (Nujol): $\nu_{C=O}$ 1758 cm^{-1}. Found: C, 53.47; H, 5.45; Cl, 28.60; N, 5.54%. Calcd for $C_{11}H_{13}Cl_2NO$: C, 53.68; H, 5.32; Cl, 28.81; N, 5.69%.

N-*Butyl*-N-*(α-chlorobenzyl)carbamoyl Chloride (2-e)*: Yield 51.9%; bp 118 °C (4×10^{-4} Torr); IR (Nujol): $\nu_{C=O}$ 1745 cm^{-1}. Found: C, 55.58; H, 5.92; Cl, 27.11; N, 5.44%. Calcd for $C_{12}H_{15}Cl_2NO$: C, 55.39; H, 5.81; Cl, 27.25; N, 5.38%.

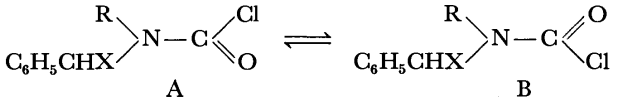
N-t-*Butyl*-N-*(α-chlorobenzyl)carbamoyl Chloride (2-f)*: A sealed tube containing 22.5 g (0.14 mol) of freshly distd *N-t*-butylbenzylideneamine and 150 g of a 12.5% soultion of phosgene in benzene (0.3 mol of phosgene) was heated at about 50 °C for three days. The white precipitate produced (*N-t*-butylbenzylideneamine hydrochloride) was removed by filtration. Removal of benzene from the solution by distillation afforded 30.7 g (84.1% yield) of crude **2-f**; mp 44.5—46.5 °C (recrystd from heptane), dec above 100 °C;[12] IR (Nujol): $\nu_{C=O}$ 1760 cm^{-1}. Found: C, 55.37; H, 5.60; Cl, 27.10; N, 5.27%. Calcd for $C_{12}H_{15}Cl_2NO$: C, 55.39; H, 5.81; Cl, 27.25; N, 5.38%.

Results and Discussion

N-*Alkyl*-N-*benzylcarbamoyl Chlorides (Series 1)*.

Chemical shifts (δ, ppm) of the *N*-alkyl-*N*-benzylcarbamoyl chlorides (**1-a**, **1-b**, **1-c**, **1-d**, **1-e**, and **1-f**) at room temperature are listed in Table 1.

Rotational Isomerism about the Amide C–N Bond: The presence of a pair of singlet signals with unequal intensities for the benzyl α protons of **1-a**, **1-b**, **1-c**, and **1-e** and also a pair of singlet signals for the methyl protons of **1-a** can be interpreted in terms of rotational isomerism between conformers represented as A and B resulting from slow rotation about the amide C–N bond.[1,2]



A ⇌ B

X=H (Series **1**); X=Cl (Series **2**)

Isbrandt and Rogers[3c] showed, by the use of a europium shift reagent, that, of the two signals for dimethylcarbamoyl chloride, the lower-field resonance is assignable to the protons of the methyl group that is cis to the chlorine atom. By analogy, the benzyl α proton signals of the present carbamoyl chlorides at δ=4.6—4.9 ppm (the lower-field signals) can be assigned to those of conformer B, while those at δ=4.5—4.6 ppm (the higher-field signals) can be assigned to the benzylic protons of conformer A.

The fractional populations, P_A and P_B, for each pair of these conformers, together with their coalescence temperatures, are shown in Table 2. From these data, the free energies of activation for the rotational conversion from A to B (ΔG^*_A) and the reverse (ΔG^*_B) were calculated. The results are also included in Table 2.

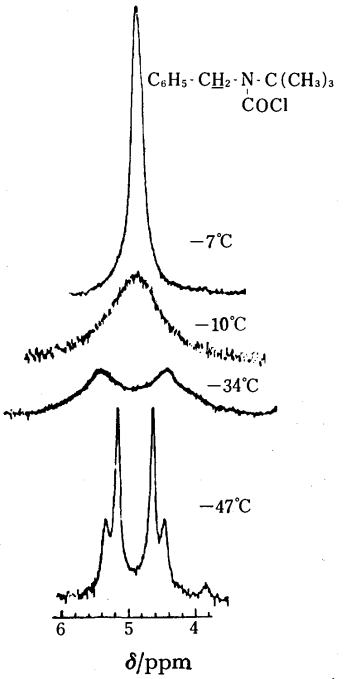


Fig. 1. The temperature dependence of the NMR spectrum of the benzyl protons of *N-t*-butyl-*N*-benzylcarbamoyl chloride, **1-f**, in $CDCl_3$.

For those compounds in which the *N*-alkyl substituent, R, is primary (**1-a**, **1-b**, **1-c**, and **1-e**), conformer A is more stable than conformer B. In those cases in which R is secondary (**1-d**) or tertiary (**1-f**), the reverse occurs. The order of relative populations of conformer A (P_A) is **1-a**≈**1-b**>**1-c**≈**1-e**>**1-d**≫**1-f**. That is, the sterically larger alkyl groups exibit a preference for sites which are further from the chlorine atom (cis to the oxygen atom). For the *N*-methyl derivative (**1-a**), the free energies of activation, ΔG^*_A and ΔG^*_B, are 17.3 and 17.1 kcal/mol, respectively, which are comparable with the value (17 kcal/mol) reported for dimethylcarbamoyl chloride.[3a,3b,4,5,6] With increasing bulkiness of the *N*-alkyl group, the free energy of activation for such rotations decreases. This trend is the same as observed with *N,N*-dialkylamides.[14]

Nonequivalence of the Benzyl α Protons of 1-f: The geminal protons at the benzyl α position of **1-f**, which exists in conformation B exclusively (*cf.* Table 2), resonate nonequivalently at temperatures below −34 °C (AB quartet, ν_{AB}=72.3 Hz, J_{AB}=19.0 Hz), as shown in Fig. 1. Although the benzyl α protons of some *N*-alkyl-*N-t*-butylbenzylamines are nonequivalent because of slow rates of nitrogen inversion,[15] such explanation is unlikely in the present case. The rationale for this conclusion is based on a comparison of the infrared spectrum of **1-f** with that of its α-chlorobenzyl analogue (**2-f**). The carbonyl absorptions are indicative of as much double bond character of the amide C–N bond of **1-f** ($\nu_{C=O}$=1753 cm^{-1}) as that of **2-f** ($\nu_{C=O}$=1760 cm^{-1}). Such double bond character of the amide C–N bond in **2-f** is established by NMR data, which indicates that **2-f** exists in two conformations as a results of restricted rotation about this bond (see the following section). Therefore, the hybridization state of the nitrogen atom of **1-f** is probably sp^2 or nearly so.

C D

Fig. 2. The Newman projection formulas for staggered conformations of *N*-*t*-butyl-*N*-benzylcarbamoyl chloride, **1-f**, with respect to the rotation about the benzyl–nitrogen bond.

The nonequivalence of the benzyl α protons of **1-f** at temperatures below −34 °C can be explained in terms of the molecular asymmetry produced by slow rotation about the benzyl–nitrogen bond, the rotational barriers of which result from the rigidity of the amide plane and the bulkiness of the *t*-butyl group. The most stable conformations are probably staggered conformations C and D in Fig. 2. When the interconversion is slow, the asymmetric field will be brought about on the benzyl α geminal protons. The mean barrier height between C and D was calculated to be 11.4

kcal/mol from the values of T_c, $\Delta\nu_{AB}$, and J_{AB}.[16]

Kiefer[17] reported that the geminal protons of the chloromethyl group of *N*-*t*-butyl-*N*-(chloromethyl)carbamoyl chloride are nonequivalent. This can be interpreted in terms of slow rotation about the chloromethyl–nitrogen bond, in view of the present conclusion on the case of **1-f**.

N-Alkyl-N-(α-chlorobenzyl)carbamoyl Chlorides (Series 2). The chemical shifts (δ, ppm) of **2-a**, **2-b**, **2-c**, **2-d**, **2-e**, and **2-f** at room temperature are given in Table 3. The signals of the benzyl α proton were not detectable, hidden by the signals of the aromatic protons.

Rotational Isomerism about the Amide C–N Bond: Calculations pertaining to equilibrium A⇌B were made from the signals of the methyl protons of **2-a** and **2-f**, and of the 1-methylene protons, H^1, of **2-b**, **2-c**, and **2-e**. In these compounds, as in the compounds of series **1**, the protons of the alkyl groups which are cis to the chlorine atom of the chloroformyl group (conformer A) are assumed to resonate at lower-field regions than those which are trans to the chlorine atom (conformer B). Calculated fractional populations (P_A, P_B) and free energies of activation (ΔG^*_A and ΔG^*_B) are shown in Table 4.

The *N*-methyl derivative (**2-a**) prefers conformation A, while the *N*-*t*-butyl derivative (**2-f**) prefers conformation B, which is consistent with that found for **1-a** and **1-f**. The values of P_A/P_B for **2-a**, **2-b**, and **2-f**, which were relatively precisely estimated, are greater than the values for the corresponding compounds of series **1**, **1-a**, **1-b**, and **1-f**, respectively. The free energies of activation for rotation about the C–N bond of the compounds of series **2** are smaller than the corresponding compounds of series **1**. These facts are attributed to the increase in repulsive interactions of the benzyl group with the chloroformyl group, especially its chlorine atom, in stable conformations A and B, by introduction of the α-Cl substituent. The free energies of activation are lowest for **2-f**. This is probably due to destabilization of conformations A and B by steric repulsion of the chloroformyl group with the bulky *t*-butyl group in addition to that with the α-chlorobenzyl group.

The δ value of the signal of the *t*-butyl protons of **2-f** in conformation B is 1.40 ppm, while that in conformation A is 1.67 ppm. Since the δ value of the signal of the *t*-butyl protons of **1-f** is 1.43 ppm, the aforementioned assignment of B to the most preferred conformation of **1-f** is consistent.

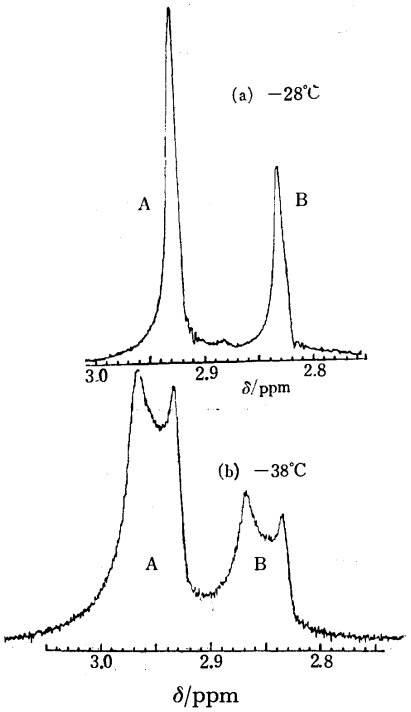

Fig. 3. NMR spectra of the methyl protons of *N*-methyl-*N*-(α-chlorobenzyl)carbamoyl chloride, **2-a**, (a) at −28 °C and, (b) −38 °C.

Rotational Isomerism about the α-Chlorobenzyl–Nitrogen Bond of 2-a: **2-a** shows two kinds of spectral change at low temperatures. The first one is due to the conformational interconversion A⇌B with the signal coalescence temperature at 24.5 °C. The second one is the splitting of each of the methyl signals for conformations A and B into two signals, shown in Fig. 3. The latter spectral change is ascribed to freezing of the interconversion of two relatively stable conformations about the α-chlorobenzyl–nitrogen bond. The values of ΔG^* for this conversion is estimated at about 10 kcal/mol. This comparatively large restriction to the conversion is probably caused by rigidity of the amide plane.

In light of a result of calculation of van der Waals energy by Allinger's modification[18a,b] of Hill's method[19] a qualitative potential energy curve for the rotation about the α-chlorobenzyl–nitrogen bond of **2-a** is

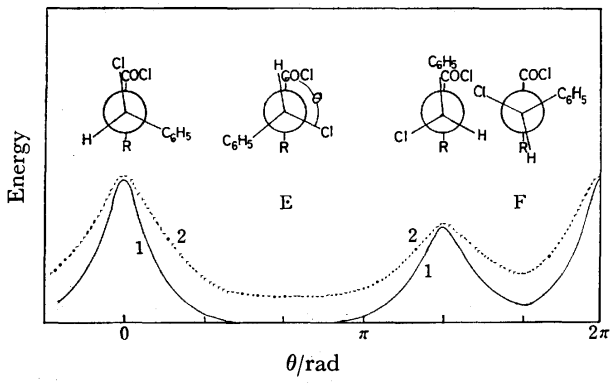

Fig. 4. Schematic potential-energy diagram for the rotation about the benzyl–nitrogen bond of *N*-alkyl-*N*-(α-chlorobenzyl)carbamoyl chlorides. θ represents the dihedral angle between the chlorine–carbon bond of the α-chlorobenzyl group and the chloroformyl–nitrogen bond. Curve 1——: **2-a**; curve 2……: **2-c**.

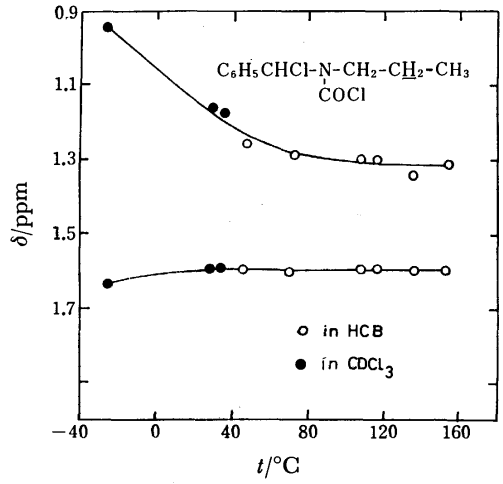

Fig. 5. Temperature-dependence of nonequivalent chemical shifts (from TMS) of the 2-methylene geminal protons of *N*-propyl-*N*-(α-chlorobenzyl)carbamoyl chloride, **2-c**. ●: in $CDCl_3$; ○: in hexachlorobutadiene.

depicted with a solid line (curve 1) in Fig. 4, which shows two stable conformations, E and F, intervened by potential energy barriers at $\theta=0$ and $4\pi/3$ rad. θ is the dihedral angle between the chlorine–carbon bond of the α-chlorobenzyl group and the chloroformyl–nitrogen bond. Of the two peaks of each of the methyl signals for A and B in Fig. 3(b), the more intense one at lower field is assigned to the more stable conformation, E, and the weaker one at higher field to the less stable conformation, F. In conformation E, the phenyl group and the chlorine atom of the α-chlorobenzyl group are close to the methyl group, and hence, must exert a downfield effect on it.

Nonequivalence of the 2-Methylene Protons of ***2-c*** *and* ***2-e***: As is seen in Table 3, even above the coalescence temperature for the interconversion of conformations A and B, the geminal protons of the 2-methylene group, H^2, of **2-c** as well as those of **2-e**, give rise to two signals of equal intensity, that is, are nonequivalent, although the geminal protons of the other methylene groups appear

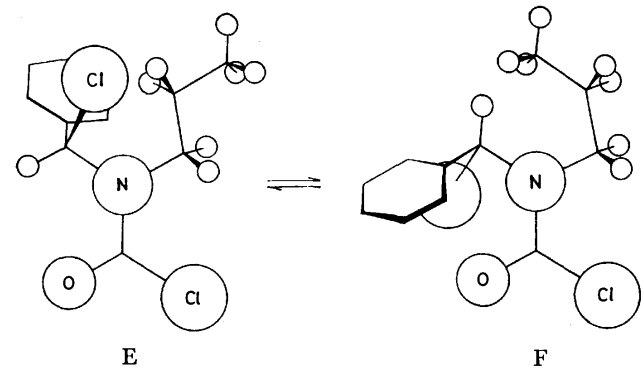

Fig. 6. Molecular model representation for a conversion between conformations E and F of *N*-propyl-*N*-(α-chlorobenzyl)carbamoyl chloride, **2-c**: rotation about the α-chlorobenzyl–nitrogen bond.

as equivalent. It is evident that these nonequivalences are originated from the chirality of the configuration about the α-carbon atom of the α-chlorobenzyl group.

These nonequivalences decrease with rising temperature. In the case of **2-c**, the difference in chemical shift between the two signals is about 80 Hz at −30 °C, and decreases to 40 Hz at 80 °C, as shown in Fig. 5. In spite of the shift, the splitting patterns of the nonequivalent signals do not essentially change. This fact indicates that rotation about any bond other than the amide C–N bond is not frozen even at the lowest temperature measured (−30 °C).

The shift may be elucidated by the change in population of the conformers about the α-chlorobenzyl–nitrogen bond, as follows. The potential energy curve of **2-c** as well as **2-e** about this bond may be similar to that of **2-a**, as a whole, but may be somewhat shallower, as shown with a dotted line (curve 2) in Fig. 4. In the more stable conformation E, the alkyl group is in close proximity of the phenyl group and the chlorine atom, both of which have large magnetic anisotropies and must impart large asymmetric field gradient to the 2-methylene protons. The terminal methyl or ethyl group of the alkyl group of the molecule in conformation E forces the protons of the 2-methylene group to face the chiral center, as a result of avoiding its repulsive interaction with the α-chlorobenzyl group (Fig. 6). When the molecule is in conformation F, the field gradient experienced by the same protons should be small because of the long distance from the chiral center. Therefore, increasing contribution of conformation F with rising temperature reduces the nonequivalence of the 2-methylene protons.

Nonequivalence of the Geminal Methyl Groups of ***2-d***: The protons of the geminal methyl groups, H^2 and $H^{(2)}$, of **2-d** are also nonequivalent. Raising temperature causes a decrease in the separation of the signals accompanied by a gradual movement to higher fields, as shown in Fig. 7. This nonequivalence is not caused by the conformational interconversion A⇌B. The difference in chemical shift of H^1 between conformations A and B is not so large to permit the analysis of multiplets. As to the chemical shift of the methyl groups, there is no difference between conformations A and B of **2-d**, while the corresponding chemical shifts of **2-f**

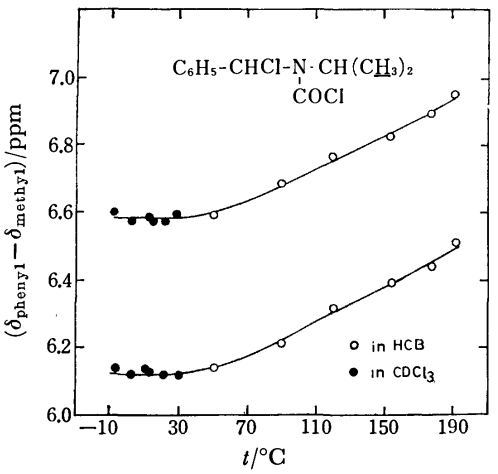

Fig. 7. Temperature-dependence of nonequivalent chemical shifts, $(\delta_{phenyl}-\delta_{methyl})$/ppm, of the geminal methyl protons of *N*-isopropyl-*N*-(α-chlorobenzyl)-carbamoyl chloride, **2-d**. ●: in $CDCl_3$; ○: in hexachlorobutadiene.

are separated 0.27 ppm from each other. This implies that both methyl groups of the isopropyl group can be apart from the chloroformyl group, while, at least, one of the methyl groups of the *t*-butyl group must be in close proximity to the chloroformyl group. The preferable conformation of **2-d** may resemble conformation E of **2-c** shown in Fig. 6. In this conformation, the nonequivalence of the two methyl signals may be largest, because one of the methyl groups approaches the chlorine atom, receiving a downfield effect from it, and the other methyl group comes just above the plane of the phenyl ring, receiving an upfield effect from it.

In the present cases, nonequivalent protons is three bonds removed from the chiral center. In a study of the NMR spectra of a series of compounds, $C_6H_5CH(CH_3)CH(CH_3)_2$, $C_6H_5CH(CH_3)O(CH_2)_nCH(CH_3)_2$ (n=0,1,2) and $C_6H_5CH(CH_3)O(CH_2)_2O(CH_2)_nCH(CH_3)_2$($n$=0,1), Whitesides *et al.*[20] have found that the nonequivalence of the geminal methyl protons does not decrease monotonically as the number of bonds separating the chiral center from the geminal methyl groups increases, and that it is unexpectedly large when these methyl groups are five bonds removed from the chiral center. The difference may originate from a greater flexibility of an ether molecule compared with the present carbamoyl chloride molecules, which bear a rigid amide plane and bulky phenyl and chlorine substituents.

The σ-Bonded Palladium(II) Complex of 2-Pyridylferrocene

Akira KASAHARA, Taeko IZUMI, and Mitsugi MAEMURA

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa 992

(Received February 22, 1977)

2-Pyridylferrocene reacts with lithium tetrachloropalladate(II) in the presence of sodium acetate to give an *ortho*-palladated binuclear complex (**4**). The σ-bonded structure of **4** was confirmed by studies of the IR and NMR spectra and of the reactions of **4** with thallium(I) acetylacetonate and lithium aluminum deuteride. The reactions of **4** with carbon monoxide, butyllithium, and bromine were also examined.

Following the first report of the intramolecular *ortho*-palladation of azobenzene and *N,N*-dimethylbenzylamine[1] there has been considerable interest in the intramolecular *ortho*-metalation of nitrogen, phosphorus, and sulfur donor ligands by transition metals.[2] With reference to the *ortho*-metalation, Alper[3] reported the first example of the intramolecular *ortho*-palladation of a metallocene by the reaction of thiopivaloylferrocene with sodium tetrachloropalladate(II); Gaunt and Shaw[4] also described the intramolecular *ortho*-palladation of (dimethylaminomethyl)ferrocene. One might, therefore, expect that 2-pyridylferrocene (**1**) would undergo palladation very readily, since it is well known that a ring in ferrocene is much more susceptible to electrophilic attack than a benzene ring.[5] In this report, we wish to report on the intramolecular *ortho*-palladation of **1** and the reaction of the metalation product with various reagents.

Results and Discussion

The treatment of **1** in methanol or dioxane with lithium tetrachloropalladate(II) gave dichlorobis(2-pyridylferrocene)palladium(II) (**2**) containing the unpalladated ligand. The **2** structure was consistent with the results of the elemental analysis and the IR spectrum of the compound. Rosenblum and Howells[6] have previously suggested that the IR spectra may serve to define the structures of homoannularly-disubstituted ferrocene derivatives; the 1,2-isomer possesses one band near 917 cm^{-1}. Compound **2** exhibited no absorption near 917 cm^{-1}. Furthermore, the reaction of **2** with triphenylphosphine in a ligand-replacement reaction gave a quantitative yield of dichlorobis(triphenylphosphine)-palladium(II) (**3**), as identified by comparison with an authentic sample.

On the other hand, when mole equivalents of lithium tetrachloropalladate(II), **1**, and sodium acetate trihydrate were stirred together in methanol, a new complex (**4**) was obtained. On the basis of the microanalytical and spectroscopic data, the molecular weight, and the reactions, **4** was shown to be an intramolecularly *ortho*-palladated complex. It has previously been shown that the acetate ion promoted an internal metalation reaction.[7] The **4** complex shows reactions typical of a chlorine-bridged binuclear complex of palladium; the reactions with thallium(I) acetylacetonate and triphenylphosphine produce the monomeric acetylacetonate (**5**) and triphenylphosphine (**6**) derivatives respectively. The IR spectra of the ferrocene derivatives prepared in this study are recorded in Table 1. Compounds **4**, **5**, and **6** exhibited absorptions near 1100, 1000, and 910 cm^{-1} characteristic of homoannularly 1,2-disubstituted ferrocene derivatives.[6] In addition, in the far-infrared spectrum of **4** there are three bands, assigned to bridged Pd–Cl stretching absorptions at 317, 296, and 255 cm^{-1}. Presumably the band at 296 cm^{-1} is due to a solid-state effect. The lithium aluminum hydride reduction of **4** gave **1**, whose mass spectrum was identical with that of an authentic sample. On the other hand, the lithium aluminum deuteride reduction of **4** gave 1-(2-pyridyl)ferrocene-2-d_1 (**7**). The position of the deuterium and, therefore, the site of the carbon-to-palladium σ-bond were established by a comparison of the NMR spectrum of **7** with that of the undeuterated **1**. The above evidence established that a σ-bond has been formed between the palladium and the ferrocene moiety.

Recently, the reactions of *ortho*-palladation products from numerous α-arylnitrogen derivatives with carbon monoxide,[8,9] chlorine,[10] and alkyllithium or a Grignard reagent[11,12] have been reported. The carbonylation of *ortho*-palladation products of azobenzene, Schiff bases, and tertiary benzylamines usually gives a variety of heterocyclic compounds.[8,9] The attempted carbonylation of the **4** complex in ethanol was unsuccessful, even at 100 °C; however, the triphenylphosphine derivative, **6**, in ethanol was readily carbonylated at 100 °C to produce an uncyclized ester, 2-ethoxycarbonyl-1-(2-pyridyl)ferrocene (**8**), in a 37% yield. The **6** complex was also smoothly brominated in chloroform at room temperature, forming 2-bromo-1-(2-pyridyl)ferrocene (**9**) in a 35% yield. Furthermore, the treatment of **6** with

Table 1. The IR absorption frequencies (cm^{-1}) of 2-pyridylferrocene derivatives

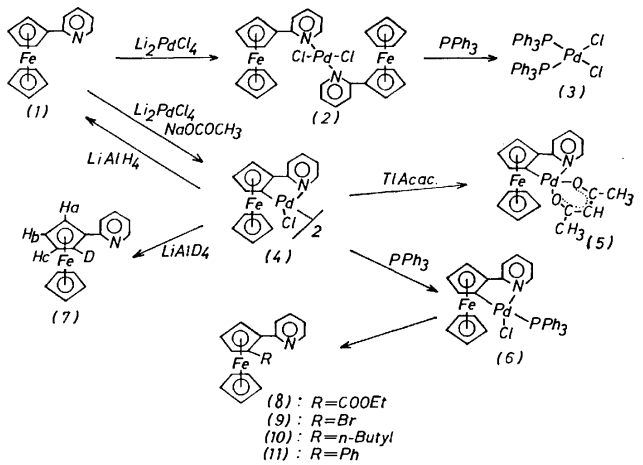

Fig. 1.

butyllithium and phenyllithium gave 2-butyl-1-(2-pyridyl)ferrocene (**10**) (34% yield) and 2-phenyl-1-(2-pyridyl)ferrocene (**11**) (27% yield) respectively. Compounds **8**, **9**, **10**, and **11** exhibit absorptions near 1100, 1000, and 910 cm^{-1} characteristic of homoannularly 1,2-disubstituted ferrocene derivatives.[6] Moreover, the NMR and mass spectra of the compounds were all consistent with the proposed structures.

Experimental

Materials and Analysis. All the melting points are uncorrected. The 2-pyridylferrocene (**1**) was prepared by the method previously reported.[13] The IR spectra were measured on KBr disks (4000—650 cm^{-1}) or in Nujol mulls mounted on thin polythene windows (700—200 cm^{-1}), using Hitachi 215 and EPI-L spectrometers. The NMR spectra were taken in $CDCl_3$ with TMS as the standard and were recorded with a Hitachi R-22 spectrometer at 90 MHz. The mass spectra were obtained with a Hitachi RMU-6M mass spectrometer, using a direct inlet and an ionization energy of 70 eV. The molecular weight was determined in $CHCl_3$, using a Hitachi 115 vapor-pressure osmometer.

Dichlorobis(2-pyridylferrocene)palladium(II) (2). A solution of 1.31 g (5 mmol) of lithium tetrachloropalladate(II) in 30 ml of methanol or 30 ml of a mixture of dioxane and water (1 : 1) was stirred drop by drop at room temperature, into a solution of 1.31 g (5 mmol) of **1** in 20 ml of methanol or dioxane. The brownish precipitate which formed immediately was filtered and washed successively with several portions of water and then ether. The solid (3.4 g, 97% yield) was insoluble in all common solvents; mp 185—190 °C (dec). Found: C, 51.02; H, 3.56; N, 3.77%. Calcd for $C_{30}H_{26}Cl_2Fe_2N_2Pd$: C, 51.21; H, 3.72; N, 3.98%.

*Ligand-replacement Reaction of **2** with Triphenylphosphine.* 0.35 g of **2** and 0.13 g of triphenylphosphine were placed in 15 ml of ethanol, and the mixture was stirred at 80 °C for 24 h. The resultant solid was collected and washed several times with ethanol to give a quantitative yield of dichlorobis(triphenylphosphine)palladium(II) (**3**) (mp 250—260 °C (dec)), whose IR spectrum was identical to that of an authentic sample.[14] The concentration of the filtrate *in vacuo* gave **1** (mp 91—92 °C (lit,[13] mp 92—93 °C)).

Di-μ-chlorobis[2-(2-pyridyl)ferrocenyl]dipalladium(II) (4). A solution of 1.31 g (5 mmol) of **1** in methanol (30 ml) was added to a mixture of lithium tetrachloropalladate(II) (1.31 g, 5 mmol) and sodium acetate trihydrate (0.68 g, 5 mmol) in methanol (50 ml). The new mixture was then stirred for 20 h at room temperature, and the reddish precipitate which formed was filtered off and dried (yield: 4.20 g; 99% yield). A portion was recrystallized from chloroform-cyclohexane; mp 240—244 °C (dec). NMR δ: 4.31 (6H, H_b+unsubstituted ferrocene ring protons, singlet); 5.14 (1H, H_a, multiplet); 5.33 (1H, H_c, multiplet); 7.01—8.64 ppm (4H, pyridyl protons, multiplet). Found: C, 44.46; H, 2.87; N, 3.41%; mol wt 786. Calcd for $C_{30}H_{24}Cl_2Fe_2N_2Pd_2$: C, 44.60; H, 2.99; N, 3.46%; mol wt, 808.

Acetylacetonato[2-(2-pyridyl)ferrocenyl]palladium(II) (5). A solution of thallium(I) acetylacetonate (0.30 g, 1 mmol) and the **4** complex (0.40 g, 0.5 mmol) in benzene (20 ml) was stirred for 24 h at room temperature and then filtered. The filtrate was then evaporated under reduced pressure, giving a red oil. After purification by column chromatography on silica gel (benzene), the product, **5**, was obtained as orange prisms from hexane–benzene; mp 151—152 °C, NMR δ: 2.06 (6H, CH_3 of acac group, singlet); 4.18 (5H, unsubstituted ferrocene ring protons, singlet); 4.40 (1H, H_b, double-doublet); 4.63 (1H, H_a, doublet); 4.76 (1H, H_c, doublet); 5.41 (1H, **H**–C of acac group, singlet); 6.97—8.70 ppm (4H, pyridyl protons, multiplet). Found: C, 51.25; H, 3.97; N, 2.91%; M^+, 467. Calcd for $C_{20}H_{19}FeNO_2Pd$: C, 51.37; H, 4.09; N, 2.99%; M, 467.

Chloro[2-(2-pyridyl)ferrocenyl](triphenylphosphine)palladium(II) (6). Triphenylphosphine (0.26 g, 1 mmol) and the **4** complex (0.40 g, 0.5 mmol) were dissolved in benzene (20 ml), and then the mixture was stirred for 4 h. The solvent was removed under reduced pressure, and the product (0.60 g, 90% yield) was obtained as orange plates from ethanol; mp 136—138 °C (dec). Found: C, 59.25; H, 3.96; N, 2.03 %; mol wt, 654 (in $CHCl_3$). Calcd for $C_{33}H_{27}ClFeNPPd$: C, 59.49; H, 4.07; N, 2.12%; mol wt, 666.

*Reduction of the **4** Complex with Lithium Aluminum Hydride.* Lithium aluminum hydride (0.02 g, 0.5 mmol) in anhydrous ether (50 ml) was slowly added to a solution of the **4** complex (0.4 g, 0.5 mmol) in anhydrous ether (50 ml). The resulting black mixture was stirred at room temperature for 4 h; then water (10 ml) was added with cooling. The ether layer was washed with water and dried over anhydrous magnesium sulfate. After the removal of the solvent, **1** was obtained as reddish plates from benzene-cyclohexane; mp 91—92 °C (lit,[13] mp 92—93 °C). NMR δ: 4.07 (5H, unsubstituted ferrocene ring protons, singlet); 4.42 (2H, H_b, multiplet); 4.94 (2H, H_a, multiplet); 7.01—8.59 ppm (4H, pyridy protons, multiplet). MS: M^+ 263. Calcd for $C_{15}H_{13}FeN$: M, 263.

*Reduction of the **4** Complex with Lithuim Aluminum Deuteride.* The reduction of **4** (0.40 g) in anhydrous ether with lithium aluminum deuteride (0.02 g) was carried out as in the preceding experiment; this gave a product (mp 92—93 °C) which can be identified as 1-(2-pyridyl)ferrocene-2-d_1 (**7**) on the basis of the following evidence: NMR δ: 4.07 (5H, unsubstituted ferrocene ring protons, singlet); 4.42 (2H, H_b, multiplet); 4.92 (1H, H_a, multiplet); 7.00—8.60 ppm (4H, pyridyl protons, multiplet). Found: C, 68.05; H, 5.31; N, 5.19%; M^+, 264. Calcd for $C_{15}H_{12}DFeN$: C, 68.13; H, 5.38; N, 5.30%; M, 264.

*Carbonylation of the **6** Complex in Ethanol.* In ethanol (50 ml), the **6** complex (3.33 g, 5 mmol) was carbonylated at 100 °C under a carbon monoxide pressure of 80 atm for 10 h with shaking. The product was then isolated by filtering to remove a precipitated palladium and distilling under reduced pressure to remove the solvent. The residue was dissolved in chloroform and chromatographed on silica gel to afford red crystals (0.62 g; 37% yield), which can be identified as 2-ethoxycarbonyl-1-(2-pyridyl)ferrocene (8); mp 108

—110 °C. NMR δ: 1.21 (3H, CH_3 of ester group, triplet); 4.29 (5H, unsubstituted ferrocene ring protons, singlet); 4.40 (3H, $\mathbf{H_b}+\mathbf{CH_2}$ of ester group, multiplet); 4.68 (1H, $\mathbf{H_a}$, multiplet); 4.87 (1H, $\mathbf{H_c}$, multiplet); 7.06—8.74 ppm (4H, pyridyl protons, multiplet). Found: C, 64.38; H, 5.06; N, 4.05%; M^+, 335. Calcd for $C_{18}H_{17}FeNO_2$: C, 64.52; H, 5.11; N, 4.17%; M, 335.

Reaction of the ***6*** *Complex with Bromine.* Under a nitrogen atmosphere, bromine (0.90 g, 5 mmol) in chloroform (15 ml) was slowly added in a solution of the **6** complex (3.33 g, 5 mmol) in chloroform (50 ml). After stirring at room temperature for 4 h, the reaction mixture was filtered and the chloroform phase washed several times with water, dried over anhydrous magnesium sulfate, and concentrated. The residue was dissolved in chloroform and chromatographed on silica gel afford reddish crystals (0.60 g; 35% yield), which can be identified as 2-bromo-1-(2-pyridyl)ferrocene (**9**); mp 95—97 °C. NMR δ: 3.70 (5H, unsubstituted ferrocene ring protons); 4.32 (2H, $\mathbf{H_b}+\mathbf{H_c}$, multiplet); 4.85 (1H, $\mathbf{H_a}$, multiplet); 7.16—8.64 ppm (4H, pyridyl protons, multiplet). Found: C, 52.21; H, 4.10; N, 3.89%; M^+, 344. Calcd for $C_{15}H_{12}BrFeN$: C, 52.37; H, 4.01; 4.07%; M, 344.

Reaction of the ***6*** *Complex with Butyllithium.* Under a nitrogen atmosphere, the **6** complex (3.33 g, 5 mmol) in dry benzene (50 ml) was reacted with 10 mmol of butyllithium in ether. After stirring at 50 °C for 8 h, the products were isolated by diluting the cooled reaction mixtures with water and chloroform. The chloroform phase was separated, washed several times with water, dried over anhydrous magnesium sulfate, and concentrated. The residue was dissolved in chloroform and chromatographed on silica gel. The first elution with chloroform afforded red crystals (0.21 g, mp 91—93 °C); they were identified as 2-pyridylferrocene (**1**) by a comparison of the IR and NMR spectra with those of an authentic sample and by a mixed-melting-point determination. The second elution with chloroform afforded a heavy reddish oil (0.54 g, 34% yield) which can be identified as 2-butyl-1-(2-pyridyl)ferrocene (**10**) on the basis of the following evidence: NMR δ: 0.92 (3H, $\mathbf{CH_3}$ of butyl group, triplet), 1.15—1.87 (4H, $\mathbf{CH_2}$ of butyl group, multiplet); 2.80 (2H, ferrocenyl-$\mathbf{CH_2}$–, triplet); 4.11 (5H, unsubstituted ferrocene ring protons, singlet); 4.38 (2H, $\mathbf{H_b}+\mathbf{H_c}$, multiplet); 4.96 (1H, $\mathbf{H_b}$, multiplet); 6.80—8.60 ppm (4H, pyridyl protons, multiplet). Found: C, 71.28; H, 6.55; N, 4.26%; M^+, 319. Calcd for $C_{19}H_{21}FeN$: C, 71.49; H, 6.63; N, 4.38%; M, 319.

Reaction of the ***6*** *Complex with Phenyllithium.* The reaction of **6** (3.33 g, 5 mmol) with 10 mmol of phenyllithium in ether was carried out as in the preceding experiment; it gave a product (0.46 g, yield, 27%) which can be identified as 2-phenyl-1-(2-pyridyl)ferrocene (**11**); mp 235 °C (dec). NMR δ: 3.93 (5H, unsubstituted ferrocene ring protons); 4.12 (1H, $\mathbf{H_b}$, multiplet); 4.77 (2H, $\mathbf{H_a}+\mathbf{H_c}$, multiplet); 7.18—8.49 ppm (9H, phenyl and pyridyl protons, mutiplet). Found: C, 74.25; H, 4.87; N, 4.03; M^+, 339. Calcd for $C_{21}H_{17}FeN$: C, 74.40; H, 5.05; N, 4.13; M, 339.

The Effect of Water Vapor on Contamination of Metallic Oxide Surfaces

Yasukatsu TAMAI, Toshiaki MATSUNAGA, and Kazutomi SUZUKI

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira, Sendai 980

(Received February 2, 1977)

Synopsis. The contamination rates of the clean surfaces of metallic oxides by liquid-paraffin vapor are largely reduced by the coexisting water vapor. They are related to the hydrophilicity of oxides evaluated as the water-solid interaction free energy by the two-liquid-contact-angle method.

High energy surfaces such as those of metallic oxides or metals are liable to be contaminated by organic vapor in the air. The sensitive change in the contact angle of water can be utilized for the detection of organic contaminant.[1] As White[2] pointed out, organic contamination should be regarded as adsorption and not the "falling out" of materials onto a surface.

Since oxide surfaces have strong affinity to water, coexisting water vapor would have some effect on the adsorption of organic compounds on a high energy surface. In order to study the effect of coexisting water vapor on organic contamination of several metallic oxides by liquid-paraffin vapor, we have measured the contact angles of water drops. The results are discussed in relation to the affinity of oxide surfaces to water.

Experimental

A quartz glass plate for an optical cell, and five single crystal plates of oxides, rutile (TiO_2)(001), chromia (Cr_2O_3)(0001), α-alumina (Al_2O_3)(0001), nickel oxide (NiO)(100), and strontium titanate ($SrTiO_3$) were examined. The numbers in parentheses indicate the crystal planes investigated. The surface of strontium titanate was not a low index crystal plane. The purity of single crystals was 99.9—99.99%.

All the surfaces were polished up to specular surfaces with emery paper and diamond-powder paste. The surfaces were cleaned before each measurement with an ultrasonic cleaner in a detergent solution, followed by thorough washing with redistilled water. Water could perfectly wet the surfaces.

In order to detect possible impurities originating from the cleaning process, the Auger spectra for alumina samples were measured with a Physical Electronics Instruments, Type CAS 545, apparatus. Only traces of phosphorus and carbon other than aluminum and oxygen were detected. Their coverage was estimated to be smaller than 1% Carbon might have come from the contaminants in the Auger apparatus.

The oxide plate was subjected to contamination in a Petri dish containing two small vessels, one filled with liquid paraffin and the other with water for wet atmosphere and with phosphorus pentoxide for dry atmosphere. The oxide sample was picked out after a certain time and transfered to an optical cell for measurement of contact angles of water drops by means of a goniometer-telescope system at 20±0.5 °C. The points in Figs. 1 and 2 represent the average of ten to twenty advancing contact angles, the accuracy being *ca.* ±2 degrees.

Liquid paraffin (spectroscopic grade) was used as an organic contaminant. Water was redistilled from an alkaline permanganate solution in a Pyrex glass apparatus.

Results and Discussion

Changes in contact angle of water with time in dry atmosphere and in saturated water are shown in Figs. 1 and 2, respectively. The order of contamination rates is: silica<α-alumina<nickel oxide<chromia<strontium titanate<rutile. This order is the same under both conditions, regardless of the coexisting water vapor. However, water vapor supresses organic contamination of all the oxides. The tendency is larger for the surfaces which are more easily contaminated, such as rutile or strontium titanate.

Since surface contamination can be regarded as competitive adsorption of organic and water vapor, the contamination rates would be related to the affinity of

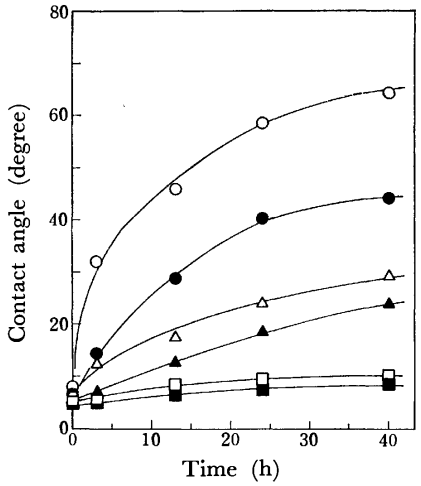

Fig. 1. Variation of contact angles under the dried atmosphere.

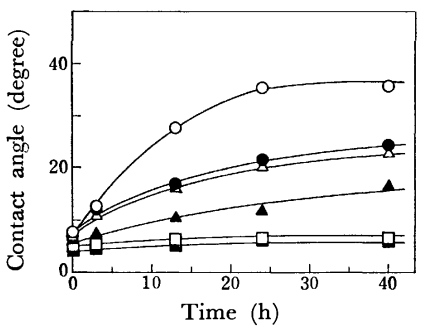

Fig. 2. Variations of contact angles under the wet atmosphere. (Symbols are the same in Fig. 1.)

oxide surface to water. Evaluation of the hydrophilicity of oxides can be carried out by such methods as adsorption of water and the heat of immersion in water, but they are restricted to powder samples.

The interaction free energy due to nondispersive forces (mainly the hydrogen bonding force) at the interface between solid and water, I^n_{sw}, can be obtained from the contact angles of water drops in hydrocarbon liquid. This can be defined in terms of surface tension γ by

$$I^n_{sw} = \gamma^n_s + \gamma^n_w - \gamma^n_{sw},$$

where subscripts s, w, and sw denote solid, water, and solid/water interface, respectively, and n indicates the component due to nondispersive forces. The details of the method[3,4] and the results for the oxides have been reported.[5]

The I^n_{sw} values obtained for the oxides are[5] as follows: TiO_2, 91.4; $SrTiO_3$, 93.2; Cr_2O_3, 93.6; NiO, 94.0; Al_2O_3, 97.6; and SiO_2, 99.2 in mJ m^{-2} at 20 °C. The accuracy is *ca.* ± 0.3 mJ m^{-2}. The order of the I^n_{sw} values corresponds to the reverse order of the contamination rates (Figs. 1 and 2). The oxides which have smaller I^n_{sw} values and are thus less hydrophilic are more easily contaminated by organic vapors. This seems reasonable in view of the competitive adsorption.

It was found that the coexisting water vapor can largely reduce the contamination rates of the clean surfaces, suggesting an appropriate method for keeping the washed oxide surface clean.

The authors wish to express their appreciation to Dr. I. Shiota for the measurement of Auger spectra.

Catalytic Behavior of Sulfonium Trihalides in the Low-temperature Liquid-phase Oxidation of Tetralin

Katsutoshi OHKUBO, Teruo AOJI, and Kohji YOSHINAGA

Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860

(Received November 25, 1975)

Synopsis. Homogeneous oxidation of nonpolar tetralin catalyzed by sulfonium trihalides was found to proceed *via* a radical chain mechanism in which the trihalide catalysts promoted the reaction through the activation of molecular oxygen.

Although numerous investigations have hitherto been performed on the bond property of trihalide ions with the conclusion that the trihalide ions can be well explained by their Rundle 3c-4e (three center four-electron) bonds without the participation of d-orbitals to their almost covalent linear bonds,[1] onium trihalides, especially of the sulfonium type, have received only limited attention in terms of their chemical reactivity in solutions. An interesting chemical property of sulfonium trihalides has recently been found in this laboratory: their remarkable catalytic activity in the low-temperature liquid-phase oxidation of hydrocarbons. In this paper, experimental and MO-theoretical studies of the sulfonium trihalides are reported with a view of examining how they accelerate the liquid-phase oxidation of hydrocarbons.

Experimental

Materials and Experimental Procedure. The triphenylsulfonium and tetrabutylammonium compounds used as oxidation catalysts were prepared by the usual methods.[2-4] A portion (10 ml) of the fresh distillate of tetralin was subjected to homogeneous liquid-phase oxidation with a catalyst (0.005 mmol) in the temperature range of 45—85 °C under atmospheric pressure. UV spectroscopic measurements of triphenylsulfonium trihalides were carried out in CH_3OH at 25 °C using Shimadzu 200 and Hitachi 200-10 spectrophotometers.[5]

Results and Discussion

Let us first examine the activities of several triphenylsulfonium trihalides for homogeneous oxidation of tetralin at 65 °C. As can be seen from Table 1, the sulfonium trihalides markedly accelerate the oxidation rate with no induction period (in an autocatalytic fashion) resulting in a monotonic accumulation of tetralin hydroperoxide (HPO) only as an oxidation product, although tetralin autoxidation indicated an induction period of 24 min. Also, the sulfonium trihalides are more active than ammonium salts having the corresponding trihalide anions. It is also noteworthy that the maximum O_2-absorption rate (R_{max}) appearing during the initial short reaction stage (up to 7 min) without appreciable decomposition of HPO showed a first-order dependence on the concentration of the sulfonium trihalide and that more than 85% of the trihalide can be recovered from the reaction mixture after a reaction time of about 15 min.[6] From these observations the following dissociation of sulfonium trihalide ($R_3SX^1X^2X^3$: X^2=middle halogen and X^1=X^3=terminal halogen) into sulfonium monohalide (R_3SX^2) and a halogen molecule (X^1X^3), within a reaction time of up to 10 min, is not believed to be very important:

$$R_3SX^1X^2X^3 \overset{K}{\rightleftharpoons} R_3SX^2 + X^1X^3 \quad (1)$$

where K is an equilibrium constant, and X^2 is assumed to be more electronegative than either X^1 or X^3. The dissociation of $R_3SX^1X^2X^3$ is also not expected in such nonpolar hydrocarbons as tetralin, in view of the fact that the K values are very small even in $CHCl_3$ at 20 °C (about 10^{-5}—10^{-4} mol/l[4]).

Now, we consider how $R_3SX^1X^2X^3$ initiates the present oxidation reaction which was confirmed to proceed *via* the usual radical-chain mechanism. The formation of radical initiators through the decomposition of peroxides (ROOH) by $R_3SX^1X^2X^3$ does not occur during the initial short reaction stage, because ROOH is monotonically accumulated in amount (mol) corresponding almost quantitatively to the oxygen absorbed (mol) and because the addition of ROOH to the reaction system markedly depressed the reaction rate. These results are due to the promotion of the dissociation of $R_3SX^1X^2X^3$ or partly due to the blocking effect by species containing lone-pair electrons against interaction of the oxidation catalyst ($R_3SX^1X^2X^3$ or R_3SX^2) with O_2 (see later).[7] The dissociation products (R_3SX^2 and X^1X^3) in equimolar amounts did not initiate the reaction in spite of the existence of effective oxidation catalysts (R_3SX^2) in the reaction system. This might also be due to the above-mentioned blocking effect of X^1X^3.

The markedly higher activity of $R_3SX^1X^2X^3$ as compared with the ammonium trihalides, despite the nearly identical K values (*ca.* 10^{-4} mol/l[4]) in $CHCl_3$ at 20 °C) of ammonium trihalide as that of $R_3SX^1X^2X^3$ does not support the halide-anion catalysis which is expected in ammonium halides.[8]

The following initial step, in which $R_3SX^1X^2X^3$ accelerates the reaction *via* the activation of O_2, appears to be most reasonable in connection with the catalytic behavior of R_3SX for hydrocarbon oxidation:[5,8,9]

$$R_3SX^1X^2X^3 + O_2 \rightleftharpoons [R_3S(X^1X^2X^3)^{\delta+}\cdots O_2^{\delta-}] \xrightarrow{RH} R\cdot + HO_2\cdot + R_3SX^1X^2X^3 \quad (2)$$

If Reaction 2 is plausible, one can expect direct interaction between $R_3SX^1X^2X^3$ and O_2, and hence, some specific orbitals of the former should play an important role in the activation of the latter. In regard to the interaction molecular oxygen appreciably shifts the

sulfur $(3p)^2\rightarrow(3p)(3d)$ transition (λ_{max}=208—210 nm and $\log\varepsilon$=4.61—4.72 in CH_3OH at 25 °C in an N_2 atmosphere) of the sulfonium cation[10] to longer wavelengths over an energy scale from 0.03 to 0.09 eV. This implies that the lowering of the partially-occupied sulfur d-orbitals (see below), which results from charge transfer from the d-orbitals (especially, the d_{xz} orbital in Fig. 1) to O_2, simplifies the above-mentioned electron excitation mechanism. In this sense, it can be believed that the more the electron density of the d_{xz} orbital increases, the higher becomes the catalytic activity (as reflected in the R_{max} value) of $R_3SX^1X^2X^3$. In fact, as Fig. 2 indicates, the R_{max} values of $R_3SX^1X^2X^3$ (and

The Titanium Trichloride-catalyzed Oxidation of Triphenylphosphine with Oxygen in Acetonitrile

Yasuo CHIMURA and Kimio TARAMA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received October 29, 1976)

Synopsis. Titanium trichloride catalyzed very rapidly the oxidation of triphenylphosphine with oxygen in acetonitrile, yielding triphenylphosphine oxide and a yellow precipitate. The main catalytic cycle did not contain Cl_3Ti–O–$TiCl_3$ which was produced in the oxidation of $TiCl_3$ alone, but the precursors of Cl_3Ti–O–$TiCl_3$ as intermediates. The yellow precipitate was a titanium(IV) complex with a discrete TiO group.

Titanium(III) complexes are oxidized by molecular oxygen in anhydrous organic solvents to give a μ-peroxo dimeric complex,[1] μ-oxo dimeric complexes,[2,3] or monomeric complexes containing TiO groups.[4] The oxidations of organic compounds with oxygen using titanium complexes as catalysts, however, are unknown. This paper will describe briefly the $TiCl_3$-catalyzed oxidation of triphenylphosphine (PPh_3) with oxygen in acetonitrile as a continuation of previous studies[5] of dioxygen complexes of transition metals.

Experimental

Materials. The acetonitrile was distilled from diphosphorus pentaoxide and again from calcium hydride and then stored under nitrogen. The titanium trichloride was converted to trichlorotris(acetonitrile)titanium(III),[6] which was then dissolved in acetonitrile to yield a 0.130 M solution (M=mol/dm^3). The triphenylphosphine was recrystallized from methanol and stored under nitrogen. Commercial oxygen gas was used without further purification.

Apparatus and Procedure. A 200-cm^3, three-necked, flat-bottomed flask containing a Teflon-coated magnetic stirrer was fitted with a thermometer and a serum cap at each of the two necks, while through the other neck it was connected to a vacuum system with a manometer, a gas buret, *etc.* The flask was then immersed in a constant-temperature bath operated at 20 °C. The system was filled with atmospheric oxygen after the introduction of PPh_3 (1.00—8.93 mmol) and acetonitrile (35.0 cm^3). Then, the acetonitrile solution of $TiCl_3$ (5.0 cm^3) was injected as soon as possible by means of a syringe through the serum cap, with vigorous stirring. The uptake of oxygen was followed at the constant pressure of 1 atm. After 2 days, the resulting yellow precipitate was filtered, washed with acetonitrile, and dried under a vacuum. The filtrate was hydrolyzed with dilute hydrochloric acid and extracted with ether. The ether layer was evaporated under a vacuum, leaving a pale yellow residue, which was then chromatographed over silica gel to give PPh_3 and triphenylphosphine oxide ($OPPh_3$).

Spectra. The IR spectra of the yellow precipitate and the reaction solution were measured by means of a JASCO IRA-2 spectrophotometer as Nujol mulls and using a solution cell respectively. The visible spectra of mixtures of $TiCl_3$ and PPh_3 in acetonitrile were recorded under nitrogen with a JASCO UVIDEC-1 spectrophotometer. The ESR spectrum of the precipitate was recorded on a JEOL-JES-3BS-X spectrometer.

Analysis. Carbon, hydrogen, phosphorus, and chlorine analyses of the yellow precipitate were carried out by specialists. The titanium was chelatometrically back-titrated at pH 5.5 with a 0.05 M zinc(II) nitrate solution in 50% aqueous ethanol using Xylenol Orange as an indicator.

Results and Discussion

In the absence of PPh_3, the blue color of an injected $TiCl_3$ solution immediately turned yellow. The uptake of oxygen was very rapid and ceased within a minute. The amount of oxygen taken up was about a fourth of the $TiCl_3$ concentration (Table 1). The IR spectrum of the yellow solution showed a peak at 788 cm^{-1} and a shoulder at 749 cm^{-1}. They were assigned to the stretching vibrations of a Ti–O–Ti group, since Cl_3Ti–O–$TiCl_3(CH_3CN)_4$[7] showed a strong peak and a shoulder at 800 and 740 cm^{-1} respectively. Thus, $TiCl_3$ seems to be oxidized to the same Cl_3Ti–O–$TiCl_3$ complex (**1**) in acetonitrile as in pyridine.[3]

In the presence of PPh_3, an injected $TiCl_3$ solution immediately turned brown, and after several minutes a yellow powder was precipitated. The rate of oxygen uptake was initially very fast, and then it fell rapidly. The amounts of oxygen uptake and of the products formed are shown in Table 1. The ratio of oxygen taken up after 1 min to that after 2 days changed from 0.51 to 0.93 as the amount of PPh_3 decreased. At every stage of the reaction, the amount of oxygen uptake increased with an increase in the amount of PPh_3 and exceeded the amount of $TiCl_3$; that is, the oxidation proceeded catalytically, and the turnover number increased with the increasing amounts of PPh_3. The PPh_3 introduced was recovered almost quantitatively as $OPPh_3$ and unreacted PPh_3. The oxygen taken up was also found almost quantitatively in $OPPh_3$ and in the oxidized catalyst, assuming that the oxidized catalyst bound oxygen in a Ti : O atomic ratio of 2 : 1.

The precipitated yellow complex was air-stable and was hardly soluble in acetonitrile at room temperature. The yield was 33—60%. The complex when recovered from different runs showed the same IR spectra, which contained a strong band at 1146 cm^{-1} and very strong bands at 726 and 1121 cm^{-1} due to the P=O stretching vibration and the X-sensitive vibrations[8] of the coordinating $OPPh_3$ respectively. The spectra also showed a sharp and very strong band at 1060 cm^{-1}, which was assigned to a Ti=O stretching vibration.[4,9] The lack of any absorption between 2000 and 2600 cm^{-1} and between 770 and 960 cm^{-1} indicates the absence of acetonitrile and of a Ti–O–Ti group respectively. The absence of an ESR signal of the complex either at room temperature or at 77 K indicates that the titanium ion is not trivalent but tetravalent. The results of the

a) The calculated ratio is 15/18/1 for $OPPh_3$. b) An oxidized $TiCl_3$ solution was used as the catalyst.

elemental analysis of the complex are shown in Table 2. The composition depended a little upon the reaction conditions. However, the H/C/P and Cl/Ti ratios were nearly equal to 15/18/1 and 3/1. This shows that a PPh_3 moiety is the sole organic component, and that anionic ligands other than a chloride anion must be present, with a negative charge per titanium ion, since the titanium ion is tetravalent. Thus, the complex must have the following structural features: (1) The titanium ion is tetravalent, (2) a discrete TiO group is present, and (3) the other ligands are chloride anions and $OPPh_3$. Oxotitanium(IV) complexes are apt to have polymeric chain-type structures, *i.e.*, –Ti–O–Ti–O–; complexes such as this complex with discrete titanyl groups (TiO^{2+}) are rare.

There have been no reports on the isolation of the complex formed between $TiCl_3$ and PPh_3. The two d-d transition bands of $TiCl_3$ in acetonitrile under nitrogen, however, were changed a little by the addition of PPh_3; that is, the two bands which were at 585 nm (ε, 25.6) and 680 nm (ε, 15.4) for a triphenylphosphine-free acetonitrile solution of $TiCl_3$ (0.025 M) appeared at 588 nm (ε, 24.3) and 680 nm (ε, 17.7), and at 590 nm (ε, 24.7) and 680 nm (ε, 19.0), when the concentrations of added PPh_3 were 0.104 and 0.203 M respectively. This indicates the presence of a weak interaction between $TiCl_3$ and PPh_3 in an acetonitrile solution.

The oxidation mechanism of $TiCl_3$ with oxygen in acetonitrile seems to be similar to that in pyridine,[3] involving $Cl_3Ti–O_2$ (**2**), $Cl_3Ti–O_2–TiCl_3$ (**3**), and $Cl_3–Ti–O$ (**4**) as intermediates. Species like **2**,[5b,10,11] **3**,[11] and **4**[10] have been reported.

The oxidation of PPh_3 catalyzed by **1** had a much slower rate than that catalyzed by $TiCl_3$ (Table 1). Therefore, **1** is not contained in the main catalytic cycle of the $TiCl_3$-catalyzed oxidation, but seems to play a large part in the slow oxygen uptake in the later stage of the oxidation. The **2**, **3**, and/or **4** species reacting with PPh_3 would yield $OPPh_3$ and $TiCl_3$, and also $TiCl_3$ coordinated by PPh_3 would react with oxygen to give **2** coordinated by PPh_3, which would then decompose to $TiCl_3$ and $OPPh_3$. Thus, the main catalytic cycle seems to be composed. Since the oxidation of $TiCl_3$ to **1** was very rapid, the reactions of **2**, **3**, and/or **4** with PPh_3 and the decomposition must also be very rapid.

The authors are grateful to Dr. Toshimitsu Suzuki of this department for his gift of $TiCl_3$.

Purification of Xylenol Orange by the High-Speed Liquid Chromatography

Shoji NAKADA, Mutsuo YAMADA, Tasuku ITO, and Masatoshi FUJIMOTO
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received January 8, 1977)

Synopsis. A relatively large amount of 3,3′-bis[*N*, *N*-bis(carboxymethyl)aminomethyl]-*o*-cresolsulfonphthalein (Xylenol Orange, XO) is purified easily by the high-speed liquid chromatography (HSLC).

Despite of many interesting problems concerning the solution chemistry of metal complexes of a multidentate ligand XO, serious discrepancies have often been noted among the data reported by different authors. The discrepancies are primarily caused by the use of commercial or incompletely purified XO, which usually contains iminodiacetic acid (IDA), Semi-Xylenol Orange (SXO), and/or *o*-Cresol Red (*o*-CR) as the starting materials or a by-product of the synthesis of XO.[1-4] Since SXO and IDA also form metal complexes, the use of XO free from these impurities is essential for the quantitative studies of metal complex formation. Among the impurities *o*-CR is easy to remove, but the separation of IDA and SXO from XO is quite difficult.[3] Recently, a new method was established for the sharp separation of SXO and XO by the preparative thin-layer chromatography.[3] However, the method for easy separation of XO and IDA on a preparative scale has not been reported so far. In the present study we applied a technique of preparative HSLC and obtained easily a relatively large amount of pure XO.

The sample for HSLC was preliminarily purified by the cellulose column chromatography using an eluent, 1-butanol saturated with 10 or 25% aqueous acetic acid.[2,5] The paper partition chromatography (PPC) of the pretreated sample gave no spots of SXO and *o*-CR, but IDA still remained unremoved.

Figure 1 shows a typical elution curve of the preparative HSLC for the pre-purified sample. One gram of the sample was dissolved in 5 ml of water. Six hundred microliters of the solution were injected for each run. For the elution 5% aqueous acetic acid–methanol (80/20, v/v) was used as a solvent at a flow rate of 6.0 ml min^{-1} (pressure: 2400 psi). XO was clearly separated from the impurities on a preparative scale. The retention time assigned for IDA, XO, and SXO was measured beforehand with corresponding pure substances. Even a trace amount of SXO undetected by PPC was sharply discriminated as a peak of the preparative HSLC. The peak of *o*-CR, if any, is expected to appear at a retention time longer than 2 h under this condition.* The component for a peak at the retention time of 10 min was yellow and unidentified. After the elution of SXO the column was regenerated by washing with methanol for 20 min. This procedure flushed out the unknown yellow material. The column thus regenerated was used repeatedly.

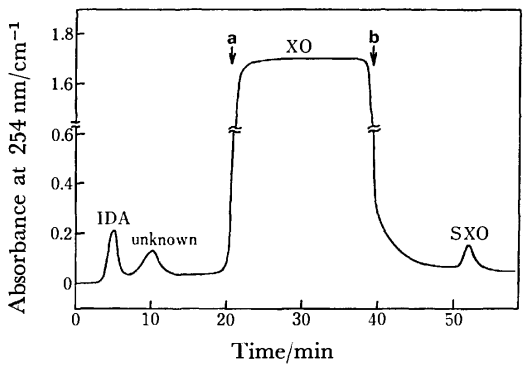

Fig. 1. Elution curve of the crude sample of XO.

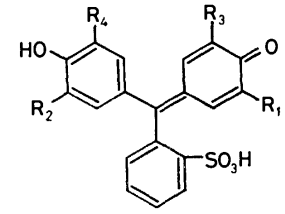

XO: $R_1=R_2=CH_2N(CH_2COOH)_2$, $R_3=R_4=CH_3$
SXO: $R_1=CH_2N(CH_2COOH)_2$, $R_2=H$, $R_3=R_4=CH_3$

The effluent between **a** and **b** as shown in Fig. 1 was collected as a portion of pure XO for each run. Each effluent was combined and concentrated in a rotary evaporator at 60—65 °C and dried in a vacuum desiccator. About 560 mg of the sodium salt of pure XO were obtained on eight runs from 960 mg of the pre-purified sample. From the elution curve and the amount of the isolated XO, the injected sample was found to consist of more than 58% XO, at most 19% IDA, 0.01% SXO, and other unknown materials.

Increasing methanol content in the developing solvent accelerated the elution of XO and SXO, but did not affect the retention time of IDA. The solvent composed of 5% aqueous acetic acid and methanol in the ratio 80/20 (v/v) gave the best separation of XO from IDA and SXO. This solvent is volatile and is more suitable for the subsequent treatment than the 1-butanol–acetic acid–water system used for the ordinary chromatographic method.

The pre-purification is not essential for the purification of XO by HSLC. By lowering the methanol content of the eluent, the present technique of HSLC is applicable to the sample obtained directly from the synthesis. *o*-CR, which is present in the synthetic mixture and is removable in the step of pre-purification, is

* A preliminary work of HSLC with a small column Microbondapak C_{18}, 4 mm × 300 mm, and a solvent of higher methanol content as 5% aqueous acetic acid–methanol (60/40, v/v) revealed that the retention time of *o*-CR was 17 min and much longer than that of IDA, XO, and SXO, 1.8, 3.5, and 8 min, respectively.

easily eliminated by the HSLC. However, since a crude XO obtained directly from the synthesis contains usually a fairly large amount of SXO, the unavoidable cross-contamination of SXO and XO might occur. In the present study, therefore, the pre-purification was carried out for the sake of the better yield and efficiency.

It is interesting to note that the sodium salt of the XO purified by the HSLC was not retained at all on a column of Dowex 50W-X8, a strongly acidic cation-exchange resin of medium cross-linking and in the hydrogen-form, whereas the sodium salt of the XO purified by the ordinary cellulose column chromatography was always partly and strongly retained on the exchanger.

Experimental

Materials. Acetic acid of analytical grade and an HSLC grade methanol were used for the elution chromatography. Water was deionized. A crude XO was synthesized according to the literature.[2)]

Instruments. All separations were carried out with a Waters Model ALC/GPC 244 chromatographic instrument equipped with two 7 mm×610 mm columns in series and a spectrophotometric detector (λ=254 nm). The columns were packed with Bondapak C_{18}/Porasil.

The Free Acid of the XO. An aqueous solution of the sodium salt of the purified XO was passed through a column of Dowex 50W-X8 in the hydrogen-form. The effluent was concentrated at *ca.* 60 °C in a rotary evaporator and dried in a vacuum desiccator. Mp *ca.* 286 °C (dec). Found: C, 53.33; H, 4.94; N, 4.14; S, 4.67%; S/N =1.13. Calcd for $C_{31}H_{32}O_{13}N_2S\cdot H_2O$: C, 53.91; H, 4.96; N, 4.06; S, 4.64%; S/N=1.14.

The authors wish to thank Messrs. C. Nakayama and M. Sato, Nihon Waters Ltd., for the kindness in the use of the HSLC instrument.

Polarographic Catalytic Currents Observed in Mixtures of Pb(II) and H_2O_2 in Neutral Solutions

Sadayuki HIMENO

Department of Chemistry, College of General Education, Kobe University, Nada-ku, Kobe 657

(Received January 13, 1977)

Synopsis. Normal pulse polarography has shown that the catalytic wave observed in neutral mixtures of Pb(II) and H_2O_2 is caused by $Pb(OH)^+$ at the electrode surface, and that OH^- ions are liberated in the vicinity of the electrode due to the catalytic reaction.

It was first noticed by Strnad that traces of Pb(II) ions in neutral air-saturated solutions greatly increased the first oxygen wave.[1] This effect of Pb(II) ions was explained as being due to the reduction of H_2O_2 arising from the reduction of oxygen.

This paper will describe the results of a polarographic investigation of the Pb(II)–H_2O_2 system.

Apparatus and Reagents

Apparatus. The polarograms were obtained with a PAR (Princeton Applied Research) Polarograph, Model 174. The polarograms were recorded on a Riken Denshi X-Y Recorder, Model D-8C. The dropping mercury electrode (DME) used had a $m^{2/3} t^{1/6}$ of 1.45 $mg^{2/3} s^{-1/2}$ in 0.1 M KNO_3 in an open circuit. The drop time of the DME was controlled at 1.0 s by means of a Mechanical Drop Time Controller, Model 172-A. The pH values of the test solutions were measured with a Hitachi-Horiba pH Meter, Model M-7. A saturated calomel electrode (SCE) was used as the reference electrode. The solutions were deoxygenated by bubbling nitrogen gas through them. All the experiments were carried out at (25±0.1)°C.

Reagents. All the chemicals were of a reagent grade and were used without further purification.

Results and Discussion

Figure 1(A) shows the effect of the pH on the DC polarogram of 1.0 mM Pb(II) in 0.1 M $NaNO_3$ without dissolved oxygen. When pH <5, a single wave was observed with a half-wave potential of −0.38 V. As the pH was increased, the wave split into two waves, the relative heights being pH-dependent. When pH >8.5, the first wave disappeared and only the second one remained.

Figure 1(B) shows the percentage distribution curves calculated from the data[2] for the four possible species present in Pb(II) solutions. The observed dependence of the relative wave heights on the pH corresponds to the changing ratio of the aquated Pb(II) ion to the hydroxide species. Therefore, the first wave is ascribed to the reduction of the aquated Pb(II) ion, and the second, to the reduction of $Pb(OH)^+$.

Figure 2 illustrates DC polarograms of 0.4 mM Pb(II) in 0.1 M $NaNO_3$ (pH 4.6) containing 5 mM H_2O_2. The catalytic wave was observed in unbuffered solutions in the pH range of 4—8 (Curve a).

The polarographic behavior of the Pb(II) ion in buffered solutions of various pH values was also investigated. When the pH was adjusted with either an acetate or barbital buffer to lie in the range of 4—5, where $Pb(OH)^+$ did not exist to any appreciable extent in the solution, no catalytic wave appeared (Curve b in Fig. 2). However, in either a borate or barbital buffer with a pH of about 7.5 (in the pH region where $Pb(OH)^+$ exists), the catalytic wave appeared.

Normal pulse polarography was applied to elucidate a catalytically active Pb(II) species. Figure 3 shows normal pulse polarograms of 1.0 mM Pb(II) in 0.1 M $NaNO_3$ (pH 4.8) containing various concentrations of H_2O_2. With the H_2O_2 concentration of 2 mM, the initial single wave split into three waves. Above this

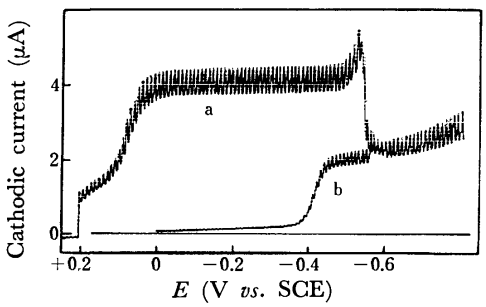

Fig. 2. Catalytic wave.
a) 0.4 mM Pb(II) in 0.1 M $NaNO_3$ (pH 4.6) containing 5 mM H_2O_2.
b) Solution (a) with acetate buffer (pH 4.6).

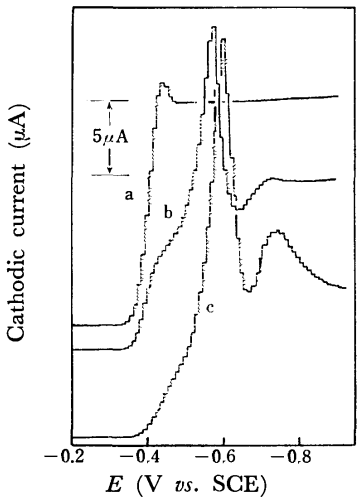

Fig. 3. Normal pulse polarograms of 1.0 mM Pb(II) in 0.1 M $NaNO_3$ (pH 4.8) containing various concentrations of H_2O_2. H_2O_2 concentration (mM) a) 0. b) 2.0. c) 3.0. $E_1 = -0.2$ V.

H_2O_2 concentration, the first wave disappeared with an increase in the height of either the second or the third one.

To identify the Pb(II) species responsible for each wave, normal pulse polarograms in unbuffered solutions containing 1 mM Pb(II) and dissolved oxygen were also recorded. When the initial potential was set at +0.3 V, which was more anodic than the reduction potential of the first oxygen wave, the normal pulse polarogram of Pb(II) had two reduction waves. The first wave was interpreted as being due to the reduction of the aquated Pb(II) ion, and the second, to the reduction of $Pb(OH)^+$, the behavior of which was analogous to that observed in DC polarography. When the initial potential was set at −0.2 V, where the reduction of oxygen took place, the normal pulse polarogram consisted of three waves similar to Curve (b) of Fig. 3. Under these conditions, the concentration of OH^- ions increases in the vicinity of the electrode at the initial potential because of the reduction of the oxygen.

By buffering the solution, either the second or the third wave disappeared completely and the first wave became well defined.

As has been reported previously,[3,4] $Ni(OH)_2$ and $Fe(OH)_2$ produced similar waves on a normal pulse polarogram under the same conditions. Similarly, the third wave reflects the reduction of the $Pb(OH)_2$ formed at the electrode surface.

By analogy with the system composed of Pb(II) and dissolved oxygen, it is conculded that the first wave of Fig. 3(b) corresponds to the reduction of the aquated Pb(II) ion, and that the two remaining waves are due to the reduction of $Pb(OH)^+$ and $Pb(OH)_2$. This means that the catalytic reaction between Pb(II) and H_2O_2 proceeds with the formation of OH^- ions in the vicinity of the electrode.

Figure 4 shows the effect of the pH on the normal pulse polarogram of 1.0 mM Pb(II) in 0.1 M $NaNO_3$ containing 5 mM H_2O_2. Clearly, under the conditions where the catalytic reaction occurs, the aquated Pb(II) ion does not exist in the solution, and the region where $Pb(OH)^+$ is present is about from pH 4 to 8, this range agreeing with that where the catalytic wave appears in DC polarography.

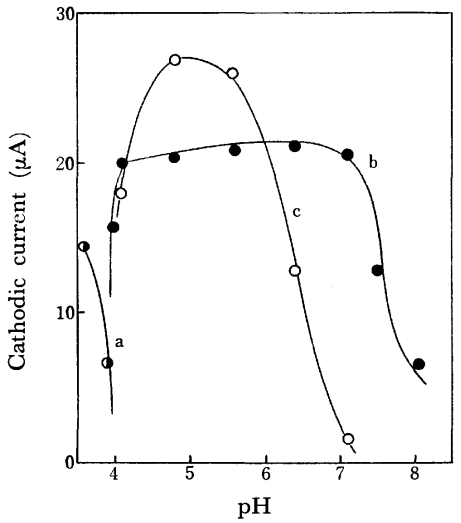

Fig. 4. Effect of pH on normal pulse polarographic wave of 1.0 mM Pb(II) in 0.1 M $NaNO_3$ containing 5 mM H_2O_2.
a) lst wave. b) 2nd wave. c) 3rd wave.
$E_1 = -0.2$ V.

As is shown in Fig. 2, the catalytic current drops at −0.55 V, which is about 0.17 V more negative than the reduction potential of the aquated Pb(II) ion. This result also indicates that the aquated Pb(II) ion is converted to $Pb(OH)^+$ as a result of the catalytic reaction. This is inconsistent with the work of Strnad, who explained the current drop in terms of the direct reduction of the aquated Pb(II) ion to Pb(0).

The most likely mechanism for the catalytic reaction is that $Pb(OH)^+$ is oxidized by H_2O_2 to the Pb(IV) ion, which is then rapidly reduced at DME to produce a catalytic wave. Traces of $Pb(OH)^+$ may cause the catalytic reaction in unbuffered solutions in the pH range of 4—5. An increase in $Pb(OH)^+$ at the electrode surface is necessary for the catalytic reaction to proceed under these conditions.

The author wishes to thank Professor Atsuyoshi Saito for his valuable advice and for his helpful discussions throughout this study.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 50 (7), 1891—1892 (1977)

Preparation and Resolution of (4-Aminobutanoic acidato)bis-(ethylenediamine)cobalt(III) Ion

Masaaki KOJIMA, Hiromichi TAKAYANAGI, and Junnosuke FUJITA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received January 31, 1977)

Synopsis. A new complex containing a seven-membered chelate ring, $[Co(amb)(en)_2]^{2+}$ (amb=4-aminobutanoato ion) was prepared and resolved. The complex is decomposed in 1.0 M $HClO_4$ at room temperature to give $[Co(H_2O)(Hamb)(en)_2]^{3+}$ in which the Hamb acts as a unidentate ligand with a free carboxyl group.

Although complexes of the type, $[Co(am)(en)_2]^{2+}$ (am=amino acidate ion) have been prepared and resolved for a variety of amino acids, no complex has been reported for 4-aminobutanoato ion (amb) which forms a seven-membered chelate ring. This Note will describe the preparation and resolution of $[Co(amb)(en)_2]^{2+}$ and compare the absorption and circular dichoism(CD) spectra with those of the corresponding glycinato and β-alaninato complexes. Koine *et al.*[1] prepared a complex containing amb, *trans*(*N*)-K[Co(nta)(amb)]·$3H_2O$(nta =nitrilotriacetate ion). However, no evidence was given for the formation of a seven-membered chelate ring. Such large chelate ligands as amb tend to coordinate to a metal ion as a unidentate ligand or to two metal ions as a bridging ligand.[2,3]

Experimental

Ligands. Guaranteed reagent grade 4-aminobutanoic acid, β-alanine, and glycine were obtained from Wako Pure Chemical Industries Co. and used without further purification.

$[Co(amb)(en)_2]Cl_2\cdot 2.5H_2O$. A solution of sodium methoxide (0.16 g, 3.0 mmol) and 4-aminobutanoic acid (0.31 g, 3.0 mmol) in methanol (7 cm^3) was added to a solution of *trans*-$[CoCl_2(en)_2]ClO_4$ (0.9 g, 3.0 mmol) in DMSO(250 cm^3). The solution was stirred for 20 h at 40 °C, and then diluted with 3 dm^3 of water. This was passed through an SP-Sephadex column ($\phi 4.5\times 30$ cm), and the adsorbed complexes were chromatographed with a 0.2 M Na_2SO_4 solution. The column showed seven separate bands. The effluent of the first red band was diluted with 3 dm^3 of water and poured again on an SP-Sephadex column ($\phi 2.7\times 3$ cm). The adsorbed complex was eluted with a 1.0 M $CaCl_2$ solution, and the effluent was concentrated to a syrup in a vacuum desiccator over P_2O_5. The excess $CaCl_2$ was extracted repeatedly with a small amount of isopropyl alcohol until the complex began to crystallize. The complex was dissolved in a small amount of water, and isopropyl alcohol was added to the solution. Purplish red crystals which formed on cooling the mixing solution in a refrigerator were filtered off and washed with isopropyl alcohol. The complex was recrystallized from water by the addition of isopropyl alcohol. Found: C, 24.24; H, 7.38; N, 18.10%. Calcd for $CoC_8H_{29}N_5O_{4.5}Cl_2$=[Co(amb)$(en)_2]Cl_2\cdot 2.5H_2O$: C, 24.19; H, 7.36; N, 17.63%.

$[Co(gly)(en)_2](ClO_4)_2$ and $[Co(\beta\text{-ala})(en)_2](ClO_4)_2\cdot H_2O$. $[Co(gly)(en)_2](ClO_4)_2$ was prepared by the method of Shimura and Tsuchida.[4] $[Co(\beta\text{-ala})(en)_2](ClO_4)_2\cdot H_2O$ was obtained from the corresponding chloride.[5] The complex chloride adsorbed on SP-Sephadex was eluted with a 1.0 M $NaClO_4$ solution, and the effluent was concentrated to a small volume in a vacuum desiccator over P_2O_5. The concentrate was mixed with ethanol, and cooled. Red crystals were filtered off, washed with ethanol, and recrystallized from water by the addition of ethanol. Found: C, 17.40; H, 4.99; N, 14.46%. Calcd for $CoC_7N_5H_{24}O_{11}Cl_2$=$[Co(\beta\text{-ala})(en)_2](ClO_4)_2\cdot H_2O$: C, 17.36; H, 5.00; N, 14.46%.

Chromatographic Resolution of the Complexes. A solution containing about 0.1 mmol of the amb complex (or the β-ala or the gly complex) was poured on an SP-Sephadex column ($\phi 2.7\times 120$ cm) and the adsorbed band was eluted with a 0.1 M sodium $(+)_{589}$-tartrate or a 0.08 M sodium $(+)_{589}$-tartratoantimonate(III) solution. Two bands, the $(+)_{589}$- and $(-)_{589}$-isomers, were eluted in this order. Each eluate was passed through an SP-Sephadex column ($\phi 1.5\times 3$ cm) after dilution with water and the adsorbed complex was eluted with a 1.5 M $NaClO_4$ solution.

Measurements. Absorption and CD spectra were obtained on a Hitachi 323 spectrophotometer and a JASCO J-20 spectropolarimeter, respectively.

Results and Discussion

$[Co(gly)(en)_2]^{2+}$ and $[Co(\beta\text{-ala})(en)_2]^{2+}$ can easily be prepared by the reactions of *trans*-$[CoCl_2(en)_2]^+$ with gly or β-ala, respectively in water at fairly high concentration of the reactants. A reaction with amb under a similar condition is not expected to give the desired complex, since such large chelate ligands as amb or tmd(tetramethylenediamine) tend to act as a bridging

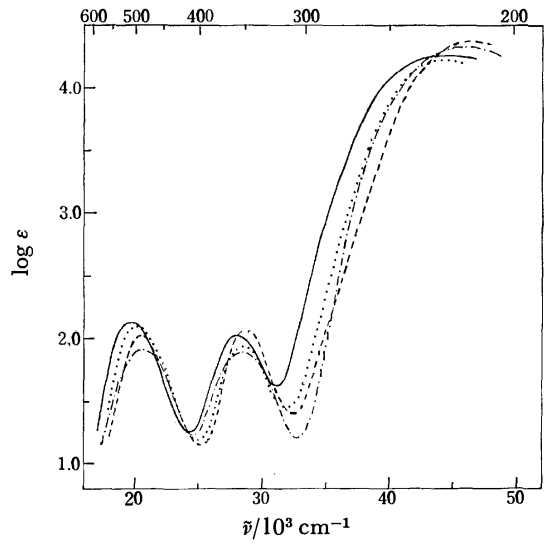

Fig. 1. Absorption spectra of $[Co(gly)(en)_2]^{2+}$(----), $[Co(\beta\text{-ala})(en)_2]^{2+}$(·····), and $[Co(amb)(en)_2]^{2+}$(——) in water, and $[Co(H_2O)(Hamb)(en)_2]^{3+}$(—·—) in 1.0 M $HClO_4$.

a) In water except for $(+)_{589}$[Co(H_2O)(Hamb)(en)$_2$]$^{3+}$ which was measured in 1.0 M $HClO_4$. b) In 1.5 M $NaClO_4$ except for $(+)_{589}$[Co(H_2O)(Hamb)(en)$_2$]$^{3+}$ which was measured in 1.0 M $HClO_4$.

ligand to yield polymeric complexes.[3] Thus, we have carried out the reaction in a highly dilute solution as described in the Experimental part. The use of organic solvent, DMSO is known to be useful for preparing complexes containing large chelate rings.[6]

The formation of the amb chelate ring is evidenced by the following observations. The absorption spectrum of the amb complex in a 1.0 M $HClO_4$ solution changes with isosbestic points(416, 458 nm), the change at room temperature(25 °C) being completed in a day. Since the first absorption band (487 nm) of the final spectrum is nearly the same as that (485 nm) of *cis*-[Co(H_2O)(NH_3)(en)$_2$]$^{3+}$,[7] the spectral change may correspond to a ring-opening reaction of the amb chelate to give *cis*-[Co(H_2O)(Hamb)(en)$_2$]$^{3+}$ (Fig. 1). The absorption spectra of the gly and β-ala complexes in 1.0 M $HClO_4$ remained unchanged over a prolonged heating. Further, the amb complex adsorpbed on SP-Sephadex is eluted with a 0.2 M Na_2SO_4 solution with a similar R_f value to those of the gly and β-ala complexes.

As Fig. 1 and Table 1 show, the d-d absorption bands of the present series of complexes, [Co(am)(en)$_2$]$^{2+}$ shift to longer wavelengths as the number of ring members of the amino acidate ligands increases. A similar shift was observed for complexes of the type, [Co(en)$_2$(diamine)]$^{3+}$; the first absorption bands of [Co(en)$_3$]$^{3+}$, [Co(en)$_2$(tn)]$^{3+}$(tn=trimethylenediamine), and [Co(en)$_2$(tmd)]$^{3+}$ are at 21.3, 21.0, and 20.9×10^3 cm^{-1}, respectively.[3]

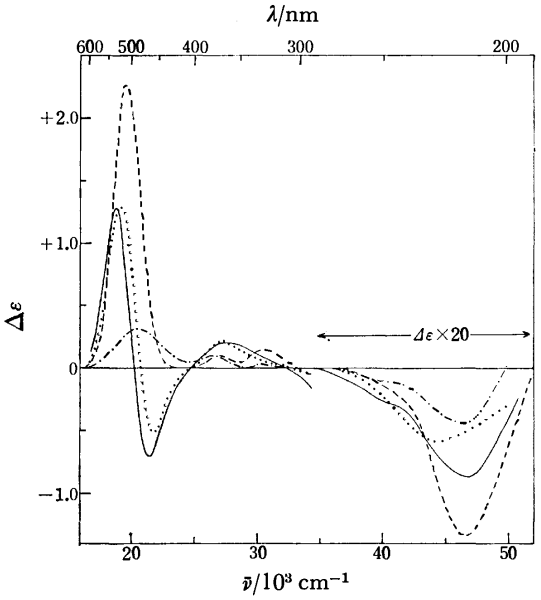

Fig. 2. CD spectra of $(+)_{589}$[Co(gly)(en)$_2$]$^{2+}$(----), $(+)_{589}$[Co(β-ala)(en)$_2$]$^{2+}$(·····), and $(+)_{589}$[Co(amb)-(en)$_2$]$^{2+}$(——) in 1.5 M $NaClO_4$, and $(+)_{589}$ [Co(H_2O)-(Hamb)(en)$_2$]$^{3+}$(—·—) in 1.0 M $HClO_4$.

All the complexes have been completely resolved by SP-Sephadex column chromatography. Figure 2 shows the CD spectra of the $(+)_{589}$-isomers. The CD spectrum of the gly complex agrees well with that reported previously.[8] All the $(+)_{589}$-isomers give a main positive and a strong negative CD band in the first absorption and the charge transfer region, respectively. Therefore, it can be concluded that these isomers have the same absolute configuration, *Λ*. The β-ala and the amb complexes exhibit negative CD components at a shorter wavelength side of the first absorption band. Although no such a component is observed for the gly complex, these negative components seem to increase the strength as the number of ring member of the amino acidate ligand increases.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 50 (7), 1893—1894 (1977)

An X-Ray Diffraction Study on the Structure of the Aqua Indium(III) Ion in the Perchlorate Solution

Masunobu MAEDA[1] and Hitoshi OHTAKI

Laboratory of Solution Chemistry, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received March 4, 1977)

Synopsis. The structure of the aqua indium(III) ion has been studied in a 3 mol dm^{-3} $In(ClO_4)_3$ solution at 25 °C by an X-ray diffraction method. The result showed that the indium(III) ion has six nearest water molecules and the In–OH_2 bond distance is 2.15±0.03 Å.

Only a few investigations have been carried out on the structure of indium(III) ion in aqueous solution. Fratiello *et al.*[2] reported from NMR measurements that the indium(III) ion is coordinated by six water molecules in aqueous acetone mixtures. Celeda and Tuck[3] found the $In(OH_2)_6^{3+}$ complex in an aqueous perchlorate solution by densitometry. However, no X-ray analysis has been carried out both for crystal hydrates and solutions, and no datum for the bond length between the indium(III) ion and the coordinated water molecules is available. In the present work, we aimed at determining the bond distance within the aqua indium(III) complex as well as the coordination number of the indium(III) ion in solution.

Experimental Procedure and Treatment of Data

Indium(III) perchlorate was prepared by dissolving indium oxide (99.99% purity) in perchloric acid and recrystallized twice from water. Crystals were dissolved in dilute perchloric acid in order to suppress hydrolysis of the indium(III) ions. The concentration of indium(III) ions in the sample solution was determined gravimetrically by using 8-quinolinol.[4] The concentrations of hydrogen and perchlorate ions were determined as described previously.[5] The atomic composition of the sample solution is listed in Table 1.

TABLE 1. ATOMIC COMPOSITIONS OF THE INDIUM(III) PERCHLORATE SOLUTION (in g-atom dm^{-3})

In	3.023
Cl	9.388
O	71.61
H	68.44

X-Ray scattering data were obtained at 25 °C on a θ-θ diffractometer (JEOL Co., Tokyo) equipped with a Philips Mo-X-ray tube (wavelength λ=0.7107 Å). The measured scattering angles (2θ) ranged from 2 to 140°. Details of measurements and treatments of data are described elsewhere.[5]

Results and Discussion

The radical distribution curve $D(r)$ calculated from the scattered intensities is shown in Fig. 1. Two distinct peaks are seen at around 1.4 and 2.3 Å. The first peak is readily identified to be due to the Cl–O bond within the ClO_4^- ion.[5] The second peak may be ascribed to the In^{3+}–OH_2 bond within the aqua indium(III) ion, because the peak appears at the position as is expected from the sum of the ionic radius of In^{3+} (0.81 Å[6]) and the size of a water molecule ({O–O in water}/2=1.4 Å[7]). This peak contains the contribution from the O–O contact within the tetrahedral ClO_4^- ion (1.4 Å×$\sqrt{8/3}$=2.3 Å). The contribution of the Cl–O and O–O contacts within the perchlorate ion (curve b) was subtracted from the radial distribution curve. The bond distances r, temperature factors b, and frequency factors n of the atom pairs are quoted from Ref. 5. The rest is depicted as curve c in Fig. 1.

The bond distance between In^{3+} and the water molecules in the first hydration shell and the number of hydrated water molecules were determined from curve c by the trial-and-error method. The assumption of r=2.15 Å, b=0.004 $Å^2$, and n=6 led to a smooth background curve (curve e) without an indication of other atom pairs having bond distances less than 2.5 Å. The theoretical peak calculated by using these parameters is drawn as curve d in the same figure. The uncertainty in r is estimated approximately to be ±0.03 Å by the trial-and-error method. We could not find a clear indication for the octahedral structure of the $In(OH_2)_6^{3+}$

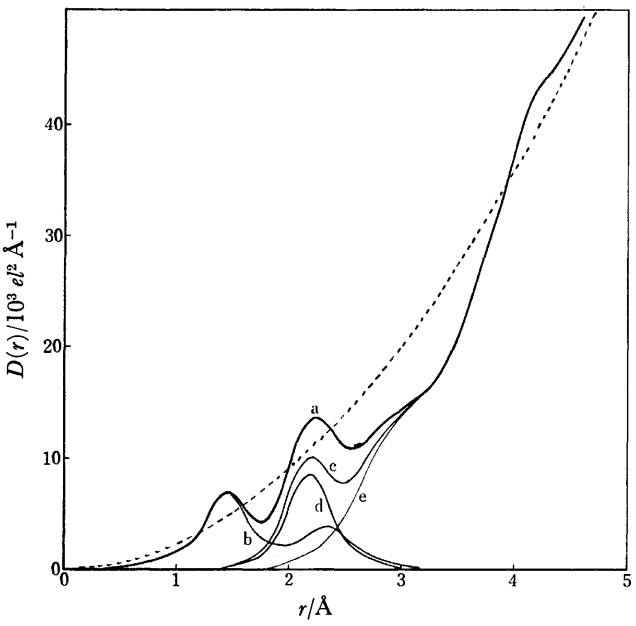

Fig. 1. a: $D(r)$ curve, b: theoretical peak shapes for the Cl–O and O–O contacts within ClO_4^-, c: residual curve ($D(r)$ − curve b), d: theoretical peak shape for the In–OH_2 bond within $In(OH_2)_6^{3+}$, e: background curve (curve c − curve d). The broken curve denotes $4\pi r^2\rho_0$.

complex, because the radial distribution curve did not give distinct peaks (although humps are observed) at about 3.04 Å ($=2.15\ Å \times \sqrt{2}$) and about 4.30 Å ($=2.15\ Å \times 2$) for the *cis*-O–O and *trans*-O–O contacts, respectively, within the $In(OH_2)_6^{3+}$ ion.

The present work is financially supported in part by the Japan Society for Promotion of Science.

The Reactions of Several Anilides with Phosphoryl Chloride

Masahiro FUKUDA, Yoshiki OKAMOTO, and Hiroshi SAKURAI

The Institute of Scientific and Industrial Research, Osaka University, Yamada-kami, Suita-shi, Osaka 565

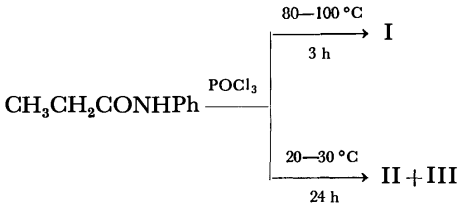
(Received July 8, 1976)

Synopsis. Chloroacetanilide and *p*-methylchloroacetanilide reacted with phosphoryl chloride to give 2-chloromethyl-3-chloro-4-anilinoquinoline and 2-chloromethyl-3-chloro-4-(*p*-toluidino)-6-methylquinoline respectively. In the case of propionanilide, 2-ethyl-3-methyl-4-anilinoquinoline was obtained when the reaction was carried out at 20—30 °C. On the other hand, when the reaction temperature was raised to 80—100 °C, *N*-(1-chloro-1-propenyl)-*N*,*N*′-diphenylacetamidine was obtained.

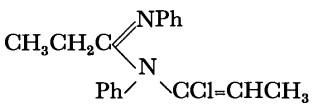
It is well known that a Vilsmeier reagent can be prepared from an *N*,*N*-disubstituted amide, such as *N*,*N*-dimethylformamide or *N*,*N*-dimethylbenzamide, with phosphoryl chloride.[1] *N*,*N*-Unsubstituted amides, such as acetamide and benzamide, are also known to be converted into the corresponding nitrile in good yields by treatment with phosphoryl chloride.[2] In this paper, we wish to report the reaction of anilides with phosphoryl chloride.

Results

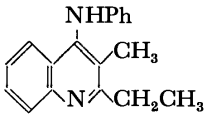
Propionanilide was allowed to react with phosphoryl chloride at 80—100 °C for 3 h, thus giving *N*-(1-chloro-1-propenyl)-*N*,*N*′-diphenylpropionamidine(I). When the reaction was carried out in the temperature range between 20 and 30 °C for 24 h, 2-ethyl-3-methyl-4-anilinoquinoline(II) and *N*,*N*′-diphenylpropionamidine (III) were obtained.



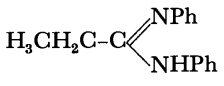
(1)



(I)

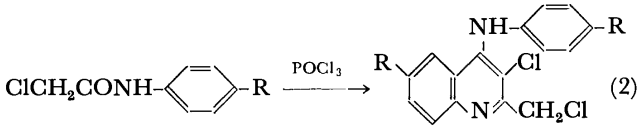


(II)



(III)

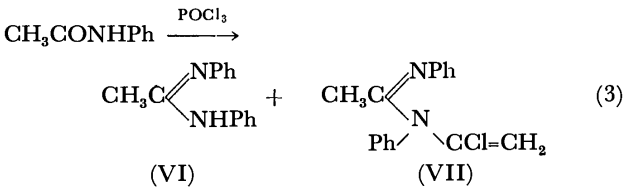
When chloroacetanilide(IVa) and *p*-methylchloroacetanilide(IVb) were used in place of propionanilide, 2-chloromethyl-3-chloro-4-anilinoquinoline(Va) and 2-chloromethyl-3-chloro-4-(*p*-toluidino)-6-methylquinoline(Vb) were isolated in 50—60 and 26% yields respectively. Amidine derivatives were not detected, regardless of the reaction temperature.



(2)

(IVa, R=H; IVb, R=Me) (Va, R=H; Vb, R=Me)

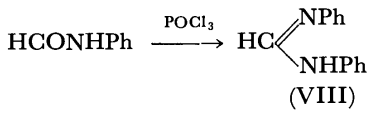
On the other hand, when the reaction of acetanilide with phosphoryl chloride was run at 80 °C for 3 h, *N*,*N*-diphenylacetamidine(VI) and *N*-(1-chlorovinyl)-*N*,*N*′-diphenylacetamidine(VII) were yielded in an equimolar ratio. When the reaction conditions were controlled at 20—30 °C for 24 h, the distribution of products VI and VII was changed to the molar ratio of 74 : 26.



(3)

(VI) (VII)

In the case of formanilide with phosphoryl chloride, *N*,*N*′-diphenylformamidine(VIII) was obtained in a 10% yield.



(VIII)

The results of these experiments are summarized in Table 1.

Experimental

All the melting and boiling points are uncorrected. The NMR spectra were measured at 100 MHz on a JNM-TS-100 spectrometer, with TMS as the internal reference in deuteriochloroform. The mass spectra were recorded on a Hitachi RMU-6 or RMU-7 spectrometer.

Materials. Commercial first-grade acetanilide and formanilide were used after recrystallization. Chloroacetanilide (mp 138 °C), *p*-methylchloroacetanilide (mp 163 °C), and propionanilide (mp 104 °C) were prepared in the usual way.

Reaction of Anilides with Phosphoryl Chloride. General Procedure: In a 150-ml flask fitted with a reflux condenser we placed 50 mmol of anilide and 55 mmol of phosphoryl chloride. The mixture was then magnetically stirred, and the temperature was maintained at 20—30 or 80—100 °C for an appropriate period. After cooling, the mixture was poured into 150 ml of ice water, the solution was then allowed to stand for an additional 24 h. The HCl salt of the quinoline derivative(II, V, and VIII) was precipitated if quinoline was present, and easily separated by filtration. The filtrate was extracted twice with ether to remove the unreacted anilide. The aqueous layer was neutrallized with a 1 M NaOH aq solution to pH 7. The crude amidine derivative (I or VII) was extracted with ether. The aqueous layer was treated

Table 1. The reaction of several anilides with phosphoryl chloride

Reaction of Camphene with Chloroacetic Acid and the Synthesis of 2-(8-Camphenyl)ethanol[1,2]

Takao KISHIMOTO, Hiroshi ISHIHARA, and Yoshiharu MATSUBARA

Department of Applied Chemistry, Faculty of Science and Technology, Kinki University, Kowakae, Higashiosaka 577

(Received October 14, 1976)

Synopsis. Camphene (**1**) reacts with chloroacetic acid (**2**) or its polymer, polyacetoxamer; α-chloro, ω-carboxy in the presence of potassium bromide at reflux temperature to give the 2,2-dimethyl-*exo*-3-hydroxynorbornane-*endo*-3-propanoic acid lactone and the 2,2-dimethyl-*endo*-3-hydroxynorbornane-*exo*-3-propanoic acid lactone in a 50% yield. The synthesis of 2-(8-camphenyl)ethanol from **1** was simplified by utilizing this reaction.

There are no reports on the reactions of terpenes with halocarboxylic acids and also few reports on the reactions of olefins with halocarboxylic acids. These are reports on the carboxymethylation of olefins making use of iodo- and bromoacetic acids.[3] Specifically, the carboxymethylation of naphthalene[4] in the presence of potassium bromide was carried out using chloroacetic acid or its polymer, polyacetoxamer; α-chloro, ω-carboxy in the title reaction. However, it is of interest to note that the reaction of manganese(III) acetate with olefins in cyanoacetic acid was recently reported by Heiba *et al.*[5] and therefore, γ-lactones can be obtained in a single step.

As a part of the study of the reactions of olefins with halocarboxylic acids, the reaction of camphene (**1**) with chloroacetic acid (**2**) or its polymer, polyacetoxamer; α-chloro, ω-carboxy (**3**) was first investigated in the presence of potassium bromide. As a result, it was found that **1** reacts with **2** or **3** to give γ-lactones, which are useful in the synthesis of 2-(8-camphenyl)ethanol (**7**). Therefore, the structure of the γ-lactones and a simple method for synthesizing **7** from **1** are reported here.

Results and Discussion

The results of the experiments are shown in Table 1. In the presence of potassium bromide (KBr), the treatment of camphene (**1**) with chloroacetic acid (**2**) at reflux temperature gave, after distillation, the maximum yield (50%) of the γ-lactones which was composed of two components, **4A** and **4B**, in a gas chromatogram. These components (**4A** and **4B**) were isolated by redistillation and gas chromatography. Their structures were confirmed by IR and NMR spectroscopy or by a comparison of their physical constants with those reported in the literature. Table 2 shows the properties of **4A** and **4B**. The IR and NMR spectra showed the characteristic absorptions of γ-lactones and the *gem*-dimethyl group. These data indicate a configurational isomer **4A** or **4B** in Fig. 1. Of the two γ-lactones obtained, the melting point for the **4B** isomer agreed precisely with that reported by Bhati.[6] Therefore, the **4B** isomer can be assigned to the 2,2-dimethyl-*endo*-3-hydroxynorbornane-*exo*-3-propanoic acid lactone (**4B**) in Fig. 1. Consequently, the **4A** isomer supported the structure of the 2,2-dimethyl-*exo*-3-hydroxynorbornane-*endo*-3-propanoic acid lactone (**4A**) in Fig. 1. The structure of **4A** was confirmed, moreover, by deriving 2-(8-camphenyl)ethanol (**7**) from a mixture of **4A** and **4B**. The γ-lactone **4A** has not as yet been synthesized.

On the other hand, when **1** was treated with **2** in the absence of KBr, the γ-lactone fraction was afforded in only an 8% yield (Table 1). A gas chromatogram of the γ-lactone fraction also showed the two components, **4A** and **4B**. Their structures were confirmed by IR and NMR spectroscopy. In contrast with the reaction in the presence of KBr, the yield of γ-lactones was much lower. This behavior shows that in the presence of KBr, bromoacetic acid may initially be formed. The decomposition of bromoacetic acid can result in the formation of the carbonium ion ($^{+}CH_2C$-OOH),[4] which might account for an attack upon the

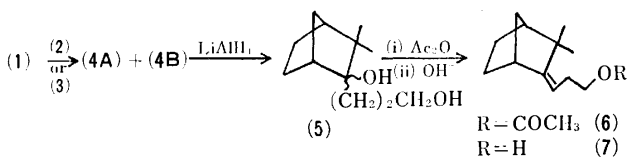

Fig. 2. Synthesis of **7**.

methylene group of **1** to give the γ-lactones (**4A** and **4B**) by lactonization of an intermidiate (**X**), as is shown in Fig. 1.

Next, polyacetoxamer; α-chloro, ω-carboxy (**3**) in the presence of KBr was also allowed to react with **1** to give the γ-lactones which comprised the two components, **4A** and **4B**. However, the γ-lactone yield was only about 17% (Table 1). These components were isolated using gas chromatography and their structures were confirmed by comparisons of their IR and NMR spectra with those of authentic samples. From this method, the lactonization could be explained by assuming the formation of carbonium ions of the type $^{+}CH_2CO_2(CH_2CO_2)_pCH_2CO_2H$.[4]

Lactone **4B** has in general been prepared by the hydration of tricycloekasantalic acid, which was obtained by the oxidation of the higher boiling fraction of East Indian sandalwood oil or α-santalene, as well as by the hydration of bicycloekasantalic acid or isobicycloekasantalic acid.[6-8] However, no simple synthesis of the γ-lactones (**4A** and **4B**) from **1** has yet been established. Bhati[6] has reported only that **4B** was synthesized *via* a multi-step process starting from **1**, in order to determine whether **4A** or **4B** is the hydration product (70 % yield) of tricycloekasantalic acid. The method described by Bhati is the only route for synthesizing **4B** from **1**, but it is not a method applicable to the synthesis of **7** from **1**. Using the present method, the γ-lactones (**4A** and **4B**) were prepared in a 50% yield in a single step from **1**, which is readily available. The synthesis of **7** was carried out according to known procedures,[7] as shown in Fig. 2. The γ-lactones (**4A**/**4B**=39/61) upon reduction with lithium aluminium hydride afforded a crystalline diol (**5**) which was converted to the corresponding unsaturated alcohol **7** by treatment with acetic anhydride, followed by saponification of the resultant acetate (**6**).

Experimental

Material. Camphene (**1**): bp 157—159 °C/760 Torr, mp 51—53.5 °C, purity 95% (in gas chromatogram, contains 5% tricyclene). Potassium bromide: commercial material (Wako Pure Chemical Industries) was used without purification. Polyacetoxamer; α-chloro, ω-carboxy (**3**): this polymer was prepared by the method of Southwick *et al.*[4] The resulting black powder was dried under reduced pressure for one day. Mp 115—158 °C (lit,[4] mp 118—138 °C)

Measurements. The NMR spectra were recorded on a Hitachi Perkin-Elmer R-24 (60 MHz) instrument. The IR spectra were obtained on a Yanagimoto ISG-25 spectrometer.

*Reaction of **1** with **2**.* *In the Presence of KBr*: In a flask fitted with a thermometer, stirrer and reflux condenser were placed 24.9 g (0.32 mol) of **2** and 3.0 g of KBr. The mixture was stirred vigorously in a sand bath for one hour at reflux temperature and 35.8 g (0.25 mol) of **1** was added to the solution dropwise for 30 min. The stirring was then continued for 30 h at the reflux temperature. At the end of the heating period, the temperature of the refluxing liquid was 189 °C. After cooling and benzene extraction, the extract was washed with a 10% aqueous solution of sodium carbonate and then water. The benzene extracts were dried over magnesium sulfate. Evaporation of the dried benzene layer followed by distillation gave the γ-lactone fraction (bp 122—125 °C/1 Torr, 18 g, 50% yield based on the amount of **1** used), which was composed of two components, **4A** and **4B**, in a 35 : 65 ratio based on gas chromatographic analysis. The γ-lactone fraction was crystallized from hexane: mp 98—99.5 °C; IR(KBr): 1780, 1760, 1386, and 1365 cm^{-1}.

In the Absence of KBr: A mixture of 24.9 g (0.32 mol) of **2** and 35.8 g (0.25 mol) of **1** was heated with stirring for 20 h at reflux temperature. At the end of the heating period, the temperature of the refluxing liquid was 178 °C. The conventional working-up described above and distillation afforded a mixture of 2.85 g (an 8% yield) of **4A** and **4B** in a 42 : 58 ratio.

*Reaction of **1** with **3** in the Presence of KBr.* The reaction was carried out with the same apparatus as used in the reaction of **1** with **2**. A mixture of 10 g of **3** and 1.0 g of KBr were heated with stirring for one hour at 160±2 °C and then 10.0 g (0.07 mol) of melted **1** was added to the solution dropwise for 30 min. Stirring was then continued for 20 h at reflux temperature. At the end of the heating period, the temperature of the refluxing liquid was 172 °C. The conventional work-up and distillation afforded 1.7 g (17% yield) of a mixture of **4A** and **4B** in a 35 : 65 ratio.

*Synthesis of **7**.* The alcohol was prepared according to the method of Ramaswami *et al.*[7] The diol (**5**): yield 85%, mp 99—107 °C, (lit,[7] mp 112 °C); IR: 3350, 1380, 1365, 1062, and 1040 cm^{-1}, NMR ($CDCl_3$) δ=0.91, 0.98 (two s, 6, CMe_2), 2.05 (br s, 2, OH, disappeared with D_2O), 3.90—3.75 ppm (m, 2, CH_2O), 2-(8-camphenyl)ethyl acetate (**6**): yield 90%, bp 107—109 °C/1 Torr, d_4^{25}=0.9915, n_D^{25}=1.4775, IR: 1740, 1666, 1380, 1365, and 842 cm^{-1}, NMR ($CDCl_3$) δ=0.98, 1.00 (two s, 6, CMe_2), 2.01 (s, 3, OAc), 3.88—4.11 (t, 2, CH_2O), and 4.69—4.98 ppm (t, 1, =CH–), (lit,[8] bp 105—110 °C/0.5 Torr, n_D^{28}=1.4749). 2-(8-Camphenyl)ethanol (**7**): yield 82%, bp 95—97.5 °C/2 Torr, n_D^{25}=1.4970, IR: 3300, 1666, 1383, 1366, and 842 cm^{-1}, NMR ($CDCl_3$) δ=1.02 (br s, 6, CMe_2), 1.86 (br s, 1, OH, disappeared with D_2O), 3.46—3.68 (t, 2, CH_2O), and 4.72—4.68 ppm (m, 1, =CH–), (lit,[8] bp 96—98 °C/2 Torr, n_D^{25}=1.4963).

The Intramolecular Cyclization Reaction of Unsaturated Acid with Palladium(II) Salt

Akira KASAHARA, Taeko IZUMI, Kazuhiro SATO, Mitsugi MAEMURA, and Tomohide HAYASAKA

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa 992

(Received January 13, 1977)

Synopsis. The stoichiometric reaction of sodium salts of 3-butenoic acid, 3-pentenoic acid, 4-pentenoic acid, and 4-hexenoic acid with lithium tetrachloropalladate(II) affords 2-buten-4-olide, 4-methyl-2-buten-4-olide (**2b**), **2b**, and 4-ethyl-2-buten-4-olide respectively. Similarly, the reaction of 2-styrylbenzoic acid with palladium(II) salt leads to the formation of 3-phenylisocoumarin.

It is well known that most of the 2-buten-4-olides can be synthesized by the dehydrohalogenation of α-halobutyrolactones,[1] by the lactonization of γ-keto-acids,[2] or by the oxidation of α,β-unsaturated esters with selenium dioxide.[2,3] Recently, an intramolecular cyclization of olefinic compounds *via* oxypalladation[4-6] has received wide attention. In relation to these reactions, we wish to report herein the palladium-induced intramolecular cyclization of both 3-butenoic acids and 4-pentenoic acids to 2-buten-4-olides.

The sodium salts of 3-butenoic acid (**1a**) and 3-pentenoic acid (**1b**) were treated with lithium tetrachloropalladate(II) in water to produce 2-buten-4-olide (**2a**) and 4-methyl-2-buten-4-olide (β-angelica lactone) (**2b**) in 38 and 32% yields respectively. In the reactions of both **1a** and **1b** with palladium(II) salt, no formation of 3-buten-4-olide derivatives was observed. Henry and Ward[7] have reported that the reaction of cyclohexene with palladium(II) acetate gave products which were consistent with a *trans* acetoxypalladation, followed by Pd(II)-hydride elimination and readdition. In the reaction of **1a** and **1b** with palladium(II) salt, the formation of **2a** and **2b** can be explained by the Scheme 1, involving intramolecualr oxypalladation to give the intermediate (**3**), followed by the β-elimination of the HPdCl species.

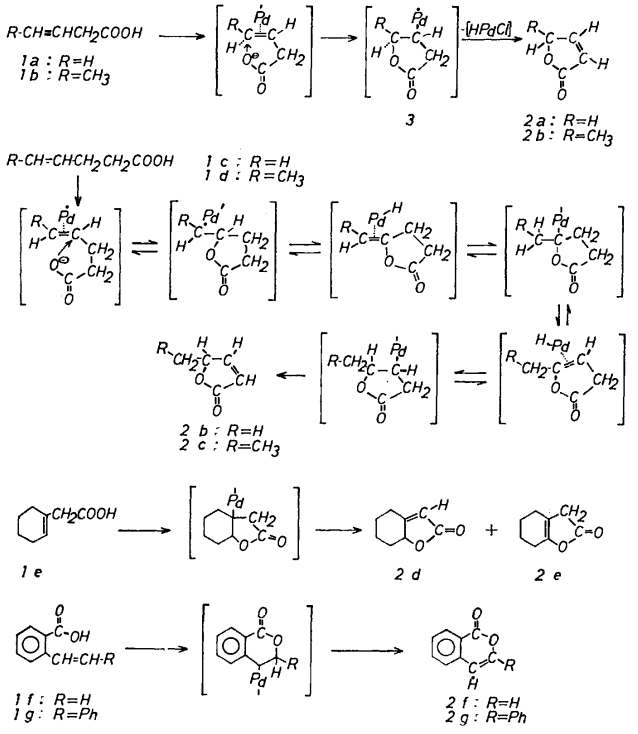

Fig. 1.

Furthermore, under the same conditions, 4-pentenoic acid (**1c**) and 4-hexenoic acid (**1d**) afforded **2b** and 4-ethyl-2-buten-4-olide (**2c**) in 38 and 30% yields respectively. In the reactions of both **1c** and **1d** with palladium(II) salt, no formation of the six-membered ring products was observed. The results are summarized in Table 1.

Hosokawa *et al.*[4f] have recently reported the regioselectivity of the palladium(II)-induced intramolecular cyclization of 2-(3-methyl-2-butenyl)phenol. However, in the reaction of **1c** and **1d** with palladium(II) salt, the formation of the five-membered ring products indicated that the cyclization of **1c** and **1d** involves a preferential attack of the oxygen atom of the carboxyl group on the 4-position of unsaturated acid (**1c** or **1d**), followed by a Pd(II)-hydride elimination-readdition process (see Scheme 1).

On the other hand, the reaction of 1-cyclohexenylacetic acid (**1e**) with palladium(II) salt led to the formation of a mixture of 5,6,7,7a-tetrahydro-2(4*H*)-benzofuranone (**2d**) and 4,5,6,7-tetrahydro-2(3*H*)-benzofuranone (**2e**). Similarly, the reaction of 2-vinylbenzoic acid (**1f**) and 2-styrylbenzoic acid (**1g**)

Table 1. Reaction of unsaturated acid (**1**) with lithium tetrachloropalladate(II)

Substrate	Solvent	Product (yield, %)
1a	H_2O	**2a** (R=H)[a] (38%)
1b	H_2O	**2b** (R=CH_3)[b] (32%)
1c	H_2O	**2b** (R=H) (38%)
1d	H_2O	**2c** (R=CH_3)[c] (30%)
1e	H_2O	**2d**[d] (28%) + **2e**[e] (10%)
1f	H_2O-dioxane	**2f** (R=H)[f] (46%)
1g	H_2O-dioxane	**2g** (R=Ph)[g] (42%)

with palladium(II) salt afforded isocoumarin (**2f**) and 3-phenylisocoumarin (**2g**) respectively. The palladium-promoted reaction of **1e**, **1f**, and **1g** also proceeds *via* a intramolecular oxypalladation, followed by an elimination of HPdCl.

Experimental

Materials. The following compounds were synthesized by the methods described in the literature: 3-butenoic acid (**1a**),[8] 3-pentenoic acid (**1b**),[9] 4-pentenoic acid (**1c**),[10] 4-hexenoic acid (**1d**),[11] 1-cyclohexenylacetic acid (**1e**),[12] 2-vinylbenzoic acid (**1f**),[13] and 2-styrylbenzoic acid (**1g**).[14]

General Procedure for The Reaction of Unsaturated Acid with Palladium(II) Salt. A solution of 10 mmol of unsaturated acid and 5 mmol of sodium carbonate in water (50 ml) or dioxane–water (1 : 1, 50 ml) was stirred with 10 mmol of lithium tetrachloropalladate(II) at room temperature. After stirring for 24 h, the reaction mixture was then extracted with ether. The ether extract was washed with aqueous sodium hydrogencarbonate and dried over anhydrous magnesium sulfate. After the evaporation of the solvent, the product was isolated by distillation or by column chromatography on silica gel. The structures of the products were confirmed by a mixed-melting-point determination, by comparing the retention times on gas chromatograms, and by the observation of the IR and NMR spectra.

Synthesis of Manninotriose Undecaacetate

Ryoichi ADACHI and Tetsuo SUAMI*

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama 223

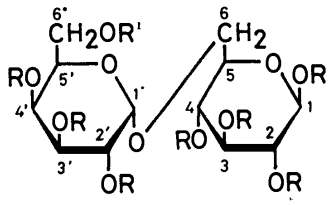
(Received January 17, 1977)

Synopsis. Manninotriose undecaacetate has been prepared from melibiose. Tritylation of melibiose, followed by acetylation gave 6′-*O*-trityl-*β*-melibiose heptaacetate. Detritylation of the compound gave hepta-*O*-acetyl-*β*-melibiose, which was condensed with tetra-*O*-benzyl-D-galactopyranosyl chloride. Deacetylation of the condensation product, followed by hydrogenolysis and acetylation afforded the title compound.

Manninotriose, *O*-α-D-galactopyranosyl-(1→6)-*O*-α-D-galactopyranosyl-(1→6)-D-glucose, has been found in a free form in an ash manna from *Fraxinus ornus* and *F. rotundifolia*, and it has been well known that this trisaccharide is a component of a tetrasaccharide: stachyose.[1] The enzymic synthesis of manninotriose from melibiose has been reported in a literature,[2] but a chemical synthesis has never been described.

In connection with the preceding papers,[3,4] we have attempted to synthesize manninotriose undecaacetate (**6**) from melibiose (**1**) chemically. When **1** was treated with trityl chloride in pyridine and the product was subsequently acetylated, 6′-*O*-trityl-*β*-melibiose heptaacetate (**2**) was obtained as crystals in 65% yield.

Detritylation of **2** with hydrogen bromide in glacial acetic acid afforded 1,2,2′,3,3′,4,4′-hepta-*O*-acetyl-*β*-melibiose (**3**). Condensation between **3** and 2,3,4,6-tetra-*O*-benzyl-D-galactopyranosyl chloride[5] (**4**) gave 1,2,2′,3,3′,4,4′-hepta-*O*-acetyl-2″,3″,4″,6″-tetra-*O*-benzyl-*β*-manninotriose (**5**) as a chromatographically homogeneous solid. Deacetylation of **5**, followed by catalytic hydrogenolysis and subsequent acetylation afforded **6** as crystals in 30% yield. Compound **6** was identified by direct comparison with an authentic sample prepared by hydrolysis of stachyose.[6]



1: R=R′=H
2: R=Ac, R′=Tr
3: R=Ac, R′=H
5: R=Ac, R′=2,3,4,6-tetra-*O*-benzyl-α-D-galactopyranosyl
6: R=Ac, R′=2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranosyl

Experimental

General. Melibiose and stachyose were purchased from a commercial source. Melting points were determined in capillary tubes, and are uncorrected. Solutions were evaporated under diminished pressure. IR spectra were determined for potassium bromide discs with a Hitachi 225 spectrophotometer. Optical rotations were recorded on a Japan Spectroscopic DIP-SL polarimeter. ^{1}H NMR spectra were determined at 60 MHz with a Varian A-60D spectrometer in deuteriochloroform with tetramethylsilane as an internal standard, and the peak positions are given in δ-values. TLC was performed on a silica gel (Wakogel B-10) plate, and silica gel (Wakogel C-200) was used for a column chromatography.

1,2,2′,3,3′,4,4′-Hepta-O-acetyl-6′-O-trityl-β-melibiose (2). To a solution of melibiose (**1**, 200 mg, 0.58 mmol) in dry pyridine (10 ml), trityl chloride (976 mg, 3.50 mmol) was added, and the mixture was agitated for 97 h at ambient temperature. Then, acetic anhydride (5 ml) was added to the reaction mixture. After 15 h, the mixture was poured into ice cold water (200 ml) and triphenylmethanol was removed by filtration. The filtrate was evaporated, and the residue was purified by a column chromatography using 1 : 5 (v/v) 2-butanone–toluene as eluent to give 424 mg of a chromatographically homogeneous product (R_f 0.43 on TLC in 1 : 4 (v/v) 2-butanone–toluene). Recrystallization from 80% aqueous ethanol gave 332 mg (65%) of **2**, mp 108—112 °C, $[\alpha]_D^{22}$+79.1° (*c* 1.05, chloroform), ^{1}H NMR: δ 1.88 (s, 3, OAc), 1.98 (s, 6, 2×OAc), 2.02 (s, 12, 4×OAc), 5.74 (d, 1, *J*=8.0 Hz, H-1), 6.35 (d, 1, *J*=3.5 Hz, H-1′).

Found: C, 61.22; H, 5.71%. Calcd for $C_{45}H_{50}O_{18}$: C, 61.50; H, 5.73%.

1,2,2′,3,3′,4,4′-Hepta-O-acetyl-β-melibiose (3). To a solution of **2** (318 mg) in glacial acetic acid (2.0 ml), glacial acetic acid (0.2 ml) saturated with hydrogen bromide was added under ice cooling. After stirring for 2 min, the precipitated bromotriphenylmethane was filtered off and the filtrate was quenched into ice cold water (60 ml). The solution was extracted with chloroform repeatedly and the combined chloroform layer was washed with dilute sodium hydrogencarbonate solution and water. After drying over sodium sulfate, the extract was evaporated. The residue was purified by a column chromatography using 1 : 2 (v/v) 2-butanone–toluene as eluent to give 181 mg (79%) of **3** as a chromatographically homogeneous solid (R_f 0.39 on TLC in 20 : 1 (v/v) chloroform–ethanol), $[\alpha]_D^{21}$+132.9° (*c* 0.82, chloroform). ^{1}H NMR: δ 1.98 (s, 6, 2×OAc), 2.04 (s, 3, OAc), 2.09 (s, 6, 2×OAc), 2.12 (s, 3, OAc), 2.13 (s, 3, OAc), 5.67 (d, 1, *J*=8.0 Hz, H-1), 6.27 (d, 1, *J*=4.0 Hz, H-1′).

Found: C, 49.07; H, 5.56%. Calcd for $C_{26}H_{36}O_{18}$: C, 49.06; H, 5.70%.

2,3,4,6-Tetra-O-benzyl-D-galactopyranosyl Chloride (4). The compound was prepared by the method of Austin *et al.*[5]

1,2,2′,2″,3,3′,3″,4,4′,4″,6″-Undeca-O-acetyl-β-manninotriose (6). To a solution of **3** (1.10 g, 1.73 mmol) and **4** (3.14 g, 5.62 mmol) in dry benzene (30 ml), mercury(II) cyanide (1.5 g) and "Drierite" (3.0 g) were added. The mixture was heated under reflux for 17 h, and an insoluble matter was removed by a centrifugal separator. The supernatant solution was washed with sodium hydrogencarbonate solution and water. The benzene solution was dried over sodium sulfate and evaporated. The residue was purified by a column chromatography using 1 : 5 (v/v) 2-butanone–toluene as eluent to give

* To whom correspondence should be addressed.

1.78 g (89%) of 1,2,2′,3,3′,4,4′-hepta-*O*-acetyl-2″,3″,4″,6″-tetra-*O*-benzyl-β-manninotriose (**5**) as a chromatographically homogeneous solid (R_f 0.52 on TLC in 1 : 3 (v/v) 2-butanone–toluene).

Compound **5** (1.70 g) was deacetylated in 0.1 M methanolic sodium methoxide (30 ml) overnight. The solution was neutralized with Amberlite IR-120 (H^+) resin and evaporated. The residue was hydrogenated in methanol (35 ml) in the presence of palladium black under a hydrogen atmosphere (3.4 kg/cm²) for 20 h in a Parr apparatus. The catalyst was filtered off and the filtrate was evaporated. The residue was acetylated with acetic anhydride (3 ml) and sodium acetate (0.3 g). The product was purified by a column chromatography using 1 : 5 (v/v) acetone–benzene to give 409 mg of a product which showed a single spot at R_f 0.38 on TLC in the same solvent. Recrystallization from ethanol afforded 268 mg (30%) of **6**, mp 106—107.5 °C, $[\alpha]_D^{21}$+132.7 °C (*c* 0.98, chloroform). ^{1}H NMR: δ 1.96 (s, 6, 2×OAc), 2.00 (s, 6, 2×OAc), 2.01 (s, 3, OAc), 2.05 (s, 9, 3×OAc), 2.09 (s, 6, 2×OAc), 2.11 (s, 3, OAc), 5.70 (d, 1, J=8.0 Hz, H-1). The IR and ^{1}H NMR spectra were superimposable on those of an authentic sample.

Found: C, 49.46; H, 5.51%. Calcd for $C_{40}H_{54}O_{27}$: C, 49.69; H, 5.63%.

*Compound **6** from Stachyose.* Manninotriose was prepared from stachyose by the method of Tanret.[6] The product was acetylated to give **6** in 47% yield, mp 106—107.5 °C, $[\alpha]_D^{21}$+137° (*c* 1.27, chloroform). (Found: C, 49.48; H, 5.56%).

Syntheses with 2-Furylmagnesium Bromides. I. Synthesis of Rosefuran and Sesquirosefuran*

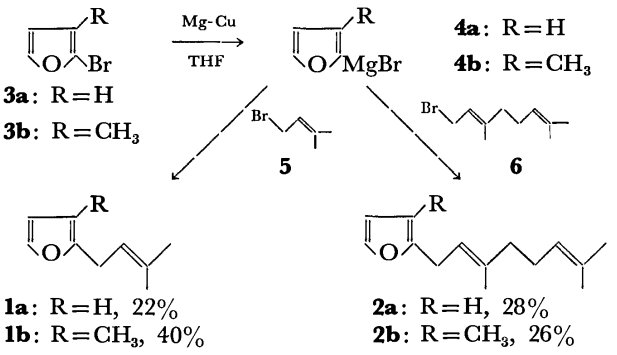
Akira TAKEDA, Kōichi SHINHAMA, and Sadao TSUBOI

Department of Synthetic Chemistry, School of Engineering, Okayama University, Tsushima, Okayama 700

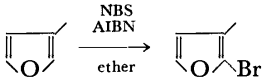
(Received February 2, 1977)

Synopsis. The preparation and reactions of 2-furylmagnesium bromide and 3-methyl-2-furylmagnesium bromide (**4b**) have been studied. Activated 90% magnesium–copper alloy was used to prepare the Grignard reagents. The reaction of 1-bromo-3-methyl-2-butene with **4b** gave rosefuran in a 40% yield; that of geranyl bromide with **4b** gave sesquirosefuran in a 26% yield.

Furylmetal compounds such as 2-furyllithium[1,2] and di-2-furylmercury(II)[1–3] are widely used for introducing 2-furyl moiety of natural products, *i.e.* rosefuran (**1b**), a trace component of Bulgarian rose oil (*Rosa damascene* Mill.),[1] and sesquirosefuran (**2b**), a constituent isolated from the oil of the leaves of *Actinodaphne longifolia* (Blume) Nakai.[4] The scheme of synthesis with 2-furylmagnesium derivatives has not been studied before. It seems worth while to devise a synthetic route leading to these natural products in which innoxious Grignard reagents are used in place of organomercury compounds. We have studied the preparation and reaction of 2-furylmagnesium bromides, and wish to report a new synthesis of compounds **1b** and **2b** by the reaction of 3-methyl-2-furylmagnesium bromide (**4b**) with 1-bromo-3-methyl-2-butene (**5**)[6] for the former, and geranyl bromide (**6**)[2] for the latter.



Few studies have been carried out on the reaction of 2-furylmagnesium compounds, except for the first work on the preparation of 2-furylmagnesium bromide (**4a**),[5] which was transformed into furoic acid by the action of carbon dioxide solely for the sake of confirming its formation. We have thus carried out the synthesis of 2-(3-methyl-2-butenyl)furan (**1a**)[7] and 2-geranylfuran (**2a**). The solution of 2-furylmagnesium bromide was prepared by reacting 2-bromofuran (**3a**)[8] with an activated magnesium–copper alloy (90 : 10) in THF, at room temperature for 3.5 h. Conversion of **3a** into the Grignard reagent was confirmed by a test with Michler's ketone.[9] Since the 12.75% Cu–Mg alloy recommended by Shepard *et al.*[5] was not available, we used the powder alloy obtained from a mixture of 90 parts of magnesium powder and 10 parts of copper powder by heating to red-hot under nitrogen. For each reaction, the alloy was reactivated by heating with half its weight of iodine at 50 °C. The reaction of the Grignard reagent **4a** with the bromide **5** gave furan **1a** in a 22% yield and that with bromide **6** gave furan **2a** in a 28% yield. The structures of these products were confirmed by spectral data (IR, NMR, and MS).



3b

The solution of Grignard reagent **4b** was prepared from 2-bromo-3-methylfuran (**3b**) in a way similar to that for the formation of **4a**. Bromofuran **3b** was obtained in a 56% yield by the action of *N*-bromosuccinimide (NBS) on 3-methylfuran by means of the procedure of Prugh *et al.*[8] The reaction of **4b** with compound **5**, gave furan **1b** in a 40% yield and that with compound **6** gave furan **2b** in a 26% yield. The spectral data (IR, NMR, and MS) of these synthetic furans were identical with those reported.[1,4] Although the yields are small as compared with those of the Friedel-Crafts-type alkenylation of furan,[7] the present route has a merit for the synthesis of 2,3-disubstituted furans, since it affords no other disubstituted isomers.

Experimental

Elemental analysis was carried out by Mr. Eiichiro Amano. Analytical determinations by GLPC were performed on a Hitachi Model K-53 gas chromatograph fitted with the following columns (3 mm o.d. × 1 m): A, 10% Apiezon Grease L on Chromosorb W; B, 10% poly(neopentyl succinate) on Chromosorb W; C, 10% SE-30 on Chromosorb W. Mass spectra were obtained with a Hitachi Model RMS-4 mass spectrometer. ^{1}H NMR spectra were taken at 60 MHz on a Hitachi Model R-24 apparatus. ^{13}C NMR spectra were obtained with a JEOL Model JNM-FX-100 spectrometer. Thin layer chromatograms were prepared with Merck Kieselgel 60 PF_{254} (E. Merck AG, Darmstadt). Compounds **3a**,[8] **5**,[6] **6**,[2] and 3-methylfuran[10] were prepared according to reported methods.

Preparation of a 90% Mg–Cu Alloy. A small glass tube (15 mm i.d. × 15 cm) was charged with a mixture consisting of 1.8 g of magnesium powder and 0.2 g of copper powder. After the air in the tube was sufficiently replaced by nitrogen, the mixed metal powder was heated to red-hot with a colorless flame for 20 min under nitrogen. After being cooled, the lump of alloy was crushed in a mortar, and stored in a small rubber-stoppered bottle.

*2-(3-Methyl-2-butenyl)furan (**1a**).*[7] A mixture of 0.21 g of 90% Mg–Cu alloy and 0.1 g of iodine was heated for 1 h at 50 °C under nitrogen. To the resulting mixture was added

* Presented at the 36th Annual Meeting of the Chemical Society of Japan, Higashiōsaka, April 1977.

slowly a solution of 2-bromofuran (0.73 g, 5.0 mmol) in 2 ml of THF, over a period of 20 min. Stirring was continued for 3 h at room temperature. After the formation of the Grignard reagent **4a** in the solution had been confirmed by a test with Michler's ketone,[9] it was added dropwise to a boiling solution of 1-bromo-3-methyl-2-butene (**5**) (0.74 g, 5.0 mmol) in 2 ml of THF over a period of 1 h under nitrogen. The mixture was refluxed for 1 h, and then allowed to stand at room temperature for 12 h. It was neutralized with dilute H_2SO_4, extracted with ether, and dried over $MgSO_4$. Distillation of the residue obtained after removal of the solvent gave 147 mg (22%) of **1a**: IR (neat) 1670, 1595, 1563, 1508, 1093, 1012, and 736 cm^{-1}; NMR ($CDCl_3$) δ 1.64 (s, 6H, $=\langle^{CH_3}_{CH_3}$), 3.29 (d, J=7 Hz, 2H, $-CH_2-$), 5.28 (t, J=7 Hz, 1H, $\rangle=\langle H$), 5.90 (m, 1H, β'-H of furan), 6.20 (m, 1H, β-H of furan), and 7.24 ppm (m, 1H, α-H of furan).

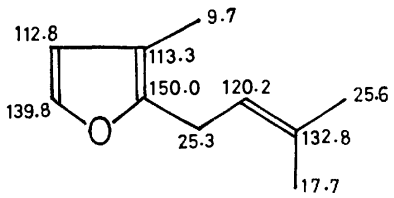
*2-Geranylfuran (**2a**).* A solution of **4a** prepared from 1.1 g (7.5 mmol) of **3a** in 3 ml of THF and 0.33 g of Mg–Cu alloy was reacted with a solution of geranyl bromide (**6**) (1.63 g, 7.5 mmol) in the same way as in the foregoing experiment of **1a**. A crude product (700 mg, 28%) with a 62% purity by GLPC was obtained by distillation: bp (bath temperature) 100—120 °C (2 Torr). It was purified by preparative TLC (silica gel, hexane, R_f=0.3) and analyzed: IR (neat) 1596, 1503, 1007, 798, and 728 cm^{-1}; NMR (CCl_4) δ 1.59 (s, 3H, $\diagup=\langle CH_3$), 1.67 (s, 6H, $=\langle^{CH_3}_{CH_3}$), 2.0 (br, s, 4H, H_2  H_2), 3.27 (d, J=8 Hz, 2H, $-CH_2-$), 5.04 (br, m, 1H, $H\rangle=\langle^{CH_3}_{CH_3}$), 5.29 (t, J=8 Hz, 1H, $H\rangle=\langle CH_3$), 5.80 (m, 1H, β'-H of furan), 6.12 (t, 1H, β-H of furan), and 7.18 ppm (m, 1H, α-H of furan); MS (70 eV) *m/e* (rel intensity) 204 (1, M^+), 162 (3), 123 (18), 81 (47), 67 (100).

Found: C, 82.14; H, 9.76%. Calcd for $C_{14}H_{20}O$: C, 82.30; H, 9.87%.

*2-Bromo-3-methylfuran (**3b**).* A 50 ml flask was charged with 5.4 g (34 mmol) of NBS and 0.26 g of AIBN. To the mixture was added a solution of 3-methylfuran[10] in 25 ml of dry ether under nitrogen. The resulting mixture was stirred for 3 h under reflux. It was then filtered, washed with 1% aqueous $NaHCO_3$, and dried over anhydrous $MgSO_4$ containing 20 mg of hydroquinone and 0.1 g of $CaCO_3$. After removal of the solvent and subsequent addition of 5 ml of quinoline, the mixture was subjected to fractional distillation under diminished pressure to yield 3.1 g (56%) of **3b**: bp 56—57 °C (60 Torr) [lit,[8] bp 28—30 °C (12 Torr)]; IR (neat) 1495, 1160, 1075, 892, and 736 cm^{-1}; NMR (CCl_4) δ 1.97 (s, 3H, $-CH_3$), 6.18 (d, J=2 Hz, 1H, β-H of furan), and 7.29 ppm (d, J=2 Hz, 1H, α-H of furan).

*2-(3-Methyl-2-butenyl)-3-methylfuran (**1b**). Synthesis of Rosefuran*: A solution of the Grignard reagent **4b** was prepared from 1.21 g (7.5 mmol) of 2-bromo-3-methylfuran (**3b**) dissolved in 4 ml of THF and 0.33 g of 90% Mg–Cu alloy, which was reactivated as usual. It was then added to a boiling solution of **5** (1.11 g, 7.5 mmol) in 3 ml of THF under nitrogen in the course of 45 min. Refluxing was continued for 3 h. It was then cooled and acidified with dilute H_2SO_4. The organic layer was extracted with ether and the ethereal extract was dried over anhydrous $MgSO_4$. After removal of the solvent the residue was distilled to give 512 mg of **1b** (87% purity by GLPC), yield 40%: bp (bath temperature) 80—100 °C (18 Torr) [lit,[1] bp 39—40 °C (1 Torr)]; IR (neat) 1670, 1628, 1512, 1450, 1380, 1158, 1088, 899, 857, and 733cm^{-1}; NMR ($CDCl_3$) δ 1.70 (d, J=1 Hz, 6H, $=\langle^{CH_3}_{CH_3}$), 1.94 (s, 3H, ring $-CH_3$), 3.26 (d, J=7 Hz, 2H, $-CH_2-$), 5.23 (t, J=7 Hz, 1H, $H\rangle=\langle$), 6.10 (d, J=2 Hz, 1H, β-H of furan), 7.16 (d, J=2 Hz, α-H of furan); MS (70 eV) *m/e* (rel intensity) 150 (79, M^+), 135 (100).

The natural abundance ^{13}C NMR spectrum of **1b** is summarized in the following structure. Off-resonance decoupling was used to support the assignment.



*2-Geranyl-2-methylfuran (**2b**). Synthesis of Sesquirosefuran*: A solution of **4b** prepared from 1.45 g (9.0 mmol) of **3b** and 0.4 g of 90% Mg–Cu alloy was reacted with a solution of **6** (1.96 g, 9.0 mmol) in the same way as in the foregoing experiments. A crude product (909 mg, 26%) with a 56% purity by GLPC was obtained by distillation: bp (bath temperature) 100—120 °C (0.3 Torr). A pure sample was obtained by preparative TLC (silica gel, hexane, R_f=0.3): IR (neat) 1623, 1560, 1507, 1148, 1079, 886, and 720 cm^{-1}; NMR (CCl_4) δ 1.58 (s, 3H, $\diagup=\langle CH_3$), 1.68 (d, J=1 Hz, 6H, $=\langle^{CH_3}_{CH_3}$), 1.93 (s, 3H, ring $-CH_3$), 2.0 (br, s, 4H, H_2  H_2), 3.21 (d, J=8 Hz, 2H, $-CH_2-$), 5.07 (br, m, 1H, $H\rangle=\langle^{CH_3}_{CH_3}$), 5.19 (t, J=8 Hz, 1H, $H\rangle=\langle CH_3$), 6.10 (d, J=2 Hz, 1H, β-H of furan), and 7.07 ppm (d, J=2 Hz, 1H, α-H of furan).

Emission Spectra of CH($A^2\Delta$) Produced from CH_3CN in the Argon Flowing-Afterglow Reaction

Kaoru SUZUKI and Kozo KUCHITSU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received January 7, 1977)

Emission spectra from CH($A^2\Delta$) formed in the reaction of positive ionic species of argon with CH_3CN were studied by the flowing-afterglow method. The rotational distributions for the $v'=0$, 1, and 2 of CH($A^2\Delta$) are characterized by effective rotational temperatures of *ca.* 5000, 2000, and 1500 K, respectively, whereas the distributions in lower levels ($N' \lesssim 11$), especially for $v'=0$, are characterized by that of *ca.* 700 K. The average vibrational and rotational energies distributed in the CH radicals produced initially are estimated to be 0.32 ± 0.04 and 0.34 ± 0.06 eV, respectively.

When a rare gas is subjected to microwave discharge, metastable atoms and ions are generated. The active species can react with molecules and produce fragments in electronically excited states. Photoemissions of such fragments formed in reactions of metastable argon atoms have been studied in detail.[1,2] On the other hand, emissions followed by dissociative reactions with active ionic species of thermal kinetic energy have scarcely been reported.

When the flowing afterglow method was applied to the reaction of metastable argon atoms with CH_3CN, it was suggested that the formation of CH($A^2\Delta$) was caused by a different mechanism from that of CN($B^2\Sigma^+$), because the dependence of CH $A^2\Delta$-$X^2\Pi$ and CN $B^2\Sigma^+$-$X^2\Sigma^+$ emission intensities on the argon pressure was different.[3,4] The present article reports that the active species of argon mainly contributing to the production of CH($A^2\Delta$) radicals in the reaction with CH_3CN are ionic. The vibrational and rotational structures of the visible emission spectrum from CH($A^2\Delta$) have been analyzed to obtain information about the energy distributed to the vibrational and rotational motions of the CH($A^2\Delta$) radical.

Experimental

The experimental apparatus is essentially the same as that described in previous reports.[3-5] The flow tube was evacuated by a 500 l/s mechanical booster pump. The argon gas of 99.99% nominal purity was purified by passage through a trap at 77 K before it was introduced into the discharge section. Positive ions and metastable atoms, $Ar(^3P_{2,0})$, were produced by a 2450 MHz microwave discharge. An output power of about 450 W from a magnetron was fed into the discharge section. The reactant gas was introduced into the flow through a nozzle (0.4 mm in diameter) placed 15 cm downstream from the discharge section. The acetonitrile sample was of extra pure grade.

The gas pressure was measured in the reaction zone by a Pirani gauge calibrated against a McLeod gauge. The argon pressure was varied from 0.3 to 1.7 Torr. The pressure of CH_3CN was about 0.01 Torr.

Emission spectra were observed through a quartz window by using a 1-m Spex 1704 scanning monochromator with a 1200 grooves/mm grating blazed at 500 nm, an HTV R585 photomultiplier, and a photon counting system.

The CH($A^2\Delta$-$X^2\Pi$, 0-0, 1-1, and 2-2) emission was observed in the 420—440 nm region at an argon pressure above about 0.3 Torr. The spectrum shown in Fig. 1 was obtained at an argon pressure of about 0.7 Torr with a spectral resolution of about 0.05 nm FWHM. The R-branch lines of the 0-0 band were resolved from those of the 1-1 band for $N' \gtrsim 6$ (except for $N'=12$). The CH $B^2\Sigma^-$-$X^2\Pi$ band was also observed in the 385—405 nm region, where the R-branch was overlapped by the CN violet band.

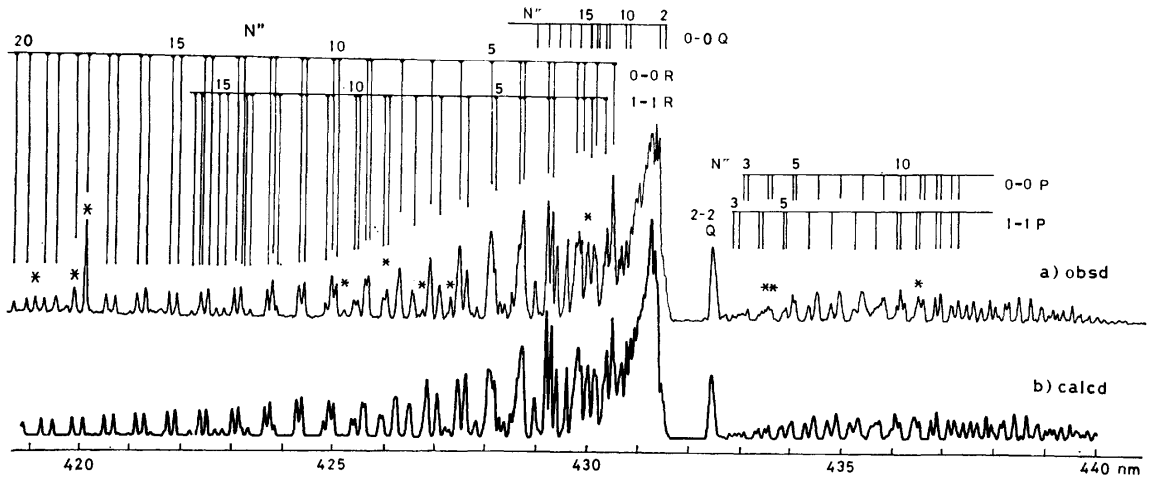

Fig. 1. Observed (a) and simulated (b) spectra of CH $A^2\Delta$-$X^2\Pi$. Lines marked * are overlapped by stray argon lines.

Estimation of Active Ionic Species

In order to remove the ionic species reaching the reaction zone, grids (stainless steel mesh, transparency *ca.* 0.74) were placed between the discharge section and the reaction zone, and an electrostatic potential was applied. The collected ion currents and the emission intensities of CH $A^2\Delta$-$X^2\Pi$ and CN $B^2\Sigma^+$-$X^2\Sigma^+$ are plotted against the potential applied to the grid in

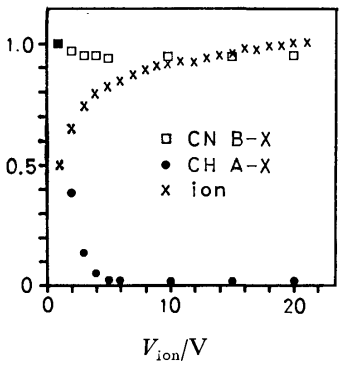

Fig. 2. The relative emission intensities of CN $B^2\Sigma^+$-$X^2\Sigma^+$ (□) and CH $A^2\Delta$-$X^2\Pi$ (●) formed from CH_3-CN in the flowing afterglow reaction of argon, and the relative ion currents (×) collected with an ion-collector grid are plotted against a potential applied to the ion-collector grid, V_{ion}, at an argon pressure of 0.4 Torr. The relative currents due to the ions reaching the reaction zone is proportional to the difference from the saturated ion current at $V_{ion}>20$ V.

Fig. 2. The CH $A^2\Delta$-$X^2\Pi$ emission intensity was monitored at 431 and 424 nm, which correspond to the 0-0 head and the R(12) line of the 0-0 band, respectively, with a band pass of about 1.6 Å. These emission intensities had essentially the same dependence on the potential applied to the grid. Therefore, the trend for CH $A^2\Delta$-$X^2\Pi$ shown in Fig. 2 is regarded as representing that of the total emission from $CH(A^2\Delta)$, *i.e.*, the dependence of the density of $CH(A^2\Delta)$ produced in the reaction on the potential. The CN $B^2\Sigma^+$-$X^2\Sigma^+$ emission monitored at 385 and 386 nm had only slight dependence on the potential. It is therefore evident that ionic species are mainly responsible for the $CH(A^2\Delta)$ formation, whereas $CN(B^2\Sigma^+)$ is mainly produced by neutral atoms.

Attempts have been made to identify the ionic species. If a single collision of active species produces $CH(A^2\Delta)$, there are energetically possible channels in which singly charged argon ions in the metastable states, $Ar^{+M}(^4D_{7/2}$, $^4F_{9/2,7/2}$, $^2F_{2/7}$, $^2G_{9/2,7/2})$,[6] and multiply charged ions, especially doubly charged ions, are involved. In the present experiment, Ar^{+M} seems to have a lifetime long enough to reach the reaction zone and take part in the dissociative excitation. The radiative lifetime of Ar^{+M} has not been measured, but it is estimated to be longer than 1 s[7] if multiple-quantum transitions do not contribute significantly. The lifetime for collisional relaxation is also estimated to be longer than the time of flight under the present experimental conditions. Hence, Ar^{+M} seems to be a plausible candidate. On the other hand, argon ions in the ground electronic state, $Ar^+(^2P_{3/2,1/2})$, or argon molecular ions, Ar_2^+, can be excluded by energetic considerations: Their available energies are 15.76[6] and 14.4 eV,[8] respectively, whereas the minimum energy to produce $CH(A^2\Delta)$ by charge exchange and dissociation is 25.3 eV.[9]

However, the possibility that $CH(A^2\Delta)$ is produced by successive collisions of ionic and neutral species (Ar^+, Ar_2^+, $Ar(^3P_{2,0})$, *etc.*) cannot be excluded. In order to specify the reaction channels involved in the $CH(A^2\Delta)$ formation, it is necessary to identify and monitor the positive ions present in the flow at the reaction zone.

Analysis of Rotational and Vibrational Distributions

The relative intensities of the emission spectrum was analyzed to estimate the vibrational and rotational populations of $CH(A^2\Delta)$ formed in the reaction with active species discussed above. In the following procedure, production of the $CH(A^2\Delta)$ state by cascading from higher states is ignored for the following reasons: a) The CH $B^2\Sigma^-$-$A^2\Delta$ and CH $C^2\Sigma^+$-$A^2\Delta$ transitions are forbidden. b) The allowed CH $D^2\Pi$-$A^2\Delta$ emission (near 280 nm) was not observed in the present experiment. c) No cascading effect from higher states (D, E, F, *etc.*) has been reported in the lifetime measurement of $CH(A^2\Delta)$[10,11] produced by electron impact on CH_4 and C_2H_2.

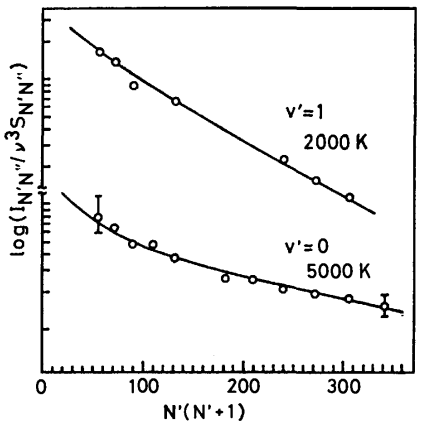

Fig. 3. Estimation of effective rotational temperatures from the slopes of $\log(I_{N'N''}/\nu^3 S_{N'N''})$ *vs.* $N'(N'+1)$. Solid lines represent a two-temperature distribution estimated by Eq. 2, with $n_L/n_H=0.27$, $T_L=700$ K, and $T_H=5000$ K for the $v'=0$ state and $T_H=2000$ K for the $v'=1$ state. Typical uncertainties are indicated by error bars.

Relative rotational populations are estimated by using the intensities of the R-branch. In Fig. 3, $I_{N'N''}/\nu^3 S_{N'N''}$ is plotted against $N'(N'+1)$, where $I_{N'N''}$ is the relative transition intensity, ν is the transition frequency, and $S_{N'N''}$ is the rotational line-strength calculated by the Hönl-London formula.[12]

An approximately linear relationship, *i.e.*, approximately a Boltzmann distribution, is obtained for the $v'=1$ state. From the slope, $-hcB_{v'}/kT_{rot}$, where $B_{v'}$ is the rotational constant,[13] the effective rotational

temperature, T_{rot}, is estimated to be 2000 ± 500 K. For the $v'=0$ state, however, the populations at lower ($N'\lesssim11$) levels appear to deviate from the linear relationship, their effective rotational temperature being an order of magnitude lower. A similar remark was made by Brennen and Carrington,[14] who observed a two-temperature distribution in the CH($A^2\Delta$) spectrum produced in the $O+C_2H_2$ reaction. Though they seem to have disregarded the overlapping of the R-branch by the Q-branch near 430 nm, as remarked by Beenakker *et al.*,[15] their observations indicate that the distribution characterized by a lower effective rotational temperature was produced by rotational relaxation to the equilibrium distribution corresponding to the ambient temperature. They also observed that the distribution corresponding to the higher temperature was unaffected by the rotational relaxation.

The observed rotational distribution is analyzed on the assumption that the distribution is represented by a superposition of two Boltzmann distributions. It is called a two-level model;[14,16] *i.e.*, CH radicals initially produced in a distribution with a higher rotational temperature, T_H, are relaxed by collisions to another distribution with a lower temperature, T_L (see Appendix). In this model the ratio of the number of CH radicals in the "relaxed" low-temperature distribution, n_L, to that in the "initial" high-temperature distribution, n_H, is given by

$$n_L/n_H = \tau k_e[\mathrm{Ar}], \tag{1}$$

where τ is the radiative lifetime of the CH($A^2\Delta$) state, k_e is the effective rate constant for the rotational relaxation of CH($A^2\Delta$, $v'=0$), and [Ar] is the number density of the argon atoms. The observed values of τ and k_e are 460 ns[17] and 2.6×10^{-11} cm^3 molecule^{-1} s^{-1}, respectively. (The k_e value reported in Ref. 14 has been modified slightly in accordance with the τ taken from Ref. 17.) The ratio, n_L/n_H, is thus estimated to be 0.27 when the argon pressure is 0.7 Torr. The relative intensity, $I_{N'N''}/\nu^3S_{N'N''}$, is expressed as

$$I_{N'N''}/\nu^3S_{N'N''} \propto (n_H/T_H)\exp[-hcB_{v'}N'(N'+1)/kT_H] + (n_L/T_L)\exp[-hcB_{v'}N'(N'+1)/kT_L]. \tag{2}$$

By adjustment of the T_H and T_L in Eq. 2 to reproduce the observed relative intensity, as shown in Fig. 3, the temperatures are estimated to be $T_H=5000\pm1000$ K and $T_L=700\pm200$ K. These T_H and T_L values are essentially independent of the argon pressure between 0.4 and 0.7 Torr.

It is shown in Fig. 3 that the observed relative intensities are well represented by Boltzmann distributions with two different effective rotational temperatures, T_H and T_L. This implies that the two-level model adopted in our analysis holds good for accounting for the observed relative intensities phenomenologically.

The distribution for the $v'=1$ state is also consistent with a two-temperature distribution with $T_H=2000\pm500$ K and $T_L=700\pm200$ K, although the contribution from the low-temperature component is less conspicuous, as shown in Fig. 3.

Relative vibrational populations for $v'=0$, 1, and 2 and the effective rotational temperature for $v'=2$ are estimated by simulation of the spectrum. A computer program was written following Baas and Beenakker[18] for the MELCOM 7700 computer at the Educational Computer Center of the University of Tokyo. Transition frequencies, line intensities, and the band envelope were calculated using the molecular constants reported in the literature.[12,13,19,20]

The ratio of the vibrational populations, $P_{vib}(1)/P_{vib}(0)=0.5\pm0.1$, is obtained by simulation of the R-branch 0-0 and 1-1 transitions for $N'\gtrsim11$. For the $v'=2$ level, the effective rotational temperature, $T_{rot}=1500\pm500$ K, and the vibrational population, $P_{vib}(2)/P_{vib}(0)=0.07\pm0.02$, are obtained by simulation of the Q-branch of the 2-2 transition. The calculated spectrum based on the estimated values reproduces the overall feature of the observed spectrum, as shown in Fig. 1.

Distributions of mean internal energies listed in Table 1 are estimated in the following way.[5] The mean rotational energy possessed by the CH($A^2\Delta$) radicals produced "initially" is approximated by

$$\langle E_{rot}\rangle = [\sum_{N'=2} hcB_{v'}\{N'(N'+1)-4\}R_{N'}]/(\sum_{N'=2} R_{N'}), \tag{3}$$

where $R_{N'}$ is the rotational distribution,

$$R_{N'} = (2N'+1)\exp[-hcB_{v'}N'(N'+1)/kT_H]. \tag{4}$$

The mean vibrational energy is calculated from the vibrational energies, $E_{vib}(v)$, and the relative vibrational population, $P_{vib}(v)$, by

$$\langle E_{vib}\rangle = \sum_v E_{vib}(v)P_{vib}(v). \tag{5}$$

As shown in Table 1, approximately equal energies, *ca.* 0.3 eV, are distributed to the vibrational and rotational motions of the CH radicals formed in the reaction of CH_3CN with active ionic species of argon.

Table 1. Relative vibrational populations, effective rotational temperatures, and average vibrational and rotational energies for CH($A^2\Delta$) produced in the argon afterglow reaction with CH_3CN

v	P_{vib}	E_{vib}/eV[a]	T_{rot}/K
0	0.63 ± 0.05	0.179	5000 ± 1000[b]
1	0.32 ± 0.10	0.518	2000 ± 500[b]
2	0.05 ± 0.02	0.834	1500 ± 500
		$\langle E_{vib}\rangle$/eV	$\langle E_{rot}\rangle$/eV
		0.32 ± 0.04	0.34 ± 0.06

The authors are grateful to Drs. T. Kondow, T. Fukuyama, T. Urisu, I. Tokue, and W. Shearer-Izumi for their critical reading of the manuscript.

Appendix. Two-level Model.

The two-level model for rotational relaxation is a phenomenological treatment, in which microscopic level-to-level transitions among the rotational levels are overlooked. Its main idea[14,16] is to represent the whole rotational distribution by two distributions characterized by different parameters. In the present case an effective Boltzmann temperature was chosen as one of the parameters. A sophisticated treatment was

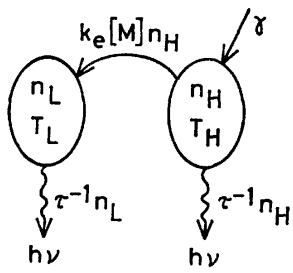

Fig. 4. Schematic diagram of the two-level model for rotational relaxation by collisions.

carried out by Sokabe[16] for the $OH(A^2\Sigma^+)$ rotational distributions formed from H_2O in the reaction with metastable argon atoms, but in the present study a simpler model shown in Fig. 4 was used. Photoemitting species are formed in the distribution characterized by an effective rotational temperature, T_H, at a rate, γ. These species, then, suffer collisional relaxation with surrounding particles to the other distribution characterized by a lower temperature, T_L, at an effective rate constant, k_e. The populations in these "levels" are denoted by n_H and n_L. Photoemissions are observed from these levels with a radiative lifetime, τ.

Rate equations for the two states are written as

$$dn_H/dt = \gamma - k_e[M]n_H - n_H/\tau, \quad (6)$$

$$dn_L/dt = k_e[M]n_H - n_L/\tau. \quad (7)$$

When the steady-state condition, *i.e.*, $dn_H/dt = dn_L/dt = 0$, is assumed, the following relation is obtained from Eq. 7:

$$n_L/n_H = \tau k_e[M]. \quad (8)$$

Spectroscopic and Kinetic Studies of the Photochromism of *N*-Salicylideneanilines and Related Compounds

Ryoichi NAKAGAKI, Takayoshi KOBAYASHI,* Junko NAKAMURA,* and Saburo NAGAKURA

Institute for Solid State Physics, The University of Tokyo, Minato, Tokyo 106

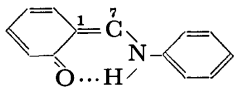
**Institute of Physical and Chemical Research, Wako, Saitama 351*

(Received January 10, 1977)

Photochromism of *N*-salicylideneanilines and related compounds was studied by measuring the electronic and vibrational spectra of the transient species. The rise time of the transient electronic spectra of the photochromic colored species was measured by picosecond time-resolved spectroscopy and was found to be dependent upon solvent viscosity. FT IR spectra showed that the photochromic colored species took the keto amine form. Picosecond kinetic analysis demonstrated that an intermediate existed in the transfer process from *cis*-keto amine to the photochromic species. These facts led us to the conclusion that the photochromic phenomenon of *N*-salicylideneanilines occurred through enol imine$\xrightarrow{h\nu}$enol imine*→*cis*-keto amine*→the intermediate→*trans*-keto amine(photochromic species).

A number of *N*-salicylideneanilines have been reported to be photochromic both in crystal and in rigid and fluid solutions.[1-5] Cohen and his co-workers showed that the hydroxyl group is essential for the photochromic effect: The effect vanishes when the *o*-hydroxyl group is methylated or the Schiff's bases are derived from benzaldehyde or *p*-hydroxybenzaldehyde.[2a]

Several studies have indicated that photochromic change occurs through hydrogen transfer followed by a geometrical rearrangement of the molecule.[1a,2a,3b,4a,5] Ottolenghi and his co-workers first proposed that the rearrangement is the cis-trans isomerization due to rotation about the C_1–C_7 bond,[5b] and later proposed mainly on the basis of theoretical consideration that the rotation takes place both about the C_1–C_7 bond and about the C_7–N bond, resulting in two non-planar photochromic colored species.[5c]



In the present investigation we attempted to elucidate the primary process of photochromism of *N*-salicylideneanilines and related compounds by using the time-resolved spectroscopy techniques in the time range of millisecond to picosecond and to clarify the molecular structure of the photochromic colored species by means of FT(Fourier transform) IR spectroscopy.

Experimental

The compounds employed in the present work are *N*-salicylidene-*p*-toluidine (**1**), *N*-salicylidene-*o*-toluidine (**2**), 2-chloro-*N*-salicylideneaniline (**3**), *N*-salicylidene-*m*-toluidine (**4**), *N*-salicylidene-*m*-toluidine[hydroxy-*d*] (**5**), *N*-3-methoxysalicylidene-4-nitroaniline (**6**), *N*-[1-(*o*-hydroxyphenyl)ethylidene]-aniline (**7**), *N,N'*-disalicylideneethylenediamine (**8**), and 2-(*o*-hydroxyphenyl)benzothiazole (**9**).

Compounds **1**—**4** and **6**—**8** were synthesized by direct condensation of the appropriate carbonyl compounds with corresponding amines in ethanol, and were purified by recrystallization and vacuum sublimation. **5** was prepared by treating **4** in excess CH_3OD for 8 h, the isotopic purity being determined to be about 90% by means of NMR spectroscopy. Commercially available **9** was chromatographed from benzene on activated alumina. Spectrograde diethyl ether, methylcyclohexane, and toluene, GR grade cyclohexanol and liquid paraffin were used without further purification. The other solvents used were purified according to the usual method.[6]

A flash photolysis apparatus constructed by Kira and Nishi[7] was used for measurements of time-resolved absorption spectra in the time range longer than microsecond. A Blumlein type N_2 laser with a pulse-width of 3.6 ns (FWHM) and with a peak power of 500 kW was constructed to be used as an exciting light source for photolysis in the nanosecond time range and for determination of the fluorescence decay time. For the nanosecond time-resolved spectroscopy, a pulsed Xe flash with about 3 μs half-duration was used as an analyzing light source. The light intensity was detected with an HTV 1P28 photomultiplier through a 0.25 m Jarrel-Ash grating monochromator (JE 25). A TRW Model 32A decay time computer was used for determination of the fluorescence lifetime.

An amplified single pulse selected from a pulse train of a mode-locked ruby laser (JEOL JLS-R10) was used for the picosecond time-resolved spectroscopy experiment. The pulse width was *ca.* 20 ps. The exciting light pulse at 347.2 nm was obtained by the frequency-doubling of 694.3 nm fundamental through an ADP crystal. Details of the apparatus were published elsewhere.[8]

FT IR spectra were measured with a JEOL FT IR spectrophotometer JIR-03F at the Department of Chemistry, The University of Tokyo.

Results and Discussion

Photochromic Colored Species of N-*Salicylideneanilines.* Transient absorption spectra of **1**—**3** and **7**—**9** were measured in PM (a mixed solvent of isopentane and methylcyclohexane with 1 : 1 volume ratio) at room temperature. Photochromic effect was examined for **4** and **5** in crystalline state. Since **6** is scarcely soluble in PM, the mixed solvent of diethyl ether and toluene (1 : 1 volume ratio) was used for the measurement of the transient absorption spectrum of **6**. Some of the transient absorption spectra are shown in Figs. 1 and 2. The observed spectra and their decay kinetics are not affected by dissolved O_2. This result is consistent with the previous result.[3] The fact that compounds **1**—**9** commonly having the enol imine structure show the photochromic effect leads us to the conclusion that the structure is essential to formation of the photochromic species.

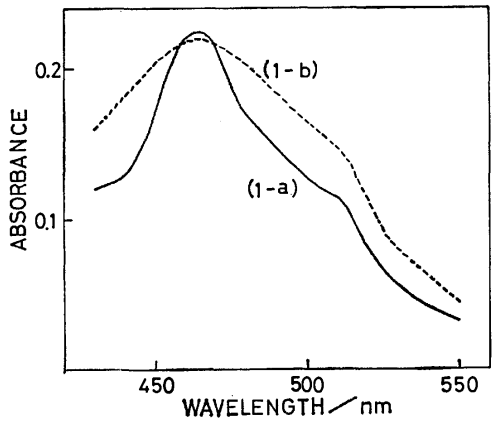


Fig. 1. The photochromic transient absorption spectrum of **1** in PM at 293 K: 1-a, 10 ns after triggering (the 1.4×10^{-3} M solution, 10 mm cell length); 1-b, 35 μs after triggering (the 1.4×10^{-4} M solution, 100 mm cell length).

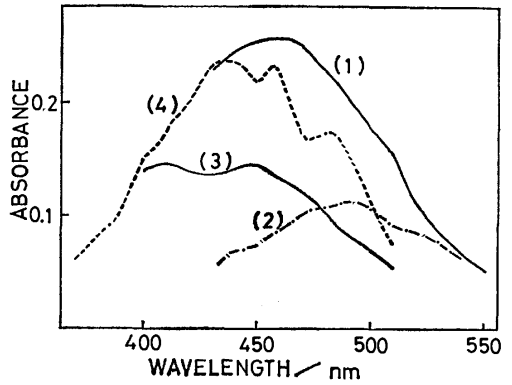

Fig. 2. The photochromic transient absorption spectra of **3**, **6**, **7**, and **8** at 293 K: (1), **3** in PM, 35 μs after triggering (1.7×10^{-4} M); (2), **6** in diethyl ether–toluene (1: 1), 90 μs after triggering (8.4×10^{-5} M); (3), **7** in PM (1.0×10^{-3} M), 10 ns after triggering; (4), **8** in PM (1.8×10^{-4} M), 35 μs after triggering.

Fading of the photochromic colored species of **3** and **6** follows first-order kinetics within the limitations of experimental error, and their decay times were derived to be 55 and 440 μs, respectively, while that of **1**, **2**, **8**, and **9** follows neither first-order nor second-order kinetics. Kinetic analysis at every 10 nm in the measured wavelength region for **1**, **2**, **8**, and **9** shows that there are two different kinds of contributions to the fading: a large but narrowly-distributed contribution from the short-lived component and a small but widely-distributed contribution from the long-lived component. This can explain the observation that the transient absorption bands of **1** becomes blurred with increasing time.

The decay curves observed with **1**, **2**, **8**, and **9** were analyzed by resolving into the long- and short-lived components. The results are given in Table 1 together with those for **3** and **6**. We can see that the decay time of the photochromic colored species is dependent on the solvent viscosity. This is important in connection with the mechanism of the photochromic phenomenon.

The Structure of the Photochromic Colored Species. On the basis of indirect evidence there have been several proposals that the photochromic colored species is formed by hydrogen transfer in the excited state followed by a molecular rearrangement.[1-5] We obtained for the first time the direct evidence that the photochromic colored species take the keto amine form in the crystalline state. IR difference spectra recording transmittance ratios ($T=I_1/I_2$) *vs.* wave numbers were measured with **4** and **5** in KBr disk at room temperature. Here I_1 and I_2 represent transmitted light intensity before and after irradiation with UV light (Hg 365 nm line), respectively. Crystal of **4** was taken as a sample since it gave a long-lived photochromic colored species at room temperature. For the convenience of assignment of the vibrational bands deuterated anil **5** was examined at the same time. The result of **4** is shown in Fig. 3. The frequencies of the characteristic bands observed with **4** and **5** are given in Table 2. Bands with $T>1$ and $T<1$ are attributed to the parent compounds (**4** and **5**) and the photochromic colored species, respectively.

From the characteristic bands with $T>1$ such as C=N stretching at 1616 cm^{-1}, the skeletal streching of a benzene ring at 1597 and 1570 cm^{-1}, and the OH out-of-plane angle bending at 837 cm^{-1}, we can see that the parent compounds **4** and **5** take the enol imine form in the crystalline state. This is consistent with the

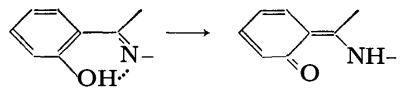
results obtained by X-ray crystal analysis.[9] Concerning the bands with $T<1$, strong absorption bands at 1651 cm^{-1} for **4** and 1644 cm^{-1} for **5** show that the photochromic colored species has the carbonyl group. Furthermore, the species show the skeletal stretching of a quinoid ring and the amide vinylog NHC=CC=O vibration at 1539, 1510, and 1487 cm^{-1}, and the C–N stretching at 1319 cm^{-1} for **4**. These results clearly demonstrate that the photochromism is caused by photoisomerization of the enol imine to the keto amine:



enol imine keto amine

Photochromic Schiff's bases are known to exhibit similar transient electronic absorption spectra in crystalline state and in rigid and fluid solutions.[1-5,10] This means that the photochromic colored species has the same structure, the keto amine form, both in crystalline phase and in rigid and fluid solutions.

Picosecond Photolysis and the Mechanism of Photochromism. We determined for the first time the rise times of the photochromic transient absorption for **1** and **9**, and clarified the existence of the precursor of the photochromic colored species by using the picosecond time-resolved spectroscopy technique. In the PM solution of **1** with viscosity of 0.40 cP at 25 °C, absorbance at 465 nm was saturated 200 ps after photoexcitation and the rise time was determined to be 84 ps (Fig. 4-A). On the other hand, in the cyclohexanol solution with viscosity of 47 cP at 27 °C, the absorbance of **1** at 475 nm continued to increase 200 ps after photoexcitation and its rise time was estimated to be longer than 180 ps (Fig. 4-B). This means that the enol imine in the excited singlet state passes over an energy barrier sensitive to viscosity in the course of transformation into the photochromic colored species; in other words, that in the photochromic phenomenon the hydrogen transfer in the excited state is followed by a geometrical change in the molecular framework which is sensitive to viscosity. The occurrence of the geometrical change in the photochromic process is also supported by the fact that the electronic absorption spectrum of the photochromic

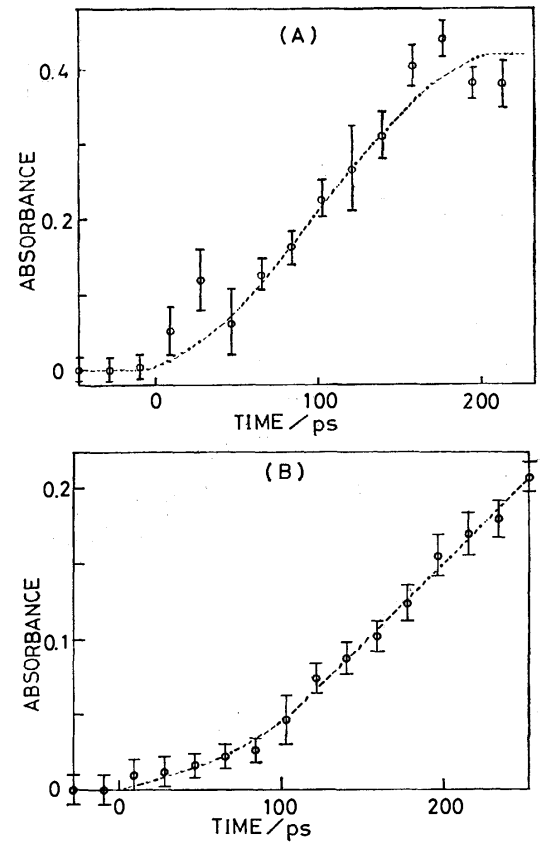


Fig. 4. Formation of the photochromic colored species of **1**. (A) Absorbance at 460 nm plotted as a function of time at 298 K (1.1×10^{-3} M in PM). (B) Absorbance at 475 nm plotted as a function of time at 300 K (1.7×10^{-3} M in cyclohexanol).

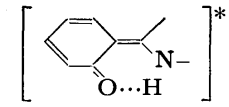
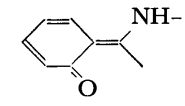
colored species is different from that of the *cis*-keto amine formed simply by the hydrogen transfer in the ground state.[5c]

Since the keto amine can take *cis*- and *trans*-forms, it is reasonable to consider that the photochromic colored species is the *trans*-keto amine, and that the photochromic process involves the transformation of the *cis*-keto amine in the excited state into the *trans*-keto amine in the ground state.



cis-keto amine in the excited state



trans-keto amine

According to this mechanism, the thermal bleaching of the photochromic colored species is conversion of the *trans*-keto amine to the enol imine and involves the rearrangement of the molecular framework besides the intramolecular hydrogen transfer. This scheme for the thermal bleaching gives a reasonable explanation to the following findings:

(1) The half-life of the photochromic colored species of **4** in crystalline phase is 1300 and 200 min at 16 and 27 °C, respectively.[11]

(2) The fading kinetics of the photochromic colored species in fluid solution is dependent on viscosity of the solvent.

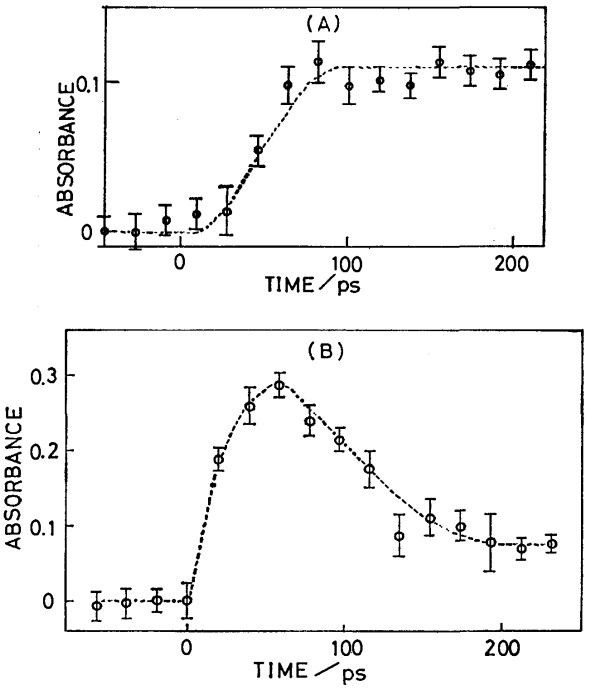


Fig. 5. (A) Formation of the photochromic colored species of **9** at 293 K (1.3×10^{-3} M in PM). Absorbance at 470 nm plotted as a function of time. (B) Decay of the intermediate X* of **9** at 293 K (8.8×10^{-4} M in PM).

The rise time of the photochromic colored species was measured with **9** in PM at 20 °C to be 56 ps (Fig. 5-A). In addition, the transient absorption with very short lifetime was observed with **9** in PM at 20 °C. Absorbance at 385 nm was plotted as a function of time in Fig. 5-B. There are two kinds of contributions to absorbance at 385 nm; the short-lived and the long-lived components. The decay time of the short-lived component was determined to be 53 ps[12] in agreement with the rise time of the long-lived component (the photochromic colored species). Therefore, the short-lived component is considered to be the precursor of the photochromic colored species. On the other hand, the decay time of the fluorescent state of the *cis*-keto amine was determined to be 0.7 ns. These observations clearly show that the molecular rearrangement of the *cis*-keto amine to the photochromic colored species does not occur from the fluorescent state, but originates from the precursor with the lifetime of 53 ps, which may be considered to be the higher vibrationally excited state of the *cis*-keto amine. Rosenfeld *et al.* derived a similar conclusion for *N*-salicylideneaniline from the exciting wavelength dependence of the quantum yields of the photochromic colored species and the fluorescence of the *cis*-keto amine.[5c] We have concluded directly and definitely the existence of the precursor.

A scheme for formation of the photochromic colored species by photoexcitation of the enol imine in the ground state, E, is represented in Fig. 6. The excited singlet state E* of the enol imine produced by photoexcitation of E results in formation of the photochromic colored species in the ground state, P, through the hydrogen transfer and the molecular rearrangement (cis-trans isomerization). The intermediate X* is an excited singlet state from which the photochromic colored species and the fluorescent state of the *cis*-keto amine, K_f*, originate.

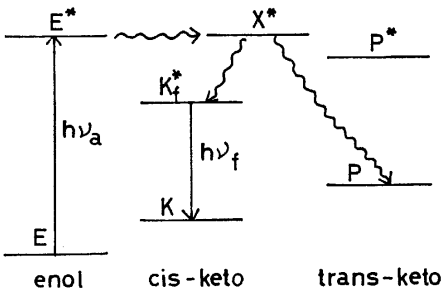

Fig. 6. Schematic explanation of the photochromic species formation.

The authors wish to thank Professor Kenji Tamaru and Professor Takaharu Onishi, The University of Tokyo, for their kind help in measuring the IR difference spectra, and Dr. Akira Kira, Institute of Physical and Chemical Research, for the kindness in putting the flash photolysis apparatus at their disposal and valuable discussion.

Reactivity of Excited Triplet Alkyl Ketones in Solution. I. Quenching and Hydrogen Abstraction of Triplet Acetone

Masakazu ANPO and Yutaka KUBOKAWA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Mozu-Umemachi, Sakai, Osaka 591

(Received January 18, 1977)

The photolysis of acetone in various solutions has been investigated by analysis of reaction products as well as absorption spectroscopy. The rate of photolysis of acetone in aqueous solution decreases on addition of methanol or with increasing concentration of acetone, being much higher than that in methanol and heptane solutions. The results suggest that intermolecular hydrogen abstraction plays a significant role in quenching of triplet acetone. This is supported by spectroscopic studies which reveal formation of the enol form of acetone as an intermediate in the decay process of triplet acetone.

The photolysis of acetone in the liquid as well as in the gas phase has been studied by many workers.[1] The quantum yields for the photolysis were found to be much lower in neat acetone than in aqueous solution, the nature of such a difference being discussed. Porter *et al.*[2] investigated the lifetime of the excited triplet state of acetone in various solutions, and suggested that intermolecular hydrogen abstraction plays a significant role in quenching of triplet acetone, *i.e.*, photolysis and triplet self-quenching by intermolecular hydrogen abstraction may be competitive processes.

Although information on the intermolecular hydrogen abstraction of the excited triplet state of alkyl ketones is important for understanding its reactivity in solution, there is relatively little work along this line. Intermolecular and intramolecular hydrogen abstraction of the excited carbonyl compounds appears to be of interest from a theoretical point of view.[3] We have investigated the photolysis of alkyl ketones in various solutions in order to obtain more detailed information on the relationship between the quenching and the intermolecular hydrogen abstraction in the photolysis of alkyl ketones.

Experimental

Materials. All the compounds (Tokyo Kasei Kogyo Co., Ltd., Grade SG) were purified by fractional distillation. Deionized double-distilled water was degassed by alternate freezing and thawing *in vacuo*. Acetone-d_6 of 99.5 mol% and deuterium oxide of 99.9 mol% isotopic purity (E. Merck, Darmstadt) were used without further purification. Particular care was taken to remove water and oxygen completely from the solvents and reactants.

Apparatus and Procedure. Details of the apparatus and procedure were described previously.[4] A conventional vacuum system was used in conjunction with a rectangular quartz cell (4.0×1.0 cm) of path length 0.5 cm, having two outlets. One was sealed off after admission and degassing of the sample solution. Another had a breakable seal which made it possible to attach the cell to a conventional analytical system after irradiation. Photolysis was carried out at 25±2 °C with light of 270±2.5 nm using a monochromator equipped with a 500 W xenon lamp. The intensity of incident light was determined by means of potassium ferrioxalate actinometry. Intensity in the range 6.4—6.7×10^{13} quanta/s was used. The analytical system consists of three traps and a modified Ward still. The gaseous products were separated by fractional distillation and analyzed by gas chromatography. The absorption spectra before and after irradiation were measured with a Hitachi EPS 3T spectrophotometer. Details of the isotopic analysis of the deuterated methane and acetone were described previously.[5] The CD_2HCOCD_3/CD_3COCD_3 ratio was determined by measurement of the parent peaks at $m/e=63$ [$CD_2HCOCD_3^+$] and $m/e=64$ [$CD_3COCD_3^+$].

Results and Discussion

Table 1 shows the effect of solvents upon the quantum yield of methane formation in the photolysis of acetone. The corresponding results with 2-butanone and 2-pentanone are also included. It should be noted that the quantum yield for the photolysis of acetone is much lower than that for other alkyl ketones, especially in heptane and methanol.

TABLE 1. QUANTUM YIELDS FOR DISAPPEARANCE OF ALKYL KETONES IN THE PHOTOLYSIS IN VARIOUS SOLVENTS AT 25 °C

	Heptane	Methanol	Water
Acetone[a]	0.003	0.004	0.061
Acetone-d_6[b]	—	0.004	0.064
2-Butanone[c]	0.217	0.297	0.306
2-Pentanone[d]	0.237	0.319	0.337

The concentration of alkyl ketones was a) 0.085—0.091 mol/l, b) 0.085 mol/l, c) 0.048 mol/l, and d) 0.051 mol/l. a, b) As seen in Table 3, in view of much lower yield of ethane (less than 2% of methane formation) the value can be regarded as the quantum yield for disappearance of acetone. c, d) The values are obtained from the quantum yields of major products (larger than 95% of total products) such as ethane for 2-butanone and propane (type I) as well as ethylene (type II) for 2-pentanone.

TABLE 2. CD_3H CONTENT OF THE METHANE FORMED FROM THE PHOTOLYSIS OF ACETONE-d_6 AT 25 °C

	Heptane	Methanol	Water
CD_3H content (%)[a]	97.9	97.5	8.80
$\frac{CD_2HCOCD_3}{CD_3COCD_3}$ (%)	—	—	7.01

The concentration of acetone-d_6, 0.090 mol/l. Irradiation time, 60 min. a) The methane consists of only CD_4 and CD_3H, other species being negligible.

The contents of CD_3H in methane formed from the photolysis of acetone-d_6 in various solvents are given in Table 2. Very large contents observed with heptane and methanol solutions show that methyl radicals formed from the primary processes abstract hydrogen atoms only from the solvent molecules. Table 2 also suggests that in aqueous solution most part of CD_3H in methane arises from the H-D exchange reaction between acetone-d_6 and water molecules. It is therefore concluded that methyl radicals scarcely abstract hydrogen atoms from water molecules. Although the conclusion has already been suggested by Pieck and Steacie,[6] the above results offer an unambiguous evidence for it.

Table 3. Effect of added methanol upon the photolysis of acetone in aqueous solution at 25 °C

Concentration of added methanol mol/l	Yield of methane 10^{-4} ml/h	Yield of ethane 10^{-6} ml/h
0	6.67	8.01
0.901	3.63	3.51
1.61	2.69	1.02
2.49	2.02	0.50
2.90	1.85	0
4.40	1.32	0

The concentration of acetone, 0.102 mol/l.
Irradiation time, 60 min.

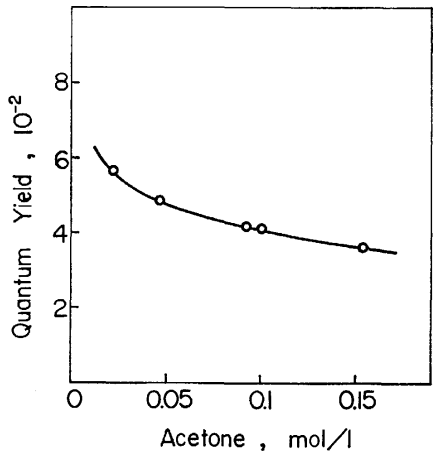

Fig. 1. The effect of the concentration of acetone upon the quantum yields for methane formation from the photolysis of acetone in aqueous solution at 25 °C. Irradiation time, 60 min.

Table 3 shows the effect of added methanol upon the photolysis of acetone in aqueous solution. The rates of methane and ethane formation decrease with increasing concentration of methanol. A similar decrease in the quantum yields for the photolysis of acetone in aqueous solution was obtained when the concentration of acetone increased (Fig. 1). Considering that acetone besides methanol is an efficient hydrogen donor, the results suggest that quenching of the excited acetone molecule is closely associated with hydrogen abstraction reactions. It is well-known that in the condensed phase efficiency of the intersystem crossing from the excited singlet state to the triplet state of acetone is unity.[7] In fact, it was found in the present work that the rate of photolysis is reduced to zero on addition of oxygen. Thus, there is no doubt that the photolysis of acetone in solution proceeds *via* the excited triplet state. Porter *et al.*[2] found that the lifetime of the triplet acetone molecule is much shorter in neat acetone than in aqueous solution and suggested that self-quenching of triplet acetone molecules occurs by intermolecular hydrogen abstraction and may compete its α-cleavage. Thus, the decrease in the rate of photolysis of acetone in aqueous solution caused by addition of methanol or with increasing concentration of acetone would be explicable on the basis of quenching of triplet acetone due to such intermolecular hydrogen abstraction. Furthermore, markedly higher quantum yields of the photolysis in aqueous solution as compared with those in heptane and methanol solutions could be attributed to an unefficient hydrogen abstraction in aqueous solution.

For quenching by methanol of radical products formation from acetone photolysis in aqueous solution, the following Stern-Volmer quenching equation holds:

$$Q_0/Q = 1 + \tau k_q[\text{Methanol}],$$

where Q_0 and Q are the rates of formation in the absence and presence of methanol, respectively; τ and k_q are the lifetime of excited triplet acetone and the quenching rate constant, respectively. The value of τ under our conditions (0.09 mol/l) can be determined to be 17.5×10^{-6} s by using the τ value at 0.05 mol/l, 20×10^{-6} s reported by Porter *et al.*,[8] together with its dependence upon the concentration of acetone (Fig. 2). The value of k_q thus determined is 0.54×10^5 l/mol s, being smaller than the corresponding value for acetonitrile solution, *i.e.*, 1×10^5 l/mol s reported by Porter *et al.*[2] Such a difference would be attributed to the fact that hydrogen bond strength is larger between acetone and water than between acetone and acetonitrile.

Information on the mechanism of quenching of excited

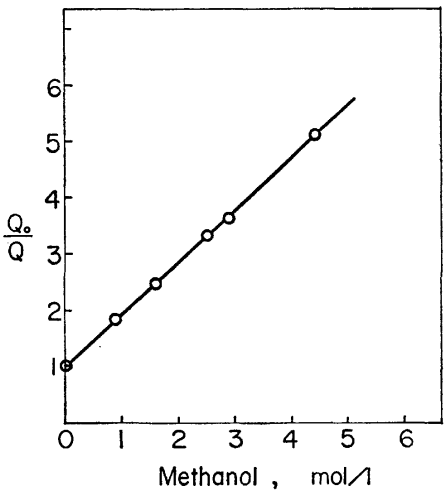

Fig. 2. Stern-Volmer quenching plots for the effect of added methanol upon the yields of methane formed from the photolysis of acetone in aqueous solution at 25 °C. The concentration of acetone, 0.120 mol/l. Irradiation time, 60 min.

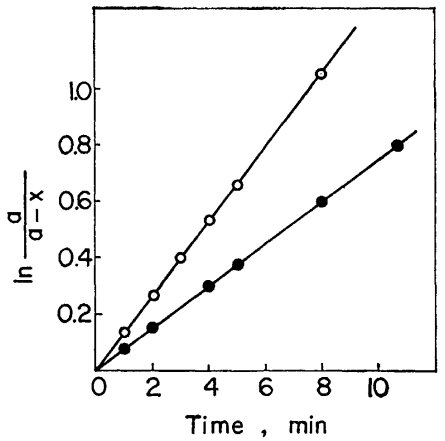

Fig. 3. The recovery of the (n, π^*) band of acetone as a function of time at 25 °C. x represents the recovery of the absorbance at λ_{max} (271 nm). The concentration of acetone, 0.120 mol/l. Irradiation time, 60 min. ○: Acetone, ●: acetone-d_6.

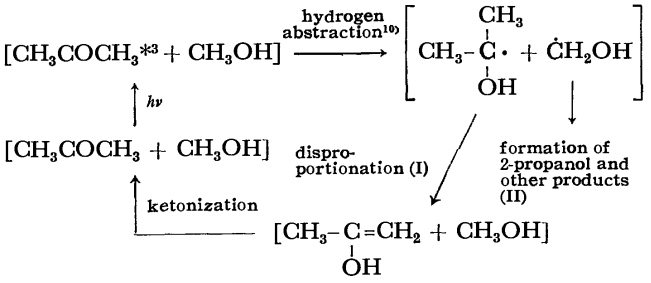
triplet acetone molecules by hydrogen abstraction was obtained from the following results. In methanol and heptane, except in aqueous solution, the UV irradiation led to a much larger decrease in the intensity of the (n, π^*) band of acetone than what would be expected from the extent of its photolysis. As soon as the irradiation ceased, the reduced intensity of the (n, π^*) band began to increase, an almost original intensity being recovered. Such a recovering process was found to obey the first order rate law as shown in Fig. 3. The half-lives obtained from the plots were 5.2 min for acetone and 8.9 min for acetone-d_6. Such a phenomenon was not observed with the photolysis of 2-pentanone or 2-butanone, where the rate of photolysis was unaffected by addition of methanol.

It has been found by ESR and UV studies that ketyl radicals are formed by hydrogen abstraction of excited triplet acetone from 2-propanol.[8,9] Henne and Fischer[9c] found by NMR studies that disproportionation of ketyl radical pairs leads to formation of the enol form of acetone and 2-propanol, and proposed that by ketonization of the former the ground state of acetone is reformed. A similar situation would be expected for the photolysis of acetone in methanol solution. The following mechanism is proposed:



According to the above mechanism, such a recovering process of the reduced intensity of the (n, π^*) band (Fig. 3) would be explicable by the occurrence of ketonization of the enol form of acetone formed by irradiation.

McMillan *et al.*[11] found that in the gas phase photolysis of 2-pentanone enol acetone formed by Norrish type II reaction rearranges to the keto form with a half-life of 4.7±0.3 min, in approximate agreement with that of ketonization determined from Fig. 3. The rate of reactions within the solvent cage such as the disproportionation reaction seems to be greater than that of reaction (II) such as formation of pinacol as well as 2-propanol as has been found by Singh.[12] As regards the disproportionation path, the reaction resulting in formation of enol acetone will be predominant by taking into consideration the fact that $\dot{C}H_2OH$ radicals are more reactive than ketyl radicals toward hydrogen abstraction. Thus, the rate of reaction (II) is expected to be negligibly small as compared with that of reaction (I). In fact, the products of reaction (II) such as 2-propanol and others were found to be negligible.[13]

The absence of such a recovery of the reduced intensity of the (n, π^*) band observed with 2-butanone as well as 2-pentanone would be attributable to a much lower efficiency of hydrogen abstraction of its excited triplet state than that of acetone triplet. In contrast with the case of acetone, a small difference between the rate of photolysis in water and that in heptane or methanol solution was observed for the cases of 2-butanone as well as 2-pentanone. Such behavior would be explained on a similar basis.

We would like to express our thanks to Messrs. K. Yamamoto and T. Shimatani for carrying out some parts of the experiments.

Electronic Structures of Meso-ionic Azapentalenes Studied by X-Ray Photoelectron Spectroscopy

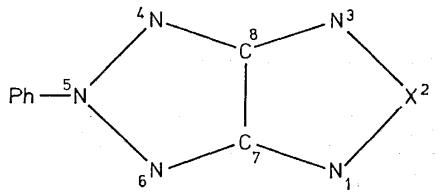
Toshiaki OHTA, Masayuki YOSHIDA, and Haruo KURODA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received January 28, 1977)

X-Ray photoelectron spectra of meso-ionic azapentalenes were observed in the solid phase. The charge distributions in these molecules were investigated by using the observed chemical shifts of core-electron levels, employing Siegbahn's electrostatic potential model and the results of CNDO/2 calculations.

Pentalene is very unstable because of 8π electron system, and pentalene itself has not yet been synthesized.[1] If a carbon atom in the five-membered ring is replaced by a hetero atom with 2π electrons, the resulted molecule has aromaticity and would be stabilized. As shown in Fig. 1, a series of hetero aza-pentalenes, namely, 2,5-diphenyl[1,2,3]triazolo[4,5-*d*][1,2,3]triazole (I), and 5-phenyl-5*H*-[1,2,3]triazolo[4,5-*c*][1,2,5]-oxadiazole (II), -thiadiazole (III), and -selenadiazole (IV) are expected to be stable compounds since the introduction of a hetero atom at position 2 and a nitrogen atom at position 5, provides 2π electrons to the pentalene skeleton so as to form 10π electron system. In effect, they have recently been synthesized by one of the authors (M.Y.) and his coworkers, and turned to be very stable solid. Syntheses and some properties of these compounds were published elsewhere.[2,3] As readily guessed from Fig. 1, these compounds have meso-ionicity and are expected to have large electronic polarization. It is therefore of great interest to investigate to what extent electronic charges are polarized in these molecules.



(I) X=N–Ph, (II) X=O, (III) X=S, (IV) X=Se

Fig. 1. Molecular structure of azapentalenes.

Recently, X-ray photoelectron spectroscopy (XPS) has proved to be a powerful means for the study of charge distribution in a molecule, having been successfully applied to a number of organic molecules.[4,5] The purpose of this paper is to elucidate charge distributions in the above-described compounds by the measurement and analyses of the chemical shifts of core electron levels with the aid of Siegbahn's electrostatic potential model and CNDO/2 calculation. In addition, a geometry optimization technique in the framework of the CNDO/2 method was used to predict the molecular geometries of these compounds, since they have not yet been determined experimentally.

X-Ray photoelectron spectra of the compounds studied were measured with a McPherson ESCA 36 electron spectrometer, by employing Al $K\alpha$ radiation. Each sample, purified by recrystallization in advance, was coated on an aluminium plate. Core electron binding energies were calibrated by using the Au $4f_{7/2}$ (84.0 eV) peak of a thin gold film deposited onto the sample surface.

TABLE 1. CORE ELECTRON BINDING ENERGIES OF HETEROAZAPENTALENES (eV)

	C 1s	N 1s	$\Delta E_{splitting}$ (N 1s)	O 1s	S $2p_{3/2}$	Se $3p_{3/2}$
I	(287.1) 284.2	(402.0) 399.3	2.7			
II	(286.1) 284.2	(402.0) 399.2	2.8	532.2		
III	(286.1) 284.2	(401.8) 398.9	2.9		164.0	
IV	(287.1) 284.2	(401.9) 398.7	3.2			160.5

A shoulder and/or a weaker peak is listed in the parenthesis.

Determined core electron binding energies are listed in Table 1. All of C 1s spectra have a small shoulder in the higher binding energy side of the main peak. The C 1s binding energy of the main peak is consistently the same for all compounds, so that it can be assigned to the phenyl carbons. The small shoulder is possibly associated with carbons in the pentalene ring. Figure 2 shows N 1s spectra of these compounds. We can see well-resolved two peaks except for compound (II), in which case the main peak is a little broader than the others. The intensity ratio of the two peaks in compound (I) is 1 : 1.9, so that the stronger peak at the lower binding energy side is easily assigned to the nitrogen atoms at the positions 1, 3, 4, 6 and the weaker peak is to the nitrogen atoms at positions 2 and 5. On the other hand, in compounds (II), (III), and (IV), intensity ratios of two peaks are nearly 1 : 4, so that the stronger peak has the same origin as compound (I), and the weaker peak is due to the nitrogen atom at position 5. These spectra show clearly that the nitrogen atom at position 5 has a less negative charge than the nitrogen atoms at positions 1, 3, 4, and 6. It is to be noted that the splitting of N 1s peaks is larger as the atomic number of the substituent atom is higher, as listed in the fourth column of Table 1.

XPS chemical shift is influenced not only by the charge density of the ionizing atom, but also by those of atoms surrounding it. Siegbahn and his coworkers have proposed the following equation for interpreting chemical shifts:[6]

$$\Delta E_A = kq_A + \sum_{B \neq A}^{\text{molecule}} \frac{e^2 q_B}{R_{AB}}, \quad (1)$$

where k is a constant characteristic of atom, q_A and q_B

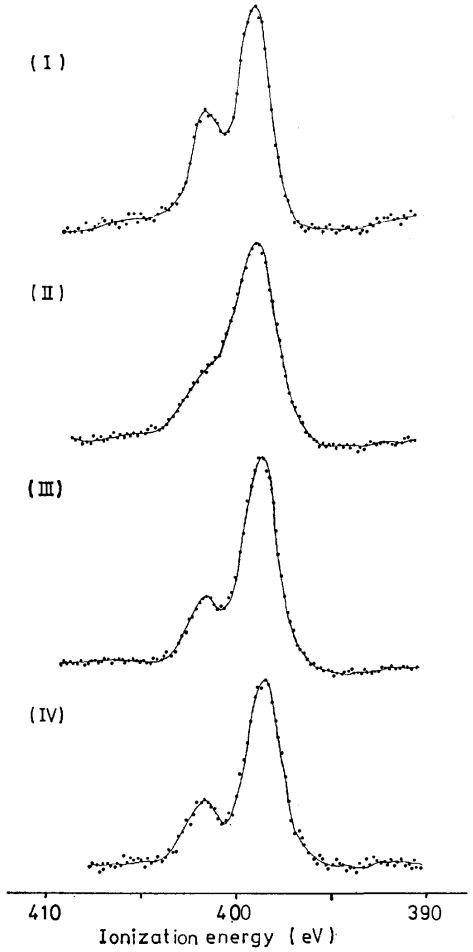


Fig. 2. N 1s spectra of azapentalenes.

are charge densities of atom A and B, respectively, and R_{AB} is the distance between them. For a variety of molecules containing carbon, nitrogen, and oxygen, the chemical shifts of core-electron levels have been successfully interpreted with Eq. 1, by use of CNDO/2 charge densities.

In the present compounds, molecular geometries have not yet been determined experimentally, so that it is difficult to obtain reliable charge densities by MO calculation since they would be influenced more or less by the molecular geometry. Accordingly, geometry optimization has been carried out for these molecules within the scheme of CNDO/2 formulation. The geometry for the CNDO/2 total-energy minimum was searched by using the differentiation of two-center integral terms. Since molecule (I) or (II) is too complex to be calculated with CNDO/2, the simplified model, in which the phenyl group is replaced by a hydrogen atom, was used for the geometry optimization. Such simplification would not affect the interpretation of N 1s chemical shifts. The model compounds are denoted as (I') and (II'), and so on. A regular pentagon structure with a bond length of 1.35 Å was used as the initial geometry for each molecule. Furthermore, the molecular symmetry, D_{2h} for (I') and C_{2v} for (II') and (III'), was retained throughout the geometry optimization. Determined geometries of (I') and (II') are shown in Fig. 3. The N–N or N–O bond length is smaller than the C–N

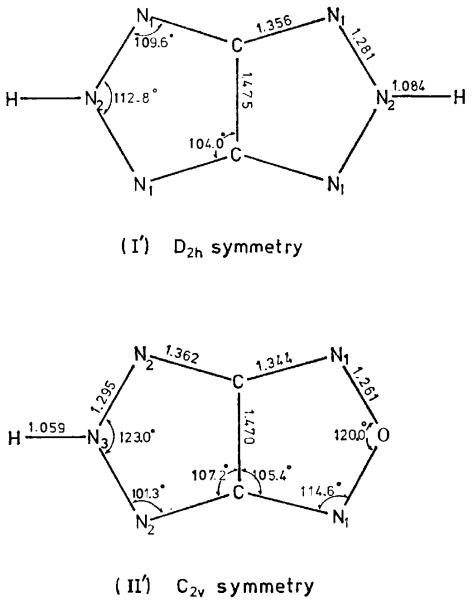

Fig. 3. Optimized geometries of molecules (I') and (II').

TABLE 2. TOTAL CHARGE AND π ELECTRON DENSITIES OF MOLECULES (I') AND (II')

	(I') D_{2h} symmetry			(II') C_{2v} symmetry	
Atom[a]	Total charge density	π electron density	Atom[a]	Total charge density	π electron density
C	0.086	−0.043	C	0.090	−0.016
N_1	−0.161	−0.275	N_1	−0.085	−0.233
N_2	0.149	0.592	N_2	−0.163	−0.295
H	0.088		N_3	0.190	0.677
			O	0.032	0.409
			H	0.095	

a) Refer to Fig. 3 about atomic species.

bond length. The C–C bond is much longer than that in benzene and has a character of single bond to large extent. These results seem to be plausible from the comparison with geometries of the related compounds whose structures have already been determined.[7] CNDO/2 charge densities in molecules (I') and (II') are listed in Table 2. In molecule (I'), the total charge density of N_1 atom is negative and that of N_2 is positive. This is in accord with the conclusion derived from the N 1s chemical shift. This tendency is much stronger in the π electron charge distribution as indicated in Table 2. By using calculated charge densities and a k value of 21.5 eV/unit charge as proposed by Siegbahn *et al.*,[6] we obtained 2.9 eV for the N 1s splitting in molecule (I'), which is very close to the observed spliting, 2.7 eV. This would mean that the calculated charge distribution in this molecule is reliable. Similar results are obtained for molecule (II'), in which there are three kinds of nitrogen atom. Calculated shifts are −0.96 eV, −0.92 eV, and 2.41 eV for N_1, N_2, and N_3, respectively. ΔE *fwhm* of the N 1s main peak of compound (II) is 2.5 eV, which is broader than the N 1s peaks of other compounds by about 0.5 eV. The main N 1s peak of compound (II) is composed of the two components,

which are due to N_1 and N_2, respectively. Consequently, its broadening can be understood as that arising from the splitting of the two components by chemical shift. The chemical shift of the N 1s level of N_3 is a little overestimated by MO calculations as compared with the observed result. We tried to carry out the geometry optimization also for molecule (III'), which contains a sulfur atom. In general, CNDO/2 method gives less reliable results for molecules containing second row atoms. In fact, the optimized geometry of molecule (III') shows an unusually long N–S bondlength, 1.8 Å. The charge densities calculated for this geometry could not explain the observed N 1s chemical shifts of compound (III).

We tried to estimate the charge distribution in molecule (III') from the observed N 1s binding energies for compound (III), using the procedure called "ACHARGE" analysis.[5,8] Since the number of obtained experimental values is too limited to give the whole charge distribution, the following assumptions were adopted to carry out the ACHARGE analysis; first, the geometry of molecule (III') was assumed to be the same as molecules (II'), and, second, the charge densities on C and H atoms were assumed to be the same as those in (II'), since they are likely to be small and relatively independent of the substitution of a hetero atom. Resulted charge densities are $-0.17e(N_1)$, $-0.16e(N_2)$, $0.15e(N_3)$, and 0.23e(S). They are almost the same as those in molecules (I') and (II'). From the above-described analyses of XPS chemical shifts, it can be concluded that in these molecules the nitrogen at position 5 and the hetero atom at position 2 have positive charges, while the nitrogen atoms at positions 1, 3, 4, and 6 have negative charges, and that the degree of charge polarization in these molecules is not so large, although they have been regarded as meso-ionic compounds.

On the Phase Transition of Ammonium Hexafluoroferrate(III)

Keiichi MORIYA, Takasuke MATSUO, Hiroshi SUGA, and Syûzô SEKI
Department of Chemistry, Faculty of Science, Osaka University, Osaka 560
(Received January 31, 1977)

The heat capacities of $(NH_4)_3[FeF_6]$ crystal have been measured from 15 to 350 K with an adiabatic calorimeter. A heat capacity anomaly was observed at 267.02 ± 0.05 K. The enthalpy and entropy changes of the transition are 6490 ± 500 J mol^{-1} and 24.8 ± 1.9 J K^{-1} mol^{-1}, respectively. This value of entropy was discussed in terms of a model involving orientational disorder of the ammonium as well as hexafluoroferrate(III) ions. Based on the assumption of the average fcc symmetry of the crystal and internal rigidity of the ions, the proposed model predicts the transition entropy equal to R ln $16=23.05$ J K^{-1} mol^{-1} which is in close agreement with the experimental value. Temperature dependent splitting of the Raman band due to the internal vibration of the anion was found to be consistent with the model. The excess heat capacity follows the prediction of the Landau theory of phase transitions of the second kind. Properties of the present and the similar crystals including ammonium and alkali salts of hexafluoro-complex ions were discussed in terms of the ionic orientational disorder.

An early X-ray diffraction work by Pauling[1] showed that ammonium hexafluoroferrate(III) has a face-centered cubic lattice at room temperature. This was confirmed later by Steward and Rooksby[2] who studied the crystal by X-ray powder method at room temperature and at 93 K. They found a tetragonal lattice at the lower temperature, a phase transition being suspected at some intermediate temperature. The phase transition was found at 263 K by Mørup and Thrane[3] in a Mössbauer line-width study of the compound. The mechanism of the phase transition has not been understood well, since the only available data are those concerned with the Bravais lattice change and Mössbauer spectrum narrowing. The latter was interpreted as indicating that the symmetry of the iron site becomes lower in the low temperature phase.[4]

There are a number of factors in the $(NH_4)_3[FeF_6]$ crystal that can lead to the phase transition. The ammonium ion is, of course, well-known for its tendency toward disordering in a number of crystals, the most notable example being ammonium chloride in which the ammonium ion takes at random one of the two allowed orientations. The ammonium ions in the present crystal are not all equivalent, but are grouped into two sets.[5] Those which belong to one set occupy the octahedral sites (the 4b positions)[6] in the fcc lattice, while those belonging to the other set are in the tetrahedral sites (the 8c positions). Consequently, the role played by the ammonium ions in this phase transition may be more complicated than in the ammonium halides. The hexafluoroferrate(III) ion, $[FeF_6]^{3-}$, has the octahedral ionic symmetry and occupies the octahedral 4a position. One might hence expect that the hexafluoroferrate(III) ions are in a uniquely determined orientation in the crystal and, as such, would play a rather passive role in the phase transition. However, consideration based on the lattice dimension and empirical radii of Fe^{3+}, F^- and NH_4^+ ions[7] shows that coincidence of the ionic and crystalline tetrad axes might not be taken for granted: the ions are too bulky to lie simultaneously on the tetrad axis. Instead, the high crystal symmetry might be a result of the orientational disorder of the $[FeF_6]^{3-}$ ions. Therefore, the orientational degree of freedom of the anion has also to be taken into account in a satisfactory description of the mechanism of the phase transition. This type of ionic disorder is an interesting possibility which the heat capacity measurement can prove or refute.

Another motivation for studying the present substance is that it belongs to a large family of crystals which contain fluorine octahedra as their major constituent and for which a vast amount of structural information has been accumulated.[5] Specifically, three closely related ammonium salts are of particular interest: $NH_4[PF_6]$,[8] $(NH_4)_2[SiF_6]$,[9] and $(NH_4)_3[AlF_6]$.[2] The structural relation among these fcc crystals are briefly as follows. The NH_4^+ ion in $NH_4[PF_6]$ crystal occupies the site corresponding to the octahedral position (4b) of the $(NH_4)_3[FeF_6]$ structure, with the 8c tetrahedral positions unoccupied. This is the rock-salt structure with the sodium and chloride ions replaced by the ammonium and the hexafluorophosphate(V) ions, respectively. In the cubic $(NH_4)_2[SiF_6]$ crystal, the occupations is just reversed, *i.e.*, the tetrahedral 8c sites are occupied by the ammonium ions while the octahedral 4b sites are vacant. In $(NH_4)_3[AlF_6]$ both the 4b and 8c positions are occupied. This last crystal is isomorphous with ammonium hexafluoroferrate(III) crystal. The heat capacities of the fluorophosphate,[10] fluorosilicate,[11] and fluoroaluminate[12] have been measured. It will be shown below that comparison of the properties of these compounds leads to an insight into the molecular mechanism of the phase transitions in these ammonium salts.

Finally a peculiar property of the present crystal is noticed in Table 1 which summarizes the room temperature crystal systems and the molar volumes of $A_3[FeF_6]$ type crystals (A; alkali or ammonium ions). The

TABLE 1. ROOM-TEMPERATURE CRYSTAL PROPERTIES OF SOME CRYOLITE-TYPE COMPOUNDS $A(I)_3[FeF_6]$

A(I)	Crystal system	Molar volume/cm^3 mol^{-1}
Li	(complex)	—
Na	monoclinic	76.0
K	tetragonal	96.2
Rb	tetragonal	106.6
Cs	tetragonal	122.3
NH_4	cubic	111.3

structure of the lithium compound is complicated and is not successfully analysed, but the symmetry of the crystal is certainly the lowest.[13] The sodium compound is monoclinic, while the potassium, rubidium and cesium compounds are tetragonal. A gradual trend toward the higher symmetry with increasing cationic size is evident. The ammonium compound, whose molar volume lies between those of the rubidium and cesium compounds (this fact is itself somewhat anomalous because the apparent ionic volume of the ammonium ion is usually between those of potassium and rubidium) has the highest cubic symmetry in the series of the crystals. It should be noted that the enhancement of the crystal symmetry is caused by substitution of the less symmetric ammonium ion for spherical alkali ions. This unusual property of the ammonium salt will be explained below as an entropy effect. This paper reports on the heat capacity measurement of $(NH_4)_3[FeF_6]$ crystal and the interpretation of the experimental results in terms of the above general consideration.

Experimental

Sample Preparation. Extra-pure grade reagent of $Fe(NO_3)_3 \cdot 9H_2O$ crystal (Wako Pure Chemical Industries, Ltd.) was dissolved in distilled water. This solution was added dropwise to a concentrated aqueous solution of extra-pure grade reagent of NH_4F (Wako Pure Chemical Industries, Ltd.). $(NH_4)_3[FeF_6]$ crystal precipitated rapidly as finely divided powder. The crystal was separated from the mother liquor and dried at 70 °C. Contamination of the sample with the fluorosilicate was avoided by using polyethylene ware throughout the sample preparation. Elemental analysis gave F, 50.9±0.4%; Fe, 24.94±0.04%; H, 5.39±0.2% (Fe by EDTA gravimetric method, F by thorium nitrate titration, and H by gravimetric method). The calculated values for $(NH_4)_3[FeF_6]$ are F, 50.90%; Fe, 24.94%; H, 5.40%. It was important to use an excess amount of ammonium fluoride solution slightly acidified with hydrofluoric acid. Otherwise, the hydrated crystal appeared to precipitate as noted by Cox and Sharpe.[14] Several other attempts were made until the above preparation was found to be successful. These other attempts gave less than ideal elemental analysis. As an additional guide for the preparation, the differetial thermal analysis (DTA) was employed. The crystal used for the heat capacity measurement gave a sharp endothermic peak on heating through 266±1K. Table 2 summarized the chemical analyses and the DTA results for five different preparations. It should be emphasized that, contrary to Cox and Sharpe's statement,[14] the stoichiometric $(NH_4)_3[FeF_6]$ crystal was prepared by the wet method.

Calorimetry. The heat capacities of $(NH_4)_3[FeF_6]$ crystal were measured from 15 to 350 K with an adiabatic calorimeter. The apparatus is described elsewhere.[15-18] The calorimetric sample crystal, 32.4949 g (0.14510 mol) in weight, was put in the calorimeter cell together with helium heat-exchange gas. The procedure of the measurement was standard one, *i.e.*, intermittent heating method with the temperature increment of 1 K at 20 K and 2 K above 80 K. Smaller steps were employed near the phase transition. The total enthalpy change of the transition was determined by introducing electric energy to the specimen from approximately 4 K below the transition temperature to 4 K above under the adiabatic condition.

Raman Spectrum. Temperature dependence of Raman spectra were recorded with a laser-excited Raman apparatus. The high symmetry of $[FeF_6]^{3-}$ ion is particularly suitable for the vibrational-spectroscopic study because changes in its ionic environment affect the degenerate internal vibration, causing well-resolved splitting of the spectral band. The same situation was exploited in a study of the phase transition in $[Co(NH_3)_6]Cl_2$,[19] in which the hexaamminecobalt(II) ion has a similar high ionic symmetry. The sample crystal was sealed in a thin wall glass ampule and attached to the cold finger in a cryostat. The sample temperature was controlled by adjusting the amount of liquid nitrogen introduced into the coolant chamber and monitored with a copper-constantan thermocouple fixed to the glass ampule.

Table 2. Elemental analysis and DTA of $(NH_4)_3[FeF_6]$ crystals prepared by different methods

	Chemical composition		DTA peak
	Fe	F	
(1)	24.87%	50.0%	sharp[a]
(2)	24.95	50.2	sharp
(3)	24.61	50.5	broad
(4)	25.06	50.7	broad
(5)	24.94	50.9	sharp
Calcd	24.94	50.9	

a) A small peak was found at 257 K besides the main peak at 267 K. The crystals were prepared as follows. (1) From aqueous solutions of $Fe(NO_3)_3 \cdot 9H_2O$ and $NH_4F \cdot HF$. (2) From aqueous solutions of $FeCl_3 \cdot 6H_2O$ and NH_4F. (3) Direct reaction of $Fe(NO_3)_3 \cdot 9H_2O$ crystal with NH_4F solution. (4) The same as described in the text but without addition of hydrofluoric acid. (5) As described in the text.

Results

The experimental values of the molar heat capacity of $(NH_4)_3[FeF_6]$ crystal are given in Table 3 and also shown in Fig. 1. Graphically smoothed heat capacities and derived thermodynamic functions are given in Table 4. The heat capacity changes smoothly with temperature except in the transition region which spans approximately from 180 to 270 K. The highest value of the heat capacity reaching 20000 J K^{-1} mol^{-1} was observed at 267.02±0.05 K. This temperature is 4 K higher than the line width transition temperature 263 K reported by

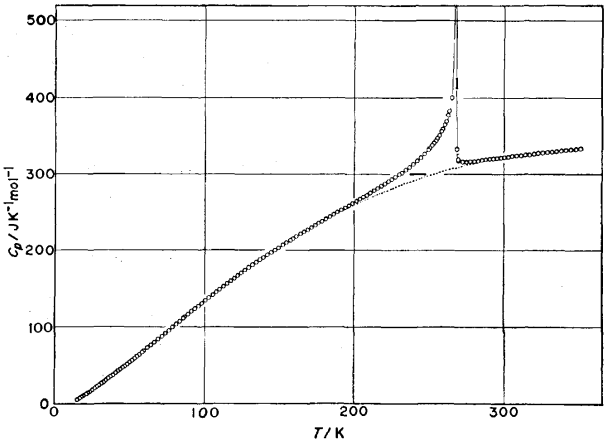

Fig. 1. Molar heat capacity of $(NH_4)_3[FeF_6]$.

Mørup and Thrane in the Mössbauer study. The difference between these two temperatures is well beyond the claimed accuracies of the temperature measurements. The origin of the discrepancy is not clear at present. The time required for thermal equilibration in the calorimeter increased near the phase transition to about an hour compared with ten minutes normally required. Such a behavior is often observed in first order transitions.

In order to evaluate the enthalpy and the entropy of transition, the "normal" heat capacity has to be estimated. However, the spectroscopic data on which the estimation of the vibrational heat capacity should be based are insufficient at present, because not only the long wavelength optical vibrations but also the normal modes of the every branch from the entire Brillouin zone contribute to the heat capacity. Thermal motion of the ammonium ions adds further difficulty since their torsional lattice vibration is certainly highly anharmonic. One of the practicable resorts is to interpolate the low and high temperature heat capacities smoothly into the transition region and to make the

"normal" heat capacity thus estimated available to the reader, as is done here (Table 5). The dotted curve in Fig. 1 represents the assumed normal heat capacity. The enthalpy and entropy of the phase transition based on this normal heat capacity are 6490 ± 500 J mol^{-1} and 24.8 ± 1.9 J K^{-1} mol^{-1}, respectively.

The Raman spectra are shown in Fig. 2. The

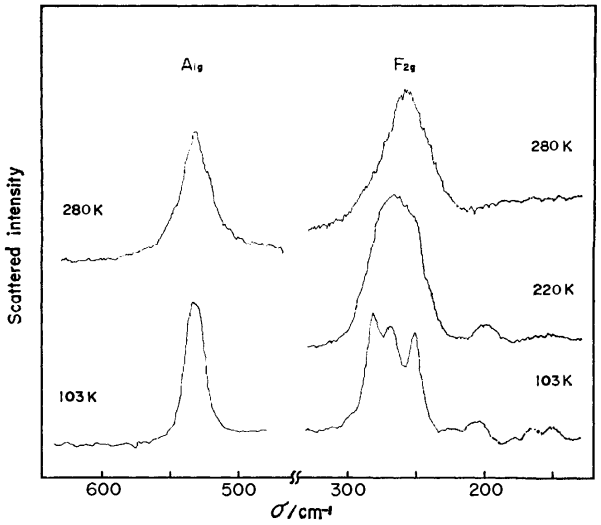

Fig. 2. Temperature dependence of the Raman scattering from the $\nu_1(A_{1g})$ and $\nu_5(F_{2g})$ modes of $[FeF_6]^{3-}$ ion.

frequency of the $\nu_1(A_{1g})$ mode of the $[FeF_6]^{3-}$ ion is 535 cm^{-1} at 280 K, which is compared favorably with 538 cm^{-1} reported by Wieghardt and Eysel.[20] The $\nu_5(F_{2g})$ vibration was observed at 256 cm^{-1} compared with Wieghardt and Eysel's value at 253 cm^{-1}.[20] The weak band at 374 cm^{-1} was assigned to the $\nu_2(E_g)$ mode. Raman bands of the ammonium ion were not informative because of their low intensity. They are not discussed in the following. Effect of the phase transition on the Raman spectra is most explicitly shown in the temperature dependence of the A_{1g} and F_{2g} modes. On cooling to 103 K, the A_{1g} band narrows appreciably but does not show any splitting. On the other hand, the triply degenerate F_{2g} mode, which is relatively broad at 280 K, broadens further on cooling through the transition temperature with a gradually emerging structure resulting in a well-resolved triplet at 103 K. In view of the relatively large separation between the component frequencies, this splitting is a site group splitting of the threefold degenerate vibration rather than a Davydov splitting. Another explanation that assumes presence of three distinct sets of octahedral sites for the $[FeF_6]^{3-}$ ions may be a least probable possibility and will not be considered further. We conclude, therefore, that the site symmetry of $[FeF_6]^{3-}$ ion is lower than axial. This low site symmetry is rather surprising, because structural and spectroscopic investigations of the related compounds containing octahedral hexafluoride complex have shown that the site symmetry is trigonal or higher if the counter-cation is potassium or a larger ion.[5,21]

The Mössbauer spectra of the present compound have also been interpreted on the assumption of the tetragonal axial symmetry.[3,4] The present Raman data seem to require revision of the interpretation of the Mössbauer results.

Discussion

In the present section we will be concerned with interpretation of the experimental transition entropy, $\Delta S_{tr}=24.8\pm1.9$ J K^{-1} mol^{-1}, by assuming that it is

related to the ionic configurations by the expression

$$\Delta S_{tr} = R \ln (W_h/W_l).$$

Here, R is the gas constant, W_h and W_l the numbers of accessible ionic configurations in the high and low temperature phases, respectively. We assume that W_l is equal to unity, *i.e.*, the ionic configuration is uniquely determined in the low temperature phase. The ionic disorder in the high temperature phase is assumed to be orientational rather than positional in the sense that the dositions of the nitrogen and iron atoms are fixed. We assume further that the $[FeF_6]^{3-}$ and NH_4^+ ions themselves are rigid so that they retain the O_h and T_d symmetries, respectively, in the crystal. Our problem is then to enumerate the allowed ionic orientations compatible with the average face-centered cubic symmetry. The ammonium ion in the 8c position is surrounded by twelve fluorine atoms. At first sight, this seems to offer large number of orientations to the ammonium ion. However, a closer examination of the ionic environment shows that this is not the case. The twelve fluorine atoms are grouped into four sets, each belonging to one of the four iron atoms that form a tetrahedron around the ammonium ion. The other four corners, which, together with the four iron atoms, form the cube around the ammonium ion, are occupied by the other set (4b) of the ammonium ions. Therefore, the environment of the 8c ammonium ion is predominantly tetrahedral. The ammonium ion will settle snugly into this tetrahedral environment without disorder. We assign zero configurational entropy to the 8c ammonium ions.

The ammonium ion in the 4b position is surrounded octahedrally by six fluorine atoms. We associate two distinct orientations with this ammonium ion, assuming that the stable orientation of the ion is such that each of the N–H bonds is directed to the unoccupied corner of the cube surrounding the ammonium ion. Evidently, there are two equivalent orientations of this type for each of the 4b ammonium ions. These orientations would be the most favorable, because it avoids too close a contact between the hydrogen and fluorine atoms. Thus far, we have treated the fluorine atoms as situated on the 24e position on the tetrad axis of the crystal. We consider next the possibility of the orientational disorder of the $[FeF_6]^{3-}$ ion. There are in general twelve types of positions (one general and eleven special) in the fcc lattice. Of these positions, only 192a and 24e are acceptable as the fluorine site. The other special positions are incompatible with the rigid $[FeF_6]^{3-}$ ion. These statements are derived algebraically as follows. We express the position of the fluorine atom by $(u\ v\ w)$, where the first, second and third positions in the parentheses designate, respectively, the x, y, and z coordinates of the atom. The coordinate axes are so chosen as to coincide with the cubic axes, the Fe atom being on the origin. Without loss of generality we may put

$$u \geqq v \geqq |w|.$$

Here, u, v, and w are related to the Fe–F bond length r by the following expression:

$$u^2 + v^2 + w^2 = r^2.$$

The rigidity assumption requires that the coordinates of the six fluorine atoms belonging to the iron atom should be

$$\begin{array}{llll} (u & v & w), & (\bar{u} \ \bar{v} \ \bar{w}), \\ (w & u & v), & (\bar{w} \ \bar{u} \ \bar{v}), \\ (v & w & u), & (\bar{v} \ \bar{w} \ \bar{u}). \end{array} \quad (1)$$

The three fluorine atoms on the left column in (1) are related to the three on the right through the inversion about the origin. The orthogonality condition of the first three Fe–F bonds are expressed by

$$vw + wu + uv = 0. \quad (2)$$

One solution of this equation is

$$\begin{aligned} u &= r \\ v &= 0 \\ w &= 0. \end{aligned} \quad (3)$$

The six fluorine coordinates corresponding to this solution are

$$\begin{array}{llll} (r & 0 & 0), & (\bar{r} \ 0 \ 0), \\ (0 & r & 0), & (0 \ \bar{r} \ 0), \\ (0 & 0 & r), & (0 \ 0 \ \bar{r}). \end{array}$$

These are the 24e positions mentioned above and corresponds to the ordered orientation of the fluorine octahedron. It should be noted that application of the O_h site symmetry operations to this arrangement does not produce any different orientations. Another solution, which is of more interest, is given by

$$u > v > 0, \quad w < 0.$$

This solution corresponds to the disordered orientation of the $[FeF_6]^{3-}$ ion. There are eight distinct orientations of this type. The other seven are derived from the general expression (1) by successive application of the operations of the site symmetry O_h as follows:

$$(u\ v\ \bar{w})\ (w\ u\ \bar{v})\ (\bar{v}\ \bar{w}\ u), \quad (4)$$
$$(u\ \bar{w}\ v)\ (\bar{v}\ u\ \bar{w})\ (w\ \bar{v}\ u), \quad (5)$$
$$(u\ w\ v)\ (v\ u\ w)\ (w\ v\ u), \quad (6)$$
$$(u\ \bar{v}\ \bar{w})\ (\bar{w}\ u\ v)\ (\bar{v}\ w\ u), \quad (7)$$
$$(u\ \bar{v}\ w)\ (\bar{w}\ u\ \bar{v})\ (v\ \bar{w}\ u), \quad (8)$$
$$(u\ w\ \bar{v})\ (v\ u\ \bar{w})\ (\bar{w}\ \bar{v}\ u), \quad (9)$$
$$(u\ \bar{w}\ \bar{v})\ (\bar{v}\ u\ w)\ (\bar{w}\ v\ u). \quad (10)$$

Here, we have given only the coordinates of three fluorine atoms corresponding to the three on the left column of the expression (1). Other three are easily derived from them by the inversion operation. Figure 3 illustrates the above argument. The eight orientations given by the expressions (1), (4), (5), ···, (10) correspond to the fluorine positions numbered as 1, 2, 3, ···, 8 in the Fig. 3. We conclude that the orientational entropy of the fluorine octahedra is either zero or R ln 8. Intermediate values of R ln N (N=2, 3, 4, or 6) often encountered in various models or orientational disorder are incompatible with the rigidity of the ion or the equivalence of the fluorine atoms in the ion in the present crystal.

Morfee *et al.*[22] considered a similar situation in connection with a phase transition in $K_2[SnCl_6]$, but seem to have failed to take into account the restrictive nature of the fcc symmetry. The transition entropy ($\simeq R$ ln 2) of $K_2[SnCl_6]$ is too small to support this

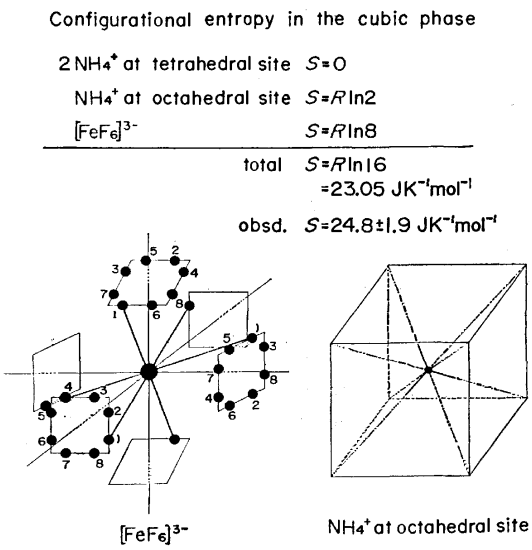

Fig. 3. Orientational disorder of $[FeF_6]^{3-}$ and NH_4^+ ions in the cubic phase of $(NH_4)_3[FeF_6]$.

mechanism in this crystal. The total entropy ΔS of the ionic orientation is given by the sum of the contributions from the ammonium and hexafluoroferrate(III) ions:

$$\Delta S = R \ln 2 + R \ln 8$$
$$= 23.05 \text{ J K}^{-1} \text{ mol}^{-1}$$

The experimental value of the transition entropy 24.8 ± 1.9 J K^{-1} mol^{-1} is in close agreement with this value, giving a support to the disorder mechanism considered above. In recent papers Heyns and Pistorius[23,24] considered a closely related structural disorders in $K[PF_6]$ and $K[AsF_6]$. From an entropy argument they concluded that the location of the fluorine atom may be smeared into a torus-like distribution instead of the eight distinct positions considered here. Precise determination of the electron distribution in these disordered crystals will be rewarding in this respect.

Next we compare the behavior of the present crystal with those of $NH_4[PF_6]$ and $(NH_4)_2[SiF_6]$ crystals. $NH_4[PF_6]$ has the NaCl structure at room temperature and undergoes phase transitions at 131.3 and 191.8 K. The total entropy change of the transitions is 19.7 J K^{-1} mol^{-1}.[10] The cubic modification of $(NH_4)_2[SiF_6]$, on the other hand, has no phase transitions down to 25 K,[11] although a disordering of ammonium ion with quite different nature has been suspected.[9] These observations, in conjunction with the structural information outlined in the introduction, lead to a conjecture that presence of ammonium ion at the 4b site causes lattice instability which is restored at the higher temperatures by increased orientational entropy pertaining both to the ammonium and hexafluoro-complex ions. If the ammonium ions are absent from the 4b positions, the cubic symmetry is maintained without invoking the ionic disorder. Consequently the crystal is expected to remain cubic down to the lowest temperature as does ammonium hexafluorosilicate.

The concept of the ionic disorder is useful also for rationalizing the structural relation of $(NH_4)_3[FeF_6]$ with other alkali hexafluoroferrates(III). As pointed out earlier, replacement of the spherical ion by the tetrahedral ammonium ion enhances the symmetry of the crystal (Table 1). This observation is understood if the orientational disorder is taken into account as follows. As is well known, the relative stability of phases of a substance is determined by the enthalpy and entropy of the phases involved. In the ammonium salt, the highly symmetric environment of the ammonium ion is stabilized relative to the less symmetric ordered arrangement by the increased entropy due to the increased ionic disorder at the higher temperatures even if the disordered arrangement may be enthalpically less favorable. In contrast, such a stabilization due to the entropy effect is not available for the alkali salts because the alkali ions do not possess orientational degree of freedom. This explains the apparent paradox that less symmetric ammonium ion enhances the crystal symmetry in the $A_3[FeF_6]$ type crystals. Other effects may also be responsible for the stabilization of the cubic phase of the ammonium salts. For instance, change in the ionic radius of the alkali ion will change the (tetragonal) axial ratio of the crystal. The axial ratio might happen to be unity with the ammonium ion. This would augment the tendency toward ionic disorder, and hence toward stabilization of the cubic phase.

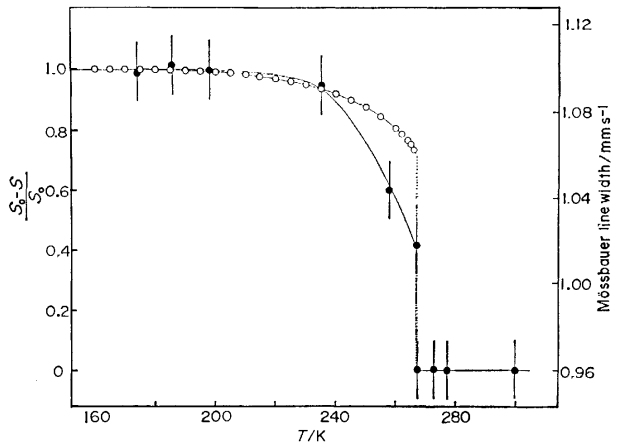

Fig. 4. Temperature dependence of the reduced anomalous entropy $(S_0-S(T))/S_0$ (-○-○-, present data) and the Mössbauer line width (-●-●-●-, from Ref. 3).

Finally we discuss briefly the temperature dependence of the anomalous heat capacity of $(NH_4)_3[FeF_6]$ crystal. In Fig. 4, the quantity $(S_0-S(T))/S_0$ is plotted against the temperature, together with the temperature dependence of the Fe Mössbauer line width.[3] Here, $S(T)$ is the anomalous part of the entropy at the temperature T and S_0 is the high temperature limit of the entropy. This quantity is equivalent to the square of the order parameter in the Landau theory of phase transitions of the second kind.[25] These two quantities change similarly with the temperature, implying that there is a close relation between the ionic ordering and the relaxation mechanism of the iron nuclear spin. In the Mössbauer study,[3] the nuclear quadrupole effect is *a priori* neglected in the cubic phase. Although the iron environment is certainly cubic on the average, our model proposed

above for the ionic disorder implies that it deviates from the cubic symmetry if observed in a short duration of time.[26] The Mössbauer data[3] seem to set an upper limit for the time during which the proposed local non-cubic ionic arrangement persists: it is less than the electronic relaxation time 10^{-9}—10^{-11}. It may be noted that the averaging to the octahedral symmetry is effected by random jumping of the $[FeF_6]^{3-}$ ion over the eight configurations illustrated in Fig. 3. It is not necessary for the anion to reorient by 90°. The former smaller-scale reorientation would involve a smaller barrier to be overcome, and thus would be consistent with the small value of the orientational life time. In passing, Fig. 4 indicates clearly that the phase transition is of the first order. The total entropy change, 24.8 ± 1.9 J K^{-1} mol^{-1} is absorbed gradually up to 6.3 J K^{-1} mol^{-1} and the remaining part is absorbed isothermally at the transition point.

Landau's thermodynamic theory predicts that the anomalous heat capacity C_{an} follows the temperature dependence:

$$\frac{C_{an}}{T} = A(T_k - T)^{-1/2},$$

provided that the temperature is not too close to the critical value. Figure 5 illustrates an attempt to fit the expression to the experimental anomalous heat capacity. The parameter T_k was so chosen as to yield the widest linear portion in the plot. Actually, the experimental points fit closely to the linear plot up to the onset of the first order effect. This means that we are not in the critical region even at the transition temperature. The large value of the isothermally absorbed entropy is in line with this observation. A conclusion drawn from the favorable comparison with the Landau theory as shown in Fig. 5 is that a restriction is placed on the crystal symmetry of the low temperature phase: the space group of the low temperature phase is a subgroup of the space group of the cubic phase. This is not particularly informative for the present crystal because the high temperature phase involved has the highest symmetry Fm3m.

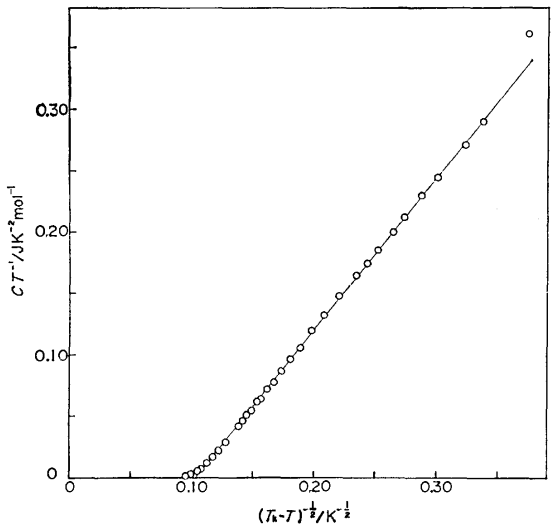

Fig. 5. C_p/T plotted against $(T_k - T)^{-1/2}$ with T_k= 272.8 K. Linearity of the plot implies conformity of the anomalous heat capacity to the Landau theory.

We are grateful to Mr. Mitsuo Ohama for the measurements of the Raman spectra and to Messrs. Masakazu Okuniya and Hiroshi Minari for the chemical analyses.

26) Recently, W. von der Ohe (*J. Chem. Phys.*, **65**, 3575 (1976)) reported a Raman study of the trigonal $(NH_4)_2[TiF_6]$ single crystal in which the $[TiF_6]^{2-}$ ion has a similar octahedral configuration but is situated at a trigonal site. The $\nu_5(F_{2g})$ mode of the complex ion is site-group-split by 1 cm^{-1} at the room temperature. The overall width of the ν_5 spectrum is reported to be 20 cm^{-1}. This is considerably smaller than the width ($\approx$38 cm^{-1}) of the corresponding mode of the $[FeF_6]^{3-}$ ion in the cubic phase of the $(NH_4)_3[FeF]_6$ crystal, suggesting that the latter is composed of overlapping modes. This, in turn, implies that local environment of the $[FeF_6]^{3-}$ ion has a trigonal or lower symmetry when observed in such a short time as is relevant to the Raman scattering, even though the diffraction symmetry of the site is O_h. The orientational disorder model considered in the text is thus consistent with the spectroscopic observation.

The Nuclear Quadrupole Spin-Lattice Relaxation of ^{35}Cl in Methylammonium Hexachlorostannate(IV) and Hexachloroplatinate(IV)

Yoshihiro FURUKAWA, Hideko KIRIYAMA, and Ryuichi IKEDA*

The Institute of Scientific and Industrial Research, Osaka University, Yamadakami, Suita 565

**Department of Chemistry, Nagoya University, Chikusa, Nagoya 464*

(Received February 17, 1977)

The ^{35}Cl nuclear quadrupole spin-lattice relaxation time, T_1, in $(CH_3NH_3)_2MCl_6$ (M=Sn and Pt) was measured from 4.2 to 434 K in order to clarify the dynamic aspect of the phase transitions at 156 and 125 K respectively. The relaxation process in both low-temperature phases is dominated by the rotational vibration of the octahedral $[MCl_6]^{2-}$ ions. Far above the transition point, T_{tr}, the T_1 decreases very rapidly with an increase in the temperature. This indicates that each octahedron reorients about its threefold axis, with the activation energies of 77 ± 3 for $[SnCl_6]^{2-}$ ions and 95 ± 10 kJ mol^{-1} for $[PtCl_6]^{2-}$ ions. At T_{tr}, the $\log(T_1/s)$ *vs.* kK/T curve shows a distinct minimum, as in some K_2PtCl_6-type compounds. This anomalous behavior can be explained in terms of a soft rotary mode of the $[MCl_6]^{2-}$ ions. The softening is estimated to be about 60%, according to Armstrong's approach.

Most hexahalogenometallates(IV) with cubic antifluorite structures of the K_2PtCl_6 type are known to undergo structural transitions to low-temperature phases of less symmetric structures. Recent studies of the nuclear quadrupole resonance (NQR) in these crystals have shown that their NQR frequencies and relaxation times near the transition points are greatly affected by the condensation of rotary lattice modes.[1]

On the other hand, methylammonium hexachlorometallates (IV) form rhombohedral $R\bar{3}m$ crystals with a slightly deformed antifluorite structure.[2,3] Very recently, Kume *et al.* have, from ^{35}Cl NQR measurements, found phase transitions in $(CH_3NH_3)_2SnCl_6$ and $(CH_3NH_3)_2PtCl_6$ at 156 and 125 K respectively.[4] In interpreting the unusual behavior of the NQR frequency at the transition point, they suggested the existence of a soft mode involving the libration of the complex anions. On the other hand, the results of proton second moments and spin-lattice relaxation times showed that the methylammonium ion is reorienting as a whole about its three-fold symmetry axis in the low-temperature phase, giving rise to a deep minimum of T_1 at about 53 K for 60 MHz.[5] As the temperature increases toward the phase-transition point, the correlation times of the individual motions of CH_3 and NH_3 groups become very different. Consequently, another shallow minimum of T_1 appears on the high-temperature side of the deep minimum, but a few tens of degrees below T_{tr}. This second minimum may be ascribed to the dipole-dipole interaction between the CH_3 and NH_3 groups in the cation. Just at T_{tr}, however, the proton T_1 *vs.* $1/T$ curve showed no appreciable discontinuity, suggesting that the motion of the cation may play a rather indirect role in the phase transition.[5]

In general, spin-lattice relaxation times for quadru polar nuclei are very sensitive to EFG (electric field gradient) fluctuations associated with the phase transition. The present study of the ^{35}Cl nuclear quadrupole relaxation has been undertaken in order to clarify the motion of the $[MCl_6]^{2-}$ anion in $(CH_3NH_3)_2MCl_6$(M= Sn, Pt), and also in order to ascertain whether or not it is responsible for the phase transition, as was suggested in previous papers.[4,5]

Experimental

The spin-lattice relaxation time of ^{35}Cl were measured with a Bruker pulsed NMR spectrometer (B-KR 322s 4—62 MHz). A boxcar integrator or a NIC 1074 signal averager was set up after the spectrometer in order to increase the SN ratio. The T_1 was determined by a 90°-t-90°-t'-180° pulse sequence and by fitting the echo amplitude to the $A(t)=A_0[1-\exp(-t/T_1)]$ equation for a fixed t'. In the temperature range studied, the recovery of the nuclear magnetization was well described by a single exponential function. The error of each T_1 value is within about 5%. The T_2 was measured by means of a 90°-t/2-180° spin echo pulse sequence and by fitting the echo amplitude to $A(t)=A_0\exp[-(t/T_2)^2]$. For both compounds, the T_2 values were temperature-independent at 550 μs, except above 330 K.

The powdered samples of methylammonium hexachlorostannate(IV) and its platinum analogue were the same as those used in the earlier NQR and proton NMR experiments.[4,5]

The sample temperature was measured with a copper *vs.* constantan thermocouple and was controlled with an estimated accuracy of ±0.5 K below and ±1 K above room temperature. Temperatures lower than 77 K were obtained by allowing the sample to warm from the temperature of liquid helium and measured with a gold-cobalt *vs.* copper thermocouple.

Results and Discussion

The nuclear quadrupole interaction Hamiltonian is given by

$$\mathcal{H}_Q = \Sigma_\mu Q_\mu V_\mu, \quad \mu = 0, \pm1, \pm2, \tag{1}$$

where the Q_μ's are the quadrupole operators and the V_μ's, the electric-field-gradient components. Each V_μ can be expanded as a power series in the relative displacements or fluctuations of the nuclei from their equilibrium positions. Thus, the time-independent terms are responsible for the NQR frequency, ν_Q, while the time-dependent ones are responsible for the spin-lattice relaxation.[6]

The compounds studied gave one NQR line in both the low- and high-temperature phases,[4] consistent with the crystal structure proposed by an X-ray diffraction study.[3] It was confirmed that the ν_Q-T curve exhibits a

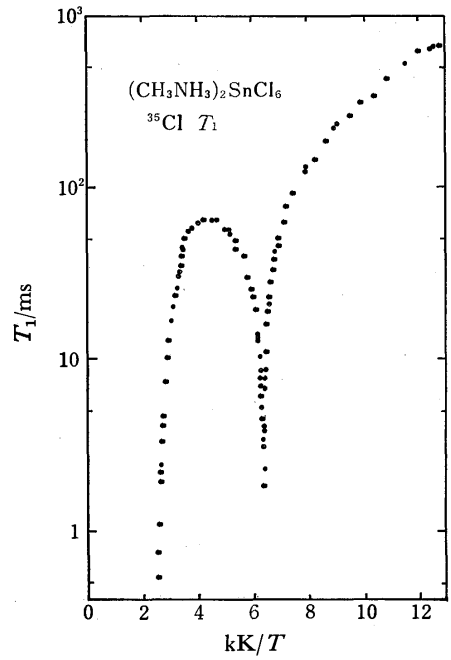

Fig. 1. A plot of the ^{35}Cl spin-lattice relaxation time in $(CH_3NH_3)_2SnCl_6$ as a function of $1/T$.

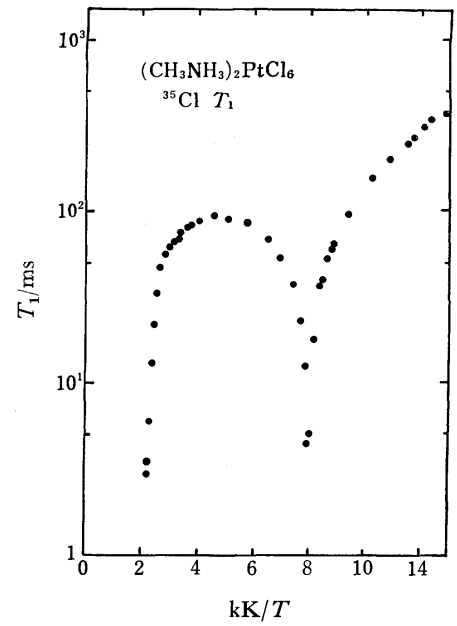

Fig. 2. A plot of the ^{35}Cl spin-lattice relaxation time in $(CH_3NH_3)_2PtCl_6$ as a function of $1/T$.

small, but distinct cusp-shaped reduction in a narrow temperature range about the T_{tr}. This cusp may be due to certain fluctuations enhanced as the transition point is approached, probably caused by soft librational modes of the octahedron, in analogy with K_2PtBr_6.[1]

The ^{35}Cl spin-lattice relaxation times in $(CH_3NH_3)_2SnCl_6$ are shown in Fig. 1 as a function of the inverse temperature. A distinct minimum was found at T_{tr}, in contrast to the proton spin-lattice relaxation time, which does not show such an anomaly.[5] The temperature dependences of the ^{35}Cl T_1, as well as of the NQR frequency, of $(CH_3NH_3)_2PtCl_6$ are very similar to those of $(CH_3NH_3)_2SnCl_6$ (Fig. 2). This indicates that the relaxation process and the mechanism of the phase transition can be interpreted from the same standpoint for both compounds.

Low-temperature Region. Armstrong *et al.* have extensively studied the lattice dynamics and phase transitions in cubic antifluorite-type crystals, R_2MX_6, and in cubic perovskite-type $CsPbCl_3$ by means of NQR spectroscopy.[1] They have derived theoretical equations for the quadrupole relaxation time and have pointed out that the most dominant relaxation process for the X nuclei is the anharmonic Raman process, with a rotary lattice mode of the $[MX_6]^{2-}$ octahedron. On the other hand, the internal vibration is less important than the former process, and so its contribution is negligible. According to them,

$$T_1^{-1} = CT^2/\bar{\omega}^5, \tag{2}$$

where C is a constant depending on the crystal structure, and $\bar{\omega}$, the zone-averaged rotary mode frequency. Then, T_1^{-1} would be proportional to T^2 in a stable lattice such as Cs_2PtCl_6.[1] The C coefficient is much too complicated to estimate for the rhombohedral lattice, although it was estimated for the cubic K_2PtCl_6-type structure.[1]

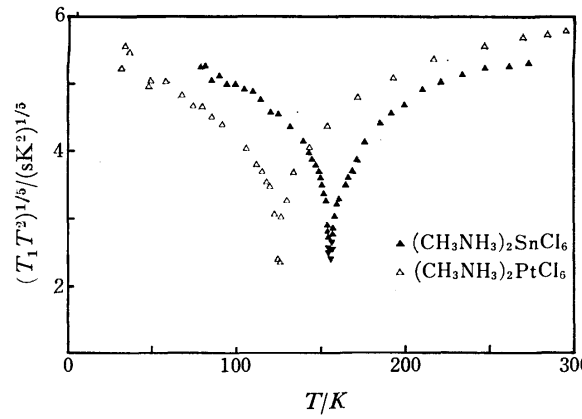

Fig. 3. Temperature dependences of $(T_1\ T^2)^{1/5}$ in $(CH_3NH_3)_2SnCl_6$ and in $(CH_3NH_3)_2PtCl_6$.

In Fig. 3 the $(T_1T^2)^{1/5}$ value is plotted against the temperature in order to see whether or not Eq. 2 holds even in the vicinity of T_{tr}.[1] Far below or above T_{tr}, the $(T_1T^2)^{1/5}$ is nearly constant, indicating that $T_1^{-1} \propto T^2$. The T_1 measurement was further extended to the region from 77 to 4.2 K only on the platinate complex, as Fig. 4 shows. The T_1^{-1} data in this temperature region show no T^2 dependence, because the high-temperature approximation breaks down in Eq. 2. In such a case, the T_1^{-1} is expressed by:

$$T_1^{-1} = C' \sinh^{-2}(\hbar\bar{\omega}/2kT). \tag{3}$$

The temperature dependence of T_1 (Eq. 3) is shown in Fig. 4 by a full line with parameters of $C'=2.69\ s^{-1}$ and $\hbar\bar{\omega}/k=137$ K. The agreement between the calculated and observed values below 80 K indicates that the relaxation of the ^{35}Cl nuclei is associated with the harmonic rotational vibration of the octahedron in this temperature region.

Phase-transition Region. The anomalous behavior

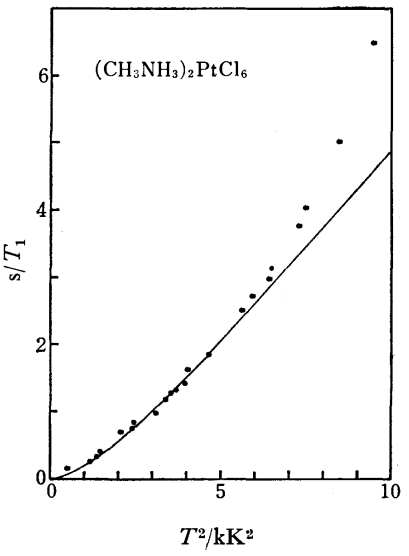

Fig. 4. The ^{35}Cl spin-lattice relaxation rate as a function of T^2 in $(CH_3NH_3)_2PtCl_6$. The full line was calculated by Eq. 3.

of T_1 around T_{tr} is very similar to that of R_2MX_6, which has the antifluorite structure.[1] This deep, distinct T_1 minimum in $(CH_3NH_3)_2MCl_6$ suggests that the phase transition is ascribable to a softening of a rotary lattice mode of the octahedron. If this is the case, then, according to Eq. 2, the temperature dependence of $(T_1T^2)^{1/5}$ reflects the variation in the average rotary mode frequency. The value of $(T_1T^2)^{1/5}$ was reduced by about 60% as the T_{tr} was approached from above for both compounds (Fig. 3). Referring to Armstrong *et al.*, this reduction denotes a 60% apparent softening of a rotary mode frequency, which is comparable to the 40 and 58% softening of zone-center phonons in K_2PtBr_6 and $(NH_4)_2PtBr_6$ respectively obtained from the Br T_1 measurements.[1]

Such softening of some rotary mode of the $[SnCl_6]^{2-}$ or $[PtCl_6]^{2-}$ octahedron suggests the possibility of a lowering of the crystal symmetry in the low-temperature phase, as is found in cubic R_2MX_6. An X-ray study was, therefore, performed on the tin complex in our laboratory.[3] It revealed that the space group ($R\bar{3}m$) and crystal structure are unchanged on passing through T_{tr}. Moreover, the X-ray results suggested that a $\boldsymbol{k}=0$ acoustic mode softens to make a bulk deformation without any structural change. This mode, however, could not explain the T_1 anomaly occuring at T_{tr}.[1] It is, therefore, conceivable that the tilting of the octahedra is too small to be detected by X-ray diffraction.

High-temperature Region. At high temperatures (above 300 K), a rapid decrease in T_1 occurs exponentially with a decrease in $1/T$, showing that another relaxation mechanism is dominant. This process is attributable to the hindered rotation of the $[MCl_6]^{2-}$ octahedron, probably around its three-fold axis, which coincides with the triad axis of the rhombohedral cell. The relaxation time is given as

$$T_1 = C \cdot \tau_0 \exp(E_a/RT) \quad (4)$$

where C is a constant, equal to 2/3 for the C_3 rotation of octahedra.[7] By fitting the data in Figs. 1 and 2 to Eq. 4, the activation energies (E_a) of the hindered rotation were determined to be 77 ± 3 for the $[SnCl_6]^{2-}$ ion and 95 ± 10 k J mol^{-1} for the $[PtCl_6]^{2-}$ ion. These values are comparable to 78.7 and 76.6 k J mol^{-1} for the C_4 rotation in cubic K_2PtCl_6 and K_2IrCl_6 respectively.[1,8]

The authors wish to express their thanks to Professor Ryôiti Kiriyama for his continuous encouragement and to Dr. Katsuki Kitahama for his helpful comments.

Multielement Analysis of Deep-Sea Sediments by Photon Activation

Toyoaki KATO,† Nobuyoshi SATO,* and Nobuo SUZUKI

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

**College of General Education, Iwate University, Morioka 020*

(Received November 26, 1976)

A nondestructive photon activation with 30 MeV bremsstrahlung has been applied to the multielement determination in the pelagic sediments in a region of the Pacific Ocean. The abundances for 6 major and 10 trace elements were measured in several deep-sea floors and the core samples, discussion being given on the results. Determination of trace elements such as Cr, Co, Ni, and Sr is valuable because of their geochemical significance.

The essential problem involved in the geochemistry of deep-sea sediments is to establish the distribution and original source of a number of their elements. Although research has been performed for this purpose, it seems to be insufficient. It is desirable to develop a method by which it is possible to analyze samples for wide spectra of elements.

The importance of photon activation, mainly with 30 MeV bremsstrahlung, as a nondestructive multielement analytical technique has been stressed for several years. A number of papers have been presented describing methods and application, ranging from the measurements of a number of the elements in round-robin materials[1-3] to the environmental pollution research.[4-7] The availability of a comprehensive body of basic reference data in the form of photonuclear reaction yields,[8-10] sensitivities,[9,10] and gamma rays emitted from numerous products[11] pertaining to 30 MeV bremsstrahlung activation with a linear electron accelerator (Tohoku University) has made the method feasible for further application to a wide variety of materials. This paper deals with the nondestructive determination for several major and trace elements present in oceanographic samples, including several pelagic deep-sea floor sediments and selected core samples of the Pacific Ocean, obtained by the Geophysical and Geological Research Project planned and carried out under the auspices of the Ocean Research Institute, the University of Tokyo (1973). The methodology of photon activation analysis in geochemical application has been reported.[1,2,10] We will descibe some additional comments in individual determinations and discuss the results.

Experimental

Materials. The study was carried out on the pelagic sediments collected in a region of the Western Equatorial Pacific. The sampling sites, depths and core lengths are given in Table 1. The deep-sea floor sediments which were dredged were dark brown and fairly homogeneous. The core samples consist of piston cores, about 10 m long. The core column was cut into segments each 1 cm thick along its entire length, and selected specimens were subjected to analyses. Age was determined on the basis of calcareous organisms and found to be *ca.* 2 million years at the bottom of the 10-m core.[12] Each sample was dried at 70 °C for 24 h, crushed and mixed in an agate mortar to attain homogeneity. 300 mg of the dried sample was wrapped in a small piece of aluminum foil and then compacted into a disc, diam. 9 mm, height 4 mm. The JB-1 basalt was used as a multielement comparative standard, because of the well-characterized nature of the matrix and the known elemental composition. The abundances of the elements of interest were taken from the data compiled by Ando *et al.*[13] An amount weighing 300 mg was wrapped in a small piece of aluminum foil and made into a diam. 9 mm disc. To assess the magnitude of interference, foils of iron with diam. 9 mm were made from a thin sheet of pure iron, about 10 μm thick, with a chemical purity of 99.99%. A unit of materials to be irradiated consists of a sample disc, two standard discs and four iron foils. They were stacked in a silica tube with the standard discs placed on both sides of the sample and the iron foils between them and at the front and back of the unit for simultaneous irradiation. The

† Present address; College of General Education, Tohoku University, Kawauchi, Sendai 980.

photon flux gradient along the length of this unit was about 10%.

Irradiation. Bremsstrahlung irradiation was carried out with a linear electron accelerator. Typically, a 70 μA beam of 30-MeV electrons was made to impinge on a 2 mm thick platinum converter. Details involving irradiation assembly and converter-sample configuration have been reported.[8-10] After irradiation for 4—5 h, the wrapping foil was rejected and the content of each sample was again wrapped in fresh aluminum foil for gamma-counting.

Counting and Abundance Determination. The counting equipment consists of a 68 cm^3 Ge(Li) detector, Canberra Model 7200-7600-1423. Its output was coupled to a 4096-channel pulse height analyzer (Toshiba Electric Co., Ltd.). Details involving counting, characterization of gamma rays and quantitative treatment of the spectrum data were essentially the same as reported.[10] A mean specific activity for any specified gamma ray in terms of the peak areas from the standard discs on both sides was used for calculating the abundance of the element in question. Because of the adverse nuclear properties, aluminum was determined separately by means of spectrophotometric measurement followed by solvent extraction with 8-hydroxyquinoline.[14]

Results and Discussion

As in the multielement analysis of standard rocks,[1,2] 6 major and 10 trace elements were subjected to determination. Pertinent nuclear data for the reaction products are given in Table 2 together with the optimal time intervals for measurement after irradiation and practical detection limits. The practical detection limits were estimated from the spectral data of the JB-1 rocks. They are the amounts of the elements giving a full-energy peak area corresponding to three times the standard deviation of the area under the peak of interest, with 5 h irradiation time with a 70 μA beam of 30 MeV electrons, counting at optimal time intervals given in Table 2. We see that major elements (Ca—Ti) in crustal materials can not be highly activated. This turns out to be advantageous over competing methods when simultaneous multielement determination is the goal. In thermal neutron activation analysis, the full capability of the method might be restricted by high levels of interference, such as that from ^{24}Na. Such difficulty is not inherent in the present method. Nondestructive analysis of several specific elements such as Nb, Y, and Zr, not readily determined by thermal neutron activation analysis, is significant in geochemical substances. Comments are given on the individual determinations in the following.

The results for calcium are the average values obtained for each of the 374 and 617 keV peaks of ^{43}K, and the 1298 keV peak of ^{47}Ca. When the values obtained from these three different peaks were averaged, the relative deviations from the means were within ±2% for all of the samples studied. The samples were relatively high in titanium. For titanium, therefore, the 1121 keV peak of 83.9 d ^{46}Sc was given prior consideration, because of the favorable peak-to-background ratios obtained at longer decay times. For the sake of confirmation, the gamma rays from ^{47}Sc and ^{48}Sc were used.

The inter-element interference problems can be found in Table 3 in which major competing reactions yielding nuclides identical to those used for abundance determinations are given. In some cases, neutron-induced reactions other than the photonuclear processes are the major sources of interferences. Degrees of their contribution were determined from relative probability of forming pertinent nuclide through different reaction

Table 2. Pertinent nuclear data and detectability of the products

Element	Process	Product nuclide	Half-life	γ-Ray used for determination (keV)	Other γ-rays observed	Suitable decay time for measurement	Detection limit (μg)

paths. The effects of interferences were expressed as a ratio of the weights of the elements to produce same amounts of nuclide under consideration. To evaluate the effects, the yield data for the reactions of various types obtained on irradiating a series of individual elements under comparable conditions to those used for samples[9] were used. The values in parentheses are not experimentally obtained, but estimated from the yield data as a function of atomic number.[9] Interfering contributions thus evaluated are for several matrices. Values for the sediments are interfering contributions for the samples used in this work. In order to provide information on geochemical application of this method, corrections necessary for the average composition of the earth's crust were also calculated in Table 3. For this purpose, the abundance data compiled by Turekian and Wedepohl[15] were used.

A severe interference problem is the $^{56}Fe(\gamma,pn)^{54}Mn$ contribution to the total ^{54}Mn activity in the manganese determination. Corrections required for the samples were made by using the production rate ratio, $^{54}Mn/^{56}Mn$, found in the irradiated iron foils.[1,2] However, it was found that the ratio varies depending on the converter-material configuration in an irradiation system. An increase of 3% of the ratio obtained in the front foil was found in the back foil in the material unit. In such cases where the interfering contributions turn out to be very large, careful corrections should be made by using monitor foils irradiated under identical conditions to those used for samples. The $^{27}Al(n,\alpha)^{24}Na$ contribution to the total ^{24}Na activity was estimated from the aluminum values determined spectrophotometrically. Corrections required for the samples studied were less than 2%. Thus this source of interference may not be serious.

All elemental abundances are given in Tables 4 and 5. Reproducibility and reliability of the method have been demonstrated by analyzing a series of standard rocks of various types.[1,2] The abundance values obtained were reproducible: The average relative deviations for all the elements determined, based on the duplicate samples, were within 4%. Agreement of the results with published data was excellent. Although no replicate analyses were made on each of the samples, we estimate that the overall uncertainties associated with individual determinations for all of the elements studied are within ±10%.

The sodium values will be high to some extent because of sea water which was trapped within the accumulating sediments. The floor samples F-6 and F-7 are very high in calcium. The marked difference coincides with a

considerable amount of calcareous shell materials found in them (Table 4).[12] These two samples were the carbonate type sediments and could be distinguished visually from the other clay type sediments. The carbonate compensation depth occurs at 3500 m in the Pacific Ocean.[16] Since the samples were collected at depths below it, the high contents of calcium can not be attributed to descent from the overlying water. Major parts of calcium in these samples may thus be due to calcareous organisms originating in the seamount which is located near the sampling sites. The deep-sea sediment of the carbonate type has only a relatively low content of most of trace elements, while the clays are generally rich in trace elements as compared to the carbonates.[16] The results in Table 4 show a typical pattern of this sort in the elemental composition. Strontium is an exception to this category. A similar exception has also been reported.[15] Samples F-3, F-4, and F-5 seem to be high in some trace elements such as Co, Cr, and Ni.

Of the core samples tested, C-1 sample contained less calcium at both the top and bottom of the core column. The elemental composition of this core can be related to the clay type sediments. In contrast, the other two core samples are highly calcareous and are characterized by their low contents of other major and trace elements except strontium. Each core sample is homogeneous in the elemental composition along the core column. No direct evidence of the early diagenesis or post-depositional migration of the elements has been obtained.

In conclusion, photon activation analysis with 30 MeV bremsstrahlung provides useful information on the elemental distribution in deep-sea sediments. The technique is nondestructive and can provide reliable abundance data for at least 6 major and 10 trace elements of geochemical significance.

We would like to express our appreciation to members of the linac machine and radioisotope groups, the Institute of Nuclear Science, Tohoku University, for their kind cooperation in the irradiation. We also thank Prof. Yokichi Takayanagi, the Institute of Geology and Palaeontology, Tohoku University, and Dr. Michio Kato, Department of Geology, Faculty of Integrated Arts and Science, Hiroshima University, for the supply of deep-sea sediments and valuable suggestions.

Polarographic Behavior of Chloramine-T in an Acidic Solution at a Rotating Platinum Electrode

Toshio MATSUDA

Department of Chemistry, Ritsumeikan University, Kyoto 603

(Received December 6, 1976)

The polarographic behavior of chloramine-T at a rotating platinum electrode has been investigated in an acidic solution. Chloramine-T gives a well-defined reduction wave at a relatively positive potential. This is found to be due to the reduction of the non-ionized species of *N*-chloro-*p*-toluenesulfonamide and of dichloramine-T produced by disproportionation reaction of chloramine-T. The chemical process attributed to the disproportionation reaction is involved in the electrode process. The shape of the wave which varies with the recording procedure is correlated with the change of surface conditions. At pH lower than 4, a small prewave of hypochlorous acid produced by hydrolysis is observed at a more positive side. The diffusion current of the total wave, very stable and proportional to the concentration, is due to a two-electron reduction.

Chloramine-T (sodium salt of *N*-chloro-*p*-toluenesulfonamide, CAT) is known to be a stable oxidizing reagent for titrimetric analysis.[1] The purpose of this work is to investigate the electrochemical characteristics of CAT and to develop the end point detection techniques for a redox titration using CAT.

Recent studies[2,3] on the polarographic behavior at a dropping mercury electrode have shown that the over-all reaction of CAT involves two electrons over the pH range 2—13. However, it was impossible to measure the reduction potential of CAT since the reduction occurs at a more positive potential than that of the mercury dissolution. In an acidic solution, the limiting current tends to decrease with time by the reaction with mercury. On the other hand, well-defined reduction waves were observed at considerable positive potential at a rotating platinum electrode (RPE).

The polarographic behavior of CAT at a RPE was investigated in an acidic solution in order to elucidate the nature of the electrode process, the results of which are given in this report.

The free acid of CAT predominates in an acidic solution, producing *N,N*-dichloro-*p*-toluenesulfonamide (dichloramine-T, DCT) by disproportionation.[4,5] Discussion is given on the disproportionation and the effect of the electrode surface conditions on the reduction process.

Experimental

Apparatus and Reagent Used. The apparatus for the measurements of d.c. and a.c. polarograms was essentially the same as that described previously.[3] A Shimadzu synchronous rotator, RE-3, was used with a vertical platinum wire microelectrode (5.0 mm long, 0.5 mm in diameter) at r.p.m., 600. The sensitivity of electrode was 9.28 μA/mM in an electrolyte solution of hexacyanoferrate(III) ion containing 0.1 M KNO_3 and Britton-Robinson buffer at pH 5.0. An electrolytic cell of glass cylinder (50 mm in height and 45 mm in diameter) was used in a thermostat maintained at 25±0.2 °C. N_2 gas was used to deoxygenate the solution, flowing over the surface of the solution during the recording of the polarogram. The potentials are referred to a SCE connected to the solution with a KNO_3-agar salt bridge.

The preparation of the stock solutions of chloramine-T, *p*-toluenesulfonamide and other chemicals has been reported.[3] A satutated solution of *N,N*-dichloro-*p*-toluenesulfonamide (dichloramine-T) was prepared from the reagent grade salt and standardized against an arsenite standard solution. Water was used after distillation of deionized water in the presence of small amounts of $KMnO_4$ and NaOH solutions in a glass apparatus.

Measurement of Polarogram. Before each run for a polarogram of CAT, the polarograms of hexacyanoferrate(III) ion were recorded by use of the electrode which had been pretreated in a 0.1 M $HClO_4$ solution.[6] The values obtained for the diffusion current and the half-wave potential of hexacyanoferrate(III) ion were used to normalize the conditions for the preoxidation and rotation of the electrode, *etc.* An electrolyte solution was prepared by adding an adequate amount of the standard solution of CAT to the base solution, *i.e.*, 0.1 M KNO_3 and Britton-Robinson (B.R.) buffer solution. An aliquot of the solution was deoxygenated in an electrolytic cell. Polarograms were recorded by forward or backward scan. By forward scan, the electrode potential was shifted from positive to negative potentials. By backward scan, the situation was reversed. The rate of the potential scan was 200 mV per minute. A damping condenser of 5 μF was used.

Results and Discussion

Polarograms of Chloramine-T at Various pH Values. Figure 1 shows typical polarographic waves of 0.4 mM chloramine-T (CAT) in a supporting electrolyte solution containing 0.1 M KNO_3 and B.R. buffer at various pH values. The reduction waves in an acidic solution appeared at more positive potential than the reduction potential of platinum oxide. A maximum current on the plateau of the forward curves is due to the cathodic dissolution pattern of platinum oxide film. With the electrode covered with the oxide film, the waves shifted to negative potential and became drawn out, as shown on the forward curves, the results thus becoming less reproducible. This indicates that the electrode reaction is strongly inhibited by the oxide film. On the other hand, when the potential was scanned backward with the electrode reduced at an adequate negative potential after preoxidation, well-defined waves were observed at more positive side, the results being reproducible. On these curves, the main wave was two-stepped at pH lower than 7, a small prewave being observed at the more positive side at pH lower than 4 and a single wave at pH about 8.

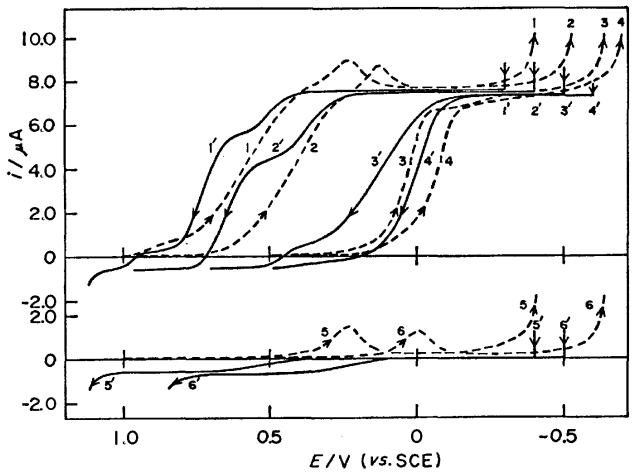

Fig. 1. Polarograms of 0.4 mM CAT in a solution containing 0.1 M KNO_3 and B.R. buffer at various pH values. (1,1') pH 3.40; (2,2') pH 5.05; (3,3') pH 7.10; (4,4') pH 8.10. Lower polarograms are residual current curves at various pH values. (5,5') pH 3.40; (6,6') pH 7.10. Dotted lines are forward curves recorded from +1.0 or +0.5 V after preoxidation at an adequate positive potential. Solid lines are backward curves recorded from between −0.3 and −0.6 V after the preoxidation.

The relations between pH and limiting current and between pH and half-wave potential of the backward wave are given in Figs. 2 and 3, respectively. The values of limiting current have been corrected for the residual current. On the main wave, the value of $\Delta E_{1/2}/\Delta$pH for the first step was −65 mV per unit pH, except at pH *ca.* 2. For the second step, the value was −80 mV per unit pH in the pH range 2—6. The limiting current of the first step varied with pH in the above pH range, giving a maximum value at pH 4—5. On the second step at pH higher than 6, the slope became remarkably drawn out, the half-wave potential shifting to negative potential. The results suggest that the reduction wave in an acidic solution can be characterized with the two-stepped wave at pH lower than 6 and that its electrode reaction differs from that at pH about 8. The half-wave potential shifts slightly to negative potential

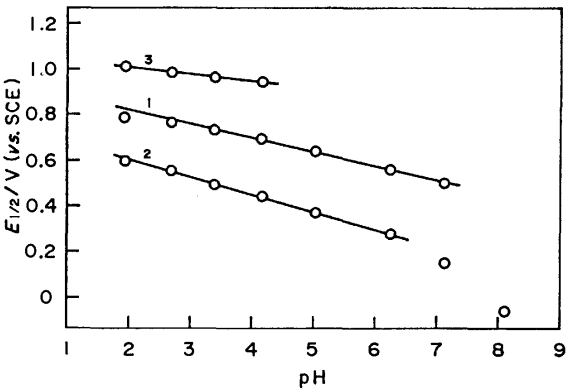

Fig. 3. Relation between the half-wave potential of the backward wave and pH for 0.4 mM CAT. (1) First wave; (2) second step; (3) prewave.

at pH *ca.* 2, which is considered to be attributable to the deactivation of the electrode surface. This tendency for the electrode surface to be rapidly deactivated, especially in an acidic solution, was also observed for the reduction of *N*-bromosuccinimide.[7]

The limiting current of the total wave was independent of the recording procedure, provided that the correction for the residual current in each case was applied. Its value remained constant within deviation of ±2.0% in the pH range 2—8, being proportional to the concentration from 0.05 to 0.6 mM CAT (Table 1). The plot of log $^{T}i_d$ *vs.* log *N* (*N* is r.p.m. of the electrode, which varied from 600 to 1200) gave a straight line, the slope of which was determined to be 1/3 (Fig. 4). A similar result was obtained for the diffusion current of hexacyanoferrate(III) ion. The temperature coefficient of $^{T}i_d$ measured in the temperature range 15—40 °C was 1.8% per degree. The limiting current can be concluded to be controlled by diffusion.

The value of $^{T}i_d/C$ for the total wave found to be 18.18±0.32 μA/mM in the above pH range. It can be seen that this value corresponds to a two-electron reduction on the basis of a similar calculation.[6] The values of diffusion coefficient used for this calculation were 0.79×10^{-5} $cm^2\,s^{-1}$ and 0.85×10^{-5} $cm^2\,s^{-1}$ for CAT[5] and hexacyanoferrate(III) ion,[5] respectively. The resut with respect to the limiting current of the

total wave was identical with that obtained at a dropping mercury electrode.[3)] It could be assumed, therefore, that the non-ionized species of *N*-chloro-*p*-toluenesulfonamide is mainly reduced in an acidic solution. However, the fact that the limiting current of the first step varies with pH as shown in Fig. 2 and that it has a kinetic character suggest that the electrode process of the main wave can not be accounted for by the reduction process of the non-ionized species only.

The limiting current of the first step was not proportional to the concentration (Table 1). The plot of $\log {}^{I}i_l$ *vs.* $\log N$ gave a straight line, the slope of which was determined to be 1/5. The temperature coefficient of ${}^{I}i_l$ determined in the temperature range 15—40 °C was 2.8% per degree, indicating that the limiting current has a kinetic character.

Effect of Surface Conditions of Electrode. In order to clarify the nature of the two-stepped wave, the effect of surface conditions of the electrode was investigated around pH 5.

With the reduced electrode, current-time curves were recorded in 0.4 mM CAT solution at pH 5.10 at +0.6 and +0.5 V, on the rising portion and the plateau of the first step, respectively, and at +0.4 V on the rising portion of the second step. As seen in Fig. 5, currents

(1) Forward scan from +1.0 V after preoxidation at +1.5 V; (2) forward scan from +0.7 V after preoxidation at +1.5 V followed by polarization at −0.4 V for a few minutes; (3) backward scan from −0.4 V after preoxidation at +1.5 V; (4) same as in curve (1) (residual current), (5) same as in curve (3) (residual current).

increased at these potentials, except at +0.6 V, after the electrode had been allowed to stand for 90 seconds at a natural electrode potential in an open-circuit condition. The natural electrode potential in this solution was found to be +0.8 V *vs.* SCE. At this potential, the platinum electrode would be oxidized (Fig. 6, curve 5). The increase of current is thus considered to be attributable to the formation of the oxide film. It is assumed that the current might not increase at +0.6 V, since the thin oxide film was produced at an earlier stage of the curve.

The height of the first step decreased due to the addition of *p*-toluenesulfonamide (TSA), a reduction product. The decrease was not detected in the presence of potassium chloride. A.c. base-current was recorded in both the presence and absence of TSA by the conventional a.c. polarographic method[3)] with the reduced electrode. It decreased in the presence of TSA at the potential region in which the platinum electrode is

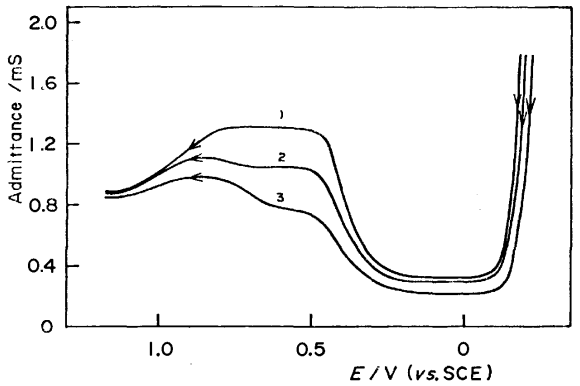

Fig. 7. Effect of TSA on the a.c. base-current curve in a solution containing 0.1 M KNO_3 and B.R. buffer at pH 5.10. (1) TSA was not added; (2) TSA was added in 0.1 mM; (3) TSA was added in 0.4 mM.

reduced (Fig. 7), which indicates that TSA is adsorbed on the surface of the reduced electrode.

It can be seen that TSA is adsorbed on the oxide-free surface and is desorbed partly by the formation of the oxide film. Thus, the two-stepped wave would be correlated with the adsorption of TSA. In fact, the curve recorded by the forward scan with an electrode covered thinly with the oxide film showed a single wave (Fig. 6, curve 2). This result is in line with the fact that the current increases as a result of the formation of the oxide film (Fig. 5).

Comparison with Reduction Wave of Dichloramine-T. Non-ionized species of CAT undergoes disproportionation in an acidic solution into dichloramine-T (DCT) and *p*-toluenesulfonamide (TSA)[4,5] according to

$$2RSO_2NHCl \rightleftharpoons RSO_2NCl_2 + RSO_2NH_2, \quad (1)$$

where $R=CH_3C_6H_4$. DCT as well as CAT act as a relatively strong oxidizing reagent in an acidic solution.[8] It can be expected, therefore, that a reduction wave of DCT is involved in the reduction wave of the CAT. A comparison with the reduction wave of DCT was made.

The value of the equilibrium constant (K_d) of the disproportionation is reported[4,5] to be 6.1×10^{-2} at 25 °C. DCT hydrolyzes to hypochlorous acid, the hydrolysis constant being 8×10^{-7}. If we assume that the amount of hydrochlorous acid is negligibly small and the non-ionized species predominates in the bulk solution, the equilibrium concentration of DCT can be calculated to be approximately 0.02 mM in the solution of 0.4 mM CAT.

DCT in an acidic solution gave a reduction wave (Fig. 8). The shape of the wave was very similar to that of CAT. The values of the half-wave potential and $\Delta E_{1/2}/\Delta pH$ for the first step were idential with those for the first step of CAT (Fig. 3). Although the slope of the second step became slightly drawn out, the value of $\Delta E_{1/2}/\Delta pH$ was close to that of CAT. At pH lower than 5, the height of the total wave remained constant. The wave obtained by the same recording procedure (Fig. 6, curve 2) became a single wave. Consequently, the behavior was identical with that of the reduction wave of CAT. The value of the diffusion current of the total wave at pH lower than 5 was found to correspond to a four-electron reduction.

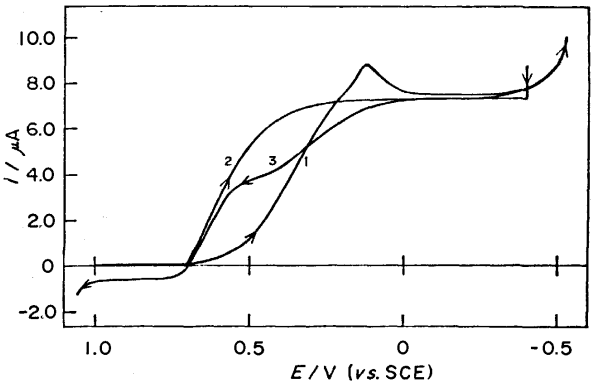

Fig. 8. Polarograms of 0.2 mM DCT in a solution containing 0.1 M KNO_3 and B.R. buffer at pH 5.20. (1) Forward scan from +1.0 V after preoxidation at +1.5 V; (2) forward scan from +0.7 V after preoxidation at +1.5 V followed by polarization at −0.4 V for a few minutes; (3) backward scan from −0.4 V after preoxidation at +1.5 V.

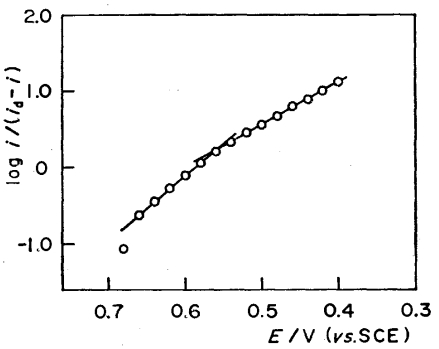

Fig. 9. Plot of log $[i/(i_d-i)]$ *vs.* E for the reduction wave of 0.4 mM CAT at pH 5.10, which was obtained by recording procedure as in curve 2 of Fig. 6.

The results suggest that the electrode process of the reduction wave in the CAT solution is essentially the same as that of DCT.

Electrode Process of the Reduction Wave of Chloramine-T. On the single wave (Fig. 6, curve 2), the plot of log-$[i/(i_d-i)]$ *vs.* E consists of two straight lines (Fig. 9). The potential at the point of intersection corresponds to that on the plateau of the first of the two-stepped wave. A similar result was obtained on the single wave in the DCT solution (Fig. 8).

The electrode process of the reduction wave in the CAT solution at pH lower than 6 can be explained as follows.

The reduction wave is made up of the following reactions:

$$RSO_2NCl_2 + H^+ + 2e^- \longrightarrow RSO_2NHCl + Cl^- \quad (2)$$

$$RSO_2NHCl + H^+ + 2e^- \longrightarrow RSO_2NH_2 + Cl^- \quad (3)$$

Reaction 2 occurs fast and is followed by Reaction 3. With the electrode from which TSA is desorbed, the two reactions occur continuously and the resulting wave becomes a single wave. With the electrode surface adsorbed with TSA, Reaction 3 is inhibited and the resulting wave becomes a two-stepped wave. It seems that, on the two straight lines of the log-plot, the left-

side branch from the point of intersection corresponds to Reaction 2 and the right-side branch to Reaction 3, *viz.*, the two-stepped wave; the first step is due to Reaction 2 and the second step to Reaction 3. According to Higuchi *et al.*,[9] the rate of disproportionation given by Reaction 1 is relatively great. We might thus expect that, over the potential region where only Reaction 2 occurs, DCT undergoes transformation on the surface by the chemical process attributed to Reaction 1. The limiting current of the first step is greater than that corresponding to the equilibrium concentration of DCT, which can be accounted for by this chemical process. This consideration is supported by the fact that the limiting current of the first step has a kinetic character and that its pH-dependence (Fig. 2, curve 2) is the same as that of the forward rate constant for Reaction 1.[9]

As regards the behavior at pH higher than 7, the reduction of ionized species might be considered.

Behavior of Prewave. The value of $\Delta E_{1/2}/\Delta$pH was determined to be -33 mV per unit pH on the small prewave obtained by backward scan with the reduced electrode at pH lower than 4. The limiting current was proportional to the concentration of CAT (Table 1) and found to be controlled by diffusion.

Hypochlorous acid gives a reduction wave at a relative positive potential on a platinum electrode,[10,11] giving a reduction wave at the same potential as that of the prewave under the same experimental conditions as in this study. The behavior was the same as that of the prewave. Thus, it is concluded that the prewave results from the reduction of hypochlorous acid produced by hydrolysis in the CAT solution.[4,5]

The value of i_d/C for the reduction wave of hypochlorous acid was determined separately to be 26.9 μA/mM in the same electrolyte solution. By use of this value and the value of the prewave (Table 1), the amount of hypochlorous acid in the solution of 0.4 mM CAT is calculated to be *ca.* 0.03 mM at pH 3. This is in line with the interpretation that the fraction of hypochlorous acid present in the CAT solution is much less than 10%.[3]

Analytical Aspect. When current-time curves were recorded at several potentials on the plateau of the total wave, no detectable variations of current were observed over a period of 10 min at pH lower than 6. This indicates that the limiting current of the total wave is remarkably stable and reproducible over the pH range studied. This behavior is advantageous for analysis as compared with that of a dropping mercury electrode,[3] in which the limiting current decrease is due to the reaction with mercury or maximum suppressor.

It can be concluded that the limiting current in an acidic solution is useful for amperometric titration in the short-circuit method.

The author wishes to express his hearty thanks to Prof. Taitiro Fujinaga, Kyoto University, for his encouragement, and to Prof. Toyoshi Nagai, Ritsumeikan University, for his helpful suggestions and discussions.

Kinetics of the Oxidation of Ethylenediaminetetraacetato and Aqua Complex of Dimeric Molybdenum(V) by the μ-Hyperoxo-bis[pentaamminecobalt(III)] Ion in Aqueous Perchloric Acid Solution

Yoichi SASAKI

Chemistry Department, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received December 21, 1976)

Kinetics of the oxidation of double-bridged Mo(V) complexes, $[Mo_2O_4(edta)]^{2-}$ (H_4edta=ethylenediaminetetraacetic acid) and $[Mo_2O_4(aq)]^{2+}$ with $[(NH_3)_5CoO_2{}^{(-)}Co(NH_3)_5]^{5+}$ has been studied in aqueous perchloric acid solution at 25—50 °C. The oxidation of $[Mo_2O_4(edta)]^{2-}$ is characterized by the electron transfer within the ion-pair formed between the two reactants. The first order rate constants for the electron transfer process (k_e) are independent of $[H^+]$ ($[H^+]=0.05$—0.1 M; $I=0.1$—2.0 M) (M=mol dm^{-3}). At 40 °C and $I=0.1$ M, k_e is equal to $(1.34\pm0.08)\times10^{-3}$ s^{-1} and the corresponding activation parameters are $\Delta H^{\ddagger}=28\pm4$ kcal mol^{-1} and $\Delta S^{\ddagger}=18\pm11$ cal K^{-1} mol^{-1}. The rate of oxidation of $[Mo_2O_4(aq)]^{2+}$ is independent of the oxidant concentration and accelerated by halide ions and Mo(VI). The rate-determining step is the formation of a single-bridged Mo(V) dimer (A) prior to electron transfer. The first order rate constants for the formation of A (k_1) are reciprocally dependent on $[H^+]$ ($[H^+]=0.5$—2.0 M; $I=2.0$ M). k_1 is $(4.3\pm0.3)\times10^{-6}$ s^{-1} at 25 °C and for $[H^+]=1.0$ M. The difference in the oxidation mechanism of the two complexes has been discussed in terms of the charge of the complex, stabilization of the Mo_2O_4-unit by the ligands, and the role of coordinated water.

The redox and substitution properties of molybdenum ions in various oxidation states are of current interest[1,2] in view of the involvement of molybdenum ions in biological systems.[3] The redox properties of simple molybdenum(V) complexes have been studied by many workers.[1,4-11]

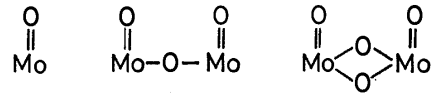

Fig. 1. Basic units of three types of structure of molybdenum(V) complexes.

Most of the molybdenum(V) complexes can be classified into three types (Fig. 1). Recent studies on the oxidation of some type I complexes by nitrate[6,10,11] and nitrite[7] ions revealed that they are much more readily oxidized than dimeric complexes. The oxidation of dimeric Mo(V) complex (structure not clearly described) by nitrate ions is considered to involve a small amount of monomeric Mo(V) which is in equilibrium with the Mo(V) dimer.[12] For the oxidation of the Mo(V) dimer with I_3^- and O_2, Mo(IV) was proposed as a redox active intermediate.[13] On the other hand, for the oxidation of $[Mo_2O_4(edta)]^{2-}$ with $[IrCl_6]^{2-}$ or $[Fe(phen)_3]^{3+}$ (phen=1,10-phenanthroline), it is not necessary to consider an intermediate formation prior to the electron transfer process.[8]

The purpose of this work is to get further information on the oxidation mechanism of the molybdenum(V) complexes of type III, by comparing the behavior of two complexes, $[Mo_2O_4(edta)]^{2-}$ [14] and $[Mo_2O_4(aq)]^{2+}$.[15,16] Coordinated water molecules in the latter are labile to substitution,[17] whereas $[Mo_2O_4(edta)]^{2-}$ is inert unless acid concentration is sufficiently high ($[H^+]>0.5$ M; M=mol dm^{-3}).[14] The μ-hyperoxo dicobalt(III) ion, $[(NH_3)_5CoO_2{}^{(-)}Co(NH_3)_5]^{5+}$ was used as an oxidizing reagent which is known to be reduced through an outer-sphere mechanism to the corresponding μ-peroxo ion by one electron transfer process.[18,19]

Experimental

Materials. *Disodium μ(N,N′)-Ethylenediaminetetraacetato-di-μ-oxo-bis[oxomolybdate(V)] Dihydrate, $Na_2[Mo_2O_4(edta)]\cdot2H_2O$*: The complex was prepared by a method similar to that described previously;[14] dipyridinium pentachlorooxomolybdate(V) ($(pyH)_2[MoOCl_5]$)[20] was used instead of the corresponding ammonium salt.

A Solution of the Aqua Complex of Di-μ-oxo-bis[oxomolybdenum(V)], $[Mo_2O_4(aq)]^{2+}$: Ten grams of $(pyH)_2[MoOCl_5]$ was dissolved in 500 cm^3 of 0.1 M perchloric acid ($HClO_4$). An orange solution was obtained, containing $[Mo_2O_4(aq)]^{2+}$ as the main species. In order to remove impurities, the solution was treated with an ion-exchange column, Dowex 50W-X8 resin (H^+-form). An orange band remained on the column. The column was washed with 100 cm^3 each of 0.1, 0.2, and 0.5 M $HClO_4$ and 50 cm^3 of 1 M $HClO_4$ successively. $[Mo_2O_4(aq)]^{2+}$ was eluted with 2 M $HClO_4$. About 0.05 M (as dimer) solution of $[Mo_2O_4(aq)]^{2+}$ was obtained (*ca.* 150 cm^3). All the preparative and the ion-exchange work was carried out under nitrogen atmosphere to avoid air oxidation of $[Mo_2O_4(aq)]^{2+}$.[14] This procedure is important since Mo(VI)[21] did not seem to have been completely removed by ion-exchange purification. The concentration of $[Mo_2O_4(aq)]^{2+}$ in the eluate was determined spectroscopically from the optical density at 384 nm ($\varepsilon=103$ per dimer[14]).

Other Materials: μ-Hyperoxo-bis[pentaamminecobalt(III)] perchlorate dihydrate, $[(NH_3)_5CoO_2{}^{(-)}Co(NH_3)_5](ClO_4)_5\cdot2H_2O$, was prepared from the chloride salt[23] according to the method of Linhard and Weigel.[24] Sodium perchlorate (special grade) was used for the adjustment of ionic strength without further purification. Lithium perchlorate, used for the adjustment of ionic strength, was prepared from lithium carbonate and perchloric acid, and recrystallized twice. The concentration of the solution of lithium perchlorate (*ca.* 3 M) was determined by exchanging the lithium ion for proton with an ion-exchange regin of H^+-type (Amberlite IR-120), and titration with a standard sodium hydroxide solution.

Measurements. A Hitachi 124 spectrophotometer with

a Hitachi recorder QPD-34 was used for the measurement of visible and ultraviolet absorption spectra and for kinetic studies.

Kinetic Runs. Solutions of $[(NH_3)_5CoO_2{}^{(-)}Co(NH_3)_5](ClO_4)_5 \cdot 2H_2O$ and $Na_2[Mo_2O_4(edta)] \cdot 2H_2O$ were prepared every day, whereas that of $[Mo_2O_4(aq)]^{2+}$ was kept in a refrigerator for *ca.* a week under nitrogen atmosphere. Each solution was kept in a thermostat at the desired temperature for at least 30 min, and mixed to start kinetic runs. The rate of decrease in concentration of the μ-hyperoxo ion was followed at 670 nm, where it has a strong absorption peak (ε= 832 per dimer[25]), and no other compounds involved in the reaction have significant absorption. The reaction cell was shaken quickly at appropriate time intervals in order to remove the bubbles of oxygen gas on the cell walls formed during the course of reaction. For the reaction of $[Mo_2O_4(aq)]^{2+}$, all the procedures were carried out under nitrogen atmosphere with use of syringes, needles and rubber caps. Without such a precaution, it was difficult to get reproducible results. A strong catalytic effect of Mo(VI) on the rate of the reaction seems to be responsible. It was difficult to get the solution of $[Mo_2O_4(aq)]^{2+}$ free from pyridinium ion by the ion-exchange separation. $[Mo_2O_4(aq)]^{2+}$ seems to be eluted easily for dipositive ion. It was found that pyridinium ion does not affect the rate of the reaction up to the concentration 0.01 M.

Results

Kinetics of the Oxidation of $[Mo_2O_4(edta)]^{2-}$ with $[(NH_3)_5CoO_2{}^{(-)}Co(NH_3)_5]^{5+}$. $[Mo_2O_4(edta)]^{2-}$ undergoes acid hydrolysis in aqueous perchloric acid solution ($[H^+]>0.5$ M).[14] In this work, $[H^+]$ was adjusted to 0.1 M or lower so that it was not necessary to consider the effect of acid hydrolysis. When an aqueous solution of $[Mo_2O_4(edta)]^{2-}$ was mixed with that of the μ-hyperoxo dicobalt(III) ion in 0.1 M $HClO_4$, the light absorption of these two ions in the visible region decreased slowly, no rapid change in absorption spectra preceding. No rapid reaction between these two ions other than weak interaction such as ion-pair formation is feasible.

The stoichiometry of the reaction corresponding to the slow change was determined as follows. 0.1 M perchloric acid solutions containing the μ-hyperoxo ions more than twice $[Mo_2O_4(edta)]^{2-}$ in molar concentration were kept at 40 °C for a day, and the amount of remaining μ-hyperoxo ions was estimated from the intensity of the absorption peak at 670 nm. Two moles of the μ-hyperoxo ions were consumed per one mol of $[Mo_2O_4(edta)]^{2-}$. Thus each molybdenum(V) ion in the complex was oxidized to Mo(VI) by one μ-hyperoxo ion. The μ-peroxo ion, $[(NH_3)_5CoO_2{}^{(2-)}Co(NH_3)_5]^{4+}$, the initial product of the electron transfer reaction should have decomposed rapidly in acid solutions to give Co(II), O_2, and ammonium ions.[26] Mo(VI) is in dimer-monomer equilibrium.[22] The coordination of the edta-ligand is unlikely under the given acid concentration.[27] The entire reaction can be written as follows.

$$[Mo_2O_4(edta)]^{2-} + 2[(NH_3)_5CoO_2{}^{(-)}Co(NH_3)_5]^{5+} + (20+n)H^+ \longrightarrow 2Mo(VI) + H_nedta^{(4-n)-} + 4Co(II) + 2O_2 + 20NH_4^+ \quad (1)$$

Kinetics of the reaction was studied at 35—50 °C and ionic strength 0.1—2.0 M (adjusted with $NaClO_4$). The molybdenum(V) complex was used in at least 10 fold excess to the μ-hyperoxo ion. The first-order plots log (OD_t) against time t are linear to over 90% of the course of reaction (OD_∞ was approximated to zero), where OD_t stands for the absorbance at 670 nm at time t. The first-order rate constant k_{obsd} is independent of $[H^+]$ in the range 0.05—0.1 M. The dependence of k_{obsd} on the concentration of $[Mo_2O_4(edta)]^{2-}$ at various ionic strengths is shown in Fig. 2. The rate constant increases with decrease in the ionic strength, tending to be saturated at higher concentrations of $[Mo_2O_4(edta)]^{2-}$. The plots $k_{obsd}{}^{-1}$ against $[Mo_2O_4(edta)^{2-}]^{-1}$ are linear (Fig. 3). Intercepts of the straight

The dependence of k_{obsd} on $[Mo_2O_4(edta)^{2-}]$ for the oxidation of $[Mo_2O_4(edta)]^{2-}$ with $[(NH_3)_5CoO_2{}^{(-)}Co(NH_3)_5]^{5+}$ in 0.1 M perchloric acid, with $[Mo_2O_4(edta)]^{2-}$ in large excess at various ionic strengths (adjusted with $NaClO_4$), at 40 °C and $[\mu\text{-}O_2{}^{(-)}] = (2—5) \times 10^{-4}$ mol dm^{-3}.

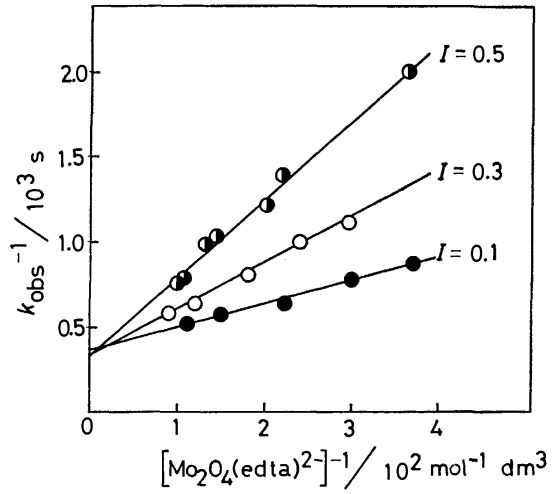

Fig. 3. The dependence of $k_{obsd}{}^{-1}$ on $[Mo_2O_4(edta)^{2-}]^{-1}$ for the oxidation of $[Mo_2O_4(edta)]^{2-}$ with $[(NH_3)_5CoO_2{}^{(-)}Co(NH_3)_5]^{5+}$ in 0.1 M perchloric acid, with $[Mo_2O_4(edta)]^{2-}$ in large excess at various ionic strength (adjusted with $NaClO_4$), at 40 °C and $[\mu\text{-}O_2{}^{(-)}] = (2—5) \times 10^{-4}$ mol dm^{-3}.

lines at three different ionic strengths coincide with each other within experimental error. The rate of Reaction 1 does not change in the presence of Cl^- up to 0.1 M.

Kinetics of the Oxidation of $[Mo_2O_4(aq)]^{2+}$ *with* $[(NH_3)_5CoO_2^{(-)}Co(NH_3)_5]^{5+}$. Similar to the case of the oxidation of $[Mo_2O_4(edta)]^{2-}$, the reaction of $[Mo_2O_4(aq)]^{2+}$ with the μ-hyperoxo ion is expressed as follows from the change of absorption spectra and stoichiometric studies in 2 M $HClO_4$:

$$[Mo_2O_4(aq)]^{2+} + 2[(NH_3)_5CoO_2^{(-)}Co(NH_3)_5]^{5+} + 20H^+ \longrightarrow 2Mo(VI) + 4Co(II) + 2O_2 + 20NH_4^+. \quad (2)$$

Kinetics of the reaction was studied at 25—40 °C for $[H^+]=0.5$—2.0 M. It was difficult at lower $[H^+]$ to get the concentration of $[Mo_2O_4(aq)]^{2+}$ high enough for the kinetic studies. $[Mo_2O_4(aq)]^{2+}$ undergoes structural change for $[H^+]<0.1$ M.[14,17] The molybdenum complex was used in large excess as compared to the μ-hyperoxo ion. The concentration ranges of the reactants are $(8—35)\times10^{-3}$ M for $[Mo_2O_4(aq)]^{2+}$ and $(2.5—5)\times10^{-4}$ M for the μ-hyperoxo ion.

The decrease of absorbance (OD) at 670 nm did not obey the first order rate law. The OD decreased linearly with time at the initial stage of the reaction (until the concentration of the μ-hyperoxo ion reached *ca.* 1.5×10^{-4} M), and subsequently more slowly. The slope of the plots, OD_t against t, did not change when the concentration of the μ-hyperoxo ion changed from 3×10^{-4} to 5×10^{-4} M at a constant concentration of $[Mo_2O_4(aq)]^{2+}$.

The OD change per second was converted into the molar consumption of the μ-hyperoxo ion per second (denoted by k_i) by using the ε value (832)[25] at 670 nm. The dependence of k_i on the concentration of $[Mo_2O_4(aq)]^{2+}$ at $[H^+]=2.0$ M (Fig. 4) suggests that k_i is of first-order with respect to $[Mo_2O_4(aq)^{2+}]$.

The effect of $[H^+]$ on k_i was studied with a fixed concentration of the reactants and at $I=2.0$ M ($LiClO_4$). The k_i values seem to be inversely proportional to $[H^+]$.

The effect of anions added was studied for Cl^- and Br^-. Significant acceleration of the rate by both ions was observed. The rate of disappearance of the μ-hyperoxo ion turned out to be of first-order. Under the conditions $[H^+]=2.0$ M, $[Mo_2O_4(aq)^{2+}]=8.55\times10^{-3}$ M, $[\mu\text{-}O_2^{(-)}]=3.50\times10^{-4}$ M, and $[Cl^-]=0.12$ M and at 35 °C, $\tau_{1/2}$ is about 4 min, whereas under similar conditions in the absence of Cl^-, it took more than 8 h for the reaction to complete. The effect of Br^- is of similar magnitude to that of Cl^-. Mo(VI) also accelerates the rate. The rate of disappearance of the μ-hyperoxo ion remained in zero-order for a much longer part of the reaction. Under the conditions $[H^+]=2.0$ M, $[Mo_2O_4(aq)^{2+}]=8.55\times10^{-3}$ M, $[\mu\text{-}O_2^{(-)}]=3.50\times10^{-4}$ M and [Mo(VI)] (as sodium molybdate) $=0.015$ M, the rate was *ca.* 4 times greater than that without Mo(VI). The extent of enhancement depends approximately linearly on the concentration of the Mo(VI) ($[Mo(VI)]=(0.5—3)\times10^{-2}$ M). The effect was more remarkable at lower acid concentrations. Apparently the effect depends on the time after mixing of $[Mo_2O_4(aq)]^{2+}$ and Mo(VI).

It must be considered whether the Mo(VI) which is built up during the kinetic runs is catalytic to Reaction 2. The Mo(VI) concentrations are equal to the initial concentrations of the μ-hyperoxo ion at the end of the runs: $(2.5—5)\times10^{-4}$ M. It is therefore concluded that the Mo(VI) produced does not have a significant effect upon the rate of the reaction, at least at the initial part of the reaction which is important in this study.

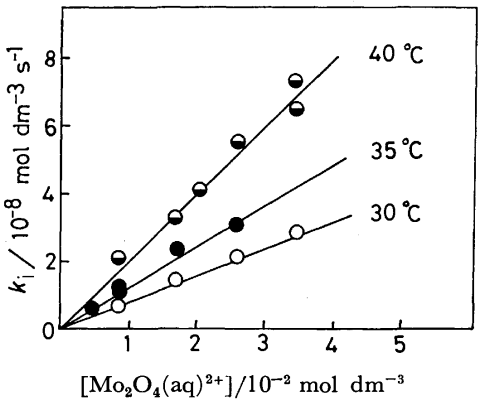

Fig. 4. The dependence of k_i on $[Mo_2O_4(aq)^{2+}]$ for the oxidation of $[Mo_2O_4(aq)]^{2+}$ with $[(NH_3)_5CoO_2^{(-)}Co(NH_3)_5]^{5+}$ in 2 M perchloric acid, with $[Mo_2O_4(aq)]^{2+}$ in large excess, at various temperatures and $[\mu\text{-}O_2^{(-)}]=(2.5—5)\times10^{-4}$ mol dm^{-3}.

Discussion

Mechanism of the Oxidation of $[Mo_2O_4(edta)]^{2-}$ *by* $[(NH_3)_5CoO_2^{(-)}Co(NH_3)_5]^{5+}$. The results shown in Figs. 1 and 2 can be interpreted in terms of an ion-pair formation between the two reactants, the formation constant being expected to be large since they have high opposite charges (+5 and −2).

Since the μ-hyperoxo ion is one electron oxidizing reagent, oxidation of dimeric $[Mo_2O_4(edta)]^{2-}$ should proceed in two steps, and an immediate product of the first electron transfer process should be a mixed valence dimer, "$Mo^{V}Mo^{VI}$," the structure of which is not known. Wharton *et al.*[8] studied the oxidation of $[Mo_2O_4(edta)]^{2-}$ with $[IrCl_6]^{2-}$ and $[Fe(phen)_3]^{3+}$, and found that the following reactions are reversible:

$$[Mo_2O_4(edta)]^{2-} + \underset{([Fe(phen)_3]^{3+})}{[IrCl_6]^{2-}} \rightleftharpoons \underset{([Fe(phen)_3]^{2+})}{\text{“}Mo^{V}Mo^{VI}\text{”} + [IrCl_6]^{3-}}. \quad (3)$$

They suggested that the mixed valence dimer most likely decomposes into two monomers Mo(V) and Mo(VI), the former being rapidly oxidized by the oxidant. In the present case, the process corresponding to Reaction 3 is not reversible since the reduced form of the oxidant decomposes rapidly under the experimental conditions.[26] The oxidation of "$Mo^{V}Mo^{VI}$" by the second μ-hyperoxo ion should be rapid possibly through the decomposition into the monomers. There was no intermediate (corresponding to "$Mo^{V}Mo^{VI}$") detectable from the change of absorption spectra during the course of reaction and from the kinetic treatment.

The following mechanism (4—7) is proposed for

Reaction 1, where μ-$O_2^{(-)}$ and μ-$O_2^{(2-)}$ stand for $[(NH_3)_5CoO_2^{(-)}Co(NH_3)_5]^{5+}$ and $[(NH_3)_5CoO_2^{(2-)}Co(NH_3)_5]^{4+}$, respectively:

$$[Mo_2O_4(edta)]^{2-} + \mu\text{-}O_2^{(-)} \overset{K_{IP}}{\rightleftharpoons} \text{ion-pair}, \quad (4)$$

$$\text{ion-pair} \xrightarrow{k_e} \text{“}Mo^{V}Mo^{VI}\text{”} + \mu\text{-}O_2^{(2-)}, \quad (5)$$

$$\text{“}Mo^{V}Mo^{VI}\text{”} + \mu\text{-}O_2^{(-)} \xrightarrow{\text{fast}} 2Mo(VI) + \mu\text{-}O_2^{(2-)}, \quad (6)$$

$$\mu\text{-}O_2^{(2-)} \xrightarrow[H^+]{\text{fast}} 2Co(II) + O_2 + 10NH_4^+. \quad (7)$$

From this, we obtain

$$-\frac{d[\mu\text{-}O_2^{(-)}]}{dt} = \frac{2k_eK_{IP}[Mo_2O_4(edta)^{2-}][\mu\text{-}O_2^{(-)}]}{1+K_{IP}[Mo_2O_4(edta)^{2-}]}, \quad (8)$$

which is in line with the experimental results. k_{obsd} can be expressed by

$$k_{obsd} = \frac{2k_eK_{IP}[Mo_2O_4(edta)^{2-}]}{1+K_{IP}[Mo_2O_4(edta)^{2-}]}, \quad (9)$$

which can be rearranged to

$$\frac{1}{k_{obsd}} = \frac{1}{2k_eK_{IP}[Mo_2O_4(edta)^{2-}]} + \frac{1}{2k_e}. \quad (10)$$

For I=2.0, where the ion-pair formation is less favorable due to the presence of higher concentration of the electrolyte, $NaClO_4$, the assumption $1 \gg K_{IP}[Mo_2O_4(edta)^{2-}]$ would be useful for interpretation of the experimental results. The values of k_e, K_{IP}, and k_eK_{IP} are calculated from the data for various ionic strengths (Table 1). The k_e values are almost constant regardless of ionic strength, suggesting that the rate of electron transfer process within the ion-pair is not affected by ionic strength. The results provide an excellent example of electron transfer within an ion-pair.

Table 1. Rate constants and ion-pair formation constants for the oxidation of $[Mo_2O_4(edta)]^{2-}$ with $[(NH_3)_5CoO_2^{(-)}Co(NH_3)_5]^{5+}$ in 0.1 M perchloric acid[a]
(Ionic strengths were adjusted with $NaClO_4$)

Ionic strength (I)	Temperature (°C)	k_e (10^{-3} s^{-1})	K_{IP} (mol dm^{-3})	k_eK_{IP} (10^{-1} s^{-1} mol dm^{-3})
0.1	35.4	0.64±0.01	320±10	2.02±0.05
0.1	40.0	1.34±0.08	270±40	3.62±0.05
0.1	45.0	2.5 ±0.2	350±70	8.9 ±1.3
0.3	40.0	1.5 ±0.1	120±20	1.8 ±0.1
0.5	40.0	1.5 ±0.2	70±20	1.07±0.05
2.0	40.0			0.40±0.02
2.0	45.0			0.78±0.04
2.0	51.2			1.8 ±0.2

a) Errors were determined by the least-square treatment with no weighing (confidence level, 0.7).

The activation parameters were compared with those of oxidation of $[Mo_2O_4(edta)]^{2-}$ with other oxidants (Table 2). The parameters vary remarkably with the charge of the oxidant. This suggests the important role of electrostatic interactions on the reaction mechanism.

Table 2. Comparison of the activation parameters for the oxidation of $[Mo_2O_4(edta)]^{2-}$ with various oxidants

Oxidant	Term	I (M)	$\Delta H^{\ddagger}$ (kcal mol^{-1})	$\Delta S^{\ddagger}$ (cal K^{-1} mol^{-1})
$[(NH_3)_5CoO_2^{(-)}Co(NH_3)_5]^{5+}$	k_e	0.1	28 ±4	18 ±11
$[(NH_3)_5CoO_2^{(-)}Co(NH_3)_5]^{5+}$	k_eK_{IP}	2.0	26.5±0.8	21 ± 3
$[Fe(phen)_3]^{3+}$ [a]	k_eK_{IP} [b]	1.0	16.6±0.4	12.3±1.3
$[IrCl_6]^{2-}$ [a]	k_e [b]	1.0	13.3±0.3	−10.0±1.0

a) From Ref. 8. b) The term was assumed from the charge of the reactants.

Kinetics of the Oxidation of $[Mo_2O_4(aq)]^{2+}$ with $[(NH_3)_5CoO_2^{(-)}Co(NH_3)_5]^{5+}$. The following mechanism is proposed to explain the experimental results: It involves the conversion of $[Mo_2O_4(aq)]^{2+}$ into an intermediate A which is then oxidized by the μ-hyperoxo ion;

$$[Mo_2O_4(aq)]^{2+} \overset{k_1}{\underset{k_{-1}}{\rightleftharpoons}} A, \quad (11)$$

$$A + \mu\text{-}O_2^{(-)} \xrightarrow{k_2} \text{“}Mo^{V}Mo^{VI}\text{”} + \mu\text{-}O_2^{(2-)}. \quad (12)$$

Reaction 12 is followed by similar steps to those of Reactions 6 and 7. By applying stationary state approximation to A, we obtain

$$-\frac{d[\mu\text{-}O_2^{(-)}]}{dt} = \frac{2k_1k_2[\mu\text{-}O_2^{(-)}][Mo_2O_4(aq)^{2+}]}{k_{-1}+k_2[\mu\text{-}O_2^{(-)}]}. \quad (13)$$

If $k_{-1} \ll k_2[\mu\text{-}O_2^{(-)}]$, this can be simplified to

$$-\frac{d[\mu\text{-}O_2^{(-)}]}{dt} = 2k_1[Mo_2O_4(aq)^{2+}], \quad (14)$$

which is consistent with the observed zero-order dependence of the rate on $[\mu\text{-}O_2^{(-)}]$ at the initial part of the reaction.

For most of the runs, only k_i (equal to $2k_1$) was estimated from the initial part of the absorbance change. No other rate constants were estimated since the reaction was too slow to be followed until completion. Attempts to work with a large excess of the μ-hyperoxo ion as compared to the molybdenum complex, which may be more useful for checking Eq. 13, were not successful. No appropriate wavelength was found at which absorbance change was sufficiently big.

The reciprocal dependence of k_i on $[H^+]$ can best be explained by assuming a conjugate base of the aqua ion, $[Mo_2O_4(OH)(aq)]^+$. As the $[H^+]$-independent path is negligible, intermediate A should be formed almost exclusively from this conjugate base. k_i is then expressed by

$$k_i = 2k_1 = 2k_{OH}K_a[H^+], \quad (15)$$

where k_{OH} is the rate constant for the formation of A from $[Mo_2O_4(OH)(aq)]^+$. K_a is the acid dissociation constant of $[Mo_2O_4(aq)]^{2+}$. It is assumed to be negligibly small as compared with $[H^+]$. The K_a value was not obtained, and the only relevant datum is the pK_a value (3.02) of the aqua ligand of $[Mo_2O_4(hedta)(H_2O)]^-$ (H_3hedta = *N*-(2-hydroxyethyl)ethylenediamine-*N*,*N*′,*N*′-triacetic acid).[28] At 25 °C, $k_{OH}K_a = (4.3 \pm 0.3) \times 10^{-6}$

mol dm^{-3} s^{-1} and the corresponding activation parameters (25—40 °C) are $\Delta H^{\ddagger}=18.5\pm1.4$ kcal mol^{-1} and $\Delta S^{\ddagger}=-21\pm5$ cal K^{-1} mol^{-1}.

Structure of the Intermediate of the Oxidation of $[Mo_2O_4(aq)]^{2+}$. Intermediate A is considered to have a structure similar to that of the type II species (Fig. 1), a single bridged Mo(V) species.

The conversion of type III complexes into type II is known. The structure of Mo(V) was studied in hydrochloric and sulfuric acid solutions of various acid concentrations.[29] Equilibrium 17 exists in these acid solutions, and shifts in a rightward direction as the concentation of acid becomes higher.

$$\underset{\text{(type III)}}{Mo_2O_4^{2+}} \rightleftharpoons \underset{\text{(type II)}}{Mo_2O_3^{4+}} \rightleftharpoons \underset{\text{(type I)}}{2MoO^{3+}} \qquad (16)$$

Our preliminary observation suggests that the rate of interconversion is very great, the interconversion finishing within several seconds at 25 °C in *ca.* 5 M HCl solution. Type II species is known to be predominant in 5 M HCl, and type III in 5 M $HClO_4$.[14] Thus the formation of type II (and possibly type I) complexes seems to be mainly due to the presence of Cl^- or HSO_4^- and not that of proton.

Also the color change of $[Mo_2O_4(L\text{-cys})_2]^{2-}$ (L-cys= L-cysteinate dianion) from orange to blue in basic solution (pH=*ca.* 10) was claimed to be due to slow formation of a single-bridged species.[30,31] Such a change was not observed in a solution of lower pH (<7). The resulting single-bridged species was far more easily oxidized by flavines[32] and cytochrome c[9] than was the parent complex.

Guymon and Spence studied the oxidation of dimeric Mo(V) with NO_3^-,[12] I_3^-,[13] and O_2[13] in tartrate and phosphate buffer solutions, but did not discuss the detailed structure of the Mo(V) dimer they were dealing with. It is now possible to assume reasonably that the complex had type III structure with some buffer anions coordinated.[1] From the EPR measurement and half-order dependence of the rate on the Mo(V) dimer concentration, they proposed monomeric Mo(V) species as an intermediate of the reaction with NO_3^-. For the reaction with I_3^- and O_2, they observed zero-order dependence of the rate on the dimer concentration, and proposed Mo(IV)[33] as a redox active intermediate, assuming the disproportionation of Mo(V) dimer to Mo(IV) and Mo(VI). Reports have recently been given on the disproportionation of some dimeric Mo(V) complexes,[34,35] but they are of only type II complexes with sulfur-donor ligands. No disproportionation of type III complex is yet known. Both Mo(IV) and monomeric Mo(V) species would be regarded as secondary products of type III complexes through type II species. The results of Guymon and Spence on the reactions with I_3^- and O_2 might be explained also in terms of a single-bridged intermediate.

It should be noted that we cannot deny the existence of Mo(IV) and monomeric Mo(V) as a real reacting species for our reaction, if the postulated single-bridged species formed Mo(IV) or monomeric Mo(V) very rapidly (*viz.*, the rate-determining step is still the formation of the single-bridged species). However, the positive catalytic effect of Mo(VI) would not support the involvement of Mo(IV), since the addition of Mo(VI) would be expected to suppress the disproportionation of Mo(V) dimer.[34]

We thus concluded that A is a single-bridged Mo(V) dimer rather than the Mo(V) monomer or the Mo(IV) species.

Influence of Halide Ions and Mo(VI) on the Oxidation of $[Mo_2O_4(aq)]^{2+}$. The presence of Cl^- and HSO_4^- makes a single-bridged Mo(V) dimer predominant over a double-bridged dimer in aqueous acid solutions. The positive catalytic effect of Cl^- and Br^- on Reaction 2 can be explained by this fact. Since the aqua ligands in $[Mo_2O_4(aq)]^{2+}$ are labile,[17] Cl^- and Br^- would readily substitute for the water and might facilitate bridge cleavage. The halide ions and OH^- in $[Mo_2O_4(OH)(aq)]^+$ may exert a similar electronic effect on the bridge cleavage.

We have no explanation for the catalytic effect of Mo(VI) on the rate of Reaction 2. It is possible that a similar interaction to that in molybdenum blue would reduce the stability of Mo_2O_4-moiety, increasing the sensitivity to oxidative attack. The effect depends on the time after mixing Mo(VI) with $[Mo_2O_4(aq)]^{2+}$.

Comparison of the Oxidation Mechanism of the Two Mo(V) Complexes. The most interesting feature of the present results is the difference in the kinetic behavior of the two complexes $[Mo_2O_4(edta)]^{2-}$ and $[Mo_2O_4(aq)]^{2+}$ towards their oxidation by $[(NH_3)_5CoO_2^{(-)}Co(NH_3)_5]^{5+}$. The ion-pair formation was important for the oxidation of $[Mo_2O_4(edta)]^{2-}$ but not favorable for that of positively charged $[Mo_2O_4(aq)]^{2+}$, which gave the zero-order dependence on $[\mu\text{-}O_2^{(-)}]$. In the latter case, formation of a more easily oxidizable intermediate was proposed.

Recently Cayley *et al.*[36] examined the oxidation of $[Mo_2O_4(aq)]^{2+}$ by $[Fe(phen)_3]^{3+}$ or $[IrCl_6]^{2-}$ and found two term rate laws, one term independent of the oxidant concentration and the other linearly dependent on it. Their oxidants ($E_0=1.06$ V and 1.017 V respectively)[37] are marginally better than the μ-hyperoxo ion ($E_0=ca.$ 1.0 V)[38] in terms of redox potentials, and the 5+ charge and inaccessibility of the μ-hyperoxo group are presumably responsible for exclusion of the direct bimolecular route.

Oxidation of $[Mo_2O_4(edta)]^{2-}$ by these three oxidants gave no oxidant independent path. Multidentate edta-ligand would stabilize the Mo_2O_4-moiety through firm coordination, making the cleavage of the oxo bridge more difficult. Also the lack of coordinated water may be an important factor to determine the reaction pattern, since the water ligands of $[Mo_2O_4(aq)]^{2+}$ play important roles for the formation of intermediate. The absence of the effect of Cl^- and the independence of $[H^+]$ for the rate of the reaction of $[Mo_2O_4(edta)]^{2-}$ are explained also by the lack of water ligand.

The author thanks Professor Kazuo Saito for his valuable discussions. He also thanks Dr. A. G. Sykes, The University of Leeds, England, for making his results available prior to publication and also for helpful comments.

Potentiometric and Polarographic Studies on Complex Formation of Cadmium(II) Ion with Ethylenediaminemonoacetic Acid

Noboru OYAMA, Masashi HORIE, Hiroaki MATSUDA, and Hitoshi OHTAKI

Department of Electronic Chemistry, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received January 13, 1977)

The complex formation equilibria between Cd(II) ion and ethylenediaminemonoacetic acid (EDMA) were examined by potentiometry in a 1.0 mol dm^{-3} $NaClO_4$ solution at (25.00±0.02) °C, and it was found that neither protonated nor hydrolyzed complex was formed in the range of pH from 2 to 10. The formation constants of Cd(II)–EDMA complexes as well as the protonation constants of EDMA anion determined were as follows: log-β_{101}=6.86, log β_{102}=12.32; log β_{011}=9.97, log β_{021}=16.71, log β_{031}=18.76, where $\beta_{pqr}=[M_pH_qL_r]/[M]^p[H]^q[L]^r$. The formation constants were also examined polarographically.

In the previous works[1,2] we examined the complex formation equilibria of Cd(II) ion with *N*-(2-hydroxyethyl)ethylenediamine-*N,N',N'*-triacetate (L=hedta^{3-}) and ethylendiamine-*N,N,N',N'*-tetraacetate (L=edta^{4-}) by potentiometric titrations over a wide range of pH, and found that a number of protonated complexes of the type MH_qL (q=1, 2 for the HEDTA complex and q=1, 2, 3 for the EDTA complex) are formed in the acidic region (pH<*ca.* 3.5). Furthermore, from comparison of the successive protonation constants of the complexes with those of the corresponding ligands, we derived the conclusion that the protons of the protonated complexes are located at the acetate groups of the ligands. It can be deduced therefrom that the chelate formation between Cd(II) ion and the ligands occurs through the two nitrogen atoms and at least one acetate group of the ligands and thus when all the acetate groups of the ligands are protonated, such ligands do not form any complex with Cd(II) ion. Then, a question may arise: if the ethylenediamine skeleton has only one acetate group, does such a ligand form a protonated complex with Cd(II) ion ? The present work thus aims at examining the possibility of the formation of protonated complexes between Cd(II) and ethylenediaminemonoacetate (L=edma$^-$) ions. Although the complex formation of Cd(II) ion with edma$^-$ anion was already studied by Fujii *et al.*[3] by polarography, their measurements were done only in a neutral solution (pH 6.0—7.0) of ionic strength of 0.2 mol dm^{-3}. Thus, in the present work we shall reexamine the equilibria between Cd(II) and edma$^-$ ions by potentiometric titrations over a wide range of pH, especially noting the acidic region, in which protonated complexes might be formed. Furthermore, for comparison, we shall describe the results of polarographic measurements performed under the same experimental conditions as for the potentiometric titrations.

Symbols

h	Concentration of hydrogen ion at equilibrium
m	Concentration of metal ion at equilibrium
H	Analytical excess of hydrogen ion in a test solution
c_{Cd}	Total concentration of Cd(II)
L	Ethylenediaminemonoacetate anion (edma$^-$)
c_L	Total concentration of L
l	Concentration of free L
X	Degree of neutralization of HL: $(-H+h-K_w/h)/c_L$
K_w	Autoprotolysis constant of water in 1 mol dm^{-3} $NaClO_4$ solution ($10^{-13.95}$ mol^2 dm^{-6}).[4]
$\bar{n}$	Average number of protons bound to one L
$\bar{Z}$	Average number of edma anions bound to one Cd(II)
p	Number of cadmium ions bound to complex species
q	Number of protons bound to complex species
r	Number of edma anions bound to complex species
s	Number of chloride anions bound to complex species
β_{pqrs}	Equilibrium constant for the reaction $pCd + qH + rL + sCl = Cd_pH_qL_rCl_s$
[ ]	Concentration
[ ]$_t$	Total concentration
D_{Cd}	Diffusion coefficient of aqua cadmium(II) ion
D_c	Average diffusion coefficient of Cd(II)–EDMA complexes
$(E^r_{1/2})_{Cd}$	Reversible half-wave potential of aqua Cd(II) ion
$(E_{1/2})_{rev}$	Reversible half-wave potential of the Cd(II)–EDMA system

All ionic charges are omitted for the sake of convenience.

Experimental

Reagents. *Ethylenediaminemonoacetic acid bis(hydrogen chloride) dihydrate* (Hedma·2HCl·2H_2O) was prepared and purified by the method described by Fujii *et al.*[5] Though we first attempted to obtain crystals of diperchlorate of ethylenediaminemonoacetic acid (EDMA), it was not successful because of their large solubility. The replacement of chloride ions of Hedma·2HCl with perchlorate ions was not attempted, because the stock solution of the ligand may not be accurately standardized with any standard metal solution and the replacement procedure may introduce impurities. Thus, the EDMA solutions used in the present work necessarily contained chloride ions exactly twice as much as edma$^-$ anions. The result of the elemental analysis of the EDMA crystals obtained was as follows: Calcd for $C_4H_{10}N_2O_2$·2HCl·2H_2O: C, 21.26; H, 7.10; N, 12.34%. Found: C, 21.65; H, 7.12; N, 12.29%.

All other chemicals were prepared and purified by the methods described previously.[1,2]

Potentiometric Measurements. The apparatus and the experimental procedures used for potentiometric titrations have been described in the previous paper.[1] The measurements were carried out in a paraffin oil thermostat at (25.00±0.02) °C

by using glass and cadmium-amalgam electrodes. Sodium perchlorate was used as an indifferent salt to keep the perchlorate concentration at 1.0 mol dm^{-3} in all runs.

Polarographic Measurements. The polarographic appratus and the experimental procedures have been described previously.[6]

Results and Discussion

Evaluation of Protonation Constants of EDMA. Overall protonation constants of the edma base, β_{0n1}, were determined from the formation function, $\bar{n}$ and $\bar{n}_{\mathrm{calcd}}$, by using the generalized least squares method;[1]

$$\bar{n}_{\mathrm{calcd}} = (\sum_{n=1}^{3} n\beta_{0n1}h^n)/(1+\sum_{n=1}^{3}\beta_{0n1}h^n), \quad (1)$$

$$\bar{n} = \frac{c_{\mathrm{L}}+H-h+(K_{\mathrm{w}}/h)}{c_{\mathrm{L}}}. \quad (2)$$

The protonation constants obtained were $\log \beta_{011}=9.97$, $\log \beta_{021}=16.71$, and $\log \beta_{031}=18.76$. Fujii *et al.*[7] reported the values of $\log \beta_{011}=10.15$, $\log \beta_{021}=16.80$, and $\log \beta_{031}=18.95$ at an ionic strength 0.2 at 25.0 °C.

Determination of the Composition and the Formation Constants of Complexes by Potentiometric Titrations. Titration curves of the Cd(II)–EDMA solution were shown in Fig. 1. The experiments were carried out under the conditions that the ratios of $c_{\mathrm{Cd}}/c_{\mathrm{L}}$ were 1/1, 1/2, and 1/5, where c_{Cd} and c_{L} were changed from 1 mmol dm^{-3} to 5 mmol dm^{-3} and from 5 mmol dm^{-3} to 25 mmol dm^{-3}, respectively. For each run, c_{Cd} and c_{L} were kept practically constant. As can be seen in Fig. 1, the values of X were independent of c_{Cd} and c_{L} over the pH range 2—5. This result showed that no proton was released from the ligand by the complex formation.

Since a stock solution of the ligand EDMA contains chloride ions, the equilibria of the Cd(II)–EDMA system may be described by the general formula including chloride ions;

$$p\mathrm{Cd}^{2+} + q\mathrm{H}^{+} + r\mathrm{L}^{-} + s\mathrm{Cl}^{-} = \mathrm{Cd}_p\mathrm{H}_q\mathrm{L}_r\mathrm{Cl}_s^{(2p+q-r-s)}, \quad (3)$$

with the equilibrium constant, β_{pqrs}. From the material balance for Cd(II) ion, we obtain

$$c_{\mathrm{Cd}} = [\mathrm{Cd}] + \sum_p\sum_q\sum_r\sum_s p[\mathrm{Cd}_p\mathrm{H}_q\mathrm{L}_r\mathrm{Cl}_s]$$
$$= m + \sum_p\sum_q\sum_r\sum_s p\beta_{pqrs}m^p h^q l^r[\mathrm{Cl}]^s. \quad (4)$$

Rearrangement of Eq. 4 leads to

$$\xi = \log\{(c_{\mathrm{Cd}}-m)/m\}$$
$$= \log\{\sum_p\sum_q\sum_r\sum_s p\beta_{pqrs}m^{p-1}h^q l^r[\mathrm{Cl}]^s\}. \quad (5)$$

As a first approach for analyzing data, we assume that only one complex is formed; then Eq. 5 is reduced to

$$\xi = \log p\beta_{pqrs} + (p-1)\log m + q\log h + r\log l + s\log[\mathrm{Cl}]. \quad (6)$$

The plots of ξ *vs.* $-\log h$ are shown in Fig. 2. From this figure, we can see the following facts in the pH range 2—5. (1) Although ξ seemed to depend on c_{L}, it was independent of $-\log h$, and therefore, ξ can not be a

function of l, which may be approximately calculated by the following equation:

$$l \simeq c_L / \sum_{n=1}^{3} \beta_{0n10} h^n. \quad (7)$$

(2) The dependence of $\bar{\xi}$ on c_L should be explained in terms of the contribution of chloride ions, instead of EDMA anion, in the complex formation. The concentration of chloride ion was $2c_L$ in the present experiment. (3) $\bar{\xi}$ was independent of c_{Cd} at constant c_L (0.005 mol dm^{-3}) within experimental errors. From these results, we can conclude that no Cd–edma complex but a mononuclear $CdCl_s^{(2-s)+}$ complex formed in the pH range of 2—5.

Since $c_{Cd} < c_{Cl}$ in all cases and the degree of complexation of Cd(II) ion with chloride ion is rather small, we can assume that the concentration of free chloride ion ($[Cl]_f$) is almost equal to that of total chloride ion ($[Cl]_t$). When $\bar{\xi}$ is plotted against log $[Cl]_t$ calculated as $\log(2 \times c_L)$, a linear relation of the unit slope resulted (see Fig. 3). Thus, the complex formation, $Cd^{2+} + Cl^- = CdCl^+$, ($p=1$, $q=0$, $r=0$, and $s=1$), took place, and the formation constant was determined as $\log \beta_{1001} = 1.35$ by application of a successive approximation to Eq. 6.

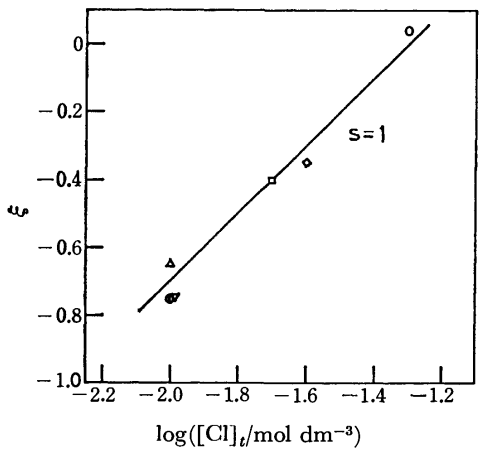

Fig. 3. Plot of $\bar{\xi}$ against log $[Cl]_t$ at $-\log(h/\text{mol dm}^{-3}) = 2.4$. $[Cl]_t$ denotes the total concentration of choride ion.

The constant coincides with the value of 1.35 reported by Vanderzee and Dawson in a 1 mol dm^{-3} $NaClO_4$ solution at 25 °C.[8]

Above pH 5.5, the titration curves of solutions containing Cd(II) ions deviated from that of the solution containing only the ligand, as shown in Fig. 1. In the cases of $c_{Cd}/c_L = 1/1$ and 1/2, white precipitates were separated out in an alkaline region and stable emf's could not be recorded. On the other hand, the titration curves for the case of $c_{Cd}/c_L = 1/5$ converged on a single curve over the pH range 5.5—10.0. Since the titration curves at $c_{Cd}/c_L = 1/5$ were independent of the total concentration of Cd(II) ion (0.001—0.005 mol dm^{-3}), it is seen that no polynuclear complex species was formed. Then, the concentration of free edma is expressed as follows:

$$l = \{c_L + H - h + (K_w/h)\}/(\sum_{n=1}^{3} n\beta_{0n10} h^n), \quad (8)$$

and the formation function $\bar{Z}$ is expressed by

$$\bar{Z} = (c_L - \sum_{n=1}^{3} \beta_{0n10} l h^n)/c_{Cd} \quad (\beta_{0010} = 1), \quad (9)$$

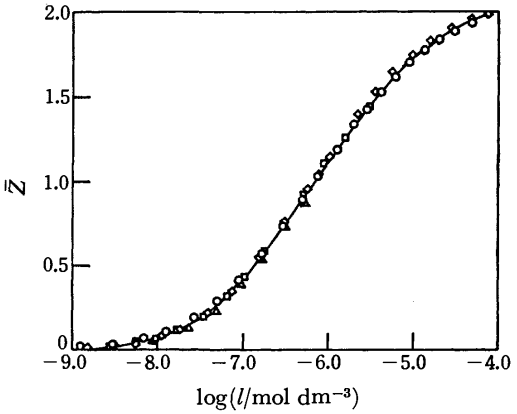

Fig. 4. Relationships between the formation function $\bar{Z}$ and log l. Solid line is the best fit curve calculated by Eq. 11. Symbols are the same as those in Fig. 1.

where c_{Cd} is the total concentration of Cd(II) ion. Figure 4 demonstrates the plots of $\bar{Z}$ *vs.* log l. As can be seen in this figure, a single curve was obtained regardless of the variations of c_{Cd}, c_L, and $[Cl]_t$. Therefore, no mixed complexes of Cd(II) ion with chloride and $edma^-$ ions were formed. Furthermore, the values of $\bar{Z}$ approached 2.0 as the values of log l increased. The formation curve thus obtained could be overlapped with a normalized curve

$$\bar{Z}_{calcd} = (pv + 2v^2)/(1 + pv + v^2), \quad (10)$$

with $p = \beta_{1010}/\sqrt{\beta_{1020}}$, and $\log v = \log l + 1/2 \log \beta_{1020}$,[9] and thus the formation of the CdL^+ and CdL_2^0 complexes was concluded. The formation constants of these complexes were evaluated from the best fit curve with the experimental one. By using the values, $\log \beta_{1010} = 6.9$ and $\log \beta_{1020} = 12.3$, thus determined as the initial values, the formation constants were refined by means of a generalized least squares method in which the minimum error square sum $U = \Sigma(\bar{Z}_{calcd} - \bar{Z})^2$ was

searched, where $\bar{Z}_{calcd}$ is given by

$$\bar{Z}_{calcd} = (\beta_{1010}l+2\beta_{1020}l^2)/(1+\beta_{1010}l+\beta_{1020}l^2). \quad (11)$$

The results were shown in Table 1. The solid curve in Fig. 4 represents the calculated one by using the final values.

Determination of the Formation Constants by Polarography. As described in the section of potentiometric measurements, the CdL^+ and CdL_2 complexes were formed at pH>6.0. In order to examine the polarographic behavior of these complexes, the change of the half-wave potential with l was measured over the pH range 6.0—7.5. No buffer reagent was used, because the test solutions have a sufficient buffer capacity due to the ligand itself which is present in a large excess in comparison with Cd(II) ion. Single waves with the diffusion-controlled limiting current were observed and the conventional log-plots of the current-potential curves yielded straight lines with the reciprocal slopes of (30±1) mV, in accord with the fact that the reversible two-electron reduction occurred. Since the half-wave potential shifted to the negative side with the increase of pH, the formation constants of the complexes can be determined from this shift by the method developed by DeFord and Hume.[10,11]

DeFord and Hume's function F_0 is defined as follows:

$$F_0 = \sum_{r=0}^{N}\beta_{10r0}l^r$$

$$= (D_{Cd}/D_c)^{1/2}\exp\left(\frac{nF}{RT}\right)\{(E_{1/2}^r)_{Cd}-(E_{1/2})_{rev}\}. \quad (12)$$

The factor $(D_{Cd}/D_c)^{1/2}$ was obtained from the ratio of the diffusion current of Cd(II) ion to that of the complexes. The measured value of −0.575 V *vs.* SCE was used for $(E_{1/2}^r)_{Cd}$. A new function $F_1=(F_0-1)/l$ is defined and extrapolation of the F_1 curve toward $l=0$ gives an intercept corresponding to β_{1010}. The procedure was repeated until a horizontal line was obtained. The sets of the plots analyzed to obtain β_{10r0} are shown in Fig. 5. The formation constants β_{1010} and β_{1020} thus found are given in Table 1. In these procedures, the complex formation of Cd(II) ion or Cd–edma complex with chloride ion was neglected.

As can be seen from Table 1, the values of the formation constants of 1 : 1 and 1 : 2 Cd(II)–edma complexes obtained by polarography were larger than the values

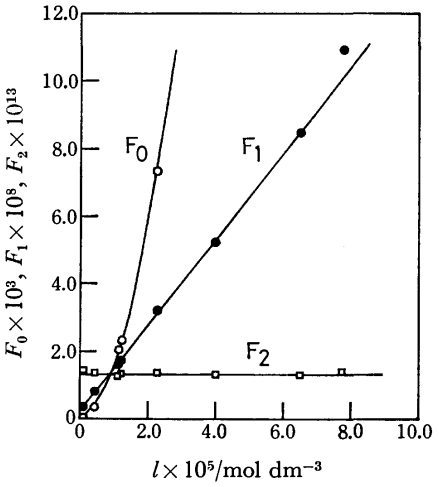

Fig. 5. Dependence of F_p (p=0, 1, 2) on l at total EDMA concn=0.0100 mol dm^{-3}.

obtained by potentiometry. Such discrepancies have sometimes been observed for the complex formation of Cd(II) ion with other multidentate ligands. The value of log β_2 of the Cd(II)–diethylenetriamine complex obtained by potentiometry[12,13] is 13.9, whereas the value determined by polarography[14] is 14.8. Log β_1 of the Cd(II)–triethylenetetramine complex is estimated to be 10.8 by potentiometry,[15] whereas the value for this complex obtained by polarography[14] is 13.9. Thus the values obtained by polarography are often larger than those obtained by potentiometry. The difference in these values may be attributed to the difference in the methods employed, but the reason is not clear yet.

The ethylenediaminemonoacetate ligand formed no protonated complex with Cd(II) ion. In combination with the results obtained in the previous works for the Cd(II)–edta[2] and –hedta[1] complexes, we concluded that the two nitrogen atoms and at least one acetate group are indispensable for the chelate formation of a diaminepolyacetate ligand with Cd(II) ion.

The authors thank Dr. Yuki Fujii, Department of Chemistry, Ibaraki Univ., for his suggestion for preparing and purifying ethylenediaminemonoacetic acid.

Semiintegral Electroanalysis in the Absence of Supporting Electrolyte

Masashi GOTO,* Morten GRENNESS,** and Keith B. OLDHAM
Department of Chemistry, Trent University, Peterborough, Ontario, Canada
(Received January 24, 1977)

The limiting semiintegral of the current which flows when a stationary electrode is progressively polarized in the presence of electroactive species has been investigated under the condition of no supporting electrolyte present in the solution. The semiintegral, $m(t)$, of the current, $i(t)$, is defined by

$$m(t) = \frac{d^{-1/2}}{dt^{-1/2}} i(t) = \frac{1}{\pi^{1/2}} \int_0^t \frac{i(\lambda)}{(t-\lambda)^{1/2}} d\lambda.$$

The electroreduction of a number of heavy metal ions has been studied at a mercury drop electrode and it was found that the limiting semiintegral is larger than that observed with excess supporting electrolyte present. The finding is in agreement with a simple theory which considers both diffusion and migration mass transfer processes. The factor by which the limiting semiintegral increases has been shown to depend on the diffusion coefficients and charge numbers of the cation and anion.

Basic theory of the new electroanalytical method "semiintegral electroanalysis" has been presented and experimentally verified in previous papers.[1,2] It has been also demonstrated[1,3] that semiintegral electroanalysis has the merit of being completely independent of the signal under typical electroanalytical conditions. The independence of the limiting semiintegral of current, $m(\tau)$, from the form of the applied potential signal permits a large resistance to be present in the solution without impairment of the analysis, so that semiintegral electroanalysis can tolerate very low or even zero supporting electrolyte concentrations. Existing theory,[1] however, is based on the assumption that the mass transport is by diffusion only, whereas migration must also be admitted if the supporting electrolyte concentration is not in excess. In this article we show both theoretically and experimentally that the proportionality between $m(\tau)$ and the electroactive concentration is maintained even in the total absence of supporting electrolyte. The constant of proportionality is, however, different from the excess supporting electrolyte case. The implication of these findings for semiintegral electroanalysis in such fresh waters as lakes and rivers is clear.

Theory

The exact treatment of any electroanalytical experiment under conditions in which both migration and diffusion are important is inordinately difficult. Nevertheless, there have been numerous attempts to overcome this difficulty,[4-10] especially in the context of chronopotentiometry. Some of these treatments have been very sophisticated and, in comparison, our present treatment is naive.

Consider a plane indicator electrode immersed in an unstirred solution containing only two ions: those of species O (cation) and P (anion), without any supporting electrolyte. Only the species O is reduced by the z_O electron reaction,

$$O(soln) + z_O e^- \longrightarrow R(solid\ or\ amalgam) \quad (1)$$

to the initially-absent species R, which is uncharged. The solution is assumed to extend to infinity in the direction perpendicular to the electrode. According to the established theories,[11-13] the rate of change in concentration of O at a distance x from the electrode surface at a time t is presented by

$$\frac{\partial C_O(x,t)}{\partial t} = -\frac{\partial J_O(x,t)}{\partial x} = \frac{D_O D_P[z_O - z_P]}{[z_O D_O - z_P D_P]} \frac{\partial^2 C_O(x,t)}{\partial x^2}, \quad (2)$$

where C is the concentration, J is the flux, D is the diffusion coefficient, z is the charge number, and the subscripts represent the species concerned. The flux of O is given by the following equation:

$$J_O(x,t) = -\frac{1}{[z_O D_O - z_P D_P]} \times \left\{ D_O D_P [z_O - z_P] \frac{\partial C_O(x,t)}{\partial x} + \frac{D_O i(t)}{AF} \right\}, \quad (3)$$

where $i(t)$ is the faradaic current at a time t, A is the electrode area, and F is the Faraday constant.

Equation 2 is identical with Fick's second law except that the diffusion coefficient is replaced by the composite constant $D_O D_P (z_O - z_P) / (z_O D_O - z_P D_P)$. Accordingly, when combined with the initial condition,

$$C_O(x, 0) = C_O = \text{constant}, \quad (4)$$

corresponding to a uniform O concentration before electrolysis, and the boundary condition,

$$C_O(\infty, t) = C_O, \quad (5)$$

appropriate to semiinfinite conditions, the equation

$$\frac{\partial^{1/2}}{\partial t^{1/2}} [C_O(x,t) - C_O] = -\sqrt{\frac{D_O D_P (z_O - z_P)}{z_O D_O - z_P D_P}} \frac{\partial C_O(x,t)}{\partial x} \quad (6)$$

may be derived in a strictly analogous way to that used[14] in establishing the theory of semiintegral electroanalysis with excess supporting electrolyte. $\partial^{1/2}/\partial t^{1/2}$ is the partial semidifferentiation operator with respect to t and the semidifferentiation operator, $d^{1/2}/dt^{1/2}$, is defined by

$$\frac{d^{1/2}}{dt^{1/2}} f(t) = \frac{d}{dt} \left[\frac{1}{\pi^{1/2}} \int_0^t \frac{f(\lambda)}{(t-\lambda)^{1/2}} d\lambda \right].$$

Since only the species O reacts at the electrode, the

** Present address: Chloride Technical Limited, Swinton, Manchester, England.

fluxes of each species at the electrode surface are given by

$$J_O(0,t) = \frac{-i(t)}{z_O AF}, \quad (7)$$

and

$$J_P(0,t) = 0. \quad (8)$$

The combination of Eqs. 3, 6, and 7 produces

$$\frac{\partial^{1/2}}{\partial t^{1/2}}[C_O(0,t) - C_O] = \frac{z_P\sqrt{D_P}\,i(t)}{z_O AF\sqrt{D_O}\sqrt{z_O - z_P}\sqrt{z_O D_O - z_P D_P}}. \quad (9)$$

Semiintegrating Eq. 9 and rearranging terms, we obtain

$$m(t) = z_O AF\sqrt{D_O}[C_O(0,t) - C_O]\frac{\sqrt{z_O - z_P}\sqrt{z_O D_O - z_P D_P}}{z_P\sqrt{D_P}}. \quad (10)$$

The limiting semiintegral of current at the time τ, when the concentration of O at the electrode surface is equal to zero, is

$$m(\tau) = z_O AF\sqrt{D_O}C_O\left[\frac{\sqrt{z_O - z_P}\sqrt{z_O D_O - z_P D_P}}{-z_P\sqrt{D_P}}\right] \quad (11)$$

$$= m(\tau)_{xse}\sqrt{\frac{D_O}{D_{OC}}}\sqrt{1 - \frac{z_O}{z_P}}\sqrt{1 - \frac{z_O D_O}{z_P D_P}}, \quad (12)$$

where $m(\tau)_{xse}$ and D_{OC} are the semiintegral of current at the time τ and the diffusion coefficient of O respectively in the solution containing excess supporting electrolyte. Equation 11 is the basic relationship between the limiting semiintegral and concentration for this method in the absence of supporting electrolyte. Equation 11 will be verified by testing experimentally Eq. 12 in the remainder of this paper.

Experimental

The salts $Cd(NO_3)_2$, $CdCl_2$, $CdSO_4$, $Ni(NO_3)_2$, $NiCl_2$ $NiSO_4$, $Cu(NO_3)_2$, $CuSO_4$, $Cu(CH_3COO)_2$, $Zn(NO_3)_2$, $ZnSO_4$, $Pb(NO_3)_2$, $TlNO_3$, and $InCl_3$ were used as solutes. The concentration of solutions for the present study was 1.00 mmol/l or 5.00 mmol/l. In order to measure limiting semiintegral in excess supporting electrolyte, 100 mmol/l or 200 mmol/l KNO_3 was used as a supporting electrolyte. The electrolytic solutions were deoxygenated by bubbling argon gas. The reagents were generally of laboratory grade or in some cases analytical grade. The distilled water for solutions and cleaning of glassware was further deionized by ion exchange resin, the conductivity corresponding to less than 0.02 ppm NaCl.

Three electrodes, cell and instrumentation were substantially the same as previously reported.[1,2] Simple or capped ramp signals were applied to a hanging mercury drop electrode *vs.* a saturated calomel electrode by using a mercury pool as a counter electrode. All the experimental work was carried out at room temperature (≈22°C).

In polarography, difficulties frequently arise from the presence of polarographic maxima. Similar difficulties have been experienced in the present study. The maxima were suppressed, whenever possible, by prepolarizing the hanging mercury drop electrode at the initial (equilibrium) potential for a few minutes. In more severe cases the addition of small quantities of methyl red or a freshly prepared solution of gelatin (0.2%) was required. In general it was found that the maxima were more pronounced in solutions without supporting electrolyte, possibly because the current density is less uniform.

Results and Discussion

As typical examples of investigated species, Figs. 1 and 2 show the neopolarograms of 1.00 mmol/l $Cd(NO_3)_2$ and $TlNO_3$, respectively, in the absence of supporting electrolyte together with those in excess supporting electrolyte. The "neopolarograms" are the graphs *vs.* potential, E, of the semiintegral of current, m. The value m is measurable in the unit[1] of A $s^{1/2}$ or C $s^{-1/2}$. The shape of neopolarograms in the absence of supporting electrolyte is apparently deformed by the potential drop resulting from a large resistance present in solution, however the semiintegral levels off at a plateau. The upward slope of the plateau is more pronounced than in the presence of supporting electrolyte.[15] The limiting semiintegral values were determined by the empirical procedure illustrated by the dashed lines in curve I of Fig. 1.

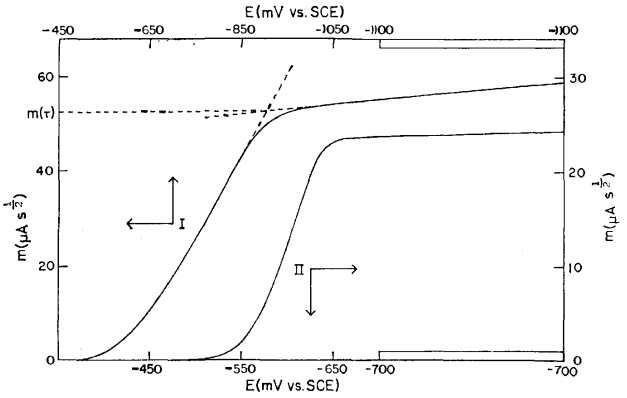

Fig. 1. Neopolarograms of 1.00 mmol/l $Cd(NO_3)_2$ in the absence and presence of supporting electrolyte. Electrode area: 4.69×10^{-2} cm^2, Scan rate: 100 mV/s, supporting electrolyte: I none, II 100 mmol/l KNO_3.

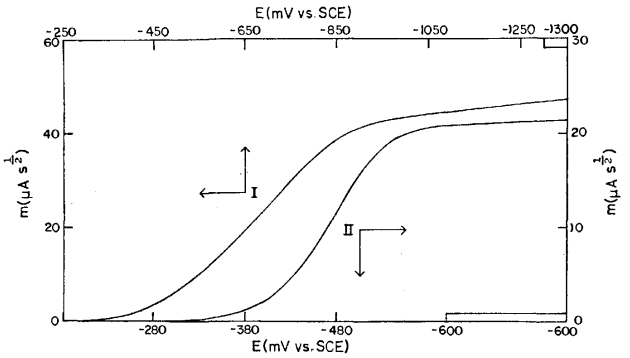

Fig. 2. Neopolarograms of 1.00 mmol/l $TlNO_3$ in the absence and presence of supporting electrolyte. Conditions as in Fig. 1.

In order to verify Eq. 12 the limiting semiintegrals in both the absence of supporting electrolyte and the presence of excess supporting electrolyte were measured for various salts of uni-, bi-, and ter-valent cations, and their ratios are listed in Table 1. The limiting semi-

Table 1. $m(\tau)/m(\tau)_{xse}$ ratios for various salts

	100	31.0		

integral in the absence of supporting electrolyte was, in general, about twice larger than that observed in the excess supporting electrolyte, the ratio $m(\tau)/m(\tau)_{xse}$ being the largest for $Pb(NO_3)_2$ and the smallest for $CuSO_4$.

Table 2. Diffusion coefficients at infinite dilution at 25 °C[16]

Cation	$D\times10^6$ (cm^2/s)	Anion	$D\times10^6$ (cm^2/s)
K^+	19.8	Cl^-	20.3
Tl^+	20.0	NO_3^-	19.2
Pb^{2+}	9.8	CH_3COO^-	10.9
Cd^{2+}	7.2	SO_4^{2-}	10.8
Zn^{2+}	7.2		
Cu^{2+}	7.2		
Ni^{2+}	6.9		
In^{3+}	5.6		

Table 2 shows literature values[16] of diffusion coefficients (except the case of In^{3+}) for various ions under the condition of infinite dilution at 25 °C. For the case of In^{3+}, the known limiting equivalent conductances of ions λ°,[17] of ter-valent lanthanide cations were plotted against the crystal ionic radii, r.[18] There is a linear relationship between the two quantities as shown in

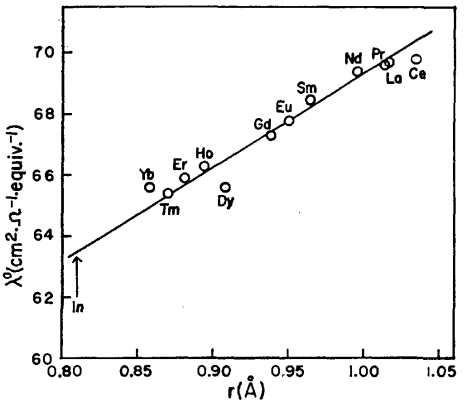

Fig. 3. Relationship between limiting equivalent ionic conductances and crystal ionic radii for ter-valent cations at 25 °C.

Table 3. Diffusion coefficients in excess supporting electrolyte at 25 °C[19]

Ion	Supporting electrolyte		$D\times10^6$ (cm^2/s)
Tl^+	0.1 mol/l	KNO_3	18.2
Pb^{2+}	0.1 mol/l	KNO_3	8.28
Cd^{2+}	0.1 mol/l	KNO_3	6.90
Zn^{2+}	0.1 mol/l	KNO_3	6.38
Cu^{2+}	0.1—0.2 mol/l	KNO_3	6.94[a]
Ni^{2+}	0.1 mol/l	KNO_3	6.86[a]
In^{3+}	0.1 mol/l	KNO_3	5.23[a]

a) Value evaluated by semiintegral electroanalysis.

Fig. 3. The limiting equivalent conductance of 1/3 In^{3+} was estimated to be 63.5 cm^2 Ω^{-1} equiv^{-1} from the line of Fig. 3 and the ionic radius 0.81 Å,[18] whence the diffusion coefficient at infinite dilution of In^{3+} was calculated from the Nernst-Einstein equation. Table 3 shows the diffusion coefficients of metal ions in excess supporting electrolyte from the literature[19] together with the values of Cu^{2+}, Ni^{2+}, and In^{3+} evaluated by semiintegral electroanalysis. The theoretical $m(\tau)/m(\tau)_{xse}$ ratios were calculated from Eq. 12 by using the diffusion coefficients in Tables 2 and 3, and are listed in Table 1. Apart from $InCl_3$, the theoretical ratios generally compare well with the values obtained by experiment, though the theoretical ratios are usually slightly larger than the experimental values. This tendency possibly suggests some existence of hydrolysis reaction such as

$$Cu^{2+} + H_2O \rightleftharpoons CuOH^+ + H^+,$$

$$CuOH^+ + 2e^- \rightleftharpoons Cu(amalgam) + OH^-.$$

In the case of $InCl_3$, the experimental ratio is much smaller than the theoretical value. We believe this result to be due to a hydrolysis reaction of In^{3+}, because 10 mmol/l aqueous solutions of $InCl_3$ began to produce white suspensions in the originally clear solutions a few hours after preparing at a room temperature. The formation rate was accelerated on heating, but the suspension disappeared on adding acid. Another possible cause is the presence of complex ions such as $[InCl]^{2+}$ and $[InCl_2]^+$ formed with chloride ion, but this explanation is unlikely because a similar $m(\tau)/m(\tau)_{xse}$

ratio was observed in the case of $In(NO_3)_3$ solute.

Table 1 shows that Eq. 12 applies whether the reduction product is solid or amalgam, because most metals among investigated species are soluble in a mercury electrode but the metallic nickel does not form an amalgam.

In the classical polarography using a dropping mercury electrode, Lingane and Kolthoff[20] obtain the following relation between the initial limiting current, i_l, without supporting electrolyte present and the diffusion current, i_d, in an excess of indifferent electrolyte

$$\frac{i_l}{i_d} = \sqrt{\frac{D_O D_P [z_O - z_P]}{D_{OC}[z_O D_O - z_P D_P]}} \left[\frac{1}{1-T_O}\right] \qquad (13)$$

for cation reductions, where T_O is the transference number of O. It should be realized by the comparison between Eqs. 12 and 13 that $m(\tau)/m(\tau)_{xse}$ ratio observed in this semiintegral electroanalysis at higher scan rate of potential is identical with i_l/i_d ratio in classical polarography.

TABLE 4. $m(\tau)/m(\tau)_{xse}$ RATIOS AT DIFFERENT SCAN RATES OF POTENTIAL

Conditions: Electroactive species: 1.00 mmol/l $CdCl_2$, electrode area: 4.69×10^{-2} cm².

		$m(\tau)$ (μA s$^{1/2}$) Scan rate (mV/s)				
		50	100	200	500	
Concn of KNO_3 (mmol/l)	100	20.8	21.1	21.0	21.1	
	0	46.6	45.8	46.5	46.2	
$\frac{m(\tau)}{m(\tau)_{xse}}$ Exptl		2.23	2.17	2.22	2.19	2.21(av.)
Theor.		2.31	2.31	2.31	2.31	

TABLE 5. $m(\tau)/m(\tau)_{xse}$ RATIOS AT DIFFERENT CONCENTRATIONS OF ELECTROACTIVE SPECIES

Condition: Electrode area: 4.69×10^{-2} cm².

		$m(\tau)$ (μA s$^{1/2}$)			
Species		$Cd(NO_3)_2$		$TlNO_3$	
Concn of species (mmol/l)		1.00	5.00	1.00	5.00
Concn of KNO_3 (mmol/l)	100	23.0	120	20.4	95.7
	0	57.2	273	42.0	210
$\frac{m(\tau)}{m(\tau)_{xse}}$ Exptl		2.49	2.28	2.06	2.19
Theor.		2.34	2.34	2.12	2.12

The dependencies of $m(\tau)/m(\tau)_{xse}$ ratio on the scan rate for $CdCl_2$ and on concentration for $Cd(NO_3)_2$ and $TlNO_3$ are tested in Tables 4 and 5, respectively. The ratio is independent of scan rate and concentration as the theory predicts.

Thus the applicability of semiintegral electroanalysis in the absence of supporting electrolyte has been demonstrated. It is found that the sensitivity of detection is about twice as great as that with excess supporting electrolyte, but is dependent on the nature of the counter ion.

The financial support of the National Research Council of Canada is gratefully acknowledged.

Structure and Characterization of Copper(II) and Nickel(II) Complexes with 3-Acetyl-5,6-dimethylpyridazine Hydrazone, the Condensation Product of Biacetyl and Hydrazine

Hisashi OKAWA, Naohide MATSUMOTO, and Sigeo KIDA

Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812

(Received February 21, 1977)

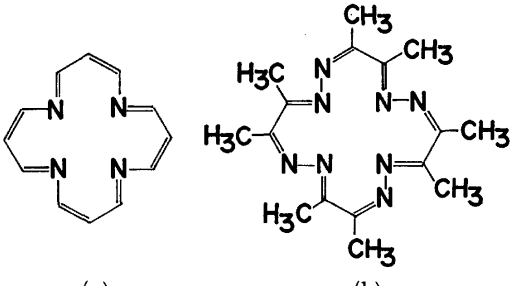
Copper(II) and nickel(II) complexes, $MLX_2 \cdot nH_2O$ (L=$C_{16}H_{24}N_8$; X=Cl^-, Br^-, NO_3^-, ClO_4^-, BF_4^-; n=0, 2), were obtained by reacting diacetyl with hydrazine in the presence of a metal ion and characterized. The condensation product L was found to be 3-acetyl-5,6-dimethylpyridazine hydrazone. The molecular structure of $NiL(ClO_4)_2 \cdot 2H_2O$ has been determined, the configuration around the nickel(II) ion being a distorted octahedron.

Metal complexes of 1,5,9,13-tetraaza[16]annulene (Fig. 1, a), which is the inner-ring system of porphyrins, are of interest in connection with the study on metalloenzymes such as peroxidases and cytochromes. Busch *et al.*[1-4] obtained tetrabenzo[*b*,*f*,*j*,*n*][1,5,9,13]tetraaza[16]annulene complexes by condensing 2-aminobenzaldehyde in the presence of a metal ion. Step-wise oxidation of metal complexes with tetraazamacrocycles of lower unsaturation seems a promising method for synthesizing tetraazaannulene metal complexes. By this method 5,7,12,14-tetramethyl-1,4,8,11-tetraaza[14]annulene has been prepared.[5] Tang and Holm[6] oxidized 15- and 16-membered tetraazamacrocyclic complexes and synthesized corrin-like macrocyclic complexes. However, 1,5,9,13-tetraaza[16]annulene and its homologues with simple substituents are not known.

In order to prepare 3,4,7,8,11,12,15,16-octamethyl-1,2,5,6,9,10,13,14-octaaza[16]annulene complexes (Fig. 1, b), we treated biacetyl and hydrazine in the presence of copper(II) or nickel(II) ion and obtained metal complexes of the type $MLX_2 \cdot nH_2O$ (M=Cu(II), Ni(II): X=Cl^-, Br^-, NO_3^-, ClO_4^-, BF_4^-; n=0, 2) where L denotes the condensation product with the composition $C_{16}H_{24}N_8$. The composition is the same as that of the desired compound 3,4,7,8,11,12,15,16-octamethyl-1,2,5,6,9,10,13,14-octaaza[16]annulene. However, L can not be the annulene, since the infrared spectrum of each complex clearly indicates the presence of an amino group. The purpose of this study is to characterize the condensation product and the metal complexes.

Experimental

Syntheses. *$CuL(ClO_4)_2$*: A methanol solution (50 ml) of biacetyl (4.3 g) and hydrazinium chloride (3.5 g) was refluxed for 10 min. To this was added copper(II) acetate monohydrate (2.5 g) and the mixture was heated under reflux for 3 h. A yellow precipitate formed was separated from the solution by filtration, and an aqueous solution of sodium perchlorate was added to the filtrate to give yellow-brown prisms. These were recrystallized from water. The yield was 0.7 g.



(a) (b)

Fig. 1.

Found: C, 32.43; H, 3.98; N, 19.03; Cu, 10.85%. Calcd for $C_{16}H_{24}N_8O_8Cl_2Cu$: C, 32.52; H, 4.09; N, 18.96; Cu, 10.75%.

$CuLBr_2$: Biacetyl (4.3 g) and hydrazinium bromide (5.7 g) were dissolved in methanol (70 ml) and the mixture was refluxed for 10 min. To this was added copper(II) acetate monohydrate (2.5 g) and the mixture was heated under reflux for 3 h. The reaction mixture was filtered while it was hot and the filtrate wes allowed to stand overnight to give greenish brown prisms. The yield was 0.2 g.

Found: C, 34.70; H, 4.35; N, 20.22; Cu, 11.79%. Calcd for $C_{16}H_{24}N_8Br_2Cu$: C, 34.83; H, 4.38; N, 20.31; Cu, 11.52%.

$NiL(ClO_4)_2 \cdot 2H_2O$: This complex was obtained in the same way as that for $CuL(ClO_4)_2$ from biacetyl (4.3 g), hydrazine hydrochloride (3.5 g) and nickel(II) chloride hexahydrate (3.0 g). A yellow precipitate formed was separated from the reaction mixture. To the filtrate was added an aqueous solution of sodium perchlorate (3.0 g) to give yellow prisms. A small amount of the product was recovered from the solid part of the reaction mixture by extraction with hot water and treatment with an aqueous solution of sodium perchlorate. The product was recrystallized from water to give yellow brown prisms (3.9 g).

Found: C, 30.76; H, 4.71; N, 17.84%. Calcd for $C_{16}H_{28}N_8N_8O_{10}Cl_2Ni$: C, 30.89; H, 4.54; N, 18.01%.

$NiL(BF_4)_2 \cdot 2H_2O$: The complex was obtained as golden yellow needle by addition of an aqueous solution of sodium tetrafluoroborate to an aqueous solution of $NiL(ClO_4)_2 \cdot 2H_2O$.

Found: C, 32.13; H, 4.73; N, 18.50%. Calcd for $C_{16}H_{28}N_8O_2B_2F_8Ni$: C, 32.20; H, 4.73; N, 18.78%.

$NiLCl_2$: The complex was obtained as red-orange prisms, when an aqueous solution of excess sodium chloride was added to an aqueous solution of $NiL(ClO_4)_2 \cdot 2H_2O$.

Found: C, 41.44; H, 5.32; N, 24.33%. Calcd for $C_{16}H_{24}N_8Cl_2Ni$: C, 41.96; H, 5.28; N, 24.46%.

$NiL(NO_3)_2$: The complex was obtained as yellow-brown prisms by mixing an aqueous solution of $NiL(ClO_4)_2 \cdot 2H_2O$ and an aqueous solution of excess sodium nitrate.

Found: C, 37.36; H, 4.77; N, 27.41%. Calcd for $C_{16}H_{24}N_{10}O_6Ni$: C, 37.60; H, 4.73; N, 27.40%.

Isolation of the Condensation Product. To an aqueous solution (200 ml) containing $Na_2H_2edta \cdot 2H_2O$ (4.0 g) and NaOH (4.0 g) was added $NiL(ClO_4)_2 \cdot 2H_2O$ (3.0 g), and the mixture was heated under reflux for 5 h. Pale yellow needles which separated were collected and recrystallized from metha-

nol. The yield was 1.3 g; mp 185 °C.

Found: C, 64.81; H, 6.75; N, 28.53%; MS: *m/e*, 296 and 297. Calcd for $C_{16}H_{20}N_6$: C, 64.86; H, 6.80; N, 28.38%; mol wt, 296.38.

Measurements. Infrared spectra were measured with a Hitachi Infrared Spectrophotometer Model 215 on a KBr disk, electronic spectra with a Shimadzu Multipurpose Spectrophotometer Model MSP-5000, and NMR spectra with a Hitachi NMR Spectrophotometer Model R-20B in CD_3CN using tetramethylsilane as the internal standard.

Structure Determination of $NiL(ClO_4)_2\cdot 2H_2O$. The crystal is yellow-brown rhombic prisms elongated along the c-axis. Unit cell dimensions were determined by the least-squares method from high-angle fifteen reflections measured on a Syntex $P\bar{1}$ four-cycle automatic diffractometer. The crystal data are givin in Table 1. Three-dimensional intensity data were collected by the 2θ-θ scan technique on a Syntex $P\bar{1}$ diffractometer using Mo$K\alpha$ radiation made monochromatic by means of graphite plate. Of 2345 independent reflections collected in $2\theta \lesssim 48°$, 1636 reflections greater than $2.33\sigma(F)$ were used in the analysis. They were corrected for the Lorentz and polarization effects, no corrections being made for absorption.

Solution and Refinement of the Structure

The structure was solved by the heavy atom method. For two molecules in a unit cell of space group $P2_1/c$, the nickel atom is required to be in a special position. The chlorine atom was easily deduced from the three dimensional Patterson synthesis and the minimum function. All the remaining non-hydrogen atoms were revealed by the Fourier syntheses. The positional and anisotropic thermal parameters were refined by the block diagonal least-squares method, the final disagreement factor being 11.2% for the observed reflections. The final positional and thermal parameters and their standard deviations are given in Table 2. In the least-squares procedure, weight ω is taken to be equal to unity for $|F_0| \geqq 5.0$ reflections and zero for $|F_0| < 5.0$ reflections. The F_o-F_c table is kept at the office of the Chem. Soc. Japan (Document No. 7712). The scattering factors for all the atoms were taken from the International Table for X-ray Crystallography.[7] All calculations were carried out by the UNICS program system using a Facom 230-75 Computer in the Computer Center of Kyushu University.

Description of the Structure

The molecule has a center of symmetry, the nickel atom being required to be in its position. Two molecules of 3-acetyl-5,6-dimethylpyridazine hydrazone are coordinated to nickel(II) ion with two water molecules in apical positions. The molecular structure of $NiL(ClO_4)_2\cdot 2H_2O$ with the numbering systems utilized for description of the molecule is shown in Fig. 2. Bond distances and bond angles with their standard deviations are given in Table 3. Two organic moieties and nickel(II) ion are almost coplanar. The deviation of each atom from the least-squares plane formed by N2, N3, and Ni atoms is given in Table 4.

Discussion

As is seen in Fig. 2, the organic moiety is demonstrated

Table 2. The final positional and thermal parameters with their standard deviations ($\times 10^4$)
The anisotoropic thermal parameters are in the form of $\exp[-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{13}hl+B_{23}kl)]$.

to be 3-acetyl-5,6-dimethylpyridazine hydrazone. This acts as a bidentate chelating agent, in which the ring nitrogen adjacent to the acetyl and the imino-nitrogen of hydrazone coordinate to nickel(II) ion to form a five-membered chelate ring. Two 3-acetyl-5,6-dimethylpyridazine hydrazone and nickel(II) ion are almost coplanar, although C8 (methyl carbon at the 6-position of pyridazine) slightly deviates from the least-squares plane formed by N2, N3, and Ni atoms. The distance between the nickel(II) ion and the water oxygen is 2.102 Å, the direction being nearly at right angles to the least-squares plane. Thus, the molecule has a twofold axis, the symmetry around the nickel(II) ion being approximately D_{2h}.

Table 4. Deviation of atoms from the least squeares plane (Å)

N1	−0.10	C4	0.21
N4	0.03	C5	0.26
C1	−0.10	C6	0.17
C2	0.00	C7	0.20
C3	0.08	C8	0.48

The least squares plane is defined by Ni, N2, and N3.

One of the characteristics of this molecule is a distorted configuration around the metal ion. Equatorial nitrogens form a rectangle; the distance between N2 and N3 is 2.58 Å, while the distance between N2 and N3′ is 3.215 Å. Thus, the N2–Ni–N3 angle is only 77.4°, while the N2–Ni–N3′ angle is 102.5°. These interatomic distances and bond angles are comparable with those in the nickel(II) complex with 2-pyridinecarboxamide anion.[8] The marked distortion around the metal ion can be attributed to the strain inherent in the ligand, which forms a five-membered chelate ring with conjugated double bonds.

In general, hydrazines condense with carbonyl compounds to form heterocyclic compounds.[9] However, the condensation between hydrazine and biacetyl has not yet been fully elucidated. Biacetyl hydrazone, the initial condensation product between diacetyl and hydrazine, has an active methyl group in addition to amino and carbonyl groups. Accordingly, under acidic and alkaline conditions the Aldol type condensation reaction as well as Schiff base formation are possible It is likely that 3-acetyl-5,6-dimethylpyridazine hydrazone was formed by the scheme shown in Fig. 3.

In order to separate and characterize the hydrazone, $NiL(ClO_4)_2 \cdot 2H_2O$ was decomposed with ethylenediaminetetraacetic acid in an alkaline solution. The isolated product, however, differs in composition from that of 3-acetyl-5,6-dimethylpyridazine hydrazone.

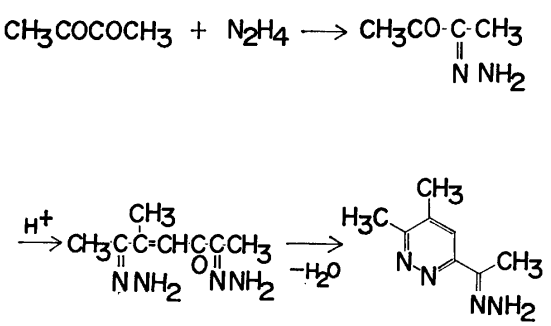

Fig. 3. The possible reaction scheme for 3-acetyl-5,6-dimethylpyridazine hydrazone formation.

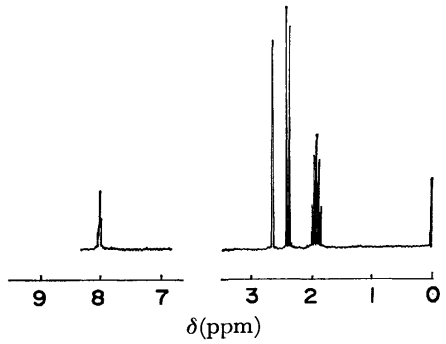

Fig. 4. NMR spectrum of 3-acetyl-5,6-dimethylpyridazine azine.

Judging from elemental analyses and the molecular weight determined from mass spectroscopy (m/e=296 and 297), the compound is likely to be 3-acetyl-5,6-dimethylpyridazine azine. This is supported by its NMR spectrum (Fig. 4) in which only four singlet signals are observed at 2.36, 2.42, 2.64, and 8.01 ppm with the intensity of 3, 3, 3, and 1 in ratio, respectively. The quintet around 1.9 ppm is due to CHD_2CN. The signals at 2.65 and 8.01 ppm are assigned to the α-methyl and the hydrogen on the ring, respectively. The signals at 2.36 and 2.42 ppm are ascribed to the methyl on the pyridazine ring. Infrared spectrum of 3-acetyl-5,6-dimethylpyridazine azine displays the C=N stretching vibration at 1670 cm^{-1} and the skeletal vibrations at 1595 and 1445 cm^{-1}. Thus, it is evident that 3-acetyl-5,6-dimethylpyridazine hydrazone in the complex was transformed into to 3-acetyl-5,6-dimethypyridazine azine by demetallation. Since azines are more stable than hydrazones, it is likely that a relatively severe reaction conditions (reflux around 100 °C in an alkaline solution) caused the azine formation.

Selected infrared absorption bands, molar conductivities and magnetic moments of the complexes are given in Table 5. Antisymmetric and symmetric N–H stretching vibrations of the amino group were found around ≈3340 and ≈3180 cm^{-1}, respectively. The C=N stretching vibration and the skeletal vibrations in the complexes were observed at 1640 cm^{-1} and at ≈1580 and ≈1440 cm^{-1}, respectively. Each band is lower in frequency as compared with that in the free ligand. The skeletal vibrations for 3-acetyl-5,6-dimethylpyridazine hydrazone should be practically the same in frequency as 3-acetyl-5,6-dimethylpyridazine azine because of the similarity in structure, while the C=N band in the hydrazone may be slightly higher than that in the azine because of the lower conjugation in the former. This is attributable to the coordination of the hydrazone nitrogen and the pyridazine nitrogen to the metal ion. Effective magnetic moment of each complex is comparable to the value for common copper(II) or high-spin nickel(II) complexes.

Electronic spectra of the complexes are given in Figs. 5 and 6. Reflectance spectra of $CuL(ClO_4)_2$ and $CuBr_2$ differ a great deal from each other, indicating the different structures in solid state. However, their solution spectra in methanol are nearly the same. Since the powder spectrum of $CuL(ClO_4)_2$ is similar to the solution spectrum, the configuration around the metal is nearly the same in solid and in solution. The fact

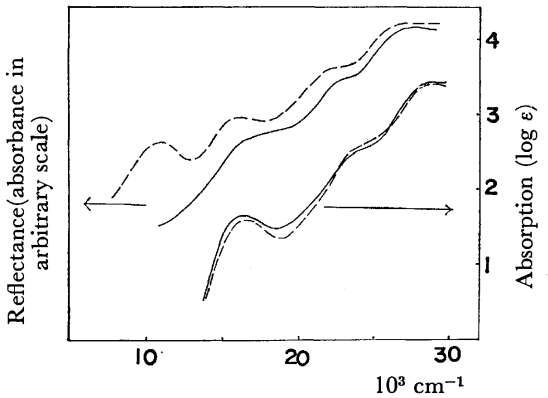

Fig. 5. Electronic spectra of $CuL(ClO_4)_2$ (——) and $CuLBr_2$ (– – –).

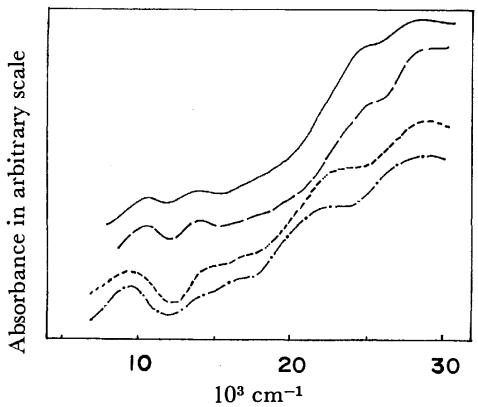

Fig. 6. Reflectance spectra of $NiL(ClO_4)_2 \cdot 2H_2O$ (——), $NiL(BF_4)_2 \cdot 2H_2O$ (– – –), $NiLCl_2$ (- - - - -), and $NiL(NO_3)_2$ (- · - · -).

Table 5. Selected IR bands (cm^{-1}), molar conductivity Λ (Ω^{-1} cm^2 mol^{-1}), and effective magnetic moment μ_{eff} (Bohr magneton) of complexes

	IR									Λ	μ_{eff}
	N–H		C=N	Skeletal		X–					
$CuL(ClO_4)_2$	3350	3150	1640	1580	1445	1105	1050			182 (MeOH)	1.75
$CuBr_2$	3280	3125	1640	1580	1440					171 (MeOH)	1.76
$NiL(ClO_4)_2 \cdot 2H_2O$	3340	3180	1640	1585	1440	1120—1080				165 (MeOH)	2.96
$NiL(BF_4)_2 \cdot 2H_2O$	3330	3180	1640	1583	1440	1080—1020				178 (MeOH)	3.00
$NiLCl_2$	3340	3190	1640	1585	1440					257 (H_2O)	3.06
$NiL(NO_3)_2$	3350	3190	1640	1587	1440	1420	1305	825		235 (H_2O)	3.04

that the infrared spectral band due to perchlorate ion splits considerably (1105 and 1050 cm^{-1}) implies that perchlorate oxygen coordinates weakly to the copper(II) ion at the apical positions.[10]

The d-d band of $CuLBr_2$ in solid state splits into two bands, the lower band being very low in frequency (11100 cm^{-1}). The splitting of the ligand field bands in the low energy region is generally caused by the fifth coordination to copper(II) ion.[11] Since the spectrum of $CuLBr_2$ resembles spectra[12] of [Cu(trien)SCN]SCN, $[Cu(NH_3)_5](BF_4)_2$, and $[Cu(en)_2NH_3]X_2$ whose configuration is supposed to be tetragonal-pyramidal, it is likely that $CuLBr_2$ has a distorted five-coordinate structure with a bromide ion at the apical position. Molar conductivity of the copper(II) complexes indicates that they are 2: 1 electrolyte in methanol.

The nickel(II) complexes are also 2: 1 electrolyte in methanol or water. Because of relatively low solubility in most solvents the electronic spectra of the nickel(II) complexes were measured on a solid sample. The spectra of $NiL(ClO_4)_2 \cdot 2H_2O$ and $NiL(BF_4)_2 \cdot 2H_2O$ are similar to each other, where there are some d-d bands in the region 16000—22000 cm^{-1} in addition to the well resolved bands at $\approx$10500 and $\approx$14000 cm^{-1}. Since the symmetry around the metal in $NiL(ClO_4)_2 \cdot 2H_2O$ is approximately D_{2h} (or lower symmetry), the transitions $^3T_{2g} \leftarrow {}^3A_{2g}$ and $^3T_{1g} \leftarrow {}^3A_{2g}$ for nickel(II) under O_h-symmetry split into two (or three) components respectively in $NiL(ClO_4)_2 \cdot 2H_2O$ and $NiL(BF_4)_2 \cdot 2H_2O$, hence producing a complicated spectrum.

Spectra of $NiLCl_2$ and $NiL(NO_3)_2$ are similar to each other, but differ from those of $NiL(ClO_4)_2 \cdot 2H_2O$ and $NiL(BF_4)_2 \cdot 2H_2O$. Since these spectra also show complicated d-d bands in the region 14000—23000 cm^{-1}, the configuration around the metal may be a distorted octahedron, where it is presumed the apical ligands are chloride or nitrate ion. In fact the infrared spectrum of $NiL(NO_3)_2$ indicates characteristic bands of nitrate ion at 1420, 1305, and 825 cm^{-1} indicating that the nitrate ion acts as a unidentate ligand.[13]

The authors are grateful to Assoc. Prof. T. Inazu, Kyushu Univesity, for measuring NMR spectra, and to Prof. M. Yamaguchi and Dr. T. Katsuki, Kyushu University, for measuring mass spectra. Thanks are also due to Prof. T. Komori for allowing us to use the Syntex Pī automatic diffractometer.

Photoreaction of 4-Substituted Quinoline *N*-Oxide and 2(1*H*)-Quinolinone in Propionic Acid[1)]

Akio IDE, Yukinori MORI, Kunihiko MATSUMORI, and Hiroyasu WATANABE
Department of Agricultural Chemistry, Faculty of Agriculture, Ehime University, Tarumi, Matsuyama 790
(Received September 1, 1976)

4-Substituted *cis*-3-ethyl-2-oxo-1,2,3,4-tetrahydro-2-quinoline was formed as a major product, by irradiation of quinoline *N*-oxide and 2(1*H*)-quinolinone substituted with an electron-withdrawing group at the C-4 position in propionic acid. Also, the products were confirmed by direct comparison with synthesized compounds.

Recently, photoalkylation reactions of aza aromatic compounds have been reported by several authors.[2)] Concerning this reaction, Ide *et al.* have also described the photoalkylation of quinolinecarbonitriles and isoquinolinecarbonitriles in propionic acid.[3)] The reaction products were found to be ethylated in the aza aromatic rings of quinoline and isoquinoline. Moreover, the position of alkylation was explained well by the reaction indices of nucleophilic or radical superdelocalizability in a simple HMO calculation.[3)] The present paper is concerned with photoinduced reactions of quinoline *N*-oxide and 2(1*H*)-quinolinone (carbostyril) having an electron-withdrawing group at the C-4 position in propionic acid.

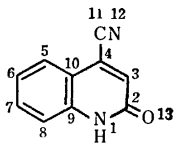
Results and Discussion

It is well known that azanaphthalene *N*-oxide are predominantly transformed into lactams, as a result of ultraviolet irradiation in hydroxylic solvents.[4,5)] As seen from Table 1, a simple HMO calculation indicates that the C-3 position of the lactam, 2-oxo-1,2-dihydro-4-quinolinecarbonitrile, is the most reactive site in the molecule. Accordingly, irradiation of 4-quinolinecarbonitrile *N*-oxide (**1a**) in propionic acid may give the lactam (**2a**) which then undergoes photoalkylation at the C-3 position. An experimental proof of these assumptions is of interest with respect to the mechanism of the photoalkylation of aza aromatic compounds. Therefore, the present authors carried out the irradiation of **1** and **2** in propionic acid using a high-pressure mercury lamp and a quartz filter.

Table 1. Reaction indices for 2-oxo-1,2-dihydro-4-quinolinecarbonitrile

No[a)]	Superdelocalizability[b)]		
	Electrophilic	Nucleophilic	Radical
1	1.570	0.348	0.959
2	0.314	0.711	0.513
3	1.275	1.363	1.319
4	0.705	1.101	0.903
5	0.905	1.004	0.854
6	1.053	0.747	0.900
7	0.844	0.943	0.894
8	1.116	0.810	0.963
9	0.743	0.843	0.793
10	0.959	0.654	0.806
11	0.460	0.996	0.728
12	0.833	1.035	0.934
13	0.987	0.423	0.705

a) Numbered as follows.



b) Calculated according to the method of Fukui.[6)] The following parameters were adopted from the textbook of Pullmann[7)] and were used in the simple HMO calculation. Coulomb integral: $\alpha_N^{CN}=\alpha+1.1\beta$, $\alpha_C^{C=O}=\alpha$, $\alpha_O^{C=O}=\alpha+1.2\beta$, $\alpha_N^{CON}=\alpha+\beta$. Resonance integral: $\beta_{C-N}^{C\equiv N}=1.4\beta$, $\beta_{C-N}^{CON}=0.9\beta$, $\beta_{C-O}^{C=O}=2\beta$.

Both compounds **1** and **2** gave the same products in the yields given in Table 2. The products were determined to be 4-substituted 3-ethyl-2-oxo-1,2,3,4-tetrahydroquinoline on the basis of the spectral data listed in Tables 3 and 4. It is difficult to assign either a *cis* or a *trans* configuration on the basis of the coupling costant between C^3–H and C^4–H. Accordingly, synthesis of the two isomers was attempted accordingly to the scheme shown in Chart 2.

Following the synthesizing method for (*Z*)-2-(2-oxo-3-indolinylidene)propionic acid of Julian *et al.*,[8)] (*Z*)-2-(2-oxo-3-indolinylidene)butyric acid (**6**) was prepared from oxindole (**5**) and 2-oxobutyric acid. Heating of **6** in hydrochloric acid gave 3-ethyl-2-oxo-1,2-dihydro-4-quinolinecarboxylic acid (**7**) which was identical with the compound obtained by Mulert[9)] from *N*-butylisatin, with respect to the chemical and physical data. Compound (**7**) was catalytically reduced, giving colorless needles. The needles were determined from their infrared spectrum to be *cis*-3-ethyl-2-oxo-1,2,3,4-tetra-

Table 2. Photochemical reaction yields

Starting compound	Product	Yield[a)] (%)	Product	Yield[a)] (%)
1a	**3a**	41 (26)	**4a**	8
2a		53 (40)		9
1b	**3b**	28 (8.7)	**4b**	5
2b		15 (7.0)		8

TABLE 4. NMR DATA OF PHOTOLYSATES AND RELATED COMPOUNDS (from internal TMS, δ value (ppm))[a]

Compound	$-CH_2CH_3$ (3H)	$-CH-CH_2-CH_3$ (2H)	$-CH-CH-CH_2-$ (1H)	$-CH-CH$ (1H)	Others
3a[b]	1.10 (t, J=7 Hz)	1.6—2.5 (m)	2.7—3.0 (m)	4.6 (d, J=6 Hz)	7.0—7.5(4H, m, Ar-**H**), 9.5(1H, bs, N-**H**)
3b[b]	1.10 (t, J=7 Hz)	1.7—2.5 (m)	2.6—3.0 (m)	4.10 (d, J=6 Hz)	6.9—7.5(4H, m, Ar-**H**), 9.25(1H, bs, N-**H**), 3.65(3H, s, CO_2CH_3)
3c	1.21 (t, J=7 Hz)	1.8—2.1 (m)	2.6—2.9 (m)	4.28 (d, J=5 Hz)	
4a	1.11 (t, J=7 Hz)	1.91 (d×q, J=7 and 7 Hz)	3.00 (d×t, J=8 and 7 Hz)	4.59 (d, J=8 Hz)	
4b	1.02 (t, J=7 Hz)	1.67 (d×q, J=7 and 7 Hz)	3.11 (d×t, J=4 and 7 Hz)	4.02 (d, J=4 Hz)	3.56(3H, s, CO_2CH_3)
4c[b]	1.08 (t, J=7 Hz)	1.69 (d×q, J=7 and 7 Hz)	3.28 (d×t, J=3 and 7 Hz)	4.08 (d, J=3 Hz)	
8	1.21 (t, J=8 Hz)	1.8—2.4 (m)	2.6—2.9 (m)	4.32 (d, J=6 Hz)	
10	1.14 (t, J=7 Hz)	1.82 (d×q, J=7 and 7 Hz)	3.45 (d×t, J=4 and 7 Hz)	4.23 (d, J=4 Hz)	
6	1.36(3H, t, J=7 Hz, $-CH_2CH_3$), 2.94(2H, q, J=7 Hz, $-CH_2CH_3$), 6.9—7.7(4H, m, Ar-**H**)				

a) Measured in pyridine, except for b). S, di t, q, m, and bs stand for singlet, doublet, triplet, quartet, multiplet, and broad singlet, respectively. b) Measured in acetone-d_6.

hydro-4-quinolinecarboxylic acid (**3c**) with bands at 1720 (ν C=O, acid) and 1662 cm^{-1} (ν C=O, lactam), and by the *cis*-addition mechanism for catalytic hydrogenation. Compound (**6**) was catalytically reduced, giving an oily product which was presumed to have the structure of **9** shown in Chart 2. The crude oily product was refluxed in hydrochloric acid yielding colorless prisms, mp 127 °C. The prisms were determined to be *trans*-3-ethyl-2-oxo-1,2,3,4-tetrahydro-4-quinolinecarboxylic acid (**4c**), since the physical properties of

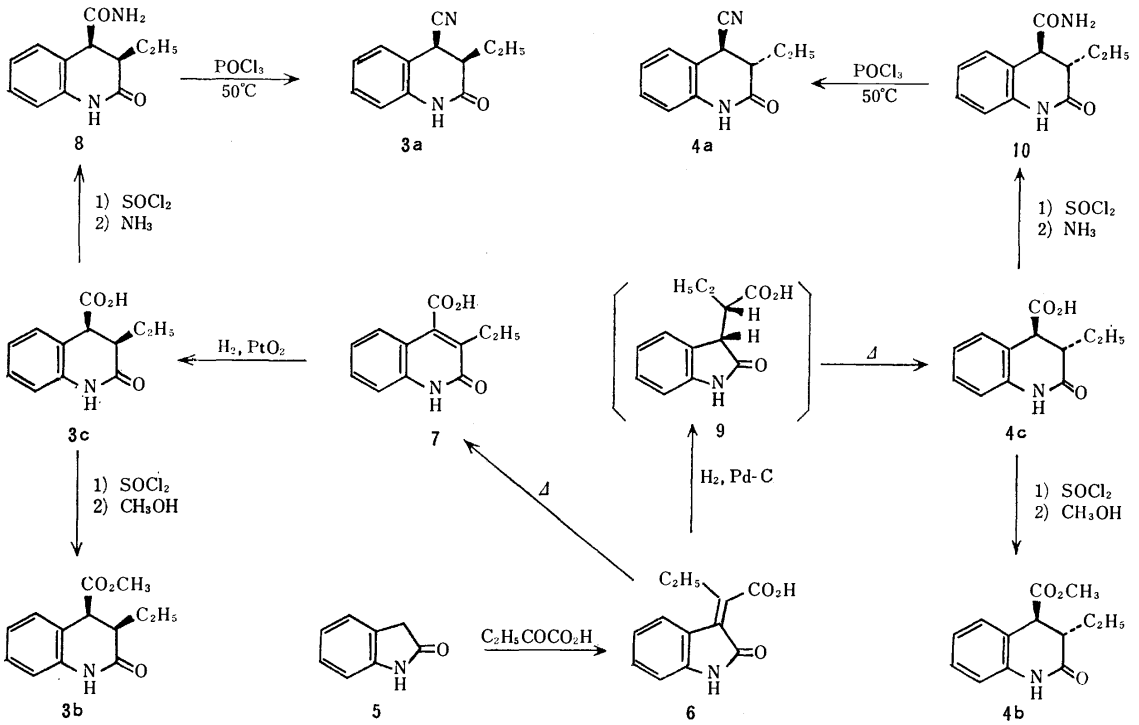

Chart 2.

4c were similar but not identical to those of **3c**. *cis*-(**3a**) and *trans*-3-ethyl-2-oxo-1,2,3,4-tetrahydro-4-quinolinecarbonitrile (**4a**) were synthesized from **3c** and **4c** *via cis*-(**8**) and *trans*-3-ethyl-2-oxo-1,2,3,4-tetrahydro-4-quinolinecarboxamide (**10**), respectively. The main product isolated from the mixture of the photoreactions of **1** and **2** coincided with compound **3**, the *cis* isomer obtained above. However, a small amount of the *trans* isomer, although difficult to isolate, was detected in the mixture by means of gas chromatography, as indicated in Table 2.

The fact that the *cis* isomer was obtained as a major product indicates that the *trans*-addition of ethyl and hydrogen groups occurs at the C-3 double bond of 2(1*H*)-quinolinone. This also indicates that the alkylated position in the present alkylation reaction is easily explained by the reaction indices in the simple HMO calculation. These results are important to an understanding of the mechanism of photoalkylation of aza aromatic compounds.

Experimental

All melting points were determined using a YANACO micromelting point apparatus and are uncorrected. Infrared spectra were recorded on a JASCO IR-S infrared spectrometer. Ultraviolet spectra were determined with a Hitachi 124 spectrophotometer. Nuclear magnetic resonance spectra were measured with a JEOL JNM-100H spectrometer at 100 MHz using TMS as an internal standard. Mass spectra were obtained with a JEOL JMS-OlSG-2 mass spectrometer, using a direct inlet and an electron energy of 75 eV.

Irradiation was carried out using a high-pressure mercury arc (USHIO UM-102) surrounded by a quartz water jacket at 30 °C.

The yield of the reaction products was determined by analysis on a SHIMADZU GC-5A gas chromatograph using a column (3 mm×2 m) packed with OV-225 (1.5%) on chromosorb-W (DMSC-A/W). The oven temperature was 186 °C for **3a** and **4a**, and 155 °C for **3b** and **4b**. The flow rate of the carrier gas (N_2) was 60 ml/min.

Materials. 2-Oxo-1,2-dihydro-4-quinolinecarboxylic acid, 2-oxo-1,2-dihydro-4-quinolinecarbonitrile, methyl 2-oxo-1,2-dihydro-4-quinolinecarboxylate and 4-quinolinecarbonitrile *N*-oxide were prepared according to the methods of Jacobs *et al.*,[10] Daeniker *et al.*,[11] Mayer,[12] and Daeniker,[11] respectively.

4-Substituted quinoline *N*-oxide were synthesized by the method of Ochiai.[14]

Methyl 4-Quinolinecarboxylate N-*Oxide* (**1b**). Colorless needles (from methanol), mp 149—150 °C. IR(KBr): 1701 (*ν* C=O), 1250 (*ν* N–O) cm^{-1}, Found: C, 70.72; H, 4.81; N, 7.36%. Calcd for $C_{11}H_9NO_2$: C, 70.58; H, 4.86; N, 7.48%.

4-Quinolinecarboxylic Acid N-*Oxide* (**1c**). Colorless prisms (from acetic acid), mp 256 °C (dec). IR (KBr): 2400—2900 (b, *ν* OH), 1714 (*ν* C=O), 1170 (*ν* N–O) cm^{-1}. Found: 63.53; H, 3.65; N, 7.49%. Calcd for $C_{10}H_7NO_3$: C, 63.49; H, 3.37; N, 7.41%.

(Z)-*2-(2-Oxo-3-indolinylidene)butyric Acid* (**6**). Metallic sodium (2.1 g) was added to absolute ethanol (70 ml). To this solution was added a solution of oxindol (**5**, 3.9 g) in absolute ethanol (30 ml) with stirring and then a solution of 2-oxobutyric acid (3.0 g) in absolute ethanol (30 ml). The mixture was refluxed for 3 h with stirring. The solid formed upon cooling was collected by filtration and dissolved in water (50 ml). The solution was acidified with 2M-hydrochloric acid. The resulting solid was dried and recrystallized from ethyl acetate to give yellow prisms, mp 203—204 °C, in 3.7 g (58.1%) yield. UV (λ_{max}^{EtOH} nm (ε)): 346(1600), 293 (7200), 258 (31300), 252(28000). Found: C, 66.52; H, 5.12; N, 6.43%. Calcd for $C_{12}H_{11}NO_3$: C, 66.35; H, 5.11; N, 6.45%.

3-Ethyl-2-oxo-1,2-dihydro-4-quinolinecarboxylic Acid (**7**).
A suspension of **6** (2.2 g) in hydrochloric acid (6%, 200 ml) was refluxed for 20 h and the mixture was concentrated under

reduced pressure. The residue was recrystallized from 50% ethanol to give colorless needles (1.1 g, 50%), mp 308—310 °C (lit,[9] 289 °C). IR (KBr): 1705 (ν C=O, acid), 1655 (ν C=O, lactam)cm^{-1}. MS (*m/e* (%)): 217 (M^+, 98), 172 (M^+ −COOH, 100).

cis-*3-Ethyl-2-oxo-1,2,3,4-tetrahydro-4-quinolinecarboxylic Acid (3c).* *(a) By Photochemical Reaction Involving* **1c**: A solution of **1c** (1.0 g) in propionic acid (500 ml) was irradiated for 3 h. The mixture was concentrated to dryness *in vacuo*. The residue was shaken in a sodium hydrogencarbonate solution (2%, 20 ml). The aqueous solution was washed three times with ethyl acetate, acidified with concentrated hydrochloric acid, and extracted with ethyl acetate (20 ml×3). The combined extract was washed with a saturated sodium chloride solution, dried over sodium sulfate, and evaporated. The syrupy residue was purified through a silica gel column (120 g, 3×40 cm) with a mixed solvent of dichloromethane–methanol (9: 1, v/v). The purified **3c** was recrystallized twice from water to afford colorless needles (0.43 g, 37%), mp 221—222 °C. Found: C, 65.93; H, 5.82; N, 6.41%. Calcd for $C_{12}H_{13}NO_3$: C, 65.74; H, 5.98; N, 6.31%.

(b) By Photochemical Reaction Involving **2c**: Photolysis of **2c** (0.5 g) in propionic acid (400 ml) was performed in a manner similar to that described in *(a)*, and **3c** was obtained (0.27 g, 46%).

(c) By Catalytic Reduction of 3-Ethyl-2-oxo-1,2-dihydro-4-quinolinecarboxylic Acid (7) in the Presence of Platinum Oxide: A mixture of **7** (217 mg), methanol (40 ml) and platinum oxide (0.1 g) prepared according to the method of Bruce[13] was shaken in an atmosphere of hydrogen for 4 h. The mixture was filtered and the filtrate was concentrated to dryness. The residue was taken up with methanol and subjected to chromatography on a preparative silicagel thin layer with dichloromethane–methanol (4: 1, v/v). The product was recrystallized from water. Mp 211—212 °C. Yield 156 mg (71%).

trans-*3-Ethyl-2-oxo-1,2,3,4-tetrahydro-4-quinolinecarboxylic Acid (4c).* *(Z)*-2-(2-Oxo-3-indolinylidene)butyric acid (2.17 g) and palladium on charcoal (10%, 0.5 g) were stirred in ethanol (30 ml) in a hydrogen atmosphere at room temperature and normal pressure. After 30 min, the catalyst was removed by filtration, and then the filtrate was evaporated. The residue was distilled at 0.08 Torr to give 2.17 g of colorless oils, bp 210 °C (bath temp). The oily product was refluxed in hydrochloric acid (6%, 200 ml) for 20 h. The reaction mixture was concentrated to dryness. The residue was recrystallized from water to give colorless prisms (1.56 g, 71.2%), mp 127 °C. Found: C, 60.88; H, 6.45; N, 5.97%. Calcd for $C_{12}H_{13}NO_3 \cdot H_2O$: C, 60.75; H, 6.37; N, 5.90%.

cis-*3-Ethyl-2-oxo-1,2,3,4-tetrahydro-4-quinolinecarboxamide(8).* **3c** (380 mg) was refluxed in thionyl chloride (5 ml) for 3 h. The reaction mixture was concentrated to dryness and the residue was suspended in absolute ether. Through this suspension, dry ammonia gas was passed with stirring. The precipitate was collected, washed with and recrystallized from ethanol to give colorless needles (212 mg, 56%), mp 246—247 °C. Found: C, 66.17; H, 6.58: N, 12.81%. Calcd for $C_{12}H_{14}N_2O_2$: C, 66.04; H, 6.47; N, 12.83%.

trans-*3-Ethyl-2-oxo-1,2,3,4-tetrahydro-4-quinolinecarboxamide (10).* **4c** (474 mg) was allowed to react in a manner similar to that described for the preparation of **8** to give 240 mg (55%) of colorless flakes, mp 205 °C. Found: C, 66.12; H, 6.51; N, 12.86%. Calcd for $C_{12}H_{14}N_2O_2$: C, 66.04; H, 6.47; N, 12.83%.

cis-*3-Ethyl-2-oxo-1,2,3,4-tetrahydro-4-quinolinecarbonitrile (3a)* *(a) By Photochemical Reaction Involving* **1a**: A solution of **1a** (5 g) in propionic acid (500 ml) was irradiated for 28 h. The mixture was concentrated and the residue was taken up with ethyl acetate. The ethyl acetate layer was successively washed with 2M-hydrochloric acid, an aqueous 2M-ammonia solution and a saturated sodium chloride solution, dried over sodium sulfate, and evaporated. The residue was recrystallized from methanol and then from ethanol to give colorless needles (1.5 g, 26%), mp 191—192 °C. Found: C, 72.09; H, 6.12; N, 14.10%. Calcd for $C_{12}H_{12}N_2O$: C, 71.98; H, 6.04; N, 13.99%.

(b) By Photochemical Reaction Involving **2a**: A solution of **2a** (1.5 g) in propionic acid (500 ml) was irradiated for 20 h. The mixture was treated in a manner similar to that for *(a)*, giving 0.7 g (40%) of **3a**, mp 191—192 °C.

(c) By Synthesis: A mixture of **8** (108 mg) and phosphoryl chloride (3 ml) was stirred at 50 °C for 2.5 h. The mixture was concentrated under reduced pressure (5 Torr). The residue was taken up with ethyl acetate. The ethyl acetate solution was washed sodium hydrogen carbonate and saturated sodium chloride solutions, dried over sodium sulfate and evaporated. The residue was recrystallized twice from ethanol to give colorless needles (50 mg, 50%), mp 192—193 °C.

trans-*3-Ethyl-2-oxo-1,2,3,4-tetrahydro-4-quinolinecarbonitrile(4a).* A mixture of **10** (109 mg) and phosphorylchloride (5 ml) was treated in a manner similar to that for *(c)* to give colorless prisms (53 mg, 53%), mp 194—195 °C. Found: C, 72.13; H, 5.93; N, 14.04%. Calcd for $C_{12}H_{12}N_2O$: C, 71.98; H, 6.04; N, 13.99%.

Methyl cis-*3-Ethyl-2-oxo-1,2,3,4-tetrahydro-4-quinolinecarboxylate (3b).* *(a) By Photochemical Reaction Involving Methyl 4-Quinolincarboxylate* N-*Oxide*: A solution of **1b** (5.0 g) in propionic acid (500 ml) was irradiated for 22 h. The mixture was concentrated under reduced pressure. The residue was fractionally distilled *in vacuo*. The distillate having a boiling point from 190 to 200 °C at 0.02 Torr was collected and crystallized by the addition of a mixture of hexane and ethyl acetate (1: 1, v/v). The crystals were recrystallized from ethanol to give colorless needles (0.5 g, 8.7%), mp 166—167 °C. Found: C, 67.02; H, 6.53; N, 5.94%. Calcd for $C_{13}H_{15}NO_3$: C, 66.94; H, 6.84; N, 6.00%.

(b) By photochemical Reaction Involving **2b**: A solution of **2b** (0.50 g) in propionic acid (100 ml) was irradiated for 4 h. The mixture was concentrated to dryness under reduced pressure. The residue was taken up with ethyl acetate (100 ml). The ethyl acetate solution was washed with sodium hydrogencarbonate (5%) and saturated sodium chloride solutions, dried over sodium sulfate, and evaporated. The residue was treated with methanol (20 ml) and filtered. The filtrate was concentrated. The syrupy residue was purified on a column (1×30 cm) of silica gel (30 g) with a mixed solvent of benzene and ethyl acetate (9: 1, v/v). The resultant crystals were recrystallized twice from ethanol to give colorless needles (0.04 g, 7.0%).

(c) By Esterification of **3c**: A mixture of **3c** (119 mg) in thionyl chloride (5 ml) was refluxed for 2 h. After evaporation of the excess thionyl chloride, the residue was refluxed in absolute methanol (10 ml) for 1 h. The mixture was concentrated under reduced pressure. The residue was recrystallized from ethanol to give colorless needles (85 mg 67.1%), mp 165—166 °C.

Methyl trans-*3-Ethyl-2-oxo-1,2,3,4-tetrahydro-4-quinolinecarboxylate (4b).* A mixture of **4c** (226 mg) in thionyl chloride (3 ml) was refluxed for 2 h. A procedure was carried out similar to that described of the preparation of **3b**. The crops were recrystallized from diisopropyl ether to give colorless prisms (107 mg, 42%), mp 121—122 °C. Found: C, 66.98; H, 6.51; N, 5.91%. Calcd for $C_{13}H_{15}NO_3$: C, 66.94;

H, 6.48; N, 6.00%.

The authors are indebted to the members of the Laboratory of Organic Analysis, Tanabe Pharmaceutical Co., Ltd., for the elemental analysis and also to Miss M. Maeda of the Faculty of Engineering, Ehime University, for the NMR measurements.

The Chemistry of Phenalenium Systems. XXIII.[1] Syntheses and Properties of Cyclohepta[*cd*]phenalen-6-one and the Cyclohepta[*cd*]phenalenium Ion[2]

Kagetoshi YAMAMOTO, Yutaka KAYANE, and Ichiro MURATA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received August 5, 1976)

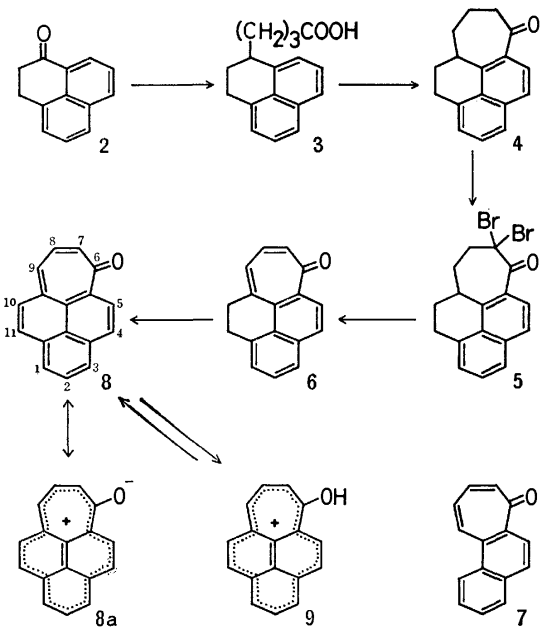
The syntheses of cyclohepta[*cd*]phenalen-6-one (**8**) and the cyclohepta[*cd*]phenalenium tetrafluoroborate (**1**) are reported. As expected, it is apparent that in the transition from 10,11-dihydrocyclohepta[*cd*]phenalen-6-one to the fully conjugated ketone **8**, all the vinyl protons move downfield by 0.22 to 0.53 ppm. The plausible explanation suggests that these shifts arise from deshielding due to the existence of a diamagnetic ring current induced in the 14π periphery of **8**. In accord with theoretical prediction, the cation **1** is extremely stable. The substantial thermodynamic stability of **1** is reflected to its pK_{R^+} of 8.4. The ion **1** can be regarded as a perturbed [15]annulenium ion weakly coupled with a localized central vinyl crosslink.

Although there has been considerable interest in the neutral nonalternant isomers of pyrene such as cyclohept[*fg*]acenaphthylene (acepleiadiene),[3] cyclohepta[*def*]fluorene,[4] cyclohept[*bc*]acenaphthylene,[5] cyclohepta[*klm*]benz[*e*]indene,[6] dicyclopenta[*ef,kl*]heptalene (azupyrene),[7] pentaleno[6,6a,1,2-*def*]heptalene,[8] and dicyclohepta[*cd,gh*]pentalene,[9] the ionic 14π perimeter species which are isoelectronic with pyrene have received little attention. The ionic 14π perimeter species so far known have been confined to the anions, *e.g.* cyclopenta[*cd*]phenalenide ion,[10] pyracylene dianion,[11] dibenzo[*cd,gh*]pentalenyl dianion,[12] and cyclopenta[*def*]-phenanthrenide ion,[13] no cationic species have been reported to date. According to theoretical (HMO) prediction by Zahradnik *et al.*[14] the cyclohepta[*cd*]-phenalenium ion (**1**) ought to be quite stable and might be reasonably accessible.

On the other hand, cyclohepta[*cd*]phenalen-6-one (**8**), a key intermediate for the synthesis of **1**, is of interest in connection with current studies on the peripheral conjugation in peri-condensed polyarenes. We have recently reported the synthesis and properties of cyclopenta[*cd*]phenalen-4-one,[15] cyclopenta[*cd*]phenalen-5-one,[16] cyclohepta[*cd*]phenalen-1-one,[17] and cyclohepta[*cd*]phenalen-4-one,[18] wherein the structural phenalenone moiety is incorporated into the molecule. In these cases, we have proposed that these compounds can be regarded as [13]- and [15]annulenone perturbed by internal vinyl crosslink. Here we describe the synthesis of **1** as the first example of a 14π perimeter cationic system along with **8** as an adequate model compound for perturbed [15]annulenone.

Results and Discussion

Synthesis and Properties of Cyclohepta[cd]*phenalen-6-one (8).* Reduction of the hydroxy ester, which was obtained by the Reformatsky reaction of 2,3-dihydrophenalenone (**2**)[19] with methyl 4-bromocrotonate, over palladium hydroxide on charcoal proceeds accompanying with hydrogenolysis of the benzylic hydroxyl group. The butylate thus obtained was hydrolyzed with potassium hydroxide in ethanol to give the carboxylic acid (**3**) in 48% yield. Cyclization of **3** with polyphosphoric acid at 90 °C for 1 h afforded the tetracyclic ketone (**4**) in 75% yield. The ketone (**4**) was converted into the α,α-dibromo ketone (**5**) in quantitative yield by treatment with bromine in dry carbon tetrachloride. Dehydrobromination of **5** to give 10,11-dihydrocyclohepta[*cd*]phenalen-6-one (**6**) was accomplished by heating in hexamethylphosphoric triamide with lithium chloride for 1 h at 95—100 °C. The structure of **6** was



confirmed on the basis of its spectroscopic properties. The mass spectrum of **6** showed intense peaks at *m/e* 232 (M^+, 64%), 204 (M^+-CO, 100%), 203 (93%) and 202 (pyrene ion, 82%). The IR spectrum exhibited characteristic absorption of tropone skeleton at 1625, 1590, and 1580 cm^{-1}.[20] The absorption bands of the UV spectrum of **6**, 243 nm (log ε, 4.38), 287 (4.33), and 344 (3.91), are in good agreement with those of cyclohepta[*a*]-naphthalen-7-one (**7**).[21] The conversion of **6** into the desired fully conjugated ketone (**8**) was effected by treatment with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone in benzene in a sealed tube at 120 °C for 20 h in 21% yield. However, it was found that the compound (**8**) could be more readily obtained in a higher yield (33%) on treatment of **6** with triphenylmethyl tetrafluoroborate in refluxing acetic acid under nitrogen

a) Chemical shifts are given in δ-values with respect to TMS as an internal standard and coupling constants are given in Hz.

atmosphere for 2 h. The identity of **8** was established in the following manner. Mass spectrometry gave a parent peak at *m/e* 230. As would be expected for a compound containing tropone moiety, the base peak in the mass spectrum was found to be M^+-CO (*m/e* 202).[22)] The UV spectrum of **8** showed maxima at 249 nm (log ε, 4.48), 311 (4.07), 321 (4.08), 430 (4.23) indicating an extend conjugation. Further evidence was also provided by ^{1}H-NMR spectrum.

The NMR chemical shifts and coupling constants of **8** compared with those of the reference compound **6** are summarized in Table 1. Although complete assignments of the proton chemical shifts could not be made except H-4 and H-5 due to their complex spectral pattern, it is apparent that (i) in the transition from the dihydro ketone (**6**) to the fully conjugated ketone (**8**), all the vinyl protons move downfield by 0.2—0.5 ppm (ii) the downfield shift is enhanced (0.4—0.95 ppm) when **8** is protonated in trifluoroacetic acid (iii) in the case of **6**, only protons of seven-membered ring (H-7, 8, and 9) move downfield in trifluoroacetic acid compared with those of the neutral form whereas the full conjugated ketone (**8**) exhibited marked downfield shifts of all the vinyl protons. These findings suggest the existence of a diamagnetic ring current induced in the 14π periphery (**8a**) of **8**. The diatropic effect is enhanced in trifluoroacetic acid owing to the formation of the 6-hydroxycyclohepta[*cd*]phenalenium ion (**9**). Furthermore, supportive evidence for the formation of **9** in an acidic media was provided by the UV-visible spectrum of **8** in concentrated sulfuric acid which was closely similar to that of the parent cation (**1**) [*vide infra*] in acetonitrile both in absorption maxima and in band shape [see Fig. 1].

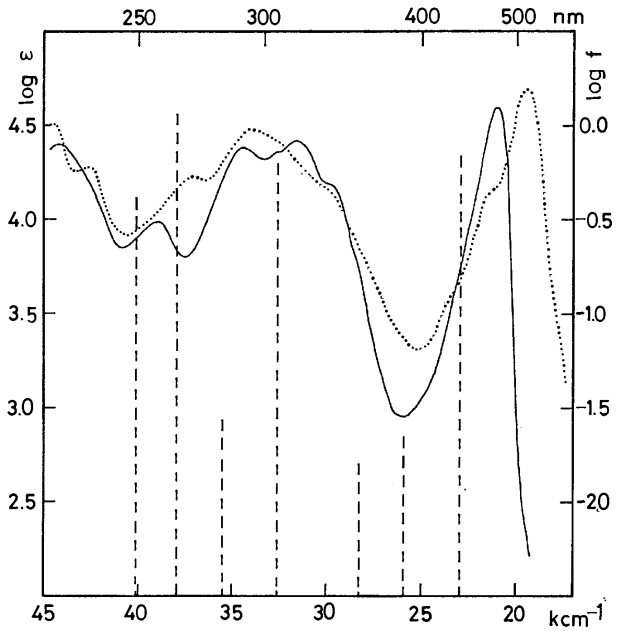

Fig. 1. Electronic spectra of the cyclohepta[*cd*]phenalenium tetrafluoroborate (**1**) in CH_3CN and cyclohepta-[*cd*]phenalen-6-one (**8**) in concd H_2SO_4.
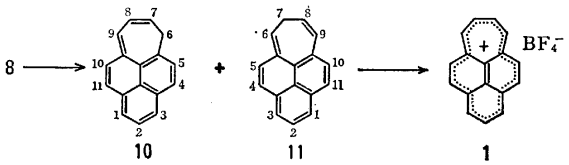
——: (**1**), ……: (**8**).
Vertical dashed lines denote calculated transitions for (**1**).

Synthesis and Properties of Cyclohepta[cd]*phenalenium Tetrafluoroborate (1).* Reduction of **8** with lithium aluminum hydride–aluminum chloride complex in ether at −50 °C for 2 h led to a mixture of isomeric hydrocarbons, 6*H*-cyclohepta[*cd*]phenalene (**10**) and 7*H*-cyclohepta[*cd*]phenalene (**11**) in a ratio of about 9: 13. The mixture was isolated in 56% yield after chromatography on alumina deactivated with 10% water. Owing to their highly unstable nature, compounds **10** and **11** have to be handled under nitrogen atmosphere throughout reaction and isolation. Although **10** and **11** could



not be separated due to their pronounced sensitivity toward air and heat, their structural assignments were readily borne out by 100 MHz ^{1}H-NMR and NMDR experiments. The mixture of **10** and **11** showed signals assignable to **10** at δ 2.71 (H-6,6′, d, $J_{6,7}$=6.7 Hz), 5.51 (H-7, dt, $J_{7,6}$=6.7, $J_{7,8}$=9.2 Hz), 6.33 (H-8, dd, $J_{8,7}$=9.2, $J_{8,9}$=6.5 Hz), 6.84 (H-9, d, $J_{9,8}$=6.5 Hz), and **11** at 1.66 (H-7,7′, dd, $J_{7,6}$=7.3, $J_{7,8}$=6.5 Hz), 4.82 (H-8, dtd, $J_{8,7}$=6.5, $J_{8,9}$=8.5, $J_{8,6}$=2.4 Hz), 5.27 (H-6, td, $J_{6,7}$=7.3, $J_{6,8}$=2.4 Hz), and 6.66(H-9,d, $J_{9,8}$=8.5 Hz) along with multiplet of the aromatic protons at 7.02—8.07. Irradiation at δ 2.71 (H-6,6′ of **10**) converted the doublets of triplet at δ 5.51 attributed to H-7 of **10** into a clean doublet with J=9.2 Hz. Another irradiation at δ 1.66 assigned to H-7,7′ of **11** changed the triplets of doublet at δ 5.27 and the doublets of triplets of doublet at δ 4.82 into a broad singlet and a broad doublet, respectively. Additional evidence in favor

of the assigned structures is the mass spectrum of the mixture which showed peaks at *m/e* 216 (M^+, 100%), 215 (M^+—H, 73%), and 202 (pyrene ion, 21%).

Hydride abstraction from the freshly prepared mixture of **10** and **11** with triphenylmethyl tetrafluoroborate in chloroform at room temperature immediately gave the desired cation (**1**).

In conformity with the theoretical prediction by Zahradnik *et al.*[14] the cyclohepta[*cd*]phenalenium tetrafluoroborate (**1**) is extremely stable reddish brown crystals which sinter at 199—201 °C and show no definite melting point. **1** can be stored without any change under atmospheric condition. The electronic spectrum of **1** is reproduced in Fig. 1. At least three major bands can be discerned. In either acetonitrile or water **1** shows essentially the same spectrum. The analysis of the electronic spectrum was kindly carried out by Zahradnik and Slanina[23] and was summarized in Table 2 and displayed in Fig. 1. The 100 MHz ^{1}H-NMR spectrum of **1** in deuteriotrifluoroacetic acid (see Fig. 2) consists of superimposed signals of AA'XX',[24] 2×AB, and A_2B spin systems at δ 9.08 (H-7, 8 or H-6, 9), 9.66 (H-6, 9 or H-7, 8), 9.16 (H-5, 10),[25] 9.50 (H-4, 11),[25] 9.40 (H-1, 3), and 9.00 (H-2) with coupling constants of $J_{6,7}=J_{8,9}=10.9$, $J_{7,8}=9.0$, $J_{6,8}=J_{7,9}=1.4$, $J_{6,9}=0$, $J_{4,5}=J_{10,11}=8.9$, and $J_{1,2}=J_{2,3}=7.7$ Hz. The observed vicinal coupling constants in the six-membered ring are in good agreement with those predicted by the empirical correlation against SCF bond orders.[26] Thus using SCF bond orders,[23] we obtain 8.5 Hz for $J_{4,5}$ and $J_{10,11}$ and 7.6 Hz for $J_{1,2}$ and $J_{2,3}$. The comparative uniformity of the coupling constants indicates no appreciable bond fixation exists in the periphery of **1**. Both the substantial downfield chemical shifts with rather narrow range (δ 9.00—9.66 ppm) and the symmetrical pattern of the signals show the cation **1** to have fully delocalized structure with C_{2v}-symmetry.

Despite the fact that an unit positive charge resides over the fifteen peripheral carbon atoms, the ^{1}H-NMR signals of **1** are comparable to those of the tropylium ion (δ 9.20 in acetonitrile)[27] and the phenalenium ion (δ 9.30 and 8.48 in arsenic trichloride).[28] This provides evidence of the existence of a strong induced diamagnetic ring current associated with the 14π perimeter of **1**. These evidences support the idea that the cation **1** is best thought of as a perturbed [15]annulenium ion weakly coupled with a localized central vinyl cross-link.[29]

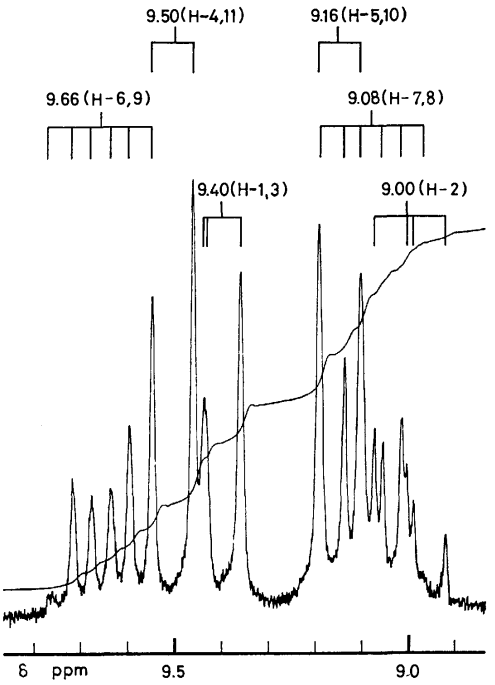


Fig. 2. 100 MHz ^{1}H-NMR spectrum of the cyclohepta-[*cd*]phenalenium tetrafluoroborate (**1**) in CF_3COOD.

The thermodynamic stability of **1** is clearly reflected in its pK_R^+ value. Standard spectrophotometric method was used for the pK_R^+ determination in 20% aqueous acetonitrile solution. The pK_R^+ value of 8.4 thus obtained is the lower limit, since the intensity of absorbancy decreases with elapse of time in the pH range near pK_R^+. Thus the measurement at 180 s after preparation of the solution yields a somewhat small value of 8.1. In any way, pK_R^+ value of **1** is about 1 pK unit larger than that of the 8-cycloheptatrienyl-heptafulvenyl cation ($pK_R^+=7.1$,[30] 7.49[31]). To our knowledge, **1** is the most stable hydrocarbon cation so far reported.

TABLE 2. ELECTRONIC SPECTRA OF **1**

No.	Calcd[a]						Obsd[b]	
	E (eV)	10^{-3} ν(cm^{-1})	λ (nm)	Polarization[c]	log f	Configuration	λ	log ε

8	4.99	40.2	249	y	−0.38	5—9		

a) The calculations are based upon the LCI-SCF (PPP-type) method. Parameters used are: I_c= 11.42 eV, A_c=0.58 eV, β_{cc}^{core}= −2.318 eV. Singly excited configurations were formed by promotions of electrons between the four highest occupied and the four lowest unoccupied MO's. b) The values are obtained in acetonitrile solution. c) x and y denote polarization along short and long axes of **1**, respectively.

Experimental

All melting points are uncorrected. The IR spectra were obtained on a Hitachi EPI G21 spectrometer. The electronic spectra were taken with a Hitachi 124 double beam spectrophotometer and were recorded in nm and the log ε values were given in parentheses. The mass spectra were obtained on a Hitachi RM-50 spectrometer at 70 eV. The ^{1}H-NMR spectra measured on a Varian T-60 and a Varian XL-100-15 spectrometers were given in δ-values with respect to tetramethylsilane as an internal standard, and the coupling constants (*J*) are given in Hz.

γ-(2,3-Dihydrophenalenyl)butyric Acid (3). A soln of 2,3-dihydrophenalenone (**2**) (9.1 g, 50 mmol) in a 1:1 mixture of anhyd benzene and ether (100 ml), zinc amalgam (10 g), and a small amount of iodine were placed in a three-necked flask. To this mixture methyl 4-bromocrotonate (2.2 g, 20 mmol) was added. The mixture was heated to 60 °C to start the reaction. After exothermic reaction occur additional methyl 4-bromocrotonate (8.8 g, 40 mmol) was added dropwise. After refluxing for 24 h the mixture was cooled and treated with dil hydrochloric acid. The organic layer was separated and washed successively with water, saturated sodium hydrogencarbonate soln, and water, dried (Na_2SO_4) and the solvent was removed to give methyl γ-(2,3-dihydro-1-hydroxyphenalenyl)crotonate as a viscous oil. IR (neat): 3450 (OH), 1700 cm^{-1} (C=O); NMR ($CDCl_3$): 1.8—2.1 (m, 2H), 2.4 (d, J=7, 2H), 2.8—3.1 (m, 2H), 2.9 (s, 1H), 3.6 (s, 3H), 5.6 (d, J=15, 1H), and 6.7—7.6 (m, 7H).

The crude ester thus obtained, palladium hydroxide charcoal (2 g), and 100 ml of ethanol were placed in a flask. The mixture was stirred under hydrogen atmosphere in an usual manner. After filtration of the catalyst, resulting soln was concd and the residue was dist under reduced pressure to give methyl γ-(2,3-dihydrophenalenyl)butylate as yellow oil, bp 170—174 °C/2 Torr, 8.4 g; IR (neat): 1730 cm^{-1} (C=O); NMR (CCl_4): 1.5—2.4 (m, 8H), 2.9—3.3 (m, 3H), 3.6 (s, 3H), and 7.0—7.7 (m, 6H).

Found: C, 80.34; H, 7.52%. Calcd for $C_{18}H_{20}O_2$: C, 80.56; H, 7.51%.

A mixture of the ester (8.4 g), 50% aq potassium hydroxide (10 ml), and ethanol (50 ml) was stirred for overnight at room temp. Most of the ethanol was removed and replaced by water. The aq layer was then washed with ether and acidified with 3M hydrochloric acid. The mixture was extracted with ether and the extract was washed with water and dried (Na_2SO_4). Evaporation of the solvent gave crude **3**. Recrystallization of the crude **3** from benzene–hexane yielded pure **3** as colorless plates, mp 90.0—90.5 °C; 6.11 g (48% yield based on **2**). IR(KBr): 3500—2500 (OH), 1700 cm^{-1} (C=O); NMR($CDCl_3$): 1.6—2.5(m, 8H), 2.9—3.3(m, 3H), 7.0—7.7(m, 6H), 10.7(bs, 1H).

Found: C, 80.42; H, 7.13%. Calcd for $C_{17}H_{18}O_2$: C, 80.28; H, 7.13%.

6H-7,8,9,9a,10,11-Hexahydrocyclohepta[cd]*phenalen-6-one (4).* To polyphosphoric acid prepared from 130 ml of phosphoric acid and 260 g of phosphorus pentaoxide was added 6.11 g of **3** at 90 °C by portion with care. The resultant soln was stirred at this temp for 1 h, then poured onto ice. Extraction with ether and the extract was washed successively with water, saturated aq soln of sodium hydrogencarbonate, and water, and dried (Na_2SO_4). Evaporation of the solvent gave crude **4** which on recrystallization from benzene–hexane afforded **4** as colorless plates, mp 97.5—98 °C; 4.7 g (75%); IR(KBr): 1665 cm^{-1} (C=O); NMR(CCl_4): 1.6—2.2(m, 6H), 2.5—2.7(m, 2H), 2.9—3.5(m, 3H), 7.0—7.7(m, 5H); MS: *m/e* 236(M^+, 100%), 208(M^+—CO, 27%).

Found: C, 86.65; H, 6.85%. Calcd for $C_{17}H_{16}O$: C, 86.40; H, 6.83%.

7,7-Dibromo-6H-7,8,9,9a,10,11-hexahydrocyclohepta[cd]*phenalen-6-one (5).* To a soln of **4** (1.0 g, 4.2 mmol) in carbon tetrachloride (30 ml) was added a soln of bromine (1.5 g, 9 mmol) in carbon tetrachloride (8 ml). The resultant soln was stirred for overnight at room temp and then washed with saturated aq soln of sodium hydrogensulfate and water, and dried (Na_2SO_4). Evaporation of the solvent under reduced pressure at 0 °C gave crude dibromide **5** as viscous oil in quantitative yield. IR(neat): 1695 cm^{-1} (C=O); NMR(CCl_4): 1.5—2.7(m, 6H), 2.8—3.3(m, 3H), 7.0—7.7(m, 5H). The crude **5** was used for subsequent reaction without further purification.

6H-10,11-Dihydrocyclohepta[cd]*phenalen-6-one (6).* Anhyd lithium chloride (0.55 g, 13 mmol) was added at once to a soln of **5**, prepared from 10 g of **4** described as above, in hexamethylphosphoric triamide (40 ml). The stirred mixture was heated at 95—100 °C for 1 h under nitrogen. After cooling the mixture was poured into 300 ml of water and the product, which was isolated by ether extraction, was chromatographed on 10 g of alumina eluted with benzene to give the tetracyclic ketone **6** (650 mg, 66.7%). Further elution with ether gave the full conjugated ketone **8** (110 mg, 10%). **6**: pale yellow plates, mp 90.0—90.5 °C, MS: *m/e* 232(M^+, 64%), 204(M^+—CO, 100%), 202(82%); IR (KBr): 1625, 1590, 1580 cm^{-1}; UV(ethanol): 243(4.38), 287 (4.33), 344(3.91); (cyclohexane): 240(4.39), 283(4.31), 337 (3.98); (concd H_2SO_4): 249(4.51), 299(4.57), 418(3.90); NMR: see text.

Found: C, 87.73; H, 5.28%. Calcd for $C_{17}H_{12}O$: C, 87.90; H, 5.21%.

Cyclohepta[cd]*phenalen-6-one (8).* (i) To a dry Pyrex tube were added 100 mg of **6** (0.43 mmol), 120 mg of 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (0.53 mmol) and anhyd benzene (20 ml). The tube was evacuated and sealed and placed in a 120 °C oil bath for 20 h. Upon cooling, a small amount of ppt's was removed by filtration and the solvent was evaporated. Chromatography on alumina with benzene gave 41 mg of the starting material. Successive elution with ether afforded **5** (13 mg, 22%).

(ii) To a soln containing **6** (1.2 g, 5.2 mmol) in 30 ml of glacial acetic acid was added 1.8 g of triphenylmethyl tetrafluoroborate (5.5 mmol). The soln was refluxed under a nitrogen atmosphere for 1.5 h. After cooling, the mixture was poured into 200 ml of water and extracted with ether. The ethereal extracts were washed successively with a saturated soln of sodium hydrogencarbonate and water, dried (Na_2SO_4) and concentrated. The residue was purified by column chromatography on alumina with ether gave 500 mg of **5** (42%): orange scales, mp 144—146 °C, MS: *m/e* 230 (M^+, 27%), 202(M^+—CO, 100%); IR(KBr): 1600, 1590, 1560 cm^{-1}; UV(ethanol): 249(4.48), 311(4.07), 321(4.08), 430 (4.23); cyclohexane): 246(4.47), 311(4.10), 430(4.19); (concd H_2SO_4): 235(4.29), 269(4.27, sh), 294(4.45), 469(4.16, sh), 494 (4.58); NMR: see text.

Found: C, 88.41; H, 4.41%. Calcd for $C_{17}H_{10}O$: C, 88.67; H, 4.38%.

6H-(10) and 7H-Cyclohepta[cd]*phenalene (11).* Lithium aluminum hydride–aluminum chloride complex was prepared from 1.2 g (31.6 mmol) of $LiAlH_4$, 4.2 g (31.5 mmol) of $AlCl_3$ and 100 ml of ether under reflux. The clear supernatant (40 ml) was transferred into dry flask precooled to −55 °C by syringe. To this soln was added dropwise a soln of 120 mg of **7** (0.52 mmol) in 25 ml of dry THF over a period of 1 h at −55 °C. After stirring for 2 more h at −50 °C the mixture was stand for overnight maintained at −80 °C. To this soln was added a moist THF to prevent the reaction. The resultant yellow supernatant was transferred under nitrogen into a flask containing anhyd sodium sulfate by decantation and filtered. The solvent was concd at 0 °C under reduced pressure and replaced by hexane. The hexane soluble portion was chromatographed on a column of alumina deactivated with 10% water with light pet. ether afforded a 9:13 mixture of **10** and **11** (63 mg, 56%) as a yellow oil. MS: *m/e* 216(M^+, 100%), 215(M^+—H, 73%), 202(21%); NMR: see text. All manipulations have to be carried out under a nitrogen atmosphere to avoid decomposition.

Cyclohepta[cd]*phenalenium Tetrafluoroborate (1).* A suspen-

sion of 70 mg (0.21 mmol) of triphenylmethyl tetrafluoroborate in 2 ml of chloroform was stirred under a nitrogen atmosphere and a soln of a mixture of **10** and **11** in 2 ml of chloroform was added *via* syringe. The resultant reddish brown ppt's of **1** were filtered and washed thoroughly with chloroform followed by carbon tetrachloride. Reddish crystals, 50 mg (79%), mp sinter at 199—201 °C and show no definite melting point. IR(KBr): 1040 cm^{-1} (BF_4^-); UV(acetonitrile): 224(4.40), 257(3.99), 291(4.37), 307(4.37, sh), 316(4.40), 334 (4.18, sh), 475(4.49); NMR: see text.

Found: C, 67.96; H, 3.59%. Calcd for $C_{17}H_{11}BF_4$: C, 67.59; H, 3.67%.

*p*K *Determinations.* The cation **1** (1.968 mg) was dissolved in 50 ml of acetonitrile. Each 2 ml of the soln was then made up to 10 ml with the buffer soln. The region between pH 4.3 to 8.0 was covered with buffers made up from mixtures of 0.1 M citric acid and 0.2 M Na_2HPO_4. The pH's greater than 8.0 were obtained with a buffer containing 0.1 M ammonium chloride and 0.1 M ammonia water.

The standard procedure was adopted of examining the electronic spectrum of **1** in thirteen soln's of buffer spaced through a pH range of about 5.4 to 9.5. The absorbancy at a wavelength characteristic of the cation was plotted against pH and the mid-point of the resulting titration curve was taken as the pK_R^+. The wavelength used was 475 nm. The pH's were read on a Beckman model G pH meter. Because after long periods the absorbancy was irreversibly changed on the basic side (pH>7), all spectra were taken just after 90 s of mixing the soln of the cation with that of the buffer. The pK_R^+ value thus obtained was found to be 8.4. When the spectra were taken after 180 s of mixing, the pK_R^+ was found to be 8.1.

The authors wish to thank Prof. R. Zahradnik and Dr. Z. Slanina, Czechoslovak Academy of Sciences, for their PPP-LCI-SCF calculations on **1** and for their generous permission to quote the results in this paper.

(Received December 22, 1975)

A kinetic study has been made of the reaction between 2,2-diphenyl-1-picrylhydrazyl and phenols in various solvents. Polar effects in the rate-determining transition state are discussed in terms of the Hammett type relationship. Remarkable solvation effects were observed. For *p*-methoxyphenol the reaction rate is the greatest in the solvents which do not form strong H-bond with phenols, and the smallest in aprotic H-accepting solvents. For *o*-methoxyphenol the rate is the greatest in protic solvents. The results are interpreted in terms of the difference in the mode of hydrogen bondings. The rate for the reaction of the radical with α-naphthol was followed in dioxane–2,2,4-trimethylpentane mixtures. The results are explained by the theory of Kondo and Tokura, indicating that the free energy depression in the ground state takes place mainly through hydrogen bonding.

The oxidation of phenols is known to be complicated from the fact that different products are obtained from the same phenols by use of different oxidants.[1] The stable free radical 2,2-diphenyl-1-picrylhydrazyl (DPPH) has been used not only as a radical scavenger but also as a hydrogen acceptor. The strong H-accepting property of DPPH has been demonstrated by a number of reactions between the radical and compounds containing C–H, N–H, O–H, and S–H bonds.[2-7]

The hydrogen abstraction reactions of DPPH from phenols have been a subject of interest. Hogg *et al.*[6] found that the rate is first-order with respect to DPPH and phenols; about two moles of DPPH is consumed by one mol of the phenols; retardation by the major product, 2,2-diphenyl-1-picrylhydrazine ($DPPH_2$), is generally observed; the rates are roughly correlated with the Hammett σ in the range $-0.4<\sigma<0.2$ ($\rho=-6$), but not beyond the entire range, the *o*-substitution lowering the rate remarkably. They suggested that the H-abstraction is involved in the rate-determining step. McGowan *et al.*[4] suggested that the rate-determining step involves the removal of a hydride ion to give a cation, since the substituent effect is very similar to the solvolysis of α,α-dimethylbenzyl chlorides.

Among the factors that influence the rate, the solvent effect is considered to be one of the most important. However, information is scanty. If we select closely related phenols and carry out the reaction in a variety of selected solvents, the effect of individual factors could be observed. Bivalent phenols, *o*- and *p*-methoxyphenols, and α-naphthol were chosen and the reaction was carried out in various solvents and their binary mixtures.

Experimental

Materials. $DPPH_2$ was prepared according to the method given by Goldschmidt and Renn,[8] or Poirier *et al.*[9] Recrystallization was carried out from a chloroform–ethanol mixture. DPPH was prepared by oxidizing $DPPH_2$ in benzene with lead dioxide, and purified by repeated crystallization from a benzene–ligroin mixture, and then from carbon disulfide. Solid phenols of reagent grade were purified by means of sublimation. The reagents were stored in the dark and sublimed again just before use. *o*-Methoxyphenol was distilled twice under reduced pressure. Solvents were dried and purified in the usual way.

Procedures. DPPH exhibits a strong absorption around 520 nm. The absorbance at this wavelength was followed by means of a Hitachi 101 or 124 Spectrophotometer. The solutions of these phenols(10^{-3}—10^{-5} M) and DPPH(*ca.* 10^{-5} M) of desired concentrations were prepared separately and allowed to stand for about 30 min in a thermostat. The mixture of the two solutions was transferred quickly into a 3 cm optical cell equipped with a jacket through which thermostated water is circulated. The reaction temperature was controlled within ±0.2 °C. The absorbance at 520 nm was recorded at appropriate time intervals. In transforming the absorbance into concentration, a small correction due to the production of $DPPH_2$ was made. The rate constants were checked by duplicate runs.

Results

Effects of Oxygen, $DPPH_2$, and Picryl Chloride. It is possible that oxygen exerts some effect on the rate and nature of products. In order to examine this, the reaction was carried out in aerated and deaerated solutions. No appreciable difference in rates was observed for hydroquinone and catechol. Thus all the reactions involving them were carried out in the presence of air. No retardation was observed even when a great excess of $DPPH_2$ was added with respect to DPPH. For resorcinol, the rate was somewhat greater in aerated solutions than in deaerated ones (Table 1). Retardation occurred for phenols other than hydroquinone and

catechol in the presence of $DPPH_2$. An example is shown in Fig. 1. Picryl chloride was added to the system, since substances having a picryl group often form picrates with many compounds and this might exert a specific effect on the rate. However, no appreciable change in rate was observed.

Stoichiometry and Reaction Products. Aliquots of the DPPH and phenol solutions were mixed and allowed to stand. After the reaction had ceased, the concentrations of the remaining DPPH were determined and plotted against $[DPPH]_0/[Phenol]_0$. We see that the molar ratios of DPPH to both hydroquinone and catechol reacted are 2: 1 (Fig. 2). The same holds for α-naphthol. For resorcinol the reaction was too slow to determine the ratio exactly, more than two moles of DPPH being consumed per mole of resorcinol after a long time. More than 75% of consumed DPPH was converted into $DPPH_2$, the isolation of which from a reaction mixture being made by alumina column chromatography. The quantities of the produced quinones were estimated by iodometry recommended by Mahoney and DaRooge.[10] It was found that 90 and 93% of hydroquinone and catechol were converted into the corresponding quinones, respectively. Isolation and identification of the products from other phenols were unsuccessful.

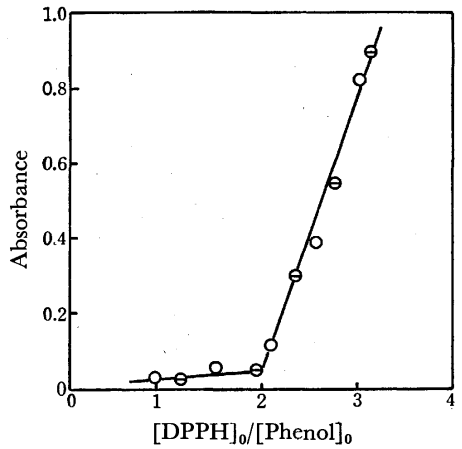

Fig. 2. Stoichiometry for the reaction between DPPH and bivalent phenols. ○: Catechol, ⊖: hydroquinone.

Order of Reaction. The reaction between DPPH and hydroquinone (and catechol) was found to follow strictly the second-order kinetics over almost the entire course of reaction. The apparent rate constants were estimated on the basis of the integrated second-order rate equation in which the above stoichiometry was taken into account. For other phenols, the conventional initial-rate method was applied to determine the order. The reaction was found to be first-order with respect to both DPPH and the phenols.

Reaction Rates. The values of the rate constants in benzene at various temperatures are given in Table 1 together with the Arrhenius parameters. The rate constants in various solvents are given in Tables 2 and 3. The activation parameters in benzene are $E_a=9.4$ kcal/mol. $\Delta S^*(300\text{ K})=-25$ gibbs/mol for *o*-methoxyphenol, and $E_a=4.7$ kcal/mol, $\Delta S^*(300\text{ K})=-22$ gibbs/mol for *p*-methoxyphenol. The values for the latter are in good agreement with those reported.[6] The difference in the activation energies (4.7 kcal/mol) in benzene can be ascribed to the energy of intramolecular H-bonding for the *o*-isomer. The rate constants for α-naphthol in the binary dioxane-2,2,4-trimethylpentane(isooctane) mixtures are given in Table 4 together with the activation parameters.

Table 2. Rate constants for the reaction of DPPH with hydroquinone and catechol in various solvents

Solvent	Temp (°C)	$k(M^{-1}s^{-1})$ Hydroquinone	$k(M^{-1}s^{-1})$ Catechol

a) Rate measured at temperatures as indicated in parentheses, because of a great reaction rate and low activation energy in pure isooctane.

Discussion

Reaction Sequence. A possible main reaction sequence for the reaction of DPPH with bivalent phenols can be given by

$$QH_2 + DPPH \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} QH\cdot + DPPH_2$$

(1) (foward reaction), (1′) (reverse reaction)

$$QH\cdot + DPPH \xrightarrow{k_2} Q + DPPH_2 \quad (2)$$

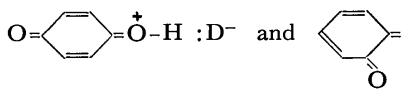
$$2QH\cdot \xrightarrow{k_3} \text{Combination, Disproportionation}^{12-15)} \quad (3)$$

$$QH\cdot + O_2 \xrightarrow{k_4} \text{Peroxide}^{16)} \quad (4)$$

where QH_2 and Q denote the bivalent phenols and the corresponding quinones, respectively, and QH· the phenoxy radical.

For hydroquinone and catechol, Reactions 1′ and 4 can be neglected on the basis of experimental evidence. In order to be consistent with the rate equation and the reaction products, Reaction 3 could also be neglected as compared with Reaction 2. This may be rationalized by the following consideration: The termination constants for unhindered phenoxy radicals have been measured by flash photolysis[14,15] and ESR[12] techniques. The reported values are 10^6—10^9 M^{-1} s^{-1} depending on substituent and solvent. If we assume that $k_3 \approx 10^9$ M^{-1} s^{-1} (diffusion-controlled rate constant), then it can be shown that Reaction 3 can be neglected only when k_2 is approximately larger than 10^7 M^{-1} s^{-1}. Since DPPH has been used as a radical scavenger, a value as large as $\approx 10^7$ M^{-1} s^{-1} is not surprising.

The free energy of activation for Reaction 2 would be favored by the resonance contribution such as



in the transition states for hydroquinone and catechol, where D denotes DPPH. Using the data given by Ayscough and Russell[13] and Mahoney *et al.*,[17] the heat of reaction of DPPH with hydroquinone was calculated to be $\Delta H = -12.3$ kcal/2 mol of DPPH. Since the heat of reaction of 1 can be estimated to be *ca.* 26 kcal/mol from the difference in the dissociation energy of N–H and O–H bonds, the driving forces of Reaction 2 must be the large exothermicity ($\Delta H = -38.3$ kcal/mol) and probably a low activation energy of this step. It can thus be concluded that the rate-determining step is involved in Reaction 1.

The rates for hydroquinone and catechol are of the same order of magnitude.* This indicates that the first abstracted hydrogen atom for catechol is the one which is not intramolecularly H-bonded. For resorcinol, the phenoxy radicals may be consumed *via* competition reactions (1′, 2, 3, and 4) making kinetic analysis difficult. The existence of opposing reaction (Reaction 1′) might be responsible for the upward deviation from the pseudo first-order plot and the retardation by $DPPH_2$ (Fig. 1), as suggested for other phenols.[6] The fact that a small increase in rates in aerated solutions was observed for resorcinol (Table 1) seems to suggest the importance of Reaction 1′.

An alternative explanation for the retardation effect of $DPPH_2$ is to assume complex formation between DPPH and $DPPH_2$; it was introduced to explain the kinetics of the reaction of DPPH with amines and solvents.[2,18] It cannot be excluded since we found that the absorbance of DPPH–$DPPH_2$ mixture at 520 nm is slightly smaller than that expected from the additivity rule. However, if any complex formation were to occur, it would not exert remarkable effect on the reaction rate, since no retardation was observed for hydroquinone and catechol.

Substituent Effects. The reaction between DPPH and resorcinol proceeds much more slowly, the activation energy being *ca.* 5 kcal/mol higher than that for other bivalent phenols. Since the activation energies of univalent phenols are between 4.8 and 16.1 kcal/mol,[6] the difference in the rate is considered to be due to the substituent effects rather than the change in mechanism. Hogg *et al.*[6] studied the dependence of the rate on substituents and obtained a linear relation with a break point at σ nearly equal to 0.2 in the normal Hammett plot. On the other hand, McGowan *et al.*[4] found that the relative rates of the reactions in carbon tetrachloride are very close to those for the solvolysis of α,α-dimethylbenzyl chlorides, and suggested an ionic mechanism involving the abstraction of a hydride ion from phenols.

The polar effect arguments[19-21] in hydrogen abstraction reactions by radicals have been introduced to rationalize the substituent effects in the radical reactions. It was found that the correlation is better when log (relative-reactivity) is plotted against σ^+-values than against σ-values.[22-26] The contribution of polar mesomeric structures for the interpretation of radical reactions has been recognized to be useful.[19,27] It may

* The apparent rate constant for hydroquinone in Table 1 should be divided by two for comparison with other univalent phenols and catechol. Catechol reacts about three times faster than hydroquinone.

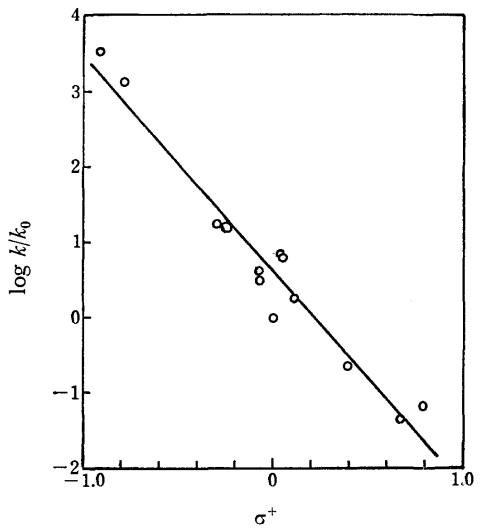


Fig. 3. Corelation of the rate constants for the reaction between DPPH and phenols with σ^+-values; in benzene at 30 °C.

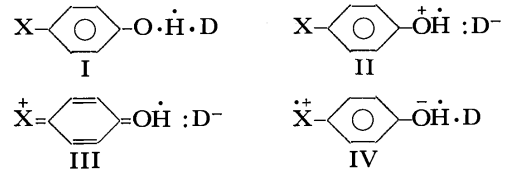
be worthwhile to reexamine the polar effect in this reaction series. Using the data of Hogg *et al.*[6] and those in the present study, log k/k_0 is plotted against σ^+ (Fig. 3). ρ is calculated to be -2.8 by the least-squares method. The correlation coefficient $r=-0.970$ of the σ^+-plot is much better than for the normal Hammett σ-plot ($r=-0.883$). It is noted that ρ has a very large negative value as compared with that for other H-abstraction reactions with more reactive radicals than DPPH.[22-26] Mahoney and DaRooge[10] reported that $\rho=-2.8$($\rho\sigma^+$-plot) for the reaction of 2,4,6-tri-*t*-butylphenoxyl with substituted phenols. We also found that $\rho=-3.1$($\rho\sigma^+$-plot, $r=-0.993$) for the reaction of 2,6-di-*t*-butyl-α-(3,5-di-*t*-butyl-4-oxo-2,5-cyclohexadiene-1-ylidene)-*p*-tolyloxyl(galvinoxyl) with substituted phenols.[28] Such high selectivity would be caused by the extremely stable and electrophilic nature of these radicals. Thus the large ρ-value in this reaction series is not regarded as exceptional. The existence of a better correlation with σ^+-substituent constants and the very large negative value indicate that the contribution of the resonance structures such as II, III, and IV virtually plays an important role in stabilizing the transition state. Hence DPPH acts as an electrophile as in the case of aromatic amines.[4]



Zavitsas[29,30] suggested that σ merely reflects the difference in the bond dissociation energies. However, since the reaction rates are not always directly related to the bond dissociation energies, his suggestion is questionable.[20,21]

In order to interpret the large substituent effect, we might assume the formation of a CT-complex between the phenols and DPPH, followed by a slow proton transfer. However, we have no spectroscopic evidence. Addition of picryl chloride has no effect on the rate. The kinetic data are not in line with the assumption. Thus such a CT-complex may exist, if any, only as a transient species.

Solvent Effects. Although bulk properties such as the dielectric constant of medium are important in radical reactions, specific solvation effect such as H-bonding would be more important. We see from Table 2 that the rate is the greatest in solvents which do not usually form H-bond, and the slowest in aprotic H-accepting solvents. Acetone, dioxane, and diethyl ether act as H-acceptors. Since the reaction involves the abstraction of the H-bonded hydrogen, extra energy is required for desolvation in the transition state. The rates in protic solvents seem to suggest that the solvents act as a proton-donor as well as a proton-acceptor. There is a marked difference between *o*- and *p*-methoxyphenols in reactivity (Table 3). It seems that the difference is too large to be ascribed to the steric and/or electronic effects since the reactivity ratios depend strongly on the nature of solvent. It is reasonable to ascribe the slower rate for *o*-methoxyphenol to the intramolecular H-bonding. In diethyl ether and dioxane, there should be an intermolecular H-bond formation between the *p*-isomer and these solvents. This may be responsible for the pronounced decrease in rates. It is noted that the rates are of the same order as those for the *o*-isomer in benzene and carbon tetrachloride. On the other hand, since the *o*-isomer is already intramolecularly H-bonded, no serious solvent effect is expected for this compound. However, the rates decreased one order of magnitude in dioxane and diethyl ether as compared with benzene and carbon tetrachloride (Table 3). This could be interpreted in terms of the masking effect through partial H-bonding with the solvents. For the *o*-isomer the rates are greater in methanol and 2-propanol than in other solvents. The alcohols would behave as a proton donor as well as a proton acceptor. The hydroxyl group of the solvents would help push out the hydrogen atom being abstracted. The fact that the rate is greater for catechol than for hydroquinone supports this idea. Judging from the experimental results, the pushing effect overwhelms the masking effect for the *o*-isomer. Since the hydroxyl group of this compound is fixed by the neighboring methoxy group, the pushing effect may become predominant. On the other hand, the masking effect is operative for the *p*-isomer. The rate can be determined by a compromise between the two effects.

An alternative interpretation is that a rapid proton exchange in protic solvents results in only a small difference in the rates of the two isomers. In this respect, the comparatively poor reproducibility in the protic solvents (Tables 2 and 3) deserves attention.

Reaction in Binary Mixtures. If the thermodynamic quantities for solvation are known, they can be correlated with the rate factors. If we examine the dependency of the reaction rate on the composition of mixed solvents, with one of which the reactant is solvated, the result would be of interest. Kondo *et al.*[31] have developed a theory of the reaction rates in binary mixed solvents.

They derived rate equations

$$A + B \longrightarrow M^* \longrightarrow X + Y \cdots$$

for a general second-order reaction in mixed solvents which consist of two components denoted by 1 and 4. If only one of the reactants, say B, is solvated in the solvent 4 to form an addition product, the simplified rate equation is given by

$$\ln k_{mix} = x_1 \ln k_1 + x_4 \ln k_4 + x_4 \ln (K_x + 1) - \ln (x_4 K_x + 1), \quad (5)$$

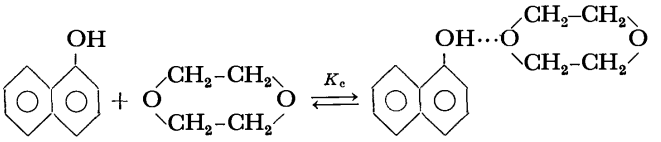
where K_x denotes the association constant expressed in terms of mole fractions for the formation of the addition product; x_1 and x_4 are the mole fractions of 1 and 4, respectively. The expression for the activation energy is given by differentiating Eq. 5 with respect to temperature;

$$E_{mix} = x_1 E_1 + x_4 E_4 - \frac{x_1 x_4 \Delta H^\circ}{(1 + 1/K_x)(x_4 + 1/K_x)}, \quad (6)$$

where ΔH° denotes the heat of formation of the adduct.

In acetone–cyclohexane mixtures, the rate deviates considerably from that expected from an ideal solution (Figs. 4 and 5). Although the deviation is as expected from Eq. 5, the rate in pure cyclohexane and the K_x-value could not be obtained in this system.

For examination of Eqs. 5 and 6, we carried out the reaction of DPPH with α-naphthol in isooctane–dioxane mixtures; the results are given in Table 4. The system was chosen since Baba and Suzuki[32] reported that the association constant for the reaction



is K_c(20 °C)=20.9 M^{-1} and the heat of formation is ΔH° = −5.4 kcal/mol. The heat of formation of the adduct agrees with the difference in activation energy for the reaction in pure dioxane and isooctane (Table 4). In the

papers of Kondo *et al.*[31] K_x-values were tacitly assumed to be independent of the solvent composition. However, this is not the case generally. In the present case the K_x-value varies from 245 in pure dioxane to 126 in pure isooctane when $K_c=20.9\ M^{-1}$ is used. By means of Eq. 5, the rate constant k_{mix} at any composition can be calculated using the values for k_1 and k_4 (Table 4) and the K_x-values estimated from the K_c-values obtained by Baba and Suzuki. The predicted k_{mix}-values are plotted in Fig. 6 as a function of the mole fraction of isooctane (solid line), together with the experimental points (open circles). It can be seen that the behavior of the specific solvation interaction in the binary dioxane–isooctane system is expressed by this theory. A similar treatment has been carried out for the energy of activation (Fig. 7). As a results of the specific solvation, the energy of activation decreases sharply as the mole fraction of isooctane approaches unity, as predicted by the theory.

It is concluded that in the hydrogen abstraction reaction in this system, the most important factors which govern the reaction rate are the polar mesomeric and H-bonding effects which affect greatly the free energies in the transition and ground states, respectively.

The authors wish to thank Proffessor S. Hasegawa, Dr. M. Kimura, and Dr. S. Yamamoto for their valuable discussions and suggestions.

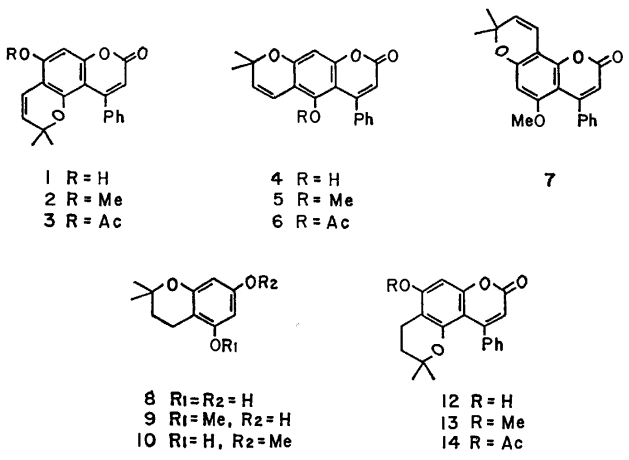
(Received January 26, 1977)

Three isomers of 2*H*,8*H*-benzo[1,2-*b*: 3,4-*b*']dipyran and 2*H*,8*H*-benzo[1,2-*b*: 5,4-*b*']dipyran, were synthesized by dehydrogenation of the dihydrobenzodipyran derivatives using DDQ or NBS and by dehydration of the secondary alcohol prepared by reduction of 4-phenylcoumarin derivatives bearing dihydropyranone ring with sodium borohydride.

A number of coumarins containing a dimethylpyran ring have been found in nature, *e.g.* calophyllolide,[1] inophyllolide,[1,2] ponnalide,[3] tomentolide A[4] as 4-phenylcoumarins. Total syntheses of these compounds and several synthetic routes of a dimethylpyran ring or dimethylchromene ring have been reported.[5-9] In the case of these 4-phenylcoumarins, it is known that the chemical shifts of dimethyl groups in fused dimethylpyran ring at 5,6-position and of the other substituents situated in the proximity of 4-phenyl ring show marked shifts from their normal values in NMR spectra.[4,10]

We have synthesized three isomers of 2*H*,8*H*-benzo[1,2-*b*: 3,4-*b*']dipyran and 2*H*,8*H*-benzo[1,2-*b*: 5,4-*b*']dipyran, (**1**—**7**), by dehydrogenation of the dihydropyran ring using 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) or *N*-bromosuccinimide (NBS) and by reduction of the dihydropyranone ring with sodium borohydride, followed by dehydration of the corresponding alcohol. The chemical shifts of methyl protons (*gem*-dimethyl, acetoxyl, and methoxyl groups) of 4-phenylcoumarin derivatives bearing dimethylpyran, dimethyldihydropyran, or dimethyldihydropyranone ring were investigated with respect to a shielding effect of 4-phenyl ring in NMR spectra.



Scheme 1.

Dimethylchromans (**8**—**10**) and dimethylchromanone (**11**) were used as the starting material for an approach to syntheses of the isomeric 2*H*,8*H*-benzodipyran derivatives (**1**—**7**). The Pechmann reaction of **8** with ethyl benzoylacetate in the presence of sulfuric acid in acetic acid afforded hydroxy-4-phenylcoumarin (**12**), whose structure was proved on the basis of the accompanying evidences. The methyl ether (**13**) of **12** could be synthesized from **9** by a method similar to that for **8**. Bromination of the acetate (**14**) of **12** with NBS in benzene, followed by treatment with zinc dust gave the desired dehydro compound (**1**). The IR spectrum of **1** exhibited absorption due to the hydroxyl group at 3240 cm^{-1} and the double bond at 1647 cm^{-1}. In its NMR spectrum, the signals at δ 0.94 ppm (6H, s) and 5.42, 6.45 ppm (each 1H, d, J=10.0 Hz) showed the presence of a dimethylpyran ring. Therefore, the structure of **1** was established as 5-hydroxy-2,2-dimethyl-10-phenyl-2*H*,8*H*-benzo[1,2-*b*: 3,4-*b*']dipyran-8-one. On the other hand, the dehydrogenation of **13** with DDQ afforded the corresponding dehydro compound (**2**), which was identical with the methyl ether of **1** by a mixed-melting-point determination and by IR and NMR spectral comparison.

The linear isomers (**4**), (**5**), and (**6**) bearing dimethylpyran ring on 6,7-position of coumarin nucleus were prepared by the following procedure. Treatment of **11** with ethyl benzoylacetate in the presence of polyphosphoric acid (PPA) gave two products, 6,7-dihydro-5-hydroxy-4-phenyl-2*H*,8*H*-benzo[1,2-*b*: 5,4-*b*']dipyran-2,6-dione (**15**) and 3,4-dihydro-5-hydroxy-10-phenyl-2*H*,8*H*-benzo[1,2-*b*: 3,4-*b*']dipyran-4,8-dione (**18**), as expected, both of which could be separated by column chromatography. The IR spectrum of **15** exhibited absorption bands due to the α-pyrone at 1740 and 1623 cm^{-1}. The NMR spectrum indicated the presence of a phenolic proton at δ 13.00 ppm (1H, s) having an intramolecular hydrogen bonding. Reduction of the methyl ether (**16**) of **15** with sodium borohydride, followed by dehydration of the resulting secondary alcohol (**21**) with pyridine–acetic anhydride gave the corresponding dehydro compound (**5**). The NMR spectrum of **5** showed signals at δ 1.46 ppm (6H, s) and 5.63, 6.43 ppm (each 1H, d, J=10.0 Hz) due to *gem*-dimethyl protons and vinyl protons of the dimethylpyran ring. By a similar method, the dehydro compound (**2**) was obtained from the methyl ether (**19**) of **18** *via* secondary alcohol (**25**). However, reaction of the acetate (**17**) or (**20**) with sodium borohydride converted the carbonyl function of the pyranone ring into the methylene function to give **22** or **12** as the main product, respectively. The structures of **12** and **22** were assigned by IR and NMR spectral comparisons. The acetate (**24**) of **22** was treated with NBS. Subsequent dehydrobromination of the resulting brominated product with zinc dust yielded the dehydro compound (**6**). After hydrolysis of **6** with hydrochloric acid in methanol, the

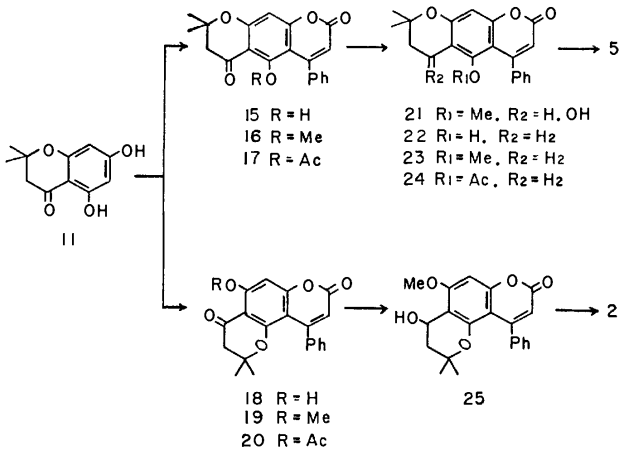
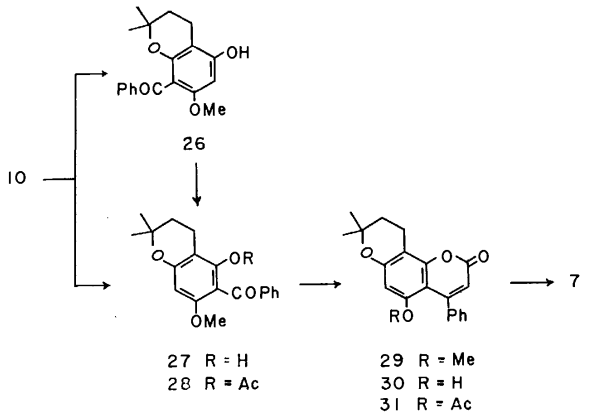
resulting hydroxy derivative (**4**) was methylated with methyl iodide in the presence of anhydrous potassium carbonate to give a methyl ether, which was shown to be identical with **5**.



Scheme 2.

The synthesis of another isomer (**7**) bearing dimethylpyran ring on 7,8-position was carried out as follows. The Hoesch reaction of **10** with benzonitrile using zinc chloride as a catalyst afforded 8-benzoyl-5-hydroxy-7-methoxy-2,2-dimethylchroman (**26**) in higher yield than that of 6-benzoyl isomer (**27**). **26** was readily transformed into **27** in the presence of an acidic catalyst such as sulfuric acid or aluminium chloride.[11] Confirmation of the structures was performed by spectral data and an alcoholic ferric chloride reaction. The acetate (**28**) of **27** was then converted into the coumarin derivative (**29**) by dehydration in the presence of a mixture of acetic anhydride and sodium acetate. **29** was also obtained together with **12** and **30** by the Pechmann reaction of **10** with ethyl benzoylacetate. **29**, **30**, and **31** have been derived from natural mammeisin, and their IR, UV spectra and melting points are compatible with those of authentic samples.[12] Dehydrogenation of **29** with DDQ gave the expected dehydro compound (**7**), which showed signals at δ 1.48 ppm (6H, s) and 5.90, 6.90 ppm (each 1H, d, J=10.0 Hz) due to methyl protons and vinyl protons of the dimethylpyran ring in the NMR spectrum.

It is significant to compare the NMR spectral data of some synthetic samples. The chemical shifts of dimethyl protons of **2**, **3**, **13**, **14**, **19**, and **20** (δ 0.84—0.98 ppm) containing dimethylpyran, dimethyldihydropyran, or dimethyldihydropyranone ring at 5,6-position, appeared in a higher magnetic field than those of **5**, **6**, **7**, **16**, **17**, **23**, **24**, **29**, and **31** (δ 1.33—1.48 ppm) containing a pyran ring at 6,7- or 7,8-position in coumarin nucleus (Table 1). The methyl protons of acetoxyl or methoxyl group substituted at 5-position showed chemical shifts in a higher magnetic field than those at 7-position. These characteristic shifts are though to be due to the anisotropic shielding effect of the phenyl ring at 4-position,[13] as has been found to be the case[2,4,10] in calophyllolide and inophyllolide. Thus, NMR spectral analysis might be useful for the structural confirmation of 4-phenylcoumarin derivatives.



Scheme 3.

Experimental

All the melting points are uncorrected. Unless otherwise stated, the NMR spectra were taken in deuteriochloroform using tetramethylsilane as an internal standard on a Hitachi

Model R-20 NMR spectrometer (60 MHz) or a JEOL JNM-MH-100 spectrometer (100 MHz). The chemical shifts are expressed in δ values; s: singlet; br: broad; d: doublet; t: triplet. The data of the UV spectra are described in terms of λ_{max}^{EtOH} nm (log ε). The column chromatography was carried out using Merck silica gel (0.063 or 0.08 mm). PPA was prepared by stirring a mixture of phosphoric acid and phosphorus pentoxide (wt ratio of 1: 1) at 85—90 °C for 3 h.

2,2-Dimethyl-5-methoxy-7-hydroxychroman (9). 2,2-Dimethyl-5-methoxy-7-hydroxychromanone (1 g), which had been prepared by hydrolysis of 2,2-dimethyl-5-methoxy-7-(*p*-tolylsulfonyloxy)chromanone[14] with 7% aq potassium carbonate, was refluxed with zinc amalgam (prepared from zinc dust (12.7 g), mercuric chloride (0.68 g), concentrated hydrochloric acid (0.7 ml), and water (18 ml)), in 10% aq ethanol (100 ml) for 15 h, 1 ml of hydrochloric acid being added at 1 h intervals. After removal of an inorganic material, the solution was concentrated under reduced pressure. The concentrated solution was extracted with ether and the ether layer was washed with water, dried and evaporated. The residue was recrystallized from ethanol to give **9** as colorless needles; mp 107—108°C; yield, 0.4 g, IR (KBr) cm^{-1}: 3330, 1605; Found: C, 69.32; H, 8.01%. Calcd for $C_{12}H_{16}O_3$: C, 69.21; H, 7.74%.

The Pechmann Reaction of 8. 75% sulfuric acid (4 ml) was added to a mixture of **8**[15] (0.8 g) and ethyl benzoylacetate (0.8 g) in acetic acid (6 ml) at room temp and the mixture was allowed to stand for 2 day. After the mixture had been poured into ice–water, the resulting solid was collected, washed, dried and then recrystallized from ethanol to give **12** as colorless prisms, mp 320 °C (lit,[16] 315—320 °C); yield, 0.7 g; IR (Nujol) cm^{-1}: 3245, 1680, 1640, 1590, 1565; UV: sh 253 (3.98), 260 (3.99), 338 (4.16); Found: C, 74.48; H, 5.59%. Calcd for $C_{20}H_{18}O_4$: C, 74.52; H, 5.63%.

Acetate (14): Acetic anhydride–pyridine method; mp 144—145 °C (from methanol) (lit,[16] 140—141 °C), colorless needles; IR (Nujol) cm^{-1}: 1775, 1725, 1605, 1560; UV: 255 (3.95), 310 (4.11); Found: C, 72.45; 5.55%. Calcd for $C_{22}H_{20}O_5$: C, 72.51; H, 5.53%.

Methyl Ether (13): Methyl iodide–potassium carbonate method; mp 202—203 °C (from ethanol) (lit,[16] 200—202 °C), colorless prisms; IR (Nujol) cm^{-1}: 1720, 1605, 1570, 1550; UV: 259 (3.90), 331.5 (4.00); Found: C, 74.80; 6.05%. Calcd for $C_{21}H_{20}O_4$: C, 74.98; H, 5.99%.

The mother liquor of the recrystallization was concentrated to give a small amount of the isomer (**30**) as colorless plates; mp 292—294 °C (lit,[12] 273—276 °C); IR (KBr) cm^{-1}: 3256, 1678, 1628, 1600, 1560; UV: 266 (4.20), 338 (4.10); Found: C, 74.46; H, 5.64%. Calcd for $C_{20}H_{18}O_4$: C, 74.52; H, 5.63%.

Acetate (31): Acetic anhydride–pyridine method; mp 155—156 °C (from aq ethanol) (lit,[12] 161—163 °C), colorless prisms; IR (Nujol) cm^{-1}: 1773, 1730, 1618, 1588; UV: 251 (4.03), 260 (4.00), 334 (4.12); Found: C, 72.60; H, 5.60%. Calcd for $C_{22}H_{20}O_5$: C, 72.51; H, 5.53%.

Methyl Ether (29): Methyl iodide–potassium carbonate method; mp 133—134 °C (from aq ethanol) (lit,[12] 130—132 °C), colorless needles; IR (Nujol) cm^{-1}: 1715, 1615, 1590; UV: 263 (4.16), 286 (3.72), 337 (4.10); Found: C, 74.68; H, 6.01%. Calcd for $C_{21}H_{20}O_4$: C, 74.98; H, 5.99%.

The Pechmann Reaction of 9. A mixture of **9** (0.3 g), ethyl benzoylacetate (0.3 g), and 75% sulfuric acid (4 ml) in acetic acid (7 ml) was allowed to stand at room temp for 2 day. By a treatment to that described above, the crude solid was recrystallized from ethanol to give **13** (0.4 g), which showed superimposable IR and NMR spectra and non-depression of mixed-melting-point with the sample prepared from **12**.

The Pechmann Reaction of 10. A mixture of **10**[17] (2 g), ethyl benzoylacetate (1.8 g), and 75% sulfuric acid (17 ml) in acetic acid (20 ml) was allowed to stand at room temp for 2 day. After the usual work-up, the crude product was purified by a fractional crystallization from aq ethanol to give **12** (1.2 g), **29** (0.2 g), and a small amount of **30**. **12**, **29**, and **30** were identical with the above samples.

*5-Hydroxy-2,2-dimethyl-10-phenyl-2*H, *8*H-*benzo*[*1*, *2*-b : *3*, *4*-b′]-*dipyran-8-one (1).* A mixture of **14** (0.6 g), NBS (0.3 g), and a trace of benzoyl peroxide in dry carbon tetrachloride (30 ml) was refluxed for 1.5 h. The cooled mixture was filtered and the filtrate was evaporated to dryness under reduced pressure. The residue was dissolved in a mixture of acetic acid (15 ml) and sodium acetate (2 g) and gently refluxed for 1 h. The mixture was poured into ice–water and the resulting material was collected, washed and dried. The crude material was refluxed with fresh zinc dust (0.3 g) in acetic acid (15 ml) for 8 h. The mixture was filtered and the filtrate was poured into water. The resulting solid was collected, washed, dried and recrystallized from methanol to give **1**, as colorless prisms; mp 281—283 °C (lit,[8c] 260—263 °C); yield 0.2 g; IR (Nujol) cm^{-1}: 3240, 1695, 1647, 1585; UV: 233 (4.33), 283 (4.32), 337 (4.12); NMR (DMSO): 0.94 (6H, s, $(CH_3)_2\dot{C}$–), 5.45, 6.45 (each 1H, d, and J=10.0 Hz, –CH=CH–), 5.77 (1H, s, C_3–H), 6.36 (1H, s, C_8–H); Found: C, 74.85; H, 5.21%. Calcd for $C_{20}H_{16}O_4$: C, 74.99; H, 5.03%.

Acetate (3): Acetic anhydride–pyridine method; mp 171—173 °C (from aq methanol), colorless plates; IR (Nujol) cm^{-1}: 1758, 1722, 1635, 1610; UV: 231 (4.29), 261.5 (4.14), 270 (4.17), 295 (4.23); Found: C, 72.68; H, 5.03%. Calcd for $C_{22}H_{18}O_5$: C, 72.92; H, 5.01%.

*5-Methoxy-2, 2-dimethyl-10-phenyl-2*H, *8*H-*benzo*[*1*, *2*-b : *3*, *4*-b′]-*dipyran-8-one (2).* A mixture of **13** (0.17 g) and DDQ (0.5 g) in dry benzene (60 ml) was refluxed under a stream of nitrogen for 25 h until the hydroquinone separated out. While the mixture was hot, it was filtered and the filtrate was evaporated to a solid which was purified by means of column chromatography on silica gel (20 g), using chloroform–petroleum ether (1: 1) as the eluent, to give **2**; mp 183—185 °C, colorless prisms (lit,[19] 184—185 °C; lit,[3b] 192—194 °C); yield, 0.15 g, IR (Nujol) cm^{-1}: 1722, 1640, 1598, 1553; UV: sh 276 (4.28), 283 (4.31), 329 (4.11); Found: C, 75.68; H, 5.39%. Calcd for $C_{21}H_{18}O_4$: C, 75.43; H, 5.43%. **2** was also derived by methylation of **1** with diazomethane.

The Pechmann Reaction of 11. A mixture of **11**[18] (1 g), ethyl benzoylacetate (1 g), and PPA (16 g) was stirred at 75—80 °C for 1 h. After cooling, ice–water was added to the mixture in order to decompose PPA. The resulting solid was collected, washed, dried and then was chromatographed on silica gel (20 g), with chloroform as the eluent. The faster effluent yielded a solid, which was recrystallized from ethanol to give **15** as colorless needles; mp 235—237 °C; yield, 0.15 g. This is shown by the deep violet coloration with ferric chloride in ethanol. IR (Nujol) cm^{-1}: 1740, 1648, 1623, 1603, 1564; UV: 283 (4.49), 328 (4.08); NMR: 1.42 (6H, s, $(CH_3)_2\dot{C}$–), 2.68 (2H, s, $-COCH_2-$), 5.94 (1H, s, C_3–H), 6.33 (1H, s, C_8–H), 7.40 (5H, br, $-C_6H_5$), 13.00 (1H, s, OH); Found: C, 71.30; H, 4.64%. Calcd for $C_{20}H_{16}O_5$: C, 71.42; H, 4.80%.

Acetate (17): Acetic anhydride–sodium acetate method; mp 196—198 °C (from aq ethanol), colorless prisms; IR (Nujol) cm^{-1}: 1767, 1738, 1693, 1613, 1595; Found: C, 69.54; H, 4.79%. Calcd for $C_{22}H_{18}O_6$: C, 69.83; H, 4.80%.

Methyl Ether (16): Dimethyl sulfate–potassium carbonate method; mp 218.5—219.5 °C (from ethanol), colorless prisms; IR (Nujol) cm^{-1}: 1743, 1708, 1613, 1598; Found: C, 71.99; H, 5.12%. Calcd for $C_{21}H_{18}O_5$: C, 71.99; H, 5.18%.

The slower effluent was recrystallized from ethanol to give

18 (0.3 g) as colorless prisms; mp 246—247 °C; this is shown by the deep violet coloration with ferric chloride in ethanol; IR (Nujol) cm^{-1}: 1733, 1650, 1624, 1586; UV: 282 (4.47), 329 (4.08); NMR: 0.97 (6H, s, $(CH_3)_2\dot{C}$–), 2.56 (2H, s, –CO-CH_2–), 5.94 (1H, s, C_3–H), 6.44 (1H, s, C_8–H), 7.38 (5H, br, $-C_6H_5$), 12.27 (1H, s, OH); Found: C, 71.55; H, 4.94%. Calcd for $C_{20}H_{16}O_5$: C, 71.42; H, 4.80%.

*Acetate (**20**)*: Acetic anhydride–sodium acetate method; mp 187—189 °C (from ethanol), colorless flocks; IR (Nujol) cm^{-1}: 1765, 1738, 1688, 1610, 1600, 1587; Found: C, 69.97; H, 4.91%. Calcd for $C_{22}H_{18}O_6$: C, 69.83; H, 4.80%.

*Methyl Ether (**19**)*: Dimethyl sulfate–potassium carbonate method; mp 225—226.5 °C (from ethanol) (lit,[16] 216—218 °C), colorless prisms; IR (Nujol) cm^{-1}: 1746, 1690, 1604, 1598; Found: C, 71.99; H, 5.08%. Calcd for $C_{21}H_{18}O_5$: C, 71.99; H, 5.18%.

*Reduction of **16** and **19**. From **16***: A mixture of **16** (150 mg) and sodium borohydride (30 mg) in ethanol (40 ml) was stirred at 20—25 °C for 4 h. The mixture was made slightly acidic with acetic acid–water to decompose an excess sodium borohydride and concentrated to a solid under reduced pressure. The solid was collected, washed, dried and then chromatographed on silica gel, with chloroform as the eluent, to give **21**. This was further recrystallized from benzene; mp 181.5—182.5 °C, colorless prisms; yield, 63 mg; IR ($CHCl_3$) cm^{-1}: 3540, 1720, 1605, 1550; NMR: 1.39, 1.48 (each 3H and s, $(CH_3)_2\dot{C}$–), 2.08 (2H, d, J=6 Hz, $(CH_3)_2$-$\dot{C}CH_2$–), 3.06 (3H, s, OMe), 3.31 (1H, s, OH), 4.95 (1H, t, J=6 Hz, –$\dot{C}$HOH), 6.05 (1H, s, C_3–H), 6.65 (1H, s, C_8–H), 7.40 (5H, s, $-C_6H_5$); Found: C, 71.81; H, 5.71%. Calcd for $C_{21}H_{20}O_5$: C, 71.58; H, 5.72%.

*From **19***: A mixture of **19** (200 mg) and sodium borohydride (42 mg) in ethanol (40 ml) was stirred at 20—23 °C for 4.5 h. The mixture was treated in a similar way to that described above. The crude product was recrystallized from ethanol to give **25** as colorless needles; mp 205—207 °C; yield, 164 mg; IR ($CHCl_3$) cm^{-1}: 3580, 1720, 1605, 1560; NMR: 0.82, 1.04 (each 3H and s, $(CH_3)_2\dot{C}$–), 1.84 (2H, d, J=6 Hz, $(CH_3)_2$-$\dot{C}CH_2$–), 3.04 (1H, s, OH), 3.96 (3H, s, OMe), 4.92 (1H, t, J=6 Hz, –$\dot{C}$HOH), 5.96 (1H, s, C_3–H), 6.49 (1H, s, C_8–H), 7.30 (5H, br, $-C_6H_5$); Found: C, 71.45; H, 5.82%. Calcd for $C_{21}H_{20}O_5$: C, 71.58; H, 5.72%.

*Reduction of **17** and **20**. From **17***: A mixture of **17** (200 mg) and sodium borohydride (40 mg) in ethanol (50 ml) was stirred at 23—26 °C for 5 h. After the usual work-up, the resulting solid was chromatographed on silica gel, with benzene as the eluent, to give **22**, which was further recrystallized from benzene; mp 233—234 °C, colorless prisms; yield, 110 mg; IR ($CHCl_3$) cm^{-1}: 3510, 1720, 1620, 1560; NMR: 1.32 (6H, s, $(CH_3)_2\dot{C}$–), 1.76, 2.52 (each 2H, t, and J=6.7 Hz, $-CH_2CH_2$–), 5.38 (1H, s, OH), 5.87 (1H, s, C_3–H), 6.44 (1H, s, C_8–H), 7.51 (5H, br, $-C_6H_5$); Found: C, 74.60; H, 5.64%. Calcd for $C_{20}H_{18}O_4$: C, 74.52; H, 5.63%.

*Acetate (**24**)*: Acetic anhydride–pyridine method; mp 195—196 °C (from ethanol), colorless prisms; IR ($CHCl_3$) cm^{-1}: 1765, 1720, 1618, 1552; Found: C, 72.25; H, 5.45%. Calcd for $C_{22}H_{20}O_5$: C, 72.51; H, 5.53%.

*Methyl Ether (**23**)*: Methyl iodide–potassium carbonate method; mp 179—180 °C (from aq ethanol), colorless plates; IR ($CHCl_3$) cm^{-1}: 1710, 1610, 1550; Found: C, 74.95; H, 6.03%. Calcd for $C_{21}H_{20}O_4$: C, 74.98; H, 5.99%.

*From **20***: A mixture of **20** (200 mg) and sodium borohydride (40 mg) in ethanol (70 ml) was stirred at 24—27 °C for 5 h. After the usual work-up, the crude product was recrystallized from ethanol to give **12** (70 mg), which was identical with the sample described above.

*Dehydration of **21** and **25**. From **21***: **21** (160 mg) was refluxed in a mixture of acetic anhydride (5 ml) and pyridine (2—3 drops) for 5.5 h. After cooling, the mixture was poured into ice–water and acidified with dilute hydrochloric acid. The resulting solid was collected, washed, dried and then chromatographed on silica gel (5 g), with chloroform as the eluent, to give **5** (60 mg), which was further recrystallized from ethanol; mp 211—212 °C, colorless prisms; IR ($CHCl_3$) cm^{-1}: 1715, 1640, 1605; Found: C, 75.29; H, 5.45%. Calcd for $C_{21}H_{18}O_4$: C, 75.43; H, 5.43%.

*From **25***: **25** (160 mg) was dehydrated to give **2** (110 mg), which was identical with the above mentioned sample.

*5-Acetoxy-8,8-dimethyl-4-phenyl-2H,8H-benzo[1,2-b:5,4'-b]dipyran-2-one (**6**)*. A mixture of acetate (**24**: 225 mg), NBS (210 mg), and a trace of benzoyl peroxide in dry carbon tetrachloride (20 ml) was refluxed for 3 h. The resulting succinimide was then filtered off and the solvent was removed. The residue was successively treated according to the usual work-up. The crude product was chromatographed on silica gel (7 g), with benzene as the eluent, to give **6**, which was further recrystallized from methanol; mp 227.5—228.5 °C, colorless prisms; yield, 140 mg, IR ($CHCl_3$) cm^{-1}: 1773, 1720, 1640, 1620; Found: C, 72.87; H, 4.99%. Calcd for $C_{22}H_{18}O_5$: C, 72.92; H, 5.01%.

*5-Hydroxy-8,8-dimetyl-4-phenyl-2H,8H-benzo[1,2-b:5,4-b']dipyran-2-one (**4**)*. **6** (95 mg) was hydrolyzed with a mixture of concentrated hydrochloric acid (1 ml) and methanol (24 ml), refluxing for 4 h. After removal of the solvent, the resulting solid was collected, washed and dried. This was recrystallized from benzene to give **4** (24 mg) as colorless needles; mp 197—198 °C; IR ($CHCl_3$), cm^{-1}: 3510, 1720, 1640, 1617; NMR: 1.45 (6H, s, $(CH_3)_2\dot{C}$–), 5.53, 6.46 (each 1H, d, and J=10.0 Hz, –CH=CH–), 5.29 (1H, s, OH), 5.90 (1H, s, C_3–H), 6.44 (1H, s, C_8–H), 7.55 (5H, br, $-C_6H_5$); Found: C, 74.25; H, 5.05%. Calcd for $C_{20}H_{16}O_4$: C, 74.99; H, 5.03%.

*6-Benzoyl-5-hydroxy-7-methoxy-2,2-dimethylchroman (**27**) and 8-Benzoyl Isomer (**26**)*. A mixture of **10** (4.7 g), benzonitrile (4.0 g), and anhydrous zinc chloride (3.5 g) in dry ether (80 ml) was saturated with dry hydrogen chloride under ice-cooling and the mixture was allowed to stand at room temp overnight. After removal of the upper ethereal layer by decantation, the residue was heated with 1% hydrochloric acid (100 ml) on a water bath for 3 h. The resulting solid was collected, washed and dried and then recrystallized from ethanol to give **27** as pale yellow needles; this is shown by the violet brown coloration with ferric chloride in ethanol; mp 122—123 °C; yield, 0.9 g; IR (Nujol) cm^{-1}: 1620, 1600, 1585; UV: 253 (3.68), 312 (4.09); Found: C, 73.08; H, 6.60%. Calcd for $C_{19}H_{20}O_4$: C, 73.06; H, 6.45%.

*Acetate (**28**)*: Acetic anhydride–sodium acetate method; mp 126—127 °C (from ethanol), colorless prisms; IR (Nujol) cm^{-1}: 1769, 1669, 1619, 1593, 1580; UV: 251 (4.19), 283 (3.65); NMR: 1.35 (6H, s, $(CH_3)_2\dot{C}$–), 2.02 (3H, s, OAc), 1.78, 2.52 (each 2H, t, and J=6.7 Hz, $-CH_2CH_2$–), 3.60 (3H, s, OMe), 6.35 (1H, s, C_8–H), 7.65 (5H, br, $-C_6H_5$); Found: C, 71.02; H, 6.27%. Calcd for $C_{21}H_{22}O_5$: C, 71.17; H, 6.26%.

The mother liquor of the recrystallization was concentrated to give **26** as pale yellow prisms, which showed a negative ferric chloride reaction in ethanol; mp 213—215 °C; yield, 1.7 g; IR (Nujol) cm^{-1}: 3280, 1645, 1605, 1515; UV: 247 (4.17), 292 (3.41), 308 (3.41); Found: C, 73.23; H, 6.71%. Calcd for $C_{19}H_{20}O_4$: C, 73.06; H, 6.45%.

*Conversion of **26** to **27**. a) Aluminium Chloride Method*: A mixture of **26** (1 g) and anhydrous aluminium chloride in dry ether (125 ml) was refluxed for 12 h. After removal of the solvent, ice–water was added to the residue which was then acidified with dilute hydrochloric acid. The resulting

solid was collected, washed, dried and recrystallized from methanol to give **27** (0.7 g); mp 123—124 °C, pale yellow needles. The compound was identical with the sample prepared above.

b) Sulfuric Acid Method: Concentrated sulfuric acid (0.5 ml) was added to a solution of **26** (100 mg) in acetic acid (5 ml) and heated at 65—67 °C for 5 h. After cooling, ice–water was added to the mixture and the resulting solid was collected, washed, dried and recrystallized from methanol to give **27** (50 mg).

*Preparation of **29** from **28**.* A mixture of **28** (200 mg), acetic anhydride (1 ml), and anhydrous sodium acetate (500 mg) was heated at *ca.* 130 °C for 2 min. After cooling, ice–water was added to the mixture and the resulting solid was collected, washed and recrystallized from aq ethanol to give **29** (30 mg); mp 133—134 °C. This was shown to be identical with the above mentioned samples.

*5-Methoxy-8,8-dimethyl-4-phenyl-2*H,*8*H-benzo[*1,2*-b:*3,4*-b′]-*dipyran-2-one (7).* A mixture of **29** (150 mg) and DDQ (150 mg) in dry benzene (25 ml) was treated in a similar way to that described above. The crude product was recrystallized from ethanol to give **7** (70 mg) as colorless plates; mp 143—144 °C. IR (Nujol) cm^{-1}: 1718, 1648, 1618, 1587, 1578; UV: 234 (4.56), 284 (4.25), 330 (4.02); Found: C, 75.67; H, 5.52%. Calcd for $C_{21}H_{18}O_4$: C, 75.43; H, 5.43%.

Synthesis and ^{13}C NMR Spectra of *endo*-5-(4-Imidazolyl)bicyclo-[2.2.2]oct-*endo*- and *exo*-2-yl *trans*-Cinnamates

Masanori UTAKA, Mamoru AKIYAMA,* and Akira TAKEDA

Department of Synthetics Chemistry, School of Engineering, Okayama University, Tsushima, Okayama 700

(Received February 4, 1977)

The Synthesis of *endo*-5-(4-imidazolyl)bicyclo[2.2.2]oct-*endo*- and *exo*-2-yl *trans*-cinnamates was carried out starting from 2-butyn-1,4-diol. The key intermediate, *endo*-5-(4-imidazolyl)bicyclo[2.2.2]octan-2-one, was obtained by oxidation of *endo*-5-(4-imidazolyl)bicyclo[2.2.2]oct-2-ene with palladium chloride, the oxidation being stereo- and regiospecific. The mode of 2,5 disubstitution and endo, exo stereochemistry were determined by means of ^{13}C chemical shifts of the bicyclo[2.2.2]octane framework.

In a previous paper[1] a report was given on the synthesis and separation of *endo*- and *exo*-5-(4-imidazolyl)bicyclo[2.2.1]hept-*endo*-2-yl *trans*-cinnamates *via* 5-(1-oxo-2-hydroxyethyl)bicyclo[2.2.2]hept-2-enes. These cinnamates were synthesized as a model for acyl-α-chymotrypsin since the bicyclo[2.2.1]heptane ring system possesses a rigid framework which can bear the imidazolyl and acyloxy groups with correct spatial alignment as in the acyl enzyme.

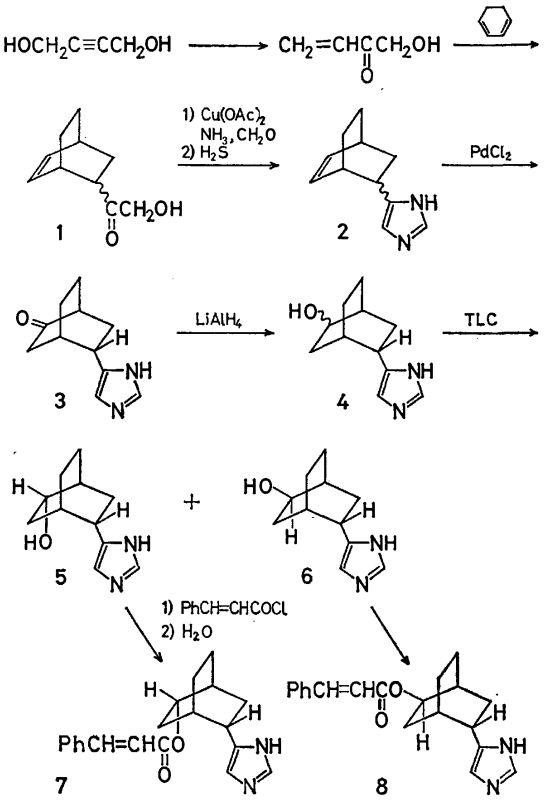
In this report we describe the synthesis of the title compounds which also simulate the acyl enzyme and have a less rigid framework of bicyclo[2.2.2]octane as compared to that of bicyclo[2.2.1]heptane. It seems of interest to investigate the difference in reactivity caused by the less rigid framework.[2,3] The endo, endo compound has a correct stereochemistry, but not the endo, exo compound. Properties of the former can be compared with those of the latter.

The synthesis was carried out following the scheme for the bicyclo[2.2.1]heptane derivatives, several key steps being found to be quite different. For elucidation of the structures of the title compounds ^{13}C NMR spectroscopy was indispensable, although ^1H NMR spectra were used effectively for the corresponding bicyclo-[2.2.1]heptane derivatives.

Results and Discussion

Synthesis. The synthetic route is shown in Scheme 1. The starting ketone **1** was obtained in 12% yield from 2-butyn-1,4-diol. The yield is lower than the 20% yield for the corresponding bicyclo[2.2.1]-heptenyl ketone which can be attributed to the low reactivity of 1,3-cyclohexadiene as a Diels-Alder diene. The endo: exo ratio of the ketone **1** was determined to be 9: 1 referring to the relative intensity of the ^1H NMR signals of the alcoholic methylene protons at δ 4.30 (exo) and 4.26 (endo). The signals of the olefinic protons were useless for the determination unlike the case of the corresponding bicyclo[2.2.1]heptenyl ketone.

Formation of the imidazolyl derivative **2** was achieved in a similar way to that for the corresponding bicyclo-[2.2.1]heptane derivative. The yield was 60—70%, comparable to that of the latter. The endo: exo ratio was 3: 1 as determined by the ^1H NMR signals of the imidazolyl C-4 proton at δ 6.87 (exo) and 6.65 (endo).



Scheme 1.

These values are similar to those (6.83 and 6.63) for 5-(4-imidazolyl)bicyclo[2.2.1]hept-2-enes.

Introduction of an oxo group to the olefinic bond of **2** was attained effectively using palladium chloride in dilute hydrochloric acid. The crude oxidation product obtained from the endo, exo mixture of **2** was chromatographed over basic alumina to give the endo ketone **3** in 30% yield (40% based on the *endo*-imidazolyl derivative of **2**). Neither exo ketone nor the isomeric 2,6-disubstituted product was detected. The reaction conditions such as temperature, time, speed of addition of the substrate, acidity of the solution, and mole ratios of the substrate to the oxidant were varied without any appreciable increase in the yield. The *exo*-imidazolyl derivative of **2** was recovered only in part by chromatography, being lost mostly as unidentified products.

The oxidation was stereo- and regiospecific. It seems to proceed *via* a palladium complex intermediate which requires both the ethylenic double bond and the *endo*-

* Present address: Nippon Goseikagaku Kogyo Co., Ltd., Mizushima, Kurashiki 712.

imidazolyl ring as a bidentate ligand. So far, no such palladium complex seems to have been reported.[4,5]

The mode of 2,5 disubstitution and the endo stereochemistry of **3** were determined by the ^{13}C chemical shift.

In order to obtain the desired compounds **7** and **8**, the endo ketone **3** was reduced to the hydroxy derivative **4** followed by acylation and partial hydrolysis after separation of the endo, endo derivative **5** and the endo, exo derivative **6**. The procedure is similar to that for the corresponding bicyclo[2.2.1]heptane derivatives.

An alternative method of introducing an oxo group to the olefinic double bond was the use of 98—100% formic acid which was utilized for the corresponding bicyclo[2.2.1]heptene. An addition reaction of formic acid to the olefinic double bond of **2** proceeded slowly at 160 °C over a period of 50 h to give the expected formate and its corresponding alcohol in a combined yield of 50—60% and these reaction products afforded the oxo derivative by oxidation with chromium trioxide. However, the total yield from **2** was not improved. The presence of both the *endo*- and *exo*-imidazolyl derivatives in the oxidation product complicated the isolation of the isomers. The situation became more serious when the oxo derivative were reduced to the hydroxy derivatives since almost equimolecular amounts of the *endo*- and *exo*-hydroxy derivatives were produced. Thus the use of formic acid was abandoned.

Hydrogenation of **2** with 10% Pd–C gave a hygroscopic glassy solid of 2-(4-imidazolyl)bicyclo[2.2.2]-octane (**9**), which could be distilled but not crystallized. The ^{13}C chemical shifts are indispensable for elucidation of the stereochemistry of **3**, **7**, and **8** as shown in Tables 1 and 2.

^{13}C Chemical Shifts. The ^{13}C chemical shifts for a number of bicyclo[2.2.2]octanes substituted in the 2 and 2,5 positions have been reported by Garratt and Riguera.[3] They derived substitution parameters from the 2-substituted compounds and utilized them for the determination of the relative stereochemistry of substituents at C-2 and C-5. Their parameters for the hydroxyl and oxo groups are given in Table 1. The down field shifts for the α-, β-, and γ-carbon atoms were obtained by comparing the chemical shifts in the 2-substituted bicyclo[2.2.2]octanes with those in the parent hydrocarbon, where the α-carbon atom is C-2 and the γ-carbon atom is C-6 or C-7. The parameters for the 4-imidazolyl and *trans*-cinnamoyloxy groups (Table 1) were derived from the present work.

Table 1. Substituent effects on ^{13}C chemical shifts for 2-substituted bicyclo[2.2.2]octanes[a]

Substituent	α	β(C-1)	β(C-3)	γ-syn	γ-anti
4-Imidazolyl	8.3	5.7	5.8	−5.2	−0.9
trans-Cinnamoyloxy	46.5	6.3	8.8	−7.0	−3.0
Hydroxy[b]	43.3	7.5	11.3	−7.5	−2.3
Oxo[b]	190.7	18.3	18.6	−2.7	−2.7

a) The values show downfield shifts in ppm. Values for the 4-imidazolyl group were derived from the chemical shifts of 5-(4-imidazolyl) bicyclo[2.2.2]-octane (Table 2) by comparison with the shifts (24.14 for C-1 and 26.16 for C-2) for bicyclo[2.2.2]-octane. For the *trans*-cinnamoyloxy group an average value has been taken from the endo and exo cinnamates (Table 2). b) Values taken from Ref. 3.

The ^{13}C chemical shifts for various 2-substituted 5-(4-imidazolyl)bicyclo[2.2.2]octanes are given in Table 2. The agreement between the observed and the calculated values is good within $\pm$0.6 ppm. Deviations as large as 0.8—1.2 ppm are seen for C-2 and C-3 of the oxo derivative and C-4 and C-5 of the *exo*-cinnamoyloxy derivative, but no ambiguity in their assignment results from these deviations.

In order to obtain the substitution parameters for the 4-imidazolyl group, the ^{13}C NMR spectrum of 5-(4-imidazolyl)bicyclo[2.2.2]octane (**9**)[6] was assigned as follows. The tertiary carbons C-1, C-4, and C-5 were shown to be doublets by an off-resonance experiment and the chemical shift of 24.44 ppm was attributed to C-1 since it shifts least from the value of 24.14 ppm[3] for the C-1 of the parent hydrocarbon. The largest and the moderate downfield shifts from the value of 26.16 ppm[3] for the C-2 of the parent hydrocarbon are ascribed to the carbons C-5 and C-4, respectively. The

Table 2. ^{13}C Chemical shifts for 2-substituted *endo*-5-(4-imidazolyl)bicyclo[2.2.2]octanes[a]

2-Substituent (Compound)	C-1	C-2	C-3	C-4	C-5	C-6	C-7	C-8	Imidazolyl carbons
Unsubstituted (**9**)	24.44	26.55*	20.95	29.80	34.43	31.91	25.82*	25.25	140.83
									134.57
									117.92
Oxo (**3**)	42.98	218.11	40.40	33.74	33.91	29.35	22.92	25.61	142.85
	(42.4)	(216.9)	(39.6)	(29.8)	(34.5)	(29.1)	(23.5)	(25.3)	135.25
				(33.8)[b]					114.38
endo-trans-Cinnamoyloxy (**7**)	30.40	72.90	29.49	29.49	34.30	25.46	22.87	25.46	140.99
	(30.4)	(72.7)	(29.8)	(29.8)	(34.5)	(25.0)	(23.2)	(25.3)	134.49

	(30.4)	(72.7)	(29.8)	(29.8)	(34.5)	(29.0)	(19.2)	(25.3)	134.90
									115.62

a) The chemical shifts are in ppm downfield from internal tetramethylsilane in chloroform-*d*. The values in parentheses are those calculated with use of parameters in Table 1. The chemical shifts for the *trans*-cinnamoyloxy group were found to be essentially the same as those for ethyl *trans*-cinnamate. The asterisks designate a reversible pair of shifts. b) Corrected for the downfield shift (4.0 ppm) of C-4 in bicyclo[2.2.2]octan-2-one (Ref. 3).

remaining five carbons showed triplets by an off-resonance experiment. The carbons C-2 and C-7 are expected to show chemical shifts nearest to 26.16 ppm The largest downfield shift of 31.91 ppm was assigned to C-6 and the largest upfield shift of 20.95 ppm to C-3 which is γ-syn to C-5. The remaining shift of 25.25 ppm corresponds to the carbon C-8 which is γ-anti to C-5.

The parameters for the *trans*-cinnamoyloxy group were calculated from the *endo*- and *exo-trans*-cinnamoyloxy derivatives **7** and **8** by subtracting the shifts due to the imidazolyl group. An average was taken from the values for **7** and **8**. As expected, the parameters for the imidazolyl and *trans*-cinnamoyloxy groups show a similar trend in their magnitudes as compared with that for the hydroxyl group.

Physical Properties and endo, exo Stereochemistry. Using ^{13}C chemical shifts as described above, we determined the mode of 2,5 disubstitution and the endo, exo stereochemistry of the oxo, hydroxy, and cinnamoyloxy derivatives. In conformity with the determination, the *exo*-hydroxy-*endo*-imidazolyl derivative **6** and the hydrochloride of the *exo*-cinnamoyloxy-*endo*-imidazolyl derivative **8** were observed to have higher melting points than their corresponding *endo*-hydroxy-*endo*-imidazolyl derivative **5** and hydrochloride of the *endo*-cinnamoyloxy-*endo*-imidazolyl derivative **7**, respectively. The exo, endo derivative **6** was also found to have a smaller R_f value than the corresponding endo, endo derivative **5**. These observations are understandable on the basis of the relative spatial alignment of the two functional groups, the same situation being observed for the bicyclo[2.2.1]heptane system previously.[1)]

Another means for differentiating the endo or exo stereochemistry is the ^1H chemical shift for the proton attached to the C-4 carbon of the imidazolyl group. The chemical shifts for the endo, endo derivatives **5** and **7** were found to be 0.08 ppm downfield from those of the corresponding exo, endo derivatives **6** and **8**. Although it cannot be explained clearly, a similar downfield shift of 0.06—0.15 ppm is also observed for the bicyclo-[2.2.1]heptane system.[1)]

Thus the physical properties so far observed are consistent with the endo, exo stereochemistry determined by the ^{13}C chemical shift.

Experimental

All melting points and boiling points are uncorrected. ^1H NMR spectra were obtained on a Hitachi Model R-24 spectrometer at 60 MHz. Tetramethylsilane was used as an internal standard unless otherwise noted. ^{13}C NMR spectra were recorded with a JEOL JNM FX-100 spectrometer at 25.05 MHz equipped with Fourier transform facilities. Mass spectra were obtained with a Hitachi Model RMS-4 mass spectrometer at 70 eV. Elemental analyses were carried out by Mr. E. Amano of our laboratory.

endo- *and* exo-*5-(1-Oxo-2-hydroxyethyl)bicyclo[2.2.2]oct-2-enes* (*1*). In order to obtain a Diels-Alder dienophile, 26.8 g (0.313 mol) of 2-butyn-1,4-diol was isomerized to hydroxymethyl vinyl ketone.[1)] The crude ketone was heated with 5.0 g (0.063 mol) of 1,3-cyclohexadiene at 100—120 °C for 13 h. The resulting viscous reddish oil was distilled to give 6.1 g (0.037 mol) of crude **1**: bp 110—125 °C (12 Torr); IR (neat) 3650—3200 (OH), 3030 (=C–H), 1710 (C=O), 1615 (C=C), and 1065 cm^{-1} (C–O); ^1H NMR ($CDCl_3$) δ 6.4—5.9 (m, 2, CH=CH), 4.30 (s, *ca.* 0.2, *exo*-CH_2–O), 4.26 (s, *ca.* 1.8, *endo*-CH_2–O), 3.3 (s, 1, OH), 3.0—2.3 (m, 3), and 2.0—1.0 ppm (m, 6).

endo- *and* exo-*5-(4-Imidazolyl)bicyclo[2.2.2]oct-2-enes* (*2*). The hydroxymethyl ketone **1** was treated with 28% aq ammonia, copper(II) acetate, and 37% aq formaldehyde,[1)] giving a very viscous, transparent, and reddish oil of crude **2** in 60—70% yield: IR (neat) 3500—2200 (NH), 1615 (CH=CH), and 1580—1560 cm^{-1} (imidazole ring); ^1H NMR ($CDCl_3$) δ 9.1 (s, 1, NH), 7.58, 7.48 (two s, 1, N=CH–N), 6.87 (s, 0.25, N–CH=C), 6.65 (s, 0.75, N–CH=C), 6.5—5.95 (m, 2, CH=CH), 3.0 (m, 1, H_5), 2.85—2.4 (m, 2, H_1 and H_4), and 2.3—1.0 ppm (m, 6).

In order to obtain the picrate of **2**, an equimolar amount of picric acid in chloroform was added to a solution of **2** in chloroform. The picrate precipitated by cooling was collected and recrystallized: mp 151—152 °C; ^1H NMR (DMSO-d_6) δ (solvent peak, δ 2.50 as internal standard) 8.98 (d, 0.15, N–CH=N), 8.88 (d, 0.85, N–CH=N), 8.55 (s, 2, picrate anion), 7.57 (d, 0.15, N–CH=C), 7.18 (d, 0.85, N–CH=C), 6.5—5.85 (m, 2, CH=CH), 3.04 (m, 1, H_5), 2.9—2.4 (m, 2, H_1 and H_4), and 2.3—1.0 ppm (m, 6). Found: C, 50.99; H, 4.18; N, 17.19%. Calcd for $C_{17}H_{16}N_5O_7$: C, 50.75; H, 4.01; N, 17.46%.

endo-*5-(4-Imidazolyl)bicyclo[2.2.2]octan-2-one* (*3*). In a solution of 2.85 ml of 1 M hydrochloric acid and 25 ml of water, 560 mg (3.16 mmol) of palladium chloride was dissolved by heating at 80 °C for 30 min. To this solution was added dropwise 500 mg (2.87 mmol) of **2** in 2.85 ml of 1 M hydrochloric acid and 8 ml of water over a period of 10 min with stirring. The mixture was then heated at 95 °C for 30 min and filtered. The filtrate was concentrated to half the original volume and extracted with chloroform after the pH of solution had been adjusted to 9 with 28% aq ammonia. After being dried over magnesium sulfate, the solvent was removed to give 320 mg of a viscous yellow oil. This oil was developed three times over basic alumina (Merck, HF_{254} Type E) using dichloromethane–methanol (50/1 vol/vol), to give 170 mg (31%) of the ketone **3** (R_f value 0.1—0.4). This was recrystallized from chloroform–carbon tetrachloride: mp 147—148 °C; IR (KBr) 3500—2200 (NH), 1720 (C=O), and 1580—1560 cm^{-1} (imidazole ring); ^1H NMR ($CDCl_3$) δ 9.15 (s, 1, NH), 7.55 (s, 1, N–CH=N), 6.75 (s, 1, N–CH=C), 3.18 (m, 1, H_5), and 2.6—1.5 ppm (m, 10); MS *m/e* 190 (M^+). Found: C, 69.60; H, 7.42; N, 14.68%. Calcd for $C_{11}H_{14}N_2O$: C, 69.45; H, 7.42; N, 14.72%.

Twenty mg of **2** was recovered (R_f value 0.5).

endo-*5-(4-Imidazolyl)bicyclo[2.2.2]octan*-endo- *and* exo-*2-ols* (*4*). With lithium aluminum hydride in THF 1.48 g of the crude oil of **3** was reduced to give 1.23 g of a crude solid of **4**.[1)]

endo-*5-(4-Imidazolyl)bicyclo[2.2.2]octan*-endo-*2-ol* (*5*). Isolation of **5** from **4** was achieved by preparative TLC. About 240 g of basic alumina (Merck, HF_{254} Type E) was coated on ten glass plates (20×20 cm) and activated. After application of 1.23 g of the crude **4** in methanol, the plates were developed four times with use of dichloromethane–methanol (15/1 vol/vol). The endo alcohol **5** obtained (R_f value 0.4—0.65) amounted to 450 mg. This gave white crystals from methanol by adding carbon tetrachloride: mp 144—146 °C; IR (KBr) 3550 (OH), 3400—2200 (NH), and 1580—1560 cm^{-1} (imidazole ring); ^1H NMR ($CDCl_3$) δ 7.48 (s, 1, N–CH=N), 6.82 (s, 1, N–CH=C), 3.82 (m, 1, H_2), 2.89 (m, 1, H_5), and 2.3—1.2 ppm (m, 10).

endo-5-(4-Imidazolyl)bicyclo[2.2.2]octan-exo-*2-ol (6)*. The exo alcohol **6** obtained (R_f value 0.1—0.4) amounted to 420 mg. This gave white crystals from methanol–carbon tetrachloride: mp 219—220 °C; IR (KBr) 3550 (OH), 3400 2200 (NH), and 1580—1560 cm^{-1} (imidazole ring); ^1H NMR ($CDCl_3$) δ 7.51 (s, 1, N–CH=N), 6.74 (s, 1, N–CH=C), 3.88 (m, 1, H_2), 2.90 (m, 1, H_5), and 2.4—1.0 ppm (m, 10). Found: C, 68.59; H, 8.11; N, 14.28%. Calcd for $C_{11}H_{16}N_2O$: C, 68.72; H, 8.39; N, 14.57%.

endo-5-(4-Imidazolyl)bicyclo[2.2.2]octan-endo-*2-yl* trans-*Cinnamate (7)*. In 5 ml of freshly distilled ethanol-free chloroform 230 mg (1.2 mmol) of **5** was heated with 720 mg (4.3 mmol) of *trans*-cinnamoyl chloride at 85 °C for 2 h. The clear, light yellow solution was evaporated to dryness and the residual solid was dissolved in THF–methanol–water. The pH of the solution was then adjusted to 9 with aqueous sodium carbonate and allowed to stand for 6 h at room temperature. Removal of the organic solvents by a rotary evaporator gave a heterogeneous aqueous solution, which was extracted with chloroform twice. The extract was washed with water and dried over magnesium sulfate. Removal of the solvent gave 390 mg (100%) of crude **7**. This was passed through a column of basic alumina using dichloromethane–methanol to give 220 mg of a colorless brittle solid of **7**: IR (KBr) 3400—2200 (NH), 1700 (C=O), 1635 (C=C), 1575 (imidazole ring), and 1170 cm^{-1} (C–O); ^1H NMR ($CDCl_3$) δ 8.3 (s, 1, NH), 7.59 (d, 1, J=16 Hz, C*H*=CH), 7.53 (s, 1, N–CH=N), 7.65—7.15 (m, 5, phenyl), 6.87 (s, 1, N–CH=C), 6.33 (d, 1, J=16 Hz, CH=C*H*), 4.98 (m, 1, H_2), 2.94 (m, 1, H_5), and 2.4—1.2 ppm (m, 10).

To crystallize **7** as hydrochloride, 93 mg of **7** was dissolved in 0.1 M hydrochloric acid and the solution was evaporated to dryness. The residual solid was crystallized from a minimum quantity of chloroform by dilution with warm carbon tetrachloride and cooling in a refrigerator, giving 91 mg of the colorless hydrochloride of **7**: mp 167.5—170 °C (dec). Found: C, 66.61; H, 6.49; N, 8.17%. Calcd for $C_{20}H_{23}N_2O_2Cl$: 66.93; H, 6.46; N, 7.81%.

endo-5-(4-Imidazolyl)bicyclo[2.2.2]octan-exo-*2-yl* trans-*Cinnamate (8)*. In a similar way to that for **5**, 200 mg of **6** was converted into 109 mg of a colorless brittle solid of **8**: IR (KBr) 3400—2200 (NH), 1700 (C=O), 1635 (CH=CH), 1575 (imidazole ring), and 1170 cm^{-1} (C–O); ^1H NMR ($CDCl_3$) δ 9.4 (s, 1, NH), 7.63 (d, 1, J=16 Hz, C*H*=CH), 7.55 (s, 1, N–CH=N), 7.6—7.15 (m, 5, phenyl), 6.79 (s, 1, N–CH=C), 6.37 (d, 1, J=16 Hz, CH=C*H*), 5.00 (m, 1, H_2), 3.00 (m, 1, H_5), and 2.4—1.1 ppm (m, 10).

In a similar way to that for **7**, 47 mg of **8** gave 44 mg of the hydrochloride: mp 208 °C (dec). Found: C, 66.72; H, 6.56; N, 8.09%. Calcd for $C_{20}H_{23}N_2O_2Cl$: C, 66.93; H, 6.46; N, 7.81%.

2-(4-Imidazolyl)bicyclo[2.2.2]octane (9). To 200 mg of crude **2** in 10 ml of methanol was added 50 mg of 10% Pd–C[7] and the mixture was shaken under a hydrogen atmosphere (1 atm) for 3 h until the theoretical volume of hydrogen was absorbed. The mixture was filtered and the catalyst was washed with methanol. The combined filtrate and washings were evaporated to give 173 mg (87%) of a slightly yellow, brittle solid. This was distilled in a glass tube at 160 °C (0.15 mmHg) to give a colorless viscous oil, which solidified on cooling. The hygroscopic solid obtained could not be crystallized: IR (neat) 3400—2200 (NH) and 1590—1560 cm^{-1} (imidazole ring); ^1H NMR ($CDCl_3$) δ 9.3 (s, 1, NH), 7.56 (s, 1, N–CH=N), 6.83 (s, 1, N–CH=C), 2.97 (m, 1, H_2), and 2.3—1.1 ppm (m, 12); MS *m/e* (rel intensity), 176 (M^+, 50), 175 (14), 147 (16), 146 (10), 145 (13), 119 (10), 110 (8), 109 (8), 96 (25), 95 (100), 94 (25), 82 (18), 81 (25), 80 (13), and 79 (10).

The present work was supported partially by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Chemical Studies on Tuberactinomycin. XI.[1] Semisyntheses of Tuberactinomycin Analogs with Various Amino Acids in Branched Part[2]

Tateaki WAKAMIYA, Tadashi TESHIMA, Hideo SAKAKIBARA,*
Kiyoshi FUKUKAWA,* and Tetsuo SHIBA

(Received February 7, 1977)

Thirty two semisynthetic tuberactinomycins were prepared by introduction of various amino acids to amino group of tuberactinamine N, a cyclic peptide moiety of tuberactinomycin N and O, which was isolated from natural tuberactinomycin N by acid treatment with liberation of γ-hydroxy-β-lysine of the branched part. Among introduced amino acids, β-amino acids were synthesized from corresponding α-amino acids by modified Arndt-Eistert reaction. After couplings of N-protected amino acids with tuberactinamine N, deprotections were carried out to give semisynthetic tuberactinomycins. From their minimum inhibitory concentrations against many bacteria, it was suggested that a branched part effects significantly to the strength of antimicrobial activities though most important active site must locate in the cyclic peptide moiety, and basicity and/or hydrophobicity of the branched part seemed to strengthen the antibacterial activity especially.

In our recent studies on the antibiotics tuberactinomycins,[3] tuberactinamine N, the cyclic peptide moiety of tuberactinomycin N as well as O, could be isolated as fine crystals by acid treatment of tuberactinomycin N with liberation of γ-hydroxy-β-lysine of the branched part[4] (Fig. 1). Tuberactinamine N thus obtained showed a comparable antituberculous activity to that of original tuberactinomycin N, maintaining the intramolecular hydrogen bond between α-amide proton of capreomycidine residue and carbonyl group of serine[3] residue as in all of tuberactinomycins.[5] From these facts, tuberactinamine N seemed to be a very promising key-intermediate for preparation of novel semisynthetic tuberactinomycins, which have more favorable properties, *e.g.*, high biological activities, less toxicities, and different antibacterial spectra. Such study may also afford very valuable informations concerning relationships between structure and antibacterial activity in tuberactinomycins. Although the cyclic peptide part, *i.e.*, tuberactinamine N, may be the most important site for exhibition of biological activities in tuberactinomycins, its activity is weakened as compared with tuberactinomycin N. This may indicate that the branched amino acid as β-lysine or γ-hydroxy-β-lysine in original tuberactinomycins is required to strengthen the microbial activities.

Along this line, various amino acids were attempted to be linked to the free α-amino group of α,β-diaminopropionic acid residue in tuberactinamine N in this investigation. A number of protected amino acids with benzyloxycarbonyl or *t*-butoxycarbonyl group[6] were coupled with tuberactinamine N by active ester method and then the protecting groups were removed by catalytic hydrogenation or acid treatment respectively (Fig. 2). The second functional groups of α-amino acids like aspartic acid, glutamic acid, serine, histidine, and arginine were protected with *t*-butyl, benzyl, *t*-butyl, tosyl, and nitro groups, respectively, which were removed later together with α-amino-protecting groups. β-Amino acids as materials were prepared from the corresponding α-amino acids by the modified Arndt-Eistert reaction.[7] Furthermore, in this study, we introduced a new convenient way for direct preparation of β-(acylamino) acid *N*-hydroxysuccinimide active

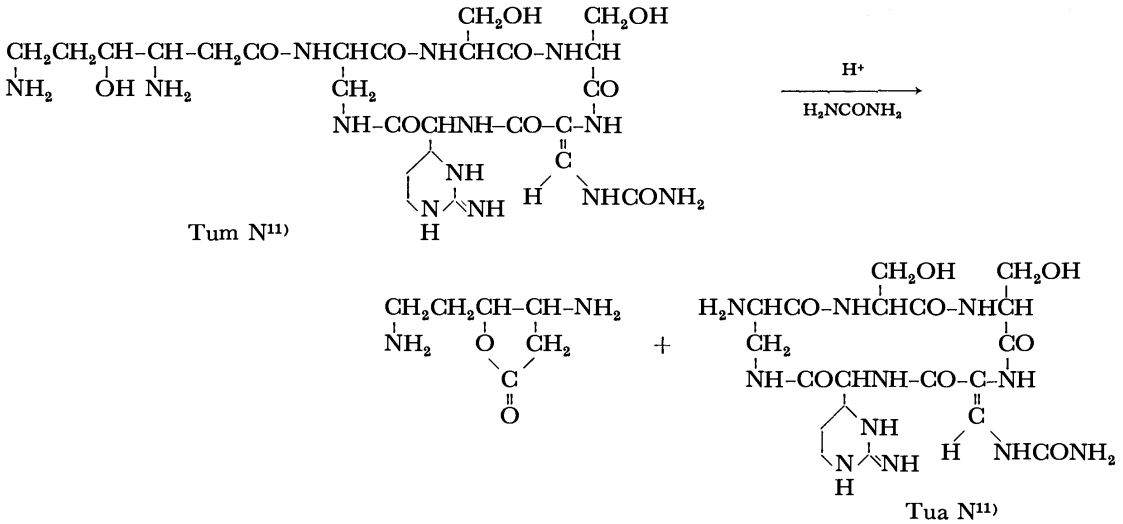

Fig. 1.

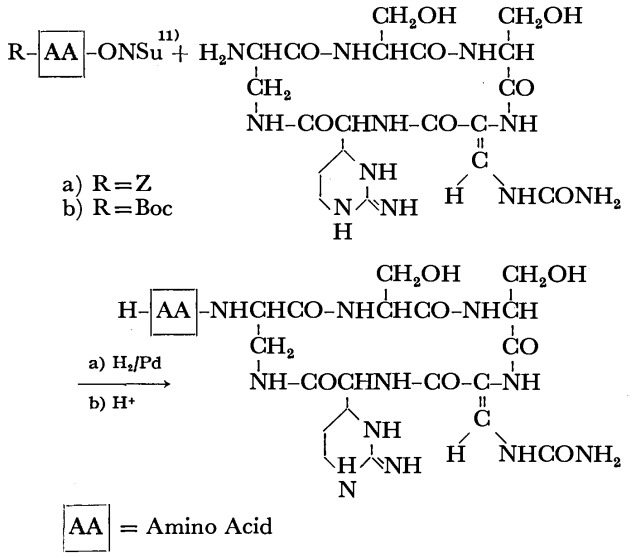

Fig. 2.

ester from diazo ketone derivative of α-(acylamino) acid by use of *N*-hydroxysuccinimide instead of methanol at the step of Wolff rearrangement (Fig. 3).

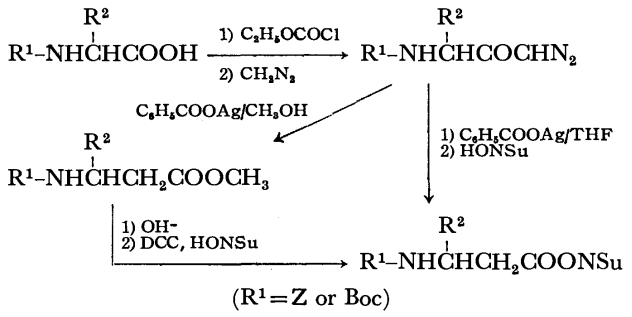

Fig. 3.

Many semisynthetic tuberactinomycins thus prepared were measured their minimum inhibitory concentration (MIC) to various bacilli and studied their ORD and CD spectra.

Experimental

All melting points are uncorrected. The specific rotations were obtained with a Perkin-Elmer 141 Polarimeter. ORD and CD spectra were obtained with a JASCO Model ORD/UV-5 in water. Thin-layer chromatography was carried out by the ascending method on silica gel G using a developing solvent of butanol-acetic acid-water (4: 1: 2).

Z-L-A_2pr(Z)-ONSu.[11] To a solution of Z-L-A_2pr(Z)-OH (372 mg, 1.0 mmol) in 5 ml of THF, DCC (227 mg, 1.1 mmol) and HONSu (127 mg, 1.1 mmol) were added with stirring at 0 °C. Stirring was continued at this temperature for 1 h and then at room temperature for 6 h. *N,N'*-Dicyclohexylurea was filtered off and filtrate was concentrated *in vacuo*. When crystalline residue was dissolved in ethyl acetate and stored in refrigerator, *N,N'*-dicyclohexylurea was again precipitated. After removal of the precipitate by filtration, hexane was added to the filtrate to obtain fine needles, yield 390 mg (83%), mp 113—116 °C, $[\alpha]_D^{24}$ −36.2° (*c* 1.00, DMF).

Found: C, 58.93; H, 4.99; N, 8.96%. Calcd for $C_{23}H_{23}O_8N_3$: C, 58.84; H, 4.94; N, 8.95%.

Boc-L-A_2bu(Boc)-ONSu. Boc-L-A_2bu(Boc)-OH (oily; 3.18 g, 10.0 mmol), DCC (2.06 g, 10.0 mmol) and HONSu (1.15 g, 10.0 mmol) were treated as described in the preparation of Z-L-A_2pr(Z)-ONSu. The product was recrystallized from dioxane and hexane, yield 3.50 g (84%), mp 141—142 °C, $[\alpha]_D^{26}$ −34.4 ° (*c* 1.00, DMF).

Found: C, 52.04; H, 7.03; N, 10.13%. Calcd for $C_{18}H_{29}O_8N_3$: C, 52.04; H, 7.04; N, 10.12%.

Preparation of β-(Acylamino) Acids N-*Hydroxysuccinimide Active Ester. Method A (Preparation of Boc-L-β-Lys(Z)-ONSu)*: To a solution of Boc-L-Orn(Z)-OH (3.66 g, 10.0 mmol) in 30 ml of ethyl acetate, *N*-methylmorpholine (1.01 g, 10.0 mmol) and then ethyl chloroformate (1.08 g, 10.0 mmol) were added under cooling in an ice-salt bath and then diazomethane in ether was added. The reaction mixture was stirred for 2 h and allowed to stand at room temperature overnight. A small amount of precipitate was filtered off and filtrate was concentrated *in vacuo*. The yellowish crystalline residue was dissolved in 50 ml of methanol and silver benzoate (100 mg, 0.436 mmol) in 1 ml of triethylamine was added. The reaction mixture was stirred at room temperature for 4 h in the dark, and then concentrated *in vacuo*. Insoluble material of the residue in ethyl acetate was filtered off. Filtrate was washed with 1M hydrochloric acid or 10% citric acid, water, saturated sodium hydrogencarbonate solution, and water to neutral successively. Organic layer was dried over anhydrous sodium sulfate and concentrated *in vacuo*. Crystalline residue (3.20 g, 81%) was recrystallized from ethyl acetate and hexane to give a fine Boc-L-β-Lys(Z)-OMe, yield 2.38 g (60%), mp 69—71 °C, $[\alpha]_D^{14}$ −5.1 ° (*c* 1.00, DMF).

Found: C, 60.86; H, 7.74; N, 7.12%. Calcd for $C_{20}H_{30}O_6N_2$: C, 60.89; H, 7.67; N, 7.10%.

To a solution of Boc-L-β-Lys(Z)-OMe (960 mg, 2.43 mmol) in 5 ml of dioxane, 2.43 ml of 1 M sodium hydroxide was added with stirring at 0 °C. Stirring was continued at this temperature for 30 min, and then at room temperature for additional 2 h. The reaction mixture was acidified with 10% citric acid and extracted with ethyl acetate. Organic layer was washed with water to neutral, and was dried over anhydrous sodium sulfate and concentrated *in vacuo*. Crystalline residue thus obtained was recrystallized from ethyl acetate and hexane to give Boc-β-L-Lys(Z)-OH, yield 740 mg (80%), mp 89—91 °C, $[\alpha]_{365}^{14}$ +4.5 ° (*c* 1.01, DMF).

Found: C, 59.98; H, 7.45; N, 7.30%. Calcd for $C_{19}H_{28}O_6N_2$: C, 59.98; H, 7.42; N, 7.36%.

Boc-L-β-Lys(Z)-OH (1.90 g, 5.00 mmol), DCC (1.24 g, 6.00 mmol) and HONSu (690 mg, 6.00 mmol) were allowed to react as described in the preparation of Z-L-A_2pr(Z)-ONSu. The product was recrystallized from ethyl acetate and hexane, yield 1.70 g (71%), mp 73 (sintered)—80 °C, $[\alpha]_D^{14}$ −6.1 ° (*c* 1.00, DMF).

Found: C, 57.74; H, 6.56; N, 8.82%. Calcd for $C_{21}H_{31}O_8N_3$: C, 57.85; H, 6.54; N, 8.80%.

Method B (Preparation of Boc-L-β-Orn(Boc)-ONSu): To a solution of Boc-L-A_2bu(Boc)-OH (1.59 g, 5.0 mmol) in 25 ml of ethyl acetate, *N*-methylmorpholine (506 mg, 5.0 mmol) and then ethyl chloroformate (543 mg, 5.0 mmol) were added with stirring in an ice-salt bath and stirring was continued for 3 h. *N*-Methylmorpholine hydrochloride was filtered off. A large excess of diazomethane in ether was added to the cold filtrate. A solution was stirred in the cold for 1 h and then at room temperature overnight. Oily residue obtained after vacuum concentration was dissolved in 10 ml of THF. To the solution, HONSu (2.30 g, 20 mmol) and silver benzoate (100 mg, 0.44 mmol) in 1 ml of triethylamine were added. The mixture was stirred at room temperature in the dark for

4 h and then concentrated *in vacuo*. After the residue was triturated with ethyl acetate, insoluble inorganic material was filtered off. Filtrate was washed with 10% citric acid, water, saturated sodium hydrogencarbonate solution, and finally water to neutral. Ethyl acetate layer was dried over anhydrous sodium sulfate and concentrated *in vacuo*. Oily residue was treated with hexane to be crystallized, yield 1.52 g (71%). Recrystallization from ethyl acetate and hexane afforded pure substance, yield 1.26 g (59%), mp 130—132 °C, $[\alpha]_D^{23}$ −13.8° (*c* 0.99, DMF).

Found: C, 52.76; H, 7.27; N, 9.65%. Calcd for $C_{19}H_{13}O_8N_3$: C, 53.13; H, 7.28; N, 9.79%.

β-(Acylamino) acid active esters were mainly prepared by method B and their physicochemical properties were listed in Table 1.

Preparation of New Tuberactinomycin Analogs. [L-*Lys*[1]]-*Tum N·3HCl*: To a suspension of Tua N·2HCl[4] (300 mg, 0.49 mmol) in 10 ml of DMF, Boc-L-Lys(Boc)-ONSu (324 mg, 0.73 mmol) and triethylamine (51 mg, 0.50 mmol) were added, and stirred at room temperature overnight. Disappearance of Tua N was checked by TLC. A clear solution was concentrated *in vacuo* and the residue was triturated with dioxane or THF.[8] Gelatinous precipitate was filtered or collected by centrifugation. For a complete removal of unreacted active ester, an aqueous solution of the product is better extracted with ethyl acetate. Concentration of the aqueous layer *in vacuo* gave a pure coupling product in a quantitative yield as hygroscopic powder. It was immediately dissolved in 3 ml of 3 M hydrochloric acid and allowed to stand for 45 min at room temperature. Additions of ethanol and ether gave precipitate, yield 340 mg (89%). It was recrystallized from water and ethanol to give fine needles 307 mg, 81%), mp 236—237 °C (dec), $[\alpha]_D^{24}$ −9.8° (*c* 1.00, H_2O).

Found: C, 38.36; H, 6.13; N, 23.01; Cl, 13.36%. Calcd for $C_{25}H_{43}O_9N_{13}\cdot 3HCl\cdot 1/2H_2O$: C, 38.10; H, 6.01; N, 23.11; Cl, 13.50%.

[L-β-*Leu*[1]]-*Tum N*: To a suspension of Tua N·2HCl[4] (307 mg, 0.50 mmol) in 10 ml of DMF, Z-L-β-Leu-ONSu (217 mg, 0.60 mmol) and triethylamine (61 mg, 0.60 mmol) were added. After Tua N was consumed, a clear solution was concentrated *in vacuo*. The residue was triturated with THF and gelatinous product was collected by centrifugation. Powder obtained quantitatively was dissolved in water containing 0.1 ml of concentrated hydrochloric acid and extracted with ethyl acetate several times. The aqueous layer was subjected to hydrogenation by use of palladium black catalyst. The reaction was followed by TLC and catalyst was filtered off after completion of debenzyloxycarbonylation. Filtrate was concentrated *in vacuo* and the residue was treated with ethanol to make it powder, yield 350 mg (96%). It was recrystallized from water and ethanol, yield 300 mg (82%), mp 238 °C (dec), $[\alpha]_D^{24}$ −22.7° (*c* 1.00, H_2O).

Found: C, 40.07; H, 6.16; N, 22.23; Cl, 9.25%. Calcd for $C_{25}H_{42}O_9N_{12}\cdot 2HCl\cdot H_2O$: C, 40.27; H, 6.22; N, 22.54; Cl, 9.51%.

All of the other acids applied were coupled to the Tua N *via* *N*-hydroxysuccinimide ester, in similar manners, by

either procedure mentioned above depending on the protecting group used except in the case of arginine. All protecting groups in the products were finally removed with acid or by hydrogenation in the presence of acid. However N^{im}-tosyl group of histidine was readily removed with HOBt after coupling reaction.[9] Physicochemical data for all other semisynthetic tuberactinomycins are listed in Table 2.

[L-Arg¹]-Tum N·3HCl. To a solution of Tua N·2HCl[4] (300 mg, 0.49 mmol), Nps–Arg(NO_2)–OH (181 mg, 0.54 mmol), and HOBt (72 mg, 0.54 mmol) in a mixture of 5 ml of DMF and 4 ml of water, 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (78 mg, 0.54 mmol) was added with stirring in an ice bath. It was stirred in an ice bath for 3 h and then at room temperature overnight. The solution thus obtained was concentrated *in vacuo* and the residue was triturated with ethyl acetate. Precipitate was filtered and then suspended in 10 ml of 1 M hydrochloric acid and 10 ml of ether. The mixture was stirred at room temperature for 30 min. Aqueous layer separated was washed with ether three times. The aqueous solution was concentrated *in vacuo* and the residue was reprecipitated from water and ethanol to remove sulfur-containing compound completely. Precipitate was again dissolved in 20 ml of water containing 0.5 ml of concd hydrochloric acid and hydrogenated in the presence of palladium black. After completion of deprotection, the catalyst was removed by filtration. Filtrate was concentrated *in vacuo* and the residue was treated with ethanol to give powder, yield 355 mg (90%). For purification, it was applied to Amberlite IRC 50 (CG 50 Type 1 1.5×23 cm) column and eluted gradiently with pH 3.1 to pH 5.0 buffer (0.2—2 M pyridine–acetate). Eluates containing [L-Arg¹]-Tum N were collected and concentrated *in vacuo*. To a solution of the residue in 6 M hydrochloric acid, ethanol was added to precipitate the product, yield 208 mg (53%), mp >250 °C, $[\alpha]_D^{16}$ −8.7 ° (*c* 1.01, H_2O).

Found: C, 37.05; H, 5.84; N, 24.86; Cl, 12.76%. Calcd for $C_{25}H_{43}O_9N_{15}\cdot 3HCl\cdot H_2O\cdot 1/2C_2H_5OH$: C, 36.82; H, 6.06; N, 24.77; Cl, 12.54%.

[Ac–L-β-Lys¹]-Tum N (Nᵝ-Ac–Tum O)·2HCl. To a suspension of Tua N·2HCl[4] (1.50 g, 2.44 mmol) in 50 ml of DMF, Boc–L-β-Lys(Z)–ONSu (1.28 g, 2.69 mmol) and triethylamine (245 mg, 2.44 mmol) were added. After completion of reaction, a clear solution was concentrated *in vacuo* and oily residue was triturated with THF to make gelatinous precipitate of diacyl peptide, which was collected by centrifugation, yield 1.94 g (89%).

For removal of Boc group, an aliquot of the product (200 mg, 0.22 mmol) was dissolved in a mixture of 50% acetic acid (1 ml) and concd hydrochloric acid (0.5 ml), and then stirred at room temperature for 1.5 h. Addition of ethanol and ether to the solution gave white precipitate, yield 179 mg (92%). To a solution of the product (179 mg, 0.20 mmol) in 10 ml of DMF, AcONSu (35 mg, 0.22 mmol) and triethylamine (23 mg, 0.22 mmol) were added. The mixture was stirred at room temperature overnight and then concentrated *in vacuo*. When oily residue was triturated with THF, gelatinous precipitate was formed which was immediately hydrogenated in aqueous solution containing 0.5 ml of 1 M hydrochloric acid by use of palladium black catalyst. After completion of hydrogenolysis, catalyst was filtered off and filtrate was concentrated *in vacuo*. The residue was treated with ethanol to make it powder, yield 113 mg (71%), which was reprecipitated from water and ethanol to give pure desired material, yield 89 mg (55%), mp 239 °C (dec), $[\alpha]_D^{26}$ −34.0 ° (*c* 1.00, H_2O).

Found: C, 40.79; H, 6.12; N, 22.76; Cl, 8.99%. Calcd for $C_{27}H_{47}O_{10}N_3\cdot 2HCl\cdot 1/2H_2O$: C, 40.86; H, 6.10; N, 22.93; Cl, 8.93%.

[L-β-Lys(Ac)¹]-Tum N (Nᵋ-Ac–Tum O)·2HCl. [Boc–L-β-Lys(Z)¹]-Tum N (*N*ᵝ-Boc–*N*ᵋ-Z–Tum O)·2HCl (200 mg, 0.22 mmol) obtained during the above procedure was dissolved in DMF and hydrogen was bubbled with stirring in the presence of palladium black. Debenzyloxycarbonylation was completed in 30 h and thereafter catalyst was filtered off. After addition of AcONSu (35 mg, 0.22 mmol) to filtrate, the reaction mixture was stirred at room temperature for 15 h and concentrated *in vacuo*. The residue was treated with THF to give a single product of solid which was then dissolved in 4 M hydrochloric acid to remove Boc group. After 1 h, ethanol was added to the solution precipitating a product. Addition of ether completed the precipitation, yield 143 mg (82%). Product was reprecipitated from water and ethanol to obtain a pure compound, yield 114 mg (65%), mp 236 °C (dec), $[\alpha]_D^{26}$ −24.2 ° (*c* 1.01, H_2O).

Found: C, 40.70; H, 6.14; N, 22.66; Cl, 9.00%. Calcd for $C_{27}H_{45}O_{10}N_3\cdot 2HCl\cdot 1/2H_2O$: C, 40.86; H, 6.10; N, 22.93; Cl, 8.93%.

[Ac-β-Lys(Ac)¹]-Tum N (Nᵝ,Nᵋ-(Ac)₂-Tum O)·HCl. AcONSu (88 mg, 0.56 mmol) and triethyl amine (53 mg, 0.52 mmol) were added to a suspension of Tum O·3HCl (200 mg, 0.26 mmol) in 10 ml of DMF. The mixture was stirred for 20 h. Gelatinous residue obtained after vacuum concentration was treated with THF to give powder in a quantitative yield. Recrystallization from water and ethanol gave a pure product, yield 139 mg (68%), mp 215 °C (dec), $[\alpha]_D^{25}$ −34.6 ° (*c* 1.02, H_2O).

Found: C, 43.28; H, 6.23; N, 22.55; Cl, 4.32%. Calcd for $C_{29}H_{47}O_{11}N_{13}\cdot HCl\cdot H_2O$: C, 43.09; H, 6.24; N, 22.53; Cl, 4.39%.

Results and Discussions

Minimum inhibitory concentrations of semisynthetic tuberactinomycins preparated in this study to many bacteria were listed in Table 3. Several noticeable features were summarized as follows: 1) Although most of the synthetic compounds showed more or less antimicrobial activity against *Mycobacterium* and *Corynebacterium*, the coupling of basic amino acids gave favorable results in general. 2) Acidic amino acids as branch part extinguish the activity at all. 3) Coupling of neutral amino acids with bulky or hydrophobic side chain was relatively effective particularly against *Mycobacterium* as well as in the case of basic amino acids. 4) Remarkable relationship between methylene lengths in diamino acids and their activities against *Mycobacterium* (Table 4) was recognized. 5) Among semisynthetic tuberactinomycins prepared in this study only [L-β-Orn¹]-Tum N showed a similar antimicrobial spectrum and comparable activity to that of natural Tum N. From above results, it can be inferred that a fairly strict structure is required at a branch amino acid part to maintain a full antimicrobial activity of natural compounds, *i.e.*, presence of β-amino group and of longer chain than three carbons between two amino groups in diamino acid are necessary.

In connection with the last assumption, the role of both amino groups of β-lysine in natural tuberactinomycins was next investigated by the preparation of five following derivatives, *i.e.*, [β-Ahx¹]-Tum N, [ε-Ahx¹]-

a) MIC: Minimum inhibitory concentration.
b) Tum O.

Tum N, N^{β}-Ac–Tum O, N^{ε}-Ac–Tum O, and $N^{\beta}.N^{\varepsilon}$-$(Ac)_2$–Tum O.[11] Antimicrobial activities of them were markedly affected by such modifications as can be seen in Table 3. Disappearance of the activities in all derivatives indicated the indispensability of both free amino groups, being consistent with the results mentioned before. From observation that weak activities remain in [β-Ahx[1]]-Tum N and N^{ε}-Ac–Tum O compared to three other derivatives, β-amino group seems to be slightly rather effective than ω-one. Recently, Kitagawa and his collaborators also pointed out the significance of both amino groups in β-lysine residue from their study on viomycin.[10]

In order to elucidate a relationship between the structure and biological activity of those semisynthetic antibiotics prepared here, ORD and CD of several synthetic as well as natural tuberactinomycins were measured. Their spectra were depicted in Fig. 4, in which extreme similarities in patterns are noticed. Thus we could understand that molecules of semisynthetic tuberactinomycins are forced to a definite conformation fixed by an intramolecular hydrogen bond[5] in cyclic peptide moiety despite of large difference in branched

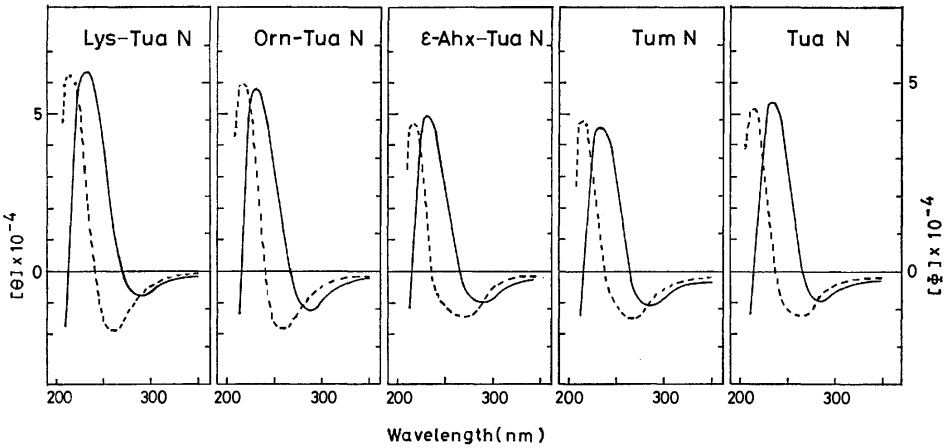

Fig. 4. ORD and CD curves of Tum analogs. ——: ORD, ------: CD, solvent: water.

part structure. Most important conclusion is that such conformation of whole molecule is not necessarily related to the biological activity, since inactive [ε-Ahx[1]]-Tum N showed quite similar pattern of ORD and CD spectra to natural antibiotics.

Activities against human tubercule bacilli, either sensitive or resistant to tuberactinomycin B, were also measured for some of the semisynthetic tuberactinomycins which are active to *Mycobacterium* ATCC 607, as shown in Table 5. While they showed significant antibacterial activity to sensitive human tubercule bacillus, none of them showed antibacterial activity to human tubercule bacillus resistant to tuberactinomycin B. Therefore any changes of the branched amino acid could not effect on cancellation of drug-resistancy of human tubercule bacilli so far.

In conclusion, all the results obtained in the present study can be summarized as follows. Most important active site in antibiotics of tuberactinomycin family must be in the cyclic peptide moiety, though its presence does not assure an exhibition of full biological activity, and basicity and/or hydrophobicity of the molecule seems to be the second important requisite for antimicrobial activity. At present time, there are found no semisynthetic compounds with stronger activity or more favorable quality than natural ones. However this study could explore a new way to modify natural tuberactinomycins by different kinds of acylation for the purpose of searching more desirable analogs.

Table 5. Minimum inhibitory concentrations[a] of semisynthetic tuberactinomycin analogs against mycobacterium and human tubercule bacilli

(Received February 21, 1977)

Reaction of α,α'-dibromo ketones and *N,N*-dimethylcarboxamides with the aid of $Fe_2(CO)_9$ affords the corresponding reductive cyclocoupling products, 5-(dimethylamino)tetrahydro-3-furanones. In usual, the adducts derived from di-*s*-alkyl ketone dibromides easily eliminated dimethylamine to afford 3(2*H*)-furanones. *N,N*-Dimethylformamide (DMF), *N,N*-dimethylacetamide, *N,N*-dimethylbenzamide, and *N*-methylpyrrolidone have been used as dibromo ketone receptors. Thus, this general method provides a new, singleflask procedure for the preparation of the oxygen-containing five-membered ketones. The iron carbonyl-promoted 3+2 cyclocoupling reaction is interpreted as proceeding *via* a stepwise cycloaddition of a reactive 2-oxyallyl–Fe(II) intermediate and carboxamide. A facile conversion of such furanones to muscarine alkaloids is described.

We have developed the iron carbonyl-assisted cyclocoupling reaction between α,α'-dibromo ketones and olefins[3] or dienes,[4] which provides a new tool for making various carbocyclic frameworks. Our recent work has shown that this reaction can be extended to the preparation of a heterocyclic system, 3(2*H*)-furanones, when carboxamides are employed as the unsaturated substrate.[2] The furanones are an important class of compounds in connection with the chemistry of various natural products; particularly, they may be expected to serve as versatile precursors of muscarine alkaloids. These unsaturated five-membered compounds are also followed with great theoretical interest as significant substances for the examination of possible keto-enol tautomerization of heterocycles.[5] Consequently, a variety of preparative methods have been reported.[5] However, most of them can form the derivatives of only certain paticular types and are not generally useful. The approaches that have a general usefulness are, we feel: (1) The preparation of 5-alkyl derivatives by the hydrogenolysis of 3-alkylisoxazoles, followed by acid-catalyzed cyclization;[6] (2) the acid-catalyzed rearrangement of 4-alkylidene-1,3-dioxolanes to alkylated 3(2*H*)-furanones;[7,8] (3) the synthesis of 2-acyl-3-alkyl derivatives by the pyrolytic reaction of dimethylsulfonium acyl-(3-alkylpropionyl)methylide,[9] and (4) the formation of the 2,2-dialkyl compounds *via* the reaction of 2-lithio-2-(2,2-dimethoxyethyl)-1,3-dithiane and ketones, followed by hydrolysis.[10] This paper will describe a general, expeditious route to 2,4-dialkyl-3(2*H*)-furanones *via* the iron carbonyl aided 3+2 cyclocoupling of α,α'-dibromo ketones and carboxamides, and its application to the synthesis of muscarines.

Results and Discussion

Cyclocoupling Reaction between α,α'-Dibromo Ketones and Carboxamides. A. Reaction with Tertiary Dibromoketones: Reduction of 2,4-dibromo-2,4-dimethyl-3-pentanone (**1**) with $Fe_2(CO)_9$ (1 : 1 mol ratio) was carried out in dry DMF solvent containing disodium dihydrogen ethylenediaminetetraacetate (Na_2H_2edta) under nitrogen atmosphere. The reaction proceeded smoothly at room temperature to give, after usual extractive work-up, the cyclic product **2** and the enone **3** in 3 and 80% yields, respectively. The minor compound **2** gave, in its IR spectrum, the carbonyl absorption at 1756 cm^{-1} characteristic of five-membered ketones, and NMR data identical with those previously reported.[7]

Scheme 1.

B. Reaction with Secondary Dibromo Ketones: As is outlined in Scheme 1, the reaction of secondary dibromo ketones and *N,N*-dimethylated carboxamides with the aid of $Fe_2(CO)_9$ first led to labile 2,4-dialkyl-5-(dimethylamino)tetrahydro-3-furanones of type **7**, which in turn underwent the facile elimination of dimethylamine to produce 3(2*H*)-furanone derivatives **8**—**15**. The overall transformation can be viewed formally as the construction of a carbon-oxygen bridge between the α and α' positions of the parent dialkyl ketones.

For example, stirring of a mixture of the dibromide **4** and $Fe_2(CO)_9$ (1 : 1.2 mol ratio) in DMF in the presence of Na_2H_2edta at room temperature for 22 h gave, after extractive work-up and distillation, the 3(2*H*)-

furanone **8** in 53% yield. Here, the absence of Na_2H_2-edta in the reaction system resulted in a drastic decrease in yield of this coupling product. Structure determination of **8** was based on the spectral analysis. This product showed strong IR stretching bands at 1704 (C=O) and 1624 cm^{-1} (C=C),[11] and a UV maximum at 270 nm (log ε 3.89) characteristic of 3(2*H*)-furanones.[5-10,12] The NMR spectrum also supported the assigned structure. The presence of an $OCH(CH_3)$-C=O linkage was deduced from a methyl doublet appearing at δ 1.39 with J=7.5 Hz and a one-proton quartet with the same coupling constant at a rather low field, δ 4.31. The vinylic methyl group exhibited a doublet signal at δ 1.67, indicating that the splitting (J=2 Hz) is due to a long-range coupling with the vinylic proton, giving a quartet at δ 7.90.[7] The mass spectrum exhibited a molecular-ion peak confirming the the formula of $C_6H_8O_2$. Notably, this product exists solely in a keto form and did not give a positive $FeCl_3$ test.

This cyclocoupling reaction is operationally quite simple and has a wide application. In place of DMF, *N*,*N*-dimethylacetamide and *N*,*N*-dimethylbenzamide can be employed as well. Furanones obtained by the cyclocoupling reaction of the secondary dibromides and carboxamides are summarized in Table 1. The product

Table 1. Iron carbonyl-promoted furanone synthesis

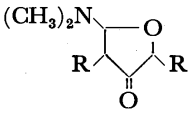
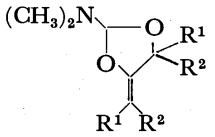
a) Determined by an NMR analysis of the crude reaction mixture. b) Isolated yield. c) Na_2H_2edta (three equiv of the dibromide) was added to the reaction system. d) In CCl_4 solution. e) Result obtained after heating the initial product at 110 °C for 10 min.

yield is usually moderate to high. When the dibromide bears bulky alkyl substituents, the initial adduct **7** can be isolated in a stable form after usual work-up. In such a case, in order to attain complete deamination, brief heating at an elevated temperature is required. Thus, the highly sterically crowded adduct **17** produced from the dibromo ketone **16** and DMF was quite stable and remained unchanged even after heating at 110 °C

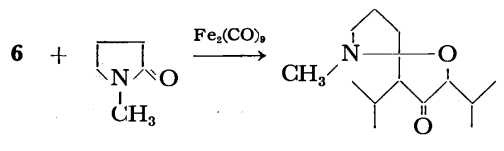


17: R=C(CH$_3$)$_3$
21: R=CH(CH$_3$)$_2$

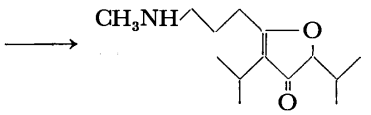


20: R^1=alkyl; R^2=H
29: R^1=R^2=CH$_3$

for 20 min. Certain lactams can also be used as dibromo ketone receptors. For instance, the reaction of the dibromo ketone **6** and *N*-methylpyrrolidone at room temperature gave rise to the amino furanone **19** in 26% yield. Apparently the formation of **19** resulted from intramolecular deamination of the initial spiro-fused intermediate **18**. Unfortunately, methyl ketone dibromides gave no or little cyclocoupling products. For example, the reaction of α,α′-dibromoacetone and DMF under ordinary reaction conditions failed to afford the coupling product. The use of $Fe(CO)_5$ in place of



18



19

$Fe_2(CO)_9$ did not reduce dibromo ketones under comparable thermal conditions; in this case, irradiation by visible light was necessary to achieve the reaction. As has been reported previously,[13] the use of Zn–Cu couple as the reducing agent forms another type of 1 : 1 coupling product, 1,3-dioxolane **20**, in a fair to good yield; the product can be converted to the furanones by acid treatment.

Reaction Mechanism of the 3+2 Cyclocoupling Reaction. A. The Reactive Species: In the absence of $Fe_2(CO)_9$, no reaction took place between dibromo ketones and carboxamides. By contrast, when a reducing agent was added to such a mixture, the cyclocoupling reaction proceeded smoothly. When the reaction of **6** and $Fe_2(CO)_9$ was carried out in a 1 : 1 DMF–furan mixture, both the DMF adduct **21** (65%) and the furan adduct **22**[4a,c] (27%) were produced. These observations strongly indicate that reactive 2-oxyallyl–Fe(II) intermediates of type **23**[14] are generated under the present reaction conditions. The occurrence of such species in DMF has also been suggested by the reductive rearrangement of 2,4-dibromo-6,6-diphenylbicyclo[3.1.0]-hexan-3-one[14] and nucleophilic trapping experiments.[14] This view is also consistent with the formation of the enone **3** as a major product in the reaction of **1**. Thus, carboxamides serve as extremely efficient trapping agents of the oxyallyl intermediate and even compete well with furan. It is also worthwhile to note that the oxyallyl–Fe(II) species **24**, which smoothly undergoes a neopentyl-type rearrangement in benzene,[14] affords the DMF adduct **17** prior to the skeletal change.

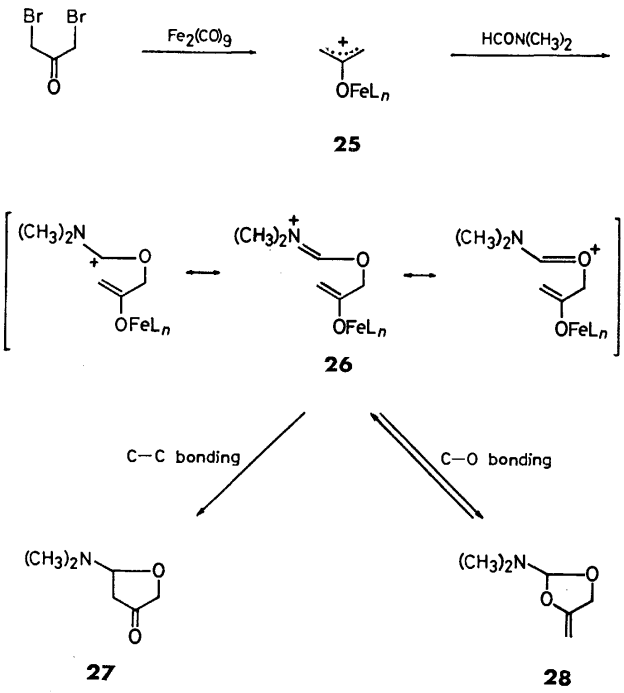
24, R^1=R^4=C(CH$_3$)$_3$; R^2=R^3=H
L=CO, Br, solvent, *etc.*

B. Reaction Course of Cycloaddition of the Oxyallyl Species and Carboxamides: The cycloaddition is best accounted for by the path outlined in Scheme 2, where, for the sake of simplicity, the reaction of unsubstituted oxyallyl **25** and DMF is taken up. First, there occurs the electrophilic attack of **25** on the oxygen atom of DMF, producing the highly stable ionic intermediate **26**. Subsequent cyclization through bonding between the cationic and enolate carbons results in the adduct **27**. The zwitterionic intermediate **26** may also undergo the C–O cyclization, thus giving the dioxolane product **28**;[13] the reverse process, if possible, could lead ultimately to the more stable product **27**. Indeed, treatment of **29** with $FeBr_2$ in DMF gave **2** in a moderate (20—30%) yield. However, there has not yet been any direct evidence for the presence of the equilibrium, **26**⇄**28**. When the reaction course was monitored, the dioxolane

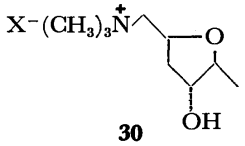


Scheme 2.

product **28** could not be detected at any stage of the reaction.

In any events, the intermediacy of the resonance-stabilized ionic intermediate **26** appears to be crucial for the cyclization to proceed. Thus, the overall process can be envisaged as a stepwise [$_\pi$2+$_\pi$2] cycloaddition. A related stepwise mechanism has been claimed for the reaction forming certain carbocyclic five-membered skeletons.[3] The dioxolane **28**, even if formed, cannot be derived through a concerted [$_\pi$2+$_\pi$4]-type cycloaddition of an electron-accepting oxyallyl, **23**, and an electron-donating carboxamide, because, in the lowest unoccupied molecular orbital of **23**, the orbital does not develop over the oxygen atom to any great extent.[15]

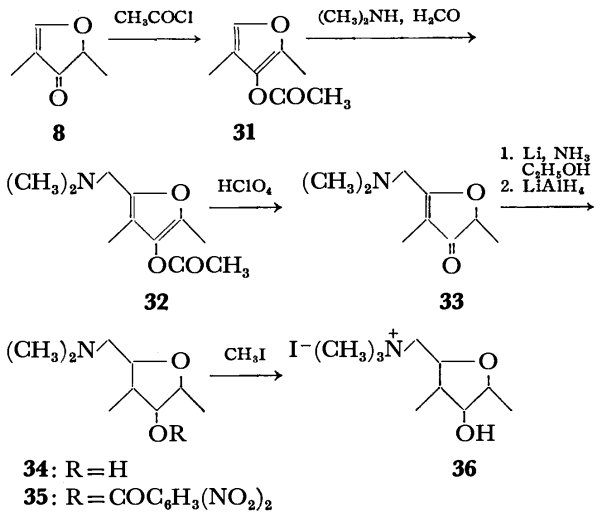
Application to Muscarine Synthesis. In the natural field, there are many compounds with the furanone or related skeletons. Muscarine (**30**) isolated from fly agaric [*Amantia muscaria* (L. ex Fr.) Quel.] is a representative compound. This alkaloid has long attracted the attention of pharmacologists and chemists because of its marked and peculiar actions on the autonomic nervous system. This product, however, exists in such small amounts in natural plants that a satisfactory supply of the alkaloids is difficult to obtain only by extraction; hence, an efficient method of preparing muscarine



30

chemically has been sought for a long period. The synthetic methods thus far developed can be broadly divided, in terms of the construction mode of the heterocyclic system, into the following four types:[16] (1) the diazotization of β,γ-dihydroxy α-amino acids such as glucosamine[17] and 2-amino-4,5-dihydroxyhexanoic acid,[18] affording 3-hydroxytetrahydrofuran rings; (2) the condensation of iodopropionic ester and malic ester[19] or, more conveniently, of α-hydroxypropionic ester and maleic or fumaric ester[20] to form 4,5-bis-(ethoxycarbonyl)-2-methyltetrahydro-3-furanone; (3) the condensation of epichlorohydrin and sodioacetoacetic ester, giving α-acetyl-δ-chloro-γ-valerolacetone;[21] and (4) the condensation of glucose or mannose and β-keto carboxylic ester to produce 2-methyl-5-tetrahydroxybutylfuran-2-carboxylic ester.[22] We will describe here a new general entry into muscarine analogs[23] starting from the 2,4-dialkyl-3(2*H*)-furanones obtained by the iron carbonyl-promoted cyclocoupling reaction of dibromo ketones and DMF. The method is based on the introduction of a dimethylaminomethyl group to the C_5 position of the furanones.

The route to 4-methylmuscarine iodide (**36**) is shown in Scheme 3. First, treatment of **8** with acetyl chloride in 1,2-dimethoxyethane afforded the acetoxy furan **31** in 68% yield. The IR absorption at 1760 cm^{-1} was instructive in determining the enol acetate structure. Further, in the NMR spectrum, a sharp three-proton singlet appeared at δ 2.21, confirming the presence of an acetyl group. The furan-ring structure was supported



Scheme 3.

by a finely splitting quartet at δ 6.92. The Mannich aminomethylation of **31** was performed with 40% aq dimethylamine and 37% aq formaldehyde in acetic acid[24] at 70 °C, producing the amino furan **32** in 80% yield. The IR spectrum showed absorptions of the $N(CH_3)_2$ group at 2840, 2795, and 2745 cm^{-1}. In addition, the introduction of the dimethylaminomethyl function to C_5 was confirmed by the NMR characteristics, *viz.*, the appearance of two singlets at δ 2.28 and 3.42 (3: 1 ratio), and the disappearance of a low-field signal due to the vinyl proton. Hydrolysis of **32** by heating with 70% $HClO_4$ gave the furanone **33** in >95% yield. The occurrence of 3(2*H*)-furanone skeleton was confirmed by strong IR bands at 1698 (C=O) and 1623 cm^{-1} (C=C) as well as by a UV maximum at 274 nm (log ε 4.01).[12] In the NMR spectrum, there appeared a coupled three-proton doublet and a one-proton quartet at δ 1.37 and 4.24 (J=7.0 Hz), respectively, indicating the presence of an $OCH(CH_3)C{=}O$ moiety. The Birch reduction of **33** using Li–ethanol, followed by $LiAlH_4$ treatment,[25] formed desired 4-methylnormuscarine (**34**, two stereoisomers) in 61% yield. The presence of the OH function was confirmed by a broad IR absorption at 3400—3200 cm^{-1}, and the NMR spectrum confirmed the existence of two secondary methyls. Finally, treatment of **34** with methyl iodide in benzene produced 4-methylmuscarine iodide (**36**) quantitatively. The quaternization was monitored by appearance of the NMR signal at δ 3.21 due to $\overset{+}{N}(CH_3)_3$.[26] 4-Methylmuscarine iodide (**36**) thus obtained displayed the physiological activities characteristic of muscarine alkaloids; the smooth muscle of the intestinal tract was stimulated, increasing tone and mobility, while atropine inhibited these actions.

Experimental

General. All melting and boiling points are uncorrected. The IR spectra were measured on a JASCO IR-A-I or JASCO DS-402G spectrometer in the noted phase. The UV spectra were taken on a Perkin-Elmer Model 202 or a Hitachi Model 323 spectrometer in ethanol solution. The IR and UV spectral data of 3(2*H*)-furanones **8**—**15** are listed in Table 1.

The NMR spectra were recorded on a JEOL C-60H instrument in CCl_4 solution unless otherwise stated; the chemical shifts are given in ppm downfield from internal tetramethylsilane. 1,1,2,2-Tetrachloroethane or tetralin was used as the standard for the quantitative analysis. The mass spectra (MS) were obtained on a Hitachi RMU-6C mass spectrometer, operating with an ionization energy of 70 eV. The exact MS were performed at the Faculty of Agriculture, Nagoya University, and at the Hitachi Naka Works. Elemental analyses were carried out at the Analytical Centers of Kyoto University and Meijo University. All $Fe_2(CO)_9$-assisted cyclocoupling reactions were performed under nitrogen atmosphere. Drying of organic extracts was done over anhyd Na_2SO_4. For concentration of organic solvents, a vacuum (60—90 Torr) rotary evaporator was used. Products on TLC plates were detected by irradiation of UV-light (254 nm), by a spray of $Ce(SO_4)_2$ in 65% H_2SO_4 or molybdophosphoric acid in 10% ethanol, followed by heating, or by exposure to I_2 vapor.

Chromatography. GLPC analysis and separation were performed on a Yanagimoto Model G-8, Yanagimoto Model GCG-3D, or Varian 1700 instrument. Columns used were: A, 3 mm×2 m 5% poly(ethylene glycol succinate) on Chromosorb W AW; B, 3 mm×2 m 5% poly(ethylene glycol) on Celite 545; C, 4 mm×4 m 10% LAC on Chromosorb W AW; D, 3 mm×2 m 5% Silicone OV-1 on Chromosorb W AW; E, 4 mm×2 m 12% diisodecyl phthalate on Neopak 1A; F, 3 mm×2 m 5% Apiezon grease L on Diasolid M; G, 5 mm×2 m 33% Apiezon grease L on Neopak 1A. Analytical and preparative TLC were done on E. Merck alumina GF_{254} plates. For column chromatography, Woelm basic alumina (Activity I) was employed.

Solvents and Materials. α,α′-Dibromo ketones **1**, **4**—**6**, and **16** were prepared by the procedures in the literature.[27,28] Oily dibromides were purified by passing them through a short alumina column immediately before use. Photolytic preparation of $Fe_2(CO)_9$ from $Fe(CO)_5$ was carried out according to the method of King.[29] The carbonyl complex was used after drying over KOH in a vacuum desiccator. 2-Dimethylamino-4-isopropylidene-5,5-dimethyl-1,3-dioxolane (**29**) solution in DMF (*ca.* 0.3 M) was obtained by the procedure of Hoffmann.[13] Dry DMF was produced by refluxing over CaH_2 at 60 °C under reduced pressure (20 mm) for 4 h, followed by distillation *in vacuo*; it was stored over molecular sieves 3A under nitrogen. Other carboxamides were used after a simple distillation of the commercially supplied ones. Benzene, tetrahydrofuran (THF), and 1,2-dimethoxyethane (DME) were distilled from $LiAlH_4$. Furan was distilled from CaH_2. Disodium dihydrogen ethylenediaminetetraacetate (Na_2H_2edta) dihydrate was dehydrated by heating it at 120 °C (0.01 mm) for 12 h.

Reaction of 2,4-Dibromo-2,4-dimethyl-3-pentanone (1) with $Fe_2(CO)_9$ in DMF. A mixture of the dibromo ketone **1** (833 mg, 3.06 mmol), $Fe_2(CO)_9$ (1.31 g, 3.60 mmol), and octane (32.5 mg, 0.29 mmol, an internal standard for GLPC analysis) in DMF (10.5 ml) was stirred at room temperature for 18 h. GLPC analysis of the reaction aliquots taken up at appropriate intervals showed the formation of three products. These products were identified, by comparison with authentic samples, as 5-(dimethylamino)tetrahydro-2,2,4,4-tetramethyl-3-furanone (**2**) [retention time (t_r) 9.8 min, column F, 130 °C, 3% yield], 2,4-dimethyl-1-penten-3-one (**3**) (t_r 7.8 min, column E, 90 °C, 80% yield), and 2,4-dimethyl-3-pentanone (t_r 6.5 min, column E, 90 °C, 9% yield). An analytical sample of **2** was obtained by GLPC separation (column G, 123 °C). Its spectral (IR, NMR, and mass) data were identical with the reported ones[9] (Found: C, 65.00; H, 10.47%).

2,4-Dimethyl-3(2H)-furanone (8). A mixture of 2,4-dibromo-3-pentanone (**4**) (8.70 g, 35.6 mmol), $Fe_2(CO)_9$ (15.6 g, 42.8 mmol), and Na_2H_2edta (18.0 g, 53.3 mmol) in DMF (80 ml) was stirred at room temperature for 12 h. After addition of benzene (80 ml), the reaction mixture was left at room temperature for 10 h and then poured into water (400 ml). The aq mixture was extracted with 1:1 ether-petroleum ether (160 ml×5). The combined organic extracts were washed with water (120 ml×3) and dried. The solvent was removed to give a dark brown oil (4.06 g). Upon addition of petroleum ether (80 ml), dark brown precipitates appeared immediately, which were then removed by filtration. Concentration of the filtrate gave a yellow oil (2.46 g), which was distilled at room temperature—70 °C (0.2 Torr) to afford the furanone **8** (2.11 g, 53% yield) as a colorless oil. NMR δ 1.39 (d, 3, J=7.5 Hz, $CHC\underline{H}_3$), 1.67 (d, 3, J=2 Hz, $=CC\underline{H}_3$), 4.31 (q, 1, J=7.5 Hz, $C\underline{H}CH_3$), and 7.90 (q, 1, J=2 Hz, =CH); MS *m/e* 112 (M^+). Found: *m/e* 112.0519. Calcd for $C_6H_8O_2$: M, 112.0523.

2,4,5-Trimethyl-3(2H)-furanone (9). A mixture of the dibromide **4** (488 mg, 2.00 mmol), $Fe_2(CO)_9$ (876 mg, 2.40 mmol), and Na_2H_2edta (2.03 g, 6.00 mmol) in *N,N*-dimethylacetamide (7.0 ml) was magnetically stirred at room temperature for 19 h. The reaction mixture was quenched by addition of saturated KNO_3 solution (20 ml) and extracted with ethyl acetate (5 ml×6). The combined organic extracts were washed with water (5 ml×3), dried, and concentrated, thus giving a red oil (168 mg). The NMR analysis showed that the furanone **9** was produced in 21% yield. An analytical sample (R_f 0.70) was obtained by TLC separation (CH_2Cl_2), followed by distillation. NMR δ 1.35 (d, 3, J=7.5 Hz, $CHC\underline{H}_3$), 1.62 (s, 3, $=CC\underline{H}_3$), 2.15 (s, 3, $=CC\underline{H}_3$), and 4.25 (q, 1, J=7.5 Hz, $C\underline{H}CH_3$); MS *m/e* 126 (M^+). Found: *m/e* 126.0690. Calcd for $C_7H_{10}O_2$: M, 126.0680.

2,4-Dimethyl-5-phenyl-3(2H)-furanone (10). To a suspension of $Fe_2(CO)_9$ (876 mg, 2.40 mmol) and Na_2H_2edta (2.03 g, 6.00 mmol) in benzene (5.0 ml) were added *N,N*-dimethylbenzamide (7.0 ml) and then the dibromo ketone **4** (488 mg, 2.00 mmol). The resulting mixture was stirred at room temperature for 19 h. The mixture was added to saturated KNO_3 solution (10 ml), and the aq mixture was extracted with 1:2 benzene–hexane (6 ml×6). The organic layers were collected, washed with water (6 ml×6), and dried. Evaporation of the solvent afforded a pale yellow oil, NMR analysis of which indicated the formation of the furanone **10** in 25% yield. TLC (1:10 ether–hexane, R_f 0.70), followed by short-path distillation, formed an analytical specimen of **10**. NMR δ 1.48 (d, 3, J=7.5 Hz, $CHC\underline{H}_3$), 1.95 (s, 3, $=CC\underline{H}_3$), 4.46 (q, 1, J=7.5 Hz, $C\underline{H}CH_3$), and 7.45 (m, 3) and 7.74 (m, 2) (C_6H_5); MS *m/e* 188 (M^+). Found: *m/e* 188.0854. Calcd for $C_{12}H_{12}O_2$: M, 188.0836.

2,4-Diethyl-3(2H)-furanone (11). A mixture of 3,5-dibromo-4-heptanone (**5**) (462 mg, 1.70 mmol) and $Fe_2(CO)_9$ (876 mg, 2.40 mmol) in DMF (7.0 ml) was stirred at room temperature for 12 h. The reaction mixture was treated with saturated aq Na_2H_2edta solution (40 ml) and extracted with 1:1 ethyl acetate–hexane (8 ml×5). The collected organic extracts were washed with water (8 ml×3) and dried. The solvent was removed under reduced pressure at room temperature to afford a residual oil (273 mg). Its NMR spectrum indicated that the furanone **11** was produced in 92% yield. This oil was dissolved in ethyl acetate (5 ml) and passed through a short column packed with alumina using ethyl acetate as eluent. Concentration of the filtrate gave the

furanone **11** (152 mg, 64% yield) as a pale yellow oil. An analytical sample was obtained by preparative GLPC (column A, 120 °C). NMR δ 0.97 (t, 3, J=7.0 Hz, CH_3), 1.08 (t, 3, J=7.0 Hz, CH_3), 1.5—2.4 (m, 4, 2 CH_2), 4.21 (dd, 1, J=4.5 and 7.0 Hz, OCHCO), and 7.90 (br s, 1, =CH); MS *m/e* 140 (M^+). Found: C, 68.38; H, 8.87%. Calcd for $C_8H_{12}O_2$: C, 68.54; H, 8.63%.

*2,4-Diethyl-5-methyl-3(2H)-furanone (**12**).* To a mixture of $Fe_2(CO)_9$ (876 mg, 2.40 mmol) and Na_2H_2edta (2.03 g, 6.00 mmol) was added *N,N*-dimethylacetamide (7.0 ml), followed by the dibromo ketone **5** (462 mg, 1.70 mmol). The resulting mixture was stirred at room temperature. After 19 h, saturated KNO_3 solution (20 ml) was added to the reaction mixture, and the aq layer was extracted with ethyl acetate (6 ml×5). The combined organic extracts were washed with water (40 ml×3) and dried. On removal of the solvent there was obtained a pale yellow oil. Addition of benzene (2 ml) yielded insoluble brown solides. The precipitates were removed by filtration through a short column of alumina and evaporation of the solvent afforded a colorless oil (130 mg). Yield of the furanone **12**, as estimated by NMR analysis, was 51%. Preparative TLC (1: 1 benzene–hexane) gave **12** as an oil. An analytical sample was obtained by preparative GLPC (column A, 120 °C). NMR δ 0.96 (t, 3, J=7.0 Hz, $CH_2C\underline{H}_3$), 1.01 (t, 3, J=7.5 Hz, $CH_2C\underline{H}_3$), 2.15 (s, 3, $=CCH_3$), 1.4—2.4 (m, 4, 2 CH_2), and 4.12 (dd, 1, J= 6.0 and 7.0 Hz, OCH); MS *m/e* 154 (M^+). Found: C, 70.32; H, 9.57%. Calcd for $C_9H_{14}O_2$: C, 70.01; H, 9.15%.

*2,4-Diethyl-5-phenyl-3(2H)-furanone (**13**).* To a mixture of $Fe_2(CO)_9$ (876 mg, 2.40 mmol) and Na_2H_2edta (2.03 g, 6.00 mmol) in benzene (5.0 ml) was added *N,N*-dimethylbenzamide (7.0 ml) and the dibromide **5** (462 mg, 1.70 mmol). The resulting mixture was kept, with stirring at room temperature for 14 h and then quenched with saturated KNO_3 solution. The aq layer was extracted with ethyl acetate (6 ml×5), and the combined organic extracts were washed with water (6 ml ×2) and dried. Removal of the solvent gave a feebly yellow oil (6.0 g), which without solvent, was heated at 110 °C for 15 min under nitrogen. After dilution with 1: 2 benzene–hexane (10 ml), the product was washed with water (4 ml×4) and dried. The organic solvent was evaporated to afford a pale yellow oil (873 mg). Purification by preparative TLC (benzene) yielded the furanone **13** (R_f 0.38, 175 mg, 42% yield) as a colorless oil. NMR δ 1.00 (t, 3, J=7.0 Hz, CH_3), 1.13 (t, 3, J=7.0 Hz, CH_3), 1.6—2.2 (m, 2, $CHC\underline{H}_2$), 2.41 (q, 2, J=7.0 Hz, $=CCH_2$), 4.32 (dd, 1, J=5.0 and 6.5 Hz, OCH), and 7.40 (m, 3) and 7.72 (m, 2) (C_6H_5); MS *m/e* 216 (M^+). Found: *m/e* 216.1119. Calcd for $C_{14}H_{16}O_2$: M, 216.1149.

*2,4-Diisopropyl-3(2H)-furanone (**14**).* A mixture of 3,5-dibromo-2,6-dimethyl-4-heptanone (**6**) (300 mg, 1.00 mmol) and $Fe_2(CO)_9$ (437 mg, 1.20 mmol) in DMF (3.5 ml) was stirred at room temperature for 12 h. The reaction mixture was poured into saturated aq $NaHCO_3$/KNO_3 solution (10 ml) and extracted with ethyl acetate (4 ml×5). The collected organic extracts were washed with water (4 ml×3) and dried sufficiently. The solvent was removed under reduced pressure to give a crude yellow oil (192 mg) containing mainly 5-(dimethylamino)-2,4-diisopropyltetrahydro-3-furanone (**21**). IR (neat film) 1753 cm^{-1} (C=O); NMR δ 0.8—1.3 (m, 12, 2 $CH(C\underline{H}_3)_2$), 1.8—2.4 (m, 3, 2 $C\underline{H}(CH_3)_2$ and $CHC\underline{H}CO$), 2.47 (s, 6, $N(CH_3)_2$), 3.40 (d, 1, J=4.5 Hz, OCHCO), and 4.57 (d, 1, J=9.0 Hz, OCHN); MS *m/e* 213 (M^+). The neat oil was heated at 140 °C for 15 min under nitrogen, followed by distillation *in vacuo* (60 °C, 1 Torr), to afford the furanone **14** (149 mg, 89% yield). NMR δ 0.83 (d, 3, J= 7.0 Hz, $CHCH(C\underline{H}_3)_2$), 1.12 (d, 3, J=6.5 Hz, $CHCH(C\underline{H}_3)_2$), 1.15 (d, 6, J=7.0 Hz, $=CCH(C\underline{H}_3)_2$), 2.0—2.8 (m, 2, 2 $C\underline{H}(CH_3)_2$), 4.10 (d, 1, J=3.8 Hz, OCHCO), and 7.89 (br s, 1, =CH); MS *m/e* 168 (M^+). Its structure was further confirmed by converting it through hydrogenation, into 2,4-diisopropyltetrahydro-3-furanone. A suspension of 10% Pd–C (500 mg) in ethanol (4 ml) was stirred at room temperature for 24 h under 1-atm hydrogen. To this was added a solution of **14** (1.00 g, 5.95 mmol) in ethanol (4 ml), and the resulting mixture was stirred at room temperature for 24 h under an atmospheric pressure of hydrogen. The mixture was passed through a Celite 545 column, and the filtrate was concentrated, giving the tetrahydro-3-furanone (*ca.* 1 g) as a single isomer (stereochemistry unconfirmed). An analytical sample of the product was collected by GLPC separation (column B, 100 °C). IR (neat film) 1750 cm^{-1} (C=O); NMR δ 0.8—1.1 (m, 12, 4 CH_3), 1.5—2.4 (m, 3, 2 $C\underline{H}(CH_3)_2$ and $C\underline{H}CH_3$), 3.40 (d, 1, J=5.5 Hz, OCH), and 3.9—4.2 (m, 2, OCH_2); MS *m/e* 170 (M^+). Found: C, 70.30; H, 10.75%. Calcd for $C_{10}H_{18}O_2$: C, 70.54; H, 10.66%.

*2,4-Diisopropyl-5-methyl-3(2H)-furanone (**15**).* To a mixture of $Fe_2(CO)_9$ (874 mg, 2.40 mmol) and Na_2H_2edta (2.03 g, 6.00 mmol) was added a solution of the dibromo ketone **6** (600 mg, 2.00 mmol) and tetralin (26.4 mg, 0.20 mmol) in *N,N*-dimethylacetamide (7.0 ml). The resulting mixture was stirred at room temperature for 12 h. The reaction mixture was poured into saturated $NaHCO_3$/KNO_3 solution (20 ml) and extracted with ethyl acetate (8 ml×5). The combined organic extracts were washed with water (8 ml ×3) and dried. After evaporation of the solvent, an oil was obtained. The NMR spectrum of this residue showed two doublets at δ 3.95 (J=3.8 Hz) and 3.38 (J=4.5 Hz) due to the C_2 methine proton of **15** and 5-(dimethylamino)-2,4-diisopropyl-5-methyltetrahydro-3-furanone (**7**, R=$CH(CH_3)_2$; R′=CH_3), respectively. The intensity of signals, as compared with that of a singlet due to the aromatic protons of tetralin internal standard, indicated that **15** and the amino tetrahydro-3-furanone were produced in 49 and 39% yields, respectively. When the crude oil was heated at 110 °C for 15 min under nitrogen, **15** was obtained as an oily product (316 mg, 87% yield). Distillation (90 °C, 3 mm), followed by preparative GLPC (column C, 108 °C), afforded an analytical sample. NMR δ 0.79 (d, 3, J=6.5 Hz, $CHCH(C\underline{H}_3)_2$), 1.05 (d, 3, J=6.5 Hz, $CHCH(C\underline{H}_3)_2$), 1.15 (d, 6, J=7.0 Hz, $=CCH(C\underline{H}_3)_2$), 2.15 (s, 3, $=CCH_3$), 2.0—2.8 (m, 2, 2 $C\underline{H}(CH_3)_2$), and 3.95 (d, 1, J=3.8 Hz, OCH); MS *m/e* 182 (M^+). Found: *m/e* 182.1295. Calcd for $C_{11}H_{18}O_2$: M, 182.1305.

*2,4-Di-t-butyl-5-(dimethylanmio)tetrahydro-3-furanone (**17**).* To a mixture of 3,5-dibromo-2,2,6,6-tetramethyl-4-heptanone (**16**) (110 mg, 0.34 mmol) and $Fe_2(CO)_9$ (146 mg, 0.40 mmol) was added DMF(1.0 ml). The resulting suspension was stirred at room temperature for 17 h. The reaction mixture was diluted with 1:1 ethyl acetate–hexane (5 ml) and then quenched by saturated aq $NaHCO_3$ solution (5 ml). The organic layer was washed with water and dried. After removal of the solvent, the residue was purified TLC (ethyl acetate) to give **17** (79 mg, 98% yield) as a slightly yellow oil. IR (CCl_4) 1746 cm^{-1} (C=O); NMR δ 0.97 (s, 9, $C(CH_3)_3$), 1.02 (s, 9, $C(CH_3)_3$), 1.93 (d, 1, J=9.0 Hz, $CHC\underline{H}C(CH_3)_3$), 2.48 (s, 6, $N(CH_3)_2$), 3.18 (s, 1, OCHCO), and 4.59 (d, 1, J=9.0 Hz, OCHN); MS *m/e* 241 (M^+). Found: *m/e* 241.2017. Calcd for $C_{14}H_{27}NO_2$: M, 241.2042.

Quaternization of **17** with CH_3I(excess) in benzene at 50 °C for 14 h afforded colorless plates; mp 152—156 °C (from 1: 1 acetone–hexane).

*2,4-Diisopropyl-5-(3-methylaminopropyl)-3(2H)-furanone (**19**).* Dry *N*-methylpyrrolidone (25 ml) and the dibromide **6** (0.90 g, 3.00 mmol) were added sequentially to $Fe_2(CO)_9$ (1.30 g, 3.60

mmol), and the resulting mixture was stirred at room temperature for 48 h, during which period a characteristic dark red color developed. The reaction mixture was quenched by saturated NaCl solution and extracted with ethyl acetate. The organic layer was washed with brine and dried. Evaporation of the solvent at room temperature *in vacuo* left a deepred oil (644 mg). This residue was distilled under reduced pressure to give a yellow oil; bp 140 °C (0.05 Torr). Purification by TLC (1 : 1 ether–hexane) afforded the amino furanone **19** (187 mg, 26% yield) as a pale yellow oil. IR (CCl_4) 1690 (C=O) and 1620 cm^{-1} (C=C); UV 274 nm (log ε 4.04); NMR δ 0.83 (d, 3, J= 6.5 Hz, $CHCH(C\underline{H}_3)_2$), 1.09 (d, 3, J=6.5 Hz, $CHCH(C\underline{H}_3)_2$), 1.17 (d, 3, J=7.0 Hz, $=CCH(C\underline{H}_3)_2$), 1.20 (d, 3, J=7.0 Hz, $=CCH(C\underline{H}_3)_2$), 1.4—2.5 (m, 9, 2 $C\underline{H}(CH_3)_2$, 3 CH_2, and NH), 2.39 (s, 3, NCH_3), and 3.97 (d, 1, J=3.5 Hz, OCH); MS *m/e* 239 (M^+). Found: *m/e* 239.1877. Calcd for $C_{14}H_{25}NO_2$: M, 239.1885.

*Reduction of the Dibromo Ketone **6** with $Fe_2(CO)_9$ in a Mixture of Furan and DMF.* A mixture of the dibromide **6** (300 mg, 1.00 mmol) and $Fe_2(CO)_9$ (437 mg, 1.20 mmol) in freshly distilled furan (2.00 ml, 1.87 g, 27.5 mmol) and DMF (2.13 ml, 2.01 g, 27.5 mmol) was stirred at room temperature for 22 h. The reaction mixture was poured into aq $NaHCO_3$ solution and extracted with 1 : 1 ethyl acetate–hexane (10 ml×4). The organic layer was washed with water (10 ml) and dried. Concentration *in vacuo* gave a yellow oil (213 mg), the NMR spectrum of which indicated the formation of **21** (49% yield) and 2,4-diisopropyl-8-oxabicyclo[3.2.1]oct-6-en-3-one (**22**) (only the *cis* isomer, 20% yield), and the recovery of the starting dibromide **6** (25%). Yields of **21** and **22** based on **6** consumed were 65 and 27%, respectively.

Reaction of 1,3-Dibromo-2-propanone with $Fe_2(CO)_9$ in DMF. 1,3-Dibromo-2-propanone (216 mg, 1.00 mmol) was added to $Fe_2(CO)_9$ (437 mg, 1.20 mmol) in DMF (3.5 ml), and the resulting mixture was stirred at room temperature for 12 h. The complex mixture was obtained after usual work-up, but no coupling product with an appropriate GLPC retention time was detected (column A, 70 °C).

*Reaction of the Dibromide **5** with $Fe(CO)_5$ in* N,N-*Dimethylacetamide. A. Under Thermal Conditions*: To a mixture of $Fe(CO)_5$ (470 mg, 2.40 mmol) and Na_2H_2edta (1.01 g, 3.00 mmol) in *N,N*-dimethylacetamide (3.5 ml) was added the dibromo ketone **5** (230 mg, 0.85 mmol). The mixture was then magnetically stirred at room temperature for 45 h. After quenching by saturated KNO_3 solution (10 ml), the reaction mixture was extracted with ethyl acetate (6 ml×5). The combined organic layers were washed with water (6 ml×2 and 4 ml×5) and dried. Removal of the solvent gave a pale yellow oil (181 mg). The NMR spectrum indicated the recovery of most of the starting dibromide and the absence of any cyclocoupling reaction.

B. Under Photo-irradiation Conditions: A mixture of the dibromide **5** (230 mg, 0.85 mmol), $Fe(CO)_5$ (470 mg, 2.40 mmol), and Na_2H_2edta (1.01 g, 3.00 mmol) in *N,N*-dimethylacetamide (3.5 ml) was stirred at room temperature with irradiation by >350 nm-light with a 200 W high-pressure Hg arc through 5% aq $CuSO_4$ solution. After 24 h the reaction mixture was quenched by the addition of saturated KNO_3 solution (15 ml) and extracted with ethyl acetate (6 ml×5). The collected organic extracts were washed with water (6 ml×4), dried, and concentrated, producing a viscous red oil (125 mg). The residue was dissolved in benzene (2 ml) and passed through a short alumina column. Evaporation of the filtrate gave a pale yellow oil (65 mg). NMR analysis of the oil indicated that the furanone **12** was formed in 41% yield.

*Reaction of the Dibromide **6** and DMF in the Absence of Reducing Agent.* A solution of the dibromide **6** (30.0 mg, 0.10 mmol) and hexadecane (10.0 mg, 0.05 mmol, an internal standard for GLPC analysis) in DMF (0.5 ml) was allowed to stand at room temperature for 12 h. GLPC (column D, 150 °C) of the mixture showed that **6** (t_r 6.8 min) remained unchanged.

*Treatment of 2-(Dimethylamino)-4-isopropylidene-5,5-dimethyl-1,3-dioxolane (**29**) with $FeBr_2$ in DMF.* A solution of $FeBr_2$ in DMF was prepared according to the following known method.[30] Into a solution of $Fe(CO)_5$ (20.0 mg, 0.01 mmol) in DMF (0.5 ml) was added bromine (16.0 mg, 0.01 mmol) with stirring. The color of bromine immedately disappeared, and vigorous gas evolution was observed. To the resulting deep red mixture was added a solution of the dioxolane **29** (26.8 mg, 0.15 mmol) in DMF (0.5 ml), and the mixture was stirred at room temperature for 24 h. The reaction aliquot was passed through a short column packed with alumina–Celite 545 under nitrogen and immediately subjected to NMR analysis, which showed the formation of the amino tetrahydro-3-furanone **2** in 24% yield.

*3-Acetoxy-2,4-dimethylfuran (**31**).* A mixture of the furanone **8** (1.60 g, 14.3 mmol), acetyl chloride (11.3 g, 143 mmol), and DME (20 ml) was heated at 55 °C for 14 h. The reaction mixture was added to ethyl acetate (10 ml), washed with saturated $NaHCO_3$ solution (10 ml×2) and KNO_3 solution (5 ml), and dried. Evaporation of the solvent gave a pale yellow oil (2.0 g), which was distilled with a bulb-to-bulb apparatus (bath temperature 70—110 °C, 20 Torr) to afford the acetate **31** (154 mg, >97% pure, 68% yield). IR (CCl_4) 1760 cm^{-1} (C=O); NMR δ 1.82 (d, 3, J=1.3 Hz, $CH{=}CCH_3$), 2.12 (s, 3, $C{=}CCH_3$), 2.21 (s, 3, $COCH_3$), and 6.92 (q, 1, J=1.3 Hz, =CH); MS *m/e* 154 (M^+). The acetate thus obtained was highly volatile and hydrolyzable (especially in the presence of acids); hence, the structure was assigned on the basis only of the spectral characteristics. Its immediate use, without purification, was required for obtaining a high yield in the next step.

*3-Acetoxy-5-(dimethylaminomethyl)-2,4-dimethylfuran (**32**).* To cooled (0—5 °C) acetic acid (0.19 ml) were added 40% aq dimethylamine (0.13 ml; 47.3 mg, 1.05 mmol as dimethylamine), 37% aq formaldehyde (0.08 ml; 32.3 mg, 1.08 mmol as formaldehyde), and the acetate **31** (120 mg, 0.78 mmol). The heterogeneous mixture was allowed to stand at room temperature for 5 min and then heated at 70 °C for 40 min with stirring. The resulting homogeneous solution was diluted with ethyl acetate (5 ml) and washed with saturated $NaHCO_3$/KNO_3 solution (5 ml). After drying, the organic layer was concentrated to leave a pale yellow oil (150 mg) consisting mainly of the amino furan **32**. This product was homogeneous on TLC (ethyl acetate, R_f 0.61), but the NMR analysis showed it to be only 85—90% pure. Yield of the amine was estimated as *ca.* 80%. Bulb-to-bulb distillation of this crude oil (bath temperature 100 °C, 0.2 Torr) gave analytically pure amine (115 mg, 70% yield) as a pale yellow oil. IR (CCl_4) 2840, 2795, and 2745 ($N(CH_3)_2$), and 1760 cm^{-1} (C=O); NMR δ 1.85 (s, 3, $=CCH_3$), 2.15 (s, 3, $=CCH_3$), 2.28 (s, 9, $COCH_3$ and $N(CH_3)_2$), and 3.42 (s, 2, CH_2); MS *m/e* 211 (M^+), 167 ($M^+-N(CH_3)_2$), and 125. Its picrate melted at 170—171 °C. Found: C, 46.23; H, 4.44; N, 12.63%. Calcd for $C_{17}H_{20}N_4O_{10}$: C, 46.36; H, 4.58; N, 12.72%. This amino furan is sensitive to air, turning brown, and so its immediate use is recommended.

*5-(Dimethylaminomethyl)-2,4-dimethyl-3(2H)-furanone (**33**).* A mixture of the amino furan **32** (70 mg, 0.33 mmol), 70% $HClO_4$ (0.5 ml), and DME (1.25 ml) was heated at 50 °C for 30 min. The mixture was then diluted with ethyl acetate (5 ml) and chilled at 0 °C by an ice bath. To the cooled mixture was added saturated $NaHCO_3$ solution until the separated aq layer changed to basic (pH *ca.* 8). The aq layer was extracted with ethyl acetate (5 ml×4). The combined organic extracts were washed with cold saturated KNO_3 solution (5 ml), dried,

and concentrated, affording a colorless oil (66 mg) which contained the amino furanone **33** as a major component [R_f 0.61 (ethyl acetate), >80% pure based on NMR]. Yield of **33** was >95%. IR (CCl_4) 2840, 2795, and 2745 ($N(CH_3)_2$), 1698 (C=O), and 1623 cm^{-1} (C=C); UV 274 nm (log ε 4.01); NMR δ 1.37 (d, 3, J=7.0 Hz, $CHC\underline{H}_3$), 1.66 (s, 3, $=CCH_3$), 2.25 (s, 6, $N(CH_3)_2$), 3.25 (s, 2, CH_2), and 4.24 (q, 1, J=7.0 Hz, OCH); MS *m/e* 169 (M^+). Found: *m/e* 169.1080. Calcd for $C_9H_{15}NO_2$: M, 169.1103.

*5-(Dimethylaminomethyl)-3-hydroxy-2,4-dimethyltetrahydrofuran (4-Methylnormuscarine) (**34**).* Into a 30-ml, two-necked flask equipped with a rubber septum and a Dry Ice condenser connected at its top with a bubbler was charged liquid NH_3 (*ca.* 15 ml). To this, ethanol (4.0 ml) and a solution of **33** (66 mg, 0.39 mmol) in DME (1.0 ml) were added through the septum by means of a syringe. After a few minutes, the septum was removed and small-cut Li (540 mg, 90.0 mg-atom) was added quickly. The resulting bronze-colored mixture was magnetically stirred for 1.5 h, quenched by the addition of solid NH_4Cl (2 g) with cooling by a Dry Ice–methanol bath, and warmed up to room temperature. To the voluminous gel was added ice water (20 ml), and the aq mixture was extracted with ethyl acetate (10 ml×4). The combined organic extracts were dried and concentrated to yield an oil (70 mg). The oil was dissolved in benzene, passed through an Na_2SO_4 column, and concentrated, giving a viscous oil. To a solution of the residue in THF (3.0 ml) was added $LiAlH_4$ (100 mg, 2.63 mmol) at −50 °C, after which the mixture was stirred at the same temperature for 1.5 h. The mixture was quenched with ethyl acetate at −78 °C, warmed up, and treated water. The aq layer was extracted with ethyl acetate (20 ml×2 and 10 ml×2), and the organic extracts were collected. Removal of the solvent produced viscous, oily material (60 mg), which was then subjected to preparative TLC (ethyl acetate) to afford the alcohol **34** (R_f 0.3—0.4, 41 mg, 61% yield). IR (CCl_4) 3400—3200 cm^{-1} (OH); NMR δ 1.18 (d, 3, J=7.0 Hz, $CHC\underline{H}_3$), 1.25 (d, 3, J=6.0 Hz, $CHC\underline{H}_3$), 2.45 (s, 6, $N(CH_3)_2$), 1.8—3.0 (complex, 4, $C\underline{H}CH_3$, CH_2, and OH), and 3.3—4.0 (m, 3, 2 OCH and $C\underline{H}OH$); MS *m/e* 173 (M^+) and 155 (M^+-H_2O). The structure of **34** was further confirmed through its quantitative transformation to 5-(dimethylaminomethyl)-3-(3,5-dinitrobenzoyloxy)-2,4-dimethyltetrahydrofuran (**35**).

A solution of **34** (15.0 mg, 0.09 mmol) in 1: 5 DME–benzene (0.8 ml) was mixed with 3,5-dinitrobenzoyl chloride (38 mg, 0.15 mmol) and pyridine (0.03 ml) and then left at room temperature for 20 h. The reaction mixture was diluted with ethyl acetate (4 ml) and washed with water (2 ml×2), saturated $NaHCO_3$ solution (2 ml×2), and KNO_3 solutiom (1 ml). The organic layer was dried and concentrated, affording an oil. TLC separation (1: 5 ether–hexane) of this crude product yielded the 3,5-dinitrobenzoate **35** (R_f 0.4, 31 mg, 97% yield). The NMR spectrum showed two kinds of singlets due to $N(CH_3)_2$ protons at δ 2.25 and 2.49 (*ca.* 9: 1 ratio), suggesting that **35** was a mixture of two difficult-to-separate diastereomers. NMR (major isomer) δ 1.25 (d, 6, J=6.5 Hz, 2 $CHC\underline{H}_3$), 2.0—2.4 (m, 1, $CHC\underline{H}CH_2$), 2.25 (s, 6, $(NCH_3)_2$, 2.4—2.6 (m, 2, CH_2), 3.50 (q-like m, 1, OCH), 3.97 (m, 1, OCH), 5.03 (m, 1, $C\underline{H}OCOC_6H_3(NO_2)_2$), and 8.8—9.0 (m, 3, $C_6H_3(NO_2)_2$). The signals of minor isomer could not be observed for certain. Other spectral data of the diastereomeric mixture were: IR (CCl_4) 1730 cm^{-1} (C=O); MS *m/e* 367 (M^+), 195, and 172 ($M^+-COC_6H_3(NO_2)_2$). Found: *m/e* 367.1392. Calcd for $C_{16}H_{21}N_3O_7$: M, 367.1379.

*4-Methylmuscarine Iodide (**36**).* A solution of the alcohol **34** (12 mg, 0.07 mmol) in benzene (0.5 ml) was mixed with methyl iodide (0.01 ml, 22.8 mg, 0.19 mmol) at room temperature. After 1 min, a yellow oil was separated. The heterogeneous mixture was left at room temperature for 5 min and then at 50 °C for 5 min. Most of the organic solvents were evaporated by bubbling in nitrogen gas. The heterogeneous residue, contaminated with a small amount of benzene, was mixed with methanol, and the solvents were removed azeotropically, affording viscous, oily material **36** (20 mg, 100% yield) as a mixture of difficult-to-separate diastereomers. NMR (CD_3OD) [major isomer (*ca.* 90%)] δ 1.07 (d, 3, J= 6.5 Hz, $CHC\underline{H}_3$), 1.11 (d, 3, J=6.5 Hz, $CHC\underline{H}_3$), 1.6—2.4 (m, 1, $C\underline{H}CHCH_2$), 3.21 (s, 9, $\overset{+}{N}(CH_3)_3$), and 3.25—4.25 (m, 5, 2 OCH, $C\underline{H}OH$, and CH_2). The ammonium salt **36** increased the tone and mobility of the smooth muscle of the intestinal tract.

We are grateful to the Ministry of Education, Japanese Government (Grant-in-Aid for Scientific Research, Nos. 743005 and 147022, and Grant-in-Aid for Developmental Scientific Research, No. 984014) for partial financial support. We also wish to thank Mr. Osamu Asano of the Sanwa Kagaku Kenkyusho Co. for testing the physiological effects of 4-methylmuscarine iodide.

Studies of Peptide Antibiotics. XXXV.[1] Synthesis of Gramicidin S by a Fragment Solid-Phase Method

Kazuki SATO, Hayao ABE,* Tetsuo KATO, and Nobuo IZUMIYA

Laboratory of Biochemistry, Faculty of Science 33, Kyushu University, Higashi-ku, Fukuoka 812

(Received March 18, 1977)

In order to examine the usefulness of a fragment condensation procedure in solid-phase peptide synthesis, gramicidin S (GS) was synthesized by three different procedures such as stepwise elongation, fragment condensation with dipeptide fragments, and fragment condensation with tripeptide fragments. The two fragment condensation procedures gave intermediate peptide derivatives in high yields and in high purity. Such differences in the purity of the intermediate peptides disappeared in the final product, GS dihydrochloride. The GS synthesized by the three procedures exhibited the same antibacterial activities as those of natural GS.

A large number of peptides have been synthesized by a solid-phase method.[2] This technique has obvious merits to simplify and accelerate peptide synthesis.[3] However, a crucial defect in this method is unavoidable accumulation of contaminating by-products, and this makes purification of desired products very difficult.[4] Application of a fragment condensation procedure to the solid-phase synthesis is undoubtedly an attractive approach for the improvement in this solid-phase synthesis.[5] Although several biologically active peptides have been prepared by the solid-phase fragment condensation procedure,[6] various aspects of this procedure remain insufficiently explored. Furthermore, there is scarcely any experiment on the comparison between the stepwise elongation procedure and the fragment condensation procedure in the solid-phase synthesis of a biologically active peptide as a target compound.

This paper deals with the solid-phase synthesis of gramicidin S (GS) by various procedures and compares the properties of the synthesized peptides. The solid-phase synthesis of the open-chain linear decapeptide corresponding to the sequence of GS was carried out with three procedures as follows: procedure **a**, stepwise elongation using Boc-amino acids;[7] procedure **b**, fragment condensation with Boc-dipeptide fragments except for Boc-D-phenylalanine at N-terminus; and procedure **c**, fragment condensation with Boc-tripeptide fragments. The syntheses of the peptide fragments are outlined in Fig. 1.

The peptide fragments were prepared by the active ester method with HONSu[8] in order to prevent racemization and to simplify synthetic procedures. Each coupling reaction proceeded quickly in a good yield, unreacted active ester being removed as a water-soluble amide by the addition of 1-(2-aminoethyl)piperazine.[9] Each peptide fragment obtained was carefully recrys-

* Present address: Institute of Biological Science, Mitsui-Toatsu Chemicals, Inc., Mobara 297.

tallized to remove the possible contamination of Boc-amino acid derived from the hydrolysis of the active ester during the coupling reaction in an aqueous solution. The δ-amino group of ornithine was protected by NO_2Z group.[10] Since this group showed extremely intense absorption at 268 nm, the purity of the synthetic intermediate peptides was ascertained spectrophotometrically by measuring the absorption of the group.[11]

TABLE 1. SCHEDULE FOR SOLID-PHASE SYNTHESIS[a]

Step	Reagent	Volume (ml)	Times of repetition	Time (min)
1	AcOH wash	20	3	5
2	1 M HCl in AcOH	20	1	30
3	AcOH wash	20	3	5
4	EtOH wash	20	3	5
5	DMF wash	13	3	5
6	10% TEA in DMF	13	1	10
7	DMF wash	13	3	5
8	CH_2Cl_2 wash	12	3	5
9	Boc-amino acid in CH_2Cl_2	7	1	10
10	DCC in CH_2Cl_2	5	1	240[b]
11	CH_2Cl_2 wash	12	3	5
12	EtOH wash	20	3	5

a) Schedule in procedure **a** is described. b) 480 min for Val and Pro.

The solid-phase synthesis of GS is outlined in Fig. 2. The schedule for each coupling reaction is shown in Table 1. As a coupling reagent, DCC (four equivalents) was used in procedure **a**, and DCC and HOBt[12] (four equivalents, each) were used in procedures **b** and in **c**. The progress of each coupling reaction was followed by chloride titration[13] and by the Kaiser test.[14] The results of the chloride titration were shown in Fig. 3. An aliquot of the peptidyl resin was withdrawn, hydrolyzed, and subjected to amino acid analysis after fourth, fifth, and ninth coupling steps in

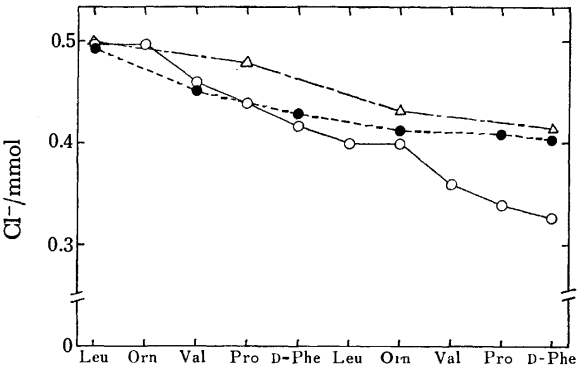

Fig. 3. Titration pattern of chloride ion in the course of synthesis of protected decapeptidyl-resin (**14**) by precedure **a** (○——○), by procedure **b** (●——●), and by procedure **c** (△·····△). Final value was determined by a portion of the peptidyl-resin.

procedure **a** and after each coupling step in procedure **b** and **c**. The yield of each coupling reaction was calculated on the basis of the results of amino acid analysis as shown in Fig. 4.

NO_2Z NO_2Z
Boc-D-Phe-Pro-Val-Orn-Leu-D-Phe-Pro-Val-Orn-Leu-resin

Procedure a	98	97	87	100	96	94	96	95	100
Procedure b	98	97		100		92		95	
Procedure c	95			94			96		

Fig. 4. Coupling yield in each coupling step.

In procedure **a**, the coupling reaction of Boc-valine gave the unsatisfactory yield of 87%. In procedure **b**, the coupling of Boc-D-Phe-Pro-OH (**4**) with the tripeptidyl resin resulted in the low yield of 92%. The low yield in this step may be due to steric hindrance caused by the bulky side chain of the valine residue in the tripeptidly resin. The coupling reactions of the other three peptide fragments (**3**, **5**, **6**) and of the final Boc-D-phenylalanine gave good yields. In procedure **c**, all the coupling reactions gave excellent yields. Repetition of the coupling reaction was avoided in order to compare the reactivity of each reactant under the same reaction conditions. As shown in Fig. 4, the yield of each coupling reaction in procedure **a** was good except for valine; however, the nine consecutive coupling reactions caused lowering of the over-all coupling yield. The over-all yields calculated from the results of the amino acid analyses were 68, 83, and 86% in procedure **a**, **b**, and **c**, respectively.

After completion of the final coupling cycle, peptidyl resin (**14**) was dried under a reduced pressure and weighed. The yield estimated from the weight increase in procedure **a** agreed with those estimated from amino acid analysis and chloride titration. In procedures **b** and **c**, however, the yields estimated from the weight increases were lower than those estimated from the other methods. A possible reasoning of this disagreement

TABLE 2. AMINO ACID RATIOS OF SYNTHETIC INTERMEDIATES AND SYNTHETIC GRAMICIDIN S

Compound	Procedure **a**					Procedure **b**					Procedure **c**				
	D-Phe	Pro	Val	Orn	Leu	D-Phe	Pro	Val	Orn	Leu	D-Phe	Pro	Val	Orn	Leu
14	0.85	0.88	0.92	1.00	1.00	0.91	0.92	0.93	0.95	1.00	0.92	0.94	0.95	0.98	1.00
15	0.86	0.85	0.97	1.14	1.00	0.96	1.00	0.97	1.01	1.00	0.96	1.02	0.95	0.98	1.00
16	0.93	1.01	1.07	1.16	1.00	1.03	1.00	1.01	1.00	1.00	0.97	1.00	0.98	1.00	1.00
18	0.97	1.01	0.95	0.99	1.00	1.01	1.01	1.02	1.01	1.00	1.01	1.00	0.99	1.02	1.00
19	0.90	0.90	0.98	0.95	1.00	1.02	0.98	0.97	1.04	1.00	0.96	0.99	1.00	1.00	1.00

is that frequent withdrawals of the peptidyl resin in the latter procedures caused much more loss of the resin than expected.

Hydrazinolysis of **14** was carried out as described previously,[11] and yielded a crude protected decapeptide hydrazide (**15**), this hydrazide being purified with recrystallization. The properties of **15** and purified hydrazide (**16**) were compared. Crude hydrazides **15a**, **15b**, and **15c** showed similar physical constants and chromatographic behavior. However, after recrystallization, purified hydrazides **16b** and **16c** showed some improvements in physical constants such as melting points and optical rotations and also in the results in amino acid analyses as shown in Table 2. The properties of **16a** were not changed significantly. Partially protected decapeptide hydrazide (**17**) was obtained quantitatively by the deprotection of Boc-group in **16** with hydrogen chloride in formic acid.[15] Thin-layer chromatography and paper electrophoresis of each of **17a—c** showed a main spot and another faint spot. All three hydrazides **17a**, **17b**, and **17c** revealed similar chromatographic behavior and similar results in measurements of the melting points and UV absorptions.

Cyclization of **17** by an azide method gave a protected cyclic decapeptide (**18**). Properties of **18a**, **18b**, and **18c** were compared, an acylated derivative (**18n**) of natural GS being used as a reference compound. There was no distinct differences in the patterns in thin-layer and Sephadex LH-20 column chromatography. However, products **18b** and **18c** showed better results in amino acid analyses and the optical rotations.

Hydrogenation of **18** gave synthetic GS·2HCl (**19**) as fine needles similar to the crystals of natural GS·2HCl. The synthetic and natural GS·2HCl showed the same results in thin-layer, paper, and carboxymethylcellulose column chromatography, paper electrophoresis, and measurements of the optical rotations and the melting points. The antibacterial activities of **19** also were the same as those of natural GS·2HCl.

The purities of the compounds obtained from the three different procedures turned to nearly the same in the final stage of the synthesis. A small amount of impurities seemed to be removed in the course of repeated chemical reactions and recrystallizations. Minute differences in purity, observed in **15** and **16**, were disappeared in **19**. Thus, the results of this solid-phase synthesis of GS indicated that the fragment condensation procedure had advantage of the ease of purification, the advantage being shown in the purification of **15**. In the usual fragment condensation, peptide fragments which placed glycine or proline at C-terminus have been employed to avoid racemization.[16] The results in this synthesis revealed that the use of DCC–HOBt as coupling reagents gave satisfactory results in coupling yield and in prevention of racemization, when applied to the solid-phase fragment condensation.

Experimental

All the melting points are uncorrected. The ratio in parentheses after a solvent system was indicated by vol. TLC was carried out on silica gel G (Merck) with the following solvent systems: R_f^1, $CHCl_3$–MeOH (5:1); R_f^2, 1-BuOH–AcOH–pyridine–H_2O (4:1:1:2). Paper chromatography was carried out on Toyo Roshi No. 52 paper; R_f^3, the same solvent as R_f^2 for TLC. PEP was carried out on the same paper under conditions of 500 V/30 cm with the solvent system; HCOOH–AcOH–MeOH–H_2O (1:3:6:10) at pH 1.8, the mobilities of samples being reported as the ratio to that of lysine (R_{Lys}). UV spectra were determined on a Hitachi-Perkin-Elmer spectrophotometer, Model 139. Optical rotations were measured on a Yanagimoto polarimeter, OR-20. Amino acid analyses were performed on a Hitachi amino acid analyzer, KLA-3B, after hydrolysis in a mixture of 6 M HCl and propionic acid (1:1) at 110 °C for 24 h.[17] Molecular weight was determined with a Hitachi Osmometer, Model 115, DMF being used as a solvent.

*Boc–Orn(NO_2Z)–OH·DCHA (**1**·DCHA).* To a solution of δ-NO_2Z-ornithine[11] (12.4 g, 40 mmol) and TEA (16.8 ml, 120 mmol) in water (40 ml) was added Boc-N_3 (8.22 g, 60 mmol) in dioxane (50 ml). The reaction mixture was treated according to the procedure of Sakakibara *et al.*,[18] and the product was recrystallized from MeOH–ether–petroleum ether; yield, 20.24 g (85%); mp 89—90 °C; $[\alpha]_D^{20}+13.6°$ (*c* 1, MeOH); UV_{max} (EtOH) 268 nm (ε 1.01×10^4).

Found: C, 60.76; H, 8.53; N, 9.16%. Calcd for $C_{30}H_{48}O_8N_4$: C, 60.79; H, 8.16; N, 9.45%.

*Boc–Orn(NO_2Z)–ONSu (**2**).* Compound **1** (8.23 g, 20 mmol) which was derived from **1·DCHA** by the usual procedure was converted to the corresponding HONSu ester according to the procedure of Anderson *et al.*[19] The product was recrystallized from EtOAc–ether; yield, 5.56 g (55%); mp 87—88 °C; $[\alpha]_D^{20}-4.4°$ (*c* 1, $CHCl_3$).

Found: C, 51.80; H, 5.78; N, 10.87%. Calcd for $C_{22}H_{28}O_{10}N_4$: C, 51.96; H, 5.55; N, 11.02%.

*Boc–Val–Orn(NO_2Z)–OH (**3**).* To a solution of δ-NO_2Z-ornithine (3.74 g, 12 mmol) and TEA (1.68 ml, 12 mmol) in water (25 ml) was added a solution of Boc–Val–ONSu (3.50 g, 10 mmol) in dioxane (25 ml) at room temperature. The reaction mixture was stirred overnight, and a few drops of 1-(2-aminoethyl)piperazine was added to the solution. After being stirred for 30 min, dioxane was evaporated *in vacuo* and the solution was acidified with 10% citric acid under cooling. Separated oil was extracted with EtOAc, and the organic layer was washed with water and dried (Na_2SO_4). The solution was evaporated to leave an oil, which was crystallized by the addition of ether. The product was recrystallized from

MeOH–ether; yield, 4.89 g (96%); mp 86—88°C; $[\alpha]_D^{20}$ −9.3° (*c* 1, MeOH); R_f^1 0.52.

Found: C, 54.55; H, 6.92; N, 10.72%. Calcd for $C_{23}H_{34}O_9N_4$: C, 54.11; H, 6.71; N, 10.98%.

Other protected peptide fragments (**4**—**6**, **8**, **9**, **11**, **13**), were prepared by a manner similar to that described for **3**.

Boc-D-Phe-Pro-OH (**4**). Yield, 81%; mp 171—173 °C; $[\alpha]_D^{20}$ −46.9° (*c* 1, MeOH); R_f^1 0.54.

Found: C, 62.90; H, 7.30; N, 7.75%. Calcd for $C_{19}H_{26}O_5N_2$: C, 62.96; H, 7.23; N, 7.73%.

Boc-Orn(NO$_2$Z)-Leu-OH (**5**). Yield, 82%; mp 73—75 °C; $[\alpha]_D^{20}$ −10.2° (*c* 1, MeOH); R_f^1 0.66.

Found: C, 55.10; H, 7.12; N, 10.42%. Calcd for $C_{24}H_{36}O_9N_4$: C, 54.95; H, 7.12; N, 10.42%.

Boc-Pro-Val-OH·DCHA (**6·DCHA**). Yield, 63%; mp 126—127 °C; $[\alpha]_D^{20}$ −40.4° (*c* 1, MeOH); R_f^1 0.61.

Found: C, 65.39; H, 10.08; N, 8.35%. Calcd for $C_{27}H_{49}O_5N_3$: C, 65.43; H, 9.98; N, 8.84%.

Boc-Pro-Val-Orn(NO$_2$Z)-OH (**8**). Yield, 69%; mp 159—161 °C; $[\alpha]_D^{20}$ −48.2° (*c* 1, MeOH); R_f^1 0.51.

Found: C, 54.96; H, 6.72; N, 11.58%. Calcd for $C_{28}H_{41}O_{10}N_5$: C, 55.34; H, 6.80; N, 11.53%.

Boc-Leu-D-Phe-OH·DCHA (**9·DCHA**). Yield, 82%; mp 115—116 °C; $[\alpha]_D^{20}$ −46.3° (*c* 1, MeOH); R_f^1 0.67.

Found: C, 68.73; H, 9.73; N, 7.46%. Calcd for $C_{32}H_{53}O_5N_3$: C, 68.66; H, 9.54; N, 7.51%.

Boc-Orn(NO$_2$Z)-Leu-D-Phe-OH (**11**). Yield, 80%; mp 90—91 °C; $[\alpha]_D^{20}$ −24.1° (*c* 1, MeOH); R_f^1 0.58.

Found: C, 58.91; H, 6.88; N, 10.23%. Calcd for $C_{33}H_{45}O_{10}N_5$: C, 59.00; H, 6.75; N, 10.43%.

Boc-D-Phe-Pro-Val-OH (**13**). Yield, 54%; mp 172—173 °C; $[\alpha]_D^{20}$ −78.8° (*c* 1, MeOH); R_f^1 0.61.

Found: C, 62.37; H, 7.69; N, 9.14%. Calcd for $C_{24}H_{35}O_6N_3$: C, 62.45; H, 7.64; N, 9.11%.

H-Val-Orn(NO$_2$Z)-OH·HCl (**7·HCl**). Compound **3** (2.55 g, 5 mmol) was dissolved in 2.6 M hydrogen chloride in dioxane (39 ml). The solution was allowed to stand for 1 h at room temperature and then evaporated. Resulting oil was solidified by the addition of ether. The product was recrystallized from EtOH–ether; yield, 1.93 g (86%); mp 159—161 °C; $[\alpha]_D^{20}$ +10.3° (*c* 1, 6 M HCl); R_f^2 0.80.

Found: C, 48.98; H, 6.53; N, 11.79%. Calcd for $C_{18}H_{27}O_7N_4Cl$: C, 48.37; H, 6.09; N, 12.54%.

H-Leu-D-Phe-OH·HCl (**10·HCl**). Compound **9** was treated as described for **7**; yield, 83%; mp 200—202 °C; $[\alpha]_D^{20}$ +37.0° (c 1, 6 M HCl); R_f^2 0.78.

H-Pro-Val-OH (**12**). Compound **6** (1.57 g, 5 mmol) was treated as described for **7**. The oily residue (**12·HCl**) was dissolved in water (50 ml) and the solution was neutrallized with TEA (0.7 ml, 5 mmol). The addition of EtOH (50 ml) gave crystals, which were recrystallized from water–EtOH; yield, 0.88 g (82%); mp 242—243 °C (dec); $[\alpha]_D^{20}$ −70.2° (*c* 1, 6 M HCl); R_f^2 0.56.

Found: C, 55.80; H, 8.62; N, 12.98%. Calcd for $C_{10}H_{18}O_3N_2$: C, 56.05: H, 8.47; N, 13.08%.

Boc-(D-Phe-Pro-Val-Orn(NO$_2$Z)-Leu)$_2$-resin (**14a—c**).

14a: Boc-Leu-resin[20] (1.88 g, containing 0.5 mmol of Boc-leucine), which was prepared from chloromethylated copolystyrene divinylbenzene (2%) resin (0.65 mmol of Cl/g), was placed in a reaction vessel and swollen with AcOH (15 ml) overnight; this starting material was prepared similarly for **14b** and **14c**. Elongation of peptide chain was carried out according to the schedule shown in Table 1. The coupling time was generally 4 h and exceptionally 8 h for Boc-valine and for Boc-proline. After completion of the final coupling cycle, the resin was washed with DMF, EtOH, AcOH, and CH_2Cl_2 successively, and dried *in vacuo*. Weight increase, 473 mg (68%).

14b: Instead of Boc-amino acid in procedure **a**, the Boc-dipeptide fragment and HOBt (four equivalents, each) were added. After the addition of DCC (four equivalents), the vessel was shaken for 24 h. Weight increase, 542 mg (78%).

14c: The Boc-tripeptide fragment, HOBt, and DCC (four equivalents, each) were added, and the reaction time was 48 h. Weight increase, 508 mg (73%).

Boc-(D-Phe-Pro-Val-Orn(NO$_2$Z)-Leu)$_2$-N$_2$H$_3$ (**16a—c**).

16a: To a suspension of **14a** (1.19 g, 0.18 mmol) in DMF (13 ml) was added 100% hydrazine hydrate (0.35 ml, 7.2 mmol). The mixture was shaken for 3 days at room temperature, the resin was removed by filtration and washed with DMF (13 ml×3), and the combined filtrate was evaporated *in vacuo*. The residue was treated with water (100 ml) to give yellowish powder; yield of crude hydrazide (**15a**), 273 mg (94%); mp 141—148 °C; $[\alpha]_D^{20}$ −103° (*c* 0.5, MeOH); purity estimated from absorption at 268 nm, 98%; R_f^1 0.76 with a faint tailing strip; R_f^2 0.93. Compound **15a** (200 mg) was dissolved in hot MeOH (20 ml), an insoluble material in a small amount being filtered off. The filtrate was evaporated to 4 ml and white precipitate of purified hydrazide (**16a**) was obtained by the addition of ether; yield, 178 mg (89%); mp 150—151 °C; $[\alpha]_D^{20}$ −119° (*c* 0.5, MeOH); purity at 268 nm, 96%.

Found: C, 58.98; H, 7.12; N, 13.82%. Calcd for $C_{79}H_{110}O_{20}N_{16}\cdot H_2O$: C, 58.50; H, 6.96; N, 13.82%.

16b: Compound **14b** (1.06 g, 0.18 mmol) was treated as described for **15a**; yield of crude hydrazide (**15b**), 286 mg (98%); mp 136—143 °C; $[\alpha]_D^{20}$ −117° (*c* 0.5, MeOH); purity at 268 nm, 96%; R_f^1 0.76 with a faint tailing strip; R_f^2 0.93. Compound **15b** (200 mg) was treated as described for **16a**; yield of **16b**, 188 mg (94%); mp 152 °C; $[\alpha]_D^{20}$ −145° (*c* 0.5, MeOH); purity at 168 nm, 98% (Found: C, 58.06; H, 6.96; N, 13.62%).

16c: Compound **14c** (1.14 g, 0.18 mmol) was treated as described for **15a**; yield of crude hydrazide (**15c**), 285 mg (98%); mp 134—140 °C; $[\alpha]_D^{20}$ −125° (*c* 0.5, MeOH); purity at 268 nm, 95%; R_f^1 0.76 with a faint tailing strip; R_f^2 0.93. Compound **15c** (200 mg) was treated as described for **16a**; yield **16c**, 184 mg (92%); mp 153 °C; $[\alpha]_D^{20}$ −135° (*c* 0.5, MeOH); purity at 268 nm, 97% (Found: C, 58.29; H, 6.96; N, 14.37 %).

H-(D-Phe-Pro-Val-Orn(NO$_2$Z)-Leu)$_2$-N$_2$H$_3$·2HCl (**17a—c**).

17a: A solution of **16a** (164 mg, 0.1 mmol) in 0.1 M hydrogen chloride in formic acid (2.2 ml) was allowed to stand for 8 h at room temperature and then evaporated. The oily residue was solidified by the addition of ether; yield, 160 mg (99%); mp 168—171 °C; R_f^1 0.49 with a faint tailing strip; R_f^2 0.79; R_{Lys} 0.53 with a faint tailing strip; purity at 268 nm, 96%.

17b: This was prepared from **16b** (164 mg, 0.1 mmol) as described for **17a**; yield, 161 mg (100%); mp 175 °C; R_f^1 0.49 with a faint tailing strip; R_f^2 0.79; R_{Lys} 0.53 with a faint tailing strip; purity at 268 nm, 95%.

17c: This was prepared from **16c** (164 mg, 0.1 mmol) as described for **17a**; yield, 157 mg (97%); mp 175 °C; R_f^1 0.49 with a faint tailing strip; R_f^2 0.79; R_{Lys} 0.53 with a faint tailing strip; purity at 268 nm, 94%.

cyclo(-(D-*Phe-Pro-Val-Orn(NO$_2$Z)-Leu)$_2$-*) (**18a—c**).

18a: To a solution of **17a** (144 mg, 0.09 mmol) in a mixture of AcOH (0.45 ml) and DMF (1.8 ml) were added 1 M HCl (0.1 ml) and 1 M $NaNO_2$ (0.1 ml) at −30 °C. After being left for 30 min, the reaction mixture was added into pyridine (37 ml) at 0 °C. After being stirred for 3 days at 5 °C, the

solution was evaporated and the residue was dissolved in a mixture (12 ml) of MeOH and water (10: 1). The solution was applied on columns (1.9×20 cm, each) of Dowex 1 (OH^- form) and Dowex 50 (H^+ form). The columns were washed with the same solvent (200 ml) and the combined effluent was evaporated to leave an oily residue, which was crystallized by the addition of ether. The product was recrystallized from MeOH–ether; yield, 63 mg (46%); mp 218—223 °C; $[\alpha]_D^{20}$ −230° (*c* 0.3, MeOH); purity at 268 nm, 96%; R_f^1 0.71; R_f^2 0.94.

Found: C, 59.67; H, 6.95; N, 12.64%; mol wt, 1509. Calcd for $C_{76}H_{102}O_{18}N_{14}\cdot 2H_2O$: C, 59.38; H, 6.90; N, 12.76%; mol wt, 1500.

18b: This was prepared from **17b** (144 mg, 0.09 mmol) as described for **18a**; yield, 64 mg (47%); mp 225—230 °C;$[\alpha]_D^{20}$ −242° (*c* 0.3, MeOH); purity at 268 nm, 101%; R_f^1 0.71; R_f^2 0.94; mol wt, 1504 (Found: C, 60.16; H, 6.94; N, 12.74 %).

18c: This was prepared from **17c** (144 mg, 0.09 mmol) as described for **18a**; yield, 48 mg (35%); mp 225—230 °C; $[\alpha]_D^{20}$ −243° (*c* 0.3, MeOH); purity at 268 nm, 101%; R_f^1 0.71; R_f^2 0.94; mol wt, 1507 (Found: C, 60.30; H, 6.97; N, 12.71%).

*Preparation of **18n** from Natural GS.* To a solution of natural GS (21 mg, 0.017 mmol) in pyridine (1.7 ml) was added *p*-nitrobenzyloxycarbonyl chloride[10] (0.36 g, 1.7 mmol) at −10 °C. After being stirred for 7 h at 0 °C, the solution was evaporated. The resulting residue afforded a yellowish precipitate (0.25 g) by the addition of water. The precipitate was dissolved in MeOH (5 ml), and the solution was applied on a column of Sephadex LH-20 (1.8×110 cm) and developed with MeOH. The fractions with the desired product were collected and evaporated, the resulting oily residue being crystalized by the addition of ether; yield, 23 mg (75 %); mp 245—247 °C; $[\alpha]_D^{20}$ −248° (*c* 0.3, MeOH); purity at 268 nm, 100%; R_f^1 0.71; R_f^2 0.94 (Found: C, 59.54; H, 6.96; N, 12.61%).

*Sephadex LH-20 Column Chromatography of **15a—c** and **18a—c**.*
15a: A portion (10 mg) of **15a** was applied on a column of Sephadex LH-20 (1.8×110 cm) using MeOH as an eluate. The chromatogram showed a single peak at 145 ml.

15b** and **15c: The chromatograms of **15b** and **15c** in the same conditions also showed the same patterns as that of **15a**.

18a: A portion (5 mg) of **18a** was applied on the same column as described for **15a**. The chromatogram showed the same single peak at 149 ml as that of the reference compound (**18n**).

18b** and **18c: The chromatograms of **18b** and **18c** in the same conditions also showed the same patterns as that of **18n**.

cyclo*(-(D-Phe-Pro-Val-Orn-Leu)$_2$-)·2HCl (**19a—c**).*

19a: Compound **18a** (30 mg, 0.02 mmol) dissolved in 0.01 M hydrogen chloride in MeOH (6 ml) was hydrogenated using palladium black as a catalyst. The filtrate was evaporated and the residual solid was recrystallized from EtOH–1 M HCl; yield, 18 mg (76%); mp 269—275 °C; $[\alpha]_D^{20}$ −260° (*c* 0.4, EtOH); R_f^2 0.83, R_f^3 0.80.

Found: C, 56.53; H, 7.79; N, 12.41%. Calcd for $C_{60}H_{92}O_{10}N_{12}\cdot 2HCl\cdot 4H_2O$: C, 56.01; H, 7.94; N, 13.07%.

19b: This was prepared from **18b** (30 mg, 0.02 mmol) as described for **19a**; yield, 15 mg (60%); mp 274—279 °C;$[\alpha]_D^{20}$ −252° (*c* 0.4, EtOH); R_f^2 0.83; R_f^3 0.80 (Found: C, 55.85; H, 7.63; N, 12.46%).

19c: This was prepared from **18c** (30mg, 0.02 mmol) as described for **19a**; yield, 16 mg (65%); mp 274—279 °C; $[\alpha]_D^{20}$ −253° (*c* 0.4, EtOH); R_f^2 0.83; R_f^3 0.80 (Found: C, 56.12; H, 7.65; N, 12.64%).

*Comparison of Synthetic GS·2HCl (**19a—c**) with Natural GS·2HCl.* Physical constants and R_f values of **19a—c** were shown above. Physical constants and R_f values of natural GS·2HCl; mp, 274—276 °C; $[\alpha]_D^{20}$ −258° (*c* 0.6, EtOH); R_f^2 0.83 R_f^3; 0.80. In addition to showing the same R_f values in paper and thin-layer chromatography, the natural and all three synthetic GS·2HCl revealed indistinguishable paper electrophoretic patterns and identical behavior in the carboxymethylcellulose column chromatography in the conditions described previously.[21]

Microbiological Assays. The minimum amount of the synthetic and natural GS·2HCl necessary for the complete inhibition of growth of several microorganisms was determined by a dilution method using a nutrient agar. All three synthetic GS·2HCl exhibited the same antibacterial activities as those of natural GS·2HCl. The minimum inhibitory concentration of the compounds were 2—4 μg/ml on *Staphylococcus aureus*, 4—7 μg/ml on *Bacillus subtilis*, and 50—100 μg/ml on *Escherichia coli*.

The authors wish to express their thanks to the staff of Institute of Biological Science, Mitsui-Toatsu Chemicals, Inc., Mobara, for the biological assays. They also thank to Meiji Seika Kaisha, Ltd. for the donation of natural GS.

The Isolation and Structure of Toxic Principles, Milliamines A, B, and C, from *Euphorbia Millii*

Daisuke UEMURA and Yoshimasa HIRATA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received November 30, 1976)

Toxic compounds were isolated from *Euphorbia Millii* Ch. des Moulins (*Euphorbiaceae*). The structure of the milliamines was established from chemical and spectral evidence. Furthermore, the acute toxicity of milliamine A was examined.

Although *Euphorbia Millii* Ch. des Moulins (Japanese name, Hanakirin) is widely cultivated for decorative purposes, its toxicity is also known. The toxic compound of this plant is of interest. A detailed survey of methanol extracts gave three alkaloidal toxic compounds, namely, milliamines A (**1**),[1] B (**2**),[1] C (**3**).[2] Particularly milliamine A hydrochloride possesses high toxicity (LD_{50}=0.64 mg/kg).

Isolation of Milliamines. Dried roots were extracted with methanol over a period of a few days. The evaporation of methanol under reduced pressure gave a moist oily material, which was extracted with ether several times. The organic layers were concentrated and the residual oily material was subjected to chromatography on silicic acid. The toxic material responded positively to the Dragendorff test. A fraction (responding positively to the Dragendorff test) afforded milliamine A, which was purified as a hydrochloride. Milliamine A hydrochloride was recrystallized from acetone. Milliamines B and C were purified by preparative thin-layer chromatography. Milliamine B hydrochloride was obtained as a powder. Milliamine C was unstable in acidic media, and was purified by repetitive preparative thin-layer chromatography. The physical and spectral data of these new compounds are summarized in Table 1.

The Structure of Milliamine A. Milliamine A (**1**) possesses the molecular formula, $C_{45}H_{49}N_3O_{10}$. Strong hydrogen bonding was present in **1** judging from the absorption in the region of 2800—3600 cm^{-1} in the IR spectrum. Also, the IR spectrum showed the presence of carbonyl groups (1725, 1690, 1670, and 1645 cm^{-1}) including an ester group, which is cleavable by methanolysis. In practice, treatment of milliamine A (**1**) with sodium methoxide afforded an alkaloidal part, compound **4**, and an alcohol (**5**).

Compounds **4** was purified by recrystallization from methanol and possesses the molecular formula $C_{24}H_{23}N_3O_5$: mp 160—161 °C; IR (KBr) 3400, 3250, 2400—3000, 1690, 1670, 1630, 1590, 1510, and 1300 cm^{-1}; NMR (60 MHz, acetone-d_6) δ 2.73 [6H, s, $-N(CH_3)_2$], 3.77 (3H, s, $-COOCH_3$), 6.8—7.6 (8H, m), 7.7—8.1 (2H, m), 8.60 (1H, d of d, J=1.0 and 10 Hz), 9.26, 11.3, and 12.9 (1H each, br s, exchangeable with D_2O). The IR spectrum of compound **4** indicates the presence of α,β-unsaturated ester group (1690 cm^{-1}), and reduction with lithium aluminum hydride of **4** afforded an alcohol (**6**). Furthermore, the presence of two amide

TABLE 1. PHYSICAL CONSTNATS AND SPECTRAL DATA OF MILLIAMINES

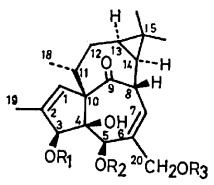
groups was indicated by the IR spectrum (1670, 1630, 1510, and 1300 cm^{-1}). The remaining nitrogen atom was deduced to be present in a dimethylamino group, judging from the signal in the NMR spectrum of compound **4** [δ 2.73 (6H, s)]. Also, the remaining oxygen atom was suggested to be in a hydroxyl group forming strong a hydrogen bond, which was assigned to the signal at δ 12.9 in the NMR spectrum. This data suggests that compound **4** possesses aromatic rings. A high-resolution mass spectrum showed the presence of three fragment ions, $C_9H_{10}NO^{+\cdot}$, $C_7H_5NO_3^{+\cdot}$, and $C_8H_9NO_2^{+\cdot}$. This indicates that these fragments are dimethylanthraniloyl, hydroxyanthraniloyl, and methyl anthranilate groups, respectively. In particular, the dimethylanthraniloyl group was confirmed by the fact that oxidation of **4** with $KMnO_4$ afforded a quinazolone (**7**), which was identified with a naturally-occurring alkaloid (**7**), glycomicine,[3] from spectral data[4] and physical constants. This compound (**7**) was produced by the oxidation of one methyl group in the dimethylanthraniloyl group and the aromatic ring in the hydroxyanthraniloyl group, followed by cyclization. The hydrolysis of **4** with an aqueous NaOH solution afforded a carboxylic acid (**8**), but with 6 M HCl–MeOH gave methyl *N*-(dimethylanthraniloyl)-3-hydroxyanthranilate (**9**) and methyl anthranilate. Compound **9** was deduced to possess a dimethylanthraniloyl group and a hydroxyanthraniloyl from its fragmentation of mass spectrum. The fragment peak resulting from dehydration, in this spectrum, was much stronger than that of the usual phenolic compounds. This observation is explained by the next reaction: **9** was readily dehydrated to a benzoxazole (**10**) in a gas-liquid chromatograph. That the hydroxyanthraniloyl group is 3-hydroxyanthraniloyl, but not 6-hydroxyanthraniloyl (*i.e.* a 3-aminosalicyloyl group), was supported by a comparison of the NMR spectra of compound **9** and a 3-aminosalicyloyl derivative. The structure of compound **9** was confirmed by synthesis. Dimethylanthranilic acid was converted to the imidazolide by the action of *N,N'*-carbonyldiimidazole with no solvent. To a THF solution of this imidazolide was added 3-hydroxyanthranilic acid, and the subsequent addition of CH_2N_2 gave methyl *N*-(dimethylanthraniloyl)-3-hydroxyanthranilate, which exhibits IR, NMR, and mass spectra and a melting point identical with compound **9**.

On the other hand, alcohol **5** was converted to a triacetate (**11**), which was identical with ingenol triacetate. The structure of ingenol triacetate was unambiguously established using X-ray analysis by Hecker *et al.*[5]

Milliamine A is an ingenol derivative esterified by acid **8**, as described above, and by acetic acid, the presence of the latter acid being apparent in the NMR spectrum (see Table 1). Although the esterified position of ingenol remains to be defined, this problem was solved by the following chemical and spectral evidence. Treatment of the hydrochloride of milliamine A with methanol–aqueous $NaHCO_3$ gave ingenol monoacetate (**12**), whose NMR spectrum showed that the signal due to two protons at C-20, which appeared at δ 4.10 in ingenol (**5**), was observed as an AB quartet at δ 4.25 and 4.80 (J=10 Hz), indicating that a primary acetoxyl group is present in milliamine A (**1**). Furthermore, in the 100 MHz NMR spectrum of milliamine A, the singlet observed at δ 5.80 (δ 4.32 in ingenol) was converted into a sharp singlet upon irradiation of the doublet attributed to three protons at C-19 [δ 1.83 (J=1.0 Hz)]. This phenomenon can be understood as long-range coupling through the sp^2 carbon atom. In addition, the fact that this signal, appearing at δ 5.80, can be attributed to the proton at C-3 was clarified by the following chemical evidence. Ingenol (**5**) was converted to a monocarbonate (**13**) by a reaction with *N,N'*-carbonyldiimidazole, which possesses a six-membered carbonate ring (IR 1745 cm^{-1}). The monocarbonate, **13**, gave a dicarbonate (**14**) using the same procedure at elevated temperatures, in which six-membered (1780 cm^{-1}) and five-membered (1830 cm^{-1}) carbonate rings were present. A comparison of the NMR spectra of carbonates **13** and **14** showed that only for the formation of the five-membered carbonate ring can the signal assigned to H-3 (δ 5.3) undergo a downfield shift. Moreover, cleavage of the bond between C-3 and C-4 in the monocarbonate (**13**) by $NaIO_4$ was attempted giving compound **15**: IR ($CHCl_3$) 3400, 1820, and 1725 cm^{-1}; MS *m/e* 372 (M^+); NMR (100 MHz, $CDCl_3$) δ 0.97 (3H, s), 1.08 (3H, s), 1.11 (3H, d, J=6.0 Hz, H-18), 1.90 (3H, br s, H-19), 2.80 (1H, m, H-11), 3.13 (1H, br d, J=10 Hz, H-8), 4.18, 4.50 (2H, AB q, J=13 Hz, H-20), 5.53 (1H, s, H-3), 5.82 (1H, br s, H-1), and 6.40 (1H, d, J=4.5 Hz, H-7). In the NMR spectrum of the urethane (**16**) of this compound **15**, the signal due to the protons at C-20 appears at δ 4.80 as a singlet. It is believed that this compound **15** was formed by aldol condensation of the desired keto-aldehyde intermediate (**17**) and subsequent migration of the carbonate group.

On the basis of these results, it is concluded that the



1 R_1=X, R_2=H, R_3=Ac

structure of milliamine A is **1**.

Examination of the Acute Toxicity of Milliamine A. The acute toxicity of milliamine A was examined using 30 male ICR-SLC strain mice. The mode of administration was intraperitoneal injection. For one week after njection, LD_{50} was determined from the mortality rate of the mice according to Weil's method.[6] The LD_{50} of milliamine A was 0.642 mg/kg. The symptoms observed 2—3 h after the injection were slight ptosis, diarrhea, decreased respiration, decreased body temperature, tremors, *etc.*, and occasionally, dyspnoe and clonic-tonic convulsion. From autopsies of the mice, hemorrhaging and lung and spleen congestion were observed. It is assumed that the cause of death was respiratory arrest derived from injuries to the circulatory system. In a control experiment, 20% ethanol was used as a solvent, but no deaths were observed. These results are summarized in Table 2.

Table 2. Toxicity of milliamine A

Dose injected intraperitoneally (μg/kg)	Mortality	LD_{50} (μg/kg)
270	0/5	
400	1/5	
600	1/5	642
900	5/5	
1350	4/5	
2025	5/5	

The Structure of Milliamine B. In milliamine B (**2**) an acetoxyl group is present. The structure of milliamine B is suggested from the result that methanolysis of milliamine B afforded a compound (**4**) and an ingenol (**5**), which was identified as ingenol triacetate (**7**). The position esterified by the alkaloidal moiety was at C-20, on the basis of the NMR spectrum in which the signals attributed to two protons appeared at δ 4.43 and 4.83 as an AB quartet.

Thus, the structure of milliamine B is represented by **2**.

The Structure of Milliamine C. Milliamine C (**3**) afforded a compound **4** and ingenol (**5**) upon methanolysis with NaOMe in MeOH. The ingenol (**5**) was converted to triacetate **7** for identification with an authentic sample. In the NMR spectrum of **3**, the acetoxyl group observed in the NMR spectrum of milliamine A, was absent and the signal assigned to the proton at C-3 appeared at δ 5.75 as a singlet. Consequently, the structure of milliamine C was determined to be **3**.

Although the relationship between the toxicity and the structure is complex, the following facts are suggested. Ingenol and the triacetate are non-toxic, but ingenol derivative, in which the hydroxyl group at C-3 was esterified with fatty acids[2,7] or an alkaloidal moiety, indicate toxicity. However, according to our results, it appears that at least the acetylation of the hydroxyl group at C-20 has no relation to the toxicity of these derivatives because milliamines A and C are toxic. On the other hand, the presence of a 3-hydroxyanthraniloyl derivative is rare[8] and its carcinogenic properties may influence the cocarcinogenic characteristics of ingenol derivatives reported by Hecker.[7] During this work, experiments concerning the carcinogenic activity of milliamine A were undertaken, but no results were obtained due to interference of the strong toxicity.

Experimental

All melting points are uncorrected. The UV spectra were measured in MeOH on a Perkin-Elmer Model 202 spectrophotometer. The IR spectra were recorded with a Jasco Model IRS spectrometer. The NMR spectra were determined on JNMC-60H, JNM4H-100, and Varian HA-100 spectrometers; Chemical shifts (δ) are given in ppm relative to the internal TMS. The mass spectra were determined on a Hitachi RMU-6C mass spectrometer equipped with a direct inlet system, and the high-resolution mass spectra on a JEOLCO GMS-O1SG mass spectrometer. A Hitachi K-53 gas chromatograph was employed for analytical GLC. A Varian 1820-4 gas chromatograph was used for preparative GLC. For TLC, silica gel GF_{254}, PF_{254} (E. Merck, A. G., Germany) and alumina PF_{254}-Type T (E. Merck, A. G., Germany) were used; the thickness employed were 0.25 mm for analytical purposes, and 1.00 mm for preparative purposes. For column chromatography, silica gel (100 mesh, Mallinckrodt, U.S.A.) was used. The organic solutions were dried over Na_2SO_4 and evaporated in a vacuum evaporator.

Extraction of Milliamines A (1), B (2), and C (3). Roots (7.7 kg) of *Euphorbia Millii* Ch. des Moulins (45 kg) were dried and cut into small pieces. 20 l of methanol was added to the roots. The mixture was left for a few days at room temp and was filtered with suction. This methanol-extraction procedure was repeated twice. The combined methanol extracts were concentrated below 60 °C, to afford a green solution (50 ml) which was diluted with ether (500 ml). The ether layer was separated from a water layer which was extracted with ether three times. The combined ether

solutions were washed with saturated NaCl aq solution, dried, and concentrated, giving an oily mixture (41 g). The resulting material was subjected to chromatography on silicic acid (500 g) with $CHCl_3$. The eluates of $CHCl_3$ afforded some triterpene compounds. After changing the solvent to $CHCl_3$–MeOH (V/V=20/1), the early fraction gave an oily material (7 g) containing milliamine A. To an ethereal solution (100 ml) of this mixture was added 15 ml of ether saturated with HCl gas. Filtration with suction afforded a green powder of hydrochloride (1.2 g), which was dissolved in acetone (5 ml) and the solution was allowed to stand, giving crude crystals (691 mg). Recrystallization from acetone afforded 480 mg of milliamine A hydrochloride. The next eluate gave a mixture of milliamines B and C, which were purified by repeated TLC. Milliamine B (67 mg) was obtained as a hydrochloride following the same procedure as for milliamine A. The unstable properties of milliamine C in acidic conditions did not permit further purification *via* hydrochloride formation. After repeated TLC, 30 mg of milliamine C was obtained. The physical and spectral data are recorded in Table 1. **1**, (Found: C, 64.80; H, 5.99; N, 4.84; Cl, 4.30%. Calcd for $C_{45}H_{50}N_3O_{10}Cl$: C, 64.76; H, 6.10; N, 5.07; Cl, 4.28%). **2**, (Found: C, 64.53; H, 6.04; N, 5.19%. Calcd for $C_{43}H_{48}N_3O_9Cl$: C, 64.50; H, 6.09; N, 5.32%).

*Methanolysis of Milliamine A (**1**).* To a solution of milliamines A hydrochloride (30 mg) in anhydrous MeOH (2 ml) was added a solution (0.5 ml) of NaOMe in MeOH (prepared from 100 mg of Na and 20 ml of anhydrous MeOH) at room temp. The solution was stirred at room temp for 1 h. Neutralization through a column of Amberlite IRC-50 (H-form) (4 ml) was performed. This eluate and a methanol washing solution were combined and concentrated. The resulting yellow oily material was subjected to chromatography on silicic acid. The $CHCl_3$ eluate afforded compound **4** (17 mg), which was recrystallized from MeOH, and the 10% MeOH–$CHCl_3$ eluate gave glassy **5** (15 mg). **4**, Found: *m/e* 433.1638. Calcd for $C_{24}H_{23}N_3O_7$: *m/e* 433.1631. Found: *m/e* 151.0614. Calcd for $C_8H_9NO_2$: *m/e* 151.0633. Found: *m/e* 148.0747. Calcd for $C_9H_{10}NO$: *m/e* 148.0762. Found: *m/e* 135.0304. Calcd for $C_7H_5NO_2$: *m/e* 135.0304. **5**, IR ($CHCl_3$) 3410, 1705, and 1635 cm^{-1}; NMR (60 MHz, $CDCl_3$) 0.6—1.2 (2H, m, H-13 and H-14), 0.94 (3H, d, J=6.0 Hz, H-18), 1.12 (3H, s), 1.52 (3H, s), 1.82 (3H, d, J=1.0 Hz, H-19), 3.77 (1H, br s, H-5), 4.10 (2H, br s, H-20), 4.32 (1H, s, H-3), 4.0—4.4 (1H, m, H-8), 3.0—4.0 (4H, br s, OH), 5.84 (1H, q, J=1.0 Hz, H-1), and 6.02 (1H, br d, J=3.0 Hz, H-7); MS 348 (M^+).

*Alcohol (**6**).* A mixture of **4** (5 mg) and LAH (3 mg) in anhydrous ether (2 ml) was stirred at 0 °C for 1 h, and diluted with 5 ml of water. The mixture was extracted with three 5 ml portions of $CHCl_3$. The combined $CHCl_3$ layers were washed with saturated NaCl aq solution, dried, and concentrated to afford an oily product. The product was purified by preparative TLC. **6**, IR ($CHCl_3$) 3600, 3550, 1655, 1630, 1595, 1515, and 1315 cm^{-1}; NMR (60 MHz, acetone-d_6) 2.72 (6H, s), 4.70 (2H, br s,) 4.70 (1H, s, OH), 7.0—7.5 (10H, m), 8.00 (1H, m), 9.42, 9.80, and 13.2 (1H each, br s, OH); MS 405 (M^+).

*Quinazolone (**7**).* A mixture of **4** (37 mg) and $KMnO_4$ (40 mg) in a 6% aq NaOH solution was stirred at room temp for 15 min. After the addition of water (5 ml), the aq solution was repeatedly extracted with $CHCl_3$. The $CHCl_3$ layer were dried over Na_2SO_4, and concentrated giving an oily material (10 mg). The water layer was neutralized with HCl and extracted with $CHCl_3$ (5 ml). The extracts were dried over Na_2SO_4 and concentrated to give compound **7**. Recrystallization from ether afforded crystalline **7** (3 mg); mp 269—270 °C (lit, 269—270 °C);[3] IR (KBr) 3410, 1708, 1690, 1660, and 1605 cm^{-1}; MS 176 (M^+) (Found: *m/e* 176.0585. Calcd for $C_9H_8N_2O_2$: *m/e* 176.0587).

*Hydrolysis of **4**.* Compound **4** (5 mg) was dissolved in MeOH (2 ml). After the addition of a 5% aq NaOH solution (2 ml) to the solution, the mixture was stirred at room temp for 2 h. After acidification (to *ca.* pH 2) with an aq HCl solution, a cloudy solution was extracted with three 3-ml portions of $CHCl_3$. The $CHCl_3$ layers were combined, dried over Na_2SO_4, and concentrated to give an oily compound **8** (3 mg); IR ($CHCl_3$) 2800—3500, 1690, 1670, 1625, and 1590 cm^{-1}; NMR (60 MHz, $CDCl_3$) 2.90 (6H, s), 7.1—7.6 (8H, m), 8.0—8.3 (3H, m), and 9.5—10.0 (4H, br s, OH) (Found: *m/e* 419.1500. Calcd for $C_{23}H_{21}N_3O_5$: *m/e* 419.1506).

*Methyl N-(Dimethylanthraniloyl)anthranilate (**9**).* A solution of compound **4** in MeOH (2 ml)–6 M HCl (2 ml) was stirred at 60 °C for 18 h. After dilution with 10 ml of water, the mixture was extracted with five 5-ml potions of $CHCl_3$. The extracts were dried over Na_2SO_4 and concentrated to give an oily product (15 mg). Purification by preparative TLC on alumina with benzene yielded **9** (7 mg) and methyl anthranilate (2 mg), **9**, mp 89—90 °C (recrystallized from methanol); IR ($CHCl_3$) 2800—3450, 1705, 1630, 1595, and 1300 cm^{-1}; NMR (60 MHz, acetone-d_6) 2.84 (6H, s), 3.88 (3H, s), 7.0—7.7 (6H, m), 8.10 (1H, m), 9.43, and 13.1 (1H each, br s,); MS 314 (M^+), 296 (Found: *m/e* 314.1266. Calcd for $C_{17}H_{18}N_2O_4$: *m/e* 314.1283).

*Benzoxazole **10**.* Injection of compound **9** (10 mg) into a column (5% SE-30 on chromosorb W, 1′/4×10 ft) for GLC (270 °C, 60 ml/h flow of He carrier gas) afforded **10** after a period of 4.2 min. **10**, IR ($CHCl_3$) 1715, 1600, 1570, 1540, 1490, and 1300 cm^{-1}; NMR (60 MHz, acetone-d_6) 2.76 (6H, s), 3.90 (3H, s), and 6.8—8.0 (7H, m) (Found: *m/e* 296.1199. Calcd for $C_{17}H_{16}H_2O_3$: *m/e* 296.1190).

*The Synthesis of Methyl N-(Dimethylanthraniloyl)anthranilate (**9**).* A mixture of methyl dimethylanthranilate (50 mg) and *N,N′*-carbonyldiimidazole (50 mg) was heated to 90 °C for 2 min and maintained at room temp for 30 min. To the mixture, 50 mg of 3-hydroxyanthranilic acid was added. This oily mixture was maintained at 90 °C for 10 min, and was dissolved in a 30-ml solution of THF and stirred at 90 °C for 2 h. After dilution with water (10 ml), the solution was extracted with five 10-ml portions of $CHCl_3$. The extracts were dried over Na_2SO_4 and concentrated to afforded an oily mixture. The oily product was methylated in ether with CH_2N_2, giving crude **9**. The mixture was separated by preparative TLC on alumina with benzene. The eluate from alumina with $CHCl_3$–AcOEt (1: 1) which was then evaporated afforded **9** (72 mg), which was recrystallized from methanol to give **9** (55 mg); mp 89—90 °C.

*Ingenol Triacetate (**11**).* A solution of ingenol (**5**) (32 mg) in Ac_2O (0.06 ml) and dried pyridine (2 ml) was maintained at room temp overnight, to which 10 ml of water was added. The solution was extracted with five 10-ml portions of $CHCl_3$. The $CHCl_3$ layers were combined, washed with an aq HCl solution, an aq $NaHCO_3$ solution, and saturated NaCl aq solution dried over Na_2SO_4, and concentrated to give an oily compound. This oily product was recrystallized from MeOH to afford crystalline ingenol triacetate (**11**) (25 mg); mp 197—198 °C (lit, 196—197 °C);[5] IR ($CHCl_3$) 3440, 1740, 1710, and 1635 cm^{-1}; NMR (60 MHz, $CDCl_3$) 0.6—1.0 (2H, m), 1.00 (3H, d, J=6.0 Hz), 1.07 (3H, s), 1.11 (3H, s), 1.78 (3H, d, J=1.5 Hz), 2.03 (3H, s), 2.15 (3H, s), 2.23 (3H, s), 3.25 (1H, s, OH), 4.0—4.3 (1H, m), 4.18, 4.62 (2H, AB q, J=12 Hz), 5.00 (1H, s), 5.41 (1H, br s), 6.10 (1H, q, J=1.0 Hz), and 6.25 (1H, br d, J=4.5 Hz) (Found: *m/e*

474.2259. Calcd for $C_{26}H_{34}O_8$: *m/e* 474.2253).

Ingenol Monoacetate (12). Milliamine A hydrochloride (52 mg) was dissolved in an aq solution (10 ml) of $NaHCO_3$ (300 mg) and 20 ml of MeOH. This mixture was stirred for 1 h at room temp. Water was added to this solution, which was extracted with five 10-ml portions of $CHCl_3$. The $CHCl_3$ layers were combined, washed with a saturated NaCl solution, dried over Na_2SO_4, and concentrated to give an oily product (55 mg). This product was purified by preparative TLC to give ingenol monoacetate (**12**) (15 mg); IR ($CHCl_3$) 3480, 1725, and 1645 cm^{-1}; NMR (60 MHz, $CDCl_3$) 0.95 (3H, d, J=6.0 Hz), 1.03 (3H, s), 1.07 (3H, s), 1.80 (3H, d, J=1.0 Hz), 2.01 (3H, s), 3.60 (1H, br s), 3.8—4.2 (1H, m), 4.40 (1H, s), 4.25, 4.80 (2H, AB q, J=10 Hz), 5.90 (1H, q, J=1.0 Hz), and 6.05 (1H, m) (Found: *m/e* 390.2014. Calcd for $C_{22}H_{30}O_6$: *m/e* 390.2041).

Ingenol Monocarbonate (13). A mixture of ingenol (**5**) (20 mg) and *N,N'*-carbonyldiimidazole (15 mg) was dissolved into THF (2 ml), stirred for 2 h at room temp and monitered by TLC on silicic acid. Evaporation of THF at 40 °C afforded an oily product, which was dissolved into a 1% aq HCl solution (5 ml) and $CHCl_3$ (5 ml) by shaking. The $CHCl_3$ was separated and purified by preparative TLC to give monocarbonate **13** (13 mg) and ingenol (5 mg) **13**, IR ($CHCl_3$) 3450, 1745, 1725, and 1665 cm^{-1}; NMR (60 MHz, $CDCl_3$) 0.90 (3H, d, J=6.0 Hz), 1.05 (3H, s), 1.10 (3H, s), 1.83 (3H, d, J=1.0 Hz), 4.0—5.0 (7H, m), 5.80 (1H, q, J=1.0 Hz), and 6.20 (1H, m); MS 374 (M^+).

Ingenol Dicarbonate (14). A THF solution (1 ml) of monocarbonate (**13**) (10 mg) and *N,N'*-carbonyldiimidazole (10 mg) was stirred at 40 °C for 2 h and concentrated to give a mixture. After preparative TLC, an oily product was recrystallized from ether to afford crystalline **14**; mp 204—206 °C; IR ($CHCl_3$) 1830, 1780, 1740, and 1660 cm^{-1}; NMR (60 MHz, $CDCl_3$) 0.9 (3H, d, J=6.0 Hz), 1.1 (3H, s), 1.2 (3H, s), 2.1 (3H, d, J=1.0 Hz), 3.7 (1H, br. d, J=12 Hz), 4.5—4.8 (2H, AB q, J=13.5 Hz), 4.7 (1H, m), 5.3 (1H, s), 5.9 (1H, q, J=1.0 Hz), and 6.2 (1H, m) (Found: *m/e* 400.1510. Calcd for $C_{22}H_{24}O_7$: *m/e* 400.1521).

Compound 15. A mixture of monocarbonate **13** and an aq $NaIO_4$ solution (100 mg/5 ml H_2O) in THF was stirred for 7 h at 40 °C. After the addition of water (5 ml), the mixture was extracted with four 5-ml portions of $CHCl_3$. The extracts were washed with saturated NaCl aq solution, dried, and concentrated to give oily **15** (13 mg) (Found: *m/e* 372.1518. Calcd for $C_{21}H_{24}O_6$: *m/e* 372.1571).

Urethane 16. A mixture of compound 15 (10 mg) and phenyl isocyanate (30 mg) in THF containing a trace of pyridine was stirred at 80 °C for 3 h. After dilution with water, the aq solution was extracted with three 5-ml portions of $CHCl_3$. The extracted layers were combined, dried over Na_2SO_4, and concentrated to yield a product. Separation and purification by preparative TLC on silicic acid afforded glassy **16**; IR ($CHCl_3$) 3430, 1830, 1730, 1605, and 1525 cm^{-1}; NMR (60 MHz, $CDCl_3$) 4.80 (2H, s), 5.50 (1H, q, J=1.0 Hz), 5.95 (1H, m), 6.50 (1H, br d, J=4.5 Hz), 6.90 (1H, s, NH), and 7.00 (5H, m); MS 491 (M^+).

Methanolysis of Milliamine B (2). To a solution of **2** (29 mg) and anhydrous MeOH (2 ml) was added a solution (0.3 ml) of NaOMe in MeOH (prepared from 374 mg of Na and 40 ml of anhydrous MeOH). The solution was maintained at room temp for 1 h and was added the Amberlite IRC-50 (H-form) required for neutralization of the NaOMe. The resin was filtered with suction and the filtrate was concentrated, affording an oily mixture (32 mg), which was separated by preparative TLC on silica gel. Two eluates of AcOEt were concentrated, affording **4** and **5**. Compound **4** was recrystallized from methanol to give crystalline **4** (7 mg); mp 160—162 °C. Ingenol (**5**) was acetylated with Ac_2O and pyridine (2 ml) to give ingenol triacetate (**11**). **11**, mp 196—198 °C (recrystallized from MeOH).

Methanolysis of Milliamine C (3). To a solution of milliamine C (22 mg) in anhydrous MeOH (2 ml) was added a solution (0.1 ml) of NaOMe in MeOH (prepared from 200 mg of Na and 40 ml of anhydrous MeOH). The solution was maintained at room temp for 1 h and the Amberlite IRC-50 (H-form) required for neutralization of the NaOMe. The resin was filtered with suction and the filtrate was concentrated, affording an oily mixture (18 mg). The mixture was separated by preparative TLC on silica gel. Two eluates of AcOEt were concentrated to yield **4** and **5**. Compound **4** was recrystallized from MeOH to afford crystalline **4** (2 mg); mp 159—161 °C. Alcohol **5** was treated with Ac_2O (0.1 ml) and pyridine (2 ml), followed repeated by evaporation of the Ac_2O and pyridine under reduced pressure after addition of benzene. The residue was recrystallized from MeOH to give crystalline **11**, mp 195—198 °C.

Aromatic Sextets and Aromaticity in Benzenoid Hydrocarbons

Jun-ichi AIHARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received December 27, 1976)

The aromatic sextet theory of Clar was used to estimate the degree of aromaticity in benzenoid hydrocarbons. The resonance energies obtained correlate well with the Dewar-type resonance energies calculated in a previous paper.

An aromatic sextet is defined as a benzene unit (six sp^2 carbon atoms arranged in a hexagon) which can be chosen from a benzenoid hydrocarbon, on condition that when the benzene unit and all the adjacent π bonds are removed from the π system, one or more Kekulé structures can be written for the residual π system.[1] One or more aromatic sextets may further be chosen from the residual π system. Clar long ago stressed the importance of writing the structural formula of a benzenoid hydrocarbon with a maximum number of aromatic sextets.[1] These aromatic sextets, isolated from each other in the same π system, are considered to be the main origin of aromatic stabilization.[1-7] A structural formula thus defined is termed a sextet formula.[4] In this paper, the degree of aromaticity in a benzenoid hydrocarbon is examined on the basis of the Clar aromatic sextet theory.[1]

Theoretical

First, a new polynomial $A(X)$ characterizing the aromaticity of a benzenoid hydrocarbon is proposed in the form

$$A(X) = \sum_{k=0}^{m}(-1)^k r(k) X^{2m-2k}, \tag{1}$$

where $r(k)$ denotes the number of ways in which k disconnected aromatic sextets can be chosen from the π system. Each coefficient of this polynomial has exactly the same meaning as the corresponding coefficient of a sextet polynomial $B(X)$ defined by Hosoya and Yamaguchi.[5] By definition $r(0)$ is equal to unity. Therefore, k is less than, or equal to, the number of aromatic sextets m in the sextet formula. This type of polynomial is termed a resonance polynomial. For example, the resonance polynomial for triphenylene is

$$A(X) = X^6 - 4X^4 + 3X^2 - 1. \tag{2}$$

Furthermore, the sextet polynomial[5] for this compound is

$$B(X) = 1 + 4X + 3X^2 + X^3. \tag{3}$$

Next, the roots of the equation, $A(X)=0$, are arranged in decreasing order,

$$X = X_1, X_2, \cdots, X_m, X_{m+1}, \cdots, X_{2m-1}, X_{2m}. \tag{4}$$

We then define a new quantity, RE^*, as

$$RE^* = K\sum_{k=1}^{m} X_k, \tag{5}$$

where the proportionality constant, K, is equal to the resonance energy of benzene (*i.e.*, of a single aromatic sextet).

Let us consider the physical meaning of this equation. We remember that, for an acyclic polyene, the HMO characteristic polynomial $P(X)$ can be written as[8]

$$P(X) = \sum_{k=0}^{n}(-1)^k p(k) X^{2n-2k}, \tag{6}$$

where $p(k)$ is the number of ways in which k disconnected π bonds are chosen from the π system, and n is the number of formal double bonds in the canonical structure. The roots of the secular equation $P(X)=0$ can be related to the π energy of the formal double bonds plus the additional π energy associated with a migration of this double bond character throughout the π system. By close analogy in form with this secular equation, the roots of the equation $A(X)=0$ can be formally expected to give some energetic quantity related to the aromatic sextets and their migration throughout the π system. To be more concrete, RE^* in Eq. 5 can be interpreted as the resonance energy induced by the aromatic sextets in a benzenoid hydrocarbon. This quantity refers to the resonance energy in Dewar's sense.[9-12]

Discussion

The following considerations help one to interpret RE^* as the resonance energy. The resonance energy for a π system composed of aromatic fragments, connected by essentially single bonds, should be additive. This requirement is fulfilled by the definition of RE^*. For example, a resonance polynomial for a polyphenyl (*p*-polyphenyl) composed of m phenyl groups is written in the form

$$A(X) = \sum_{k=0}^{m}\frac{m!}{k!(m-k)!}X^{2m-2k} = (X^2-1)^m. \tag{7}$$

Therefore, for the polyphenyl,

$$RE^* = mK. \tag{8}$$

This result is consistent with the two resonance theoretical approaches proposed by Herndon and others.[2,3,13,14]

Further support for RE^* is given by the close relationship found between the resonance energy and the Kekulé structure count for benzenoid hydrocarbons. As mentioned in a previous paper,[12] the following approximation holds fairly well for any polynomial $Q(X)$, if all the roots of equation $Q(X)=0$ lie in the interval between -3.0 and 3.0;

$$\sum_{k=1}^{2m}|X_k| \approx 6.0846 \log |Q(i)|, \tag{9}$$

where $2m$ indicates the degree of the equation and $i=\sqrt{-1}$. For most benzenoid hydrocarbons, the resonance polynomial $A(X)$ fulfils the prerequisite for

this approximation. Accordingly,

$$RE^* \approx 3.0423K \log |A(i)|. \quad (10)$$

Here, the fact was used that if X' is a root of the equation $A(X)=0$, $-X'$ is also a root. By comparing $A(X)$ with the corresponding sextet polynomial $B(X)$ defined by Hosoya and Yamaguchi,[5] $|A(i)|$ is evaluated as

$$|A(i)| = B(1) = SC, \quad (11)$$

where SC is the Kekulé structure count. We then arrive at the interesting expression

$$RE^* \approx 3.0423K \log SC. \quad (12)$$

This is none other than one of the expressions previously proposed by Herndon *et al.*[13,14] The confluence of their resonance theory and the present approach obviously provides mutual support for arguing the essential correctness of both approaches.

Extensive numerical analysis gives definite support to the view that RE^* represents the resonance energy of a benzenoid hydrocarbon. For this purpose, the equation $A(X)=0$ were solved for 30 typical benzenoid hydrocarbons. The RE^* values obtained were compared with the Dewar-type resonance energies, RE, analytically obtained by Aihara[11] (see Table 1 and Fig. 1). A refined definition of RE is given in the Appendix. Figure 1 shows fairly good correlation between the values for RE and RE^*/K. As indicated by Eq. 5, RE^*/K signifies the sum of the first m roots of equation $A(X)=0$. On the basis of this figure, the coefficient K actually appears close to the resonance energy of benzene ($0.2726\,\beta$).[11] These facts firmly establish the above view of RE^*, namely,

$$RE \approx RE^*. \quad (13)$$

However, if Fig. 1 is examined in detail, it is found that the benzenoid hydrocarbons investigated must be classified into groups, depending on the number of aromatic sextets, m, in the sextet formula. First, compounds with $m=1$ (polyacenes) form the first group. The resonance polynomial for a polyacene with n hexagons is

$$A(X) = X^2 - n. \quad (14)$$

RE^* can be expressed as

$$RE^* = \sqrt{n}K. \quad (15)$$

The solid line in Fig. 1 indicates that the resonance energies of the polyacenes fit Eq. 15 well if the resonance energy of benzene is assigned to K. This suggests that the aromatic character of benzene is fully retained in the aromatic sextet of all polyacenes.

Moreover, the present interpretation of Clar's aromatic sextets shows that the migration of a single aromatic sextet in a polyacene considerably increases the overall resonance energy. This is in marked contrast to the structure-resonance theory of Herndon,[2,3] which predicts the limiting resonance energy of a polyacene to be 2.8 times the resonance energy of benzene. Equation 15 strongly suggests that such a small value for the resonance energy of an infinitely large polyacene is rather doubtful.

Compounds with $m=2$ form the second group of benzenoid hydrocarbons, in the sense that the RE^* values correlate differently with the RE values. In this case, if the coefficient K in Eq. 5 is slightly decreased, good linear correlation is maintained. As indicated by

Table 1. Resonance energies of benzenoid hydrocarbons

Compound	m	RE^*/K	Resonance energy (β)	
			RE^*	RE
Benzene	1	1.000	0.273[a]	0.273

a) $K=0.2726\beta$. b) $K=0.2503\beta$. c) $K=0.2343\beta$.

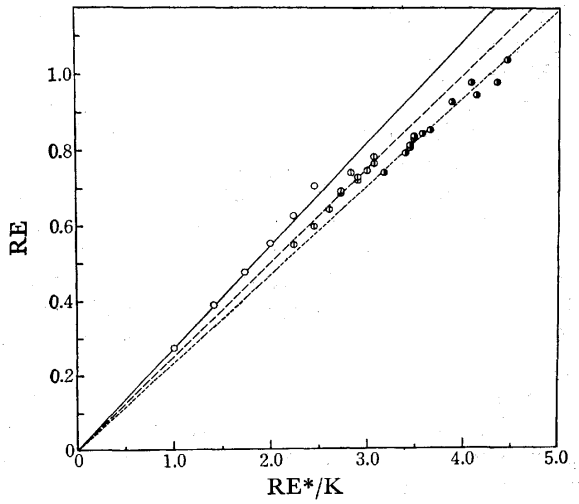

Fig. 1. Plot of *RE versus* RE^*/K for benzenoid hydrocarbons. Compounds with $m=1$ are marked by ○, those with $m=2$ by ①, and those with $m\geq 3$ by ◑.

the slope of long dashes in Fig. 1, the best K value is $0.2503\,\beta$ for compounds with $m=2$.

In this context, there is some evidence showing that each aromatic sextet in a polycyclic π system should rather be considered as a kind of substituted benzene. The resonance energy of any substituted benzene is somewhat smaller than that of benzene itself.[11] This effect can readily be understood by comparing the resonance energies of benzene and biphenyl. The resonance energy of biphenyl ($0.5017\,\beta$) is somewhat smaller than twice the resonance energy of benzene ($0.2726\,\beta$).[11] Accordingly, the effective resonance energy assignable to each aromatic sextet in a polycyclic π system should be somewhat smaller than that of benzene. This may be the reason why the K-value for compounds with $m\geq 2$ becomes somewhat smaller than the resonance energy of benzene.

Compounds with $m\geq 3$ constitute the third group of benzenoid hydrocarbons. For these compounds, the good linear relationship between the values for RE and RE^* is characterized by a K-value of $0.2343\,\beta$. The short-segmented broken line in Fig. 1 represents this situation. Here, it is noteworthy that 86% of the resonance energy of benzene is still retained in the K for such large benzenoid systems.

Concluding Remarks

As seen above, an analysis of Clar's aromatic sextet theory[1] appears to form the important basis for a resonance-theoretical consideration of conjugated hydrocarbons. It is interesting to note that some energetic quantities can be derived from such polynomials as Eqs. 1 and 6. Finally, one minor difficulty must be admitted in the present approach. This is caused by the fact that some roots of the equation $A(X)=0$ for certain compounds have a small imaginary part. Considering that the value of RE^* is always real and is a good approximation to the exact resonance energy RE, this aspect of the approach need not be a cause for concern.

Appendix

The definition of resonance energy previously given by Aihara[11] can be refined within the HMO theory as follows. Let the characteristic polynomial for a conjugated compound $P(X)$ and the corresponding reference polynomial $R(X)$ be written, respectively, as

$$P(X) = X^N + \sum_{k=1}^{N} a_k X^{N-k}, \tag{A1}$$

and

$$R(X) = X^N + \sum_{k=1}^{N} b_k X^{N-k}, \tag{A2}$$

where N is the number of atoms in the π system. The roots of the secular equation $P(X)=0$, arranged in decreasing order, are

$$X = X_1, X_2, \cdots, X_{N-1}, X_N. \tag{A3}$$

Each root, X_t, can be considered to be a function of N coefficients of $P(X)$, *i.e.*,

$$X_t = X_t(a_1, a_2, \cdots, a_{N-1}, a_N). \tag{A4}$$

If each variable a_k in the function X_t takes the value for a corresponding coefficient b_k of $R(X)$, X_t becomes the energy of the reference orbital related to the t-th molecular orbital in an actual π system. The resonance energy of the compound, RE, is then defined as

$$RE = \sum_{t}^{\text{occ}} g_t\{X_t(a_1, a_2, \cdots, a_{N-1}, a_N) - X_t(b_1, b_2, \cdots, b_{N-1}, b_N)\}, \tag{A5}$$

where t extends over all occupied π-molecular orbitals, and g_t is the number of electrons which occupy the t-th orbital. The resonance energies given in Table 1 are, of course, in agreement with this definition.

(Received January 5, 1977)

Deoxygenative reduction of nitrobenzene by tributylphosphine in the presence of primary or secondary alcohols gave 2-alkoxy-3*H*-azepines in good yields. The use of acidic hydroxylic compounds, such as phenol or acetylacetone, in place of the alcohols did not lead to ring enlargement. Triphenylphosphine could be used as a reducing agent, but the yields of the azepines were relatively low. 2-Alkoxy-3*H*-azepines were converted into 2-amino-3*H*-azepine in good yields by the reaction with ammonium carbonate. 2,3-Dihydro-1*H*-azepin-2-one was prepared by the hydrolysis of 2-butoxy-3*H*-azepine or 2-amino-3*H*-azepine.

Deoxygenation of nitro- and nitrosobenzene by tervalent phosphorus reagents in the presence of primary or secondary alkylamines results in the ring enlargement giving 2-alkylamino-3*H*-azepines.[1] Phenylnitrene is postulated as an intermediate for this reaction. It is accepted that nucleophilic attack of amines on 7-azabicyclo[4.1.0]heptatriene, assumed to be in equilibrium with phenylnitrene, leads to ring enlargement.[2] Such a ring enlargement is also observed in the thermolysis[3] or photolysis[4] of phenyl azide and in the photolysis of oxaziridines[5] or anthranils.[6] Although the formation of 2-methoxy-3*H*-azepines by photolysis of phenyl azide[7,8] or anthranils[6] in methanol is known, no report has appeared on the ring enlargement of nitro- and nitrosobenzene in the presence of alcohols as the nucleophile. Sundberg and Smith, Jr. observed the formation of alkoxyanilines in the deoxygenation of nitrosobenzene by triethyl phosphite in the presence of alcohols.[7,9]

This paper deals with the deoxygenation of nitrobenzene by tertiary phosphines in the presence of alcohols, providing a convenient method for the preparation of 2-alkoxy-3*H*-azepine, 2,3-dihydro-1*H*-azepin-2-one and several other azepine derivatives in good yields.

Results and Discussion

Tervalent phosphorus reagents for the deoxygenation of nitrobenzene include phosphorus triamide, trialkyl phosphite and phosphonite. Cadogan and Todd studied the order of reactivity of the reagents in the deoxygenation of 2-nitrobiaryl, and observed that tributyl- and triphenylphosphine are not reactive as phosphorus triamide or diethyl methylphosphonite,[1b] while Odum and Brenner reported the deoxygenative ring enlargement of nitrosobenzene by means of triphenylphosphine in the presence of alkylamines.[1a] We have confirmed that tributylphosphine and tripiperidinophosphine are most reactive for the deoxygenation of nitrobenzene in piperidine giving 2-piperidino-3*H*-azepine.

When nitrobenzene was treated with tributylphosphine in refluxing 1-butanol for 1 h, 2-butoxy-3*H*-azepine (**1d**) was formed in 89% yield. The structure of **1d** was determined by IR, NMR, and mass spectra as well as elemental analysis. The IR spectrum exhibited a strong intensity band at 1615 cm^{-1} and a medium band at 1515 cm^{-1}, both of which are due to C=C and C=N stretching vibration. The NMR spectrum shows peaks at τ 7.43 (d, 2H), 4.85 (q, 1H), 4.20 (m, 1H), 3.88 (m, 1H), and 3.21 (d, 1H) other than peaks due to protons of butyl group. The peak pattern indicates 3*H*-azepine skelton since it is very close to that reported for 2-diethylamino-3*H*-azepine.[4a] The mass spectrum of **1d** shows the molecular ion (*m/e* 165) as the highest mass feature, which corresponds to the parent peak of the expected structure.

The deoxygenative ring enlargement of nitrobenzene by tributylphosphine was then studied in the presence of various hydroxylic compounds. The results are summarized in Table 1.

Deoxygenation in the presence of primary or secondary alcohols led to ring enlargement to give the corresponding 2-alkoxy-3*H*-azepines (**1**) in moderate or good yields (Eq. 1). Attempted reactions in the presence of tertiary alcohols (2-methyl-2-propanol and 2-phenyl-2-propanol) failed to give the azepine, probably owing to the bulkiness of the nucleophiles. The use of 2,2,2-trifluoroethanol (pK_a 12.3) results in a formation of 2-(2,2,2-trifluoroethoxy)-3*H*-azepine (**1i**) but only in 19% yield.[9] Phenol (pK_a 9.98) and acetylacetone (pK_a 8.24) were also examined as a nucleophile in the deoxygenation, but no ring enlargement product was obtained.

The results show that hydroxylic compounds whose pK_a value is greater than *ca.* 12 are available as the nucleophiles for the ring enlargement.[10]

Solvent and temperature effects on the ring enlargement reaction were examined by means of deoxygenation in the presence of benzyl alcohol as a nucleophile. The solvent effect was hardly observed, since the reactions in dioxane, pyridine, 4-methyl-2-pentanone and toluene at the same temperature led to the formation of 2-benzyloxy-3*H*-azepine (**1h**) in nearly equal yields. On the other hand, temperature effect was remarkable. The results of the reactions in xylene at various tempera-

a) Triphenylphosphine was used in place of tributylphosphine. b) See Experimental.

Table 2. Temperature effect on the formation of 2-benzyloxy-3*H*-azepine (**1h**) in xylene

Reaction conditions		Yield of **1h**, %	$PhNO_2$ recovered, %
Temp, °C	Time, h		
80	20	51	33
100	20	70	16
120	7	76	12
150	3	93	4
180	1	94	5

tures are summarized in Table 2. **1h** was obtained in 99% yield based on nitrobenzene consumed at 180 °C, and in 76% yield at 80 °C. Lowering the reaction temperature decreases the yield of **1h** based on nitrobenzene consumed. This might be related to the fact that the deoxygenation of nitrosobenzene in the presence of methanol at 0 °C gives *o*- and *p*-anisidine.[7]

Triphenylphosphine could also be used in place of tributylphosphine for the deoxygenation of nitrobenzene in the presence of 1-butanol or benzyl alcohol, but the

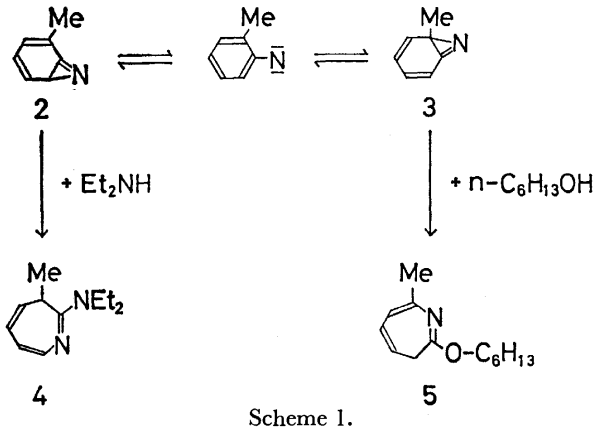
a) The peaks due to alkoxy group in 2-position are omitted.

yield of the azepine (**1d** or **1h**) was relatively low.

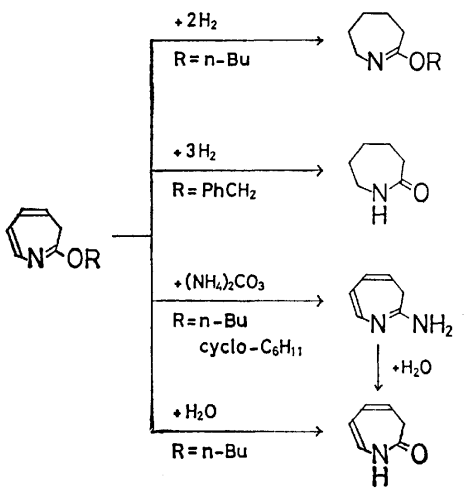
Deoxygenation of 4- and 2-nitrotoluene was also carried out in the presence of 1-hexanol, 5-methyl- (58%), and 7-methyl-2-hexyloxy-3*H*-azepine (**5**, 30%), respectively, being isolated. The position of the methyl group was determined by NMR spectroscopic examination. Although two isomeric products were possible in the deoxygenation of 2-nitrotoluene, no formation of 2-hexyloxy-3-methyl-3*H*-azepine took place. The deoxygenation of 2-nitrotoluene in the presence of diethylamine has been reported to give 2-diethylamino-3-methyl-3*H*-azepine (**4**, 36%) by de Boer *et al.*,[2] who explained the predominant formation of 3-methyl isomer by an attack of a relatively small nucleophile, diethylamine, on 5-methyl-7-azabicyclo[4.1.0]hepta-2,4,6-triene (**2**) which is expected to predominate in the equilibrium with 1-methyl isomer (**3**) of the azabicycle on steric grounds. The formation of **5** is due to the nucleophilic attack of 1-hexanol on the 1-methyl azabicyclic intermediate **3** (Scheme 1) as in the case where the nucleophile is triethyl phosphite.[11]



Scheme 1.

Transformation of 2-alkoxy-3*H*-azepines into some azepine derivatives was examined (Scheme 2).

Hydrogenation of 2-butoxy-3*H*-azepine (**1d**) on palladium-carbon gave 7-butoxy-3,4,5,6-tetrahydro-2*H*-azepine in 80% yield, and the hydrogenation of 2-benzyloxy-3*H*-azepine (**1h**) on the same catalyst gave hexahydro-2*H*-azepin-2-one in 77% yield. 2-Amino-3*H*-azepine was obtained in 90 and 75% yields by the reactions of 2-butoxy (**1d**) and 2-cyclohexyloxy-3*H*-azepine (**1f**), respectively, with ammonium carbonate in methanol, while the reactions of 2-cyclohexyloxy-3*H*-azepine (**1f**) with ammonium acetate and ammonium chloride[12] gave 2-amino-3*H*-azepine in 55 and 5% yields, respectively. Hydrolysis of 2-amino-3*H*-azepine afforded 2,3-dihydro-1*H*-azepin-2-one in 97% yield, which was alternatively obtained in 83% yield by the hydrolysis of 2-butoxy-3*H*-azepine (**1d**) under neutral conditions at 150 °C. The hydrolysis of 2-butoxy-3*H*-azepine hardly proceeds below 100 °C under neutral or alkaline conditions. Mineral acids promote the hydrolysis remarkably but subsequent hydrolysis of the product takes place. Paquette observed that 3,7-dimethyl- or 3,5,7-trimethyl-2,3-dihydro-1*H*-azepin-2-one is readily hydrolyzed under acidic conditions to give dihydro-2(3*H*)-furanones.[13]



Scheme 2.

Experimental

All the organic reagents and solvents were purified by distillation or recrystallization before use, while commercial inorganic materials were used without further purification. All the melting and boiling points were uncorrected. The GLPC analyses were carried out on a Shimadzu GC-4APT instrument with a thermal conductivity detector, using a 20% PEG 20 M on Celite 545 column (2 m; Temp: 180 °C; Carrier gas: He 30 ml/min; Internal standard: biphenyl). IR spectra were measured on a Hitachi G-2 instrument, NMR spectra on a JEOL C-60HL instrument in CCl_4 solution using TMS as an internal standard, and mass spectra on a Hitachi RMU-6E instrument.

Deoxygenation of Nitrobenzene by Tervalent Phosphorus Reagents in the Presence of Piperidine. A solution of nitrobenzene (3.08 g, 25 mmol) in piperidine (10 ml) was added drop by drop to a solution of tripiperidinophosphine[14] (bp 125 °C/0.5 Torr, 14.17 g, 50 mmol) and biphenyl (3.86 g, 25 mmol) in piperidine (40 ml) under reflux in nitrogen atmosphere. After being refluxed for 30 h, the mixture was analyzed by GLPC. 2-Piperidino-3*H*-azepine[1d] was formed in 88% yield.

When tributylphosphine (10.2 g, 50 mmol), triphenylphosphine (13.2 g, 50 mmol), and triethyl phosphite (8.35 g, 50 mmol) were used in place of tripiperidinophosphine, the yields of 2-piperidino-3*H*-azepine were 94, 16, and 24%, respectively.

Deoxygenation of Nitrobenzene by Tervalent Phosphorus Reagents in the Presence of Hydroxylic Compounds. The following three typical procedures are employed depending on the kind of hydroxylic compound or the reaction temperature. The results are summarized in Table 1, the analytical and spectral data of 2-alkoxy-3*H*-azepines (**1**) being given in Table 3.

Method A. A mixture of nitrobenzene (9.23 g. 75 mmol), tributylphosphine (34.89 g, 172 mmol), and methanol (20 g, 624 mmol) was heated in a sealed tube at 110 °C for 25 h and then evaporated by using a rotary evaporator under reduced pressure. Distillation of the residue afforded 2-methoxy-3*H*-azepine (**1a**, 5.5 g, 60%).

Method B. A mixture of nitrobenzene (14.77 g, 120 mmol), tributylphosphine (48.56 g, 240 mmol), and 1-butanol (57 g, 720 mmol) was heated under reflux (127—139 °C) for 4 h. The resulting mixture was stripped of 1-butanol and the product was distilled under reduced pressure. 2-Butoxy-3*H*-azepine (**1d**) was obtained 17.69 g (89%).

Method C. A solution of nitrobenzene (3.08 g, 25 mmol), tributylphosphine (11.13 g, 55 mmol), and 1-hexanol (15.33 g, 150 mmol) in pyridine (50 ml) was refluxed for 7 h. The

mixture was fractionated under reduced pressure and the fraction (bp 65.5—146 °C/3.5 Torr, 7.32 g) was subjected to redistillation to yield 2-hexyloxy-3*H*-azepine (**1e**, 3.19 g, 66%).

*2-Hexyloxy-7-methyl-3*H*-azepine (**5**).* A mixture of 2-nitrotoluene (6.86 g, 50 mmol), tributylphosphine (22.26 g, 110 mmol) and 1-hexanol (100 ml) was heated under reflux for 3.5 h. The resulting mixture was fractionated under reduced pressure and the fraction (bp 53—141.5 °C/4.5 Torr, 21.4 g) was subjected to redistillation to give **5** (3.13 g, 30%): bp 81.5—82.5 °C/1.5 Torr; IR 1610, 1545, 1310, 1260, 1195, and 1150 cm^{-1}; NMR[16] τ=7.94 (s, 3H), 7.45 (d, 2H), 4.95 (m, 1H), 4.31 (d, 1H), and 3.98 (q, 1H). Found: C, 74.71; H, 10.28; N, 6.97%. Calcd for $C_{13}H_{21}NO$: C, 75.36; H, 10.14; N, 6.76%.

*2-Hexyloxy-5-methyl-3*H*-azepine.* A solution of 4-nitrotoluene (6.86 g, 50 mmol) and tributylphosphine (22.35 g. 60 mmol) in hexanol (100 ml) was heated under reflux for 6.5 h. The resulting mixture was distilled and the fraction (bp 117.5—148.5 °C/4.5 Torr, 7.92 g) was subjected to redistillation to give 2-hexyloxy-5-methyl-3*H*-azepine (6.05 g, 58%): bp 97—100 °C/3 Torr; IR 1610, 1535, 1325, 1250, 1195, and 1160 cm^{-1}; NMR[16] τ=8.13 (s, 3H), 7.51 (d, 2H), 5.05 (q, 1H), 4.29 (d, 1H), and 3.28 (d, 1H). Found: C, 75.62; H, 10.40; N, 6.80%. Calcd for $C_{13}H_{21}NO$: C, 75.32; H, 10.41; N, 6.76%.

*Hydrogenation of 2-Butoxy-3*H*-azepine (**1d**).* 2-Butoxy-3*H*-azepine (**1d**, 6.73 g, 41 mmol) was hydrogenated at room temperature in 1-butanol (40 ml) with palladium catalyst (10% on carbon, 1.6 g) at an initial hydrogen pressure of 65 kg/cm^2. Hydrogenation was completed in 15 min. The catalyst and solvent were removed and the product was distilled to give 7-butoxy-3,4,5,6-tetrahydro-2*H*-azepine (3.8 g, 80%): bp 128—128.5 °C/48 Torr (lit, 214—216 °C;[15a] 80 °C/3.5 Torr,[15b] Found: C, 71.19; H, 11.25; N, 8.31%).

*Hydrogenation of 2-Benzyloxy-3*H*-azepine (**1h**).* Hydrogenation of **1h** (4.96 g, 25 mmol) was performed in toluene (40 ml) with palladium catalyst (10% on carbon, 1.33 g) at 80 °C for 2.5 h, the initial hydrogen pressure being 70 kg/cm^2. Removal of the catalyst and solvent gave crude hexahydro-2*H*-azepin-2-one (2.61 g, 92%). The crude substance was dissolved in diisopropyl ether (60 ml) and extracted with water (50 ml×10). The combined extracts were concentrated to *ca.* 45 ml and extracted with chloroform (40 ml×7). The combined extracts were dried over anhydrous sodium sulfate and evaporated to give hexahydro-2*H*-azepin-2-one (mp 67—69.5 °C, 2.18 g, 77%), which was identified by comparing its retention time in GLPC and its IR spectrum with those of an authentic sample.

*6-Amino-3*H*-azepine.* A solution of 2-butoxy-3*H*-azepine (**1d**, 3.3 g, 20 mmol) and commercial ammonium carbonate (2.3 g) in methanol (50 ml) was kept at 40 °C for 3 days. The mixture was concentrated under reduced pressure and the residue was treated with benzene (100 ml) and the precipitate was removed by filtration. The filtrate was evaporated to give crude 2-amino-3*H*-azepine (1.94 g, 90%). Sublimation at 90 °C and 1 Torr yielded 1.74 g (81%) of 2-amino-3*H*-azepine: mp 90—91 °C (lit,[4a] 90—91 °C, Found: C, 66.40; H, 7.25; N, 25.69%).

2-Amino-3*H*-azepine was isolated by treatment of 2-cyclohexyloxy-3*H*-azepine (**1f**, 3.3 g, 17 mmol) with commercial ammonium carbonate (1.95 g) in methanol (50 ml) at room temperature for 4 days, treatment of **1f** (3.83 g, 20 mmol) with ammonium acetate (3.09 g, 40 mmol) in methanol (50 ml) at room temperature for 6 days, and treatment of **1f** (2.92 g, 15 mmol) with ammonium chloride (1.63 g, 30 mmol) in methanol (50 ml) at room temperature for 9 days in 75, 55, and 5% yields, respectively.

*2,3-Dihydro-1*H*-azepin-2-one. a) Hydrolysis of 2-Amino-3*H*-azepine*: A solution of 2-amino-3*H*-azepine (1.5 g, 14 mmol) in water (40 ml) was refluxed for 5 h, treated with aqueous hydrochloric acid (3 drops of a 3M solution), and extracted with chloroform (30 ml×10). The combined extracts were concentrated to give 2,3-dihydro-1*H*-azepin-2-one (1.47 g, 97%): mp 48—49 °C. Recrystallization from hexane afforded colorless crystals: mp 49—50 °C (lit, 48—50 °C;[17] 47.5—48.5 °C,[4a] Found: C, 66.06; H, 6.38; N, 12.91%).

*b) Hydrolysis of 2-Butoxy-3*H*-azepine (**1d**)*: A mixture of **1d** (4.6 g, 28 mmol), ethanol (36 ml), and water (10 ml) was heated at 150 °C in a stainless steel autoclave for 3.5 h. The mixture was stripped of ethanol, water, and 1-butanol and the oily residue was dissolved in diethyl ether (50 ml). The solution was extracted with water (40 ml×7) and the combined extracts were concentrated to give crude 2,3-dihydro-1*H*-azepin-2-one (2.52 g, 83%). Recrystallization from cyclohexane afforded colorless crystals of mp 48—50 °C, which showed no depression on admixture with the sample obtained above.

Photochemical Reaction of Diphenylcyclobutenedione Derivatives. Formation and Reaction of Conjugated Bisketene and Its *N*-Analog*

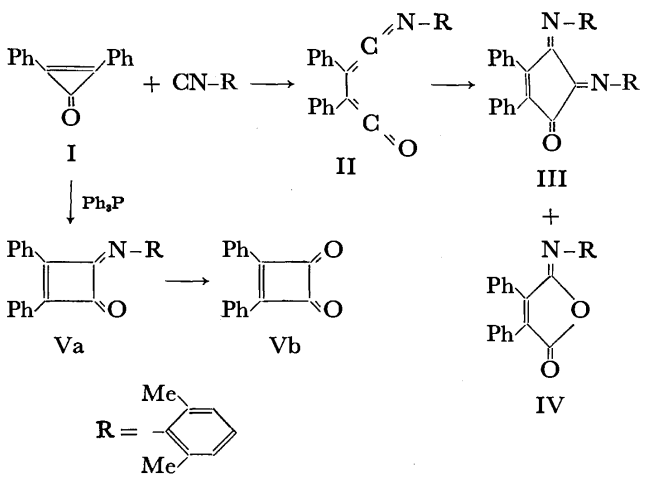
Naruyoshi OBATA and Takeo TAKIZAWA

Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received January 12, 1977)

The photolysis of diphenylcyclobutenedione derivatives (Va, b) under N_2 and that in the presence of substrate, O_2 or isocyanide, have been studied. The former resulted in the recovery of a large amount of V and the fragmentation; the latter gave the insertion products into V, diphenylmaleic anhydrides and iminocyclopentenones in good yield. The intermediates, bisketene and ketene-ketenimine as primary photo products were confirmed by the photolysis of Va in methanol to give succinates and by low-temperature IR-technique. Structural aspects of bisketene intermediate were discussed.

In a previous paper,[1] we reported facile ring-enlargement reactions of diphenylcyclopentenone (I) with 2,6-xylyl isocyanide to give cyclopentenetrione (III) together with a small amount of isomaleimide (IV), and cyclobutenedione (Va) in the presence of catalytic amount of triphenylphosphine. Since Va did not react further with the isocyanide in the dark, we proposed a tentative mechanism *via* ketene-ketenimine intermediate (II) rather than that of stepwise insertion of isocyanide into carbon-carbon bond of I *via* Va.

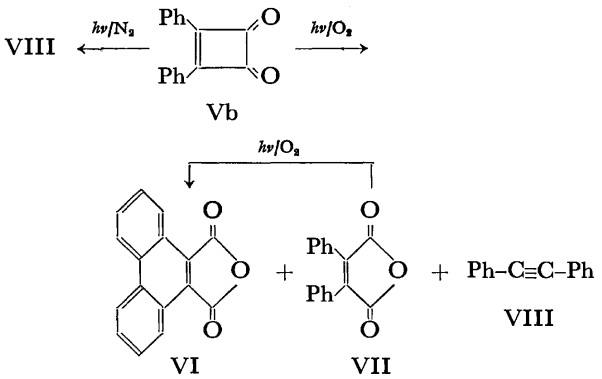


Scheme 1.

We found that diphenylcyclobutenedione (Vb) obtained from the hydrolysis of Va readily undergoes photochemical reaction to give a yellow solid on exposure to direct sunlight in the air. The same phenomenon to give a tan solid was observed by Blomquist and LaLancette[2b] who assumed it was a dimer of Vb. However, details of the photochemical reaction and the structure of the products have remained unsolved. A few photochemical reactions of cyclobutenedione derivatives were reported,[2,3] in which bisketene derivatives were only postulated as an intermediate. In view of the possible isolation of bisketenes under certain photochemical reactions, the photolysis of cyclobutenediones Va and Vb with and without O_2 or isocyanide were investigated.

Result and Discussion

Vb in benzene was irradiated with a high-pressure mercury lamp for 6 h under a slow stream of O_2 at room temperature. The reaction products were chromatographed on silica gel. 9,10-Phenanthrenedicarboxylic anhydride (VI, in 52% yield), diphenylmaleic anhydride (VII, in 4% yield), and diphenylacetylene (VIII, in 4% yield), were obtained together with the recovery of Vb in 30% yield. These compounds could not be obtained without light under O_2. Photolysis of VII under the same conditions as above gave VI in good yield *via* oxidative cyclization.[4]



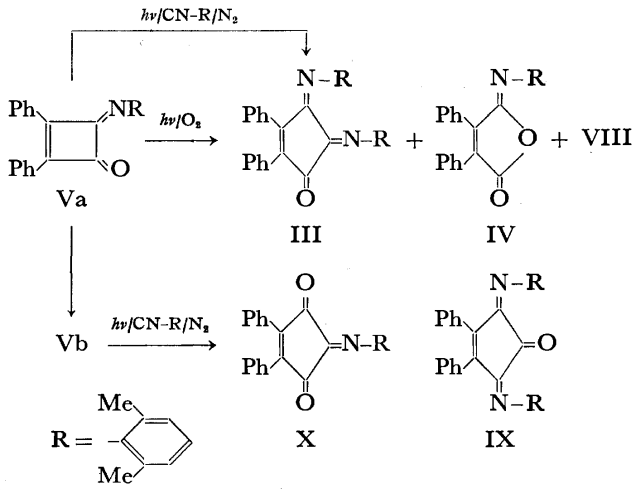
Scheme 2.

The structures of VI, VII, and VIII were confirmed by elemental analysis, molecular weight determination, spectroscopic data, and direct comparison with the samples prepared by the authentic route.[5,6] The mp and IR spectrum of VI agreed with those of the compound assumed to be a dimer of Vb.[2b]

Irradiation of Vb in benzene under N_2 stream for 6 h at room temperature gave VIII in 28% yield as the sole product accompanied by the recovery of Vb in 69% yield.

Photolysis of Va under O_2 stream gave *N*-(2,6-dimethylphenyl)diphenylisomaleimide (IV, in 25% yield), 4,5-bis(2,6-dimethylphenylimino)-2,3-diphenylcyclopenten-1-one (III, in 5% yield), and VIII in 8% yield.

* A part of this work has been published: N. Obata and T. Takizawa, *Chem. Commun.*, **1971**, 587. It was also presented at the 23rd National Meeting of the Chemical Society of Japan, Tokyo, April 1970.



Scheme 3.

The molecular formula for III was found to be $C_{33}H_{28}ON_2$ on the basis of elemental analysis and molecular weight. In the IR spectrum, III showed characteristic two peaks at 1640 and 1710 cm^{-1} due to νC=N and νC=O on cyclopentene skeleton. In the NMR spectrum, III showed multiplets at 2.40—2.90 τ(10H) and 3.10—3.40 τ(6H), and two singlets at 7.95 τ(6H) and 8.25 τ(6H) due to 2,6-disubstituted methyl group on phenyl ring, suggesting that III is not symmetrical 2,5-bis(2,6-dimethylphenylimino)-3,4-diphenylcyclopenten-1-one (IX).

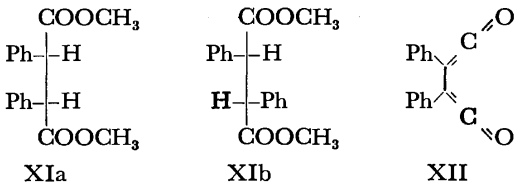
IV, the molecular formula $C_{24}H_{19}O_2N$, showed characteristic IR bands at 1710 and 1800 cm^{-1} due to νC=N and νC=O on cyclopentene ring, and UV spectrum in ethanol at 230 nm (log ε 4.26), 253 nm (4.12) and 330 nm (3.98). All these data were similar to those of *N*-substituted isomaleimide reported.[7] Treatment of IV with dil. HCl in methanol gave *N*-substituted diphenylmaleimide, which was prepared by a modification of the reaction by Reimer[6] and characterized.

The structures of III and IV were further confirmed by comparison with those obtained from the reaction of I with 2,6-xylyl isocyanide.[8] In contrast to the photolysis of VII in O_2, IV was not further photooxidized to phenanthrene derivatives upon prolonged irradiation.

III might be produced by the insertion of 2,6-xylyl isocyanide eliminated from Va with concomitant formation of VIII and CO during the course of photolysis. The isocyanide eliminated so far was also detected by thin-layer chromatography on silica gel and UV spectrum. Photolysis of Va in the presence of the isocyanide under N_2 gave III in 80% yield. However, no reaction of Va with the isocyanide in benzene at 80 °C was observed in the dark.

The photolysis of Vb in the presence of the isocyanide gave 5-(2,6-dimethylphenylimino)-2,3-diphenylcyclopenten-1,4-dione (X, in 86% yield). The structure of X was established by elemental analysis, molecular weight determination and spectral data. IV as well as VI and VII could be formed as a result of the insertion of O_2[9] into Va and Vb in a similar way to that for III.

In order to trap the intermediate in the photochemical reactions of Va, Vb with O_2 and isocyanide to give their insertion products, photolysis of Va and Vb in methanol at room temperature was carried out.[10] When Vb in methanol was irradiated at room temperature, dimethyl *meso*-diphenylsuccinate (XIa, in 67% yield) and dimethyl *dl*-isomer (XIb, in 17% yield) were obtained.



Scheme 4.

The photolysis of Vb in THF–methanol at −78 °C gave the same products in about the same ratio. The structures of XIa and XIb were confirmed by direct comparison with samples prepared by an authentic route.[11]

A solution of Va or Vb in THF was irradiated under N_2 at −78 °C (10 h for Va: 2 h for Vb). Addition of 2,6-xylyl isocyanide to both solution at −78 °C in the dark gave III and X in 78 and 82% yield, respectively. When O_2 was bubbled into the solution obtained from the photolysis of Vb at −78 °C in the dark, VII was obtained in 42% yield. Addition of cold methanol to the solution gave succinate XIa (39%) and XIb (14%) along with a trace amount of VIII. All these results indicate that the primary intermediacy of the photolysis of Va and Vb would be bisketene (XII) and keteneketenimine (II) which are stable at −78 °C.

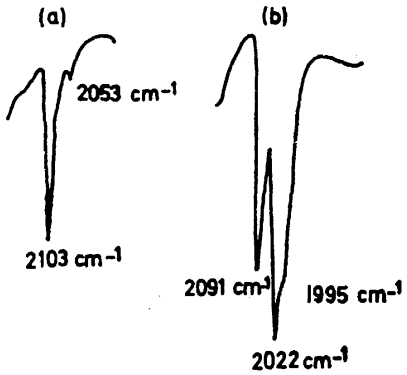


Fig. 1. IR spectra (tetrahydrofuran solution) of (a) XII at −50°C and (b) II at −46°C.

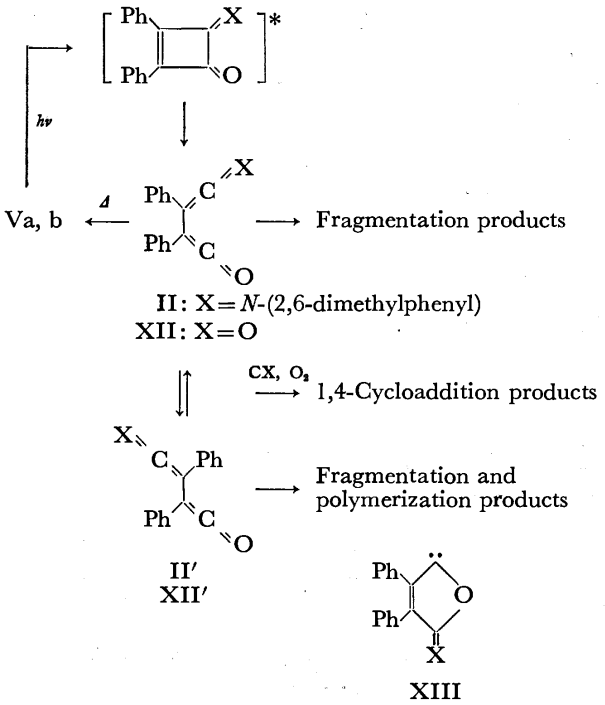
For direct observation of the intermediates II and XII, IR spectra of the solution irradiated at low temperature (−46 °C for II: −50 °C for XII) were determined using a Nihon-Bunko DS-403G IR spectrophotometer equipped with a low-temperature solution cell.[12] The results are shown in Fig. 1. The band at 2103 cm^{-1} for XII is readily assigned to the νC=O of the ketene. It follows that the 2091 and 2022 cm^{-1} bands of II are attributable to ketene νC=O and ketenimine νC=N, respectively.

II and XII in THF are stable in the dark for several days at −78 °C, but on warming slowly the THF solution of XII to above 0 °C, the characteristic peak at

2103 cm^{-1} disappears completely. When methanol was added to the THF solution of XII after the solution had been warmed to room temperature, no more succinate was obtained. However, Vb was recovered in 15% yield together with a small amount of VIII and a large amount of glassy material, while no Vb was recovered on addition of methanol to the solution at −78 °C following the work-up at room temperature.

These results seems to indicate that by photolysis at room temperature under N_2, primary photo products II and XII come to equilibrium with Va and Vb, which is responsible for the retardation of the photochemical fragmentation *via* II and XII to give VIII, CO and/or isocyanide. This is in marked contrast to the photolysis at low temperature which is very effective in the transformation of Va and Vb into II and XII.



Scheme 5.

On the other hand, the ratio (4: 1) of XIa and XIb isolated on the direct photolysis of Vb in methanol at room temperature and in THF–methanol at −78 °C differs a great deal from that (3: 2) on addition of cold methanol to a THF solution at −78 °C after photolysis. This indicates that II and XII in high concentration at low temperature might be equilibrated with geometrical isomers II′ and XII′, warming of which to room temperature might favor the formation of polymeric glassy materials for reverting to the starting ketones.

In conclusion, the superficial insertion of the substrate CX (*e.g.*, isocyanide) or O_2 into V in the present photolysis might take a route of 1,4-cycloaddition reaction of the substrate with primary photo products II and XII which might be equilibrated with starting ketones Va, Vb and their geometrical isomers II′, XII′, although some other mechanism, *e.g.*, *via* carbene (XIII)[2b,13] cannot be excluded completely.

Experimental

All the melting points were uncorrected. IR spectra were determined using a Nihon-Bunko DS-402G infrared spectrophotometer. UV spectra were obtained with a Carry 11 recording spectrophotometer. NMR spectra were obtained with a Varian A-60 spectrometer, using tetramethylsilane as an internal standard. The molecular weight was determined by use of a Hitachi 105 vapor pressure osmometer.

Photolysis of Diphenylcyclobutenedione (Vb) under O_2 Stream. A solution of Vb (0.4 g, 1.7 mmol) in dry benzene (40 ml) was irradiated with a high-pressure mercury lamp for 6 h under O_2 stream at 15 °C. Yellow crystals precipitated gradually. Recrystallization from THF gave 9,10-phenanthrenedicarboxylic anhydride (VI, 0.16 g, 52%), mp 320—322 °C (lit,[5] 321—322 °C). The mother liquor was concentrated and the residue was chromatographed on silica gel. Diphenylacetylene (VII, 0.03 g, 14%) was obtained from the eluent with hexane. Elution with hexane–benzene (1: 1) gave diphenylmaleic anhydride (VII, 0.01 g, 4%), mp 156—158 °C (lit,[6] 155—156 °C). The structures of VI and VII were established by direct comparison of the melting point and spectral data with those of the authentic samples.[5,6] The starting ketone Vb (0.21 g, 30%) was recovered from the eluent with benzene.

Photolysis of VII under O_2 Stream. A solution of VI (0.1 g, 0.4 mmol) in dry benzene (10 ml) was irradiated under similar conditions to those given above. Chromatography on silica gel gave VI (0.08 g, 78%).

Photolysis of Vb under N_2 Stream. Vb (0.3 g, 1.3 mmol) was dissolved in dry benzene (30 ml) and irradiated with a 500 W high-pressure mercury lamp for 6 h under N_2 stream at 15 °C. After removal of the solvent, the residue was subjected to silica gel chromatography. Elution with hexane gave VIII (0.066 g, 28%) and elution with benzene resulted in the recovery of Vb (0.21 g, 69%).

Photolysis of Iminocyclobutenone (Va) under O_2 Stream. A solution of Va (0.5 g, 1.5 mmol) in dry benzene (40 ml) was irradiated with a high-pressure mercury lamp for 15 h under O_2 stream at 15 °C. After removal of the solvent under reduced pressure, the residue was subjected to silica gel chromatography. Elution with hexane gave VIII (0.022 g, 8%) and from the eluent with hexane–benzene (7: 3), *N*-(2,6-dimethylphenyl)diphenylisomaleimide (IV, 0.13 g, 25%), mp 172—173 °C was obtained.

Found: C, 81.57; H, 5.42; N, 4.31%; mol wt: 353 (by MS). Calcd for $C_{24}H_{19}O_2N$: C, 81.56; H, 5.42; N, 3.96%; mol wt: 353.4. IR (KBr): 1710 (νC=N) and 1800 cm^{-1} (νC=O). NMR (CCl_4): 2.65 (m, 10H), 3.10 (m, 3H), and 7.85τ (s, 6H). UV (Ethanol) max: 230^{sh} (log ε 4.26), 253 (4.12), and 330 nm (3.98).

Further elution with benzene gave a small amount of 4,5-bis(2,6-dimethylphenylimino)-2,3-diphenylcyclopenten-1-one (III, 0.005 g, 5%), mp 184 °C and unidentified substances.

Found: C, 84.62; H, 5.98; N, 6.06%; mol wt: 468 (by MS). Calcd for $C_{33}H_{26}ON_2$: C, 84.58; H, 6.02; N, 5.98%; mol wt: 468.7. IR (KBr): 1640 (νC=N) and 1710 cm^{-1} (νC=O). NMR (CCl_4): 2.4—2.9 (m, 10H), 3.1—3.4 (m, 6H), 7.95 (s, 6H), and 8.25 τ (s, 6H), UV (Ethanol) max: 240 (log ε 4.4) and 330 nm (4.18).

Hydrolysis of IV. IV (0.05 g, 0.14 mmol) in methanol containing a catalytic amount of HCl was refluxed for 2 h. Recrystallization from methanol gave *N*-(2,6-dimethylphenyl)-diphenylmaleimide (0.035 g, 72%), mp 191—192 °C. The compound was rigorously characterized by comparison with

a sample prepared by the reaction of diphenylmaleic anhydride with 2,6-dimethylaniline, a modification of reported reaction.[6]

Found: C, 81.66; H, 5.55; N, 4.24%; mol wt: 340 (by osmometer). Calcd for $C_{24}H_{19}O_2N$: C, 81.56; H, 5.42; N, 3.96%; mol wt: 353.4. IR (KBr): 1770 and 1710 cm^{-1} (νC=O). NMR ($CDCl_3$): 2.60 (m, 10H), 2.8 (m, 3H), and 7.75 τ (s, 6H).

Photolysis of Va in the Presence of 2,6-Xylyl Isocyanide. A solution of Va (0.3 g, 0.9 mmol) and 2,6-xylyl isocyanide (0.13 g, 1 mmol) in dry benzene (30 ml) was irradiated with a high-pressure mercury lamp under N_2 at 15 °C. After removal of the solvent, recrystallization of the residue from hexane–benzene gave III (0.34 g, 80%).

Photolysis of Vb in Methanol. A solution of Vb (0.3 g, 1.3 mmol) in dry methanol (30 ml) was irradiated with a high-pressure mercury lamp at 15 °C. While crystals precipitated within 10 min and yellow solution was completely decolorized in 40 min. Filtration and repeated recrystallization from hexane–CH_2Cl_2 gave dimethyl *meso*-diphenylsuccinate (XIa, 0.26 g, 67%), mp 220—221 °C (lit,[11] 219—220 °C). The mother liquor was concentrated. Repeated recrystallization from hexane gave dimethyl *dl*-diphenylsuccinate (XIb, 0.065 g, 17%), mp 171—172 °C (lit,[11] 173.5—174 °C). NMR ($CDCl_3$) for XIa: 2.70 (m, 10H) and 6.6 (s, 6H); for XIb: 3.0 (m, 10H) and 6.35 τ (s, 6H).

Photolysis of Va at Low Temperature (−78 °C) Followed by Addition of Methanol. A solution of Vb (0.30 g, 1.3 mmol) in dry THF (30 ml) was irradiated with a high-pressure mercury lamp at −78 °C under N_2 stream. After irradiation for 1.5 h, the lamp was turned off and cold methanol was added to the solution at −78 °C in the dark. The solution was then warmed slowly to room temperature. After removal of the solvent, recrystallization of the residue from hexane–CH_2Cl_2 gave XIa (0.11 g, 29%). The mother liquor was concentrated and the residue was subjected to silica gel chromatography. Elution with hexane gave a trace amount of VIII. Elution with benzene gave additional XIa (0.03 g, 8%). XIb (0.05 g, 13%) and a small amount of unidentified high-melting compound were obtained from the eluent with benzene–CH_2Cl_2 (1: 1). When the irradiated solution was allowed to warm slowly to room temperature, starting Vb was recovered in 15% yield and a large amount of glassy material was obtained by chromatography on silica gel.

Photolysis of Vb at Low Temperature (−78 °C) Followed by the Reaction with O_2. A solution of Vb (0.2 g, 0.86 mmol) in dry THF (20 ml) was irradiated for 1.5 h under N_2 stream at −78 °C. The lamp was turned off and O_2 gas was bubbled into the solution in the dark to warm it to room temperature. After removal of the solvent under reduced pressure, the residue was chromatographed on silica gel. Elution with hexane gave VIII (0.01 g, 7%) and elution with hexane–benzene gave VII (0.09 g, 42%). Elution with benzene–CH_2Cl_2 gave unidentified glassy materials.

Photolysis of Vb in the Presence of 2,6-Xylyl Isocyanide. A solution of Vb (0.3 g, 1.3 mmol) and 2,6-xylyl isocyanide (0.17 g, 1.3 mmol) in dry benzene (10 ml) was irradiated with a high-pressure mercury lamp under N_2 at room temperature for 1.5 h. After removal of the solvent, the residue was recrystallized from hexane–benzene to give 5-(2,6-dimethylphenylimino)-2,3-diphenylcyclopenten-1,4-dione (X, 0.41 g, 86%), mp 142—143 °C.

Found: C, 81.88; H, 5.35; N, 3.94%; mol wt: 362 (by osmometer). Calcd for $C_{25}H_{19}O_2N$: C, 82.17; H, 5.24; N, 3.83%; mol wt: 365.4. IR (KBr): 1780, 1770, 1745, and 1700 cm^{-1} (νC=O and νC=N). UV (Ethanol) max: 230^{sh} (log ε 4.39), 280^{sh} (4.00), 332 (4.23), and 535 nm (2.84). NMR (CCl_4): 2.70 (broad s, 10H), 3.20 (broad s, 3H), and 8.00 τ (s, 6H).

Reaction of Coordinated Phosphines. III. Reaction of Phenyl Compounds of Typical Groups V and VI Elements with Palladium(II) Salts in the Presence of Olefinic Compounds[1]

Teruo KAWAMURA, Kiyoshi KIKUKAWA, Makoto TAKAGI, and Tsutomu MATSUDA

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

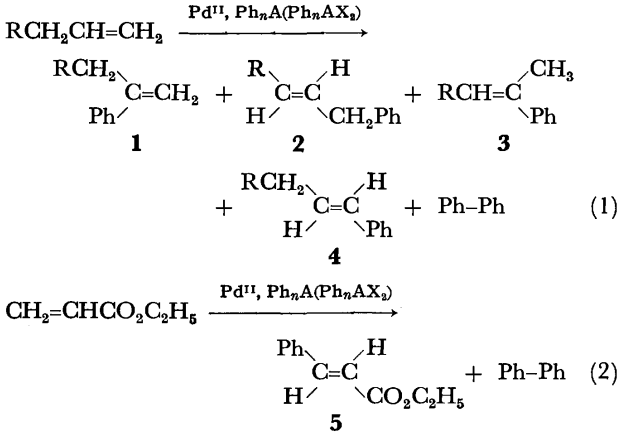
(Received January 18, 1977)

The reaction of phenyl compounds of typical groups V and VI elements, Ph_nA and Ph_nAX_2 (n=2, 3; A=P, As, Sb, Bi, S, Se, Te; X=Cl or X_2=O), with Pd(II) salts was studied in the presence of olefinic compounds (1-octene and ethyl acrylate) in acetonitrile. The phenyl migration from A to Pd to produce phenylpalladium species, which lead to the phenylation of olefin, was observed for all Ph_nA and Ph_nAX_2 (except for A=S and Ph_3PX_2) when $Pd(OAc)_2$ was utilized. The reaction, however, was inhibited or greatly suppressed for the compounds of P and As when $PdCl_2$ was used in place of $Pd(OAc)_2$. The compounds of Sb and Bi readily react with $PdCl_2$. Mechanistic discussion was given in terms of the extent of nucleophilic assistance by acetate ion when Pd(II) attacks the aromatic nucleus electrophilically at the carbon atom bonded to A.

Previous observations on the migration of the aryl group from Ar_3P (coordinated to $Pd(OAc)_2$) to Pd under mild conditions,[2] prompted us to examine other typical groups V and VI elements for similar reaction. Since the resulting phenylpalladium species is expected to show a similar reactivity to that derived from Ph_3P or phenylmercury(II) salts, the rate and extent of phenyl migration were assessed by the phenylation of added olefin. Asano *et al.* found that Ph_3As, Ph_3Sb and Ph_3Bi give *trans*-stilbine and biphenyl on reaction with $Pd(OAc)_2$ and styrene in refluxing dioxane–acetic acid.[3] The present study deals with a more detailed aspect of the reactions under milder conditions with the aim of obtaining a general mechanistic insight into this type of phenyl migration.

Results

The reaction of Ph_nA with $Pd(OAc)_2$ in the presence of 1-octene or ethyl acrylate in acetonitrile is summarized in Table 1, and given in the following. The reaction was nearly complete within 5 h. It is seen that all the phenyl groups in Ph_3Sb, Ph_3Bi, and Ph_2Te can be mobilized under suitable conditions. Only one phenyl group of Ph_3As was mobilized in the 5 h reaction, but



the final yield (24 h reaction) of the phenylated olefins and biphenyl indicates that two phenyl groups out of three could migrate from As to Pd. No phenyl of Ph_2S was mobilized in 5 h. However, a trace of phenylated olefins could be detected on GLC after 25 h. The time dependence of the reaction shows that the phenyl migration was especially rapid for Ph_3Sb, Ph_3Bi, and Ph_2Te as compared with Ph_3As or Ph_2Se. The variation

in A/Pd ratio did not cause much difference in the reaction rate for the compounds of Bi, Sb, Te, and Se. However, the increase in As/Pd ratio over 1 considerably decreased the rate of phenyl migration. A similar observation was made for the reaction of Ph_3P.[2a] It is probable that as in the case of Ph_3P, the coordination of the second molecule of Ph_3As to Pd exercises some unfavorable effect on the phenyl migration process.

Some reaction systems show a marked tendency to form biphenyl rather than phenylated olefins. This is especially true for the system where the formation of the phenylpalladium species is rapid (*e.g.*, Ph_3Sb and Ph_3Bi). This is at least partially due to the fact that without sufficient supply of olefin the phenylpalladium species decompose to form biphenyl. A slight modification was made in experimental procedure for the reaction of Ph_3Sb and Ph_3Bi (Table 1). A mixture of the olefin and Ph_nA (A=Sb, Bi) was added to a solution of $Pd(OAc)_2$ in acetonitrile. When they were subjected to reaction by the standard procedure (prior reaction of $Pd(OAc)_2$ and Ph_3A in acetonitrile, see Experimental), most of the organic products were biphenyl. The reaction of PhHgOAc studied under comparative conditions indicates that the formation of biphenyl is unimportant (1—2% yield). The marked tendency of Ph_3Bi to form biphenyl seems to reflect a certain inherent nature of the compound.

The time-yield profiles for various Ph_nA are given in Fig. 1 to show the phenylation of ethyl acrylate under the same reaction conditions. Solid Ph_3A (0.50 mmol) was added to a solution of $Pd(OAc)_2$ (0.50 mmol) in a mixture of ethyl acrylate (5.0 mmol) and acetonitrile (3.0 g) at 50 °C. Some discrepancy in yields (at 5 h of reaction) from those in Table 1 reflects a subtle difference in the experimental procedure.[4]

Phenylation of olefins with Ph_3P–$Pd(OAc)_2$ under nitrogen proceeds much more slowly than that under ordinary atmosphere.[1] The aerobic reaction might remove excess phosphine ligand from the coordination sphere of Pd through oxidation. Thus, the reaction of Ph_3As is greatly suppressed under nitrogen, while no major effect is observed with the compounds of Sb, Bi, Te, and Se. The reaction of PhHgOAc with olefin under nitrogen was also shown not to differ from that under aerobic conditions.

Ph_3P–$PdCl_2$ does not phenylate olefins in the absence of added sodium acetate.[2a] A similar study indicates that the compounds of P, As, and Se are completely or almost inactive without acetate ion. The compounds of Sb, Bi, and Te, on the other hand, exhibit somewhat decreased reactivity, but still phenylate ethyl acrylate effectively. Phenylmercury(II) chloride coupled with $PdCl_2$ has been utilized as an effective phenylating agent for olefin.[6] Hg requires no assistance by acetate ion in the migration of phenyl group from Hg to Pd. These observations indicate an essential difference in the mechanism of phenyl migration according to the nature of elements. If the nucleophilic attack by acetate ion on the coordinated A atom[2a] is important for the reaction of Ph_3P, Ph_3As, and Ph_2Se with bivalent Pd, we might expect that the reaction is suppressed for quinquevalent P and As (or with quadrivalent Se), since the coordination through A atom is impossible. The reactions of Ph_3PO or Ph_3PCl_2 were completely inhibited, those of Ph_3AsO or Ph_3AsCl_2 being suppressed a great deal. The reactions of Ph_2SeCl_2 were slightly suppressed. On the other hand, no major influence on the phenyl transfer activity was observed for Ph_3SbCl_2 and Ph_3BiCl_2. These observations are in line with the idea that the mechanism of phenyl migration can vary among elements A.

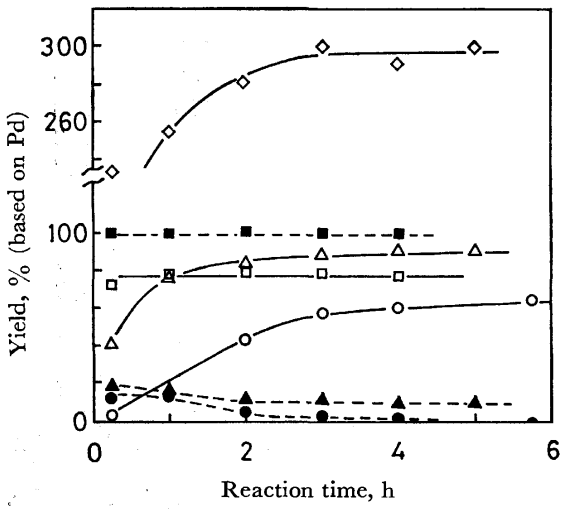

Fig. 1. The reaction of Ph_3A with $Pd(OAc)_2$ in the presence of ethyl acrylate (50 °C). Ph_3A, 0.50 mmol; $Pd(OAc)_2$, 0.50 mmol; ethyl acrylate, 5.0 mmol; acetonitrile, 3.0 g. ——, **5**; ——, biphenyl. A: P(○,●), As(△,▲), Sb(◇), Bi(□,■).

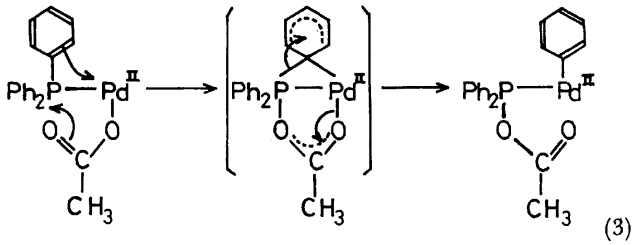
B: Ph_3P, 0.50 mmol; $Pd(OAc)_2$, 0.50 mmol; ethyl acrylate, 5.0 mmol; acetonitrile, 3 g.
yield: (mol of bromobenzene or **5**/mol of $Pd(OAc)_2$) × 100.

The formation of phenylpalladium species has hitherto been studied by the phenylation of olefins. As a more direct method for characterizing the unstable intermediate, the quenching experiments with bromine were attempted for the reaction of Ph_3P and $Pd(OAc)_2$ at 25 °C (Fig. 2). The aliquots withdrawn at appropriate time intervals were allowed to react with excess bromine in carbon tetrachloride. Bromobenzene which seems to be formed by the "bromodepalladation reaction"[7] of the phenylpalladium salts increased approxi-

mately linearly with the reaction time, supporting the formation of the chemical species containing the phenylpalladium bond. Phenylation of ethyl acrylate under similar conditions was obviously slow as compared to the formation of phenylpalladium species. A problem remains in the quenching practice as to a satisfactory way for standardizing the analytical method. In the reaction of $PhPd(Ph_3P)_2I$ with excess bromine, 67% of bromobenzene was obtained along with 4% of iodobenzene, indicating that the bromodepalladation of the complex is not quantitative.

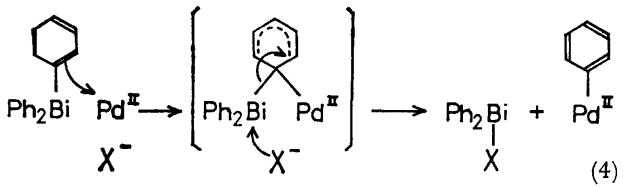
Discussion

The results could be rationalized by two extreme reaction mechanisms for the phenyl transfer from A to Pd. The first is represented by Ph_3P given in Scheme 3 where only the relevant ligands on Pd are shown. PPh_3 coordinated to bivalent Pd is in effect phosphonium ion, which is attacked by acetate ion on P, and concurrently, the phenyl group on P migrates to the vacant coordination site on Pd. Thus, the mechanism is an electrophilic aromatic substitution of P by Pd (or a 1,2-shift of phenyl group from P to Pd) promoted by nucleophilic assistance by acetate ion. It is not at all certain, however, whether the acetate ion which attacks P requires a prior coordination to Pd (Scheme 3). The process of phenyl migration



(3)

from an electron rich to electron deficient center (1, 2-shift of aryl group[8]) and the ability of acetoxyl group for anchimeric assistance[9] are familiar in organic chemistry. On the other hand, the reaction of the compounds of Bi seems neither to require the prior coordination of A to Pd nor necessitate the nucleophilic assistance by acetate ion. Thus, a simple electrophilic aromatic substitution by bivalent Pd would be enough to describe the reaction (Scheme 4). Phenylmercury (II) salts might react with bivalent Pd in a similar way.



(4)

For the elements other than P and Bi, the entity of the reaction would be somewhere between the two extremes, and no discontinuous change in mechanism seems to be involved. The reactions of As are more related to those of P, while the reactivity of Sb and Te seems to be close to that of Bi or Hg. The factors responsible for these varying reactivities of Ph_3A would be the decreasing A–C bond energy in the order Bi< Sb<As<P[3] coupled with the decreasing electronegativity Bi<Sb<P<As,[10] both facilitating the electrophilic aromatic substitution on the carbon atom bonded to Bi or Sb. In order to cleave the more stable P–C bond *via* electrophilic process on carbon, a prior coordination of phosphorus to palladium is required, which not only brings the reactants into close proximity but also enables the nucleophilic assistance by acetate ion on the coordinated P atom. The donor ability of Ph_3A increases in the order P>As>Sb≫Bi.[11]

Experimental

Materials. $Pd(OAc)_2$ was prepared by the method of Stephenson *et al.*[12] Commercial transition metal salts were used. The following phenyl derivatives of groups V and VI typical elements were synthesized according to the reported procedures and identified by elemental analyses as well as by comparison of IR and melting points; Ph_3Sb,[13] Ph_3Bi,[14] Ph_2Se,[15] Ph_2Te,[16] Ph_3PCl_2,[17] Ph_3AsCl_2,[17,18] Ph_3AsO,[19] Ph_3SbCl_2,[14] Ph_3BiCl_2,[20] Ph_2SO,[21] Ph_2SeCl_2.[22] Commercial Ph_3P and Ph_3As were used with or without further purification. Phenylpalladium complex, $PhPd(Ph_3P)_2I$, was prepared[23] and identified by elemental analysis.

Reaction of Ph_nA with Pd(II) Salt in the Presence of Olefinic Compounds. The reaction was carried out in the following way with slight modifications. In a reaction cell fitted with a constant-temperature water jacket were placed 0.50 mmol of Ph_nA (or Ph_nAX_2), desired amount (0.25—1.0 mmol) of Pd(II) salt and 3.0 g of acetonitrile. After the mixture had been stirred for 5 min, 5.0 mmol of olefin (1-octene or ethyl acrylate) and an internal standard (diethylene glycol dibutyl ether or 1,2-diphenylethane) were added. The reaction was monitored by analyzing the phenylated olefins and biphenyl, until the precipitation of palladium black was complete (usually 24 h). Identification of the reaction products was reported.[2]

Reaction of Ph_3P with $Pd(OAc)_2$, Quenching with Bromine. $Pd(OAc)_2$ (0.50 mmol) was dissolved in acetonitrile (3.0 g, with chlorobenzene as an internal standard) in a thermostatted cell at 25 °C. Ph_3P (0.50 mmol) was then added. Samples were withdrawn from the reaction mixture and added to the excess bromine (≈2 mmol) dissolved in carbon tetrachloride. The mixture was shaken with 10% aq $Na_2S_2O_3$, and the organic layer was separated. The latter solution was analyzed by GLC after being dried with $MgSO_4$. The use of iodine in place of bromine proved inadequate, since the reaction of Ph_3P with iodine did not reach completion and the phenyl transfer reaction continued to take place. The reaction of $PhPd(Ph_3P)_2I$ with bromine was carried out in a similar way. The complex was dissolved in acetonitrile or in a mixture of acetonitrile and dichloromethane and treated with 4—5 folds molar excess bromine in carbon tetrachloride.

Synthesis of Amino Compounds under Phase Transfer Conditions

Yosuke NAKAJIMA, Ryo-ichi KINISHI, Jun'ichi ODA, and Yuzo INOUYE

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received January 20, 1977)

The phase transfer process was applied to the reaction of organic bromides with azide anion. The reduction of intermediary azide derivatives gave the corresponding amino compounds, benzylamine, glycine, alanine, butyrine, and serine in fairly good yields. Effective catalytic activity was demonstrated by the difference in chemical yields in the case of methyl bromoacetate and ethyl α-bromopropionate. In order to examine the role of phase transfer catalyst, two bromohydrins (methyl β-hydroxy-α-bromopropionate and styrene bromohydrin) were subjected to the present reaction. Methyl β-hydroxy-α-bromopropionate afforded serine exclusively in the presence of 18-crown-6 and tetrabutylammonium bromide, but in the absence of the catalyst a mixture of serine and isoserine was obtained. A different regioselectivity was observed in the case of styrene bromohydrin.

Use of quaternary ammonium and phosphonium salts and crown ethers as a phase transfer catalyst is epochal in synthetic organic chemistry. Many synthetic routes are now being developed, giving products in good yields under simple and mild conditions.[1]

The mechanism proposed by Starks[2] was verified[3] in accord with the reactivity of 2-bromooctane toward aqueous alkali solution. Herriott and Picker[3] concluded that the catalyst functions so as to solubilize the anionic reagents into the organic phase in their system, but not rigorously applicable to others.[1,4]

We describe herewith the substitution reaction of organic halides with sodium azide under phase transfer-catalyzed conditions, which permit easy access to amino compounds. The probable mechanism for the present systems in connection with the reactivity of bromohydrins is discussed.

Experimental

IR spectra were recorded on a Hitachi 215 grating spectrophotometer and PMR spectra on a Varian model EM-360 spectrometer.

The general procedure for nucleophilic substitution of organic bromide with azide anion is exemplified by a typical run (run 1, Table 1). The reactions were repeated with the reaction parameters modified.

Benzyl bromide (10 mmol; 1.71 g) and sodium azide (15 mmol; 0.98 g) were stirred in a mixture of water (4 ml) and tetrabutylammonium bromide (0.5 mmol; 161 mg) at room temperature for 6 h, after which the solution was extracted 3 times with dichloromethane. The dried dichloromethane solution was evaporated and the residue was reduced with LAH. Benzylamine was obtained in the usual way. Yield, 936 mg (87.4%). IR and PMR spectra were identical with those of an authentic specimen. Identification of other products was also confirmed in satisfactory agreement with respective data in literature.

Determination of the ratio of isomeric serines, and amino alcohols (I and II) was made by a comparison of integral values of β-methylene and α-methin protons. The chemical shift of β-methylene proton of isomeric serines in D_2O–NaOH and TMDS as an internal standard: δ 3.80 for serine; 3.08 for isoserine. The chemical shift of α-methin proton in $CDCl_3$ and TMS of I and II: δ 4.58 for I; 3.97 for II.

Results and Discussion

Organic bromides reacted with sodium azide in a two-phase (liquid–liquid or solid–liquid) system in the presence of a phase transfer catalyst such as tetrabutylammonium bromide and 18-crown-6,[5] to give the corresponding azides in good yields, which were easily converted into the amines. For example, benzyl bromide underwent nucleophilic substitution at room temperature. The end product, benzylamine, was obtained by the LAH reduction of intermediate azide (Table 1). Benzene was found to be superior to ether in the solid–liquid system.

TABLE 1. NUCLEOPHILIC DISPLACEMENT OF BENZYL BROMIDE BY SODIUM AZIDE

yields. Effectiveness of the phase transfer catalyst was reflected in the distinct difference in chemical yield (runs 2, 3 and 4, 5, 6 in Table 2).

The data obtained for the amination of methyl β-methoxy-[6] and β-hydroxy-α-bromopropionate[7] to give serine in moderate yields by phase transfer catalysis are summarized in Table 3.

Levene and Schormüller[8] reported the formation of β-azido-α-hydroxypropionate as the sole product of the reaction of methyl β-hydroxy-α-bromopropionate with sodium azide in methanol–water medium. In contrast, we obtained a mixture of serine and isoserine (60: 40) as the end product of the same reaction under exactly the same conditions in the absence of catalyst (run 4, Table 3).[9] With ammonium halide and crown ether as a phase transfer catalyst, the reaction gave serine as the sole product in improved yields.

The present reaction would proceed through intermediate formation of methyl glycidate from bromohydrin followed by the nucleophilic attack of azide anion to give isomeric serines depending on whether it takes on α- or β-carbon of the glycidate. In order to confirm the mechanism, we subjected ethyl glycidate[10] as the substrate to the same reaction under the same conditions. We see from Table 4 that isoserine was the sole product in all cases, regardless of the presence or absence of catalyst and difference in medium. The intervention of glycidate is thus excluded. Consequently, in the phase transfer-catalyzed reactions, the nucleophilic attack of azide anion took place directly on the α-carbon of methyl β-hydroxy-α-bromopropionate to displace bromine.

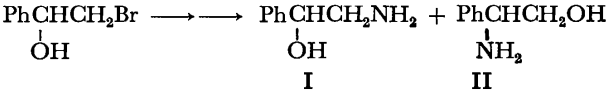
a) Heated under reflux.

The complete regiospecificity as well as improved chemical yields found for the present reaction systems can be utilized in synthetic organic chemistry.

In order to elucidate the function of phase transfer catalyst in the present systems, it seemed of interest to examine the reactivity of other substrates capable of easy rearrangement. For this purpose, styrene bromohydrin[11] seems to be suitable since it is prone to rearrangement. Upon nucleophilic substitution, styrene bromohydrin may give rise to the substitution product I and/or the rearrangement product II (Scheme 1).



Scheme 1.

The experimental results are given in Table 5. In the system of styrene bromohydrin also, styrene oxide is considered to be the probable intermediate. However, the results with styrene oxide used as a substrate suggest that the contribution of oxiran intermediate is negligible (Table 6).

Styrene bromohydrin reacted with sodium azide in benzene in the presence of crown ether to give exclusively the substitution product I (run 1, Table 5). In polar protic environment (run 3, Table 5), only the rearrangement product II was obtained from the same substrate. The difference might be attributed to the ability of medium to solvate anion species; the reduced solvation of azide anion in crown ether–benzene system suppresses intramolecular hydroxyl rearrangement, whereas in polar protic medium, the neighboring

Table 5. Reaction of styrene bromohydrin with sodium azide

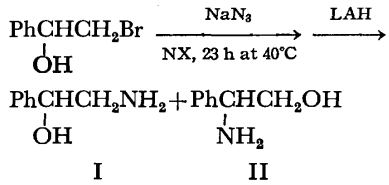
CE	Buffer(pH 7)	6	room temp	50

hydroxyl participation has preference to the attack of solvated azide anion.

In the liquid–liquid system with tetrabutylammonium bromide used as phase transfer catalyst (run 2, Table 5), however, no clear-cut selectivity was observed.

For the purpose of clarifying the function of quaternary ammonium salt, we examined to what extent the product distribution is affected by the change in dosage of catalyst and by the addition of organic solvent such as chloroform and benzene to the organic phase. Since the solubility of azide anion in organic phase would be greatly increased under these circumstances, we could predict the preferential formation of the substitution product I due to the enhanced reactivity of azide anion. In accordance with expectation, the product ratio I: II increased with increase in the amount of catalyst and by addition of organic solvent (Table 7).

Table 7. Influence of the reaction parameters on the product distribution of isomeric amino alcohols



I II

4	0	H_2O	10.6			100
5	5	C_6H_6–H_2O	36.2	77		23
6	5	$CHCl_3$–H_2O	48.6	85		15

The experimental results in the present systems (Tables 5, 6, and 7) show that the reaction takes place in rather aprotic environment as indicated by the high product ratio (runs 3, 5, and 6, Table 7). The mechanism proposed by Starks and Herriott seems to be operative under these conditions. However, in the reaction system which involves the substrate alone as organic phase (run 1, Table 7), the predominant formation of rearrangement product II is observed in spite of the presence of quaternary ammonium salt. This might result from the sparing solubility of ammonium azide ion-pair in organic phase. Under such conditions as employed in run 1 (Table 7), therefore, the function of a co-sphere outside the interface between organic and aqueous phases to furnish a possible reaction site could not be entirely neglected. As another likelihood, the protic character of styrene bromohydrin constituting an organic phase may be responsible for the observed preferential formation of II, despite the fact that the reaction occurs in organic phase.

(Received February 14, 1977)

The covalent hydration forming geminal diol is shown to be general in six-membered aza-aromatic aldehydes substituted by a formyl group at ortho or para-position to the nitrogen atom, and the equilibrium constants and thermodynamic quantities of the reaction are determined by NMR spectroscopic measurements. The results are compared with those of their hemiacetal formation. In several cases, solid monohydrates are isolated and identified.

In contrast to easy formation of hemiacetals,[1] hydration of carbonyl compounds is much less predominant, and only a few examples have been reported.[2,3] Trichloroacetaldehyde crystallizes as monohydrate, and its geminal diol structure is confirmed by ultraviolet spectroscopy.[2] Formaldehyde also exists to some extent as methanediol in aqueous solution. Some aliphatic aldehydes were also found to exist as equilibrium mixtures between the carbonyl and geminal diol forms in aqueous solutions.[4-6] However, the hydrate forms of most complex aldehydes are rather unstable, aldehydes behaving as normal carbonyl compounds even in aqueous or alcoholic solutions. The $n\rightarrow\pi^*$ absorption of many aldehydes including formaldehyde, acetaldehyde, and other simple aldehydes have been measure in these solutions, and their intensities were shown to be in the same order as those in aprotic solvents.[7]

Since the hydration and hemiacetal formation of carbonyl compounds both proceed *via* nucleophilic attack of water and alcohol molecules towards the carbonyl carbon atom, electron-withdrawing moieties attached to the carbonyl group should favor the formation of these addition products. The hydration of aza-aromatic aldehydes carrying so-called electron deficient rings was investigated. The position of the carbonyl function relative to the intra-ring nitrogen atoms affects the equilibrium of the hydration remarkably. The difference in equilibrium constants was interpreted in terms of the electronic effect and hydrogen bonding.

Experimental

Preparation of Materials. Most of the quinoline- and naphthyridinecarbaldehydes were prepared by the methods reported.[8] The samples of pyridinecarbaldehydes were obtained by distilling twice the commercial materials.

3-Quinolinecarbaldehyde (**5**) was perpared from 3-aminoquinoline by a modified method.[11] The starting material(3.6 g) was dissolved in diluted hydrochloric acid(3.5 M, 23 ml), aqueos sodium nitrite solution(1.75 g in 2.5 ml water) being added gradually to the solution. The pH of the diazonium salt solution thus prepared was adjusted to be *ca.* 5 by addition of sodium carbonate, and 10% aqueous formaldehyde oxime was added to the diazotized solution with efficient stirring during 30 min, the temperature of the reaction mixture being kept at 5—10 °C. The mixture was acidified with diluted hydrochloric acid (to pH=3). A ferric chloride solution(15 g in 15 ml water) was added, and the solution was digested at 100 °C for about 1 h. Neutralization by sodium carbonate, extraction by ether, and evaporation of the solvent gave the crude 3-quinolinecarbaldehyde. Colorless needles(recrystd from pentane). Mp 68—70 °C(lit, 70 °C). MS, m/e=157(M^+).

Their hydrates were prepared by crystallization from aqueous or aqueous-dimethyl sulfoxide solutions. Dimethyl sulfoxide seems to accelerate and to favor formation of the hydrates. 4-Pyridinecarbaldehyde monohydrate. Mp 65—80 °C (dec). Found: C, 57.80; H, 5.58; N, 11.32%. Calcd for $C_6H_7O_2N$: C, 57.59; H, 5.64; N, 11.20%. 1,8-Naphthyridine-4-carbaldehyde monohydrate. Mp 129—130 °C (dec). Found: C, 61.57; H, 4.39; N, 15.65%. Calcd for $C_9H_8O_2N_2$: C, 61.36; H, 4.58; N, 15.90%.

Measurement of the Spectra. The IR spectra were recorded with a Hitachi Model 225 grating infrared spectrophotometer and the UV spectra with a Hitachi EPS-3T spectrophotometer. Proton NMR spectra were measured with a JMN C-60H spectrometer equipped with a JES-VT-3 apparatus for variable temperature measurements. Chemical shifts are given in terms of part per million (ppm) downfield from TMS, and temperatures were calibrated by measuring the chemical shifts of 1,3-propanediol before and after scan of the spectrum.

Results and Discussion

Isolation of Crystalline Monohydrates of Aza-aromatic Aldehydes. In the course of synthetic and pharmaceutical investigations on naphthyridines and related heterocycles,[8-10] a series of aza-aromatic aldehydes were prepared and their infrared spectra were measured. Among these aldehydes, 1,8-naphthyridine-4-carbaldehyde (**8**), prepared by the oxidation of 4-methyl-1,8-naphthyridine, crystallizes to form monohydrate, and shows no carbonyl absorption in the frequency range 1750—1650 cm^{-1} when the spectrum is obtained in the solid state (as a potassium bromide pellet). Some absorption bands of the aldehyde under discussion are given in Table 1. The broad and intense absorption of 1,8-naphthyridine-4-carbaldehyde hydrate at *ca.* 3200 cm^{-1} can be assigned to the associated (or chelated) hydroxyl group. The broad bands at the lower frequencies might originate from the OH bending and CO stretching modes of vibration of geminal diol group. Mass spectrum of the hydrate shows no molecular ion peak but M−18 (m/e: 158) peak which corresponds to the parent peak of the anhydrous aldehyde. Further studies on its infrared spectrum in solution reveal the existence of the carbonyl form in aprotic solvents. The

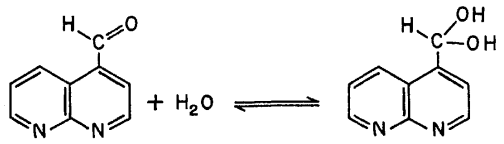
acetonitrile solution of the hydrate shows the carbonyl stretching absorption at 1706 cm^{-1} with ε_{max}=595. In aprotic solvents, the hydrated molecule seems to dissociate into the free aldehyde as follows.



(I) (II)

Since the carbonyl chromophore is destroyed to form the saturated dihydroxymethyl group in the course of hydration, the process of hydration is best pursued by means of ultraviolet spectrometry. The spectra of 1,8-naphthyridine-4-carbaldehyde (**9**) were measured in various solvents. The results are illustrated in Fig. 1. For the sake of comparison, the spectrum of the parent 1,8-naphthyridine is also shown. The spectrum of **9** in water resembles remarkably that of 1,8-naphthyridine. The similarity is reasonanble since the hydrated form of **9** has a 1,8-naphthyridine chromophore slightly perturbed by the dihydroxymethyl moiety. Similar

changes in spectra have been observed during the course of acetal formation of some heteroaromatic aldehydes.[3] The hypsochromic shifts of the bands caused by acetal formation are also explained to be due to the saturation of the carbonyl chromophore to form the geminal dialkoxy-compound.

Crystalline hydrates can also be obtained in several cases (*e.g.* 1,8-naphthyridine-2-carbaldehyde (**8**), 4-pyridinecarbaldehyde (**3**)) as solids which deposit spontaneously on the wall of the sample tube when their NMR spectra were measured in aqueous organic solvents (especially in D_2O–DMSO solvent system). Their geminal diol structures were proved by observing the presence of the two OD stretching bands (2438 and 2322 cm^{-1} in the case of **3**) and the absence of the C=O stretching band in their infrared spectra. In the case of **3**, the solid hydrate ($C_6H_5NO \cdot H_2O$) obtained from aqueous solution is identified by the NMR spectrum in DMSO-d_6 [δ=6.58 (d, 2, J=7.5 Hz, OH's of *gem*-diol) and 5.77 ppm (α-CH) and also by elementary analysis (see Experimental). The ultraviolet spectra of the aldehydes in water are also compared with those in aprotic solvents, hypsochromic shifts attributable to the covalent hydration being again observed (Table 2).

Determination of the Equilibrium Constants and Thermodynamic Quantities of the Hydration and Hemiacetalization of the Aza-aromatic Aldehydes. Further investigation on their NMR spectra shows that hydration of the heteroaromatic aldehydes of this class occurs generally, and proceeds reversibly in various solvents.[12] Thus, the measurement provides a suitable means to study the reaction quantitatively. An example of the NMR spectra of 4-pyridinecarbaldehyde–D_2O-dimethyl sulfoxide-d_6 ternary system is given in Fig. 2. The rate of the hydration is sufficiently small to make it possible to observe the proton signals of the free and the hydrate species of the aldehyde separately, the CHO and the $CH(OD)_2$ protons resonating at about 10.1 and 6.0 ppm, respectively. The relative intensities of these

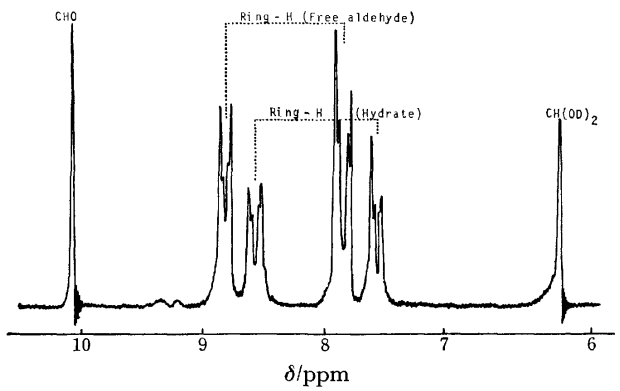

Fig. 2. The proton NMR specrum of 4-pyridinecarbaldehyde in deuterium oxide–dimethyl sulfoxide-d_6.

signals vary with the displacement of the equilibrium between the free and hydrate species. The relative intensities of the signals were determined as the average of integrated intensities recorded by the scan of the integrator. The scan was repeated at least three times to obtain a reliable equilibrium constant, the data with larger deviations being omitted. When the proton NMR signals of the ring are relatively simple (as in the spectrum of 4-pyridinecarbaldehyde in Fig. 2), the intensity measurement on these signals gives a more reliable equilibrium constant. The equilibrium constants thus obtained are given in Table 3. The temperature dependence measurements gave the enthalpies and

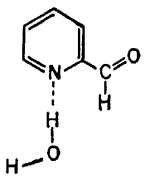
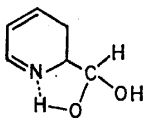
entropies of hydration as shown in Table 4. Since 3-pyridine- and 3-quinoline-carbaldehydes show by far less inclination to form hydrates than the rest of the aza-aromatic aldehydes (Table 3), the hydration would be strikingly favored by the mesomeric effect of the ring nitrogen atoms. The electonegative nitrogen atom in the six-membered heteroaromatic ring attracts the π-electrons on the ring, producing positive charges on ortho- and para-carbon atoms. The charges, in turn induce the positive charges on the carbonyl carbon atoms by displacement of the σ-bonding electrons, facilitating the nucleophilic attack of water and the alcohol molecules.

Bond orders have often been used as reactivity indices for the addition reactions,[13–16] a higher C=O bond order being expected to favor the addition reaction of the water molecule. The PPP[17] bond orders for aldehydes **1**—**9** were calculated and tabulated together with their C=O frequencies (Table 1). Since the stretching force constant of the bond increases with increase in the bond order, the C=O stretching frequency can be a measure for its bond order. Trichloroacetaldehyde, which forms a very stable hydrate, has its C=O absorption band at a remarkably higher frequency (1764 cm^{-1}) than those of simple aliphatic aldehydes. When compared with isomers of the above aza-aromatic aldehydes, the C=O stretching absorption of the "meta"-aldehydes (**2** and **5**) are considerably lower than those of the other aldehydes capable of forming the hydrate to a larger extent. This is in line with the above discussion. The bond order as well as the amount of the positive charge on carbon atom predicts the tendency of covalent hydration.

When the equilibrium constants and other thermodynamic properties are compared, the hydration of the para-isomer is more favorable than that of the ortho-isomer in the three series of the aldehydes, *i.e.* pyridinecarbaldehydes (**1** and **3**), quinolinecarbaldehydes (**4** and **6**), and 1,8-naphthyridinecarbaldehydes (**8** and **9**). The mechanism of this ortho-effect has not been clarified as yet. However, the effect can be interpreted in the following way. The dihydroxymethyl group generated in the course of hydration is bulkier than the formyl group and might cause the desolvation of the water molecule originally hydrogen-bonded to the ring



(III)



(IV)

nitrogen atom ortho to the carbonyl group (at least partially) by the steric hindrance. As a result, an energetically more favorable OH···N intermolecular hydrogen bond in III is replaced by a weaker intramolecular hydrogen bond in IV during the course of hydration. Thus, a somewhat unfavorable effect is expected with the hydration of "ortho"-aldehydes **1**, **4**, and **8**. The hydration of the naphthyridinecarbaldehydes seems a little more favorable than in the cases of other monoaza-aromatic aldehydes.

Table 5. Thermodynamic quantities for the hemiacetal formation of 4-pyridinecarbaldehyde

Alcohol	Solvent	K(34.5 °C) / 1 mol^{-1}	ΔH / kJ mol^{-1}	ΔS / J mol^{-1} K^{-1}
Methanol	DMSO-d_6	5.77×10^{-1}	−27.7	95
	Acetone-d_6	4.72×10^{-1}	—	—
Ethanol	DMSO-d_6	2.85×10^{-1}	−33.3	118
Isopropyl alcohol	DMSO-d_6	8.79×10^{-2}	−25.8	105
t-Butyl alcohol	DMSO-d_6	4.3×10^{-3}	—	—
Methanol with aldehyde **10**	DMSO-d_6	2.35×10^{-1}	−33.1	−119

In order to compare the hydration reactions with hemiacetal formation of these aldehydes, similar measurements were carried out on the ternary system of the aldehyde–alcohol–solvent (mostly dimethyl sulfoxide-d_6). The results are given in Table 5. In general, hemiacetal formation is more predominant than hydration, due probably to the stronger nucleophilicity of alcohols. However, the equilibria tend to be less favorable as the alkyl groups of the alcohols become bulkier,[4,5] and the acetal formation is remarkably hindered in *t*-butyl alcohol. The equilibrium constant for the hydration

is comparable with that of ethyl or isopropyl alcohol.

The experiments on *p*-nitrobenzaldehyde (**10**) reveal the fact that hemiacetalization is again more favorable than hydration in benzaldehydes carrying electron-withdrawing substituents, and the hydration of benzaldehydes without electron-attracting groups is practically negligible even in aqueous solutions. The hydration of **10** is considerably less favorable than those of 4-pyridinecarbaldehyde (**3**) and its analogs but more favorable than those of 3-pyridine- and 3-quinoline-carbaldehydes. This indicates that the electron-withdrawing power of intra-ring nitrogen atom is more predominant than that of nitro group attached to the aromatic ring. The hydration reactions are sensitive to the nature of the solvents, and the hydrogen accepting power of the solvent in hydrogen bond formation seems to favor the reaction remarkably.[12]

The authors are grateful to Miss Hiroko Endo for her technical assistance in the measurements of the spectra.

Synthesis and Absolute Stereochemistry of (+)-6,15-Dihydro-6,15-ethanonaphtho[2,3-*c*]pentaphene as Determined by Exciton Chirality and X-Ray Bijvoet Methods[1)]

Nobuyuki HARADA, Yuki TAKUMA, and Hisashi UDA

Chemical Research Institute of Nonaqueous Solutions, Tohoku University, Katahira, Sendai 980

(Received February 18, 1977)

(6*R*,15*R*)-(+)-6,15-Dihydro-6,15-ethanonaphtho[2,3-*c*]pentaphene (**1**) was synthesized from (9*R*,10*R*)-(+)-dimethyl 9,10-dihydro-9,10-ethanoanthracene-1,5-dicarboxylate, the absolute configuration of which has been established by the X-ray Bijvoet method and chemical correlations. The CD spectrum of **1** clearly exhibits very strong positive first and negative second Cotton effects due to coupling of the ^1B_b transitions ($\Delta\varepsilon_{268.0}=+931.3$ and $\Delta\varepsilon_{249.7}=-720.8$; $A(=\Delta\varepsilon_1-\Delta\varepsilon_2)=+1652.1$), the positive sign of the A value being in accord with the positive exciton chirality between the two long axes of the anthracene moieties in **1**. The results demonstrate an ideal case of chiral exciton coupling in CD spectra, and provide evidence of the consistency between nonempirical CD exciton chirality and X-ray Bijvoet methods.

The circular dichroic Cotton effects due to a chiral exciton coupling between two or more chromophores enable one to determine the absolute stereochemistry in a nonempirical manner, as does the X-ray crystallographic Bijvoet method. The present circular dichroic method has been extensively studied in the fields of biopolymers,[2)] inorganic complexes,[3)] physical chemistry,[4,5)] synthetic organic compounds,[6)] as well as in natural products.[7)] In the cases of steroidal glycol dibenzoates and several natural products, we have quantitatively calculated the coupled Cotton effects on the basis of the molecular exciton theory, obtaining excellent agreement between observed and calculated Cotton effects. Not only the sign of a Cotton effect but also its amplitude, location, and shape were satisfactorily reproduced based on the quantum mechanical calculation.[8)]

Although the optical circular dichroic exciton chirality and X-ray crystallographic Bijvoet methods are independent of each other, the two nonempirical methods should give the same absolute stereochemistry. The X-ray Bijvoet method utilizes the anomalous dispersion effect by heavy atoms, and is therefore applicable to all compounds containing a heavy atom. Actually, the X-ray Bijvoet method has been employed for various chemical compounds, since the first determination of the absolute configuration of (+)-tartaric acid was reported by Bijvoet *et al.* in 1951.[9)]

On the other hand, the circular dichroic exciton chirality method is based on the Cotton effects due to the chiral exciton coupling between two or more chromophores. The assignment of Cotton effects should be unambiguous and reliable in view of a nonempirical quantum mechanical calculation. Thus for the determination of the absolute stereochemistry by the application of the present optical method, it is important to choose a proper electronic transition of proper chromophores which satisfy the following requirements of a chiral exciton coupling: (i) Large extinction coefficient values in UV spectra; (ii) isolation of the band in question from other strong absorptions; (iii) established direction of the electric transition moment in the geometry of the chromophore; (iv) unambiguous determination of the exciton chirality in space, inclusive of configuration and conformation; (v) negligible molecular orbital overlapping between the chromophores.

The syntheses and chiroptical properties of optically active triptycene derivatives and 1,5-disubstituted 9,10-dihydro-9,10-ethanoanthracenes have been extensively studied by Nakagawa *et al.*[10)] They determined the absolute configurations of two key compounds, (1*R*,6*S*)-(+)-2,5-dimethoxy-7-aminotriptycene hydrobromide (**2**) and (9*S*,10*S*)-(−)-9,10-dihydro-9,10-ethanoanthracene-1,5-diamine dihydrobromide (**3**) by the X-ray Bijvoet method (Fig. 1).[11)] The absolute stereochemistry of other compounds has been established by the chemical correlations to these key compounds.[10,12)] For example, (+)-dimethyl 9,10-dihydro-9,10-ethanoanthracene-1,5-dicarboxylate (**6**) was converted into the antipode of (−)-diamino derivative (**3**), which corroborated the

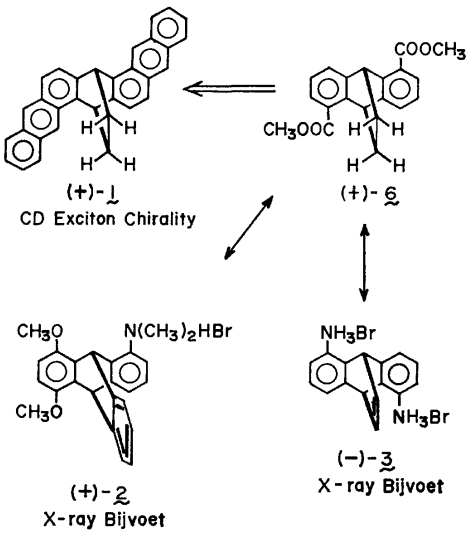

Fig. 1. Correlations between absolute stereochemistries of 9,10-dihydro-9,10-ethanoanthracene derivatives; absolute configurations of (+)-**2** and (−)-**3** have been determined by Tanaka, *et al.*,[11)] using the X-ray Bijvoet method. The arrow (↔) indicates the chemical correlations made by Nakagawa, *et al.*[10,11b)] The synthesis indicated by the arrow (⇐) and the absolute stereochemistry of (+)-**1** as determined by the CD exciton chirality method are described in this paper.

(9*R*,10*R*) absolute configuration of diester (+)-**6**.

Theoretical determination of the absolute stereochemistry of these compounds in view of the chiral exciton coupling mechanism was attempted by Tanaka *et al.*[11b,13] Their analyses of circular dichroic spectra led to the antipodal absolute configurations, contradictory with X-ray Bijvoet data. On the other hand, the absolute stereochemistry calculated by Hagishita and Kuriyama,[14] and others[15–17] is consistent with the X-ray Bijvoet data. Therefore, it is necessary to determine the absolute configurations of these cage compounds on the basis of reliable and unambiguous assignment of exciton coupled Cotton effects. It is also of significance to clarify the applicability of the present optical method.

This paper reports the synthesis and the (6*R*,15*R*) absolute stereochemistry of (+)-6,15-dihydro-6,15-ethanonaphtho[2,3-*c*]pentaphene (**1**) as determined by both circular dichroic exciton chirality and X-ray Bijvoet methods (Fig. 1). Hydrocarbon **1** was found to be the ideal compound satisfying the requirements of a chiral exciton coupling. It should be emphasized that the results obtained by the exciton chirality method are consistent with those by the X-ray Bijvoet method.

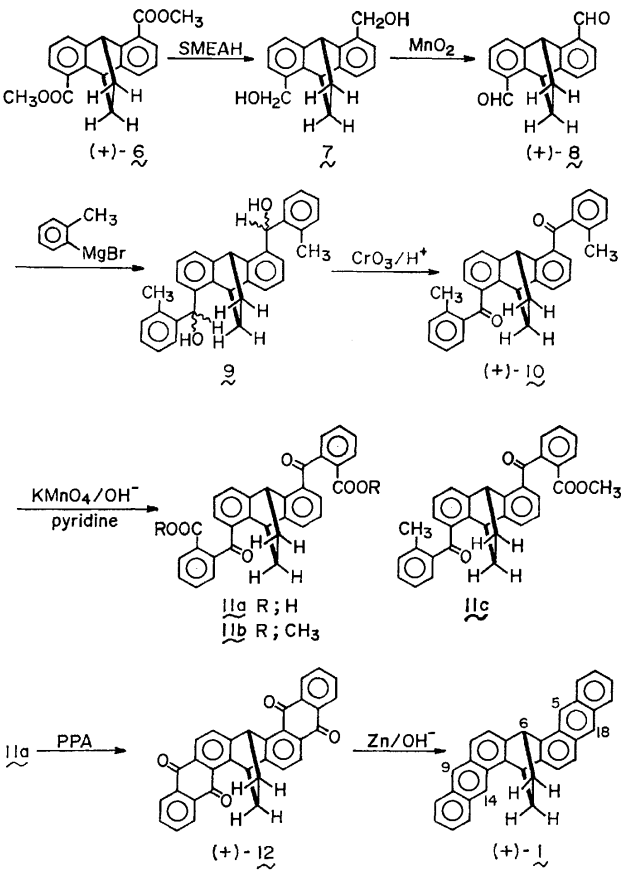
Results and Discussions

*Synthesis of (6*R*,15*R*)-(+)-6,15-Dihydro-6,15-ethanonaphtho[2,3-*c*]pentaphene (**1**).* The hydrocarbon (+)-**1** was synthesized from (9*R*,10*R*)-(+)-dimethyl 9,10-dihydro-9,10-ethanoanthracene-1,5-dicarboxylate (**6**), the absolute configuration of which has been established by the X-ray Bijvoet method and chemical correlations (Scheme 1).[10–12]

The diester (+)-**6**, mp 120.0—120.5 °C, $[\alpha]_D$ +359.2°, was quantitatively reduced to 9,10-dihydro-9,10-ethanoanthracene-1,5-dimethanol (**7**) with sodium bis(2-methoxyethoxy)aluminumhydride (SMEAH), followed by oxidation with activated manganese (IV) oxide under nitrogen giving (+)-9,10-dihydro-9,10-ethanoanthracene-1,5-dicarbaldehyde (**8**), mp 128.0—129.5 °C, $[\alpha]_D$ +487.3°. Since dialdehyde **8** was air-sensitive the crude product was immediately used for the subsequent Grignard reaction. Dialdehyde **8** was treated with excess *o*-tolylmagnesium bromide at room temperature to afford an epimeric mixture of 9,10-dihydro-α,α′-bis(*o*-tolyl)-9,10-ethanoanthracene-1,5-dimethanol (**9**). Since the additional chiralities of the secondary alcoholic moiety collapse at the next stage, the epimeric mixture of glycol **9** was used without separation. The Jones oxidation of glycol **9** afforded (+)-9,10-dihydro-9,10-ethanoanthracene-1,5-diylbis(*o*-tolyl)methanone (**10**), mp 151.0—152.5 °C, $[\alpha]_D^{20}$ +177°, (56% yield from (+)-dialdehyde **8**).

The selective oxidation of two aromatic methyl groups of diketone (+)-**10** was achieved by refluxing with $KMnO_4$ in aqueous NaOH–pyridine to give 2,2′-(9,10-dihydro-9,10-ethanoanthracene-1,5-diyldicarbonyl)dibenzoic acid (**11a**) contaminated with a small amount of monocarboxylic acid. The oxidation occurred exclusively on the aromatic methyl groups, the bridge head hydrogens remaining unchanged. The stability of the bridgehead hydrogens to oxidation can be accounted for by the fact that the carbon-hydrogen bond is perpendicular to the π-orbitals of the aromatic moiety and the rigidity of the molecular frame prevents the enolization of the bridgehead hydrogens. The structure of dibenzoic acid **11a** was characterized by the physical data of diester **11b**, and also by those of monoester **11c** derived from the intermediate monocarboxylic acid.

Cyclization of dibenzoic acid **11a** in polyphosphoric acid yielded (+)-6,15-dihydro-6,15-ethanonaphtho[2,3-*c*]pentaphene-5,9,14,18-tetrone (**12**), mp 268.0—268.5 °C, $[\alpha]_D^{20}$ +1000°, as the sole product (64% from diketone (+)-**10**). Finally, reduction of quinone (+)-**12** with zinc powder and successive dehydration catalyzed with acetic acid gave a very strong fluorescent hydrocarbon, (+)-6,15-dihydro-6,15-ethanonaphtho[2,3-*c*]-pentaphene (**1**), $[\alpha]_D$ +1157°, in solid masses.



Scheme 1.

Since the configuration of the ethano-bridge remains unchanged throughout all the reactions, it is concluded that the (6*R*,15*R*) absolute stereochemistry of hydrocarbon (+)-**1** has been established by the X-ray Bijvoet method and chemical correlations.

Circular Dichroic Spectra and Absolute Stereochemistries. The characterization of the electronic spectra of polyacene chromophores has been established by theoretical and experimental studies since the discovery of quantum mechanics. For example, anthracene exhibits at least four absorptions above 200 nm wavelength: the ^1L_a transition of medium-intensity around 380—300 nm

(ε 7600) with vibrational structures, the weak ^1L_b transition buried under the ^1L_a band, the intense ^1B_b transition at 251.9 nm (ε 204000), and the ^1C_b transition around 200 nm. Among these transitions, the allowed ^1B_b transition has been well established to have the electric transition moment along the long axis of the chromophore, while the ^1L_a transition has been assigned to be polarized parallel to the short axis, as illustrated in Fig. 2.[18]

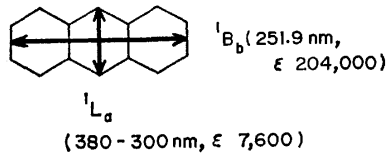


Fig. 2. Polarizations of the electric transition moments of anthracene.

The electronic spectrum of (+)-**1** resembles that of anthracene; it exhibits the ^1L_a transition around 410—300 nm (ε 11200) with five peaks, the very strong ^1B_b transition at 267.2 nm (ε 268600) with an inflection around 250 nm, and the broad ^1C_b transition around 220 nm (ε 34200) (Fig. 3).

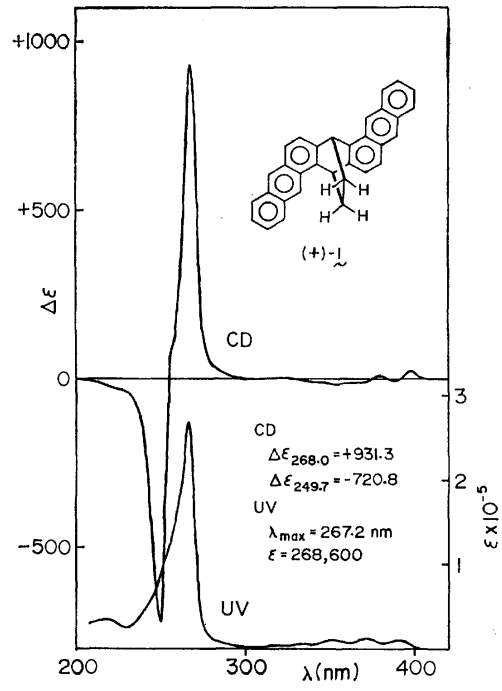

Fig. 3. CD and UV spectra of (6*R*,15*R*)-(+)-6,15-dihydro-6,15-ethanonaphtho[2,3-*c*]pentaphene (**1**) (see text for the solvent systems).

From these electronic properties and the rigidity of the molecular frame, it is obvious that the hydrocarbon **1** meets the requirements of the exciton chirality method: Namely, (i) the allowed ^1B_b transition of the component chromophore of **1**, *i.e.*, anthracene, exhibits a very strong ε value of the order of 10^5, (ii) the location of the present band around 260 nm is sufficiently separated from the weak ^1L_a and ^1L_b transitions around 400—300 nm and also from the ^1C_b transition so that the contribution of the weak absorption bands can be neglected, (iii) the polarization of the ^1B_b transition in anthracene is well established, (iv) because of the rigidity of the present cage compound **1**, the positive exciton chirality in space can be definitely determined, and (v) there is no direct conjugation between the two component chromophores, and the contribution of homoconjugation if any, is negligible[19] because of the large exciton dipole-dipole coupling term.

As expected, the circular dichroic spectrum of (+)-**1** clearly exhibits very strong positive first and negative second Cotton effects due to the coupling of the ^1B_b transitions ($\Delta\varepsilon_{268.0}=+931.3$, and $\Delta\varepsilon_{249.7}=-720.8$; $A(\Delta\varepsilon_1-\Delta\varepsilon_2)=+1652.1$) (Fig. 3). These Cotton effects are about one hundred times larger than those of common organic compounds.

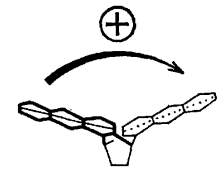

Fig. 4. Positive exciton chirality between the two axes of the anthracene moieties in hydrocarbon (+)-**1**.

Since the sign of the *A* value is positive, it is concluded that the hydrocarbon (+)-**1** has a positive exciton chirality, *i.e.*, a clockwise screwness, between the two long axes of the anthracene moieties, which corresponds to the (6*R*,15*R*) absolute stereochemistry in consistency with the X-ray data (Fig. 4). The present data thus not only determine the absolute configuration of (+)-**1** in a nonempirical manner, but also provide *definite evidence of the consistency between nonempirical circular dichroic and X-ray Bijvoet methods.*

In contrast to the case of intense absorption, the simple exciton coupling mechanism is not always applicable to the Cotton effects due to a weak absorption. For example, the ^1L_a transition of (+)-**1** exhibits weak and complicated Cotton effects around 400—300 nm, which are of positive sign at longer wavelength side and of negative sign at shorter wavelength side, in conflict with the signs expected from the negative exciton chirality between the two short axes of anthracene moieties (Fig. 3). It seems that the homoconjugation effect between the two chromophores and/or the mixing of the ^1L_a transition with the intense ^1B_b transition[20] make a dominant contribution to these weak Cotton effects.

A similar situation was observed for dialdehyde (+)-**8**; both the ^1L_b transition at 307.5 nm and the intramolecular charge transfer band at 252.5 nm exhibit only weak positive Cotton effects instead of split ones (Fig. 5). The circular dichroism of (+)-**10** also shows a simple pattern; two weak positive Cotton effects of the ^1L_b and intramolecular charge transfer bands and a negative one at 228 nm (Fig. 6). The small amplitude ($\Delta\varepsilon\simeq 10$) of these Cotton effects can be ascribed to the complicated polarization spectra of benzophenone chromophore[21] and to the conformational flexibility of the *o*-toluoyl group.

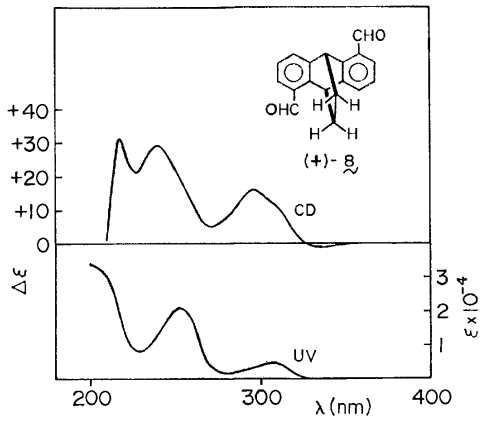

Fig. 5. CD and UV spectra of (+)-9,10-dihydro-9,10-ethanoanthracene-1,5-dicarbaldehyde (**8**)(see text for the solvent systems).

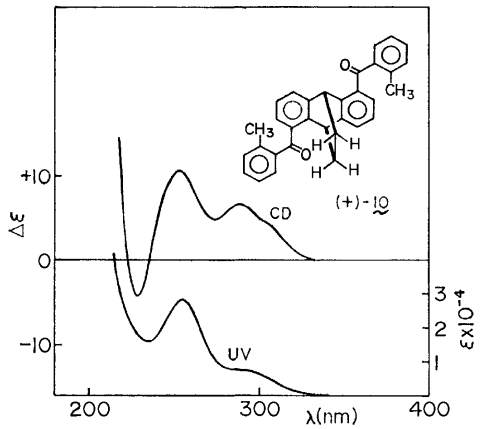

Fig. 6. CD and UV spectra of (+)-9,10-dihydro-9,10-ethanoanthracene-1,5-diylbis(*o*-tolyl)methanone (**10**) (see text for the solvent systems).

In contrast to (+)-**8** and (+)-**10**, quinone (+)-**12** exhibits relatively strong Cotton effects over 400—200 nm ($\Delta\varepsilon$ −44—+133) (Fig. 7). The polarization of the electronic transitions of 9,10-anthraquinone is established on the basis of the polarized phosphorescence spectrum;[22] the π-π^* transition (I) at 360—300 nm, the transition (II) at 300—260 nm, and the transition (III) at 260—240 nm are polarized along long, short, and long axes, respectively, of the chromophores. On the basis of the present polarization spectra, we have tentatively assigned the CD spectrum of (+)-**12** as follows: The positive Cotton effect at 360 nm and the negative one at 324 nm are attributable to the coupling of transition I, corresponding to the positive exciton chirality. In a similar way, the negative exciton coupling of transition II and the positive one of transition III give rise to the negative/positive and positive/negative Cotton effects, respectively, in which the two positive Cotton effects overlap each other at 260 nm. The present assignment is not definite because of the proximity of the two intense transitions II and III, and the weak intensity of transition I. It is difficult to determine the absolute stereochemistry of (+)-**10** based on the circular dichroic data.

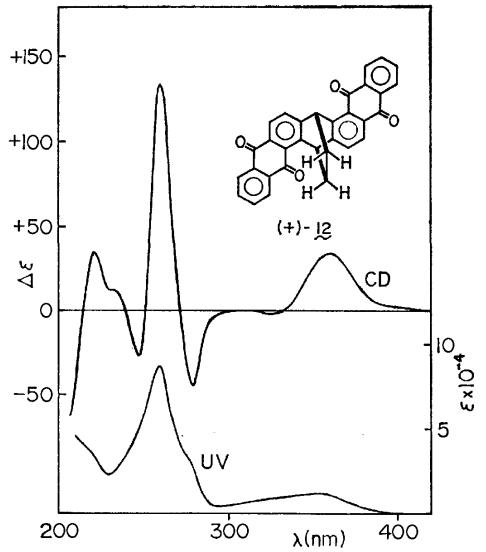

Fig. 7. CD and UV spectra of (+)-6,15-dihydro-6,15-ethanonaphtho[2,3-*c*]pentaphene-5,9,14,18-tetrone (**12**) (see text for the solvent systems).

As in the case of hydrocarbon (+)-**1**, the ^1B_b transition of polyacenes is ideal for the nonempirical determination of absolute stereochemistry on the basis of a chiral exciton coupling. On the other hand, the use of chromophores which exhibit weak transitions and/or complicated polarization spectra is undesirable for the present purpose. Therefore *one should choose a proper electronic transition of proper chromophores which satisfy the requirements of the exciton chirality method*, if one wish to determine absolute stereochemistry on sound grounds.

Experimental

General Procedures. Melting points are uncorrected. Spectral data were recorded on the following instruments: NMR, Jeol C-60HL, PMX60, and JNMPS-100 spectrometers; IR, Hitachi EPI-G2 infrared spectrophotometer; MS, Jeol JMS-01SG-2 mass spectrometer; UV, Hitachi EPS-3T spectrophotometer; CD, Jasco J-20 spectropolarimeter;optical rotations, Jasco DIP-4 and ORD/UV-5 spectropolarimeters.

The following CD data are those of the extrema and zero line interactions.

Elemental analyses were carried out in the microanalytical laboratories of our institute.

Both (+)- and (−)-dimethyl 9,10-dihydro-9,10-ethanoanthracene-1,5-dicarboxylate (6) were prepared according to the reported procedure;[10e] 9,10-dihydro-9,10-ethenoanthracene-1,5-dicarboxylic acid (**4**) was optically resolved with (−)-strychnine. The crystalline salt of (−)-**4** and (−)-strychnine was recrystallized four times from ethanol to afford a salt of constant rotation, $[\alpha]_D$ −305.1° (*c* 0.20059, pyridine). The optically pure salt was treated with 50% acetic acid to give (−)-diacid **4**, which was esterified by refluxing in methanol containing concd H_2SO_4, followed by recrystallization three times from methanol giving (−)-dimethyl 9,10-dihydro-9,10-ethenoanthracene-1,5-dicarboxylate (**5**) of constant rotation: mp 149.5—150.0°C; $[\alpha]_D$ −350.0° (*c* 0.30048, methanol), $[\alpha]_{405}$ −1016° (*c* 0.03100, methanol) (lit,[10e] mp 151.5—151.8 °C; $[\alpha]_{405}$ −1160° (*c* 0.00546, methanol)).

Catalytic hydrogenation of (−)-**5** over PtO_2 in tetrahydrofuran and recrystallization three times from methanol yielded

optically pure diester (−)-**6**: mp 121.0—121.5 °C; $[\alpha]_D$ −360.4° (*c* 0.30032, methanol), $[\alpha]_{405}$ −1064° (*c* 0.03055, methanol) (lit,[10e] mp 121.8—122.4 °C; $[\alpha]_{405}$ −1170° (*c* 0.00600, methanol)).

The mother liquor obtained after the first recrystallization of the strychnine salt of (±)-diacid **4** was evaporated to dryness. The residual crystalline salt was acidified and esterified in the same way as described for the (−)-diacid **4**, giving diester (+)-**5**: mp 147.5—148.0 °C from methanol; $[\alpha]_{405}$ +1000.1° (*c* 0.006344, methanol), optical purity 98.4% based on the rotation.

Catalytic hydrogenation of (+)-**5** and recrystallization four times from methanol afforded optically pure diester (+)-**6**: mp 120.0—120.5 °C; $[\alpha]_D$ +359.2° (*c* 0.30037, methanol).

Found: C, 74.59; H, 5.80%. Calcd for $C_{20}H_{18}O_4$: C, 74.52; H, 5.63%.

9,10-Dihydro-9,10-ethanoanthracene-1,5-dimethanol (7). A 7.0 % solution of sodium bis(2-methoxyethoxy)aluminumhydride in toluene (30.6 ml, 11.0 mmol) was added dropwise to a solution of 1.0 g (3.1 mmol) of diester (+)-**6** in 20 ml of dried benzene under ice-cooling. The ice bath was removed and the solution was stirred at room temp for 2.5 h. The reaction mixture was quenched with a minimum amount of water to precipitate hydroxides. After decantation of the supernatant, the precipitate was washed with ether, and the combined organic solution was dried over anhyd Na_2SO_4. Evaporation of the solvent gave a syrup of dimethanol **7** in a quantitative yield: IR($CHCl_3$) ν_{max} 3580, 3550—3090, 2990, 2940, 2850, 1460, 1435, 1380, 1140, 1000 cm^{-1}; NMR(100 MHz, $CDCl_3$) δ 1.64 (br s, 4H, ethane bridge), 2.60 (br s, 2H, hydroxy), 4.64 (br s, 6H, $-CH_2O-$ and bridgehead), 6.93—7.30 ppm (m, 6H, aromatic).

(+)-9,10-Dihydro-9,10-ethanoanthracene-1,5-dicarbaldehyde (8). A solution of 830 mg of dimethanol **7** in 150 ml of acetone was stirred overnight with 10.0 g of activated MnO_2 at room temp under nitrogen. The reaction mixture was filtered through celite, and MnO_2 was washed with acetone. The filtrate was evaporated to give 791 mg (97%) of crude crystalline dialdehyde (+)-**8**. Since dialdehyde **8** is air sensitive, the crude product was used for the next reaction without purification.

An analytical sample was obtained by recrystallization from ethanol, mp 128.0—129.5 °C; IR(KBr) ν_{max} 2960, 2925, 2850, 1670, 1580, 1460, 1440, 1405, 1240, 1140, 1060, 1030, 790, 770, 750, 730 cm^{-1}; NMR (100 MHz, $CDCl_3$) δ 1.79 (br s, 4H, ethane bridge), 5.75 (s, 2H, bridge head), 7.28 (t, J=7.5 Hz, 2H, aromatic meta to formyl), 7.57 (dd, J= 7.5, 2.0 Hz, 2H, aromatic para to formyl), 7.59 (dd, J= 7.5, 2.0 Hz, 2H, aromatic ortho to formyl), 10.28 ppm (s, 2H, formyl); $[\alpha]_D$ +487.3° (*c* 0.01026, $CHCl_3$); UV(EtOH) λ_{max} 307.5 (ε 4400), 252.5 nm (ε 20200); CD(EtOH) $\Delta\varepsilon_{335.0}=-1.1$, $\Delta\varepsilon_{328.0}=0.0$, $\Delta\varepsilon_{296.5}=+16.0$, $\Delta\varepsilon_{240.0}=+29.4$, $\Delta\varepsilon_{218.5}=+31.2$.

Found: C, 81.97; H, 5.46%. Calcd for $C_{18}H_{14}O_2$: C, 82.42; H, 5.38%.

9,10-Dihydro-α,α′-bis(o-tolyl)-9,10-ethanoanthracene-1,5-dimethanol (9). A solution of 4.245 g (24.8 mmol) of *o*-bromotoluene in 150 ml of ether was stirred overnight with 603 mg (24.8 mmol) of magnesium filings at room temp under nitrogen. To the greenish black solution of the Grignard reagent of *o*-tolylmagnesium bromide was added dropwise, over a period of 20 min, a solution of 781 mg (3.1 mmol) of dialdehyde (+)-**8** in 50 ml of abs ether. The reaction mixture was stirred for 4 h at room temp, then quenched by addition of wet ether. After addition of water to precipitate hydroxides and decantation of the supernatant, the precipitate was washed with ether and the combined ethereal solution was dried over anhyd Na_2SO_4. Evaporation of the solvent afforded 1.360 g (*ca.* 100%) of crude solid glycol **9**.

Thin layer chromatography of **9** on silica gel ($CHCl_3$–methanol 10: 1) showed partially overlapping three spots, which indicates that glycol **9** is a mixture of epimers (theoretically three epimers are possible). Product **9** was used for the next oxidation reaction, without separation of epimers.

(+)-9,10-Dihydro-9,10-ethanoanthracene-1,5-diylbis(o-tolyl)-methanone (10). To a cold solution of 1.360 g (6.1 mmol of hydroxyl group) of an epimeric mixture of **9** in 40 ml of acetone was added dropwise over 2 min, under ice-cooling, 1.52 ml of Jones reagent (6.1 mmol of oxygen equivalent; a standard solution made by dissolving 26.72 g of CrO_3 in 23 ml of concd H_2SO_4 diluted with water to a volume of 100 ml). The reaction mixture was stirred for 3 min. Addition of ethanol and water, extraction with ether, washing with water and brine, and evaporation of solvent gave 1.193 g of crystalline material, which was recrystallized from ethanol to yield 746 mg (56% from dialdehyde **8**) of diketone (+)-**10**: mp 151.0—152.5 °C from ethanol; IR(KBr) ν_{max} 1662, 1640, 1270, 758, 752, 740 cm^{-1}; NMR(60 MHz, $CDCl_3$) δ 1.72 (br s, 4H, ethane bridge), 2.46 (s, 6H, aromatic methyl), 4.95 (br s, 2H, bridgehead), 6.91—7.56 ppm (m, 14H, aromatic); $[\alpha]_D^{20}$ +177° (*c* 0.02032, ethanol); UV (EtOH) λ_{infl} 298 (ε 6800), λ_{max} 255.1 nm (ε 28200); CD (EtOH) $\Delta\varepsilon_{289.0}=+6.6$, $\Delta\varepsilon_{254.0}=+10.6$, $\Delta\varepsilon_{236.0}=0.0$, $\Delta\varepsilon_{228.0}=-4.1$, $\Delta\varepsilon_{222.5}=0.0$.

2,2′-(9,10-Dihydro-9,10-ethanoanthracene-1,5-diyldicarbonyl)-dibenzoic Acid (11a). A mixture of 231 mg (0.52 mmol) of diketone (+)-**10**, 30 ml of pyridine, 20 ml of 4% aq NaOH, and 4.0 g of $KMnO_4$ was gently refluxed for 2 h. Additional 20 ml of 4% aq NaOH and 4.0 g of $KMnO_4$ were added and the reaction mixture was refluxed for 3 h, during which the reaction was monitored by TLC on silica gel ($CHCl_3$–methanol 10: 1). After cooling to room temp, the reaction mixture was acidified with 6 M HCl, followed by addition of aq satd Na_2SO_3 solution in order to dissolve the brown precipitate of MnO_2. Extraction with ether, washing with brine, and evaporation of solvent afforded 253 mg (96%) of syrup, which was predominantly dibenzoic acid **11a**, contaminated with a small amount of monocarboxylic acid.

Dimethyl 2,2′-(9,10-Dihydro-9,10-ethanoanthracene-1,5-diyldicarbonyl)dibenzoate (11b). The crude dibenzoic acid **11a** (70 mg) was treated with ethereal diazomethane solution under ice-cooling and the reaction mixture was allowed to stand for 30 min. Evaporation of solvent gave 66 mg of syrup, which was subjected to preparative TLC (petroleum ether–ethyl acetate 10: 3) to yield 27 mg (56%) of pure dibenzoate **11b**: IR($CHCl_3$) ν_{max} 1724, 1663, 1282, 1138 cm^{-1}; NMR (100 MHz, $CDCl_3$) δ 1.81 (br s, 4H, ethane bridge), 3.53 (s, 6H, ester methyl), 5.43 (s, 2H, bridgehead), 6.95—7.13 (m, 4H, aromatic), 7.34—7.66 (m, 8H, aromatic), 7.85—8.02 ppm (m, 2H, aromatic).

By preparative TLC, a monoester product, methyl 2-(9,10-dihydro-5-*o*-toluoyl-9,10-ethanoanthracene-1-ylcarbonyl)-benzoate (**11c**) was isolated as a minor product: NMR (60 MHz, $CDCl_3$) δ 1.75 (br s, 4H, ethane bridge), 2.43 (s, 3H, aromatic methyl), 3.49 (s, 3H, ester methyl), 4.90 (br s, 1H, bridgehead 9-H), 5.40 (br s, 1H, bridgehead 10-H), 6.88—7.66 (m, 13H, aromatic), 7.76—7.97 ppm (m, 1H, aromatic).

(+)-6,15-Dihydro-6,15-ethanonaphtho[2,3-c]pentaphene-5,9,14,18-tetrone (12). A mixture of 253 mg of dibenzoic acid **11a** in 26 ml of polyphosphoric acid (prepared by dissolving 100 g of P_2O_5 in 100 ml of 85% H_3PO_4) was heated at 90 °C for 1.5 h under stirring. At the end of the reaction period, TLC on silica gel ($CHCl_3$–acetone 50: 1) revealed only one yellow spot with strong UV absorption. After cooling to room temp, the reaction mixture was poured into ice-water and extracted with ether. The ethereal solution was dried over anhyd

Na_2SO_4; evaporation of the solvent yielded 191 mg of crystals, which were purified by short column chromatography on silica gel giving 157 mg (64% yield from **10**) of quinone (+)-**12**: mp 268.0—268.5 °C from benzene–ether; IR(KBr) ν_{max} 1662, 1588, 1567, 1348, 1325, 1280, 1137, 988, 717 cm^{-1}; NMR (60 MHz, $CDCl_3$) δ 1.85 (br s, 4H, ethane bridge), 6.43 (br s, 2H, bridgehead), 7.53—7.76 (m, 6H, aromatic meta to carbonyl), 7.95—8.22 ppm (m, 6H, aromatic ortho to carbonyl); $[\alpha]_D^{20}$ +1000° (*c* 0.01009, 10% dioxane in ethanol); UV(0.47% dioxane in ethanol) λ_{max} 350.0 (ε 11100), λ_{infl} 278 (ε 30300), λ_{max} 259.2 nm (ε 86500); CD(1.0% dioxane in ethanol) $\Delta\varepsilon_{360}=+33.6$, $\Delta\varepsilon_{332}=0.0$, $\Delta\varepsilon_{324}=-2.1$, $\Delta\varepsilon_{308}=0.0$, $\Delta\varepsilon_{278.5}=-44.1$, $\Delta\varepsilon_{271}=0.0$, $\Delta\varepsilon_{260}=+133.4$, $\Delta\varepsilon_{251}=0.0$, $\Delta\varepsilon_{247}=-26.3$, $\Delta\varepsilon_{239}=0.0$, $\Delta\varepsilon_{232}=+12.3$, $\Delta\varepsilon_{221}=+34.2$, $\Delta\varepsilon_{214.5}=0.0$.

*(+)-6,15-Dihydro-6,15-ethanonaphtho[2,3-c]pentaphene (**1**).* To a solution of 76 mg of quinone (+)-**12** in 20 ml of benzene were added 4.0 g of activated zinc powder, 20 ml of 10% aq NaOH, and 0.5 ml of aq satd $CuSO_4$. The reaction mixture of a deep red color was refluxed under vigorous stirring for 10 h, during which the red color faded.

The reaction was monitored by TLC on silica gel ($CHCl_3$–acetic acid 5: 0.03). In this case, acetic acid in a developing solvent is important for catalyzing the dehydration of hydroxy intermediates which are more polar than the starting material **10**.

After cooling to room temp, zinc metal was filtered and washed with water and benzene. The combined filtrate was neutralized with acetic acid, followed by extraction with ether and evaporation of solvent to give 70 mg of a syrup. The remaining material was dissolved in 30 ml of chloroform containing 0.04 ml of acetic acid and gently refluxed for 3 h to complete the dehydration. The solvent was evaporated *in vacuo*, and the residual matter was subjected to preparative TLC on silica gel (petroleum ether–benzene 10: 3), giving 52 mg (78%) of a strong fluorecent hydrocarbon (+)-**1**. Attempts to carry out recrystallization from various solvents were unsuccessful. Instead, yellow solid masses were obtained from benzene–ethanol. Hydrocarbon **1** was characterized by the following spectral data: IR(KBr) ν_{max} 3040, 2955, 1615, 1150, 874, 740, 467 cm^{-1}; NMR(60 MHz, $CDCl_3$) δ 1.79 (br s, 4H, ethane bridge), 5.41 (br s, 2H, bridgehead), 6.89—8.07 (m, 12H, aromatic), 8.22 (s, 2H, 9-H and 18-H), 8.75 ppm (s, 2H, 5-H and 14-H); $[\alpha]_D$ +1157° (*c* 0.034, dioxane); UV 0.08% dioxane in ethanol) λ_{max} 391.0 (ε 9130), λ_{max} 371.2 (ε 11170), λ_{max} 352.7 (ε 8950), λ_{max} 267.2 (ε 268600), λ_{max} 219.5 nm (ε 34200); CD(0.18% dioxane in ethanol) $\Delta\varepsilon_{397.2}=+26.4$, $\Delta\varepsilon_{390.6}=0.0$, $\Delta\varepsilon_{388.1}=-2.3$, $\Delta\varepsilon_{384.9}=0.0$, $\Delta\varepsilon_{378.0}=+6.3$, $\Delta\varepsilon_{374.5}=0.0$, $\Delta\varepsilon_{370.0}=-9.7$, $\Delta\varepsilon_{362.9}=-9.7$, $\Delta\varepsilon_{352.8}=-14.5$, $\Delta\varepsilon_{330.5}=0.0$, $\Delta\varepsilon_{268.0}=+931.3$, $\Delta\varepsilon_{256.0}=0.0$, $\Delta\varepsilon_{249.7}=-720.8$; MS *m/e* (relative intensity), 406 (39, M^+), 378 (100, $M-C_2H_4$), 188 (29).

Found: *m/e* 406.1718. Calcd for $C_{32}H_{22}$: M, 406.1720.

The authors thank Dr. Hiroshi Hayashi, Asahi Chemicals Industry, Co., for measurements of the mass spectra. The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

The Cycloaddition of Dispiro[2.2.2.2]deca-4,9-diene with the Styrene Derivatives. The Syntheses and Spectral Properties of the [4.2]Paracyclophane Derivatives

Tohru SHIBATA, Takashi TSUJI, and Shinya NISHIDA

(Received March 8, 1977)

The thermal cycloaddition of dispiro[2.2.2.2]deca-4,9-diene **1** with the styrene derivatives has afforded [4.2]paracyclophane derivatives, **3**. A reaction mechanism by way of the biradical intermediates, involving the initial homolytic cleavage of the cyclopropane ring in **1** followed by the addition to the styrene molecule, is proposed. In the reaction of **1** with styrene, and methyl α-phenylacrylate, the yields of **3** were improved with the dilution of the reactants, while in the reaction with *trans*-stilbene, no appreciable dependence on the reactant concentration was observed. The mass spectra of the substituted [4.2]paracyclophanes show a predominant fragmentation to the substituted *p*-xylene-α,α'-diyl (or elements thereof) ion radical. [4.2]Paracyclophane exhibited a temperature-dependent NMR spectrum which could be ascribed to the rapid equilibration between two structurally equivalent conformers. Bulky substituents on C-1 and C-2 shifted the equilibrium to one side.

We have previously reported the thermal cycloaddition of dispiro[2.2.2.2]deca-4,9-diene **1**[1] with 1,3-butadiene derivatives, which afforded [8]paracycloph-4-enes by way of the biradical intermediate formed through the homolytic cleavage of the cyclopropane ring in **1**.[2] In the course of our continuing study of the cycloaddition reaction of **1**, we found that the thermal cycloaddition of the styrene derivatives, **2**, to **1** gave [4.2]paracyclophanes, **3**, in fair to good yields.[3] Although the chemistry of cyclophanes is currently a subject of considerable interest,[4] relatively few preparation methods of [4.2]-paracyclophanes are known.[5] The present reaction is experimentally simple and provides a convenient route to [4.2]paracyclophanes functionalized at C-1 and C-2. In this report we will describe the preparation and the spectral properties of [4.2]paracyclophane derivatives and will discuss the probable mechanism of this novel cycloaddition reaction.

Results and Discussion

Reaction of Dispiro[2.2.2.2]deca-4,9-diene 1 with the Styrene Derivatives, 2. A solution of **1** (0.16 M) and 1,1-diphenylethylene **2g** (0.37 M) in *t*-butyl alcohol was heated at 150—155 °C for 12 h under argon in a sealed glass ampoule. The subsequent separation of the reaction product by column and preparative gas chromatographies afforded 1-phenyl[4.2]paracyclophane **3g** as colorless crystals in a 67% yield. Analogously, the reaction of **1** with some related styrene derivatives, **2a—2f**, gave **3a—3f** respectively. The results are summarized in Table 1. Proof of the structures of those products was provided by the elemental analysis and their spectral properties. In the NMR spectra, the signals of the aromatic ring protons appeared at an unusually high field, δ 6.2—6.6, reflecting the shielding effect by the facing aromatic ring,[5b] and in the UV spectra, a bathochromic shift of λ_{max} to 282—283 nm and the disappearance of the fine structure were noted.[5a] The mass spectra of **3** showed prominent peaks which could be explained in terms of the predominant fragmentation to the *p*-xylene-α,α'-diyl (or methylenetropylium) ion radicals. These characteristics clearly show

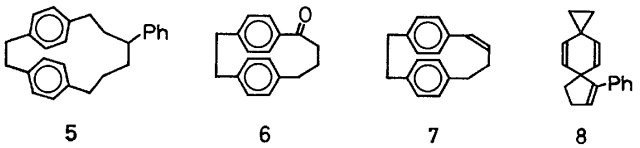
a) The spectra were taken in hexane unless otherwise noted. The shoulder was denoted as sh.
b) The ions of each spectrum were normalized to the spectrum's most intense ion set equal to 100. The spectra were taken at an ionizing voltage of 80 eV. c) Reported to be 74.4—75.0°C.[5b] d) The spectrum was taken in 95% ethanol. e) Reported to be 100—101°C.[5d]

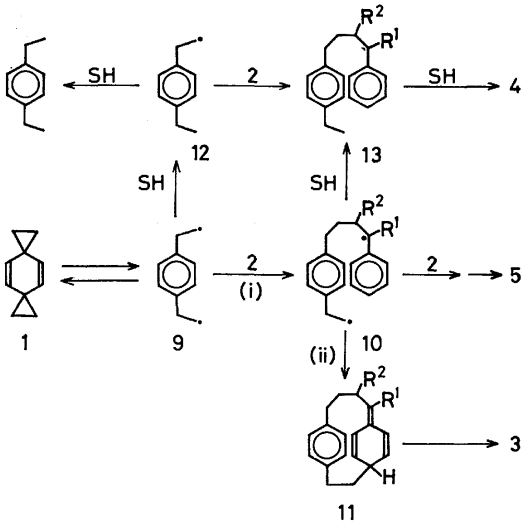
that the products, **3**, have a paracyclophane structure. The spectra and melting point of **3a** also agreed very well with those previously reported.[5a,b]

In the reaction of **1** with **2a**, besides the 1:1 cycloadduct, **3a**, an open-chain addition product, **4a** (0.7%), and a 1:2 cycloadduct, **5** (3.4%), were isolated from the reaction mixture. Open-chain adducts were also produced in the reactions of **2b** and **2f**. The reaction with **2c** proceeded rather anomalously and afforded [4.2]paracyclophan-1-one **6** as the most abundant product, together with **3c**. The alcohol obtained by the $NaBH_4$ reduction of **6** was identical in all respects with the hydrolysis product of **3c**. The application of the present reaction to the acetylenic compound was also examined. The reaction of **1** (0.20 M) with ethynylbenzene (0.40 M) in *t*-butyl alcohol at 160 °C, however, gave [4.2]paracycloph-1-ene, **7**, in only a low yield (2.3%) and was accompanied by the formation of a dispiro[2.2.4.2]dodecane derivative, **8** (13%).



5 6 7 8

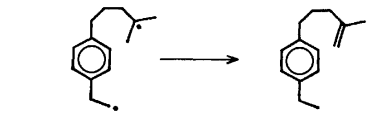
Mechanism. The present reaction may be explained by the pathway outlined in Scheme 1. We have previously demonstrated that the cyclopropane ring in **1** cleaves homolytically at an appreciable rate above 150 °C.[1,6] The biradical, **9**, thus generated reversibly from **1** adds to **2** to give **10**. The intramolecular coupling of the biradical, **10**, at the *p*-position of the benzylic radical moiety leads to the formation of **11** which subsequently rearranges to **3** under the present reaction conditions. Hydrogen abstraction by **9** and/or **10** would result in the formation of *p*-diethylbenzene and the open-chain adduct **4**. The addition of **10a** to another molecule of



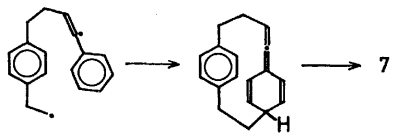
Scheme 1.

2a, followed by the ring closure, afforded **5**. The isomerization of 1-methylene-2,5-cyclohexadiene to toluene, which corresponds to the rearrangement of **11** to **3**, has been known to take place at the boiling point of diethyl ether.[7] Interestingly, the reaction of **1** with **2b** did not afford the intramolecular (formally at least) disproportionation product of the biradical intermediate, **10b**, in a detectable yield (<0.5%); this is in contrast to the reaction with isobutene, which gave **15** as the major product, probably *via* **14**.[8] These results imply that the cyclization of **10** at the *p*-position of the benzylic radical moiety is not hampered in the presence of such a potential hydrogen donor in the molecule.

The reaction of **1** with ethynylbenzene resulted in the formation of the dispiro compound, **8**, and the yield of the cyclophane, **7**, was low. In the reaction of **1** with **2**, no adducts with the dispiro[2.2.4.2]dodecane structure were isolated. The different behavior of the biradical, **16**, from that of **10** may be accounted for by the higher structural barrier imposed on the approach of the reaction sites in **16** to give **17** than in **10** to give **11** and/or a higher strain in the cyclized intermediate **17** than in **11**.



14 15



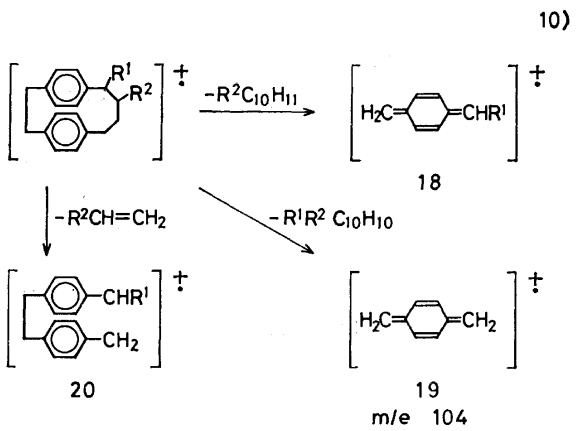
16 17

In the reaction of **1** with dimethyl *trans,trans*-2,4-hexadienoate, CIDNP has been observed in the cycloaddition product.[2b] Therefore, one may expect CIDNP in the reaction of **1** with **2** as well. The NMR spectrum recorded during the reaction of **1** and **2g** in biphenyl at 190 °C indeed showed CIDNP, and the characteristic signal of the aromatic protons in **3g**, shifted up-field, appeared as a weak emission substantiating the radical pathway of the reaction. The attempts to detect a signal which could be ascribed to the probable intermediate **11g** have, however, been fruitless thus far.

The addition of the biradical intermediate **9** to **2** is in competition with side reactions including the hydrogen abstraction to **12**, and, to give **3**, the resulting biradical **10** must collapse before side reactions including the addition to another molecule of **2** can take place. Therefore, the concentration of **2** should exert opposite effects on the yield of **3** at Steps (i) and (ii). with a few of the styrene derivatives, the effect of dilution on the yield of **3** was examined. In the reaction of **1** with **2e**, the yield of **3e** increased with the dilution of the reactants, and a similar trend was noted with **2a**. In the reaction with **2f**, however, no clear relationship between the yield of **3f** and the reactant concentration was observed. Since **2e** has a high reactivity toward the alkyl radical,[9] and since the addition of **9** would proceed efficiently even in a dilute solution, the dilution of the reactants might act favorably for the intramolecular cyclization of **10e**. In the case of **2f**, which has a relatively low reactivity, the opposite effects of the olefin concentration at Steps (i) and (ii) might balance. The reaction with **2a**, which very rapidly polymerizes, resulted in a low yield of **3a** probably because the addition of **10a** to another molecule of **2a** rather than the collapse to **11a** might predominate even in a dilute solution.

Although the reaction could be carried out in other solvents, such as benzene and hexane, *t*-butyl alcohol was used simply because of its low reactivity toward hydrogen abstraction. In benzene, the addition of **9** took place and 1-phenyl-2-*p*-tolylethane was formed, though in a small amount.

Mass Spectra of Substituted [4.2]Paracyclophanes. The mass spectra of [4.2]paracyclophane and its derivatives showed a fair generality in the fragmentation pattern and are in good accord with the assigned structures. In the spectrum of **3a**, the most intense peak occurred at *m/e* 104; its origin could be reasonably formulated by the cleavage at the benzylic positions to the *p*-xylene-α,α′-diyl (or methylenetropylium) ion radical, **19**.[10] The above fragmentation appeared common to the [4.2]paracyclophane derivatives. Thus, in the spectra of **3d** and **3f**, the most intense peak occurred at the same *m/e*, and, in those of 1-substituted derivatives, **3b**, **3c**, and **3g**, the fragment corresponding to the substituted *p*-xylene-α,α′-diyl[10] appeared as the base peak. In that of **3e**, the *p*-xylene-α,α′-diyl fragment ion peak was not the most intense, but it was still prominent. The appearance of the most intense peak at *m/e* 130 in the spectrum of **7**, which might be ascribed to **21**,[10] was also in line with the above fragmentation pattern.[11] The spectrum of **6** was distinct from the others and showed two dominant peaks, at *m/e* 117 (base peak) and 133, which could be explained by the cleavage at the ethano-bridge, followed by the McLafferty rearrangement.[12] Besides the above fragments characteristic peaks, though not intense, were observed at *m/e* corresponding to **20**[10] which demonstrated unambiguously the position of the substituent.



Thus, the mass spectrum provides a convenient tool for the structural analysis of [4.2]paracyclophane derivatives.

Temperature Dependence of NMR Spectrum and Conformation of 3. An examination of the NMR spectra of **3** provided information regarding the conformation. The parent [4.2]paracyclophane **3a** shows four peaks in the NMR spectrum at room temperature: two singlets at δ 6.45 (8H, aromatic protons) and 2.96 (4H, H-5, and H-6), and two relatively narrow multiplets at δ 2.22 (4H, H-1, and H-4) and 1.40 (4H, H-2, and H-3). Upon cooling, all the signals broadened from about −40 °C and resharpened again by −110 °C, accompanying the splitting of those signals into two sets of signals equal in intensity: the singlet at δ 6.45 into an AB quartet (J=8 Hz) centered at δ 6.55 and a singlet at δ 6.22, the singlet at δ 2.96 into an AA'BB' multiplet, the multiplet at δ 2.22 into a doublet of doublets (J=4 and 12 Hz) centered at δ 2.54 and a triplet (J=13 Hz) at δ 1.82, and the multiplet at δ 1.40 into two complex multiplets centered at δ 1.89 and 0.67. These observations may be explained in terms of the equilibration between two equally numerous conformers, **25a** and **26a**. A similar conformational equilibration has been invoked by Cram *et al.* to explain the temperature-dependent NMR spectrum of *cis*-2,3-diacetoxy[4.2]paracyclophane.[13] The signals observed at low temperatures can reasonably be assigned as is shown in Fig. 2, which indicates the shielding of Ha and Hd by 0.8 and 0.9 ppm respectively and the deshielding of Hc by 0.3 ppm, while there is no apparent shift of Hb compared with the corresponding protons in propylbenzene. An examination of the molecular models supports the above explanation and also reveals that R^1 in the **25** conformer is less sterically hindered than in **26** and that for R^2 the situation is the same.[14] The NMR spectrum of the 1-methyl derivative, **3b**, exhibited a similar temperature dependence and the characteristic doublet signal of the methyl protons split into two sets of doublets, 3: 1 in intensity, at δ 1.20 and 1.03 upon cooling; these sets of doublets might be ascribed to the conformers, **25b** and **26b**, respectively. More bulky substituents on C-1 and C-2 would displace the equilibrium to one side, and the chemical shifts of protons in the NMR spectra of **3d**—**g** can be explained reasonably on the basis of the **25d**—**g** conformers respectively. The coupling constants in **3d** and **3g** which have been determined thus far are also consistent with the above conformations.

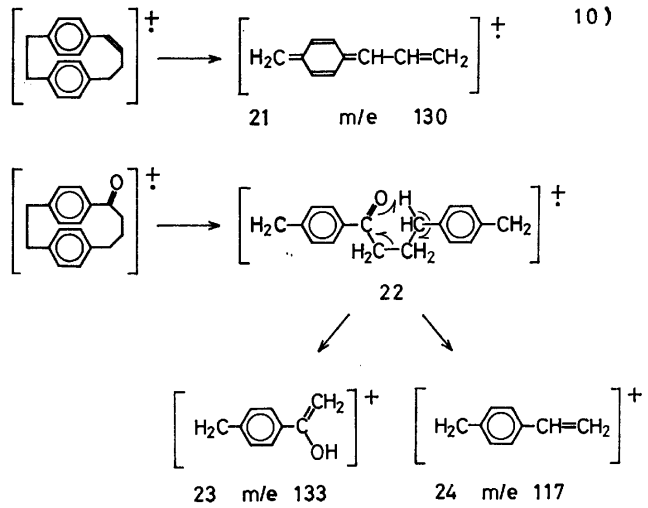
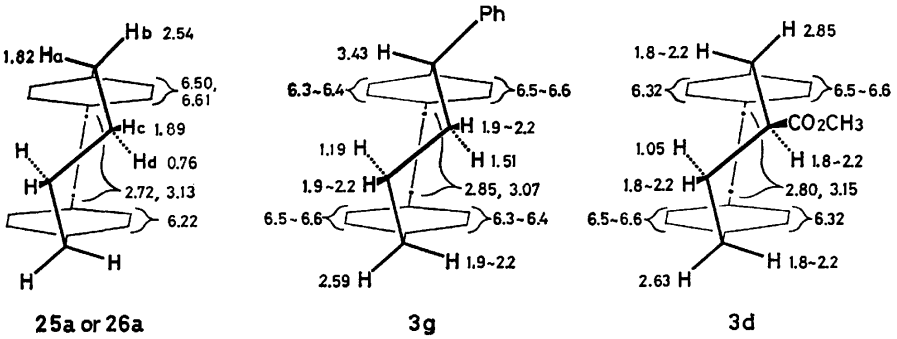
Fig. 1. Conformational equilibration in [4.2]paracyclophane derivatives.



Experimental

General. Melting points are corrected. NMR spectra were obtained with JEOL PS-100 and Hitachi R-24 spectrometers at 100 and 60 MHz respectively; chemical shifts are given in ppm from $Si(CH_3)_4$. IR spectra were taken on a Hitachi Model 215 grating spectrometer and are given in cm^{-1}. Mass spectra were recorded on a Hitachi Model RMU-6E spectrometer at an ionizing voltage of 80 eV; ions of each spectrum were normalized to the spectrum's most intense ion set equal to 100. UV spectra were taken on a



25a or 26a 3g 3d

Fig. 2. Chemical shifts in [4.2]paracyclophane derivatives. Chemical shifts in **25a** were obtained from the spectrum taken at *ca.* −115°C in CS_2 and those in **3d** and **3g** were obtained from the spectra at 23°C in CCl_4.

Cary Model 17 spectrophotometer and are given in nm. GLC work was done on a Hitachi Type 063 gas chromatograph with a thermal conductivity detector, using helium as a carrier gas. The following glass columns were used: A, 3% Apiezon Grease L on Celite 545, 3 mm×70 cm; B, 15% Apiezon Grease L on Celite 545, 3 mm×1 m; C, 20% Apiezon Grease L on Celite 545, 3 mm×1 m; D, 20% PEG phthalate on Celite 545, 4 mm×2 m; E, 20% Silicon DC-550 on Celite 545, 4 mm×1.5 m. Yields were calculated on the basis of **1** used in the reaction.

Materials. The preparation of dispiro[2.2.2.2]deca-4,9-diene **1** was carried out as has been described previously.[1] Styrene, α-methylstyrene, 1,1-diphenylethylene, and methyl cinnamate were obtained from commercial sources and were purified by fractional distillations. α-Trimethylsiloxystyrene was prepared by the method of House *et al.*[15] Methyl α-phenylacrylate was prepared following the procedure of Saquet and Thuillier.[16] *trans*-Stibene was obtained by the $NaBH_4$ reduction of desyl chloride.[17] Ethynylbenzene was prepared through the bromination and dehydrobromination of styrene.[18] *t*-Butyl alcohol was purified by fractional distillation from sodium.

*Reaction of **1** with Styrene **2a**.* A solution of 108 mg of **1** (0.82 mmol) and 345 μl of **2a** (3.0 mmol) in 80 ml of *t*-butyl alcohol was distributed among glass ampoules, bubbled with argon for 10 min, and heated at 160 °C for 10.5 h under argon (50 atm) in an autoclave. After the reaction, only a trace amount of **1** and *ca.* one fifth of the starting **2a** remained. The solvent was then removed and the residue was chromatographed on silica gel. Elution with a petroleum ether–benzene 5: 1 mixture produced an oil which was shown by GLC analysis to consist of one major and three minor components. Separation by preparative GLC (column C, 210 °C) geve 14.7 mg of [4.2]paracyclophane **3a** (7.6%) which when recrystallized from methanol had a mp of 71.0—72.0 °C (lit, 74.4—75.0 °C),[5b] 1.4 mg of **4a** (0.7%) and 3.3 mg of a mixture of two uncharacterized products. Elution with a petroleum ether–benzene 1: 1 mixture and separation by preparative GLC (column A, 210—230 °C) yielded three products in comparable amounts: 8.6, 9.4, and 4.1 mg . The second component was cheracterized as 3-phenyl[6.2]paracyclophane **5** (3.4%) on the basis of its physical properties. Further elutions with benzene and benzene–methanol produced only a polymeric, intractable material. **3a**, NMR (CS_2, 100 MHz): 1.40 (m, 4H), 2.22 (m, 4H), 2.96 (s, 4H), 6.45 (s, 8H). **4a**, NMR (CCl_4, 60 MHz): 1.17 (t, J=7.5 Hz, 3H), 1.4—1.7 (complex m, 4H), 2.2—2.7 (complex m, 8H), 6.90 (s, 4H), 7.02 (br s, 5H); mass: *m/e* 238 (M^+, 34), 131 (32), 120 (17), 119 (100), 117 (19), 115 (12), 105 (21), 104 (21), 92 (12), 91 (84), 78 (13), 77 (16), 65 (16), 41 (17). **5**,[19] NMR (CCl_4, 100 MHz): 0.9—2.6 (complex m, 11H), 3.00 (s, 4H), 6.2—6.7 (m, 8H), 6.9—7.3 (m, 5H); UV (hexane): λ_{max} (ε), 268 (1160), 282 (sh, 400); mass: *m/e* 341 (31), 340 (M^+, 100), 235 (15), 208 (30), 207 (99), 149 (15), 145 (10), 131 (45), 129 (13), 128 (11), 118 (16), 117 (85), 116 (14), 115 (34), 105 (21), 104 (47), 103 (15), 91 (88), 79 (10), 78 (14), 77 (14), 65 (19).

*Reaction of **1** with α-Methylstyrene **2b**.* From a reaction mixture of 133 mg of **1** (1.00 mmol) and 390 μl of **2b** (3.0 mmol) in 20 ml of *t*-butyl alcohol, the solvent was removed after heating at 155 °C for 12 h. Chromatography of the residue on silica gel, with petroleum ether–benzene (4: 1) elution, gave 183 mg of a mixture of four components, two of which were found by GLC analysis to be very minor (less than one hundredth of the major component in the peak area). The isolation of the two major products by preparative GLC (column D, 200 °C) afforded 115 mg of colorless crystals, **3b** (46%), which when recrystallized from methanol had a mp of 58.1—58.8 °C and 14.3 mg of **4b** (5.7%). Further elution with a petroleum ether–benzene 1: 1 mixture and benzene produced 65 mg of a viscous oil whose NMR spectrum indicated it to be a mixture of 1: 1 and 1: 2 adducts which have not yet been separated. **3b**, NMR (CS_2, 100 MHz): 0.9—1.7 (complex m containing d at 1.14, J=7 Hz, 7H), 1.9—2.5 (complex m, 3H), 2.96 (m, 4H), 6.37 (s, 4H), 6.47 (s, 2H), 6.56 (s, 2H). Found: C, 91.15; H, 8.78%. Calcd for $C_{19}H_{22}$: C, 91.14; H, 8.86%. **4b**, NMR (CCl_4, 100 MHz): 1.1—1.3 (t at 1.20, J=7.5 Hz, and d at 1.21, J=7 Hz, 6H), 1.3—1.7 (m, 4H), 2.4—2.8 (complex m, 5H), 6.93 (s, 4H), 6.9—7.3 (m, 5H);mass: *m/e* 252 (M^+,24), 119 (34), 117 (16), 115 (10), 106 (11), 105 (100), 104 (18), 103 (14), 91 (37), 79 (17), 78 (11), 77 (20). Found: C, 90.54; H, 9.58%. Calcd for $C_{19}H_{24}$: C, 90.41; H, 9.58%.

*Reaction of **1** with α-Trimethylsiloxystyrene **2c**.* A solution of 132 mg of **1** (1.00 mmol) and 416 mg of **2c** (2.0 mmol) in 10 ml of hexane was heated at 155 °C for 12 h under argon. The solvent was then removed and the residue was chromatographed on silica gel which had been dried at 150 °C under 1—2 Torr. Elution with dry benzene produced 183 mg of an oily complex mixture which has not been characterized. Further elution with dry benzene produced 21 mg of crystals which, when recrystallized from petroleum ether, gave 15 mg of analytically pure **3c** (4.4%), mp 82.0—82.8 °C. Elution with a chloroform–ethyl acetate 3: 1 mixture produced 70 mg of an oil which contained **6** and acetophenone. Dry air was bubbled in at 100 °C under 1—2 Torr to remove the acetophenone. The subsequent recrystallization of 33 mg of the crystalline residue from petroleum ether gave 18 mg of **6** (7.2 %, mp 104.4—106.8 °C) which, when recrystallized again from petroleum ether, had a mp of 107.3—108.0 °C. **3c**, NMR (CCl_4, 100 MHz): 0.04 (s, 9H), 1.0—1.8 (br s, 4H), 2.27 (br s, 2H), 3.01 (s, 4H), 4.44 (br s, 1H), 6.46 (m, 7H), 6.81 (d, J=8 Hz, 1H). **6**, NMR (CCl_4, 100 MHz): 2.04 (m, 2H), 2.60 (m, 4H), 2.97 (m, 4H), 6.27 (d, J=8 Hz, 2H), 6.45 (d, J=8 Hz, 2H), 6.52 (d, J=8 Hz, 2H), 6.96 (d, J=8 Hz, 2H); IR (KBr): 1665 (C=O). Found: C, 86.21; H, 7.20%. Calcd for $C_{18}H_{18}O$: C, 86.36; H, 7.25%.

*Reaction of **1** with Methyl Cinnamate **2d**.* A mixture of 64 mg of **1** (0.48 mmol) and 191 mg of **2d** (1.18 mmol) in 5.9 ml of *t*-butyl alcohol was placed in a glass ampoule and bubbled with argon. The ampoule was then sealed off and kept at 150 °C for 14 h. After concentration, the residual mixture was chromatographed on silica gel and eluted with benzene. The preparative GLC separation (column B, 220 °C) of the eluted mixture afforded 39.5 mg of **3d** (28%) which when recrystallized from methanol had a mp of 85.2—86.9 °C, besides 68 mg of unreacted **2d**. **3d**, NMR (CCl_4, 100MHz): 1.05 (t, J=13 Hz, 1H), 1.7—3.4 (complex m, 10H), 3.73 (s, 3H), 6.2—6.7 (m, 8H); IR (KBr): 1731 (C=O). Found: C, 81.62; H, 7.55%. Calcd for $C_{20}H_{22}O_2$: C, 81.60; H, 7.53%.

*Reaction of **1** with Methyl α-Phenylacrylate **2e**.* Following the procedure described for the reaction of **1** with **2d**, 103 mg of **3e** (43%) was obtained from the reaction of 108 mg of **1** (0.82 mmol) with 306 mg of **2e** (1.89 mmol) in 5 ml of *t*-butyl alcohol. **3e**, mp 70.6—71.7 °C; NMR (CCl_4, 100 MHz): 0.8—3.2 (complex m, 11H), 3.59 (s, 3H), 6.4—6.8 (m, 8H); IR (KBr): 1743 (C=O). Found: C, 81.57; H, 7.54%. Calcd for $C_{20}H_{22}O_2$: C, 81.60; H, 7.53%.

*Reaction of **1** with* trans-*Stilbene **2f**.* A mixture of 108 mg of **1** (0.82 mmol) and 336 mg of **2f** (1.87 mmol) in 10 ml of *t*-butyl alcohol was heated in a sealed glass ampoule at 150 °C for 14 h under argon. The solvent was then removed *in vacuo* and the partially crystallized, unreacted **2f** was filtered off from the residue. The oily residue was chromatographed on silica gel and eluted with a petroleum ether–benzene 4: 1 mixture to separate the reaction product from **2f**. The con-

centration of the fraction containing the reaction product afforded 48 mg of crystalline **3f** and an oily mixture, which was subjected to preparative GLC (column A, 220 °C) to yield 15.5 mg of **3f** (combined yield, 25%) and 10 mg of **4f** (3.9%). **3f**, mp 148.0—148.5 °C; NMR (CCl_4, 100 MHz): 1.40 (t, J= 12 Hz, 1H), 1.8—3.4 (m, 10H), 6.3—6.8 (m, 8H), 7.24 (s, 5H). Found: C, 92.12; H, 7.72%. Calcd for $C_{24}H_{24}$: C, 92.26; H, 7.74%. **4f**, NMR (CCl_4, 100 MHz): 1.23 (t, J= 7.5 Hz, 3H), 1.98 (m, 2H), 2.40 (m, 2H), 2.55 (quart, J=7.5 Hz, 2H), 2.7—3.0 (complex m, 3H), 6.8—7.3 (complex m, 14H); mass: *m/e* 314 (M^+, 9), 145 (15), 119 (100), 117 (13), 104 (24), 91 (43), 77 (10), 65 (10). Found: C, 91.61; H, 8.44%. Calcd for $C_{24}H_{26}$: C, 91.67; H, 8.33%.

Reaction of **1** *with 1,1-Diphenylethylene* **2g**. A mixture of 108 mg of **1** (0.82 mmol) and 330 μl of **2g** (1.87 mmol) in 5 ml of *t*-butyl alcohol was heated at 150—155 °C for 12 h as has been described above. The subsequent removal of the solvent and chromatography on silica gel with petroleum ether–benzene (4: 1) elution gave 138 mg of unreacted **2g** and then 176 mg of oil. A part of the latter, which was found on the GLC analysis to consist of one major and two minor components was subjected to preparative GLC (column A, 210 °C) and the major component was collected. The viscous oil thus obtained crystallized slowly on standing. The residual oil was seeded with the crystals obtained above to give 172 mg of **3g** (67%) which when recrystallized from ethanol had a mp of 70.8—71.8 °C. Further elution with benzene produced only a polymeric material (115 mg). **3g**, NMR (CCl_4, 100 MHz): 0.9—3.2 (complex m, 10H), 3.43 (d, J=10 Hz, 1H), 6.2—6.6 (m, 8H), 7.18 (s, 5H). Found: C, 92.36; H, 7.71%. Calcd for $C_{24}H_{24}$: C, 92.26; H, 7.74%.

1-Hydroxy[4.2]paracyclophane **3h**. The treatment of **3c** with methanol containing a trace amount of potassium hydroxide produced **3h** which when recrystallized from petroleum ether had a mp of 116.3—116.8 °C. The reduction of **6** with $NaBH_4$ in 2-propanol as usual gave **3h** (mp 115.5—117.0 °C), which showed no depression of the melting point on a mixed-melting-point measurement with the **3h** obtained above. **3h**, IR (KBr): 3340 (O–H), 1089 (C–O). Found: C, 85.58; H, 8.07%. Calcd for $C_{18}H_{20}O$: C, 85.67; H, 7.99%.

Reaction of **1** *with Ethynylbenzene*. A solution of 132 mg of **1** (1.00 mmol) and 220 μl of ethynylbenzene (*ca.* 2 mmol) in 5 ml of *t*-butyl alcohol was heated at 160 °C for 11 h. A GLC analysis of the reaction mixture showed that 71% of the ethynylbenzene was consumed. The solvent was removed and the residue was chromatographed on silica gel. Elution with petroleum ether produced unreacted ethynylbenzene. Further elution with petroleum ether–benzene 5: 1 and 3: 1 mixtures produced 81 mg of the product mixture. Preparative GLC (column B, 200 °C) afforded 29.9 mg of **8** (13%), 6.0 mg of an unidentified product, and 15.3 mg of a mixture which was again subjected to preparative GLC (column D, 210 °C) to give 5.4 mg of **7** (2.3%) which when recrystallized from methanol had a mp of 102.6—103.0 °C (lit, 100—101 °C).[5d] Further elution with benzene produced only a highly viscous polymeric oil (176 mg). **7**, NMR (CCl_4, 100 MHz): 2.2—3.1 (m, 8H), 5.3—5.8 (m, 1H), 6.0—6.8, (m, 9H).[5d] **8**, NMR (CCl_4, 100 MHz): 0.80 (s, 4H), 2.02 (t, J=7 Hz, 2H), 2.45 (t of d, J=2.5 and 7 Hz, 2H), 5.00 (d, J=10 Hz, 2H), 5.33 (d, J=10 Hz, 2H), 5.97 (t, J=2.5 Hz, 1H), 7.06 (m, 3H), 7.38 (m, 2H).

Effect of the Reactant Concentration on the Yield of **3e**. A solution of *ca.* 7 mg of **1** (0.05 mmol) and 16 μl of **2e** (each accurately weighed) in a specified volume of *t*-butyl alcohol was heated at 155 °C for 14 h in a sealed glass ampoule under argon. The solvent was then removed *in vacuo* and the residue was dissolved in 0.50 ml of benzene. The yield of **3e** was determined on GLC using triphenylethylene as the internal standard.

Run	**1** (mg)	*t*-BuOH (ml)	**1** (mol/l)	**2e** (mol/l)	Yield of **3e**(%)
1	6.6	3.0	0.017	0.033	78
2	6.9	1.0	0.052	0.10	61
3	6.6	0.33	0.15	0.30	59
4	7.4	0.11	0.51	0.90	35

Effect of the Reactant Concentration on the Yield of **3f**. A solution of *ca.* 10 mg of **1** and *ca.* 36 mg of **2f** in a specified volume of *t*-butyl alcohol was heated at 160 °C for 13.3 h as has been described above. The solvent was then removed *in vacuo* and the residue was dissolved in 1.00 ml of benzene. The yield of **3f** was calculated from the ratio of the peak area on GLC to that of the standard solution of **3f**.

Run	**1** (mg)	*t*-BuOH (ml)	**1** (mol/l)	**2f** (mol/l)	Yield of **3f**(%)
1	10.1	4.0	0.019	0.050	25
2	9.9	2.0	0.038	0.10	27
3	11.1	1.0	0.084	0.20	31
4	10.3	0.50	0.16	0.40	34
5	10.1	0.25	0.31	0.79	32

(Received December 13, 1976)

The formation mechanism of protonated molecular ions by cross-reactions in ethylene oxide–trioxane mixtures has been studied with use of a modified time-of-flight mass spectrometer. The precursors of the product ions were determined by analysis of the fine structure of their ionization efficiency curves using deuterated ethylene oxide. Protonated ethylene oxide is formed by the hydrogen atom transfer reaction of ethylene oxide molecular ion with trioxane, and protonated trioxane by the proton transfer reaction of CHO^+ (from ethylene oxide) with trioxane. In the ion-molecule reactions of ethylene-d_4 oxide–trioxane mixtures, appreciable isotope effect was observed. The CHO^+ from ethylene oxide is an important reactant ion as compared with that from trioxane in the proton transfer reaction, and CHO^+ from ethylene oxide was suggested as a thermal reactive ion. The order of proton affinity could be estimated from the proton transfer reactions involving CHO^+. It was found that the proton affinity of trioxane is smaller than that of ethylene oxide.

The ion-molecule reactions in trioxane (1,3,5-trioxane) and ethylene oxide have been studied in connection with an elementary process in radiation and ion chemistry.[1,2] In trioxane, consecutive-association reactions of protonated ions with trioxane were observed, but the reactions were not carried out in ethylene oxide. The results of the ion-molecule reactions could be correlated with the behavior of observed radiation-induced polymerization in which trioxane was easily polymerized,[3,4] appreciable polymerization taking place less easily in ethylene oxide.[5] On the other hand, protonated ethylene oxide was mainly formed by the proton transfer reaction from CHO^+ in ethylene oxide, CHO^+ from trioxane not playing an important role for the formation reaction of protonated trioxane.[1] It seems that the reactivity of CHO^+ in proton transfer reaction is attributed to the molecular source producing CHO^+. The proton transfer reaction due to CHO^+ would be affected by the property of neutral molecule. Futrell *et al.*[6] studied the effect of the kinetic energy of CHO^+ in proton transfer reactions with a tandem mass spectrometer, and stated that the reactivity of CHO^+ is affected by its energy state. Various oxygenated fragment ions are produced by electron impact from compounds containing oxygen. Since oxygenated ions giving the same structure are produced from various cyclic ether, it is of interest to examine the reactivity of these ions. The formation reaction of protonated molecular ions has been studied for alcohols,[7–9] ketones,[10–12] aldehydes,[11–13] and dimethyl ether,[11,12] but not for cyclic compounds containing oxygen. The ion-molecule reactions in pure system of ethylene oxide and trioxane have been studied.[1,2] The present work deals with the formation mechanism of the protonated molecular ions by cross-reactions (reactions between ions of one molecule and the molecules of the other) in ethylene oxide (or ethylene-d_4 oxide)–trioxane mixtures. The reactivity of the CHO^+ ions from both ethylene oxide and trioxane was examined by means of proton transfer reactions.

Experimental

A Bendix Model 12-101 time-of-flight mass spectrometer was used. A part of the spectrometer was modified in order to study ion-molecule reactions.[2] Some pulse electronic circuits of the apparatus were modified. A Hewlett Packard 214A pulse generator and a pulse generator (Sanwa Denshi Production Co., Ltd.) were used for suppling the ionizing and ion withdrawal pulses. A variable delay time circuit permitted a variation of the time between the end of the ionizing pulse and the onset of the ion withdrawal pulse.[2] During the delay time, the entire ionization chamber is field-free, so that ion-molecule reactions occurring during the time interval are under purely thermal conditions.

The retarding potential differential technique (RPD) was adopted for appearance potential and ionization efficiency curve measurement. A report has been given on the technique.[14] The measurement of the ionization efficiency curves of two ions was simultaneously performed by the two-channel ion detection method. The ion currents of two different ions were recorded with a Rikadenki R-34 three-pen recorder.

The gas-sample inlet-system consisting of a dual-leak and dual-reservoir was used. Two kinds of samples are introduced individually into the ionization chamber through two separate leaks from separate reservoirs (5L). The partial pressure of the two samples was indirectly measured with an MKS Baratron 90-X RP-2 capacitance manometer and the pressure was calibrated by known rate constant (1.11×10^{-9} cm^3 molecule^{-1} s^{-1}) of CH_5^+ in the ion-molecule reaction of methane.[15]

The following reagents were used: trioxane (Celanese Chemical), ethylene oxide (Nisso Yuka Industly Co., Ltd.), and ethylene-d_4 oxide (Merck Sharp and Dohme of Canada, deuterium atom purity, least 98%). The samples were used after being subjected to vacuum distillation several times.

Results and Discussion

Delay Time Dependence. The delay time dependence plots of fragment ions in a 1 : 1 mixture of ethylene oxide and trioxane are shown in Fig. 1. The plots were obtained as a function of delay time at ionization chamber pressure of 1.70×10^{13} molecules cm^{-3}. The *m/e* 44 ($C_2H_4O^+$), 43 ($C_2H_3O^+$), and 29 (CHO^+) are

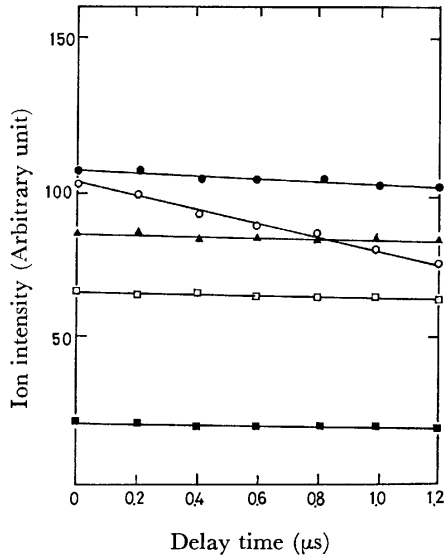

Fig. 1. Delay time dependence of fragment ions in ethylene oxide–trioxane mixtures.

□: $C_3H_5O_3^+$, ■: $C_2H_3O^+$.

major fragment ions from ethylene oxide, while *m/e* 89 ($C_3H_5O_3^+$), 61 ($C_2H_5O_2^+$), and a part of *m/e* 29 are those from trioxane.

The delay time dependence plots of product ions are shown in Fig. 2. The formation of protonated ethylene oxide (*m/e* 45, $C_2H_5O^+$) is remarkable as compared with protonated trioxane (*m/e* 91, $C_3H_7O_3^+$), the ion intensity ratio of $C_2H_5O^+$ to $C_3H_7O_3^+$ being *ca.* 5.5 at delay time of 1.0 μs.

The ion-molecule reactions in ethylene-d_4 oxide–trioxane mixtures were studied in order to clarify the formation mechanism of product ions under the same conditions as for ethylene oxide–trioxane mixtures. The plots of delay time dependence for fragment and isotopic product ions are shown in Figs. 3 and 4, respectively.

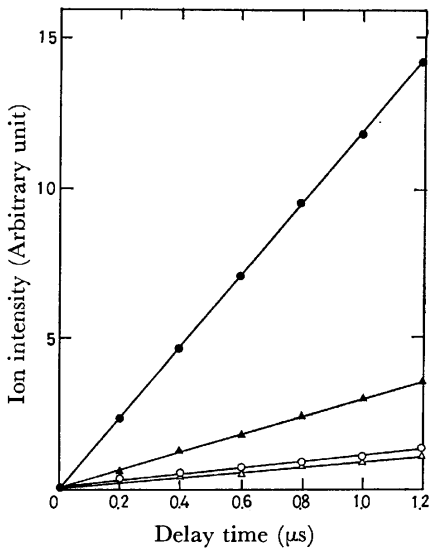

Fig. 4. Delay time dependence of protonated and deuteronated molecular ions in ethylene-d_4 oxide–trioxane mixtures.
●: $C_2D_4HO^+$ (×2), ▲: $C_2D_5O^+$ (×2), ○: $C_3H_7O_3^+$,
△: $C_3H_6DO_3^+$ (×5).

The CHO^+ ions from both molecules are separated into CHO^+ and CDO^+. The ions markedly decreased with increasing delay time as compared with other fragment ions of high mass number (Fig. 3). The cause of decrease is mainly due to a mass discrimination effect though there is a contribution of these ions to ion-molecule reactions. The isotopic distribution of product ions is given in Fig. 4. The *m/e* 49 ($C_2D_4HO^+$) and 50 ($C_2D_5O^+$) are protonated and deuteronated trioxane, respectively. The $C_2D_4HO^+$ and $C_3H_6DO_3^+$ ions are formed by cross-reactions and the $C_2D_5O^+$ and $C_3H_7O_3^+$ ions by homo-reactions. The ion intensity ratios of $C_2D_4HO^+$ to $C_2D_5O^+$, and $C_3H_6DO_3^+$ to C_3H_7-

●: $C_2H_5O^+$, ○: $C_3H_7O_3^+$.

O_3^+ are *ca.* 5 and 0.2 at delay time of 1.0 μs, suggesting that a drastic reaction occurs in the mixture system.

Pressure Dependence. The pressure dependence of the product ions on each molecule was examined in order to clarify the contribution of molecules of ethylene oxide and trioxane. The pressure dependence plots of the protonated molecular ions on the pressure of ethylene oxide, shown in Fig. 5, were obtained by the pressure variation of ethylene oxide at fixed pressure (8.5×10^{12} molecules cm^{-3}) of trioxane and delay time of 1.0 μs. Protonated ethylene oxide shows a dependence of *ca.* second order on the pressure of ethylene oxide, while protonated trioxane shows one of *ca.* first order. This suggests that the formation of protonated trioxane is correlated with ethylene oxide.

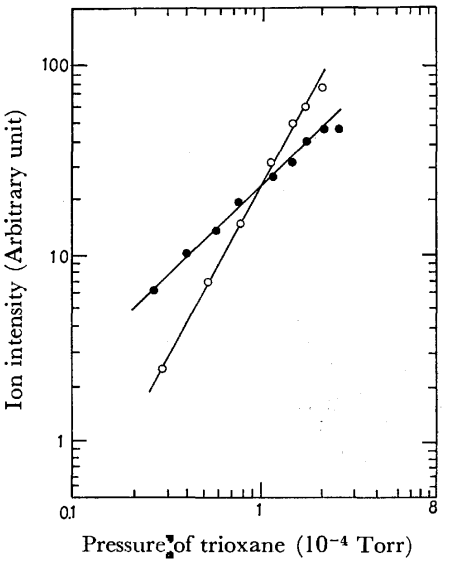

Fig. 6. Pressure dependence of protonated molecular ions to trioxane at delay time of 1.0 μs.
●: $C_2H_5O^+$, ○: $C_3H_7O_3^+$.

The pressure dependence plots of protonated molecular ions to trioxane at fixed pressure (8.5×10^{12} molecules cm^{-3}) of ethylene oxide are shown in Fig. 6. Protonated trioxane shows the dependence of second order on trioxane pressure and protonated ethylene oxide that of the first order on trioxane one. These results suggest that protonated ethylene oxide and trioxane are formed by means of proton or hydrogen atom transfer reactions.

Ionization Efficiency Curves. The ionization efficiency curves of fragment and product ions in ethylene-d_4 oxide–trioxane mixtures were measured at delay time of 1.0 μs. The ionization efficiency curves of $C_2D_4HO^+$, $C_2D_4O^+$, and $C_3H_5O_3^+$ are shown in Fig. 7, and those of $C_3H_6DO_3^+$, $C_2D_5O^+$, and CDO^+ in Fig. 8. The precursors of the product ions can be identified by comparison of the onset and fine structures of the curves of these product ions with those of fragment ions.

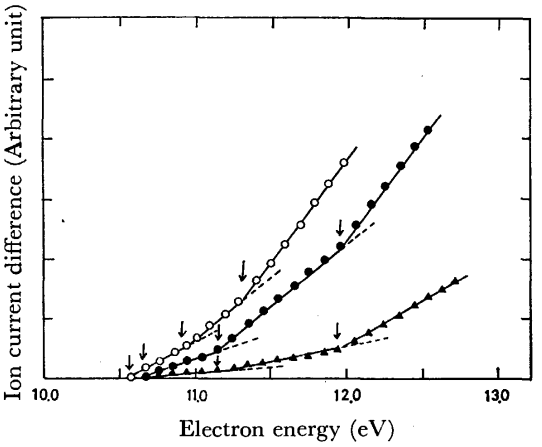

Fig. 7. Ionization efficiency curves of $C_2D_4O^+$(●), $C_2D_4HO^+$(▲), and $C_3H_5O_3^+$(○) in ethylene-d_4 oxide–trioxane mixtures.

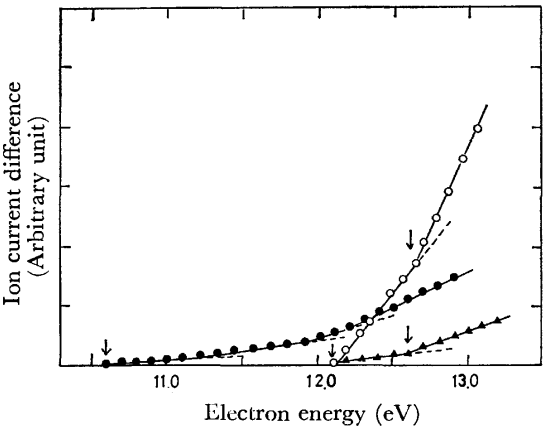

Fig. 8. Ionization efficiency curves of CDO^+(○), $C_2D_5O^+$(●), and $C_3H_6DO_3^+$(▲) in ethylene-d_4 oxide–trioxane mixtures.

The ionization potential of ethylene oxide and the appearance potential of $C_3H_5O_3^+$ from trioxane were 10.64 ± 0.1 and 10.59 ± 0.05 eV, respectively.[2,14] The onset and break points in the ionization efficiency curves of both $C_2D_4HO^+$ and $C_2D_4O^+$ agree. The onset of

$C_2D_4HO^+$ approached that of $C_3H_5O_3^+$; however, the fine structures of both curves differ from each other. The appearance potential of other fragment ions from trioxane is higher than that of $C_2D_4HO^+$.[14] The break points of the curve of $C_2D_4HO^+$ does not agree with the appearance potentials of these fragment ions. It is concluded that the precursor of $C_2D_4HO^+$ is $C_2D_4O^+$ and fragment ions from trioxane does not correlate as a precursor.

The onset of $C_3H_6DO_3^+$ agrees with that of CDO^+ and is higher than the ionization potential of $C_2D_4O^+$ by *ca.* 1.5 eV. The fine structures of the ionization efficiency curves of $C_3H_6DO_3^+$ and $C_2D_4O^+$ differ from each other. The appearance potentials of other fragment ions from ethylene oxide deviate from that of $C_3H_6DO_3^+$, and thus these ions do not contribute to the formation of $C_3H_6DO_3^+$. From the results, we see that the precursor of $C_3H_6DO_3^+$ is CDO^+ from ethylene-d_4 oxide.

Reaction Mechanism. It is found that a part of $C_2H_5O^+$ and $C_2D_5O^+$ is formed by the following reactions in ethylene oxide (or ethylene-d_4 oxide)–trioxane mixtures, as observed in the ion-molecule reactions in pure ethylene oxide.[2]

$$\underset{\backslash O /}{CH_2\text{–}CH_2^+} + \underset{\backslash O /}{CH_2\text{–}CH_2} \longrightarrow \underset{\backslash OH /}{CH_2\text{–}CH_2^+} + C_2H_3O, \quad (1)$$

$$CHO^+ + \underset{\backslash O /}{CH_2\text{–}CH_2} \longrightarrow \underset{\backslash OH /}{CH_2\text{–}CH_2^+} + CO, \quad (2)$$

$$\underset{\backslash O /}{CD_2\text{–}CD_2^+} + \underset{\backslash O /}{CD_2\text{–}CD_2} \longrightarrow \underset{\backslash OD /}{CD_2\text{–}CD_2^+} + C_2D_3O, \quad (3)$$

$$CDO^+ + \underset{\backslash O /}{CD_2\text{–}CD_2} \longrightarrow \underset{\backslash OD /}{CD_2\text{–}CD_2^+} + CO. \quad (4)$$

The ion intensity of $C_2D_4HO^+$ increases with increasing delay time (Fig. 4), and the appearance potential of this ion agrees with the ionization potential of ethylene-d_4 oxide (Fig. 7). Thus, it is suggested that $C_2D_4HO^+$ is formed by hydrogen atom transfer reaction as follows.

$$\underset{\backslash O /}{CD_2\text{–}CD_2^+} + \begin{array}{c} CH_2 \\ /\quad\backslash \\ O \quad O \\ | \quad | \\ CH_2 \quad CH_2 \\ \backslash\quad/ \\ O \end{array} \longrightarrow \underset{\backslash OH /}{CD_2\text{–}CD_2^+} + C_3H_5O_3. \quad (5)$$

This shows that predominant formation of $C_2H_5O^+$ in ethylene oxide–trioxane mixtures is due to Reaction 6 rather than Reactions 1 and 2.

$$\underset{\backslash O /}{CH_2\text{–}CH_2^+} + \begin{array}{c} CH_2 \\ /\quad\backslash \\ O \quad O \\ | \quad | \\ CH_2 \quad CH_2 \\ \backslash\quad/ \\ O \end{array} \longrightarrow \underset{\backslash OH /}{CH_2\text{–}CH_2^+} + C_3H_5O_3. \quad (6)$$

$C_3H_7O_3^+$ was formed by Reaction 7 in ion-molecule reactions of trioxane.[1]

$$C_3H_5O_3^+ + \begin{array}{c} CH_2 \\ /\quad\backslash \\ O \quad O \\ | \quad | \\ CH_2 \quad CH_2 \\ \backslash\quad/ \\ O \end{array} \longrightarrow \begin{array}{c} CH_2 \\ /\quad\backslash \\ O \quad OH^+ \\ | \quad | \\ CH_2 \quad CH_2 \\ \backslash\quad/ \\ O \end{array} + C_3H_4O_3. \quad (7)$$

It was observed that the ion intensity of $C_3H_6DO_3^+$ increases slightly with increasing delay time in ethylene-d_4 oxide–trioxane mixtures (Fig. 4). From the ionization efficiency curves (Figs. 7 and 8), it is concluded that $C_3H_6DO_3^+$ in ethylene-d_4 oxide–trioxane mixtures is formed by deuteron transfer from CDO^+ to trioxane molecule.

$$CDO^+ + \begin{array}{c} CH_2 \\ /\quad\backslash \\ O \quad O \\ | \quad | \\ CH_2 \quad CH_2 \\ \backslash\quad/ \\ O \end{array} \longrightarrow \begin{array}{c} CH_2 \\ /\quad\backslash \\ O \quad OD^+ \\ | \quad | \\ CH_2 \quad CH_2 \\ \backslash\quad/ \\ O \end{array} + CO. \quad (8)$$

In the ion-molecule reactions of ethylene oxide, CHO^+ was an important reactant ion in the formation reaction of protonated ethylene oxide.[2] CHO^+ is a proton donor ion. It follows that Reaction 8 predominates in the formation of $C_3H_6DO_3^+$. Similarly, Reaction 9 would participate in the formation of $C_3H_7O_3^+$ in ethylene oxide–trioxane mixtures.

$$CHO^+ + \begin{array}{c} CH_2 \\ /\quad\backslash \\ O \quad O \\ | \quad | \\ CH_2 \quad CH_2 \\ \backslash\quad/ \\ O \end{array} \longrightarrow \begin{array}{c} CH_2 \\ /\quad\backslash \\ O \quad OH^+ \\ | \quad | \\ CH_2 \quad CH_2 \\ \backslash\quad/ \\ O \end{array} + CO. \quad (9)$$

Rate Constants. In the calculation of the rate constant for $C_2H_5O^+$ formed in the mixture system, the ion intensities of $C_2H_4O^+$ and $C_2H_5O^+$ are corrected. The equation of rate constant (k_6) for Reaction 6 can be expressed as follows:

$$\frac{I_{C_2H_5O^+(M)} - I_{C_2H_5O^+(E)}}{I_{C_2H_4O^+(M)}} = k_6[C_3H_6O_3]t + C, \quad (10)$$

where $I_{C_2H_5O^+(M)}$ and $I_{C_2H_4O^+(M)}$ are the ion intensities of $C_2H_5O^+$ and $C_2H_4O^+$ in ethylene oxide–trioxane mixtures, respectively; $I_{C_2H_5O^+(E)}$ is the ion intensity of $C_2H_5O^+$ formed in the ion-molecule reactions of pure ethylene oxide;[2] $[C_3H_6O_3]$ is the concentration of trioxane in the ionization chamber, and t is delay time. The rate constants obtained are given in Table 1. The rate constants of the formation reactions of protonated and deuteronated molecular ions in ethylene oxide (or ethylene-d_4 oxide)–trioxane mixtures are summarized in Table 1.

Table 1. Rate constants

Ethylene oxide–trioxane		Ethylene-d_4 oxide–trioxane

(9)	0.121	(8)	0.101

a) Ref. 2.

Reactivity. The molecular ion from trioxane is unstable. Its ion intensity is relatively low, while that from ethylene oxide is high (Fig. 1). Thus, the reactivity of molecular ion from trioxane can not be discussed in comparison with that from ethylene oxide. On the other hand, it is of interest to examine the reactivity of the CHO^+ ions from both molecules. The CHO^+ from ethylene oxide participates preferentially for

proton transfer reaction as compared with that from trioxane in the mixture system. No contribution of CHO^+ for protonated trioxane has been observed in the ion-molecule reactions of trioxane.[1] A proton transfer reaction involving CHO^+ seems to be affected by its energy state. It was demonstrated that the energy of CHO^+ from trioxane is considerably higher than that of ethylene oxide in the measurement of the translational enrgies of the CHO^+ ions from oxygen-containing organic compounds.[16] It is suggested that CHO^+ from ethylene oxide is a thermal reactive ion as compared with that from trioxane.

Proton Affinity. The proton affinity of ethylene oxide has been reported to be 183 kcal mol^{-1}.[17,18] The proton affinity of trioxane is not known but the basicities for trioxane and ethylene oxide which correlate with their proton affinities have been found to be 10 and 7.3 respectively.[19] In this mixture system, the reactant, ions in Reactions 2 and 9 are CHO^+ from ethylene oxide, the rate constant ratio (k_2/k_9) being 17.3. This indicates that the proton affinity of ethylene oxide is larger than that of trioxane. The proton affinity of a molecule is defined as the enthalpy change for proton transfer reactions. A number of determinations of absolute proton affinity have been undertaken by the appearance potential method and an empirical correlation of excess energies in ion-molecule reactions.[18] The relative proton affinity was also studied from observation of ion-molecule reactions.[20-22] It is found that the order of relative proton affinity can be estimated using rate constant in proton transfer reaction involving CHO^+. The general scheme is as follows:

$$MH^+ + M_1 \longrightarrow M_1H^+ + M, \quad (11)$$

$$MH^+ + M_2 \longrightarrow M_2H^+ + M, \quad (12)$$

where the order of proton affinity (PA) for neutral molecule (M_1, M_2) is $PA(M_1) > PA(M_2)$, when the rate constant in both reactions is $k_{11} > k_{12}$. A proton donor ion such as CHO^+ which is a thermal energy ion is desirable for reactant ion (MH^+).

Isotope Effects. The difference of the rate constant in the proton and deuteron transfer reactions was observed (Table 1). The ratios k_1/k_3, k_2/k_4, and k_9/k_8 were 1.12, 1.15, and 1.20, respectively. The values of k_5 and k_6 were almost equal. Gupta *et al.*[23] studied the isotope effects in the ion-molecule reactions of water and methane. They reported that the ratio of the rate constant for proton (from OH^+) and deuteron transfer (from OD^+) is 2.10, and the ratio of the rate constant for the formation of CH_5^+ and CD_5^+ 1.49. Chong and Franklin[24] observed that the rate constants for the transfer of an H or a D atom are the same, but the rate constant of the transfer of D^+ is only *ca.* 0.62 times as great as that for an H^+ in ion-molecule reactions of methane–methane-d_4 mixtures. The isotope effect we observed is smaller than theirs.

The authors wish to express appreciation to Prof. K. Hayashi, Osaka University, and Dr. A. Ito and Mr. K. Arakawa of our Establishment for interesting and stimulating discussions.

Shock Tube Study on the Mechanism of Hydrogenation and Pyrolysis of Acetylene

Hiroo OGURA

Institute of Space and Aeronautical Science, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153

(Received January 27, 1977)

Mixtures of acetylene and deuterium have been subjected to shock heating in a single-pulse shock tube in the temperature range 1000—1600 K. The reaction products were quite the same as those obtained from the pyrolysis of acetylene alone, with a considerable increase in the yields of the minor products. The predominance of 1-buten-3-yne formation and no appreciable dependence of its rate on the concentration of deuterium suggest that the initiation step is the same as that proposed in the pyrolysis of acetylene by itself, *viz.* $2C_2H_2 \rightarrow C_4H_3+H$, the initiation step of the bimolecular reaction of C_2H_2 with D_2 not being important. A complementary analysis of the isotopic distributions of 1-buten-3-yne, ethylene, and acetylene shows that hydrogenation also occurs by a free-radical chain mechanism, and the C_4H_3 radical and H atom generated by the initiation step are mainly responsible for the formation of1-buten-3-yne and ethylene, respectively. The ethylene formation was of first-order in both acetylene and deuterium, and the second-order rate constant was obtained as

$$k(\mathrm{cm^3\ mol^{-1}\ s^{-1}}) = (4.9\pm1.3)\times10^{11}\exp((-34900\pm600)/RT).$$

The hydrogenation of acetylene has been studied by several investigators.[1-6] Skinner and co-workers aimed at clarifying the pyrolysis of ethylene.[2,3] Benson and Haugen, in an attempt to estimate the elementary reaction rate constants of radical reactions which might participate in the pyrolysis of the unsaturated hydrocarbons,[4] made a kinetic analysis of the hydrogenation of acetylene, and concluded that a free-radical chain mechanism should predominate. Skinner *et al.* showed that C_2H_3D is the most abundant among the ethylene isomers produced in the shock heated mixture of acetylene and deuterium. The result is in line with the prediction from the free-radical chain mechanism proposed by Benson and Haugen. In their scheme the chain propagation is initiated by the bimolecular reaction of acetylene and deuterium, $C_2H_2+D_2 \rightarrow C_2H_2D+D$.

On the other hand, the effects of added hydrogen on the yields of the pyrolysis products were extensively examined in static and flow systems.[7-10] It was shown that the addition of hydrogen has little influence on the yields of the major products of the pyrolysis.

The pyrolysis of acetylene proceeds *via* the free-radical chain mechanism initiated by the bimolecular reaction of acetylene,[11] $2C_2H_2 \rightarrow C_4H_3+H$. The H atom produced by the initiation step can lead to the formation of ethylene as well as 1-buten-3-yne in the presence of hydrogen. When deuterium instead of hydrogen is added, the product distribution and isotopic distribution can be utilized for clarifying the mechanisms of the pyrolysis and hydrogenation of acetylene.

Experimental

Apparatus and Procedure. The hydrogenation and pyrolysis of acetylene in the presence of deuterium was studied in a 4-cm single-pulse shock tube, the length of the driven section being 277 cm long, and that of the driver section adjustable but fixed at 157 cm. The design and operation of the shock tube were reported previously.[11,12]

The driver section was isolated from the pump when the vacuum of the tube reached below 10^{-3} Torr, and then filled with the driver gas at about 2 atm of pressure in order to optimize the rupture of the diaphragms by the needle. The driven section was further pumped to a vacuum better than 10^{-4} Torr before each run. The leak plus outgassing rate was measured by a cathode ionization gauge immediately after the isolation of the tube from the pump, 6×10^{-5} Torr per minute being obtained. Helium was used as the driver gas. The shocks were fired within 5 min after the driven section had been filled with test gases.

Materials. Three different mixtures with the composition of $C_2H_2/D_2/Ar = 10/10/80$; 5/10/85; and 10/5/85 were prepared in a 5-l glass vessel and allowed to stand for at least one day before use.

Acetylene(Matheson Co.) was washed with concd sulforic acid and dried through a soda lime tower and then purified by bulb-to-bulb vacuum distillation. Deuterium (Showa Denko Co., 99.5% D atom) and argon (Nippon Sanso Co., nominal purity of 99.9995%) were used without further purification.

A variety of pure gas mixtures with the desired concentrations were prepared for the calibration of the gas chromatography. Argon was also used as the diluent.

1-Buten-3-yne and 1,3-butadiyne synthesized in a pyrolysis experiment were used. The other pure gases (Takachiho Shoji Co., research grade) were used as received.

Analytical. The shock heated sample was introduced into 60-ml volume bulb, and analyzed by gas chromatography. Details of the gas chromatographic analysis were reported.[11]

The isotopic distributions of acetylene, 1-buten-3-yne, and ethylene were determined with a Hitachi Model RM-50 mass spectrometer. Acetylene and ethylene were separated on a 3 mm×2 m Porapak T column at 50 °C with helium as the carrier. Each gas component was collected in a trap cooled by liquid nitrogen. The cooled trap was then evacuated for several minutes to remove the carrier gas and contaminants, especially nitrogen and oxygen.

For the measurement of mass spectra of ethylene isomers, the ionization potential was maintained at *ca.* 12 eV to simplify the fragmentation patterns, in which only the parent peaks of the isomers appeared in the mass spectra. The influence of nitrogen and oxygen on $m/e=28$ and 32 in the mass spectra, respectively, can be neglected at a low ionization potential. The mass spectra of 1-buten-3-yne and acetylene isomers were measured at an ionization potential of 50 eV. The method of mass spectral analyses for acetylene and 1-buten-3-yne isomers was described elsewhere.

Results

Three mixtures were heated behind the reflected shock waves in the temperature range 1000—1600 K. The total densities behind the reflected shock waves were maintained within $(2.35\pm0.11)\times10^{-5}$ mol/cm^3, which were the same as those in the pyrolysis experiment in the absence of deuterium.

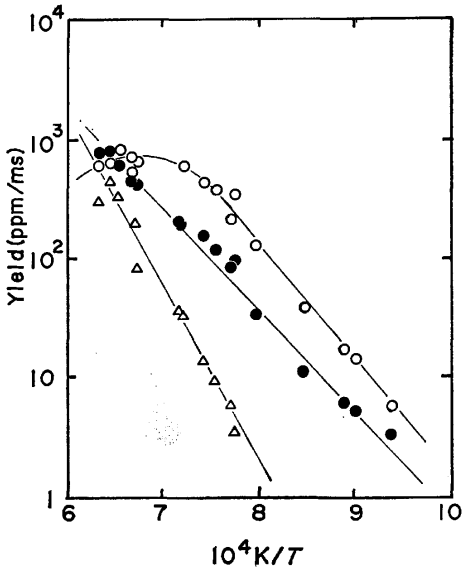

Fig. 1. Major product distribution as a function of temperature($C_2H_2/D_2/Ar=5/10/85$).
○; 1-Buten-3-yne, ●; ethylene, △; 1,3-butadiyne.

Major Products. The shock heated gas samples were analyzed by gas chromatography. The analytical results in the case of the mixture with the ratio of $C_2H_2/D_2/Ar$ equal to 5/10/85 are shown in Fig. 1. The major products were 1-buten-3-yne, ethylene, and 1,3-butadiyne in the decreasing order of amount, 1-buten-3-yne and 1,3-butadiyne being the major products of the pyrolysis of acetylene by itself. This indicates that under the present experimental conditions the hydrogenation of acetylene occurs simultaneously with the pyrolysis of acetylene, and in the temperature range up to 1400 K the formation of 1-buten-3-yne dominates that of ethylene.

1-Buten-3-yne and 1,3-Butadiyne: As shown in Fig. 1, the yields of 1-buten-3-yne and 1,3-butadiyne as a function of temperature are similar to those of the pyrolysis in the absence of deuterium. The concentration of 1-buten-3-yne also reaches maximum at *ca.* 1500 K.

The effects of added deuterium on the production of 1-buten-3-yne and 1,3-butadiyne for the three mixtures are shown in Figs. 2 and 3, respectively. We see that the yields of 1-buten-3-yne and 1,3-butadiyne seem to be entirely dependent on the initial acetylene concentration, and are little affected by that of deuterium. The rate (yield expressed in ppm/ms) of 1-buten-3-yne formation is approximately of second-order with respect to acetylene, which is the same as that in the C_2H_2–Ar system. The second-order rate expression fits the

a) T_5 is the temperature behind the reflected shock wave. b), c) The total amounts of 1-buten-3-yne and acetylene are taken to be equal to 1.000. d) Total yield of 1-buten-3-yne isomers expressed in ppm/ms. e) τ is the dwell time. f) Composition of the mixture. g) Undetectable. h) Deuterated 1-buten-3-ynes are not detected at 1290 and 1340 K in the mixture of $C_2H_2/D_2=10/5$.

analyses of the 1-buten-3-ynes together with the acetylenes were carried out for several samples taken out of the three mixtures. The results are summarized in Table 1. No appreciable amount of deuterium-substituted 1-buten-3-ynes is formed at lower temperatures. No detectable amount of deuterated 1-buten-3-ynes is observed in the case of the mixture with the composition $C_2H_2/D_2/Ar=10/5/85$. The effect of added deuterium (hydrogen) on the formation of 1-buten-3-yne is small.

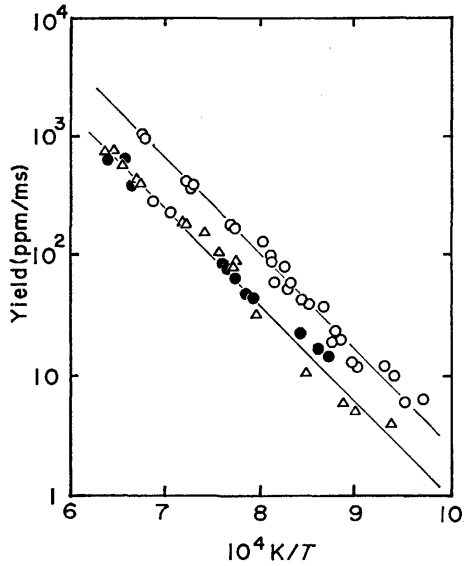

Fig. 4. Concentration dependence of the ethylene formation.

Ethylene: Although the formation of ethylene was not the predominant reaction under the present experimental conditions, the yield of ethylene remarkably increased in the presence of deuterium.

The yield of ethylene is plotted against the reciprocal of the reaction temperature in Fig. 4. The dependence of the rate on the concentrations of acetylene and deuterium is approximately equal, being approximately of first-order with respect to acetylene and deuterium. Assuming that the rate equation has the form $d[\text{total ethylene}]/dt=k_2[C_2H_2][D_2]$, the second-order rate constant was obtained by the least-squares method:

$$k_2(\text{cm}^3\ \text{mol}^{-1}\ \text{s}^{-1}) = (4.9\pm1.3)\times10^{11} \times \exp((-34900\pm600)/RT). \quad (2)$$

The isotopic distribution of ethylene was determined by mass spectrometry for several samples out of the shock heated mixture of 10% C_2H_2 and 10% D_2 in argon. The results of the mass spectral analyses are given in Table 2. We see that C_2H_3D is the most abundant species among the ethylene isomers. Considerable amounts of $C_2H_2D_2$ and C_2H_4 are produced.

Minor Products. Methane, ethane, allene, propyne, and 1,3-butadiene were detected as minor products. Although all of them are observed in the pyrolysis of acetylene alone, their yields as a function of temperature differ from those in the case of the C_2H_2–Ar system. The yields, especially that of 1,3-butadiene, considerably increased in the presence of deuterium.

The influence of the addition of deuterium to acetylene system on the yields of 1,3-butadiene and methane is shown in Figs. 5 and 6, respectively. The yields of 1,3-butadiene and methane are dependent on both acetylene and deuterium concentrations, those of allene and propyne showing a similar dependence on concentration. This distinct dependence of the minor product yields on the deuterium concentration suggests that they are

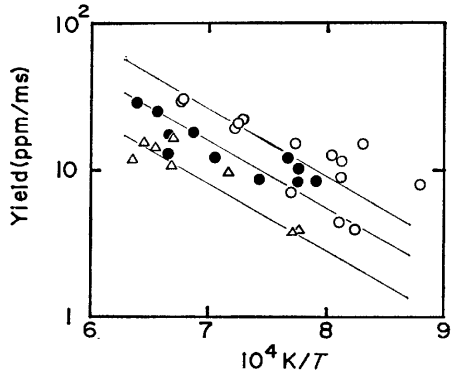

Fig. 5. Effect of deuterium on the 1,3-butadiene formation.

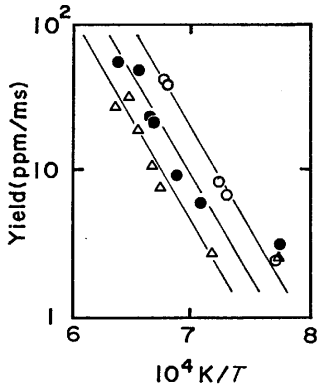

Fig. 6. Effect of deuterium on the methane formation.
○; $C_2H_2/D_2/Ar=10/10/80$, △; $C_2H_2/D_2/Ar=5/10/85$, ●; $C_2H_2/D_2/Ar=10/5/85$.

formed by different paths from those in the C_2H_2–Ar system. Thus the direct participation of deuterium in their formation reactions appears evident.

Discussion

Mechanism of Ethylene and 1-Buten-3-yne Formation. The formation of 1-buten-3-yne was the predominant reaction, the shape of the yield-temperature plots for 1-buten-3-yne not being affected by the addition of deuterium. The dependence of rate on the concentration of acetylene was the same as that observed in the pyrolysis of acetylene by itself, deuterium being a negligible effect on the production rate of 1-buten-3-yne. This suggests that the mechanism of 1-buten-3-yne formation is the same as that proposed for the pyrolysis of acetylene in the C_2H_2–Ar system. The scheme is represented as follows:[11]

$$2C_2H_2 \longrightarrow C_4H_3 + H, \quad (3)$$

$$H + C_2H_2 \longrightarrow C_2H_3, \quad (4)$$

$$C_2H_3 + C_2H_2 \longrightarrow C_4H_4 + H, \quad (5)$$

$$C_4H_3 + C_2H_2 \longrightarrow C_6H_5, \quad (6)$$

$$C_6H_5 + C_2H_2 \longrightarrow C_4H_4 + C_4H_3. \quad (7)$$

The yield of ethylene increases markedly in the presence of deuterium. If the addition of deuterium to acetylene occurred by a molecular mechanism, $C_2H_2D_2$ would be expected primarily among the ethylene isomers. However, actually C_2H_3D was produced in a large amount. The isotopic distribution obtained in the present analysis is in line with that obtained by Skinner *et al.*,[3] who supported a free-radical chain mechanism for the formation of ethylene.

In the temperature range up to 1400 K, the formation of 1-buten-3-yne is predominant. The initiation step for the formation of ethylene is expected to be the same as that for the production of 1-buten-3-yne. In the above mechanism, Reactions 3 and 4 should be responsible for the formation of ethylene. The scheme of ethylene production is thus completed by the following reactions:

$$C_2H_3 + H_2 \longrightarrow C_2H_4 + H, \quad (8)$$

$$2C_2H_3 \longrightarrow C_4H_6, \quad (9)$$

$$H + C_2H_3 \longrightarrow C_2H_4. \quad (10)$$

The recombination of H atoms with argon as a third body is a relatively slow process and could be neglected. For the sake of simplicity, hydrogen, instead of deuterium, is considered, only bimolecular recombination reactions being taken into account in Reactions 9 and10.

Against the initiation Reaction 3, an alternative initiation step was proposed for the hydrogenation of acetylene:[4]

$$C_2H_2 + H_2 \longrightarrow C_2H_3 + H. \quad (11)$$

Reactions 3 and 11 would compete with each other. When Reaction 11 becomes predominant in the C_2H_2–H_2 system, 1-buten-3-yne should be formed by the subsequent Reactions 4 and 5. Assuming steady-state concentrations of H atom and C_2H_3 radical in the above mechanism with the termination of Reaction 9, the steady-state rate of 1-buten-3-yne formation is given by

$$d[C_4H_4]/dt = k_5(k_{11}/k_9)^{1/2}[C_2H_2]^{3/2}[H_2]^{1/2}. \quad (12)$$

The same concentration dependence of the rate of 1-buten-3-yne generation is also derived in the case of the termination of Reaction 10. Equation 12 shows that the yield of 1-buten-3-yne in the C_2H_2–H_2 system should be dependent on the concentration of hydrogen, which is in conflict with the observed dependence on the concentration of deuterium.

Another support for the insignificance of Reaction 11 may be presented by the estimation of the rate constants of Reactions 3 and 11. The adopted rate constant[13] was $k_{-3}=k_{-11}(\mathrm{cm^3\ mol^{-1}\ s^{-1}})=2\times10^{13}$. The approximate rate constant of the forward Reaction 3 was estimated to be[11]

$$k_3(\mathrm{cm^3\ mol^{-1}\ s^{-1}}) = 3.5\times10^{13}\exp(-47400/RT). \quad (13)$$

In the estimation of the equilibrium constant of Reaction 11, the heat of formation of 59.6 kcal/mol[14] is used for C_2H_3 radical, the enthalpy and entropy being the same as those evaluated by Benson.[15] The approximate rate constant of forward Reaction 11 is given by

$$k_{11}(\mathrm{cm^3\ mol^{-1}\ s^{-1}}) = 8\times10^{13}\exp(-56400/RT). \quad (14)$$

The estimated k_{11} is about two and one order of magnitude smaller than k_3 at 1000 and 1600 K, respectively.

Reaction 11 is not likely to occur as the primary initiation step for the pyrolysis and hydrogenation of acetylene in the C_2H_2–$H_2(D_2)$ system.

As regards the role of C_4H_3 radical and H atom in the pyrolysis, previously we could not determine the relative importance of C_4H_3 radical and H atom, since the kinetic behavior of the propagation steps initiated by C_4H_3 radical and H atom was expected to be similar, but we have obtained more data which may be useful to determine the relative importance of the above two radicals in the pyrolysis of acetylene.

Although the total yield of 1-buten-3-yne was little affected by the addition of deuterium, appreciable amounts of deuterated 1-buten-3-ynes were produced in the C_2H_2–D_2 system. Thus the isotopic distribution of 1-buten-3-yne together with those of ethylene and acetylene could be utilized for testing formation reactions of deuterated 1-buten-3-ynes, especially 1-buten-3-yne-d_1, the most abundant species among the deuterated isomers. The formation of 1-buten-3-yne and ethylene isomers in the C_2H_2–D_2 system seems complicated, a schematic reaction diagram being shown in Fig. 7.

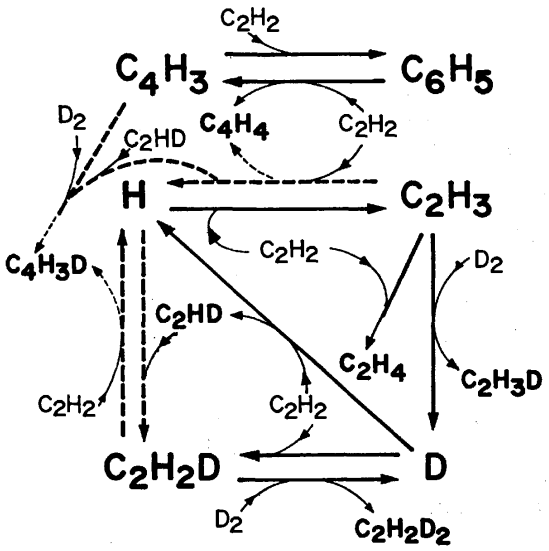

Fig. 7. Schematic reaction diagram for the major product formation in the C_2H_2–D_2 system. Solid line represents the reaction which is responsible for the formation of the relevant product, and broken line denotes ineffective reaction.

First the chain propagation step initiated by H atom, Reactions 4 and 5, will be considered. A considerable amount of C_2HD is produced, which may result from the H–D exchange reaction between C_2H_2 and D_2 (Table 1). The C_2HD in a considerable amount as well as C_2H_2 might participate in the formation of 1-buten-3-yne-d_1. If C_4H_3D were mainly formed by the reaction of C_2HD with the radicals, as an example, with C_2H_3 radical;

$$C_2H_3 + C_2HD \longrightarrow C_4H_3D + H, \quad (15)$$

the ratio of $[C_4H_3D]/[C_4H_4]$ would be given by

$$[C_4H_3D]/[C_4H_4] = (k_{15}/k_5)([C_2HD]/[C_2H_2]). \quad (16)$$

Since k_5 and k_{15} (kinetic isotope effect) are expected to be approximately equal at high temperatures, the ratios of $[C_4H_3D]/[C_4H_4]$ and $[C_2HD]/[C_2H_2]$ as a function of temperature should be nearly same. However, this is not the case. Thus the paths of this type to form deuterated 1-buten-3-ynes are insignificant.

In the C_2H_2–D_2 system, C_2H_3D, instead of C_2H_4, is formed by the following reaction:

$$C_2H_3 + D_2 \longrightarrow C_2H_3D + D. \quad (17)$$

In order to be compatible with the observed isotopic distribution of ethylene, the D atom thus generated is quickly converted into H atom by

$$C_2H_2 + D \longrightarrow C_2HD + H. \quad (18)$$

Simultaneously a reaction analogous to Reaction 4 would occur as follows:

$$C_2H_2 + D \longrightarrow C_2H_2D. \quad (19)$$

The concentration of the C_2H_3 radical present in the system should be greater than that of the C_2H_2D radical, since C_2H_3D is the predominant species among the ethylene isomers. C_2H_2D radical reacts with D_2 in a similar way:

$$C_2H_2D + D_2 \longrightarrow C_2H_2D_2 + D. \quad (20)$$

Reactions 17 and 20 are competitive with each other, the relative abundance of C_2H_3D and $C_2H_2D_2$ being given by

$$[C_2H_2D_2]/[C_2H_3D] = (k_{20}/k_{17})([C_2H_2D]/[C_2H_3]). \quad (21)$$

On the other hand, the C_2H_2D radical present in the system could lead to the formation of C_4H_3D by a reaction with C_2H_2 analogous to Reaction 5:

$$C_2H_2D + C_2H_2 \longrightarrow C_4H_3D + H. \quad (22)$$

Similarly, the ratio of $[C_4H_3D]/[C_4H_4]$ is givn by

$$[C_4H_3D]/[C_4H_4] = (k_{22}/k_5)([C_2H_2D]/[C_2H_3]). \quad (23)$$

As in Eq. 16, $k_{17}=k_{20}$ and $k_5=k_{22}$ can be expected at the present temperatures. Then Eqs. 21 and 22 show that the relative abundance of C_4H_3D and C_4H_4 would be comparable with that of $C_2H_2D_2$ and C_2H_3D. The observed ratios of $[C_4H_3D]/[C_4H_4]$ and $[C_2H_2D_2]/[C_2H_3D]$ as a function of temperature are summarized in Table 3. The above two ratios as a function of temperature differ from each other. Thus H atom may be an insignificant radical in the pyrolysis, but is primarily responsible for the formation of ethylene. It is concluded that C_4H_3 radical plays an important role in the formation of 1-buten-3-yne.

Table 3. Observed ratios of $[C_4H_3D]/[C_4H_4]$ and $[C_2H_2D_2]/[C_2H_3D]$ as a function of temperature

T_5/K[a]	1205	1245	1296	1371	
$[C_4H_3D]/[C_4H_4]$[b]	—[c]	0.006	0.058	0.354	
T_5/K[a]	1271	1313	1388	1407	1480
$[C_2H_2D_2]/[C_2H_3D]$[b]	0.171	0.176	0.258	0.266	0.538

a) T_5 is the temperature behind the reflected shock wave. b) The values are calculated from Tables 1 and 2 for the case of the mixture of $C_2H_2/D_2/Ar$= 10/10/80. c) Value not determined.

C_4H_3D could not be formed by the reaction of C_4H_3 radical with D_2, since the concentration of C_4H_3 radical is a function of acetylene alone, and about half the

amount of C_4H_3D produced in the mixture of $C_2H_2/D_2/Ar=10/10/80$ at around 1300 K could have been detected in the mixture of $C_2H_2/D_2/Ar=10/5/85$.

The ineffectiveness of the reaction of C_4H_3 radical with $H_2(D_2)$ may be understood in view of the heat of the reaction:[16]

$$C_4H_3 + H_2 \longrightarrow C_4H_4 + H, \quad \Delta H^\circ = 24.9. \quad (24)$$

The heat is greater than the activation energy of Reaction 7, which was estimated to be 17.9—22.6 kcal/mol.[11] The chain propagation process of Reactions 6 and 7 is more effective for the formation of 1-buten-3-yne than Reaction 24.

The occurrence of ethylene in a considerable amount is also in accordance with the prediction from the viewpoint of

$$C_2H_3 + H_2 \longrightarrow C_2H_4 + H, \quad \Delta H^\circ = 5.0. \quad (8)$$

The formation of C_2H_4 in a considerable amount in the C_2H_2–D_2 system cannot be accounted for by the reactions of the vinyl radicals with D_2. C_2H_4 thus can be formed by the hydrogen atom abstraction reaction of C_2H_3 radical from C_2H_2 molecule in the same way as in the pyrolysis of acetylene alone:

$$C_2H_3 + C_2H_2 \longrightarrow C_2H_4 + C_2H, \quad \Delta H^\circ = 12.7. \quad (25)$$

In a previous work the main primary C_4 product in the early stage of the pyrolysis of acetylene was concluded to be 1-buten-3-yne. If 1,3-butadiyne were formed at first and then reacted with D_2 to produce 1-buten-3-yne behind reflected shock wave and/or in the cooling process[17]

$$C_4H_2 + D_2 \longrightarrow C_4H_2D_2, \quad (26)$$

a significant amount of $C_4H_2D_2$ would be generated. This is inconsistent with the present isotopic distribution of 1-buten-3-yne.

Formation Reaction for the Minor Products. The secondary products of the pyrolysis were considerably affected by the addition of deuterium. The dependence of their yields on the deuterium concentration suggests that the minor products are produced by the reactions of the relevant radicals in the pyrolysis of acetylene by itself with deuterium.

In the present analysis, however, only the total yield of each minor product is obtained, and the C_2H_2–H_2 system will be considered in the following discussion. In the C_2H_2–Ar system the formation of CH_4 and C_3H_4 was interpreted in terms of the reactions of CH_3 and C_3H_3 radicals with acetylene molecule, respectively. In the C_2H_2–H_2 system, however, the radicals would react with H_2 rather than C_2H_2 molecule. In the case of the CH_4 formation the following two reactions would be competitive:

$$CH_3 + H_2 \longrightarrow CH_4 + H \quad \Delta H^\circ = -0.6, \quad (27)$$

$$CH_3 + C_2H_2 \longrightarrow CH_4 + C_2H \quad \Delta H^\circ = 7.1. \quad (28)$$

The heat of Reaction 27 is *ca.* 8 kcal/mol lower than that of Reaction 28. Reaction 27 is expected to have lower activation energy than that of Reaction 28.

A remarkable increase in the 1,3-butadiene yield in the C_2H_2–H_2 system can be ascribed to the reaction of C_4H_5 radical with hydrogen in a similar way:

$$C_2H_3 + C_2H_2 \longrightarrow C_4H_5, \quad \Delta H^\circ = -18.7, \quad (29)$$

$$C_4H_5 + H_2 \longrightarrow C_4H_6 + H, \quad \Delta H^\circ = 11.0. \quad (30)$$

All the minor products observed in the C_2H_2–H_2 system were also found in the pyrolysis of acetylene by itself at temperatures above 1300 K. On the other hand, in the presence of hydrogen (deuterium) they were produced at temperatures above 1100 K. This may be accounted for by the reactions stated above. Thus the addition of hydrogen to acetylene system appreciably increases the consumption of acetylene.

Rate of Ethylene Formation. The H atom generated by the initiation step is responsible for the formation of ethylene. The kinetic isotope effect is neglected and the C_2H_2–H_2 system is considered, since the total yield of ethylene was obtained for all runs. The rate of ethylene formation will be derived from the proposed mechanism.

In our mechanism the steady-state treatment is applicable in the same way as in the 1-buten-3-yne formation.[11] The recombination reaction of H atom with C_2H_3 radical is not important, since C_2H_3 radical is predominant. Neglecting the backward reactions, the steady-state assumption is applied to the scheme of Reactions 3, 4, 8, and 9. The steady-state rate of the ethylene formation is given by

$$d[C_2H_4]/dt = k_8(k_3/2k_9)^{1/2}[C_2H_2][H_2]. \quad (31)$$

k_8 is calculated from k_{-8} evaluated by Schofield[18] by the combination of the equilibrium constant of Reaction 8 at 1300 K, and k_9 is taken equal to k_t in Ref. 11:

$$k_8(\mathrm{cm^3\ mol^{-1}\ s^{-1}}) = 5.39\times10^{11}\exp(-12900/RT), \quad (32)$$

$$k_9(\mathrm{cm^3\ mol^{-1}\ s^{-1}}) = 2.9\times10^{12}. \quad (33)$$

Substituting these values in Eq. 30, the second-order rate constant is given by

$$k_8(k_3/2k_9)^{1/2}(\mathrm{cm^3\ mol^{-1}\ s^{-1}}) = 1.6\times10^{12}\exp(-36600/RT). \quad (34)$$

The steady-state rate constant agrees with the observed (Eq. 2) within a factor of 2 in the temperature range studied.

When a large excess of hydrogen present relative to acetylene, the initiation step of Reaction 11 may become more important. Taylor and Van Hook[1] reported the higher activation energy of 42 kcal/mol for the mixtures of $C_2H_2/H_2=1$—$1/32$ in the temperature range 770—810 K. This might be related to the change of the initiation step from Reaction 3 to 11, the activation energy of which is estimated to be higher than that of Reaction 3.

The author wishes to express his gratitude to Professor Kenji Kuratani, The University of Tokyo, for his helpful discussions and suggestions throughout this work.

Determination of Micropore Volumes of Active Carbon Using Dubinin-Radushkevich Plots

Ryoichi TSUNODA

Industrial Research Institute of Kanagawa Prefecture, Showa-machi, Kanazawa-ku, Yokohama 236

(Received January 27, 1977)

The adsorption of methanol on active carbons at 30 °C was carried out and a new method for determining the micropore volume in the Dubinin-Radushkevich plot is presented. From this method, it was found that the adsorption volume (V) corresponding to the adsorption potential ($A=RT\ln P_0/P$), at which the plot of $dV/d(-A)$ *vs.* A has its minimum value, is the value of the micropore volume in cases where extrapolation of the Dubinin-Radushkevich plot cannot be applied because of non-linearity of the Dubinin-Radushkevich plot.

The Dubinin-Radushkevich equation has been extensively used in studies of gas adsorption on microporous carbons. Its application has been reported in the determination of the micropore volume of heat-treated and activated carbons. For this application, the Dubinin-Radushkevich equation[1] is written as

$$V = V_0 \exp[-k(A/\beta)^2], \quad (1)$$

where V is the volume adsorbed at relative pressure P/P_0, $A=RT\ln P_0/P$, and k and β are constants. Equation 1 is converted to its linear form

$$\log V = \log V_0 - D\log^2 P_0/P, \quad (2)$$

where $D=2.303\,k\,R^2T^2/\beta^2$, and the micropore volume (V_0) is obtained by extrapolation.

However, deviations from linearity can be observed at low values of $\log^2 P_0/P$ and great care must be taken in the extrapolation for the determination of the micropore volume.

Furthermore, the pore structure of carbon is customarily classified into three types, micropores (radii< 15—16 Å), transitional pores (15—16 Å<radii<1000—2000 Å), and macropores (radii>1000—2000 Å).[1]

Generally speaking, the lower limit of pore size for which the Kelvin equation is applicable is about 15 Å in radius.[1] The pore-volume distribution in the transitional pore range (15 Å<radii<≈100 Å) can usually be obtained by application of the Kelvin equation on the adsorption isotherm, and that in the transitional and macropore range (≈100 Å<radii) using a mercury porosimeter. However, there is no satisfactory method for estimating the pore-volume distribution in the micropore range, although the micropore volume can be obtained by subtracting the cumulative pore volume (15 Å≦radii≦100 Å) from the volume adsorbed at the relative pressure corresponding to a radius of 100 Å in the Kelvin equation.

In this paper, the applicability of the proposed method for determining micropore volumes is discussed.

Experimental

Active Carbons. Commercially available Pittsburgh SGL- and PCB-type activated carbons were used. PCB-type activated carbons were treated with steam at 600 and 800 °C, respectively, for 6 h with supply of *ca.* 1.4 g-H_2O/g-carbon h. The percentages of burn-off of these treated PCB carbons were 5.3 and 33.3%, respectively, and can be described as PCB (5.3% burn-off) and PCB (33.3% burn-off).

Methanol Adsorption. The adsorption of methanol on active carbons at 30 °C was measured gravimetrically by means of a conventional quartz spring balance. Prior to the adsorption measurement, the active carbon dried overnight at 110 °C was outgassed at a pressure of 10^{-6} Torr at 30 °C for 14 h. In all cases, the time required for adsorption equilibrium was rapid and was established within 45 min.

Pore-volume Distribution. From the adsorption isotherms, the pore-volume distribution, lying in the radius range between 15 and 100 Å, was calculated employing the Kelvin equation.[2]

In transitional pores, there occur monomolecular and multimolecular adsorption and filling of the free space between the adsorption layers by the capillary condensation mechanism. The Kelvin equation is applicable to the space of the capillary condensate.

In the desorption step, the volume, ΔV, of the capillary condensate is lost between the beginning and the end of a step between two relative pressures P_1/P_0 and P_2/P_0. When the capillary condensate is lost, monolayers and multilayers remain on the pore walls and, thus, the radius of the meniscus of the capillary condensate is less than the actual radius of the pores by the adsorption thickness t. Thus, the quantity ΔV must be multiplied by the factor $[\bar{r}/(\bar{r}-\bar{t})]^2$, where $\bar{r}=(r_1+r_2)/2$ and $\bar{t}=(t_1+t_2)/2$. Multiplication by $[\bar{r}/(\bar{r}-\bar{t})]^2$ is also used in the calculation for the adsorption side of the adsorption isotherm.

The Kelvin equation, giving the relationship between the relative pressure P/P_0 and the pore radius r(Å), can be expressed as follows:

$$\ln P/P_0 = -2\gamma v\cos\theta/RT(r-t), \quad (3)$$

$$\log P/P_0 = -2\times 21.7\times 41.0\times 1/2.303\times 8.31\times 10^7 \times 303.2\times(r-t)\times 10^{-8} = -3.07/(r-t), \quad (4)$$

and

$$t = 4.6\times(-\ln P/P_0)^{-1/6}, \quad (5)$$

where γ is the methanol surface tension, v the molar volume of methanol, θ the contact angle between the methanol and the carbon (=0), R the gas constant, and t the thickness of the adsorbed methanol layer.[3]

Discussion

In his early work, Dubinin[1,4] demonstrated the linearity of the Dubinin-Radushkevich plots for gas adsorption on active carbon, however, afterward many investigators[5-7] frequently observed deviations from linearity.

Marsh and Siemieniewska[8] have suggested that the linearity of the Dubinin-Radushkevich plots occurs

because the distribution of the adsorption potential with adsorption volume follows the Rayleigh distribution. On the other hand, Gregg and Sing[9] and Sutherland[10] have considered that the apparent wide applicability of the Dubinin-Radushkevich equation arises because the log V *vs.* $\log^2 P_0/P$ plot is inherently insensitive and that the distribution of adsorption potential with adsorption volume need not be of the Rayleigh-distribution type.

Since, there have been many discussions of the determination of micropore volumes using Dubinin-Radushkevich plots.

Dubinin[1] suggested that upward deviations from linearity for low values of $\log^2 P_0/P$ can be attributed to the filling of transitional pores and that extrapolation in the Dubinin-Radushkevich plots of the linear section for high values of $\log^2 P_0/P$ can be used to predict the micropore volume. Chiche, Marsh, and Prégermain[5] have adopted extrapolation in the second section of the Dubinin-Radushkevich plots for estimations of the micropore volume when the Dubinin-Radushkevich plot is composed of two linear sections with downward deviations for low values of $\log^2 P_0/P$. In a recent paper, Rand[7] has applied the more generalized Dubinin-Astakhov equation

$$V = V_0 \exp\left[-k(A/E)^n\right], \qquad (6)$$

with E being a constant, in order to linearize the data. In this case, the micropore volume was obtained by the extrapolation of the linearized Dubinin-Astakhov equation.

If the Dubinin-Radushkevich plot can be shown to be strictly linear in form, a plot of $dV/d(-A)$ must be of the Rayleigh-distribution type. Thus, the plot of $dV/d(-A)$ *vs.* A can be considered to give more important information about the micropore volume using the Dubinin-Radushkevich plot.

Assuming the micropore volume to be equivalent to the V_0 obtained by extrapolating the Dubinin-Radushkevich plot only in cases when the Dubinin-Radushkevich plot is strictly linear and when the plot of $dV/d(-A)$ *vs.* A follows the Rayleigh distribution, upward deviations of $dV/d(-A)$ *vs.* A from the Rayleigh distribution for low values of A can be considered to indicate filling of the transitional pores. The adsorption volume corresponding to the adsorption potential A at the point of the upward deviation from the Rayleigh distribution, which is really of Rayleigh-like distribution, can be evaluated as the micropore volume.

Results

The adsorption isotherms, Dubinin-Radushkevich plots, characteristic curves, distribution curves of the adsorption potential, and pore volume distributions of the activated carbons are shown in Figs. 1—5.

The Dubinin-Radushkevich plot of SGL-type activated carbon is linear for low values of $\log^2 P_0/P$, as is shown in Fig. 2. If the plot is extrapolated, the micropore volume is evaluated to be 0.370 cm³/g, which is considerably higher than that calculated using the Kelvin equation (Table 1). This means that the Dubinin-Radushkevich plot is insensitive and great care must be taken in extrapolation. However, as shown in Figs. 4(a) and 5 and in Table 1, the value of the adsorption volume corresponding to the adsorption potential at which the plots of $dV/d(-A)$ *vs.* A deviate upward, *i.e.*, at the minimum value of $dV/d(-A)$, occur coincides with that of the micropore volume obtained using the Kelvin equation.

In the cases of PCB, PCB (5.3% burn-off) and PCB (33.3% burn-off), the Dubinin-Radushkevich plots are curved and the conventional method of extrapolation cannot be applied (see Figs. 2(a)—(b)). However, the

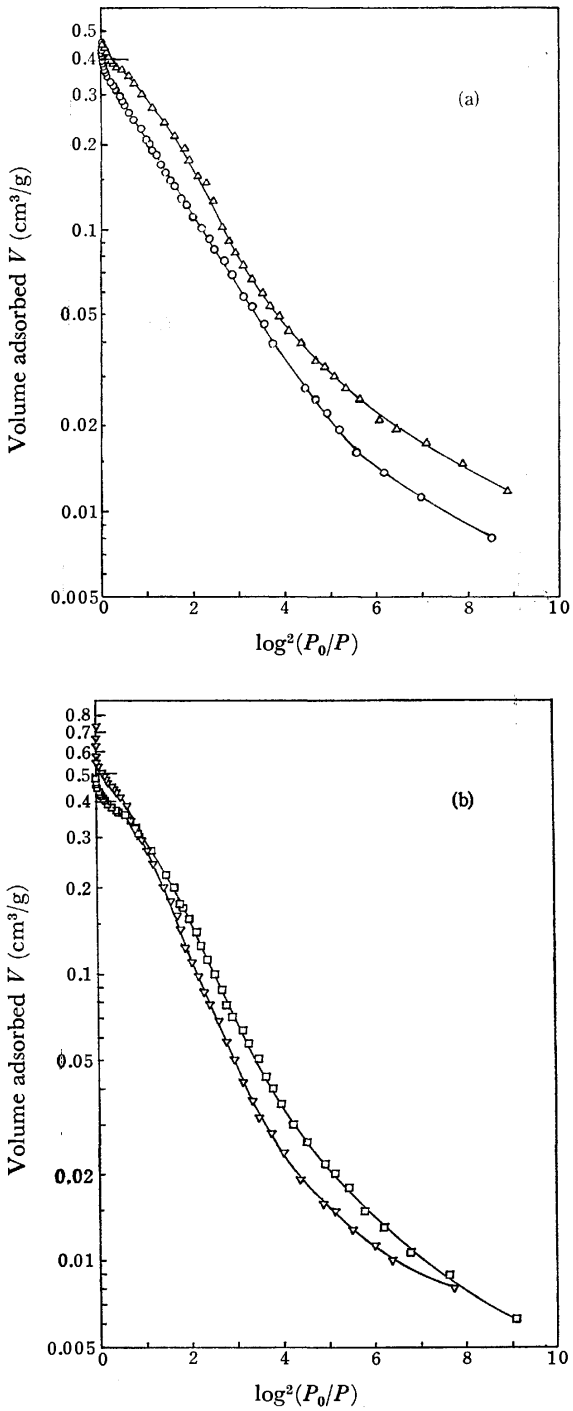

Fig. 2. Dubinin-Radushkevich plots of active carbons.

distribution curves of the adsorption potential clearly show upward deviations for low values of A. As in the case of SGL-type activated carbon, the values of the adsorption volume corresponding to the adsorption potential at which the upward deviations occur in the distribution curves coincide with those of the micropore volume calculated using the Kelvin equation, as shown in Figs. 4(a)—(b) and 5 and in Table 1.

There are three points to be discussed concerning the applicability of the new method proposed for deter-

mining micropore volumes.

1) The effective radius at the beginning of hysteresis loop is considered to be 15 Å and the hysteresis is attributed to the filling of transitional pores by the mechanism of capillary condensation.[1)]

However, in both the adsorption and desorption steps, monolayers and multilayers exist on the walls of pores larger than those filled due to capillary condensation. The adsorption volume, V_h, at the beginning of hysteresis loop is considered to be the sum of the adsorption volume in the micropore and that of monolayers and multilayers on the walls of transitional pores. The values of the adsorption volume, V_h, for SGL, PCB, PCB (5.3% burn-off), and PCB (33.3% burn-off) activated carbons are 0.360, 0.415, 0.430, and 0.535 cm³/g, respectively, as shown in Figs. 1(a) and (b). These are somewhat higher than the micropore volume determined by the method proposed in this paper, as shown in Table 1.

2) Concerning the calculation of the pore-volume distribution, there are two assumptions.

a) The shapes of the pores are assumed to be cylindrical, although the true shapes are complicated and not necessarily cylindrical.

b) The walls of active carbon pores are heterogeneous surfaces and it is impossible to observe the actual thickness, t, of the adsorption layers on active carbons. The thickness, t, observed for substances with nonporous and homogeneous surfaces is assumed to be equal to the actual thickness on active carbon.

Due to these assumptions, discrepancies between the actual micropore volume and the volume calculated using the Kelvin equation will occur.

3) According to the theory of Dubinin,[1)] if the Dubinin-Radushkevich plot is strictly linear, V_0 in Equation 1 is the micropore volume. In this case, the potential-distribution curve $dV/d(-A)$ *vs.* A is really a type of Rayleigh distribution.

The shape of the Rayleigh distribution is shown in Ref. 6 with a maximum value at $A=\beta/\sqrt{2k}$ below which $dV/d(-A)$ decreases to zero.

If active carbons were ideally composed only of micropores, the shape of the plot of $dV/d(-A)$ *vs.* A would have the form of a Rayleigh distribution. However real active carbons have transitional pores, in addition to micropores. Due to the filling of the transitional pores, the Dubinin-Radushkevich plot deviates upward from linearity, and at the same time the plot of $dV/d(-A)$ *vs.* A also deviates upward from the Rayleigh distribution. It can be assumed that the point of deviation, *i.e.*, the point of the $dV/d(-A)$ minimum represents the end of micropore filling and, at the same time, the beginning of transitional-pore filling by capillary condensates and, strictly speaking, the beginning of the adsorption of mono- and multilayers on

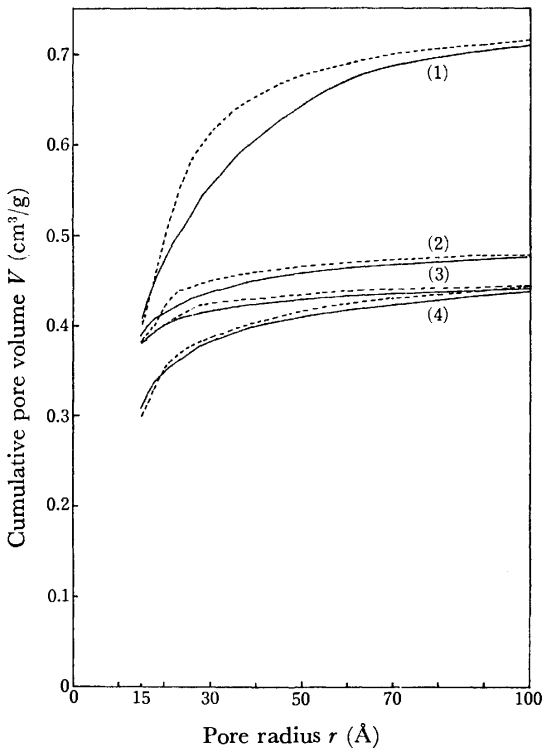

Fig. 5. Pore volume distributions of active carbons.

—— Calculated from the desorption side of the isotherms.
—— Calculated from the adsorption side of the isotherms.

the transitional pores. The present experimental results show that the proposed method is applicable to the determination of micropore volumes.

From these results, the micropore volume can be estimated by plotting the values of $dV/d(-A)$ *vs.* A and by finding the adsorption volume corresponding to the adsorption potential at which the plots of $dV/d(-A)$ *vs.* A show a minimum value, in cases where extrapolation of the Dubinin-Radushkevich plot cannot be applied because of non-linearity of the Dubinin-Radushkevich plot.

Formation of a Charge-Transfer Complex between the 1-Methyl-1-phenylethylperoxyl Radical and Pyridine during Decomposition of 1-Methyl-1-phenylethyl Hydroperoxide

Shun-ichi FUKUZUMI and Yoshio ONO

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received February 4, 1977)

The apparent rate constant for the self-reaction of 1-methyl-1-phenylethylperoxyl radicals ($RO_2^{\cdot}$) in the presence of pyridine was determined from simultaneous measurements of the rate of oxygen generation and the concentration of the peroxyl radical during the decomposition of 1-methyl-1-phenylethyl hydroperoxide with lead dioxide. The apparent rate constant decreased markedly with an increase in the concentration of pyridine, which clearly demonstrates the low reactivity of $RO_2^{\cdot}$ in the presence of pyridine. This behavior is taken as evidence that the charge-transfer complex between the peroxyl radical and pyridine is formed and that the reactivity of complexed peroxyl radicals is much lower than that of uncomplexed peroxyl radicals. The equilibrium constant for the formation of the charge-transfer complex has been determined to be 0.55 M^{-1} at 293 K and the values of $-\Delta H$ and $-\Delta S$ were found to be 31 kJ mol^{-1} and 109 J mol^{-1} K^{-1}, respectively.

The effects of solvents on the reactivity of free radicals due to complex formation between the radicals and the solvents have been investigated by several authors.[1-10] Porter and Smith[1] have explained the influence of chaperon molecules on the recombination rate of iodine atoms in terms of a charge-transfer complex intermediate between the two species, spectroscopic support of which has also been reported.[2-4] Russell[5] has shown that the pronounced solvent effects on chlorine atom-substrate complexes of similar nature. Boozer and Hammond[6,7] have postulated the formation of charge-transfer complexes between alkylperoxyl radicals and inhibitors (aromatic amines and phenols) in the autoxidation of hydrocarbons. Thomas[8] has also examined the possibility of complex formation between the 1-methyl-1-phenylethylperoxyl radical and pyridine in a study on the autoxidation of cumene at 330 and 347 K, but no clear evidence was obtained. Thus, an inhibition mechanism involving charge-transfer between a chain propagating radical and the antioxidant has often been suggested,[6-8] but has rarely been identified with any certainty.

Previously, the present authors postulated the following complex formation between the 1-methyl-1-phenylethylperoxyl radical and 1-methyl-1-phenylethyl hydroperoxide as the result of electron spin resonance and kinetic studies of hydroperoxide decomposition with lead dioxide.[9]

$$RO_2^{\cdot} + n\,ROOH \rightleftharpoons (RO_2^{\cdot} \cdots n\,ROOH).$$

The value $n=2$ was obtained from the change in the ESR line width of the peroxyl radical, as well as from kinetic results of the hydroperoxide decomposition. The reactivity of the complexed radicals was found to be much lower than that of uncomplexed radicals. Similar results indicating that complex formation between radicals and solvents leads to a decrease in the apparent reactivity of the radicals has been obtained in the case of the autoxidation of ethyl methyl ketone in aqueous solutions.[10] It was shown that equilibrium in the reaction

$$RO_2^{\cdot} + m\,H_2O \rightleftharpoons (RO_2^{\cdot} \cdots m\,H_2O)$$

is rapidly established in the system. In this case, the value, $m=1$, was obtained. Thus, there are cases in which the apparent reactivity of radicals decreases markedly as the results of complex formation between radicals and solvents, although these processes remain some of the least understood of all inhibition mechanism.[11]

Pyridine is known to form strong charge-transfer complexes with acceptors such as iodine.[12] Therefore, in the present study, the change in apparent reactivity of the 1-methyl-1-phenylethylperoxyl radical for the self-reaction in the presence of pyridine was investigated by electron spin resonance and kinetic methods, and evidence of the formation of charge-transfer complexes between the peroxyl radical and pyridine is presented. The equilibrium constant, K, and the values of ΔH and ΔS for complex formation are reported.

Experimental

The apparatus has been described in detail elsewhere.[9,13] The decomposition of 1-methyl-1-phenylethyl hydroperoxide in CCl_4 and pyridine in the presence of lead dioxide powder was carried out in a 50- or 100-cm^3 flask immersed in a temperature-controlled bath, stirred magnetically and attached to a wet-gasometer. In order to determine the concentration of the peroxyl radical as well as the rate of oxygen generation under the same conditions, simultaneous measurements of the radical concentration and the rate of oxygen generation were performed as follows. While the rate of oxygen generation was measured with a wet-gasometer, the part of the solution involving the catalyst powder was circulated, using a roller pump, through the ESR cavity where the ESR measurements were carried out. The intensity of the ESR signal was confirmed to be independent of the feed rate of the roller pump over the range from 50—200 cm^3/min. A JEOL-X-band spectrometer (JES-PE-1X) with 100-kHz magnetic modulation was used to detect the radicals. The radical concentration was determined by comparing the absorption area of the radical with that of 1,1-diphenyl-2-picrylhydrazyl in benzene. The change in sensitivity of the spectrometer due to the decrease in the Q factor caused by introducing a polar solvent such as pyridine was calibrated using an ESR marker in the ESR cavity.

Results and Discussion

When lead dioxide powder is added to the hydroperoxide solution, the ESR spectrum of the 1-methyl-1-phenylethylperoxyl radical is observed and oxygen gas evolves. The ESR spectrum consists of a single symmetrical line with no detectable hyperfine structure and an isotropic g-factor of 2.0148 ± 0.0004, which is in good agreement with the values reported previously.[9,13-15] No ESR signal was obtained and no oxygen gas evolved unless lead dioxide powder was added. Simultaneous measurements of the radical concentration and the rate of oxygen generation were carried out both in the absence of and in the presence of pyridine. All the experiments were performed in hydroperoxide concentrations below 0.3 M, for which complex formation between the peroxyl radical and the hydroperoxide is negligible.[9]

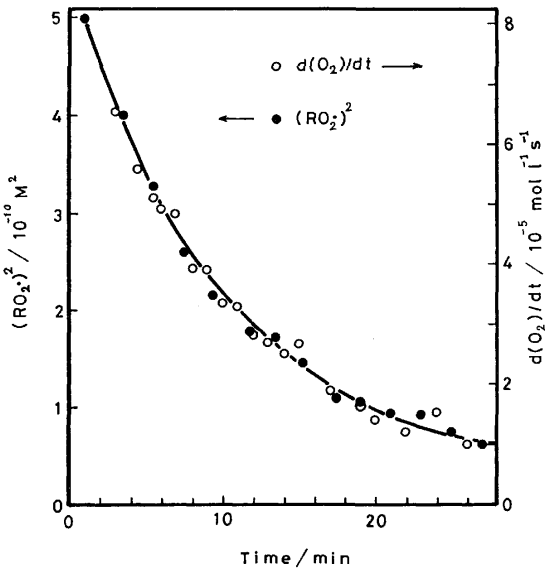

Fig. 1. The square of the 1-methyl-1-phenylethylperoxyl radical concentration and the rate of oxygen generation are plotted against time for the decomposition of 1-methyl-1-phenylethyl hydroperoxide with lead dioxide in the presence of pyridine at 303 K.
Initial concentration of the hydroperoxide: 0.254 M, initial ratio of PbO_2 weight to liquid volume: 40.5 g/l, pyridine concentration: 1.70 M, solvent: CCl_4.

A typical example of the change in the rate of oxygen generation and the peroxyl radical concentration with reaction time is shown in Fig. 1, in which the ordinates are the square of the radical concentration and the rate of oxygen generation. The initial concentrations of the hydroperoxide and pyridine were 0.254 and 1.70 M, respectively, and the ratio of catalyst weight to liquid volume was 40.5 g/l. As shown in Fig. 1, by selecting appropriate ordinate scales, the square of the radical concentration and the rate of oxygen generation behave in exactly the same manner, that is, the rate of oxygen generation is proportional to the square of the radical concentration, thus

$$\frac{d[O_2]}{dt} = k_6^{exp}[RO_2\cdot]^2, \quad (1)$$

where k_6^{exp} is a constant. It is well accepted that 1-methyl-1-phenylethyl hydroperoxide undergoes induced decomposition as follows:[16-18]

$$RO_2\cdot + RO_2\cdot \xrightarrow{k_6} 2RO\cdot + O_2, \quad (2)$$

$$RO\cdot + ROOH \xrightarrow{k_5} ROH + RO_2\cdot. \quad (3)$$

Equation 1 clearly indicates that the oxygen generation reaction involves a bimolecular reaction of $RO_2\cdot$ (2) and that most $RO\cdot$ radicals react with ROOH and thus regenerate $RO_2\cdot$; the fraction of $RO\cdot$ radicals which do not react with ROOH (*e.g.*, due to β-sission resulting in the absorption of O_2) is negligible.[9] In fact, the main product, ROH (90%), and only a small amount of acetophenone (7%) were obtained by decomposition of the hydroperoxide with lead dioxide. Furthermore, it was confirmed that the molar ratio of the ROH produced to the oxygen evolved was very close to 2.[9] Then, it should be obvious that the proportionality constant, k_6^{exp}, gives the rate constant of the bimolecular reaction for the peroxyl radicals, Reaction 2.

In the same manner for the case shown in Fig. 1, the proportionality constant, k_6^{exp}, was determined for various pyridine concentrations. Figure 2 shows the relation between k_6^{exp} and the pyridine concentration at various reaction temperatures from 293—313 K. As is shown in Fig. 2, k_6^{exp} decreases with increasing pyridine concentration. This clearly demonstrates the decrease in the $RO_2\cdot$ reactivity for the $RO_2\cdot$ self-reaction, Reaction 2, with increasing pyridine concentration. It should be noted that complex formation between the hydroperoxide and pyridine, if occurs, cannot have any influence on k_6^{exp} since the rate-determining step for chain propagation is Reaction 2 and relation 1 is valid.

Solvent effects on the rate constants for reactions involving polar solvents have frequently been described using Kirkwood's equation:[19]

$$\log k_6 = \log k_6^0 - \frac{1}{kT}\frac{\varepsilon-1}{2\varepsilon+1}\left(\frac{\mu_1^2}{r_1^3}+\frac{\mu_2^2}{r_2^3}+\frac{\mu_3^2}{r_3^3}\right), \quad (4)$$

where k_6^0 is the rate constant at $\varepsilon=1$, k is the Boltzmann constant, μ_1, μ_2, r_1, and r_2 are the dipole moments and effective radii of the reactants, and μ_3 and r_3 refer to those of the activated complex. According to Kirkwood's equation, the rate constant should increase with increasing polarity of the solvent. This has been reported to be the case for the oxidation of ethyl methyl ketone in benzene solutions.[10] In the present case, however, the apparent rate constant, k_6^{exp}, decreases with the pyridine concentration even though the polarity of the medium increases. Then, the following complex formation between the peroxyl radical and pyridine is postulated in order to explain the experimental observations in Fig. 2;

$$RO_2\cdot + n\,Py \overset{K}{\rightleftharpoons} (RO_2\cdot\cdots n\,Py). \quad (5)$$

Two types of peroxyl radicals, uncomplexed ($RO_2\cdot$) and complexed ($RO_2\cdot\cdots nPy$), are in equilibrium in the system. The peroxyl radical concentration $(RO_2\cdot)_t$ measured using ESR is equal to the sum of the concentration of the two species, thus

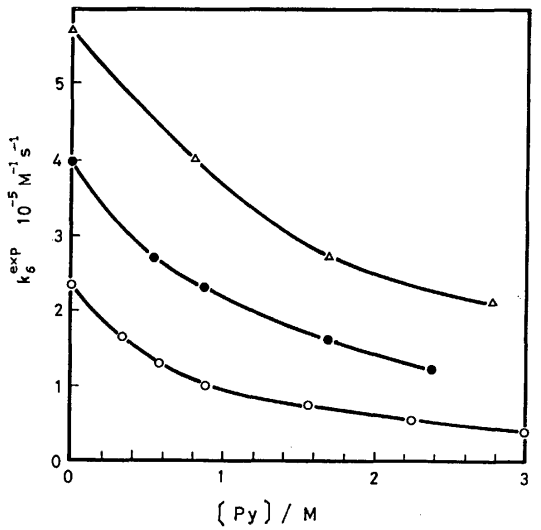

Fig. 2. k_6^{exp} as a function of the pyridine concentration for different temperatures.
○ 293 K, ● 303 K, △ 313 K.

$$[RO_2^\cdot]_t = [RO_2^\cdot] + [RO_2^\cdot \cdots n\,Py]. \quad (6)$$

The peroxyl radical self-reactions may be represented as

$$RO_2^\cdot + RO_2^\cdot \xrightarrow{k_6} O_2 + 2RO\cdot, \quad (7)$$

$$RO_2^\cdot + (RO_2^\cdot \cdots n\,Py) \xrightarrow{k_6'} O_2 + 2RO\cdot + n\,Py, \quad (8)$$

$$(RO_2^\cdot \cdots n\,Py) + (RO_2^\cdot \cdots n\,Py) \xrightarrow{k_6''} O_2 + 2RO\cdot + 2n\,Py. \quad (9)$$

From Eqs. 5—9, the rate of oxygen generation is given by

$$\frac{d[O_2]}{dt} = \frac{k_6 + k_6'K[Py]^n + k_6''K^2[Py]^{2n}}{(1+K[Py]^n)^2}[RO_2^\cdot]_t^2. \quad (10)$$

Thus, the experimental rate constant, k_6^{exp}, is expressed as

$$k_6^{exp} = \frac{k_6 + k_6'K[Py]^n + k_6''K^2[Py]^{2n}}{(1+K[Py]^n)^2} \quad (11)$$

If one assumes that the reactivity of the complexed peroxyl radical is much lower than that of the uncomplexed radical, that is, that k_6' and $k_6'' \ll k_6$, then, Eq. 11 reduces to

$$k_6^{exp} = \frac{k_6}{(1+K[Py]^n)^2}. \quad (12)$$

Equation 12 can be rewritten as

$$\log\left(\left(\frac{k_6}{k_6^{exp}}\right)^{1/2} - 1\right) = n \log [Py] + \log K. \quad (13)$$

In Fig. 3, the plot of log $((k_6/k_6^{exp})^{1/2}-1)$ as a function of log [Py] is a straight line for each temperature, which indicates the validity of the above mechanism. The value $n=1$ is obtained from the slopes of these lines. This indicates the association of one pyridine molecule with a single peroxyl radical.

a) Obtained for the autoxidation of cumene with lead dioxide. b) Activation parameters for the charge-transfer complex between pyridine and iodine.

The temperature dependence of k_6 and K obtained from Fig. 3 is shown in Fig. 4. The values of the activation parameters for the radical self-reaction, A_6 and E_6, as well as ΔH and ΔS for the complex formation derived from Fig. 4, are summarized in Table 1 together with the activation parameters, A_6 and E_6, obtained from the autoxidation of cumene with lead dioxide.[13] The Arrhenius parameters of the peroxyl radical self-reaction in hydroperoxide decomposition are in good agreement with those obtained for the autoxidation of cumene. The high ΔH value, 31 kJ mol^{-1}, explains why Thomas[8] was unable to estimate the equilibrium constant K

for the $RO_2^{\cdot}$–pyridine complex in the autoxidation of cumene; his experiments were carried out at higher temperatures (330 and 347 K) since he used the thermal initiator AIBN. The equilibrium constant K has the small values 0.14 M^{-1} at 330 K and 0.08 M^{-1} at 347 K, as estimated from the ΔH and ΔS values given in Table 1. These K values are consistent with the estimation of Thomas that K cannot have a value in excess of 0.4 M^{-1}. Since pyridine is known to form strong charge-transfer complexes with acceptors such as iodine,[12] the values of ΔH and ΔS for the formation of the charge-transfer complex between pyridine and iodine are compared with those for the present case in Table 1. The ΔH value for the $RO_2^{\cdot}$–pyridine complex is in good agreement with that for the charge-transfer complex between pyridine and iodine. Hence, the complex formation between 1-methyl-1-phenylethylperoxyl radical and pyridine can be considered to follow a charge-transfer process analogous to the pyridine–iodine complex, *i.e.*,

$$RO_2^{\cdot} + Py \rightleftarrows (RO_2^{\delta-}\ Py^{\delta+}). \qquad (14)$$

Thus, the 1-methyl-1-phenylethylperoxyl radical is an electron acceptor in complex formation with pyridine.

The authors thank Professor T. Keii for helpful discussions.

Mechanism of the Photochemical Ring Expansion of *N*-Vinyl-2-pyrrolidone. Estimation of the Recombination-Time of Biradical

Haruo SHIZUKA, Toshio OGIWARA, and Toshifumi MORITA
Department of Chemistry, Gunma University, Kiryu, Gunma 376
(Received February 15, 1977)

The photochemical ring expansion of *N*-vinyl-2-pyrrolidone (NVP) has been carried out at 254 nm. The reaction quantum yield depends a great deal on the solvnet viscosity and temperature. The recombination time of the biradical of RP produced by Norrish type I fission was estimated to be $\approx 10^{-10}$ s by application of the Einstein and Smoluchowski-Debye equations. The spin inversion of the biradical in a solvent cage is also discussed according to Kaptein's theory of the radical-pair mechanism.

Geminate recombinations[1] of primary products (radicals or free ions) produced in a solvent cage by irradiation have been studied experimentally and theoretically.[2-8] Since the processes involved in cage effect reactions[9] are in a range beyond the scope of conventional dynamic methods, the geminate recombination was monitored indirectly *via* the dependence of the products on the concentration of added scavengers.[10] A more powerful experimental technique involves the application of pulsed excitation. Eisenthal *et al.*[5] have carried out direct measurements of the geminate recombination of a radical-pair (iodine atoms) with picosecond pulses at 5300 Å, the recombination time τ being 70 and 140 ps in hexadecane and carbon tetrachloride, respectively. The fast reactions can be explained by a theory similar to that of the radical-pair mechanism for CIDNP and CIDEP.[11]

According to the mechanism developed by Kaptein,[12] the radical-pair model can be divided into two types depending upon the distance r between radicals in a solvent cage.

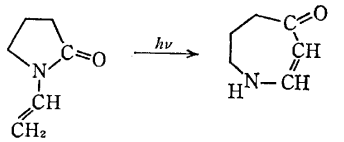
1) Closed Radical-pair $\overline{\mathrm{A}\cdot\cdot\mathrm{B}}$. The distance of r in this pair is shorter than that of r_0 ($\approx$6Å)[13] which is roughly given by the condition that the exchange integral J is of the order of the nuclear hyperfine interactions. In the region $r<r_0$, no Zeeman effects in CIDNP and CIDEP experiments can be detected from the pair except very high fields; no singlet-triplet mixing in the pair exists appreciably since the S-T energy gap ($2J$) is very large. The geminate recombination of the triplet closed radical-pair $\overline{{}^3\mathrm{A}\cdot\cdot\mathrm{B}}$ would therefore occur *via* a triplet separated radical-pair $\overline{{}^3\mathrm{A}\cdot|\cdot\mathrm{B}}$. In contrast, the geminate recombination of the singlet pair $\overline{{}^1\mathrm{A}\cdot\cdot\mathrm{B}}$ is very fast ($\approx 10^{-11}$ s).[6]

2) Separated Radical-pair $\overline{\mathrm{A}\cdot|\cdot\mathrm{B}}$. The radicals in this pair are separated by solvent molecules[14] to give the distance r ($\geq r_0$), but they are enclosed within a solvent cage. The $\overline{\mathrm{A}\cdot|\cdot\mathrm{B}}$ is produced from $\overline{\mathrm{A}\cdot\cdot\mathrm{B}}$ or diffusing radicals. The exchange term J becomes small[15] in the region $r\geq r_0$, and the singlet-triplet mixing takes place due to the nuclear hyperfine and the spin-orbit interactions, resulting in the recombination of $\overline{{}^3\mathrm{A}\cdot|\cdot\mathrm{B}}$. In the presence of the external magnetic field, Zeeman terms also contribute to the S-T mixing in the pair, and CIDNP and CIDEP phenomena would be observed from $\overline{\mathrm{A}\cdot|\cdot\mathrm{B}}$ as has been proposed by Kaptein.[12] As for the recombination of $\overline{{}^1\mathrm{A}\cdot|\cdot\mathrm{B}}$, its recombination probability may decrease with increasing S-T mixing.

Brocklehurst[2] applied the radical-pair model to the rate of loss of spin correlation in geminate pairs of radical ions produced by radiolysis. Schulten *et al.*[16] have recently studied the fast intersystem crossing in an exciplex due to the radical-pair mechanism.

In contrast to the cases of pair radicals and radical ions, the lack of recombination time of a biradical was pointed out.[17] It seems that the behavior of the biradical in a solvent cage is similar to that of the radical-pair. However, the radical site of the biradical is always combined with a molecular chain: the structure allows a reversible change similar to $\overline{\mathrm{A}\cdot\cdot\mathrm{B}}\leftrightarrow\overline{\mathrm{A}\cdot|\cdot\mathrm{B}}$ without escape of the radicals from solvent cage. Thus, an appreciable S-T mixing may be expected, effecting the recombination of biradical. The kinetic behavior of a biradical has been studied from these viewpoints.

N-Vinyl-2-pyrrolidone (NVP) yields photochemically the ring expansion product (P) of 4-azacyclohepten-1-one in alcohols[18] as follows:



NVP P (1)

In this ring expansion, α-cleavage (the Norrish type I fission) to give the biradical RP (Eq. 2) may be involved as considered from the other photochemical ring expansion.[19] In the present work, the compound NVP was chosen in order to estimate the recombination time of biradical. We have measured the quantum yields for the intramolecular ring expansion of NVP at 254 nm as a function of η/T, where η and T denote viscosity and absolute temperature of solutions, respectively.

Experimental

N-Vinyl-2-pyrrolidone (E.P-grade, Tokyo Kasei Co., Ltd.) was purified by distillation before use. Ethanol (G.R.-grade, Tokyo Kasei Co., Ltd.) and spectrograde glycerol were used without further purification. The viscosity of sample solutions was adjusted with a mixed solvent (ethanol–glycerol system).[20]

A low-pressure mercury lamp with a Vycor glass filter was

used as the 254 nm radiation source. Actinometry was carried out using a ferric oxalate solution.[21] The quantum yields for the product formation were measured by spectrophotometry. For the measurement of temperature effect on the quantum yield, a quartz Dewar flask designed for spectrometry was used as a reaction cell, the temperature being controlled to within ±2 °C. In the measrements of degassed samples, the solutions were thoroughly degassed on a high-vacuum line by the freeze-pump-thaw method. Absorption and fluorescence spectra were measured with Hitachi 139 and 124 spectrophotometers and with a Hitachi MPF-2A fluorimeter, respectively.

Results

The spectrum of the degassed ethanol solution of *N*-vinyl-2-pyrrolidone (NVP) changed markedly upon irradiation with the 254 nm light at 293 K as shown in

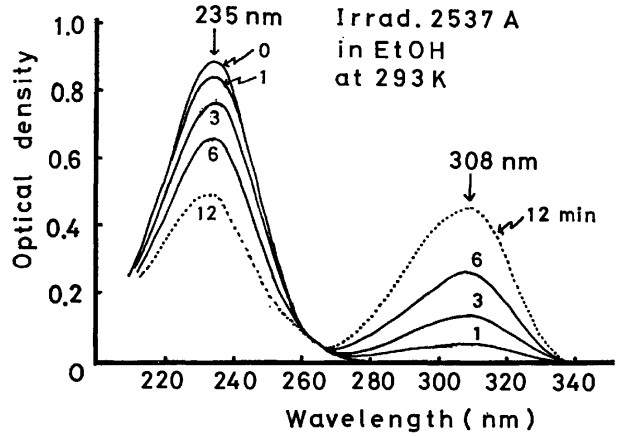


Fig. 1. The spectral change of ethanol solution of NVP with lapse of time at 254 nm. Numbers refer to time of measurement in minutes.

Fig. 1. The 235 nm band of NVP (ε: 1.68×10^4 M^{-1} cm^{-1}) and a new band with maximum at 308 nm (ε: 1.96×10^4 M^{-1} cm^{-1}) appeared. The spectral change shows the formation of ring expansion product of 4-aza-cyclohepten-1-one. The photochemical conversion from NVP into the photoproduct P in the initial stages of the reaction was very efficient (>90%). The photoproduct was separated by column chromatography and confirmed by UV, IR, and NMR, and comparison of its mp with that in the literature.[18]

The quantum yields for the product formation Φ_R in ethanol [Φ_R=5.4 ($\pm$0.2)$\times10^{-2}$ at 293 K, η=12.2 mp] did not change with variations of irradiation time (2—15 min), initial concentration of NVP (0.5×10^{-4}—1×10^{-2} M) and the addition of piperylene ($\leq2.2\times10^{-2}$ M). There was no dissolved oxygen effect on Φ_R. The results are shown in Fig. 2. However, significant effects of viscosity (η) and temperature (T) on Φ_R at 254 nm were observed (Table 1). The Φ_R values decreased with increase in η and decreased with fall in temperature. The dependence of Φ_R on η at 254 nm in ethanol or an ethanol–glycerol mixture is shown in Fig. 3. The difference between the two curves is due to the temperature effect on Φ_R.

No photochemical ring expansion of NVP was

observed in a rigid EPA matrix at 77 K. Neither fluorescence (at 77 and 293 K) nor phosphorescence (at 77 K) could be observed. The emission quantum yields should be less than 10^{-4}. The photochemical ring expansion took place even in the gas phase. No quantitative work has been made.

Discussion

The Norrish Type I Dissociation. The Norrish type I fission (α-cleavage) of organic carbonyl compounds

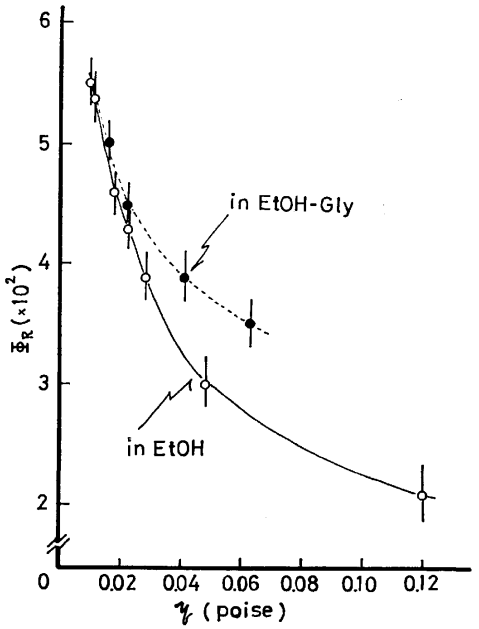

Fig. 3. The quantum yield for the product formation Φ_R as a function of viscosity η.

can be divided into three typical classes as follows:[22]

1) Photochemical fission of alkyl ketones occurs *via* both $^1(n, \pi^*)$ and $^3(n, \pi^*)$ states.[23,24]

2) Photochemical dissociation of aryl ketones[25] and some cyclohexanones[24] takes place *via* $^3(n, \pi^*)$, which might be due to the rapid intersystem crossing in the excited molecules.

3) Photochemical cleavages of aryl esters originate from $^1(\pi, \pi^*)$ $^1B_2$ states.[26]

The rate constants for the fissions are estimated to be 10^7—10^8 s^{-1} in case 1,[23,24] $\approx 10^{10}$ s^{-1} or more in case 2[25] and $\approx 10^9$ s^{-1} in case 3.[26] However, little is known about the reactive state responsible for photochemical ring expansions. The photochemical reaction of spiro[2.4]-heptan-4-one in methanol is an exception; the triplet state of the ketone ($\tau_T \simeq 2\times10^{-9}$ s) seems to be the reactive state from the result of the quenching experiment by 3 M 1,3-pentadiene.[27] The presence of triplet quenchers [1,3-pentadiene$\leq 2.2\times10^{-2}$ M[28a] and dissolved oxygen $\simeq 2.1\times10^{-3}$ M[29]] do not affect the Φ_R values. The results indicate that the photochemical ring expansion of NVP proceeds *via* a singlet precursor and/or very short-lived triplet state. The reactive state of $^3(n, \pi^*)$ is more likely than that of $^1(n, \pi^*)$, if we consider the allowed transition of $^1(\pi, \pi^*)\rightarrow{}^3(n, \pi^*)$ according to the El-Sayed rule.[30] The $^1(n, \pi^*)$ state in NVP lies energetically under the $^1(\pi, \pi^*)$ state, which was calculated by the CNDO/2 method.[28b] The $^1(n, \pi^*)$ band should be masked by the $^1(\pi, \pi^*)$ band at 235 nm.[31] The lack of emission from NVP shows that the excited state of NVP decays *via* rapid radiationless transitions [intersystem crossing, internal conversion, and the photochemical channel in part ($\leq 6.7\times10^{-2}$)]. Recent studies deal with the rapid radiationless processes in the excited molecules.[22,23]

Kinetics of Photochemical Ring Expansion of NVP. Viscosity and temperature dependence upon the reaction quantum yields Φ_R can be accounted for by the scheme shown in Fig. 4, which is simplified with respect to the processes of internal conversion and intersystem crossing, where NVP and NVP* are the ground and the electronically excited states of the staring material, respectively: RP the radical-pair (biradical) formed by the Norrish type I fission of NVP* (Eq. 2); and RP′ the biradical produced by rotational diffusion of RP resulting in the ring expansion product P (Eq. 3).

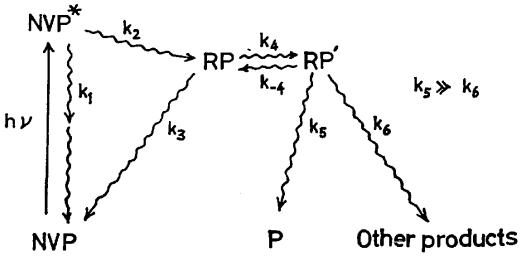

Fig. 4. A schematic energy state diagram for the photochemical ring expansion of NVP.

RP:  (2)

RP′:  (3)

By use of the usual steady-state approximation, the quantum yield for the product formation Φ_R is given by

$$\Phi_R = \left(\frac{k_2}{k_1+k_2}\right)\left\{\frac{k_4}{k_4+k_3\left(1+\frac{k_{-4}}{k_5+k_6}\right)}\right\}\left(\frac{k_5}{k_5+k_6}\right). \quad (4)$$

From the result of high efficiency (>90%) for the photochemical conversion NVP→P, the following should hold:

$$k_5 \gg k_6. \quad (5)$$

Using this we obtain

$$\Phi_R = \Phi_{RP}\left\{\frac{k_4}{k_4+k_3\left(1+\frac{k_{-4}}{k_5}\right)}\right\}, \quad (4')$$

where Φ_{RP} is the efficiency for the RP formation from NVP*. From Eq. 4′, we obtain

$$\frac{1}{\Phi_R} = \frac{1}{\Phi_{RP}}\left(1+\frac{k_{-4}k_3}{k_4k_5}\right) + \frac{1}{\Phi_{RP}}\cdot\frac{k_3}{k_4}. \quad (6)$$

The rate constants k_4 and k_{-4} in the structural change between RP and RP′ seem to be diffusion-controlled, and should be proportional to $T\eta^{-1}$. Thus, Eq. 6 can be further simplified to

$$\frac{1}{\Phi_R} = a + b\frac{\eta}{T} \quad (7)$$

where a denotes the first term in Eq. 6 and b the term $\alpha k_3 \Phi_{RP}^{-1}$ (α: constant). The plot of Φ_R^{-1} *vs.* ηT^{-1} obtained experimentally, which agrees with Eq. 7, is shown in Fig. 5. The values of a and b are taken from the plot.

$$a = 15, \quad (8)$$

and

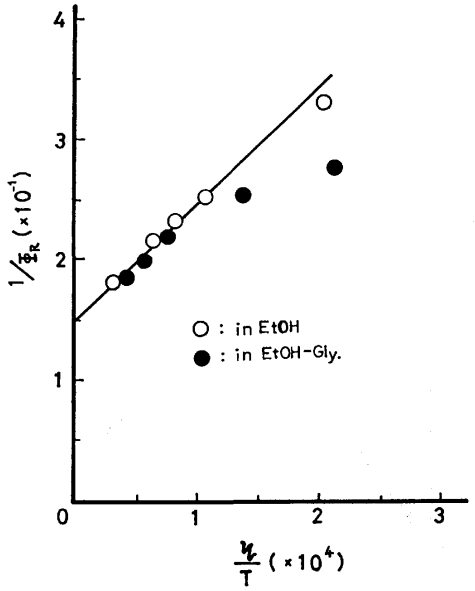

Fig. 5. Plot of Φ_R^{-1} as a function of ηT^{-1}.

$$b = 8.3\times10^{4}(\mathrm{dyn^{-1}\,s^{-1}\,cm^{2}\,deg}). \quad (9)$$

Deviations at high viscosity in the ethanol-glycerol system (Fig. 5) might be caused by inhomogeneity in the solvent.

Estimation of the Recombination Time of RP. Noyes's treatment[33] based on a random flight model is not applicable to the recombination of a biradical, since the radical sites of the biradical are combined with a molecular chain. Let us consider the recombination of the biradical of RP (or RP') using the following approximations (Cases A, B, and C).

Case A: If we assume that the reversible process RP←RP' is negligible, *i.e.* $k_{-4}\ll k_5$, Eq. 6 can be simplified to

$$\frac{1}{\Phi_R} = \frac{1}{\Phi_{RP}}\left(1+\frac{k_3}{k_4}\right) \quad (6')$$

Using the experimental values a and Φ_R^{-1}, a linear plot of k_3/k_4 *vs.* η/T is obtained, showing that k_3/k_4 is less than unity in the range $\eta\ T^{-1}<1.5\times10^{-4}$ poise deg^{-1}. This indicates that the diffusion rate constant k_4 (or k_{-4}) is greater than that of the recombination k_3 (or k_5). Thus, the assumption is not adequate.

Case B: If we assume that k_4 is approximately equal to k_{-4}, since both k_4 and k_{-4} are diffusion-controlled, we obtain from Eq. 6

$$\frac{1}{\Phi_R} = \frac{1}{\Phi_{RP}}\left(1+\frac{k_3}{k_5}+\frac{k_3}{k_4}\right). \quad (6'')$$

The value of k_4 (or k_{-4}) is related to the Debye rotational correlation time τ_0:[34]

$$\tau_0(\simeq k_4^{-1}) = \frac{4\pi a_0^3\eta}{3\kappa T}, \quad (10)$$

where a_0 is the radius of rotating particle and κ the Boltzmann constant. We thus get

$$k_4 = \frac{RT}{V\eta} \quad (11)$$

(*e.g.* $k_4\simeq4.0\times10^{10}\ \mathrm{s^{-1}}$ in EtOH at 293K),

where R is the gas constant and V the specific volume of rotating sphere (the specific volume of rotating part (C–N–CH=CH$_2$) in RP is assumed to be about 50 ml).

Substituting Eq. 11 into Eq. 6'', we get

$$\frac{1}{\Phi_R} = \frac{1}{\Phi_{RP}}\left(1+\frac{k_3}{k_5}\right) + \frac{k_3V}{\Phi_{RP}R}\cdot\frac{\eta}{T}, \quad (12)$$

where

$$\frac{1}{\Phi_{RP}}\left(1+\frac{k_3}{k_5}\right) = a, \quad \text{and} \quad \frac{k_3V}{\Phi_{RP}R} = b.$$

The reaction quantum yield Φ_R at $\eta\ T^{-1}\to0$ is found to be 6.7×10^{-2} (Fig. 5); *viz.*, $\Phi_{RP}\geq6.7\times10^{-2}$ by means of Eq. 12. Thus, we can estimate the value of k_3 from Eqs. 8, 9, and 12 as follows:

$$k_3 \geq 9.2\times10^{9}\ \mathrm{s^{-1}}. \quad (13)$$

If we assume that the rate constants k_3 and k_5 are approximately the same, the value of $(\Phi_{RP})^{-1}$ is equal to 7.5 from Eq. 12. We then obtain

$$k_3 \simeq 1.8\times10^{10}\ \mathrm{s^{-1}}. \quad (14)$$

However, there are some problems in the approximations.

(1) The assumption $k_4\simeq k_{-4}$ holds under the conditions that the potential energy and the frequency factor in the process k_4 are equal to those in the process k_{-4}. Strictly speaking, such conditions are unlikely, since there may be a difference in the steric hindrance between RP and RP'. Similarly, both k_3 and k_5 values may not be the same.

(2) The Debye equation is applicable to an entire molecule; the rotational diffusion in the present case is a restricted rotation.

Case C: We assume that the structural change of biradical (RP→RP') occurs due to the Brownian movement of solvent molecules surrounding it. Einstein's theory of the Brownian movement can be applied to the diffusion of a molecule to an adjacent site.[35] When a solvent molecule adjacent to RP moves into a solvent hole with the rate constant τ_D^{-1}, an empty space may be

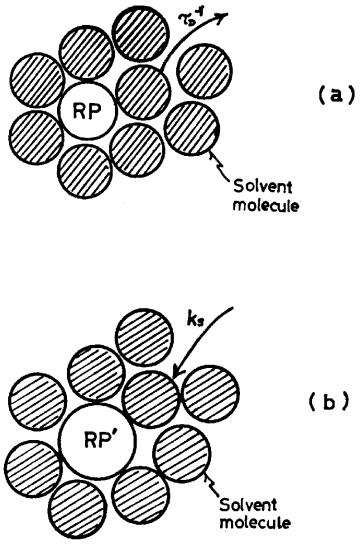

Fig. 6. Schematic models (a) for the Brownian movement of the proper solvent molecule with the rate constant τ_D^{-1} and (b) for the translational diffusion of a solvent molecule into the site adjacent to RP' with the rate constant k_s. See the text.

produced as shown in Fig. 6(a). This makes the conformational change RP→RP′ possible. The value of k_4 may be equal to that of τ_D^{-1}. From the Einstein's equation for the Brownian movement, we have

$$k_4 \simeq \tau_D^{-1} = \frac{6(D_1+D_2)}{\bar{r}^2}, \quad (15)$$

where D_1 and D_2 are the diffusion constants of EtOH and RP respectively, and $\bar{r}$ is the average distance of the movement of the proper ethanol molecule ($\bar{r}=2\,a_1$, where a_1 denotes the radius of an ethanol molecule). The values of D_1 and D_2 can be determined by Stoke's formula for the translational diffusion:

$$D = \frac{\kappa T}{6\pi a_i \eta}, \quad (16)$$

where a_i is the radius of the corresponding species ($a_1\simeq$ 2.85 Å for EtOH; $a_2\simeq$3.48 Å for RP). From Eqs. 15 and 16, the value of k_4 can be estimated as a function of $T\eta^{-1}$:

$$k_4 = 8.6\times10^5\, T\eta^{-1} \quad (17)$$

(*e.g.* $k_4\simeq 2\times10^{10}\,s^{-1}$ in EtOH at 293K).

On the other hand, the rate constant k_{-4} can be evaluated by applying the Smoluchowski-Debye equation.[35,36] We assume that the conformational change RP′→RP is accomplished by the diffusion of a solvent molecule to an adjacent site with the rate constant k_s (Fig. 6(b)). The value of k_{-4} seems to be close to that of k_s:

$$k_{-4} \simeq k_s = \frac{4\pi PN\sigma(D_1+D_2)[\mathrm{solv}]}{1000}, \quad (18)$$

where D_1 and D_2 are diffusion coefficients in $cm^2\,s^{-1}$; σ is the effective collision diameter in cm ($\sigma\simeq a_1+a_2=6.33\times10^{-8}$ cm); N is Avogadro's number; P the steric factor (assumed to be unity); [solv] the concentration of neat EtOH (17.1 M). Thus, the value of k_{-4} is estimated from Eq. 18 to be

$$k_{-4} \simeq 5.4\times10^{10}\,s^{-1} \text{ at } 293K. \quad (19)$$

From Eqs. 6 and 17, we get

$$\frac{k_3}{\Phi_{RP}} \geq 7.1\times10^{10}\,s^{-1}, \quad (20)$$

where $\Phi_{RP}\geq6.7\times10^{-2}$. Thus

$$k_3 \geq 4.8\times10^9\,s^{-1}. \quad (21)$$

However, the value of k_3 should not exceed that of diffusion-controlled k_4 (*e.g.* $2\times10^{10}\,s^{-1}$ at 293 K). Thus, we can estimate the recombination time τ of RP as follows:

$$50\text{ ps} < \tau \leq 200\text{ ps}. \quad (22)$$

The τ value of the biradical RP is the order of $\approx10^{-10}$ s, which is the same order of magnitude of the geminate recombination times between iodine atoms measured with picosecond pulses (70 ps in hexadecane and 140 ps in CCl_4).[5] The approximation in Case C seems to be the best.

Multiplicity and Spin Inversion of RP. The question arises as to the multiplicity of the biradical RP. If the singlet RP is produced *via* $^1(n,\pi^*)$, the direct back reaction $^1RP\rightarrow NVP$ is faster than the recombination of ^3RP, since the recombination should occur after the spin inversion of $^3RP\rightarrow{}^1RP$. The time for the direct back reaction is the same as that ($\approx10^{-11}$ s) of $\overline{^1A\cdot\cdot B}$. The processes $^1(n,\pi^*)\rightarrow{}^1RP\rightarrow NVP$ can not be observed in the present experiment, even if they are involved in the radiationless processes of NVP*. Judging from the recombination time of RP ($\approx10^{-10}$ s) and the reactive state of NVP $^3(n,\pi^*)$, it is probable that the multiplicity of RP is triplet. The spin inversion time of ^3RP can be evaluated to be $\approx10^{-10}$ s, since spin inversion is the rate-determining step in the recombination of ^3RP. The spin inversion of ^3RP needs time of $\approx10^{-10}$ s to cause appreciable enhancement due to the radical-pair mechanism. Several re-encounters between the radical sites of ^3RP would occur before recombination. This supports Adrian's model[37] for the radical-pair mechanism.

The structure of biradical RP allows a reversible change similar to $\overline{A\cdot\cdot B}\leftrightarrow\overline{A\cdot|\cdot B}$ without further complete separation between radical sites, since the molecular chain joints them. The possibility for the formation of the $\overline{^3A\cdot|\cdot B}$ type of ^3RP is greater than that of freely diffusing radicals. The J value of a reorienting biradical fluctuates depending upon the distance between the radical sites [the correlation time of reorientation k_4^{-1} (or k_{-4}^{-1}) is $\approx10^{-11}$ s in EtOH at room temperature], which decreases exponentially with increasing distance.[15] A small S-T energy gap ($2J$) of the triplet biradical gives rise to an efficient S-T mixing due to the nuclear hf and the spin-orbit interactions. The rapid spin inversion of ^3RP might be caused by the appreciable S-T mixing.

A similar fast spin inversion has been studied by Eisenthal *et al.*[5] using a picosecond laser at 5300 Å. At this frequency I_2 molecules are excited to the $^3\Pi_{o^+u}$ ($v'\simeq33$) state. Only a small fraction of I_2 molecules are excited to the $^1\Pi_u$ state, dissociating directly. The I_2 molecules excited to the $^3\Pi_{o^+u}$ state undergo a predissociation induced by collision *via* the $^3\Pi_{1u}$ state leading to a pair of ground state, $^2P_{3/2}$, iodine atoms. According to the spin conservation rule, the radical-pair of iodine atoms in a solvent cage should be triplet. However, the geminate recombination time τ is very short (70—140 ps),[38] indicating that spin inversion takes place within τ. The fast geminate recombination of iodine atoms can be understood by the radical-pair mechanism resulting in the S-T mixing. The large spin-orbit coupling due to the heavy atom and the nuclear hf interactions may be involved in the system.

Conclusion

The mechanism of the photochemical ring expansion of NVP involving the Norrish type I dissociation at 254 nm in EtOH is shown in Fig. 4. The recombination time τ of the biradical RP was estimated to be $\approx10^{-10}$ s. The spin inversion of the triplet biradical requires a time of about 10^{-10} s to cause efficient enhancement due to the radical-pair mechanism.

The authors are grateful to Professor I. Tanaka, Tokyo Institute of Technology, for his valuable discussions. They would also like to thank Professor S.

Nagakura, the University of Tokyo, and Dr. H. Hayashi, the Institute of Physical and Chemical Research, for their interest and helpful discussions.

38) Eisenthal *et al.*[5] have also shown that the iodine atoms which have escaped will recombine at a much later time ($\approx 10^{-8}$ s). It seems that, except for very high fields, the CIDNP and CIDEP phenomena can be observed in slow recombination [*i.e.* secondary recombination, with time longer than $\approx 10^{-9}$ s (probably 10^{-6}—10^{-8} s)], but not in rapid geminate recombination.

ESR and ENDOR Studies of the Ion Pairs of Double-, Triple-, and Quadruple-layered [2.2]Paracyclophane Radical Anions and Alkali Metal Cations

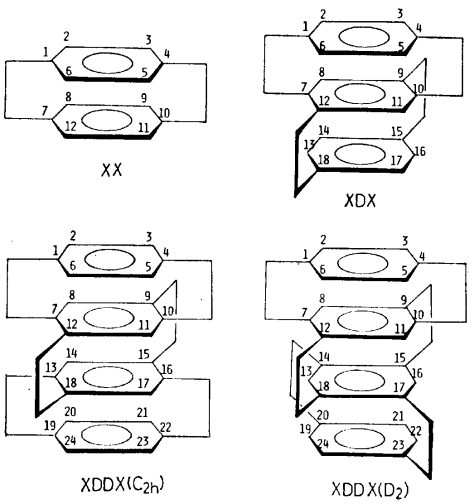
(Received February 28, 1977)

The radical anions of double-, triple-, and two kinds of quadruple-layered [2.2]paracyclophane $XX^{\cdot-}$, $XDX^{\cdot-}$, $XDDX(C_{2h})^{\cdot-}$ and $XDDX(D_2)^{\cdot-}$, were examined by means of ESR and ENDOR spectroscopy. The spin distributions in these radical anions are largely polarized by interaction with counter ions. An MO calculation has been attempted to account for the observed ion-pairing effects. It is shown by the calculations that the observed ion-pairing effects can be explained by the ion-pair models where the cation is located above the center of the outermost benzene ring. It is also shown that the potassium ion migrates from one side of the radical molecule to the other in a loosely bound ion pair of $XDX^{\cdot-}$ in a 1,2-dimethoxyethane(DME)–tetrahydrofuran(THF) 1 : 1 mixed solvent, as in the ion pair of $XX^{\cdot-}$ with the potassium ion in DME–THF (2 : 1) which has been previously reported by Gerson *et al.* Such migration of cations in ion pairs was not observed for the quadruple-layered [2.2]paracyclophane radical anions.

Several ESR investigations of the radical anion of double-layered [2.2]paracyclophane, $XX^{\cdot-}$, and its related compounds have been reported.[1-6] The use of ENDOR spectroscopy has also been tried in an attempt to confirm the analysis by the ESR method.[7] Of prime interest in these investigations in the electron transfer between the two aromatic rings and the effects of counter ions on the spin distributions in the radical anions. It has been shown[3,7] that, in $XX^{\cdot-}$, the unpaired electrons are distributed equally on both benzene rings when the radical anion is free from interaction with alkali metal cations. Ion pairing with alkali metal cations remarkably affects the spin distribution in the radical molecules. Gerson *et al.* have shown[6] that the alkali ion resides above the one benzene ring in the ion pair of $XX^{\cdot-}$. The present work was undertaken in order to investigate the distribution of unpaired electrons in the multilayered-paracyclophane radical anions and the interaction of these multilayered paracyclophane radical anions with counter ions in solutions. The radical anions of triple- and two kinds of quadruple-layered [2.2]paracyclophane, XDX, $XDDX(C_{2h})$, and $XDDX(D_2)$, were examined by the ESR and ENDOR methods. Though the observation of the spectra for the free anions was unsuccessful, ESR and ENDOR data concerning ion pairs of the radical anions could be obtained. In this paper we will discuss the ion-pair structures of $XDX^{\cdot-}$, $XDDX(C_{2h})^{\cdot-}$, and $XDDX(D_2)^{\cdot-}$ on the basis of the observed ion-pairing effects on the hfs constants and theoretical calculations about the effects. Though the ion pairs of $XX^{\cdot-}$ have been extensively examined by Gerson *et al.*,[3,6,7] the ESR spectra of $XX^{\cdot-}$ have also been measured in order to obtain wider information about the ion-pairing effects on the hfs constants, and the theoretical calculations used above are used to confirm that the calculations predict well the observed results and the ion-pair structures.



Experimental

The XX, XDX, $XDDX(C_{2h})$, and $XDDX(D_2)$ were synthesized according to the procedure described previously.[8] These substances were purified by column chromatography on silica gel or by preparative gel permeation liquid chromatography and then repeated recrystallizations (XX from chloroform, mp 285 °C; XDX from toluene, 231.5—232.5 °C dec; $XDDX(C_{2h})$ from toluene, 250 °C dec; $XDDX(D_2)$ from carbon tetrachloride–acetone (1 : 3), 240 °C dec).

The radical anions were prepared by reduction with potassium or a potassium/sodium alloy, and in a few cases, by reduction with caesium in ethereal solvents. Reduction with sodium was attempted, but no formation of the radical anions was observed. 1,2-dimethoxyethane (DME), tetrahydrofuran (THF), 2-methyltetrahydrofuran (MTHF), diethyl ether (DEE), mixtures of DME and THF, and DME containing a low percentage of hexamethylphosphoric triamide (HMPA), were tried as solvents. When DME and DME–HMPA were used for XDX, $XDDX(C_{2h})$, and $XDDX(D_2)$, the observed radicals were attributable to secondary production, and no ESR spectra due to the radical anions of XDX, $XDDX(C_{2h})$, and $XDDX(D_2)$ could be observed.[9] For experiments with $XDX^{\cdot-}$, $XDDX(C_{2h})^{\cdot-}$, and $XDDX(D_2)^{\cdot-}$, it was necessary to keep the solutions below −90 °C, but $XX^{\cdot-}$

was more stable than the above and the ESR measurements for XX^{τ} could be carried out at temperatures up to −50 °C.

The glass apparatus used for the alkali-metal reduction of ordinary aromatic compounds was modified for the preparation of XDX^{τ}, $XDDX(C_{2h})^{\tau}$, and $XDDX(D_2)^{\tau}$ by coating alkali-metal mirror inside the side arm for ESR or ENDOR measurements so that the reduction could proceed in the side arm. Thus, the radicals were prepared in an ESR or ENDOR cavity cooled to the desired temperatures; ESR and ENDOR measurements could thus be carried out immediately after the completion of the reduction reaction. This was accomplished without any movement of the sample tube which may accompany the decomposition of the radical anions, while increasing the solution temperature. Such a modification of the apparatus was very effective for the preparation of XDX^{τ}, $XDDX(C_{2h})^{\tau}$, and $XDDX(D_2)^{\tau}$.

The ESR and ENDOR spectra were recorded with a Hitachi 771 X-band ESR spectrometer and a JEOL ES-EDX-1 ENDOR spectrometer respectively.

Results

ESR Spectra for XX^{τ}. The ESR spectra have been reported[3] for XX^{τ} reduced with potassium in several ethereal solvents. The same ESR spectra for these systems were reproduced in the present work. In addition, the temperature dependencies of the hfs constants in THF and MTHF were measured. The results are shown in Fig. 1, together with the values obtained from the DME–HMPA solutions at −90 °C.

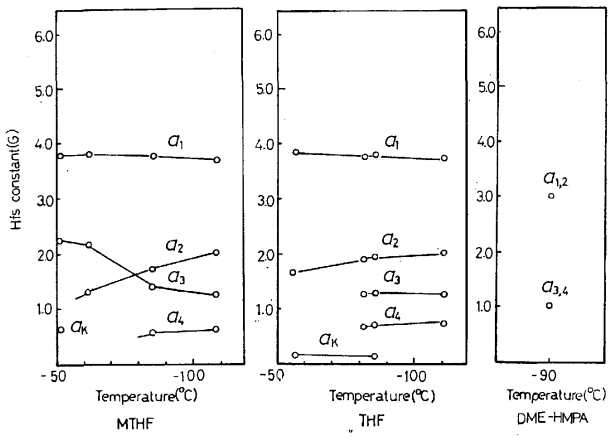


Fig. 1. Temperature dependence of the hfs constants for XX^{τ}. The subscripts of a are given in order of magnitude of the hfs constants. The counter ion is the potassium ion.

ESR Spectra for XDX^{τ}. The ESR spectrum observed for XDX^{τ} in DME–THF (1 : 1), with the potassium ion as a cation, consists of seven groups with a separation of 5.68 G. Moreover, each group shows further resolution. When XDX^{τ} is prepared with caesium in DME–THF (1 : 1) or with potassium in MTHF or DEE, the ESR spectra change to broad triplet patterns with splittings of 5.95, 6.13, and 6.48 G. On the other hand, XDX^{τ} in THF, with the potassium ion, shows an ESR spectrum which appears to be a superposition of the two hyperfine patterns of septet and triplet splittings. The ESR spectra observed for XDX^{τ}, with the potassium ion as a cation, are shown in Fig. 2.

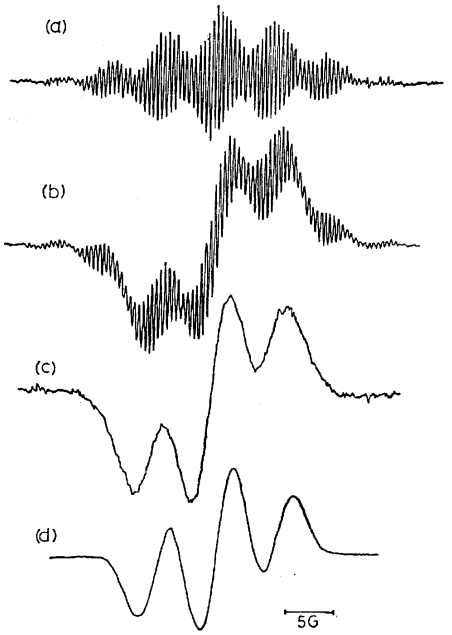

Fig. 2. ESR spectra for XDX^{τ}, with the potassium ion as a cation in (a) DME–THF(1 : 1), (b) THF, (c) MTHF, and (d) DEE at −100 °C.

ESR Spectra for $XDDX(C_{2h})^{\tau}$ and $XDDX(D_2)^{\tau}$. $XDDX(C_{2h})^{\tau}$ and $XDDX(D_2)^{\tau}$, with the potassium ion as a cation, show ESR spectra with a triplet pattern similar to those observed for XDX^{τ} in MTHF and DEE, regardless of the solvent used. Slight changes of the triplet splittings with solvents were observed; those for $XDDX(C_{2h})^{\tau}$ increase in this order of the solutions: DME–THF (1 : 1) (6.28 G), THF (6.40 G), MTHF (6.54 G), and DEE (6.62 G), while those for $XDDX(D_2)^{\tau}$ increase in another order: DME–THF (1 : 1) (6.20 G) and THF (6.30 G). Some typical ESR spectra for these radicals are shown in Figs. 3 and 4.

ENDOR Spectra for XDX^{τ}. As has been seen above, most of the systems of XDX^{τ}, $XDDX(C_{2h})^{\tau}$ and $XDDX(D_2)^{\tau}$ showed the broad triplet ESR pattern; hence, it is impossible to obtain detailed information about the hyperfine interaction of radicals from the ESR spectra only. Thus, ENDOR spectroscopic analysis was attempted for XDX^{τ}, $XDDX(C_{2h})^{\tau}$, and $XDDX(D_2)^{\tau}$. Figure 5 shows the ENDOR spectra observed for XDX^{τ} in MTHF. No ENDOR spectra

were obtained from $XDX^{\cdot-}$ in DME-THF mixed solvents or in THF with the potassium cation. It is interesting that the ENDOR spectra were successfully observed only for systems showing the ESR spectra with the broad triplet pattern. However, it should be noted that even in systems where the ENDOR spectra were successfully observed, ENDOR signals due to the protons responsible for the triplet splittings in ESR spectra could not be detected. These protons may have different optimum temperature conditions for ENDOR observation from those of the other protons.

As Fig. 5 shows, the ENDOR spectra vary appreciably with the temperature. Changes with different solvents

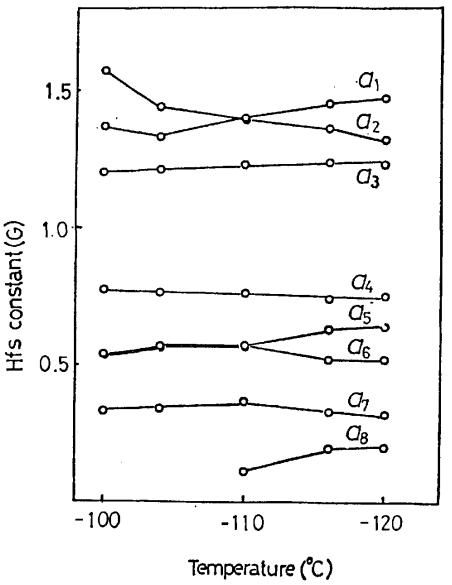

Fig. 6. Changes of the hfs constants with temperature, for $XDX^{\cdot-}$ in MTHF with the potassium ion.

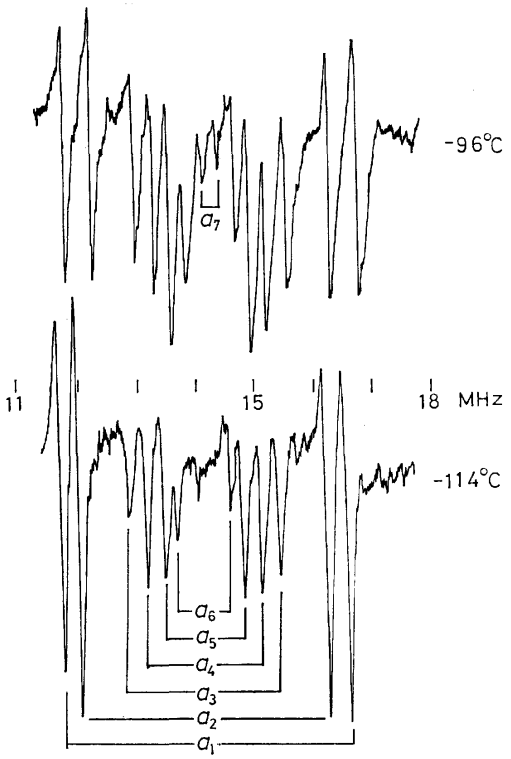

Fig. 7. ENDOR spectra for XDDX$(C_{2h})^{\cdot-}$ in THF, with the potassium ion at different temperatures.

and cations were also observed (Table 1). The hfs constants observed from the MTHF solution with the potassium cation are shown as a function of the temperature in Fig. 6.

ENDOR Spectra for XDDX(C_{2h})$^-$ and XDDX(D_2)$^-$. The ENDOR spectra for XDDX(C_{2h})$^-$ and XDDX(D_2)$^-$ were obtained from all the systems treated here, but, as is the case for XDX$^-$, the ENDOR signals due to the protons which caused the triplet splittings in the ESR spectra could not be detected. Some typical ENDOR spectra for XDDX(C_{2h})$^-$ and XDDX(D_2)$^-$ are given in Figs. 7—9. Although there are no appreciable differences between the ESR spectra for the XDDX(C_{2h})$^-$ and XDDX(D_2)$^-$ radical anions, their ENDOR spectra clearly show different hyperfine

interactions corresponding to their different molecular structures. The variation in the hfs constants with the solvent and the temperature is shown in Figs. 10 and 11. The values of the hfs constants obtained at −114 °C are summarized in Table 2.

Analysis of ESR Spectra by Means of Fourier Transform

As has been described above, although the ESR spectrum of $XDX^{\cdot}$ in DME–THF (1 : 1) with the potassium ion gave a better resolution than the spectra in other systems, a direct analysis of the ESR spectrum was impossible and an ENDOR spectrum could not be obtained. For the purpose of ESR-spectrum analysis, we employed the Fourier transform of the ESR spectrum. The method used here is nearly the same as that used by Silsbee[11] and by Gubanov *et al.*[12]

We expressed the observed ESR spectra $F(x)$ by the Fourier transform

$$F(x) = \frac{1}{2\pi}\int_{-\infty}^{+\infty} G(y)e^{-ixyx}dx, \tag{1}$$

with an inverse transform

$$G(y) = \int_{-\infty}^{+\infty} F(x)e^{-ixxy}dx. \tag{2}$$

Here,

$$G(y)^2 = G_a(y)^2 + G_b(y)^2, \tag{3}$$

where $G_a(y)$ and $G_b(y)$ are the cosine and sine coefficients of the Fourier transform, expressed by

$$G_a(y) = \frac{1}{N}\sum_{x=-N}^{N} F(x)\cos\left(\frac{\pi}{N}yx\right), \tag{4}$$

$$G_b(y) = \frac{1}{N}\sum_{x=-N}^{N} F(x)\sin\left(\frac{\pi}{N}yx\right). \tag{5}$$

If the observed ESR spectra are expressed as an odd function of x (as in the case of the ordinary isotropic 1st derivative ESR spectra), $G(y)$ is expressed in terms of $G_b(y)$, and $G_a(y)$ need not be taken into account. Since the ESR spectrum including hyperfine interactions with n nuclei is the n-fold convolution of the spectrum including a hyperfine interaction with a single nucleus, its Fourier transform can be expressed as the product of the transforms of $f_i(x)$:

$$G(y) = \prod_{i=0}^{n} g_i(y), \tag{6}$$

where

$$g_i(y) = \int_{-\infty}^{+\infty} f_i(x)e^{-ixxy}dx.$$

Hence, the Fourier transform of the observed 1st derivative ESR spectra can be simulated by this equation

$$G(y) = Kg_0(y)\prod_{i=1}^{KA}\left[\cos\left(\frac{a_i}{2}y\right)\right]^{Na_i} \times \prod_{j=1}^{KB}[1+2\cos(a_jy)]^{Na_j} \times \prod_{k=1}^{KC}\left[\cos\left(\frac{3}{2}a_ky\right)+\cos\left(\frac{1}{2}a_ky\right)\right]^{Na_k}, \tag{7}$$

where a_i, a_j, and a_k are the hfs constants of the i, j, and k nuclei, with spin $I=1/2$, 1, and 3/2 respectively. Na_i, Na_j, and Na_k are the numbers of protons with hfs constants of a_i, a_j, and a_k. KA, KB, and KC are the numbers of different kinds of nuclei with spins of 1/2, 1, and 3/2 respectively, and where $g_0(y)$ is a function expressed as

$$g_0(y) = \exp(-3\pi\Delta H|y|), \tag{8}$$

when the ESR lines are Lorentzian, and as

$$g_0(y) = \exp(-\pi^2\Delta H^2y^2/2), \tag{9}$$

when the ESR lines are Gaussian. Here, $\Delta H=2/T_2$.

The ESR charts recorded by a Hitachi 771 X-band ESR spectrometer were converted to the digital form with a JEC-CR-114 chart reader and a JEC-6 spectrum computer. The inverse Fourier transforms and the simulation of the transformed spectra were done by means of the NEAC 700 computer at the Tohoku University Computer Center. Figure 12 shows the Fourier transform of the observed ESR spectrum, its computer simulation, and the simulation of the observed

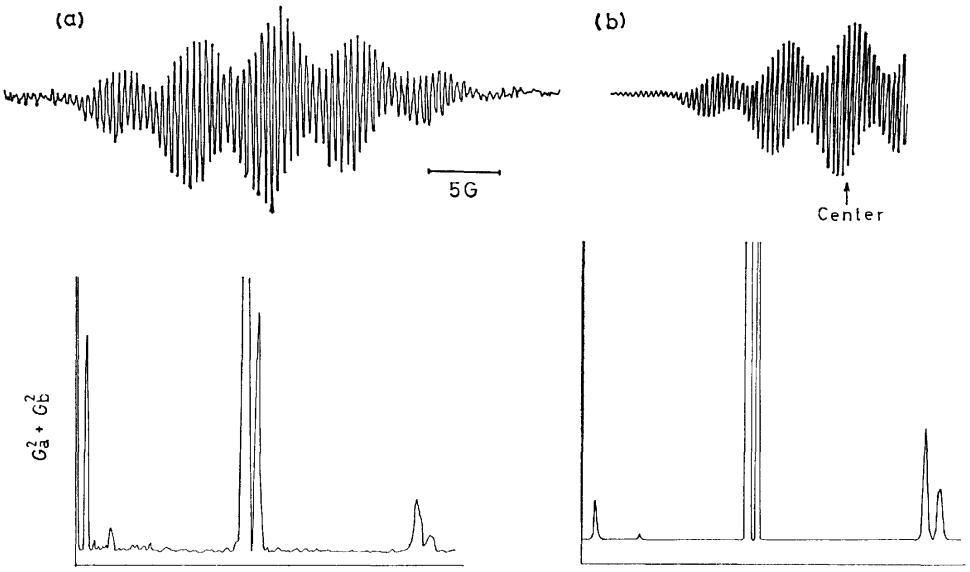

Fig. 12. Observed and theoretical ESR spectra and corresponding Fourier transform, for $XDX^{\cdot}$ in DME–THF(1 : 1) with the potassium ion.

Table 3. Hfs constants obtained by fourier transform and computer simulation of the ESR spectrum for $XDX^{\cdot-}$ in DME–THF (1:1) with the potassium ion

Hfs constants(G)	Nuclear spins	Numbers of nuclei
5.83	1/2	6
1.37	1/2	4
0.92	1/2	8
0.46	1/2	8

ESR spectrum. The hfs constants thus obtained are listed in Table 3.

Calculations of the Spin Densities, the Hfs Constants, and the Effects of Counter Ions

The spin distributions in $XX^{\cdot-}$, $XDX^{\cdot-}$, $XDDX(C_{2h})^{\cdot-}$ and $XDDX(D_2)^{\cdot-}$ were calculated by the McLachlan method.[13] In this calculation the resonance integrals are taken to be proportional to the overlap integrals.[14] The interatomic distances required for the calculation of the overlap integrals were taken from the X-ray data for the compounds XX[15] and $XDDX(C_{2h})$.[16] For the other compounds, estimates were made with reference to $XDDX(C_{2h})$ because of the absence of X-ray data. The hyperconjugation of the ethylene bridges was ignored in the MO calculation, but induction effects were taken into account for atoms directly bonded to the alkylbridges; therefore, $\alpha_C=\alpha_C^\circ-0.1\beta_{CC}$. The λ coefficient in the McLachlan calculation was taken to be 1.1. The proton hfs constants were calculated by using the obtained spin densities and McConnell's equation. The Q values used in the equation were 20.5 and 25.1 for the ring and the alkyl protons respectively; this gives consistent hfs constants for $XX^{\cdot-}$ in the free anion state.

On the other hand, the effects of the counter ions were calculated by combining the McClelland treatment of the counterion effect[17] with the McLachlan MO calculation by means of the following effective Hamiltonian:

$$\mathcal{H}_{eff} = \mathcal{H}^\circ - \frac{e^2}{e(r)\cdot r}, \qquad (10)$$

where $\mathcal{H}^\circ$ is the usual Hückel Hamiltonian; the second term is the electrostatic attraction of the radical anions and the counter ion. The $e(r)$ in the second term are the dielectric constants in a microscopic meaning; they may be referred to as screening constants and vary with the solvent and with the position in the radical anions. In the present case, however, for convenience $e(r)$ is taken to be 1.5 throughout the calculations. The oscillational motion of the cation around the potential minimum point in the ion pairs is also ignored in the calculation. Because of the approximation of $e(r)$ and the cation motion in the ion pair, the distances between the anion and the cation in the calculation do not have any quantitative meaning, but these distances can be regarded as a qualitative measure of either the strength of the cation-anion interaction or the cation-anion distances. The hfs constants of the ion pairs were calculated as functions of the cation-anion distances. The results will be shown later.

The cation-anion interaction energies were also calculated by means of this equation:

$$E = \sum_x \nu_x(E_x - E_x^\circ) - \sum_t \frac{e^2}{r_t} \qquad (11)$$

where E_x° and E_x are the energies of the Hückel MO Ψ_x° of the free anion and the modified Hückel MO Ψ_x of the ion pair respecively, and where ν_x is the occupation number of the relevant MOs. The last term represents the Coulomb repulsion between the cation and the effective positive charge of the carbon cores. Calculations have been done for the radical anions of the layered compounds and for some ordinary aromatic hydrocarbons. The result shown below is for the case where the cation moves along the axis connecting the 1 and 4 positions (x axis) for the layered compounds, or along the long molecular axis (x axis) for the other aromatic compounds, at a distance of 0.38 nm from the (outermost) nuclear plane of the radical anions.

Discussion

Ion-pair Structure of $XX^{\cdot-}$. It is known that $XX^{\cdot-}$ in DME–HMPA exists as a free anion, but when $XX^{\cdot-}$ is prepared by means of potassium in DME–THF, THF, or MTHF, the radical anion forms ion pairs with the counter ion.[3,7] This ion-pair formation can be concluded on the basis of the observation of the hyperfine splitting due to the potassium nucleus and the appreciable polarization in the spin distributions due to the cation. Ion pairing divides both the ring and alkyl protons into two groups with equal numbers of protons and different hfs constants. Three ion-pair models

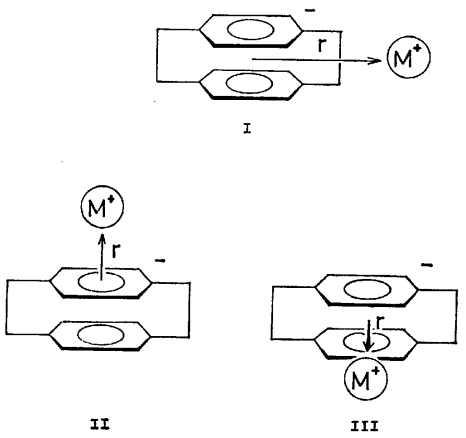

Fig. 13. Ion pair models of $XX^{\cdot-}$.

(Fig. 13) were first considered,[3] but a recent paper by Gerson *et al.*[6] has concluded, based on experiments with deuterio compounds, that the ion pair takes the structure of Model II where the cation is situated above the center of the one benzene ring. Before proceeding to discuss the ion pairs of the triple- and quadruple-layered radical anions, let us examine the ion-pair structure of $XX^{\cdot-}$ by means of the theoretical calculation of the cation effects on the hfs constants. The calculated

results will be compared with the experimental results shown in Fig. 1.

Calculations have been done for the three ion-pair models. In Model I the unpaired electron comes to occupy the MO level which gives the alkyl proton hfs constants larger than those of the ring protons when the cation-anion interaction becomes appreciable. This model is apparently improper, because the experimental results indicate that the larger hfs constant is due to the ring protons.[3,6]

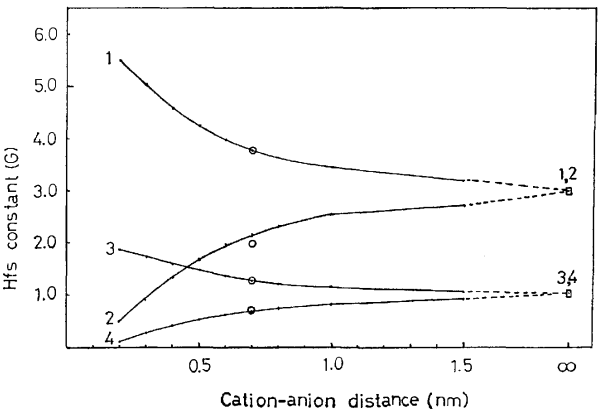

Fig. 14. Effects of the counter ion on the hfs constants of XX^- calculated for ion pair model II in Fig. 13 as a function of anion-cation distance r. □ and ○ are the plots of the experimental hfs constants for XX^- in the free anion state and thos observed in THF with the potassium ion. The numbers given to the curves are the carbon positions to which the corresponding ring proton or methylene group is bonded.

The observed trend of the ion-pairing effects on the hfs constants is predicted by calculations based on Models II and III, though in the calculation of Model III our approximation can not give different hfs constants for the two protons within one CH_2 group; the calculations for both models indicate that the hfs constant for ring protons at the cation side increases by the ion pairing, while the hfs constant for the opposite side decreases. Figure 14 shows the results for Model II. In view of the well-known facts that ion pairing is more favored at higher temperatures and in MTHF than in THF,[18] the changes observed in hfs constants with the temperature and the solvents (Fig. 1) can be surprisingly well predicted by calculations based on Model II. Both the theoretical and empirical results indicate that, as the cation-anion interaction increases, the hfs constants of the ring and methylene protons on the cation side increase, while those on the opposite side decrease. When the cation-anion interaction becomes more marked, the hfs constant of the methylene protons on the cation side becomes larger than that for the ring protons on the opposite side.

Though the calculation for Model III predicts the observed trend of the ion-pairing effects, the polarization effect due to the cation is less than 1/3 of that in Model II, and it seems to be too small to explain the observed magnitude of the effects. Apparently the calculations for Model II show the best fit with the observed changes in the hfs constants; the results indicate that the calculations used here can well predict the correct ion-pair structure.

XDX^- in DME–THF. As in the case of XX^-, the remarkable changes in ESR spectra for XDX^- can be attributed to the ion-pairing effect. In view of the general features of the solvent effects on ion pairing, the interaction of the radical anion in DME–THF is considered to be the weakest among the systems treated here. According to the MO calculation (*vide infra*), the largest hyperfine interaction of XDX^- in the free anion state should arise from protons at the 8 and 11 positions, which show triplet splitting in the ESR spectrum. The septet splitting observed for the DME–THF solution (Fig. 2(a)) suggests that there may still be some appreciable interaction with the cation in the solution.

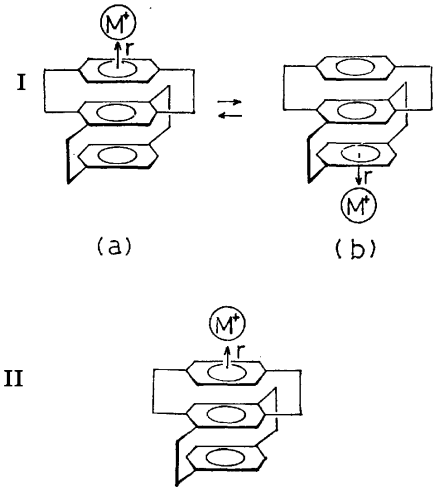

Fig. 15. Ion pair models for XDX^-.

To explain the ESR pattern observed, the ion-pairing effect on the hfs constants was calculated for both ion-pair models in Fig. 15. In these models, the cation is assumed to favor a location above the plane of the outermost benzene rings of the molecule, as in the case of XX^-. However, in Model I the cation rapidly changes position from one side of the molecule to the other. In this case the observed hfs constants are given by the average of ion-pair states, (a) and (b). In Model II it is assumed that XDX^- forms a tighter ion pair where the cation is positioned on one side of the molecule.

The calculated results (Fig. 16) show that the septet splitting in the ESR spectrum seems due to the ion pair corresponding to the area marked by Arrow A, where the six protons at the 2, 5, 8, 11, 14, and 17 positions have hyperfine interactions of the same magnitude so as to give the septet hyperfine splitting in the ESR spectrum. The calculated result also indicates that the other protons have hyperfine interactions much smaller than the septet splitting. These results are in accord with the results of the Fourier transform analysis of the ESR spectrum. Since the other ion-pair models can not explain the observed septet ESR pattern, it can be concluded that XDX^- in DME–THF (1:1) has the ion-pair state predicted by Model I (Fig. 15).

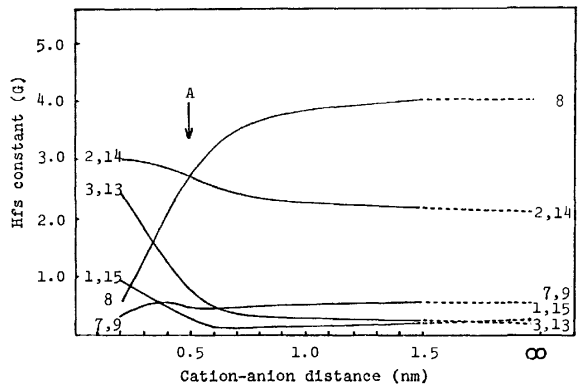

Fig. 16. Effects of the counter ion on the hfs constants of XDX^- calculated for ion pair model I in Fig. 15. The numbers given to the curves have the same meaning as in Fig. 14. Mark A: see text.

XDX^- in THF, MTHF, and DEE. As has been mentioned above, the ESR spectra observed from XDX^- in THF with the caesium ion, and in MTHF and DEE with the potassium ion, show broad triplet splitting. Considering that these systems are in a more favorable condition for ion pairing than is the DME–THF mixed solvent system, the triplet splitting can be attributed to their ion pairs being bound more tightly than in the DME–THF mixed solvent. The calculation shown in Fig. 17 predicts well this triplet splitting; *i.e.*, it indicates that the unpaired electron is redistributed on the benzene ring on the cation side (especially at the 2 and 5 positions) by the formation of strong ion pairs of the Model II type. The hyperfine interaction of the 2 and 5 protons gives the triplet splitting observed in the ESR spectrum. In the ENDOR spectra for XDX^- in MTHF, the presence of eight kinds of protons was observed (Figs. 5 and 6). However, the ENDOR signal corresponding to the triplet splitting in the ESR spectrum could not be detected. Taking into account this triplet splitting in the ESR spectrum, the observed ENDOR spectra indicate that there are nine types of protons in the radical anion; this finding is in agreement with the expectation from the ion-pair model being considered here.

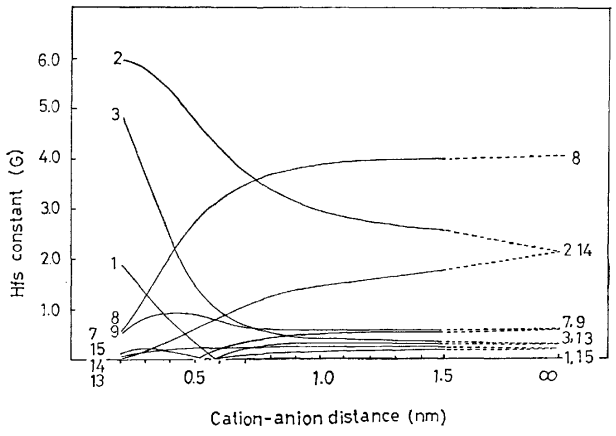

Fig. 17. Effects of the counter ion on the hfs constants of XDX^- calculated for ion pair model II in Fig. 15. The numbers given to the curves have the same meaning as in Fig. 14.

The changes observed in the hfs constants with the temperature and the solvent can be explained by this ion-pair model. It has already been noted that the triplet splitting observed in the ESR spectra increases from 6.13G to 6.48G when the solvent is changed from MTHF to DEE. This indicates that the largest hyperfine interaction in the XDX^- ion pair will increase with an increase in the cation-anion interaction. It may also be seen from Fig. 6 that the hfs constant, a_1, observed in the ENDOR spectra increases with an elevation of the temperature, while a_2 decreases; as the cation-anion interaction increases, a_1 increases, but a_2 decreases. These experimental results correspond well to the behavior of the hfs constants calculated for the ion-pair state with a cation-anion distance of about 0.4 nm (Fig. 17).

Thus, it seems reasonable to conclude that, in these cases, XDX^- exists as a relatively tight ion pair with the structure shown in Fig. 15 II. The change in the cation position from one side of the molecule to the other is slow. From a comparison with the calculated results, the triplet splitting observed in the ESR spectra may be attributed to the hyperfine interaction of protons at the 2 and 5 positions, while the a_1 and a_2 observed in the ENDOR spectra may be attributed to protons at the 8 and 11, and 3 and 6 positions, respectively. The reliable assignment of the other hyperfine interactions is difficult.

For XDX^- in THF with the potassium ion, the ESR spectrum appeared to be a superposition of two types of spectra, a triplet pattern and a septet pattern. This indicates that there is an equilibrium between the two types of ion pairs, loosely bound and tightly bound.

Ion Pairs of $XDDX(C_{2h})^-$ and $XDDX(D_2)^-$. The triplet hyperfine pattern observed in the ESR spectra strongly suggests, as in the case of XDX^-, that $XDDX(C_{2h})^-$ and $XDDX(D_2)^-$ are the ion pairs where the alkali metal ion is situated above either of the outermost benzene rings of the molecules. The unpaired electron is mainly distributed on the benzene ring at the cation side, producing the large triplet splittings due to the two ring protons. However, because of the complex molecular structure, it was difficult to find perfect correlations between the observed and the calculated effects of the cation on the hfs constants. Considering only the largest three or four hfs constants, however, some correlation can be seen, as will be discussed below.

For $XDDX(C_{2h})^-$, the triplet splitting in the ESR spectra increases with the change in solvent from THF to MTHF and DEE (*vide ante*). In other words, the splitting increases with an increase in the cation-anion interaction. Taking into account the general effects of the solvent and temperature on ion pairing, it may be seen from Fig. 10 that the hfs constant, a_1, observed in the ENDOR spectra increases with an increase in the cation-anion interaction, while a_2 and a_3 decrease. These changes correspond to the changes in the hfs constants with a cation-anion distance of about 0.4 nm (Fig. 18), as with the ion pair model in Fig. 19. That is, the triplet splitting in the ESR spectra corresponds to

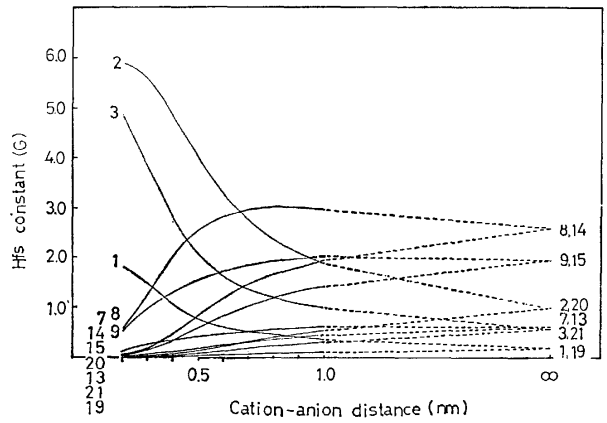

Fig. 18. Effects of the counter ion on the hfs constants of $XDDX(C_{2h})^-$ calculated for the ion pair model in Fig. 19. The numbers given to the curves have the same meaning as in Fig. 14.

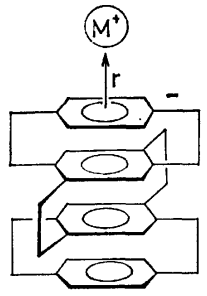

Fig. 19. Ion pair model for $XDDX(C_{2h})^-$.

the hfs constant at the 2 and 5 positions, while a_1, a_2, and a_3 in the ENDOR spectra correspond to those at 3 and 6, 8 and 11, and 9 and 12, respectively.

In a similar way, the hyperfine interactions observed in the ESR and ENDOR spectra for $XDDX(D_2)^-$ correspond to the results calculated in the region of about 0.5 nm in Fig. 20; the interactions are calculated for a similar ion-pair model in Fig. 19. Though the quantitative fit is not necessarily sufficient, the ion-pair model where the alkali metal cation is placed above the benzene ring at the outermost side of the molecules

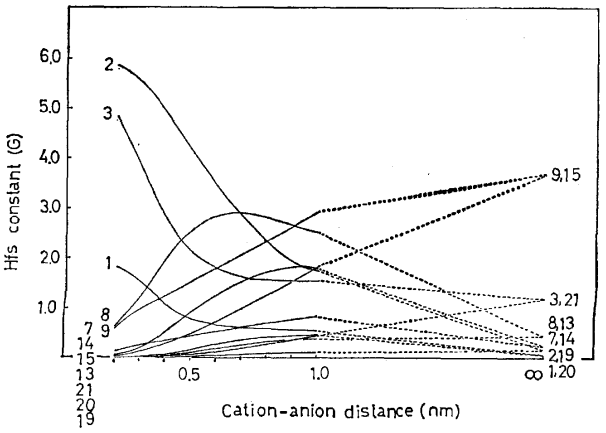

Fig. 20. Effects of the counter ion on the constants of $XDDX(D_2)^-$ calculated for the ion pair model in Fig. 19. The numbers given to the curves have the same meaning as in Fig. 14.

seems reasonably to account for the experimental results.

It may be notable that the cation-anion distances at which the behavior of the predicted hfs constants correspond well to the observed ones are different for $XDDX(C_{2h})^-$ and $XDDX(D_2)^-$. Since the distance for $XDDX(C_{2h})^-$ is smaller, this may imply that $XDDX(C_{2h})^-$ has a more tightly bound ion pair than does $XDDX(D_2)^-$. On the contrary, the results calculated for the cation-anion interaction enrgies (Fig. 21) suggest that $XDDX(D_2)^-$ may form a stronger ion pair than $XDDX(C_{2h})^-$. The difference in the ion pairing between the isomers is very interesting, but a reliable conclusion regarding this problem must await further investigation.

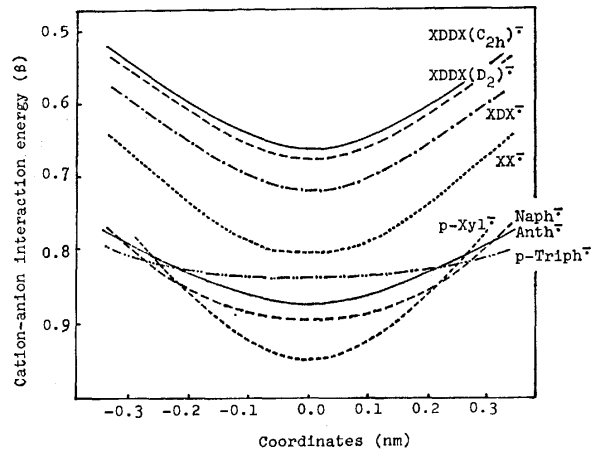

Fig. 21. Cation-anion interaction energies calculated for the radical anions of the layered compounds and for some aromatic hydrocarbons.

Motion of the Alkali Metal Ion in the Ion Pairs. Gerson *et al.*[3] reported that the ESR spectrum of XX^- in DME–THF (2: 1) shows a line-width alternation effect; they explained this as arising from the motion of the alkali ion between the two symmetrical positions. In this paper we also found that the potassium ion in the ion pair of XDX^- in DME–THF (1: 1) changes its position from one side of the anion molecule to the other. Whether such alkali metal motion is an intramolecular or an intermolecular effect (Eqs. 12 and 13) is an interesting problem.

$$XDX^-M^+ \rightleftharpoons M^+XDX^-, \quad (12)$$

$$M^{*+} + XDX^-M^+ \rightleftharpoons M^{*+}XDX^- + M^+. \quad (13)$$

The motion of the cation in the XX^- ion pair can be concluded to be intramolecular in nature by the observation of the distinct hyperfine splitting due to the potassium nucleus in the ESR spectrum showing the linewidth-alternation effect. In the case of XDX^- however, no such potassium hyperfine splitting could be found in the ESR spectrum. However, an intramolecular exchange mechanism is suggested by the fact that the quadruple-layered compounds, which tend to form looser ion pairs than XDX^- (see Fig. 21), are in the ion pairs having a long enough lifetime in the ESR time scale and by the fact that no effects due to the dissociation of the ion pair are observed, not even

in the DME–THF solution.

In the case of $XDDX(C_{2h})^{\cdot-}$ and $XDDX(D_2)^{\cdot-}$, the intramolecular migration of the alkali ions in the ion pairs is considered to be much slower than for $XDX^{\cdot-}$, even though the alkali ions are bound more loosely to the radical anions, because of the long distance between the two potential minimum sites in the ion pairs.

Polarization by Ion Pairing. The radical anions of the layered compounds reveal marked effects of ion pairing in the ESR and ENDOR spectra. However, this large effect does not necessarily mean that the radical anions form strong ion pairs. Figure 21 shows that the cation-anion interaction energies in the radical anions of the layered compounds are smaller than those of ordinary aromatic hydrocarbon radical anions. The most remarkable feature of these radical anions is that they show a large redistribution of unpaired electrons by the counter ions. In $XDX^{\cdot-}$, for example, when the radical is in the free anion state, a large portion of the unpaired electrons will be distributed on the inside benzene ring; hence, a large hfs constant at the 8 and 11 positions is expected (Fig. 17). Because of the ion pairing, the unpaired electron distribution is polarized towards the cation side and the hfs constants of the protons in the benzene ring on the cation side increase significantly. In the ordinary aromatic hydrocarbon radical anions, the redistribution of the unpaired electrons is usually very small. In the case of the naphthalene radical anion, the changes in the hfs constants by ion pairing are only about 0.12G or less.[19] Aside from such layered compounds, only a few examples are known which show such a large redistribution of the unpaired electrons upon interaction with the counter ion.[20,21] The 9,10-dihydroanthracene radical anion is one example.[21]

We hoped to obtain the ESR or ENDOR spectra for the triple-, and quadruple-layered [2.2]paracyclophane radical anions in the free anion state. However, such attempts have been unsuccessful. It should be noted that the unpaired electrons in free $XDX^{\cdot-}$, $XDDX(C_{2h})^{\cdot-}$, and $XDDX(D_2)^{\cdot-}$ can be expected, according to theoretical calculations, to be distributed more on the inside benzene rings. In the present calculation, the unpaired electron densities on the inside benzene ring in free $XDX^{\cdot-}$ amount to about 50%. Further efforts to observe free $XDX^{\cdot-}$, $XDDX(C_{2h})^{\cdot-}$, and $XDDX(D_2)^{\cdot-}$ are in progress.

The authors wish to express their hearty thanks to Dr. Hiroshi Sugiyama, Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, for his valuable advice.

Fluorescence and Laser Photolysis Studies on the Intramolecular Exciplex Systems in Micellar Solutions

Hiroshi MASUHARA, Katsumi KAJI, and Noboru MATAGA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received March 2, 1977)

The behavior of intramolecular exciplex systems consisting of pyrene and *N,N*-dimethylaniline was studied in cationic, anionic and neutral micellar solutions. These systems are favorable for the study of photoinduced CT interaction in micellar systems, since (i) a pair of donor-acceptor is always solubilized in the micelle and (ii) the complicated effect of the intermolecular interaction can be prevented. No exciplex emission was detected and relative quantum yields as well as lifetimes were measured on the monomer fluorescence. The results are interpreted by assuming two solubilized forms in the micelle-water interface. Efficient quenching occurs in the dodecyltrimethylammonium chloride solution irrespective of the length of the methylene chain, suggesting a different solubilization from the cases of other detergents. The efficient quenching is ascribed to the rapid ion-pair formation in the micelle-water interface, which was directly demonstrated by the ns laser photolysis method.

Studies on the photoprimary processes of the excited electron donor-acceptor (EDA) systems are indispensable for the interpretation of photooxidation-reduction reactions. They are closely related to mechanistic organic photochemistry.[1-4] We have investigated the electronic structure and dynamic behavior of these systems, and shown that the dependence upon the molecular interaction between donor-acceptor pairs and upon the environment is essential.[1-3] Studies on the excited EDA systems in micellar solution are of interest from the view that (i) basic aspects of the EDA interaction in inhomogeneous systems of biological importance will be clarified, and (ii) new information might be obtained on the structure and function of the micelle, not obtained by means of fluorescence polarization and photoionization (electron ejection). So far the following two exciplex-micelle systems have been reported. The quaternary ammonium groups of the *N*-dodecyl-*N,N*-dimethylbetaine quenches the excited pyrene and forms an exciplex showing a fluorescence band with maximum at 480 nm and the lifetime of 70 ns.[5] A similar exciplex emission was also obtained in the case of pyrene solubilized in the mixed micelle of sodium dodecyl sulphate and dodecylamine.[6] However, since the distance and relative orientation between pyrene and the amines, and the environmental conditions of the solubilized probe molecule were not made clear, the quenching mechanism including an exciplex formation is unknown. Thus we have studied the typical intramolecular exciplex compounds (pyrene)-$(CH_2)_n$-(*N,N*-dimethylaniline) (abbreviated as P_n).

Experimental

Sodium dodecyl sulphate (SDS) and α-dodecyl-ω-hydroxypoly(oxyethylene) (Brij) (special grade, Nakarai), and dodecyltrimethylammonium chloride (DTAC), (pure grade, Tokyo Kasei), were used. Brij and SDS were recrystallized twice from ethanol; DTAC was recrystallized from benzene. They were dried under reduced pressure for a few days. The concentration of Brij was adjusted to 0.065 M, while, 0.1 M solutions were prepared in the case of ionic surfactants. The concentrations lead to $\approx 1.6 \times 10^{-3}$ M micelle concentration.[7] Deionized water was distilled, refluxed over potassium permanganate and redistilled. A 50 μl acetone solution of 10^{-3} M P_n was poured into a 5 ml measuring flask and dried. The prepared micellar solution was then added and treated with the ultrasonic cleaner for ten minutes. This gave the same solution as that prepared by stirring the solution for 3 h at 50 °C. The concentration of 10^{-5} M solubilizate was checked by optical density measurements. These solutions were flushed with nitrogen gas for 25 min.

Absorption spectra were measured with a Shimadzu MPS-50 L UV spectrophotometer. The fluorescence and excitation spectra were obtained with an Aminco-Bowman spectrophotofluorometer. The fluorescence rise and decay curves were observed with a pulsed nitrogen laser and Tektronix 585A oscilloscope.[8] Transient absorption spectra were obtained by the usual nanosecond laser photolysis method.[3]

Results and Discussion

1. Fluorescence Studies and the Solubilized Site of the P_n Compounds in Micellar Solutions. The effects of surrounding environments upon the exciplex have been revealed by the analysis of spectra, quantum yields and lifetimes of monomer as well as exciplex fluorescence. In the case of organic solvents,[1,2] the red shift of the fluorescence maxima and the decrease in the yield as well as lifetime is observed with the increase of solvent polarity. Exciplex emission is no longer detected, ionic dissociation being observed in polar solvents such as acetonitrile. On the other hand, exciplex formation is retarded with increase in the viscosity of the solvent. In the rigid solvents the molecular motion is completely suppressed and only the monomer fluorescence can be measured. The present P_n compounds in micellar solution have been investigated in view of the above tendencies.

The experimental conditions of the present probe molecules are suitable for studying the interaction between the donor-acceptor groups in micellar solutions for the following reasons. (i) A donor-acceptor pair is always solubilized in the micelle; (ii) the appropriate concentration of P_n for the laser photolysis, given that the absorbance at 337 and 347 nm is larger than 0.3, is *ca.* 10^{-5} M, one-hundredth of the micelle concentration, which indicates that the intermolecular interaction between the P_n molecules in the same micelle is completely neglected; (iii) without detergents the concentration of the aromatics in question is so low that the

contribution of the molecules dissolved in water phase is neglected. The problem is to find a standard compound which is not quenched by the *N,N*-dimethylaniline moiety. Ethylpyrene (EP) is appropriate since (i) the absorption bands in the 300—360 nm region are almost identical with those of P_n compounds within 2 nm, although detailed information on the 380 nm band could not be obtained because of low concentration, and (ii) the absolute fluorescence yield of EP in cyclohexane (0.5) is almost equal to the value of P_1 in hexane (0.6), where no exciplex emission is observed.[9]

Table 1. Relative quantum yields of pyrene monomer fluorescence of P_n compounds in N_2-bubbled micellar solutions

	EP	P_1	P_2	P_3
Brij	1.0[a]	0.5_0	0.4_7	0.4_2

DTAC	1.0[a]	0.0_1	0.0_3	0.0_3

a) Normalized to unity.

Table 2. Lifetimes of pyrene monomer fluorescence of P_n compounds in N_2-bubbled micellar solutions (nanoseconds)[a]

	EP	P_1	P_2	P_3
Brij	150	150	140	110
SDS	225	270	260	240
DTAC	170	short,[b] 130[c]	short,[b] 130[c]	short,[b] 180[c]

a) All values averaged, fluctuations being within 10 ns. b) Rise and decay curves determined with our time constant, *ca.* 5 ns with a Tektronix 475 oscilloscope. c) Errors large due to low intensity.

As regards the experimental results in micellar solutions, relative quantum yields and lifetimes of pyrene monomer fluorescence of EP and P_n are given in Tables 1 and 2, respectively. Although fluorescence quenching occurs in the case of P_n as compared to the results of EP, no new exciplex emission was detected. The monomer fluorescence intensity decreases with increase in the number of methylene (abbreviated as *n*) observed in the Brij and SDS solutions. The lifetime of P_1 is larger than that of EP in SDS solution, which may be due to the different solubilized sites of their molecules. Efficient quenching was observed independent upon *n* in the case of DTAC surfactant. As shown in Fig. 1, the decay in DTAC solution shows rapid and slow components. The latter seems to be single exponential, while the former is too short to be analysed. In the cases of Brij and SDS, no rapid component was observed, the values of the slow component decreasing with the increase of *n*. This might suggest dynamic quenching by the DMA group. In the case of DTAC solution the experimental error of the lifetimes is rather large because of their low intensity. No detailed discussion on the slow component can be given.

The micellar effect on the exciplex systems will be discussed on the basis of the present results. One problem of the micellar systems is the location of the probe molecule. Large aromatic molecules such as pyrene are often considered to be in the interior of the micelle. In fact a recent NMR study of pyrene in hexadecyltrimethylammonium bromide supports this view.[10] If the present P_n compound is also dissolved in the interior of the micelle, an exciplex emission can be expected because of the analogy between the aliphatic part of micelle and the viscous aliphatic solvents. We have observed no exciplex emission in the present system, although it is observed in viscous decaline.[9] If the large viscosity of the interior prohibits a molecular motion for exciplex formation, the fluorescence yield and lifetimes should remain unchanged when *n* is changed. Thus, the simple solubilization model is inconsistent with the present results.

We see from Tables 1 and 2, that yield and lifetime show different dependence upon *n*. The yield decreases with *n*, while the change of lifetime with *n* is rather small. This can be interpreted by assuming two solubilized forms of P_n in micellar systems. In one form the fluorescence quenching occurs quite rapidly, while in the other the molecular motion for the interaction between the two moieties is prohibited. The probability of taking the latter form decreases with the increase of *n*. The interpretation is also in line with the two-component decay of pyrene monomer fluorescence in DTAC solution. The solubilized forms are considered

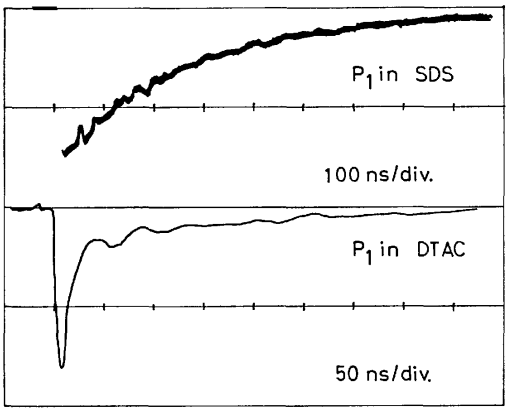

Fig. 1. Oscillograms observed at 400 nm, showing the pyrene monomer fluorescence decay of P_1 in SDS and DTAC solutions.

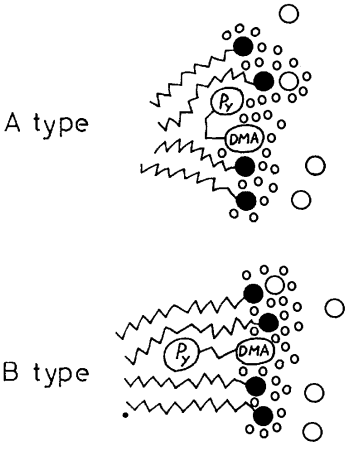

Fig. 2. Schematic representation of the solubilized form of intramolecular exciplex systems in micellar solution. ●: Head groups; ○: counter ion; ○: H_2O molecule.

to be as follows. (i) Pyrene seems to be dissolved in the interior of the micelle, while DMA in hexadecyltrimethylammonium bromide indicates the predominating solubilization mechanism to be absorption close to the α-CH_2 groups.[11] The other data show the existence of DMA in the water-micelle interface.[6] The results suggest that both the solubilized sites are in the vicinity of the water phase. (ii) The fluorescence quantum yields of EP and P_1 in hexane are almost equal to each other, no exciplex emission of the latter being observed. This implies that the quenching by the DMA group of the P_1 system is impossible in nonpolar aliphatic environments such as the interior of the micelle. The yield of P_1 is about a half of that of EP even in Brij and SDS solutions, while no exciplex emission was observed. This is also ascribed to the more polar character of environments, in which the probe molecule is dissolved.

The above considerations are schematically given in Fig. 2. In the solubilization form of A, pyrene and DMA groups are in contact with water molecules and the excited states are easily quenched immediately after excitation. On the other hand, in the case of B the interaction between the pyrene and DMA groups hardly arises during the lifetime of the excited pyrene. The P_n compound may thrust the DMA moiety into the head groups of the surfactant, leaving the pyrene moiety in the interior. This form might be too rigid to undergo quenching interaction. The probability of form A being taken may increase from P_1 to P_3 as the freedom of the molecular motion increases. In the DTAC solution particularly, almost all the probe molecules take the A configuration, which might be ascribed to a different solubilization mechanism of DTAC from that of anionic and neutral detergents.

2. Quenching Mechanism of P_n in the DTAC Solution. Quenching is very efficient in the DTAC solution, irrespective of *n*. An oscillogram showing the short-lived transient is given in Fig. 3. The transient absorption spectra of P_1 obtained immediately after the excitation is shown in Fig. 4(a). These spectra are reproduced by a superposition of the bands of the pyrene anion and the DMA cation and easily assigned to the ion-pair of the acceptor anion and the donor cation. This is supported by the fact that the present spectra are similar to those of P_3 in acetonitrile,[12] shown in Fig. 4(b). Similar spectra were observed also in the cases of P_2 and P_3, while no such ionic species with short lifetime was detected in the Brij solution of P_2. Thus it is concluded that the rapid ion-pair formation leading to the quenching occurs easily in the DTAC solution. In general the

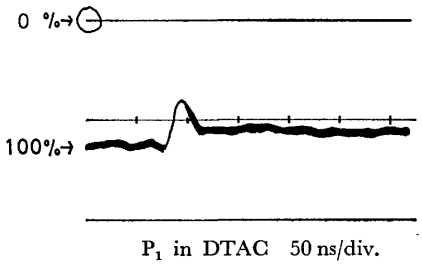

Fig. 3. Oscillogram observed at 500 nm, showing the transient absorption of P_1 in DTAC solution.

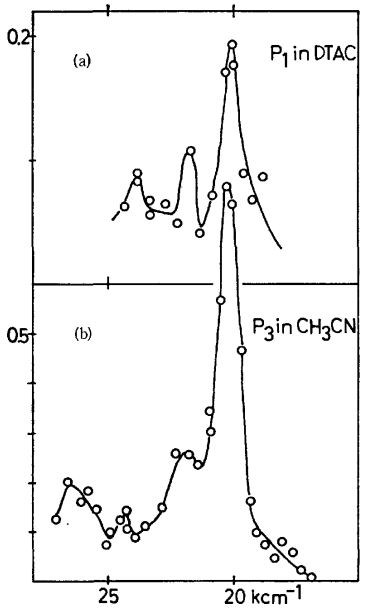

Fig. 4. (a) Transient absorption spectra of P_1 in DTAC solution obtained immediately after laser excitation. (b) Reference spectra of P_3 in acetonitrile.[12]

formation of ionic species is possible when the molecular pair are set in the polar environment, as confirmed by the systems in organic solvents. The P_n compounds in the DTAC systems seem to be dissolved near the water-micelle interface and influenced by the polar water molecules, which is consistent with the result of the fluorescence studies. The ionic species of the exciplex systems are also formed in the micellar solution, as in the polar organic solvents. Confirmation by nanosecond photolysis indicates that the ionic dissociation processes play an important role in the photoprimary processes of aromatic molecules in water and micellar solutions.

The authors wish to express their sincere thanks to Profs. S. Misumi and Y. Sakata of this University for supplying the intramolecular exciplex systems.

The Structural Role of the Aluminum Ion in Alkali Aluminophosphate Glass Containing Less Than 50 mol% of P_2O_5

Akira KISHIOKA

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioicho, Chiyoda-ku, Tokyo 102

(Received December 10, 1976)

Several series of alkali (Na and K) aluminophosphate glasses with a constant P_2O_5 content of less than 50 mol % were prepared. From the infrared absorption spectra of these glasses, and also from the paper chromatograms of aqueous solutions of these glasses, we obtained the following results: The PO_4^{3-} ion increased with an increase in the amount of Al_2O_3 when the P_2O_5 content was kept constant. The PO_4^{3-}/P_2O_5 ratio in the glass increased with an increase in the Al_2O_3 content, whereas it decreased with an increase in the P_2O_5 content. In the composition of 32.5 mol % of P_2O_5, the glass containing exclusively PO_4^{3-}-type ions as a phosphate species was found. The PO_4^{3-}/Al^{3+} ratio was smaller than unity in the case of a lower Al_2O_3 content and larger than unity in the case of a higher Al_2O_3 content. From these results, the structural role of the Al^{3+} ion can be revealed as follows: In the glass with a lower Al_2O_3 content, two kinds of Al^{3+} ions exist—(1) the Al^{3+} ion, which forms the P–O–Al linkage by the substitution of the P^{5+} ion in the P–O–P linkage, and (2) the Al^{3+} ion, which does not form such a linkage, whereas in the glass with a higher Al_2O_3 content all the Al^{3+} ions substitute the P^{5+} ion to form the P–O–Al linkage.

It is well known that Al_2O_3 stabilizes the structure of phosphate glass and increases the chemical durability. It has been considered that this effect of the Al_2O_3 in the phosphate glass is due to the formation of an ($AlPO_4$) group in the glass structure.[1] The detailed structural role of Al^{3+} ion in aluminophosphate glass, however, has not yet been clarified. The coordination number of the Al^{3+} ion in phosphate glass is particularly interesting in connection with the role of this ion in the glass structure. Sakka[2] has reported that most of the Al^{3+} ions in the glass with a higher P_2O_5 content were 6-fold coordinated, while those with a lower P_2O_5 content were 4-fold coordinated; the present authors[3] have also reported a similar change in the glass-forming regions in the Na_2O–Al_2O_3–P_2O_5 and K_2O–Al_2O_3–P_2O_5 systems.

In this investigation, several series of sodium and potassium aluminophosphate glasses with the same P_2O_5 content of less than 50 mol % (polyphosphate composition) were prepared, and the infrared absorption spectra of these glasses were examined and the aqueous solutions of these glasses were subjected to paper chromatography in order to separate the orthophosphate from the other polyphosphate ion species. The contents of the Al_2O_3, P_2O_5, and PO_4^{3-} ion were gravimetrically determined. The structural role of the Al^{3+} ion was discussed in terms of the Al_2O_3 and P_2O_5 contents as well as the PO_4^{3-}/P_2O_5 and PO_4^{3-}/Al^{3+} ratios obtained by these analyses.

Experimental

Preparation of Glass. Twenty-two kinds of glasses with the compositions represented in Tables 1 and 2 were prepared. Most of these compositions are selected inside the glass-forming regions of less than 50 mol % of P_2O_5 in the Na_2O–Al_2O_3–P_2O_5 and K_2O–Al_2O_3–P_2O_5 systems.[3]

The materials used were sodium dihydrogenphosphate, anhydrous sodium carbonate, potassium dihydrogenphosphate, anhydrous potassium carbonate, aluminum oxide, and orthophosphoric acid (85%). They were all of a reagent grade. About a 40-g portion of a mixture obtained by mixing the necessary amounts of the above compounds was used for each batch. The samples were placed in platinum dishes and heated in a electric furnace. After the samples had been dehydrated by gradually heating them up to 500 °C over about a 5-h period, they were kept at this temperature for 2 h. Then, the temperature was raised further to 1350 °C over a 2-h period and kept at this temperature for 1 h. The melt of each batch was poured out and quenched by pressing it with copper plates cooled with water. All the quenched melts were obtained as transparent colorless glasses except for the sample with the initial composition of $30K_2O \cdot 30Al_2O_3 \cdot 40P_2O_5$ which was obtained as a mixture of glass and crystal, the glassy part being used for the experiment.

Determination of Al_2O_3. Glass powder containing about 0.1 g of Al_2O_3 was dissolved in 150 ml of 1 M (1 mol dm^{-3}) HCl by boiling, after which the polyphosphate ion species in the sample were hydrolyzed to orthophosphate ions by prolonged boiling for 30 min. The Al^{3+} ion in this solution was gravimetrically determined as $AlPO_4$.[4]

Determination of Total Phosphate as P_2O_5. Glass powder containing about 0.1 g of P_2O_5 was dissolved in 80 ml of 1 M HCl. The experimental procedure after the hydrolysis of the polyphosphate ions to orthophosphate ions was the same as in the determination of the PO_4^{3-} ion.[5]

Determination of the Orthophosphate Ion. After 0.25—1.5 g of the pulverized glass had been dissolved in 40 ml of a 0.5 M (0.5 mol dm^{-3}) NaOH solution at room temperature, the PO_4^{3-} ion was gravimetrically determined as $Mg_2P_2O_7$ by the method described in a previous paper.[5]

Paper Chromatography. One-dimensional paper chromatography was used for the separation of orthophosphate from other polyphosphates.[6] The solvent was prepared by mixing 25 ml of a 20% trichloroacetic acid solution, 7 ml of water, and 68 ml of acetone. This solvent is a modification of the Solvent A reported by Bernhart and Chess.[7] Pulverized glass containing about 0.1 g of phosphorus was dissolved in 50 ml of a 0.5 M NaOH solution at room temperature. A spot of about 5 μl of this solution was developed on a strip of filter paper of No. 51A (2 cm × 50 cm) for about 3 h at room temperature. After a perchloric acid–molybdate solution had been sprayed on the paper, the paper was exposed to day light until blue spots appeared. The phosphate species on the chromatogram was identified by comparing it with the spots of a reference solution containing known phosphates.

Infrared Spectra. The infrared absorption spectra of the glasses were obtained by means of a Hitachi EPI-2G

spectrophotometer, using the KBr pellet technique.

Results and Discussion

Composition of Glass. The composition of the glasses determined from the analyses is shown in Tables 1 and 2. The Na_2O or K_2O content given in parentheses is the value obtained by subtracting the Al_2O_3 and P_2O_5 contents from the weight of the sample. Since the phosphate glass usually contains a small amount of water in its structure,[8,9] the Na_2O or K_2O content shown in parentheses is actually the (Na_2O+H_2O) or (K_2O+H_2O) content in the glass. As is shown in Tables 1 and 2, in each series of the glasses with a constant P_2O_5 content, the heating loss of P_2O_5 was less than 0.8 wt %. Therefore, it can be said that the contents of P_2O_5 in these glasses are practically constant.

Papaer Chromatography. The paper chromatography was carried out for each sample of 37.5 mol % of P_2O_5 in the Na_2O–Al_2O_3–P_2O_5 system and of 40 mol % of P_2O_5 in the K_2O–Al_2O_3–P_2O_5 system. As is shown in the chromatograms in Figs. 1 and 2, the amount of the PO_4^{3-} ion increased with an increase in the Al_2O_3 content. When a two-component sample of 62.5 $Na_2O \cdot$ 37.5 P_2O_5 was heated for 1 h at 1350 °C, converted to an aqueous solution, and examined by paper chromatography, the P O $^{4-}$ and $P_3O_{10}^{5-}$ ions were found, while

the PO_4^{3-} ion was not found. Thus, it seems that the above PO_4^{3-} ion was given by the substitution of the P^{5+} ion in P–O–P linkage by the Al^{3+} ion, and the increase in the amount of this PO_4^{3-} ion may be due to the increase in the P–O–Al linkage in the glass. The phosphate species in the glasses with the highest Al_2O_3 content ($x=25$ in Fig. 1 and $x=30$ in Fig. 2) were substantially composed of the PO_4^{3-} ion. It is natural to consider that a large number of the chains in these

glasses are in the form of an alternate arrangement of the PO_4 tetrahedron and the AlO_4 tetrahedron.

Infrared Spectra. The infrared absorption spectra of the same series of glasses as those examined by paper chromatography are shown in Figs. 3 and 4. Between the glasses with a lower Al_2O_3 content ($x=5$ and 10) and those with a higher Al_2O_3 content ($x=20$, 25, and 30), marked differences are found in the absorption spectra in the range from 1100 to 900 cm^{-1}. With the increase in the Al_2O_3 content, the absorptions in the above-noted range increased and the absorption bands became broad. According to Corbridge and Lowe,[10,11] the absorption band in the range from 1100—900 cm^{-1} is to be assigned to ionic P–O stretching, $-P\langle^{O}_{O}{}^{(2-)}_{O}$ group, P–O–P stretching, and P–O–H bending vibrations; especially, the absorption of the $-P\langle^{O}_{O}{}^{(2-)}_{O}$ group appears at about 1030—960 cm^{-1}. Therefore, the change in the infrared spectra with the increase in the Al_2O_3 content can be considered to be concordant with the results of the paper chromatography. It can also be mentioned that the broad absorption in the glasses with a higher Al_2O_3 content is due to the increase in the disorder derived from the formation of P–O–Al linkage in the glass structure.

Orthophosphate Ion in the Glass. The contents of the PO_4^{3-} ion in all the glasses were determined gravimetrically. In Figs. 5 and 6 these results are given by plotting the change in the PO_4^{3-}/P_2O_5 ratio (the ratio of the amount of PO_4^{3-} ion, expressed as P_2O_5 against the total P_2O_5 content) with the Al_2O_3 content in the glass. In all the series of glasses with a constant P_2O_5

content in both the Na_2O–Al_2O_3–P_2O_5 and K_2O–Al_2O_3–P_2O_5 systems, the PO_4^{3-}/P_2O_5 ratio increases with an increase in the Al_2O_3 content, while this ratio decreases with an increase in the P_2O_5 content. In the glass with 32.5 mol % of P_2O_5, the PO_4^{3-}/P_2O_5 ratio rises to unity when the Al_2O_3 content approaches 25 mol % or more, as is shown in Fig. 5.

In Figs. 7 and 8, the PO_4^{3-}/Al^{3+} ratios are plotted *vs.* the Al_2O_3 content. The ratio increases with an increase in the Al_2O_3 content except for the Na_2O–Al_2O_3–P_2O_5 glass with 32.5 mol % of P_2O_5 (Fig. 7), whereas the ratio decreases with an increase in the P_2O_5 content in all the glasses. The PO_4^{3-}/Al^{3+} ratio can be regarded as showing the degree of the substitution of the P^{5+} ion in P–O–P linkage by the Al^{3+} ion. Therefore, the above-mentioned change in this value can be explained as follows. When the PO_4^{3-}/Al^{3+} ratio is smaller than unity, there exist two sorts of Al^{3+} ions, the Al^{3+} ion forming the P–O–Al linkage and the Al^{3+} ion not forming such a linkage. When this ratio is equal to or larger than unity, however, all the Al^{3+} ions are in the form

◑: 32.5 mol % P_2O_5, ○: 37.5 mol % P_2O_5,
●: 42.5 mol % P_2O_5.

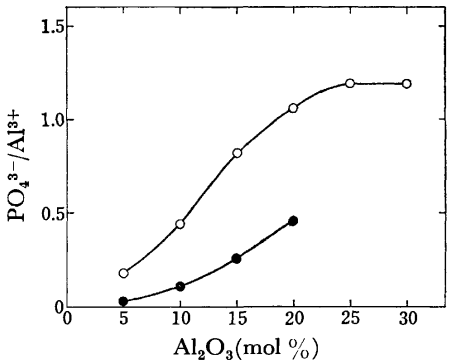

Fig. 8. Relation between PO_4^{3-}/Al^{3+} ratio and Al_2O_3 content in K_2O–Al_2O_3–P_2O_5 glass.
○: 40 mol % P_2O_5, ●: 45 mol % P_2O_5.

of P–O–Al linkage. Since the PO_4^{3-}/Al^{3+} ratios of the glasses with a lower Al_2O_3 content are smaller than 0.5, it can be considered that more than half of the Al^{3+} ions do not form the P–O–Al linkage. In the glass with 32.5 mol % of P_2O_5, when the value of PO_4^{3-}/Al^{3+} is larger than 1.5, it is possible that the "cluster" may be formed by the linkage between more than two PO_4 tetrahedra and one AlO_4 tetrahedron.

From the results of the determination of the PO_4^{3-} ion in the glasses, it can also be presumed that, in metaphosphate (50 mol % of P_2O_5) and ultraphosphate (more than 50 mol % of P_2O_5) compositions, no substitution of the P^{5+} ion by the Al^{3+} ion occurs; hence, the P–O–Al linkage described above is not formed in these compositions of glasses.

The author wishes to thank Associate Professor Makio Kinoshita of Sophia University for his interest and encouragement, and also Mr. Samon Isogai for his assistance in the experimental work.

Induced Circular Dichroism Spectra of Cobalt(III) Complexes in a Chiral Medium Containing $(+)_{589}$-Diethyl Tartrate

Yutaka TANIGUCHI, Jinsai HIDAKA,* and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received January 20, 1977)

The induced circular dichroism (CD) spectra of 21 achiral or racemic cobalt(III) complexes have been measured in a chiral medium containing $(+)_{589}$-diethyl tartrate in the region of the first d-d transition bands. The absolute value of the molar circular dichroism ($\Delta\varepsilon$) observed for these complexes is in the range of about 0.04—0.3 cm^{-1} mol^{-1} dm^3. The induced CD spectra of the racemic complexes show a different pattern from the natural CD spectra of their resolved enantiomers. The observed induced CD spectra have been discussed in relation to the stereochemistry of the complexes.

Circular dichroism (CD) is induced for some achiral or racemic compounds when they are dissolved in a chiral medium. Since Mason and Norman[1] observed this phenomenon, several workers have reported the CD induced for organic[2-6] and inorganic[2,7-10] compounds. The mechanism of this phenomenon has been discussed generally in terms of the following effects; (1) the CD may be induced by a direct interaction between a symmetric chromophore and a chiral field produced by chiral solvents, (2) a symmetric chromophore may be solvated by chiral solvents forming a chiral configuration, and (3) one enantiomer in a racemate may be associated with chiral solvents preferentially. It was initially suggested that the hydrogen bonding was the main origin of the phenomenon,[1-4] but later it was found that such hydrogen bonding was not a prerequisite.[5,6] Thus the precise mechanism of the phenomenon is still unknown.

In the works on cobalt(III) complexes, so far as we know, the induced CD has been observed for only four chromophores: $[Co(NH_3)_6]^{3+}$,[1] $[Co(en)_3]^{3+}$,[9] *trans*-$[CoCl_2(en)_2]^+$,[2] and *trans-meso*-$[CoCl_2(2,3,2\text{-tet})]^+$.[8] In the present paper, it will be shown that twenty-one achiral or racemic cobalt(III) complexes also exhibit the induced CD in the region of their first d-d transition bands when the complexes are dissolved in a chiral medium containing $(+)_{589}$-diethyl tartrate, and that the spectral feature of those induced CD is dependent on the properties of ligands.

Experimental

Materials. $(+)_{589}$-Diethyl tartrate was prepared by the method of Sugasawa[11] and distilled *in vacuo*, bp 123.5—124.5 °C at 2 Torr, $[\alpha]_D$ +7.71 ° (neat). Found: C, 46.57; H, 6.82%. Calcd for $C_8H_{14}O_6$: C, 46.60; H, 6.84%.

All the cobalt(III) complexes were prepared by well-known methods and identified spectrophotometrically. Many of the complexes were converted into their tetraphenylborate salts by adding the equivalent amount of sodium tetraphenylborate in water to an aqueous solution of the complex ion. Found: C, 70.58; H, 7.32; N, 6.91%. Calcd for $[Co(NH_3)_6](BPh_4)_3\cdot 6H_2O$: C, 70.48; H, 7.39; N, 6.85%. Found: C, 71.87; H, 7.34; N, 7.01%. Calcd for $[Co(NH_3)_4(en)](BPh_4)_3\cdot 5H_2O$: C, 72.03; H, 7.35; N, 6.81%. Found: C, 74.55; H, 7.30; N, 6.51%. Calcd for *cis*-$[Co(NH_3)_2(en)_2](BPh_4)_3\cdot 4H_2O$: C, 73.44; H, 7.30; N, 6.76%. Found: C, 73.52; H, 7.33; N, 6.83%. Calcd for *trans*-$[Co(NH_3)_2(en)_2](BPh_4)_3\cdot 4H_2O$: C, 73.44; H, 7.30; N, 6.76%. Found: C, 71.84; H, 7.34; N, 6.44%. Calcd for $[Co(en)_3](BPh_4)_3\cdot 6H_2O$: C, 71.79; H, 7.42; N, 6.44%. Found: C, 67.01; H, 6.86; N, 9.68%. Calcd for $[Co(NO_2)(NH_3)_5](BPh_4)_2\cdot 2H_2O$: C, 66.68; H, 6.88; N, 9.72%. Found: C, 49.49; H, 6.38; N, 14.33%. Calcd for *cis*-$[Co(NO_2)_2(NH_3)_4](BPh_4)\cdot 2H_2O$: C, 50.19; H, 6.32; N, 14.63%. Found: C, 50.49; H, 6.23; N, 14.76%. Calcd for *trans*-$[Co(NO_2)_2(NH_3)_4](BPh_4)\cdot 2H_2O$: C, 50.19; H, 6.32; N, 14.63%. Found: C, 67.03; H, 6.89; N, 8.16%. Calcd for $[CoF(NH_3)_5[(BPh_4)_2\cdot 2H_2O$: C, 68.83; H, 7.10; N, 8.36%. Found: C, 67.45; H, 6.96; N, 8.17%. Calcd for $[CoCl(NH_3)_5](BPh_4)_2\cdot 2H_2O$: C, 67.50; H, 6.96; N, 8.20%. Found: C, 65.88; H, 6.59; N, 8.05%. Calcd for $[CoBr(NH_3)_5](BPh_4)_2\cdot H_2O$: C, 65.48; H, 6.53; N, 7.95%. Found: C, 55.57; H, 6.22; N, 10.76%. Calcd for *trans*-$[CoCl_2(NH_3)_4](BPh_4)$: C, 55.73; H, 6.24; N, 10.83%. Found: C, 57.38; H, 6.36; N, 10.30%. Calcd for *trans*-$[CoCl_2(NH_3)_2(en)](BPh_4)$: C, 57.49; H, 6.31; N, 10.31%. Found: C, 58.83; H, 6.39; N, 9.78%. Calcd for *trans*-$[CoCl_2(en)_2](BPh_4)$: C, 59.07; H, 6.37; N, 9.84%. Found: C, 67.90; H, 6.98; N, 7.70%. Calcd for $[Co(CH_3COO)(NH_3)_5](BPh_4)_2\cdot 2.5H_2O$: C, 67.73; H, 7.16; N, 7.90%. Found: C, 59.86; H, 6.86; N, 9.48%. Calcd for *cis*-$[Co(CH_3COO)_2(NH_3)_4](BPh_4)\cdot 0.5H_2O$: C, 58.65; H, 6.86; N, 9.77%. Found: C, 59.81; H, 6.87; N, 9.88%. Calcd for *trans*-$[Co(CH_3COO)_2(NH_3)_4](BPh_4)$: C, 59.59; H, 6.79; N, 9.93%. Found: C, 17.57; H, 7.61; N, 20.47%. Calcd for $[Co(en)_3]Cl_3\cdot 3.5H_2O$: C, 17.64; H, 7.65; N, 20.57%. Found: C, 9.32; H, 5.01; N, 22.01%. Calcd for $[Co(ox)(NH_3)_4]Cl\cdot 0.5H_2O$: C, 9.26; H, 5.05; N, 21.59%. Found: C, 22.42; H, 5.67; N, 17.32%. Calcd for $[Co(ox)(en)_2]Cl\cdot H_2O$: C, 22.48; H, 5.66; N, 17.47%. Found: C, 21.33; H, 2.89; N, 8.25%. Calcd for $Na[Co(ox)_2(en)]\cdot H_2O$: C, 21.44; H, 3.00; N, 8.33%. Found: C, 25.90; H, 3.71; N, 7.15%. Calcd for $K[Co(mal)_2(en)]\cdot H_2O$: C, 25.27; H, 3.71; N, 7.37%.

Measurements. The electronic absorption spectra were measured by a Shimadzu spectrophotometer UV-200. The CD spectra were recorded with a Jasco Model J-20 spectropolarimeter with the CD attachment. All measurements were made at room temperature in chiral media in a constant concentration of the complex ion, 0.002 mol dm^{-3}. The chiral media were prepared by mixing $(+)_{589}$-diethyl tartrate (17 cm^3) with water (3 cm^3) for the oxalato and malonato complexes, and with acetone (3 cm^3) for the other complex tetraphenylborates. The concentration of $(+)_{589}$-diethyl tartrate in the chiral media was approximately 4.96 mol dm^{-3}. The CD measurements were confined in the region of the first d-d transition band, because the chiral media showed very strong absorption in the ultraviolet region.

* Present address: Department of Chemistry, The University of Tsukuba, Ibaraki 300-31.

Results and Discussion

Each of the complexes reported here has an identical electronic absorption spectrum of the first d-d transition band in the chiral media containing diethyl tartrate and in the aqueous solution. This shows that the inner coordination sphere remains unchanged in the chiral media. For the induced CD intensity of the $[Co(NH_3)_6]^{3+}$ complex dissolved in a mixture of acetone and $(+)_{589}$-diethyl tartrate (4.96 mol dm^{-3}), Beer's law holds good over the concentration range $0—7\times10^{-3}$ mol dm^{-3} of the complex. For the same chromophore, the induced CD intensity increases with an increase in the concentration of $(+)_{589}$-diethyl tartrate, steeply in the range of 0—0.1 in its mole fraction, and reaches to a saturation at the mole fraction *ca.* 0.3. The saturated intensity is dependent on the solvent mixed with $(+)_{589}$-diethyl tartrate; the increasing order of intensity is water<methanol<acetone. This suggests that the association of the complex ion with diethyl tartrate by hydrogen bonding has an important contribution to the induced CD.

Ammine–Ethylenediamine Mixed Complexes (Fig. 1). These $[Co(N)_6]^{3+}$ type complexes show a single negative CD band at or near the position of their first absorption band with an exception of *trans*-diammine complex, which has a small positive CD band at the lower energy side of the dominant negative one. The absolute CD intensity decreases in the following order: $[Co(NH_3)_6]^{3+} > [Co(NH_3)_4(en)]^{3+} > [Co(en)_3]^{3+} > cis$-$[Co(NH_3)_2(en)_2]^{3+} > trans$-$[Co(NH_3)_2(en)_2]^{3+}$. The sequence shows that the ammonia ligand is more effective to the induction of CD than ethylenediamine. This is consistent with the fact that the former ligand has more N–H groups available for hydrogen bonding than the latter. Moreover the N–H groups of the ethylenediamine ligand cannot interact so freely with the chiral solvent molecules as those of ammonia. The tris(ethylenediamine) complex gives somewhat larger induced CD than the diamminebis(ethylenediamine) complexes, and both the racemic tris- and *cis*-bis(ethylenediamine) complexes have a different type of CD pattern from the natural CD of their resolved enantiomers. Such racemic complexes cannot be discussed equally with the achiral complexes. Since the chiral solvent molecules interact with a chiral complex ion in a different way from its enantiomer, the observed induced CD of a racemate comes from the overall effect, and differs from the individual induced CD of the enantiomers. The *trans*-bis(ethylenediamine) complex shows an induced CD pattern analogous to the natural CD of the *trans*-$[Co(NH_3)_2(S\text{-pn})_2\delta\delta]^{3+}$ complex which also has a small positive band at the lower energy side of a dominant negative band.[12] Thus the positive band of the bis(ethylenediamine) complex may be attributed to the ethylenediamine chelate rings which take preferentially the δ-conformation on the interaction with the chiral slovent.

Ammine–Nitro Mixed Complexes (Fig. 2). These

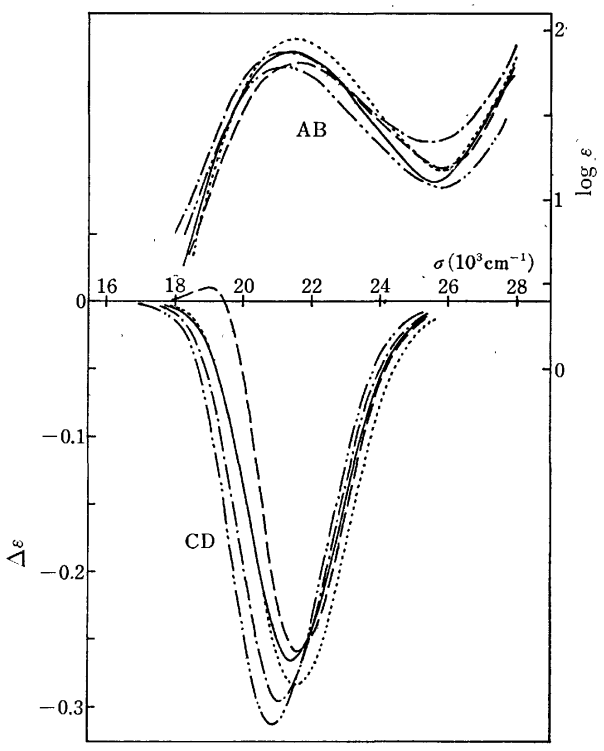

Fig. 1. Absorption (AB) and induced CD spectra of ammine–ethylenediamine mixed complexes in a chiral medium $(+)_{589}$-diethyl tartrate–acetone. $[Co(NH_3)_6]^{3+}$ (–···–), $[Co(NH_3)_4(en)]^{3+}$ (– · –), *rac-cis*-$[Co(NH_3)_2(en)_2]^{3+}$ (——), *trans*-$[Co(NH_3)_2(en)_2]^{3+}$ (– – – –), *rac*-$[Co(en)_3]^{3+}$ (·····).

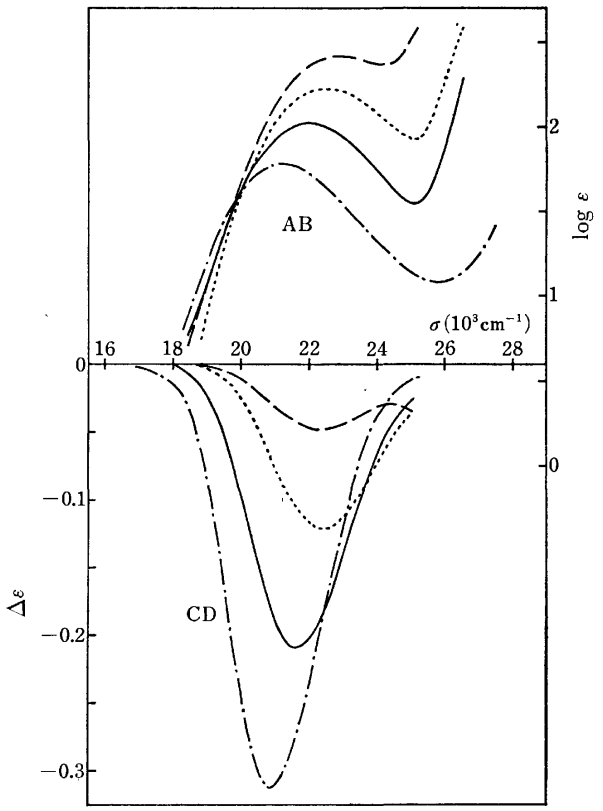

Fig. 2. Absorption (AB) and induced CD spectra of ammine–nitro mixed complexes in a chiral medium $(+)_{589}$-diethyl tartrate–acetone. $[Co(NH_3)_6]^{3+}$ (– · –), $[Co(NO_2)(NH_3)_5]^{2+}$ (——), *cis*-$[Co(NO_2)_2(NH_3)_4]^{+}$ (·····), *trans*-$[Co(NO_2)_2(NH_3)_4]^{+}$ (– – – –).

complexes also show a single negative CD band. The position of the CD peak shifts regularly to the higher energy side by replacing ammine ligands with nitro ones, as in the case of the absorption peak. The CD intensity decreased stepwise with the same replacement, in contrast to absorption. In the dinitro complexes, there is a marked difference between the geometrical isomers, that is, the induced CD of the *trans* isomer is about a half of that of the *cis* isomer.

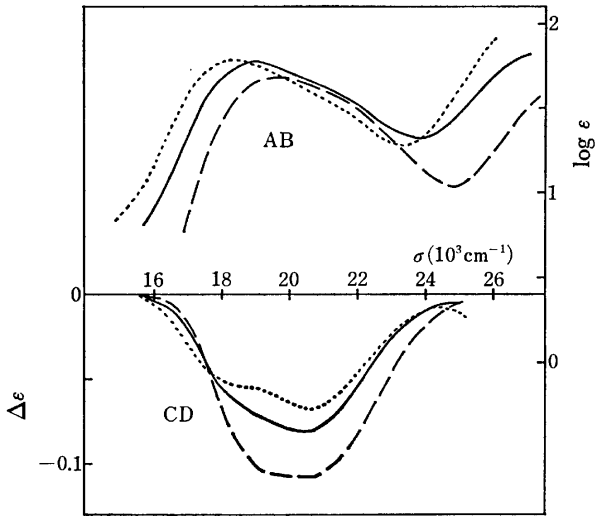

Fig. 3. Absorption (AB) and induced CD spectra of three pentaamminehalogeno complexes in a chiral medium $(+)_{589}$-diethyl tartrate–acetone. $[CoF(NH_3)_5]^{2+}$ (——), $[CoCl(NH_3)_5]^{2+}$ (——), $[CoBr(NH_3)_5]^{2+}$(·····).

Pentaamminehalogeno Complexes (Fig. 3). The first absorption band of these complexes splits clearly into the A_2 and E components of C_{4v} symmetry. The induced CD spectra also show splitting into the two components with a negative sign. The A_2 non-degenerate component is dominant contrary to the absorption spectrum, and as expected from Yamatera's rule,[13] the A_2 component with higher energy remains at about the same position as that of the T_{1g} transition of the $[Co(NH_3)_6]^{3+}$ chromophore, irrespective of the kinds of halogens. On the other hand, the E component, which appears as a shoulder at the lower energy side of the dominant A_2 component, shifts according to the spectrochemical series of halogens. As for the CD intensity, the smaller the atomic number of halogens, the stronger the CD intensity. It is evident that the halogeno ligands have an important contribution to the induced CD.

trans-*Tetraamminedichloro Type Complexes (Fig. 4).* The induced CD of the *trans*-$[CoCl_2(N)_4]^+$ chromophores also shows a marked splitting for the first absorption band region. If we adopt the representation of D_{4h} symmetry for these complexes, their CD peaks correspond to the A_{2g} (higher energy) and E_g (lower energy) components. The induced CD of the E_g component increases proportionally with the number of ethylenediamine rings, but that of the A_{2g} component shows a tendency to decrease. The induced CD of the tetraamminedichloro complex does not contain any contribution from the chiral ring conformation, whereas the induced CD of the other two complexes having one or

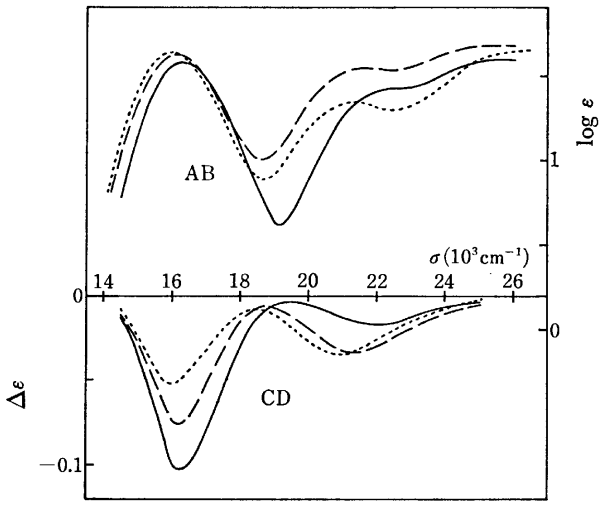

Fig. 4. Absorption (AB) and induced CD spectra of *trans*-tetraamminedichloro type complexes in a chiral medium $(+)_{589}$-diethyl tartrate–acetone. *trans*-$[CoCl_2(NH_3)_4]^+$ (·····), *trans*-$[CoCl_2(NH_3)_2(en)]^+$(——), *trans*-$[CoCl_2(en)_2]^+$ (——).

two puckered ethylenediamine rings would contain some contribution from the chelate ring conformation. The conformational contribution in these two complexes would be approximated by the CD difference from the tetraamminedichloro complex. On the E_g component, it is really found that the ratio of the differences is about 1:2 for the mono(ethylenediamine) to the bis(ethylenediamine) complex. Hawkins and his coworkers[14] reported that the natural CD spectra of the analogous chromophore having one or two (*R*)-propylenediamine chelate rings of λ-conformation instead of ethylenediamine rings showed a positive sign for the E_g component, and that the rotational strength of the bis(propylenediamine) complex was approximately twice that of the mono(propylenediamine) complex. From the analogy with this, it is suggested that the ethylenediamine chelate rings of the present complexes are partially fixed to a preferable δ-conformation because of the interaction with the chiral solvent. In the A_{2g} region, the propylenediamine complexes gave a negative natural CD band, whose sign is opposite to the induced CD of the present ethylenediamine complexes. This result, however, is not in conflict with the above discussion, because Bosnich and Harrowfield[15] showed that the natural CD displayed in such a region for several *trans*-$[CoCl_2(N)_4]^+$ chromophores is markedly dependent on solvents.

Acetato–Ammine Mixed Complexes (Fig. 5). Three complexes in this group show induced CD spectra quite different from each other. The monoacetato complex exhibits a single negative CD band in its A_2 region, *i.e.* in the region of T_{1g} band of the $[Co(N)_6]^{3+}$ chromophore. The *trans* diacetato complex shows a positive and a negative CD band of comparable intensities which correspond to the E_g (lower energy) and A_{2g} (higher energy) components, respectively. The *cis* diacetato complex shows a dominant positive and a small negative CD band in the order of increasing energy; the former corresponds to the B_1 component and the latter to the

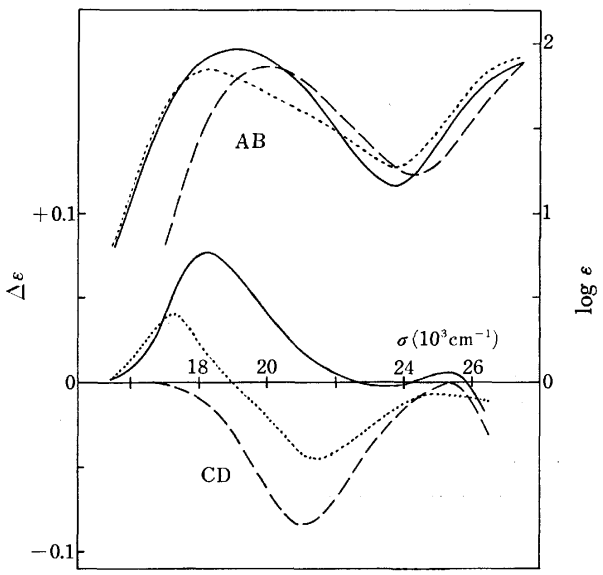

Fig. 5. Absorption (AB) and induced CD spectra of acetato–ammine mixed complexes in a chiral medium $(+)_{589}$-diethyl tartrate–acetone. $[Co(CH_3COO)(NH_3)_5]^{2+}$ (----), *cis*-$[Co(CH_3COO)_2(NH_3)_4]^+$ (——), *trans*-$[Co(CH_3COO)_2(NH_3)_4]^+$ (·····).

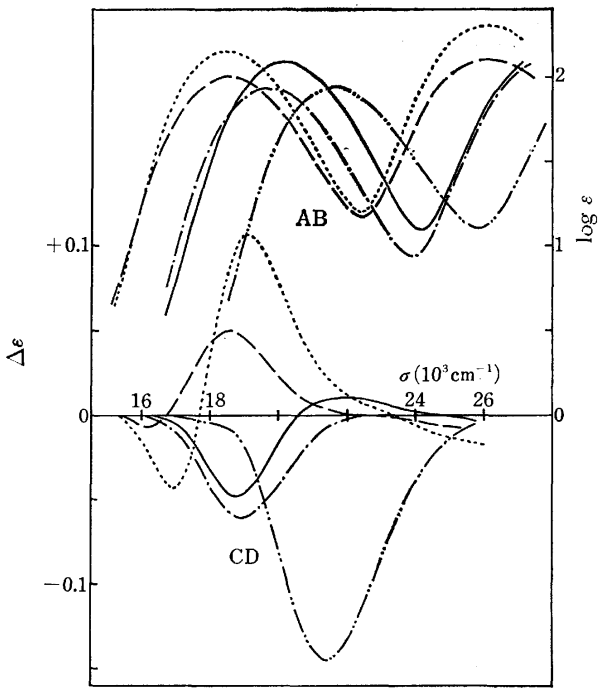

Fig. 6. Absorption (AB) and induced CD spectra of oxalato and malonato complexes in a chiral medium $(+)_{589}$-diethyl tartrate–water. *rac*-$[Co(en)_3]^{3+}$ (-·-·-), $[Co(ox)(NH_3)_4]^+$ (- · -), *rac*-$[Co(ox)(en)_2]^+$ (——), *rac*-$[Co(ox)_2(en)]^-$ (·····), *rac*-$[Co(mal)_2(en)]^-$ (----).

A_2+B_2 component. The monoacetato complex has the induced CD intensity of the same order as the natural CD intensity of the (α-amino carboxylato)-pentaamminecobalt(III) complexes,[16] which also belong to the chromophore $[Co(O)(N)_5]^{2+}$, its natural CD being contributed by the so-called vicinal effect of the coordinated chiral amino carboxylate ligand. In this respect, the induced CD of these three acetato–ammine complexes may be recognized as a kind of vicinal effect of the chiral solvent molecules.

Oxalato and Malonato Complexes (Fig. 6). Figure 6 shows the absorption and induced CD spectra of these four complexes measured in a chiral medium $(+)_{589}$-diethyl tartrate–water. The induced CD spectra of the $[Co(en)_3]^{3+}$ and $[Co(ox)(en)_2]^+$ complexes in this medium showed essentially the same pattern as in the $(+)_{589}$-diethyl tartrate–acetone medium, except that the intensity in the aqueous medium is reduced to about one-half of that in the acetone medium.

The $[Co(ox)(en)_2]^+$ complex has a dominant negative and a small positive induced CD band in the order of increasing energy. The $[Co(ox)(NH_3)_4]^+$ complex gives a single negative band at the position of the dominant band of the bis(ethylenediamine) complex. The tetraammine complex has a slightly more intense induced CD than the ethylenediamine complex. The $[Co(ox)_2(en)]^-$ and $[Co(mal)_2(en)]^-$ complexes of the *cis*-$[Co(O)_4(N)_2]^-$ chromophore also show a negative and a positive induced CD band in the order of increasing energy. The band at the higher energy side is dominant in contrast to the above *cis*-$[Co(O)_2(N)_4]^+$ chromophore; thus it is common to both kinds of chromophores that the dominant band appears in the region of the non-degenerate component. Although the induced CD patterns are alike in the oxalato and malonato complex anions, the intensity for the latter complex is about one-half of that for the former. As has been noted in one of the preceding sections, the induced CD spectra of the racemic complexes of this group have quite a different pattern from the natural CD spectra of their enantiomers.[17,18]

Evaluation of PAC, TAC, 2-IAC as Metallochromic Indicators in the EDTA Titrations of Nickel

Hiroko WADA, Osamu NAKAZAWA, and Hajime TAKADA

Laboratory of Analytical Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466

(Received March 29, 1977)

The rates of color change of 2-(2-pyridylazo)-4-methylphenol (PAC), 2-(2-thiazolylazo)-4-methylphenol (TAC) and 2-(2-imidazolylazo)-4-methylphenol (2-IAC) during EDTA–nickel titration have been determined. The rate is a thousand times greater for TAC and 2-IAC than for PAC. From equilibrium considerations, the rate of color change and the color contrast change, an evaluation of PAC, TAC, and 2-IAC as metallochromic indicators for nickel is given. The optimum pH ranges with TAC and 2-IAC are from 6 to 7 and from 5 to 7, respectively, at 80 °C. With PAC, the titration should be conducted with boiling at pH 4—5. 2-IAC is the best indicator due to the good visual color contrast and the wide pH range over which it is applicable.

In EDTA titrations, the sharpness of the color change of metallochromic indicators is governed by the reaction rate for substitution of the metal-indicator chelate with EDTA, as well as the equilibrium conditions involved. Usually, the reaction rate for substitution of nickel-indicator chelates with EDTA being slow, the rate of indicator color change is important. The PAC[2-(2-pyridylazo)-4-methylphenol],[1] TAC[2-(2-thiazolylazo)-4-methylphenol],[2] and 2-IAC[2-(2-imidazolylazo)-4-methylphenol][3] synthesized previously can be used as indicators for nickel–EDTA titrations. In a previous paper,[4] the reaction rate for substitution of nickel–TAC chelates with EDTA was determined and the mechanism of the color change was proposed. Since PAC, TAC, and 2-IAC have different heterocyclic rings, differences in the rate of color change is expected.

In the present paper, the substitution reaction rate for PAC and 2-IAC are presented and PAC, TAC, and 2-IAC are evaluated as metallochromic indicators for nickel–EDTA titration.

Experimental

Reagents. PAC, TAC, and 2-IAC, which had been previously synthesized and purified, were dissolved in dioxane and 10^{-3} M solutions were prepared.

A nickel(II) solution was prepared from reagent grade nickel nitrate and standardized with dimethylglyoxime by gravimetry.

EDTA·2Na was recrystallized from water and standardized against zinc metal(99.99% pure).

An MES[2-morpholino-1-ethanesulfonic acid]–potassium hydroxide solution was used as a buffer.

All other reagents used were of reagent grade.

Apparatus. A Union Giken RA-401 Stopped-Flow Spectrophotometer, a Union Giken SM-401 High-Sensitivity Spectrophotometer, and a Radiometer PHM 26c pH meter were used.

All experiments were carried out in 20% dioxane solutions at μ=0.1 (KNO_3) and at 25±1 °C.

Results

The Reaction for Substitution of Ni–PAC or Ni–2-IAC with EDTA. In the presence of a large excess of PAC or 2-IAC, nickel forms a 1 : 2 chelate (NiL_2) over the pH range from 5 to 7, as well as in the case of TAC. When EDTA is added to the nickel chelate solution in highly excessive amounts, the following substitution reaction proceeds to completion:

$$NiL_2 + edta' \longrightarrow Ni(edta)^{2-} + 2L', \quad (1)$$

where L is an anion of the PAC or 2-IAC. The rate law can be expressed as

$$-\frac{d[NiL_2]}{dt} = k_{0(L,EDTA,H)}[NiL_2], \quad (2)$$

where $k_{0(L,EDTA,H)}$ is the conditional rate constant involving the indicator, EDTA, and hydrogen ion concentrations. By representing the absorbances at reaction times 0, t, and ∞ by A_0, A_t, and A_∞, we obtain

$$\log (A_t - A_\infty) = -\frac{k_{0(L,EDTA,H)}}{2.303}t + \log (A_0 - A_\infty). \quad (3)$$

A solution containing nickel, an indicator and a buffer was vigorously mixed with a solution containing

EDTA and a buffer, and the absorbance at 570 nm for PAC or at 555 nm for 2-IAC was recorded as a function of the reaction time. From plots of $\log(A_t-A_\infty)$ *vs.* the reaction time (t), Reaction 1 was recognized to be of pseudo first-order with respect to NiL_2 in both cases. The conditional rate constants, $k_{0(L,EDTA,H)}$, obtained are shown in Tables 1 and 2.

These results indicate that the values of $k_{0(L,EDTA,H)}$ are proportional to the EDTA concentration and to the reciprocal of the indicator concentration in both cases, as for the case of TAC. Plots of $k_{0(H)}$ *vs.* $[H^+]$ give straight lines (Fig. 1).

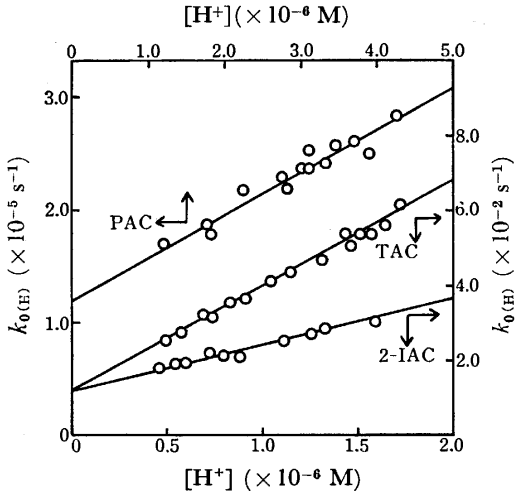

Fig. 1. Plots of $k_{0(H)}$ *vs.* $[H^+]$.

Therefore, the rate law can be expressed as

$$-\frac{d[NiL_2]}{dt}=k_{0(H)}\frac{[NiL_2][edta']}{[HL]}=(k_1'[H^+]+k_2')\frac{[NiL_2][edta']}{[HL]}, \quad (4)$$

where [edta'] is the total concentration of the EDTA not combined with nickel ions. The reaction mechanism is the same as that in the case of TAC:

$$\begin{cases} NiL_2 + H^+ \rightleftharpoons NiL^+ + HL, & (5) \\ NiL^+ + edta' \xrightarrow{k_1} Ni(edta)^{2-} + HL, & (6) \end{cases}$$

$$\begin{cases} NiL_2 + H_2O \rightleftharpoons NiL(OH) + HL, & (7) \\ NiL(OH) + edta' \xrightarrow{k_2} Ni(edta)^{2-} + HL + OH^-. & (8) \end{cases}$$

Reactions 5 and 7 precede Reactions 6 and 8, and the reactions of NiL^+ and NiL(OH) with EDTA are the rate-determining steps. Equation 4 can be rewritten as

$$-\frac{d[NiL_2]}{dt}=k_1[NiL^+][edta']+k_2[NiL(OH)][edta'], \quad (9)$$

where $k_1=k_1'K^L_{NiL_2}/K^H_{HL}$ and $k_2=k_2'K^L_{NiL_2}/K^H_{HL}K^{OH}_{NiL(OH)}K_W$. The values of k_1' and k_2' are obtained from the slopes and y-intercepts, respectively, of the straight lines in Fig. 1. For PAC and 2-IAC, the values of $K^{OH}_{NiL(OH)}$ could not be estimated. The rate constants are summarized in Table 3.

TABLE 3. RATE CONSTANTS

k_2(M^{-1} s^{-1})	—	7.9×10^6	—

Discussion

As shown in Table 4, the basicities of donor atoms of TAC are less than those of PAC, and the rate constants for TAC are smaller than those for PAC. In the substitution reactions of copper(II)–PAC and TAC chelates with EDTA, the same results were observed.[5] On the other hand, although the basicity of 2-IAC is larger than that of PAC, the rate constants for 2-IAC are much greater than those for PAC and are almost equal to those for TAC. This is in good agreement with the correlation between the reagent basicities and the nickel chelates stabilities, *i.e.*, in spite of the larger 2-IAC basicity, the formation constants for nickel chelates are smaller than those for nickel–PAC chelates. The coordination bond of the nitrogen atom in the imidazole ring of 2-IAC should be weaker than that in the pyridine ring of PAC. The characteristics of the nitrogen in the imidazole ring may be somewhat different from those of the nitrogen in the pyridine ring due to the resonance between pyridine-like and pyrrole-like nitrogens.

The rate constants, $k_{0(H)}$, are plotted against the pH in Fig. 2. In the titration of nickel, the rate of indicator color change decreases with increasing pH, so that titration at lower pH results in a higher rate of indicator color change. However, the equilibrium conditions and the color contrast between the free indicator and the nickel chelate restrict the pH range for titration to pH 6—8 (PAC), pH 6—7 (TAC), and pH 6—8 (2-IAC). Within these pH ranges, free PAC, TAC, and 2-IAC are yellow and the nickel chelates are red-violet for PAC and 2-IAC, and blue for TAC. At higher pH values, the free indicators are red-orange due to dissociation of the phenolic proton, and visual detection of end point is difficult due to the poor color contrast. The results of nickel titrations using PAC, TAC, and 2-IAC are shown in Table 5. When titration using PAC was carried out at pH 4 and at 80 °C, the end point was overshot. Thus, titration should be performed slowly with boiling. Since the conditional formation constant for the nickel–TAC chelate is too small for pH values less than 6, using TAC the end point appeared too soon. If the nickel concentration is large, even at pH values higher than 6, a negative error often occured because of the poor visibility of the color change from blue to yellow-green. In the case of 2-IAC, although the conditional formation constant for the nickel–2-IAC chelate is of the same order as that of the nickel–TAC chelate, the end point was correctly detected, even at pH 5, because it is easy for the human eye to detect the color change from red-violet to yellow or yellow-green. At pH values higher than 7, a positive error occured due to the slow rate of indicator transition. From these results, the optimum pH ranges for nickel titrations are pH 4—5 with PAC, 6—7 with TAC, and 5—7 with 2-IAC. Thus, of these three, 2-IAC is the best indicator for nickel from the standpoints of good visibility of the color change and a wide optimum pH range.

By the addition of a small amount of 1,10-phenanthroline, titrations can be carried out at 50 °C using TAC[4] or 2-IAC,[3] while in the case of PAC, the rate of color change is not sufficiently enhanced.

We thank Dr. Genkichi Nakagawa for his valuable advice and the Ministry of Education of Japan for financial support.

The Effect of 1,10-Phenanthroline on the Rate of Xylenol Orange Indicator Color Change

Hiroko WADA, Tomosuke ISHIZUKI, and Genkichi NAKAGAWA

Laboratory of Analytical Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466

(Received January 29, 1977)

1,10-Phenanthroline(phen) accelerates the rate of the color change of Xylenol Orange(XO) in the copper(II)–EDTA titrations due to the formation of a mixed-ligand complex, $(Cuphen)_2xo$. The rate of the substitution reaction of Cu_2xo with 1,10-phenanthroline or with EDTA in the presence of 1,10-phenanthroline has been determined by the stopped-flow method over the pH range of 6.9—7.6 at $\mu=0.1$ (KNO_3) and 25 ± 1 °C. At 6.2×10^{-5}—1.2×10^{-3}M 1,10-phenanthroline, the rate-law is expressed as $-d[(Cu_2xo)']/dt=k_1[H][(Cu_2xo)']$. The reaction mechanism proposed is $Cu_2xo \xrightarrow{2phen} (Cuphen)_2xo \rightleftarrows (Cuphen)_2xo\cdots H \xrightarrow[r.d.s.]{H^+} Cuphen+(Cuphen)Hxo \xrightarrow{fast} 2Cuphen+xo'$, and $k_1=5.5\times10^7$ M^{-1} s^{-1}. By the addition of 2.5×10^{-6}—10^{-5} M 1,10-phenanthroline, copper(II) can be titrated with EDTA at room temperature with XO as an indicator.

In the copper(II)–EDTA titrations with Xylenol Orange (XO) as an indicator, hexamine slows down the rate of the color change of XO. The mechanism of the color change was reported in our previous paper.[1] On the other hand, 1,10-phenanthroline accelerates the rate of color change of the XO indicator remarkably.[2,3] This may be due to the mixed-ligand complex formation of the Cu_2xo chelate with 1,10-phenanthroline, and it may contribute to the color change as in the case of PAN.[4]

In this paper the composition of the mixed-ligand complexes of Cu–XO–phen and the rate of the substitution reaction of Cu–XO–phen with EDTA are determined, and the acceleration mechanism of the color change of XO by 1,10-phenanthroline is discussed.

Experimental

Reagents. XO was synthesized by the published method.[5,6] The solvent of the reaction product was distilled off under reduced pressure, and crude XO was obtained. The fractional precipitation of XO from the reaction mixture with ethanol[5,6] gives a lower yield of XO because of decomposition. The pure XO was completely separated on a cellulose column(prepared with Toyo-Roshi cellulose powder) by elution with butyl alcohol saturated with 10% acetic acid. The free-acid form(H_6xo) was obtained by passing the solution of the sodium salt through a column of Dowex 50W-X8(H^+) cation-exchange resin(100—200 mesh). The purity of H_6xo was estimated to be almost 100% by means of paper chromatography, pH-titration with a standard sodium hydroxide solution, and spectrophotometric titration with a standard copper(II) solution.

The 1,10-phenanthroline was recrystallized from an ethanol–water solution.

The other reagents employed were the same as those reported previously.[1]

The following buffers were used for adjusting the pH: pH 6.8—7.6: 0.02 M 3-morpholino-1-propanesulfonic acid(MOPS)–NaOH; pH<6.8: 0.02 M 2-morpholino-1-ethanesulfonic acid(MES)–NaOH. MOPS and MES were obtained from Dojindo Laboratories, Kumamoto, Japan.

The ionic strength was kept at 0.1 with KNO_3.

All the experiments were carried out at 25 ± 1 °C.

Apparatus. A Union Giken Stopped-Flow Spectrophotometer, Type RA-401, a Union Giken High Sensitivity Spectrophotometer, Type SM-401, a Hitachi Spectrophotometer, Type 124, and a Radiometer pH Meter, Type PHM 26c, were used.

Results

Mixed-Ligand Complexes of Cu_2xo with 1,10-Phenanthroline. In the presence of more than a 2-fold excess of copper(II), XO forms the Cu_2xo chelate above pH 5.5; the absorption maximum appears at 574 nm. When 1,10-phenanthroline (phen) was added to the Cu_2xo solution, the absorption maximum shifted to a longer wavelength (585 nm) and the molar absorp-

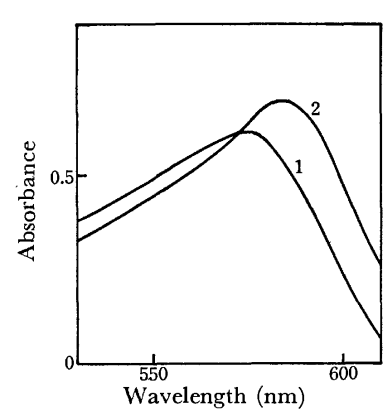

Fig. 1. Absorption spectra of Cu_2xo and $(Cuphen)_2xo$. $C_{xo}=1.32\times10^{-5}$ M, $C_{Cu}=2.58\times10^{-5}$ M. (1) Cu_2xo, pH 6.04; (2) $(Cuphen)_2xo$, $C_{phen}=3.29\times10^{-5}$ M, pH 7.00.

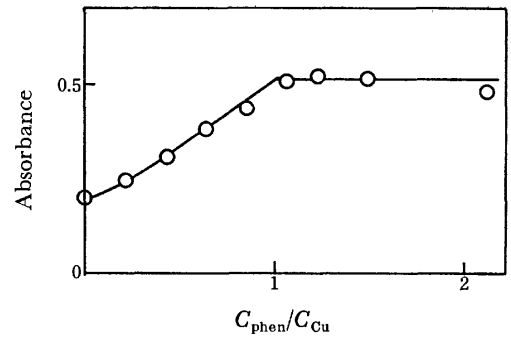

Fig. 2. Molar-ratio method of the mixed-ligand complex. $C_{xo}=1.32\times10^{-5}$ M, $C_{Cu}=2.58\times10^{-5}$ M, pH 6.93.

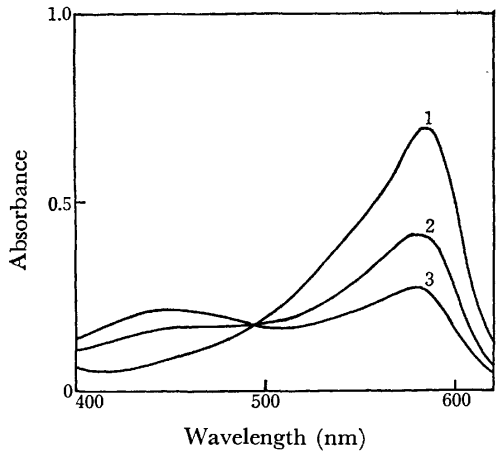

Fig. 3. Absorption spectra of the mixed-ligand complexes at different pH.
$C_{XO}=1.32\times10^{-5}$ M, $C_{Cu}=2.58\times10^{-5}$ M, $C_{phen}=3.29\times10^{-5}$ M, pH: (1) 7.00; (2) 5.98; (3) 5.50.

tivity increased by about 20% compared to that of Cu_2xo (Fig. 1). By the molar-ratio method it was found that $(Cuphen)_2xo$ was formed (Fig. 2).

The absorption spectra of a copper–XO chelate solution containing a 2.5-fold amount of 1,10-phenanthroline at different pH values are shown in Fig. 3. The absorption maximum shifts from 440 to 585 nm with an increase in the pH, an isosbestic point appears at 492 nm. Since copper(II) forms the Cu_2Hxo chelate with an absorption maximum at 444 nm at pH values lower than 4.5 in the absence of 1,10-phenanthroline, it is clear that $(Cuphen)_2Hxo$ is formed at lower pH values and that a proton may dissociate with an increase in pH. Thus, the following equilibrium exists in the pH range between 4.5 and 7.0:

$$(Cuphen)_2Hxo^- \rightleftarrows (Cuphen)_2xo^{2-} + H^+. \quad (1)$$

The equilibrium constant,

$$K^H_{(Cuphen)_2Hxo} = \frac{[(Cuphen)_2Hxo]}{[(Cuphen)_2xo][H]},$$

was evaluated to be $10^{5.7}$ from the change in the absorbance at 585 nm with the pH. The dissociation of the proton in $(Cuphen)_2Hxo$ is more difficult than that in Cu_2Hxo ($K^H_{Cu_2Hxo}=10^{4.55}$).[1]

The Substitution Reaction of Cu_2xo with 1,10-Phenanthroline. The rate of the substitution reaction of Cu_2xo with a large excess of 1,10-phenanthroline was measured by the stopped-flow method. Figure 4 shows a plot of the absorbance at 580 nm against the reaction time. The rapid increase in the absorbance at beginning indicates the formation of the mixed-ligand complex $(Cuphen)_2xo$. Then the reaction proceeds as

$$Cu_2xo^{2-} + 2phen \longrightarrow (Cuphen)_2xo^{2-}, \quad (2)$$

$$(Cuphen)_2xo^{2-} + 4phen \longrightarrow 2Cu(phen)_3^{2+} + xo'. \quad (3)$$

Under the present experimental conditions, the substitution reaction proceeds to completion and the reverse reaction can be neglected. The rate law may be expressed as:

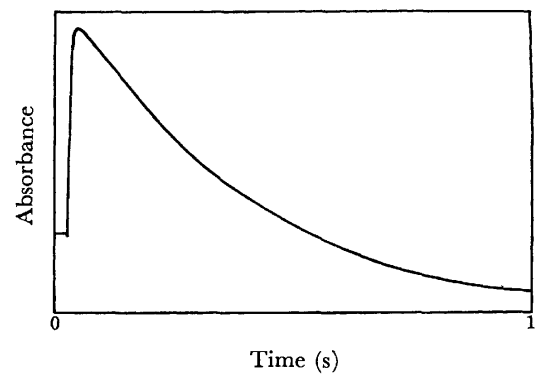

Fig. 4. Substitution reaction of Cu_2xo with 1,10-phenanthroline.
$C_{XO}=1.22\times10^{-5}$ M, $C_{Cu}=2.27\times10^{-5}$ M, $C_{phen}=8.67\times10^{-4}$ M, pH 7.43, 580 nm.

$$-\frac{d[(Cu_2xo)']}{dt} = k_{0(H,phen)}[(Cu_2xo)'], \quad (4)$$

where $[(Cu_2xo)']$ is the total concentration of copper–XO complexes and $k_{0(H,phen)}$ is the conditional rate constant involving the concentrations of the hydrogen ion and 1,10-phenanthroline. Representing the absorbances at the reaction times of 0, t, and ∞ as A_0, A_t, and A_∞ respectively, we obtain from Eq. 4

$$\log(A_t-A_\infty) = -\frac{k_{0(H,phen)}}{2.303}t + \log(A_0-A_\infty). \quad (5)$$

The experiments were carried out under the conditions where $C_{XO}=1.22\times10^{-5}$ M, $C_{Cu}=2.27\times10^{-5}$ M, and $C_{phen}=(6.19\text{—}12.4)\times10^{-4}$ M, pH 6.89—7.60. The rate plots of $\log(A_t-A_\infty)$ *vs.* t were linear for at least 90% of the reactions. The data in Table 1 indicate that the values of $k_{0(H,phen)}$ are proportional to the hydrogen-ion concentration, but independent of the 1,10-phenanthroline concentration; *i.e.*,

Table 1. First-order conditional rate constants $k_{0(H,phen)}$
$C_{XO}=1.22\times10^{-5}$ M, $C_{Cu}=2.27\times10^{-5}$ M, 25 °C, $\mu=0.1$.

$$k_{0(H,phen)} = k_1[H]. \quad (6)$$

This result indicates that the equilibrium (Eq. 2) shifts to the right completely and that the following reaction is the rate-determining step:

$$(Cuphen)_2xo^{2-} + H^+ \rightleftarrows H \cdots xo(Cuphen)_2 \xrightarrow{r.d.s.} (Cuphen)Hxo^{3-} + Cuphen^{2+}. \quad (7)$$

The resulting (Cuphen)Hxo may undergo rapid substitution with 1,10-phenanthroline. The rate constant, k_1, was evaluated as 5.5×10^7 M^{-1} s^{-1}.

The Substitution Reaction of Cu_2xo with EDTA in the Presence of 1,10-Phenanthroline. When a large excess of 1,10-phenanthroline is added to a Cu_2xo solution the substitution proceeds and the absorbance of Cu–XO complex decreases. The substitution of Cu_2xo with a solution containing a large excess of EDTA and (6.0—24.8)$\times10^{-5}$ M phenanthroline was, then, carried out.

The rate expression is given as

$$-\frac{d[(Cu_2xo)']}{dt} = k_{0(EDTA,H,phen)}[(Cu_2xo)']. \quad (8)$$

Table 2. First-order conditional rate constants $k_{0(EDTA,H,phen)}$
$C_{XO}=1.22\times10^{-5}$ M, $C_{Cu}=2.27\times10^{-5}$ M, 25 °C, $\mu=0.1$.

8.97			2.01
11.2			1.96

In this case, the values of $k_{0(EDTA,H,phen)}$ in Table 2 were proportional to only the concentration of the hydrogen ion, just as in the case of the substitution with 1,10-phenanthroline. Therefore, the mechanism of the substitution reaction of Cu_2xo is the same as that in the case of phenanthroline, and (Cuphen)Hxo may undergo rapid substitution with EDTA. The rate constant was obtained as 5.5×10^7 M^{-1} s^{-1}, which is in good agreement with the value obtained in the preceding section.

The substitution under conditions which are very close to those in practical titrations was examined; *i.e.*, a solution containing Cu_2xo and a 2.1—3-fold excess of phenanthroline was replaced with a large excess of EDTA. The values of $k_{0(EDTA,H,phen)}$ are shown in Table 3. We observed no dependence of $k_{0(EDTA,H,phen)}$ on the concentration of EDTA, but a linear relation to the hydrogen ion with the zero intercept and the 1,10-phenanthroline with an intercept were observed (Fig. 5). From these results the following equation is deduced:

Table 3. First-order conditional rate constants $k_{0(EDTA,H,phen)}$
$C_{XO}=1.32\times10^{-5}$ M, $C_{Cu}=2.58\times10^{-5}$ M, 25 °C, $\mu=0.1$.

C_{EDTA} ($\times10^{-4}$ M)	C_{phen} ($\times10^{-5}$ M)	pH	$k_{0(EDTA,H,phen)}$ (s^{-1})
5.61	2.74	6.89	4.02
		7.05	2.96
		7.25	1.92
	3.29	6.89	4.68
		7.05	3.26
		7.25	2.11
	3.84	6.89	4.76
		7.05	3.35
		7.25	2.30
6.73	3.29	7.05	3.22
7.85			3.22
8.97			3.22

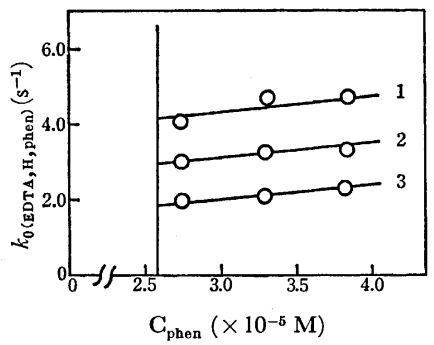

Fig. 5. Plots of $k_{0(EDTA,\ H,\ phen)}$ *vs.* C_{phen}.
$C_{XO}=1.32\times10^{-5}$ M, $C_{Cu}=2.58\times10^{-5}$ M, $C_{EDTA}=5.61\times10^{-4}$M, pH: (1) 6.89; (2) 7.05; (3) 7.25.

$$k_{0(EDTA,H,phen)} = (k_1+k_2[phen])[H]. \quad (9)$$

Under those experimental conditions the mixed-ligand complex $(Cuphen)_2xo$ may not be formed completely and a small amount of $(Cu_2phen)xo$ exists, so the second term in Eq. 9 is due to the following equilibrium preceding the rate-determining step (Eq. 7):

$$(Cu_2phen)xo^{2-} + phen \rightleftarrows (Cuphen)_2xo^{2-}. \quad (10)$$

Consequently, the substitution mechanism is virtually the same as that with 1,10-phenanthroline.

Discussion

As has been reported previously,[1] for the substitution reaction of Cu_2xo with EDTA the rate-law is expressed by

$$-\frac{d[Cu_2xo]}{dt} = k[Cu_2xo][edta'], \quad (11)$$

and the reaction mechanism is as follows:

$$Cu_2xo^{2-} + edta' \rightleftarrows edta \cdots Cu(xo)Cu \xrightarrow{r.d.s.} Cu(edta)^{2-} + CuHxo^{3-}, \quad (12)$$

$$CuHxo^{3-} + edta' \xrightarrow{fast} Cu(edta)^{2-} + xo'. \quad (13)$$

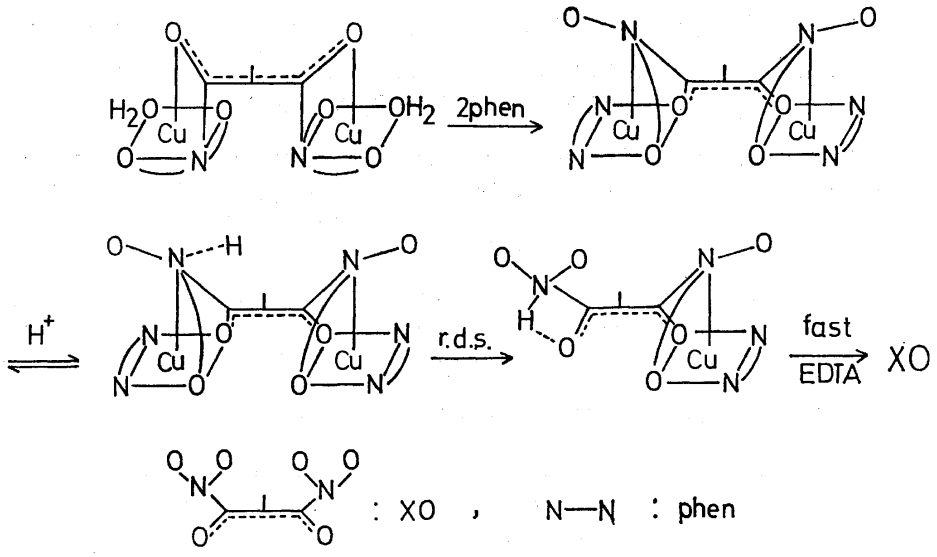

Fig. 6. Proposed reaction mechanism for substitution of $(Cuphen)_2xo$ with EDTA.

EDTA coordinates with one of the two coppers in the Cu_2xo chelate, and the release of the first copper ion from the intermediate edta···Cu(xo)Cu may be the rate-determining step, while the resulting CuHxo undergoes a rapid substitution with EDTA.

When 1,10-phenanthroline is present, the copper–XO chelate forms a mixed-ligand complex with 1,10-phenanthroline, and it may have a distorted octahedron structure, just as in the case of the copper–PAN–phen mixed-ligand complex.[4] Therefore, the release of the first copper from the $(Cuphen)_2xo$ chelate by the attack of a hydrogen ion on one of the nitrogen atoms in the iminodiacetic acid groups may be the rate-determining step (Fig. 6).

In practical titrations of copper(II) with EDTA, the rate of the color change of the XO indicator depends on the concentration of 1,10-phenanthroline and the titration pH. The rates of color change in the presence and in the absence of 1,10-phenanthroline were compared at pH 6.1 (MES buffer) using the stopped-flow spectrophotometer. A solution of copper (1.03×10^{-3} M) containing XO (1.22×10^{-5} M) and 1,10-phenanthroline and a solution containing EDTA (1.04×10^{-3} M, *i.e.* a 1% excess) were rapidly mixed. Usually in a visual titration 90% of the indicator transition is recognized as a complete color change; therefore, the time required for a 90% color transition was measured (Table 4). In the presence of 2.7×10^{-6} M 1,10-phenanthroline the rate of color change is 20-times as much as that in the absence, and with 1.2×10^{-5} M the rate increases by 50-times. Thus, 2.5×10^{-6}—10^{-5} M of 1,10-phenanthroline is sufficient for titration at room temperature. The addition of a larger amount of 1,10-phenanthroline may cause an underconsumption of EDTA.

Table 4. Effect of 1,10-phenanthroline on the rate of color change

	Concentration of 1,10-phenanthroline (M)				
	0	2.7×10^{-6}	6.2×10^{-6}	1.2×10^{-5}	2.4×10^{-5}
Time for 90% color change (s)	63	3.3	1.6	1.2	0.7

XO=1.22×10^{-5} M, Cu=1.03×10^{-3} M, EDTA=1.04×10^{-3} M, pH 6.1 (MES buffer), λ=580 nm, μ=0.1, 25 °C.

(Received March 14, 1977)

1,3-Diphenyl-1,3-propanediamine (dppn) was prepared from 1,3-diphenyl-2-propen-1-one. The meso and racemic isomers were isolated. The racemate was resolved into enantiomers with (+)$_D$-di-*O*-benzoyltartrate. The absolute configuration of the free diamine was determined by comparing the circular dichroism (CD) spectrum of *trans*-[$CoCl_2$(*S,S*- or *R,R*-dppn)$_2$]$^+$ with that of *trans*-[$CoCl_2$(*R,R*-2,4-pentanediamine)$_2$]$^+$. The absolute configurations of Δ- and Λ-[Co(*S,S*-dppn)$_3$]$^{3+}$ were also assigned on the basis of the CD spectra.

Recently, several groups have reported the stereochemistry and circular dichroism (CD) of cobalt(III) complexes containing 2,4-pentanediamine (ptn) which forms a six-membered chelate ring upon coordination.[1-4] Among possible conformations of coordinated ptn, the chair and skew forms are energetically preferred as indicated by conformational energy calculation.[5] X-Ray crystallographic studies confirm the skew form of coordinated (*R,R*)-ptn in $(-)_{546}$- and $(+)_{546}$-[Co(*R,R*-ptn)$_3$]$^{3+}$ and the chair form of (*R,S*)-ptn in $(+)_{510}$-[Co(ox)(*R,S*-ptn)$_2$]$ClO_4 \cdot H_2O$(ox=oxalate).[7] The chair form of coordinated trimethylenediamine (tn) was found in $(-)_{589}$-[Co(tn)$_3$]$^{3+}$.[8] These results indicate that chelated 1,3-diamines can take a variety of conformations in the solid state.

An equilibrium among these conformations of 1,3-diamines will be expected in solution. We have pointed out in a previous paper that the CD spectra of Δ-[Co(*R,R*-ptn)$_3$]$^{3+}$ and *cis*-Δ-[$Co(NH_3)_2$(*R,R*-ptn)$_2$]$^{3+}$ in the first absorption band region show a remarkable variation on the addition of electrolytes such as chloride and sulfate, and that the variation is accounted for the conformational change of the flexible (*R,R*)-ptn ligands.[9] Such a conformational stability of coordinated 1,3-diamines will differ depending on the kind of substituent on the six-membered chelate ring. In order to investigate the effect of substituent on the conformation of a chelate ring, we have prepared optically active 1,3-diphenyl-1,3-propanediamine (dppn) which forms a six-membered chelate ring with two phenyl groups on the asymmetric carbons. This paper will report the preparation and the absolute configuration of optically active dppn as well as the CD spectra of *trans*-[$CoCl_2$(*S,S*-dppn)$_2$]$^+$ and Δ- and Λ-[Co(*S,S*-dppn)$_3$]$^{3+}$.

Experimental

Preparation of Ligand. (1) Racemic and meso-*1,3-Diphenyl-1,3-propanediamine*: The dioxime of 1,3-diphenyl-1,3-propanedione was prepared by modifying slightly the method of Auwers and Müller.[10] An ethanol solution(95%, 1.2 dm^3) of 1,3-diphenyl-2-propen-1-one(208 g) was mixed dropwise with hydroxylamine hydrochloride(183 g) in water(200 cm^3), and then with potassium hydroxide(240 g) in water(200 cm^3) at 50 °C. The solution was refluxed for 20 min, cooled in ice water, and filtered to remove potassium chloride. The ethanol was removed under reduced pressure in a rotary evaporator. Enough water was added to the concentrate to give white precipitate. After a day the precipitate was filtered off and dried at 70 °C and then over P_2O_5 *in vacuo*. Recrystallization from hot ethanol gave white needle-like crystals of the dioxime (160 g). Mp 207 °C (dec). Found: C; 71.12, H; 5.53, N; 11.02%. Calcd for the dioxime($C_{15}H_{14}N_2O_2$): C; 70.87, H; 5.51, N; 11.02%. Recrystallization from hot benzene gave the hydroxyamino oxime. Mp 145 °C. Found: C; 70.77, H; 6.41, N; 11.27%. Calcd for the hydroxyamino oxime($C_{15}H_{16}N_2O_2$): C; 70.31, H; 6.25, N; 10.94%. These compounds were identified by IR spectra.

The dioxime was reduced with metallic sodium in ethanol according to the method used for preparing 2,4-pentanediamine.[11,12] The dioxime(80 g) was suspended in absolute ethanol(1.5 dm^3) in a three necked round bottom flask(3 dm^3) equipped with a large reflux condenser. Small pieces (5—8 cm^3) of metallic sodium (300 g) were added in portions to the suspension, to which was added additional amount of absolute ethanol from time to time. The mixture was allowed to stand for 30 min. Aqueous ethanol was added carefully to hydrolyze excess of sodium in the mixture and then 1 dm^3 of water was added. Ethanol was removed by evaporation. The aqueous solution was shaken with diethyl ether and ether layer was washed with water several times. Hydrogen chloride was bubbled into the ether solution to give white precipitate, which was filtered off and dried in air. Yield 70 g. Found: C; 56.78, H; 6.99, N; 8.83%. Calcd for 1,3-diphenyl-1,3-propanediamine dihydrochloride monohydrate($C_{15}H_{22}N_2OCl_2$): C; 57.00, H; 6.70, N; 8.49%. This diamine is a mixture of meso(*R,S*) and racemic(*R,R* and *S,S*) isomers.

(2) Separation of the meso- *and* dl-*1,3-Diphenyl-1,3-propanediamine Dihydrochloride: Method 1)*. The purified mixture of meso and racemic dihydrochloride(140 g) was suspended in boiling ethanol(400 cm^3) containing concd hydrochloric acid (20 cm^3). The suspension was stirred for 30 min and filtered in hot to remove a small amount of residue. White crystals were obtained on cooling the filtrate to room temperature. Both the products (residue and crystals) are the pure meso dihydrochloride. The PMR spectrum is shown in Fig. 1.

The filtrate was concentrated to 100 cm^3 and cooled to room temperature. White crystals(28 g) of the recemic dihydrochloride, contaminated by a small amount of the meso isomer, were filtered off. They were dissolved again in boiling ethanol(400 cm^3) and mixed with concd hydrochloric acid (10 cm^3). The solution was concentrated to 100 cm^3 to yield white crystals(9 g), which were filtered off. The pure racemic dihydrochloride(18 g) was obtained by evaporating the fil-

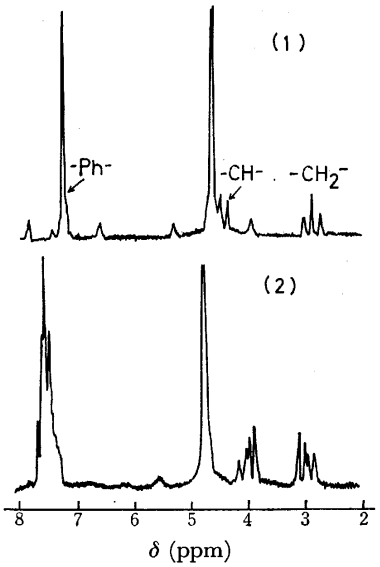

Fig. 1. PMR spectra of (1) *meso*-dppn·2HCl and (2) *dl*-dppn·2HCl in D_2O (60 MHz).

trate to almost dryness and by the addition of acetone. The PMR spectrum is shown in Fig. 1. The two isomers, meso and racemic, can be distinguished by the PMR spectra. Found for the meso isomer: C; 60.08, H; 6.99, N; 9.31%. Found for the racemic isomer: C; 59.58, H; 6.93, N; 9.22%. Calcd for 1,3-diphenyl-1,3-propanediamine dihydrochloride($C_{15}H_{20}N_2Cl_2$): C; 60.21, H; 6.74, N; 9.36%.

Method 2). Sodium hydroxide(30 g) in water(50 cm³) was added dropwise to a mixture of *meso*- and *dl*-dppn dihydrochloride(8.3 g) in cold water(50 cm³). The released dppn, insoluble in water, was extracted with chloroform(100 cm³). After removal of chloroform under reduced pressure, the oily residue was dissolved in ethanol(100 cm³). To the ethanol solution was added dropwise $(+)_D$-tartaric acid (8.3 g) in water(100 cm³). White crystals were obtained on cooling the solution in a refrigerator overnight. The crystals are *meso*-dppn $(+)_D$-tartrate. No crystal was obtained from the concentrated filtrate. The oily residue is *dl*-dppn $(+)_D$-tartrate. These isomers were identified by comparison with those prepared by method 1.

(3) Resolution of dl-*1,3-Diphenyl-1,3-propanediamine*: Potassium hydroxide (20 g) in water(20 cm³) was added dropwise to a cold aqueous solution (50 cm³) of *dl*-dppn dihydrochloride(9.2 g). The released dppn was extracted with chloroform(100 cm³), which was evaporated off and the oily residue was dissolved in methanol (40 cm³). The methanol solution was mixed with a methanol solution(40 cm³) of $(+)_D$-di-*O*-benzoyltartaric acid (10.7 g), and then with diethyl ether. The solution was allowed to stand overnight at room temperature. The precipitated white crystals were filtered off and washed with a mixture of methanol and diethyl ether (1: 1) and then with diethyl ether. Recrystallization from methanol by the addition of diethyl ether gave white crystals (7.8 g), $[\alpha]_D=-52.1°$ (*c*: 0.0048 g in 100 cm³ of a mixture of ethanol and water (1: 1)). This rotation did not change with further recrystallization. The absolute configuration of dppn in the less soluble diastereomer was assigned to the *(S,S)* configuration as described later.

Preparation of the Complexes. (1) trans-[*CoCl₂*(S,S-*dppn*)₂]-*Cl·HCl·H₂O*: Sodium hydroxide (15 g) in water(20 cm³) was added dropwise to a suspension of $(-)_D$-dppn-di-*O*-benzoyltartrate(6 g) in cold water(50 cm³). The released dppn was extracted with chloroform(100 cm³). The chloroform was removed under reduced pressure, and methanol(25 cm³) was added to the residue. The methanol solution was added dropwise with stirring to a mixture(60 cm³) of water and ethanol (2: 1) containing $Na_3[Co(NO_2)_6]$ (2 g). The total volume of the solution was adjusted to 200 cm³ with methanol. The solution was allowed to stand at 50 °C for 5 h. Hydrogen chloride was bubbled into the solution for 30 min until the color changed from orange to brown. The solution was kept in an evaporating dish at 50 °C with the addition of concd hydrochloric acid and methanol from time to time. The precipitated green solid was filtered off. Recrystallization from ethanol containing a small amount of concd hydrochloric acid gave green crystals(2 g). Found: C; 54.01, H; 5.68, N; 8.61 %. Calcd for $[CoCl_2(S,S\text{-dppn})_2]Cl\cdot HCl\cdot H_2O$ ($C_{30}H_{39}N_4OCl_4Co$): C; 53.59, H; 5.85, N; 8.33%. The perchlorate was obtained by adding sodium perchlorate to a methanol solution of the chloride.

(2) trans-[*CoCl₂*(R,S-*dppn*)₂]*Cl·H₂O*: To an aqueous solution (35 cm³) of $Na_3[Co(NO_2)_6]$(2.7 g) was added dropwise *(R,S)*-dppn(3 g) in ethanol(20 cm³). Yellow brown precipitate formed immediately. The suspension was stirred at 50 °C for 5 h and the yellow brown precipitate was filtered off(5.6 g), which was dissolved in methanol(1 dm³). When hydrogen chloride was bubbled for 10 min, the color changed from yellow to violet. The violet solution was concentrated in an evaporating dish to yield green precipitate, which was filtered off and washed with 4 M hydrochloric acid, then cold ethanol and diethyl ether. Yield 4 g. Found: C; 56.19, H; 6.09, N; 8.75%. Calcd for $[CoCl_2(R,S\text{-dppn})_2]Cl\cdot H_2O$ ($C_{30}H_{38}N_4OCl_3Co$): C; 56.66, H; 6.02, N; 8.81%.

(3) [*Co*(S,S-*dppn*)₃]*Cl₃*: A dimethyl sulfoxide (DMSO) solution (25 cm³) of dppn obtained from $(-)_D$-dppn-di-*O*-benzoyltartrate(2.4 g) was added dropwise to a DMSO solution(25 cm³) of *trans*-$[CoCl_2(S,S\text{-dppn})_2]Cl\cdot HCl\cdot H_2O$(1.8 g). The solution was allowed to stand at 25 °C for 7 h and then passed through a column (5×30 cm) of SE-Cellulose. The adsorbed band was eluted with a mixture of ethanol and water (1: 1). Orange yellow eluates were cooled in a refrigerator overnight to yield orange crystals (1.2 g), which were recrystallized from warm methanol(50 cm³, 60 °C). Found: C; 57.35, H; 6.73, N; 8.39%. Calcd for $[Co(S,S\text{-dppn})_3]Cl_3\cdot 5.5H_2O(C_{45}H_{65}N_6O_{5.5}Cl_3Co)$: C; 57.29, H; 6.94, N; 8.91 %. This complex has the *Δ* configuration as described later.

The unmoved band on the column was eluted with 0.5 M sodium perchlorate in a mixture of ethanol and water (1: 1). The orange eluates were concentrated to give red orange solid, which was dissolved in a mixture of water and methanol (4: 1). The solution was passed through a column(2×20 cm) of an SP-Sephadex C-25 ion exchanger. After washing with water, the adsorbed band was eluted with 1 M hydrochloric acid. The orange eluates were concentrated under reduced pressure to give orange crystals, which were filtered off and dried *in vacuo*. Yield 20 mg. Found: C; 57.62, H; 6.80, N; 8.42%. Calcd for $[Co(S,S\text{-dppn})_3]Cl_3\cdot 5.5H_2O(C_{45}H_{65}N_6O_{5.5}Cl_3Co)$: C; 57.29, H; 6.94, N; 8.91%. This complex has the *Λ* configuration as described later.

Measurements. Visible and ultraviolet absorption spectra were recorded on a Hitachi 323 spectrophotometer. CD spectra were obtained with JASCO J-20 and J-40 spectropolarimeters. PMR spectra were recorded on Varian A-60 and HA-100 spectrometers in deuterated solvents using sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) as the internal standard. All the solvents for optical measurements are of spectroscopic grade and used without further purification.

Results and Discussion

1,3-Diphenyl-1,3-propanediamine (dppn) is a six-membered chelate ligand, an analogue of 1,2-diphenyl-1,2-ethanediamine (stien) which forms a five-membered chelate ring. The skeleton is the same as that of 2,4-pentanediamine (ptn) in which the substituents on the asymmetric carbons are methyl groups. Therefore, there are two aspects for the cobalt(III) complexes of dppn: the first is the comparison with the ptn complexes and the second with the stien complexes.

Absorption Spectra. In Fig. 2, the absorption spectra of *trans*-$[CoCl_2(S,S\text{-dppn})_2]^+$ and *trans*-$[CoCl_2(S,S\text{-stien})_2]^+$ are compared in methanol. The absorption data are summarized in Table 1. We should point out some features of six-membered chelate rings from these data. (1) Red shift is observed for the complexes with six-membered chelate rings as compared with those containing five-membered chelate rings. This is commonly expected for complexes containing large chelate rings.[13] (2) The diastereomers, *Λ*- and *Δ*-$[Co(S,S\text{-dppn})_3]^{3+}$ as well as *Λ*- and *Δ*-$[Co(R,R\text{-ptn})_3]^{3+}$, give different absorption energies from each other in the first absorption band region. Such a difference is very small for the *Λ*- and *Δ*-$[Co((R)\text{-propylenediamine})_3]^{3+}$ complexes.[14] (3) The absorption peaks of the (*S*,*S*)-dppn complexes lie at lower energies than those of the corresponding (*R*,*R*)-ptn complexes. Hence, the ligand field strength may be (*R*,*R*)-ptn>(*S*,*S*)-dppn.

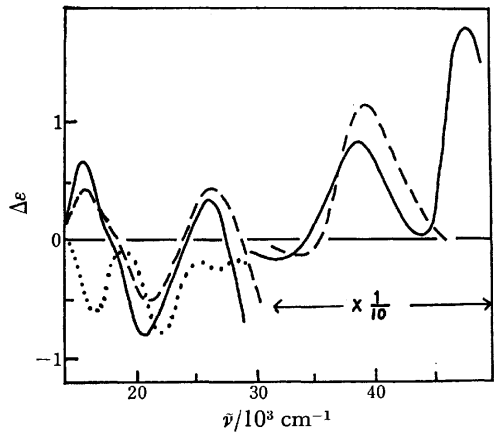

Fig. 3. CD spectra of *trans*-$[CoCl_2L_2]^+$ in methanol, L=(*S*,*S*)-dppn (——), (*R*,*R*)-ptn (– – –), and (*S*,*S*)-stien (·····).

Assignment of Absolute Configuration of dppn. The CD spectra of the complexes, *trans*-$[CoCl_2L_2]^+$ in methanol are shown in Fig. 3, where L represents (*S*,*S*)-dppn, (*R*,*R*)-ptn or (*S*,*S*)-stien. The absolute configuration of (*S*,*S*)-dppn can be assigned by comparing the CD spectrum of the (*S*,*S*)-dppn complex with that of the (*R*,*R*)-ptn complex. Both spectral patterns are similar to each other in the region of 14 to 45×10^3 cm^{-1}. It has been recognized that the optical activity of *trans*-$[CoCl_2(diamine)_2]^+$ complexes is affected strongly by the conformational contribution of the diamine and weakly by the vicinal effect of asymmetric carbons.[15] Hence, the conformation of the dppn seems to be the same

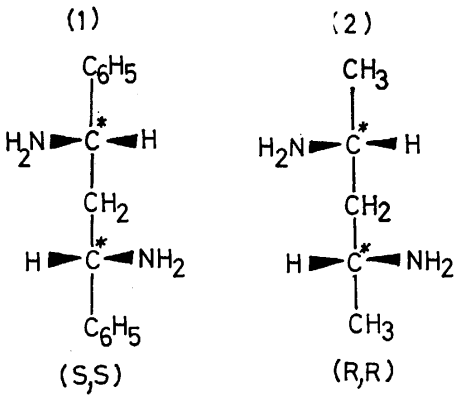

Fig. 4. Absolute configurations of (*S*,*S*)-dppn (1) and (*R*,*R*)-ptn (2).

λ-skew form as that of the ptn ligand, in which the two substituent groups on the asymmetric carbons adopt equatorial orientation. The λ-skew form of (*R,R*)-ptn chelate has been confirmed on $(+)_{546}$-[Co(*R,R*-ptn)$_3$]Cl$_3$·H$_2$O by an X-ray diffraction method.[6] According to the sequence rule,[16] the designation (*S,S*) of the dppn is opposite to that of the ptn to form the same λ-skew form (Fig. 4).

Circular Dichroism Spectra. Yano *et al.*[15] studied the CD spectra of various complexes of the type, *trans*-[CoCl$_2$(1,2-diamine)$_2$]$^+$ in methanol. In the Ib($^1A_{2g} \leftarrow {}^1A_{1g}$, D_{4h}) region, cobalt(III) complexes of (*R*)-1-phenyl-1,2-ethanediamine and (*R,R*)-stien which form five-membered λ-gauche chelate rings gave a CD peak with the opposite sign to that of the corresponding (*R*)-1-alkyl- or (*R,R*)-1,2-dialkyl-1,2-diamine complexes. However, all these complexes show similar CD patterns in the charge transfer region. They ascribed the difference to the vicinal effect of the phenyl groups on the chelate. Such a discussion is not applicable to the dppn complex. The pattern of the CD spectrum of *trans*-[CoCl$_2$(*S,S*-dppn)$_2$]$^+$ differs from that of the corresponding (*S,S*)-stien complex, while it resembles that of the corresponding (*R,R*)-ptn complex. The CD spectra of cobalt(III) complexes containing six-membered chelate diamines may not be appreciably affected by the presence of phenyl groups on the asymmetric carbons.

Figure 5 shows the absorption and CD spectra of the two diastereomers (named I and II) of [Co(*S,S*-dppn)$_3$]Cl$_3$ in DMSO. The CD spectrum of the isomer II which is eluted later from an SE-Cellulose column gives a weak minus peak at 18.2×10^3 cm^{-1} ($\Delta\varepsilon=-0.58$) and a strong plus peak at 20.2×10^3 cm^{-1} ($\Delta\varepsilon=+2.75$) in the first absorption band region. This pattern is similar to that of Λ-[Co(*R,R*-ptn)$_3$](ClO$_4$)$_3$ in DMSO (Fig. 6).[9] The CD spectrum of the isomer I which is eluted earlier from an SE-Cellulose column is similar to that of Δ-[Co(*R,R*-ptn)$_3$](ClO$_4$)$_3$ in water. Thus, we assigned

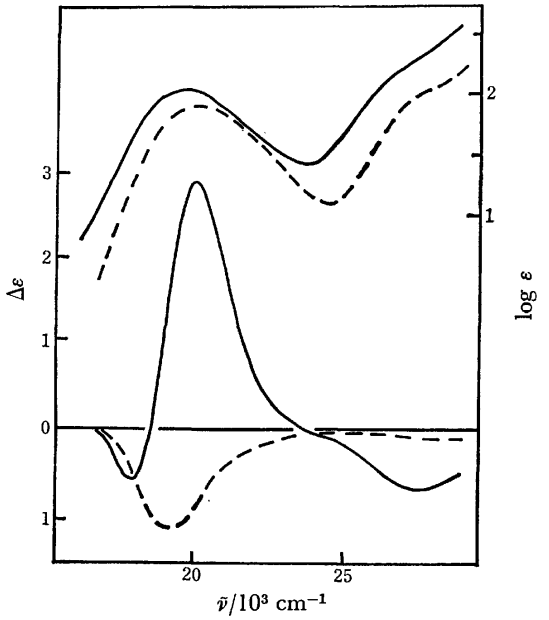

Fig. 5. Absorption and CD spectra of the diastereomers of [Co(*S,S*-dppn)$_3$]Cl$_3$ in DMSO, I(——) and II(——).

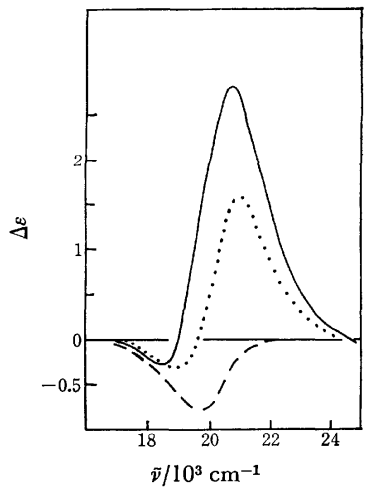

Fig. 6. CD spectra of Λ-[Co(*R,R*-ptn)$_3$](ClO$_4$)$_3$ in DMSO (——), Δ-[Co(*R,R*-ptn)$_3$](ClO$_4$)$_3$·3H$_2$O in water(– – –) and Δ-[Co(*R,R*-ptn)$_3$]Br$_3$ in DMSO (·····).[9]

II to Λ and I to Δ isomer. However, the spectrum of I is very different from that of Δ-[Co(*R,R*-ptn)$_3$]Br$_3$ in DMSO (Fig. 6). In a previous paper,[9] we have shown that the CD spectrum of Δ-[Co(*R,R*-ptn)$_3$]$^{3+}$ shows a remarkable variation in the first absorption band region in the presence of various electrolytes and in various solvents. There must be similar variations for the corresponding dppn complexes because of the flexible six-membered chelate rings. Detailed discussion for this system cannot be made unless the solvent effect is investigated. However, the solubility restriction of [Co(*S,S*-dppn)$_3$]Cl$_3$ makes us difficult to investigate the solvent effect.

The assignment of the absolute configuration of the [Co(*S,S*-dppn)$_3$]Cl$_3$ complex will be also supported by the formation ratio of the diastereomers. When the (*S,S*)-dppn takes a λ-skew form upon coordination, a tris complex can give two diastereomers, $\Lambda(\lambda\lambda\lambda)$ and $\Delta(\lambda\lambda\lambda)$. It has been known that the former complex in which the two asymmetric carbons of (*S,S*)-dppn lie oblique to the C_3 axis of the complex ion is less stable than the latter. The reason is believed to be due to large steric interactions among chelate rings in the former complex.[5,17] In fact, the formation ratio of the *lel*$_3$-$\Delta(\lambda\lambda\lambda)$ isomer to the *ob*$_3$-$\Lambda(\lambda\lambda\lambda)$ isomer is *ca.* 10 for tris(*R,R*-ptn)cobalt(III) complexes.[1] The tris(*S,S*-dppn)cobalt(III) complex gives always a large amount of the $\Delta(\lambda\lambda\lambda)$ isomer as described in the Experimental section.

Figure 7 shows the cofigurational and the vicinal effect curves derived from the CD spectra of Δ- and Λ-[Co(*S,S*-dppn)$_3$]Cl$_3$ in DMSO. The CD spectrum of [Co(NH$_3$)$_4$(*S,S*-dppn)]Br$_3$[18] in water is also shown. Although the additivity on CD curves is only an empirical rule, it may be useful to compare the difference between six-membered and five-membered chelate ligands. The additivity of the vicinal (conformational) contribution holds satisfactorily for a variety of five-membered chelate ring systems.[14,19] This is not the case for the present dppn system. The spectral pattern of the calculated vicinal effect curve of (*S,S*)-dppn in

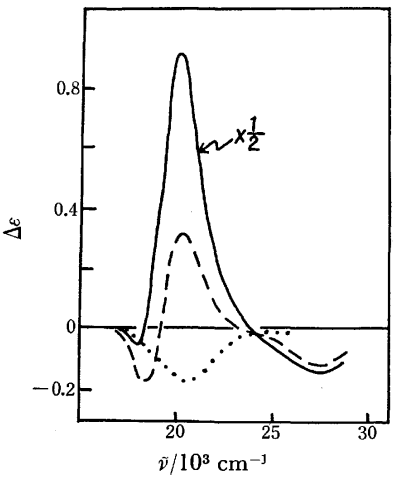

Fig. 7. The configurational (——) and the vicinal(– – –) contribution in the CD calculated from the spectra of the two diastereomers of $[Co(S,S\text{-dppn})_3]Cl_3$ in DMSO, and the CD spectra of $[Co(NH_3)_4(S,S\text{-dppn})]Br_3$ in water(·····).

$[Co(S,S,\text{-dppn})_3]^{3+}$ resembles that derived from the two diastereomers of $[Co(S,S\text{-dppn})(en)_2]^{3+}$ in water,[18] but differs completely from that of $[Co(NH_3)_4(S,S\text{-dppn})]^{3+}$ in water. Interligand steric interactions in $[Co(S,S\text{-dppn})_3]^{3+}$ must be larger than those in the tetraammine complex of dppn. The most stable conformation of each bulky and flexible six-membered chelate ring in these complexes might be somewhat different from each other.
