attacking products in reactions with 1,2-naphthoquinone. 4-Cyano-1,2-naphthoquinone behaves similarly to give both C-attacking and O-attacking products. In addition, α,β-unsaturated aliphatic aldehydes also give 1,2-naphthalenediol monoesters exclusively (see Table 2). Therefore, there is no reason to consider that the higher steric factor of the phenyl group could be the controlling factor of the product distribution.

What is, then, the controlling factor for the C-attacking or O-attacking products in these reactions? Since these photochemical reactions are undoubtedly initiated by hydrogen abstraction from aldehyde by the photo-excited 1,2-naphthoquinone molecule,[5] giving an acyl radical and a 1,2-naphthosemiquinone radical,[6] the structure of the combination product of the two resulting radicals must depend on the electronic character of the radical concerned. It has been reported that both the acetyl radical and the benzoyl radical have a nucleophilic character.[7] However, considering the photochemical reactions of 1,2-naphthoqinone with acetaldehyde, propenal, and benzaldehyde, the present author could arrange the decreasing nucleophilic character of the acyl radicals concerned in the following order: $CH_3\dot{C}$=O>CH_2=CH–$\dot{C}$=O>$C_6H_5\dot{C}$=O, on the basis of the inductive effect of the methyl, vinyl, and phenyl groups. Acyl radicals are, in general, of a strong σ-radical character and most of the free spin localizes on the acyl carbon. This was confirmed by the ESR measurement of the benzoyl radical.[8]

p-Methyl- and *p*-methoxybenzaldehyde, in reaction with *p*-benzoquinone, give 2-aroylhydroquinones as the predominant products.[9] However, as is shown in Table 1, the introduction of three methyl or three methoxyl groups on the phenyl ring has no appreciable effects on the product distributions, giving 1,2-naphthalenediol monoesters exclusively. Thus, α,β-unsaturated aldehydes, including aromatic aldehydes, are characteristic in giving the O-attacking products selectively.

As for the reactions with 10-undecenal, 3-phenylpropanal, and 3-cyclohexenecarbaldehyde, which have no olefinic π-system conjugated to carbonyl, we obtained the C-attacking product together with the O-attacking product in the reaction with 1,2-naphthoquinone derivatives, as is shown in Table 3. Whereas the carbonyl carbon of the acyl radical derived from α,β-unsaturated aldehydes attaches to the sp^2 carbon, the carbonyl carbon derived from these three aldehydes attaches to the sp^3 carbon. Therefore, it is reasonable to consider that the former acyl radical is more electrophilic than the latter. Thus, the inherent polarity of an acyl radical could exert the controlling influence on determining the attacking position on the 1,2-naphthosemiquinone radical. To support the

Table 3. The photo-addition compounds from the photochemical reaction of 1,2-naphthoquinone derivatives with aldehydes which have no conjugated olefinic π-system to carbonyl

a), b), c) See the footnotes in Table 1.

above consideration it was confirmed that, in the reactions of 6-bromo-1,2-naphthoquinone with butyraldehyde[1] and with 3-chlorobutanal, the ratios of C-attacking to O-attacking products were 47 : 53 and 9 : 91 respectively.

On the other hand, the introduction of an electron-attracting group, such as halogen or cyano groups, into the quinone ring should facilitate the C-attacking on the basis of the same considerations. Since the electron densities on the C_3-carbon of the 1,2-naphthosemiquinone radical, of the 6-bromo-1,2-naphthosemiquinone radical, and of the 4-cyano-1,2-naphthosemiquinone radical may decrease in this order, the C-attacking product would increase in the same order. The results of the photochemical reactions of 1,2-naphthoquinone, 6-bromo-1,2-naphthoquinone, and 4-cyano-1,2-naphthoquinone with acetaldehyde, propanal and 3-phenylpropanal are compared in Table 4. In actual, the amounts of the C-attacking product relative to the amounts of the O-attacking product change regularly. That is, the relative yields of the C-attacking products are 13—27, 30—57, and 80—85 % respectively. In the cases of the reaction with other aliphatic aldehydes, as has been described in a previous paper[1] and as is shown in Table 3, these tendencies can also be recognized.

Contrary to the effect of introducing some electron-attracting groups into the quinone ring, the introduction of an electron-donating group, such as methyl or methoxyl group, should exert the opposite influences on the product distributions. Actually, 4-methyl- or 4-methoxy-1,2-naphthoquinone gives only O-attacking products, without any C-attacking product, as is shown in Table 4.

The 2-butenoyl radical is also of an O-attacking character for the 1,2-naphthosemiquinone radical, but it shows a somewhat C-attacking character for the 6-halo-1,2-naphthosemiquinone radical. This might be due to the fact that the introduction of the halogen atom at the 6-position of the 1,2-naphthosemiquinone

Table 4. The relative yields of the photo-addition compounds obtained in the reaction of 1,2-naphthoquinone derivatives with several aldehydes

Quinone[a]	Aldehyde	Relative yields C-product (%)[e]	Relative yields O-product (%)[f]

a) 4-MeO-1,2-NQ: 4-Methoxy-1,2-naphthoquinone. The other quinones are shown in Table 1. The relative yields were determined by b) the integration of the ^{1}H-NMR signals of the concentrated reaction mixture, c) the weights of the isolated products, and d) the integration of the ^{1}H-NMR signals of the isolated products with TLC. e) 3-Acyl-1,2-naphthalenediol. f) 1,2-Napthalenediol monoacyl esters.

Table 5. The relative yields of the photo-addition compounds obtained in the reaction of 6-bromo- and 6-chloro-1,2-naphthoquinone with 2-butenal and 3-methyl-2-butenal

Quinone[a]	Aldehyde	Relative yields (%)[b] C-product[c]	Relative yields (%)[b] O-product[d]
6-Br-1,2-NQ	$CH_3CH{=}CHCHO$	2.6	97.4
6-Cl-1,2-NQ	$CH_3CH{=}CHCHO$	4.9	95.1
6-Br-1,2-NQ	$(CH_3)_2C{=}CHCHO$	6.3	93.7

a) 6-Br-1,2-NQ: 6-bromo-1,2-naphthoquinone, 6-Cl-1,2-NQ: 6-chloro-1,2-naphthoqinone. b) Average of three experiments. c) C-attacking product. d) O-attacking product.

radical induces a change in the electron density of the radical. Thus, the relative ratio of the C-attacking product to the O-attakcing product in the photochemical reaction of 6-chloro-1,2-naphthoquinone with 2-butenal increases slightly compared with the case of 6-bromo-1,2-naphthoquinone(see Table 5).

The reaction of 6-bromo-1,2-naphthoquinone with propenal yields the O-attacking product exclusively, but with 2-butenal a minor C-attacking product arises along with the major O-attacking product, suggesting that the methyl group somewhat enhances the nucleophilic character of the derived acyl radical.[10] However, as compared with 2-butenal, 3-methyl-2-butenal gives a slightly larger C-attacking product in the reaction with 6-bromo-1,2-naphthoquinone (Table 5).

Experimental

The melting points are uncorrected. The infrared spectra were obtained on a Hitachi 215 spectrometer, using a KBr disc. The ^{1}H-NMR spectra were taken with a JEOL MH-100 spectrometer, using TMS as the internal standard. Elemental analyses were carried out using a Yanaco MT-2 CHN corder.

Materials. *Quinones*: The 1,2-naphthoquinone (mp 121—122 °C),[11] 3-chloro-(mp 171 °C),[12] 3-bromo-(mp 164 °C),[13] 4-cyano-(mp 175—176 °C),[14] 4-methoxy-(mp 191—192 °C),[15] 6-bromo-(mp 156 °C),[16] and 6-chloro-1,2-naphthoquinone (mp 160—161 °C)[16] were prepared according to the methods described in the literature. 6-Methyl-1,2-naphthoquinone(mp 126—127 °C)[17] and 4-methyl-1,2-naphthoquinone(mp 77—80 °C)[18] were prepared by the oxidation of 6-methyl-2-naphthol and 4-methyl-1-naphthol respectively with Fremy's salt.

Aldehydes: The *p*-nitro-, *m*-nitro-, *p*-methyl-, *p*-methoxy-, 2,4-dimethoxy-, and 3,4,5-trimethoxybenzaldehyde, and cinnamaldehyde were commercially available and were used without further purification. The acetaldehyde, propanal, propenal, 2-butenal, *trans*-2-hexenal, 10-undecenal, 3-phenylpropanal, and benzaldehyde were commercially available and were further purified by distillation before use. The 2,4,6-trimethylbenzaldehyde(bp 94—95 °C/5 mmHg),[19] 2,4,6-triisopropylbenzaldehyde(bp 110—114 °C/3 mmHg),[19] cyclohexanecarbaldehyde(bp 75—77 °C/21 mmHg),[20] 1-cyclohexenecarbaldehyde(bp 82 °C/24 mmHg),[20] 3-cyclohexenecarbaldehyde(bp 70—73 °C/20 mmHg),[21] cyclopentenecarbaldehyde(bp 57—59 °C/28 mmHg),[22] 1-cyclopentenecarbaldehyde(bp 49 °C/20 mmHg),[23] 3-methyl-2-butenal(bp 67 °C/81 mmHg),[24] and 3-chlorobutanal(bp 65 °C/64 mmHg),[25] were prepared according to the methods given in the literature.

General Procedures. A 1,2-naphthoquinone derivative (1—2.5 mmol) and an aldehyde(1—10 mmol) were dissolved in benzene(25—80 ml), and the solution was irradiated for an appropriate time from outside in an ordinary glass tube by means of 300-W high-pressure mercury arc lamp through a 5-cm-thick layer of flowing water(15—20 °C) or of cold water (0—5 °C). After the removal of the solvent under reduced pressure, the residue was chromatographed on silica gel 60 (Merck, Art 7734, 0.063—0.200 mm), using benzene as the eluent. The photo-adducts thus obtained were further purified by recrystallization from benzene or benzene-light petroleum, or by TLC.

Structure Determination of Photo-adducts. 3-Acyl-1,2-naphthalenediols have characteristic IR bands at 3300—3500 (OH) and 1620—1650 (C=O) cm^{-1}. The 2-hydroxyl proton of them appeared at δ: 11—12 as a result of intramolecularly bonded hydrogen bonding with the carbonyl of the 3-acyl group. The 1,2-naphthalenediol monoesters show IR bands corresponding to carbonyl(1700—1740 cm^{-1}) and hydroxyl(3300—3400 cm^{-1}) groups. The existence of two isomers in these esters was confirmed by ^{1}H-NMR analyses. The yields and melting points of the adducts are listed in Tables 1, 2, and 3. Their physical properties and elemental analyses are shown in Table 6.

Detection of C-attacking Products. The presence of 3-acyl-1,2-naphthalenediol in a reacting system has been confirmed by inspecting the ^{1}H-NMR signal at δ: 11—12 in the concentrated reaction mixture. Thin-layer chromatography has been also used to detect the C-attacking products.

Irradiation of 6-Bromo-1,2-naphthoquinone with 2-Butenal: A benzene solution of the quinone (355.5 mg, 1.5 mmol) and

a) The protons appeared in the aromatic region, and the hydroxyl protons, except for the 2-hydroxyl proton which shifted to the low field of 3-acyl-1,2-naphthalenediols, are not listed. b) s: singlet, d: doublet, t: triplet, q: quartet, m: multiplet, dd: double doublet. c) The solvent is acetone-d_6. d) The solvent is carbon tetrachloride.

the aldehyde (350 mg, 5 mmol) was irradiated for 2 days. The reaction mixture was then worked-up as usual. 3-(2-Butenoyl)-6-bromo-1,2-naphthalenediol: orange-red needles (7.5 mg, 1.6%), mp 185—186.5 °C. IR: 3450(OH), 1655 (C=O) cm^{-1}. PMR($CDCl_3$), δ: 2.02(dd, 3H, J=1.5, 7.0 Hz), 5.96(s, 1H, removed by D_2O), 7.05—7.97(m, 6H), 11.37 (s, 1H, removed by D_2O). 6-Bromo-1,2-naphthalenediol mono-2-butenoate: white crystals (283 mg, 61.6%), mp 173.5—175 °C. IR: 3340(OH), 1710(C=O) cm^{-1}. PMR ($CDCl_3$), δ: 1.94 (dd, 3H, J=1.5, 7.0 Hz), 1.99 (dd, 3H, J=1.5, 7.0 Hz), 5.82—6.10 (m, 4H), 7.04—8.06 (m, 14H).

Irradiation of 6-Chloro-1,2-naphthoquinone with 2-Butenal: A benzene solution of the quinone (192.5 mg, 1 mmol) and the aldehyde (350 mg, 5 mmol) was irradiated for 3 days. The reaction mixture was then worked-up as usual. 3-(2-Butenoyl)-6-chloro-1,2-naphthalenediol: red crystals (6.5 mg, 2.5 %), mp 151—154 °C. IR: 3460(OH), 1655 (C=O) cm^{-1}. PMR (CCl_4), δ: 2.08 (dd, 3H, J=1.5, 7.0 Hz), 6.13 (s, 1H, removed by D_2O), 7.07—8.13 (m, 6H), 11.93 (s, 1H, removed by D_2O). 6-Chloro-1,2-naphthalenediol mono-2-butenoate: white crystals (125 mg, 47.6%), mp 179—180 °C. IR: 3340 (OH), 1708 (C=O) cm^{-1}. PMR ($CDCl_3$), δ: 2.00 (dd, 3H, J=1.5, 7.0 Hz), 2.05 (dd, 3H, J=1.5, 7.0 Hz), 6.21 (s, 2H, removed by D_2O), 7.25—8.24 (m, 14H).

Irradiation of 6-Bromo-1,2-naphthoquinone with 3-Methyl-2-butenal: A benzene solution of the quinone (476 mg, 2 mmol) and the aldehyde (504 mg, 6 mmol) was irradiated for 3 days. The reaction mixture was then worked-up as usual. 3-(3-Methyl-2-butenoyl)-6-bromo-1,2-naphthalenediol: red crystals (22 mg, 3.4%), mp 148—150 °C. IR: 3400 (OH), 1635 (C=O) cm^{-1}. PMR (CCl_4), δ: 2.10 (s, 3H), 2.27 (s, 3H), 5.94 (s, 1H, removed by D_2O), 6.93—8.00 (m, 5H), 12.04 (s, 1H, removed by D_2O). 6-Bromo-1,2-naphthalenediol mono(3-methyl-2-butenoate): white crystals, mp 147—148 °C. IR: 3345 (OH), 1700 (C=O) cm^{-1}. PMR ($CDCl_3$), δ: 2.02 (s, 3H), 2.27 (s, 3H), 6.02 (br, 1H), 6.24 (s, 1H, removed by D_2O), 7.23—8.15 (m, 5H).

Irradiation of 4-Methyl-1,2-naphthoquinone with Acetaldehyde: A benzene solution (80 ml) of the quinone (258 mg, 1.5 mmol) and the aldehyde (660 mg, 15 mmol) was irradiated for 42 h. No C-attacking product was detected by ^1H-NMR or TLC in the concentrated reaction mixture. The reaction mixture was then worked-up as usual. 4-Methyl-1,2-naphthalenediol monoacetate: white needles (165 mg, 51%), mp 174 °C (dec). IR: 3410 (OH), 1740 (C=O) cm^{-1}. PMR ($CDCl_3$), δ: 2.40 (s, 3H), 2.52 (s, 3H), 5.45 (br, 1H), 7.14—7.74 (m, 4H). Found: C, 72.01; H, 6.04%. Calcd for $C_{13}H_{12}O_3$: C, 72.21; H, 5.59%.

Irradiation of 4-Methyl-1,2-naphthoquinone with Propanal: A benzene solution (25 ml) of the quinone (86 mg, 0.5 mmol) and the aldehyde (87 mg, 1.5 mmol) was irradiated for 24 h. The reaction mixture was then worked-up as usual. 4-Methyl-1,2-naphthalenediol monopropanoate: white needles (52 mg, 45%), mp 112 °C. IR: 3400 (OH), 1730 (C=O) cm^{-1}. PMR ($CDCl_3$), δ: 1.25 (t, 3H), 1.32 (t, 3H), 2.51 (s, 6H), 2.64 (q, 2H), 2.67 (q, 2H), 5.46 (bs, 1H), 5.63 (br, 1H), 6.85 (s, 2H), 7.16—7.75 (m, 8H). The ratio of the isomer contents was 1 : 1, as estimated on the basis of the integration of the ^1H-NMR signals of the mixture. Found: C, 73.12; H, 6.08%. Calcd for $C_{14}H_{14}O_3$: C, 73.03; H, 6.13%.

Irradiation of 4-Methoxy-1,2-naphthoquinone with Acetaldehyde: A benzene solution (25 ml) of the quinone (200 mg, 1.06 mmol) and the aldehyde (500 mg, 11.4 mmol) was irradiated for 2 days at 0—5 °C. The reaction mixture was then worked-up as usual. 4-Methoxy-1,2-naphthalenediol monoacetate: white needles (186 mg, 76%), mp 105—106 °C (dec). IR: 3360 (OH), 1728 (C=O) cm^{-1}. PMR ($CDCl_3$), δ: 2.30 (s, 18%), 2.38 (s, 82%), 3.66 (s, 82%), 3.81 (s, 18%), 5.81 (br, removed by D_2O), 6.32 (s, 82%), 6.35 (s, 18%), 7.09—7.96 (m). Found: C, 67.22; H, 5.10%. Calcd for $C_{13}H_{12}O_4$: C, 67.23; H, 5.21%.

Irradiation of 4-Methoxy-1,2-naphthoqinone with Propanal: A benzene solution of the quinone (188 mg, 1 mmol) and the aldehyde (87 mg, 1.5 mmol) was irradiated for 2 days. The reaction mixture was then chromatographed on silica gel, using benzene–ether (8 : 2) as the eluent. 4-Methoxy-1,2-naphthalenediol monopropanoate: white needles (200 mg, 81%), mp 90—91 °C (dec). IR: 3320 (OH), 1725 (C=O) cm^{-1}. PMR ($CDCl_3$), δ: 1.33 (t, 21%), 1.40 (t, 79%), 2.73 (q, 21%), 2.83 (q, 79%), 3.82 (s, 79%), 3.99 (s, 21%), 6.47 (s, 79%), 6.58 (s, 21%), 7.36—8.20 (m). Found: C, 68.09; H, 5.71%. Calcd for $C_{14}H_{14}O_4$: C, 68.23; H, 5.73%.

Irradiation of 6-Bromo-1,2-naphthoquinone with 3-Chlorobutanal: A benzene solution (25 ml) of the quinone (237 mg, 1 mmol) and the aldehyde (211 mg, 2 mmol) was irradiated for 2 days. The concentrated reaction mixture was then chromatographed on silica gel, using benzene as the eluent. 3-(3-Chlorobutanoyl)-6-bromo-1,2-naphthalenediol: orange yellow needles (22.3 mg), mp 138—141 °C. IR: 3420 (OH), 1642 (C=O) cm^{-1}. PMR ($CDCl_3$), δ: 1.70 (d, 3H), 3.58 (m, 2H), 4.72 (m, 1H), 6.11 (s, 1H), 7.55—8.03 (m, 4H), 11.40 (s, 1H). 6-Bromo-1,2-naphthalenediol mono (3-chlorobutanoate): white needles (203.3 mg), mp 135—137.5 °C. IR: 3410 (OH), 1725 (C=O) cm^{-1}. PMR ($CDCl_3$), δ: 1.66 (d, 3H), 1.69 (d, 3H), 3.03 (m, 4H), 4.75 (m, 2H), 5.62 (br. 1H), 5.92 (s, 1H), 7.20—7.93 (m, 10H).

The author wishes to express his deep gratitude to Professor Kazuhiro Maruyama, Kyoto University, and Professor Osamu Soga, Shimane University, for their fruitful suggestions and invaluable encouragement. He also wishes to thank the Ministry of Education for its financial support for this research.

5) 9,9′-Bixanthenyl was obtained as one of the reaction products from the photochemical reaction of 1,2-naphthoquinone with xanthene. By means of the photo-CIDNP study of the reaction of 1,2-naphthoquinone with hydroquinone, the polarized signals of both *p*-benzoquinone (emission signal) and hydroquinone itself (enhanced absorption) were observed. On the basis of these results, it may safely be concluded that the photo-excited 1,2-naphthoquinone molecule, which is probably in its n-π^* triplet state, acts as a hydrogen abstractor.

6) Bruce and Cutts reported on the mechanism of the formation of 2-acetylhydroquinone in the photochemical reaction of *p*-benzoquinone with acetaldehyde. In their paper they considered the attack of the acetyl radical on the quinone in its ground state, followed by the subsequent enolization of the primary adduct. However, the present author confirmed that 3-acetyl-1,2-naphthalenediols were not obtained in the reaction of the acetyl radical with 1,2-naphthoquinone

derivatives in their ground state. The experimental conditions were as follows: a mixture of a 1,2-naphthoquinone (200 mg) and di-*t*-butyl peroxyoxalate (200 mg) in acetaldehyde (20 ml) was kept in the dark at room temperature for 7 days. Furthermore, CIDNP signals were observed in the photochemical reaction of 1,2-naphthoquinone with acetaldehyde in hexadeuteriobenzene. In addition, the photoinduced Fries rearrangement of the O-attacking product to C-attacking product did not occur under the experimental conditions used in this work. *Cf.* a) J. M. Bruce and E. (Received February 7, 1977)

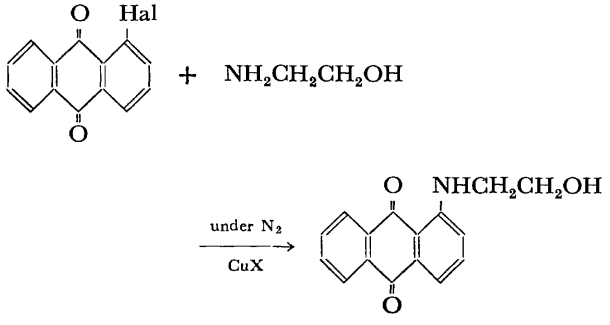
An induction period was present in the Ullmann condensation reactions of 1-bromoanthraquinone(AQBr) with 2-aminoethanol(AE) in the presence of CuBr or CuI in aprotic solvents under a nitrogen atmosphere, while there was no induction period in the reaction systems of 1-iodoanthraquinone(AQI)–AE–CuBr, AQI–AE–CuI, and AQBr–AE–$[Cu(CH_3CN)_4]ClO_4$. In the condensation system with a copper(I) catalyst, the Cu(I) species was oxidized to the Cu(II) species by means of an electron transfer from Cu(I) to haloanthraquinone as the reaction proceeded. By adding copper(II) bromide, the induction period vanished in the reaction system of AQBr–AE–CuBr. The copper(II) species increased the catalytic activity of the copper(I) species. The formation of the copper(II) species was responsible for the presence of an induction period and played an important role in the Ullmann condensation reaction of haloanthraquinones with amines in the presence of copper(I) salt as a catalyst.

The Ullmann condensation reaction, the nucleophilic substitution of aryl halides by amines or phenols in the presence of copper catalyst, is widely used for the synthesis of diaryl amines or diaryl ethers. Although many studies of the condensation of phenols with aryl bromides have been described, and although aryloxycopper(I) has been proposed as a nucleophile,[2,3] only a few mechanistic studies of the condensation with amines have been reported. We reported previously on the catalysis of copper(II) species in the reaction of sodium 1-amino-4-bromoanthraquinone-2-sulfonate with aniline in an aqueous alkaline solution.[4–7] Kurdyumova investigated the reaction of haloanthraquinones with aromatic and aliphatic amines in the presence of copper salts as catalysts.[8] However, scarcely no systematic studies of the Ullmann condensation reaction of haloanthraquinone derivatives with amines in aprotic solvents have been reported.

In our preceding paper,[1] we discussed the reactivities of haloanthraquinones, amines, and catalysts in the reaction of haloanthraquinones with amines by copper catalysts in aprotic solvents under a nitrogen atmosphere.

In this paper we will report that an induction period is observed under some reaction conditions in the reaction of 1-haloanthraquinones with 2-aminoethanol in the presence of copper(I) halides in aprotic solvents, and we will propose that the formation of the copper(II) species plays an important role in determining the presence of an induction period and the catalytic activity of copper salts.



Results and Discussion

The plot of the yield of the reaction product against the reaction time shows that the copper(I) catalyst is more effective than the copper(II) catalyst, that the catalytic activity of copper(I) salts decreases in this order: CuBr>CuI, and that 1-iodoanthraquinone (AQI) is more reactive than 1-bromoanthraquinone (AQBr) (Fig. 1). An induction period is observed in the condensation systems of AQBr–2-aminoethanol (AE)–CuBr and AQBr–AE–CuI, while an induction period is absent in the condensation systems using AQI. In explaining the presence of an induction period, the following several factors were discussed: the autocatalytic reaction, the halogen-exchange reaction between AQBr and CuI, the depolymerization of the polymeric copper(I) complex to monomeric species, and the formation and catalytic action of the copper(II) species.

Autocatalytic Reaction. When the catalytic activity of copper salt is increased by the coordination of a condensation product, the reaction rate will increase as the reaction proceeds, and there will be an induction period. If this is the case, the addition of the condensation product [1-(2-hydroxyethylamino)-anthraquinone] will enhance the reaction rate and the induction period will vanish. However, the yield of the condensation product decreased and the induction period did not vanish upon the addition of the condensation product(Fig. 2). This result probably indicates that the catalytic action of the copper(I) species diminishes by means of the coordination of the condensation product. Therefore, autocatalysis does not seem to be responsible for the presence of the induction period.

Halogen-exchange Reaction between 1-Bromoanthraquinone and Copper(I) Iodide. It has been established that the halogen atoms of haloaromatics are replaced by halogens or other groups of copper(I) salts in aprotic solvents.[9–12] In the case of the reaction of 1-bromoanthraquinone with 2-aminoethanol by the CuI catalyst, 1-iodoanthraquinone was indeed produced along

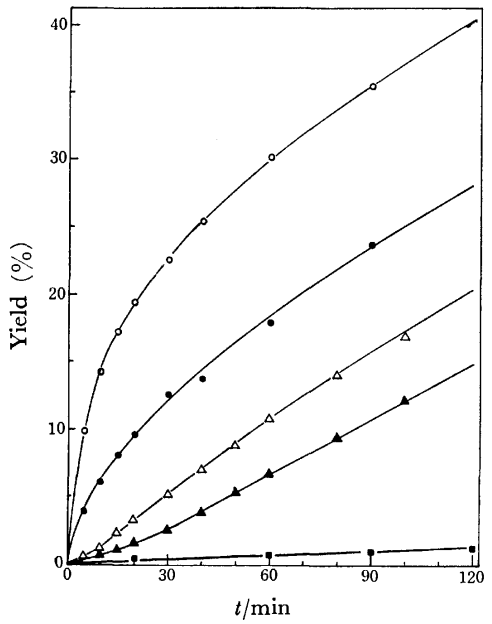


Fig. 1. Plots of the yields of products *vs.* reaction time in the reaction of 1-haloanthraquinone(AQHal) with 2-aminoethanol(AE) by copper salt(CuX) catalyst at 70 °C; $[AQHal]_0=5.00\times10^{-3}$ mol/l, $[AE]_0=0.50$ mol/l, $[CuX]_0=2.00\times10^{-3}$ mol/l, solvent 1,2-dimethoxyethane–methyl cellosolve 4 : 1. ○: AQI–CuBr, ●: AQI–CuI, △: AQBr–CuBr, ▲: AQBr–CuI, ■: AQBr–$CuBr_2$.

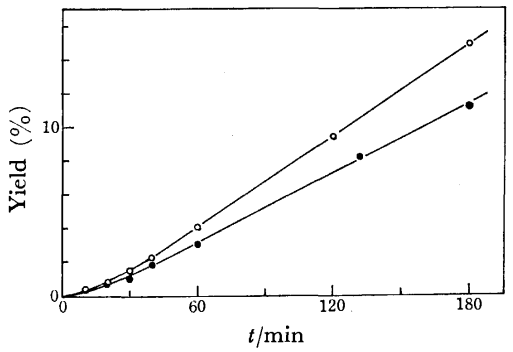

Fig. 2. Effect of the addition of condensation product; $[AQBr]_0=5.00\times10^{-3}$ mol/l, $[AE]_0=0.50$ mol/l, $[CuI]_0=2.00\times10^{-3}$ mol/l, temp 60 °C, solvent THF–ethanol 4 : 1. ○: control, ●: [1-(2-hydroxyethylamino)anthraquinone]$_0=1.30\times10^{-3}$ mol/l.

with the condensation product (Fig. 3). This result suggests that the bromine atom of 1-bromoanthraquinone is replaced by the iodine atom in the course of the condensation reaction,

$$AQBr + CuI \rightarrow AQI + CuBr.$$

Since more reactive 1-iodoanthraquinone is produced with the lapse of time, the rate of the condensation reaction will increase as the reaction proceeds, then an induction period will be observed.

If the rate law is supposed to be first-order in both concentrations of the substrate and catalyst,[10] the reaction rate can be written by

$$v = (k_1[CuBr]+k_1'[CuI])[AQBr] + (k_2[CuBr]+k_2'[CuI])[AQI]. \quad (1)$$

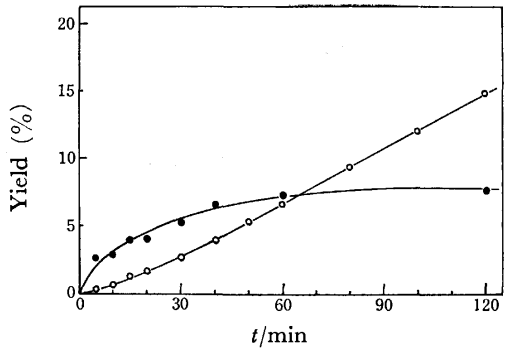

Fig. 3. Reaction of 1-bromoanthraquinone with 2-aminoethanol by CuI catalyst; $[AQBr]_0=5.00\times10^{-3}$ mol/l, $[AE]_0=0.50$ mol/l, $[CuI]_0=2.00\times10^{-3}$ mol/l, temp 70 °C, solvent 1,2-dimethoxyethane–methyl cellosolve 4 : 1.
○: 1-(2-Hydroxyethylamino)anthraquinone,
●: 1-iodoanthraquinone.

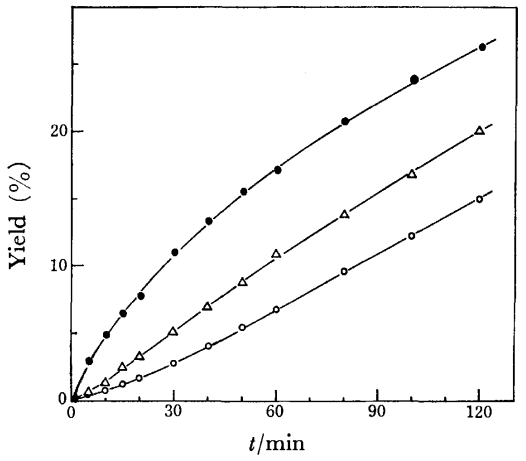

Fig. 4. Effect of anionic ligand of CuX; $[AQBr]_0=5.00\times10^{-3}$ mol/l, $[AE]_0=0.50$ mol/l, $[CuX]_0=2.00\times10^{-3}$ mol/l, temp 70 °C, solvent 1,2-dimethoxyethane–methyl cellosolve 4 : 1. ●: $[Cu(CH_3CN)_4]ClO_4$, △: CuBr, ○: CuI.

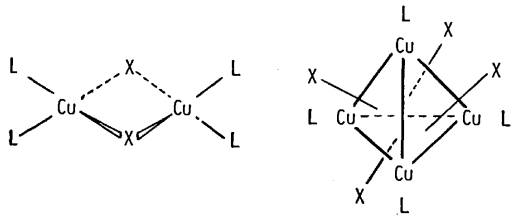
The values of k_1/k_1', k_2/k_1', and k_2'/k_1', estimated from the initial rate of each, were 2.4, 45.4, and 17.2 respectively. AQI was formed in a yield of about 7% after 60 min (Fig. 3). Since the resulting AQI is consumed in the reaction with 2-aminoethanol, the concentration of the resulting CuBr may be supposed to be higher than that of the observed AQI. Consequently, the rate after 60 min was estimated to be larger than the initial rate by a factor of more than 2.7. On the other hand, Fig. 3 shows that the rate after 60 min rises to about two times the initial rate. These values may indicate some effects of the halogen exchange on the reaction rate. However, it cannot be considered as the main reason for the presence of the induction period even in the reaction of AQBr with 2-aminoethanol caused by the CuI catalyst, for the induction period was also present in the condensation system of AQBr–AE–CuBr and it could not result from an increase in the rate by the halogen-exchange reaction.

Consequently, the presence of the induction period cannot be understood on the basis only of the halogen-

exchange mechanism.

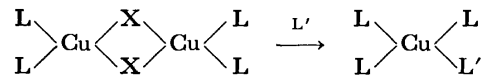
Depolymerization of the Polymeric Copper(I) Complex to Monomeric Species. As is shown in Fig. 4, the induction period was observed in the reaction systems of AQBr–AE–CuBr and AQBr–AE–CuI, while it was not present in the system of AQBr–AE–tetrakis(acetonitrile)copper(I) perchlorate ($[Cu(CH_3CN)_4]ClO_4$). Copper perchlorate complexes are known to be present as monomeric species in solution because the perchlorate ligand cannot act as a bridging group between copper(I) species.[13-14] The structures of copper(I) halide–amine complexes were proposed to be the halogen-bridged dimer(A)[15-17] or the tetramer(B)[15,16,18] on the basis of the cryoscopic data on solution and an X-ray examination of the crystalline state.



(A) L=RNH_2, R_2NH. X=Cl, Br, I.

(B) L=RNH_2; X=Cl, Br, I. L=R_2NH; X=Cl.

The $[Cu(CH_3CN)_4]ClO_4$ catalyst, which did not exhibit the induction period, was more effective catalyst than CuBr and CuI, which did exhibit the induction period(Fig. 4). These facts seem to indicate that the monomeric copper(I) species is a rather more effective catalyst than the polymeric one in the Ullmann condensation and that the induction period may be ascribed to the change from the polymeric copper(I) species to the active monomeric species. The polymeric copper(I) species will be depolymerized by the coordination of amine as follows:



X=Halogen; L=Halogen, Amine, AQBr; L′=Amine.

As is shown in Fig. 5, the induction period was shortened with the increase in the concentration of amine, and it was not observed at a high concentration of amine. This result seems to support the above consideration. The Cu(I)–amine solution was allowed to stand for a long time, either at room temperature or at 70 °C, and then the solution was added to a solution containing 1-bromoanthraquinone. If the induction period was caused by the depolymerization of the polymeric copper(I) species in the course of the reaction, the induction period would vanish under the above condition, but no change of the induction period was observed. This finding may enable us to exclude the idea that the change in copper(I) species from a polymeric complex to a monomeric one was responsible for the presence of the induction period.

Formation and Catalytic Action of the Copper(II) Species. Figure 6 shows that the plots of $-\log(1-x)$ against the time, where x denotes the yield of the reaction product, are independent of the initial concentration of AQBr. This result suggests that the reaction rate is first-order

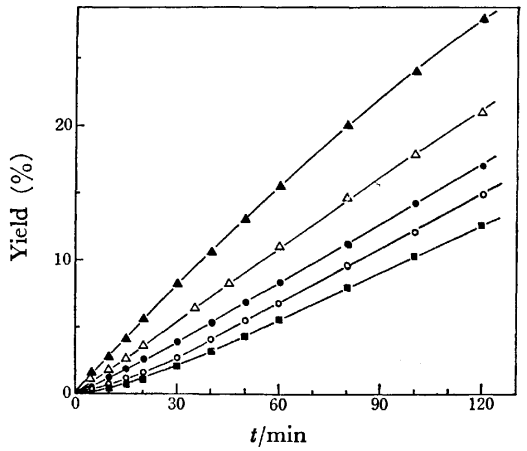


Fig. 5. Effect of the concentration of 2-aminoethanol; $[AQBr]_0=5.00\times10^{-3}$ mol/l, $[CuI]_0=2.00\times10^{-3}$ mol/l, temp 70 °C, solvent 1,2-dimethoxyethane–methyl cellosolve 4 : 1. $[AE]_0$; ▲: 2.00, △: 1.50, ●: 1.00, ○: 0.50, ■: 0.25 mol/l.

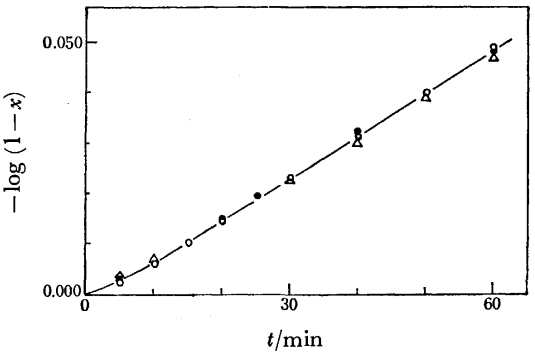

Fig. 6. Effect of the concentration of 1-bromoanthraquinone; $[AE]_0=0.50$ mol/l, $[CuBr]_0=2.00\times10^{-3}$ mol/l, temp 70 °C, solvent 1,2-dimethoxyethane–methyl cellosolve 4 : 1. $[AQBr]_0$; ●: 7.00×10^{-3}, ○: 5.00×10^{-3}, △: 3.00×10^{-3} mol/l.

in the concentration of AQBr. Since the concentration of amine used in a large excess may reasonably be supposed to be kept constant, the presence of the induction period is considered to reflect the change in the catalytic activity. We reported previously that the copper(I) species was oxidized to the copper(II) species by means of an electron transfer from copper(I) to haloanthraquinone as the reaction proceeded, but the reaction rate did not decrease in accordance with the formation of the copper(II) species, which was less active than the copper(I) species.[1] Figures 4 and 7 suggest that the induction period is observed in the case of the slow formation of the copper(II) species. As has been mentioned above, the induction period was absent at high concentrations of amine. The ESR spectra of the reaction system indicated that the formation of copper(II) species increased with the increase in the concentration of amine. The ESR spectra showed also that the formation of the copper(II) species in the reaction of 1-iodoanthraquinone with 2-aminoethanol was much faster than that in the reaction using 1-bromoanthraquinone. The reaction with 1-iodoanthraquinone did not reveal any induction period, but the

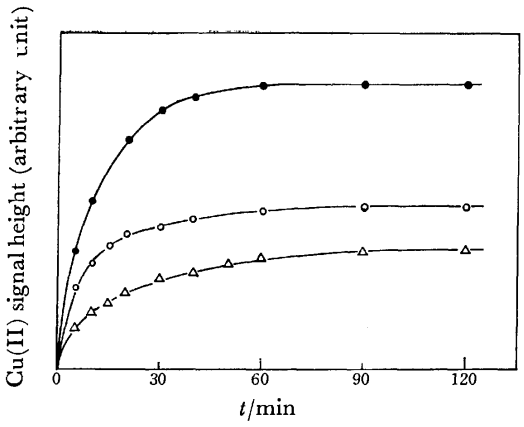

Fig. 7. Time dependence of Cu(II) signal height; $[AQBr]_0=5.00\times10^{-3}$ mol/l, $[AE]_0=0.50$ mol/l, $[CuX]_0=2.00\times10^{-3}$ mol/l, temp 70 °C, solvent 1,2-dimethoxyethane–methyl cellosolve 4 : 1. ●: $[Cu(CH_3CN)_4]ClO_4$, ○: CuBr, △: CuI.

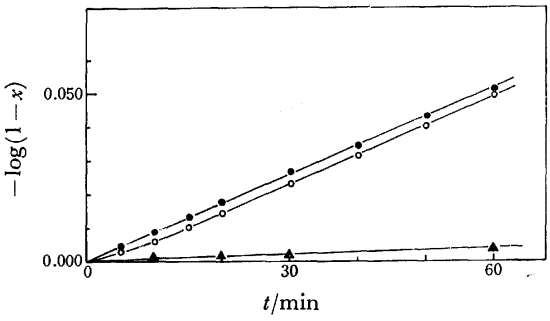

Fig. 8. Pseudo-first order plots of the condensation catalyzed by CuBr, $CuBr_2$, or CuBr+$CuBr_2$; $[AQBr]_0=5.00\times10^{-3}$ mol/l, $[AE]_0=0.50$ mol/l, temp 70 °C, solvent 1,2-dimethoxyethane–methyl cellosolve 4 : 1. ●: $[CuBr]_0=1.70\times10^{-3}+[CuBr_2]_0=0.30\times10^{-3}$ mol/l, ○: $[CuBr]_0=2.00\times10^{-3}$ mol/l, ▲: $[CuBr_2]_0=2.00\times10^{-3}$ mol/l.

reaction using 1-bromoanthraquinone revealed a marked induction period(Fig. 1).

Thus, the formation of the copper(II) species seems to be related to the presence of the induction period. If this is the case, the induction period will vanish upon the addition of copper(II) bromide to copper(I) bromide. The experimental results fit in with this expectation(Fig. 8). Although the yield of the condensation product was strikingly low when the $CuBr_2$ catalyst was used, it is noteworthy that the copper(II) species increased the catalytic activity of the copper(I) species.

All of the results support the idea that the formation of copper(II) species is closely correlated with the induction period. Thus, the presence of an induction period can be understood to be due to the effect of the formation of the copper(II) species on the catalytic activity of the copper(I) species.

Further detailed studies are in progress to elucidate the formation and role of the copper(II) species.

Experimental

Materials. The 1-bromoanthraquinone, 1-(2-hydroxyethylamino)anthraquinone, and copper(I) halides were prepared as has been reported previously.[1] The 1-iodoanthraquinone was prepared by the reaction of anthraquinone-1-diazonium salt and potassium iodide and purified by column chromatography on silica gel (using benzene as the developing solvent), followed by recrystallization from acetic acid: mp 205.3—205.5 °C (cor) (lit, mp 204—205 °C[19]) (Found: C, 50.32; H, 1.94%). Copper(II) bromide was purified by washing with ethyl acetate and anhydrous ethanol and then dried *in vacuo*. Tetrakis(acetonitrile)copper(I) perchlorate was prepared as has been described in the literature,[20] recrystallized several times from acetonitrile, and dried under a nitrogen atmosphere. The 2-aminoethanol was purified by the method described previously.[1] All the solvents were dried by the usual methods, distilled, and stored under a nitrogen atmosphere.

Kinetic Measurements. The kinetic measurements were conducted by the method described in the previous paper.[1] The 1-iodoanthraquinone formed by the halogen-exchange reaction was analyzed as follows: sample(0.5 ml) were withdrawn and diluted in ethanol. The solution was analyzed by the use of a Shimadzu Du Pont LC-1 high-speed liquid chromatograph(column: Zorbax ODS; eluent: methanol–water 67 : 33), with 1-amino-2-bromoanthraquinone as the internal standard.

ESR Measurement. The ESR spectra were measured at 70 °C by means of a JEOL-PE-3X ESR spectrometer. A single sample tube was used throughout the measurement, and the conditions of the ESR spectrometer were kept constant as far as possible.

Restricted Rotation Involving the Tetrahedral Carbon. XX. Barriers to Rotation and ^{13}C NMR Spectra of 9-(2-Alkylphenyl)fluorene Derivatives[1,2]

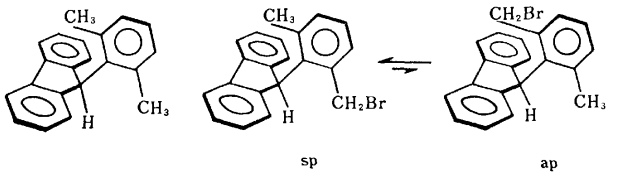
Mikio NAKAMURA,[3] Nobuo NAKAMURA, and Michinori ŌKI*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received June 22, 1977)

A series of 9-(2-alkylphenyl)fluorene derivatives are prepared and their internal rotation about the C_9–C_{ar} bond is examined. Those which have a methyl, an ethyl, or an isopropyl group in 2′ position exist as a mixture of sp and ap forms, showing coalescence phenomena in the NMR spectra at high temperatures. The barriers to rotation of these compounds are obtained by the usual DNMR method. 9-(2-*t*-Butylphenyl)fluorene, in contrast, is found to exsist exclusively as an sp form and thus the barrier to rotation must be determined by measuring the rates of conversion from the unstable ap form which is successfully obtained by the protonation of the corresponding lithium fluorenide at low temperatures. The barriers to rotation of the compounds are alike except for the *t*-butyl compound. The difference is explained in terms of the conformation of the alkyl group in the ground and the transition state for rotation. The ^{13}C NMR data also exhibit a large steric interaction between the alkyl group and the fluorene ring.

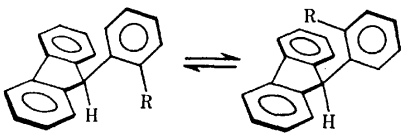
Barriers to rotation about C_9–C_{ar} bond are known to be extremely high in 9-arylfluorenes, especially when the aryl group is a 2,6-disubstituted phenyl.[4] For example, the barrier to rotation of 9-(2,6-dimethylphenyl)fluorene (**1**) was reported to be larger than 23 kcal/mol and, as expected from the barrier, we could isolate the two rotamers of structurally anologous 9-(2-bromomethyl-6-methylphenyl)fluorene (**2**). When one of the substi-



(**1**) (**2**)

tuents in 2 and 6 positions of the aryl group is replaced by hydrogen, the barrier to rotation decreases to a great extent and the rotamer is no longer isolable at room temperature. In such a case DNMR method may become a powerful tool for deciding the barriers to rotation. The barrier to rotation of 9-(*o*-tolyl)-fluorene was measured to be *ca.* 16 kcal/mol by this method.[5]

As for the equilibrium constant between rotamers, it depends mainly on the relative bulkiness of the substituents in 2 and 6 positions of the aryl, though in some cases electronic effect such as charge transfer stabilization controls the population.[1] Judging from the results on equilibrium constants, so far reported, in this series, a bulkier substituent is apt to take the position in proximity of 9-H. Thus, in the case of **2** the sp form is favored over the ap form as the bromomethyl is larger than the methyl group. If one of the substituents is exceedingly large, the populations of two rotamers must be one-sided. In such a case, information on the barrier to rotation cannot be obtained by the DNMR method. Signals due to the unfavorable ap forms of 9-(2-alkylphenyl)fluorene derivatives **4**, **5**, and **6** could be observed in the ^1H NMR spectra, whereas none of the signals attributable to the ap form could be detected when the substituent was *t*-butyl.[2] Thus compounds **4**, **5**, and **6** belong to a category which gives barriers to rotation by the DNMR method, whereas compound **7** needs a device



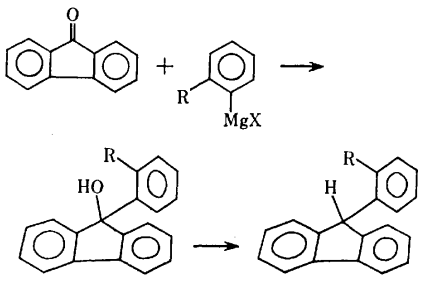
(**3**) R=H
(**4**) R=Me
(**5**) R=Et
(**6**) R=^{i}Pr
(**7**) R=^{t}Bu

for measuring the barrier. We could solve the latter problem by finding a method for preparing unstable isomer and by measuring the rates of isomerization.

In this paper we wish to describe the method for obtaining the barrier to rotation of 9-(2-*t*-butylphenyl)-fluorene (**7**) together with the substituent effects on the rotational barriers in the 9-(2-alkylphenyl)fluorene series. To identify the substituent, the positions are referred to by numbers with primes when they are carried in the 9-aryl group.

Experimental

Materials. The syntheses of 9-aryl-9-fluorenol were carried out by the Grignard reaction of fluorenone with the corresponding arylmagnesium halide followed by treatment with dilute hydrochloric acid. 9-Arylfluorenes were obtained by reducing the corresponding fluorenol with hydriodic acid. Details of the syntheses were described in a previous paper, taking **6** and **7** as examples.[6]



9-(2-Ethylphenyl)-2-fluorenol (***10***), mp 133—134 °C. Yield 75%. ^1H NMR ($CDCl_3$, δ): 0.43 (CH_3CH_2), 1.72 (CH_3-CH_2), 8.2 (6′-H). Found: C, 88.10; H, 6.36%. Calcd for $C_{21}H_{18}O$: C, 88.08; H, 6.34%.

9-(2-Ethylphenyl)fluorene (***4***), mp 65—66 °C. Yield 84%. ^1H NMR ($CDCl_3$, δ): 1.42 (sp-CH_3CH_2), 0.40 (ap-CH_3CH_2), 3.07 (sp-CH_3CH_2), 1.4 (ap-CH_3CH_2), 5.37 (sp-9-H), 4.95 (ap-9-H), 6.33 (sp-6′-H). Found: C, 93.45; H, 6.65%. Calcd for $C_{21}H_{18}$: C, 93.29; H, 6.71%.

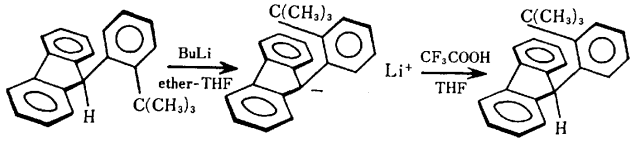
a) Data reported by Siddall *et al.*[5] for 9-(*m*-tolyl)fluorene.

Synthesis of ap Form of **7**. The synthesis of thermodynamically unstable ap form of **7** was carried out by the following procedure.

To an NMR sample tube containing *ca.* 20 mg of **7** was added *ca.* 0.2 ml of ether–THF solution of butyllithium which contained about 0.15 mmol of net butyllithium. The solution gradually changed red as lithium salt was produced. When the 9-H signal disappeared completely, the sample was cooled to *ca.* −50 °C and a small amount of pre-cooled trifluoroacetic acid in THF was added in small portions with stirring until the solution turned colorless. The ^{1}H NMR spectra of the colorless solution showed the presence of only ap form at this temperature.



sp ap

Kinetics. Although the ap form of **7** was stable at −50 °C, new signals assigned to the sp form appeared gradually when the temperature was raised up to *ca.* −10 °C. The rate of isomerization was followed by comparison of the signal height of 9-H's of two rotamers. The temperature was calibrated by the peak separation of methyl alcohol. Plots of log $(1-x/a)$ *vs.* time gave a straight line and the first order rate constants were obtained by the usual way. The rate constants were 3.9×10^{-4} s^{-1} (−1 °C), 1.2×10^{-4} s^{-1} (−9 °C), and 4.1×10^{-5} s^{-1} (−15 °C). Putting these rate constants into Eyring's equation, we could obtain the activation parameters for rotation.

As for compounds **4**, **5**, and **6**, barriers to rotation were obtained by the usual DMNR method since the signals of these compounds broadened and showed coalescence phenomena when the temperature was changed. Thus the rate constant at each temperature was obtained by the computer simulation of the observed curves. Free energies, enthalpies, and entropies of activation for rotation are given in Table 1 together with the equilibrium constants between rotamers.

NMR Measurement. ^{1}H NMR spectra were determined on a Hitachi R-20B spectrometer operating at 60 MHz. ^{13}C NMR spectra were measured on a JNM-FX 60 spectrometer operating at 15.04 MHz and ^{13}C-^{1}H coupling constants were obtained from all proton undecoupled spectra. The estimated error in reading the coupling constants was ±0.5 Hz. In every compound except **7** the chemical shifts and the coupling constants of 9-C's of two rotamers were easily obtained since these compounds existed as a mixture of sp and ap form at the equilibrium. The ^{13}C NMR parameters of the ap form of compound **7**, on the other hand, was difficult to obtain as it was prepared by the protonation of the corresponding fluorenide anion at low temperature in ether–THF solution: These solvents interfered the measurement of the 9-C signal. Thus the solvent had to be replaced by $CDCl_3$. The replacement of the solvent was easily attained, since the 9-lithio derivative crystallized when the solution was maintained at −5 °C for a day. The solvents were decanted and the red crystals of the lithium salt were dried under reduced pressure. A $CDCl_3$ solution containing a small amount of trifluoroacetic acid was added slowly at −50 °C to the crystals placed in a ^{13}C NMR sample tube. After the solution was stirred vigorously, the ^{13}C NMR spectra were measured at −40 °C to exhibit a clear 9-C signal. These data are listed in Table 2.

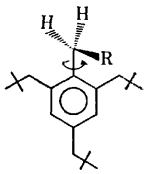
Results and Discussion

Barriers to Rotation. In Table 1, kinetic parameters for rotation of compounds **4**, **5**, and **6** at 0 °C are listed for both sp→ap and ap→sp processes. We limit our discussion here on free energies of activation, since values of entropies of activation obtained by the DNMR method are often controversial.

The free energy of activation for the process sp→ap of compound **7** was not possible to obtain, since no *t*-butyl signal of the ap form could be detected at the equilibrium state. Although the extremely concentrated solution of **7** was prepared in order to observe the *t*-butyl signal of the ap form, if any, in ^{1}H NMR spectrum, no signal could be detected at the expected position. Thus we concluded that the equilibrium constant at 0 °C is less than 1/100 which corresponds to the free energy difference of *ca.* 2.5 kcal/mol. Since the barrier to rotation was estimated at 20.3 kcal/mol for the ap→sp process, that for sp→ ap must be larger than 23 kcal/mol from the above discussion. The measurement of the ^{1}H NMR spectrum at high temperature may be another possible method for detecting the ap form, since, in general, the population of a less stable isomer increases as the temperature is raised. But neither broadening of the *t*-butyl signal due to exchange nor the change of its chemical shift was observed up to 180 °C, indicating that the sp form is more stable than the ap form at least by *ca.* 2.5 kcal/mol even at 180 °C.

To start, let us compare the barriers to rotation for the process from the sp to the ap form. Data in Table 1 indicate that a considerably large increase in energy is observed when a methyl group is introduced in 2′ position in place of a hydrogen (more than 7 kcal/mol) and when an isopropyl group is replaced by a *t*-butyl group (more than 5 kcal/mol). In contrast to these the

replacement of the methyl group by a bulkier ethyl or isopropyl group results in a small increase in activation energy. The substituent effect on the rotational barriers observed in this system is somewhat similar to that of neopentyl derivatives (**8**) reported by Dahlberg *et al.*;[7] barriers to rotation at the coalescence temperature are 10.6 (T_c=−56 °C), 10.7 (−53 °C), and 12.7 (−15 °C) kcal/mol for **8a**, **8b**, and **8c**, respectively, whereas it becomes as high as 17.6 kcal/mol (+82 °C) when R is a *t*-butyl.



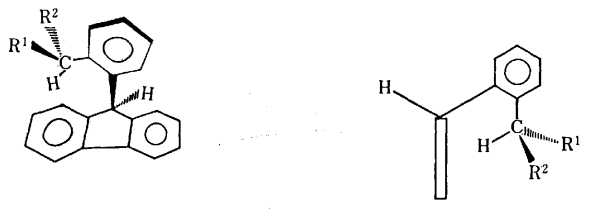
8 **a** R=Me
b R=Et
c R=^{i}Pr
d R=^{t}Bu

In principle, the barriers to rotation are relative values: even if the absolute value of a barrier is very high, the barrier may be low if the ground state is rich in energy. We must, therefore, discuss both the transition state and the ground state, if we compare the barriers.

The transition state for rotation may be considered as a conformation which gives rise to most repulsive interaction between the alkyl group in 2′-position and 1 (or 8)-position of the fluorene ring, whereas the ground state involves the interaction of the alkyl group with 9-H. The fact that substitution of 2′-hydrogen by a methyl group causes great enhancement of the barrier is interpreted as such that the destabilization of the ground state due to 2′-CH_3–9-H interaction is relatively small and that of the transition state due to 2′-CH_3–1(or 8)-H is large.

Ground state of compounds **4**, **5**, and **6** may not differ to a great extent, because they can take a conformation in which the smallest group comes to a most crowded site. This type of consideration is well documented in explaining the free energy difference of axial-equatorial alkylcyclohexanes. Likewise the destabilization of the transition state will be also comparable for compounds **4**, **5**, and **6** (Fig. 1a). Thus the similar free energies of activation for rotation is reasonable, if the substituent in 2′-position has at least a hydrogen in α-position of the alkyl group, although the entropy factor may be unfavorable for those which have smaller number of hydrogens.

The *t*-butyl compound has no hydrogen to lessen the repulsion by taking a conformation of the least strain. Thus both the ground state and the transition state are greatly destabilized relative to the lower homologs.



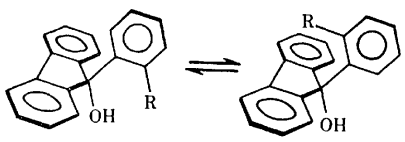
(a) Transition state (b) Ground state

Fig. 1. Possible conformations of the compound, the substituent of which has an α hydrogen.

Again the effect seems to be larger in the transition state than in the ground state. Thus the barrier is increased to a great extent, compared to that of the isopropyl compound.

The barriers to rotation of the ap→sp processes show a quite different aspect in a sense that only a 2 kcal/mol increase in energy is observed by the introduction of a *t*-butyl group instead of an isopropyl group. This clearly means that, in compound **7**, a remarkable amount of energy increase in the transition state for rotation is compensated by nearly the same degree of increase in energy in the ground state. The destabilization of the ap form of compound **7** can again be explained by taking the conformation of the alkyl group into account. In methyl, ethyl, and isopropyl derivatives the repulsive interaction between the substituent and the fluorene ring may not become so large if the α-hydrogen of the substituent faces the fluorene ring. Whereas in the *t*-butyl derivative severe repulsion inevitably occurs (Fig. 1b).

The large repulsion between the *t*-butyl group and the fluorene ring is more clearly demonstrated in 9-(2-alkylphenyl)-9-fluorenols **9**, **10**, **11**, and **12**. The ^{1}H NMR spectrum of compound **9** showed a characteristic feature of the ap form: a methyl signal appeared at a high field (δ 1.27) and 6′-H multiplet at a low field (δ 8.2). The ^{1}H NMR spectra of **10** and **11** showed the same trends as that of **9**, indicating that these compounds also existed as ap forms probably because of a large repulsion between the alkyl and the 9-hydroxyl groups compared with that between the alkyl group and the fluorene ring. The *t*-butyl derivative (**12**), on the other hand, was concluded to exist exclusively as the sp form, since the *t*-butyl signal appeared at a low field (δ 1.79) as a little broad singlet and signals due to 6′-H was observed at quite a high field (δ 6.4) also as a broad doublet. When the temperature was raised, the *t*-butyl



(**9**) R=Me
(**10**) R=Et
(**11**) R=^{i}Pr
(**12**) R=^{t}Bu

signal showed further broadening and at 50 °C its half band width amounted to 2.9 Hz. The signals of 6′-H changed more appreciably in the same temperature range: the doublet broadened with the increase in temperature and at 60 °C the fine structure of the signals almost disappeared. Both signals sharpened on further raising of the temperature. When the temperature was lowered, there appeared a trace of a signal at δ 0.7 which was assigned to the *t*-butyl group of the ap form because structurally analogous **11** gave isopropyl signals of the ap form at δ 0.5. While it was difficult to obtain an accurate equilibrium constant from the spectra, it was roughly estimated to be 1/80 at −30 °C from the integration of the two signals. These results again suggest the existence of considerably large repulsion between the *t*-butyl group and the fluorene ring.

^{13}C NMR Spectra. Above discussion implies that the deformation of molecular structure may exsist in

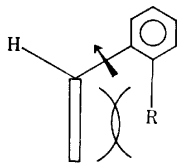

Fig. 2. Molecular deformation of the sp form.

the ap form of compound **7**, since it is less stable than the sp form by at least *ca.* 2.5 kcal/mol. Several deformations are expected for the relief of the strain which is originated by the repulsion between the bulky *t*-butyl and the fluorene ring. Of those, bending of the C_9–C_{ar} bond outwards from the fluorene ring will be of most importance (Fig. 2). If such a deformation really exists, it will affect the chemical shift and the coupling constant (^{13}C–^1H) of 9-C, making them quite different from those of other normal 9-arylfluorenes. In Table 2 ^{13}C and ^1H NMR spectral data of rotameric 9-arylfluorenes are listed. In each case, 9-C gave two distinct signals corresponding to the sp and ap form. As for the chemical shifts of the ap forms, they tend to increase as the size of the alkyl group increases: this tendency is in accordance with the above assumption of molecular deformation, because bending of the C_9–C_{ar} bond outwards from the fluorene ring is expected to change the hybridization of 9-C sp^2-like to cause the low field shift of the signal due to 9-C of the ap form. The degree of the low-field shift of the 9-C signals of the ap forms parallels somewhat with the increase in free energy difference between rotamers as the size of the alkyl group increases. In methyl, ethyl, and isopropyl derivatives the chemical shifts of 9-C lie within a small range of 0.4 ppm. Correspondingly free energy differences between rotamers are 0.3, 0.6, and 0.4 kcal/mol for the methyl, the ethyl, and the isopropyl compound. In the *t*-butyl derivative, however, the low field shift by about 3.3 ppm and the large free energy difference of more than 2.5 kcal/mol are observed. The correlation may be an indication that the population of 9-(2-alkylphenyl)fluorene is mainly regulated by the nonbonded interaction between the alkyl group and the fluorene ring. It may mean in turn that repulsion between the alkyl group and 9-H is relatively small.

Another method to check the presence of the molecular deformation, shown in Fig. 2, is the measurement of the ^{13}C–^1H coupling constant of 9-C. Inspection of Table 2 reveals that the coupling constants of the ap forms decrease as the size of the alkyl group increases. Since the magnitude of the ^{13}C–^1H coupling constant is correlated to s-character of the C-H bonding orbital, the decrease can be taken as an indication of the increase in p-character of the C–H bonding orbital.[8] This may most reasonably be caused by bending of the C_9–C_{ar} bond as shown in Fig. 2, though it may also be caused by widening any of the C–C–C angles at 9-C. As was seen in the chemical shifts of this series, the coupling constant of **7** showed a striking difference from those of other compounds. The value of 115.4 Hz may be one of the smallest C–H coupling constants ever reported for neutral molecules.[8]

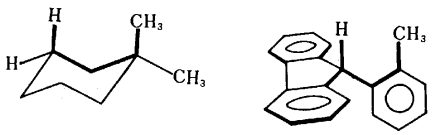

Fig. 3. The spacial arrangement of groups in 1,1-dimethylcyclohexane and **4**.

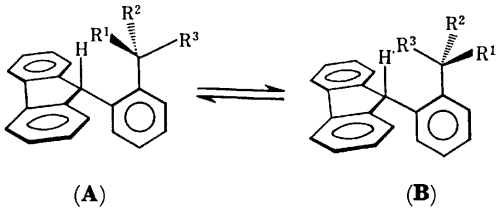

(**A**) (**B**)

Fig. 4. Conformation of the *o*-alkyl group in 9-arylfluorenes.

As for the chemical shifts of 9-C of the sp-forms, they showed rather a complicated tendency as the size of the substituents increases: a large high field shift (4.1 ppm) was observed when a methyl group was introduced in 2′ position, whereas the shift was affected to only a small extent (0.9 ppm or less) on change of the methyl group by an ethyl or an isopropyl group. In contrast, a low field shift of *ca.* 2 ppm was observed when the alkyl changed from isopropyl to *t*-butyl. A large high field shift observed in the methyl compound may be attributed to the well-known γ effect, because the spacial arrangement of the 2′-methyl and 9-C in **4** is quite similar to that of an axial-methyl and 3-C in 1,1-dimethylcyclohexane (Fig. 3).[9] In both compounds the high field shift caused by the introduction of a methyl group amounted to *ca.* 4 ppm.

The most difficult point to explain is why the chemical shift of 9-C of compound **7** showed a relatively large low field shift. We tentatively consider that the difference in the prefered conformation of the alkyl group plays some role in determining the chemical shift of the sp form. Two stable conformations are possible for the alkyl group in position 2′. One is a conformation where 9-H squeezes in R^1 and R^2 (Conformer **A**) and the other is the one where 3′-H is situated between R^1 and R^2 (Conformer **B**) as shown in Fig. 4. In each conformation R^3 opposes either 3′-H or 9-H. Thus the stability of two conformations must be decided by the relative bulkiness of R^1, R^2, and R^3. In compound **6** where R^1 and R^2 are methyl and R^3 is hydrogen, conformer **B** must be more stable than conformer **A**,

because two methyl groups are placed within a repulsive region of 9-H in the latter, whereas the repulsive force between two hydrogens in the conformation **B** will be less. There is another possibility in conformation **A**: that is, the conformation where R^1 and R^3 are methyls and R^2 is hydrogen. Contribution of this conformation will be minor because the opposing effect of R^3 (CH_3) with 3'-H is large. Likewise, conformation **B** where R^1 and R^3 are methyls and R^2 is a hydrogen may contribute to only a small extent becuase of the opposing effect between R^3 and 9-H. Similarly the stable conformation of **5** is expected to be the one where an α hydrogen of the substituent is in proximity of 9-H. In this sense ethyl and isopropyl groups give similar steric effects on carbon at position 9 and thus the chemical shift of 9-C is almost invariable for the methyl, the ethyl, and the isopropyl compounds. In the case of compound **7**, R^1, R^2, and R^3 are all methyl groups and therefore **A** must be more stable than **B**: in **B** the distance between the methyl (R^3) and 9-H is quite small and a large repulsion is expected.

Then the spacial relation between 9-C and methyl carbon of this compound is quite similar to that between the methyl and the hydroxyl group of 4a-methyl-*trans*-1-decalol (**13**) (Fig. 5).[10] In **13** a downfield shift of *ca.* 3.4 ppm was observed and was attributed to the syn-axial arrangement of two interacting groups separated by four bonds. Thus the observed downfield shift of *ca.* 2 ppm may become a support for the δ effect originally described by Stothers *et al.*

Studies of Heterocyclic Compouds. XII.[1] Structures of Acetylated Products of 5-Hydroxy-4-(2-hydroxyethyl)-3-methylpyrazole

Hisao Ochi, Tadashi Miyasaka, and Kiichi Arakawa

School of Pharmaceutical Sciences, Showa University, Hatanodai, Shinagawa-ku, Tokyo 142

(Received March 18, 1977)

Acetylation of 5-hydroxy-4-(2-hydroxyethyl)-3-methylpyrazole (**1**) produced five acetyl derivatives: 4-(2-acetoxyethyl)-5-hydroxy-3-methylpyrazole (**2**), 4-(2-acetoxyethyl)-2-acetyl-5-hydroxy-3-methylpyrazole (**3**), 4-(2-acetoxyethyl)-1-acetyl-5-hydroxy-3-methylpyrazole (**4**), 5-acetoxy-4-(2-acetoxyethyl)-2-acetyl-3-methylpyrazole (**5**), and 1-acetyl-5-hydroxy-4-(2-hydroxyethyl)-3-methylpyrazole (**6**). The partial hydrolysis of **3** and **5** in aq acetic acid gave the monoacetate (**2**). The triacetate (**5**) afforded **3** by heating in a mixture of pyridine and methanol. Migration of the acetyl group from the N_1-position to the C_5-O- and to the side chain-O-position is suggested. It is also suggested that the triacetate (**5**) may be effective for acetylation of amines.

In previous papers we have shown that five mono- and diacetyl derivatives could be prepared from 5-hydroxy-3-methylpyrazole by acetylation with acetic anhydride.[2,3] We have also shown that the acetyl derivatives were useful as mild acetylating reagents.[3]

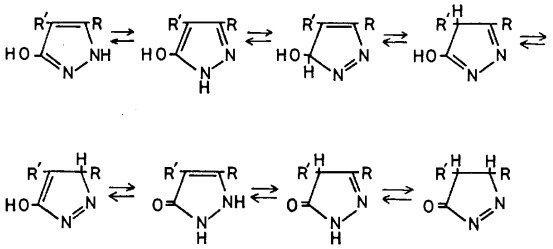
In order to improve the usefulness of this type of acetylating reagent we have prepared vinylpyrazole derivatives as a monomeric source of acetyl group-exchange resins.

In this paper we deal with the acetylation of 5-hydroxy-4-(2-hydroxyethyl)-3-methylpyrazole (**1**),[4] which is readily prepared from α-acetyl-γ-butyrolactone.[5]

The pyrazole (**1**) can be expected to give a very complicated mixture of mono-, di- and triacetyl derivatives, because, as Katritzky and Lagowski have predicted, **1** has eight possible tautomers[6] (Scheme 1), and the first attack of the acetylating reagent may occur either at N_1-, N_2-, C_5-O-, or the side chain-O-position. The structures of the reaction products were determined based on the IR, the NMR, and the UV spectra and the ferric chloride coloration test.[7]

By heating in refluxing acetic acid, **1** gave a monoacetate (**2**), whose UV spectrum was almost superimposable with that of the starting material. The IR spectrum (1750 cm^{-1}) and the NMR spectrum (1.98, 2.08 ppm) indicated that the acetyl group bonded to the oxygen atom on the side chain to furnish 4-(2-acetoxyethyl)-5-hydroxy-3-methylpyrazole.

When **1** was heated with two molar equivalents of acetic anhydride in pyridine under reflux, diacetate (**3**) was formed in good yield; this was identical in every respect with the specimen prepared by acetylation of **2** with an equimolar amount of acetic anhydride in pyridine. Hydrolysis of **3** in aq acetic acid afforded **2**. The diacetate (**3**) gave a reddish brown coloration with methanolic ferric chloride; there was one absorption maximum (257.5 nm) in the UV spectrum and a chemical shift of C_3–CH_3 at 2.50 (or 2.52) ppm.



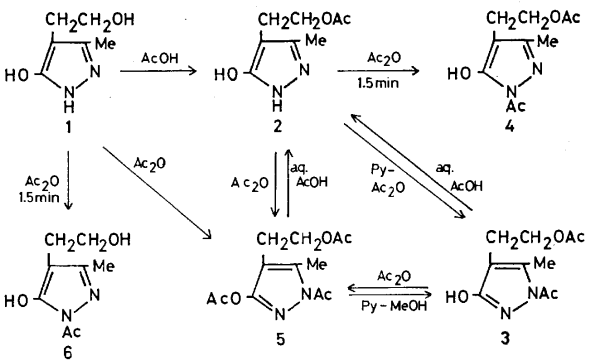
Scheme 1.

By heating **2** in acetic anhydride at 110 °C for 1.5 min the diacetate (**4**) separated; its UV spectrum displayed two absorption maxima (224 and 295.5 nm) and the NMR spectrum displayed the C_3–CH_3 peak at 2.21 ppm. According to the empirical rule that N_2-acetyl groups bring about low field shifts of a C_3–CH_3 signal,[2] the diacetate (**3**) which showed a C_3–CH_3 signal at the lower field of 2.50 (or 2.52) ppm has the N_2-acetyl group, which is 4-(2-acetoxyethyl)-2-acetyl-5-hydroxy-3-methylpyrazole, while the diacetate (**4**) is 4-(2-acetoxyethyl)-1-acetyl-5-hydroxy-3-methylpyrazole.

Heating a suspension of **1** in acetic anhydride under reflux for 4 h afforded triacetate (**5**), which did not show any coloration with ferric chloride. The IR spectrum showed a phenol ester band at 1785 cm^{-1}, and the NMR spectrum displayed a C_3–CH_3 signal at 2.53 ppm. Since the C_3–CH_3 signal shifted to the lower field of 2.53 ppm compared with that of the parent compound (**1**), the structure of **5** corresponds to 5-acetoxy-4-(2-acetoxyethyl)-2-acetyl-3-methylpyrazole.

Further acetylation of the diacetate (**3**) and monoacetate (**2**) with acetic anhydride produced the triacetate (**5**). The partial hydrolysis of **5** in aq acetic acid afforded the monoacetate (**2**) and milder hydrolysis of **5** in a mixture of methanol and pyridine afforded the diacetate (**3**). These results further supported the similarity of the structures of the triacetate (**5**), the diacetate (**3**), and the monoacetate (**2**).

Heating of **1** in acetic anhydride at 110 °C for 1.5 min gave monoacetate (**6**). In contrast to the other



Scheme 2.

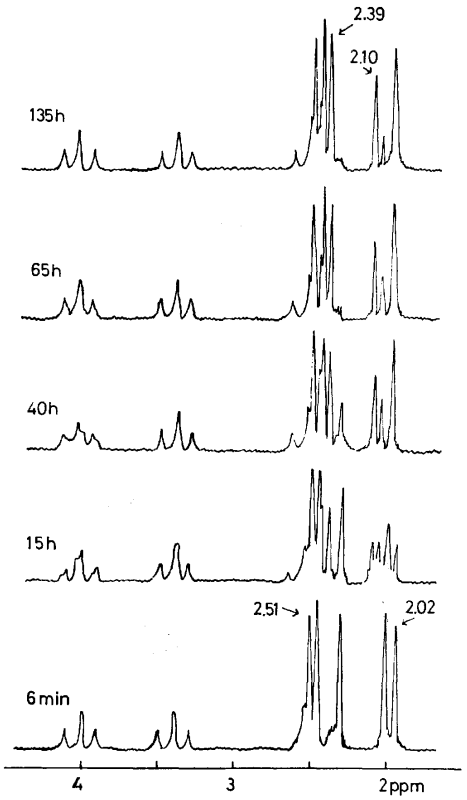


Fig. 1. NMR spectra of the time-course of the conversion of a mixture of **1** and **5** at 35 °C in DMSO-d_6 into a mixture of **3** and **6**.

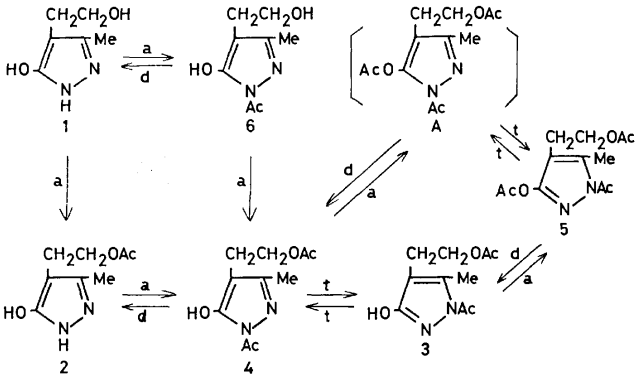
monoacetate (**2**), **6** gave bluish green coloration with ferric chloride and had two distinct absorption maxima (225.5, 296.5 nm) in the UV spectrum. The methyl signal of C_3-position (2.10 ppm) is not so much lowered in contrast to the parent compound (**1**) which has its methyl signal at 2.02 ppm; the carbonyl band shifted to the lower wave number of 1715 cm^{-1} as a result of hydrogen bonding with C_5–OH. So **6** has the N_1-acetyl group and its structure corresponds to 1-acetyl-5-hydroxy-4-(2-hydroxyethyl)-3-methylpyrazole.

Next we examined the mode of acetyl-transfer reaction during the formation of the acetyl derivatives.

Heating a solution of **5** and an equimolar amount of **1** in benzene under reflux for 28 h afforded a mixture of **1**, **2**, **3**, **5**, and **6**. Fig. 1 shows the time dependence of the NMR signals of the reaction mixture in DMSO-d_6. The chemical shifts of the methyl proton and ethylene proton signals of a mixture of **1** and **5** in DMSO-d_6 were changed at 35 °C and finally the NMR spectrum turned into that of a mixture of diacetate (**3**) and monoacetate (**6**) after 135 h. These results suggest that the acetyl group at the C_5-O-position of **5** migrates to the N_1- or N_2-position of the other pyrazole molecule.

A solution of monoacetate (**6**) in chlorobenzene was heated at 130 °C for 1 h; colorless crystals separated after cooling, and their IR and NMR spectra indicated that the product was monoacetate (**2**). On the other hand 5-hydroxy-4-(2-hydroxyethyl)-1,3-dimethylpyrazole (**7**) was heated with acetic acid under reflux to afford 4-(2-acetoxyethyl)-5-hydroxy-1,3-dimethylpyrazole (**8**). A mixture of an equivalent amount of **5** and **7** was converted by heating under reflux in benzene into four components; **2**, **3**, **4**, and **8**. This result suggests that the acetyl group at the C_5-O-position of the triacetate (**5**) was transferred to the alcoholic group at the side chain of **7** to form **3** and **8**. The fact that the two isomeric diacetates **3** and **4** were isolated from the reaction mixture suggests the existence of an equilibrium between **3** and **4**. Indeed, heating of **4** in chlorobenzene under reflux for 8 h afforded a mixture of **3** (53%) and **4** (47%). A mixture of **3** and **4** in almost the same ratio was also formed from **3**.



Scheme 3. a: acetylation t: acetyl transfer d: deacetylation

The reaction path of these conversions can be formulated as shown in Scheme 3. In the acetylation of **1**, the kinetically controlled product (**6**) was formed at the first stage. The acetyl group of 1-acetyl-5-hydroxypyrazole was formed, which easily migrates to a position like N_2- or C_5-O-.[3] By heating **6**, therefore, acetyl group at N_1-position migrated either intermolecularly or intramolecularly to the side chain-oxygen to form **2**. The formation of **2** was promptly followed by acetylation at N_1-position to give diacetate (**4**), which was rearranged by heating into the thermally more stable isomer (**3**), and the hydroxyl group at C_5-position of **3** was finally acetylated to form the stable triacetate (**5**). At this stage acetylation of **4** may promptly rearrange into **5** under the present reaction conditions.

The acetoxyl group of the compound **5** was considered to be effective as an acetylating reagent of amines, as shown in the case of 5-acetoxy-2-acetyl-3-methylpyrazole.[3,8] When **5** was treated with an equimolar amounr of aniline, acetanilide was separated in quantitative yield. Further investigation concerning the application of this reagent to other materials is proceeding in this laboratory and will be reported elswhere.

Experimental

All the melting points were measured in capillary tubes and were uncorrected. NMR spectra were measured on Hitachi R-20 60 MHz and Hitachi R-22 90 MHz spectrophotometers, using tetramethylsilane as an internal reference. IR and UV spectra were measured on a JASCO IRA-1 spectrophotometer and a Hitachi EPS-3 spectrophotometer, respectively. Column chromatography was carried out through silica gel (Merck, art. 7734, 70—230 mesh) using chloroform containing 5% methanol as the eluting solvent,

*4-(2-Acetoxyethyl)-5-hydroxy-3-methylpyrazole (**2**).* After 4-(2-hydroxyethyl)-5-hydroxy-3-methylpyrazole (**1**) (1.00 g) was heated in acetic acid (10 ml) under reflux for 1 h, the reaction mixture was evaporated to dryness *in vacuo*. The residual mass was recrystallized from methanol to give colorless plates (995 mg, 76.9% yield), mp 186—188 °C, which gave reddish brown coloration with methanolic ferric chloride. Found: C, 52.11; H, 6.38; N, 15.38%. Calcd for $C_8H_{12}O_3N_2$: C, 52.16; H, 6.57; N, 15.21%. IR (KBr): 1750 cm^{-1}. UV λ_{max}^{MeOH} nm (log ε): 227 (3.72), 239 (3.77). NMR δ ppm (DMSO-d_6): 1.98 (3H), 2.08 (3H), 3.99 (t, 2H, J= 7.5 Hz), 4.29 (t, 2H, J=7.5 Hz).

*4-(2-Acetoxyethyl)-2-acetyl-5-hydroxy-3-methylpyrazole (**3**).* A solution of **1** (284 mg) and acetic anhydride (420 mg) in pyridine (3 ml) was heated under reflux for 3 h. After pyridine was evaporated *in vacuo*, the residue was added onto ice-water. The colorless powder was collected by filtration, and recrystallized from ethyl acetate to give colorless needdles (396 mg, 88.6%), mp 113—114 °C. The material showed reddish brown coloration with methanolic ferric chloride. Found: C, 53.10; H, 6.30; N, 12.11%. Calcd for $C_{10}H_{14}O_4N_2$: C, 53.09: H, 6.24; N, 12.38%. IR (KBr): 1740, 1720, 1640 cm^{-1}. UV λ_{max}^{MeOH} nm (log ε): 257.5 (4.28). NMR δ ppm ($CDCl_3$): 2.02 (3H), 2.50 (3H), 2.52 (3H), 2.68 (t, 2H, J=7 Hz), 4.19 (t, 2H, J=7 Hz).

*4-(2-Acetoxyethyl)-1-acetyl-5-hydroxy-3-methylpyrazole (**4**).* A suspension of **2** (300 mg) in acetic anhydride (3 ml) was heated at 110 °C for 1.5 min with vigorous agitation. After cooling in an ice-salt bath crystals separated; these were collected by filtration and washed with cold ether to give a colorless powder (192 mg, 52%), mp 115—117 °C. The compound was too unstable to be purified by recrystallization from an ordinary organic solvent. The material showed bluish green coloration wtih methanolic ferric chloride. IR (KBr): 1740, 1720, 1650 cm^{-1}. UV λ_{max}^{MeOH} nm (log ε): 224 (4.00), 295.5 (3.75). NMR δ ppm ($CDCl_3$) 2.03 (3H), 2.21 (3H), 2.60 (t, 2H, J=7 Hz), 2.62 (3H), 4.18 (t, 2H, J=7 Hz).

*5-Acetoxy-4-(2-acetoxyethyl)-2-acetyl-3-methylpyrazole (**5**).* After **1** (1.00 g) was heated in acetic anhydride (20 ml) under reflux for 4 h, the acetic anhydride was evaporated *in vacuo*. The residual oil was distilled under reduced pressure to give a colorless oil (1.55 g, 81.6%), bp 178 °C (6 mmHg). The material did not show any coloration with ferric chloride. Found: C, 53.62; H, 6.04; N, 10.35%. Calcd for $C_{12}H_{16}O_5N_2$: C, 53.72; H, 6.01; N, 10.44%. IR ($CHCl_3$): 1785, 1750, 1730 cm^{-1}. UV λ_{max}^{MeOH} nm (log ε): 247 (4.06). NMR δ ppm ($CDCl_3$): 2.02 (3H), 2.33 (3H), 2.53 (3H), 2.59 (m, 5H), 4.09 (t, 2H, J=7.5 Hz).

*1-Acetyl-5-hydroxy-4-(2-hydroxyethyl)-3-methylpyrazole (**6**).* A mixture of **1** (300 mg) and acetic anhydride (3 ml) was heated at 110 °C for 1.5 min with vigorous agitation. After cooling in an ice-salt bath crystals separated; these were collected by filtration and washed with cold ether to give a colorless powder (132 mg, 33.8%), mp 115—118 °C. The compound was too unstable to be purified by recrystallization from an ordinary organic solvent. The material showed bluish green coloration with methanolic ferric chloride. IR (KBr): 1715, 1675 cm^{-1}. UV λ_{max}^{MeOH} nm (log ε): 225.5 (4.31), 296.5 (3.76). NMR δ ppm (DMSO-d_6): 2.10 (3H), 2.28 (t, 2H, J=7 Hz), 2.50 (3H), 3.43 (t, 2H, J=7 Hz).

*4-(2-Acetoxyethyl)-5-hydroxy-1,3-dimethylpyrazole (**8**).* 5-Hydroxy-4-(2-hydroxyethyl)-1,3-dimethylpyrazole (**7**) (1.00 g) was heated in acetic acid (30 ml) under reflex for 5 h. After the acetic acid was evaporated, the residue was separated by column chromatography to give colorless crystals (1.71 g) and the starting material (**7**) (78 mg). The former was recrystallized from benzene to give colorless needles (900 mg, 72%), mp 64—65 °C. Found: C, 54.43; H, 7.22; N, 14.32%. Calcd for $C_9H_{14}O_3N_2$: C, 54.53; H, 7.12; N, 14.13%. IR (KBr): 1755, 1750 cm^{-1}. UV λ_{max}^{MeOH} nm (log ε): 221 (3.72). NMR δ ppm ($CDCl_3$): 2.00 (3H), 2.12 (3H), 2.58 (t, 2H, J=7.5 Hz) 3.39 (3H), 4.10 (t, 2H, J=7.5 Hz).

*Partial Hydrolysis of the Triacetate (**5**) in 60% Aq Acetic Acid.* After **5** (500 mg) was heated in 60% aq acetic acid (10 ml) under reflux for 3 h, the solvent was evaporated under reduced pressure to give a colorless powder (270 mg, 78.7%), mp 186—188 °C. The mixed melting point and the IR spectrum showed that the material was identical with the monoacetate (**2**).

*Partial Hydrolysis of the Diacetate (**3**) in 60% Aq Acetic Acid.* The diacetate (**3**) (100 mg) was treated as described above to give colorless powder (79 mg, 96%). The IR and the NMR spectra were completely identical with those of the monoacetate (**2**).

*Partial Deacetylation of the Triacetate (**5**) with Methanolic Pyridine.* A solution of **5** (200 mg) and pyridine (0.3 ml) in methanol (3 ml) was heated under reflux for 1 h. After evaporation of the solvent *in vacuo* the residue was washed with cold ether to afford colorless crystals (155 mg, 92%), mp 112—114 °C. The IR and the NMR spectra were completely identical with those of the diacetate (**3**).

*Treatment of the Monoacetate (**2**) with an Equimolar Amount of Acetic Anhydride in Pyridine.* A mixture of **2** (368 mg), pyridine (3 ml), and acetic anhydride (210 mg) was heated at 100 °C for 1.5 h. After the pyridine was evaporated *in vacuo*, the reaction mixture was poured onto ice-water. The separated crystals (298 mg, 65.8%) were collected by filtration. The filtrate was extracted with chloroform. The organic layer was dried over magnesium sulfate and the solvent was removed to give colorless crystals (130 mg, 28.7%). The IR and the NMR spectra of each sample indicated that both of them were identical with the authentic specimen of the diacetate (**3**).

*Treatment of the Monoacetate (**2**) with Excess Acetic Anhydride.* After **2** (300 mg) was heated in acetic anhydride (6 ml) under reflux for 2 h, the acetic anhydride was evaporated *in vacuo*. The residual oil was distilled *in vacuo* to give a colorless oil (353 mg), 84.8%), bp 176—178 °C (6 mmHg). The IR and the NMR spectra were completely identical with those of the triacetate (**5**).

*Treatment of the Diacetate (**3**) with Excess Acetic Anhydride.* Diacetate (**3**) (300 mg) was treated as described above to give the triacetate (**5**) (293 mg, 82.4%), bp 176—178 °C (6 mmHg), after distillation.

*Treatment of the Pyrazole (**1**) with the Triacetate (**5**) at 80 °C in Benzene.* Into a solution of **5** (140 mg) in benzene (20 ml) was added finely powdered **1** (70 mg), after being heated under reflux for 28 h, the benzene was evaporated *in vacuo*. The residue was separated by column chromatography to give **5** (32 mg), **3** (90 mg), **6** (5 mg) **2** (958 mg), and **1** (16 mg). These materials were identical with the authentic samples by comparing the IR spectra.

*Treatment of the Pyrazole (**1**) with the Triacetate (**5**) at 35 °C in DMSO-*d_6. A sample tube for the NMR measurement which contained **5** (27 mg), **1** (14 mg), and DMSO-d_6 (0.3 ml) was sealed under a nitrogen stream. The sample tube was warmed to 35 °C and the NMR spectra were measured (TMS as an internal reference). The results are shown in Fig. 1.

*Thermal Treatment of the Monoacetate (**6**) in Chlorobenzene.* After a solution of **6** (100 mg) in chlorobenzene (8 ml) was heated under reflux for 4 h, it was cooled in an ice-salt bath.

The separated crystals were collected by filtration to give colorless leaflets (85 mg, 85%), mp 185—188 °C. The IR spectrum showed that it was identical with the monoacetate (**2**).

*Treatment of the Pyrazole (**7**) with the Triacetate (**5**) at 80 °C in Benzene.* A mixture of **7** (156 mg) and **5** (270 mg) in bezene (5 ml) was heated under reflux for 5 h. After the benzene was evaporated *in vacuo*, the residual solid was separated by column chromatography to give **4** (23 mg), **3** (157 mg), **8** (190 mg), and **2** (30 mg). These materials were found to be identical with the authentic samples by comparing the IR and the NMR spectra.

*Thermal Treatment of the Diacetate (**4**) in Chlorobenzene.* After **4** (100 mg) was heated in chlorobenzene (5 ml) under reflux for 8 h, the solvent was evaporated *in vacuo* to give a colorless powder (98 mg, 98%). The NMR spectrum indicated that the substance was a mixture of **3** and **4** (17 : 15).

*Thermal Treatment of the Diacetate (**3**) in Chlorobenzene.* The diacetate (**3**) (100 mg) was treated in the same manner as described in the case of the diacetate (**4**). After 8 hours' heating the NMR spectrum became identical with that of the compound **4**.

*Acetylation of Aniline with the Triacetate (**5**).* The triacetate (**5**) (270 mg) was added into a solution of aniline (93 mg) in benzene (7 ml) and the mixture was heated under reflux for 2 h. After the solvent was evaporated, the residue was separated by column chromatography to give diacetate (**3**) (215 mg) and acetanilide (131 mg, 97%), which was recrystallized from water to give colorless plates, mp 112—114 °C. The material was proved to be identical with the authentic sample of acetanilide by comparing the IR spectra.

The authers are grateful to the member of the Central Analysis Division of this school for the elemental analyses and the measurement of NMR spectra.

Light-induced Conformational Changes of Polypeptides. Random Copolymers of γ-Benzyl-L-glutamate with *m*- and *p*-Phenylazobenzyl-L-aspartates

Akihiko UENO, Jun-ichi ANZAI, Tetsuo OSA, and Yoshinori KADOMA*

Pharmaceutical Institute, Tohoku University, Aobayama, Sendai 980

(Received March 22, 1977)

Copolymers of γ-benzyl-L-glutamate with *m*- and *p*-phenylazobenzyl-L-aspartates were prepared for investigating the effect of side-chain photoisomerization on their conformations. A study was made of the circular dichroism associated with the n,π* transition of the amide group, as well as the extrinsic bands associated with the azo chromophore. The intensity of the 222-nm amide band seems unaffected by the interaction with the side-chain chromophore. The circular dichroism spectra before irradiation indicate that poly[β-(*m*-phenylazobenzyl)-L-aspartate] (mPALA) adopts a left-handed α-helical form and the other copolymers a right-handed form in 1,2-dichloroethane. After irradiation, remarkable changes of the 222-nm band were observed for the meta copolymer with 89.3% azo residues and mPALA. The increased absolute ellipticity for the former indicates that photoisomerization enhances the helicity of the polymer. Decrease in ellipticity for the latter indicates that photoisomerization induces significant instability of the left-handed α-helical conformation. In the course of subsequent relaxation of mPALA, an abrupt change in the CD spectra was found above 50% of cis followed by a gradual change with decreasing cis%.

The conformation of ester derivatives of poly(L-aspartic acid) has been shown to depend on the nature of the side chain. Left- and right-handed α-helical conformations are usually identified by the circular dichroism (CD), IR or NMR spectra. Poly(β-benzyl-L-aspartate) (PBLA) was shown to adopt a left-handed α-helical conformation,[1,2] but the para substitution of the benzene ring with a methyl, chloro, cyano, or nitro group induces a reversal of the helical sense to a right-handed α-helical conformation.[3–11] The chloro substituted PBLAs assume different handed helices depending on the position of the chlorine atom attached to the benzene ring.[12] These observations indicate that the balance of forces is so delicate that a small change in the side-chain conformation could reverse the helix sense. This prompted us to realize conformational changes of polyaspartates by inducing a configurational change of their side chains. From this view point we prepared some copolymer series containing azobenzene groups in their side chains. We report here the results of copolymers of γ-benzyl-L-glutamate with *m*- and *p*-phenylazobenzyl-L-aspartate. The side-chain azo chromophore undergoes trans-to-cis photoisomerization and subsequent relaxation back to the original trans form. The energy balance of the polymers might be perturbed by the configurational change, and the conformational changes as exemplified below might be possible.

$$\text{left-handed helix} \underset{\Delta}{\overset{h\nu}{\rightleftharpoons}} \text{right-handed helix} \quad (1)$$

$$\text{left-handed helix} \underset{\Delta}{\overset{h\nu}{\rightleftharpoons}} \text{random coil} \quad (2)$$

$$\text{random coil} \underset{\Delta}{\overset{h\nu}{\rightleftharpoons}} \text{right-handed helix} \quad (3)$$

Process 1 has been confirmed to occur for a copolymer of β-benzyl-L-aspartate and β-(*p*-phenylazobenzyl)-L-aspartate (41 : 59).[13] In this report, Processes 2 and 3 are discussed. Photoisomerization of polypeptide side chains itself has been reported for the copolymers of L-*p*-(phenylazo)phenylalanine[14] and also for poly(γ-cinnamyl-L-glutamate).[15] However, no conformational change could be induced by irradiation probably due to their conformational stability.

Experimental

Materials. The solvents used for recrystallization of *N*-carboxy anhydries (NCA) and for polymerization were purified shortly before use, dioxane and hexane by distillation over sodium, ethyl acetate by distillation over CaH_2, and triethylamine by drying and distillation over KOH. For the measurements of optical properties in solution, "Dotite Spectrosol" grade 1,2-dichloroethane was used without further purification.

p-*Aminobenzyl Alcohol (**1**).* A mixture of *p*-nitrobenzyl alcohol (30 g), dry methanol (50 ml) and palladium carbon (5 weight%) (1.5 g) was agitated in an autoclave under an atmosphere of hydrogen (initial pressure was 100 kg/cm²). After the catalyst had been removed by suction filtration, the filtrate was evaporated to dryness under reduced pressure. The crude product was recrystallized from ethanol. Yield, 18.5 g (77%); mp 58—60 °C (lit,[16] 63—64 °C). Found: C, 67.71; H, 7.22; N, 11.30%. Calcd for C_7H_9NO: C, 68.27; H, 7.37; N, 11.37%.

m-*Aminobenzyl Alcohol (**2**).* *m*-Nitrobenzyl alcohol (30 g) was reduced, as described above, to *m*-aminobenzyl alcohol. Yield, 15.9 g (66%); mp 91—93 °C (lit,[17] 95—96 °C). Found: C, 68.29; H, 7.47; N, 11.15%. Calcd for C_7H_9NO: C, 68.27; H, 7.37; N, 11.37%.

p-*Phenylazobenzyl Alcohol (**3**).* A mixture of alcohol **1** (12 g) and ethanol (40 ml) was added with stirring to a mixture of nitrosobenzene (12 g), ethanol (120 ml) and glacial acetic acid (12 ml). After the mixture had been stirred for 2 h, the product was crystallized upon cooling. The crude solid was recrystallized from ethanol. Yield, 9.9 g (48%); mp 142—143.5 °C (lit,[18] 142.5—143 °C). Found: C, 72.78; H, 5.72; N, 13.16%. Calcd for $C_{13}H_{12}N_2O$: C, 73.56; H, 5.70; N, 13.20%.

m-*Phenylazobenzyl Alcohol (**4**).* This alcohol was prepared from **2** (12 g) and nitrosobenzene (12 g) in the same way as for **3**. The crude product was purified by distillation (177 °C/3 mmHg). Yield, 18.8 g (91%); mp 36 °C (lit,[19] 34.5—36 °C). Found: C, 73.50; H, 5.68; N, 13.10 %. Calcd for $C_{13}H_{12}N_2O$: C, 73.56; H, 5.70; N, 13.20%.

p-*Phenylazobenzyl-L-aspartate (**5**).* A mixture of L-

Table 1. Yields, viscosities, and cis percentage in the photostationary state

m	50	45.9	46	44	0.37	75
m	70	78.0	5	4	—	68
m	90	89.3	64	53	0.28	62
m	100	100	218	75	0.23	68

a) p: para-copolymer. m; meta-copolymer. b) Mol% of *m*- or *p*-phenylazobenzyl-L-aspartate NCA reacted with γ-benzyl-L-glutamate NCA. c) Determined from the nitrogen content of elemental analysis. d) 0.1% 1,2-dichloroethane solution.

aspartic acid (5.8 g), alcohol **3** (10 g), *p*-toluenesulfonic acid (9.2 g), and dioxane (60 ml) was heated with stirring at 80 °C for 24 h. The reaction mixture was evaporated to dryness, and the residue was neutralized with a sodium hydrogencarbonate solution. The precipitated crystalline product was filtered, and washed with acetone. This was recrystallized from a mixed solution of dioxane and water (1 : 1 by volume). Yield, 1.3 g (8.4%); mp 229—229.5 °C; $[\alpha]_D = +0.63$ ($c=3.1$, dichloroacetic acid). IR: 1735, 1585 cm^{-1}. Found: C, 62.26; H, 5.38; N, 12.33%. Calcd for $C_{17}H_{17}N_3O_4$: C, 62.38; H, 5.23; N, 12.84%.

m-*Phenylazobenzyl*-L-*aspartate* (**6**). Ester **6** was prepared from alcohol **4** (10 g) and L-aspartic acid (5.8 g) in the same way as for **5**. Yield, 0.86 g (5.8%); mp 218—218.5 °C; $[\alpha]_D = +0.93°$ ($c=1.5$, acetic acid). IR: 1720, 1585 cm^{-1}. Found: C, 62.41; H, 5.45; N, 12.38%. Calcd for $C_{18}H_{15}N_3O_5$: C, 62.38; H, 5.23; N, 12.84%.

p-*Phenylazobenzyl*-L-*aspartate NCA* (**7**). This NCA was prepared from amino acid **5** (2.5 g) and phosgene using the reported procedure.[20] Yield, 1.3 g (48%); mp 240—240.5 °C. IR: 1860, 1788, 1725 cm^{-1}. Found: C, 61.41; H, 4.42; N, 12.02%. Calcd for $C_{18}H_{15}N_3O_5$: C, 61.19; H, 4.28; N, 11.89%.

m-*Phenylazobenzyl*-L-*aspartate NCA* (**8**). This NCA was prepared from amino acid **6** (2 g) and phosgene using the reported procedure.[20] Yield, 1.2 g (56%), mp 133.5—134.5 °C. IR: 1850, 1800, 1735 cm^{-1}. Found: C, 61.27; H, 4.27; N, 11.86%. Calcd for $C_{18}H_{15}N_3O_5$: C, 61.19; H, 4.28; N, 11.89%.

Poly[β-(p-*phenylazobenzyl*)-L-*aspartate*] (*pPALA*). NCA **7** was dissolved in dioxane (0.1 M), and a 0.004-M solution of triethylamine in dioxane (monomer/initiator=40) was added. Polymerizatiom was carried out at room temperature for 5 days. The reaction mixture was added to vigorously stirred ethanol. The precipitate was collected on a filter, washed with several portions of ethanol and dried *in vacuo* at 40 °C. Found: C, 65.79; H, 4.83; N, 13.03%. Calcd for $(C_{17}H_{15}N_3O_3)_n$: C, 66.01; H, 4.89; N, 13.58%.

Poly[β-(m-*phenylazobenzyl*)-L-*aspartate*] (*mPALA*). mPALA was prepared from NCA **8** in the same way as for pPALA. Found: C, 66.24; H, 4.91; N, 13.73%. Calcd for $(C_{17}H_{15}N_3O_3)_n$: C, 66.01; H, 4.89; 13.58%.

Polymers. Copolymers were prepared in an analogous way to that for homopolymers by using varing ratios of γ-benzyl-L-glutamate NCA and *m*- or *p*-phenylazobenzyl-L-aspartate NCA. Mole percentage of azo residue in the copolymers was estimated from their nitrogen contents obtained by elemental analyses. The reduced specific viscosity, η_{sp}/c, of each polymer was measured for a 0.1% 1,2-dichloroethane solution at 25 °C. Viscosity measurement could not be carried out for pPALA because of its insoluble character, or for the copolymers containing 74.0% *p*-phenylazobenzyl residue and 78.0% *m*-phenylazobenzyl residue because of low yields of the samples. Data on the homopolymers and copolymers are summerized in Table 1.

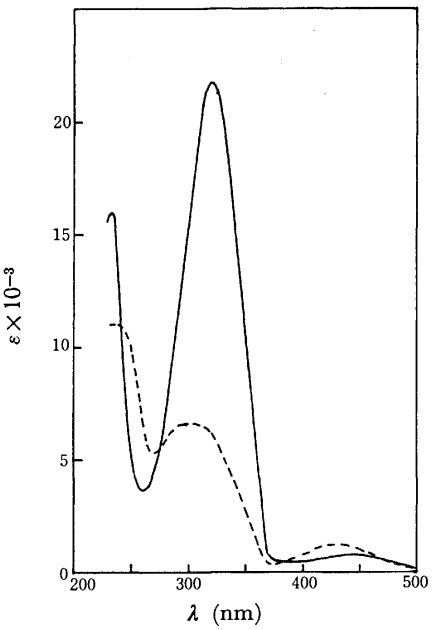

Fig. 1. Ultraviolet spectra of mPALA before (——) and after (---) irradiation.

Photoisomerization. Photoirradiation was carried out on solutions with concentration of 1-mg/ml using a Corning 7—37 filter which permits the light of 310—380 nm to pass. The cis percentage was calculated from the absorbance at 320 nm assuming that the absorbance is substantially proportional to the concentration of the trans isomer in view of the low extinction of the cis isomer at the wavelength.[21]

Measurements. CD spectra were recorded on a JASCO J-20 circular dichrograph apparatus with cell thickness of 0.1 and 0.01 cm. Due to the absorption of the solvent no spectra could be obtained below 210 nm. Molar ellipticities were calculated for the supposedly intrinsic band around 222 nm using the molar concentration of amide groups, while the molar concentration of the azo groups was used for the calculation of the ellipticities associated with the extrinsic bands. Ultraviolet (UV) spectra were measured with a JASCO UVIDEC-1 spectrophotometer.

Results and Discussion

Photoisomerization. The UV spectra of mPALA before and after irradiation are shown in Fig. 1. The major electronic transitions of this polymer are essentially those of azobenzene.[22] The band for mPALA before irradiation in the 320 nm region ($\varepsilon=22000$) is attributed to π,π^* transition and the band in the 430 nm region ($\varepsilon=700$) to n,π^* transition.[23] The spectrum after irradiation resembles the spectrum of *cis*-azobenzene reported by Gerson and co-workers.[22] The spectra

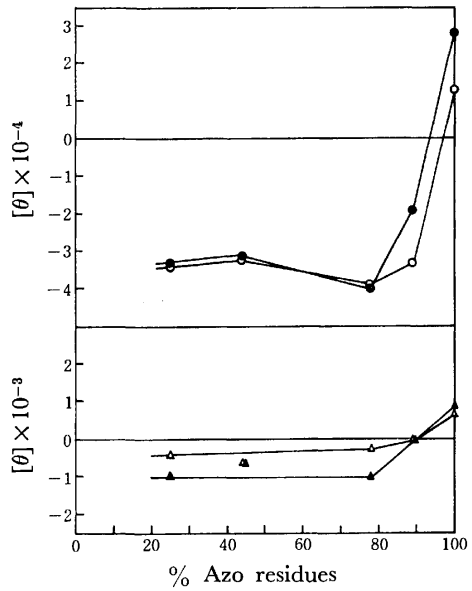

Fig. 2. Variation of the maximum or minimum ellipticities associated with the side-chain n,π^* (▲,△) and the amide n,π^* (●,○) transitions before (▲,●) and after (△,○) irradiation for the meta-copolymers as a functions of the azo content.

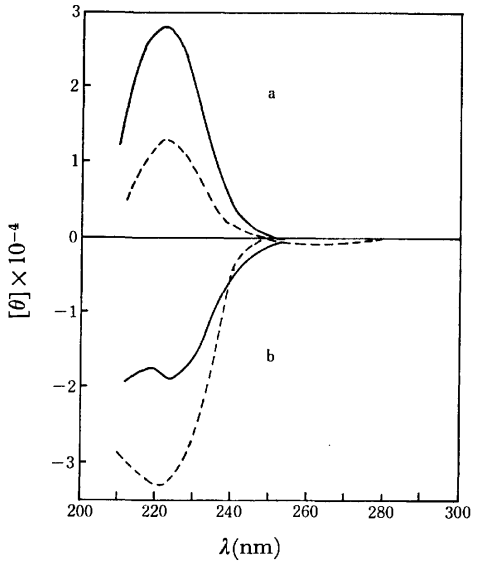

Fig. 3. CD spectra of mPALA (a) and the meta-copolymer with the azo content of 89.3% (b) before (——) and after (---) irradiation.

of the other polymers before and after irradiation are similar to those of mPALA in the regions of the azo π,π^* and n,π^* transitions.

The cis percentages of all the polymers at the photostationary state are given in Table 1. The values of the para copolymer series are almost the same and close to 70%. On the other hand, a considerable decrease in cis percentage is observed for the meta copolymer series on proceeding from the copolymer with the least azo residue to the copolymer which contains 89.3% azo residue. The decreased cis conversion for the meta-copolymers may result from steric restrictions between the side-chain meta-azobenzene groups.

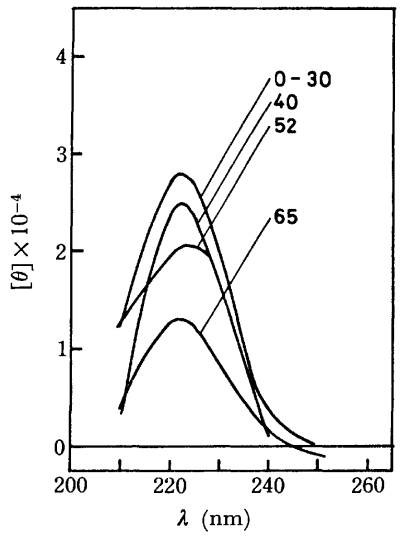

Fig. 4. CD spectra of mPALA at different cis per cents in the course of relaxation.

The cis percentage of mPALA seems slightly higher as a polymer with side-chains of maximal steric restrictions. This might be due to the conformational difference.

CD Spectra of meta-Copolymers. The maximum or minimum ellipticities associated with the amide n,π^* transition at 222 nm before and after irradiation are plotted against the mole percentage of azo residue (Fig. 2). The values are almost independent of the copolymer composition for the copolymers with less than 80% azo residue. These observations suggest that the overlapping of allowed transitions of the side-chain chromophore with those from the peptide main chain is either small or absent in the polymers. This is in contrast to that for other azoaromatic copolypeptides which contain *p*-(*p*-hydroxyphenylazo)phenylalanine residue.[24] For these polymers, decreasing intensity of the peptide main-chain band was observed with increase in mole percentage of the azo residue. If one takes $[\theta]_{222}=-40000\pm10\%$ for 100% right-handed α-helix,[25] the meta-copolymers are all confirmed to exist as right-handed α-helices. On the other hand, the CD spectrum of mPALA before irradiation shows a maximum with the value of $[\theta]_{222}=28000$ (Fig. 3), confirming the conclusion together with the results of its IR spectrum that the helix of mPALA is left-handed in 1,2-dichloroethane. The ellipticities at 222 nm seem unaffected by irradiation for the copolymers with less than 80% azo residue. However, irradiation causes significant changes in the ellipticity values of the copolymers with more azo residue. The absolute ellipticity of 89.3% azo copolymer increases from 19000 to 33000 by irradiation, confirming the increased percentage of helicity. This enhanced helix content might be due to the release of steric restrictions between the trans side chains by the formation of cis isomers. The ellipticity of mPALA decreases from 28000 to 13000 by irradiation, confirming the induced instability for its left-handed α-helical conformation. This observation could be due to the partial transition from the left-handed α-helix to a random coil or a right-handed

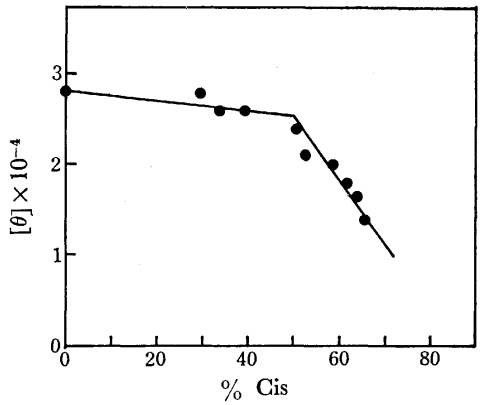

Fig. 5. Variation of the maximum ellipticities around 222 nm for mPALA as a function of the cis per cent.

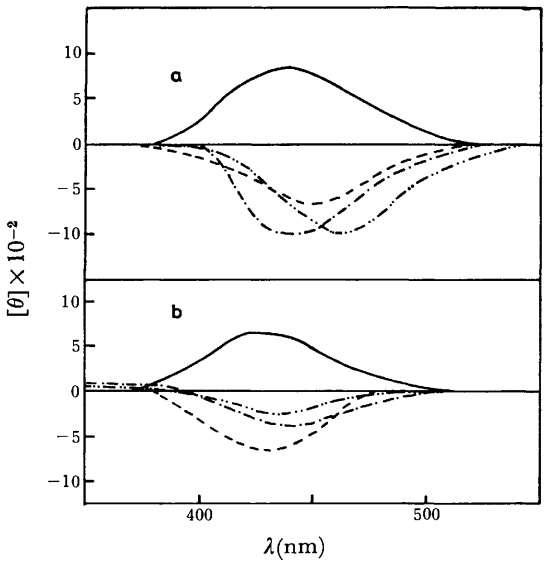

Fig. 6. CD spectra associated with the side-chain n,π^* transition before (a) and after (b) irradiation for the meta-copolymers. Azo%: 100(——); 78.0(—·—); 45.9 (---); 26.2 (—·—).

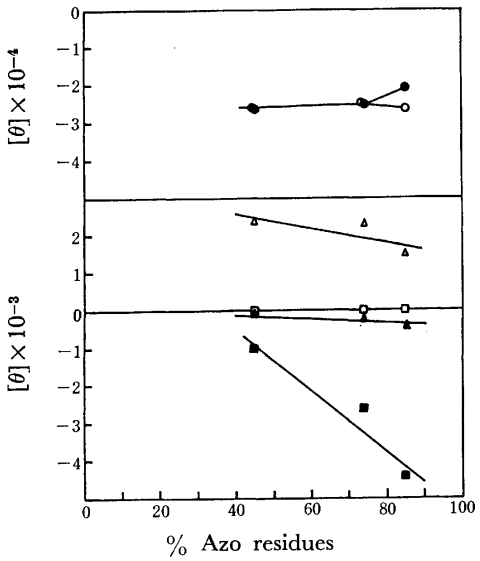

Fig. 7. Variation of the maximum or minimum ellipticities associated with the side-chain n,π^* (▲,△), π,π^* (■,□) and the amide n,π^* (●,○) transitions before (▲,■,●) and after (△,□,○) irradiation for the para-copolymers as a function of the azo content.

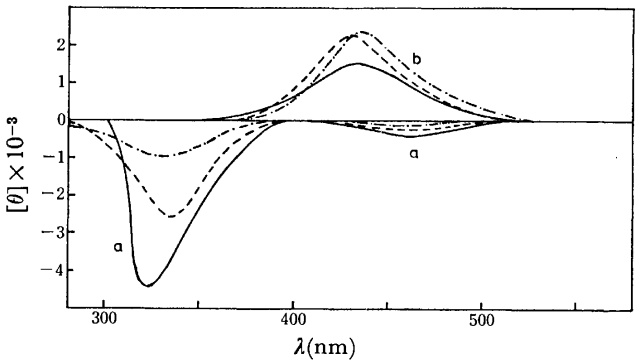

Fig. 8. CD spectra associated with the side-chain n,π^* and π,π^* transitions before (a) and after (b) irradiation for the para-copolymers. Azo%: 85.9 (——); 74.0 (---); 46.5 (—·—).

α-helix. We reported that the copolymer of *p*-phenylazobenzyl-L-aspartate and β-benzyl-L-aspartate (59 : 41) undergoes a light-induced conformational change from left- to right-handed helix.[13] The CD band associated with the peptide n,π^* transition of this copolymer changes its sign from positive to negative by irradiation, giving clear evidence for inversion of its helix sense. In the case of mPALA, however, it is difficult only by the CD spectrum to determine which of the conformational transformations is responsible for the observation. NMR spectra could, in principle, give some information.

Subsequent relaxation of mPALA back to the original conformation was followed by its CD spectra (Fig. 4). Maximum ellipticities at 222 nm are plotted as a function of cis percentage (Fig. 5). It shows an abrupt change of $[\theta]_{222}$ at over 50% followed by a gradual change with decrease. The result demonstrates that the energy required for the conformational change comes from cis forms in the side chain, *viz.*, ultimately from light energy.

The CD spectra associated with the n,π^* transition of the side-chain chromophore before and after irradiation are given in Fig. 6, maximum or minimum ellipticities being plotted against mole percentage of azo residue (Fig. 2). The copolymers show no dichroic band in the region of the π,π^* transition of the side-chain chromophore. One important aspect is the relation between the sign of the side-chain CD band and the backbone helix sense. There is a possibility that the sign of a side-chain band is opposite corresponding to the left- and right-handed helices.[20] The CD spectra of the meta copolymer series provide one example of the corresponding behavior since mPALA shows a positive band while the right-handed copolymers show negative bands. Usually the origin of induced dichroic bands are discussed in the terms of side chain-side chain and side chain-main chain interactions. In the case of the former interactions, the induced circular dichroism is expected to be dependent on the concentration of the side-chain chromophores in the copoly-

mers. No such dependency was observed for the polymers we studied. The ellipticities of the side-chain CD bands before and after irradiation are almost independent of mole percentage of azo residue in the copolymers unless conformational changes are induced. Thus the side-chain n,π^* CD band should be attributed to the coupling between the backbone and the side chain.

CD Spectra of para-Copolymers. The minimum ellipticities associated with the amide n,π^* transition are plotted against mole percentage of azo residue in Fig. 7. The CD spectrum of pPALA could not be measured since it is insoluble in 1,2-dichloroethane. The spectra of the copolymers show that they assume a right-handed α-helical conformation. Photoirradiation did not change the minimum ellipticities of the copolymers in the region of the amide n,π^* transition except for the azo 85.9% copolymer. This copolymer shows increase in absolute ellipticity after irradiation, which indicates an increase of helicity though not so remarkable as observed for the 89.3% meta-azo copolymer.

The CD spectra before and after irradiation associated with the side-chain n,π^* and π,π^* transitions are given in Fig. 8. Their maximum or minimum ellipticities are plotted against the mole percentage of azo residue in Fig. 7. The side-chain transitions are affected remarkably by irradiation. The ellipticity for the n,π^* transition increases a great deal with inversion of its sign, whereas the circular dichroism for the π,π^* transition vanishes. Similarly to the case for the meta-copolymers, the ellipticities of the side-chain n,π^* CD bands before and after irradiation seem to be almost independent of the mole percentage of azo residue. This confirms the fact that the origin of the CD bands resides in side chain-main chain interactions. However, the absolute ellipticity of the side-chain π,π^* band observed only before irradiation increases with increasing azo residue, which suggests side chain-side chain interactions as the origin of the CD band.

Conclusion

The effect of irradiation on the backbone conformation is remarkable for the two polymers of the meta copolymer series, the 89.3% azo copolymer and mPALA For the former, stability of the right-handed α-helical conformation is promoted. On the other hand, significant instability is induced for the left-handed α-helical conformation of the latter. The conformational change of mPALA occurs abruptly at greater than 50% cis. Thus, the light-induced conformational change can be compared with visual purple, rhodopsin, where its retinal component undergoes photoisomerization accompanied by a change in conformation of opsin.

The authors wish to express their appreciation for permission to use the JASCO J-20 circular dichrograph apparatus at the National Industrial Research Institute, Tohoku.

The Photocyclization of 3,3′-Diphenyl-2,2′-bi-1*H*-indene-1,1′-dione

Fumio TODA and Yozo TODO

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Matsuyama 790

(Received March 28, 1977)

The photocyclization of the title compound afforded 14-hydroxy-4b-phenylbenz[*c*]indeno[2,1-*a*]fluoren-13-(4b*H*)-one, which is easily isomerized to 4b,13b-dihydro-4b-phenylbenz[*c*]indeno[2,1-*a*]fluorene-13,14-dione. The hydrogenation of both compounds gave *anti*-4b,8b,13a,13b-tetrahydro-4b-phenylbenz[*c*]indeno[2,1-*a*]fluorene-13,14-dione.

Although the photooxidative cyclizations of stilbenes[1] and 2-styrylthiophenes[2] to phenanthrenes and naphtho-[2,1-*b*]thiophenes respectively have been proposed to proceed *via* 4a,4b-dihydrophenanthrene and 9a,9b-dihydronaphtho[2,1-*b*]thiophene intermediates, such intermediates have not yet been isolated because of their extreme instability. Recently, though, Doyle *et al.*[3] have isolated the keto-form of the 4a,4b-dihydrophenanthrene intermediate in the photocyclization of 3,4-bis-(*p*-hydroxyphenyl)-3-hexene, and Cuppen and Laarhoven[4] have clarified that this photocyclization proceeds in the first excited state and then in a conrotatory manner.

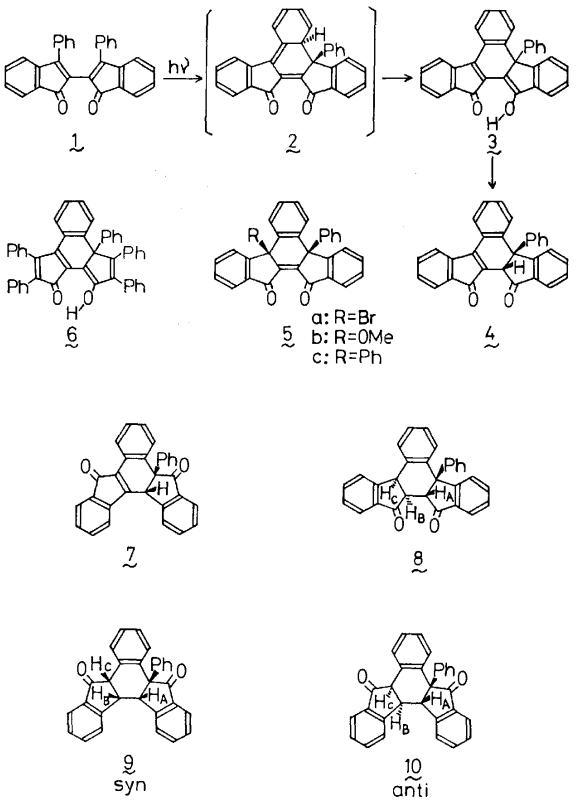
The hypothetical photocyclization product (**2**) of 3,3′-diphenyl-2,2′-bi-1*H*-indene-1,1′-dione (**1**) is expected to be isolable, because **2** has a highly conjugated enone structure, and because the conditions are unfavorable for the elimination of benzene from **2**.

The photolysis of **1**, however, gave a proton-migrated isomer of **2**, 14-hydroxy-4b-phenylbenz[*c*]indeno[2,1-*a*]fluoren-13(4b*H*)-one (**3**). We will report on this photocyclization and an some reactions of **3**.

The irradiation of **1** in benzene for 20 h afforded **3**[5] as blue-black prisms in a 70% yield. Although the νOH band of **3** was not observed, presumably because of a strong intramolecular hydrogen bond, an OH proton signal appeared at δ 9.93. The UV spectral data of **3** (604 nm (ε 2800)) were comparable to those of the analogous compound, **6** (626 nm (ε 4000)).[6,7] The UV spectral data of the acetate of **3** (513 nm (ε 2700)) were also comparable to those of the acetate of **6** (535 nm (ε 3250)).[6] It has previously been reported that the heating of 3,3′,4,4′,5,5′-hexaphenyl-2,2′-bi-2,4-cyclopentadiene-1,1′-dione in boiling benzophenone affords **6** in a 70% yield.[7] However, the heating of **1** under these conditions did not give **3**, and **1** was recovered unchanged. In contrast to the thermal stability of **6**, **3** was easily converted into 4b,13b-dihydro-4b-phenylbenz[*c*]indeno[2,1-*a*]-fluorene-13,14-dione (**4**) by heating in boiling toluene. This ketonization of **3** was performed more easily by treating it with acid. The phenyl group and the hydrogen atom marked in **4** probably bear a *syn* relationship to each other, because the signal due to this hydrogen atom was at a higher magnetic field (δ 4.25), and because the spectral data of **4** were comparable to those of **7** of the *syn*-form.[8]

The treatment of **3** and **4** with Br_2 afforded 4b,8b-dihydro-8b-bromo-4b-phenylbenz[*c*]indeno[2,1-*a*]fluorene-13,14-dione (**5a**) both in 93% yields, on treatment with $AgClO_4$ in MeOH this substance was converted into its methoxy derivative (**5b**). The spectral data of **5a** and **5b** were comparable to those of **5c**.[9] The hydrogenation of **3** and **4** over Pd–C gave *anti*-4b,8b,13a,13b-tetrahydro-4b-phenylbenz[*c*]indeno[2,1-*a*]fluorene-13,14-dione (**8**) in 50 and 25% yields respectively. These hydrogenations of **3** and **4** were performed more easily in 55 and 69% yields respectively, using the recently reported reagent, Zn–$ZnCl_2$–EtOH.[10] Interestingly, this reagent was also effective for the conversion of **5b** and the acetate of **3** into **8** in 48 and 44% yields respectively.

The *anti*-relationship between the indanone rings of **8** was determined by comparing its NMR spectral data with those of **9** of the *syn*-configuration[11] and of **10** of the *anti*-configuration, which had been prepared by the hydrogenation of **7**. The NMR spectral data of **8** (δ 4.01 (d, J_{BC}=8 Hz, H_B), 4.07 (s, H_A), 4.92 (d, H_C)) were comparable to those of **10** (δ 4.12 (d, J_{BC}= 6.5 Hz, H_C), 4.61 (s, H_A), and 4.67 (d, H_B)), but not to those of **9**, which shows complex signals of an ABX pattern.[11] The absence of spin-spin coupling between H_A and H_B in **8** and **10** is probably due to the fact that the dihedral angle between the hydrogen bonds is nearly 90°. The examination of the molecular models supports this idea.



Experimental

All the melting points are uncorrected. The IR, UV, and NMR spectra were measured in Nujol mull, $CHCl_3$, and $CDCl_3$ respectively. The mass spectra were measured with an ionization energy of 75 eV.

Photocyclization of ***1***. A solution of **1** (2 g) in benzene (400 ml) was irradiated with light from a 400-W high-pressure mercury lamp, filtered through Pyrex glass, at room temperature under N_2 for 20 h. The crude crystals after the evaporation of the solvent were recrystallized from AcOEt to afford **3** as blue-black prisms; 1.4 g (70%); mp 194 °C (dec). IR: 1670, 1615, 1590, 1560, and 1520 cm^{-1}; λ_{max}: 297 (35700), 373 (13800), and 604 nm (ε 2800); NMR δ: 7.0—8.4 (m, Ar, 17H) and 9.93 (s, OH, 1H); MS *m/e* (rel intensity): 410 (M^+, 100), 333 (M^+-Ph, 70), and 305 (333−CO, 21).

Found: C, 87.51; H, 4.35%. Calcd for $C_{30}H_{18}O_2$: C, 87.78; H, 4.42%.

The keeping of a solution of **3** (0.1 g) in Ac_2O (0.5 ml)-pyridine (2 ml) at room temperature for 12 h afforded, after recrystallization from CCl_4, the acetate of **3** as purple prisms; 0.105 g (95%); mp 254—256 °C; IR: 1760, 1695, and 1190 cm^{-1}; λ_{max}: 285 (30500), 307 (18800), and 513 nm (ε 2700); NMR δ: 2.58 (s, AcO, 3H) and 7.1—8.2 (m, Ar, 17H).

Found: C, 84.74; H, 4.30%. Calcd for $C_{32}H_{20}O_3$: C, 84.94; H, 4.46%.

Conversion of ***3*** *into* ***4***. HCl gas was bubbled through a solution of **3** (0.5 g) in $CHCl_3$ (50 ml) at 0 °C for 10 min. Recrystallization from AcOEt afforded **4** as orange prisms; 0.45 g (90%); mp 245—247 °C (dec); IR: 1710 and 1695 cm^{-1}; λ_{max}: 292 (11300), 332 sh (4700), and 430 nm (ε 1700); NMR δ: 4.25 (s, CH, 1H) and 6.9—8.5 (m, Ar, 17H); MS *m/e* (rel intensity): 410 (M^+, 100), 333 (M^+-Ph, 98), and 305 (333−CO, 28).

Found: C, 87.55; H, 4.52%. Calcd for $C_{30}H_{18}O_2$: C, 87.78; H, 4.42%.

The heating under reflux of a solution of **3** (0.1 g) in toluene (10 ml) under N_2 for 24 h afforded, after recrystallization from AcOEt, **4**; 0.06 g (60%).

Preparation of ***5a*** *and* ***5b***. To a solution of **3** (0.69 g) in $CHCl_3$ (25 ml), Br_2 (0.4 g) was added, and then the mixture was stirred for 10 min. Recrystallization from AcOEt-$CHCl_3$ afforded **5a** as yellow prisms; 0.764 g (93%); mp 209—210 °C; IR: 1740 and 1700 cm^{-1}; λ_{max} 301 nm (ε 15600); MS *m/e* (rel intensity): 490 and 488 (M^+, 5) and 409 (M^+-Br, 100).

Found: C, 73.35; H, 3.41%. Calcd for $C_{30}H_{17}O_2Br$: C, 73.63; H, 3.50%.

The treatment of **4** (0.18 g) in $CHCl_3$ (10 ml) with Br_2 (0.1 g) as above afforded **5a**; 0.2 g (93%).

The treatment of a solution of **5a** (0.27 g) in MeOH (10 ml)-tetrahydrofuran (10 ml) with $AgClO_4$ (0.5 g) afforded, after recrystallization from AcOEt, **5b** as yellow needles; 0.22 g (91%); mp 258—260 °C; IR: 1710 and 1640 cm^{-1}; λ_{max}: 302 nm (ε 17400); NMR δ: 2.29 (s, OMe, 3H) and 6.9—8.3 (m, Ar, 17H); MS *m/e* (rel intensity): 440 (M^+, 20) and 409 (M^+-OMe, 100).

Found: C, 84.27; H, 4.44%. Calcd for $C_{31}H_{20}O_3$: C, 84.53; H, 4.58%.

Hydrogenation of ***3***, ***4***, *and* ***7***. A mixture of **3** (0.2 g), tetrahydrofuran (30 ml), and a catalytic amount of Pd-C was stirred under H_2 at room temperature for 12 h. The filtrate after the filtration of Pd-C was evaporated to dryness to leave crude crystals. The recrystallization of the crude crystals from AcOEt afforded **8** as colorless prisms; 0.11 g (50%); mp 233 °C; IR: 1720 cm^{-1}; λ_{max} 247 (23200) and 295 nm (ε 4200); NMR δ: 4.01 (d, J_{BC}=8 Hz, H_B, 1H), 4.07 (s, H_A, 1H), 4.92 (d, J_{BC}=8 Hz, H_C, 1H), and 6.5—8.0 (m, Ar, 17H); MS *m/e* (rel intensity): 412 (M^+, 100), 335 (M^+-Ph, 16), and 307 (335−CO, 15).

Found: C, 87.63; H, 4.66%. Calcd for $C_{30}H_{20}O_2$: C, 87.35; H, 4.89%.

The same treatment of **4** as described above afforded **8** in a 25% yield.

The same treatment of **7** as described above afforded **10** as pale yellow needles in a 58% yield; mp 263—265 °C; IR: 1700 cm^{-1}; λ_{max}: 249 (23800), 290 (4600), 326 (800), and 340 nm (ε 800); NMR δ: 4.12 (d, J_{BC}=6.5 Hz, H_C, 1H), 4.61 (s, H_A, 1H), and 4.67 (d, J_{BC}=6.5 Hz, H_B, 1H).

Found: C, 87.55; H, 4.68%. Calcd for $C_{30}H_{20}O_2$: C, 87.35; H, 4.89%.

The treatment of **3**, **4**, and **7** with Zn-$ZnCl_2$-EtOH by the previously reported procedure[10] afforded **8** (55), **8** (69), and **10** (69%) respectively.

The authors wish to thank to Dr. R. S. Atkinson, The University of Leicester for his valuable suggestion as to the structure of the photocyclization product of **1** (**3**).

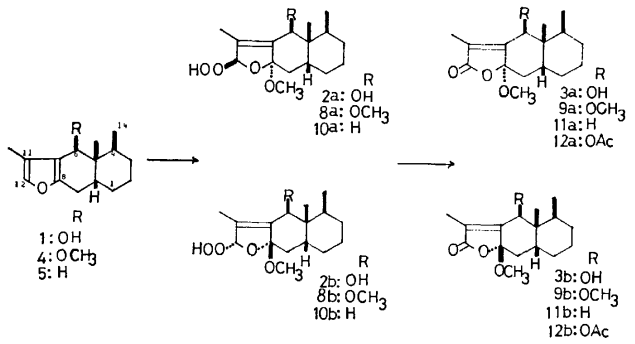
(Received March 30, 1977)

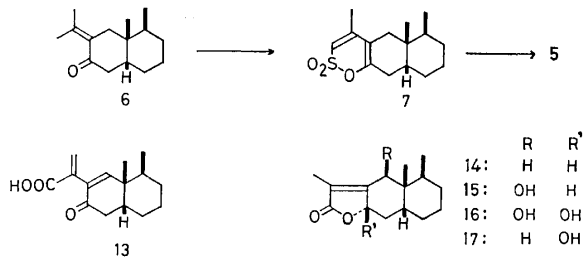
The dye-sensitized oxygenation of furanofukinin, and furanoeremophilane, in methanol gave, quantitatively, crystalline mixtures of two isomeric hydroperoxides each consisting of a pair of 8α-methoxy-12β-hydroperoxy and 8β-methoxy-12α-hydroperoxy derivatives respectively. The hydroperoxides were readily transformed to the corresponding lactones with acetic anhydride–pyridine through dehydration. The stereochemistry of the hydroperoxides and the corresponding lactones has been elucidated by spectral and chemical methods according to a previously outlined generalization. Further, furanofukinin, furanoeremophilane, and 8β-hydroxyeremophilenolide, have been synthesized from petasalbin, fukinone, and an epimeric mixture of 8α- and 8β-methoxy lactones, respectively.

In our previous paper,[1] we reported on the photosensitized oxygenation of petasalbin (**1**) to yield, quantitatively, a mixture of two isomeric hydroperoxides, (**2a**) and (**2b**), both of which were then transformed quantitatively to the corresponding lactones, (**3a**) and (**3b**), by treatment with acetic anhydride–pyridine. Their configurational assignments were ascertained by a comparison of the chemical and spectral properties between sets of the two isomeric substances. In the present paper, we will describe the photosensitized oxygenation of furanofukinin (**4**)[2] and furanoeremophilane (**5**),[3] performed in order to examine the utility of the generalization outlined in the preceding paper[1] for the configurational assignments to hydroperoxides, **2a,b**, and the corresponding lactones, **3a,b**, converted from petasalbin, **1**. Thus, a pair of 8α- and 8β-methoxy isomers have been estimated to exist in non-steroidal and steroidal A/B *cis* chair/chair conformations respectively.



Both furanofukinin, **4**, and furanoeremophilane, **5**, were isolated from the rhizomes of a wild plant,[2] *Petasites japonicus* Maxim. and its subspecies, subsp. *gigantus* Kitam. These substances, **4** and **5**, were also synthesized in good yields by the methylation of petasalbin, **1**, with methanol in the presence of acetic acid, and by Treibs' method[4,5] *via* sultone (**7**) from fukinone (**6**), respectively.

The dye-sensitized oxygenation of furanofukinin, **4**, in methanol gave a crystalline product, which showed



two spots on TLC (R_f, 0.40 and 0.20; benzene–ethyl acetate, 10 : 1) and which was then separated by fractional recrystallization from benzene to afford two hydroperoxides, (**8a**) (mp 116.0—117.0 °C (dec)) and (**8b**) (mp 136.0—137.0 °C (dec)). Both hydroperoxides have the same molecular formula, $C_{17}H_{28}O_5$, and both are positive to a peroxide test (KI–AcOH). They showed similar spectra characteristic of hydrperoxide groups: δ 11.30 (s) and 11.29 (s); IR(KBr): 3380 and 3350 cm^{-1}. Upon treatment with acetic anhydride–pyridine, the mixture of hydroperoxides, **8a,b**, gave, quantitatively, an epimeric mixture of 6β,8α-dimethoxyepieremophilenolide[6] (**9a**) (mp 132.5—133.5 °C) and 6β,8β-dimethoxyeremophilenolide (**9b**) (mp 123.0—123.5 °C) through dehydration. Subsequently each lactone was isolated by fractional recrystallization from benzene.

The stereochemistry of the hydroperoxides, **8a,b**, and the corresponding lactones, **9a,b**, can be readily determined as follows according to the previously outlined generalization.[1] The formation and the stereochemistry of the hydroperoxides, **8a,b**, can be well demonstrated by the use of the approved mechanism on the basis of the known oxygenation mode[1,7] of a furan moiety in methanol. Then, with the aid of the Dreiding model, it is evident that the introduced 8α- and 8β-methoxyl groups force the molecules to adopt exclusively non-steroidal (**A**) and steroidal (**B**) A/B *cis* chair/chair configurations respectively (*cf.* Fig. 1). Therefore, the non-steroidal 8α- (**A**) and steroidal 8β-isomers (**B**) have *cis-anti-cis* and *cis-syn-cis*-type ring-fusion systems, and they will tend to possess *trans* and

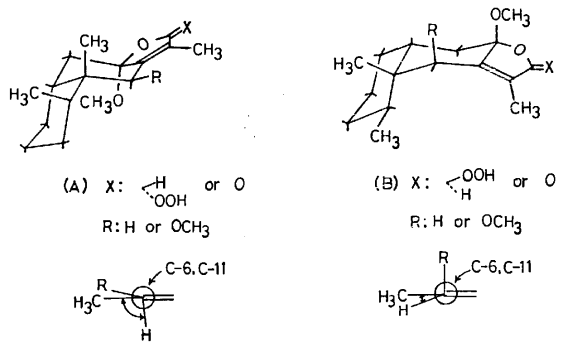

Fig. 1. Conformations of 8α- and 8β-methoxyl isomers, and the angles between 6-H and 13-CH_3.

cis characters respectively, depending on the molecular volume and the symmetric factor.[8]

Next, furanoeremophilane, **5**, lacking a C-6 substituent, was photooxygenated by a method similar to that described above to yield a single spot on TLC; it was nevertheless separated to furnish two hydroperoxides, (**10a**) (mp 123.5—124.0 °C (dec)) and (**10b**) (mp 120.5—121.0 °C (dec)), by careful recrystallization from light petroleum. Subsequently, the correspoding lactones, (**11a**) (mp 110.5—111.5 °C) and (**11b**) (mp 98.5—99.5 °C), were obtained from each hydrperoxide, **10a** or **10b**, by dehydration with acetic anhydride–pyridine, and also from the **10a,b** mixture by lactonization, followed by column chromatography and fractional recrystallization respectively. The stereochemistry of **10a,b** and **11a,b** can be settled in a similar manner; that is, the 8α- and 8β-isomers have non-steroidal (**A**) and steroidal (**B**) conformations (*cf.* Fig. 1).

Finally, the specified assignments to the 8α-(**A**) and 8β-(**B**) configurations between the two isomers were drawn by a comparison of the melting points, solubilities, adsorptive properties, specific rotations, and NMR spectra. In Table 1, the *cis*-like 8β-methoxy derivatives generally have lower melting points, higher solubilities, and stronger adsorptive properties than those of the *trans*-like 8α-isomers, in agreement with the well-known "von Auwers-Skita rule"[8] (*cf.* Experimental). There are, however, a few exceptions in which the 8β-methoxyl isomer, **8b**, has a higher melting point, together with a lower solubility, than the corresponding 8α-isomer, **8a**, much as in the relation between 6β-acetoxy-8α- and 6β-acetoxy-8β-methoxy lactones, **12a** and **12b**, described in the earlier work.[1]

In addition, in the NMR spectra of the hydroperoxides, **8a,b**, and the lactones, **9a,b**, only the 8α-methoxyl derivatives, **8a** and **9a**, exhibit homoallylic couplings[9] (1.0—1.8 Hz) between 6α-H and 13-CH_3, because the dihedral angle between the plane of the double bond—C-6–C-13— and the 6α-H is around 90°, as shown by an inspection of the configuration (**A**) with the Dreiding model (Fig. 1), whereas 8β-isomers do not show these couplings between 6α-H and 13-CH_3, all lying around 20° (*cf.* Fig. 1 and Table 1). Furthermore, the 8α-methoxy compounds showed the chemical shifts due to 14-methyls at a lower field than those due to 15-methyls; this relation of the chemical shifts between 14- and 15-methyls is reversed in the 8β-series (*cf.* Table 1). These variations in the chemical shifts may be explained similarly in terms of the effect due to the alteration in the geometry of the skeleton observed in the steroid field— by bending rings away from the angular methyl group, or by blocking the angular methyl's view over the remaining skeleton the methyl signal may cause a downfield shift.[10] On the other hand, 8β-methoxyl compounds have stronger positive rotations than the corresponding isomers. This can be expected from the helicities[1] derived from dihydrofuran/ring A fusion. The helicity was clarified by ORD-CD study in the 6-oxo derivatives of **3a** and **3b**.

All the derivatives, **10a,b** and **11a,b**, transformed

from furanoeremophilane, **5**, showed the signals due to 13-methyls with homoallylic couplings in their NMR spectra: δ 1.71 and 1.74 (each d, J=1.2 Hz) in **10a** and **10b**, and 1.76 and 1.76 (each d, J=1.2 and 1.5 Hz) in **11a** and **11b**. These couplings are obviously the expected ones between 6α-protons and 13-methyls in 8α-methoxyl compounds, and between 6β-protons and 13-methyls in 8β-isomers, as a consideration of the angles with the Dreiding model shows (Fig. 1).

Thus, summarizing the above results, the generalization outlined in the previous paper[1] was found also to be applicable to the configurational assignments of the hydroperoxides, **8a,b** and **10a,b**, and the lactones, **9a,b** and **11a,b**, prepared from furanofukinin, **4**, and furanoeremophilane, **5**.

On alkaline hydrolysis, a mixture of dimethoxy lactones, **9a,b**, gave a sole product, $C_{15}H_{20}O_3$ (mp 95.0—96.0 °C), which was identical with the expected unsaturated acid (**13**)[1] previously prepared by alkaline hydrolysis from a mixture of 6β-acetoxy-8(α and β)-methoxy lactones **12a,b**. On the other hand, a mixture of **11a,b** was treated with 1.5 M potassium hydroxide–methanol to yield also a sole product, $C_{15}H_{22}O_3$ (mp 212.0—213.5 °C), in a good yield: this product showed spectra suggesting the presence of a hydroxyl group and an α,β-unsaturated γ-lactone group: 3565, 3330 (OH), and 1745, 1697 cm^{-1} (unsaturated γ-lactone C=O), and an UV maximum at 222 nm. The structure of this lactone was easily inferred from its NMR spectrum, closely similar to that of the natural eremophilenolide (**14**)[11] except for the absence of the signal due to 8-H. Moreover, the lactone revealed a steroidal character—the chemical shift due to 14-methyl is higher than that due to 15-methyl in the NMR spectrum, and it showed a strong positive rotation (Table 1). The above conclusion can be further supported by the similar feature observed in the known natural eremophilenolides with 8β-substituents (a hydrogen or a hydroxyl) other than a methoxyl group. The specific rotations and the chemical shifts of 15- and 14-methyls in the spectra of eremophilenolide, **14**, 6β-hydroxyeremophilenolide (**15**), and 6β,8β-dihydroxyeremophilenolide (**16**) are as follows; **14**: $[\alpha]_D^{20}$+16.6° (c, 3.67, $CHCl_3$),[12,13] δ 1.01 (s) and 0.78 (br d);[11] **15**: $[\alpha]_D^{24}$+205.8° (c, 1.021, $CHCl_3$), δ 1.11 (s) and 0.78 (non-resolved methyl signal);[14] **16**: $[\alpha]_D^{16}$+169° (c, 0.985, $CHCl_3$), δ 1.11 (s) and 0.78 (non-resolved methyl signal).[1] Thus, the lactone can be represented as in the formula (**17**) with a steroidal configuration (**B**). Compound **17** has previously been derived as the by-product from the autoxidation of furanoeremophilane, **5**, by Šorm *et al.*[15]

Experimental

The IR, UV, and mass spectra were taken with Hitachi EPI-G3, Cary 14, and Hitachi RMU-6 spectrophotometers respectively. The NMR spectra were recorded with a Hitachi R-20B (60 MHz) spectrophotometer, and the chemical shifts are reported in δ-values (with TMS as the internal reference). The optical rotations were measured with a Perkin-Elmer 141 polarimeter. The TLC were run on Kieselgel G (Merck).

Synthesis of Furanofukinin (4). Petasalbin, **1** (492 mg), was dissolved in a solution of methanol (10 ml) and acetic acid (0.5 ml), and then left for three days at room temperature. After the removal of the solvent *in vacuo* and dilution with water, the reaction product was extracted with ether. Subsequent working-up as usual gave a crude product as a yellow oil (477 mg), which was purified by column chromatography on alumina (10 g, grade IV), with light petroleum–ether (100 : 1) as the eluent, and by vacuum-distillation to give furanofukinin (**4**) as a colorless oil; bp 96.0—106.0 °C (bath temperature)/6×10^{-3} mmHg. This was identical in all respects with the natural specimen.[2]

Synthesis of Furanoeremophilane (5) via Sultone (7) from Fukinone (6). *Sultone (7)*: Concentrated sulfuric acid (d= 1.84, 1.91 g) was stirred, drop by drop, into acetic anhydride (5.15 g) under ice-cooling below −10 °C, and then fukinone, **6** (3.34 g) ,was added to the stirred solution over a period of 15 min under continued cooling. After stirring for a further 1.5 h, the mixture was left for 38 h at −8 °C—−4 °C and for 1 h at room temperature. The subsequent addition to the reaction mixture of cracked ice (*ca.* 1 g) and a solution of sodium hydroxide (0.89 g) in water (1.6 ml) deposited yellowish brown crystals, which were filtered and washed with water. The crude product (3.0 g, 70%) was recrystallized from ethyl acetate to afford a sultone (**7**) as colorless prisms; mp 187.5—188.0 °C; UV: λ_{max}^{MeOH} 275.2 nm (ε, 4330); IR (KBr): 1653, 1578, 1195, 1085, 865 cm^{-1}; NMR ($CDCl_3$): 6.24 (m, 12-H), 1.96 (d, J=1.0 Hz, 13-CH_3), 0.89 (s, 15-CH_3), 0.87 (d, J=6.3 Hz, 14-CH_3).

Found: C, 63.59; H, 7.90; S, 11.38%. Calcd for $C_{15}H_{22}O_3S$: C, 63.80; H, 7.85; S, 11.35%.

Furanoeremophilane (5): A mixture of the sultone, **7** (497 mg), and zinc oxide (500 mg) was subjected to pyrolytic distillation. The distillate was collected in a 10% potassium hydroxide aqueous solution (0.3 ml) and then extracted with ether. The ethereal extract was washed with a saturated sodium hydrogencarbonate solution and then with water, and dried over anhydrous sodium sulfate. The subsequent evaporation of the solvent gave crude furanoeremophilane (**5**) as an oil (360 mg, 94%), which was purified by vacuum-distillation (bp 67—100 °C (bath temperature)/0.15 mmHg) to furnish a pure specimen (297 mg, 77%) and subsequently by GLC to obtain an analytical sample (PEG 20 M, 2.6 m; column temperature, 175 °C; H_2-flow rate, 60 ml/min; retention time, 8.8 min); IR (film): 1641, 1560, 1145, 1087, 985 cm^{-1}; $[\alpha]_D^{23}$ −13.2 °C (c, 1.0, $CHCl_3$).

Found: C, 82.35; H, 10.21%. Calcd for $C_{15}H_{22}O$: C, 82.51; H, 10.16%. This compound was identical in all respects (IR, NMR, GLC, and specific rotation) with the natural specimen.[2]

Photosensitized Oxygenation of Furanofukinin (4). A solution of furanofukinin, **4** (770 mg), and Rose Bengal (30 mg) in methanol (300 ml) was irradiated with a circular fluorescent lamp (30 watt) for 1 h under the bubbling of air. After the subsequent removal of the solvent *in vacuo*, the residue was taken up with benzene. The benzene extract was washed with water and then passed through a filter filled with anhydrous sodium sulfate for drying and taking off the dye-stuff. The removal of the solvent *in vacuo* gave a colorless solid, which showed two spots on TLC (R_f, 0.40 and 0.20; benzene–ethyl acetate, 10 : 1) and which was separated into two hydroperoxides, (**8a**) and (**8b**), by careful fractional crystallization from benzene. The **8b** compound was less soluble than **8a** in benzene.

Hydroperoxide (8a): Mp 116.0—117.0 °C (dec) as colorless prisms, $[\alpha]_D^{24}$ −54 °C (c, 1.0, MeOH); IR(KBr): 3380, 1300, 1140, 1090, 960 cm^{-1}; NMR (acetone-d_6): 11.30 (s, OOH), 5.68 (s, 12-H), 4.20 (q, J=1.5 Hz, 6-H) 3.43 and 3.17 (each s, 6- and 8-OCH_3), 1.87 (d, J=1.5 Hz, 13-CH_3),

0.96 (d, J=7.5 Hz, 14-CH_3), 0.78 (s, 15-CH_3).

Found: C, 65.43; H, 9.05%. Calcd for $C_{17}H_{28}O_5$: C, 65.36; H, 9.03%.

*Hydroperoxide (**8b**)*: Mp 136.0—137.0 °C (dec) as colorless needles, $[\alpha]_D^{24}$ +13.4° (*c*, 1.12, MeOH); MS: *m/e* 294 (M^+-H_2O), 154 (base peak); IR(KBr): 3350, 1280, 1200, 1080, 1050, 970 cm^{-1}; NMR (acetone-d_6): 11.29 (s, OOH), 5.73 (s, 12-H), 3.88 (s, 6-H), 3.27 and 3.11 (each s, 6- and 8-OCH_3), 1.85 (s, 13-CH_3), 1.02 (s, 15-CH_3), 0.78 (d, J= 5.3 Hz, 14-CH_3).

Found: C, 65.34; H, 8.97%. Calcd for $C_{17}H_{28}O_5$: C, 65.36; H, 9.03%.

*6β,8α-Dimethoxyepieremophilenolide (**9a**) and 6β,8β-Dimethoxyeremophilenolide (**9b**)*. A mixture of hydroperoxides **8a**, **b** (527 mg) was dissolved in pyridine (4 ml) and acetic anhydride (1 ml) and then left overnight at room temperature. Subsequent working-up as usual gave a colorless solid (480 mg), which was subjected to fractional crystallization from light petroleum to deposit a less soluble isomer (**9a**) (143 mg) and then an epimer (**9b**) (48 mg). In addition, the two hydroperoxides, **8a** (9 mg) and **8b** (15 mg), were transformed into the corresponding lactones, **9a** (6 mg) and **9b** (10 mg).

*6β,8α-Dimethoxyepieremophilenolide (**9a**)*: Mp 132.5—133.5 °C, colorless needles, $[\alpha]_D^{25}$ −185° (*c*, 0.80, $CHCl_3$); UV: λ_{max}^{MeOH} 224 nm (ε, 13700); IR ($CHCl_3$): 1750, 1300, 1100, 960, 920, 900 cm^{-1}; NMR (CCl_4): 4.28 (q, J=1.8 Hz, 6-H), 3.40 and 3.13 (each s, 6- and 8-OCH_3), 1.90 (d, J= 1.8 Hz, 13-CH_3), 0.96 (d, J=7.5 Hz, 14-CH_3), 0.75 (s, 15-CH_3).

Found: C, 69.39; H, 8.85%. Calcd for $C_{17}H_{26}O_4$: C, 69.36; H, 8.90%.

*6β,8β-Dimethoxyeremophilenolide (**9b**)*: Mp 123.0—123.5 °C, colorless prisms, $[\alpha]_D^{25}$ +170° (*c*, 1.0, $CHCl_3$); UV: λ_{max}^{MeOH} 220.5 nm (ε, 7600); IR($CHCl_3$): 1760, 1320, 1100, 1085, 995, 975, 920 cm^{-1}; NMR(CCl_4): 3.89 (s, 6-H), 3.25 and 3.06 (each s, 6- and 8-OCH_3), 1.81 (s, 13-CH_3), 0.99 (s, 15-CH_3), 0.75 (d, J=5.5 Hz, 14-CH_3).

Found: C, 69.44; H, 8.78%. Calcd for $C_{17}H_{26}O_4$: C, 69.36; H, 8.90%.

*Photosensitized Oxygenation of Furanoeremophilane (**5**)*. A stirred solution of furanoeremophilane, **5** (560 mg), and Rose Bengal (30 mg) in methanol (300 ml) was irradiated with a circular fluorescent lamp (30 watt) for 1 h under the bubbling of air. A subsequent working-up as has been described above gave a colorless crystalline mixture of hydroperoxides, which showed a single spot on TLC (R_f, 0.40, benzene-ethyl acetate, 10 : 1). The mixture was separated by fractional crystallization from benzene to deposit the less soluble 8α-epimer (**10a**) (181 mg) first, and then the 8β-epimer (**10b**) (167 mg) from the mother liquors.

*Hydroperoxide (**10a**)*: Mp 123.5—124.0 °C (dec) as colorless needles, $[\alpha]_D^{24}$ −15.2° (*c*, 1.0, MeOH); MS: *m/e* 264 (M^+-H_2O), 109 (base peak); IR(KBr): 3300, 1700, 1130, 1040, 960, 860 cm^{-1}; NMR (acetone-d_6): 11.20 (s, OOH), 5.70 (s, 12-H), 3.07 (s, OCH_3), 1.71 (d, J=1.2 Hz, 13-CH_3), 0.98 (d, J=6.0 Hz, 14-CH_3), 0.80 (s, 15-CH_3).

Found: C, 68.03; H, 9.24%. Calcd for $C_{16}H_{26}O_4$: C, 68.05; H, 9.28%.

*Hydroperoxide (**10b**)*: Mp 120.5—121.0 °C (dec) as colorless prisms, $[\alpha]_D^{24}$ +2.9° (*c*, 1.01, MeOH); MS: *m/e* 264 (M^+-H_2O), 109 (base peak); IR(KBr): 3300, 1710, 1160, 1070, 970, 920 cm^{-1} ;NMR (acetone-d_6): 11.21 (s, OOH), 5.73 (s, 12-H), 3.06 (s, OCH_3), 1.74 (d, J=1.2 Hz, 13-CH_3), 0.98 (s, 15-CH_3), 0.80 (d, J=6.0 Hz, 14-CH_3).

Found: C, 68.03; H, 9.30%. Calcd for $C_{16}H_{26}O_4$: C, 68.05; H, 9.28%.

*8α- and 8β-Methoxy Lactones, (**11a**) and (**11b**)*. A colorless crystalline mixture of hydroperoxides, **10a,b**, prepared from furanoeremophilane, **5** (455 mg), was dissolved in pyridine (1 ml) and acetic anhydride (2 ml) and then left overnight at room temperature. A subsequent working-up in the usual manner gave an oil (524 mg) which showed two spots on TLC (R_f, 0.78 and 0.70, $CHCl_3$) and which was then chromatographed over silica gel (12 g). Elution with light petroleum–ether (50 : 1) and subsequent fractional recrystallization from light petroleum gave 8α-methoxy lactone (**11a**) (130 mg) at first, and the 8β-epimer (**11b**) was obtained from the mother liquors.

*8α-Methoxyepieremophilenolide (**11a**)*: Mp 110.5—111.5 °C, colorless prisms, $[\alpha]_D^{24}$ −168° (*c*, 0.95, $CHCl_3$); UV: λ_{max}^{MeOH} 227 nm (ε, 12500); IR(KBr): 1750, 1690, 1310, 940 cm^{-1}; NMR(CCl_4): 3.05 (s, OCH_3), 1.76 (d, J=1.5 Hz, 13-CH_3), 0.98 (d, J=7.0 Hz, 14-CH_3), 0.77 (s, 15-CH_3).

Found: C, 72.59; H, 9.20%. Calcd for $C_{16}H_{24}O_3$: C, 72.69; H, 9.15%.

*8β-Methoxyeremophilenolide (**11b**)*: Mp 98.5—99.5 °C, colorless needles, $[\alpha]_D^{24}$ +164° (*c*, 1.08, $CHCl_3$); UV: λ_{max}^{MeOH} 225 nm (ε, 11500); IR(KBr): 1750, 1690, 1170, 990 cm^{-1}; NMR (CCl_4): 2.99 (s, OCH_3), 1.76 (d, J=1.2 Hz, 13-CH_3), 0.98 (s, 15-CH_3), 0.74 (d, J=6.0 Hz, 14-CH_3).

Found: C, 72.65; H, 9.27%. Calcd for $C_{16}H_{24}O_3$: C, 72.69; H, 9.15%.

*Unsaturated Acid (8-Oxo-eremophila-6,11-dien-12-oic Acid) (**13**)*.[1] A mixture of dimethoxy lactones, **9a,b** (200 mg), was dissolved in methanol (10 ml) and 1.84 M potassium hydroxide–methanol (8 ml) and then left for 36 h. After the removal of the solvent and dilution with water, the solution was acidified with 10% sulfuric acid and then extracted with ether. A subsequent working-up as usual gave an acid (198 mg) as a colorless oil, which was recrystallized from diisopropyl ether–light petroleum to afford the pure acid (**13**) (mp 95.0—96.0 °C). The acid, **13**, was found by a mixed-melting point determination and a comparison of the IR spectra to be identical with the 8-oxo-eremophila-6,11-dien-12-oic acid prepared from a mixture of 6β-acetoxy-8(α and β)-methoxy lactones, **12a,b**.[1]

*8β-Hydroxyeremophilenolide (**17**)*. A mixture of 8α- and 8β-methoxy lactones, **11a,b** (53 mg), was dissolved in a 1.5 M potassium hydroxide–methanol solution (1.3 ml) and then left for 3 h at room temperature. After the evaporation of the solvent *in vacuo* and acidification with 10% sulfuric acid, the reaction mixture was extracted with ether, washed with water, and dried. The removal of the solvent gave a semi-crystalline product (59 mg), which was subsequently recrystallized from methanol–diisopropyl ether to afford 8β-hydroxyeremophilenolide (**17**) (25 mg) as colorless prisms; mp 212.0—213.5 °C, $[\alpha]_D^{20}$ +157° (*c*, 0.69, $CHCl_3$); UV: λ_{max}^{MeOH} 222 nm (ε, 9200); MS: *m/e* 250 (M^+), 91 (base peak); IR($CHCl_3$): 3565, 3330, 1745, 1697 cm^{-1}; NMR (acetone-d_6): 5.90 (br s, OH), 2.83 (d, J=13.5 Hz, 6-CH_2), 1.73 (*d*, J=1.6 Hz, 13-CH_3), 1.04 (s, 15-CH_3), 0.80 (d, J=5.5 Hz, 14-CH_3).

Found: C, 71.93; H, 8.70%. Calcd for $C_{15}H_{22}O_3$: C, 71.97; H, 8.86%.

The Synthesis and Properties of Diacyl Selenides

Hideharu ISHIHARA, Shigeyuki SATO and Yoshio HIRABAYASHI
Faculty of Engineering, Gifu University, Nakamonzen-cho, Kakamihara, Gifu 504
(Received April 12, 1977)

Diacyl selenides were synthesized in good yields by the deselenization of diacyl diselenides, which have conveniently been prepared from acyl chlorides and sodium hydroselenide. The reaction of dibenzoyl selenide with piperidine at 0 °C formed a fairly stable piperidinium salt. The methanolysis of distearoyl selenide gave selenostearic acid as an unstable intermediate.

Although the reactions of diacyl sulfides with various reagents have been investigated extensively, few studies of diacyl selenides have been known. In 1932, dibenzoyl selenide was obtained by Szperl and Wiorogoski[1] by the treatment of benzoyl chloride with dry hydrogen selenide in the presence of aluminium chloride. Recently, Jensen *et al.*[2] prepared dipropionyl selenide, not selenopropionic acid, by the reaction of propionyl chloride with hydrogen selenide in the presence of an equimolar amount of pyridine, but the yield was poor. In this paper, we will describe a convenient method for synthesizing diacyl selenides, which are important as the starting material for preparations of potassium selenocarboxylates,[3] by the deselenization of diacyl diselenides with triphenylphosphine and will discuss the reactions of diacyl selenides with amines and methanol.

Results and Discussion

The reaction sequence used in the synthesis of diacyl selenides is outlined in Scheme 1.

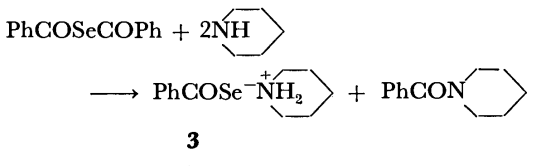
Scheme 1.

First, diacyl diselenides were prepared by a new, convenient method. The oxidation of a mixture of selenocarboxylic acid and sodium selenocarboxylate, which had been prepared by the reaction of acyl chlorides and sodium hydrogen selenide in ethanol, gave diacyl diselenides in good yields, as is shown in Table 1.[4] Next, diacyl selenides were obtained in good yields by the deselenization of diacyl diselenides. That is, the diacyl diselenides readily reacted with an equimolar amount of triphenylphosphine in benzene to give diacyl selenides and triphenylphosphine selenide. Diacyl selenides were isolated in good yields by the recrystallization of the resulting mixture from hexane–ether. The results and some properties are summarized in Table 2.

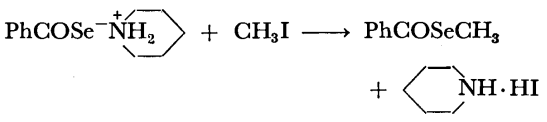
Distearoyl selenide was also prepared by the one-step reaction of stearoyl chloride with sodium selenide in benzene. The recrystallization of the crude product from benzene gave distearoyl selenide in a 67% yield, while small amounts of distearoyl diselenide and octadecylidene bis(selenostearate) were obtained as by-products. On the other hand, attempts to use the same method for the preparation of dibenzoyl selenide were unsuccessful, though some of the dibenzoyl diselenide was isolated.

Reactions of Dibenzoyl Selenide with Amines. Jensen *et al.*[2] have described that dipropionyl selenide reacted with aniline to form 2 mol of propionanilide. However, when dibenzoyl selenide was treated with 2 mol of piperidine at 0 °C, piperidinium selenobenzoate (**3**) was isolated in a 79% yield. The piperidinium salt (**3**) was fairly stable in the solid state and did not change when left standing for a day under nitrogen. However, the salt (**3**) decomposed in ether at ordinary temperatures to give 1-benzoylpiperidine, with the concurrent evolution of hydrogen selenide (Scheme 2). The salt



Scheme 2.

was confirmed by elemental analysis and by a study of its IR and NMR spectra. That is, in the IR spectrum the characteristic multiple absorption bands (νNH) at 2500—3000 cm^{-1} and a carbonyl absorption band at 1550 cm^{-1} were observed. The NMR spectrum showed peaks at 1.14 (6H, piperidine), 3.22 (4H, piperidine), 7.48, 8.28 (5H, C_6H_5), and near 9.4 ppm (about 2H, NH_2). Furthermore, the structure of the salt was chemically suported by the formation of methyl selenolbenzoate in a 90% yield by the reaction of the salt with methyl iodide in dry ether.



In a similar way, the reactions of bis(*p*-chlorobenzoyl) selenide and bis(*p*-methylbenzoyl) selenide with piperidine gave the corresponding piperidinium salts in 79 and 82% yields, respectively. Though, attempts to isolate the analogous adducts of dibenzoyl selenide with morpholine or dibutylamine failed, the infrared spectra of the oily substances, obtained by evaporating the solvent from the reaction mixture, showed multiple

Table 3. Methanolysis of distearoyl selenide at 50 °C

Reaction conditions			Yield[a] Mole ratio(%)		
Selenide	Gas	Time h	**1e**	**2e**	Ester[b]
1e	N_2	10	—	—	100
1e	N_2	0.5	22	12	66
1e	air	0.5	5	27	67
2e	N_2	0.5	10	71	19

a) The yields of these products were obtained by the UV method (Ref. 8). b) Methyl stearate.

bands(νNH) at 2500—3000 cm^{-1} and a carbonyl absorption band at 1550 cm^{-1}. These results may show that the reaction of diacyl selenide with amine gives, at first, the amine salt and amide, and that then the salt decomposes to give amide, with the evolution of hydrogen selenide.

Methanolysis of Distearoyl Selenide. It is known that the alcoholysis of diacyl sulfides gives the thio acid and the ester.[5] On the other hand, a methanolysis of distearoyl selenide (**1e**) in both a stream of nitrogen and air gave methyl stearate, distearoyl diselenide (**2e**), and **1e**, with the concurrent evolution of hydrogen selenide, but selenostearic acid was not obtained. On the other hand, as is shown in Table 3, in case of the reaction in a stream of air, the yield of **2e** was 27%, and in case of the reaction in a stream of nitrogen, that of **2e** was 12%, whereas the yields of **1e** were 5 and 22%, respectively. Furthermore, the reaction mixtures comsumed iodine in methanol. These results show that **2e** may be produced by the oxidation of selenostearic acid. That is, selenostearic acid may be formed by the methanolysis of **1e**, and the acid may change to **1e** with the evolution hydrogen selenide or may be oxidized to give **2e**, as is shown in the following equations:

$$RCOSeCOR + CH_3OH \longrightarrow [RCOSeH] + RCOOCH_3, \quad (1)$$

$$2[RCOSeH] \longrightarrow RCOSeCOR + H_2Se, \quad (2)$$

$$2[RCOSeH] \xrightarrow{(O)} RCOSeSeCOR + H_2O, \quad (3)$$

$$RCOSeSeCOR + CH_3OH \longrightarrow [RCOSeH] + RCOOCH_3 + Se + H_2Se. \quad (4)$$

These equations are supported by the reaction of **2e** with methanol in a stream of nitrogen to give **1e**, methylstearate and elemental selenium, with the concurrent evolution hydrogen selenide (Eq. 4).

Experimental

Synthesis of Dibenzoyl Diselenide. Hydrogen selenide, generated from Al_2Se_3 (0.80 mol)[7] and dilute hydrogen chloride and dried by being passed through a $CaCl_2$-tube, was led into a solution of sodium ethoxide (0.60 mol) in 400 ml of ethanol at 0 °C. Then, 71 g (0.50 mol) of benzoyl chloride was slowly added to the solution at 0 °C. After the stirring had continued for another 3 h, the mixture was treated with 100 g of iodine in ethanol and 5% aqueous

K_2CO_3. The organic layer was extracted with benzene, and the benzene solution was washed with aqueous $Na_2S_2O_3$ and then water, and dried over Na_2SO_4. The solvent was evaporated, and the residue was recrystallized from benzene–ether. Yield, 70.8 g (77%); mp 131—132 °C (lit,[1] 129—130 °C).

Synthesis of Dibenzoyl Selenide. A mixture of equimolar amounts of dibenzoyl diselenide (11.0 g; 0.03 mol) and triphenylphosphine (7.9 g; 0.03 mol) in benzene (150 ml) was stirred at room temperature for 1 h. After the benzene had then been evaporated under reduced pressure, ether was added to the residue. The resulting insoluble part (Ph_3PSe; mp 179—181 °C) was filtered off. After the ether had been removed from the filtrate, recrystallizations of the residue solid from hexane–ether gave 7.6 g (88%) of dibenzoyl selenide as white crystals; mp 60—61 °C (lit,[1] 61—62 °C).

Synthesis of Distearoyl Selenide by the Reaction of Stearoyl Chloride with Sodium Selenide. In a four-necked flask, 300 ml of ammonia dried by being passed through CaO-tube was liquefied, and then metal sodium (2.3 g; 0.10 mol) was added. Thereafter, elemental selenium (3.95 g; 0.05 mol) was slowly added to the solution at −40 °C under vigorous stirring. After the stirring had been continued for another 2 h, a small portion of selenium or sodium was added, as required. (If the solution become orange, a small quantity of sodium was added, or if it showed blue, a small quantity of selenium was added). Then, the solution turned white. After the solvent had been completely removed, to the residue in dry benzene (200 ml) stearoyl chloride (30.3 g; 0.10 mol) was added, drop by drop, at 50 °C and the stirring was continued for another 3 h. After the removal of the insoluble part from the reacting mixture by filtration, the solvent was removed. Recrystallizations of the residue from benzene gave 20.5 g (67%) of distearoyl selenide; mp 75.3—75.8 °C; Se 12.78% (Calcd for $C_{36}H_{70}O_2Se$: 12.86%), 1.5 g of distearoyl diselenide; mp 79.8—80.3 °C; Se 22.73% (Calcd for $C_{36}H_{70}O_2Se_2$: 22.79%), and 0.8 g of $(C_{17}H_{35}COSe)_2CHC_{17}H_{35}$; mp 58—59 °C; Se 16.67% (Calcd for $C_{54}H_{106}O_2Se_2$: 16.70%) νC=O 1709 cm^{-1}, νC–Se 945 cm^{-1}; NMR peaks 4.82 (–CH–, 1H, T,) 2.59 ($-CH_2CO-$, 4H, T), 1.25 ($-CH_2-$, about 92H, S) and 0.83 ppm ($-CH_3$, 9H, T).

Reaction of Dibenzoyl Selenide with Piperidine. A mixture of dibenzoyl selenide (2.90 g; 10 mmol) and piperidine (1.70 g; 20 mmol) in 50 ml of anhydrous ether was stirred at 0 °C for 30 min. The resulting precipitated were collected from the reaction mixture, and recrystallizations of the precipitate from dichloromethane–hexane gave 2.13 g (79%) of piperidinium selenobenzoate. The filtrate was concentrated under reduced pressure, giving 2.28 g (128%) of 1-benzoylpiperidine and a small amount of elemental selenium.

Reaction of Piperidinium Selenobenzoate with Methyl Iodide. The reaction of piperidinium selenobenzoate (1.0 g; 3.7 mmol) with methyl iodide (2.6 g) in 20 ml of dry ether at room temperature gave methyl selenolbenzoate (0.66 g, 90%; bp 105—106 °C/6 mmHg). The ester was identified by a comparison of its IR spectrum with that of an authentic sample.

Reaction of Distearoyl Selenide with Methanol. Methanol (15 ml) was added to a solution of 615 mg of distearoyl selenide in benzene (30 ml). The mixture was heated at 50 °C by means of N_2 gas. After 30 min, the reaction mixture was cooled and extracted with ether. The ether solution was washed with water, dried, and concentrated, giving a crystalline residue. Distearoyl selenide, distearoyl diselenide, and methyl stearate were obtained by the recrystallization of the residue, while the hydrogen selenide was evaporated during the reaction. We found nothing else. The yields (Table 3) of these products in the residue were calculated by fitting a equation[8] to extinction at 244 and 261 nm.

On the Mechanism of the Formation of Steroidal Cyclic Hydroxamic Acids in the Photolysis of Steroidal 17β-ol Nitrite[1)]

Hiroshi SUGINOME, Norihisa YONEKURA, Terutoshi MIZUGUCHI, and Tadashi MASAMUNE

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received April 18, 1977)

The Photolysis of 5α-androstane-3α,17β-diol 3-acetate 17-nitrite (**1**) in benzene with monochromatic light (372 ±4 nm) afforded two rearranged products, 17a-aza-D-homo-5α-androstane-3α,17a-diol-17-one 3-acetate (**2**) and the C-13 epimer (**8**). This result confirmed that the cyclization of the nitroso aldehyde intermediate (**C**) to the two products **2** and **8** proceeds without the involvement of excited species of the nitroso aldehyde intermediate **C**. This conclusion differs from that obtained for bornyl and isobornyl nitrites by Kabasakalian and Townley. The results of photolysis in carbon tetrachloride are also compared with that in benzene. The photolysis of the nitrite **1** in an EPA matrix at 77 K showed that essentially no β-cleavage of the 17β-oxyl radical takes place at the temperature of liquid nitrogen.

In previous papers, the formations of steroidal cyclic nitrones and spiroisoxazolines *via* the photochemical rearrangement of steroidal cyclopentyl and cyclopentenyl nitrites were reported.[2a-2e)] The reaction pathways of these photoinduced rearrangements were confirmed to involve nitroso aldehyde intermediates formed *via* the β-cleavage of the oxyl radical to afford the allyl radical, followed by the combination of NO and the allyl radical.[2b,2c)] The cyclization of the nitroso aldehyde to the products is a thermal process and proceeds without any involvement of excited species.[2c,2d)]

In connection with these investigations, we were interested in the formation of a steroidal cyclic hydroxamic acid (**2**) *via* the photochemical rearrangement of a steroidal 17-nitrite (**1**) reported by Barton and his collaborators,[3)] since the proposed pathway for this photoinduced rearrangement, which is illustrated in Scheme 1, involved also the formation of a nitroso aldehyde intermediate (**C**) and its cyclization to the product **2**.[3)] Although the proposed pathway is quite reasonable, no experimental evidence for the intermediacy of the nitroso aldehyde **C** has been available and the problem of whether the cyclization of the nitroso aldehyde **C** is a thermal process or a photochemical one seemed also to remain to be clarified.

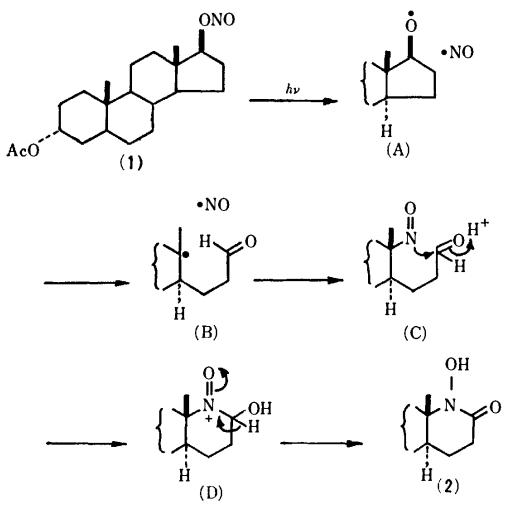
Subsequent to this work,[3)] Kabasakalian and Townley[4)] and Nakazaki and Naemura[5)] reported an analogous photorearrangement of bornyl and isobornyl nitrites. These two groups of investigators found that the photolysis of bornyl and isobornyl nitrites (*e.g.*, **3**) in benzene or in trichlorotrifluoroethane with black light or ultraviolet light led to the formation of 1,8,8-trimethyl-2-hydroxy-2-azabicyclo[3.2.1]octan-3-one (**4**) in a 27—30% yield, together with several products derived from a β-cleavage of the corresponding oxyl radical, as is depicted in Scheme 2. Moreover,

Scheme 2.

Kabasakalian and Townley were able to isolate a nitroso aldehyde intermediate (**5**), although none of its physical constants were given in the paper.[4)] They also reported that they succeeded in converting the nitroso aldehyde **5** into the hydroxamic acid **4** on exposure to sunlight or a neon lamp (585—660 nm), but failed to transform the aldehyde **5** into the hydroxamic acid **4** by heat at 60 °C (Scheme 3). On the basis of these results, they concluded that the cyclization of the nitroso aldehyde **5** to the hydroxamic acid **4** took place from an excited species of the nitroso aldehyde **5**.

Scheme 3.

It would not be unreasonable to extrapolate these results to the pathway of the analogous rearrangement of the steroidal 17-nitrite. In order to obtain independent evidence for the intermediacy of the nitroso aldehyde **C** and the mode of cyclization in the steroidal rearrangement, however, we carried out the photolysis of the nitrite **1** with a monochromatic light and the photolysis of the nitrite **1** in an EPA matrix at 77 K. Thus, if the hydroxamic acid **2** is formed from the assumed nitroso aldehyde **C**, we can readily ascertain whether this process is thermal or photochemical by the photolysis of the nitrite **1** with monochromatic light, which will be able to excite only the O–NO group of

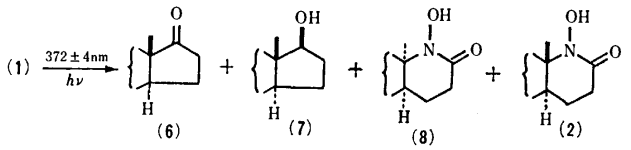


Scheme 1.

the nitrite **1**, not the C–NO group or the CHO group of the assumed nitroso aldehyde intermediate(s) **C** in Scheme 1.

Results and Discussion

The O–NO group generally has a characteristic structured band centred at *ca.* 370 nm due to the n→π^* transition.[6] The stronger absorption at the shorter wave length was ascribed to the intramolecular charge-transfer band.[7] The UV spectrum of 5α-androstane-3α-17β-diol 3-acetate 17-nitrite (**1**) in benzene or in THF exhibited a characteristic structured absorption due to the n→π^* of the ONO group centred at *ca.* 372 nm (ε; 112 in benzene). On the other hand, the nitroso aldehyde (**1**) would have one weak absorption at *ca.* 290 nm[8] due to an n→π^* transition of the aldehyde group, and another at 670 nm due to the n→π^* transition of the C-nitroso group.[9] Therefore, the nitrite **1** in dry benzene was photolyzed with 372±4 nm monochromatic light generated by a CRM-FA grating spectroirradiator in order to excite only the ONO chromophore. A careful separation of the products by preparative TLC afforded 5α-androstan-3α-ol-17-one 3-acetate (**6**) (8%), 5α- androstane-3α, 17β-diol 3-acetate (**7**) (12%), a new compound (**8**) (mp 118—120 °C), (21%), and 17a-aza-D-homo-5α-androstane-3α,17a-diol-17-one 3-acetate (**2**)[3] (20%), in the order of decreasing mobilities in TLC (Scheme 4). The electron-



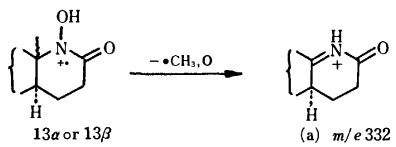
Scheme 4.

impact mass spectrum of the new compound **8** revealed a fragmentation pattern very similar to that of the hydroxamic acid **2**. They both show a molecular ion at *m/e* 363 and the principal fragment ions at *m/e* 348, 332, 272 and 150. The relative intensities of the principal ions in the mass spectra of the two compounds **2** and **8** are shown in Table 1. This mass spectrum, together with the IR and NMR spectra, suggest that the structure of the new compound is 17a-aza-D-homo-5α, 13α-androstane-3α, 17a-diol-17-one 3-acetate.

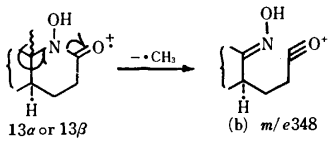
Table 1. Relative intensities (%) of the principal ions in the mass spectra of compounds **2** and **8**

Compd	$M^{+\cdot}$	*m/e*			
		348	332	272	150
2	1	12	100	10	24
8	4	48	100	16	10

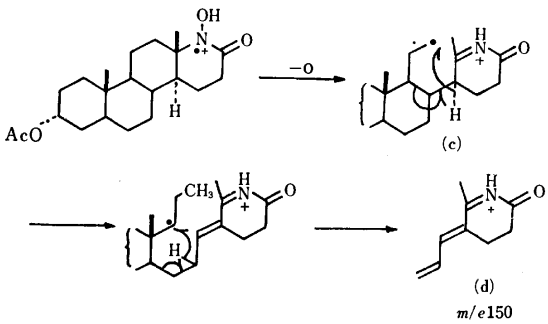
The base peak of the two compounds **2** and **8** is the fragment ion 332 corresponding to $[M-CH_3, O]^+$. The (a) in Scheme 5 is a possible representation of this fragment. The intense fragment ion at *m/e* 348 involves the elimination of CH_3, and this ion may possess the structure (b) in Scheme 6. The intense peak at *m/e* 150 is most probably formed *via* an ion (c)[10] identical



Scheme 5.



Scheme 6.



Scheme 7.

with the ion postulated for the mass spectral fragmentation[11] of 17a-aza-5α-androstan-17-one and is represented as having a structure (d). The pathway for the formation of the ion (d) from the ion (c) suggested by Budzikiewicz and his collaborators[11] is illustrated in Scheme 7.

This structure for the hydroxamic acid **8** was confirmed by its conversion into 17a-aza-D-homo-5α,13α-androstan-3α-ol-17-one 3-acetate: the reduction of the product **8** with zinc and acetic acid under reflux[3] afforded the corresponding known lactam identical with an authentic sample[12] prepared by the Beckmann rearrangement of an oxime of 5α,13α-androstan-3α-ol-17-one acetate. Very similar results were obtained in the photolysis of the nitrite **1** with Pyrex-filtered light, as is shown in Table 2.

Since the monochromatic light of 372±4 nm is unable to excite the formyl group or the nitroso group of the hypothetical intermediate **C**, it may be concluded that the cyclization of the nitroso aldehyde **C** to the observed hydroxamic acids **2** and **8** is a thermal process. This conclusion differs from the one obtained for bornyl and isobornyl nitrites by Kabasakalian and Townley.[4]

Table 2. Yields (%) of the products in the photolysis of the nitrite **1** with monochromatic light in various solvents

	6	**7**	**8**	**2**

THF	trace[b]	52	13	12
CCl_4	21	52	8	8

a) Results with Pyrex-filtered light.
b) Detected by TLC.

The mode of the transfer of the 17-hydrogen of the nitrite **1** remains to be clarified.

In order to examine the effects of solvents, the photolysis of the nitrite **1** in two aprotic solvents, THF and carbon tetrachloride, was studied. Thus, it was found that the four products, **6**, **7**, **8**, and **2**, are also formed in two solvents under conditions comparable to the case in benzene and with light of a 372±4 nm wave length. However, the ratios of the four products are different, as is shown in Table 2.

Thus, it is apparent that the hydroxamic acids are generally produced in aprotic solvents.[13] However, the main product in THF and in carbon tetrachloride is the parent alcohol **7**. Needless to say, THF is a better hydrogen-donating solvent than benzene, and hydrogen abstraction by the 17β-oxyl radical from a hydrogen attached to the oxygen-bearing carbon of THF may take place readily to produce the parent alcohol. In the photolysis in carbon tetrachloride, the ketone **6** is formed in a considerable amount, together with the parent alcohol. Some of these compounds, **6** and **7**, may perhaps be formed *via* the disproportionation of the 17β-oxyl radical (**A**).

We also carried out the photolysis of bornyl nitrite **3** in benzene. Let us discuss the results briefly. The photolysis of the nitrite **3** in benzene with monochromatic light (358±8 nm) gave the hydroxamic acid **4**,[4,5] although the yield was only 3% and the major product was the parent borneol, as was confirmed by TLC. A repetition of the photolysis with Pyrex-filtered light also afforded the hydroxamic acid **4** in an equally poor yield (*ca.* 2%) and borneol as the major product (TLC).[14] These results indicate that the hydroxamic acid **4** may also be formed by a thermal cyclization of the nitroso aldehyde **5**.

Finally, an experiment aimed at proving the intermediacy of the nitroso aldehyde **C** will be described. In a previous publication[2c] we described the photolysis of a nitrite carried out in an EPA matrix at 77 K. This technique successfully proved the intervention of a nitroso aldehyde in the photorearrangement of the nitrite to nitrone. In the present case, the nitrite **1** in an EPA matrix (8.3×10^{-3} M) was photolyzed at 77 K through a Pyrex glass filter in the hope that we might be able to trap the nitroso aldehyde intermediate **C**. The reaction was monitored by UV spectroscopy in the 250—800 nm region, as in the previous case.[2c] However, in contrast to the case of the nitrite-nitrone transformation,[2c] the increase in the absorption maximum at *ca.* 670 nm in the matrix due to the C-nitroso compound **C** was not signifcant, even after a prolonged irradiation. This is due to the fact that the β-cleavage of the 17β- oxyl radical (**A**) at 77 K took place to only a small extent, as was proved by the presence of the hydroxamic acids on the thin-layer chromatogram of the EPA solution after irradiation.

Experimental

For the instruments and general procedures, see Part 30[2d] in this series.

5α-Androstane-3α,17β-diol 3-Acetate 17-Nitrite (1). This nitrite was prepared by the procedure of Barton and his colleagues.[3] Mp 183—184 °C (lit,[3] 177—180 °C) NMR: τ 9.26 (18-H), 9.20 (19-H), 7.94 (OAc), 5.00 (bs. $W_{1/2}$=7.5 Hz) (3β-H), 4.78 (t, J=8.4 Hz) (17α-H). UV: $\lambda_{max}^{benzene}$ (nm) 372 (112), 360 (116), 348 (96), 336 (72). λ_{max}^{THF} (nm) 372 (93), 360 (96), 348 (81), 336 (64).

Photolysis of the 17-Nitrite 1 with Pyrex-filtered Light. A solution of the nitrite **1** (300 mg) in dry benzene (30 ml) was irradiated for 1.5 h under an argon atmosphere with a 100-W high pressure Hg arc at room temperature. After the removal of the solvent by means of rotatory evaporator at 30 °C, the residue was subjected to preparative TLC. Four fractions, A, B, C, and D, were obtained in order of decreasing mobilities. The most mobile fraction, A (26 mg, 10%), was 5α-androstan-3α-ol-17-one acetate (**6**). The second most mobile fraction, B (26 mg, 9%), was 5α-androstane-3α,17β-diol 3-acetate **7**. The fraction C was recrystallized from aq ethanol to afford a new compound (**8**) (60 mg, 20%); mp 118—120 °C. Found: C, 69.11; H, 9.19; N, 3.70%. Calcd for $C_{21}H_{33}O_4N$: C, 69.39; H, 9.15; N, 3.85%. IR: 1742 (OAc), 1628 (amide C=O), 3127 cm^{-1} (hydrogen bonded hydroxyl). NMR: τ 9.28 (19-H), 8.64 (18-H), 7.06 (OAc), 4.99 (bs. $W_{1/2}$=7.5 Hz) (3β-H) 7.44—7.62 (m, 2H, 16α- and 16β-H).

The fraction D was recrystallized from ether to afford 17α-aza-D-homo-5α-androstane-3α,17a-diol-17-one 3-acetate (**2**) (59 mg, 20%). Mp 230—234 °C. (Lit,[3] mp 229—233 °C). NMR: τ 9.21 (19-H), 8.74 (18-H), 7.95 (OAc), 4.99 (b.s. $W_{1/2}$=7.5 Hz) (3β-H), 7.46—7.62 (m, 2H, 16α- and 16β-H).

Photolysis of the 17-Nitrite 1 with Monochromatic Light (372±4 nm). a) Photolysis in Benzene: A solution of the nitrite (200 mg) in dry benzene (3 ml) in a quartz cell (10×10×45 mm) was flushed with argon and then placed in the chamber of a JASCO CRM-FA grating spectroirradiator. Irradiation was carried out with light of 372±4 nm. The progress of the reaction was monitored by means of TLC. After the completion of the photolysis (33.3 h), the solution was evaporated *in vacuo*. The TLC of the residue exhibited 4 spots (benzene/ether=1/5); the residue was subjected to preparative TLC (benzene/ether=1/1) as has been described above. The yields of the four products were as follows: ketone **6** (15 mg, 8%); 17β-ol **7** (22 mg, 12%); hydroxamic acid **8** (41 mg, 21%); isomeric hydroxamic acid **2** (40 mg, 20%). *b) Photolysis in THF*: A solution of the nitrite **1** (200 mg) in dry THF (3 ml) in a quartz cell was flushed with nitrogen and then photolyzed as in the photolysis in benzene. Eleven hours was required for the completion of the photolysis. The yields of the four products were as follows; ketone **6** (trace); 17β-ol **7** (96 mg, 52%); hydroxamic acid **8** (26 mg, 13%); isomeric hydroxamic acid (**2**) (23 mg, 12%). *c) Photolysis in Carbon Tetrachloride*: A solution of the nitrite (200 mg) in dry carbon tetrachloride (luminazol, dotite, Wako) (3 ml) in a quartz cell was flushed with argon and then photolyzed as has been described above. Forty hours were required for the completion of the photolysis. The yields of the four products were as follows: ketone **6** (37 mg, 21%); 17β-ol **7** (95 mg, 52%); hydroxamic acid **8** (16 mg, 8%); isomeric hydroxamic acid (**2**) (15 mg, 8%).

17a-Aza-D-homo-5α,13α-androstan-3α-ol-17-one 3-Acetate by Reduction of the Hydroxamic Acid 8. Into a solution of the hydroxamic acid **8** (14 mg) in glacial acetic acid (2.8 ml), we stirred Zn dust (70 mg). After solution has then been heated under reflux for 3 h, the reaction mixture was filtered and the filtrate poured into ice water. The solution was neutralized with saturated sodium hydrogencarbonate solution and extracted with methylene chloride. The dichloromethane solution was worked up in the usual way. The residue

(12 mg) was purified by preparative TLC to afford the lactam, **8**, R=H, (4 mg) (mp 192.5—193.5 °C), identical with an authentic specimen.[12]

Photolysis of dl-*Bornyl Nitrite* ***3*** *with Monochromatic Light 385 ±8 nm.* A solution of the nitrite (1.5 g) in dry benzene (2 ml) in a quartz cell was flushed with argon and then photolyzed as in the photolysis of steroidal nitrites. Eighty-five hours were required for the completion of the photolysis. The yellowish green solution was evaporated *in vacuo*, and the residue was subjected to preparative TLC (benzene/ether; 4/1). The polar fraction containing the hydroxamic acid was then again subjected to preparative TLC (ether). The least mobile fraction (46 mg, 3%) was the hydroxamic acid **4**. The analytical results of a specimen obtained by chromatographic purification were in agreement with the $C_{10}H_{17}NO_2$ formula. (Found: C, 65.80, H, 9.21, N, 7.48%) MS, *m/e* 183 (M^+); NMR: τ 8.65 (1-methyl), 8.95, 8.99 (8.8-gem dimethyl) IR: 1637 (amide C=O), 3131 and 3411 cm^{-1} (hydrogen-bonded hydroxyl).

Photolysis of d-*Bornyl Nitrite* ***3*** *in Benzene with Pyrex-filtered Light.* Bornyl nitrite **3** (2 g) in dry benzene (200 ml) was photolyzed for 12 h. A brownish solution was evaporated, and the residue was recrystallized from hexane to yield the crude hydroxamic acid. The compound was again recrystallized from benzene–hexane to yield 37 mg (2%) of the hydroxamic acid **4**.

Irradiation of the Nitrite ***1*** *in an EPA Matrix at 77 K.* The matrix was prepared by dissolving the nitrite **1** (30 mg) in EPA (diethyl ether–isopentane–ethanol 1 : 1 : 2 in volume) 10 ml (8.3×10^{-3} M) and by then freezing the solution with liquid nitrogen. The matrix was degassed by freeze-thaw cycles. This matrix was irradiated through a Pyrex-filter with a 250-W super high-pressure Hg arc (USHIO UI 501C). The change in the spectrum was monitored at appropriate time intervals by means of a Carry ultraviolet spectrometer. After a 30-min irradiation, a very weak broad absorption at 695 nm due to the C-nitroso compound appeared, although the banded absorption due to the O–NO (385, 372, 358, 348, and 336 nm) nearly vanished. After the matrix had been brought to room temperature, a TLC examination of the solution revealed that the major product was the 11β-ol **7**, though traces of the hydroxamic acids **2** and **8** were also present.

We thank Professor Katsumi Kimura of the Research Institute of Applied Electricity of Hokkaido University for his help in the matrix experiment. We also thank Tomoko Okayama of this laboratory for the ^1H NMR measurements.

Competitive Cyclization in the Reaction of Hexafluoropropene with 2-Aminobenzamide

Takeshi NAKAI, Nabil M. HASSAN,* and Nobuo ISHIKAWA

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received April 25, 1977)

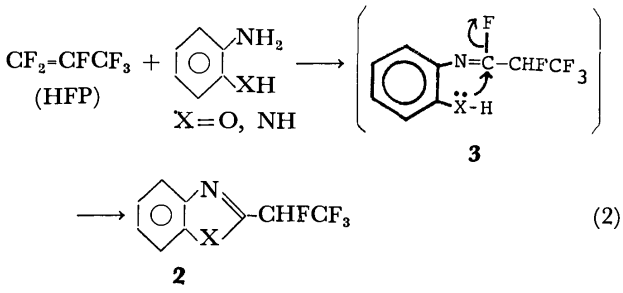
The reaction of hexafluoropropene (HFP) with 2-aminobenzamide afforded 2-(1,2,2,2-tetrafluoroethyl)-4(3*H*)-quinazolinone (**4**) and *N*-(2-cyanophenyl)-2,3,3,3-tetrafluoropropionamide (**5**) in *ca.*1 : 1 ratio, which is essentially independent of the reaction temperatures ranging from room temperature to 100 °C. The formation of the two products is explained in terms of the competitive cyclization of the imidoyl fluoride intermediate, the N-6 and O-6 ring closures ultimately yielding **4** and **5**, respectively. In contrast to the HFP reaction, 2-(trifluoromethyl)pentafluoropropene (OFIB) and 2-aminobenzamide gave only the O-6 cyclized product, *N*-(2-cyanophenyl)-2-trifluoromethyl-3,3,3-trifluoropropionamide. The difference in reactivity between HFP and OFIB is discussed.

It is well-known that amines undergo nucleophilic addition to perfluoroolefins affording acetamidine derivatives *via* reactive imidoyl fluoride intermediates (**1**)[1,2] (Eq. 1).

$$RNH_2 + CF_2{=}CFR_f \longrightarrow [R{-}N{=}CF{-}CHFR_f] \xrightarrow{RNH_2} \underset{\mathbf{1}}{R{-}N{=}C{-}CHFR_f} \quad (1)$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad \underset{}{NHR}$$

R_f=F, CF_3, *etc.*

The reaction of hexafluoropropene (HFP) with 2-substituted anilines afforded the heterocyclic compounds (**2**) in good yields[3] (Eq. 2). The formation of the heterocyclic products has been explained by the X-5[4] ring closure of the imidoyl fluoride (**3**).



(2)

The reaction of perfluoroolefins with 2-aminobenzamide is of particular interest since the carbamoyl group is expected to act as "an ambident internal nucleophile"[5] affording the N-6 and/or O-6 cyclized products. Thus we have studied the reactions of HFP and 2-(trifluoromethyl)pentafluoropropene (OFIB, octafluoroisobutylene) with 2-aminobenzamide. This paper deals with the reaction mechanisms involving the competitive cyclization of the imidoyl fluoride intermediates.

Results and Discussion

Product Determinations. The reactions of HFP with 2-aminobenzamide were carried out in *N*,*N*-dimethylformamide (DMF) under various conditions in pressure vessels. As an example, a mixture of HFP and the benzamide in DMF was stirred overnight at room temperature and then at 60 °C for 6 h. Removal of DMF *in vacuo* gave a solid residue. Its ^{19}F NMR spectrum indicates that the residue consists of two compounds in nearly 1 : 1 ratio. The two compounds were then successfully separated by utilizing the great difference in solubility in hot water. On the basis of the spectral data, the water-soluble and insoluble parts were assigned to 2-(1,2,2,2-tetrafluoroethyl)-4(3*H*)-quinazolinone (**4**) and *N*-(2-cyanophenyl)-2,3,3,3-tetrafluoropropionamide (**5**), respectively. The formation of **4** was easily anticipated but that of **5** was somewhat surprising, and it is suggested that a dehydration process permitting the conversion of the carbamoyl to the cyano group was involved in the reaction.

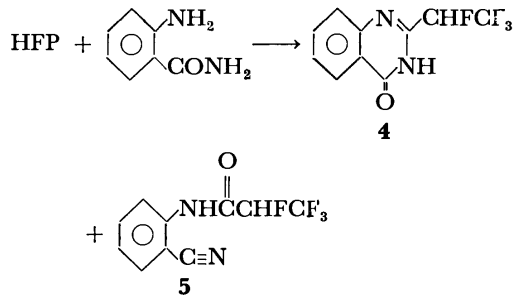


Table 1 gives the results of the reactions carried out under various conditions. The product ratio is seen to be independent of the reaction conditions.

TABLE 1. REACTIONS OF HFP WITH 2-AMINOBENZAMIDE

Run	Temp (°C)	Time (h)	Total yield (%)	Product ratio[a] **4** : **5**
1	50	10	41	1.0 : 1.06
2	60	6	63	1.0 : 1.02
3	70	5	33	1.0 : 1.19
4[b]	70	7	7.5	1.0 : 1.13
5	80	8	84	1.0 : 1.14
6	100	6	77	1.0 : 1.05
7	R. T.	5 day	28	1.0 : 1.37

a) Determined by ^{19}F NMR analysis of the reaction mixtures. The values are essentially the same as those obtained from weights of each compound separated from the reaction mixtures. b) The reaction was carried out in an open system in which which HFP was bubbled to a solution of the benzamide in DMF.

The structure proofs for **4** and **5** are as follows. Both mass spectral and elemental analytical data for **4** and **5** gave the same formula $C_{10}H_6F_4N_2O$.

For the quinazolinone **4**, the IR spectrum shows bands at 2900—3005 (NH), 1680 (C=O), and 1615 cm^{-1} (C=N). Both ^{19}F and ^{1}H NMR spectra un-

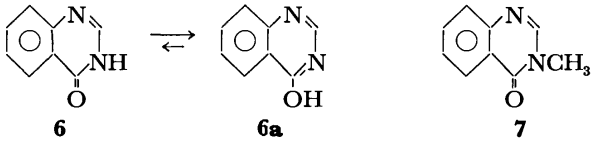
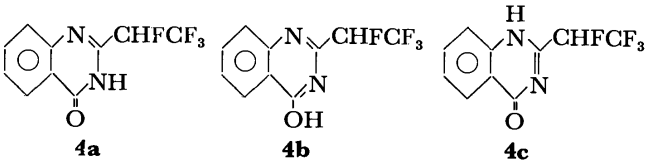
equivocally indicate the presence of the grouping of $-CHF-CF_3$ (see Experimental). Comparison of its UV spectrum with reported spectra[6] for 4(3*H*)-quinazolinone (**6**) and 3-methyl-4(3*H*)-quinazolinone (**7**) (Fig. 1) supports the quinazolinone structure for **4**. It has been established that the parent compound **6** exists mainly in the hydroxy tautomeric form (**6a**).[6,7] Although the three tautomeric forms, **4a**, **4b**, and **4c**, are possible for the product **4**, the spectrum of **4** is more similar to that of **7** than that of **6**, suggesting that **4** exists mainly in the tautomeric form **4a**.

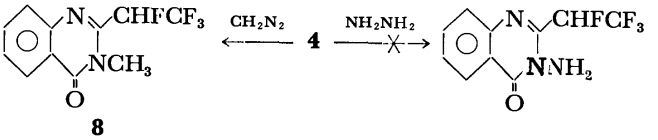


6 **6a** **7**



4a **4b** **4c**

Quinazolinone **4** fluoresces a light green color and is soluble in concentrated aqueous sodium carbonate solutions to give a salt stable even in the boiling solutions. On acidification **4** was recovered unchanged. Methylation of **4** with diazomethane in a mixture of ethanol and ether afforded a single product assigned to the 3-methylquinazolinone **8** based on the following spectral data. The IR spectrum of **8** showed bands at 1600 (C=O) and 1605 cm^{-1} (C=N), no absorption due to the NH being observed. The ^1H NMR spectrum showed not only a slightly split singlet at 3.4 ppm for the $N-CH_3$ protons but also the presence of the grouping of $-CHF-CF_3$. The finding supports the tautomeric structure **4a** for **4**. Although **6** (mainly **6a**) reacts with hydrazine hydrate giving 3-amino-4(3*H*)-quinazolinone *via* a ring-opening,[8] no similar reaction of **4** takes place under the same conditions.



8

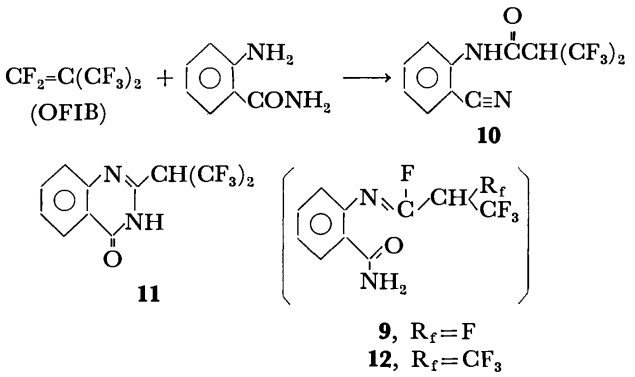
On the other hand, the structure of another product **5** was elucidated as follows. The IR spectrum of **5** showed bands at 3226 (NH), 2230 (C≡N), and 1684 cm^{-1} (C=O). Both the ^{19}F and ^1H NMR spectra indicated the presence of the grouping of $-CHF-CF_3$. The structure was confirmed by an independent synthesis of an authentic sample (Eq. 3). The authentic sample thus obtained was identical with **5**.

(3)

Reaction Mechanisms The formation of **4** and **5** can be explained in terms of the competitive N-6 *vs.* O-6 cyclization of the imidoyl fluoride intermediate (**9**) formed *via* addition of the amino group to HFP followed by elimination of HF (Scheme 1).

Imidoyl fluoride **9** thus formed undergoes the N-6 cyclization *via* the attack of the carbamoyl nitrogen at the imidoyl carbon atom followed by proton transfer and elimination of HF to give the quinazolinone **4**. Alternatively **8** undergoes the O-6 cyclization by the attack of the carbamoyl oxygen followed by elimination of HF accompanied by the cleavage of the carbon-oxygen bond, finally yielding the cyanoanilide **5**. The O-6 ring closure is of mechanistic and synthetic interest since it can be considered as an intramolecular dehydration reacion accomplishing the conversion of the amido into cyano groups.

Reaction of OFIB with 2-Aminobenzamide. The reaction of OFIB with 2-aminobenzamide was studied. The benzamide was allowed to react with OFIB in DMF at 60 °C for 4 h to afford only *N*-(2-cyanophenyl)-2-trifluoromethyl-3,3,3-trifluoropropioamide (**10**) in 82 % yield; no quinazolinone **11** was found in the resulting mixture. The IR spectrum of **10** showed a strong band at 2240 cm^{-1} due to the cyano group, and the ^{19}F NMR spectrum exhibited a doublet at −15 ppm for $CH(CF_3)_2$



It should be noted that the OFIB reaction proceeds more rapidly than the HFP reaction. Such a difference between HFP and OFIB can be interpreted by assuming the difference in the electrophilicity of the imidoyl carbon atoms in **9** and **12**; the carbon atom in **12** is more electron-deficient and might combine only with the more highly electron-donating carbamoyl oxygen rather than the carbamoyl nitrogen leading to the exclusive O-6 cyclization process.

Experimental

All melting points are uncorrected. IR and UV spectra were recorded on Hitachi 215 and EPS-3T spectrometers, respectively. ^{19}F NMR spectra were taken with a Hitachi R-24F spectrometer using trifluoroacetic acid (TFA) as an external standard, the chemical shifts being given in δ ppm upfield from TFA. ^1H NMR spectra were measured with a Hitachi R-24 and a Varian EM 360 spectrometer using tetramethylsilane (TMS) as an internal standard, the chemical shifts being given in δ ppm downfield from TMS. Mass spectra (MS) were recorded on a JEOL JMS-D100 spectrometer.

Reactions of HFP with 2-Aminobenzamide. A typical procedure is as follows. HFP (3 ml, 25 mmol) was transferred from the bomb to a trap tube cooled in a dry ice–acetone bath, and then put into a cooled pressure vessel equipped with a magnetic stirrer in which 2-aminobenzamide (2.0 g, 12 mmol) and 30 ml of DMF were placed. The vessel was then closed and brought to room temperature (internal pressure, 3.1 kg/cm^2). The mixture was stirred overnight at room temperature and then heated at 60 °C for 6 h. The vessel was carefully opened after being cooled and the resulting mixture was transferred to a distillation apparatus. The solvent was completely distilled under reduced pressure and the residual solid was cooled and collected to give a solid mixture (2.26 g, 63%). The solid mixture was separated by recrystallization from hot water (10 ml). The water-insoluble solid was filtered and recrystallized from methanol to give colorless plates of **4**; mp 210—212 °C; IR (KBr), 2900—3005 (NH), 1680 (C=O), and 1605 cm^{-1} (C=N); ^{19}F NMR (DMSO), δ −2.0 (d of d, $J_{vic\text{-}HF}$=10.8 and $J_{vic\text{-}FF}$=10.8 Hz, CHF-CF_3) and +126 (d of q, $J_{vic\text{-}FF}$=10.8 and $J_{gem\text{-}HF}$=36.2 Hz, CHF-CF_3); ^1H NMR ($CDCl_3$), δ 6.4 (d of q, CHF-CF_3) and 7.5—8.3 (m, 4H, aromatic protons); UV (ethanol) (Fig. 1), λ_{max} (log ε), 313.5 (3.47), 301 (3.57), 277.5 (3.80), 269 (3.81), and 227 nm (4.23); MS, *m/e* 246 (M^+, 100%).

Found: C, 48.41; H, 2.37; N, 11.37%. Calcd for $C_{10}H_6F_4N_2O$: C, 48.79; H, 2.46; N, 11.38%.

The filtrate was cooled in an ice box to give colorless needles of **5**; mp and mixed mp 95—96 °C; IR (KBr), 3226 (NH), 2230 (C≡N), and 1680 cm^{-1} (C=O); ^{19}F NMR (DMSO), δ −4.0 (d of d, $J_{vic\text{-}HF}$=9.9 and $J_{vic\text{-}FF}$=9.9 Hz, CHF-CF_3) and +125 (d of q, $J_{gem\text{-}HF}$=36.2 Hz, CHF-CF_3); ^1H NMR ($CDCl_3$), δ 3.3 (br s, 1H, NH), 6.08 (d of q, 1H, CHF-CF_3) and 7.2—8.0 (m, 4H, aromatic protons); MS, *m/e* 246 (M^+, 100%).

Found: C, 49.02; H, 2.66; N, 11.47%. Calcd for $C_{10}H_6F_4N_2O$: C, 48.79; H, 2.46; N, 11.38%.

Yields and product ratios are given in Table 1.

Preparation of an Authentic Sample of ***5***. 2,3,3,3-Tetrafluoropropionyl chloride (bp 48—49 °C) was prepared from phosphorus pentachloride and the tetrafluoropropionic acid[9] (7.3 g). The acid chloride (10 mmol) was added dropwise to a solution of 2-cyanoaniline (10 mmol) in 10 ml of benzene and the mixture was then refluxed for 15 min and allowed to stand overnight at room temperature. Crystals formed were filtered and recrystallized from hot water giving colorless needles; mp 95—96 °C.

Reaction of ***4*** *with Diazomethane.* Quinazolinone **4** (0.3 g) was dissolved in a mixture of ethanol (20 ml) and ether (20 ml) and diazomethane generated from Diazad (7 g) and potassium hydroxide (1.3 g) was bubbled into the mixture with stirring. The resulting mixture was stirred overnight at room temperature and the solvent was evaporated to give colorless plates (0.55 g, 84%) of the crude **8** (recrystallized from hexane); mp 132—133 °C; IR (KBr), 1660 cm^{-1} (C=O); ^1H NMR ($CDCl_3$), δ 3.4 (slightly split s, 3H, NCH_3), 5.9 (d of q, 1H, CHFCF$_3$) and 7.3—8.4 (m, 4H, aromatic protons).

Found: C, 50.70; H, 3.10; N, 10.49%. Calcd for $C_{11}H_8F_4N_2O$: C, 50.78; H, 3.09; N, 10.76%.

Reaction of OFIB with 2-Aminobenzamide. The reaction was carried out in the same way for the HFP reaction. A mixture of OFIB (2.5 ml) and 2-aminobenzamide (1.0 g) in DMF (7.5 ml) was stirred at room temperature for 2 h and then heated at 60 °C for 4 h with stirring. The resulting mixture was cooled and the vessel was opened carefully. The solvent was distilled *in vacuo* to give a solid residue (1.78 g, 82%). Recrystallization from benzene afforded colorless

needles; mp 185—186 °C; IR(KBr), 3270 (NH), 2240 (C≡N), and 1670 cm^{-1} (C=O); ^{19}F NMR (DMSO), δ −15 (d, $CH(CF_3)_2$).

Found: C, 44.89; H, 2.18; N, 9.50%. Calcd for $C_{11}H_6F_6N_2O$: C, 44.61; H, 2.04; N, 9.46%.

Nuclear Magnetic Resonance Study of Exchanging Systems. IX.[1] The Slow Rotation of the Methyl Group in Sterically Overcrowded Compounds

Hiroshi NAKANISHI and Osamu YAMAMOTO

National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151

(Received April 27, 1977)

In order to obtain information about the slow rotation of methyl groups, the ^{1}H NMR spectra of 9-*t*-butylethenoanthracene and 9-*t*-butyltriptycene derivatives were measured at very low temperatures. It was found that the signals of the two methyls of the *t*-butyl group in these compounds show a considerable line broadening at low temperatures, and it was made clear that the rotation of the methyl groups in these compounds is strongly restricted.

A rotation about the sp_3–sp_3 carbon-carbon single bond has for a long time been considered to be free, but recently it was reported[2] that, in some sterically overcrowded molecules, the rotation about the sp_3–sp_3 carbon-carbon single bond in bulky groups, such as *t*-butyl and isopropyl groups, is strongly restricted. On the other hand, the rotation of the methyl group, the smallest alkyl group, is especially rapid, and it is well known that the rotation of the methyl group in a quite overcrowded compound, for example, hexamethylbenzene, is not frozen on the NMR time scale at a temperature as low as −150 °C, even in the solid state.[3]

Most recently, however, the first example of a strongly restricted rotation of a methyl group on the NMR time scale was found in 1-*t*-butyl-1,4-dihydro-1,4-epoxynaphthalene derivatives (**1**).[4,5] Then, in 9-methyltriptycene derivatives (**2**), the methyl rotations were also found to be sufficiently slow and the activation parameters of the rotation were determined from the NMR complete line-shape analyses.[6,7] The rotation of a methyl group in the Diels-Alder adduct (**3**) of 9-methylanthracene with *p*-benzoquinone was also analysed.[8]

In this paper, we will present new examples of the slow rotation of methyl groups in two sterically overcrowded compounds.

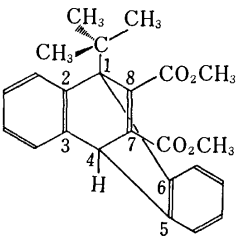
Experimental

Materials. Dimethyl 9-*t*-butyl-9,10-ethenoanthracene-11,12-dicarboxylate (**4**) was prepared by a Diels-Alder reaction between 9-*t*-butylanthracene and dimethyl acetylenedicarboxylate, heating at 180—200 °C for 10 h in a sealed Pyrex tube. The purification was made by Al_2O_3 column chromatography and three recrystalizations from ethanol. mp 146—148 °C (lit,[9] mp 182—183 °C).

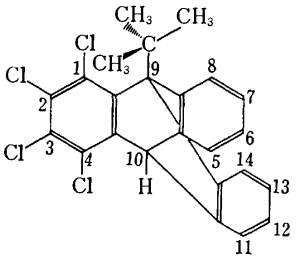
1,2,3,4-Tetrachloro-9-*t*-butyltriptycene (**5**) was prepared by the benzyne reaction of 9-*t*-butylanthracene and 1,2,3,4-tetrachloroanthranilic acid by a method similar to that described in the literature.[7,10] mp 277—278 °C. The purification of **5** was done similarly as has been described above.

The purity of these compounds was checked by studying the ^{1}H NMR spectra.

Measurements. The ^{1}H NMR spectra of **4** and **5** were recorded on Varian HA-100 D (100.0 MHz) and XL-100-15 A FT (100.1 MHz) spectrometers. The spectra of **4** at 155 and 199 °C were measured by the former spectrometer, using a 5-mmϕ sample tube. The solvent was hexachloro-1,3-butadiene. The measurements at low temperatures were made by means of the latter spectrometer. As the solubility of **4** and **5** is very poor at low temperatures, a 12-mmϕ sample tube was used and a one hundred-fold accumulation was made by means of a pulsed FT method



4

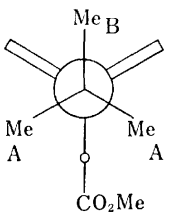


5

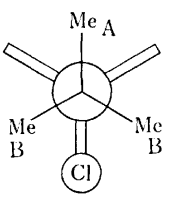
at very low temperatures. The sample concentration was 0.013 mol/l for **4** and 0.011 mol/l for **5** in the (CS_2+$CDCl_3$+CD_2Cl_2+CD_3COCD_3+$CD_3C_6D_5$, 5 : 1 : 2 : 1 : 2) solvent system. The temperature was read by means of a calibrated copper-constantan thermocouple.

Results and Discussion

The ^{1}H NMR signal of the *t*-butyl group of **4** at room temperature consists of two sharp peaks (δ: 1.733 and 1.874 from TMS), whose intensities are in a 2 : 1 ratio, as is shown in Fig. 1. The higher field peak is assigned to methyl A protons, and the lower to methyl B protons, judging from the line intensities (see the Newman projection **6**). This spectrum shows that the rotation of the *t*-butyl group is frozen at this temperature on the NMR time scale. This line shape remains unchanged at temperatures as high as 155 and 199 °C, and no line broadening occurs.* This means that the rotation of the *t*-butyl group of **4** is sufficiently slow at these temperatures.**



6



7

In order to obtain information about the rotation of a methyl group, the spectra of **4** were measured at low temperatures, since the methyl rotation is expected to be strongly restricted by the bulky phenyl and meth-

* Ōki and Suda reported the same result for the spectrum of **4** at 132 °C.[9]

** The activation free energy, ΔG^*, of the rotation of the *t*-butyl group in **4** is roughly estimated to be much larger than 30 kcal/mol.

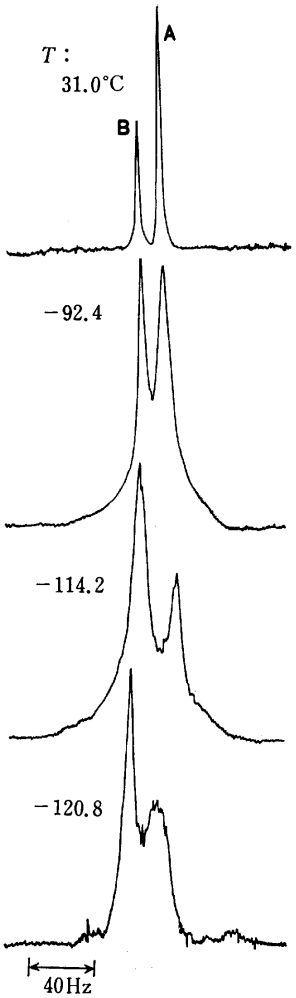


Fig. 1. ^{1}H NMR spectra of *t*-butyl group in **4** at low temperatures.

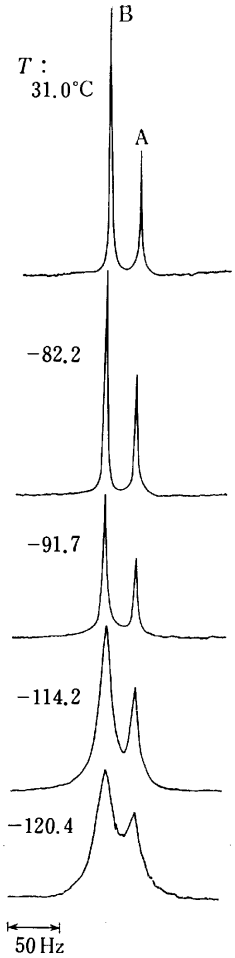

Fig. 2. Temperature-dependent ^{1}H NMR spectra of *t*-butyl group in **5**.

oxycarbonyl groups, and since the bicyclo[2.2.2]octatriene skeleton is very rigid. The spectra obtained are given in Fig. 1. Figure 1 clearly shows that the peak height of the higher field signal of methyl A protons is conspicuously reduced as the temperature is decreased. The peak hieght of the higher field signal of methyl A, which is twice that of the methyl B at room temperature, is almost the same as that of the methyl B at −92.4 °C and becomes a half of it at −114.2 °C. At −120.4 °C, the line width of the A peak is 18 Hz and that of the B peak is 8 Hz. The exceeding peak-height reduction in the signal of the methyl A protons of **4** with the decrease in the temperature clearly shows that the rotation of the methyl A group is strongly restricted at these low temperatures, and that the line-broadening occurs because of the chemical exchange among three *non-equivalent* protons of the methyl group. Figure 1 also shows that the line-broadening in the signal of the methyl B protons occurs to a small extent at such low temperatures. Nevertheless, this fact does not directly indicate a slow rotation of the methyl B group, because the line-broadening in the methoxy protons also occurs and the peak height ratio between the signals of the methyl B and methoxy methyl protons are almost the same at all temperatures. The small line-broadening in the methyl B protons may be due to the high viscosity of the sample and the poor resolution of the NMR measurements at these very low temperatures. The anomalous slow rotation of the methyl A group in **4** indicates that the bis(methoxycarbonyl)etheno bridge is more bulky than the benzo bridge, which is the same conclusion as in the ^{13}C NMR study of the isopropyl analogue.[1]

As an extension of the study of the slow rotation of the methyl groups in **4**, the 9-*t*-butyltriptycene derivatives (**5**) was also investigated, because the steric hindrance in **5** is expected to be large in the triptycene (tribenzo[b,e,h]bicyclo[2.2.2]octatriene) skeleton.[6,7,11] The spectra at low temperatures are shown in Fig. 2. The peak height ratio of the lower-field peak, B, to the higher-field peak, A (the chemical shift δ: 2.296 for B and 2.005 for A from TMS), is 2.0 at 31.0 °C, 1.8 at −91.7 °C, and 1.4 at −120.4 °C. The peak height ratios of the methyl A peak to the bridgehead methine peak (δ: 5.986 from TMS) are almost the same throughout the temperature range from 31.0 °C to −114.2 °C. These facts mean that the line-broadening due to the chemical exchange occurs at the lower-field methyl signal, which is assigned to the methyl B group surrounded by a phenyl ring and a tetrachloro-substituted phenyl ring, as is shown in the Newman projection sheme **7**, on the basis of the line intensities.

This result indicates that the rotation of the methyl B group in **5** is also strongly restricted at the low temperatures, although the degree of the restriction seems to be smaller than in the case of **4**, judging from the apparent line shapes.***

Thus, it was made clear that the rotations of the two methyl groups in the *t*-butyl group in **4** and **5** are strongly restricted at low temperatures. It is worth pointing out, from the results in this study, that, in **4** and **5**, the rotation of the methyl groups β-positioned to the bicyclo[2.2.2]octatriene skeleton is severely restricted by the bulky *peri*-substituents, while in the previously reported compounds **2** (*e.g.*, 1,2,3,4-tetrachloro-9-methyltriptycene) and **3**, the rotation of the α-positioned methyl group is restricted also by the *peri*-substituents.[6-8] In the case of **1** (*e.g.*, 1-*t*-butyl-5,6,7,8-tetrachloro-1,4-dihydro-1,4-epoxynaphthalene), the rotation of the β-positioned methyl group is restricted by the *oxide bridge* instead of the *peri*-substituent in the 1,4-dihydro-1,4-epoxynaphthalene skeleton.[5] This interesting difference may be caused by the variety in the geometries of their different skeletons and the bonded alkyl groups.

*** Strictly speaking, the comparison between the activation parameters of the rotations of the methyl groups in **4** and **5** is impossible at the present time, because we do not know the exact chemical shifts of the three protons of the methyl groups in question, and so no line-shape analyses can be made.

The authors wish to express their hearty thanks to Prof. Michinori Ōki of the University of Tokyo for his helpful discussions.

The Ethylation of Nucleic Acid-Bases with Triethyl Phosphate

Toshizumi TANABE, Kiyoshi YAMAUCHI, and Masayoshi KINOSHITA
Department of Applied Chemistry, Osaka City University, Sumiyoshi-ku, Osaka 558
(Received April 30, 1977)

Uracil, thymine, cytosine, adenine, and guanine were alkylated by triethyl phosphate in a homogeneous aqueous phase at 60—80 °C, giving the corresponding ethyl derivatives in considerable yields. The reactivity order on the ethylating site in each base was found to be as follows; uracil, thymine, and cytosine: N-1>N-3; adenine: N-9≈N-3>N-7, N-1; guanine: N-1>N-7>N-3, N-9.

It has been known that the structural deformation of nucleic acids caused by such alkylating agents as mustards may be relevant to their mutagenic and carcinogenic effects on many living systems. Therefore, the action of various alkylating agents, such as dialkyl sulfates,[1-5] alkyl alkanesulfonates,[3-6] alkyl halides,[5-8] diazoalkanes,[9] and mustards,[10] on nucleic acids and their components has been studied actively.

In previous papers, we reported that trialkyl phosphates were very useful for the *N*-alkylation of nitrogen heterocycles, such as imidazoles,[11,12] pyrimidines,[13] and purines.[14,15] Especially, trimethyl and triethyl phosphates are suited for the alkylation of many natural products because of their moderate reactivity and high solubility in water. In practice, the methylations of nucleic acid-bases with trimethyl phosphate have been carried out successfully in a homogeneous aqueous phase.[16]

While many methylation studies of nucleic acids and their components have been reported, little is known about ethylation. The ethylating reaction has though been reported to show mutagenic effects in some biological systems, and Singer *et al.* indicated that ethyl ethanesulfonate and ethyl methanesulfonate were good mutagenes.[17] Furthermore, Kononova and Gumanov reported that triethyl phosphate (TEP) inactivated phage T4V more readily than did trimethyl phosphate (TMP), although TMP was more mutagenic.[18] Industrially, TEP has been employed as a gasoline additive and a flame retardant for polymers and paints; in addition, TEP has even been proposed as a food additive.

In this regard, we have investigated the ethylation of nucleic acid-bases, such as uracil (**1**), thymine (**2**), cytosine (**3**), adenine (**11**), and guanine (**12**) with TEP in an aqueous phase.

Below we will characterize the products from these reactions. The reaction sites on ethylation will also be compared with those on methylation.

Results and Discussion

The reactions were carried out at 60—80 °C by stirring a mixture of a base and a 2—5 molar excess of TEP in water. (The pH values were 10—10.5 for **1**, **2**, **3**, and **11** and pH 12 for **12**. A relatively high pH value was used for the reaction of **12** in order to obtain a homogeneous solution.) The yields of the products were determined by means of the UV spectra. The products were isolated through extraction and column chromatography and were identified conveniently by means of their UV and NMR spectra. The results are summarized in Tables 1 and 2.

Uracil (1), Thymine (2), and Cytosine (3). Compounds **1** and **2** are generally alkylated with alkyl halide to give 1-alkyl and 1,3-dialkyl derivatives.[19,20] Diazomethane also alkylated **1** to give the corresponding *N*-methyl and *O*-methyl derivatives.[21] We reported previously that trimethyl phosphate (TMP) alkylated these pyrimidines at the N-1 and N-3 positions in almost equal amounts to give 1-methyl, 3-methyl, and 1,3-dimethyl derivatives.[16]

On the other hand, the present reactions of **1** and **2** with TEP gave results different from those of methylations, showing ethylation to take place mainly at the N-1 position. Thus, the reactions of **1** and **2** with TEP afforded the corresponding 1-ethyl derivatives (**4** and **7**) chiefly, along with 3-ethyl derivatives (**5** and **8**) in small yields. When the reaction temperature was raised to 80 °C, 1,3-diethyl derivatives (**6** and **9**) were also produced.

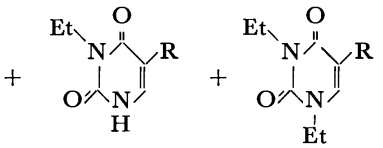
4: R=H
7: R=Me

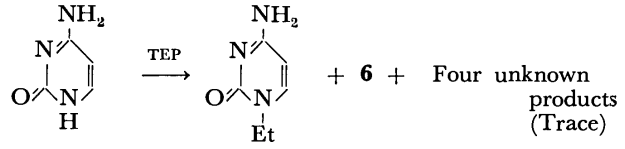


5: R=H
8: R=Me

6: R=H
9: R=Me

In cytosine (**3**), dimethyl sulfate in DMF has been reported to methylate **3** at the N-3 position mainly to give 3-methylcytosine,[1] while TMP has been shown to methylate **3** at the N-1 position predominantly to give 1-methylcytosine.[16]

The present reaction of **3** with TEP at 80 °C afforded six UV absorbing products (**6**, **10**, and four unknown products). Compound **10** was produced mainly and



3 **10**

was identified as 1-ethylcytosine through its physical constants. Compound **6** was produced in a small yield and was identified as 1,3-diethyluracil through its UV

TABLE 1. REACTIONS OF NUCLEIC ACID-BASES WITH TRIETHYL PHOSPHATE (TEP)[a]

9-Ethyladenine	10	6	80	N^6,9-Diethyladenine	4	10

a) Spectroscopic yields.

spectrum. Although 1,3-diethylcytosine was not observed in the reaction mixture, the formation of **6** may be attributed to the rapid alkaline hydrolysis of 1,3-diethylcytosine. In practice, the analogous compound, 1,3-dimethylcytosine, was converted to 1,3-dimethyluracil under similar conditions. The UV spectra of all possible alkyl derivatives of **3** were compared with those of the four unknown products (A-D), but only one compound showed an UV spectrum similar to that of O^2-methylcytosine. Although the alkylation of the cytosine ring at the O^2-atom has not been reported, Singer *et al.* have suggested the possibility of the formation of O^2-ethylcytidine from the reaction of cytidine with ethyl iodide.[5] When the reaction temperature was lowered to 37—60 °C, **10** was formed as the sole product.

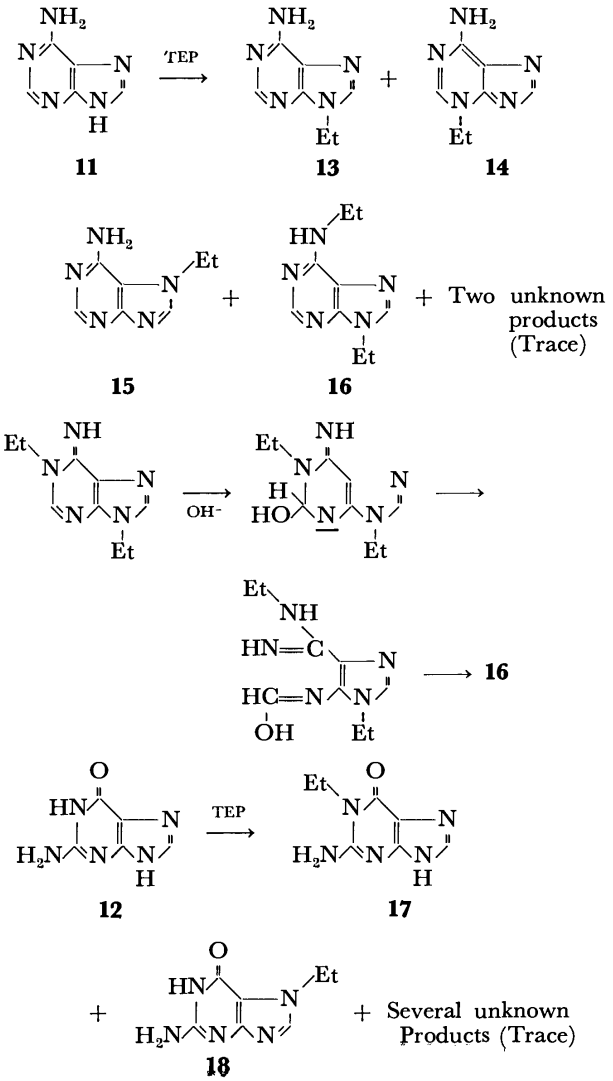
The difficulty of ethylation at the N-3 position of these three pyrimidine bases (**1**, **2**, and **3**) with TEP might be attributed to the steric hindrance on the approach of TEP to the N-3 position by two adjacent carbonyl groups of **1** and **2** and amino and carbonyl groups of **3**. Similar results were shown in the alkylation of xanthine and its derivatives.[15] However, when the reactions were performed at 80 °C, 1-alkylpyrimidines (**4**, **7**, and 1-methylcytosine) reacted with TEP to afford the corresponding 3-ethyl derivatives.

Since the rates of the reactions of **1**, **2**, and **3** were enhanced with the increase in the pH value of the reaction mixture, **1**, **2**, and **3** may react in the anionic form with TEP. The slower reaction of **3** than **1** and **2** may, therefore, be originated by the larger pK_a value of **3** (12.15) than those of **1** (9.46) and **2** (9.90).

Adenine (11) and Guanine (12). These purine bases of nucleic acids have been known to be reactive towards alkylating agents. The alkylations of **11** with various alkylating agents have been studied actively,

and, thanks to these works, **11** has been shown to be alkylated at the N-3 position under neutral conditions,[2,4,22] while under basic conditions the N-9 position was alkylated mainly, with the co-formation of N-3 substituted adenine.[8] However, a reaction of **11** with TMP in a homogeneous alkaline aqueous phase afforded 3-methyl- and 9-methyladenines chiefly in almost equal yields, with the co-formation of small amounts of N^6-methyl- and 7-methyladenines.[16]

The present reaction of **11** with TEP at 80 °C gave six UV absorbing products. Two main products (**13** and **14**) were isolated and identified as 9-ethyl- and 3-ethyladenines respectively through their physical properties. The yield of **13** was a little more than that of **14**. Compounds **15** and **16** were produced in low yields and were identified as 7-ethyl- and N^6,9-diethyladenines through their UV spectra which corresponded excellently to those of 7-methyl- and N^6,9-dimethyladenines. N^6,9-Dialkyladenine was established to be formed by the Dimroth rearrangement of 1,9-dialkyladenine under alkaline conditions.[16] When the reaction temperature was lowered to 37—60 °C, only two products, **13** and **14**, were formed. These results show that the reactivity order of the four nitrogens of **11** is similar to that in the methylation, that is, N-9≈N-3>N-7, N-1.



Although **13**, which is considered as the model of adenosine, was not as reactive as adenine itself, **13** was ethylated with TEP at 80 °C at the N-1 position, which has been established as the most nucleophilic and basic site in 9-alkyladenine. Resulting 1,9-diethyladenine was rearranged *in situ* to give N^6,9-diethyladenine.

On the other hand, only a few studies have been carried out on the alkylation of guanine (**12**); with ethyl ethanesulfonate[4] and dimethyl sulfate,[2] the formation of 7-ethyl- and 7,9-dimethylguanines has been reported. Recently, we reported that **12** was successfully methylated with TMP in water at pH 11—12 to give 1-methylguanine mainly, with the co-formation of 3-methyl-, 7-methyl-, and O^6-methylguanines.[16]

The present reaction of **12** with TEP at 80 °C afforded several UV-absorbing products; the two main products could be identified as 1-ethyl- and 7-ethylguanines (**17** and **18**) through their UV spectra. Compound **17** was produced chiefly at 80 °C, but, at 60 °C, **18** was given as the sole product. Since **12** was consumed for the ethylation reaction in a rate similar to that in the ethylation of **11**, the reactivity of **12** towards TEP may be considered to be almost the same as that of **11**. Compound **17** gradually decreased in quantity with the progress of reaction time; probably it was subsequently ethylated to diethylguanine, which, however, could not be isolated.

Conclusion

TEP was found to react with five nucleic acid-bases in a homogeneous aqueous phase because of its solubility in water. Although TEP was not so reactive as TMP, which reacted with five nucleic acid-bases at 25—37 °C very well, at 60—80 °C five nucleic acid-bases were ethylated with TEP, giving the corresponding ethyl derivatives in yields comparable with those obtained by the use of other ethylating agents.

The reactivity order of five nucleic acid-bases towards TEP was found to be as follows, based on the consumption of the starting materials of the reaction with TEP: adenine (**11**)≈guanine (**12**)>uracil (**1**)≈thymine (**2**)>cytosine (**3**). In each base, ethylation occured in the following order: uracil, thymine, and cytosine: N-1>N-3; adenine: N-9≈N-3>N-7, N-1; guanine: N-1>N-7>N-3, N-9. This reactivity order of bases and sites in each base was almost the same as in the methylation. However, the sterically hindered sites, the N-3 positions of **1**, **2**, and **3**, were less reactive in ethylation than in methylation.

The alkylated bases shown in Table 2, which have alkyl groups in the same position as nucleosides have ribose or deoxyribose, also reacted with TEP to afford the dialkyl derivatives. The reactivity order of these alkylated bases was different from that of the parent bases: 1-ethyluracil (**4**)>1-ethylthymine (**6**)>1-methylcytosine>9-ethyladenine (**13**).

Thus, TEP has a considerable ethylating ability of the base moiety of nucleic acids, therefore, it seems reasonable to pay attention to the use of TEP as an additive for commercial products.

Experimental

The UV and IR spectra were measured with Hitachi EPS-3T and Jasco IR-G spectrometers respectively. The

NMR spectra were recorded on a Hitachi-Perkin Elmer R-20 spectrometer, with a dilute solution in deuterioxide, deuteriochloroform, or trifluoroacetic acid and tetramethylsilane as an internal or an outside standard. Thin-layer chromatography was performed on silica gel [GF_{254} (type 60), Merck] or aluminium oxide [PF_{254} (type 150), Merck] or cellulose [13254, Eastman] using a mixture of chloroform and methanol in the following volume ratio. Solvent A: 10 : 1, B: 5 : 1, C: 5 : 2, or Solvent D: 1-propanol-concentrated ammonium hydroxide–water, 9 : 1 : 3. Column chromatography was carried out using silica gel (Merck, Art. 7734, 70—230 mesh) or cellulose (CF 11, Whatman).

Commercially available uracil (**1**), thymine (**2**), cytosine (**3**), adenine (**11**), and guanine (**12**) as well as TEP were used without further purification.

Ethylation of Uracil (1). *A*: A mixture of **1** (112 mg, 1.0 mmol) and TEP (1.07 g, 6.0 mmol) in water (2.0 ml) was stirred at 80 °C. The solution was maintained at pH 10—10.5 throughout the reaction by the occasional addition of 4M sodium hydroxide. After stirring for 48 h, 3 μl of the reaction mixture was spotted in aluminum oxide thin-layer chromatography. The plate was developed immediately using Solvent A. Three UV-absorbing products (**4**, **5**, and **6**) were observed. (R_f value; **1**: 0.03, **4**: 0.35, **5**: 0.56, **6**: 0.95). Each spot was then scraped individually from the plate to extract the substance on the spot with 4 ml of water. The yield of each product was calculated, by means of a procedure similar to that described in a previous paper,[16] from the absorbancy of the solution; we thus found the yields of **4**, **5**, and **6** were 34, 10, and 7% respectively.

B: A similar reaction of **1** (1.21 g, 10.8 mmol) and TEP (5.35 g, 2.90 mmol) at 60 °C was carried out. After stirring for 48 h, the reaction mixture was neutralized with concentrated hydrochloric acid to give a precipitate of **1**. The mother liquor was then extracted with chloroform. After the solvent had then been removed from the organic layer, the addition of hexane to the residue afforded the crystals of 1-ethyluracil (**4**, 0.05 g, 4%); mp 146—147.5 °C (from THF–ether) (lit,[19] mp 147.5 °C); NMR ($CDCl_3$): 1.28 (t, 3H, $-CH_2CH_3$, J=7 Hz), 3.77 (q, 1H, $-CH_2CH_3$, J=7 Hz), 5.67 (d, 1H, **H**^{5}, J=8 Hz), 7.18 (d, 1H, **H**^{6}, J=8 Hz), and 10.17 ppm (δ) (bs, 1H, N^3–**H**).

Ethylation of Thymine (2). *A*: The treatment of **2** (126 mg, 1.0 mmol) with TEP (1.07 g, 6.0 mmol) in water (2.0 ml) at 80 °C for 48 h gave 1-ethylthymine (**7**, 34%), 3-ethylthymine (**8**, 12%), and 1,3-diethylthymine (**9**, 6%), whose yields were calculated in a way similar to that used in the ethylation of **1**. (R_f value on aluminumn TLC using Solvent A; **2**: 0.06, **7**: 0.49, **8**: 0.65, **9**: 0.98)

B: The isolation of 1-ethylthymine (0.08 g, 5%) was carried out in a manner similar to that used for 1-ethyluracil after a mixture of **2** (1.30 g, 10.30 mmol) and TEP (5.35 g, 29.0 mmol) in water (10 ml) had been stirred for 48 h at 60 °C; mp 220—222 °C (from THF–ether) (lit,[23] mp 223 °C); NMR ($CDCl_3$) 1.42 (t, 3H, $-CH_2CH_3$, J=7 Hz), 2.02 (d, 3H, $-CH_3$, J=1.2 Hz), 3.88 (q, 2H, $-CH_2CH_3$, J=7 Hz), 7.09 (d, 1H, **H**^{6}, J=1.2 Hz), and 9.90 ppm (δ) (bs, 1H, N^3–**H**).

Ethylation of Cytosine (3). *A*: A mixture of **3**(111 mg, 1 mmol) and TEP (1.07 g, 6.0 mmol) in water (2 ml, pH 10—10.5, NaOH) was stirred at 80 °C for 48 h. The reaction mixture (4 μl) was then developed on a silica gel TLC using Solvent C, giving the following spots. R_f value; **3**: 0.18, **6**: 0.76, **10**: 0.45, unknown A: 0.73, B: 0.57, C: 0.49, D: 0.23. A treatment similar to that used in the ethylation of **1** showed that the yields of **10** and **6** were 17 and 3% respectively.

B: A mixture of **3** (1.0 g, 9.0 mmol) and TEP (5.25 g, 29.0 mmol) in water (15 ml, pH 10, NaOH) was stirred at 60 °C for 48 h. The subsequent neutralization of the reaction mixture with concentrated hydrochloric acid gave the precipitate of **3**. After the precipitate had been filtered out, the mother liquor was extracted with chloroform to remove the unreacted TEP. The water layer was concentrated to give a residue, which was subsequently mixed with ethanol to remove any undissolved substances. The residue which was obtained after concentrating the alcoholic solution was treated by silica gel column chromatography (1.5×60 cm). Elution with Solvent C provided the salt of 1-ethylcytosine with diethyl hydrogen phosphate (0.54 g). The salt was subsequently treated with an anionic exchange resin (Dowex 1×8, 200—400 mesh, OH form). Elution with water gave the free form of 1-ethylcytosine (**8**, 0.16 g, 13%); mp 236—238 °C (sublime) (lit,[24] 245—246 °C); NMR (D_2O): 1.22 (t, 3H, $-CH_2CH_3$, J=7 Hz), 3.76 (q, 2H, $-CH_2CH_3$, J=7 Hz), 5.95 (d, 1H, **H**^{5}, J=8 Hz), and 7.58 ppm (δ) (d, 1H, **H**^{6}, J=8 Hz); Found: C, 51.75; H, 6.31; N, 30.51%, Calcd for $C_6H_9N_3O_1$: C, 51.78; H, 6.52; N, 30.20%.

Ethylation of Adenine (11). A: Compound **11** (135 mg, 1 mmol) and TEP (1.07 g, 6.0 mmol) were stirred in water (2 ml, pH 10—10.5, NaOH) for 48 h at 80 °C. The reaction mixture (4 μl) was then developed on silica gel TLC, using Solvent B, to give the following spots. R_f value; **11**: 0.32, **13**: 0.57, **14**: 0.42, **15**: 0.23, **16**: 0.66, unknown E: 0.10, F: 0.14. Calculations from the absorbancy of the solution of each spot similar to that described above showed the yields of **13**, **14**, **15**, and **16** to be 39, 29, 6, and 3% respectively.

B: A mixture of **11** (1.35 g, 10.0 mmol) and TEP (5.25 g, 29.0 mmol) was stirred in water (10 ml, pH 10, NaOH) at 60 °C for 48 h. The reaction mixture was then neutralized with concentrated hydrochloric acid and extracted with hexane to remove any unreacted TEP. The water layer was concentrated to give a residue, which was subsequently mixed with ethanol to remove any undissolved substances. The residue which was obtained after concentrating the alcoholic solution was then treated by silica gel column chromatography (1.5×60 cm). Elution with Solvent B provided 9-ethyladenine (**12**, 0.42 g, 26%) and then 3-ethyladenine (**13**, 0.24 g, 15%); **12**: mp 202—203 °C (from ethanol) (lit,[25] mp 194—195 °C); NMR ($CDCl_3$): 1.58 (t, 3H, $-CH_2CH_3$, J=7 Hz), 4.25 (q, 2H, $-CH_2CH_3$, J=7 Hz), 6.39 (bs, 2H, $-NH_2$), 7.79 (s, 1H, **H**^{2}), and 8.32 ppm (δ) (s, 1H, **H**^{8}); **13**: mp 233—234 °C (from ethanol) (lit,[26] mp 233 °C); NMR (D_2O): 1.34 (t, 3H, $-CH_2CH_3$, J=7 Hz), 4.13 (q, 2H, $-CH_2CH_3$, J=7 Hz), 7.67 (s, 1H, **H**^{2}), and 7.95 ppm (δ) (s, 1H, **H**^{8}).

Ethylation of Guanine (12). *A*: After **12** (151 mg, 1 mmol) had been dissolved in water (2 ml, pH 13) at 80 °C, TEP (1.07 g, 6.0 mmol) was added. Soon after the reaction began, the pH of solution dropped to 11—12; this value was maintained by the occasional addition of 4M sodium hydroxide. The reaction mixture (4 μl) was developed on silica gel TLC, using Solvent A, to give the following spots: R_f value; **12**: 0.00, **17**: 0.21, **18**: 0.24, six minor unknown products: 0.03, 0.12, 0.32, 0.35, 0.45, 0.74. After a treatment similar to that described above, the yields of **17** and **18** were found to be 28 and 17% respectively.

B: A mixture of **12** (1.25 g, 8.30 mmol) and TEP (5.25 g, 29 mmol) in water (50 ml, pH 11—12, NaOH) was stirred for 48 h at 60 °C. The reaction mixture was then extracted with chloroform to remove any unreacted TEP. The water layer was concentrated to give a residue, which was subsequently treated by a cellulose column chromatography (2.5×60 cm).

Elution with Solvent D provided a viscous liquid which was crystalized by the addition of a small amount of water and identified as 7-ethylguanine through its UV spectra (**18**, 0.075 g, 5%); mp>300 °C dec; NMR (CF_3CO_2H): 1.14 (t, 3H, $-CH_2CH_3$, J=7 Hz), 4.15 (q, 2H, $-CH_2CH_3$, J=7 Hz), and 8.34 ppm (δ) (s, 1H, H^8).

The Sensitized Photooxygenation of 2-Vinylbenzofurans

Masakatsu MATSUMOTO, Satoshi DOBASHI, and Kiyosi KONDO
Sagami Chemical Research Center, Nishi-Ohnuma, Sagamihara, Kanagawa 229

(Received May 4, 1977)

The sensitized photooxygenation of benzofuran, 2-methylbenzofuran, and six 2-vinylbenzofurans was investigated. Benzofuran and 2-methylbenzofuran were stable toward singlet oxygen. On the other hand, the vinylbenzofurans were easily photooxygenated to give the 1,4-endoperoxides. The 1,4-cycloaddition of singlet oxygen to the 2-benzofurans was confirmed to proceed with stereospecificity.

Recently, it has been found that, for some styrene derivatives[1] and vinyl-substituted polynuclear aromatic hydrocarbons,[2] an aromatic double bond in conjugation with extranuclear unsaturation produces an active diene system capable of undergoing the 1,4-cycloaddition of singlet oxygen. Vinyl-substituted heteroaromatics such as 2-vinylthiophene[3] and 1-methyl-3-vinylindoles,[4] have also been found to undergo the 1,4-cycloaddition of singlet oxygen. On the other hand, such aromatics as benzene, naphthalene, phenanthrene, and thiophene are themselves known to be stable to singlet oxygen.[5] Of the heteroaromatics, furans have been most intensively studied in connection with their photooxygenation, though their benzo analogs, *i. e.*, benzofurans, have scarcely been known to undergo any sensitized photooxygenation.[5] We have studied here the sensitized photooxygenation of **1** benzofurans and 2-vinylbenzofurans, **2**, in order to investigate the reactivities of the 2,3-double bond of the ring and a conjugated system composed of the 2-vinyl group and the 2,3-double bond of these aromatics.

Results and Discussion

Preparation of 2-Vinylbenzofurans. Of six vinylbenzofurans, **2**, used in this work, 2-(2-methyl-1-propenyl)- (**2a**), *trans*-2-styryl- (**2c**), *cis*-2-styryl- (**2d**), and 2-isopropenylbenzofuran (**2f**) were prepared by the Witting reaction of 2-formylbenzofuran or 2-acetylbenzofuran and the corresponding methylenetriphenylphosphoranes. The other two, 2-vinyl- (**2b**) and 2-(1-phenylvinyl)benzofuran (**2e**) were obtained by the dehydration of the corresponding alcohols which themselves had been prepared from 2-acetylbenzofuran. The preparations of these vinylbenzofurans were described in detail in the Experimental Section.

Sensitized Photooxygenation of 2-Vinylbenzofurans

First, the sensitized photooxygenation of benzofuran (**1a**) and 2-methylbenzofuran (**1b**) as typical examples of 2- and 3-alkyl-substituted benzofurans were examined. When 2-methylbenzofuran (**1b**) was photooxygenated for 3 h as in the cases of the vinylbenzofurans **2** described below, scarcely no oxygen was consumed and the starting material was recovered. Benzofuran (**1a**) itself was also fairly stable under similar irradiation conditions. These results showed that, for benzofurans, the 2,3- double bond is more stable than for indoles,[6] though 2,3-dimethylbenzofuran (**1c**) has been known to be the only substance to undergo the 1,2-addition of singlet oxygen to give *o*-acetoxyacetophenone.[7]

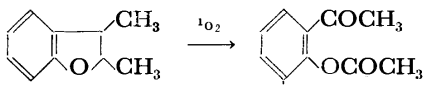
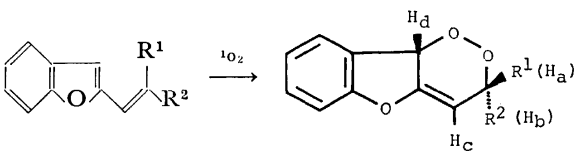
1b: R=CH_3



1c

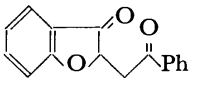
Second, the sensitized photooxygenation of 2-vinylbenzofurans **2** was carried out. A solution of 2-(2-methyl-1-propenyl)benzofuran (**2a**) and tetraphenylporphine (TPP) (used as a sensitizer) in carbon tetrachloride was irradiated externally with low-pressure sodium vapor lamps under an oxygen atmosphere at 5 °C. After the irradiation, the photolysate was condensed and purified by chromatography on silica gel to give a 1,4-endoperoxide **3a** as colorless plates in a 90% yield. The structure of **3a** was assigned on the basis of spectral evidence and combustion analyses. In this examination, scarcely no 1,2-cycloaddition of singlet oxygen to the 2,3-double bond of the side chain or the "ene" reaction was observed. The similar photooxygenation of 2-vinylbenzofuran (**2b**) afforded the corresponding 1,4-endoperoxide **3b** as an oil in a 41% yield. Then, in order to investigate the stereochemical features of the 1,4-cycloaddition of singlet oxygen to 2-vinylbenzofurans **2**, *trans*-2-styrylbenzofuran (**2c**) and its *cis*-isomer **2d** were individually photooxygenated under similar conditions. The *trans*-isomer **2c** gave the corresponding 1,4-endoperoxide **3c** in a 70% yield. On the other hand, the peroxide **3d** was obtained from the *cis*-isomer in a 75% yield. The olefin **2c** gave no **3d**, whereas the isomer **2d** gave no **3c**. Consequently the results obtained here confirm that the 1,4-cycloaddition of singlet oxygen to 2-vinylbenzofurans **2** proceeds with stereospecificity.



2a: R^1, R^2=CH_3
2b: R^2, R^2=H
2c: R^1=H, R^2=C_6H_5
2d: R^1=C_6H_5, R^2=H

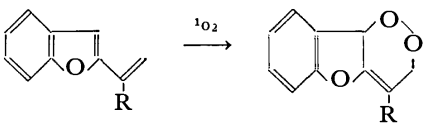
3a: R^1, R^2=CH_3
3b: R^1, R^2=H
3c: R^1=H, R^2=C_6H_5
3d: R^1=C_6H_5, R_2=H

The endoperoxides **2a**—**d** were thermally stable, but were easily changed under basic conditions. When the peroxide **3c** was treated with a catalytic amount of triethylamine in ether at an ambient temperature, 2-benzoylmethyl-3(2*H*)-benzofuranone (**4**) was obtained in a 58% yield.



4

The 1,4-cycloaddition of singlet oxygen has been found to take place with 1-vinylnaphthalenes,[2a] 9-vinylphenanthrenes,[2b] and 2-vinylthiophenes[3] bearing no substituent and a β-substituent on the side chain. An α-substituent of these aromatics has been known to cause significantly different results; for the naphthalene or the phenanthrene derivatives, no 1,4-cycloaddition but "ene" reaction of singlet oxygen occurs,[2] hereas, for the vinylthiophenes, both the 1,4-cycloaddition and the "ene" reaction occur competitively.[3] The 2-vinylbenzofurans **2** seemed to behave much like the 2-vinylthiophenes in the reaction with singlet oxygen. When 2-(1-phenylvinyl)benzofuran **2e** was photooxygenated as in the cases described above, the corresponding peroxide **3e** was formed. A similar irradiation of 2-isopropenylbenzofuran (**2f**) also gave the expected peroxide **3f**. Neither peroxide **3e** or **3f** could be isolated in a pure form because of their instabilities. In particular, the former, **3e**, was highly explosive. These differences between a pair of 2-vinylthiophenes and 2-vinylbenzofurans **2**, and a pair of 1-vinylnaphthalenes and 9-vinylphenanthrenes may be due to steric and electronic factors. For the vinylnaphthalenes and vinylphenanthrenes with an α-substituent on the side chain, a steric repulsion between the 8-hydrogen and the α-substituent may hinder the favorable conformation of the side chain for 1,4-cycloaddition, though this hindrance seems to be overcome at higher temperatures.[8] On the other hand, in the cases of 2-vinylthiophenes and 2-vinylbenzofurans **2** such steric repulsion need not be considered and carbons in both the β-position of the side chain and the 3-position of the aromatic nucleus may be activated toward electrophiles, such as singlet oxygen, more than the corresponding carbons in the naphthalene or phenanthrene analogs, by the sulfur or the oxygen atom. These suggestion may be supported by the fact that maleic anhydride reacts more easily with **2e** and **2f** (in refluxing benzene)[9b] than with naphthalene and phenanthrene analogs (in refluxing xylene).[8]



2e: R=C_6H_5 **3e**: R=C_6H_5
2f: R=CH_3 **3f**: R=CH_3

In summary, we have found that, for 2-vinylbenzofurans **2**, the 2,3-double bond, which is scarcely active itself in response to singlet oxygen, in conjugation with 2-ethylenic double bond produces an active diene system capable of undergoing the 1,4-cycloaddition of singlet oxygen.

Experimental

All the melting points and boiling points are uncorrected. The NMR spectra were recorded with a Varian HA-100 spectrometer, with TMS as the internal standard. The

NMR spectral data of the peroxide **3** are summarized in Table 1. The mass spectra were obtained with a Hitachi RMU-6E spectrometer. The light source was consisted of eight 60-W low pressure sodium-vapor lamps (National SOI-60).

*Preparation of 2-Methylbenzofuran (**1b**).* To a solution of coumarone (1.18 g, 10 mmol) in tetrahydrofuran (THF) (30 ml) was added 10 mmol of *n*-butyllithium (6.4 ml of a 10% hexane solution) under an argon atmosphere at room temperature. After 30 min, methyl iodide (1.42 g, 10 mmol) in THF (5 ml) was added to the solution of the carbanion of coumarone, and the mixture was stirred for 1 h. After the usual work-up, the crude product was purified by chromatography on silica gel. The furan **1b** was obtained as a colorless oil [bp 195 °C (lit,[10] bp 192 °C/744 mmHg)] in an 81% yield (1.07 g)

*Preparation of 2-(2-Methyl-1-propenyl)benzofuran (**2a**).* Under an argon atmosphere, to a solution of isopropylidenetriphenylphosphorane (prepared from 10 mmol of isopropyltriphenylphosphonium bromide and an equimolar amount of *n*-butyllithium) in THF (20 ml) was added 2-formylbenzofuran (1.46 g, 10 mmol) at an ambient temperature. After 1 h, the reaction mixture was poured into brine and extracted with hexane. The hexane solution was dried over $MgSO_4$ and condensed. The residue was chromatographed on silica gel and eluted with hexane to yield 1.35 g of the furan **2a** (78%) (colorless needles; mp 48—49.5 °C, from hexane); IR (KBr): 3027, 1660, 1455, 1258, 1194, 940, 750 cm^{-1}; NMR (CCl_4): δ 1.92 (s, 3H), 2.08 (s, 3H), 6.07 (m, 1H), 6.34 (s, 1H), 6.9—7.5 (m, 4H) ppm.

*Preparation of 2-Vinylbenzofuran (**2b**).* 2-Acetylbenzofuran[11] (3.6 g, 23 mmol) was reduced as usual with lithium aluminium hydride (0.4 g, 10 mmol) in dried ether (15 ml) overnight at room temperature to give 2-(1-hydroxyethyl)-benzofuran. The crude alcohol was dehydrated with alumina (Woelm neutral, for column chromatography) at 140 °C (bath temperature). Thus, **2b** was obtained as a colorless oil [bp 52 °C/2 mmHg (lit,[9b] 50 °C/0.1 mmHg)] in a 62% yield; IR (liquid film): 3050, 1548, 1452, 1255, 980, 910 cm^{-1}; NMR (CCl_4): δ 5.22 (d of d, J=11.0 and 2.0 Hz, 1H) 5.84 (d of d, J=18.0 and 2.0 Hz, 1H), 6.38 (s, 1H), 6.47 (d of d, J=18.0 and 11.0 Hz, 1H), 6.9—7.5 (m, 4H) ppm

Preparation of trans-*2-Styrylbenzofuran (**2c**) and* cis-*2-Styrylbenzofuran (**2d**).* To a solution of benzylidenetriphenylphosphorane (prepared from 10 mmol of benzyltriphenylphosphonium bromide and an equimolar amount of *n*-butyllithium in THF was added 2-formylbenzofuran (1.46 g, 10 mmol) under an argon atmosphere at room temperature. The reac-

tion mixture was then treated as in the case of **2a** to give a mixture of **2c** and **2d** (**2c**/**2d**=71/29, 1.30 g). The separation of the mixture was performed by chromatography on silica gel in hexane.

2c: Colorless crystals (mp 123 °C) from ethanol; IR (KBr): 3050, 1444, 1255, 960, 945, 805 cm^{-1}, NMR (CCl_4): δ 6.49 (s, 1H), 6.82 (d, J=16.0 Hz, 1H), 6.9—7.5 (m, 10H) ppm.

2d: A colorless viscous oil; IR (liquid film): 3050, 1452, 1260, 945, 810 cm^{-1}; NMR (CCl_4): δ 6.42 (s, 1H), 6.46 (q_{AB}, J_{AB}=13.0 Hz, 2H), 6.9—7.5 (m, 9H) ppm.

Preparation of 2-(1-Phenylvinyl)benzofuran (2e). To a solution of phenylmagnesium bromide (prepared from 25 mmol of bromobenzene and an equimolar amount of magnesium) in ether was added 2-acetylbenzofuran 3.0 g, 19 mmol) under an argon atmosphere. The usual work-up afforded the crude 2-(α-hydroxy-α-methylbenzyl)benzofuran, which was subsequently dehydrated with phosphorus pentaoxide in ether at room temperature for 2 h. The ether solution was then washed with water and dried over $MgSO_4$. After the evaporation of ether, the crude product was chromatographed on silica gel in hexane to give **2e** as a pale yellow oil in a 43% yield: the spectral data were identical with those in the literature.[9b]

2-Isopropenylbenzofuran (2f) was prepared by a Witting reaction of 2-acetylbenzofuran and methyltriphenylphosphonium bromide in accord with the method described in the literature,[9a]

Irradiation of Benzofuran (1a) and 2-Methylbenzofuran (1b). A solution of 1.00 g of **1a** and 5 mg of TPP in CCl_4 (60 ml) was irradiated under an oxygen atmosphere at 5 °C for 3h. Scarcely no oxygen was consumed, and no products were observed by TLC. The furan (**1b**) was also stable under similar irradiation conditions.

Photooxygenation of 2-(2-Methyl-1-propenyl)benzofuran (2a). A solution of 1.35 g (8 mmol) of **2a** was photooxygenated in 60 ml of CCl_4 until 158 ml of oxygen has been consumed (30 min). After the removal of the solvent, the photolysate was chromatographed on silica gel and eluted with a hexane $-CH_2Cl_2$ (1 : 1) mixture to give 1.42 g of the endoperoxide **3a** (colorless plates (mp 107.5—109.0 °C) from ether) (90% yield); IR (KBr): 3070, 2973, 1610, 1460, 1088, 1043, 760 cm^{-1}; MS *m/e*: 204 (M^+, 15), 172 (100), 161 (55), 157 (33), 131 (24), 77 (25), 43 (61).

Found: C, 70.53; H, 5.93%. Calcd for $C_{12}H_{12}O_3$: C, 70.58; H, 5.92%.

Photooxygenation of 2-Vinylbenzofuran (2b). A solution of 1.0 g (7 mmol) of **2b** and 5 mg of TPP in 60 ml of CCl_4 was irradiated for 3.5 h (O_2 uptake=129 ml). The photolysate was then condensed and chromatographed on alumina (Woelm neutral) previously treated with 20% water. Elution with hexane gave 0.50 g (41%) of the peroxide **3b** as an oil: IR (liquid film): 3050, 1610, 1460, 1095, 1050, 750, 740 cm^{-1}; MS *m/e*: 176 (M^+, 18), 147 (100), 146 (51), 134(85).

Photooxygenation of trans-*2-Styrylbenzofuran (2c).* A solution of 0.93 g (4 mmol) of **2c** and TPP in 60 ml of CCl_4 was irradiated for 3 h (O_2 uptake=91 ml). The chromatographic purification of the photolysate on silica gel in a hexane $-CH_2Cl_2$ (1 : 1) mixture afforded 0.74 g (70%) of the peroxide **3c** (colorless needles (mp 75.5—76.5 °C) from ether); IR (KBr): 3050, 1610, 1460, 1092, 1050, 755, 739, 695 cm^{-1}; MS *m/e*: 252 (M^+, 15), 220 (100), 147 (24), 105 (45), 77 (54), 51 (26).

Found: C, 76.58; H, 4.63%. Calcd for $C_{16}H_{12}O_3$: C, 76.18; H, 4.79%.

Photooxygenation of cis-*2-Styrylbenzofuran (2d).* A solution of 0.24 g (1 mmol) of **2d** and TPP in 60 ml of CCl_4 was photooxygenated for 2.5 h. After the irradiation, the photolysate was treated as in the case of **2c** to give 0.19 g (75%) of the peroxide **3d** (colorless granules, mp 115.0—116.5 °C) from ether; IR (KBr): 3040, 1622, 1465, 1095, 1045, 750, 700 cm^{-1}; MS *m/e*: 252 (M^+, 9), 220 (100), 105 (27), 77 (49), 51 (26).

Found: C, 75.83; H, 4.96%. Calcd for $C_{16}H_{12}O_3$: C, 76.18; H, 4.79%.

Photooxygenation of 2-(1-Phenylvinyl)benzofuran (2e). A solution of 1.10 g (5 mmol) and TPP in CCl_4 (70 ml) was oxygenated for 1 h. After the removal of CCl_4, the reaction mixture was chromatographed on silica gel and eluted with CH_2Cl_2 to give a viscous oil of the peroxide **3e** (10% yield), which crystallized on standing and exploded when subjected to weak friction; NMR (CCl_4): δ 4.29 (q_{AB}, J=15.0 Hz, 2H), 6.22 (s, 1H), 6.7—7.6 (m, 9H) ppm.

Photooxygenation of 2-Isopropenylbenzofuran (2f). A solution of 1.0 g (6 mmol) of **2f** and TPP in CCl_4 (60 ml) was irradiated for 3.5 h. The NMR spectrum (CCl_4) of the crude photolysate revealed the formation of the corresponding endoperoxide **3f**; δ 1.70 (s with fine coupling, 3H, CH_3), 4.56 (q_{AB} with fine coupling, J=15 Hz, 2H, $-CH_2O-$), and 6.20 (m, 1H, $-CHO-$)ppm. All the efforts to purify **3f** by chromatography on silica or alumina were unsuccessful; when the photolysate was adsorbed on the absorbent, immediately an exothermic reaction was occurred to give complex products.

Isomerization of the Peroxide 3c. Triethylamine (100 mg) was added to a solution of 350 mg of the peroxide **3c** in 10 ml of ether and the mixture was stirred for 20 min at an ambient temperature. Then, the mixture was condensed and chromatographed on silica gel. Elution with CH_2Cl_2 gave 200 mg of 2-benzoylmethyl-3(2*H*)-benzofuranone (**4**) as pale yellow granules (mp 113 °C, from ether); IR (KBr): 3070, 2930, 2900, 1725, 1710, 1687, 1615 cm^{-1}; MS *m/e*: 252 (M^+, 25), 147 (38), 105 (100), 77 (45); NMR ($CDCl_3$): δ 3.55 (m, 2H), 5.08 (m, 1H), 6.9—8.0 (m, 9H) ppm.

Found: C, 76.07; H, 4.96%. Calcd for $C_{16}H_{12}O_3$: C, 76.18; H, 4.79%.

Odor and Volatile Compounds in Liquid Swine Manure. II. Steam-distillable Substances

Akio YASUHARA* and Keiichiro FUWA**

Division of Chemistry and Physics, National Institute For Environmental Studies, Yatabe, Tsukuba, Ibaraki 300-21

***Faculty of Science, University of Tokyo, Hongo, Bunkyo, Tokyo 113*

(Received May 18, 1977)

Many aliphatic hydrocarbons, nitrogen-containing compounds, and other substances were isolated from neutral or alkaline liquid swine manure by steam distillation and column chromatography, and identified by means of gas chromatography-mass spectrometry. Aliphatic hydrocarbons have an oily odor, and nitrogen-containing substances, particularly indole, skatole, and *o*-aminoacetophenone, have a strong malodor. Sulfur-containing substances which have a strong malodor have been detected in a trace quantity.

Malodor has been the most frequent nuisance except noise in Japan. Swine buildings are among the most important sources of this malodor. Liquid swine manure evolves a very strong and offensive odor, mainly by means of an anaerobically microbial decomposition. Only a little knowledge has been obtained about the chemical nature of the odor of liquid swine manure. Seventeen carboxylic acids and four phenols in acidic liquid swine manure have been reported in a previous paper.[1] The odor of neutral or slightly alkaline swine manure is different from that of acidic swine manure. Anaerobically decomposed liquid swine manure shows a neutral or slightly alkaline nature. It has been thought that amines and sulfur-containing compounds play an important role with regard to malodor.[2,3] Steam distillation is a useful method to isolate volatile compounds containing odorous substances, although it is apt to lose very volatile compounds such as lower amines, or to decompose unstable substances such as sulfur-containing material.

This paper will deal with the separation by steam distillation and column chromatography of odorous components in neutral or slightly alkaline liquid swine manure, and with the results of the application of gas chromatography-mass spectrometry and the organoleptic technique to the determination of the compounds most responsible for the malodor.

Experimental

Gas Chromatography. A Shimadzu Model GC-5A gas chromatograph was equipped with dual-flame ionization detectors, a matrix temperature programmer, a dual-pen recorder, and a Takeda Riken *-tr-*2215 A digital integrator. The flame detectors were operated at a hydrogen-flow rate of 50 ml/min and an air-flow rate of 0.5 l/min. Some apparatus was also used for the organoleptic tests, as will be described below. The gas-chromatographic conditions were as follows: injector and detector temperatures, 300 °C; column temperatures for Fraction **A**, 80 °C for a minute, followed by an increase to 280 °C at a rate of 2 °C/min, and then held at 280 °C for 30 min; column temperatures for the other fractions, 70 °C for 3 min, followed by an increase to 270 °C at a rate of 8 °C/min, and then held at 270 °C until the completion of the analysis; carrier-gas (nitrogen) flow rate, 43 ml/min at 5 kg/cm² for Fraction **A** or 20 ml/min at 5 kg/cm² for the other fractions. A 3 m×3 mm i.d. glass column packed with 5% Silicone SE-30 on 60- to 80-mesh, acid-washed, DMCS-treated Chromosorb W was used.

Mass Spectrometry. A JEOL Model JMS-D 100 mass spectrometer was connected with a JEOL JGC-20 K gas chromatograph and a JEOL JMA-2000 data-treatment system. The gas-chromatographic conditions were the same as above except for the size of the column. A 3 m×2 mm i.d. glass column packed with 5% Silicone SE-30 on 60- to 80-mesh, acid-washed, DMCS-treated Chromosorb W was used. The mass-spectrometric conditions were as follows: ion-source temperature, 135 °C; ionizing current, 3×10^{-4} A; ionizing voltage, 25 V; accelerating voltage, 3 kV; scan range, *m/e* 35 to 400; scan time, 2.1 s; scan interval, 5 s. The data-treatment procedures were the addition of the mass spectra on several scans, the subtraction of the integrated background-mass spectra from the added mass spectra, and normalization by means of the most intense peak.

Organoleptic Test. This test was carried out by smelling the odor of compounds progressively eluted from the outlet of the gas chromatograph, which was modified as follows in order to study the quality of odors: the gas eluted from the end of the column was divided into two streams in a 10 : 1 ratio, a eleventh of the gas was led into the flame-ionization detector, and ten elevenths of the gas was emitted from the outlet of gas chromatograph for smelling. A 3 m× 3 mm i.d. stainless column was used for this test.

Sampling Procedure and Fractionation. The experiments reported here were performed using accumulated liquid swine manure collected from pits under confinement swine buildings near Takezono, Tsukuba New Town, Ibaraki, Japan The liquid manure (52 l) was steam-distilled. The distillate was saturated with sodium chloride and extracted two times with

dichloromethane. The extract was evaporated by means of a Kvrderna-Danish concentrator under atmospheric pressure. The concentrated residue was dissolved in ether (50 ml), and the solution was washed with an aqueous solution of sodium hydroxide in order to eliminate the phenol compounds. The solution was then concentrated and chromatographed over silica gel (60 g) (Wako Gel obtained from Wako Pure Chemicals Industries). As elution solvents, hexane, benzene, and ether were used. Each fraction was chromatographed again over neutral alumina (90 g), obtained from the Merck Co., Ltd. The details of the first and second chromatographies are shown in Table 1.

Results and Discussion

The steam-distillate had a malodor, but it was relatively different from the odor of neutral or slightly alkaline liquid swine manure. It is considered that lower aliphatic amines might be lost and some sulfur-containing compounds might decompose during steam distillation. Fractions **A**, **C**, **D**, **F**, and **G** have a malodor. Figures 1 to 7 show gas chromatograms of Fractions **A**, **B**, **C**, **D**, **E**, **F**, and **G** respectively. A large quantity of extracted matter was contained in Fractions **A** and **C**.

The components included in each fraction were identified by gas chromatography-mass spectrometry. No other identification method such as IR, NMR, and UV, has been practical because of the small quantity of extracted matter and the difficulty of separating components of a similar chemical nature. Fraction **A** had a roasted rubber-like or oily odor, and it consisted mainly of alkanes whose origins were unknown. Table 2 shows the results of the identification of Fraction **A** and the content ratio of each component, which was calculated from the areas of the peaks on the gas chromatogram, corrected by the relative sensitivity of each normal alkane against the gas-chromatographic detector. 2,6-Di-*t*-butyl-*p*-cresol, only a little of which was present in Fraction **A**, was the main component in Fraction **B**; its presence in liquid swine manure has already been reported in a previous paper.[1] From the mass spec-

trum normal alkanes can be distinguished from isoalkanes, but structure determinations of the isoalkanes are almost impossible using only the mass spectra.

Table 3 shows the results of the identification of Fractions **C** to **G**. Fraction **C** consisted almost entirely of indole and skatole, which are well-known to have a fecal odor and which had already been detected in liquid animal manure.[4] However, the odors of indole and skatole are quite different from that of the swine manure, although they are thought to contribute to the total odor of the swine manure. Fraction **D** contained some aldehydes besides indole and skatole. However, the aldehydes did not play any role in the odor of swine manure. Fraction **E** consisted exclusively of dibutyl phthalate (DBP), which was also confirmed, with a peak enhancement, by the co-injection of an authentic substance into the gas chromatograph. DBP is an odorless compound and a well-known pollutant; thus, its origin in liquid swine manure may not be a metabolic process, but, rather, it may be a pollution from the synthetic polymers.

Fractions **F** and **G** had a characteristic and tenacious malodor. The organoleptic test showed that a compound with a peak number of 29 had the odor. It was concluded from its mass spectrum to be aminoacetophenone. Further, it was confirmed to be *o*-aminoacetophenone by means of a comparison with an authentic substance using gas chromatography. As the odor of this compound has been recognized for the first time by column chromatography, it must fuse with odors of other odoriferous substances to become a new malodor. Many components in Fractions **F** and **G** could not be identified by mass spectrometry alone.

Trace components which did not appear as peaks in the gas chromatograms with the detector's gain,

Effects of Neighboring Functional Groups in the Asymmetric Reduction of ω-Substituted Alkyl Phenyl Ketones with Lithium Tri-*l*-Menthoxyaluminum Hydride[1]

Shozo YAMAGUCHI and Kuninobu KABUTO

Department of Chemistry, College of General Education, Tohoku University, Kawauchi, Sendai 980

(Received May 25, 1977)

In the enantioselective reduction of ω-substituted alkyl phenyl ketones, $PhCO(CH_2)_nY$, with lithium tri-*l*-menthoxyaluminum hydride, the effect of the functional groups, $Y(NR_2$, OMe, and SMe) on the stereoselectivity was examined in comparison with that of the alkyl group. Of the functional groups tested, the MeO group is more effective in enhancing the stereoselectivity than the NMe_2 or SMe group except in the case of $n=1$. The optical yields are also affected by the number of the methylene group (n) in the substrates. These results strongly suggest that the coordination of the Y group with the reducing reagent is one of the essential factors in the stereoselectivity. The absolute configurations of the resulting alcohols are correlated with the relative magnitudes of the lanthanide-induced shifts(LIS) of their (+)-MTPA esters.

There have been many studies[2] of the asymmetric reduction of achiral ketones with lithium aluminum hydride modified by chiral reagents. Although some systematic studies[3] have been done in exploring effective chiral ligands, attention has so far been mostly focused on the steric effects of the substituents around the chiral center on the asymmetric bias. Mosher and his co-workers have developed the LAH–chiral amino alcohol complexes,[4] which give excellent asymmetric yields of as much as 75% in the reduction of acetophenone. They explained this high stereoselectivity in terms of a rigid conformation of the chiral hidride reagent as a result of the coordination of such functional groups as NMe_2 in the chiral ligand with Li^+. A similar coordinating effect has also been reported[5] in the asymmetric reduction with LAH–*N*-(*o*-substituted benzyl)-α-methylbenzylamine complexes.

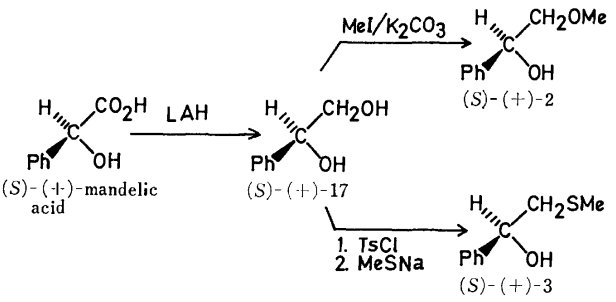
On the other hand, in order to conduct the asymmetric reduction of the substrates with functional groups effectively, it is necessary to get information on the effect of the functional group on asymmetric induction. Such investigation has, however, been limited to the diastereoselective reductions[6] of the carbonyl group, and little is known about the role of the groups[7] in substrates on enantioselective reduction.

For the purpose of clarifying the stereoselectivity enhancement by the functional group in substrates in the case of enantioselective reductions, it is desirable that a chiral ligand not have any additional group other than the one essential for complex formation with a reducing reagent, and that the asymmetric yield not be high when the functional group is absent in the substrates.[8]

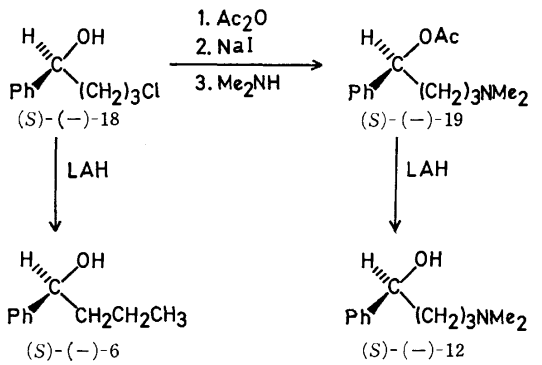
On the basis of these considerations, the asymmetric reduction of ω-substituted alkyl phenyl ketones, $PhCO(CH_2)_nY$ ($Y=NR_2$, OMe, SMe, and alkyl; $n=1-4$), with $LiAlH(O\text{-Menthyl})_3$ was carried out in order to find the most profitable group(Y) and number of the methylene group(*n*).

The reduction of ketones was conducted in ether under a nitrogen atmosphere. The synthetic yields were 80—100%, and the resulting secondary alcohols were purified by preparative GLC. The results are shown in Table 1.

Of the absolute configurations of the alcohols obtained by this reduction, those of 2-methoxy-1-phenylethanol(**2**) and 2-methylthio-1-phenylethanol(**3**) were assigned as *S*(+) by correlating them chemically to (*S*)-(+)-mandelic acid according to the procedure outlined in Scheme 1, while that of 4-dimethylamino-1-phenyl-1-butanol(**12**) was determined to be *R*(+) by correlation to 1-phenyl-1-butanol(**6**) (Scheme 2).



Scheme 1.



Scheme 2.

The absolute configurations of the other alcohols with functional groups were assigned[9] by means of the (*R*)-(+)-MTPA*/$Eu(fod)_3$ method[10] previously reported by the present authors, since it has been confirmed that this method is also applicable to 1-phenylethanols with the functional groups [$Y=NMe_2$ (**1**); OMe(**2**); SMe(**3**)] at the C-2 position.

The (*R*)-(+)-MTPA/$Eu(fod)_3$ method correlates the

* (*R*)-(+)-α-Methoxy-α-trifluoromethylphenylacetic acid (Mosher's Reagent).

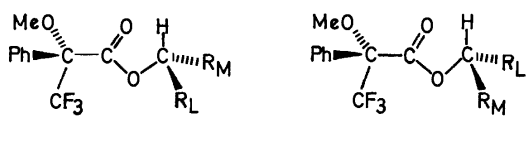
a) The optical rotations, $[\alpha]_D$, were taken in cyclopentane unless otherwise specified. b) All the data are the averages of 2—3 runs. The enentiomeric excesses were determined based on the relative peak area of the MeO signals of the (*R*)-(+)-MTPA acid moiety in the presence of $Eu(fod)_3$. c) In these three alcohols, the $-CH_2Y$ group takes nomenclatural precedence over that of the Ph group; therefore, the *S* configuration in these alcohols corresponds to the *R* of the others. d) Sign for the hydrochloride of **1** in water; H. Yoshimura, *Yakugaku Zasshi*, **84**, 305 (1963). e) Ref. 10. f) Sign for a methanol solution; Ref. 7. g) Based on the absolute rotations: **7**, $[\alpha]_D$ +27.6° (*c* 1.61, MeOH); **11**, $[\alpha]_D$ +29.3° (*c* 1.9, MeOH). Refs. 7 and 14. h) Determined on the basis of the relative peak area of carbinyl protons in the ^1H NMR spectrum of **12** in the presence of the chiral shift reagent, $Eu(hfc)_3$, since (*R*)-(+)-MTPA esters of **12** were not obtained under ordinary conditions.

relative magnitude of LIS_{OMe} (the lanthanide-induced shift by $Eu(fod)_3$ of the MeO signal of the MTPA acid moiety in (*R*)-(+)-MTPA esters of secondary alcohols) with their absolute configurations; the diastereomeric ester with the larger LIS value has Structure A, while the other ester, with the smaller LIS value, has Structure B. The results are also summarized in Table 1.



A B

$R_L > R_M$

The most pertinent observations in the asymmetric reduction are as follows: (1) When the Y group is alkyl or H, the preferential attack of the hydride ion occurs on the *si*-face of the carbonyl group, and the presence of the functional group does not alter the sense of the asymmetric induction except in the case of 2-methoxyacetophenone(Table 1, Entry 2); (2) The stereoselectivity in the reduction dependes on the functional group. Among the functional groups examined, OMe(when $n=2$ and 3) and NR_2 (when $n=2$) functioned effectively to increase the stereoselectivity (Table 1, Entries 7, 8, 11, and 13) while the SMe group did not give any higher asymmetric induction, in comparison with the non-polar ethyl group. The ethyl group was chosen as a standard, since its steric requirement, including the extention effect,[11] was considered to be similar to those of OMe and SMe, and its steric effect would be the sole controlling factor in the stereoselectivity; (3) As can be seen from Fig. 1, the stereoselectivity also depends on the number of the methylene group(n) in the case of Y=OMe or NMe_2; even the sense of asymmetric induction was reversed when Y=OMe($n=1$). The highest selectivity was observed at $n=2$(Y=NMe_2, 25%ee) or $n=3$(Y=OMe, 38%ee). On the other hand, when Y=SMe or Et, there was no distinct dependence.

It is apparent that these results could not be elucidated by an exclusive consideration of the steric effects of the functional group Y, because the similar steric requirements of the group (OMe, SMe, and Et) re-

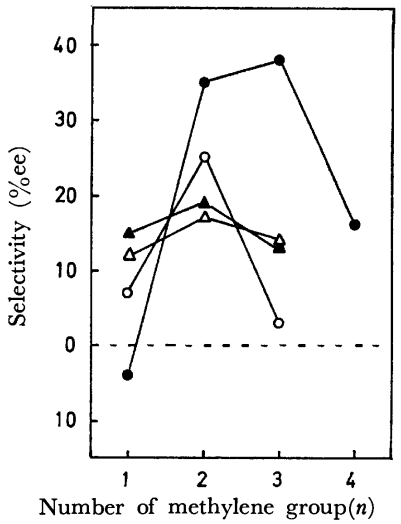


Fig. 1. Selectivity dependence on the number of methylene groups.

a) Based on the reported absolute rotation; $[\alpha]_D$ +29.3° (*c* 1.9, MeOH). Ref. 7.

sulted in two different patterns of stereoselectivity dependence (Fig. 1, Y=OMe; SMe and Et). These observations strongly suggest that the coordination of the Y group (OMe or NR_2) with the reducing reagent also plays an important role in the stereoselectivity.

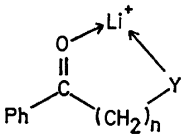
The coordination of the Y group with the reducing reagent can be substantiated by the asymmetric reduction of 3-piperidinopropiophenone (**11**) in the presence of the additive, *N,N,N′,N′*-tetramethylethylenediamine(TMEDA), which can strongly coordinate with Li^+. The reduction was conducted in toluene in order to eliminate the effect of ether oxygen, which may act as a coordinating functionality. The results are shown in Table 2. Although the change in the stereoselectivity was not very remarkable because of the rather low asymmetric induction in the absence of the additive, it can be seen that the stereoselectivity was immediately decreased by the addition of TMEDA in a 1 molar ratio and did not change upon the further addition of TMEDA. This can be interpreted as a result of the interference of the coordination of piperidino nitrogen with the reducing reagent caused by TMEDA.

The oxygen and nitrogen atoms in the functional group Y are hard bases, and they can strongly coordinate with Li^+ or Al^{3+} of hard acids, while the sulfur atom is a soft base which can hardly coordinate at all with the light metal cations. Therefore, the SMe group can be considered to act as a functionality with a poor coordinating capability in the present case. The observations that the effects of the SMe group on the stereoselectivity are almost the same as those of the non-polar Et group (see Fig. 1) is consistent with this expectation.

Experimental support for the coordination of OMe being stronger than that of SMe with Li^+ has been found in the asymmetric reduction[5] of propiophenone with LAH modified by (*S*)-(−)-*N*-(*o*-dimethylaminobenzyl)-α-methylbenzylamine, where the addition of 1,2-dimethoxyethane to the reaction mixture caused a dramatic decrease in the stereoselectivity, while that of 1,2-bis(methylthio)ethane did not.

The stereoselectivity was greatly affected by the position of the carbonyl group relative to the functional group Y (OMe, NR_2) in the present case, indicating that the reduction proceeded *via* a cyclic transition state. Concerning the mechanism of the metal hydride reduction of the carbonyl group, Pierre and Handel demonstrated that the alkali metal cation is indispensable[12] and that it also plays very important role in the stereoselectivity.[6b]

They examined the diastereomeric reduction of N-substituted 2-aziridinyl ketones and proposed a cyclic model where the alkali metal cation (not the metal hydride anion) is incorporated in the chelate ring. On the basis of this model, it can be considered that a similar coordination (C) of the carbonyl and the Y group with Li^+ occurs in the present asymmetric reduction:



C

The number of the methylene group(*n*) determines the size of the chelate ring and thus affects the rigidity of the transition state, being responsible for the stereoselectivity. As can be seen from the low stereoselectivity in the reduction of 2-methoxyacetophenone (Table 1, Entry 2), however, the ease of the chelate-ring formation, predicted from both the ring size[13] and the nature of the heteroatoms, does not always afford a high asymmetric induction.

Experimental

Instruments. The NMR spectra were taken on a Hitachi R-22 (90 MHz) spectrometer, with TMS as the internal standard. The gas-liquid chromatographic (GLC) determination was performed on a Shimadzu GC-5A apparatus, using a PEG 20 M or PDEG succinate column (3 mm × 1.5 m). The preparative GLC was carried out on a Varian Aerograph 700 using the same stationary phases (1/4″ × 1.5 m). The optical rotations were tekan on a Perkin Elmer 241 polarimeter, using a 1-dm thermostated microcell.

Reagents. The ether was distilled over sodium hydride and stored over Linde molecular sieves 3A. The toluene was dried over the same molecular sieves. A stock $LiAlH_4$

solution in ether was passed through a glass filter under nitrogen and stored in a flask closed with a rubber septem. It was analysed by iodometry just before use. Aliquots were taken up by syringe as needed. A commercially available *l*-menthol [Tokyo Kasei, $[\alpha]_D^{20}$ −50° (*c* 10, EtOH)] was used without further purification.

Materials. 2-Dimethylaminoacetophenone(**1'**),[15] 2-methoxyacetophenone(**2'**),[16] 3-dimethylaminopropiophenone (**7'**),[7] 3-methoxypropiophenone(**8'**),[17] 3-(methylthio)propiophenone(**9'**),[18] and 3-piperidinopropiophenone(**11'**)[7] were prepared according to the reported procedures.

*2-(Methylthio)acetophenone(**3'**)*: A solution of phenacyl bromide (30 g, 0.15 mol) in ethanol (120 ml) was cooled with ice, and then a 20% aq solution of sodium methyl sulfide (36 ml) was added over a period of 10 min under stirring. The reaction mixture gradually turned red, and stirring was continued for 1 h. The reaction mixture was then poured into 600 ml of ice water. After being salted out, it was extracted with ether and the extract was washed with water, dried(Na_2SO_4), concentrated, and distilled, giving 17.5 g (70%) of **3'** as a pale yellow oil: bp 118—119 °C/3 Torr; NMR(CCl_4) δ=2.02 (3H, s, SCH_3), 3.60 (2H, s, $-CH_2S$); Found: C, 65.06; H, 6.05%. Calcd for $C_9H_{10}OS$: C, 65.02; H, 6.06%.

*4-Dimethylaminobutyrophenone(**12'**)*: To a 100 ml portion of a cold ether solution of dimethylamine (25 g, 0.056 mol), was added, little by little, crude 4-iodobutyrophenone (7.35 g, 0.027 mol, prepared from 4-chlorobutyrophenone and sodium iodide, and heated at 90 °C for 18 h in ethyl methyl ketone). After standing for a day at room temperature, the reaction mixture was warmed at 30—40 °C for 1 h. The precipitates were filtered off, and then the filtrate was concentrated to yield a pale yellow oil, which was subsequently dissolved in ether. The ether solution was extracted with 2M HCl.

After the acid layer had been made alkaline with dilute sodium hydroxide solution, it was extracted with ether. The extract was washed with water, dried (Na_2SO_4), concentrated, and distilled *in vacuo*, yielding 2.6 g (50%) of **12'** as a colorless oil: bp 122—124 °C/0.5 Torr; NMR (CCl_4) δ= 1.80 (2H, quintet, $-CH_2\underline{CH_2}CH_2-N$), 2.13 (6H, s, $-N(CH_3)_2$), 2.27 (2H, t, $-CH_2-N$), 2.93 (2H, t, $-CO-CH_2-$); Found: N, 7.43%. Calcd for $C_{12}H_{17}ON$: N, 7.32%.

*4-Methoxybutyrophenone(**13'**)*: To a solution of sodium methoxide, prepared from 1.38 g (0.06 mol) of sodium and 60 ml of methanol, was added, by portions, 4-chlorobutyrophenone ethylene acetal (11.4 g, 0.05 mol; mp 55—57 °C; Found: C, 63.60; H, 6.83%. Calcd for $C_{12}H_{15}ClO_2$: C, 63.58; H, 6.67%, prepared from 4-chlorobutyrophenone, ethylene glycol, and a catalytic amount of *p*-toluenesulfonic acid, refluxed in benzene for 48 h with a Dean-Stark water separator; yield, 69%). The reaction mixture was subsequently stirred for 45 min at 50 °C and then cooled to room temperature. After the addition of a saturated sodium chloride solution, the reaction mixture was extracted with benzene and the extract was washed with water, dried (Na_2SO_4), and concentrated, yielding 10.2 g of a pale yellow oil. It was dissolved in 50 ml of methanol, and, after the addition of 10 ml of concd HCl, the methanol solution was stirred for 1 h at room temperature. The solvent was then removed, and the residue was extracted with ether. The extract was washed with a sodium hydrogencarbonate solution and brine successively, dried (Na_2SO_4), concentrated, and distilled, yielding 5.0 g (56%) of **13'** as a colorless oil: bp 93 °C/0.5 Torr; NMR (CCl_4) δ=1.96 (2H, quintet, $-CH_2\underline{CH_2}CH_2-O$), 3.01 (2H, t, $-CO-CH_2-$), 3.41 (2H, t, $-CH_2OMe$), 3.29 (3H, s, OMe); Found: C, 74.23; H, 8.01%. Calcd for $C_{11}H_{14}O_2$: C, 74.13; H, 7.92%.

*4-(Methylthio)butyrophenone(**14'**)*: To a solution of a 20% aq solution of sodium methyl sulfide (16 ml) was added, drop by drop, 4-chlorobutyrophenone ethylene acetal (9.08 g, 40 mmol) in 120 ml of ethanol, after which the reaction mixture was warmed at 60 °C for 1 h. After concentration *in vacuo*, the mixture was poured into water and extracted with ether. The extract was washed with a saturated sodium chloride solution. After the removal of the ether, the pale yellow residue was dissolved in 50 ml of methanol and stirred for 1 h with 10 ml of concd HCl at room temperature. The methanol was then removed under reduced pressure, and the residue was dissolved in ether, washed with saturated sodium hydrogencarbonate and brine successively, dried (Na_2SO_4), concentrated, and distilled, giving a pale yellow oil, which was subsequently distilled *in vacuo* to yield 5.6 g (72%) of **14'**: bp 118 °C/1 Torr; NMR (CCl_4) δ=1.8—2.1 (2H. m, $-CH_2\underline{CH_2}CH_2-S$), 2.07 (s, SMe), 2.56 (2H, t, $-CH_2-S$), 3.07 (2H, t, $-CO-CH_2-$); Found: C, 68.07; H, 7.40%. Calcd for $C_{11}H_{14}OS$: C, 68.00; H, 7.26%.

*5-Methoxyvalerophenone(**16'**)*: To a Grignard reagent prepared from 1-chloro-4-methoxybutane (12.3 g, 0.1 mol), magnesium turnings (2.6 g, 0.11 mol), and ether (35 ml) was added, drop by drop, benzonitrile (10.3 g, 0.1 mol) in toluene (50 ml). After the moderately exothermic reaction had subsided, about 50 ml of the solvent was distilled off. Reflux was continued for 4 h, and then the mixture was stood overnight at room temperature. It was subsequently poured into water containing concd HCl, extracted with ether, washed with dil NaOH and water successively, dried ($MgSO_4$), concentrated and distilled *in vacuo* to yield 16.3 g (85%) of **16'** as a colorless oil: bp 119—120 °C/0.2 Torr; NMR (CCl_4) δ=1.7 (4H, m, $-CO-CH_2\underline{CH_2}\underline{CH_2}CH_2$), 2.96 (2H, t, $-CO-CH_2-$), 3.29 (s, $-OCH_3$), 3.38 (t, $-CH_2-O$); Found: C, 74.96; H, 8.56%. Calcd for $C_{12}H_{16}O_2$: C, 74.97; H, 8.39 %.

*ω-Substituted 1-Phenyl-1-alkanols (**9**, **12**, **13**, **14**, and **16**)*: These new carbinols were obtained as a colorless oil by the $LiAlH_4$ reduction of the corresponding ketones in ether. (±)-**9**: NMR (CCl_4) δ=1.75—2.1 (m, $-CH(OH)-\underline{CH_2}$), 2.01 (s, SMe), 2.47 (2H, t, $-CH_2-S$), 4.67 (1H, dd, $-\underline{CH}-(OH)-$); Found: C, 65.85; H, 7.77%. Calcd for $C_{10}H_{14}OS$: C, 65.89; H, 7.74%. (±)-**12**: NMR (CCl_4) δ=1.65 (4H, m, $-CH(OH)-\underline{CH_2}\underline{CH_2}-$), 2.17—2.2 (8H, NMe_2 and $-CH_2-N$), 4.47 (1H, dd, $-\underline{CH}(OH)-CH_2-$); Found: C, 74.53; H, 9.95; N, 7.00%. Calcd for $C_{12}H_{19}ON$: C, 74.57; H, 9.91; N, 7.25%. (±)-**13**: NMR (CCl_4) δ=1.6 (4H, m, $-CH(OH)-\underline{CH_2}\underline{CH_2}-$), 3.21—3.28 (5H, OMe and $-CH_2-O$), 4.49 (1H, t, $-\underline{CH}(OH)-$); Found: C, 73.36; H, 9.04%. Calcd for $C_{11}H_{16}O_2$: C, 73.30; H, 8.95%. (±)-**14**: NMR (CCl_4) δ=1.6 (4H, m, $-CH(OH)-\underline{CH_2}\underline{CH_2}-$), 1.96 (3H, s, SMe), 2.36 (2H, t, $-CH_2-S$), 4.49 (1H, t, $-CH(OH)-$); Found: C, 67.25; H, 8.26%. Calcd for $C_{11}H_{16}OS$: C, 67.25; H, 8.28%. (±)-**16**: NMR (CCl_4) δ=1.6 (6H, m, $-CH(OH)-\underline{CH_2}\underline{CH_2}\underline{CH_2}-$), 3.20—3.26 (5H, OMe and $-CH_2-O$), 4.51 (1H, t, $-CH(OH)-$); Found: C, 74.18; H, 9.44%. Calcd for $C_{12}H_{18}O_2$: C, 74.19; H, 9.34%.

*Determination of Absolute Configurations by Chemical Correlation. (S)-(+)-2-Methoxy-1-phenylethanol(**2**)*: A mixture of (*S*)-(+)-1-phenyl-1,2-ethanediol(**17**) [1.38 g, 10 mmol, $[\alpha]_D^{29}$ +39.2° (*c* 2.62, EtOH)],[19] potassium carbonate (2.38 g), and methyl iodide (0.75 ml, 12 mmol) in acetone (15 ml) was refluxed for 15 h. The reaction mixture was then filtered, and the filtrate was concentrated, after which the residue was dissolved in ether. The ether solution was washed with water, dried (Na_2SO_4), and concentrated to give 1.24 g of a pale yellow oil containing about 50% of **2**. The monomethyl ether was concentrated by silica gel column chromatography,

using benzene-ether (10 : 1) as the eluent, purified by preparative GLC(PDEGS 1/4″×1.5 m, 170 °C, He 60 ml/min), and distilled *in vacuo* [115 °C (bath)/1 Torr]. 197 mg; NMR (CCl_4) δ=3.1—3.6 (AB part of ABX, $-CH_2-O$), 3.36 (3H, s, OMe), 4.73 (1H, dd, -CH(OH)-); $[\alpha]_D^{20}$+44.6° (*c* 4.54, cyclopentane).

(S)-(+)-*2-Methylthio-1-phenylethanol* (**3**): Tosyl chloride (3.14 g, 16 mmol) was added, portion by portion ,to a solution of (*S*)-(+)-**17** (2.07 g, 15 mmol, $[\alpha]_D^{20}$ +39.2° in EtOH) in pyridine (20 ml) at 0 °C. After the addition was completed, the reaction mixture was allowed to stand overnight in a refrigerator, poured into water (200 ml), and extracted with benzene. The extract was washed with 2M HCl and saturated sodium hydrogencarbonate successively, dried (Na_2SO_4), and concentrated to yield crude (*S*)-(+)-1-phenyl-1,2-ethanediol 2-tosylate (4.1 g), which was then recrystallized from benzene-hexane to give fine needles (2.6 g, 59%); mp 72—73 °C; $[\alpha]_D^{20}$ +30.3° (*c* 3.35, MeOH); Found: C, 61.75; H, 5.52%. Calcd for $C_{15}H_{16}O_4S$: C, 61.63; H, 5.52%. To a stirred solution of the tosylate (584 mg, 2 mmol) in ethanol (10 ml) was added, drop by drop 20% aq sodium methyl sulfide (0.8 ml, *ca.* 3 mmol) at room temperature. Stirring was continued for 2 h. After water had been added to the mixture, it was extracted with ether. The subsequent evaporation of the solvent afforded a pale yellow oil (290 mg), which was chromatographed on silica gel using benzene–ether (20 : 1) as the eluent and distilled [120 °C(bath)/1 Torr] to yield 150 mg (45%) of **3** as a pale yellow oil: NMR (CCl_4) δ=2.02 (3H, s, SMe), 2.4—2.9 (AB part of ABX, $-CH_2-S$), 4.6 (1H, dd, -CH(OH)-); $[\alpha]_D^{20}$ +63.8° (*c* 5.63, cyclopentane).

(S)-(−)-*4-Chloro-1-phenyl-1-butanol* (**18**): This alcohol was prepared by the asymmetric reduction of 4-chlorobutyrophenone by $LiAlH_4$ modified by (−)-(2*R*, 3*S*)-4-dimethylamino-3-methyl-1,2-diphenyl-2-butanol (LAH : R*OH=1 : 2.3) according to the reported procedure.[4b] The absolute configuration was determined to be *S*(−) by (*R*)-(+)-MTPA/$Eu(fod)_3$ method;[10] LIS_A 8.64, LIS_B 8.08, ΔLIS 0.56; 54 %ee, $[\alpha]_D^{20}$ −27.3° (*c* 2.83, cyclopentane); NMR (CCl_4) δ= 1.73 (4H, m, -CH(OH)-CH_2CH_2-), 3.42 (2H, bt, $-CH_2Cl$), 4.50 (1H, bt, -CH(OH)-). Acetate of **18**; $[\alpha]_D^{20}$ −49.3° (*c* 5.88, cyclopentane). The absolute configuration of **18** was confirmed by hydrogenolysis to (*S*)-(−)-1-phenyl-1-butanol (**6**) (see Table 1, Entry 6) as follows. A THF solution (8 ml) of $LiAlH_4$ (160 mg, 4 mmol) and **18** (277 mg, 1.5 mmol, $[\alpha]_D^{20}$ −27.3°) was refluxed at 95 °C for 3 h. The reaction mixture was then worked-up in a usual way, and the resulting colorless oil (198 mg) was submitted to preparative TLC (silica gel, 20% ethyl acetate in hexane) to yield 48 mg of (*S*)-(−)-**6** as colorless crystals; $[\alpha]_D^{20}$−31.0° (*c* 3.08, cyclopentane).

(S)-(−)-*4-Dimethylamino-1-phenyl-1-butanol* (**12**): The acetate (412 mg, $[\alpha]_D^{20}$−49.3° in cyclopentane) of **18** was refluxed for 6 h with sodium iodide (600 mg) in ethyl methyl ketone and then transformed to 493 mg of crude 4-iodo-1-phenyl-1-butanol as a colorless oil: $[\alpha]_D^{20}$ −33.6° (*c* 3.21, cyclopentane). This was used without further purification. To a solution of dimethylamine (5 g) in ether (10 ml) was added crude 4-iodo-1-phenyl-1-butanol (480 mg) in dry ether (5 ml), and the mixture was stood overnight at room temperature. The precipitates were filtered off, and the filtrate was concentrated *in vacuo*. The residue was dissolved in ether and extracted with 2M HCl. After having been washed with ether, the acid layer was made alkaline and extracted with ether, washed with water, dried (Na_2SO_4), concentrated, and distilled [120 °C (bath)/0.4 Torr], yielding 225 mg of **19**: NMR (CCl_4) δ=1.2—1.9 (4H, m, -CH(OAc)-CH_2CH_2-), 2.0 (3H, s, OAc), 2.09 (6H, s, NMe_2), 2.22 (2H, t, $-CH_2-N$), 5.67 (1H, t, -CH(OAc)-); $[\alpha]_D^{20}$ −42.5° (*c* 3.30, cyclopentane). The reduction of **19** (200 mg) with $LiAlH_4$ (150 mg) in ether (4 ml) at room temperature for 4 h afforded **12** (125 mg) as a colorless oil, which was distilled *in vacuo* [90 °C (bath)/0.2 Torr]; $[\alpha]_D^{20}$ −28.6° (*c* 3.40, cyclopentane).

Asymmetric Reduction of ω-Substituted Alkyl Phenyl Ketones with Lithium Tri-l-menthoxyaluminum Hydride. Under a nitrogen atmosphere, to a stirred solution of $LiAlH_4$ (1.2 mmol) in ether (2.5 ml) was added *l*-menthol (562 mg, 3.6 mmol) in 2 ml of the same solvent at 0 °C. The container of *l*-menthol was washed with 1 ml of ether, and the washing was added to the $LiAlH_4$ solution. Three minutes after the initial addition of menthol, ketone (1 mmol) in 0.5 ml of ether was added, drop by drop, to the LAH–menthol complex and the container of ketone was also washed with 0.5 ml of ether. The reaction mixture was stirred for 3 h at 0 °C to give a transparent solution. The excess hydride was decomposed with a small amount of water. After the addition of excess dil HCl, the mixture was extracted with ether. The extract was washed with saturated sodium hydrogencarbonate and water successively and dried (Na_2SO_4). The product was purified by preparative GLC and finally distilled *in vacuo*. In the case of the reduction of amino ketones, the products were extracted with dil HCl from the reaction mixture. After the extract had then been made alkaline, the amino alcohol liberated was extracted with ether and purified by preparative GLC and distilled *in vacuo*.

The enantiomeric purities of the resulting alcohols were determined according to a method previously reported.[10]

Optical rotations, $[\alpha]_D^{20}$ in cyclopentane, of the new optically active alcohols are as follows. (*S*)-**2**, +44.6° (*c* 4.54) optically pure; (*S*)-**3**, +63.8° (*c* 5.63) optically pure; (*R*)-**8**, +11.1° (*c* 3.78) 34%ee; (*R*)-**9**, +3.63° (*c* 3.94) 18%ee; (*R*)-**12**, +1.65° (*c* 4.67) 3%ee; (*R*)-**13**, +15.2° (*c* 4.72) 38 %ee; (*R*)-**14**, +1.43° (*c* 4.44) 12%ee; (*R*)-**15**, +2.86° (*c* 5.71) 13%ee; (*R*)-**16**, +0.322° (*c* 8.73) 16%ee.

Asymmetric Reduction of 3-Piperidinopropiophenone (**11′**) *in the Presence of TMEDA.* To a solution of $LiAlH_4$ (2.0 mmol) in 5 ml of ether was added *l*-menthol (938 mg, 6 mmol) in 4 ml of ether at 0 °C. The ether was subsequently removed *in vacuo*, and the residue was dissolved in 9 ml of dry toluene. *N,N,N′,N′*-Tetramethylethylenediamine (TMEDA) [Run 1, 0.3 ml (2 mmol); 2, 0.6 ml (4 mmol); 3, 1.2 ml (8 mmol); 4, none] was added to the solution, and the resulting solution was cooled to 0 °C. After 3 min, **11′** (217 mg, 1 mmol) in 1 ml of toluene was added. The reaction mixture was kept overnight at 0 °C. After the cautious addition of water, the reaction mixture was extracted with dil HCl. The acid layer was made alkaline with dil NaOH and extracted with ether. The solvent and TMEDA were removed *in vacuo*, and the product was purified by distillation [120 °C(bath)/0.5 Torr]. No starting ketone was detected on GLC. The results are shown in Table 2.

The authors wish to express their deep gratitude to Professor Harry S. Mosher, Stanford University, for his helpful suggestions throughout this work. The authors also wish to thank Mrs. Fujiko Yasuhara for the measurement of the NMR spectra.

Chemical Transformation of Seldomycin 5 into 3′-Episeldomycin 5 and Its Antibacterial Activity

Hideo MATSUSHIMA,* Kozo KITAURA,** and Yasuki MORI

Tokyo Research Laboratory, Kyowa Hakko, Asahimachi, Machida, Tokyo 194

***Pharmaceuticals Research Laboratory, Kyowa Hakko, Shimotokari, Suntogun, Shizuoka 411*

(Received June 6, 1977)

3′-Episeldomycin 5 (**7**) was synthesized from seldomycin 5. Reaction of hexa-*N*-ethoxycarbonylseldomycin 5 (**2**) with *o*-nitrobenzenesulfonyl chloride gave penta-*N*-ethoxycarbonylseldomycin 5-2′,3′-epicyclic carbamate (**3**) in one step. Hexa-*N*-ethoxycarbonyl-3′-*O*-tosylseldomycin 5 or hexa-*N*-ethoxycarbonyl-3′-*O*-mesylseldomycin 5, prepared from **2**, was also converted into **3** by being heated in weakly basic solvents such as *N,N*-dimethylformamide or pyridine. Compound **3** was hydrolyzed to give **7**. Structure of **7** was confirmed by PMR, CMR, MS, and Δ[M] values. Compound **7** was found to be active against resistant bacteria which carry 3′-*O*-phosphorylating enzymes. Δ[M] values for vicinal amino groups were shortly discussed.

Seldomycins are new aminoglycoside antibiotic complex produced by *Streptomyces hofuensis* and five factors are known among which factor 5 is the most active component.[1] Structure of seldomycin 5 has been shown to be 4-*O*-[2,6-diamino-2,4,6-trideoxy-α-D-*xylo*-hexopyranosyl]-6-*O*-[2,3-diamino-2,3-dideoxy-4-*O*-methyl-α-D-xylopyranosyl]-2-deoxystreptamine (**1**).[2] Seldomycin 5 has been shown to exhibit strong antibacterial activity against both gram-positive and gram-negative bacteria, but to be inactivated, similarly to other aminoglycoside antibiotics having 3′-hydroxyl group,[3] by resistant strains carrying 3′-*O*-phosphorylating enzymes.[1] Consideration of spatial specifity manifested by most enzymes led us to transform **1** into 3′-episeldomycin 5 (**7**) which has an axial hydroxyl group at 3′ position and expect it to be active against resistant strains carrying those enzymes. Hanessian *et al.* had transformed paromamine into 3′-epiparomamine by oxidation of the 3′-hydroxyl group to a carbonyl group and reducing it by sodium borohydride, but the antibacterial activity of the product had not been reported.[4]

Results and Discussion

Compound **1** was converted into hexa-*N*-ethoxycarbonyl(ecb)-seldomycin 5 (**2**) as an *N*-protected derivative. Reaction of **2** with *o*-nitrobenzenesulfonyl chloride in pyridine at 60—65 °C for 45 h surprisingly gave penta-*N*-*ecb*-seldomycin 5-2′,3′-epicyclic carbamate (**3**) in 57.9% yield. When this reaction was run at 13.5 °C for 20 h, hexa-*N*-*ecb*-seldomycin 5-3′-*O*-(*o*-nitrobenzenesulfonate) (**4**) was isolated in 70.3% yield and **4** was then converted into **3** by being heated in pyridine at 65 °C for 43 h in 80.4% yield. These results indicate that direct formation of **3** from **2** at higher temperature occurs by way of the formation of **4** *in situ*. The critical temperature above which the direct formation of **3** mainly occurs within 45 h was determined to be about 55 °C. Although the anchimeric ability of a benzyloxycarbonylamino group to a vicinal carbon atom which has an eliminating group such as halogen, mesyloxy, and epoxide is well known,[5] direct conversion of **2** into **3** may be, to our best knowledge, the first instance of epimerization of a free hydroxyl group in one step. On the other hand, reaction of **2** with *p*-toluenesulfonyl chloride or methanesulfonyl chloride in pyridine at 55—65 °C for 23 h gave hexa-*N*-*ecb*-3′-*O*-tosylseldomycin 5 (**5**) or hexa-*N*-*ecb*-3′-*O*-mesylseldomycin 5 (**6**) in 96.0 or 90.6% yield, respectively. Conversion of **5** or **6** into **3** was achieved by heating them in weakly basic solvents such as pyridine, *N,N*-dimethylformamide, at 80—110 °C for 18—19.5 h in 75.8 or 38.6% yield, respectively.

The structure of **3** was elucidated by the following evidences. (i) elemental analysis, (ii) disappearance of the signals due to the sulfonate residues in PMR and IR, (see experimental section), (iii) appearance of a new peak at 1760 cm^{-1} in IR due to a carbonyl group of a five-membered cyclic carbamate, (iv) In the CMR spectrum of **3** (Table 1), a new signal appeared at 158.8 ppm which is attributable to the carbonyl carbon of the newly formed cyclic carbamate. There were 6.5 and 9.8 ppm upfield shifts in the C-2′ and C-4′ signals, respectively, relative to the corresponding signals in the spectrum of **2**, while 7.2 ppm downfield shift in the C-3′ signal was observed resulting from the transformation of **2** into **3**. (v) hydrolysis to **7**. The reactions described above are summarized in Scheme 1 and possible mechanism for the formation of the epicyclic carbamate ring is shown in Scheme 2. This mechanism requires water for the formation of **3**, which is supposed to be contained in the solvents used. In fact both the pyridine and DMF that we used were revealed (Karl Fisher method) to contain about 650 ppm water, which is stoichiometrically enough for the

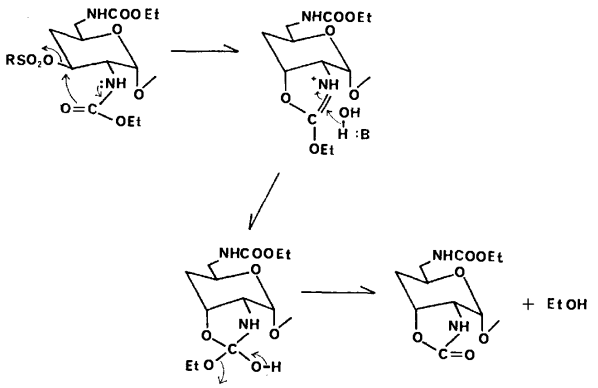
a) Measured in DMSO-d_6 solution with DMSO-d_6 as internal reference and shown by ppm from TMS, using $\delta_{TMS}=39.5-\delta_{DMSO}$. b) Measured in D_2O solution with dioxane as internal reference and shown by ppm from TMS, using $\delta_{TMS}=67.4-\delta_{dioxane}$. c) CMR data of this compound had been reported in Ref. 2. Each chemical shifts obtained here are consistent with those reported in Ref. 2 within 0.5 ppm deviation. d) All the methyls or methylenes of the ecb residues showed the single chemical shift. e) The carbonyls of the ecb residues in **2** or **3** showed the two or three chemical shifts, respectively.



Scheme 2. Possible mechanism for the formation of the epicyclic carbamate ring.

reactions.

Alkaline hydrolysis of **3** caused simaltaneous deethoxycarbonylation and fission of the epicyclic carbamate ring to give **7**. The structure of **7** was supported by the following evidences. (i) High resolution mass spectrum gave the (M+1) peak at 451.2912 (*m/e*), which means **7** is an isomer of **1**. Its fragmentation pattern is quite similar to that of **1**.[2] (ii) In the CMR spectrum of **7** (Table 1), the four signals due to the C-2′—C-5′ carbons appeared in the range of 1.1—5.8 ppm upfield compared with the corresponding signals in the spectrum of **1**. These upfield shifts resulting from epimerization of the 3′-hydroxyl group are consistent with those reported by Roberts and Dorman[6] or Perlin *et al.*[7] (iii) In the PMR spectrum of **7** (Table 2), the signals due to the H-2′, H-3′, and H-4′ax showed 0.3—0.4 ppm downfield shifts, respectively, from the corresponding shifts in the spectrum of **1**. These downfield shifts are well compared with the empirical rule proposed by Lemiuex and Stevens.[8] (iv) Optical rotatory behavior (Δ[M] value) in copper-ammonium solutions[9,10] also supported the structure of **7**. Compound **1** or **7** has two sites where the formation of copper complex are possible, *i.e.*, a pair of adjacent 2′-amino and 3′-hydroxyl groups (site A) and a pair of adjacent 2″- and 3″-amino groups (site B). Supposing that the complex formation occurs equally at site A and site B, contributions of each site to the apparently observed Δ[M] values could be calculated as shown in Table 3. These results indicate that the projected angle[9] at site A in **7** is +60° (counter-clockwise), while it is −60° (clockwise) in **1**. It seems to be noteworthy that the sign of $\Delta[M]_{cupra\ B}$ for the vicinal amino groups at site B (the projected angle: clockwise) is minus. That is in accord with the sign conventionally observed for vicinal amino and hydroxyl groups or vicinal hydroxyl groups in a chair-formed pyranose or cyclitol. On the other hand the $\Delta[M]_{CuAm}$ value for the vicinal amino groups is nearly zero.

Table 2. Selected PMR chemical shifts (τ value) of compounds **1** and **7**[a]

	H-1′	H-2′	H-3′	H-4′$_{ax}$	H-4′$_{eq}$	H-5′
Compound **1**	4.70	7.4	6.3	8.72	8.1	6.0
Compound **7**	4.86	7.1	6.0	8.3	8.1	5.9

a) Measured in D_2O solution with DSS as internal standard (100 MHz). Each chemical shifts were confirmed by spin decoupled method.

Table 3. Δ[M] value of compounds **1** and **7**

a) APH: aminoglycoside antibiotic phosphotransferase, ANT: aminoglycoside antibiotic nucleotidyltransferase, AAC: aminoglycoside antibiotic acetyltransferase. The figure in parenthesis indicates the position where the antibiotic is enzymatically modified.

No Δ[M] values for vicinal amino groups has been hitherto reported.

Table 4 shows *in vitro* antibacterial activities of **7** and **1**. It is obvious that epimerization of the 3′-hydroxyl group of **1** improves, as expected, its antibacterial activity against these resistant strains carrying 3′-*O*-phosphorylating enzyme [APH(3′)-I],[11] but does not improve its activity against other kinds of resistant strains and sensitive strains. LD_{50} value of **7** was estimated to be 183 mg/kg (mice, intravenously), while that of **1** was 667 mg/kg, namely, **7** is unexpectedly more toxic than **1** in acute toxicity.

After we had completed this work, Mallams *et al.* reported the synthesis of 3′-epigentamicin X_2, starting from 3,4,6-tri-*O*-acetyl-D-allal, with similar objective in mind.[12]

Experimental

General. Mps were determined with Yanaco micro melting point apparatus and uncorrected. IR spectra (with KBr pellet) were taken with Shimazu IR-27G or Perkin-Elmer 125 model. Varian T-60 or JEOL PS-100 was employed for NMR measurements with TMS as internal reference or in D_2O with DSS as internal reference. Samples of **1** and **7** were decarbonated by the usual manner[13] just before the NMR measurements. Optical rotations were measured with Hitachi-Perkin-Elmer 141 polarimeter at ambient temperature. Mass spectra were obtained with JEOL JMS-01SG-2 model at 75 eV using direct insertion probe. Thin layer chromatography (tlc) was carried out with Merck TLC plate and spots were visualized with iodine vapor and or UV light and or ninhydrin. Water content of solvent was measured with Tsutsui Rikagaku Kikai's Karl-Fisher automatic titrator. Evaporation of solvents was done *in vacuo* at bath temps of below 45 °C. The solutions of CuAm and Cupra B were prepared according to the literatures.[10,11] Antibacterial activity was determined with the agar dilution method at pH 7.2 specified by the Japan Society of Chemotherapy.

Hexa-N-ecb-*seldomycin 5 (2).* To an ice-cooled solution of **1** (13.5 g) in water (195 ml) and acetone (195 ml) containing sodium carbonate (anhydrous, 45.6 g), was added with vigorous stirring ethyl chroloformate (43.2 g) in ten minutes. After all the ethyl chloroformate was added, the reaction mixture was stirred for 20 h at 19 °C. The white ppt formed was filtered, washed with water (800 ml) and ether (500 ml), successively. The ppt was suspended again in water (600 ml) and stirred for 1 h at room temp. The undissolved material was filtered, washed with water (1000 ml) and dried *in vacuo* over phosphorus pentaoxide overnight to give a white powder of **2**, 18.9 g. Mp>300 °C, $[\alpha]_D^{17}$ +76.1° (*c* 0.315, DMF), R_f value on TLC (chloroform–methanol 12 : 1); 0.55.

Found: C, 48.50; H, 7.20; N, 9.36%. Calcd for $C_{36}H_{62}N_6O_{19}$: C, 48.96; H, 7.09; N, 9.52%.

Hexa-N-ecb-*3′*-O-*tosylseldomycin 5 (5).* To a solution of **2** (3.00 g) in pyridine (150 ml), *p*-toluenesulfonyl chloride (9.90 g) was added and the solution was allowed to stand at 55—65 °C for 23 h. A single spot appeared on TLC (R_f= 0.67, chloroform–methanol 12 : 1). After addition of water (10 ml), the solution was evaporated and the residue was treated with water (150 ml), the water-insoluble material was filtered, washed with water (200 ml) and then with ether (150 ml), dried *in vacuo* overnight to give a white powder, 3.42 g. Analytical sample was recrystallized from aq ethanol. Mp 193—197 °C, $[\alpha]_D^{19}$ +72.3° (*c* 0.361, DMF);

Found: C, 49.51; H, 6.65; N, 8.08; S, 2.98%. Calcd for $C_{43}H_{68}N_6O_{21}S$: C, 49.79; H, 6.62; N, 8.10; S, 3.09%. IR: 1175 cm^{-1}, PMR (in DMSO-d_6): τ 2.50 (4H, q), 7.60 (3H,s).

Hexa-N-ecb-*3′*-O-*mesylseldomycin 5 (6).* To a solution of **2** (5.20 g) in pyridine (500 ml), methanesulfonyl chloride (11.8 g) was added and the solution was allowed to stand at 24 °C for 3.5 h. On TLC with chloroform–methanol 9 : 1 a spot (R_f=0.80) appeared. After addition of water (10 ml), the solution was concentrated to *ca.* 20 ml. Water (150 ml) was added to the concentrate and the ppt formed was filtered, washed with water (80 ml) and dried *in vacuo* overnight

to give a white powder, 5.14 g. Analytical sample was recrystallized from aq ethanol. Mp 242—243 °C, $[\alpha]_D^{24}$ +118° (*c* 0.347, DMF).

Found: C, 46.30; H, 6.81; N, 8.68; S, 3.62%. Calcd for $C_{37}H_{64}N_6O_{21}S$: C, 46.23; H, 6.73; N, 8.75; S, 3.34%. IR: 1170 cm^{-1}. PMR (in DMSO-d_6): τ 6.87 (3H, s).

Hexa-N-ecb-*3'*-O-*(o-nitrophenylsulfonyl)seldomycin 5 (4).* To a solution of **2** (1.00 g) in pyridine (50 ml), *o*-nitrobenzenesulfonyl chloride (3.02 g) was added and the solution was kept at 13 °C for 20 h. Similar processing as described above gave a solid of crude **4**, which showed a major spot (R_f=0.36, chloroform–methanol 18 : 1) and two faster moving spots on TLC. Recrystallization of the crude **4** from aq ethanol gave a pure product which showed a single spot on tlc. mp 169—171 °C, $[\alpha]_D^{14}$ +34.6 ° (*c* 0.327, DMF).

Found: C, 47.08; H, 6.07; N, 8.91, S, 3.49%. Calcd for $C_{42}H_{65}N_7O_{23}S$: C, 47.22; H, 6.15; N, 9.18; S, 3.00%. PMR (in DMSO-d_6): τ 2.0 (4H, m).

Penta-N-ecb-*seldomycin 5-2',3'-Epicyclic Carbamate (3).*
i) *form 2*: To a solution of **2** (2.78 g) in pyridine (150 ml) *o*-nitrobenzenesulfonyl chloride (7.50 g) was added and the solution was kept at 60—65 °C for 45 h. On TLC with chloroform–methanol 12 : 1 a major spot of **3** (R_f=0.24) and a small spot of **4** (R_f=0.54) appeared. After a small amount of water (1.5 ml) was added, the solution was evaporated to dryness. The residue was chromatographed on a column of silica gel (Merck, 170 g) with chloroform–methanol 30 : 1—25 : 1. The portion containing **3** was evaporated to give a white powder which showed a single spot on TLC, 1.53 g. Mp 247—248 °C, $[\alpha]_D^{16}$ +47.8 ° (*c* 0.320, DMF).

Found: C, 48.37; H, 6.73; N, 9.91%. Calcd for $C_{34}H_{56}N_6O_{18}$: C, 48.79; H, 6.76; N, 10.04%. IR: 1760 cm^{-1}.

ii) *from 5*: The compound **5** (2.90 g) was dissolved in DMF (58 ml) and the solution was heated at 110 °C for 19.5 h. A small amount of ppt was filtered off and the filtrate was evaporated to dryness. The residue was chromatographed on a column of silica gel (180 g) with chloroform–methanol 30 : 1—20 : 1. From earlier fractions 0.445 g of unreacted **5** was recovered. The portion containing **3** was evaporated to give 1.49 g of a white solid. Mp 249—250 °C. IR spectrum was identical with that of **3** obtained in i).

iii) *from 6*: The solution of **6** (1.00 g) in a mixture of DMF (18 ml) and water (2ml) was kept at 110 °C for 18 h. Recovered **6** (0.47 g) and a white powder of **3** (0.18 g) was respectively isolated after similar processing and chromatography as described in ii). mp 248—249 °C IR spectrum was identical with that of **3** obtained in i).

iv) *from 4*: The solution of **4** (0.72 g) in pyridine (40 ml) was kept at 65—70 °C for 43 h. The solvent was evaporated to dryness and the residue was chromatographed as described in i). Pure **3** was obtained as a white powder, 0.45 g. Mp 248—251 °C. IR spectrum was identical with that of **3** obtained in i).

Experiment Concerning Temperature Dependence of the Reaction of 2 with o-Nitrobenzenesulfonyl Chloride. Eleven solutions of **2** (18—20 mg each) and *o*-nitrobenzenesulfonyl chloride (48—53 mg each) in pyridine (1.00 ml each) were kept at 11 different temps between 67 and 9.5 °C, respectively, using Toyo Kagaku Sangyo's Temperature Gradient Incubator TN-3. After 44 h the solutions were inspected by TLC (chloroform–methanol 12 : 1). The samples reacted at 9.5, 14.5, 20, and 26 °C showed a single spot of **4** on TLC and even a trace spot of **3** was not detected. At 31.5, 37.5, and 41.5 °C a major spot of **4** and a trace spot of **3** were visible. At 49.5 and 53 °C the spots of **4** and **3** appeared in apparently 1 : 1 ratio. At 57 and 67 °C a major spot of **3** and a tiny spot of **4** appeared.

3'-Episeldomycin 5 Free Base (7). The compound **3** (1.15 g) was suspended in a mixture of 2N-aq sodium hydroxide (25.5 ml) and methanol (25.5 ml) and heated at 110 °C in a sealed glass tube. After 15 minutes **3** dissolved completely and heating was continued for 100 minutes. A white ppt formed was filtered off, washed with aq methanol. The filtrate and washings combined were neutralized with concd hydrochloric acid and evaporated to dryness. The residue was dissolved in water (10 ml) and adjusted to pH 4.80 by hydrochloric acid. A small amount of ppt formed was filtered off and the filtrate was charged on a column of Amberlite CG-50 (ammonium cycle, 50 ml). After washing the column with water (370 ml), it was eluted stepwisely by 0.1- and 0.2 M aqueous ammonia. From a portion eluted by 0.1 M-ammonia a white powder (0.13 g) was obtained which showed no antibacterial activity. $[\alpha]_D^{18}$ +126° (*c* 0.300, water). This compound was supposed to be 1*N*,3*N*-carbonyl-3'-episeldomycin 5.[14] Fractions eluted by 0.2 M -ammonia gave a white powder of pure **7** (0.14 g) after evaporation. Mp 189—194 °C, $[\alpha]_D^{20}$ +95.1° (*c* 0.377, water). PMR (in D_2O): τ 4.86 (d, J=4 Hz, H-1'), 5.00 (d, J=3 Hz, H-1").

Found: C, 45.52; H, 7.75; N, 16.82%. Calcd for $C_{18}H_{38}N_6O_7$ 1/2 H_2CO_3: C, 46.13; H, 8.18; N, 17.45%.

The authors wish to thank Mrs. Mayumi Yoshida for the CMR measurements, Mrs. Kazuko Yamaguchi for the elemental analysis, and MissYuriko Adachi for obtaining the mass spectra. The authors are also indebted to Sagami Central Research Institute for the elemental analysis of sulfur and the IR measurements with a Perkin-Elmer 125 model.

Colloid Titration Behavior of the Maleic Acid–Methyl Vinyl Ether Copolymer

Etsuo KOKUFUTA* and Shinji IWAI

College of Industrial Technology, Nihon University, Izumi-cho, Narashino, Chiba 275

(Received March 4, 1977)

Synopsis. The colloid titration of the maleic acid–methyl vinyl ether (MA–MVE) copolymer with trimethylammonium glycol chitosan iodide (MGCH) was carried out at various pH values. The mechanism of the formation of the polyion complex between the MA–MVE copolymer and the MGCH ions was discussed.

The colloid titration, which was originated by Terayama,[1] is based on the stoichiometric complex formation between polyacidic and polybasic titrants. Strong polyelectrolytes, such as potassium poly(vinyl alcohol) sulfate (PVSK),[1] trimethylammonium glycol chitosan iodide (MGCH),[1] and poly(diallyldimethylammonium chloride),[2] are frequently used as standard titrants.

In previous studies,[3,4] the effects of the pH on the dissociation of the above-mentioned three polyelectrolytes were investigated by using colloid titration and electrophoresis. From the results obtained, the mechanism of the formation of the polyion complex between polyacidic and polybasic titrants was discussed.

In the present study, the colloid titration with MGCH was carried out for the maleic acid–methyl vinyl ether (MA–MVE) copolymer, which is a representative polydibasic acid. The colloid titration curves were compared with the results of electrophoresis and potentiometric titration reported previously,[5] and the mechanism of the formation of the polyion complex between the MA–MVE copolymer and the MGCH ions was discussed.

Experimental

Materials. The MA–MVE copolymer and the sodium salt of the copolymer (NaMA–MVE copolymer) used were prepared in the manner described in previous paper.[5] The MA–MVE copolymer was prepared by the hydrolysis of the maleic anhydride–MVE copolymer manufactured by the General Aniline & Film Co. On the other hand, the NaMA–MVE copolymer was prepared by the neutralization of the MA–MVE copolymer with sodium hydroxide. The molecular weight of the repeating unit for the MA–MVE copolymer, as estimated by elemental analysis and by potentiometric titration, was 176. This value agrees with that calculated on the assumption that this copolymer is an alternating copolymer. The intrinsic viscosity of the NaMA–MVE copolymer was 1.57 dl/g, as established by viscometric measurement in a 1M NaCl solution at 25 °C. The PVSK and MGCH were obtained from Wako Pure Chemical Industries, Ltd. These properties were characterized in previous papers.[3,4]

Colloid Titration. The sample solution (0.005 N) was titrated indirectly with MGCH (0.005 N) by the method of Terayama.[1] An excess of MGCH was added to the sample solution to precipitate a polyion complex, and then the excess of MGCH was back-titrated with PVSK (0.0025 N). A blank titration was also carried out. The titrant volume was determined by means of the difference in these titration results. The end point was indicated by the metachromatic color change of toluidine blue[1] and the turbidity measurements. The pH of the titration system was adjusted with 0.1—1M HCl, NaOH, $Ba(OH)_2$, and tetrabutylammonium hydroxide (TBAH).

Results and Discussion

The colloid titration curve was obtained by plotting the reciprocal of the equivalent weight (E_w) of the sample copolymer against the pH. A titration curve of the NaMA–MVE copolymer is shown in Fig. 1. In contrast to the results for poly(sodium acrylate) (NaPAA) and carboxymethylcellulose (CMC),[2] the titration curve shows an inflection point at about pH 6.5. From this result, it can be estimated that one of the two carboxylic groups in a monomer residue of the copolymer dissociates at first in the pH region below the inflection point, while the other dissociates in the pH region above the inflection point. This agrees with the result of the potentiometric titration.[5] The values of E_w (219) and pH (*ca.* 6.5) at the inflection point are equal to the molecular weight of the repeating unit for the NaMA–MVE copolymer and to the pH value at a half-neutralization point of the potentiometric titration curve, respectively. Therefore, this inflection point can be considered to be the half-neutralization point.

On the other hand, it is observed from the colloid titration curve that E_w^{-1} reaches a constant value above pH 9. This suggests that the two carboxylic groups in a monomer residue are completely dissociated in this pH region. However, the value of E_w (145) is not equal to one-half of the molecular weight of the repeating unit for the NaMA–MVE copolymer. The electrophoretic studies of polycarboxylic acids in previous papers[5,6] showed that the binding effect of the counterion on the MA–MVE copolymer ion is larger than that of the counterion on the NaPAA and CMC ions in the pH region from 7 to 10. The disagreement mentioned above can be explained on the basis of the assumption that the complex formation of the MA–MVE copolymer with MGCH is not stoichiometric

* Present address: Department of Chemistry, The University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 300-31.

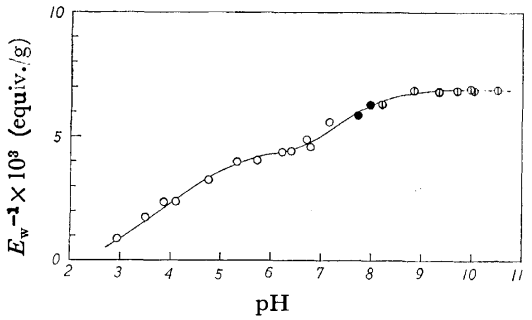

Fig. 1. Colloid titration curve of NaMA–MVE copolymer with MGCH.
pH-adjuster: ○, HCl; ⓘ, NaOH; ●, non.

because of the inhibitory effect of the counterion.

In order to confirm this assumption, a colloid titration with MGCH was carried out for the MA–MVE copolymer, using NaOH, $Ba(OH)_2$, and TBAH as pH-adjusters. The results are shown in Fig. 2. When the sample solution was titrated in the absence of any pH-adjuster, the pH of the titration system at the end point was about 6.5. Hence, the titration was carried out with adjustment of the pH with HCl in the pH region below 7 and with the bases in the pH region above 7. It is generally believed that the binding effect of a counterion on a polyacidic ion does not need to be considered if the counterion is a tetraalkylammonium ion.[7] In the case of a bivalent metal ion such as the Ba^{2+} ion, however, this effect on a polydibasic acid seems to be important, since a stable ring structure will be formed between the metal cation and the two carboxylate ions in a monomer residue. In Fig. 2, from the titration curve for which the pH was adjusted with NaOH, it is observed that E_w^{-1} is independent of the pH in the pH region above 9. The value of E_w (115) in this pH region is not equal to one-half of the molecular weight of the repeating unit for the MA–MVE copolymer. In contrast to this result, in the case of the titration curve for which the pH was adjusted with TBAH, E_w^{-1} increases in the pH region from 7 to 10, and reaches a constant value above pH 10.5. In the pH region above 10.5, the value of E_w (89) is comparable with one-half of the molecular weight of the repeating unit for the MA–MVE copolymer. On the other hand, when the pH was adjusted with $Ba(OH)_2$, E_w^{-1} rapidly decreased with the increase in the pH, since Ba^{2+} ions are bound to the MA–MVE copolymer ion. From these facts, it may be concluded that the binding effect of the counterion on the MA–MVE copolymer ion plays an important role in the complex formation of this copolymer with MGCH.

The authors wish to express their thanks to Professor Kyoji Toei, Okayama University, for his valuable guidance and encouragement in the colloid titration.

Phosphorescence Spectra of $[Cr(NH_3)_6][Co(CN)_6]$ and $[Cr(NH_3)_6][CdCl_5]$. Splitting of Their 0–0 Bands

Yusuke YAMAMOTO

Department of Chemistry, Faculty of Science, Rikkyo University, Nishi-ikebukuro, Toshima-ku, Tokyo 171

(Received May 19, 1977)

Synopsis. High resolution $^2E \rightarrow {}^4A_2$ phosphorescence spectra of $[Cr(NH_3)_6][Co(CN)_6]$ and $[Cr(NH_3)_6][CdCl_5]$ were measured. The 0–0 bands split into two components separated by 3.7 and 3.4 cm^{-1} for $[Cr(NH_3)_6][Co(CN)_6]$ and $[Cr(NH_3)_6][CdCl_5]$, respectively. The same spacings were also resolved in the ν_8 bands. The splitting in both cases is assigned as that of the ^2E phosphorescent electronic level.

There have been many studies of $^2E \rightarrow {}^4A_2$ phosphorescence spectra of hexaamminechromium(III) salts.[1–5] The phosphorescence spectrum of $[Cr(NH_3)_6][Co(CN)_6]$ was studied by Kataoka[1] in our laboratory, and by Cervone *et al.*[2] from the viewpoint of energy transfer from $[Co(CN)_6]^{3-}$ to $[Cr(NH_3)_6]^{3+}$, but no assignment of the vibronic bands was made. Flint *et al.*[3] investigated the phosphorescence spectra of $[Cr(NH_3)_6][CdCl_5]$, $[Cr(NH_3)_6][Co(CN)_6]$, and $[Cr(NH_3)_6](N_3)_3$, where the complex cation is in non-cubic environment, and they have given an assignment of vibronically active fundamentals. On the other hand, X-ray studies of $[Cr(NH_3)_6][Co(CN)_6]$[6] and $[Cr(NH_3)_6][CdCl_5]$[7] showed that the $[Cr(NH_3)_6]^{3+}$ ion occupies $\bar{3}$ site symmetry in the lattice. A ^2E level does not split by the sole action of the trigonal field or the spin orbit interaction, but splits into two Kramers doublets through the interplay of the two. Hence a splitting of the 0–0 band would be expected, but to date no splitting has been observed in $[Cr(NH_3)_6][Co(CN)_6]$ and $[Cr(NH_3)_6][CdCl_5]$.

Experimental

The materials were prepared according to the published methods[1,7] from carefully recrystallized $[Cr(NH_3)_6](NO_3)_3$, $K_3[Co(CN)_6]$, and $CdCl_2 \cdot 2.5H_2O$.

Phosphorescence spectra were recorded using excitation from a mercury lamp, the line being isolated by a Spex Michromate (f 2.5, 10 cm). The detection monochromator was a Jasco CT-100 (f 8.5, 100 cm) equipped with a cooled Hamamatsu R-649S (S-20) photomultiplier connected with Hamamatsu C-767 photon counter. Spectral slit width was 0.8 cm^{-1} for this measurement.

Results and Discussion

$[Cr(NH_3)_6][Co(CN)_6]$. The 20 K, 365 nm excited phosphorescence spectrum measured on a powdered sample ranging from the 0–0 to ν_7 band is shown in Fig. 1 together with the assignment of the vibronic bands observed. Down to 77 K, the 0–0 band clearly split into two components separated by 3.7 cm^{-1}, and the same spacing was also observed in the $\nu_8(e_u)$ band. The two components of each of these bands at 77 and 20 K are shown in Fig. 2. In the 0–0 band,

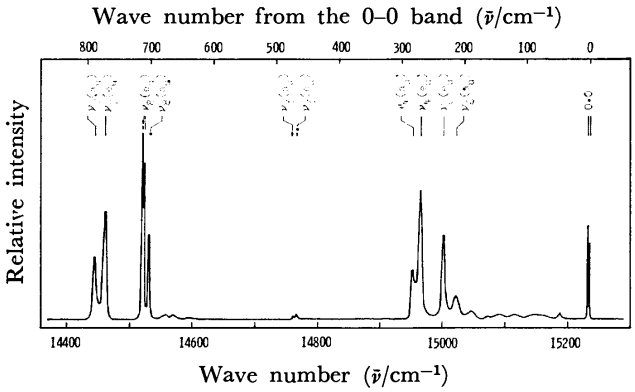

Fig. 1. Phosphorescence spectrum of $[Cr(NH_3)_6][Co(CN)_6]$ at 20 K.

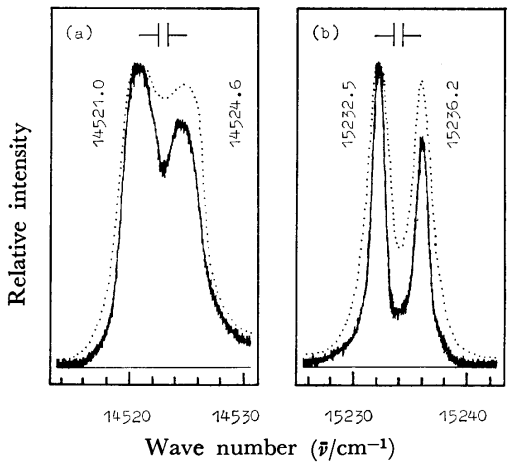

Fig. 2. Phosphorescence spectra of $[Cr(NH_3)_6][Co(CN)_6]$ at 20 K. (a) $\nu_8(e_u)$ band, (b) 0–0 band. Dotted line indicates outline of the spectra at 77 K. Lower energy component of each band is normalized.

these components, completely separated, had comparable intensities and their intensity ratios at 77 and 20 K are given by $\exp(-\Delta E/kT)$. Hence, the splitting of both the 0–0 band and the $\nu_8(e_u)$ band can be assigned as that of the ^2E phosphorescent electronic level, and can be interpreted as being due to the combined effect of the trigonal distortion of the $[Cr(NH_3)_6]^{3+}$ ion in the lattice and the spin orbit interaction. Splitting of the $^4A_2$ ground state is expected to be much smaller than that of the ^2E state.[8] In other vibronic bands, the splitting of the ^2E level could not be resolved because of their broadness.

$[Cr(NH_3)_6][CdCl_5]$. This complex salt is photosensitive even in a solid state. During a few minutes exposure to the excitation source, the original bands decreased in intensity and new bands appeared. For

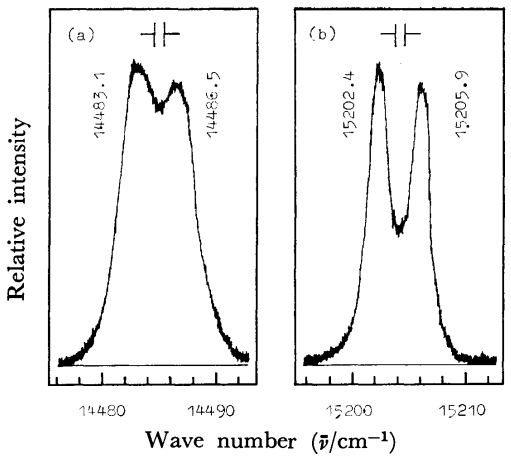

Fig. 3. Phosphorescence spectra of $[Cr(NH_3)_6][CdCl_5]$ at 77 K. (a) ν_8 band, (b) 0–0 band.

this reason, an excitation wavelength less susceptible to decomposing was selected, and measurement was done as quickly as possible, changing the sample for measuring each band. The 77 K, 313 nm excited phosphorescence spectra of a powdered sample of the 0–0 and ν_8 bands are shown in Fig. 3. Splitting of the 0–0 and ν_8 bands with a spacing of 3.4 cm^{-1} was also observed as in $[Cr(NH_3)_6][Co(CN)_6]$. The two components of these bands can be reasonably assigned as the transition from two levels, originated from the ^2E state, to the $^4A_2$ ground state, but neither of them can be a constituent band of a photodecomposition product, because long exposure gave no shift of the 0–0 and ν_8 bands, and intensity ratios of the two were constant.

The 0–0 band splitting observed is very small compared with 27 cm^{-1} for $[Cr(NH_3)_6](N_3)_3$,[3] 48 cm^{-1} for $[Cr(en)_3](ClO_4)_3$,[9] and 18 cm^{-1} for $2[Cr(en)_3]Cl_3 \cdot KCl \cdot 6H_2O$.[8,9] This indicates that the deviation from cubic symmetry is very small as expected from the X-ray studies. Since the structural studies were done at room temperature, it can be considered that phase transition might occur at low temperature, although observation of the bands while the sample was being cooled indicated no change in the spectral pattern in detail other than sharpening of the bands. This suggests that no phase transition occurred, or if it did occur, the structural difference should be little.

The author is grateful to Professor Yukio Kondo and Professor Masayoshi Nakahara for their encouragement throughout this work. He also wishes to thank Professor Gene S. Leheman for his kindness in reading the original manuscript.

(Received May 19, 1977)

Synopsis. The ultrasonic absorptions in an aqueous solution of isopropyl alcohol with sodium chloride (NaCl) were measured in the frequency range from 2.5 to 220 MHz at 25 °C. The ultrasonic properties were remarkably affected by the addition of NaCl, and a new absorption was found around 7 MHz in addition to that observed in the solution without NaCl. The results were discussed in terms of the forming effects of NaCl on the water structure.

As has been reported in previous papers,[1,2] ultrasonic absorptions in aqueous solutions of alcohols have been characterized by two kinds of relaxations. One is associated with the interaction between alcohol and water molecules, and the other, with aggregation reaction of alcohols having a relatively high hydrophobicity. However, the latter absorption was not observed in the aqueous solution of isopropyl alcohol over all the concentration range studied.[3]

In order to investigate further the properties of the aqueous solutions of alcohols and the structure of water, the ultrasonic absorption measurements were performed in the aqueous solution of isopropyl alcohol with sodium chloride (NaCl) added.

Experimental

The isopropyl alcohol and water used in this study were the same as those described in a previous paper.[3] The NaCl was the purest grade obtainable and was used without further purification. The ultrasonic absorption was measured in the manner described in previous work.[1] All the measurements were made at 25 °C.

Results and Discussion

The ultrasonic absorptions were measured under various concentrations of NaCl at a constant concentration of isopropyl alcohol (5.20 mol dm^{-3}), because the ultrasonic parameters for the aqueous solution could be determined with a relatively high accuracy at this concentration. Figure 1 shows the representative ultrasonic absorption spectra in the mixed solution. In general, the spectra associated with several relaxation processes can be expressed by the following equation:

$$\alpha/f^2 = \sum_i A_i/[1+(f/f_{ri})^2] + B, \quad (1)$$

where α is the absorption coefficient; f, the frequency; A_i, the amplitude of the excess absorption for the i-th process; f_{ri}, the relaxation frequency, and B, the constant. The absorption data in the concentration range of NaCl below 0.50 mol dm^{-3} were represented by a single relaxation formula and were analyzed graphically from the plot of α/f^2 *vs.* $[1+(f/f_r)^2]^{-1}$ so as to obtain a straight line. However, with an increase in the NaCl concentration, a new absorption appeared in the low frequency range (around 7 MHz); the absorption data were analyzed by means of a nonlinear least-squares routine. Figure 2 shows the variation in the relaxation frequencies with the NaCl concentration. The amplitudes of the excess absorptions are also shown in Fig. 3.

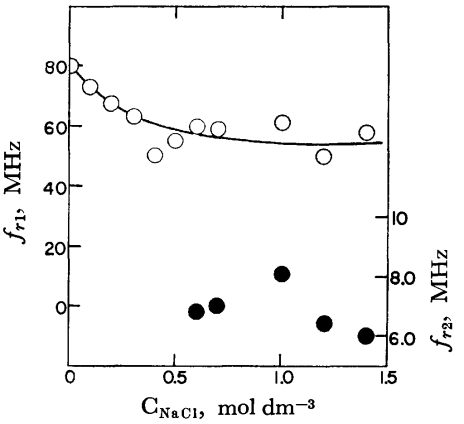

Fig. 2. Dependences of the relaxation frequencies in 5.20 mol dm^{-3} solution of isopropyl alcohol on the concentration of NaCl at 25 °C. ○: f_{r1}, ●: f_{r2}.

As has been reported in a previous study,[3] only a single relaxational absorption was observed over all the concentration range of isopropyl alcohol and the ab-

sorption mechanism was interpreted quantitatively in terms of a solute-solvent interaction as follows:

$$A + B \underset{k_b}{\overset{k_f}{\longleftrightarrow}} AB, \quad (2)$$

where A and B are the monomers of alcohol and water, and where k_f and k_b are the forward and backward rate constants respectively. The relaxation frequency for this process was related by the following equation:

$$2\pi f_r = k_f([A]+[B]) + k_b. \quad (3)$$

In this analysis, water molecules are assumed to be in two states; that is, there exists an equilibrium between hydrogen bonded and non-hydrogen bonded water, and only non-hydrogen bonded water molecules participate in the reaction with alcohol molecules. If the addition of NaCl disturbs the equilibrium in water, the ultrasonic parameters associated with the reaction of Eq. 2 will be affected. Considering that NaCl acts as the former of the water structure,[4] the relaxation frequency, f_{r1}, should be decreased through Eq. 3 by the decrease in the monomer concentration of water with an increase in the NaCl concentration. The experimental results are in agreement with this expectation, as is shown in Fig. 2.

Another important and interesting feature of the ultrasonic absorption in the mixed solution is the appearance of a new absorption in the low frequency range at concentrations of NaCl more than 0.50 mol dm^{-3}, as may be seen in Fig. 1. The frequency range in which the new absorption was found is near that in which the relaxational absorption associated with the hydrophobic effects were observed in aqueous solutions of *n*-propyl and *t*-butyl alcohols.[1,2] This shows that even the molecules with relatively low hydrophobicities can interact with each other by means of the hydrophobic effect when the enviroments of the molecules are changed by added substances.

Finally, urea is well known to be a breaker of the water structure, and its effect on the ultrasonic properties of the aqueous solution might be expected. However, no effective changes in the relaxation parameters were observed when urea was added to the aqueous solution of isopropyl alcohol.

The Silver(I) Ion-catalyzed Oxidation of Ethylenediaminetetraacetatocobaltate(II) by the Peroxodisulfate Ion

Kousaburo OHASHI and Katsumi YAMAMOTO

Department of Chemistry, Faculty of Science, Ibaraki University, Mito 310

(Received March 3, 1977)

Synopsis. A spectrophotometric study of the silver(I) ion-catalyzed oxidation of the ethylenediaminetetraacetatocobaltate(II) (Co^{II}-edta) peroxodisulfate ion ($S_2O_8^{2-}$) was carried out in acidic media. The rate is independent of the concentration of Co^{II}-edta, but first-order-dependent with respect to the concentrations of $S_2O_8^{2-}$ and Ag(I) in the 1.67×10^{-2}—7.25×10^{-2} M and 2.00×10^{-3}—2.26×10^{-2} M ranges respectively.

Recently, kinetic studies of the oxidation reaction of nitrilopolyacetatocobaltate(II) with various oxidants have been carried out.[1-4] The present authors found that the rate of the oxidation of Co^{II}-edta by $S_2O_8^{2-}$ is first-order-dependent on the concentration of $S_2O_8^{2-}$, but is independent of the Co^{II}-edta concentration for $Co^{II}(bpy)_3^{2+}$ oxidation; however, the rate is dependent on the concentrations of both $Co^{II}(bpy)_3^{2+}$ and $S_2O_8^{2-}$. Such a difference in rate law between Co^{II}-edta and $Co(bpy)_3^{2+}$ must come from the difference in charge on the cobalt(II) complexes.[5] In this note, the mechanism of the silver(I) ion-catalyzed oxidation of Co^{II}-edta[6] by $S_2O_8^{2-}$ and also the effect of other ions on the rate will be reported.

Experimental

Materials. A cobalt(II) perchlorate solution was prepared by dissolving cobalt carbonate into a slight excess of perchloric acid. This cobalt(II) solution was standardized by titration with a disodium dihydrogenethylenediaminetetraacetate (Na_2H_2edta) solution. The working solution was prepared by dilution with redistilled water.

Standard solutions of Na_2H_2 edta were prepared by dissolving known quantities of disodium dihydrogenethylenediaminetetraacetate dihydrate into redistilled water. Standard solutions of potassium peroxodisulfate were prepared by dissolving known quantities of the reagent into redistilled water. The peroxodisulfate ion solution was prepared just before use to avoid any decomposition. The standard solutions of silver(I) nitrate were prepared by dissolving silver nitrate into 0.01 M perchloric acid. These silver(I) solutions were standardized by the Volhard method. The adjustment of the pH of the solution was made by adding an acetate buffer solution. The ionic strengths of the solutions of Co^{II}-edta were adjusted to 0.50 by the addition of sodium perchlorate.

Procedure for the Measurement of the Reaction Rate. For the preparation of Co^{II}-edta solutions, the concentration of Na_2H_2edta was kept at three times that of the cobalt(II) ion. The solutions of $S_2O_8^{2-}$, the acetate buffer, Co^{II}-edta, and the silver(I) ion were each thermostated at 25 °C. In each experiment, $S_2O_8^{2-}$, acetate buffer, and Co^{II}-edta solutions were pipetted into a 50-ml measuring flask. Then the silver(I) ion solution was added to the solution. A portion of the solution was transferred into a 1-cm cell placed in a thermostated cell compartment of a Hitachi EPS-3-type spectrophotometer. The time dependence on the variation in the absorbance of the solution was measured at 540 nm. All the kinetic measurements were carried out in a large excess of the $S_2O_8^{2-}$ concentration to that of Co^{II}-edta.

Results and Discussion

Kinetics of the Silver(I) Ion-catalyzed Oxidation of Co^{II}-edta by $S_2O_8^{2-}$. The rate of the oxidation of Co^{II}-edta by $S_2O_8^{2-}$ in the absence of silver(I) ions was slow, as was shown in a previous paper.[5] In the present work, however, it was found that the silver(I) ions catalyze the oxidation of Co^{II}-edta by $S_2O_8^{2-}$. The oxidation product was characterized spectrophotometrically as $Co^{III}(edta)^-$. It was confirmed spectrophotometrically that one mole of $S_2O_8^{2-}$ oxidizes two moles of Co^{II}-edta in the presence of silver(I) ions when there is a large excess of Co^{II}-edta relative to the concentration of $S_2O_8^{2-}$. However, the attempt to confirm the stoichiometry in the presence of a large excess of $S_2O_8^{2-}$ to Co^{II}-edta was unsuccessful.

As is shown in Fig. 1, the plot of the absorbance vs. the time shows a straight line up to a 95% reaction. This behavior indicates that the oxidation rate is zero-order with respect to the Co^{II}-edta concentration. It was ascertained that no oxidation rate changes with the variation in the Co^{II}-edta concentration (Table 1).

In order to examine the effect of the $S_2O_8^{2-}$ concentration on the rate, the reaction was carried out at five different initial concentrations of $S_2O_8^{2-}$. As is shown in Fig. 2, the plot of the apparent rate *vs.* the $S_2O_8^{2-}$ concentration shows a straight line. Furthermore, it was confirmed that the oxidation rates were first-order with respect to the silver(I) ion concentration (Fig. 3). The rate law for this reaction is represented by Eq. 1:

$$\frac{d[Co^{III}(edta)^-]}{dt} = k_{obsd}[Ag(I)][S_2O_8^{2-}], \qquad (1)$$

where k_{obsd} is the second-order rate constant at a given pH value.

The effect of the pH on the oxidation rate was investigated over the pH range from 3.50 to 5.00 (Fig.

TABLE 1. THE KINETIC DATA FOR THE SILVER(I) ION-CATALYZED OXIDATION OF Co^{II}-edta BY PEROXODISULFATE

Concentration of Co^{II}-edta (10^{-3} M)	Rate[a] (10^{-6} M s^{-1})
1.5	6.4
2.5	6.3
4.0	6.4
7.5	6.4
10.0	6.3

a) $[Ag(I)]=8.0\times10^{-3}$ M, $[S_2O_8^{2-}]=8.57\times10^{-2}$ M, pH 3.60, $I=0.50$, 25 °C.

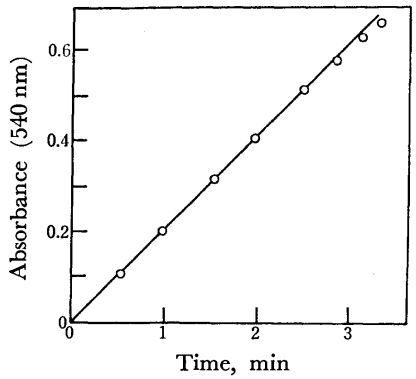

Fig. 1. A typical kinetic run of the reaction between Co^{II}-edta and peroxodisulfate ions in the presence of silver(I) ions at pH 3.60, 25 °C, and $I=0.50$ ($NaClO_4$). $[Co^{II}\text{-edta}]=2.08\times10^{-3}$ M, $[S_2O_8^{2-}]=8.57\times10^{-2}$ M, $[Ag(I)]=1.35\times10^{-2}$ M.

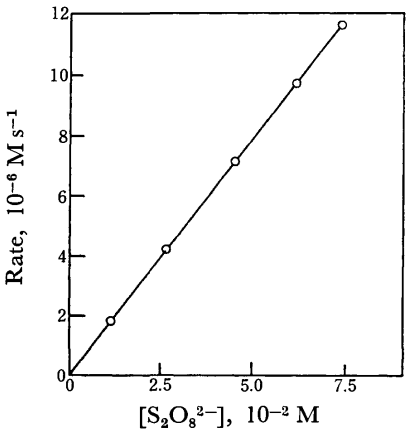

Fig. 2. Apparent rate *vs.* $[S_2O_8^{2-}]$ at pH 3.60, 25 °C, and $I=0.50$($NaClO_4$). $[Co^{II}\text{-edta}]=2.08\times10^{-3}$ M, $[Ag(I)]=1.67\times10^{-2}$ M.

4). The rate constant increases with an increase in the pH. No detailed explanations of the effect of the hydrogen ions on the rate could be given. The effect of the Na_2H_2edta concentration on the rate was not observed over the range of $1.40\times10^{-3}-7.54\times10^{-3}$ M.

The rate-determining step in the silver(I) ion-catalyzed oxidation reaction of Co^{II}-edta by $S_2O_8^{2-}$ must be the reaction between the silver(I) ion and $S_2O_8^{2-}$, since the oxidation rate is first-order with respect to the concentrations of both $S_2O_8^{2-}$ and silver(I) ions. The path for the oxidation of Co^{II}-edta may be represented by Eqs. 2, 3, 4, and 5:

$$Ag(I) + S_2O_8^{2-} \xrightarrow{\text{slow}} Ag(II) + SO_4^{2-} + SO_4^{\cdot-}, \quad (2)$$

$$Ag(I) + SO_4^{\cdot-} \xrightarrow{\text{fast}} Ag(II) + SO_4^{2-}, \quad (3)$$

$$Co^{II}\text{-edta} + SO_4^{\cdot-} \xrightarrow{\text{fast}} Co^{III}(edta)^- + SO_4^{2-}, \quad (4)$$

$$Co^{II}\text{-edta} + Ag(II) \xrightarrow{\text{fast}} Co^{III}(edta)^- + Ag(I). \quad (5)$$

The effects of the other ions on the silver(I) ion-catalyzed oxidation of Co^{II}-edta by $S_2O_8^{2-}$ were also examined. In the presence of 250 ppm Ag(I), the Zn^{2+}, Cd^{2+}, Pb^{2+}, Fe^{3+}, Mo(VI), and W(VI) metal

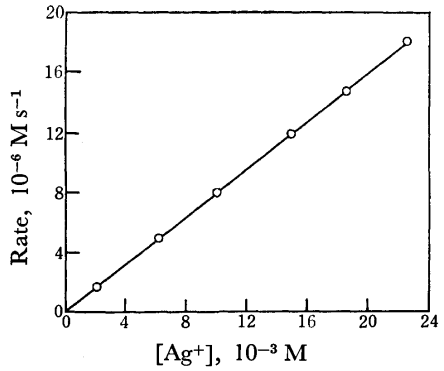

Fig. 3. Apparent rate *vs.* [Ag(I)] at pH 3.60, 25 °C, and $I=0.50$ ($NaClO_4$). $[Co^{II}\text{-edta}]=2.08\times10^{-3}$ M, $[S_2O_8^{2-}]=8.57\times10^{-2}$ M.

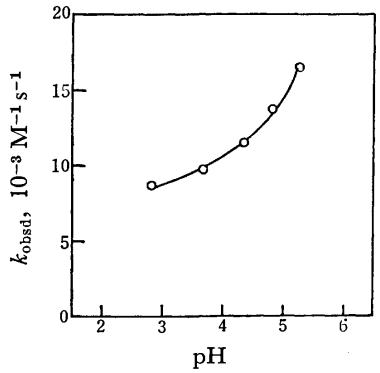

Fig. 4. The relation between the observed second-order rate constant and pH. $[Co^{II}\text{-edta}]=2.08\times10^{-3}$ M, $[S_2O_8^{2-}]=8.57\times10^{-2}$ M, $[Ag(I)]=1.67\times10^{-2}$ M, 25 °C, and $I=0.50$ ($NaClO_4$).

ions did not affect the rate at a concentration of 200 ppm, but at the same concentration the Ni^{2+}, Mn^{2+}, and Cu^{2+} metal ions increase the rate by more than 40% of the rate in the presence of the silver(I) ions.

This reaction may be applied to the determination of the concentration of the silver(I) ions, since the rate of the oxidation reaction of Co^{II}-edta is first-order-dependent on the silver(I) ions over the range of 108 to 400 ppm (Fig. 3).

(Received April 25, 1977)

Synopsis. The liquid-liquid extraction behavior of the Al(III) and Cr(III)–AcAc(acetylacetone)–$CHCl_3$ system and of the Mg(II), Pb(II), Mn(II), Co(II), Ni(II), and Cu(II)–TTA(thenoyltrifluoroacetone)–MIBK (isobutyl methyl ketone) system have been studied, and the results have been applied to the separation of these metals as their AcAc- and TTA-complexes by extraction chromatography.

The systematic and quantitative group separation of nineteen common cations by extraction chromatography has been devised in the authors' laboratory using the following six columns, in which the organic solvents were adsorbed on Kel-F(poly(chlorotrifluoroethylene)):[1]

	Stationary phase (5.5 g Kel-F)	Mobile phase (HCl(M) or pH)	Metal ions retained (each 0.5 mg)
1	100% TBP(1)	2M HCl	Fe(III), Hg(II), Sn(IV)
2	20% TOA–CCl_4	2M HCl	Ag(I), Bi(III), Cd(II), Zn(II)
3	100% TBP(2)	6M HCl	Sb(III)
4	50% AcAc–$CHCl_3$	pH 5.0	Al(III), Cr(III)
5	1.5M TTA(1)–MIBK	pH 5.0	Co(II), Cu(II), Mg(II), Mn(II), Ni(II), Pb(II)
6	1.5M TTA(2)–MIBK	pH 7.0	Ca(II), Ba(II), Sr(II)

The mutual separation of the metal ions retained on each column has already been attempted by passing a suitable eluting solution through columns of TBP (tributyl phosphate) (1),[2] TOA(trioctylamine)–CCl_4,[3] and TTA(2)–MIBK(isobutyl methyl ketone).[4] In this investigation, the extraction behavior of the Al(III) and Cr(III)–50% AcAc–$CHCl_3$ system and of the Co(II) Cu(II), Mg(II), Mn(II), Ni(II), and Pb(II)–0.2 M TTA–MIBK system have been examined, and the results have been applied to the mutual separation by extraction chromatography of the metals retained on the columns of the 50% AcAc–$CHCl_3$ system, and the 1.5 M TTA (1)–MIBK system.

Experimental

The experimental procedures were almost the same as those previously described.[1-6] Into a 50-ml centrifuge tube, 50% AcAc in chloroform(10-ml) and an aqueous solution (10-ml) containing 0.5 mg each of Al(III) and Cr(III), 10-ml of 0.2 M TTA in MIBK, and 10-ml of an aqueous solution containing 10 ppm each of Co(II), Cu(II), Mg(II), Mn(II), Ni(II), and Pb(II) were put together, and the contents for each of the metal ions were agitated with a mechanical shaker for 30—40 min at room temperature (20—23 °C). The pH of the solution was adjusted to a desired value by using 0.5 M acetic acid or an aqueous ammonia solution. The pH was checked again after every extraction by means of the pH meter. In the case of Cr(III), the mixture was heated gently for 1 h until the completion of the formation of the AcAc-chelate of Cr(III) with or without Al(III), because the quantitative extraction of Cr(III) with 50% AcAc in chloroform was impossible at room temperature.[1,7] The back extraction was carried out by shaking a 5-ml or 10-ml portion of the organic phase containing the extracted metal chelates with an aqueous solution of the desired acidity. The distribution ratios of the metals were determined radiometrically with Co-60, Cr-51, Mn-54, Ni-63, and Pb-210, colorimetrically for Al oxinate at 390 nm, or atomic absorptiometrically for Cu(II) and Mg(II). The extraction chromatography was carried out by using a glass chromatographic column (10 mm in diameter and 30 cm long, with a course frit at the bottom) containing a 5.5 g portion of Kel-F(40—80 mesh), a definite volume of 50% AcAc in chloroform (5.0-ml) and 1.5 M TTA in MIBK (6.5-ml) which had been pre-equilibrated with the eluting solution of pH 5.0, and a definite volume of the eluting solution(5.0—6.5 ml). A 50-ml sample solution containing 0.5 mg each of Co(II), Cu(II), Mg(II), Mn(II), Ni(II), and Pb(II), adjusted to pH 5.0, was passed through the column at the rate of 0.03—0.3 ml per minute, and then an eluting solution of a suitable pH, which had previously been pre-equilibrated with the organic solution of the stationary phase, was passed through at the flow rate of 0.4—0.5 ml per minute. The effluent was taken up in a fraction collector. In the case of the Al(III) and Cr(III)–50% AcAc–$CHCl_3$ system, a 100-ml sample solution of pH 5.0 containing acetylacetonates of Al(III) and Cr(III)(each 0.5 mg), which had been prepared by heating for an hour, was percolated through the column at the rate of 0.2-ml per minute, and then an eluting solution of a definite acidity was passed through at the flow rate of 0.5-ml per minute, as has previously been reported.[1]

Theoretical

The percentage of extraction, % E, and the percentage of back extraction, % E_{back}, can be calculated by means of the following equations: % $E=D/(1+D)\cdot 100$, % $E_{back}=D^*/(1+D^*)\cdot 100$, where D and D^* are the net distribution ratios of a metal in the extraction and in the back extraction respectively. The % E and the % E_{back} of metals in the column can be expressed by the following equation[5]: % $E=(1-V^*/V_m)\cdot 100$, where V^* is the volume of the mobile phase and where V_m is the volume of the eluate relative to the maximum of the eluted metal concentration.

Results and Discussion

The symbols in Fig. 1 A→O and O→A denote the extraction and the back extraction of chemical species

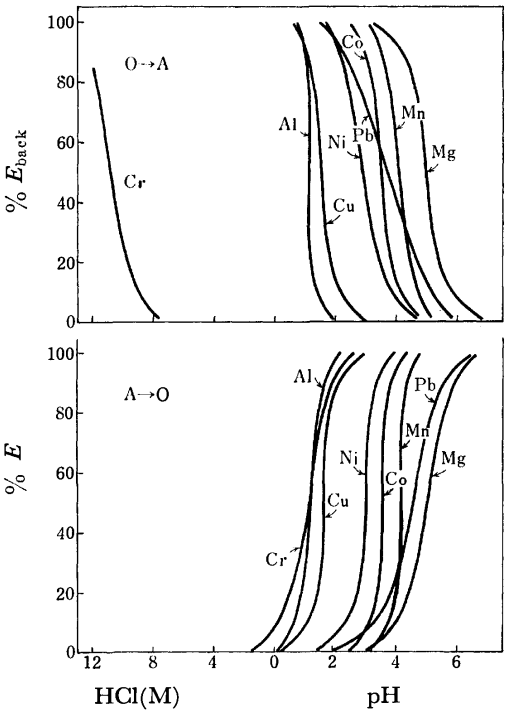

Fig. 1. The effect of pH or HCl(M) on the extraction and the back extraction of Al(III) and Cr(III)–50% AcAc–$CHCl_3$ system, and Co(II), Cu(II), Mg(II), Mn(II), Ni(II), and Pb(II)–0.2 M TTA–MIBK system.

respectively. The extraction and the back extraction are repeated in the column many times during the process of the extraction chromatography, which is closely related to the batch extraction; therefore, the optimum pH or acidity of the eluting solution can be predicted from the distribution ratios of the metals obtained by the ordinary extraction.[1-6] When the results of the batch extraction of metals with 0.2 M TTA in MIBK are applied by extraction chromatography to the mutual separation of metals retained on

Pb(II)	pH 5.0	74	13	26	pH 4.1	96
Mn(II)	pH 4.5	94	18	6	pH 3.6	98
Co(II)	pH 4.0	94	13	6	pH 3.1	94
Ni(II)	pH 4.0	100	8	0	pH 3.1	99
Cu(II)	pH 1.0	8	90	92	pH 0.1	7

a) Al(III) and Cr(III) (each 0.5 mg)–50% AcAc–$CHCl_3$, Mg(II), Pb(II), Mn(II), Co(II), Ni(II), and Cu(II) (each 10 ppm)–0.2M TTA–MIBK systems. b) Al(III) and Cr(III) (each 0.5 mg)–50% AcAc–$CHCl_3$, Mg(II), Pb(II), Mn(II), Co(II), Ni(II), and Cu(II) (each 0.5 mg)–1.5 M TTA–MIBK systems.

the column of the 1.5 M TTA–MIBK system, the eluting solution with every pH lower by 0.88 than that predicted from the batch extraction with the 0.2 M TTA–MIBK system was adopted, because the shift of the pH of the extraction curves to the lower pH region was assumed to be 0.87 when the concentration of TTA was changed from 0.2 M to 1.5 M. An optimum mutual separation of Al(III) and Cr(III) in the 50% AcAc–$CHCl_3$ system and of Co(II), Cu(II), Mg(II), Mn(II), Ni(II), and Pb(II) in the 1.5 M TTA–MIBK system was established by using the eluting solutions given in Fig. 2. The recovery of the metals was about 70—100 %. The deposit of some chelate in the column due to the loss of the stationary solvent phase was observed during the course of loading; this phenomenon may cause the lower recovery. The values of the distribution ratios of the metals obtained by the batch extraction and the extraction chromatography are summarized in Table 1. The main discrepancy between the two values may be caused by the differences in the contact times of the two phases and/or by the time-lag in the complex formation in the extraction and the back extraction, as has previously been pointed out by the present authors.[3-6]

The authors wish to thank Dr. Ikuko Akaza of Kanazawa Women's College for her helpful advice and discussion.

The Formation of the N-bound Hydroxyiminoacetylacetonato Ligand by the Reaction of Nitrosyl in Bis(2,2'-bipyridine)chloronitrosylruthenium(II) with Acetylacetone

Masao MUKAIDA, Masakazu YONEDA, and Terunosuke NOMURA

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioicho, Chiyoda-ku, Tokyo 102

(Received May 16, 1977)

Synopsis. Nitrosyl in $[RuCl(bpy)_2NO]^{2+}$ reacts with Hacac, giving the N-bound hydroxyiminoacetylacetonato ligand(hia, $CH_3COC(NO)COCH_3^-$) under mild conditions. The reaction product, $[Ru(hia)(bpy)_2(H_2O)]X$ ($X=ClO_4$, PF_6), was characterized on the basis of its IR spectra, including those of the ^{15}N-complex.

Although the reactivities of coordinated nitrosyl in transition metal complexes have been widely studied, little work has been reported on the formation of N–C bonding *via* nitrosyl complexes.[1-4] These reactions are, however, thought to be useful for the nitrosation of some organic compounds.[5] We wish now to report on the complex, $[Ru(hia)(bpy)_2(H_2O)]X$ ($X=ClO_4$, PF_6), which was formed by the reaction of $[RuCl(bpy)_2NO]^{2+}$ with Hacac. The hia ligand in this complex functions as an unidentate ligand coordinating through the nitrogen atom, as is shown in Fig. 1.

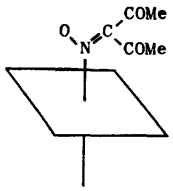

Fig. 1. N-bound hia ligand.

Experimental

Materials. The nitrosyl complex, $[RuCl(bpy)_2NO](ClO_4)_2$, was prepared by the procedure described by Meyer *et al.*, but $[RuCl_2(bpy)_2]Cl$ was used as a starting material instead of $[RuCl_2(bpy)_2]$. $[RuCl_2(bpy)_2]Cl$ was prepared by a new method using a "ruthenium blue" solution which was formed by the reaction of Ru(III) chloride with formic acid.[7]

Formation of Aquabis(2,2'-bipyridine)hydroxyiminoacetylacetonatoruthenium(II), $[Ru(C_5H_6NO_3)(C_{10}H_8N_2)_2(H_2O)]X$ ($X=ClO_4$, PF_6). The nitrosyl complex(200 mg, 0.295 mmol) was dissolved in a mixed solution of EtOH–H_2O(20 ml–10 ml), and then Hacac(1 ml) was added. After 10—15 days, a dark brown precipitate was collected, washed with water, and air-dried. The crude product(200 mg) was dissolved in water(300 ml). The resultant solution was charged on the top of a column containing SP sephadex C25 in the Na form (diameter, 12 mm; column height, 150 mm). When an aqueous solution of NH_4OAc(0.06 M) was then poured into the column at the rate of *ca.* 1—2 ml/min, a brown band appeared. Brown crystals were isolated as ClO_4 or PF_6 salt from the eluate of the band. A few further bands can be observed by the addition of an eluent containing KNO_3. The characterization of the products obtained from these bands is now under investigation. The present complex was filtered off, washed with water, and dried *in vacuo* over silica gel. Yield: about 30 mg. Found: N, 10.83; C, 45.76; H, 3.39; ClO_4, 14.70; H_2O, 2.38%. Calcd for $C_{25}H_{24}N_5O_8ClRu$: N, 10.62; C, 45.53; H, 3.64; ClO_4, 15.10; H_2O, 2.73%. Found: N, 10.23; C, 42.83; H, 3.13; PF_6, 21.01%. Calcd for $C_{25}H_{24}N_5O_4PF_6Ru$: N, 9.94; C, 42.59; H, 3.41; PF_6, 20.58%. The complex was soluble in common organic solvents. The crude product was diamagnetic. This suggests that the reaction product is a Ru(II) complex.

Results and Discussion

The complex formed by the reaction of $[RuCl(bpy)_2NO]^{2+}$ with Hacac gave the analytical data corresponding to the formula of $[Ru(hia)(bpy)_2](X\cdot H_2O)$. The complex containing the bidentate hia, $[Ru(acac)_2(hia)]$, has been found in the reaction of $[RuCl(acac)_2NO]$ with Hacac.[3] The IR spectra of the present complex, however, indicate the formula of $[Ru(hia)(bpy)_2(H_2O)]X$ containing the unidentada hia. By a comparison between the spectra of the ^{14}N-complex and the ^{15}N-complex in the 700—4000 cm^{-1} region, the isotopic effects were found two bands at 1350 and 806 cm^{-1}. In contrast, the ^{15}N substitution effects for $[Ru(acac)_2(hia)]$ have been found in three bands—at about 1400, 1160, and 800 cm^{-1}.[3] This finding can be explained by assuming the presence of different types of hia ligand in the two complexes. The bands in the present complex and its related complexes in which the ^{15}N substitution effects were observed are listed in Table 1.

Recently Mayer *et al.* reported that the nitrosyl in $[RuCl(bpy)_2NO]^{2+}$ reacts with aromatic amines to give *N*-bound *p*-nitrosoarene complexes.[2] They identified those products on the basis of the IR spectra. Armor

Table 1. Data of ^{15}N substitution shifts for the hia complexes and relevant complexes

Complex	Tentative assignments ν(N=C)	ν(N–O)	
$[Ru(hia)(bpy)_2(H_2O)]ClO_4$		1342(1327)	
$[Ru(hia)(bpy)_2(H_2O)]PF_6$		1350(1340)	806(793)
$[Ru(hia)(acac)_2]$	(1387)*	1162(1148)	807(796) 782(782) (771)
$[Ru(N(O)C_6H_4RCH_3)(bpy)_2Cl]PF_6$ [a]			
R=H		1286(1261)	875(860)
R=CH_3		1284(1276)	875(860)
$[Ru(NH_3)_5\{(NO)CH_2C(CH_3)_2OH\}]B(C_6H_5)_4$ [b]		1365(~1355)	

* New band. The bands based on ^{15}N complexes are shown in parentheses. a) Ref. 2. b) Ref. 4.

et al. also obtained an alkylnitrosoruthenium(II) complex by the radiolysis of $[Ru(NH_3)_5NO]^{3+}$ in *t*-butyl alcohol.[4] The isotopic shifts observed for the present complex are in almost the same regions and in almost the same magnitude as those of the complexes in Refs. 2 and 4, indicating the presence of the unidentate hia. The bands at 1350 and 806 cm^{-1} in the present complex can be assigned tentatively to the stretching and the rocking vibrations of the N–O and N–C respectively of the unidentate hia, according to the assignments in Ref. 2. The band characteristic of uncoordinated carbonyl in the hia ligand was found in 1660 cm^{-1}. As is shown in Table 1, the band due to the N–O stretching vibration of the unidentate hia was found in a higher region than that of the chelating hia. In addition, the stretching vibration band due to the oxime-type C=N bonding in chelating hia has also been found in a lower region than that expected.[8] No explanation for why the stretching bivrations of both N=C and N–O become lower in $[Ru(acac)_2(hia)]$ can be offered at the present time.

Bottomley *et al.* proposed that coordinated NO^+ with $\nu(NO) > 1886$ cm^{-1} behaves as an electrophile.[9] According to their criterion, $[RuCl(acac)_2NO]$(ν(NO); 1884 cm^{-1}) in Ref. 3 exists on the borderline between complexes reactive and unreactive toward nucleophiles. On the other hand, $[RuCl(bpy)_2NO](ClO_4)_2$(ν(NO); 1927 cm^{-1}) has been known to be very reactive.[2] It was found in the present work that $[RuCl(bpy)_2NO]^{2+}$ reacts with Hacac to give a Ru(II) complex containing the unidentate hia, while $[RuCl(acac)_2NO]$ gives a Ru(III) complex containing the bidentate hia under the same conditions.[3] The formation of the two types of hia seems to be connected with the difference in the reactivities of coordinated nitrosyl between $[RuCl(bpy)_2NO](ClO_4)_2$ and $[RuCl(acac)_2NO]$.

The authors wish to express their thanks to Professor Thomas J. Meyer, the University of North Carolina, for his kind consent for us to investigate the nitrosyl complex prepared by himself. The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

^{1}H and ^{13}C NMR of 2,2′-Bipyridine Adducts with Butyltin(IV) Trichloride and Tin(IV) Tetrachloride, and Tetrabromide

Gen-etsu MATSUBAYASHI and Jun IYODA*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

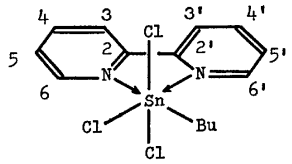
**Government Industrial Research Institute, Midorigaoka, Ikeda, Osaka 566*

(Received June 13, 1977)

Synopsis. ^{1}H and ^{13}C NMR spectra of 2,2′-bipyridine adducts of butyltin(IV) trichloride and tin(IV) tetrachloride and -bromide have been measured in *N,N*-dimethylacetamide. On the basis of the chemical shifts of the ^{13}C nucleus and spin-spin coupling constants of the $^{117/119}Sn$ with the ligand ^{1}H and ^{13}C nuclei the configuration of the adducts and the nitrogen-tin coordination bond are discussed.

Spin-spin coupling constants between the ligand atoms and the metal nucleus of complexes give important informations about the metal-ligand bond. To date, however, there have been only a few reports[1-3] on the coupling constants between $^{117/119}Sn$ nuclei and ligand protons measured in tin(IV) halide adducts of organic ligands, and tin couplings with ligand ^{13}C nuclei of the adducts have never been measured. Recently we have observed the couplings between the tin nuclei and the protons attached to the carbons adjacent to the coordinating nitrogen atoms in the 2,2′-bipyridine (bpy) adduct of butyltin trichloride.[2] This paper reports ^{1}H and ^{13}C NMR data of bpy adducts of butyltin trichloride and tin tetrachloride and tetrabromide in *N,N*-dimethylacetamide.

As described previously,[2] the bpy adduct of $BuSnCl_3$ is monomeric and a non-electrolyte in acetonitrile. Essentially the same situation is expected in *N,N*-dimethylacetamide, because the adduct in this solvent shows quite similar ^{1}H NMR spectral behavior to the observations in acetonitrile solution both in the absence and in the presence of excess bpy. The figure indicates the ^{13}C NMR spectrum of the bpy adduct of $BuSnCl_3$ in *N,N*-dimethylacetamide. Signal assignment is facilitated by the ^{13}C NMR measurement with selective $\{^{1}H\}$–^{13}C decoupling of each bpy proton signal. This assignment is consistent with that of platinum(II)–bpy complexes.[4,5] The occurrence of the doubly separated C(2,2′) and C(5,5′) signals is in agreement with the previously suggested configuration A, where the butyl group lies on the N–Sn–N plane of the hexa-coordinated complex.[2]



(A)

In the spectra of the hexa-coordinated bpy–SnX_4 (X=Cl or Br) adducts the signals were also unchanged by the addition of excess bpy, indicating no significant exchange between the complexed and free ligands on the NMR time scale in this solvent.

The ^{13}C signal assignment of the adducts, as well as their ^{1}H NMR data, is summarized in the table.

The C(2,2′) and C(6,6′) signals of free bpy move upfield and the others move downfield in the complexes. Although the same behavior concerning the direction of signal shift upon complexation was also detected in the platinum(II)-bpy complexes,[4,5] the large upfield shift of C(2,2′) and C(6,6′) signals is noticeable in the present tin halide adducts (see Table). This is rather analogous to the signal shift in the protonation of pyridine (C(2,6), +7.8 ppm; C(3,5), −5.0 ppm; C(4), −12.4 ppm).[6]

As is apparent from the figure, each ^{13}C signal has satellites due to the spin-spin coupling with the tin nuclei, while the ligand proton coupling with the tin atom is detected only at the H(6,6′) signal.[2] In the platinum(II)–bpy complexes all bpy ^{13}C signals also give satellites due to the coupling with the ^{195}Pt nucleus.[4,5] However, a marked difference in the relative magnitudes of the coupling constants in these complexes can be noticed; the C(4,4′)–platinum coupling is extremely small (≈6 Hz) compared with the platinum couplings of the other ring carbons (26—32 Hz), while the C(4,4′)–tin coupling is rather larger than the C(3,3′) and C(5,5′) couplings. This larger C(4,4′) coupling observed in the tin halide adducts may be indicative of a

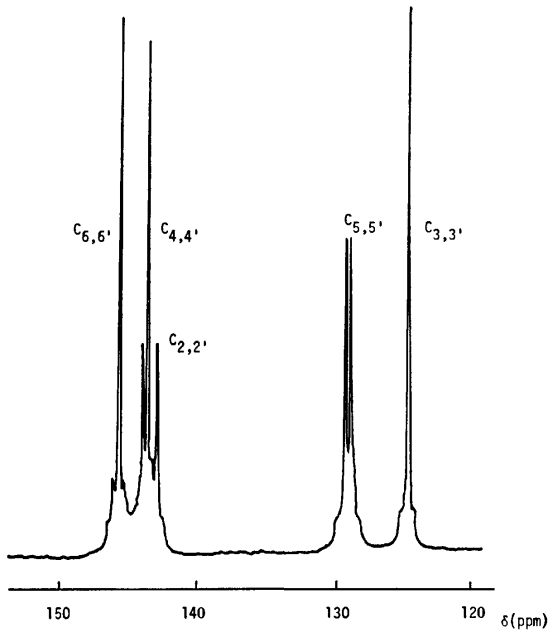


Figure. The ^{13}C NMR spectrum of $BuSnCl_3$·bpy in *N,N*-dimethylacetamide at 32 °C.

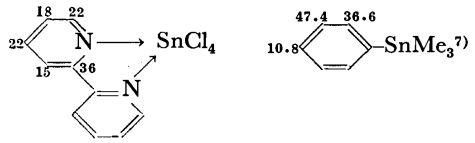
TABLE. ^{1}H AND ^{13}C NMR CHEMICAL SHIFTS (ppm) AND COUPLING CONSTANTS ($^{117/119}Sn$–^{1}H AND $^{117/119}Sn$–^{13}C) (Hz)[a] FOR 2,2′-BIPYRIDINE ADDUCTS OF Tin(IV) HALIDES IN *N,N*-DIMETHYLACETAMIDE

	^{1}H Resonances[b]					^{13}C Resonances[c]						
	$H_{3,3'}$	$H_{4,4'}$	$H_{5,5'}$	$H_{6,6'}$		$C_{2,2'}$		$C_{3,3'}$	$C_{4,4'}$	$C_{5,5'}$		$C_{6,6'}$
bpy	8.48	7.94	7.44	8.72		156.2		121.0	137.5	124.5		149.8
$SnCl_4$·bpy	9.35	8.84	8.38	9.66 (34)		142.1 (36)		125.3 (15)	145.0 (22)	129.7 (18)		145.0 (22)
$SnBr_4$·bpy	9.39	8.87	8.46	9.81 (38)		141.1 (e)		125.4 (16)	144.1 (25)	129.5 (18)		145.3 (23)
$BuSnCl_3$·bpy[d]	9.13	8.63	8.18	9.84 (38)	9.21 (11)	142.8 (15)	144.1 (e)	124.5 (20)	143.6 (22)	128.4 (24)	128.9 (e)	145.5 (22)

a) Shown in parentheses. b) Measured at 24 °C. c) Measured at 32 °C. d) For ^{1}H NMR data in Ref. (2). e) Could not be obtained since the signals were obscured by other signals.

significant π-interaction of bpy with the tin atom. This is in contrast with the fact that in trimethylphenyltin having a covalent aryl–tin bond the coupling between the tin and para-carbon nuclei is small;[7] here the phenyl-metal π-interaction may be small, as deduced in phenylplatinum derivatives.[8]



The tin–H(6,6′) or –carbon coupling constants of the $SnBr_4$ adduct are larger than those of the $SnCl_4$ adduct, indicating stronger Lewis acidity of $SnBr_4$. This is consistent with the result that stability constants of the $(CH_3)_2SnX_2$–bpy complexes increase in the order of X=Cl<Br<I.[9]

Directly bonded ^{13}C–^{1}H coupling constants of bpy obtained from the measurements without proton decoupling are larger in the adduct compared with those of the free ligand as follows.

	$^{1}J(^{13}C$–$^{1}H)$ (Hz)			
	$C_{3,3'}$–H	$C_{4,4'}$–H	$C_{5,5'}$–H	$C_{6,6'}$–H
Free bpy	170	163	163	178
$BuSnCl_3$·bpy	172	171	174	188

This is explainable as due to an increase of s-character in the C–H bond upon the adduct formation. The same behavior was reported in the directly bonded ^{13}C–^{1}H couplings on protonation of nicotinamide.[10]

Experimental

Materials. The preparation of $BuSnCl_3$·bpy was described previously.[2] SnX_4·bpy (X=Cl and Br) were prepared as white needles by mixing SnX_4 with an equimolar amount of bpy in acetonitrile. $SnCl_4$·bpy. Mp>300 °C. Found: C, 29.07; H, 2.00; N, 7.00%. Calcd for $C_{10}H_8N_2Cl_4Sn$: C, 28.82; H, 1.93; N, 6.72%. $SnBr_4$·bpy. Mp >300 °C. Found: C, 20.34; H, 1.34; N, 4.88%. Calcd for $C_{10}H_8N_2Br_4Sn$: C, 20.20; H, 1.36; N, 4.71%.

NMR Measurements. The ^{1}H NMR spectra were measured at 24 °C as described elsewhere.[1] The ^{13}C NMR spectra were obtained at 25.15 MHz using the pulse Fourier transform technique with a JEOL PS 100 spectrometer, an FT-100 FT unit, a DP-1 pulse programmer, and an EC-100 computer. ^{13}C chemical chifts in ppm were measured relative to TMS as an internal standard at 32 °C.

We wish to express our hearty thanks to Professor Toshio Tanaka for his continuous encouragement through this study.

A New Measure of Aromatic Stabilization: Resonance Energy per π Bond (REPB)

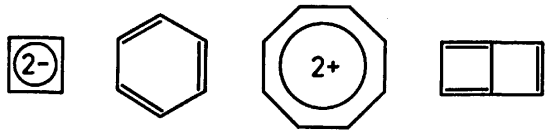
Jun-ichi AIHARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received October 18, 1976)

Synopsis. A concept of resonance energy per π electron appears unsuitable for representing the aromatic stabilization of a conjugated compound. If the resonance energy is divided by the number of π bonds constituting π rings in the conjugated system, though, a reasonable index is obtained for the same purpose.

In 1971, Hess and Schaad[1] interpreted Dewar's theory of aromaticity[2] by means of the HMO theory. They defined the aromatic resonance energy of a conjugated compound as the difference between the HMO π energy and the π energy of a "localized structure" obtained in an additive manner using the empirical π bond energies. Here, a "localized structure" signifies an olefinic reference structure which is hypothetically free from aromaticity. They further showed that if the resonance energy is divided by the number of π electrons in the compound, a quantity is obtained which correlates well with the experimental stability.[1] This was termed "resonance energy per π electron (REPE)". In previous papers,[3] we succeeded in formulating a characteristic polynomial for a "localized structure" of a conjugated compound, and analytically reproduced the resonance energies of Hess and Schaad without any parametrization. Of course, our resonance energies are Dewar-type.[1-3] In this note, we wish to point out that the definition of REPE should be modified in line with our exact resonance energies.



(I) (II) (III) (IV)

First, one should remember that Hess and Schaad defined REPE in order to overcome the wide variation in the size of conjugated systems usually compared.[1] This means that the REPE was presented as a better way of comparing resonance energies of various compounds. However, one finds that when the concept of REPE is extended to ionic conjugated systems, a serious ambiguity arises. For example, the resonance energies of the cyclobutadiene dianion(I), benzene(II), and the cyclooctatetraene dication(III) must be divided by the same number of π electrons, *i.e.*, six, to obtain their REPE values. This procedure is obviously in contradiction to the original intention of Hess and Schaad.[1] As has been suggested above, they intended to reflect the size of a conjugated system in the resonance energy by defining REPE. Therefore, the divisor should be changed if the size of a conjugated system is changed. Logically it should not depend upon the ionicity of a conjugated system.

According to the same definition of REPE, the resonance energies of benzene(II) and butalene(IV) must also be divided by the same number of π electrons, *i.e.*, six, in order to obtain their REPE values. Although butalene has one more π bond than benzene, the sizes of their conjugated systems have been tacitly considered to be identical.[1] We might say that the number of π electrons does not always reflect the size of a conjugated system, even if it is a neutral compound. Such an aspect of REPE is found among many sets of conjugated compounds.

We verified previously that aromaticity arises exclusively from a set of π rings in a conjugated system.[3] It is obvious that even if side chains and the like are conjugated with the main part of a cyclic conjugated system, they are absolutely olefinic. We might say that these side chains are neither stabilized or destabilized by the overall resonance energy. The role of the side chains is to somewhat modify the resonance energy of a π ring system (*i.e.*, a set of π rings in the conjugated system). The resonance energy obtained should, therefore, be attributed exclusively to the π rings or their constituents (*i.e.*, π bonds constituting these π rings). This fact is also inconsistent with the previous definition of REPE.

In order to avoid such REPE-based difficulties, we propose a new quantity which supposedly represents the actual stability of a conjugated system. It is defined as the Dewar-type resonance energy, divided by the number of π bonds which form a π ring system of a conjugated compound, and is termed "resonance energy per π bond" or REPB for short. As is indicated in this definition, the π bonds involved here are limited to those constituting cyclic components of Sachs graphs (*i.e.*, subgraphs of a molecular graph originally introduced by Sachs[4]).

It is noteworthy to see that, as an index of the size of a π ring system, the number of π bonds in it is preferable to the number of π electrons. It is nothing other than all the π bonds in the π ring system which must be sustained by the overall resonance energy. In this sense, the REPB reflects the size of a π ring system. The resonance energy has thus been assigned to individual π bonds forming a π ring system. Such a consideration appears to support our definition of REPB.

Table 1 contains 18 examples of conjugated compounds, shown with their values for REPE and REPB. When a conjugated system is neutral and monocyclic, REPE exactly agrees with REPB. However, when a conjugated system is ionic or polycyclic, the two quantities generally disagree. The deviation of REPE from REPB is never small for most conjugated compounds. One can see by using REPB that substituents such as a vinyl group do not stabilize a cyclobutadiene ring so

Table 1. REPE and REPB values in units of β for 18 conjugated systems

Compound	Resonance energy[a]	REPE$\times 10^3$	REPB$\times 10^3$	$100\times\frac{(\text{REPE}-\text{REPB})}{\text{REPB}}$
Cyclobutadiene	−1.226	−306.6	−306.6	0.0

a) Ref. 3.

dramatically. This is in marked contrast to the prediction based on the REPE values.[5]

So far, such a discrepancy has not been noticed, partly because the degree of aromaticity cannot be measured quantitatively, and partly because scarcely no resonance energies have been estimated for ionic species.[6] Furthermore, the resonance energies published for neutral species are all empirical ones, in the sense that they are based on empirical π bond energies.[1,2] Now the situation has been totally changed. We have shown that Dewar-type resonance energies can be exactly calculated for any conjugated systems, including ions, as long as the HMO theory is used.[3] Accordingly, a measure of the aromatic stabilization should also be refined in harmony with the exactness of these resonance energies. This is exactly why REPE must be replaced by REPB. If a more detailed discussion of aromaticity is made in the future, it should be based on the values for REPB. The same definition of REPB can be applied to any Dewar-type resonance energies.[1–3]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 50 (11), 3059—3060 (1977)

The Acid-catalyzed Reaction of Alicyclic Ketones with Formaldehyde. II.[1] The Reaction of Cycloheptanone and Cyclooctanone with Formaldehyde

Fukumi HIRANO and Shoji WAKABAYASHI

Department of Chemistry, Faculty of Science, Okayama College of Science, Ridai-cho, Okayama 700

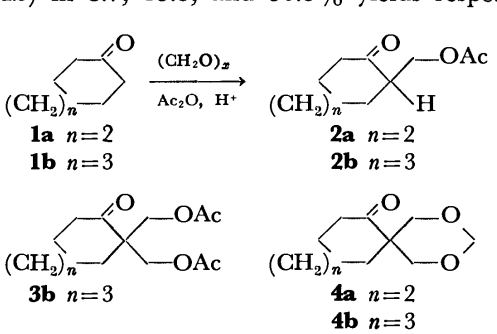
(Received January 29, 1977)

Synopsis. The acid-catalyzed reaction of cycloheptanone and cyclooctanone with formaldehyde gave predominantly 2,4-dioxaspiro[5.6]dodecan-7-one and 2,4-dioxaspiro[5.7]tridecan-7-one respectively.

In the previous paper,[1] we reported the reactions of cyclopentanone, cyclohexanone, and the alkyl-substituted cycloalkanones with formaldehyde in the presence of acid catalysts. The reactions produced hydroxymethyl derivatives, spiromono- and bis(1,3-dioxanes). The distribution of these products was markedly affected by both the skeletal structure and the substituent of the cycloalkanones. In this paper, we wish to report on the reactions of cycloheptanone (**1a**) and cyclooctanone (**1b**), together with the ring-size effect of cycloalkanones on the acid-catalyzed reaction.

The reaction of **1a** or **1b** with formaldehyde was carried out in a mixture of acetic acid and acetic anhydride in the presence of phosphoric acid at 60 °C. After the distillation of the resulting mixture, the products were isolated by preparative GLPC and were characterized on the basis of their chemical behavior and by spectroscopic methods.

The reaction of **1a** gave 2-acetoxymethylcycloheptanone (**2a**) and 2,4-dioxaspiro[5.6]dodecan-7-one (**4a**) in 21.4 and 43.8% yields respectively on the basis of the **1a** used. Similarly, the reaction of **1b** gave 2-acetoxymethylcyclooctanone (**2b**), 2,2-diacetoxymethylcyclooctanone (**3b**), and 2,4-dioxaspiro[5.7]tridecan-7-one (**4b**) in 8.7, 13.5, and 36.5% yields respectively.



Scheme 1.

The PMR spectra of **4a** and **4b** showed a methylenedioxy proton at δ 4.53 (a characteristic quartet in the AB-type) in both compounds, and their IR spectra showed an absorption due to a methylenedioxy group at 2775 cm^{-1} in **4a** and at 2745 cm^{-1} in **4b** respectively. From these results, the structure of **4a** and **4b** was assigned to spiromono(1,3-dioxane) derivatives. The structure of **3b** was confirmed by the fact that the identical diacetate was obtained by the acetolysis of **4b** in the presence of phosphoric acid.

The acid-catalyzed reaction of **1a** and **1b** was compared with that of cyclopentanone and cyclohexanone. The reactivity might decrease in the order of C_6->C_5->C_7->C_8-cycloalkanones, judging from the experiments undertaken. The product distribution was quite sensitive to the ring-size of the cyclic ketones. The reaction of C_7- and C_8-cycloalkanones afforded mainly spiromono(1,3-dioxanes), but not bis(1,3-dioxanes), which were yielded largely in the reaction of cyclohexanone. These facts seem to be explained by the increased transannular repulsions arising from the formation of bis(1,3-dioxanes) in C_7- and C_8-cycloalkanones.

Experimental

All the boiling and melting points are uncorrected. The IR spectra were measured using a JASCO model IR-A spectrophotometer. The PMR spectra were obtained on a JEOL MH-60 II spectrometer (60 MHz), using tetramethylsilane as the internal standard. The mass spectra were taken with a Hitachi Model RMU-6GC mass spectrometer at 70 eV.

Materials. The cycloheptanone (**1a**) and cyclooctanone (**1b**) were prepared by the reported method;[2] **1a**: bp 65—67 °C/2 mmHg; **1b**: mp 32—33 °C.

Reaction of Cycloheptanone (1a) with Formaldehyde. To a stirred solution of paraformaldehyde (9.0 g, 0.3 mol), acetic anhydride (10.2 g, 0.1 mol), and 85% phosphoric acid (5.7 g, 0.05 mol) in glacial acetic acid (30 ml), **1a** (11.2 g, 0.1 mol) in glacial acetic acid (20 ml) was added over a 3-h period at 60 °C, after which the mixture was stirred at the same temperature for 7 h. The usual work-up gave 15.9 g of an oily product. The oil was then distilled under reduced pressure to give an unreacted **1a** (4.2 g, 37.1% yield, based on the **1a** used) and a colorless liquid (9.5 g, bp 67—113 °C/2 mmHg; GLPC analysis showed **2a**, **4a**, and the self-condensates of formaldehyde with peak area ratios of 31, 56, and 13% respectively). The latter distillate was separated by preparative GLPC (Apparatus: Yanaco G-80. Column, 30% Diethylene Glycol Succinate Polyester on Chamelite CK, 14 mm × 3 m. Temp, 170 °C. Carrier gas, H_2 at 280 ml/min) to afford **2a** (2.4 g, 21.4%) and **4a** (4.9 g, 43.8%), each as a colorless liquid; *2-acetoxymethylcycloheptanone (2a)*: d_4^{25} 1.0682, n_D^{25} 1.4640. PMR (CCl_4): δ 1.12—2.19 (br, 8H), 1.96 (s, 3H), 2.40 (m, 2H), 2.82 (m, 1H), and 3.98 (ABX, J_{AB}=11 Hz, J_{AX}=J_{BX}=6.0 Hz, $\Delta\nu_{AB}$=19.5 Hz, 2H). IR (neat): 1732 (vs), 1692 (vs), 1236 (vs), 1040 (s), and 1024 (s) cm^{-1}. Found: C, 65.42; H, 8.73%. Calcd for $C_{10}H_{16}O_3$: C, 65.19; H, 8.75%. *2,4-Dioxaspiro[5.6]dodecan-7-one (4a)*: Bp 112—113 °C/2 mmHg, d_4^{25} 1.1217, n_D^{25} 1.4880. MS: *m/e* 184 (M^+). PMR (CCl_4): δ 1.60 (br s, 6H), 1.94 (m, 2H), 2.36 (m, 2H), 3.63 (AB-q, J=12 Hz, 4H), and 4.53 (AB-q, J=5.7 Hz, 2H). IR (neat): 2775 (w), 1684 (vs), 1160 (vs), 1152 (vs), 1028 (s), 1004 (s), and 920 (s) cm^{-1}. Found: C, 65.37; H, 8.68%. Calcd for $C_{10}H_{16}O_3$: C, 65.19; H, 8.75%.

*Reaction of Cyclooctanone (**1b**) with Formaldehyde.* In a way similar to that in the reaction of **1a**, the reaction of **1b** (12.6 g, 0.1 mol) with paraformaldehyde (9.0 g, 0.3 mol) and acetic anhydride (10.2 g, 0.1 mol) gave 17.5 g of an oily product. The oil was distilled under reduced pressure to give an unreacted **1b** (5.2 g, 41.3%) and two colorless fractions (A: 8.2 g, bp 59—132 °C/0.1 mmHg; B: 1.8 g, bp 132—134 °C/0.1 mmHg). The A fraction (GLPC analysis indicated **2b**, **4b**, and the self-condensates of formaldehyde with peak area ratios of 15, 73, and 12% respectively) was then separated by preparative GLPC to afford **2b** (1.1 g, 8.7%) and **4b** (4.6 g, 36.5%), each as a colorless liquid; *2-Acetoxymethylcyclooctanone (**2b**)*: d_4^{25} 1.0565, n_D^{25} 1.4689. PMR (CCl_4): δ 0.82—2.10 (br, 10H), 1.95 (s, 3H), 2.23 (m, 2H), 2.87 (m, 1H), and 3.93 (ABX, J_{AB}=11 Hz, J_{AX}=6.0 Hz, J_{BX}=8.7 Hz, $\Delta\nu_{AB}$=15 Hz, 2H). IR (neat): 1732 (vs), 1696 (vs), 1232 (vs), 1044 (s), and 1028 (s) cm^{-1}. Found: C, 66.90; H, 9.13%. Calcd for $C_{11}H_{18}O_3$: C, 66.64; H, 9.15%. *2,4-Doixaspiro[5.7]tridecan-7-one (**4b**)*: bp 104—105 °C/0.1 mmHg. d_4^{25} 1.1076, n_D^{25} 1.4927. MS: *m/e* 198 (M^+). PMR (CCl_4): δ 1.48 (m, 8H), 2.17 (m, 4H), 3.72 (s, 4H), and 4.53 (AB-q, J=6.0 Hz, 2H). IR (neat): 2745 (w), 1682 (vs), 1170 (vs), 1154 (vs), 1134 (vs), 1064 (vs), 1040 (s), 1028 (vs), 921 (s) cm^{-1}. Found: C, 66.91; H, 9.13%. Calcd for $C_{11}H_{18}O_3$: C, 66.64; H, 9.15%.

On the other hand, the B fraction crystallized directly on standing and was recrystallized from cyclohexane to yield *2,2-diacetoxymethylcyclooctanone (**3b**)* (1.7 g, 13.5%) as white crystals; mp 65—66 °C; PMR (CCl_4): δ 1.16—2.10 (br, 10H), 1.98 (s, 6H), 2.42 (m, 2H), and 4.05 (AB-q, J=12 Hz, 4H). IR (CCl_4): 1740 (vs), 1693 (s), 1233 (s). 1219 (s), 1040 (s), and 1021 (s) cm^{-1}. Found: C, 62.28; H, 8.23%. Calcd for $C_{14}H_{22}O_5$: C, 62.20; H, 8.20%.

*Acetolysis of Spiromono(1,3-dioxane) (**4b**).* A solution of **4b** (198 mg, 1 mmol), acetic anhydride (204 mg, 2 mmol), and 85% phosphoric acid (57 mg, 0.5 mmol) in glacial acetic acid (1 ml) was stirred at 60 °C for 10 h. After a subsequent work-up, 190 mg of an oily mixture were obtained. The PMR analysis revealed that the reaction mixture consisted of an acetolysis product (12%) and unreacted **4b** (88%), which were isolated by preparative GLPC to give 22 mg (11.1% yield, based on the **4b** used) of the acetolysis product and 158 mg (79.8%) of **4b**. The IR spectrum of the acetolysis product was completely identical with that of **3b** obtained from **1b**.

The Photochemical Sulfenylation of Hindered Phenols with Diaryl Disulfides

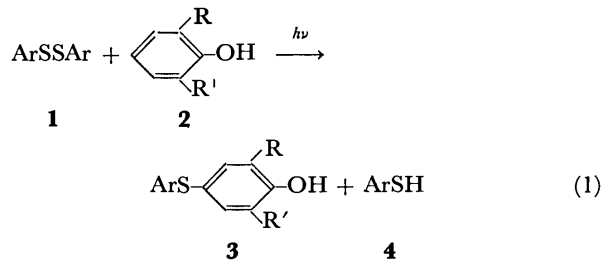
Tamotsu FUJISAWA and Takakazu KOJIMA

Sagami Chemical Research Center, Nishi-Ohnuma, Sagamihara, Kanagawa 229

(Received March 16, 1977)

Synopsis. The photochemical reaction of diaryl disulfides with 2,6-disubstituted phenols was investigated. The reaction with highly hindered phenols proceeded appreciably upon irradiation with a high-pressure mercury lamp, giving rise to 4-arylthio-2,6-disubstituted phenols. The reaction was initiated by the homolytic scission of the disulfides.

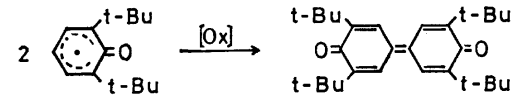
A previous report[1] concerning hindered phenols has demonstrated the synthesis of 4-arylthio-2,6-disubstituted phenols in basic media using diaryl disulfides as sulfenylating agents. We wish to report here another simple method of preparing the same sulfides by a photochemical sulfenylation of hindered phenols. The reaction proceeds smoothly and mildly upon the simple irradiation of a solution of diaryl disulfides and hindered phenols in an inert solvent with an ultraviolet lamp.



1 **2** **3** **4** (1)

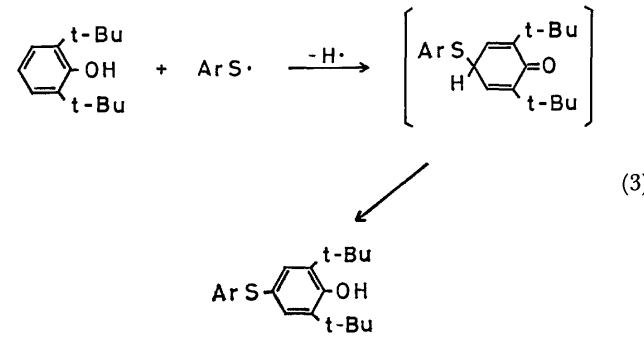
Thus, a solution of diphenyl disulfide (**1**, Ar=C_6H_5) and 2,6-di-*t*-butylphenol (**2**, R=R′=*t*-C_4H_9) in cyclohexane was irradiated with a high-pressure mercury lamp through a Pyrex filter at room temperature for 20 h. 2,6-Di-*t*-butyl-4-(phenylthio)phenol (**3**, Ar=C_6H_5, R=R′=*t*-C_4H_9) was obtained in a 65% yield based on the phenol **2** consumed (GLC). Table 1 summarizes the results of the application of this method to several disulfides and substituted phenols.

In this reaction, solvents with no hydrogen active towards abstraction, such as cyclohexane and benzene, are suitable. Carbon tetrachloride, well-known chain-transfer reagents,[2] showed itself a good solvent, perhaps by reason of the formation of arenesulfenyl chloride, which subsequently acted as a sulfenylating agent.[3,4] The yields of **3** were significantly influenced by the substituents (R and R′). A less hindered phenol, 2,6-dimethylphenol, did not afford the corresponding arylthiolated phenol and was recovered quantitatively. The reaction of 2,6-di-*t*-butylphenol with aqueous hexacyanoferrate(III) in the presence of diphenyl disulfide or thiophenol leads to the exclusive formation of a diphenoquinone derivative, **5**,[5] yielded from the dimerization of the phenoxyl radical, without forming the expected **3**. The radical reaction of **1** and **2** initiated with α,α'-azodiisobutyronitrile also failed.



5 (2)

Unlike the photochemical reaction of disulfide with the aryl radical generated from aryl halide,[6] the present reaction proceeds *via* the aryl thiyl radical formed by the homolytic scission of aryl disulfide. This radical species, then, attacks the phenol, **2**, followed by the abstraction of hydrogen by another thiyl radical to give an intermediate dienone; it subsequently rearranges to (arylthio)phenol, **3**.



(3)

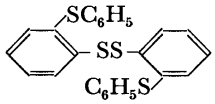
Table 1. Arylthiophenols from disulfides and phenols

Disulfide (**1**) Ar	Phenol (**2**) R	R′	Solvent	Yield of (Arylthio)phenol (**3**) (%)
C_6H_5	*t*-Bu	*t*-Bu	*c*-C_6H_{12}	29 (61)
C_6H_5	*t*-Bu	*t*-Bu	C_6H_6	25 (54)
C_6H_5	*t*-Bu	*t*-Bu	CCl_4	24 (65)
p-$CH_3C_6H_4$	*t*-Bu	*t*-Bu	*c*-C_6H_{12}	28 (61)
p-$CH_3OC_6H_4$	*t*-Bu	*t*-Bu	*c*-C_6H_{12}	10 (69)
p-ClC_6H_4	*t*-Bu	*t*-Bu	C_6H_6	23 (39)
C_6H_5	*t*-Bu	Me	*c*-C_6H_{12}	13 (36)
C_6H_5	*i*-Pr	*i*-Pr	*c*-C_6H_{12}	24 (48)
C_6H_5	Me	Me	*c*-C_6H_{12}	0 (0)

Irradiated for 24 h. The yields are based on the phenols. The yields based on the phenols consumed are shown in parentheses.

The ultraviolet spectrum of 2,6-di-*t*-butylphenol shows no notable absorption in the Pyrex-filtered region (>300 nm), and diphenyl disulfide is known to have an n-π^* transition at 320 nm (ε=783)[7] in the skirt of the strong π-π^* transition (243 nm). Two or three times as much disulfide was consumed under irradiation as was expected in the stoichiometry shown by Eq. 1. Consequently, arenethiols, **4**, were formed in greater amounts than (arylthio)phenols, **3**. One of the by-products formed in this reaction was bis[4-(2-phenylthio)phenyl] disulfide (**6**), which was isolated in an 18% yield when equimolar amounts of diphenyl disulfide and 2,6-di-*t*-

butylphenol were irradiated in cyclohexane for 50 h. This disulfide, **6**, is considered to be formed *via* 2-(phenylthio)benzenethiol, a rearranged dimer of the phenylthiyl radical.[8]



6

Experimental

Preparation of 4-Arylthio-2,6-dialkylphenol (3). The following procedure is representative of the preparation of **3**. Diphenyl disulfide (**1**, Ar=C_6H_5, 371 mg) and 2,6-di-*t*-butylphenol (**2**, R=R′=*t*-C_4H_9, 175 mg) were dissolved in cyclohexane (5 ml) and were then, after degassing, irradiated in a Pyrex ampoule with a high-pressure mercury lamp (450 W) for 20 h. The products were analyzed by GLC. Then, the solvent was removed from the reaction mixture under reduced pressure; subsequent column chromatography of the residue on silica gel (eluted by hexane) gave 2,6-di-*t*-butyl-4-(phenylthio)phenol (**3**, Ar=C_6H_5, R=R′=*t*-C_4H_9) in a 57% yield (58 mg) based on the phenol consumed. The conversion of **2** was 38%.

All of the products, (arylthio)phenols (**3**), were identified by a comparison of the mp, GLC, and IR and NMR spectra with those of the authentic sample.[1]

Bis[4-(2-phenylthio)phenyl] Disulfide (6). When diphenyl disulfide (110 mg) and 2,6-di-*t*-butylphenol (105 mg) in cyclohexane (3 ml) were irradiated using the above procedure, bis[4-(2-phenylthio)phenyl] disulfide (20 mg, 18% based on the **1**) was obtained after column chromatographic separation, along with **3** (Ar=C_6H_5, R=R′=*t*-C_4H_9, 18 mg) and **4** (Ar=C_6H_5, 8 mg). Recrystallization with aqueous ethanol gave pale yellow crystals; mp 118.5—120 °C. MS *m/e*: 434(M^+). IR (Nujol) 1582, 1440, 758, and 693 cm^{-1}. UV (cyclohexane) max: 254 nm (ε 8.2×10^4). Found: C, 66.15; H, 4.38; S, 29.59%. Calcd for $C_{24}H_{18}S_4$: C, 66.31; H, 4.18; S, 29.50%.

Photo-acylamination on Anthracene with Use of Acyl Azides

Kunihiro ICHIMURA

Research Institute for Polymers and Textiles, Sawatari 4, Kanagawa-ku, Yokohama 221

(Received April 22, 1977)

Synopsis. Irradiation of anthracene in the presence of acyl azide gives isocyanate and 9-acylaminoanthracene. The photolysis of aromatic hydrocarbon–acyl azide was followed by UV spectrophotometry and analyzed by the EDQ (quotients of extinction differences) diagram method.

Although direct photolysis of acyl azide has been extensively investigated,[1] its sensitized decomposition is scarcely known. In relation to the photolysis of acyl azide–zinc porphyrin system,[2] studies have been extended to the interaction of excited aromatic hydrocarbons with the ground state of acyl azides. In this paper a report is given on the decomposition of benzoyl azides sensitized by anthracene affording isocyanates and 9-acylaminoanthracenes. This seems to be the first example of sensitized photo-Curtius rearrangement;[3] benzophenon-sensitization has been reported to involve the free radical chain reaction initiated by benzophenone triplet which affords no isocyanate.[4]

A solution of anthracene (**1**) and excess benzoyl azide (**2a**) was irradiated in dichloromethane under nitrogen with light of >320 nm absorbed specifically by the hydrocarbon. The IR spectral change indicated the formation of phenyl isocyanate accompanied by the disappearance of **2a**. TLC revealed the formation of a non-fluorescent product. The pale yellow crystals of mp 250—251 °C were separated by means of column chromatography. The IR bands at 3250 and 1648 cm^{-1} are assignable to the amide band. The structure of the product was unequivocally confirmed by identification with 9-benzoylaminoanthracene (**3a**). In a similar way, 9-(*p*-chlorobenzoylamino)- (**3b**) and 9-(*p*-cyanobenzoylamino)anthracene (**3c**) were obtained. The formation of the corresponding isocyanates was confirmed by the presence of the characteristic IR band. The results are summarized in Tables 1 and 2.

In order to extend the sensitization to the other aromatics, the photolysis of aromatic hydrocarbon–benzoyl azide was followed UV-spectrophotometrically and analyzed by the ED (extinction differences)- and EDQ (quotients of extinction differences)-diagram methods.[5] As shown in Fig. 1-a, the family of absorption curves of **1–2a** system irradiated with light of wavelength >320 nm intersect at the early stage of photolysis, the absorption spectrum of the photoproduct being almost the same as that of **3a**. Linearity was observed in the EDQ-diagram, but not in the ED-diagram. This implies that the photolysis contains two successive reactions: the formation and subsequent slower disappearance of **3a**. It was confirmed that the irradiation of **3a** in the presence of **2a** causes the disappearance of **3a** and that the rate of photolysis of the **3a–2a** system is much slower than that of the **1–2a** system. The

a) In chloroform. b) In KBr.

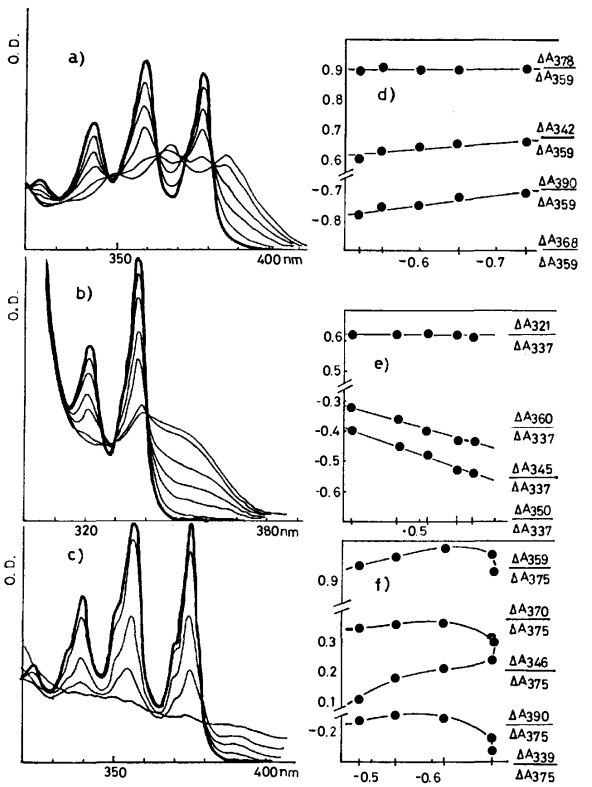

Fig. 1. The electronic absorption spectra recorded at intervals for the UV irradiation of aromatic hydrocarbon–acyl azide system ((a): anthracene–benzoyl azide in toluene, (b): pyrene–benzoyl azide in toluene, (c): anthracene–*p*-toluenesulfonyl azide in methylcyclohexane) and the corresponding EDQ diagrams ((d)—(f)).

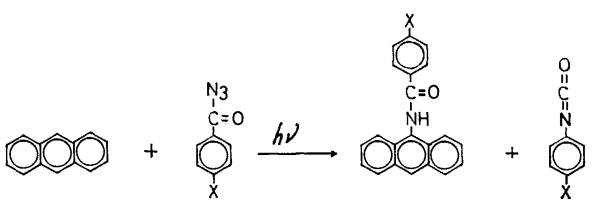
spectral change of **3a–2a** shows a linear ED-diagram, in line with the linearity of EDQ-diagram for the photolysis of **1–2a**.

When a solution containing pyrene and **2a** was irradiated with light of wavelength >320 nm, the peaks due to the hydrocarbon decreased in intensity along with the increase of peaks at 338 nm (Fig. 1-b). The EDQ-diagram was linear in this case (Fig. 1-e). Although the photoproducts are yet to be isolated because of the difficulty of product separation, the appearance of the absorption maxima at greater wavelengths suggests that the photo-induced acylamination may take place on pyrene nucleus as in the case of **1**.

In the cases of 9,10-dimethyl- and 9,10-diphenylanthracene, the absorption peaks decreased on UV irradiation. No new absorption maximum was observed, while the linear EDQ-diagram was obtained.

It was found that anthracene is photolysed in the presence of *p*-toluenesulfonyl azide (**4**). The spectral change during the course of irradiation, however, differs from that of the **1–2a** system (Fig. 1–c). A weak absorption maximum appeared at *ca.* 390 nm at an early stage of photolysis and disappeared completely on prolonged irradiation. The absorption may be due to 9-(*p*-tolylsulfonylamino)anthracene (**5**) having λ_{max} at 337.5, 354, 371, and 391.5 nm. In contrast to the **1–2a** system, linear EDQ-diagram was no longer observed in this case (Fig. 1-f), indicating the involvement of more than three elementary photoreactions. 9-Sulfonylaminoanthracene (**5**) was found to be photolysed in the presence of acyl azide including **4**, the EDQ-diagram for the photolysis being non-linear, which demonstrates the difference in photolytic behavior between **3a** and **5**. The photolysis rate of **5** was found to be *ca.* 15 times greater than that of **3a** when benzoyl azide coexists. The difference in the mode of spectral change between **1–2a** and **1–4** systems reflects the difference in the photoreactivity of the products initially formed, *i.e.*, **3** and possibly **5**. As for the effect of acylamino group on the photoreactivity of anthracene nucleus toward acyl azide, it should be mentioned that 9-acylaminoanthracenes are non-fluorescent whilst 9-sulfonylamino derivative (**5**) gives the blue fluorescence. This implies that the introduction of the acylamino group to anthracene shortens the singlet lifetime so that the photoreactivity may be reduced, whereas the sulfonylamino group shows no remarkable influence on the fluorescence behavior and the photoreactivity of anthracene nucleus.



1 2 3

The photoinduced acylamination on anthracene using acyl azide appears to closely resemble that of zinc octaethylporphin.[2] A distinct difference between both reactions should be stressed: the photolysis of acyl azide-zinc porphyrin affords no isocyanate. This suggests that the sensitization mechanism is quite different from each other.

Experimental

All melting points were not corrected. Ultraviolet and infrared spectra were recorded on a Hitachi type 323 spectrophotometer and a Hitachi EPI-3G spectrophotometer, respectively.

Photolysis of Anthracene in the Presence of Benzoyl Azide. A solution of anthracene (180 mg) and benzoyl azide (1.42 g) in dichloromethane (20 ml) was irradiated under nitrogen gas with a 450 W high pressure mercury arc passed through a Corning 0-54 filter (>320 nm). The photolysis was followed by TLC and IR- and UV-spectrophotometry. The IR band assignable to phenyl isocyanate appeared in proportion to the disappearance of anthracene. After removal of the solvent, the residue was dissolved in dichloromethane and chromatographed on a silica gel column with use of dichloromethane as an eluent. After eluting the fluorescent fraction of anthracene, a pale yellow fraction was collected and evaporated to dryness. The residue was recrystallized from acetonitrile to give 67.4 mg yellow needles of 250—251 °C which was identified with 9-benzoylaminoanthracene by the mixture melting point and IR spectra. The amount of recovered anthracene was estimated to be 72.4 mg with the aid of UV spectroscopy. The yield of 9-benzoylaminoanthracene was therefore 37% based on consumed anthracene.

In a similar way, 9-(*p*-chlorobenzoylamino)- and 9-(*p*-cyanobenzoylamino)anthracene were obtained, starting from *p*-chlorobenzoyl azide and *p*-cyanobenzoyl azide, respectively. The results are summarized in Tables 1 and 2.

EDQ-Diagram Examination of Photolysis.[5] A three ml solution of anthracene (*ca.* 10^{-5} M/l) and benzoyl azide (*ca.* 10^{-2} M/l) in toluene was irradiated with light of wavelength >320 nm, and the UV spectra were recorded at intervals. The final spectrum was essentially the same as that of 9-benzoylaminoanthracene, the yield being estimated to be 56% (Fig. 1-a).

Similarly, the photolysis of the following combinations were determined by the EDQ-diagrams; pyrene–benzoyl azide in toluene, anthracene–*p*-toluenesulfonyl azide in methyl-cyclohexane, 9,10-dimethylanthracene–benzoyl azide in toluene, and 9,10-diphenylanthracene–benzoyl azide in toluene. Typical examples are shown in Fig. 1.

The Aromatic Thiocyanation of 1-Alkoxynaphthalene by the Copper(II) Thiocyanate Method

Kiyoko FUJIKI

Department of Agricultural Chemistry, Faculty of Agriculture, Meiji University, Ikuta, Tama-ku, Kawasaki 214

(Received May 20, 1977)

Synopsis. A facile thiocyanation of 1-alkoxynaphthalene using copper(II) thiocyanate afforded 4-thiocyanato compound. The reaction proceeded at a moderate temperature (80—90 °C) even for 1-alkoxynaphthalene with higher alkyl groups (C_6, C_8, and C_{12}).

During the course of an investigation of the pesticidal activities of aryl ethers it became desirable to prepare thiocyanato compounds of 1-alkoxynaphthalene because of their effected insecticidal and fungicidal activities.[1]

As a means of introducing a thiocyanato group into the aromatic nucleus, thiocyanogen is useful as a reagent for such reactive substrates as amines and phenols.[2] Less reactive substrates, such as phenolic ethers, naphthalene derivatives, and anillides, which are unreactive towards thiocyanogen, give thiocyanates in high yields when treated with thiocyanogen chloride in acetic acid;[3] however, 2-methoxynaphthalene reacts with not only thiocyanogen chloride[3] but also thiocyanogen[2,4] to give the 1-thiocyanato compound. As to the thiocyanation of 1-methoxynaphthalene, it has been thiocyanated at the 4-position in a 10.7% yield by a mixture of KSCN and *N*-chlorourea in acetone.[5] The 4-thiocyanato compounds of 1-ethoxy, 1-propoxy, 1-butoxy, and 1-isopentyloxy naphthalene have also been synthesized in a liquid state in a similar manner.[6] Other methods for the thiocyanation of aryl ethers involve the reaction of arylthallium(III) compounds with copper(II) and (I) thiocyanate[7] or with KSCN under the irradiation of light.[8]

The present paper will deal with the preparation of 1-alkoxy-4-thiocyanatonaphthalene by the copper(II) thiocyanate method[9], which was previously applied to the thiocyanation of 1-naphthol.[2] It is considered that the copper(II) thiocyanate method shows promise of being effective for the thiocyanation of higher alkyl naphthyl ethers, since copper(II) thiocyanate releases thiocyanogen merely by the dissociation of the cupric to cuprous salt (Eq. 1). Moreover, the procedure has the advantage over the others previously described of permitting a higher temperature for thiocyanation.

$$2Cu(SCN)_2 \rightarrow 2CuSCN + (SCN)_2 \quad (1)$$

Thiocyanation with $(SCN)_2$ was less reactive in higher alkyl (C_6–C_{12}) naphthyl ethers due to an electrophilic attack of SCN^+.

To a solution of 1-alkoxynaphthalene in acetic acid we added copper(II) thiocyanate, freshly prepared[10] in advance; the mixture was then warmed while being stirred for 2.0 to 2.5 h. The reaction is accompanied by a color change from black to white[2] (actually from black to a yellowish green or yellow color) due to the formation of copper(I) thiocyanate.

$$ArH + 2Cu(SCN)_2 \rightarrow ArSCN + 2CuSCN + HSCN \quad (2)$$

Usually the 4-thiocyanato compound of 1-alkoxynaphthalene was obtained in a good yield when the molar ratio of $Cu(SCN)_2$ to the 1-alkoxynaphthalene was 4 to 1. The IR and NMR spectra[11] revealed no isomeric naphthyl isothiocyanate or 2-thiocyanato compound in the reaction product. When the molar ratio of $Cu(SCN)_2$ to 1-ethoxynaphthalene was 2 to 1, and when the reaction temperature was raised to the range from 115 to 118 °C, no thiocyanate was produced, but a small amount of the disulfide of 4-ethoxynaphthalene was obtained. The experimental results are summerized in Table 1.

Experimental

The method used in the preparation of 1-alkoxynaphthalene was a modification of the method of Yokoyama *et al.*[12] The IR spectra were recorded on a Hitachi EPI G3 spectrophotometer. The NMR spectra were taken on a Varian A-60 or on a Japan Electron JNM-G-60 or 100 spectrometer in $CDCl_3$, using TMS as the internal standard.

The following is a typical method for the thiocyanation.

Thiocyanation of 1-Methoxynaphthalene. Copper(II) thiocyanate (100 mmol), which has been prepared according to the directions of Jenkins and Kochi,[10] was suspended in a solution of 1-methoxyanphthalene (25 mmol) in glacial acetic acid (30 ml). The mixture was then warmed while being stirred until the solid of copper(II) thiocyanate turned brownish yellow. After cooling, the solid, which was extracted with ether if necessary, was filtered off. The filtrate was cooled or poured into 300 ml of ice water, and the resulting solid was extracted with ether. The ether solution was washed with water, dried over anhydrous sodium sulfate, and concentrated under reduced pressure, thus giving a crystalline residue. In the course of a number of preparations, both low-melting (95—97 °C; yellow plates) and high-melting (102—102.5 °C; colorless plates) forms were obtained. (The reported value is 105—105.5 °C.[5]) The former was converted to the high-melting variety upon numerous recrystallizations from methanol. The IR and NMR spectra of the yellow plates were exactly the same as those of the colorless ones. IR ($CHCl_3$) 2145 cm^{-1} (SCN). NMR ($CDCl_3$) δ=3.91 (3H, s, OCH_3), 6.72 (1H, d, J=7.5 Hz, aromatic proton of the 2-position[11]), 7.74 (1H, d, J=7.5 Hz), 7.4—7.7 (2H, m), 8.1—8.4 (2H, m, aromatic proton of the 5 and 8 positions[11]) Found: C, 67.13; H, 3.91; N, 6.55; S, 14.91%; M^+, 215. BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 50 (11), 3067—3068 (1977)

Formation of Indan and 2,3-Dihydrobenzofuran *via* Intramolecular Insertion of Phenylcarbene

Akira SEKIGUCHI and Wataru ANDO

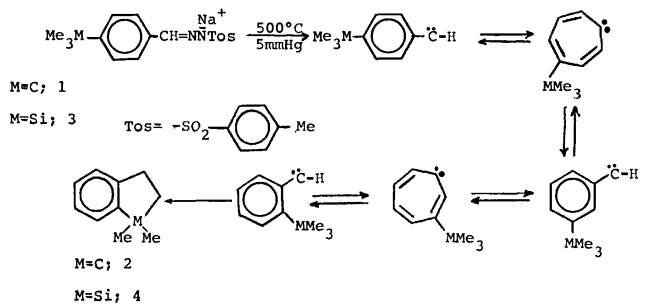
Department of Chemistry, The University of Tsukuba, Niiharigun, Ibaraki 300-31

(Received June 4, 1977)

Synopsis. Pyrolysis of *p-t*-butyl- and *p*-trimethylsilylbenzaldehyde tosylhydrazone sodium salts gave indans *via* intramolecular C-H insertions of *o*-substituted phenylcarbenes through carbene-carbene rearrangements. Pyrolysis of *o*- and *p*-alkoxybenzaldehyde tosylhydrazone sodium salts afforded 2,3-dihydrobenzofurans.

Alkylcarbenes react predominantly by insertion into β- and γ-C–H bonds to give olefins and cyclopropanes, respectively.[1] In contrast to the number of studies on the intermolecular reactions of phenylcarbenes,[2] seems to have been little reported on the intramolecular insertion reactions of phenylcarbenes[3] which are expected to be convenient for the syntheses of cyclic compounds. In this paper, we would like to report on the formation of indan and 2,3-dihydrobenzofuran by insertion of phenylcarbenes.

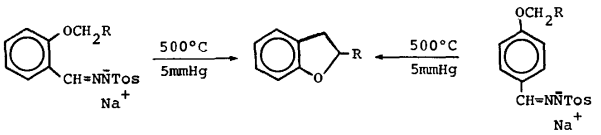
(*p-t*-Butylphenyl)carbene was generated by the pyrolysis of *p-t*-butylbenzaldehyde tosylhydrazone sodium salt (**1**) at 500 °C *in vacuo*, the volatile product being trapped in a dry ice acetone trap. 1,1-Dimethylindan (**2**) was obtained in 23% yield by separation of GLC. 1,1-Dimethyl-1-silaindan (**4**)[4] was also produced in 15 % yield by the pyrolysis of *p*-trimethylsilylbenzaldehyde tosylhydrazone sodium salt (**3**) under the above reaction conditions.



Scheme 1.

A reasonable mechanism probably involves intramolecular insertion of (*o-t*-butyl- and *o*-trimethylsilyl-)phenylcarbenes into C–H bonds of *ortho t*-butyl and trimethylsilyl groups *via* carbene-carbene rearrangements[5] of (*p-t*-butyl- and *p*-trimethylsilyl-)phenylcarbenes, giving products (**2**) and (**4**) as shown in Scheme 1. This is the first example of the formation of indans from the intramolecular reactions through the carbene-carbene rearrangements of the *p*-substituted phenylcarbenes. The yield is low, but it is a simple and handy method for the synthesis of *o*-substituted cyclic compounds from *p*-substituted phenylcarbenes since the corresponding *p*-substituted benzaldehydes can be easily obtained.

The intramolecular reaction of phenylcarbene containing a hetero atom is important as means for the synthesis of a hetero cyclic compound. The pyrolysis of *o*- and *p*- anisaldehyde tosylhydrazone sodium salts, (**5**) and (**6**), under the above conditions gave 2,3-dihydrobenzofuran (**7**) in 30 and 7% yields, respectively. The formation of (**7**) from (*p*-methoxyphenyl)carbene might involve the carbene-carbene rearrangement to (*o*-methoxyphenyl)carbene.



5: R=H **7**: R=H **6**: R=H
8: R=Me **9**: R=Me **10**: R=Me

In the pyrolysis of *o*-ethoxybenzaldyhyde tosylhydrazone sodium salt (**8**), 2-methyl-2,3-dihydrobenzofuran (**9**) was obtained in 69% yield *via* regiospecific intramolecular C-H insertion, without any formation of benzopyran *via* intramolecular β-C–H insertion of (*o*-ethoxyphenyl)-carbene. On the other hand, the pyrolysis of *p*-ethoxybenzaldehyde tosylhydrazone sodium salt (**10**) gave *p*-methylphenetole in 2—3% yield in hydrogen abstraction of (*p*-ethoxyphenyl)carbene. The major part is non-volatile substance which might be produced during the cource of carbene-carbene rearrangement. In contrast to the carbene-carbene rearrangements of (*p*-alkylphenyl)carbenes, the reason for the unfavorable carbene-carbene rearrangements of (*p*-alkoxyphenyl)-carbenes remains unclarifed.

Experimental

General. The IR and NMR data were recorded on Hitachi 215 and Hitachi R-24A spectrometers, respectively. Gas chromatographic analyses were made on an Ohkura 802 gas chromatograph with use of a 1.5 m × 5 mm stainless column packed with 15% SF-96 on Celite 545. All melting points are uncorrected.

Pyrolysis Procedure. Pyrolysis was performed with a vertical tube oven (inside diameter, 3 cm; length, 33 cm). The pyrolysis apparatus consists of a Pyrex tube, diam. 1 cm, length 18 cm. The powdered tosylhydrazone sodium salts were dropped into the pyrolysis apparatus heated at 500 °C *in vacuo*, and the product was trapped in a dry ice acetone trap.

Reagents. Tosylhydrazones were prepared in the conventional way. *p-t*-Butylbenzaldehyde tosylhydrazone was prepared in 71% yield by dissolving *p-t*-butylbenzaldehyde (14 g, 86 mmol) in MeOH, adding an equivalent of tosylhydrazine (16 g, 86 mmol) and refluxing for 30 min. Recrystallization from MeOH gave pure *p-t*-butylbenzaldehyde tosylhydrazone; mp 143.5—144.5 °C. Found: C, 65.68; H, 6.72; N, 8.78%. Calcd for $C_{18}H_{22}N_2SO_2$: C, 65.43; H, 6.71; N, 8.48%. *p*-Trimethylsilylbenzaldehyde tosylhydrazone; mp 155—156 °C. Found: C, 58.49; H, 5.96%. Calcd for $C_{17}H_{22}N_2SO_2Si$:

C, 58.93; H, 6.40%. *p*-Anisaldehyde tosylhydrazone; mp 114—115 °C. Found: C, 59.42; H, 5.25; N, 9.51%. Calcd for $C_{15}H_{16}N_2SO_3$: C, 59.19; H, 5.30; N, 9.20%. *o*-Anisaldehyde tosylhydrazone; mp 169.5—172 °C. Found: C, 59.07; H, 5.27; N, 9.47%. Calcd for $C_{15}H_{16}N_2SO_3$: C, 59.19; H, 5.30; N, 9.20%. *p*-Ethoxybenzaldehyde tosylhydrazone; mp 157—158 °C. Found: C, 60.23; H, 5.66; N, 9.07%. Calcd for $C_{16}H_{18}N_2SO_3$: C, 60.36; H, 5.70; N, 8.80%. *o*-Ethoxybenzaldehyde tosylhydrazone; mp 142—144 °C. Found: C, 60.44; H, 5.70; N, 9.15%. Calcd for $C_{16}H_{18}N_2SO_3$: C, 60.36; H, 5.70; N, 8.80%. Sodium salt (**1**) was obtained in 87% yield by dissolving the *p*-*t*-butylbenzaldehyde tosylhydrazone (6.0 g, 18 mmol) in dry THF and adding an equivalent of sodium hydride (0.88 g, 50% in mineral oil) slowly with stirring. Petroleum ether was added, and the resulting precipitate filtered. The sodium salts, (**3**), (**5**), (**8**), and (**10**) were also prepared from the above tosylhydrazones and sodium hydride in THF.

Pyrolysis of Tosylhydrazone Sodium Salts. Tosylhydrazone sodium salt (**1**, 1.61 mmol) was pyrolyzed by means of the pyrolysis apparatus at 500 °C, 5 mmHg. Dimethylindan (**2**)[6] was obtained in 23% yield by GLC analysis. The pyrolysis of (**3**, 0.99 mmol) afforded silaindan (**4**)[4] in 15% yield under the above reaction conditions. 2,3-Dihydrobenzofuran (**7**)[7] was formed by the pyrolysis of (**5**, 1.04 mmol) and (**6**, 1.01 mmol) in 30 and 7% yields, respectively. The pyrolysis of (**8**, 1.18 mmol) gave 2-methyl-2,3-dihydrobenzofuran (**9**)[7] in 69% yield, while that of (**10**) gave *p*-methylphenetole.

A Convenient Preparation of Arylthioynamines

Takeshi NAKAI, Kiyoshi TANAKA, Hiroyuki SETOI, and Nobuo ISHIKAWA
Department of Chemical Technology, Tokyo Institute of Technology, Meguro, Tokyo 152

(Received June 6, 1977)

Synopsis. (2,2,2-Trifluoroethylthio)benzenes prepared from sodium thiolates and 2,2,2-trifluoroethyl *p*-toluenesulfonate reacted with 3 equiv of lithium dialkylamides in diethyl ether to give arylthioynamines in good yields. The present procedure gives good results with aliphatic sulfide.

Ynamines have received current interest as a versatile tool in organic synthesis.[1] Of particular interest are arylthioynamines{(arylthioethynyl)amines} which we call in short "thioynamines" since the arylthio groups can be utilized for further synthetic elaboration. However, little information has been available concerning the preparation and reactions of thioynamines.[2,3] In our previous paper, it has been shown that the equimolar reaction of (2,2,2-trifluoroethylthio)benzene with lithium diisopropylamide afforded the phenylthioynamine along with the difluorovinyl sulfide(**1**). This is in contrast to the exclusive formation of the difluorovinyl ether(**2**) with (2,2,2-trifluoroethoxy)benzene.[4]

$$PhX\text{–}CH{=}CF_2$$

1, X=S
2, X=O

Herein we wish to report a convenient preparation of various thioynamines **5** by the reactions of trifluoroethyl sulfides **4** with 3 equiv of various lithium dialkylamides.

$$\underset{\mathbf{3}}{TsOCH_2CF_3} \xrightarrow{NaSR} \underset{\mathbf{4}}{RSCH_2CF_3} \xrightarrow{LiNR'_2} \underset{\mathbf{5}}{RS\text{–}C{\equiv}C\text{–}NR'_2}$$

Sulfides **4** were obtained in 73—80% yields by the reactions of trifluoroethyl *p*-toluenesufonate(**3**)[5] with the corresponding sodium thiolate. The reactions of sulfides **4** with 3 equiv of lithium dialkylamides generated *in situ* from butyllithium and dialkylamines in diethyl ether at −78 °C for 3 h afforded thioynamines **5** in good yields except for **5c** (see Table); **5c** was obtained in 12% yield due to the partial decomposition during distillation. All thioynamines **5** were identified by their ^{1}H NMR and IR data (see Experimental part). The IR spectra show strong bands at 2120—2130 cm^{-1} due to the carbon-carbon triple bonds.

These thioynamines are stable on storage free from moisture for several weeks; however, they are quite susceptible to hydration affording the corresponding arylthio- or alkylthioacetamides.[6]

The present procedure gives good results both with aromatic and aliphatic sulfides and is more advantageous than the reported one[2] in the points of the easy availability of the starting materials and the simplicity of the procedures. The synthetic utility of the thioynamines is now under study.[7]

Experimental

All boiling points are uncorrected. NMR and IR spectra were recorded on a Varian EM390 spectrometer and a Hitachi 215 spectrometer, respectively.

Preparation of Trifluoroethyl Sulfides **4**. The reaction was carried out in the dark. Thiol (36 mmol) was added to a stirred suspension of sodium hydride (36 mmol) in DMF (40 ml). After the mixture was stirred at room temperature for 30 min, tosylate **3** (30 mmol) was added to the thiolate solution over a 10-min period and the mixture was stirred for an additional 1 h at room temperature. The mixture was then poured into water, and the aqueous solution was extracted twice with ether. The combined ethereal extracts were washed with a 5% aqueous NaOH and brine, dried over magnesium sulfate, and evaporated to leave crude **4**. Purification were effected by distillation under reduced pressure. Yields and boiling points are as follows; phenyl sulfide, 73%, 82—84 °C/25 mmHg (lit,[8] 62—63 °C/5.5 mmHg); *p*-tolyl sulfide, 80%, 95—97 °C/20 mmHg (lit,[9] 87 °C/12 mmHg); ethyl sulfide, 75%. 88—91 °C (lit,[10] 90 °C).

Preparation of Thioynamines **5**; *General Procedure*. The reaction was carried out under nitrogen. A 2.0 M solution of butyllithium (22.5 ml) in hexane was added to a mixture of sulfide **4** (15 mmol) and dialkylamine (45 mmol) in diethyl ether (30 ml) cooled in a dry ice–acetone bath. The mixture was then stirred for 3 h, and allowed to stand at room temperature. The mixture was poured into a 5% aqueous sodium hydrogencarbonate solution, and the aqueous mixture

TABLE. PREPARATION OF THIOYNAMINES **5**

	Thioynamine[a]	Yield (%)	Bp (°C/mmHg) lit[c]
5a	$C_6H_5S\text{–}C{\equiv}C\text{–}N(C_2H_5)_2$	91	108—113/2 (110—115/0.01)
5b	$C_6H_5S\text{–}C{\equiv}C\text{–}N(i\text{-}C_3H_7)_2$	70	154—156/5
5c	$C_6H_5S\text{–}C{\equiv}C\text{–}N(CH_2)_5$	12[d]	128—132/1

Convenient Synthesis of α-Mercaptoalkanoic Acid Esters Using *S*-Cyanomethyl Thiocarbamates

Yoshiro MASUYAMA, Yoshio UENO, and Makoto OKAWARA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received June 18, 1977)

Synopsis. The reaction of cyanomethyl dithiocarbamate and *S*-cyanomethyl thiocarbamate with alkyl halides in aqueous medium selectively gave mono- and di-alkylated products. The treatment of the alkylated products with concd sulfuric acid gave α-mercaptoalkanoic acid esters.

Organic synthesis using phase-transfer catalyst in aqueous medium is one of the attractive subjects for effecting the C–C bond formation.[1] We previously reported the selective alkylation of cyanomethyl dithiocarbamate **1a** to give mono- (**2**) and di-alkylated cyanomethyl dithiocarbamates (**4**) and the subsequent ketone formation in aqueous medium.[2] On the other hand, it is well known that α-mercaptoalkanoic acids are useful as reducing and chelating agents in organic synthesis and medical fields.[3] Recently, α,α-diphenylmercaptoacetic acid was used effectively for the preparation of some hindered olefins.[4] α-Mercaptoalkanoic acids and their derivatives, however, have not been so easily accessible.

We wish to report here a convenient synthesis of α-mercaptoalkanoic acid esters **7** *via* stepwise alkylation and alcoholysis of cyanomethyl dithiocarbamate **1a** and *S*-cyanomethyl thiocarbamate **1b** in aqueous media.

Selective alkylation of **1a** with alkyl halides in the presence of catalytic amount of tetrabutylammonium iodide (TBA) in 50% aqueous sodium hydroxide has been previously reported.[2] Stepwise alkylation of **1b** was similarly achieved to give mono- (**3**) and di-alkylated thiocarbamates (**5**) in high yields. Dialkylated cyclic product **5d** was also obtained quantitatively by using 1,4-dibromobutane as an alkylating agent.

Alkaline hydrolysis of **4** in refluxing ethanol gave the corresponding ketones **6** in good yields.[2] On the other hand, α-mercaptoalkanoic acid esters **7** were obtained in good yields by the reaction of **4** with excess concd sulfuric acid (10 equiv) in refluxing ethanol for 20 h. The hydrolysis of **4** using lesser amounts of sulfuric acid (5 equiv) gave mainly (dimethylcarbamoylthio)acetic acid esters **9** (IR: ester C=O at 1725 and carbamoyl C=O at 1640 cm^{-1}). Meanwhile, treatment of thiocarbamates **3** and **5** with lesser amounts of concd sulfuric acid (5 equiv) gave **7** in good yields. Thus, *S*-cyanomethyl thiocarbamate **1b** seems to be a better starting material than dithiocarbamate **1a** for the preparation of α-mercaptoalkanoic acid esters **7**. Facile cleavage of the S–C bond with ethanolic sulfuric acid would be performed simultaneously with the conversion of nitrile into ester. Thiols **7** (IR: SH at 2550 cm^{-1}) were further converted to the corresponding disulfides **8** by air oxidation. The results are summarized in Scheme 1 and Table 1. The structures of all new compounds were confirmed by elemental analyses and spectral data.

TABLE 1. ALKYLATION OF **1b** AND HYDROLYSIS OF **3**, **4**, AND **5**

	R^1	R^2	Yield(%)		Yield(%)
3a	CH_3	H	86		
3b	$CH_3(CH_2)_4$	H	95	**7b**	61
5c	CH_3	$CH_3(CH_2)_5$	77	**7c**	66 (60)[a]
5d		$(CH_2)_4$	≈100	**7d**	75 (69)[a]

a) Figures in parentheses are yields *via* dithiocarbamates **4**.

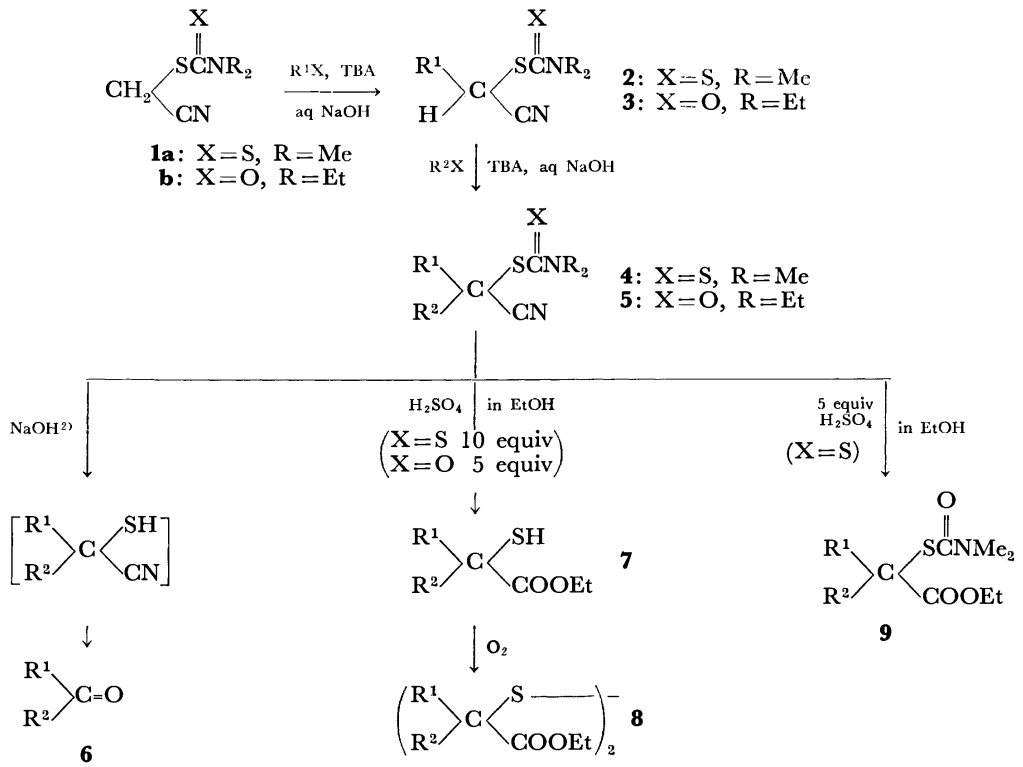
Experimental

*Dithiocarbamates **1a**, **2**, and **4**.* These compounds were prepared by the procedures described in our earlier paper.[2]

*S-Cyanomethyl Diethylthiocarbamate **1b**.* To 42 g (0.1 mol, 1.16 equiv) of 38% aq sodium diethylthiocarbamate in 25 ml of dimethylformamide was added dropwise 6.5 g (86 mmol) of chloroacetonitrile at 0—5 °C. The solution was stirred for 3 h at 25 °C, diluted with 50 ml of water, and extracted with two 50 ml portions of ether. The ether solutions were washed successively with three 30 ml portions of water and 50 ml of brine and dried over anhydrous sodium sulfate. Evaporation of the ether and distillation gave 14 g (95%) of **1b**; bp 135—136 °C/2.5 mmHg; IR (neat) 2270 (C≡N) and 1650 cm^{-1} (C=O); NMR (CCl_4) δ=1.20 (6H, t, J=7 Hz, CH_3), 3.40 (4H, q, J=7 Hz, N–CH_2), and 3.80 ppm (2H, s, S–CH_2); Found: C, 48.62; H, 7.07; N, 16.43%. Calcd for $C_7H_{12}N_2OS$: C, 48.83; H, 7.03; N, 16.27%.

*Alkylation of **1b**. 2-Diethylcarbamoylthioheptanenitrile **3b**:* To 0.86 g (5 mmol) of **1b** and 92 mg (0.25 mmol, 0.05 equiv) of TBA in 5 ml of 50% aq sodium hydroxide was added 0.62 ml (5 mmol) of 1-bromopentane. The solution was vigorously stirred for 10 h, diluted with 20 ml of water, and extracted with two 20 ml portions of ether. The ether solutions were washed successively with three 20 ml portions of water and 20 ml of brine and dried over anhydrous sodium sulfate. The crude product was purified by alumina column chromatography eluting with 4 : 1 hexane–chloroform to afford 1.16 g (95%) of **3b**; IR (neat) 2270 (C≡N) and 1655 cm^{-1} (C=O); NMR (CCl_4) δ=0.66—2.00 (11H, m), 1.17 (6H, t, J=7 Hz, N–C–CH_3), 3.35 (4H, q, J=7 Hz, N–CH_2), and 4.30 ppm (1H, t, J=7 Hz, S–CH); Found: C, 59.36; H, 9.44; N, 11.39%. Calcd for $C_{12}H_{22}N_2OS$: C, 59.48; H, 9.15; N, 11.56%.

*2-Diethylcarbamoylthiopropanenitrile **3a**:* As described above, 0.86 g (5 mmol) of **1b**, 92 mg (0.25 mmol) of TBA, and 0.62 ml (10 mmol, 2 equiv) of iodomethane were allowed to react for 8 h in 5 ml of 50% aq sodium hydroxide. After work-up, 0.80 g (86%) of **3a** was obtained; IR (neat) 2280 (C≡N) and 1660 cm^{-1} (C=O); NMR (CCl_4) δ=1.18 (6H, t, J=7 Hz, N–C–CH_3), 1.65 (3H, d, J=7.5 Hz, S–C–CH_3), 3.38 (4H, q, J=7 Hz, N–CH_2), and 4.33 ppm (1H, q, J=7.5 Hz, S–CH); Found: C, 51.67; H, 7.91; N, 15.09%. Calcd for



Scheme 1.

$C_8H_{14}N_2OS$: C, 51.58; H, 7.58; N, 15.04%.

2-Diethylcarbamoylthio-2-methyloctanenitrile **5c**: As described above, 0.93 g (5 mmol) of **3a**, 92 mg (0.25 mmol) of TBA, and 0.70 ml (5 mmol) of 1-bromohexane were allowed to react for 25 h in 5 ml of 50% aq sodium hydroxide. After work-up, 1.04 g (77%) of **5c** was obtained; IR (neat) 2270 (C≡N) and 1660 cm^{-1} (C=O); NMR (CCl_4) δ=1.15 (6H, t, J=7 Hz, N-C-CH_3), 0.77—2.00 (13H, m), 1.77 (3H, s, S-C-CH_3), and 3.33 ppm (4H, q, J=7 Hz, N-CH_2); Found: C, 62.21; H, 9.58; N, 10.34%. Calcd for $C_{14}H_{26}N_2OS$: C, 62.19; H, 9.69; N, 10.36%.

1-Diethylcarbamoylthiocyclopentanecarbonitrile **5d**: As described above, 0.86 g (5 mmol) of **1b**, 92 mg (0.25 mmol) of TBA, and 0.60 ml (5 mmol) of 1,4-dibromobutane were allowed to react for 20 h in 5 ml of 50% aq sodium hydroxide. After work-up, 1.12 g (≈100%) of **5d** was obtained; IR (neat) 2270 (C≡N) and 1655 cm^{-1} (C=O); NMR (CCl_4) δ=1.20 (6H, t, J=7 Hz, N-C-CH_3), 1.63—2.67 (8H, m), and 3.35 ppm (4H, q, J=7 Hz, N-CH_2); Found: C, 58.27; H, 8.27; N, 12.25%. Calcd for $C_{11}H_{18}N_2OS$: C, 58.39; H, 8.02; N, 12.38%.

Hydrolysis of **3b**, **4**, *and* **5**. *Ethyl 2-Mercaptoheptanoate* **7b**: To 486 mg (2 mmol) of **3b** in 5 ml of ethanol was added 1.2 ml (ca. 5 equiv) of concd sulfuric acid. The mixture was refluxed for 20 h, cooled, diluted with 10 ml of water, and extracted with two 20 ml portions of ether. The combined ether solutions were washed successively with three 20 ml portions of water and 20 ml of brine and dried over anhydrous sodium sulfate. The solvent was evaporated to yield 232 mg (61%) of **7b**; IR (neat) 2550 (SH) and 1735 cm^{-1} (C=O). **7b** was confirmed as the corresponding disulfide **8b** by allowing to stand for 2 days in contact with air; IR (neat) 1735 cm^{-1} (C=O); NMR (CCl_4) δ=0.67—2.00 (11H, m), 1.27 (3H, t, J=7 Hz, O-C-CH_3), 3.47 (1H, t, J=7 Hz, S-CH), and 4.22 ppm (2H, q, J=7 Hz, O-CH_2). An analytical sample was prepared by silica gel column Chromatography eluting with 1 : 1 hexane–chloroform; Found: C, 57.05; H, 9.12%. Calcd for $C_{18}H_{34}O_4S_2$: C, 57.12; H, 9.06%.

Ethyl 2-Mercapto-2-methyloctanoate **7c**: As described above, 540 mg (2 mmol) of **5c** and 1.2 ml (ca. 5 equiv) of concd sulfuric acid were allowed to react for 30 h in 5 ml of refluxing ethanol. After work-up, 288 mg (66%) of **7c** was obtained. **7c** was confirmed as the corresponding disulfide **8c** by air oxidation; IR (neat) 1730 cm^{-1} (C=O); NMR (CCl_4) δ= 0.70—1.93 (13H, m), 1.27 (3H, t, J=7 Hz, O-C-CH_3), 1.40 (3H, s, S-C-CH_3), and 4.20 ppm (2H, q, J=7 Hz, O-CH_2); Found: C, 60.46; H, 9.92%. Calcd for $C_{22}H_{42}O_4S_2$: C, 60.80; H, 9.74%.

Ethyl 1-Mercaptocyclopentanecarboxylate **7d**: As described above, 452 mg (2 mmol) of **5d** and 1.2 ml (ca. 5 equiv) of concd sulfuric acid were allowed to react for 25 h in 5 ml of refluxing ethanol. After work-up, 261 mg (75%) of **7d** was obtained. **7d** was confirmed as the corresponding disulfide **8d** by air oxidation; IR (neat) 1735 cm^{-1} (C=O); NMR ($CDCl_3$) δ=1.28 (3H, t, J=7 Hz, O-C-CH_3), 1.48—2.35 (8H, m), and 4.22 ppm (2H, q, J=7 Hz, O-CH_2); Found: C, 55.57; H, 7.90%. Calcd for $C_{16}H_{26}O_4S_2$: C, 55.48; H, 7.57%.

The hydrolysis of dithiocarbamates **4** was carried out similarly to the hydrolysis of thiocarbamates **5** except using 10 equiv of concd sulfuric acid. These products were identified by comparison of physical properties with those of disulfides **8** obtained from thiocarbamates **5**.

Chemical Synthesis of Antigenic Determinants of Hen Egg-White Lysozyme. II. Tetradecapeptide Corresponding to Positions 1—14 in the Primary Structure but with Ala^{6} and Met(O)^{12} *

Shin-ichiro KUMAGAE and Yasutsugu SHIMONISHI

Institute for Protein Research, Osaka University, Yamada-kami, Suita, Osaka 565

(Received August 1, 1977)

Synopsis. For characterizing one of the antigenic determinants of hen egg-white lysozyme in delayed hypersensitivity, the tetradecapaptide, H–Lys–Val–Phe–Gly–Arg–Ala–Glu–Leu–Ala–Ala–Ala–Met(O)–Lys–Arg–OH, was synthesized by the solid phase method using ultrasonic waves. This peptide corresponds to positions 1—14 of the amino acid sequence of hen egg-white lysozyme but with alanine and methionine *S*-oxide residues at positions 6 and 12, respectively.

The antigenic determinant on a macromolecule recognized by immunocytes for circulating antibody is topographically distinct from that for cellular immunity or delayed hypersensitivity induced with glucagon[1,2] as an immunogen. Recently, Miyagawa *et al.*[3,4] investigated the structural relations between the antigenic determinants of hen egg-white lysozyme for circulating antibody and those for delayed hypersensitivity, induced by hen egg-white lysozyme as an immunogen. They found that the peptide [sequence[5,6] Lys^{1} to Hse^{12} and Trp^{123} to Leu^{129} linked by a disulfide (Cys^{6} and Cys^{127})], named here peptide A, obtained by treatment of the peptide [sequence Lys^{1} to Asn^{27} and Trp^{123} to Leu^{129} linked by a single disulfide (Cys^{6} and Cys^{127})], named here peptide B, with cyanogen bromide, reacted both with circulating antibody to hen egg-white lysozyme and with cells sensitized with hen egg-white lysozyme in delayed hypersensitivity. However, when peptide A was reductively alkylated, the resulting N-terminal peptide [Lys^{1} to Hse^{12}] showed no reactivity with circulating antibody of hen egg-white lysozyme elicited to peptide B,[7] but retained its ability to induce delayed hypersensitivity in cells sensitized with hen egg-white lysozyme. These results show that the specificity of the antigenic determinant elicited to peptide B for circulating antibody is distinct from that for delayed hypersensitivity, induced with hen egg-white lysozyme as an immunogen.

For characterizing this determinant, we synthesized the N-terminal fragment of hen egg-white lysozyme, H–Lys–Val–Phe–Gly–Arg–Ala–Glu–Leu–Ala–Ala–Ala–Met(O)–Lys–Arg–OH, by the solid phase methode using ultrasonic waves.[8] The sequence contained alanine and methionine *S*-oxide residues instead of cysteine and methionine residues at positions 6 and 12 of hen egg-white lysozyme, respectively, because it seemed unlikely that a disulfide linkage between positions 6 and 127 and the methionine residue at position 12 were essential for reactivity. The crude peptide cleaved from resin with hydrogen fluoride was purified on a column of carboxymethylcellulose, as shown in Fig. 1. The tetradecapeptide thus synthesized inhibited migration of macrophages from a peritoreal exudate from guinea pigs immunized with hen egg-white lysozyme.[9] Furthermore, this peptide was found to be immunogenic in guinea pigs.[9]

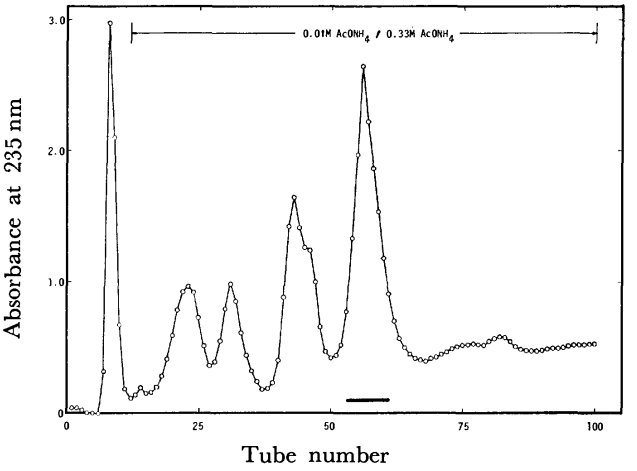

Fig. 1. Chromatogram of the crude product on carboxymethylcellulose (ammonium cycle). The column was eluted with a linear gradient of 0.01 M to 0.33 M ammonium acetate, pH 7.0, at a flow rate of 25—30 ml per h. Fractions of 3 g were collected.

Experimental

Boc–Arg(NO_2)–resin (2.00 g; 0.18 mmol of arginine per g of resin) prepared by the method of Kishida *et al.*[10] was used as starting material. The peptide was synthesized on the solid support using ultrasonic waves, as reported previously,[8] except that a mixture of trifluoracetic acid and dichloromethane (v/v, 1/1) was used instead of 1M HCl in acetic acid for removing the Boc group. The Boc amino acid derivatives were coupled in the following order: Lys(Z), Met(O), Ala, Ala, Ala, Leu, Glu(OBzl), Ala, Arg(Tos), Gly, Phe, Val, and Lys(Boc). After introductions of the Boc derivatives of Lys(Z), Met(O), and Arg(Tos), respectively, the resin was treated with acetic anhydride.[11] Peptide resin (520 mg) was weighed with anisole (0.6 ml) in the Daiflon cylinder of the HF-reaction apparatus.[12] HF (10 ml) was distilled into the cylinder previously cooled to −78 °C in a Dry-Ice–methanol bath. The sample was transfered from the bath at −78 °C to that at 0 °C and stirred for 60 min. Then the HF was evaporated off from the reaction mixture as fast as possible. The free peptide cleaved from the resin was extracted into 0.1 M acetic acid by treatment with ultrasonic waves for 3 min. The extract was passed through a column of IR-45 (acetate cycle). The eluate was lyophilized; 100 mg (*ca.* 75 %). This material (80 mg) was dissolved in 0.01 M am-

* All the amino acids used except glycine were of the L-configuration. The abbreviations used are those recommended by IUPAC-IUB: *J. Biol. Chem.*, **247**, 977 (1972).

monium acetate and charged on a column of carboxymethylcellulose (ammonium cycle, 1×33 cm). The column was eluted with 700 ml of a linear gradient of 0.01 M to 0.33 M ammonium acetate at pH 7.0. The fractions shown by a bar in Fig. 1 were collected and lyophilized; yield 30 mg; R_f (TLC) 0.34 in 1-butanol : acetic acid : pyridine : water (15 : 3 : 10 : 12, by volume); $R_{f,arg}$ (paper electrophoresis) 0.67 (0.2 M pyridinium acetate, 30 V/cm). The amino acid ratio after hydrolysis in 6M HCl for 24 h at 105 °C was Lys, 1.99 (2): Arg, 2.01 (2): Glu, 1.02 (1): Gly, 1.00 (1): Ala, 3.85 (4); Val, 0.92 (1): Met, 0.82 (1): Leu, 1.00 (1): Phe, 1.06 (1).

A Simple Method for the Synthesis of 5-Methyloxazolo-[4,5-*c*]quinolin-4(5*H*)-ones

J. R. MERCHANT and S. S. SHIRALI

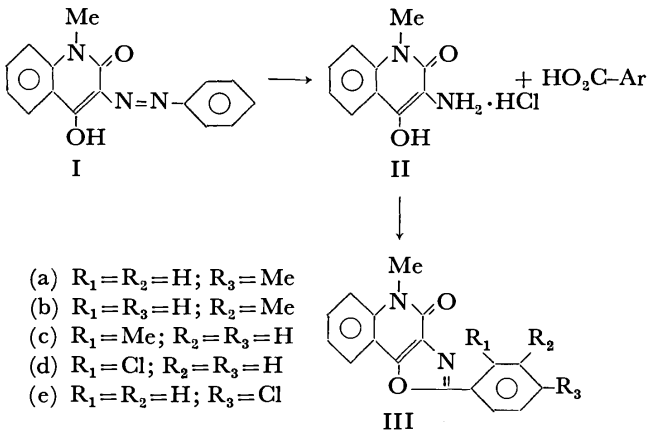
Organic Chemistry Department, Institute of Science, Madame Cama Road, Bombay 400032, India

(Received January 10, 1977)

Synopsis. A general and simple method for the synthesis of oxazolo[4,5-*c*]quinoline-4(5*H*)-ones by heating 3-amino-4-hydroxy-2-quinolone hydrochloride with aromatic acids in the presence of PPA has been described. The structures are based on spectral and analytical data.

In recent years, a number of 1-methyl-2-quinolone derivatives have been synthesised since many of them have been reported to show antiseptic properties and also exhibit fungicidal activity.[1] Also, 4-hydroxy-3-nitro-2-quinolone derivatives have been reported[2] to possess antihistaminic action. The work on 1-methyl-2-quinolone also has received importance due to the isolation of 1-methyl-4,7,8-trimethoxy-2-quinolone from the plant *Spathelia sorbifolia* L and its subsequent synthesis.[3] Further, the antibiotics nybomycin and deoxynybomycin which have also been synthesised[4] possess an oxazolo[4,5-*c*]quinoline-2-one structure.

In view of this interesting data it was thought of interest to prepare 5-methyloxazolo[4,5-*c*]quinolin-4-(5*H*)-ones (III) since the latter would also be related to the antibiotic novobiocin.[5] We describe here a simple method to synthesise these compounds by heating 3-amino-4-hydroxy-1-methyl-2-quinolone hydrochloride (II), prepared from 4-hydroxy-1-methyl-3-phenylazo-2-quinolone[6] (I), with aromatic acids in the presence of PPA at 170—180 °C for 4 h. The required new oxazole derivatives were obtained as crystalline solids from ethyl acetate in 40—50% yields.



It is evident that in the reaction first an amide is formed which then cyclizes to an oxazole derivative.

TABLE 1. 5-METHYLOXAZOLO[4,5-*c*]QUINOLIN-4(5*H*)-ONES

Compound No.	Formula	Mp (°C)	Found (%) (Calcd) (%) C	H	N
IIIa	$C_{18}H_{14}N_2O_2$	235—236	74.6 (74.5)	5.0 (4.8)	9.7 (9.6)
IIIb	$C_{18}H_{14}N_2O_2$	189—191	74.5 (74.5)	5.0 (4.8)	9.8 (9.6)
IIIc	$C_{18}H_{14}N_2O_2$	205—206	74.4 (74.5)	4.5 (4.8)	9.9 (9.6)
IIId	$C_{17}H_{11}N_2O_2Cl$	196—198	65.6 (65.8)	3.7 (3.5)	9.4 (9.1)
IIIe	$C_{17}H_{11}N_2O_2Cl$	264—266	65.7 (65.8)	3.4 (3.5)	9.3 (9.1)

Experimental

All the meltng points are uncorrected. IR spectra were recorded by means of a Perkin Elmer spectrometer, while NMR spectra were obtained by Varian NMR spectrometer at 60 MHz, using tetramethylsilane as an internal standard.

Preparation of IIIa. A typical procedure is shown for IIIa. 3-Amino-4-hydroxy-1-methyl-2-quinolone (550 mg) and *p*-toluic acid (350 mg) were added to a mixture of phosphorus pentaoxide (5.5 g) and phosphoric acid (2.5 ml) preheated at 100 °C for 30 min. The heating was continued for 4 h at 170—180 °C. The mixture was cooled and decomposed with ice. The solid which separated was filtered, treated with aq sodium hydrogencarbonate solution and washed with water. It was crystallised from ethyl acetate in colourless needles, mp 235—236 °C (IIIa).

The spectral data of a typical compound (IIIa) are as follows: λ_{max}^{MeOH} nm (log ε): 210 (4.74), 255 (4.59), 310 (4.64), and 340 (4.53); IR (KBr): 1700 (C=O), 1625, 1590, and 1570 (heteroaromatic system) cm^{-1}. The position of the carbonyl band rules out the alternate 4-quinolone structure; NMR ($CDCl_3$): δ 2.43 (3H, s, Ar-$\underline{CH_3}$), 3.8 (3H, s, N-$\underline{CH_3}$), 7.0 and 8.3 (8H, m, aromatic protons). MS: *m/e* 290 (M^+).

Oxidation of Biphenylene with Ammonium Cerium(IV) Nitrate. A Convenient Route to Biphenylene-2,3-dione

Masaru SATO, Harutoshi FUJINO, Seiji EBINE, and Josuke TSUNETSUGU

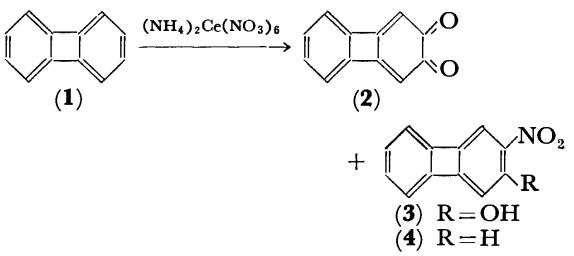
Department of Chemistry, Faculty of Science, Saitama University, Urawa, Saitama 338

(Received June 18, 1977)

Synopsis. Biphenylene was directly oxidized with ammonium cerium(IV) nitrate to give biphenylene-2,3-dione in moderate yield, along with 2-nitrobiphenylene and 3-nitrobiphenylen-2-ol.

Biphenylene-2,3-dione (**2**)[1] is considered to be a peripheral $(4n+2)\pi$-annulenoquinone containing a fused four-membered ring. The physical properties of quinones containing a fused four-membered ring were recently examined from the viewpoint of aromaticity.[2] We have payed attention to the synthesis and chemical properties of **2**, because 6,4,7-ring compounds in which we are interested[3] may be conveniently prepared by ring enlargement of **2**.[4] Thus, development of a convenient procedure to obtain **2** is necessary since the previous method is a tedious multi-step synthesis. The direct oxidation of polynuclear arenes to corresponding quinones is a convenient and valuable synthetic procedure. Various oxidizing agents were used in recent years, cerium(IV) salt being a strong and suitable reagent.[5] We have examined the oxidation of biphenylene (**1**) with cerium(IV) salt to give **2**.

Biphenylene (**1**) was treated with ammonium cerium(IV) nitrate at 0 °C and the resulting reaction mixture was separated by chromatography on silica gel to give three crystalline products.



(**1**) (**2**) + (**3**) R=OH (**4**) R=H

The first product (yellow needles, mp 137—138 °C) was identified as 2-nitrobiphenylene (**4**)[6] by the following spectral data: IR(KBr) 1500 and 1320 cm^{-1}, NMR ($CDCl_3$) δ 6.71 (d, 1H, $J_{3,4}$=8.0 Hz), 6.85 (m, 4H, aromatic protons), 7.38 (d, 1H, $J_{1,3}$=2.0 Hz), and 7.81 (dd, 1H). The second product (red-orange needles, mp 142—143 °C) was identified as 3-nitrobiphenylen-2-ol (**3**) by its NMR spectrum in line with the result of Blatchly *et al.*[7] The last product (red-orange needles, mp 213.5—214.5 °C) was identified to be biphenylene-2,3-dione (**2**)[1] by the following spectral data: IR(KBr) 1655 and 1635 cm^{-1}, NMR($CDCl_3$) δ 6.60 (s, 2H, H-1,4) and 7.78 (s, 4H, H-5,6,7,8). This was further confirmed by the fact that no depression was observed on admixture with an authentic sample.[1] The preparation of of **2** through the direct oxidation of **1** with cerium(IV) salt results in somewhat low yield but the tedius multi-step method[1] is considerably simplified. Attempt to oxidize 2-methoxybiphenylene under similar conditions was unsuccesful, no crystalline product being obtained.

Biphenylene (**1**), like benzene, was predicted to resist free-radical attack, this being confirmed experimentally.[8] However, this is in disagreement with the result described here, since all the isolable products from the direct oxidation of **1** with ammonium cerium(IV) nitrate (a one-electron oxidant)[9] seem to be formed by free-radical reaction although the pathway is unknown.

Experimental

A Typical Procedure. To a solution of biphenylene (**1**) (3.18 g, 0.02 mol) in 300 ml of tetrahydrofuran was added aqueous ammonium cerium(IV) nitrate (46.8 g, 0.08 mol in 100 ml of water) drop by drop at 0 °C on an ice-salt bath. The solution was then poured into water and the resulting mixture was extracted with dichloromethane. The extract was washed with water and dried over sodium sulfate. After evaporation, the residue was chromatographed on silica gel with dried dichloromethane to give succesively the recovered **1** (0.6%), 2-nitrobiphenylene (**4**) (0.26 g, 6.7%), 3-nitrobiphenylen-2-ol (**3**) (0.076 g, 1.8%), and biphenylene-2,3-dione (**2**) (0.78 g, 21%).

On the Conductometric Determination of the Formation Constants of the Alkali Metal Complexes of "Crown" Polyethers

Joseph JAGUR-GRODZINSKI*
Weizman Institute of Science, Rehovot, Israel
(Received March 3, 1977)

Matsuura *et al.*[1] recently published data on the formation constants of the alkali metal complexes of dibenzo-18-crown-6 (DBC). Their results are, however, at variance with the values of the formation constants in DMF of the sodium and lithium thiocyanate complexes of DBC previously reported by Shchori *et al.*[2] Both investigations were based on conductometric measurements. The discrepancy certainly calls for comment. The experimental set-ups applied in the two investigations differ. Accordingly, a different mathematical treatment should be adopted to calculate the formation constants from the experimentally determined conductances.

Shchori *et al.* performed experiments at a constant concentration of a salt, while changing the concentrations of DBC. The opposite has been done by Matsuura *et al.* In the latter case, the calculation of formation constants was based on small differences in the values of equivalent conductances due to their concentration dependence and to the differences in the degree of complexation[1].

This makes the method extremely sensitive to minor experimental errors. Moreover, the concentration dependence of the equivalent conductance of the complex differs from that of the uncomplexed salt, since the respective Λ_0 values differ.[3] An appropriate mathematical treatment should be applied taking this fact into account. Unfortunately, it has been neglected by Matsuura *et al.*

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 50 (11), 3078 (1977)

Formation Constants of Dibenzo-18-crown-6 Complexes with Alkali Metal Ions in Dimethyl Sulfoxide, *N,N'*-Dimethyl Formamide, and Propylene Carbonate at 25 °C

Niro MATSUURA, Kisaburo UMEMOTO, Yasuyuki TAKEDA, and Atsuko SASAKI

Department of Pure and Applied Sciences, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153

(Received May 19, 1977)

In a previous paper[1] we reported formation constants for 1 : 1 complexes of dibenzo-18-crown-6 (DBC) with Li^+, Na^+, K^+, Rb^+, and Cs^+ measured in DMSO (dimethyl sulfoxide), DMF (*N,N'*-dimethyl formamide), and PC (propylene carbonate). The fraction (α) of the cation in the 1 : 1 complex $M(DBC)^+$ is given by

$$\alpha=\frac{\Lambda^1-\Lambda^2}{\Lambda^1-\Lambda^3},$$

where Λ^1, Λ^2, and Λ^3 denote the corresponding phoreograms (1, 2, and 3, Figs. 1—5).[1]

Since α is equal to 0 for complete dissociation, the phoreograms 1 and 2 should coincide at zero concentration. Actually in PC as well as in DMF the curves apparently converge. However, no such trend is found between the phoreograms 1 and 3. A well defined Λ_0^3 value will be obtained at extreme dilution, if extrapolation is made. However, a straightforward extrapolation is not good for a complexed salt in the presence of excess DBC, and we must be satisfied with the values of K_f (formation constant of a 1 : 1 complex) obtained in a concentration range in which an accurate conductance measurement can be carried out.

According to the definition of K_f (Eq. 2 of the previous paper)[1], the value of K_f is approximately equal to α/C when α is much smaller than unity, where α is the fraction of the cation in the 1 : 1 complex and C is the initial molar concentration of the alkali metal ion and DBC.

This condition, however, is not easily satisfied because α has a value of the order of 0.1 or greater as is shown in phoreogram 3.

The value of K_f for $Na(DBC)^+$ at 1.44×10^{-3} M of $NaClO_4$[1] is about three times larger than that given by Shchori *et al.* at 1.0×10^{-3} M of NaSCN.[2] At this stage no prediction can be made for the discrepancy between them, since it is likely that Na^+ and ClO^-_4 dissociate completely in DMF, whereas Na^+ and SCN^- associate slightly in DMF. Moreover the K_f values in Table 1[1] are practically constant within these concentration ranges.

Interactions of Calcium Ions with Carbohydrates: X-Ray Diffraction and NMR Spectroscopic Studies on the Potassium Salt and the Calcium Salt of D-Glucaric Acid

Tooru TAGA, Yoshihiro KURODA, and Kenji OSAKI

Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606

(Received December 27, 1976)

The crystal structure of potassium D-glucarate was determined by X-ray analysis. The conformation of the glucaric anion in the potassium salt differs from that of the dianion in the crystal of the calcium salt. The proton magnetic resonance spectra of the solutions of the potassium salt and the calcium salt show that the glucarate solution is an equilibrium mixture of the two conformers observed in the crystals. Studies on the induced shifts by adding europium nitrate to the acidic solution indicate that the europium ions are selectively bound to the potassium type conformer. Calcium sequestant by the glucaric acid in alkaline solutions should occur when calcium ions bind the calcium type conformers in a dianionic state.

D-Glucaric acid is known to have high calcium sequestering effect in alkaline solutions. The calcium affinity of the glucaric acid was supposed to be due to the increased ionization of the hydrogen of the hydroxyl groups in the glucaric acid in aqueous alkaline solution, the calcium–glucaric acid complex in chelating form being expected in the solution.[1] In relation to this subject, a report was given on the crystal structure of calcium D-glucarate tetrahydrate.[2] In the crystal structure, a stable chelating structure of the glucaric dianions binding to the calcium ion was observed. However, the structural evidence for such a calcium binding or a calcium–sugar complex in the solution is still not known. We have therefore studied the crystal structure of potassium D-glucarate and the NMR spectra of several glucarate salt solutions. The relationship between the structures of the crystals and the solutions was discussed. We were particularly interested in the structure of the metal ion–glucaric acid complex, which is elucidated by NMR spectroscopy using the shift reagent.

Experimental

X-Ray Analysis of the Potassium D-Glucarate. The single crystals of potassium D-glucarate, $K^+ C_6H_9O_8^-$, were obtained by the evaporation method. Preliminary X-ray diffraction experiments showed that the crystals are monoclinic, space group $P2_1$, $Z=2$, $D_x=1.807$ g/cm^3, with cell dimensions $a=8.55$, $b=10.9$, $c=4.85$ Å and $\beta=90.0°$. The intensity data of 675 independent reflections were collected from the equi-inclination Weissenberg photographs taken by rotating the crystals about the b- and c-axes, using Cu $K\alpha$ radiation. The intensities on the films were measured on a SYNTEX AD-1 densitometer controlled by a NOVA 1200 computer. Absorption correction for a cylindrical crystal was applied ($\mu R=2.0$). The structure was solved by the direct method using the program MULTAN,[3] and refined by the block diagonal least-squares method. The hydrogens bonded to the carbons were located from the difference Fourier maps and included in the structure factor calculations. Successive cycles of the anisotropic least-squares refinement gave an R-value of 0.123. Scattering factors for all atoms were obtained from the International Table for X-Ray Crystallography IV.[4] The final structural parameters are given in Table 1.

NMR Studies on the Solution. The 100 MHz proton magnetic resonance spectra of the solutions were measured on a VARIAN HA-100D spectrometer, using an internal lock signal of tetramethylsilane sealed in a capillary tube. The deuterium oxide solutions of 0.1 mol potassium glucarate and 0.1 mol calcium glucarate were prepared and adjusted to predominantly diprotonated (LH_2), monoanionic (LH^-)

TABLE 1. ATOMIC PARAMETERS AND THEIR STANDARD DEVIATIONS IN POTASSIUM D-GLUCARATE

The values have been multiplied by 10^4. Temperature factors are in the form, $T^{-1}=\exp(\beta_{11}h^2+\beta_{22}k^2+\beta_{33}l^2+2\beta_{12}hk+2\beta_{13}hl+2\beta_{23}kl)$.

and dianionic (L^{2-}) states by adding an equimolar amount of KOH and DCl. The pH values corresponding to each state were approximately 1.5, 3.8, and 9.8 in the pH-meter readings for the potassium salts, and 0.7, 1.4, and 6.1 for the calcium salts, respectively. The concentration of calcium glucarate in the solution at pH 6.1 was extremely low, since the calcium salt was insoluble in neutral deuterium oxide. The induced shifts of protons H(2)—H(5) by europium ions were measured by adding europium nitrate to the 0.1 mol potassium salt solution at pH 1.5. The shift ratios of H(2)/H(4), H(3)/H(4) and H(5)/H(4) at null concentration of the europium ions were derived from the induced shifts observed in various ionic strengths of the solutions. The water in the commercial $Eu(NO_3)_3 6H_2O$ was removed by drying the sample solved in the deuterium oxide. All the experiments were performed at room temperature (23 °C).

Calculations of the Europium–Glucarate Complex Model. The shift ratios of ligand protons for an axially symmetric complex can be calculated by the following McConnell-Robertson equation:

$$\Delta\nu/\nu_0 = K\cdot(3\cos^2\theta - 1)/r^3,$$

where K is the constant related to the magnetic field, r is the distance between the europium ion and the proton, and θ is the angle between the principal magnetic axis of the complex and the vector r.[5] A number of europium–glucarate complex models were generated on a FACOM 230-75 high-speed computer in the Data Processing Center, Kyoto University. The most reasonable model was selected by minimizing the sum of the square errors between the calculated and observed shift ratios.[6–8] In consideration of several stereochemical situations of the present complex, the following assumptions were made. (i) The complex has a symmetric axis which coincides with the principal magnetic axis; (ii) the symmetric axis is coincident with one of the principal axes of the inertia tensor of the complex in the time average; (iii) the ligand has the rigid conformation observed in the crystals; (iv) there are no abnormally short contacts between the europium ion and the ligand oxygens, nor between the neighboring ligand atoms, and (v) each ligand has at least two oxygens bonded to the europium ion. The stoichiometric component of the europium–glucarate complex was not determined by the experiments. However, the europium ion observed in the crystal structure determined hitherto[9–12] is usually bonded to seven to nine oxygens, a similar coordination number being expected for the europium ions in the solution. A certain number of water molecules can be inculuded in this coordination. For the stable complex formation, two or three oxygens of each ligand should be bonded to the europium ion (assumption v). Hence, the stoichiometric component of the present complex was limited in the three cases of 1 : 1, 1 : 2, and 1 : 3. Since the principal axis of the inertia tensor of the complex coincides with the symmetric axis (assumption ii) and all the ligand anions are limited in the D-isomer, two-fold and three-fold axes were assigned to the symmetric axes of the 1 : 2 and 1 : 3 complexes, respectively. If such an axial symmetry of the complex is assumed and the internal freedom of the ligand is forbidden by fixing the atomic parameters of the ligand to those of the crystal structures (assumption iii), the structure of the complex can be determined by the three positional parameters of the ligand relative to the europium ion and by the three orientational parameters of the symmetric axis through the central europium ion. In the actual calculation, the positional parameters in the first place changed step by step. The atomic distance between the europium ion and ligand atoms was inspected at each position, from the criterion that an abnormally short distance less than 2.2 Å is unallowable and that at least two oxygens have Eu–O proximity in the range 2.2—3.4 Å. After fixing the position of the ligand, the directions of the principal axes of the inertia tensor and the mean direction of the Eu–O bonds were calculated, one of them being selected as the direction of the magnetic axis of the complex. The symmetric axes of the 1 : 2 and 1 : 3 complexes were determined according to the following procedure. The minimum of the sum of the square errors between the calculated and observed shift ratios was found by changing three Eulerian angles of the axis at suitable intervals. The second and third ligands corresponding to the 1 : 2 and 1 : 3 complexes were generated by the symmetric operation around this axis, and the atomic contacts between the adjacent ligands were checked. The two cases of the ligand forms, TGG and GTT, observed in the crystal state were examined by iterative application of the procedure described above. The 1 : 2 complex composed of the TGG conformers gave the best fit between the calculated and observed shift ratios.

Although the complex model derived here is based upon the assumption that the ligand has the fixed conformation observed in the crystals, the glucaric acid in the actual solution might have a flexibility and many different types of ligand conformers might interact with the europium ions. The observed shifts would result from an averaging of these various conformations. Thus, the complex models including further different conformers should be taken into account for the model calculations, and the shift ratios calculated as a mixture of these complex models. However, the large conformational change of the ligand by the complex formation was unexpected, since the J values did not change much on adding the europium ions. The mixture model of the TGG and GTT conformers also seemed impossible since the GTT conformer complex models gave a very large discrepancy between the calculated and observed shift in any assignment of the ligand positions and of the directions of the magnetic axis. The TGG conformer complex proposed here is, therefore, the most probable form in spite of the large flexibility of the ligand, and should be the main component in various complexes in the equilibrium solution.

Results and Discussion

The Crystal Structure of Potassium D-*Glucarate.* Figure 1 shows a perspective view of the crystal structure of potassium glucarate. The crystal structure is stabilized by the attractive forces between the potassium ions and the oxygen atoms of the glucaric anions. The potassium ions are surrounded by four carboxyl oxygens and four hydroxyl oxygens in a distorted cubic-prism arrangement, and one cation binds six ligand anions. The K–O distances range from 2.43 to 3.32 Å, the average value being 2.97 Å. This chelating structure differs from that of the calcium ion observed in the crystal of calcium glucarate tetrahydrate, in which the cations are surrounded by two carboxyl oxygens, three hydroxygens and three water molecules, and the central cation binds only two ligand dianions.[2] The hydrogen bonds also stabilize the crystal structure of the potassium salt. The hydrogen bond linkage –O(3)–O(2)–O(4)–O(5)– binds four hydroxyl groups of the adjacent glucaric anions. Another O(1′)–O(6′) hydrogen bond binds the carboxyl groups of the adjacent glucaric anions at the head and the tail along the molecular axis. Although the positions of the hydrogen in the O(1′)–O(6′) hydrogen bond are of interest in relation to the

dissociation state of the protons of the carboxyl groups at C(1) and C(6), they were not determined accurately because of the poor resolution of the difference Fourier maps.

Figure 2(a) shows a perspective view of the glucaric anion in the crystal of the potassium salt. The bond lengths and angles are given in Fig. 3. The carbon chain has a bent conformation. The structure differs from that of the calcium salt given in Fig. 2(b). The torsional angles about the C–C bonds in each case are given in Table 2. In the case of the potassium salt, C(1) and C(4) are located in trans positions with respective to the C(2)–C(3) bond. C(2) and C(5) are gauche for C(3)–C(4), and C(3) and C(6) are gauche for C(4)–C(5). Thus, the structure for the potassium salt can be represented in terms of "TGG form," while that for the calcium salt will be of "GTT form." In these structures, unfavorable parallel interaction between the C(2)–O(2) and C(4)–O(4) bonds,[13,14] as would occur in a fully extended structure, is avoided, both structures being more stable than other possible structures.

Table 2. Torsional angles ϕ (°) in D-glucaric acid

C(4)-C(5)-C(6)-O(6')	−71.5	−109.9		

Solutions of the Potassium Salt and the Calcium Salt. The 100 MHz NMR spectra of the potassium salt and the calcium salt consist of twelve peaks in the most separated case and each peak can be assigned to four protons H(2), H(3), H(4), and H(5) in the glucaric acid (Fig. 4). The assignments agree with those given for the sodium salt by Sawyer and Brannan.[15] When the pH value of the solution decreases, the H(2) and H(5) peaks shift lowfield to a greater extent than the H(3) and H(4) peaks. There is no significant difference between the chemical shifts in the potassium salt and the calcium salt (Table 3). The coupling constants J for both salts are also similar, the J values for each pair of protons remaining almost the same even when the dissociation states of the glucaric acid change (Table 4). The H–C–C–H torsional angles calculated from the average J values for each pair of protons by application of the modified Karplus equation[16] of Lemieux and Lown[17] are also given in Table 2. When the J values were calculated from the torsional angles observed in the two crystal structures, their arithmetic average values are given as 3.0, 5.9, and 6.2 Hz for $J_{2,3}$, $J_{3,4}$, and $J_{4,5}$, respectively. These values are close to the

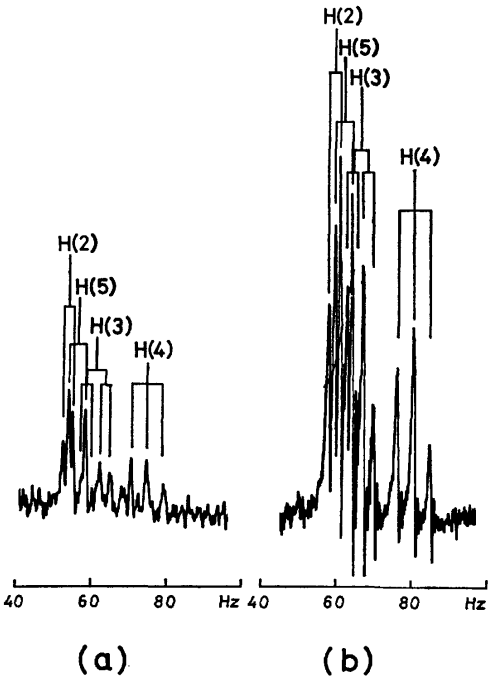

Fig. 4. The 100 MHz proton magnetic resonance spectra of D-glucaric acid. (a) For the saturated solution of the calcium salt at pH 6.1. (b) For the solution of 0.1 mol potassium salt at pH 9.8. The chemical shifts (Hz) are measured from internal HDO in upfield.

TABLE 3. CHEMICAL SHIFTS (Hz) OF D-GLUCARIC ACID UPFIELD FROM INTERNAL HDO

Proton	LH_2	LH^-	L_2^-

TABLE 4. PROTON COUPLING CONSTANTS (Hz) OF D-GLUCARIC ACID FOR K, Ca, AND Eu SALTS

Coupling constants	K salt			Ca salt		Eu salt
	LH_2	LH^-	L^{2-}	LH_2,LH^-	L^{2-}	LH_2
$J_{2,3}$	3.0	3.0	2.8	3.0	2.5	3.0
$J_{3,4}$	5.5	5.0	4.3	5.5	4.3	5.5
$J_{4,5}$	4.8	4.8	4.5	5.0	4.5	4.8

corresponding observed values of 3.0, 5.5, and 5.0 Hz. The glucaric acid in the solution is thus supposed to be an equilibrium mixture of the TGG and GTT conformers found in the crystals, although other conformers may be more or less mixed.

The Europium–Glucarate Complex in the Solution. When europium nitrate is added to an acidic solution of potassium glucarate, the H(2), H(3), and H(5) peaks shift highfield and the H(4) peak shifts lowfield (Fig. 5). The shift ratios, H(2)/H(4), H(3)/H(4), and H(5)/H(4), induced by the europium ion are linear for the relative concentration of the europium ions [Eu]/[S], and the values of the shift ratios extrapolated to the null concentration of europium ions are −2.89, −1.56, and

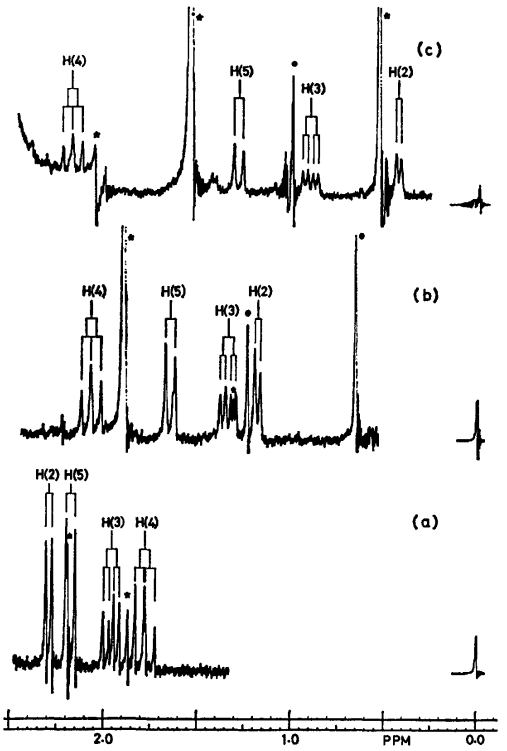

Fig. 5. Change of the 100 MHz proton magnetic resonance spectra of D-glucaric acid by adding europium nitrate to the solution of 0.1 mol potassium salt at pH 1.5.
(a) Eu was not included. (b) [Eu]: [S]=2: 3. (c) [Eu]: [S]=4: 3.
The chemical shifts were measured in relative values to the internal acetone. The peaks noted by asterisks (*) indicate the side band by the sample spinning.

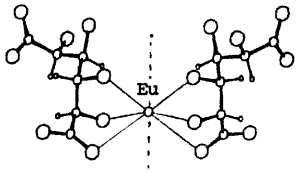

Fig. 7. Structure of Eu–glucaric acid complex. The assumed direction of the magnetic axis is indicated by the broken line through the center of the Eu ion.

−1.40, respectively (Fig. 6). The observed values were compared with the calculated shift ratios, and the best fit was obtained in the case of the 1 : 2 complex composed of the TGG conformers (see Experimental). The calculated shift ratios were −2.90, −1.57, and −1.10 for H(2)/H(4), H(3)/H(4), and H(5)/H(4), respectively. Figure 7 shows a perspective view of the obtained complex model. The three oxygens of the glucaric acid bind to the europium ion. The Eu–O distances are 3.17 Å for Eu–O(1′), 2.21 Å for Eu–O(2) and 2.64 Å for Eu–O(3). The europium–glucarate binding feature agrees with the calcium chelating form of gluconic acid found in lactobionic acid CaBr crystal, in which the gluconic acid moiety has the same TGG conformation.[18]

The Calcium Sequestering Effect by Glucaric Acid in Alkaline Solutions. Quite a large amount of the calcium salt of glucaric acid is precipitated in alkaline solutions. This can be explained as follows. The ionic radius of the calcium ion (0.99 Å) is close to that of the europium ion (1.11 Å), and in spite of their different charges, both ions show a similar behavior in glucaric acid solutions. From this analogy between the calcium and europium ions, the calcium ion should form a complex with the TGG conformers of glucaric acid as well as the europium ion did, the complex being stable in the solution over a wide pH range. The assumption of the calcium–glucarate complex is also supported by the fact that the calcium salt of glucaric acid is more easily dissolved in a high concentrated solution of calcium chloride than pure water, since the increased solubility of glucaric acid may be due to the complex formation between calcium ions and glucaric acid. Although the TGG conformers form such a calcium complex, the GTT conformers in an equilibrium state weakly interact with the calcium ions, not forming the calcium complex in the acidic solution. However, the calcium affinity of the glucaric acid is increased in the alkaline solution since the hydrogens of the carboxyl groups and probably of the hydroxyl groups in the glucaric acid are ionized in the aqueous alkaline solution. In this state, the calcium ions will bind not only to the TGG conformers but also to the GTT conformers. Once the GTT conformers bind to the calcium ions, they will form insoluble calcium salt and will be precipitated. Since the equilibrium ratio between the TGG and GTT conformers in the solution is unchangeable during the course of precipitation, the GTT conformers lost by precipitation should be supplied by the conformational change of the TGG conformers to the GTT form. Precipitation of the calcium salt would proceed until the solution attains an equilibrium state of low limited concentration of the glucaric acid in the last stage.

In conclusion, glucaric acid has two stable conformations found in the two salt crystals. The glucarate solutions are an equilibrium mixture of these two conformers. Their equilibrium ratio is not affected by the ionization states of glucaric acid or by the kind of cation in the solution. The TGG conformers form the 1 : 2 calcium complex in a wide pH range. The precipitation of the calcium salt occurs when the GTT conformers in the dianionic state bind to the calcium ions.

All the computations were performed on a FACOM 230-75 in the Data Processing Center, Kyoto University. The program system KPAX for the X-ray crystallography was used for the structure analysis of potassium glucarate crystal. The FORTRAN programs for the computations of complex models and of the chemical shifts were written by one of the authors (T.T).

A Phenomenological Description of Electron Paramagnetic Double-Resonance Relaxation of Organic Free Radicals in Solution. I. Theory of ENDOR Based on the Spin-Population Number Method

Hideo SHIKATA

Laboratory of Chemistry, Faculty of General Education, Ehime University, Bunkyo-cho, Matsuyama 790

(Received July 21, 1976)

ENDOR enhancement is phenomenologically described, applying the method of Lloyde and Pake. Emphasis is placed on the effect of incomplete hf separation. It is shown that fractional ENDOR enhancement can approximately be expressed as the product of that which Freed has formulated when the effect is absent, and an modified Allendoerfer-Maki type correlation, $T_{2e}^2\Delta\omega^2/(c+T_{2e}^2\Delta\omega^2)$, where c is a constant dependent on the microwave power. Also, a simplified method is proposed for calculating the fractional ENDOR enhancement for a multi-level system consisting of several sets of equivalent protons, when $W_n \ll W_e$, and it is proven that the week rf power irradiated leads to an ENDOR enhancement proportional to the number of equivalent protons, in the absence of the effect of incomplete hf separation.

The ENDOR measurements for an organic radical in solution give, in general, very simple spectra. The spacing among the ENDOR lines easily results in an accurate value of the hfs constant even for a proton having its hfs hidden within the ESR linewidth. On the other hand, the intensity of ENDOR lines (ENDOR enhancement) conspicuously varies with temperature (viscosity), concentration, microwave (mw) power and radiofrequency (rf) power. Thus, under the usual conditions of measurement, ENDOR enhancement does not directly reflect the number of equivalent protons which considerably helps in the assignment of the proton. Such a complicated behavior of ENDOR enhancement has stimulated some experimental and theoretical investigations for the purpose of extracting the relaxational characteristics of an observed proton. This paper covers the theoretical part of those investigations.

It has been established that the relaxation matrix theory developed by Freed and coworkers[1-5] describes ENDOR phenomena quite satisfactorily.[4-7] However, it is not easy to obtain an exact solution to the Freed equations for a simple system consisting of only a few sets of equivalent protons, even with the aid of a computer. Therefore, a simplification based on a phenomenological theory is still of value in spite of its lack of rigor, as long as it can explain, to some extent, the experimental results for complex molecules.

The Freed theory assumes that all the hfs are completely separated. However, one often encounters cases for which the hfs is of the order of the ESR linewidth (and for which ENDOR exhibits its full capability). In this situation, when one of the spin packets is saturated by mw irradiation, other packets are partially saturated because of the overlapping of the packets, which consequently reduces the ENDOR enhancement. This effect of incomplete hf separation, or the self-ELDOR effect, was first treated by Allendoerfer and Maki,[8] who have proposed the following formula,

$$I = I_{\max}\frac{T_{2e}^2\Delta\omega^2}{2.5+T_{2e}^2\Delta\omega^2}, \tag{1}$$

where $I_{\max}$ is the ENDOR enhancement in the absence of the effect, $\Delta\omega$ is a hfs constant and T_{2e} is the spin-spin relaxation time of an electron spin corresponding to the ESR linewidth. The applicability of the formula has been discussed by several authors.[9-14] The beauty of the formula is its simplicity, although it has inevitable defects. A difficult point is that it does not contain any relaxation term, except for T_{2e}, and therefore it is not clear under which conditions it is applicable. Indeed, it is known that the ratio of the ENDOR enhancement corresponding to each proton in a molecule also varies markedly with the measurement conditions mentioned above.

The present work is a direct extention of the idea of Allendoerfer and Maki. Here, the method for the spin population number of Lloyd and Pake[15] and Stephan[16] is applied. Introducing a coefficient of incomplete hf separation, we can express the ENDOR enhancement in terms of this coefficient and various kinds of transition probabilities, and thus we wish to examine the role of the effect of incomplete hf separation. In addition, a simplified method is proposed for calculating the ENDOR enhancement for a multi-level system consisting of several sets of equivalent protons, under the condition that $W_n \ll W_e$.

Theory

(a) Outline. We assume first-order formalism for the transition velocity of the spin population number in a stationary state, thus

$$\dot{\mathbf{N}} = \mathbf{CN} = 0. \tag{2}$$

$\mathbf{N}=\{N_i\}$ is the spin population number of each spin level, in which case the total spin population number should be conserved, thus

$$\sum_i N_i = N. \tag{3}$$

$\mathbf{C}$ is a conduction matrix composed of various kinds of transition probabilities. For the lattice-induced transition probabilities, we assume that

$$\frac{W_{\uparrow}^{(e)}}{W_{\downarrow}^{(e)}} = \varepsilon = \exp\left(\frac{-\gamma_e\hbar H_0}{kT}\right) \tag{4}$$

and

$$\frac{W_{\uparrow}^{(n)}}{W_{\downarrow}^{(n)}} = 1, \tag{5}$$

where $W^{(e)}$ and $W^{(n)}$ are the transition probabilities satisfying $\Delta M_s=\pm 1$, and $\Delta M_s=0$, $\Delta M_J=\pm 1$, respectively. The latter equation is assumed because the nuclear Zeeman and hf interactions are too small to bear a net population difference among electron spin levels. Also, we assume a Lorentzian shape function for the transition probabilities induced by the mw and rf fields. When the mw field, $2H_1\cos\omega_e t$, is applied, we have

$$P_e=\frac{1}{2}\gamma_e^2H_1^2T_{2e}|\langle\frac{1}{2}|S_+|-\frac{1}{2}\rangle|^2\frac{1}{1+T_{2e}^2(\omega_e-\omega_{e0})^2}, \quad (6)$$

and when the rf field, $2H_2\cos\omega_n t$, is applied,

$$P_n=\frac{1}{2}\gamma_n^2H_2^2T_{2n}|\langle M_J|J_+|M_J-1\rangle|^2\frac{1}{1+T_{2n}^2(\omega_n-\omega_{n0})^2}. \quad (7)$$

It is well known that only weak ENDOR enhancement is observed for a proton whose hfs is equal to or smaller than the ESR linewidth. In order to treat such cases, one must explicitly take into account the effect of incomplete hf separation. Now, mw excitation induces a transition between the observed spin levels at the ESR resonance, with probability,

$$P_e=\frac{1}{2}\gamma_e^2H_1^2T_{2e}. \quad (8)$$

At the same time, another transition is induced between the neighboring spin levels (Fig. 1), with probability,

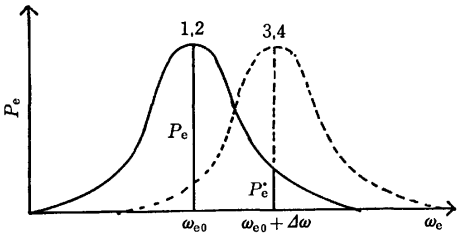

Fig. 1. Schematic diagram of the effect of the incomplete hf separation.

$$P_e'=\frac{1}{2}\gamma_e^2H_1^2T_{2e}\frac{1}{1+T_{2e}^2\Delta\omega^2}. \quad (9)$$

Therefore, a coefficient of incomplete hf separation is introduced as follows:

$$\alpha=\frac{1}{1+T_{2e}^2\Delta\omega^2}. \quad (10)$$

α takes any value between 0 and 1 which correspond to complete hf separation ($\Delta\omega=\infty$) and complete overlap ($\Delta\omega=0$), respectively. Then,

$$P_e'=\alpha P_e. \quad (11)$$

The alternating field-induced transition probabilities have inherent reversibility in contrast to the lattice-induced transition probabilities. Therefore, the role of the field-induced probabilities is thought to be that of making a partial short-circuit over the relaxation pathways, which decreases the difference in the spin population numbers among the spin levels, whereas that of the lattice-induced probabilities is to be that of keeping the Boltzmann distribution. Thus, the presence of P_e' causes the ELDOR-like effect to decrease the ENDOR enhancement.

Equations 2 and 3 result in the difference in the spin population numbers, n, between the two spin levels at which ESR is observed. Then, using the mw energy absorbed per unit time, which is given by

$$A=2\omega_e\chi''H_1^2=nP_e\hbar\omega_e, \quad (12)$$

the integral intensity of the ESR absorption line (I), the peak intensity of the first derivative (I_{ESR}), the ENDOR enhancement (I_{ENDOR}) and the fractional ENDOR enhancement (E) are defined as follows:

$$I=\chi''H_1, \quad (13)$$

$$I_{ESR}=\left(\frac{\partial I}{\partial\omega_e}\right)_{max}, \quad (14)$$

$$I_{ENDOR}=I_{ESR}(ON)-I_{ESR}(OFF), \quad (15)$$

$$E=\frac{I_{ENDOR}}{I_{ESR}(OFF)}, \quad (16)$$

where ON denotes rf irradiation and OFF the absence of rf power. As a whole, the present approach to ENDOR enhancement may be regarded as a simplified version[17] of the relaxation matrix formulation developed by Freed.

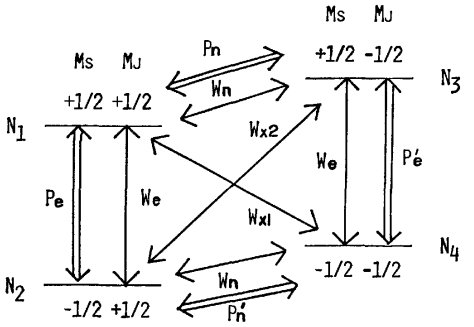

Fig. 2. Schematic diagram of the energy levels and the transition probabilities for a four-spin-level system.

(b) Four-level System (J=1/2). We first treat the four-level system shown in Fig. 2 in order to illustrate the main feature of double resonance relaxation. In the following treatment, we neglect the effects of exchange processes. It is convenient to represent transition probabilities in units of W_e, thus

$$b=\frac{W_n}{W_e},\quad b_{x1}=\frac{W_{x1}}{W_e},\quad b_{x2}=\frac{W_{x2}}{W_e},$$

$$p_e=\frac{P_e}{W_e},\quad p_n=\frac{P_n}{W_e}. \quad (17)$$

Table 1. Conduction matrix for a four-level system

For ENDOR enhancement, either p_n or p_n' is set to 0.
For ELDOR reduction, both p_n and p_n' are set to 0.

$$\begin{pmatrix} -(1+b+b_{x1}+p_e+p_n) & (\varepsilon+p_e) & (b+p_n) & b_{x1}\varepsilon \\ (1+p_e) & -(\varepsilon+b+b_{x2}+p_e+p_n') & b_{x2} & (b+p_n') \\ (b+p_n) & b_{x2} & -(1+b+b_{x2}+p_n+p_e') & (\varepsilon+p_e') \end{pmatrix}$$

TABLE 2. COEFFICIENTS IN Eq. 19

A_0, E_0: $1+2b+(1+b)(b_{x1}+b_{x2})+b_{x1}b_{x2}+(2+b_{x1}+b_{x2})p_n'$;
A_1: $1+b_{x2}$; B_0, F_0: $(1+b)\{2b+(1+b)(b_{x1}+b_{x2})+2b_{x1}b_{x2}\}$ $+\{1+2b+(1+b)(b_{x1}+b_{x2})+b_{x1}b_{x2}\}p_n'$; B_1: $2b+(1+b)(b_{x1}$ $+b_{x2})+2b_{x1}b_{x2}+(1+b_{x1})p_n'$; C_0: $1+b+b_{x1}+p_n$; C_1: 1;
D_0: $b(2+b)+(1+b)(b_{x1}+b_{x2})+b_{x1}b_{x2}+(1+b+b_{x2})p_n'$;
D_1: $2b+b_{x1}+b_{x2}+p_n'$; E_1: $1+b+b_{x2}+p_n'$;
F_1: $b(2+b)+(1+b)(b_{x1}+b_{x2})+b_{x1}b_{x2}+(1+b+b_{x1})p_n'$.

Note that $p_e=\gamma_e^2H_1^2T_{2e}/2W_e\approx\gamma_e^2H_1^2T_{1e}T_{2e}$ at the ESR resonance. Then, using the conduction matrix listed in Table 1, we obtain the difference in the spin population numbers between the 1 and 2 spin levels in the form

$$n = n_0\frac{Ap_n+B}{(Cp_n+D)p_e+Ep_n+F}\frac{F}{B}, \tag{18}$$

with

$$A = A_0+A_1p_e', B = B_0+B_1p_e', \cdots, F = F_0+E_1p_e', \tag{19}$$

A_0, A_1,……, F_0, F_1 being listed in Table 2. n_0, the difference in the spin population numbers in the absence of alternating fields, is related by $n_0=(1-\varepsilon)N/4$ and by

$$M_0 = \chi_0H_0 = \frac{1}{2}\gamma_e\hbar n_0 = \frac{N'\gamma_e^2\hbar^2}{4kT} \qquad \left(N' = \frac{N}{2}\right). \tag{20}$$

Complete hf Separation ($P_e'=0$ or $\Delta\omega=\infty$). Using Eqs. 6 and 18, Eq. 13 can be expressed as a saturated Lorentzian, thus

$$I = \frac{1}{2}\chi_0H_0\frac{\gamma_eH_1T_{2e}}{1+T_{2e}^2(\omega_e-\omega_{e0})^2+\gamma_e^2H_1^2T_{1e}(\mathrm{ON})T_{2e}}, \tag{21}$$

where $T_{1e}(\mathrm{ON})$ is the effective longitudinal relaxation time of an electron spin under NMR excitation:

$$T_{1e}(\mathrm{ON}) = \frac{1}{2W_e}\frac{C_0p_n+D_0}{A_0p_n+B_0}. \tag{22}$$

Note that when $W_n=W_{x1}=W_{x2}=0$, $T_{1e}(\mathrm{ON})=1/2W_e$. Then,

$$I_{\mathrm{ESR}} = \frac{3\sqrt{3}}{16}\chi_0H_0\frac{\gamma_eH_1T_{2e}^2}{\{1+\gamma_e^2H_1^2T_{1e}(\mathrm{ON})T_{2e}\}^{3/2}}, \tag{23}$$

$$I_{\mathrm{ENDOR}} = \frac{9\sqrt{3}}{32}\chi_0H_0\frac{\gamma_e^3H_1^3T_{2e}^3\Delta T_{1e}}{\{1+\gamma_e^2H_1^2T_{1e}(\mathrm{ON})T_{2e}\}^{5/2}}, \tag{24}$$

and

$$E = \frac{3}{2}\frac{\gamma_e^2H_1^2\Delta T_{1e}T_{2e}}{1+\gamma_e^2H_1^2T_{1e}(\mathrm{ON})T_{2e}}, \tag{25}$$

where $\Delta T_{1e}=T_{1e}(\mathrm{OFF})-T_{1e}(\mathrm{ON})$ and Eq. 23 is expanded to the first order in ΔT_{1e} to give Eq. 24. If $\gamma_e^2H_1^2T_{1e}T_{2e}\gg1$, then

$$E_\infty = \frac{3}{2}\frac{\Delta T_{1e}}{T_{1e}} = E_{\infty\infty}\frac{p_n}{p_n+D_0/C_0}, \tag{26}$$

where

$$E_{\infty\infty} = \frac{3}{2}\frac{\{b(1+b_{x2})+b_{x2}(1+b_{x1})\}^2}{(1+b)(1+b+b_{x1})\{2b+(1+b)(b_{x1}+b_{x2})+2b_{x1}b_{x2}\}}. \tag{27}$$

Equation 26 also justifies the conventional interpretation that ENDOR measures the variation in the longitudinal electron spin relaxation time by NMR excitation. Substitution of Eq. 7 into Eq. 26 again gives a saturated Lorentzian for the NMR transition, thus

$$E_\infty = E_{\infty\infty}\frac{\gamma_n^2H_2^2T_{1n}T_{2n}}{1+T_{2n}^2(\omega_n-\omega_{n0})^2+\gamma_n^2H_2^2T_{1n}T_{2n}}, \tag{28}$$

with the effective nuclear spin longitudinal relaxation time

$$T_{1n} = \frac{1}{2W_n}\frac{C_0}{D_0}. \tag{29}$$

Note that if $W_e=W_{x1}=W_{x2}=0$, then $T_{1n}=1/2W_n$.

Incomplete hf Separation. In this case, the ESR absorption line is neither expressed by a simple Lorentzian curve nor by superposition of such curves. Therefore, it is more convenient to define the fractional ENDOR enhancement by the following equation, using Eq. 12 at the ESR resonance:

$$E = \frac{n(\mathrm{ON})-n(\mathrm{OFF})}{n(\mathrm{OFF})}. \tag{30}$$

In addition, we restrict our discussion to the case of an electron-nuclear dipolar (END) mechanism and we neglect the cross relaxations to avoid complexity. Such an approximation may well be satisfied for protons in most of the organic radicals in solution except for some cases in which isotopic hf modulation may be effective.[9,13] A straight forward calculation of Eq. 30 gives

$$E=(1-\alpha)b(1+\alpha p_e)p_np_e[2(1+b+\alpha p_e)[\{2(1+b)+(1+\alpha)(2+b)p_e+2\alpha p_e^2\}b+\{1+2b+(1+\alpha)(1+b)p_e+\alpha p_e^2\}p_n]]^{-1}. \tag{31}$$

For further analysis, the reciprocal of the above equation is expanded to the first order in p_e, thus

$$\frac{1}{E} = \frac{2}{(1-\alpha)bp_np_e}[(1+b)\{2b(1+b)+p_n(1+2b)\} + (b\{(1+b)(2+b)+\alpha(2+b-b^2)\} + p_n\{(1+b)^2+\alpha(1+b-b^2)\})p_e+\alpha O(p_e^2)]. \tag{32}$$

Hence, we obtain a straight line in plotting E^{-1} *vs.* p_e^{-1}, in the region where we can neglect the quadratic terms for p_e which can be proven to be proportional to α. The reciprocal of the intercept in this plot is thus expressed as

$$E_\infty=(1-\alpha)bp_n/2[\{(1+b)(2+b)+\alpha(2+b-b^2)\}b+\{(1+b)^2+\alpha(1+b-b^2)\}p_n]^{-1}. \tag{33}$$

Also, the intercept divided the slope become proportional to the product of T_{2e} and T_{1e}, the latter being expressed, in this case, as

$$T_{1e} = \left(\frac{1}{2W_e}\right)b\{(1+b)(2+b)+\alpha(2+b-b^2)\} + p_n\{(1+b)^2+\alpha(1+b-b^2)\} [(1+b)\{2b(1+b)+p_n(1+2b)\}]^{-1}. \tag{34}$$

Substitution of Eq. 7 into Eq. 33 again gives a saturated Lorentzian for the NMR transition, with

$$T_{1n} = \frac{1}{2W_n}\frac{(1+b)^2+\alpha(2+b-b^2)}{(1+b)(2+b)+\alpha(2+b-b^2)}. \tag{35}$$

Then, we obtain a straight line in plotting E^{-1} *vs.* p_n^{-1}.

Equation 31, as well as Eq. 33, is still of too complicated a form for practical use. One may generally consider that a proton with a small hfs (or large α) has a small END term (or small b) and *vice versa*, as deduced from the McConnell-Strathdee formula.[18] If $b\ll1$, the linear part of Eq. 32 can be written as

$$E=\frac{(1-\alpha)p_e}{1+(1+\alpha)p_e}\frac{bp_n}{2(2b+p_n)}. \tag{36}$$

Hence, the effect of incomplete hf separation reduces the fractional ENDOR enhancement by the following factors, depending on p_e:

(i) for small p_e by $T_{2e}^2\Delta\omega^2/(1+T_{2e}^2\Delta\omega^2)$
(ii) at the ESR maximum ($p_e=1/2$) by $T_{2e}^2\Delta\omega^2/\{(4/3)+T_{2e}^2\Delta\omega^2\}$
(iii) at the ENDOR maximum ($p_e=3/2$) by $T_{2e}^2\Delta\omega^2/\{(8/5)+T_{2e}^2\Delta\omega^2\}$
(iv) and at infinite p_e by $T_{2e}^2\Delta\omega^2/(2+T_{2e}^2\Delta\omega^2)$.

On the other hand, if $\alpha=0$, Eq. 33 becomes

$$E_\infty^{(0)}=\frac{1}{2}\frac{bp_n}{b(1+b)(1+2b)+p_n(1+b)^2}, \tag{37}$$

which coincides with the Freed equation. Note that Eq. 37 also coincides with Eq. 27, except for a trival numerical factor, if p_n is set to infinity. Therefore, an inspection of the above two equations allows us to express approximately the fractional ENDOR enhancement as a formula including correlation of the modified Allendoerfer-Maki type and the Freed formula for $b\lesssim 1$, thus

$$E=\frac{(1-\alpha)p_e}{1+(1+\alpha)p_e}E_\infty^{(0)}. \tag{38}$$

From an experimental point of view, it is desirable to use the mw power at the ESR maximum for ENDOR signals with good S/N ratios. The maximum deviation of Eq. 38 from the linear part of Eq. 32 under these conditions is 6%, for $\alpha=1$ and $b=1$.

(c) Multi-level System—a Simplified Method. The ESR absorption line of an actual molecule is formed by the superposition of its component lines, designated by the various quantum numbers of the total nuclear spin angular momentum.[19] Therefore, for quantitative discussions of the ENDOR relaxation, we must proceed to a multi-level system consisting of several sets of equivalent protons. Treatment of this system along same lines as the scheme in (*b*) may be possible, in principle, but is too complicated and deviates from the purpose of the present work. Instead, a simplified method for calculating the fractional ENDOR enhancement for such a system is proposed with the following approximations and derivations.

In this system, the spin state is represented by

$$|\gamma\pm\rangle=|\pm\frac{1}{2}\rangle\prod_u|J_u^{(\kappa)}M_u\rangle, \tag{39}$$

where J_u and M_u are the quantum numbers of the total nuclear angular momentum for the u'th set of equivalent protons and κ denotes the different degenerate states with the same value of J_u. Now, we assume that T_{2e} is independent of J_u and M_u, so that the ESR absorption is expressed as a superposition of component lines with the same linewidth, corresponding to the transitions from $|\gamma-\rangle$ to $|\gamma+\rangle$. On the other hand the nuclear spin transition probabilities are dependent on the nuclear spin quantum numbers, as follows:[5]

$$1/T_{2n}(J_n, M_u\leftrightarrow J_u, M_u-1)=W_e\left[1+\left\{2f(J_u, M_u)+\frac{1}{3}\right\}b_u\right], \tag{40}$$

$$W_n(J_u, M_u\leftrightarrow J_u, M_u-1)=f(J_u, M_u)W_n^{(u)}, \tag{41}$$

and

$$P_n(J_u, M_u\leftrightarrow J_u, M_u-1)=f(J_u, M_u)P_n^{(u)}, \tag{42}$$

where $W_n^{(u)}$ and $P_n^{(u)}$ are the nuclear spin transition probabilities for a four-level system consisting of a single u'th proton, and with

$$f(J_u, M_u)=J_u(J_u+1)-M_u(M_u-1), \tag{43a}$$

and

$$f\left(J_u, 0 \text{ or } \frac{1}{2}\right)\equiv f_{J_u}. \tag{43b}$$

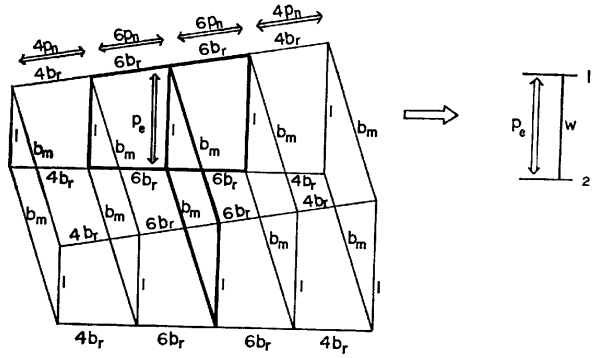

Fig. 3. Schematic diagram of the energy levels and the transition probabilities for a system with $J_m=1/2$ and $J_r=2$. The cetral line of the each quintet of the ESR absorption is observed, and the rf power corresponding to the hfs of the r'th equivalent protons is irradiated. Left side diagram draws an equivalent two-spin-level system corresponding to the relaxation pathways with thick line.

Next, we neglect the relaxation pathways passing more than twice through the W_n's, under the assumption that $b\ll 1$. For example, for the system with $J_m=1/2$ and $J_r=2$ illustrated in Fig. 3, only the relaxation pathways with thick lines are considered. Then, all of the multi-level systems are reduced to a superposition of the maximum six-level systems. This can further be reduced to the two-level system illustrated in the right side of Fig. 3, using a summing method for the electric conduction. The energy of the ESR absorption for this system is easily obtained as

$$A=\frac{n_0\hbar\omega_e WP_e}{2(W+P_e)}, \tag{44}$$

so that the spin lattice relaxation becomes the rate-determining step of the energy absorption, if P_e is set to infinity. Therefore, the fractional ENDOR enhancement, corresponding to Eq. 37, is expressed as

$$E^{(0)}=\frac{w(\text{ON})-w(\text{OFF})}{w(\text{OFF})}, \quad \left(w=\frac{W}{W_e}\right). \tag{45}$$

For actual application it is sufficient only to treat the central line of the ESR absorption. In this case, the summing method leads to the following resultant transition probability for an electron spin:

$$w=1+\sum_u\sum_{J_u}\frac{D_{J_u}}{D_u}\frac{2f_{J_u}(b_u+p_n^{(u)})}{(f_{J_u}+2)b_u+(f_{J_u}+1)p_n^{(u)}}$$

$$+\sum_{u'}\sum_{J_{u'}}\frac{D_{J_{u'}}}{D_{u'}}\left[\frac{(f_{J_{u'}}-1)b_{u'}(b_{u'}+p_n^{(u')})}{\{2+(f_{J_{u'}}-1)b_{u'}\}b_{u'}+\{1+(f_{J_{u'}}-1)b_{u'}\}p_n^{(u')}}\right.$$
$$\left.+\frac{f_{J_{u'}}b_{u'}(b_{u'}+p_n^{(u')})}{(2+f_{J_{u'}}b_{u'})b_{u'}+(1+f_{J_{u'}}b_{u'})p_n^{(u')}}\right], \quad (46)*$$

where u and u′ denote even and odd numbers equivalent protons, respectively, D_u is the total degeneracy of the central absorption line of the u'th set of equivalent protons, and D_{J_u} is the degeneracy of the state with the same value of J_u. These are given by

$$D_{J_u}=\frac{n_u(n_u-1)\cdots\{(n_u/2)-J_u+1\}(2J_u+1)}{\{(n_u/2)+J_u+1\}!}, \quad (47)$$

$$D_u=\sum_{J_u}D_{J_u}=\binom{n_u}{[n_u/2]}, \quad (48)$$

where n_u is the number of u'th equivalent protons.

It can also be proven that for a six-level system for which the hfs is incompletely separated, a calculation similar to Eq. 30 leads to the same form of the fractional ENDOR enhancement as Eq. 38. Therefore, it is considered that Eq. 38 is still valid for general multi-level systems, as long as the above approximation of treating them as the superposition of maximum six-level systems is valid. Hence, we obtain the following limiting expressions for the fractional ENDOR enhancement of the u'th proton, corresponding to Eq. 38. If p_n is set to infinity, then

$$E_{\infty}^{(u)}=\frac{(1-\alpha)p_e}{1+(1+\alpha)p_e}\sum_{J_u}\frac{D_{J_u}}{D_u}\frac{2f_{J_u}b_u}{(1+f_{J_u}b_u)(2+f_{J_u}b_u)}/w(\mathrm{OFF}) \quad (49)$$

for an even number of equivalent protons. Also, if p_n approaches 0, then

$$E_{0}^{(u)}=\frac{(1-\alpha)p_e}{1+(1+\alpha)p_e}\sum_{J_u}\frac{D_{J_u}}{D_u}\frac{2f_{J_u}p_n^{(u)}}{(2+f_{J_u}b_u)^2}/w(\mathrm{OFF}). \quad (50)$$

For an odd number of equivalent protons,

$$E_{\infty}^{(u')}=\frac{(1-\alpha)p_e}{1+(1+\alpha)p_e}\sum_{J_{u'}}\frac{D_{J_{u'}}}{D_{u'}}\left[\frac{f_{J_{u'}}}{(1+f_{J_{u'}}b_{u'})(2+f_{J_{u'}}b_{u'})}\right.$$
$$\left.+\frac{f_{J_{u'}}-1}{\{1+(f_{J_{u'}}-1)b_{u'}\}\{2+(f_{J_{u'}}-1)b_{u'}\}}\right]b_{u'}/w(\mathrm{OFF}). \quad (51)$$

$$E_{0}^{(u')}=\frac{(1-\alpha)p_e}{1+(1+\alpha)p_e}\sum_{J_{u'}}\frac{D_{J_{u'}}}{D_{u'}}\left[\frac{f_{J_{u'}}}{(2+f_{J_{u'}}b_{u'})^2}\right.$$
$$\left.+\frac{f_{J_{u'}}-1}{\{2+(f_{J_{u'}}-1)b_{u'}\}^2}\right]p_n^{(u')}/w(\mathrm{OFF}). \quad (52)$$

Equations 49 and 51 and Eqs. 50 and 52 correspond approximately to the reciprocal of the intercept and that of the slope of the plot of E^{-1} *vs.* p_n^{-1}, respectively. The linearity of this plot is approximately assured, because, in general, if $x\ll r_i/q_i$,

$$y=\sum_i\frac{p_ix}{q_ix+r_i}\simeq\frac{\sum_i(p_i/q_i)^2x}{\sum_i(p_i/q_i)x+\sum_i(p_ir_i/q_i^2)}. \quad (53)$$

Application of Eqs. 47 and 48 to a four-level system leads, of cource, to the same result as Eq. 38 with Eq. 37. Because $\sum_{J_u}f_{J_u}D_{J_u}/D_u=n_u/2$, the above equations can further be reduced to more simplified forms, if we can neglect the quadratic terms for b_u, thus

$$E_{\infty}^{(u)}\simeq\frac{(1-\alpha)p_e}{1+(1+\alpha)p_e}\frac{n_ub_u}{2}, \quad (54)**$$

$$E_{0}^{(u)}\simeq\frac{(1-\alpha)p_e}{1+(1+\alpha)p_e}\frac{n_up_n^{(u)}}{4}. \quad (55)**$$

Considering that from Eq. 36, $p_n^{(u)}$ is independent of u under this condition, Eq. 55 indicates that the fractional ENDOR enhancement is proportional to the number of equivalent protons, if $\alpha=0$ and enough weak rf power is irradiated. This conclusion is the same as the result of the "average ENDOR" proposed by Freed *et al.*[3]

Although ENDOR experiments have been reported in the literature for many radicals in solution since the first successful observation by Hyde and Maki,[20] ENDOR detection for many radicals remains impossible or at least difficult, in spite of the ease of ESR observation. Perhaps, Heisenberg and chemical exchange may be the reason. However, Eqs. 49—52 may offer an additional reason. In these equations, all the END terms of atoms with nuclear spins make contributions to the denominator, w(OFF), whereas only that of the observed proton makes a contribution to the numerator. Therefore, if a radical contains atoms with nuclear spins on which the electron spin density is moderately localized resulting in a large END term, one may observe only weak ENDOR enhancement. This may be a possible reason why ENDOR enhancement for hydrocarbon radicals is, in general, more easily observed than that for nitroxide radicals.

Summary

A simple theory has been formulated to calculate the fractional ENDOR enhancement (E) in the presence of the effect of incomplete hf separation, using the conduction matrix composed of the lattice-induced transtition probabilities and the alternating field-induced transition probabilities, the latter being assumed to be a Lorentzian. The coefficient of incomplete hf separation, α, has been introduced and it is shown that a plot of E^{-1} *vs.* H_1^2 results in a straight line even in the presence of this effect, if $\alpha p_e\ll 1$, where p_e is the mw-induced transition probability in units of W_e. Also, it is shown that the effect of incomplete hf separation reduces the fractional ENDOR enhancement formulated by Freed, by an Allendoerfer-Maki type factor. However, this factor should be modified to $T_{2e}^2\Delta\omega^2/\{(4/3)+T_{2e}^2\Delta\omega^2\}$ at the mw power corresponding to the ESR maximum.

The theory has been extended to a multi-level system consisting of several sets of equivalent protons and it is shown that the plot of E^{-1} *vs.* H_2^{-2} also results in a straight line and that the reciprocal of the slope in this plot is proportional to the number of equivalent protons, if $\alpha=0$ and $b\ll 1$. Thus, the effect of incomplete hf separation should be examined by the following procedure. The H_2 dependence of the ENDOR enhance-

* $\sum_{J_u}$ denotes the single summation over the u'th set of equivalent protons.

** In this case, u denotes odd and even numbers of equivalent protons.

ment is measured at high temperatures of which $b \ll 1$ is satisfied for all protons. E^{-1} is plotted against H_2^{-2}, and the reciprocal of the slope divided by the number of equivalent protons is compared with the proton species.

The author wishes to express his gratitude to Professors K. Ishizu of Ehime University and K. Kuwata of Osaka University for fruitful discussions and encouragement throughout the cource of this work. He also would like to express his appreciation to Professor Y. Deguchi of Kyoto University.

Appendix

TRIPLE Enhancement. Recently, Möbius and coworkers were the first to succeed in observing electron-nuclear triple resonance (TRIPLE) in solution.[12] The most attractive results of their experiments are that TRIPLE enhancement has a better S/N ratio than does ENDOR enhancement and that TRIPLE enhancement is proportional to the number of equivalent protons.

It is worthwhile to interpret TRIPLE enhancement from the standpoint of the present theory. The fractional TRIPLE enhancement is defined by Eq. 30, where OFF means, in this case, that P_e is present but P_n and P_n' are absent, and ON means that P_e, P_n and P_n' are all present. Straightforward calculation gives the following expression for the fractional TRIPLE enhancement for a four-level system, where hf is incompletely separated and $P_n = P_n'$, thus

$$E_t = (1-\alpha)p_e p_n (1+\alpha p_e)(b+p_n)[(1+b+\alpha p_e)[\{p_n^2 + 2(1+b+\alpha p_e)p_n + b(2+b+2\alpha p_e)\}p_e + (2+\alpha p_e)p_n^2 + 2\{1+2b+(1+b)\alpha p_e\}p_n + b\{2+2b+(2+b)\alpha p_e\}]]^{-1}. \quad \text{(A1)}$$

The above equation indicates that the effect of incomplete hf separation also reduces TRIPLE enhancement and that if $\alpha = 0$, TRIPLE enhancement has a S/N ratio eight times larger than does ENDOR enhancement, when Eq. A1 is compared with Eq. 37 at their optimum conditions. Indeed, the TRIPLE enhancement for 2,6-*di-t*-butyl protons in the 2,4,6-*tri-t*-butylphenoxyl radical[12] appears to support the presence of this effect.

For a multi-level system, we start with Eq. 45 as the basis of discussion. However, because P_n and P_n' are simultaneously excited, even the previous approximation to reduce a multi-level system to a superposition of the maximum six-level system is not valid. Instead, we consider the entire system in the extreme cases that $P_n = P_n' = 0$ (OFF) and that $P_n = P_n' = \infty$ (ON), under the condition that $b \ll 1$. In the former case, all the relaxation pathways are cut off except for the original two-level system (W_e). In the latter case, all the W_n pathways are completely short-circuited by P_n and P_n', so that all the W_e pathways are gathered to form a net twe-level system. Thus,

$$w(\mathrm{ON}) = \sum_{J_u} \frac{D_{J_u}}{D_u}(2J_u+1), \quad \text{(A2)}$$

with $w(\mathrm{OFF}) = 1$. Hence, the fractional TRIPLE enhancement is given by

$$E_t^{(u)} = \sum_{J_u} \frac{D_{J_u}}{D_u} 2J_u. \quad \text{(A3)}$$

Such a simple formula appears to explain fairly well the experimental results demonstrated by Möbius *et al.* For example, the ratio of the TRIPLE enhancement for 4,5,9,10-protons to that for 1,7-protons in the pyrene negative ion is obtained from Eq. A3 as 1.67, whereas the experimental ratio is 1.3 and the ratio of the number of equivalent protons is 2.

17) According to the Freed theory presented in Ref. 3, $Z''_{a'a}$, which determines the energy of the ESR absorption and the line shape, is obtained by solving the system of simultaneous equations 4.5a—4.6e of that paper. Then, the fractional ENDOR enhancement is given by $E = \{Z''_{a'a}(\mathrm{ON}) - Z''_{a'a}(\mathrm{OFF})\}/Z''_{a'a}(\mathrm{OFF})$. It is possible to calculate $Z''_{a'a}$ using an approximate method instead of the exact solution of the complicated equations. First, the coherence effect is neglected, so that Eq. 4.5c and the third term on the left-hand side of Eq. 4.5a and b are neglected. Next, the second terms on the left-hand sides of both equations are tentatively neglected. Then, both $Z''_{a'a}$ and $Z''_{a'b'}$ become Lorentzian, and both are substituted into Eq. 4.6. $\chi_a - \chi_{a'}$, thus obtained, is again substituted into Eq. 4.5a in exact form, and finally $Z''_{a'a}$ is calculated. This procedure certainly corresponds to the present approach.

(Received September 6, 1976)

The ratio of the ENDOR enhancement to the ESR intensity (E) of galvinoxyl in toluene was measured under various conditions of microwave power, rf power and temperature. The results are discussed in comparison with a phenomenological theory in part I. It is proven that the apparent longitudinal electron spin relaxation time for a *t*-butyl proton under NMR excitation is about twice as long as those for methylidyne and ring protons, which is explained by the effect of incomplete hf separation. Also, it is shown that the reciprocal of the slope of the plot of E^{-1} *vs.* (rf power)$^{-1}$ for methylidyne and ring protons is approximately proportional to the number of equivalent protons, whereas that for a *t*-butyl proton can be explained only if the effect of incomplete hf separation is taken into consideration. The value of $b=W_n/W_e$ for methylidyne and ring protons, simulated from the temperature dependence of E based on a previous theory, can be closely correlated to the spin distribution in galvinoxyl.

A phenomenological theory has been described in part I. The purpose of the present paper is to report the results of an experimental examination of the applicability and the limits of the theory.

Because the pulse technique[1,2] is not widespread in the field of ESR spectroscopy, experimental information about the relaxational behavior of a radical can usually be extracted from an analysis of the ESR saturation curve, as well as from that of the linewidth.[3] The same procedure should be applied to ENDOR, by measuring the microwave(mw)- and rf-power dependence of ENDOR enhancement. More abundant information is expected from ENDOR, because two parameters can be varied independently. Recently, Leniart *et al.*[4] have applied such a method to the study of some semiquinones. However, to the present authors' knowledge, there has been no attempt to compare this dependence for different proton species in a molecule over a wide temperature range.

In the present study, the ratio of the ENDOR enhancement to the ESR intensity was measured for different protons, as functions of the mw and rf powers at temperatures from −20 to −95 °C. The sample used in the experiments is the galvinoxyl radical which has one methylidyne proton, four ring protons and thirty-six *t*-butyl protons. It was selected because its ENDOR spectra is one of the most easily observable and because the purity of this very stable radical can be precisely determined from a measurement of the magnetic susceptibility, so that a solution of known concentration can be easily obtained. It is one of materials for which the liquid phase ENDOR was first successfully observed.[5] The results are discussed with reference to the theory in part I, forcussing our attention on a comparison of the proton species.

Experimental

The ENDOR spectra were measured using a JEOL EDX-1 ENDOR unit with a frequency modulation of 6.5 kHz, attached to a JEOL ME-X ESR spectrometer with a field modulation of 80 Hz. The rf amplifier employed can provide maximum rf power of 1 kW. The mw power was calibrated using the ESR intensity of a powdered DPPH radical. The rf power was measured using a level meter connected to a tunk circuit which was calibrated by a 100-MHz oscilloscope, using a search coil. No attempt was made to determine the absolute value of either magnetic field. The intensity of the 80-Hz field modulation was set to a value 3 db lower than that for optimum ENDOR enhancement, because overmodulation reduces the relative enhancement for a *t*-butyl proton with respect the enhancement of other protons.[6]

A toluene solution of galvinoxyl in a quartz tube was degassed using the usual method. The purity of the compound synthesized in this laboratory in the past has been determined to be 85%. The viscosity of toluene was estimated using the empirical formula reported by Barlow *et al.*[7] In most of cases, the ENDOR enhancement was observed at concentration a little more dilute than optimum. The ESR and ENDOR intensity were measured as the peak-to-peak heights of the first derivatives of lines. However, because the ENDOR enhancement for the *t*-butyl proton was not resolved completely at high temperatures, it was measured as the distance from the highest to the lowest peak of the doublet enhancement.

Results and Discussion

An example of an ESR spectrum and an ENDOR spectrum of galvinoxyl (Fig. 1) at −80 °C are shown in Fig. 2. For the latter measurement, the ESR field was adjusted to the highest peak of the low-field part of the doublet of the methylidyne proton. The ESR spectrum completely splits the doublet of quintets of methylidyne and ring protons, but does not resolve any

t-butyl proton splitting. From the ENDOR spectrum, however, the hfs constants are found to be 15.60, 3.79, and 0.13 MHz at −80 °C, corresponding to methylidyne, ring and *t*-butyl protons, respectively. No marked dependence of the hfs constants on temperature was observed. In the following discussion, the proton species in galvinoxyl are denoted by the subscripts, m, r, and tb, respectively.

In the present work, the ENDOR enhancement is always divided by the ESR intensity of the peak for which the ENDOR was observed. The quantity, which we tentatively call the ENDOR quotient, is taken to be proportional to the fractional ENDOR enhancement. This procedure will remove experimental errors which may result from, for example, a change in Q value of the cavity during the measurement of the mw-power, rf-power and the temperature dependence. Moreover, the ENDOR quotient is more favorable from the viewpoint of theoretical analysis.

Regarding variation of concentration, the ENDOR enhancement is optimized at about 3×10^{-4} M, and is sharply decreased for other concentrations. On the other hand, as the concentration decreases, the ENDOR quotient monotonically increases and appears to approach to a limiting value. More detailed results will be discussed in a subsequent paper, and it is merely noted that the ratio of the ENDOR enhancement for different protons at the concentration used here is almost the same as the limiting ratio. Thus, we temporarily neglect the Heisenberg exchange effect, as well as the chemical exchange effect, because the addition of another ambiguous parameter would not aid in understanding the essential features of the present system.

(a) Dependence on mw Power. Figure 3 shows the dependence of the ESR intensity, the ENDOR enhancement and the ENDOR quotient on the mw power, measured for ring protons at −75 °C. The rf power employed is indicated by the arrowed in Fig. 5. This figure shows that for sufficiently weak mw powers, the ESR intensity is proportional to the square root of the mw power, the ENDOR enhancement to the 3/2 power of the mw power, so that the ENDOR quotient is proportional simply to the mw power, as is predicted by Eqs. 23—25 in part I. Also, interesting features are found in Fig. 4, in which the reciprocal of the ENDOR quotient for different protons is plotted against the reciprocal of the mw power. As the mw power is increased over a moderately wide range, all the plots go down linearly, but they start to turn up as the mw power is further increased. This means that the ENDOR enhancement decreases more rapidly than does the ESR intensity with a further increase of the mw power. Such a tendency is most marked for *t*-butyl protons, and a more detailed examination reveals that the mw power corresponding to the point at which the plot deviates from a straight line for this proton is about one-half of those for methylidyne and ring protons.

From the theory of part I, the effect of incomplete hf separation is parametrized by a coefficient, α, defined by

$$\alpha = \frac{1}{1+T_{2e}^2\Delta\omega^2}, \quad (1)$$

where $\Delta\omega$ is the hfs constant. Considering that the ESR resolves no splitting for *t*-butyl protons in contrast to the case for methylidyne and ring protons and that T_{2e} ordinarily has a value of 10^{-6}—10^{-7} s, the α for galvinoxyl will be $0 \leq \alpha_m$ and $\alpha_r \ll \alpha_{tb} \leq 1$. It was shown in part I that the plot of E^{-1} *vs.* p_e^{-1} forms a straight line in the weak mw-power region and that the deviation from linearity at higher mw powers is due to the quadratic terms for p_e, which are proportional to α (Eq. 32 in part I). Thus, the theory explains well the experimental features mentioned above taking account of the difference in the α values.

Furthermore, the effective longitudinal electron spin relaxation time, T_{1e}, under rf-power excitation is given by Eq. 34 in part I. Since $b \ll 1$ at temperatures normally used for ENDOR (as shown in (*c*)), this equation is reduced to

$$T_{1e} \simeq \begin{cases} \dfrac{1}{2W_e} & (\alpha=0) \\ \dfrac{1}{W_e} & (\alpha=1). \end{cases} \quad (2)$$

On the other hand, the slope divided by the intercept of the linear part of the plot in Fig. 4 is interpreted as being proportional to $T_{1e}T_{2e}$. The experimental ratio was 1 : 1.0 : 1.9 for methylidyne, ring and *t*-butyl protons, respectively. The good agreement between the experimental and theoretical results suggests the validity of the treatment for the effect of incomplete hf separation given in part I, although coherence effects[8] may also be involved in the upward-turning tendency of the curve in the high mw-power region in Fig. 4. This is beyond of the limits of the theory in part I.

A similar situation for the mw-power saturation of ENDOR enhancement is also found for the 2,4,6-tri-*t*-butylphenoxyl radical in mineral oil,[6] where the values of the mw power for optimum ENDOR enhancement decreases in the order, 2,6-di-*t*-butyl, 4-*t*-butyl and 3,5-ring protons. Such a result suggests the importance of the effect of incomplete hf separation for the former two types of protons.

(b) Dependence on rf Power. During the analysis of ENDOR enhancement as a function of rf power, the effect of hf enhancement must be kept in mind.[9] In addition to the external rf field, the nuclear spin is affected by another field, caused by the rf modulation of the hf coupling with the electron spin, so that if $|\Delta\omega|/2 < \omega_p$, the effective rf field is given by

$$H_{2eff} = \left(1 \pm \frac{|\Delta\omega|}{2\omega_p}\right) H_2 = \frac{\omega_{n0}}{\omega_p} H_2, \quad (3)$$

where the plus and minus signs correspond to the high- and low-frequency ENDOR lines, respectively, and ω_p is the free proton frequency. However, since the rf power is usually monitored by a search coil having an ω-dependent induced voltage $V = -\partial\Phi/\partial t \propto \omega_{n0}H_2$, no correction was made for this effect in the present work.

Figure 5 shows the rf-power dependence of the high-frequency ENDOR lines measured for different protons at —80 °C, using the values of the mw power indicated

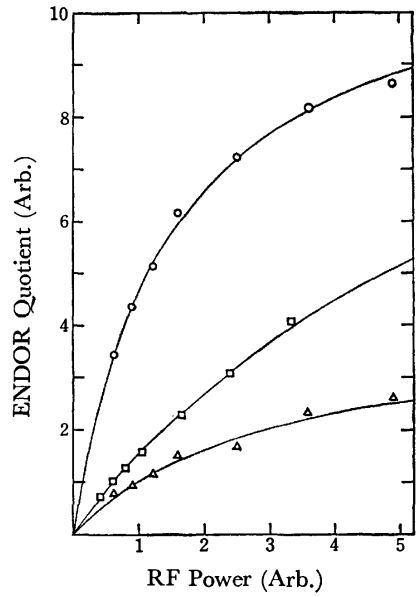

Fig. 5. ENDOR quotient as a function of rf power. The arrow indicates the rf power used for measurements of Figs. 3 and 4.

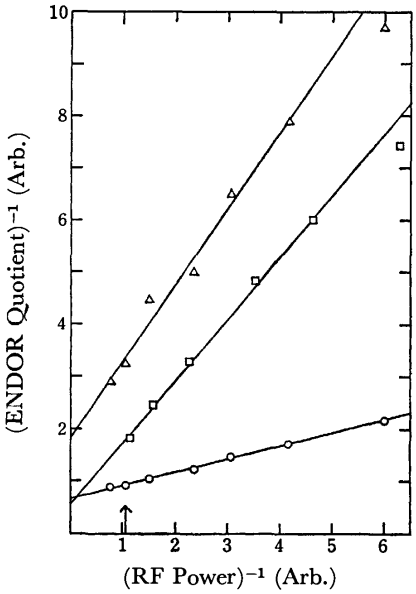

Fig. 6. Reciprocal of the ENDOR quotient as a fuction of the reciprocal of the rf power. The triangles are for *t*-butyl protons, circles for ring protons and squares for a methylidyne proton.

by arrows in Figs. 3 and 4. Figure 6, which shows a reciprocal plot of Fig. 5, indicates that the data fall well along a straight line.[10] Equation 28 in part I predicts this linearity. Also, this equation indicates that the linewidth of the ENDOR enhancement increases as the rf power increases, which agrees with what is found experimentally. On the other hand, it is found that this linewidth decreases with temperature. This is qualitatively explained using the same equation, considering that the T_{2n} of a radical is mainly composed of W_e (see Eq. 9).

(c) Dependence on Temperature. The ENDOR enhancement is known to vary with temperature in a

rather interesting fashion: it sharply increases to a maximum at a specific value of the ratio of the viscosity to the temperature, $(\eta/T)_{opt}$, independent of the kind of solvent.[11] $(\eta/T)_{opt}$ increases as the size of the molecule decreases[12] and as the spin density on the carbon atom, to which an observed proton is bonded, decreases.[11,12] All this appears to be due to the fact that the fractional ENDOR enhancement is maximum at the temperature for which $b=W_n/W_e$ has a certain value characteristic of the observed proton. Accordingly, from an analysis of the temperature dependence, it should be possible to obtain the ratio of the values of b for different protons in a molecule or even information about its spin distribution. However, because an actual molecule contains several sets of equivalent protons, it is preferable for a quantitative discussion to use a theory for a multi-level system rather than the simple theory for a four-level system. Such a theory was presented in part I and is seen to predict that the ENDOR enhancement is proportional to the number of equivalent protons,[13] if a weak rf power is irradiated with $b \ll 1$ and the effect of incomplete hf separation can be neglected. This has sufficient value for use as an analytical tool such that its applicability should be examined experimentally over the whole temperature range used in ENDOR measurements.

For the above reasons, the ENDOR quotients for different protons in galvinoxyl were measured at temperatures from −20 to −95 °C, by varying the rf power at five points for each temperature. Such measurements and a comparison of the results with theory requires specification of both the mw and rf powers. It was shown in (*a*) that the slope divided by the intercept for a methylidyne proton in the plot in Fig. 4 is identical to that for ring protons. This means the ratio of the ENDOR quotients for both protons at any

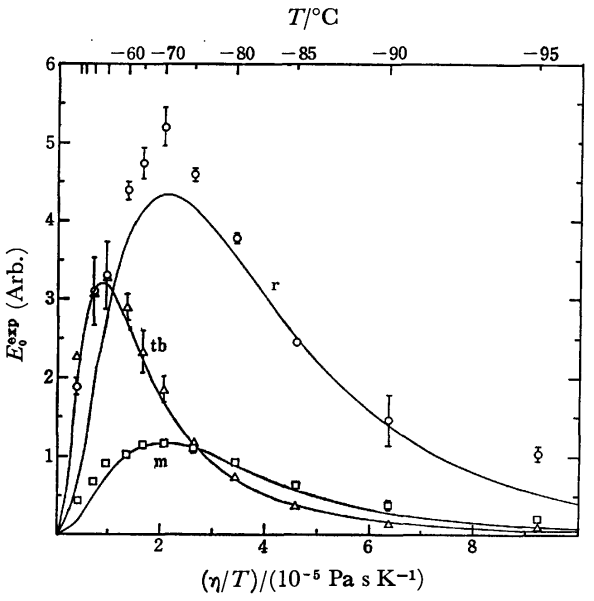

Fig. 7. E_0^{exp} as a function of η/T. The vertical lines indicate the probable error, as determined by the least-squares method. The solid lines are theoretical results. The triangles are for *t*-butyl protons, circles for ring protons and squares for a methylidyne proton.

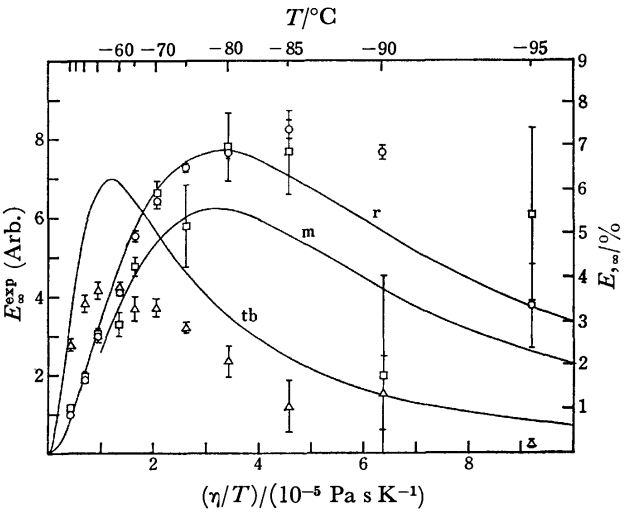

Fig. 8. E_∞^{exp} as a function of η/T. The vertical lines indicate the probable error, as determined by the least-squares method. The solid lines are theoretical results. The triangles are for *t*-butyl protons, circles for ring protons and squares for methylidyne proton.

mw power is identical to that at infinite mw power. The mw power employed in this experiment corresponds to the maximum ESR intensity. Also, the rf power can be specified if the reciprocals of the slope and the intercept are determined from a similar plot shown in Fig. 6, because they correspond to the ENDOR quotients at infinitesimal and infinite rf powers, E_0^{exp} and E_∞^{exp}, respectively. E_0^{exp} and E_∞^{exp} thus determined are shown in Figs. 7 and 8 as a function of η/T. These are analyzed using the following procedure.

Simulation. According to the theory of part I for a multi-level system consisting of several sets of equivalent protons, the fractional ENDOR enhancement at infinitesimal and infinite rf powers are approximately given by Eqs. 50 and 52 and by Eqs. 49 and 51, respectively, with Eqs. 46—48 in part I. The transition probabilities in these equations have been formulated by Freed and Fraenkel[14] and by Freed.[15] Accordingly, if we have information about the g tensor, hf tensor and the other molecular parameters of this radical, we can in principle calculate these values and thus the fractional ENDOR enhancement. Atherton and Day[16] have performed such an estimation for a methylidyne proton in galvinoxyl. However, this involves considerable ambiguities at the present stage. For instance, the rotational correlation time of a molecule, τ_R, is expressed by the extended Debye relationship as

$$\tau_R = \frac{4\pi\kappa r^3\eta}{3kT}. \quad (4)$$

The hydrodynamic radius, r, and a constant, κ, are both dependent on the molecular structures of the radical and the solvent, and consequently, involve unavoidable ambiguities.

For this reason, here, only the η/T dependence of each transition probability is assigned under the following assumptions in an attempt to examine how the fractional ENDOR enhancement varie with temperature. A moderately slow tumbling molecular motion is

assumed so that the following conditions are satisfied:

$$\omega_{e0}^2\tau_R^2 \gg 1, \quad \omega_{n0}^2\tau_R^2 \ll 1. \tag{5}$$

For W_e, we neglect the contribution from the END interaction, as well as the spin rotational interaction, and thus it is assumed to be independent of the nuclear spin quantum numbers. Then, denoting the spectral density by $j(\omega)$, the η/T dependence of the transition probabilities can be written as

$$W_e \approx 2j_{G_s}(\omega_{e0})H_0^2 \approx \frac{1}{\tau_R} \approx \frac{T}{\eta}, \tag{6}$$

and

$$W_n^{(u)} \approx \frac{1}{2}j_D^{(u)}(0) \approx \tau_R \approx \frac{\eta}{T}, \tag{7}$$

so that

$$b_u \approx \frac{j_D^{(u)}(0)}{4j_{G_s}(\omega_{e0})} \approx \tau_R^2 \approx \left(\frac{\eta}{T}\right)^2. \tag{8}$$

Also, the η/T dependence of T_{2n} is derived from

$$\frac{1}{T_{2n}(J_u)} = W_e\left\{1+\left(2f_{J_u}+\frac{1}{3}\right)b_u\right\}. \tag{9}$$

We assume p_e and T_{2e} to have constant values of 1/2 and 1.2 μs, respectively, independent of the temperature. (The choice of the latter value is discussed below.)

If we choose given values of b_m, b_r, and b_{tb} at any temperature and apply these equations to Eqs. 50 and 52 in part I, the relative values of $E_{,0}$ for each proton in galvinoxyl are readily evaluated for all temperatures. Thus, the values of b_m, b_r, and b_{tb} are determined in such a way that the experimental and theoretical T_{opt} for $E_{,0}$ are in complete agreement, since the T_{opt} for $E_{,0}^{exp}$ are known precisely for each proton. Then, using the values of b thus determined, the values of $E_{,\infty}$ are calculated for each proton from Eqs. 49 and 51 in part I. The results are shown by solid lines in Figs. 7 and 8. In Fig. 7, the values of $E_{,0}$ are normalized to that of E_0^{exp} for a methylidyne proton at the optimum temperature for this proton.

Comparison of Experimental and Theoretical Results. Because the determination of the E_0^{exp} involves much smaller errors than that of the E_∞^{exp}, the T_{opt} in Fig. 7 are unambiguously obtained to be −70, −70, and −50 °C for the methylidyne, ring and *t*-butyl protons, respectively. On the other hand, these temperatures are not clear in Fig. 8. However, repeated experiments indicate the T_{opt} to be about −55 °C for the *t*-butyl protons and in the neighborhood of −80——85 °C for the methylidyne and ring protons. Thus, E_0^{exp} has a maximum at a value of η/T of about one-half of that for E_∞^{exp}. In addition, E_0^{exp} decreases more rapidly than does E_∞^{exp} for temperatures below the T_{opt}. The theoretical curves describe these features well. However, at very low temperatures, the theoretical curves tend to be below the experimental points in both figures, as was more evidently confirmed from repeated experiments. This is believed to arise from the $b_u \ll 1$ assumption which is invalid at these temperatures. In Eqs. 49—52 in part I, the relaxation pathways for the END terms of protons other than that observed contribute only to the denominator, so that the fractional ENDOR enhancement tends to be underestimated when $b_u \gtrsim 1$.

Regarding the relative intensity, E_0^{exp} for the methylidyne proton in Fig. 7 is about four times smaller than that for the ring protons. This is more clearly indicated in Fig. 9, in which the ratios of the values of $E_{,0}$ for the ring and *t*-butyl protons to that for the methylidyne proton are plotted against η/T. It is encouraging that the experimental and theoretical values of $E_{,0}$ for the methylidyne and ring protons are approximately proportional to the number of equivalent protons even at temperatures for which the condition, $b_u \ll 1$, is not necessarily valid. On the other hand, in Fig. 8, the E_0^{exp} for a methylidyne proton agrees with that for ring protons (see also Fig. 6), whereas the theoretical counterparts at optimum temperatures, −79 °C (b_m=0.84 and b_r=0.29), are 5.6 and 6.9% for methylidyne and ring protons, respectively, with a ratio of 1.26. The quantitative justification of these values is left until absolute measurements of fractional ENDOR enhancement are performed. However, it should be noted that the calculated values are much smaller than the value, 12.5%, expected from the simple theory for a four-level system.

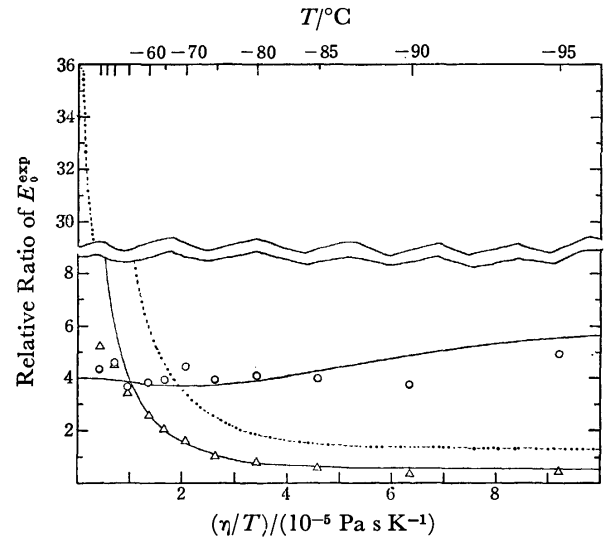

Fig. 9. Ratio of E_0^{exp} values for *t*-butyl protons (△) and ring protons (○) to E_0^{exp} for a methylidyne proton as a function of η/T. The solid lines are theoretical results.

It is worthwhile to discuss the correlation of the values of b estimated from Fig. 7 with the spin distribution in galvinoxyl. The value of b obtained at −70 °C (η/T= 2.05×10^{-5} Pa s K^{-1}) are b_m=0.32 and b_r=0.11 with b_m/b_r=2.9. Luckhurst[17] has studied in detail the structure and the spin distribution of galvinoxyl, and has found ρ_m=−0.0748 and ρ_r=−0.0448. It is considered that $W_n^{(u)}$ is proportional to the square of the spin density on the carbon atom to which the u'th proton is bonded.[11,18] Thus, the above ratio of b values should be 2.79. The good agreement between both values shows the close correlation between the spin density and the ENDOR relaxation. Also, the agreement seen at high temperatures between the E_∞^{exp} values for the methylidyne and ring protons in Fig. 8 leads to a ratio in the neighborhood of 2, using Eq. 54 in part I.

Now the ENDOR quotient for *t*-butyl protons will be considered. The experimental results show two peculiar features, (1) the high optimum temperature, as seen in both Figs. 7 and 8, in spite of the fact that a

proton with a smaller END term should have a lower optimum temperature, and (2) the much smaller ratio of E_0^{exp} for this proton to that for the methylidyne proton than would be expected from the number of equivalent protons (see Fig. 9).

Such a high optimum temperature for this proton is also found for 2,4,6-tri-*t*-butylphenoxyl,[6] 2,5-di-*t*-butyl-*p*-benzosemiquinone[11] and *m,m,m'm'*-tetra-*t*-butylbiphenyl[12] and appears to be characteristic of *t*-butyl protons. Allendoerfer and Maki[6] have suggested that this is attributable to the effect of incomplete hf separation. Considering only the secular terms for the same assumption under which Eq. 6 is based, T_{2e} may decrease with temperature as follows:

$$\frac{1}{T_{2e}} \approx \frac{8}{3} j_{G_s}(0) H_0^2 \approx \tau_R \approx \frac{\eta}{T}, \tag{10}$$

so that this effect is more prominent at lower temperatures and results in a higher optimum temperature. However, simulation shows that this effect requires a T_{2e} as short as 10 ns at −50 °C in order to produce such a high temperature with the result that the ENDOR enhancement becomes negligibly small. In addition, the apparent ESR linewidth for galvinoxyl was found to decrease with temperature down to −20 °C, is constant as a whole from −20 to −70 °C, and increases rapidly at lower temperatures. This implies that nonsecular and pseudosecular terms, as well as the contribution from the spin-rotational interaction, compete with secular terms in Eq. 10 at high temperatures.

It is believed that the high optimum temperature is attributable rather to the large average total nuclear-spin quantum number of the *t*-butyl protons. Let us assume a crude four-level system for *t*-butyl protons whose relaxation pathways involve only the W_e and the $\langle f_{Ju} \rangle W_n^{(u)}$, the average nulear-spin transition probability, which is given by

$$\langle f_{Jn} \rangle W_n^{(u)} = \sum_{Jn} \frac{D_{Jn}}{D_u} J_u(J_u+1) W_n^{(u)} = \frac{1}{2} n_u W_n^{(u)}. \tag{11}$$

Then the fractional ENDOR enhancement is optimized when

$$\frac{1}{2} n_u b_u \approx 1. \tag{12}$$

Therefore, the fractional ENDOR enhancement for a proton species with many equivalent protons has a high optimum temperature.

The much smaller value of E_0^{exp} for *t*-butyl protons than for other protons evidently results from the effect of incomplete hf separation. However, the choice of the value of T_{2e} involves ambiguities, because inhomogeneous broadening unfortunately prevents an estimate of T_{2e} from the unsaturated ESR linewidth. The T_{1e} of galvinoxyl in *s*-butylbenzene, determined by Huisjen and Hyde[19] from saturation recovery, has a value in the range of 1—10 μs at −30 °C. If the extreme narrowing condition is satisfied at this temperature, T_{2e} may also be of the same order of magnitude. Here, T_{2e} was taken as a constant with a value of 1.2 μs, from consideration of the behavior of the ESR linewidth mentioned above. Then, the optimization process for *t*-butyl protons gave $b_{tb}=0.13$ at −70 °C, whereas $b_{tb}=1/18$ at −55 °C or $b_{tb}=0.19$ at −70 °C, from Eq. 12. It is felt that these values of b_{tb} are rather large compared with those for other protons. A possible explanation may be the closeness of the location of *t*-butyl protons to oxygen atom which has large spin density, resulting in large END terms. The theoretical solid curves, calculated from Eqs. 49—52 in part I, are close the experimental curves in Figs. 7 and 8. Also, Fig. 9 shows that the ratio of E_0^{exp} for *t*-butyl protons to that for a methylidyne proton decreases monotonically with temperature, in contrast to the ratio for ring protons. Such a feature is again described by the theoretical solid lines. It is to be noted that the dotted line, calculated from Eq. 50 in part I in which the first factor is omitted, has a value much smaller than 36, except at extremely high temperatures. The above discussion should not be taken too seriously since the present lack of information about the internal motion of the *t*-butyl group prevents further considerations, such as of the isotopic hf modulation. Nevertheless, it is felt that the essential features of the ENDOR quotient for *t*-butyl protons can be explained by the effect of incomplete hf separation and the large average multiplicity for this proton discussed above.

In conclusion, it may be said that the theory in part I describes fairly well the ENDOR relaxation of galvinoxyl.

The authors wish to express their gratitude to Professor K. Kuwata of Osaka University for stimulating and helpful discussions throughout the course of this work.

Electronic Absorption Spectra of Pyrene and Hydropyrenes

Tetsutaro YOSHINAGA, Hiroshi HIRATSUKA, and Yoshie TANIZAKI

Department of Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received August 31, 1976)

Vibronic π-π^* transition bands of pyrene, 4,5-dihydropyrene (DHP), and 4,5,9,10-tetrahydropyrene (THP) were assigned by means of dichroism analysis using stretched poly(vinyl alcohol) films. The absorption spectra of the samples in the non-stretched films were divided into two component spectra polarized along the long (x) and short (z) axes of the molecular plane. For pyrene, in addition to the four conventionally-assigned band systems (^1L_b, ^1L_a, ^1B_b, and ^1B_a), some forbidden bands were found in the respective band regions. Most of the vibronic DHP and THP bands were also reasonably well assigned from comparisons with the calculated results for phenanthrene and biphenyl, respectively.

Three fundamental factors, the transition energy (wavelength), the transition moment (polarization), and the transition probability (intensity) must be considered in making assignments of electronic absorption spectra. Generally speaking, it is almost impossible to determine exactly all of these three factors for solution spectra, except in special cases where well-separated band systems are observed. Apparent bands observed in most cases are considered as consisting of more than two different kinds of transition bands. Accordingly, in order to precisely determine the three factors experimentally, we must separate or resolve the overlapped bands from one another, using methods such as photoselection techniques,[1] an external electric field,[2,3] a single or mixed crystal[4,5] and stretching of the polymer film.[6-8]

The stretching film method can be applied to various kinds of compounds and has the merit that the substrate of the film is transparent to the very short wavelengths of 220 nm for the poly(vinyl alcohol) [PVA] film, for example. If we choose planar molecules with proper symmetries, the π electronic spectra can be divided into components polarized parallel and perpendicular to a symmetry axis in the molecular plane.

The experience of the dichroism investigation tells us that the orientation direction of the sample molecule in the stretched PVA film depends mainly on molecular geometry. And it is expected that the three compounds, pyrene, 4,5-dihydro- and 4,5,9,10-tetrahydropyrene, in the stretched PVA films have the same orientation state since their skeletal structures are similar to one another (see Fig. 1).

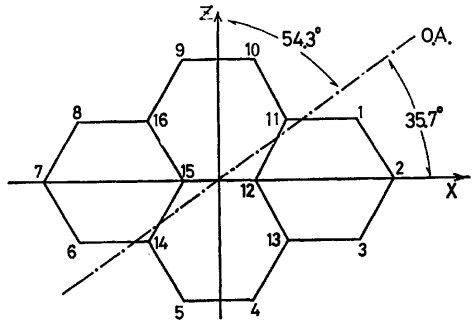

Fig. 1. Co-ordinates of the pyrene molecule. The orientation axis of the molecule in the streched PVA film is represented by O. A. which is determined by the orientation angle (54.3°) for the third band of pyrene [Fig. 2(a)].

The purpose of this paper is to make assignments of the π-π^* electronic spectra of pyrene, 4,5-dihydropyrene(abbreviation, DHP) and 4,5,9,10-tetrahydropyrene (THP). Pyrene shows well separated band systems and, therefore, its orientation direction is precisely determined by dichroism analysis with this orientation direction necessary in obtaining the divided spectra. On the other hand, the absorption spectra of DHP and THP do not show any isolated bands. Therefore, in order to divide these spectra into components, it is assumed here that the orientation direction determined for the pyrene molecule can be applied to the DHP and THP molecules.

Experimental

Commercially-available pyrene (ultra pure reagent, zone refined; Tokyo Kasei Kogyo Co., Ltd.) was used. The guaranteed reagents, 4,5-dihydropyrene (abbreviation:DHP) and 4,5,9,10-tetrahydropyrene (THP) were used with furtherpurification made at our request by the Tokyo Kasei Kogyo Co., Ltd.

Poly(vinyl alcohol) [PVA] having a mean polymerization of 1400 was obtained commercially (Koso Chemical Co., Ltd.) and used without further purification for making the PVA films.

Dichroism Analysis. The dichroic spectra were determined with a Shimadzu QV-50 Spectrophotometer equipped with a Glan-Thompson type calcite polarizer. Both the sample and reference films were stretched at 70—80 °C. The stretching ratio, R_s, was limited to 6.0 throughout the experiments.

The optical density ratio, R_d, is defined as $D_{//}/D_{\perp}$, where $D_{//}$ and $D_{\perp}$ are optical densities measured with light polarized parallel and perpendicular to the stretched direction of the film, respectively. The R_d values are plotted in the figures showing the dichroic spectra.

From the dichroism analysis,[9] the orientation angle of any absorption band is defined as the angle between the transition moment and the orientation direction of the molecule, and it is obtained using the experimental values of R_s and R_d. The orientation angles thus obtained are indicated at the maxima and minima of the R_d curves of the dichroic spectra.

It is necessary to make a few remarks concerning the "orientation direction," which is a direction peculiar to molecular geometry. It is empirically known that, upon stretching, a sample molecule in the PVA substrate is longitudinally inclined in the stretched direction. In this case, the longitudinal direction does not, in general, coincide with the geometrically-defined long axis, say, the x-axis of the molecule (see Fig. 1).

It is a natural consequence of the inclination of the molecule, as mentioned above, that the absorption band having the

greater R_d value (or smaller orientation angle) must be polarized principally along the long (x) axis. Accordingly, if a planar molecule has at least one C_2-symmetry axis in the molecuar plane (xz-plane) and if one or more bands are found to be pure in the transition directions (x or z), we can divide the absorption spectrum (D) in the non-stretched PVA film into two component spectra (D_x, D_z) that are polarized parallel and perpendicular to the axis of symmetry.[9] In the present case, the relative errors in the absorbance of the component spectra were less than 10% and the oscillator strength of the relatively strong band was reproduced to within a relative error of 4—7%.

Calculation

The sample molecules, DHP and THP, have π-electron systems equivalent to those of phenanthrene and biphenyl, respectively. Therefore, for convenience, the latter were calculated instead of the former.

The MO calculations were carried out using the Pariser-Parr-Pople method.[10,11] The one-center repulsion integrals were evaluated in the Pariser-Parr approximation,[10] in which the ionization potential and the electron affinity were taken, respectively, as $I_p(C)=11.16$ eV and $E_a(C)=0.03$ eV for the carbon atom. The two-center repulsion integrals were evaluated using the Nishimoto-Mataga equation.[12] All the singly-excited configurations associated with the transitions between the occupied and vacant MO levels were included in the CI calculation.

The co-ordinates of the molecular framework of pyrene were taken as shown in Fig. 1. All the bond lengths and bond angles were assumed to be 1.395 Å and 120°, respectively. The framework of the π-electron system of DHP(4,5-dihydropyrene) was considered excluding the Nos. 4 and 5 carbon atoms in Fig. 1. Similarly, for THP(4,5,9,10-tetrahydropyrene), the Nos. 4, 5, 9, and 10 carbon atoms were excluded, and the C^{12}–C^{15} bond length (inter-ring distance) was assumed to be 1.48 Å. The x and z axes denote the long and short axes, respectively, in the molecular plane for the case of both the D_{2h} (pyrene and THP) and C_{2v} (DHP) point groups.

Results and Assignment

Dichroic Spectra. Figures 2(a)—(c) show the dichroic spectra and R_d curves of pyrene, DHP and THP, respectively.

The dichroic spectra of pyrene in Fig. 2(a) exhibits four well-separated absorption bands. The shape of the R_d curve clearly shows that these four bands are distinguished by transition directions; that is, the R_d values for the first (350—380 nm) and third (250—280 nm) bands are small, while those for the second (340 nm) and fourth (*ca.* 245 nm) are great. This indicates that the transition vectors of the former are in the same direction as the short axis of the molecule and the latter in that of the long axis. It is concluded, therefore, that the directions of the electronic transition moments of pyrene are z-, x-, z-,and x- polarized, in order of decreasing wavelength. Since the symmetry of the pyrene molecule is D_{2h}, the four corresponding excited

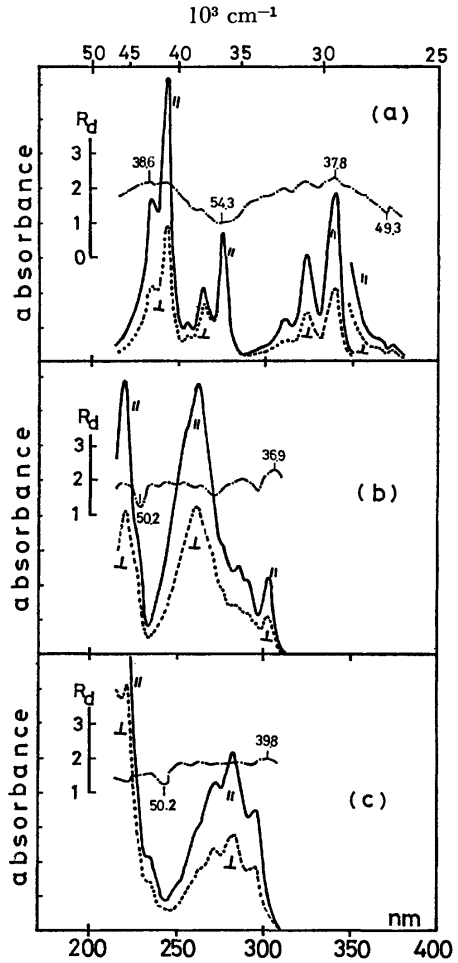

Fig. 2. Dichroic spectra and R_d curves for (a) pyrene, (b) DHP (4,5-dihydropyrene) and (c) THP (4,5,9,10-tetrahydropyrene). $R_s=6.0$. The numerals at the maxima and minima of R_d curves indicate the orientation angle (in degree) of the polarizations at those wavelengths.

states are assigned to B_{2u}, B_{1u}, B_{2u} and B_{1u}, respectively. According to the Platt notation, these are L_b, L_a, and B_b and B_a, respectively (see Fig. 3). In Figs. 2(b) and (c), no remarkable variations of the R_d curves similar to those in Fig. 1(a) are found. Only for a couple of bands, however, are the polarizations distinguishable by the relative R_d values; for example, for DHP (C_{2v}) in Fig. 2(b), the R_d value at 305 nm is the greatest and that at 228 nm (shoulder) the smallest in the region observed. This suggests that the 305-nm band and the shoulder consist mainly of bands with long- and short-axis transitions, respectively. Indeed, the sum (87.1°) of the orientation angles of these bands becomes nearly 90°. Thus, we can conclude that the 305-and 230-nm bands are polarized along the molecular long (x, B_2) and short (z, A_1) axes, respectively. It must be noted here that in the DHP spectra in Fig. 2(b), the 305-nm band is not first but is second. The first band at 343 nm, which corresponds to the ^1L_b of phenanthrene at the longest wavelength, could not be determined in the present work owing to experimental difficulties.

For the THP(D_{2h}) spectra in Fig. 2(c), polarizations of at least two absorption bands were also observed;

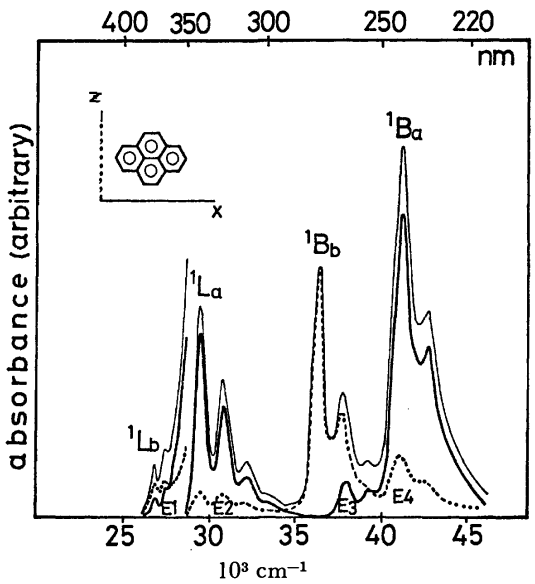

Fig. 3. Divided spectra of pyrene. The fine line means the absorption spectrum (D) of pyrene in the non-stretched PVA film. The conventional assignment is indicated by ^1L_b, ^1L_a, ^1B_b and ^1B_a. The solid line is the x-component spectrum (D_x) and the dotted line the z-component (D_z). Extra band systems are temporarily marked with E_1 to E_4.

main absorption at 300 nm being due to the long-axis transition (x, B_{1u}) and that at 240 nm to the short-axis transition (z, B_{2u}).

Divided Spectra. In order to make more precise assignments of the electronic bands, especially for DHP and THP, the absorption curves in the non-stretched PVA films were divided into two component spectra (D_x and D_z).[9] To divide the spectra, it was necessary to determine a standard direction relative to the geometry of the molecule. A standard direction, namely, in general, an orientation direction, can be determined for a symmetrical molecule provided that at least two electronic bands with polarizations orthogonal to each other can be observed separately. Fortunately, the pyrene molecule satisfies such a condition.

It has already been mentioned that the second and third bands of pyrene [Fig. 2(a)] are due to the electronic transitions along the x (long) and z (short) axes of the molecule, respectively, and that the sum of the orientation angles for the second (37.8°) and third (54.3°) bands becomes 92.1°. This value is somewhat greater than 90°. This fact indicates that the degree of mixing of the z-polarized absorption in the x band (second) is greater than that of the x-polarized absorption in the z band (third band). Considering that the absolute deviation from 90° is small, let us assume here that the transition direction at 276 nm, for the third band, is exactly in accord with the transition direction of the z axis of the pyrene molecule. Then, the orientation direction of the molecule relative to the coordinates is determined as shown in Fig. 1, that is, the orientation axis (O.A.) is 35.7° with respect to the x axis.

The skeletal structure of the other molecules are very similar to that of the pyrene molecule. It was assumed, therefore, that the other molecules have the same orientation direction as pyrene. Thus, by taking the standard angles of other sample molecules to be 35.7°, the component spectra are obtained from the spectra of the non-stretched sample film.

The divided spectrum of pyrene is shown in Fig. 3, and those of DHP and THP in Fig. 4. It is seen that every band is more or less composed of overlapping of the x and z bands. For this reason, it is expected that some additional absorptions will be found from a comparison with the calculated results. These extra absorption bands may be explained in terms of vibronic interactions or intensity borrowing, neglecting the so-called hot absorptions.

Assignments for Pyrene Spectrum. The results of an MO calculation for pyrene, which is shown in Table 1, indicate four symmetry-allowed transitions below 46×10^3 cm^{-1}, which is the limit of the spectral region observed. These allowed transitions may correspond to the divided component bands shown in Fig. 3, as follows.

The peak at 26.8×10^3 cm^{-1} is considered to be the 0-0 transition of the very weak first band system. Since the intensity at the peak is stronger for the z component than for the x component, the former is regarded as the first band. Therefore, the I transition calculated as $B_{2u}\leftarrow A_g$ for pyrene must be compared with the first band which is z-polarized. The other three allowed transitions, II, V, and IX, correspond to the three strong band systems in Fig. 3, respectively. The II

a) Calculated using the dipole-length method with off-diagonal (adjacent) terms included in the calculation of the oscillator strength. R. S. Mulliken, *J. Chem. Phys.*, **7**, 14 (1939). b) Determined using $f=4.32\times10^{-9}\int\varepsilon d\sigma$, assuming that the molar extinction coefficient ε at the band maximum in the non-stretched PVA film is equivalent to that of the corresponding band in an ethanol solution.

transition ($B_{1u}\leftarrow A_g$) corresponds to the second band system starting at 29.4×10^3 cm^{-1}, which is x-polarized and reveals a progression of five vibrational bands reaching as far as 35×10^3 cm^{-1}. The V transition ($B_{2u}\leftarrow A_g$) corresponds to the third band system which is z-polarized and has its 0-0 peak at 36.4×10^3 cm^{-1}. Finally, the IX transition corresponds to the fourth band with x-polarization, which has its 0-0 peak at 41.2×10^3 cm^{-1}. The bands thus assigned are designated in the Platt notation as ^1L_b, ^1L_a, ^1B_b, and ^1B_a, respectively, as shown in Fig. 3.

For the oscillator strengths, a very good correlation is observed between the calculated and observed results; the calculated values are nearly twice as large as the corresponding observed values.

According to the above correspondence between the band systems and the calculated transitions, the other four absorption bands remain as extra bands which are temporarily designated as E_1 to E_4, as is shown in Fig. 3. In order to discuss the extra absorption bands, it will be necessary to determine some basis for making assignments. Fortunately, it was found that the calculated and experimental transition energies (in wavenumbers) correspond well to each other. That is to say, when the calculated (abscissa) and experimental wavenumbers (ordinate) are plotted on a graph, a straight line is obtained as shown in Fig. 5, in which the wavenumbers at the 0-0 peaks are taken from the experimental values and the white circles represent the allowed transitions. The fact that almost all the white circles lie on a straight line shows that the semi-empirical calculations employed here lead to quite reliable results for making assignments. Accordingly, utilizing this linear relation as a basis, the extra absorption bands are assigned.

First of all, from the point of view of the linearity between the calculated and experimental results, only the experimental value for ^1L_a is unexpected. If we

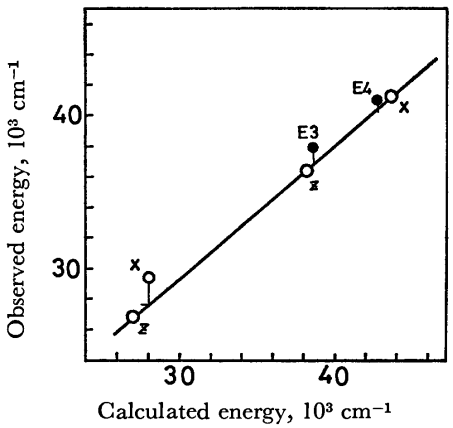

Fig. 5. Correlation between the observed (ordinate) and calculated wave numbers (abscissa) of pyrene. White circles represent the 0-0 peaks of band systems and the corresponding transitions calculated, where x and z mean the polarizations along the long and short axes of the molecule, respectively.

take the linearity seriously, the peak at 29.4×10^3 cm^{-1} may not be a 0-0 but a 1-0 transition. In this case, if we regard the shoulder of the x component band at 27.8×10^3 cm^{-1} in Fig. 3 to be the 0-0 peak of ^1L_a, linearity for all the allowed transitions, including ^1L_a, is nearly satisfied.

Now, utilizing the linear relation, the extra bands are assigned as follows. According to Fig. 3, the E_1 band, which is x-polarized and has fine structure, starts at about 26.8×10^3 cm^{-1}, but, strictly speaking, this is slightly lower than 26.8×10^3 cm^{-1}. It is clear from Table 1 that no excited state relevant to E_1 exists. Therefore, the E_1 band may be induced by intensity borrowing from the second (^1L_a, x) band. The E_2 band, which is z-polarized, has its first peak at 29.5×10^{-3} cm^{-1}. In Table 1, no transition corresponding to

a), b) See footnote in Table 1. c) See Ref. 18.

29.5×10^3 cm^{-1} is found, because, according to the linear relation of Fig. 5, the calculated energy corresponding to the E_2 band must be less than 30.0×10^3 cm^{-1}. Therfore, the E_2 band may also be attributed to an intensity-borrowing absorption from the $^1B_b(z)$ band.

The E_3 band of which the first peak occurs at 37.9×10^3 cm^{-1} is polarized in the x direction. According to the linear relation of Fig. 5, the calculated transition energy corresponding to 37.9×10^3 cm^{-1} is 39.8×10^3 cm^{-1}. If the E_3 band is electronically forbidden, E_3 must vibronically be allowed. Then the calculated energy should be less than 39.8×10^3 cm^{-1}, at least by one vibrational quantum number. The only relevant transition in Table 1 is the VI transition, which has A_g symmetry. Consequently, the vibration to be coupled with the A_g electronically excited state must have a mode of b_{1u} symmetry. The vibrational energy of b_{1u} for the present case is estimated to be about 1×10^3 cm^{-1} from the linear relation of Fig. 5.

Similarly, it is considered that the E_4 band, which has its first peak at 41.0×10^3 cm^{-1}, is a vibronically-induced transition of VIII (A_g) resulting from the coupling of a b_{2u}-type vibration because of the z-polarized absorption. From the linear relation of Fig. 5, the coupled vibrational energy is estimated to be about 0.6×10^3 cm^{-1}.

Assignment of DHP and THP Spectra. The DHP and THP component spectra are shown in Figs. 4(a) and (b), respectively. In Fig. 4(a), the first band, which is observed at 343 nm (29.15×10^3 cm^{-1}) in an ethanol solution, is not shown here as explained above. Therefore, the first peak at 33.1×10^3 cm^{-1} is the 0-0 peak of the second band which is evidently x-polarized. Generally speaking, when both the x and z component spectra are complicated, the band shape can not be easily determined. For this reason, let us first examine only the prominent band peaks and compare them with the calculated results for phenanthrene. The prominent band peaks are found at 33.1 (x), 37.3 (z), 38.2 (x), 44.0 (z), and 45.7×10^3 cm^{-1} (x).

On the other hand, the calculated results for phenanthrene (C_{2v}) are shown in Table 2: The transitions with oscillator strengths stronger than 0.01 are the II (B_2), IV (A_1), V (B_2), VII (A_1) and X (B_2) transitions. These transitions and the above-mentioned band peaks are compared in Table 2. The calculated and experimental polarizations are in complete agreement. Furthermore, the correspondence between the transition energies, as well as the intensities, is fairly good.

In order to observe the correlation between the calculated and experimental transition energies for DHP, the wavenumbers were plotted in the same way

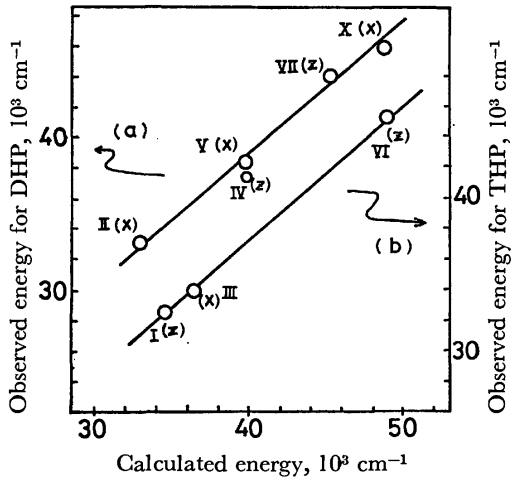

Fig. 6. Correlation between the observed (ordinate) and calculated wave numbers (abscissa) of (a) DHP (4,5-dihydropyrene) and (b) THP (4,5,9,10-tetrahydropyrene), where the calculated values are taken for (a) phenanthrene and (b) biphenyl. Roman numerals represent the transition numbers calculated.

as in the case of pyrene. In this case, however, on the abscissa are plotted the calculated wavenumbers for phenanthrene instead of DHP. The result is illustrated in Fig. 6(a), in which the Roman numerals represent the calculated transition numbers. The linearity is not as good as that shown in Fig. 5 for pyrene. This may be interpreted as resulting from the fact that the calculation for phenanthrene is used instead of that of DHP itself, with the result that the effect of the methylene groups at the 4 and 5 positions of DHP was neglected (see Fig. 1). At any rate, let us use the straight line shown in Fig. 6(a) as a basis for discussing the DHP spectrum.

According to Table 2, transition III (37.4×10^3 cm^{-1}) is of weak intensity and x (B_2) polarization. The linear relation in Fig. 6(a) indicates that the calculated value of 37.4×10^3 cm^{-1} corresponds to the experimental value of 36.3×10^3 cm^{-1} on the x-component curve of Fig. 4(a). For this reason, the peak may be attributed to transition III. The z-polarized band in Fig. 4(a), which extends from 32×10^3 cm^{-1} to about 36×10^3 cm^{-1}, could not be assigned, since no relevant transition is listed in Table 2. Other calculated transitions, transitions VI (41.8×10^3 cm^{-1}, A_1), VIII (46.9×10^3 cm^{-1}, B_2), and IX (47.8×10^3 cm^{-1}, A_1), which are of very weak intensity, correspond respectively to the experimental wavenumbers of 40.2×10^3 cm^{-1} (z), 44.8×10^3 cm^{-1} (x) and 45.4×10^3 cm^{-1} (z). They may appear as shoulders at the corresponding positions which are indicated respectively by the Roman numerals in parenthesis in Fig. 4(a), VI, VIII, IX.

Figure 4(b) illustrates the component spectra of THP (D_{2h}). Table 3 shows that the calculation for biphenyl (D_{2h}) produces four allowed transitions. Transition I (z, B_{2u}) is of very weak intensity and the other three transitions, transitions III (x, B_{1u}), VI (z, B_{2u}) and VIII (x, B_{1u}) are strong. Accordingly, the first three transitions can easily be assigned as indicated in Fig. 4(b) by the Roman numerals. Again, a linearity similar to the case of DHP is found [Fig. 6(b)]. Using the linear relation in Fig. 6(b), the experimental wavenumber corresponding to the fourth allowed transition, transition VIII (49.66×10^3 cm^{-1}), becomes 45.7×10^3 cm^{-1}. However, no prominent band peak appears although a very slight shoulder appears, as indicated by VIII in Fig. 4(b).

Figure 4(b) shows that an additional z absorption, the first peak of which is at 33.9×10^3 cm^{-1}, occurs together with the x band indicated by III. This z absorption can be interpreted in two ways. One possible interpretation is that the band is vibronically induced by the coupling of transition II (35.09×10^3 cm^{-1}, B_{3g}) with a b_{1u} type vibration. In this case, the experimental band origin must be located at 33.7×10^3 cm^{-1} as estimated from the linear relation in Fig. 6(b). The other interpretation is to consider the additional z absorption as a progression of the first z band starting at 32.6×10^3 cm^{-1}, which is assigned to the very weak allowed transition I.

Discussion

The first four allowed π-π^* transitions of pyrene have been established theoretically to have z-, x-, z-, and x-polarizations.[13–15] Experimental studies on the polarization of pyrene have been carried out for the crystalline state[16] using the photoselection method[17] and the stretched polyethylene sheet technique.[8] These experimental results agree quite well with one another and also with the theoretical values. Thulstrup, Michl and Eggers[8] have obtained a reduced spectrum of pyrene from a dichroic spectrum in a stretched polyethylene sheet. Their reduced spectrum for pyrene is very similar as a whole to the separated spectra shown in Fig. 3. However, the weak first band and some of the extra bands are not found in their reduced spectra.

A few spectroscopic studies have been carried out on DHP[18] and THP.[19] On the other hand, many descriptions[20–30] have been given for phenanthrene and biphenyl, which are iso-electronic with DHP and THP, with respect to the π-electron systems, respectively. For instance, according to Zimmermann and Joop[28] and other workers,[30] the third and fourth transition bands of phenanthrene occur close together, but with different polarization directions. Regarding the polarization directions, however, most of the experimental studies reported were only qualitative and were not effective in analyzing overlapping bands, such as the third band of phenanthrene, without aid of theoretical calculations, while the component spectra presented here give quantitative information.

The separated spectra of DHP shown in Fig. 4(a) are in agreement with the case of phenanthrene.[7,8] But in Fig. 4(a), the z-polarized absorption in the 32—36 $\times10^3$ cm^{-1} region, which should be distinguishable from the third band (transition IV, z), could not be clearly assigned. Even in phenanthrene itself, this third (z-polarized) band shows anomalous width in the component spectra. Thulstrup *et al.*[8] have considered this band to be the result of vibronic coupling.

For THP, as is shown in Fig. 4(b), a very weak hidden band at 33.9×10^3 cm^{-1} is revealed as a z-polarized band.

The presence of such an extraordinarily weak absorption in the case of biphenyl has been confirmed by Berlman *et al.*[23] from an investigation of the fluorescence lifetimes of biphenyls. However, there are some ambiguities in the number of allowed transitions in the first band region of biphenyl.[26] On the other hand, the results of the present work for THP show that there are an extremely weak (hidden) z band, a relatively strong x band and an additional intensity-borrowing or vibronically-induced z band in the first-band region, though THP has a structured band shape and a considerable red shift relative to biphenyl. The oscillator strength for the very weak first band of THP was determined from the component spectra, even though the estimated value may contain a large error because of the extreme weakness of the intensity.

There are few experimental studies on the oscillator strengths. Furthermore, in most cases, the conventional value has been determined from a band which is composed of overlapping bands of different polarizations. In order to make a more precise comparison with theory, the experimental values should be determined using the component spectra. The experimental oscillator strengths in Tables 1—3 are determined from the component spectra. The values calculated using the dipole length method are about twice as large as the experimental results. In the calculations of the oscillator strengths, it should be noted that, when only diagonal matrix elements are considered, the oscillator strengths for the allowed L_b bands become zero, while those including the off-diagonal elements give non-zero values in agreement with the experimental results. It must be emphasized, therefore, that the off-diagonal elements of the transition density matrix become very important in the calculation of the allowed L_b band, especially when using the dipole-length method.

The Effect of Temperature on the Mass Spectra of 1-Alkenes. II

The late Hiroko HOSHINO, Susumu TAJIMA, Fusako ISOGAI, and Toshikazu TSUCHIYA
National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151

(Received January 20, 1977)

The mass spectra of 1-alkenes ranging from C_5 to C_{10} were measured at temperatures of the ion source 120—250 °C. Fragmentation $M^+ \xrightarrow{m_{28}} (M-28)^+$ and $M^+ \xrightarrow{m_{29}} (M-29)^+$, where m_{28} and m_{29} denote the metastable peaks of the fragmentations, were studied. The behavior of the curve of the intensity ratios $R'_{28}=m_{28}/F_{28}$ and $R'_{29}=m_{29}/F_{29}$ (F_{28} and F_{29} denote the intensities of the $(M-28)^+$ ion and the $(M-29)^+$ ions, respectively), *versus* temperature T of the ion source of the mass spectrometer is explained by the quasi-equilibrium theory (QET).

Many theoretical studies have been carried out[1-7] on the mechanism of fragmentation of ions produced by elecron impact from various organic compounds. These works can be divided roughly into two categories, one using QET and the other based on the molecular orbital calculation (MOT).[2,4] So far nothing definite has been given on a comparison of the two methods. It seems difficult to interpret the mechanism of each fragmentation by either one of the methods. It was shown[2] that the intensities of some peak in the mass spectra of a few derivatives of aromatic compounds can be interpreted by MOT. Subsequently, QET was applied to explain some experimental results for a series of primary alcohols and of 1-alkenes,[6] and found to give satisfactory results. QET was also successfully applied to the elucidation of the behavior of common ions, such as $C_5H_5^+$,[8] $C_6H_5CO^+$,[9] and $C_7H_7^+$ [10] from various precursors.

For 1-hexene, the slope of the curve R'_{28} *versus* T becomes positive though it is expected to take a negative value according to QET, when a simple form is assumed for the internal energy distribution function, $P(E)$, for M^+. The behavior of the curve can be explained by using the measured photoelectron spectrum as $P(E)$ instead of a simple function.[6]

We have obtained the curves R'_{29} *versus* T for C_5—C_{10} 1-alkenes and a curve R'_{28} *versus* T for 1-pentene, and studied the behavior of these curves and the R'_{28} curves for C_6—C_{10} 1-alkenes. The slopes of a few curves for smaller compounds take a negative sign as expected with QET having a simple $P(E)$ function. In contrast, the tangents of most of the curves for larger compounds are found to take a positive sign. The behavior of these curves can be elucidated on the same basis as in the case of R'_{28} for 1-hexene.

Experimental

A CEC 21-103C mass spectrometer was used to obtain the mass spectra. $R'_{28}=m_{28}/F_{28}$ and $R'_{29}=m_{29}/F_{29}$ were measured in the temperature range 120—250 °C. The results for R'_{28}, including those for C_6—C_{10}, and for R'_{29} are given in Figs. 1 and 2, respectively, the curves being given in Table 1. The result was investigated by QET. For the investigation, curve log k *versus* E, where k is the rate constant for the decomposition of M^+ into F^+, and E is the internal energy of M^+, should be drawn in order to estimate the location,* of the "metastable window" on the E axis. The corresponding curve for 1-hexene is given in Fig. 11 in a previous report.[6] In order to construct curve log k *versus* E, the ionization potential, I, of M^+ and the appearance potential, A, of F^+ were measured at the ion source temperature 250 °C using the EDD technique[11] (Table 1).

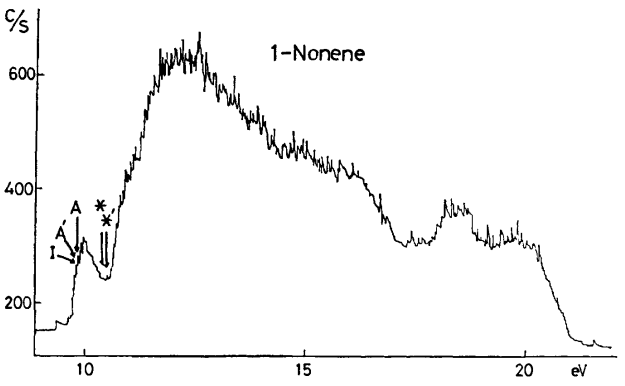

Fig. 7.

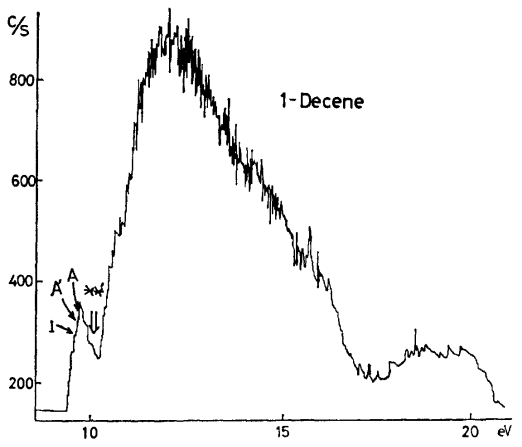

Fig. 8.

Figs. 3—8. The photoelectron spectra of 1-alkenes. The meanings of the notations are given in the text.

A JASCO PE-1 photoelectron spectrometer was used to obtain photoelectron spectra with HeI as a light source. The photoelectron spectra measured were used as $P(E)$. The spectra for each compound are shown in Figs. 3—8. The conditions of measurement are the same as already described.[6]

The olefins used were API standard samples, the purity being greater than 99.7%. All the reagents were mass-spectroscopically confirmed to be pure.

Results and Discussion

The relation between the temperature of the ion source, T, and the intensities, [M$^+$], [m], and [F$^+$], of the ions in the following fragmentation was investigated by QET.

$$M^+ \xrightarrow{m} F^+$$

Though more sophisticated expressions are proposed for

Table 1. Ionization potential, I, activation energies, ε_{28} and ε_{29}, in eV, and the schematic curves of the behavior of R' *versus* T (Figs. 1 and 2)
$\varepsilon_n = A(M-n)^+ - I$, where $A(M-n)^+$ is the appearance potential of the fragment ion $(M-n)^+$. Errors in the measured I and A values are estimated to be ± 0.1 eV.

a) F. H. Field and J. L. Franklin, "Electron Impact Phenomena and the Properties of Gaseous Ions," Academic Press Inc. (1957), p. 108.

the rate constant and intensities of ions, the rate constant for the fragmentation was assumed to be given by

$$k = \nu(1-\varepsilon/E)^{n-1}$$

where the notations have their usual meanings.[6] The intensities of the ions were assumed to be given by[12]

$$[M^+] = \int_0^{\varepsilon} P(E)dE + \int_{\varepsilon}^{\infty} P(E)\exp[-k(E)t_4]dE, \quad (4)$$

$$[F^+] = \int_{\varepsilon}^{\infty} P(E)[1-\exp\{-k(E)t_1\}]dE, \quad (5)$$

$$[m] = \int_{\varepsilon}^{\infty} P(E)[\exp\{-k(E)t_2\} - \exp\{-k(E)t_3\}]dE. \quad (6)$$

The mean time spent by a newly-formed ion in the ionization chamber is t_1. After being accelerated, the ions dissociated between the times t_2 and t_3 are observed as a metastable peak, and the M^+ ions which do not dissociate until t_4 are observed as the parent ion, M^+. The internal energy distribution function, $P(E)$, was assumed to be

$$P(E) = \exp[-E/kT]E/(kT)^2. \quad (7)$$

The values of t were estimated from the dimensions of the mass spectrometer and the conditions of measurement. Substituting these values in Eqs. 4—7, graphs showing the relationship between $R=[F^+]/[M^+]$, $R^*=[m]/[M^+]$ and $R'=[m]/[F^+]$ *versus* T were obtained and compared with the experimental results. The graphs for R and R^* obtained by calculation increased, and the graph for R' decreased with rise in temperature. Comparing the behavior of these curves with those obtained by experiments for M^+, $F^+=(M-28)^+$, R_{28}, R^*_{28} and R'_{28} *versus* T, it was found that while values of R_{28} and R^*_{28} for 1-alkenes of C_5—C_{10} increase with rise in temperature in line with the theoretical prediction, those of R'_{28} for 1-alkenes for C_6—C_{10} also increase, contrary to the prediction based on the assumption mentioned above. Taking R'_{28} for 1-hexene as an example, this anomaly was shown[6] to be adequately explained if the photoelectron spectrum for the compound was used as $P(E)$, instead of Eq. 7.

In the present study, R_{29}, R^*_{29}, and R'_{29} for 1-alkenes of C_5—C_{10} are measured in addition to R'_{28} for 1-pentene, and their behavior, when the temperature of the ion source is increased, is compared with that expected by QET using Eq. 7 as $P(E)$. As the result, the behavior of the curves for R' is found to be inconsistent with the expectation by QET with Eq. 7, except for R'_{28}, R'_{29} for 1-pentene and R'_{29} for 1-hexene, while the behavior of R'_{29} and R^*_{29} is found to be consistent with the prediction, *i.e.*, both the ratios increase with rise in temperature. Namely, the schematic curves shown in the 6 and 7th columns of Table 1, (*cf.* Figs. 1 and 2) increase with the temperature increase, except for R'_{28}, R'_{29} for 1-pentene and R'_{29} for 1-hexene.

The experimentally obtained ionization potential, I, appearance potentials, A and A', of $(M-28)^+$ and $(M-29)^+$ ions, respectively, and approximate positions of the metastable windows, * and *', of the $(M-28)^+$ and $(M-29)^+$ ions, respectively, estimated by the same procedure as described,[6] are shown by arrows in Figs. 3—8. In calculating the location of * and *', ν was assumed to be 10^7 for $(M-28)^+$, the rearrangement ion, and 10^{13} for $(M-29)^+$, the ion considered to be produced by simple cleavage of a bond.

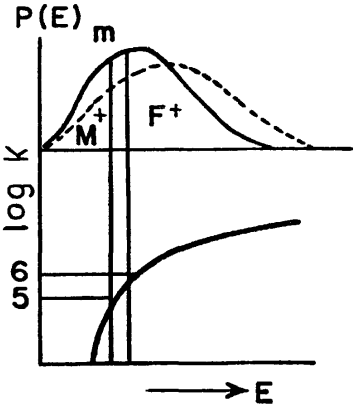

Fig. 9. Relationship of $P(E)$ and k (E) for unimolecular ion decompositions in the mass spectrometer; see text for definitions.

Using the positions * and *', of the metastable windows, the behavior of curves of R, R^*, and R' *versus* T can be explained as follows. For the sake of simplicity, the internal energy distribution function, $P(E)$, is assumed to be given by Eq. 7 for the moment. Figure 9 shows the relation between $P(E)$ and the internal energy, E, and the position, m, of metastable window schematically. The positions of the origin and the onset of the curve in the lower diagram are located by the measured I and A, respectively. The dotted curve in the upper diagram shows the behavior of the $P(E)$ curve schematically when the temperature T increases.[14] The intensities of molecular ion, $[M^+]$, metastable ion, [m], and fragment ion, $[F^+]$, are assumed to be proportional to the area under the $P(E)$ curve (upper diagram) denoted by M^+, m, and F^+, respectively. As the temperature rises and the $P(E)$ takes a flatter shape, shown by the dotted curve in Fig. 9, the areas for both M^+ and m decrease and that for F^+ increases and consequently $R=[F^+]/[M^+]$ increases and $R'=[m]/[F^+]$ decreases. As for R,* the calculated result based on Eqs. 4—7, and

shown in Fig. 9 of the previous report,[6] suggests its increase with the temperature increase.

First, R' curves obtained by experiments are compared with those predicted by the theory. In the following investigation, the photoelectron spectrum for each compound is assumed to represent the internal energy distribution function, $P(E)$, for the compound instead of Eq. 7. In the case of 1-pentene given in Fig. 3, since the metastable windows * and *′ are both situated near the shoulder of the wider band of its photoelectron spectrum (*cf.* the $P(E)$ curve in Fig. 9), the behavior of R'_{28} and R'_{29}, with the temperature increase is consistent with that expected from the simple consideration mentioned above. The behavior of R'_{29} in the case of 1-hexene (Fig. 1 and Table 1) can be explained in exactly the same manner from the location of *′ given in Fig. 4.

The values of * and *′ for all other compounds studied including * for hexene[6] are located on the higher energy side of the narrower band of the photoelectron spectrum of each compound. This band is considered to originate from the π electron. When T increases and the band takes a flatter shape, the area corresponding to the metastable peak increases, while the fractional increase of the area for F^+ is very small, resulting in the increase in R'_{28} or in R'_{29}, in contrast to the theoretical expectation based on Eq. 7.

The values of $R=[F^+]/[M^+]$ and $R^*=[m]/[M^+]$ show no "anomaly," *i.e.*, they both increase with temperature. This can easily be explained by the consideration for R'.

As far as these phenomena are concerned, they can be qualitatively elucidated by QET with photoelectron spectra used as the internal energy distribution functions. Various investigations[13-18] have been made of possible methods for the evaluation of the internal energy distribution functions resulting in ions from the impact of energetic electrons. Meisels *et al.*[19] postulate that the photoelectron spectrum of a compound gives a reasonable representation of the actual function under certain conditions. Innorta *et al.*[20] report that it is too crude an approximation to use photoelectron spectra as a representation of the internal energy distribution function for some compounds in interpreting their mass spectra. The former idea receives support from the present investigation for a series of 1-alkenes ranging from C_5 to C_{10}.

The diagrams of the measured appearance potentials of $(M-28)^+$ and $(M-29)^+$ ions *versus* the number of carbon atoms were found to be smooth curves which decrease at first and then approach gradually nearly constant values as the carbon number increases. The behavior of these curves deserves further investigation.

It is not clear whether the reactions producing $(M-28)^+$ and $(M-29)^+$ are competing reactions or reactions starting from different electronic states, into which the sample molecules are excited with certain probabilities. Judging from the present result, the effect of the reaction mechanism on the result is not so large that it influences the qualitative elucidation based on QET, aside from whether the reactions compete with each other or not.

In conclusion the "anomaly" in the mass spectra of 1-alkenes ranging from C_5 to C_{10} is explained qualitatively by QET using photoelectron spectra of the compounds as the internal energy distribution functions, $P(E)$.

The authors are indebted to Mr. Hiroshi Matsumoto and Mr. Tadashi Miyazaki for carrying out the photoelectron spectrometry experiment.

Spin-Probe Study of Aqueous Soap and Polysoap Solutions

Masayuki AIZAWA, Tsuyoshi KOMATSU, and Tsurutaro NAKAGAWA
Department of Polymer Science, Faculty of Science, Hokkaido University, Sapporo 060
(Received January 29, 1977)

Poly(2-vinylpyridine) partially quaternized with 1-dodecylbromide, a "polysoap," sodium dodecyl sulfate (SDS), and dodecylpyridinium bromide (DPBr) in their micellar solutions were investigated by the spin-probe technique. It was found that the alkyl side chains in polysoap micelles associate more rigidly than in low-molecular surfactant micelles. This fact is attributed to the surface active groups covalently connected to long polymer chains in the polysoap molecule. By a recently developed method, the rotational correlation times of 2,2,6,6-tetramethyl-4-benzoyloxypiperidin-1-oxyl radical in SDS and DPBr micelles were found to be 5.9×10^{-10} and 3.5×10^{-10} s/rad, respectively. From the values of the isotropic hyperfine splitting constants, it was estimated that the DPBr micelle solubilizes the probe molecule at a more inner site of the hydrophobic portion than does the SDS micelle.

In the aqueous solutions of amphiphile substances, some intermolecular and/or intramolecular structures are formed by the "hydrophobic interaction." Surfactant molecules form the ordered aggregates known as micelles, so that their aqueous solutions manifest such properties as solubilization of hydrophobic compounds and hydrolysis of ester bonds. In the case of amphiphile macromolecules, their hydrophobic portions tend to an intramolecular association which contributes to stabilize the conformation of the macromolecules.

Strauss and coworkers[1] have studied polysoap, which is defined as an amphiphile macromolecule with a surface active side chain. According to the results of the measurement of viscosity, solubilization of hydrophobic compounds, scattering of light, and surface tension, the polysoap molecules dissolve with a relatively compact structure and can solubilize more hydrophobic compounds than low-molecular surfactant molecules corresponding to the monomer units of the polysoap molecule can. These properties, which differ from those of ordinary polyelectrolytes, result from the formation of polysoap micelle, as in the case of low-molecular surfactant micelles.

Thus the hydrophobic interaction plays an important role in the properties of such aqueous amphiphile solutions. But details of the interaction have not yet been sufficiently clarified with respect to energy and structure.

Recently, the spin-probe or spin-label technique developed by McConnell and coworkers[2] has become available for the study of various systems[3] such as polymeric materials, aqueous micellar solutions, and natural or artificial membranes. In these studies one could obtain information about the microscopic environment of the stable radical molecules; the molecular motion and structure of the host materials can thus be uncovered.

In this paper, the authors present some results obtained from the application of the spin-probe technique to aqueous polysoap solutions. Some results about the structure of the inner hydrophobic portion of polysoap micelles, by comparison with that of low-molecular surfactant micelles are also given. The authors finally examine the manner in which the hydrophobic probe is solubilized in micelles.

Experimental

Polysoap (Fig. 1(a)) derived from poly(2-vinylpyridine) (PVP) was synthesized according to the method of Inoue.[4] PVP was obtained by radical polymerization and its elemental analysis was as follows. Found: C, 80.01; H, 6.73; N, 13.22%. Calcd for $(C_7H_7N)_n$: C, 79.97; H, 6.71; N, 13.32%. From viscosity measurements in 95% ethanol solution the molecular weight and the degree of polymerization of PVP were found to be 3.0×10^5 and 2.8×10^3, respectively. Polysoap was prepared by heating a DMF solution of PVP with excess (*ca.* 2 mol) 1-dodecylbromide in an ampoule at 100 °C for 41.5 h. The partially quaternized PVP was precipitated with ether and dried under vacuum. Then the product was dissolved into water and purified by dialysis using a cellophane tubing. The degree of quaternization was estimated to be 32.2% from elemental analysis.

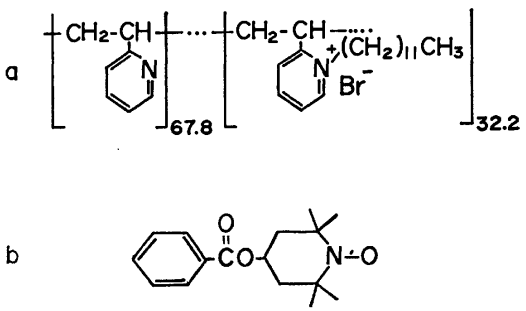

Fig. 1. (a) Polysoap, (b) BzONO.

Sodium dodecyl sulfate (SDS) was supplied from Nakarai Chemicals Ltd., and dodecylpyridinium bromide (DPBr) was obtained by ion-exchange of guaranteed grade dodecylpyridinium chloride.

The hydrophobic nitroxide radical used as the spin probe, 2,2,6,6-tetramethyl-4-benzoyloxypiperidin-1-oxyl(BzONO, Fig. 1(b)) was synthesized by Rozantzev's method.[5] Its melting point was 105.6 °C (lit, 105 °C) and its elemental analysis was as follows. Found: C, 69.63; H, 8.13; N, 4.91%. Calcd for $C_{16}H_{22}NO_3$: C, 69.53; H, 8.02; N, 5.07%; mol wt 276.4.

The concentration of the spin probe, BzONO, was 1.06×10^{-4} mol/dm^3 in all sample solutions. Besides these solutions, those saturated with BzONO were also prepared for comparison.

ESR spectra were recorded on a JEOLCO model ME-3X spectrometer equipped with a variable temperature accessory.

Results and Discussion

ESR spectra of BzONO in water are shown in Fig. 2. The three main lines of the spectra result from the contact hyperfine interaction between electron spin ($S=1/2$) and ^{14}N nuclear spin ($I=1$), corresponding to nitrogen nuclear spin quantum numbers $M_I=+1$, 0, and -1, respectively, toward the high field direction. One finds out that a less resolved hyperfine structure appears in each line, due to some protons in the BzONO molecule. In Fig. 2(b) (full line), the magnified spectrum of the central line ($M_I=0$), the proton hyperfine structure is observed clearly. Thus, the previous analysis[6] which neglected the proton hyperfine structure of nitroxide radicals cannot be applicable to our systems.

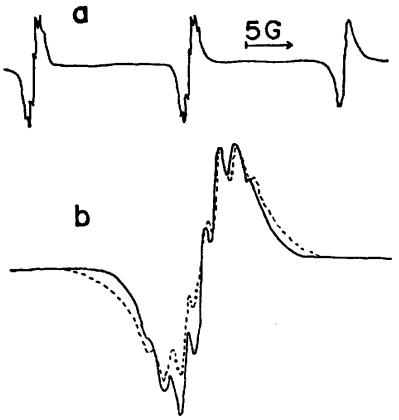

Fig. 2. (a) ESR spectrum of 1.06×10^{-4} mol/dm^3 BzONO in water at 30 °C. (b) The magnified spectrum of central line ($M_I=0$) (full line) and the simulated spectrum (dashed line).

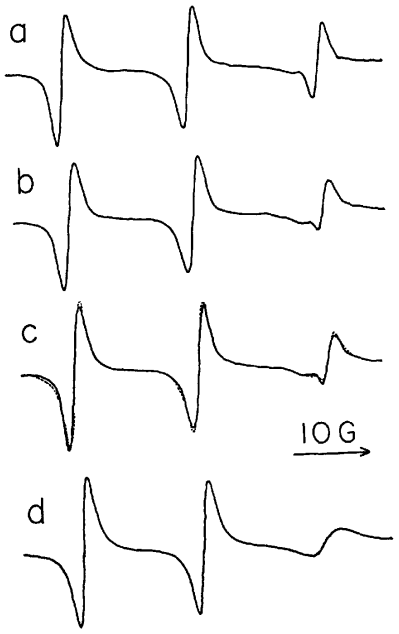

Fig. 3. ESR spectra of 1.06×10^{-4} mol/dm^3 BzONO in aqueous polysoap solutions at 30 °C and the simulated spectrum of BzONO in polysoap micelle. Polysoap concentration: (a) 1.02%, (b) 2.99%, (c) 3.94%. (d) The simulated spectrum in polysoap micelle.

ESR spectra of the aqueous polysoap solutions are shown in Fig. 3. The resolved hyperfine structure in Fig. 2 disappears here, owing to a broadening of each proton hyperfine line. From the shape of the high field line ($M_I=-1$), however, it is clear that two different components are superposed. The changes in line shape with increase in polysoap concentration indicate that the broad component is due to BzONO in the polysoap micellar environment and that the sharp one is due to BzONO in bulk water. The fact that the two different components of BzONO from two media are simultaneously observed indicates that the exchange rate of BzONO molecules between the two media is relatively low. In order to separate the broad component from the sharp one, the experimental spectra were simulated by two sets of three Lorentzian lines. As a sharp component, a spectrum with $T_2^{-1}(M_I)$ of 1.06×10^{-4} mol/dm^3 BzONO in water is used after wiping out the proton hyperfine structure. The dashed line in Fig. 3(c) is a simulated spectrum and Fig. 3(d) is the broad component used in the simulated spectrum.

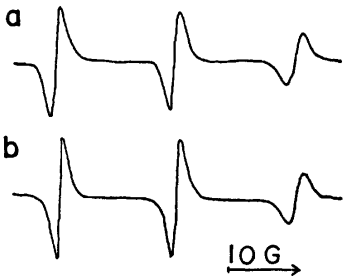

Fig. 4. ESR spectra of 1.06×10^{-4} mol/dm^3 BzONO in (a) 6.3% aqueous SDS solution and (b) 3.0% aqueous DPBr solution at 30 °C.

Figures 4(a) and 4(b) show the spectra of BzONO in the SDS and DPBr solutions, respectively. In the low-molecular surfactant solutions, above CMC which is 0.22 wt% for SDS aqueous solution and 0.37 wt% for DPBr aqueous solution, the spectra are almost independent of surfactant concentration. All over the concentration range of these solutions, the authors cannot distinguish the two different components associated with two media, that is, the micelle and the bulk water. According to the previous studies[7,8] of similar systems, the above finding does not imply that the exchange rate of the probe is too high to be resolved by ESR method, but implies that the g- and A-tensors of the probe radical are only slightly different between the two media, and that the probe is isotropically tumbling in the low-molecular surfactant micelle. By computer simulation employing the modified Bloch equations which take account of both the micelle-water exchange and the spin exchange in the micelle, the exchange rate of BzONO between SDS micelle and bulk water is estimated to be $(2.5—5.0)\times10^4$/s. This value supports the previous interpretation of spectra of probes in low-molecular surfactant micellar solutions.

Comparing the line width of these spectra, one notices that the line width of spectra of BzONO is broader in the polysoap micellar environment than in either the low-molecular surfactant micellar environment or bulk

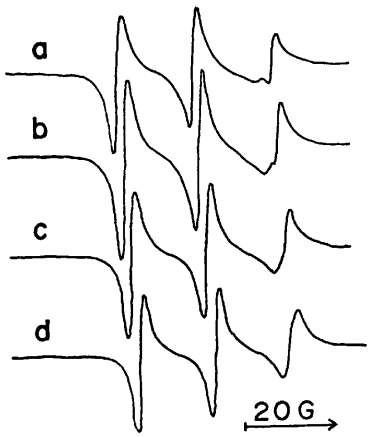

Fig. 5. ESR spectra at various temperatures of BzONO saturated at 30 °C in 4.45% aqueous polysoap solution. Temperature: (a) 30, (b) 40, (c) 50, (d) 60 °C.

water. As the causes of the line width broadening in polysoap micelle, two assumptions are possible; one is the appearance of anisotropy of g- and A-tensors and the other is Heisenberg spin exchange interaction between probe radicals solubilized in polysoap micelle where the local concentration of radicals is extremely high. Here, if the latter occurs, the broadening must decrease with the increase in polysoap concentration at the constant radical concentration, and, on the other hand, it must be intensified with an increase in radical concentration or in temperature. But the present results are not consistent with these suppositions, as shown in Figs. 3 and 5. Therefore, it is quite reasonable that the broadening of the line width in the polysoap micelle results from anisotropy of g- and A-tensors, which depends on nitrogen spin quantum number M_I and is remarkable especially in the high field line ($M_I=-1$). Thus, it is concluded that the probe molecule tumbles more slowly in polysoap micelle than in low-molecular surfactant micelles. From another point of view, the result may reflect the fact that the inner alkyl chains in polysoap micelle form more rigid structures than those in low-molecular surfactant micelles.

Recently, in the measurement of NMR relaxation times of poly(4-vinylpyridine) partially quaternized with 1-octylbromide in methanol, Ghesquire and coworkers[9] have found that the spin-lattice relaxation times T_1 of ^{13}C in the octyl group decrease with the increase in degree of quaternization. This result partly supports the present supposition about the structure of alkyl chains in polysoap micelle, since in a system with dipole-dipole interaction T_1 is inversely proportional to mobility about the spin under consideration. The authors suppose that surface active groups connected covalently into long polymer chains are mainly responsible for the mobility reduction of alkyl chains. Moreover, if the hydrophobic portion of amphiphile macromolecules used as synthetic enzymes has a rigid structure similar to that of the polysoap micelle, the rigidity may partly contribute to the rate of enzyme reactions such as hydrolysis of esters.[10]

For quantitative discussion, the authors determined the rotational correlation time τ_c of probe molecule, BzONO, in SDS and DPBr micelles, respectively, and roughly estimated it in the polysoap micelle. According to the Debye and BPP theory,[11] the rotational correlation time τ_c of a molecule in solution has the following relation to the environmental viscosity η:

$$\tau_c = 4\pi a^3\eta/3kT, \tag{1}$$

where a is the spherical radius of the molecule, k the Boltzmann constant, and T is the absolute temperature.

The spectra are analyzed by Poggi and Johnson's method[12] taking into account the unresolved proton hyperfine structure of ESR spectra of nitroxide radicals. The main assumptions required for the spectra analysis are as follows:

(1) Each spectra line consists of unresolved hyperfine splitting lines from 12 equivalent methyl protons of a BzONO molecule.

(2) Proton hyperfine lines have Lorentzian shape and an equal splitting constant. Their line widths are equal in the same M_I line.

(3) The g- and A-tensors of ^{14}N are axially symmetric, that is, $A_X=A_Y$ and $g_X=g_Y$.

By a spectral simulation using these assumptions, each line width, $W_H(M_I)$, of the proton hyperfine lines in the three lines is obtained. The dashed line in Fig. 2(b) is the simulated spectrum for the experimental spectrum (full line) of the central line ($M_I=0$) of BzONO in water. The agreement between the two spectra is satisfactory except for the unsymmetry of the experimental spectrum. These $W_H(M_I)$ are substituted into the following equation derived from Kivelson's theory:[13]

$$\tau_c = \frac{T_2^{-1}(-1)+T_2^{-1}(+1)-2T_2^{-1}(0)}{0.25b} = \frac{\frac{\sqrt{3}}{2}\{W_H(-1)+W_H(+1)-2W_H(0)\}}{0.25b}, \tag{2}$$

$$b = \frac{2}{3}\left\{A_z-\frac{1}{2}(A_x+A_y)\right\},$$

where A_X, A_Y, and A_Z are the three components of the A-tensor.

The obtained rotational correlation times for SDS and DPBr micelles are 5.9×10^{-10} and 3.5×10^{-10} s/rad, respectively. The values of the nitrogen hyperfine splitting constants a_N in SDS and DPBr micelles are 16.7 and 16.3 G, respectively. It should be noted that the values of both τ_c and a_N in SDS micelle are greater than those in DPBr micelle. From the previous study,[14] the nitrogen hyperfine splitting constant a_N is in a proportional relationship to the polarity of environment. By considering that the values of a_N in water and dodecane are 17.1 and 15.4 G, respectively, and that τ_c is proportional to environmental viscosity η, the above findings are interpreted as follows. The SDS micelle solubilizes BzONO in the vicinity of the polar surface of micelle, whereas the DPBr micelle solubilizes in the internal hydrophobic portion where the BzONO molecule is more mobile. The order of τ_c of the present results also indicates that the state of the internal hydrophobic portion in the low-molecular surfactant micelles is not solid-like, but liquid-like, as was reported

in the previous papers.[15,16]

The rotational correlation time τ_c of BzONO in the polysoap micelle is roughly estimated to be 9.8×10^{-10} s/rad by a similar procedure, except for employing $T_2^{-1}(M_I)$ evaluated by the peak-to-peak width of the above spectrum (Fig. 3(d)) instead of $T_2^{-1}(M_I)$ obtained by the spectra simulation taking account of the proton hyperfine structure. If τ_c in the low-molecular surfactant micelles are also estimated by the same rough estimation, the values in SDS and DPBr micelles are 4.3×10^{-10} and 2.1×10^{-10} s/rad, respectively. The result confirms quantitatively the preceding suggestion that BzONO tumbles more slowly in the polysoap micelle than in the low-molecular surfactant micelles.

"Molecular Orbital Analysis" of Naphthalene Derivatives. An Application of Configuration Analysis to the Assignment of Photoelectron Spectra

Tsuneo FUJII and Satoshi SUZUKI

Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano 380

(Received February 4, 1977)

Molecular orbital analysis, which is an application of configuration analysis proposed by Baba *et al.*, has been applied to the interpretation of the photoelectron spectra of substituted naphthalenes, with particular attention paid to the dependence of the spectra on the position of substitution and on the character of the substituents. The results of MO calculations based on the Pariser-Parr-Pople method have been analyzed in terms of the π-MO's of naphthalene and the π-AO or π-MO's of a substituent. The results of the molecular orbital analysis for naphthalene derivatives with an electron-donating group are compared with the results for those with an electron-accepting group.

Since Turner first succeeded in measuring high resolution photoelectron (PE) spectra,[1] the PE spectra of many compounds have been reported. The PE spectra give precise data on the vertical ionization potentials (I_v) of atoms and molecules. Assuming Koopmans' theorem,[2] one may also easily obtain information on the orbital energies. Recently Kimura *et al.* have found a sum rule—that the sum of the experimental ionization energies may be reproduced by the sum of the calculated orbital energies of the localized orbitals.[3] Heilbronner *et al.* have calculated the π-orbital energies of naphthalene by three different approximations and compared them with experimental data.[4] Marschner and Goetz could reproduce the experimental values of the PE spectra of naphthalene by using modified Pariser-Parr-Pople (PPP) parameters.[5]

The PE spectra of substituted naphthalenes have been observed by several authors.[6-8] The changes in the π-MO energies of naphthalene caused by the introduction of a substituent depend on the position and properties of the substituent. Although the change in the energy and character of MO's due to the introduction of a substituent into the parent naphthalene is a very interesting problem for chemists, the origin of such a change in the π-MO character and energy has not been fully understood. From the experimental results on monosubstituted naphthalenes with an electron-donating group,[6-8] it has been found that the individual bands are apparently shifted to a higher energy compared with those of naphthalene. In contrast to this, the PE spectra of monosubstituted naphthalenes with an electron-accepting group are apparently shifted to a lower energy compared with that of naphthalene.

The method of configuration analysis proposed by Baba *et al.* has enabled us to give a quantitative interpretation of the electronic absorption spectra of the derivatives of aromatic hydrocarbons in terms of locally excited and charge-transfer states.[9] In the calculation process of configuration analysis, the matrix which transforms the set of MO's of a derivative into a set of reference MO's, that is, the MO's of a corresponding parent compound and a substituent, is obtained. This matrix gives us information on the correlation between the MO's of a derivative and the MO's of a parent compound and a substituent. This procedure will be called "Molecular Orbital Analysis" (MOA), by analogy with configuration analysis. The quantitative assignments of the MO's of the derivatives to their reference MO's can be made by the application of MOA.

This paper will present the assignments of the MO's of monosubstituted naphthalenes in terms of the MO's of naphthalene and a substituent and will make a comparison between the electron-donating and electron-accepting cases. In the present paper, naphthalene and its derivatives, *i.e.*, 1- and 2-naphthols, 1- and 2-naphthylamines, 1- and 2-naphthonitriles, and 1- and 2-naphthaldehydes, will be considered. The LCAO-SCF-MO calculations of the PPP type have been performed, and the results subjected to the MOA.

Procedure and Calculation

The semiempirical MO's of substituted compounds may be obtained by the PPP procedure. Although the quantitative correlation between the MO's of substituted compounds and those of the corresponding parent compounds is an interesting problem in such fields of chemistry as PE spectroscopy, such information cannot be obtained by means of the usual MO calculations. It can, though, be derived in the course of the calculation of configuration analysis. This procedure will be outlined below.

The MO's of a substituted compound, ϕ_i's, which are obtained by the usual procedure, can be written in a matrix form as

$$\boldsymbol{\phi} = \boldsymbol{\chi}\mathbf{C}, \tag{1}$$

where $\boldsymbol{\chi}$ represents the row vector of n orthonormal AO's, χ_p, and where $\mathbf{C}$ is an $n \times n$ unitary matrix, the elements of which are AO coefficients of ϕ_i's. In the present study, systems composed of naphthalene and a substituent are employed as the reference systems; therefore, the reference MO's used are the LCAO-SCF-MO's of naphthalene and the π-AO or π-MO's of a substituent. The MO's of the reference system, $\boldsymbol{\phi}^\circ$, are expressed in terms of the same basis set, $\boldsymbol{\chi}$, as well as ϕ_j's

$$\boldsymbol{\phi}^\circ = \boldsymbol{\chi}\mathbf{C}^\circ. \tag{2}$$

It follows, then, that

$$\boldsymbol{\phi} = \boldsymbol{\phi}^\circ\mathbf{B}, \tag{3}$$

with

$$\mathbf{B} = (\mathbf{C}^{\circ})^{\dagger}\mathbf{C}, \quad (4)$$

where $(\mathbf{C}^{\circ})^{\dagger}$ is the Hermitian conjugate of the $\mathbf{C}^{\circ}$ matrix. The **B** matrix represents the correlation between $\boldsymbol{\phi}$ and $\boldsymbol{\phi}^{\circ}$. This matrix is used in the calculation of the configuration analysis. When the configuration analysis of a certain compound has been completed, the **B** matrix of the compound has also been obtained as a matter of course.

Calculations have been made for the π-electron systems of naphthalene, naphthols, naphthylamines, naphthonitriles, and naphthaldehydes by the semiempirical LCAO-SCF-MO method. The parameters used in this study have been given elsewhere.[10,11]

Results

Tables 1 and 2 give the calculated π-MO energies, ε_i, and the I_v's for ϕ_i° and ϕ_j in the first and third rows for individual compounds; the values of I_v's were obtained from the PE spectroscopy. The MO's of the compounds are numbered in the order of increasing energy. The corrected MO energies, $\varepsilon_i^{corrd}=\varepsilon_i+1.65$ eV, are also included in the second row of Tables 1 and 2. The correction factor of 1.65 eV is taken to give a general agreement between the experimental and theoretical data.

The results of MOA are shown in Tables 3—10. The reference MO's consist of ϕ_1°, ϕ_2°,$\cdots$, ϕ_{10}°, which are the SCF-MO's of naphthalene, and ϕ_X°'s, which represent the π-AO or the π-MO of the substituents, X being

O, N, CN, and CHO, corresponding to naphthols, naphthylamines, naphthonitriles, and naphthaldehydes respectively. The symmetry types shown in the tables are those for the naphthalene SCF-MO's, where the X- and Y-axes are chosen as the long and short axes of the naphthalene ring respectively. The band notations for the PE bands of naphthalene and the substituents, B_1, B_2,···, B_X, are also given in the tables. In columns of these tables, the elements of **B** matrix defined by Eq. 4 are given. The square of the element represents the weight of the individual ϕ_i°'s. When a reference MO, ϕ_i°, makes a contribution of more than 50% to ϕ_j, the ϕ_j is assigned to the ϕ_i°; the band notation for the ϕ_i° is given in the assignment column.

Figures 1 and 2 show the energy diagrams for the occupied π-orbitals of the compounds studied. When ϕ_i° makes a contribution of more than 50% to ϕ_j, the level of the ϕ_i° is connected to that of the ϕ_j by —·—. When the ϕ_i° makes a contribution of between 30 to 50% to the ϕ_j, the level of the ϕ_i° is connected to that of the ϕ_j by ·····. The MO energy levels of monosubstituted naphthalenes with an electron-donating group look as if they are shifted toward a higher energy

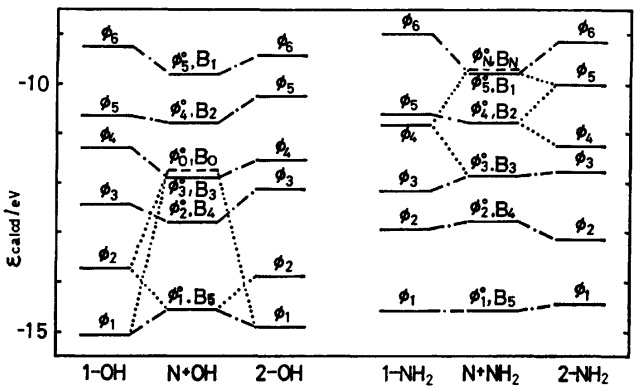

Fig. 1. Orbital energy diagram for the occupied π-orbitals of naphthalene(N), 1- and 2-naphthols(1-OH and 2-OH), and 1- and 2-naphthylamine(1-NH_2 and 2-NH_2). OH and NH_2: the π-AO of the substituents; ——: SCF-MO energies of the compounds; ——: π-AO of the substituents. A semibroken line(—·—) indicates that ϕ_i° makes a contribution higher than 50% to ϕ_j and a dotted line (·····)a contribution ranging from 30% to 50%. B_1, B_2, ···, correspond to the band notation (see text).

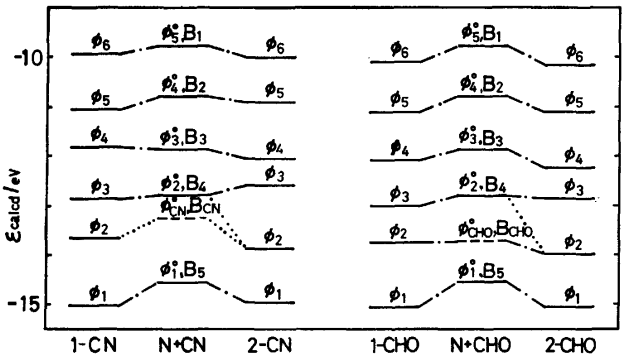

Fig. 2. Orbital energy diagram for the occupied π-orbitals of naphthalene(N), 1- and 2-naphthonitriles(1-CN and 2-CN), and 1- and 2-naphthaldehydes(1-CHO and 2-CHO). CN and CHO: the occupied π-MO of the substituents; ——: π-MO of the substituents. Other symbols are the same as in Fig. 1.

compared with those of naphthalene, although the case of naphthylamines is somewhat complicated. On the other hand, the MO energy levels of naphthonitriles and naphthaldehydes are apparently shifted toward a lower energy.

Discussion

Usually the ionization potentials are evaluated from the SCF molecular wavefunction by the use of Koopmans' theorem,[2] according to which the energy required to remove an electron from the ith orbital of a molecule, leaving the nuclei fixed and the orbital unaltered, is given by

$$I_i = -\varepsilon_i. \tag{5}$$

Tables 1 and 2 show that the $\varepsilon_i^{\text{corrd}}$'s for the compounds studied in the present paper are in good agreement with the observed I_v's. The $\varepsilon_i^{\text{corrd}}$ of the unoccupied orbital ϕ_6° of naphthalene is equal to 0.25 eV. The reported value of the electron affinity is 0.16 eV[12] or 0.20 eV.[13] Hence, $\varepsilon_i^{\text{corrd}}$ is found to be a reasonable value for both the I_v and the electron affinity. Below, discussion will be limited to the occupied orbitals.

Orbital Assignment. Let us now proceed to discuss the results of the MOA, beginning with naphthols.

Tables 3 and 4 show that the ϕ_1, ϕ_3, ϕ_4, ϕ_5, and ϕ_6 of naphthols are assigned to the ϕ_1°, ϕ_2°, ϕ_3°, ϕ_4°, and ϕ_5° of naphthalene respectively. There is a relatively strong interaction among the ϕ_1°, ϕ_2°, and ϕ_0° of which the ϕ_2 of naphthols is composed. The most important reference MO's in the ϕ_2 of naphthols are the ϕ_1° and ϕ_0°. There is a splitting of the reference MO's. For example, the ϕ_1° splits into the ϕ_1 and ϕ_2 of nearly equal weights, the ϕ_1 lying on the lower-energy side, and the ϕ_2 on the higher-energy side, relative to ϕ_1°. The ϕ_5 of 1-naphthol has almost the same property as the ϕ_4°. The ϕ_0° makes an important contribution to the ϕ_1, ϕ_2, ϕ_4, and ϕ_6 by weights of 31.7, 30.9, 14.4 and 10.6% in 1-naphthol and to the ϕ_1, ϕ_2, and ϕ_3 by weights of 33.3, 24.7, and 13.7% in 2-naphthol, respectively.

With reference to the results shown in Tables 5 and 6, the ϕ_1, ϕ_2, ϕ_3, and ϕ_6 of naphthylamines can reasonably be assigned to the ϕ_1°, ϕ_2°, ϕ_3°, and ϕ_5° respectively. The ϕ_5° of 1-naphthylamine has almost the same property as the ϕ_4°, the situation being the same as in 1-naphthol. There is a relatively strong interaction among the ϕ_3°, ϕ_5°, and ϕ_N° of which the ϕ_4 of 1-naphthylamine is composed. They make nearly equal contributions to the ϕ_4. However, in the case of 2-naphthylamine, the interaction among the ϕ_2°, ϕ_3°, ϕ_4°, ϕ_5°, and ϕ_N° is large, yielding the ϕ_4 and ϕ_5. A splitting of the reference MO's is also found, as in the case of naphthols. For example, ϕ_4° splits into the ϕ_4 and ϕ_5 with nearly equal weights. The ϕ_4° is the most important reference MO in the ϕ_4 and ϕ_5 of 2-naphthylamine. The weight of the ϕ_4° to the ϕ_4 is larger than that of the ϕ_3°. The ϕ_4 lies on the higher-energy side, and the ϕ_5 lies on the lower-energy side, relative to the ϕ_4°. The ϕ_N° makes an important contribution to the ϕ_2, ϕ_3, ϕ_4, and ϕ_6 by weights of 16.5, 13.2, 32.2, and 25.5% in 1-naphthylamine, and to the ϕ_2, ϕ_4, ϕ_5, and ϕ_6 by weights of 18.1, 19.9, 15.3, and 27.0% in 2-naphthylamine, respectively.

It may be seen in Tables 7 and 8 that the ϕ_1, ϕ_3, ϕ_4, ϕ_5, and ϕ_6 of naphthonitriles can reasonably be assigned to the ϕ_1°, ϕ_2°, ϕ_3°, ϕ_4°, and ϕ_5° respectively and that the ϕ_5 of 1-naphthonitrile has the same property as the ϕ_4°, just as in 1-naphthol and 1-naphthylamine. The ϕ_2 of naphthonitriles is mainly composed of the ϕ_{CN1}° and ϕ_2°. The ϕ_{CN1}° makes an important contribution to the ϕ_2, ϕ_3, and ϕ_4 by weights of 48.1, 15.4, and 20.1% in 1-naphthonitrile and to the ϕ_2 and ϕ_3 by weights of 44.7 and 27.1% in 2-naphthonitrile respectively. The splitting of the reference MO's is also found, as in the case of electron-donating.

Tables 9 and 10 show that the ϕ_1, ϕ_2, ϕ_3, ϕ_4, ϕ_5, and ϕ_6 of naphthaldehydes are assigned to the ϕ_1°, ϕ_{CHO1}°, ϕ_2°, ϕ_3°, ϕ_4°, and ϕ_5°, respectively, irrespective of the substitution at the 1- or 2-position. The ϕ_{CHO1}° mixes mainly with the ϕ_2°. It is also found that the reference MO's split into several MO's of naphthaldehydes. The ϕ_5 of 1-naphthaldehyde also has the same property as the ϕ_4°. The ϕ_{CHO1}° makes an important contribution to the ϕ_3 and ϕ_4 by weights of 12.5 and 12.0% respectively in 1-naphthaldehyde and to the ϕ_3 by a weight of 27.6% in 2-naphthaldehyde.

As may be seen from Tables 3, 5, 7, and 9, the weight of the ϕ_4° in the ϕ_5 is always 99.9% in the case of the naphthalene derivatives with a substitution at the 1-position. The ϕ_4° of naphthalene is little affected by the substitution at the 1-position. This situation can be well interpreted in terms of the property of the orbital. Since the ϕ_4° orbital of naphthalene has a node at the 1-position, its energy is little changed by the ϕ_0°, ϕ_N°, ϕ_{CN}°'s, and ϕ_{CHO}°'s in the cases of 1-naphthol,[8] 1-naphthylamine,[8] 1-naphthonitrile,[8] and 1-naphthaldehyde.

Assignment of the Photoelectron Spectra. The results of the orbital assignment will now be related to the PE spectra. The PE spectra of naphthalene have five bands in the region from 8 to 13 eV.[4,6,7,14] Table 1 shows that Bands I, II, III, IV, and V are assigned to the ionization corresponding to taking an electron away from the ϕ_5°, ϕ_4°, ϕ_3°, ϕ_2°, and ϕ_1° respectively. The PE bands corresponding to these ionization processes are con-

veniently indicated by the B_1, B_2, B_3, B_4, and B_5 notations respectively. The B_O, B_N, B_{CN}, and B_{CHO} notations indicate taking an electron away from the $\phi_O°$, $\phi_N°$, $\phi_{CN1}°$, and $\phi_{CHO1}°$ respectively (see Tables 3—10).

The PE spectra of naphthalene derivatives have been reported by several authors.[6-8] 1-Naphthol[8] has three bands, I, II, and III, in the region from 7 to 10 eV, while 2-naphthol has four bands, I, II, III, and IV, in the region from 7 to 11 eV. From Table 3, Bands I, II, and III of 1-naphthol are assigned to the B_1, B_2, and B_3 of naphthalene, while from Table 4 Bands I, II, III, and IV of 2-naphthol are assigned to the B_1, B_2, B_3, and B_4 of naphthalene respectively.

In the cases of 1- and 2-naphthylamines, there are six bands in the region from 7 to 13 eV.[7,8] Bands I, II, IV, V, and VI of 1-naphthylamine are assigned to the B_1, B_2, B_3, B_4, and B_5, while Bands I, IV, V, and VI of 2-naphthylamine are assigned to the B_1, B_3, B_4, and B_5 respectively. Band III of 1-naphthylamine is composed of the B_N, B_1, and B_3. Bands II and III of 2-naphthylamine are composed of the B_1 and B_2 and of the B_2 and B_3 respectively.

The PE bands of naphthonitriles have been reported by the same authors.[8] Bands I, II, and III for 1-naphthonitrile and Bands I, II, III, and IV for 2-naphthonitrile have been found. It may be seen from Tables 7 and 8 that they are assigned to the B_1, B_2, and B_3 for 1-naphthonitrile and to the B_1, B_2, B_3, and B_4 for 2-naphthonitrile.

Effects of the Electron-donating and Electron-accepting Properties on the Photoelectron Spectra. It is well known that the amino and hydroxyl groups have an electron-donating property, while the formyl and cyano groups have an electron-accepting property. In this subsection we will discuss the effect of these properties of the substituent on the PE spectra.

The PE spectra of naphthylamine, on the whole, are similar in appearance to the PE spectra of the corresponding naphthols. However, in passing from naphthols to naphthylamines, the individual bands undergo considerable changes in location.

The weight of the most important reference orbitals in naphthylamines is considerably smaller than that of the corresponding orbitals in naphthols. This suggests that amino substitution has a greater influence on the PE bands of naphthalene than does hydroxyl substitution. Since the calculated orbital energy is −9.7 eV for an amino group and −11.7 eV for a hydroxyl group, the higher the energy of the orbital of the substituent, the greater the mixing among the reference orbitals in the case of electron-donating substitution.

There may also be a similarity of the PE spectra between naphthonitriles and naphthaldehydes, as in the case between naphthols and naphthylamines.

It may be seen from Tables 7—10 that the weight of the most important reference orbitals in the individual orbitals of naphthaldehydes and the mixing among the local π-MO's of naphthalene and the orbital of the formyl group in naphthaldehydes are smaller than those in naphthonitriles. This suggests that the cyano substitution has a greater influence on the lower-energy PE bands of naphthalene than does the formyl substitution. The cyano and formyl groups have one occupied MO and one unoccupied MO. The calculated π-MO energies for the cyano group are $\varepsilon_{CN1} = -13.2209$ eV and $\varepsilon_{CN2} = -0.1855$ eV, while those for the formyl group are $\varepsilon_{CHO1} = -13.7252$ eV and $\varepsilon_{CHO2} = -0.7651$ eV. The energy difference between the unoccupied orbital of the formyl group and the occupied π-MO's of naphthalene is smaller than that between the unoccupied orbital of the cyano group and the occupied π-MO's of naphthalene. Therefore, the smaller the energy difference between the unoccupied orbital of the substituent and the occupied π-MO's of naphthalene, the smaller the mixing among the reference orbitals, this is in contrast with the electron-donating case.

The individual electronic absorption bands of naphthalene derivatives shift to the red relative to the corresponding bands of naphthalene whether the substituents are electron-donating or electron-accepting. The behavior of the individual electronic absorption bands of naphthalene derivatives can now be satisfactorily interpreted by the method of configuration analysis.[10,11,15] On the other hand, the PE spectra of naphthonitriles and naphthaldehydes shift to the lower energy of the corresponding bands of naphthalene. The PE spectra of naphthols and naphthylamines seem to shift to the higher energy relative to the corresponding bands of naphthalene. No simple explanation of the relationships observed in the PE spectra of naphthalene derivatives can be offered at the present time.

Application of INDOR Method to a Relatively Slow Exchange System. OH Protons of the 1,3-Dihydroxyacetone Dimer in Dimethyl-d_6 Sulfoxide

Yoshihiro KURODA

Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606

(Received February 21, 1977)

The nuclear magnetic multiple-resonance method developed by Forsén and Hoffman for the study of exchange rates has been applied to the two different types of OH protons of the 1,3-dihydroxyacetone dimer in dimethyl-d_6 sulfoxide, *i.e.*, OH (α) and CH_2OH (β). Here, "decay" and "recovery" curves were obtained using the so-called "INDOR" method, instead of a rapid repetitive scan method. Since the INDOR method continuously monitors a peak height, decay and recovery curves as fast as 1 s can be drawn by storing them in a computer after a single scan. The concentration dependence was examined as a two-site exchange system by neglecting the small amount of water (γ) contained in the dimethyl sulfoxide solvent. Both the lifetime, τ, and the longitudinal relaxation time, T_1, obtained from this assumption correlate well with the concentration variation of the 1,3-dihydroxyacetone dimer. The difference in the types of OH protons on the concentration dependence is clearly seen for the latter parameter, T_1. From the triple-resonance experiments including γ, it was found that the β proton is more "labile" than the α.

One of the most powerful uses of nuclear magnetic resonance spectroscopy in physical chemistry is its application to rate processes, such as chemical exchange reactions, restricted internal rotations and ring inversions. Two types of experimental and analysis methods have been developed so far for studies using a continuous wave (cw) NMR spectrometer, one is the line-shape analysis method originated by Gutowsky, McCall, and Slichter[1,2] and further extended and widely applied by many investigators[3] and the other is the double- or multiple-resonance method presented by Forsén and Hoffman,[4,5] which will hereafter be referred to as the FH method. This latter method is somewhat specific, since it can be applied for relatively slow-rate processes and in a narrower range than the former, *i.e.*, in the 0.01—1 s^{-1} range of a first-order rate constant. Therefore, examples of investigations using the FH method have been relatively few up to now.[6] These limitations arise for theoretical and technical reasons, *i.e.*, the lifetime of an exchanging nucleus must be comparable with its spin-lattice relaxation time, T_1, and the "decay" of the signal intensity upon sudden irradiation to another signal must be accurately followed. This latter gives the upper limit of the rate process which can be followed. Forsén and Hoffman have employed the rapid repetitive scan method in a state of no spin and misadjustment of the field homogeneity which prevents signal distortion due to wiggling and maintains slow passage conditions. Anet and Bourn have devised their equipment to continuously receive the intensity of a sharp signal with the sample spining and with the help of a field-frequency lock system.[7] This method can handle somewhat more rapid processes and closer signals of exchanging nucleus than the rapid repetitive scan method.

In the present work, an attempt was made to deal with relatively fast rate processes for the FH method, *i.e.*, processes with lifetimes less than about one second. This fills the gap between the fast limit of the FH method and the slow limit of the line-shape analysis method and extends the rate constant range over which the FH method can be applied. For this purpose, continuous observation of the signal height, a method similar to that of Anet and Bourn was adopted although the necessary decay curves were obtained differently. The so-called "INDOR" technique, first described and applied by Baker,[8] was employed in this work. In order to follow and record fast changes in the signal height, CAT (time-averaging computer) was used. For a preliminary examination, a dimethyl sulfoxide solution of a 1,3-dihydroxyacetone dimer was chosen as an example and it was examined to what extent this INDOR technique could follow a fast rate process within the framework of the FH method.

Experimental

Materials. The highest purity 1,3-dihydroxyacetone dimer (hereafter abbreviated as DAD) was obtained from the Tokyo Kasei Kogyo Co., Ltd, and dimethyl-d_6 sulfoxide (DMSO-d_6) was obtained from the Stohler Isotope Chemicals (SIC) Co., Ltd. These were used without further purification including in the deoxygenation and drying procedures, since from the preliminary experiment the magnitude of the lifetimes, τ, and spin-lattice relaxation times, T_1, of the OH protons of DAD were appropriately suited to this purpose. The balancing of the magnitudes of these two parameters is a very important point of the FH method.[4,5]

NMR Measurements. All measurements were performed at 26 °C with a Varian HA-100 D spectrometer operating in the frequency sweep mode at 100 MHz and with a 20-dB RF-field attenuation. Tetramethylsilane was used as an internal lock signal. The leakage from the transmitter coil to the receiver coil was minimized as much as possible with probe tuning paddles to avoid receiver overload when perturbing H_2 and H_3 fields were switched on. The "INDOR" experiments were performed using a Hewlett-Packard Model 4204 A oscillator as an additional oscillator for observing the H_1 field. Attention was paid to the amplitude of the H_1 field so as not to reduce the observing signal height by saturation. For triple-resonance experiments, a Wavetek Model 111 oscillator was employed. The perturbing field strengths of H_2 and H_3 used were determined to sufficiently saturate the signals but not to cause receiver overload. A Varian C-1024 time-averaging computer (CAT) operating in the internal trigger mode was used to follow and to store the fast changes in the signal intensity and then to read out the data on the recorder of the HA-100 D spectrometer. The sweep time of the C-1024 was

arbitrarily set in the range from 2.5 to 10 s depending on the duration of the decay and recovery curves. A pen response time of 5 Hz was used for filtering.

Results and Discussion

1,3-Dihydroxyacetone (I) is known to be present as a dimer having a 1,4-dioxane structure (II) in the crystalline state. This form is maintained as the main species in a dimethyl sulfoxide solution, at least for a few hours after dissolution.[9] Figure 1 shows a typical proton magnetic resonance spectrum of DAD in a DMSO-d_6 solution (2.0 M) together with assignments using the notation and numbering shown in II. The weak signal at about 3.65 ppm is due to water protons and is also designated as γ. As is seen in Fig. 1, since the

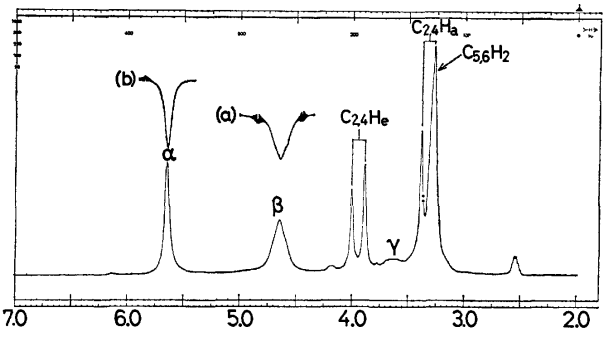

Fig. 1. The proton magnetic resonance spectrum of DAD observed in 2.0 M solution in DMSO-d_6, together with the assignments and INDOR spectra for α and β resonances. (a) INDOR spectrum for $\alpha(\beta)$, (b) INDOR spectrum for $\beta(\alpha)$.

two types of OH protons, α and β, are well separated from each other and also from the other signals, DAD can be irradiated safely by the strong rf fields inherent to the FH method. The concentration dependence of the features of the α and β signals is shown in Fig. 2, in which the α and β signals for 2.0, 1.0, 0.5, and 0.25 M solutions are presented. When the concentration was lowered, both the α and β signals became sharp. This was particularly clear for the β signals. This sharpening implies a slowdown in the exchange rate, although an increase in the spin-spin relaxation time, T_2, may also contribute to this sharpening. Accordingly, the sharpening of the α and β signals cannot be explained simply. It was difficult to monitor the γ signal for 2.0 M by the INDOR technique due to its weakness. When the solutions were diluted from 2.0 M, the γ signal shifted to higher field with concomitant narrowing of the line

width and at 0.25 M it overlapped the low-field signal of the $C_{2,4}H_a$ doublet. For these reasons, the exchange reactions of the α and β protons were first investigated using the INDOR technique over the 2—0.25 M range neglecting the presence of the γ proton. The elimination of the γ proton from the exchange pathway in the experiment gives an apparent lifetime, τ, and a spin-lattice relaxation time, T_1, which may be useful as relative parameters to observe trends. Subsequently, a three-site exchange system, which includes γ as an exchangeable site, was investigated for 1.0 and 0.5 M and compared with the results of the two-site exchange approximation.

Two-site Exchange System between α and β Protons. Figures 1 (a) and (b) show examples of INDOR spectra in cases where the α and β signals were monitored and the β and α signals were perturbed, respectively. Only one negative INDOR signal is obtainable in each case, since the spin transferred by chemical exchange from the saturating site simply reduces the monitoring signal intensity. Here, an abbreviation for the formal description of the multiple resonance experiment, is used with the nucleus under study outside the parenthesis and the nucleus being irradiated inside the parenthesis, *e.g.*, $\alpha(\beta)$ for case (a) and $\beta(\alpha)$ for case (b). If a recorder pen is set at the frequency of the bottom position of the INDOR spectrum and then if the irradiation field is switched on, the decay curve of the monitoring signal can be obtained by sweeping the CAT at a constant speed. Similarly, a recovery curve can be obtained when the radiation is switched off after the transient decay reaches a steady state. Figures 3 and 4 show the decay and recovery curves obtained at 2.0 and 0.25 M

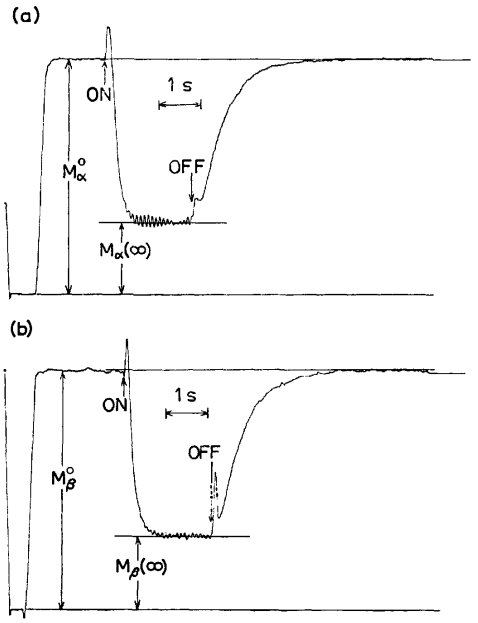

Fig. 3. The decay and recovery of the magnetization of DAD, 2.0 M in DMSO-d_6 solution for (a) $\alpha(\beta)$ and (b) $\beta(\alpha)$ arrangements. "ON" and "OFF" indicate the start and the removal of the irradiation, respectively.

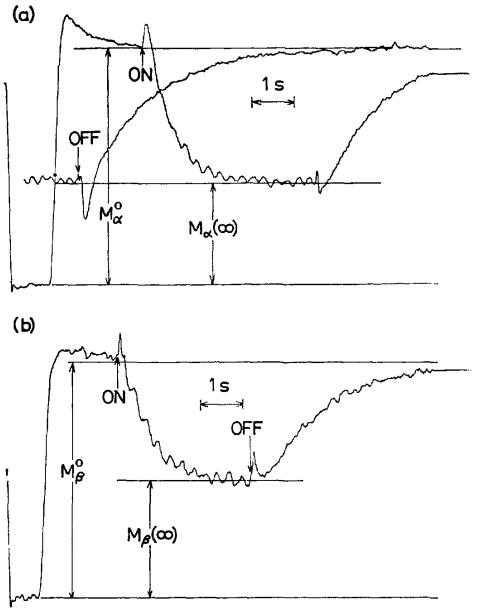

Fig. 4. As for legend to Fig. 3, except that 0.25 M in DMSO-d_6 solution was used.

for both $\alpha(\beta)$ and $\beta(\alpha)$ experimental arrangements. In analyzing the decay curves, the following three points were taken into account:

(a) There is a time lag until complete saturation after the irradiation power is switched on.

(b) A time lag due to pen response may be present. For example, in this experiment, a response frequency of 5 Hz was used, which causes a time lag of at most 0.2 s for the decay curve as a whole.

(c) "Shock noise" appears when the irradiation rf power is switched on or off, as Figs. 3 and 4 show. This noise also causes a lag in the recovery curve.

These three points introduce errors in the analysis of the decay curves. However, in practice, the scale of the decay curves is less than 10 cm, so that the time lag due to (b) may be less than 0.1 s. This time lag may have some effect in the case of the decay of a 2.0 M solution, but may not be as large for the case of the slow decay of a 0.25 M solution. The time lag due to (a) is inevitable, in principle, but due to (c), the decay curves were analyzed after the decay had passed through its initial value, *i.e.*, $M_\alpha{}^0$ or $M_\beta{}^0$. This delay may compensate the time lags due to (a) and (b) to approximately the same extent. Figure 5 shows the logarithmic plots $(\ln[M_1(t)-M_1(\infty)]$ *versus* $t)$ of the magnetization decay for 2.0, 1.0, 0.5 and 0.25 M solutions. The slopes of the lines give $\tau_{1\alpha}$=0.14, 0.21, 0.38, and 0.55 s and $\tau_{1\beta}$= 0.15, 0.31, 0.47, and 0.62 s from 2.0 to 0.25 M, respectively. From these τ_1, τ, and T_1 for each concentration can be calculated using Eqs. 2 and 10 of Ref. 4 and are plotted in Figs. 6(a) and (b), respectively. The results of two series of experimental trials are shown. In

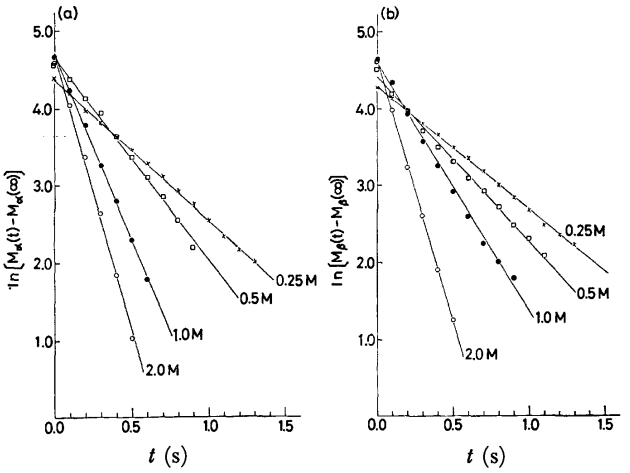

Fig. 5. Logarithmic plots (base e) of the decay of magnetization for (a) $\alpha(\beta)$ and (b) $\beta(\alpha)$ arrangements at various concentrations. The experimental points are taken from a smooth curve drawn through the decay curve "by-eye".

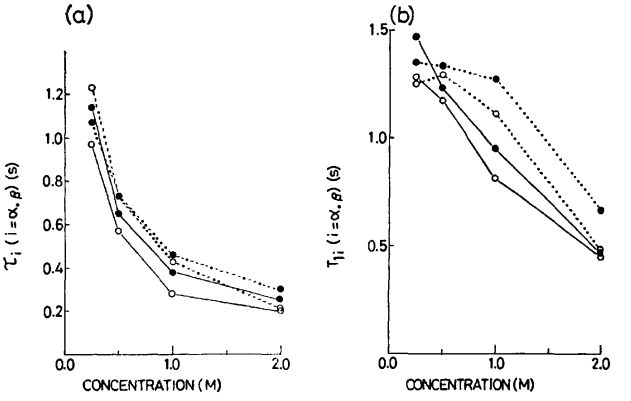

Fig. 6. The effect of concentration on (a) τ_i and (b) T_{1i} (i=α,β). ○: Experiment 1, ●: Experiment 2. ——: α, ------: β.

Experiment 1, sample solutions of 1.0, 0.5, and 0.25 M were prepared by successive dilution from a 2.0 M solution, whereas in Experiment 2, each sample solution was prepared by weighing the corresponding amount of DAD individually. These two series were made to see the extent of scatter of τ and T_1 by the sampling method. However, as shown in Figs. 6(a) and (b), both Experiments 1 and 2 give similar trends. This indicates that τ and T_1 are not appreciably influenced by a small difference in the water content arising from the difference in sampling methods.

As shown in Fig. 6(a), when the concentration is lowered, both τ_α and τ_β increase steeply. This trend clearly shows the slowing down of the exchange rate between the α and β protons which was implied by sharpening of the signals upon dilution, as seen in Fig. 2. The steep increase in τ indicates that the exchange reaction may be controlled by the collision probability which depends on the concentration. On the other hand, with regard to T_1, $T_{1\alpha}$, and $T_{1\beta}$ show different tendencies with $T_{1\alpha}$ increasing monotonically and $T_{1\beta}$ reaching a maximum at about 1.0 M. This difference may be caused by the difference in the magnetic environments of the α and β protons, namely, the β proton has neighboring methylene protons while the α proton does not.

For both Experiments 1 and 2, τ_β was slightly larger than τ_α. This is reasonable since $M_\beta{}^0$ is 1.1—1.2 times larger than $M_\alpha{}^0$. Another important point for checking

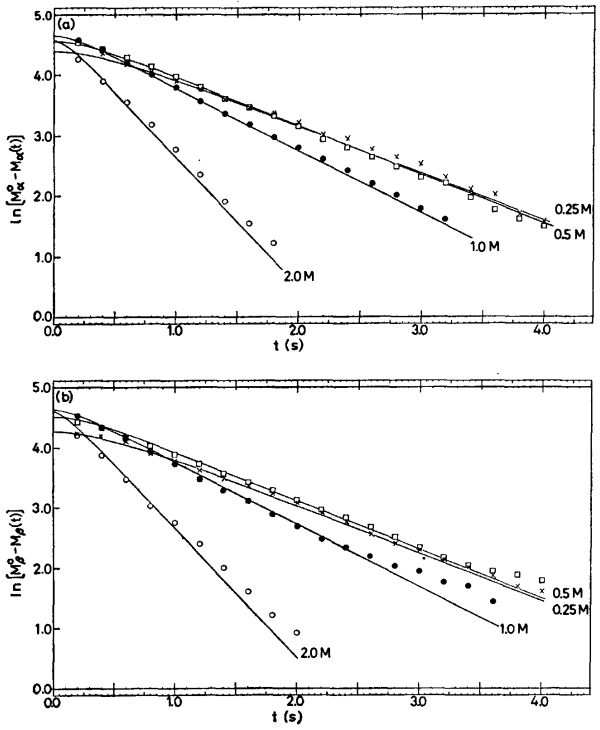

Fig. 7. Logarithmic plots (base e) of the recovery of magnetization for (a) α and (b) β nuclei at various concentrations. The full curves represent the theoretically predicted recoveries. The experimental points are taken from a smooth curve drawn through the recovery curve and are shown by the following symbols for each concentration: ○, 2.0 M; ●, 1.0 M; □, 0.5 M; ×, 0.25 M.

Table 1. Calculated parameters used to draw the recovery curves in Fig. 7

Concentration	type of proton	C_1(mm)	C_2(mm)	$\lambda_1(s^{-1})$	$\lambda_2(s^{-1})$
2.0 M	α	21.8	−119.8	11.8	2.1
	β	21.9	−120.3		
1.0 M	α	18.9	−124.4	7.0	1.0
	β	18.4	−120.9		
0.5 M	α	24.7	−120.2	3.9	0.8
	β	23.4	−113.9		
0.25 M	α	34.7	−115.7	2.6	0.8
	β	30.7	−102.2		

the reliability of τ and T_1 is to observe the degree of fitness between the recovery curve calculated using these parameters and the experimental recovery points. Since the recovery process is slower than the decay process and also is free from apprehension for receiver overload, a more precise curve than the decay curve is obtainable. Figure 7 shows the calculated recovery curves and the experimental points, with $\ln[M_i{}^0 - M_i(t)]$ plotted *versus* t. The necessary parameters for drawing the theoretically-determined full curves were calculated from Eqs. 15, 19, and 20 of Ref. 4 and are shown in Table 1. The scales of C_1 and C_2 are adjusted to the present experimental size in terms of $M_i{}^0$. All the theoretically-predicted curves are nearly straight on the whole and, since λ_1 is much larger than λ_2, the exponential part of λ_1 decays quickly to zero. In order to obtain the best fit, the experimental points were read off by delaying the null-point time by about 0.1—0.2 s from the actual moment that the irradiating field was removed. This type of time lag has also been reported by Forsén and Hoffman.[4] The resulting fit between the theoretically-predicted curves and the experimental points is satisfactory for all cases. These results show clearly that the two-site exchange approximation is justifiable for determining the relative tendencies and that the INDOR technique used here can follow the fast rate processes which is impossible by the rapid repetitive-scan method used up to now.

Three-site Exchange System for α, β, and γ Protons. In the case of a three-site exchange system, including γ which originates from the water protons, exactly the same procedures as those for the two-site exchange system can be utilized, except that a triple resonance is considered. The triple resonance is rather difficult to carry out, since it causes more beating than does double resonance. However, fortunately, this was not such a serious problem in the present experiments. Figure 8 shows, in level-diagram form, the concentration dependence of the steady-state ratios necessary for calculating τ_1 and λ_{ij}. Ratios for a 0.25-M solution are included for reference, although the measurement of the γ signal at this concentration is somewhat questionable because of overlapping with other signals. The parameter λ_{ij} is the probability per unit time for a nucleus at site i to be transferred to site j and is generally related to the life time τ_i by

$$1/\tau_i = \sum_{j \neq 1} \lambda_{ij}. \quad (1)$$

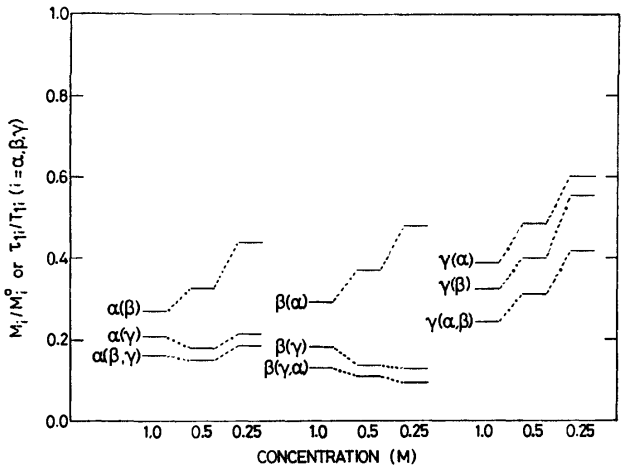

Fig. 8. The schematic illustration of the intensity ratios M_i/M_i^0 and τ_{1i}/T_{1i} for various experimental arrangements. Experiment 1 series of samples were used. Double resonance experiments ($\alpha(\beta)$ *etc.*) give ratios M_i/M_i^0 and triple resonance experiments ($\alpha(\beta,\gamma)$ *etc.*) give ratios τ_{1i}/T_{1i}.

TABLE 2. TIME CONSTANTS OBTAINED FROM THE DECAY CURVES TREATED AS THREE-SITE EXCHANGE SYSTEMS

Concentration	Type of proton i	τ_{1i}(s)	T_{1i}(s)	τ_i(s)	τ_i(s) from Eq. 1
1.0 M	α	0.13	0.85	0.16	0.18
	β	0.11	0.91	0.12	0.16
	γ	0.14	0.58	0.18	0.21
0.5 M	α	0.17	1.05	0.20	0.23
	β	0.14	1.32	0.16	0.18
	γ	0.26	0.84	0.39	0.41

Table 2 shows the time constants which were obtained from an analysis of the triple-resonance decay curves. In the triple-resonance experiment, when the γ site was included as the irradiation site, the transient decay rate increased above that of the double-resonance case. This effect results in a smaller value of τ_1 than that of the corresponding two-site exchange approximation. However, it is interesting to note that it only affects the magnitude of τ leaving that of T_1 almost unchanged.

TABLE 3. CALCULATED λ_{ij} IN s^{-1} FOR 1.0 M (LEFT) AND 0.5 M (RIGHT) SOLUTIONS

i \ j	α	β	γ
α	—	2.5, 1.2	3.0, 3.0
β	1.9, 1.1	—	4.6, 4.3
γ	1.8, 0.9	3.0, 1.6	—

Table 3 shows the values of λ_{ij} calculated from Eqs. 7 and 8 of Ref. 5, using the necessary values given in Table 2 and Fig. 8. The following ratios were also utilized: $M_\alpha^0 : M_\beta^0 : M_\gamma^0 = 1 : 1.1 : 1.4$ for 1.0-M and 1 : 1.2 : 3.0 for 0.5 M-solutions. These were obtained by integrating the corresponding band of the single-resonance spectrum. Before using the values of λ_{ij} to attempt to obtain significant information, the reliability

TABLE 4. THE RATIO OF THE MAGNETIZATION WHICH FLOWS IN A SITE TO THAT WHICH EFFUSES FROM THE SITE PER UNIT TIME

Type of proton	Concentration 1.0 M	0.5 M
α	0.8	1.0
β	0.9	0.9
γ	1.2	1.1

of these values must be checked. Since λ_{ij} depends on the difference between two asymptotic intensity ratios of similar magnitude, they may include large errors.[5] One way of checking the reliability of λ_{ij} is to test the agreement between the τ_i calculated from λ_{ij} using Eq. 1 and those calculated from the decay curves. In the last column of Table 2, the values of the τ_i calculated from λ_{ij} are given. As can be seen from this table, the agreement is satisfactory for all cases. The another important check is to test whether or not these λ_{ij} satisfy the balance equations of Ref. 5, namely, the magnetization which flows into a site must be equal to that which effuse from the site per unit time. This is shown in Table 4 as the ratio of the former to the latter for each site. All the calculated ratios are nearly equal to unity, so that the balance equations can be said to be well satisfied. Based on these checks, it can be said that the probability of proton transfer is in the following order of magnitude: $\beta\rightarrow\gamma > \alpha\rightarrow\gamma > \gamma\rightarrow\beta > \alpha\rightarrow\beta > \beta\rightarrow\alpha > \gamma\rightarrow\alpha$. This order indicates that:

(a) The probability of proton transfer is larger in the direction of the β and α protons to the γ proton than is the direct exchange between α and β protons. This implies that proton exchange between α and β sites is accelerated by the presence of water protons.

(b) The β proton is more "labile" than is the α proton. This is consistent with the well-known fact that primary alcohols are more acidic than tertiary alcohols and that the extent of esterification of the former is larger than that of the latter *etc.*,[10] although for DAD, the β nucleus is the hydrogen of the hydroxyl of a hemiacetal, which can be thought of as a fairly labile hydrogen.

Presently, the INDOR technique is a very popular method for analyzing spin-coupled spectra, with an appropriate attachment often being installed in commercially-available CW NMR spectrometers. This work was undertaken with the intention of applying this technique to the investigation of rate processes. It was shown that with the aid of CAT, the INDOR technique is more suitable and easier to use for following fast changes in magnetization than is the rapid repetitive-scan method. This will enable relatively fast rate processes to be investigated using the elegant multiple-resonance method presented by Forsén and Hoffman for the study of rate processes together with relaxation processes.

Pentamethylnitrosobenzene as a Spin-trapping Agent

Takahisa DOBA, Tsuneki ICHIKAWA, and Hiroshi YOSHIDA
Faculty of Engineering, Hokkaido University, Kita-ku, Sapporo 060
(Received March 3, 1977)

Pentamethylnitrosobenzene synthesized readily from pentamethylbenzene was studied for utilization in a spin-trapping technique. In a benzene solution it forms a dimer with a dissociation constant of $10^{5.26}\exp(-50/RT)$ in units of kJ/mol. It traps the *t*-butyl radical with the trapping rate constant of 1.4×10^{8} mol^{-1} dm^{3} s^{-1} at 299 K. It is thus an efficient spin-trapping agent, even though only a fraction of it is reactive with the short-lived free radicals because the equilibrium lies more on the side of the dimeric form. Electron spin resonance parameters were determined for the spin-adduct radicals derived from alkyl, alkoxyl, and phenyl radicals with this trapping agent. These free radicals were found to attach exclusively to the nitrogen atom of the nitroso compound.

Aliphatic and aromatic nitroso compounds have been widely used as spin-trapping agents for the spin-trapping technique, whereby short-lived free radicals in a reaction system attach to the trapping agents to form stable nitroxide (or anilino-type) radicals and are indirectly identified by means of conventional electron spin resonance (ESR) measurements.[1,2] Although available rate constant is very scanty for reactions between a trapping agent and a short-lived free radical,[3-5] nitrosobenzene appears more reactive compared with its alkyl-substituted derivatives. A drawback of this trapping agent is that its spin-adduct radicals generally show complex hyperfine structures in ESR spectra because of the ring protons, which renders difficult the identification of the trapped radicals.[6] On the other hand, 2,4,6-tri-*t*-butylnitrosobenzene (BNB) yield well-resolved hyperfine structures of its adduct radicals, but is much less reactive with short-lived free radicals.[7] Pentamethylnitrosobenzene (PMNB) is expcted to give a simpler hyperfine structure and to be moderately reactive, as is nitrosodurene,[8] thus being a useful spin-trapping agent. However, PMNB has not been studied as yet. This particular nitroso compound has one advantage as a spin-trapping agent in that it can be synthesized very readily from commercially-available pentamethylbenzene.[9,10] The present report will present several aspects of PMNB as a spin-trapping agent.

Results and Discussion

ESR Spectra of Spin-adduct Radicals. A typical ESR spectrum of spin-adduct radicals is shown in Fig. 1A. When a methyl radical generated in a benzene solution of methyl iodide and tributylstannane is trapped with PMNB, an adduct radical of the nitroxide type is formed and can be identified from the hyperfine splittings due to one nitrogen nucleus and three protons at the β-position with respect to the oxygen atom of the nitroxyl group (see the observed hyperfine splitting constants given in Table 1). Figure 1 also shows methyl-radical adducts from nitrosobenzene and BNB, for comparison. The adduct from PMNB shows broader

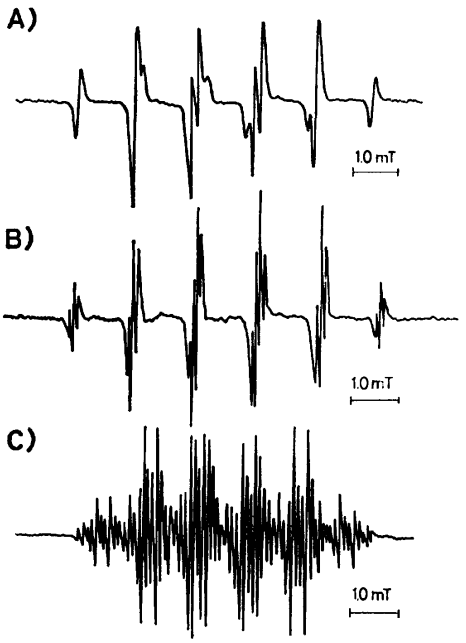

Fig. 1. ESR spectra of the spin adduct radicals generated by trapping methyl radical with (A) PMNB, (B) BNB, or (C) nitrosobenzene in benzene solution. The methyl radical was generated by the photolysis of tributylstannane in the presence of methyliodide.

hyperfine lines than do the adducts from nitrosobenzene and BNB, but it gives a much simpler hyperfine structure facilitating the identification of the trapped radical.

Table 1 summarizes the observed ESR parameters at 299 K for a number of adduct radicals generated from short-lived free radicals with PMNB in benzene. The short-lived free radicals were in turn generated by the photolysis or γ-radiolysis of appropriate radical sources. The observed ESR parameters are similar to those reported for nitrosodurene.[8] The hyperfine splitting due to the nitrogen atom lies in the range 1.42—1.30 mT, except for the phenyl radical adduct. Hyperfine splitting due to the β-proton(s) of the alkyl-radical adducts tends to decrease with the number of hydrogen (or with an increasing number of carbon) atoms attached to the β-carbon atom (the α-carbon in the trapped alkyl radicals). This trend is similar to that for nitrosobenzene and nitrosodurene,[8] being opposite to that for BNB[11] as shown in Table 1.

All the short-lived free radicals examined were found to attach to the nitrogen atom rather than to the oxygen atom of the nitroso compound, thereby giving nitroxide radicals. No formation of anilino-type adduct radicals was observed.

Monomer-Dimer Equilibrium. As in the case of aliphatic nitroso compounds[12] and nitrosodurene,[8] PMNB is present in solution mostly as a dimer, which is inactive in trapping short-lived free radicals. PMNB shows a weak optical absorption band with a maximum at 790 nm and an intense band with a maximum at 324 nm. The former band is due to the $n\pi^*$ transition of the monomeric form, and the latter to the dimeric form. Changing the temperature causes complementary change in the intensity of both the bands, higher temperature favoring the monomeric form. According

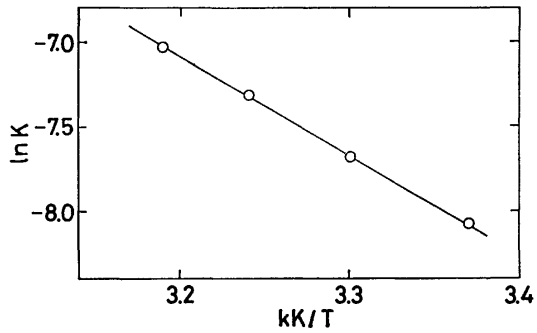

Fig. 2. Dependence of the dimer-monomer equilibrium constant for PMNB in benzene on reciprocal temperature.

to the well-known relationship, $c/OD = 1/2\varepsilon + 1/K\varepsilon^2 OD$, where OD represents the optical density at 790 nm and c represents the total concentration of PMNB based on its dimeric form, the dissociation constant K was determined at several temperatures, as shown in Fig. 2. The extinction coefficient ε was also determined to be 83.3 $mol^{-1}\ dm^3\ cm^{-1}$, almost independent of temperature.

The temperature dependence of the equilibrium constant is expressed by the equation, $K = 10^{5.26}\exp(\Delta H/RT)$, where the heat of dissociation is -50 kJ/mol. This means that only 12% of the 10 mmol dm^{-3} PMNB in a benzene solution is in monomeric form and is effective in the trapping reaction at 300 K. This behavior is very similar to that of nitrosodurene.[8]

Rate Constant for the Spin-trapping Reaction. In a separate investigation, the rate constant for the spin-trapping reaction of 2-methyl-2-nitrosopropane with the *t*-butyl radical, being $3.3 \times 10^6\ mol^{-1}\ dm^3\ s^{-1}$ at 299 K in benzene solution, was investigated.[7] Based on this figure, the rate constant for PMNB was determined by studying the competition between PMNB and 2-methyl-2-nitrosopropane in trapping the *t*-butyl radical generated by the photolysis of the latter. Figure 3 shows the linear increase in the concentration of the

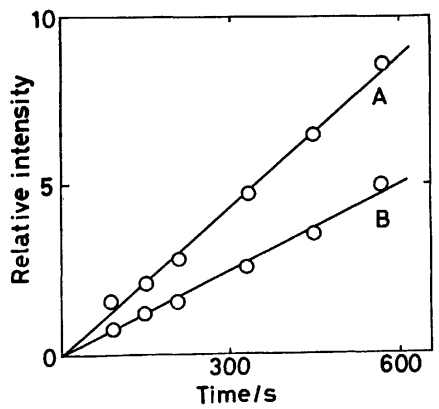

Fig. 3. Yield of the *t*-butyl radical adducts formed from (A) PMNB and (B) 2-methyl-2-nitrosopropane in benzene at 299 K as a function of photolysis time. The *t*-butyl radical was generated by the photolysis of the latter spin trapping agent 0.0276 mol dm^{-3} in benzene solution, where the former trapping agent (0.0012 mol·dm^{-3}) was coexisting.

t-butyl adducts with both the trapping agents coexisting in the benzene solution during the early period of photolysis. From the observed slopes and the concentration of the trapping agents present, the rate constant for PMNB was determined to be 1.4×10^8 mol^{-1} dm^3 s^{-1}, based on the concentration of PMNB in monomeric form, in the reaction with the *t*-butyl radical at 299 K.

Although very little has been reported on spin-trapping rate constants, the data so far available indicate that trapping reactions proceed with rate constants of 10^5—10^8 mol^{-1} dm^3 s^{-1}, depending on the spin-trapping agent used and the radical trapped.[3-5] PMNB appears to be a comparatively reactive spin-trapping agent. It was also found to be a more efficient trapping agent than BNB, even when the monomer-dimer equilibrium of PMNB is taken into account.

Experimental

Synthesis. According to McKillop *et al.*,[9] pentamethylbenzene is converted to $C_6(CH_3)_5Tl(OCOCF_3)_2$, with the yield of this organothallium compound being *ca.* 60%. It was then converted into PMNB upon treatment with nitrosyl chloride with a yield of almost 100% by applying the method reported by Taylor and Danforth for the general synthesis of aromatic nitroso compounds.[10] The PMNB thus obtained was purified by recrystallization from an acetone solution three times. Its observed melting point of 427 K was unchanged by further purification. This value is in agreement with the previously-reported melting point of 425—428 K.[13] Elementary analysis gave the following results. Found: C, 74.51; H, 8.56; N, 7.8%. Calcd for $C_{11}H_{15}NO$: C, 74.52; H, 8.54; N, 7.9%.

PMNB was synthesized much more easily than nitrosodurene. This is an advantage of PMNB as a spin-trapping agent over nitrosodurene, although PMNB shows similar behavior in spin-trapping reactions and gives similar features of the hyperfine structures of the adduct radicals as does nitrosodurene.

Photolysis and Radiolysis. The short-lived free radicals trapped were generated by photolysis or radiolysis at room temperature from appropriate radical sources present in a benzene solution of 10 mmol dm^{-3} PMNB sealed in a quartz ESR tube after degassing by the freeze-pump-thaw technique. The solvent and the radical sources were of the highest purity commercially available and were used as received. The photolysis was carried out with light from an ultra-high pressure Hg lamp using a wavelength selected by a set of filters, so that only the radical sources were excited. The radio ysis was carried out with ^{60}Co γ-rays to a dose of approximately 0.1 Mrad.

ESR Measurements. Spin-adduct radicals were observed using a conventional X-band ESR spectrometer (JEOL, Model 2X) at 299 K. Their *g*-value was determined with reference to that of polycrystalline DPPH, 2.0036.[14] The hyperfine splittings were corrected with reference to that of Fremy's salt in aqueous solution, 1.300 mT.[15]

Optical-absorption Measurements. The optical absorption of PMNB in benzene was recorded with a recording spectrophotometer (Hitachi, Model EPS-3T). The sample solutions in a quartz cell having an optical path length of 1.0 cm were examined without degassing. Temperature was controlled in a water bath using a Dewar vessel with quartz windows.

Crystal Structure and Electrical Conductivity of Tetrathiafulvalene Thiocyanate (TTF)(SCN)$_{0.57}$

Hayao KOBAYASHI and Keiji KOBAYASHI*

Department of Chemistry, Faculty of Science, Toho University, Chiba 274

**Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguroku, Tokyo 153*

(Received March 8, 1977)

The organic conductor, (TTF) (SCN)$_{0.57}$, is a quasi-one-dimensional non-stoichiometric compound, which crystallizes in a tetragonal system having a $P4_2/mnm$ space group. The lattice constants are $a=11.154$ (3) and $c=3.607$ (2) Å. TTF molecules form segregate eclipsed stacks with thiocyanate ions occupying the channels between the stacks. The intermolecular distance between adjacent TTF molecules is 3.607 Å. The room-temperature electrical conductivity is 85—310 $(\Omega\,cm)^{-1}$. A series of *resistance jumps* are observed in the temperature-dependent resistivity curves.

Considerable work has recently been focussed on attempting to understand the unusual physical properties of the quasi-one-dimensional salts of organic radicals. Unlike a crystal of (TTF)(TCNQ) composed of segregated stacks of TTF and TCNQ, crystals of (TTF)(X) (X=I, Br, Cl) contain only TTF columns. The large room-temperature conductivities of (TTF)(X) (200—500 $(\Omega\,cm)^{-1}$), comparable to that of (TTF)-(TCNQ), are attributed to the characteristic columnar structures.[1-4]

In this paper, the crystal structure and the elctrical conductivity of 1,4,5,8-tetrathiafulvalene thiocyanate, (TTF)(SCN)$_{0.57}$, are reported.

Experimental

Tetrathiafulvalene was synthesized according to the published procedure.[5] After recrystallization twice from a cyclohexane–hexane solution, TTF was converted to tetrafluoroborate $(TTF)_3(BF_4)_2$. Tetrathiafulvalene thiocyanate crystals having the approximate composition, $(TTF)_{11}(SCN)_6$ (or (TTF)(SCN)$_{0.545}$),[6] were easily prepared from $(TTF)_3(BF_4)_3$ and tetrabutylammonium thiocyanate[7] *via* methathesis in hot acetonitrile.

Oscillation and Weissenberg photographs show the crystals to be tetragonal. The systematic absence of $h0l$ with $h+l=2n+1$ and of $0k0$ with $k=2n+1$ indicate that the space group is $P4_2/mnm$, $P4_2nm$ or $P\bar{4}n2$. The unit-cell dimensions, as determined by means of a diffractometer using Mo $K\alpha$ radiation, are $a=11.154(3)$ and $c=3.607(2)$ Å. The density measured using the flotation method was 1.756 ± 0.015 g cm^{-3} and the corresponding composition of the complex was calculated to be (TTF) (SCN)$_{0.57\pm0.03}$. No additional weak satellite-type reflections[1,2] indicating the existence of two distorted sublattice cations and anions were observed (see note added in proof). The intensity data were collected with a Rigaku automated four-circle diffractometer. Owing to the small size of the specimen, only 120 independent reflections of 461 accessible reflections ($2\theta\leqq55°$) were recorded sufficiently accurately ($|F|>3\sigma$).

Structure Determination and Discussion

The trial structure was easily deduced from the Patterson syntheses and refined by the block-diagonal least-squares method. In view of the planar structure of TTF, the space group was assumed to be $P4_2/mnm$ which was confirmed by the reasonable convergence of the structure at a later stage of refinement. Fourier calculations based on the atomic parameters of TTF showed a columnar distribution of the electron densities at $(0,1/2,z)$ $(0\leqq z<1)$ and that the magnitude of the electron density is almost constant along the crystallographic c axis, indicating one-dimensional disorder of the atomic positions of the S, C, and N atoms. Therefore, the scattering factors of the S, C, and N atoms were evaluated by assuming a one-dimensionally random distribution and a common isotropic thermal parameter. The R value was reduced smoothly to 0.045. The final atomic parameters are given in Table 1.

The structure viewed along the c axis is shown in Fig. 1. TTF has D_{2h}(mmm) symmetry and is stacked in an eclipsed column. Similar eclipsed stacks have been found in the crystals of TTF–halogen systems. The c axis is perpendicular to the molecular plane. The interplanar distance of 3.607 Å is comparable to those in (TTF)(Br)$_{0.71-0.76}$ (3.57 Å[1]) and (TTF)(I)$_{0.71}$ (3.55 Å[2]) crystals, but is much larger than the interplanar distances of TCNQ in the "ring-external bond type" columns of the high-conductive TCNQ salts (3.17—3.26 Å[8]). Considering the large intermolecular distances, the "metallic" conductivities[1,3,4] are undoubtedly due

Table 1. The final atomic parameters ($\times10^4$)

The standard deviations are in parenthesis. The temperature factors are of the form $\exp[-2\pi^2(h^2U_{11}a^{*2}+k^2U_{22}b^{*2}+l^2U_{33}c^{*2}+2hkU_{12}a^*b^*+2hlU_{13}a^*c^*+2klU_{23}b^*c^*)]$.

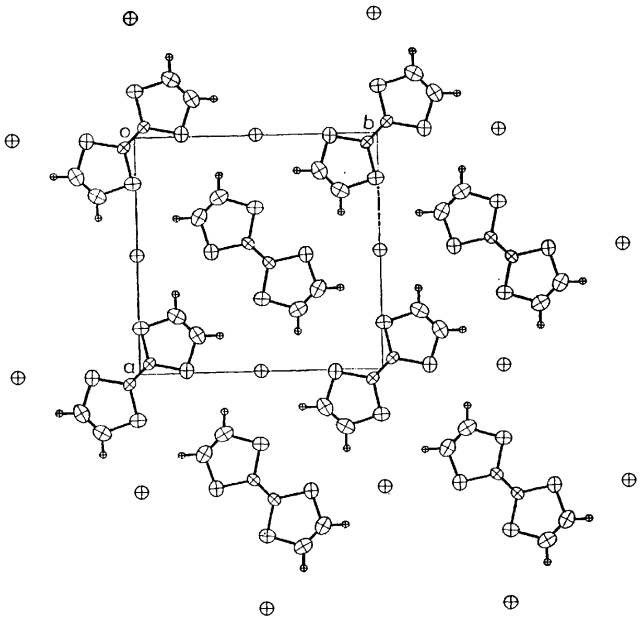

Fig. 1. The (001) projection of the $(TTF)(SCN)_{0.57}$.

to the intermolecular overlap of the atomic orbitals of the sulfur atoms. As observed in the TTF-halogen crystals, the TTF columns form tunnels. Like $(TTF)(SCN)_{0.57}$, $(TTF)(Cl)_{0.92}$ has a tetragonal structure and the tunnels are occupied by the disordered chlorine anions.[2] (see note added in proof). However in $(TTF)(Br)_{0.71-0.76}$ and $(TTF)(I)_{0.71}$, there are separate cation and anion sublattices.[1,2] This incommensurability produces additional "satellite-type" reflections[1,2] due to the periodically-modulated superstructure. As originally pointed out by Johnson and Watson,[2] the general features of the crystal structure of these salts can be summarized as follows:

(1) If the radius of the cation is small enough to enter the tunnel formed by the TTF columns ($r \leqq 1.8$ Å (the Cl ionic radius)), the crystal is tetragonal. Owing to loose packing, the atomic positions of the anions tend to be disordered in the tunnels.

(2) If $r \geqq 1.96$ Å (the Br ionic radius), the anions cannot enter the tunnel without distortion of the "TTF sublattice" so that a modulated superlattice is formed. Due to compact packing, the atoms are regularly arranged.

Consequently, it may be said that the repulsive force between anions and cations plays an important role in the appearance of the modulated superlattices of the TTF-halogen systems.

The tunnel structure of $(TTF)(SCN)_{0.57}$ appears to indicate the non-stoichiometric nature of the crystal. Considering that monoclinic $(TTF)(Br)_x$ can exist over the range of compositions, $0.71 \leqq x \leqq 0.76$, the number of anions stacked in a tunnel does not appear to be necessarily constant. Therefore, the composition obtained by Wudl *et al.*, $(TTF)_{11}(SCN)_6$, may be regarded as approximate. Since the distance between the adjacent atoms (ions) must be larger than the sum of the two van der Waals (ionic) radii, the value of x for the $(TTF)(X)_x$ system must be smaller than $R/2r$, where $R(\approx 3.60$ Å) is the intermolecular distance between neighboring TTF molecules and r is the ionic radius of the anion. The calculated maximum values (with observed values in parenthesis) are 0.83 (0.71), 0.92 (0.71—0.76), 1.0 (0.92), and 0.59 (0.583) (see note added in proof) for the iodide, bromide, chloride and thiocyanate, respectively. In this connection, it may be worthwhile to point out that 1 : 1 bromide ($x=1.0$) is stacked quite differently.[1]

The bond lengths and angles are given in Table 2. Considering the fairly large standard deviations, the values for $(TTF)(SCN)_{0.57}$ appear to be in good agreement with those for other TTF salts.

Electrical Conductivity

The room-temperature conductivities of $(TTF)(I)_{0.71}$ and $(TTF)(Br)_{0.71-0.76}$ are continuous in the range from 200—500 $(\Omega\,cm)^{-1}$. [1,3,4] For the iodide, a transition occurs between 200 and 230 K, which is similar to that which occurs near 180 K for the bromide. Unlike $(TTF)(Br)_{0.71-0.76}$, $(TTF)(I)_{0.71}$ displays a hysteresis in its conductivity curve upon temperature cycling. Although these systems are considered to undergo metal-insulator transitions at about 200 K, no

a) Ref. 9. b) Ref. 10. c) Ref. 2.

direct evidence has been obtained from the temperature dependence of the conductivities.

The conductivity measurements of (TTF)(SCN)$_{0.57}$ were performed along the crystallographic c axis (needle axis of the crystal) using the standard four-probe method with a 25 μm diameter gold wire bonded to the crystal by *duPont* 4817 conductivity paint and/or colloidal graphite (aquadag). The crystals became less conductive after they had been stored for a long time in contact with air. In addition, they are very fragile and are frequently broken by a rapid change in temperature, especially when the temperature change passes through *ca.* 0 °C. Thus, measurements of the temperature-dependent conductivities (300—120 K) were performed for only a few specimens. The room-temperature conductivities for the five samples are 85, 100, 200, and 310 $(\Omega\,\mathrm{cm})^{-1}$, respectively which agree with the value $(250\ (\Omega\,\mathrm{cm})^{-1})$ of Wudl. The discrepancies between the conductivities for the various specimens is not as large as those reported for many one-dimensional conductors.[11] Figure 2 shows the d.c. resistivity of (TTF)(SCN)$_{0.57}$ ($R(\Omega\,\mathrm{cm})=1/\sigma$). For most of the specimens, the resistivity does not decrease with temperature. Curve IIa is a typical result and is similar to those for (TTF)(Br)$_{0.71-0.76}$ and (TTF)(I)$_{0.71}$;[3,4] the conductivities decrease slightly with temperature in the high-temperature region ($T>230$ K) and decrease sharply with temperature in the low-temperature region ($T<200$ K). However, for one specimen (σ(R.T.)$=100$ $(\Omega\,\mathrm{cm})^{-1}$), a minimum point, indicative of the possible existence of a metal-insulator transition, is observed in temperature-dependent resistivity curve Ia. This result appears to be consistent with the conductivities reported by wudl who showed that (TTF)(SCN)$_{0.57}$ becomes more conductive over certain low-temperature regions (σ(R.T.)$=250$ $(\Omega\,\mathrm{cm})^{-1}$ and $\sigma(200\ \mathrm{K})=310$ $(\Omega\,\mathrm{cm})^{-1}$).[6] Considering that the disorder and defects in a crystal have great influence on the electrical conductivity and frequently smear out the metal-insulator transition,[12] the difference between the curves can be attributed to a difference in the quality of the samples.

As the temperature was changed, a series of *resistance jumps* were observed. Similar *jumps* observed for (TTF)-(I)$_{0.71}$ have been attributed to separate occurrences of the transition in different portions or domains of the crystal. A similar explanation appears to be probable, since a microscopic examination revealed that a (TTF)-(SCN)$_{0.57}$ crystal is composed of many *blocks*. At first, it appeared that a *resistance jump* accompanied a *break*

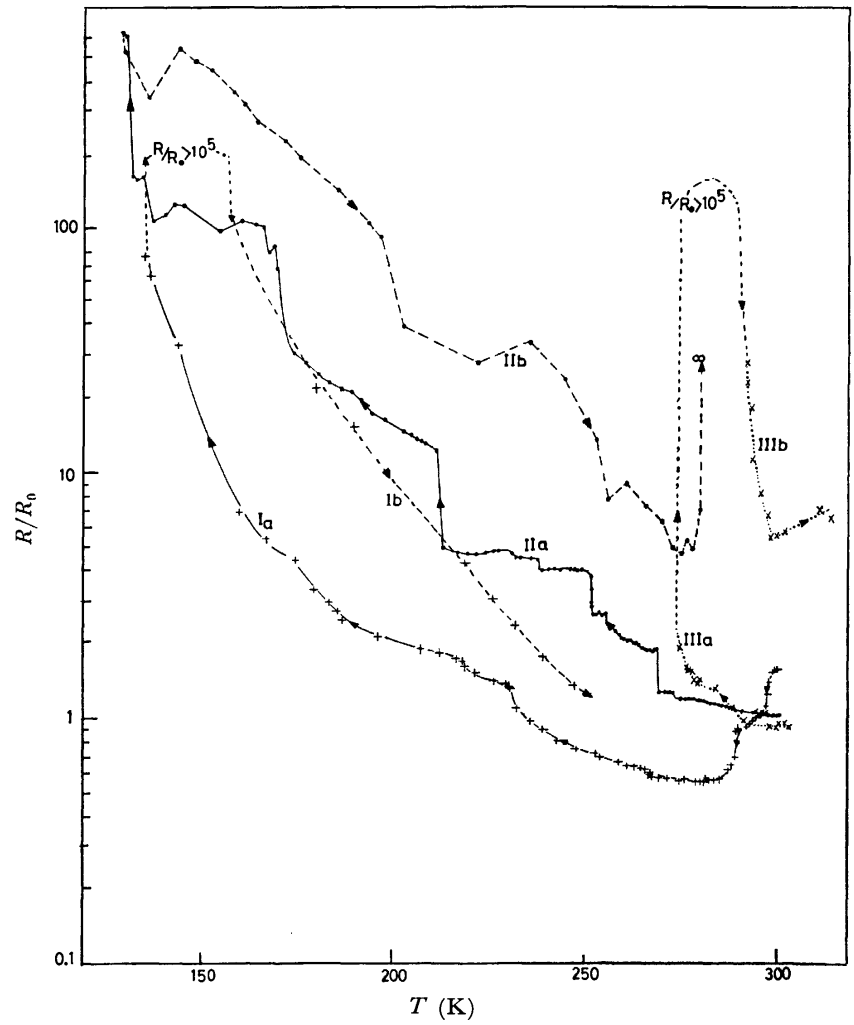

Fig. 2. Temperature dependence of the conductivity along the c axis for three samples. Arrows indicate the direction of temperature change.

TABLE 3. COMPARISON OF THE CRYSTAL STRUCTURE DETERMINATIONS

		$(TTF)(SCN)_x$ x	System	Space group	a (Å)	c	D(g cm^{-3}) Obsd	D(g cm^{-3}) Calcd
i.	This work	0.57±0.03	tetragonal	$P4_2/mnm$	11.154	3.607	1.756±0.015	—
ii.	Wudl *et al.*	0.545 (=6/11)	tetragonal	P4n2[a]	11.205	3.633	—	1.700
iii.	Somoano *et al.*	0.583 (=7/12)	tetragonal (or pseudotetragonal)	—	$\sqrt{2}\times 11.11$	3.61[b] 6.15	—	1.76

a) This space group[13] is probably incorrect and the correct one is P$\bar{4}$n2. b) The *C*-centered lattice is used to facilitate comparisons with the $(TTF)_7(I)_5$ structure. 3.61 and 6.15 Å are the lattice constants of the TTF and the SCN sublattices, respectively.

in the *blocks*, because the crystals are very fragile. According to this conjecture, many blocks can be considered to be broken during the cooling process and then the electric conduction paths would become very limited. However, in fact, upon heating to room temperature after cooling to about 130 K, the resistivities again decrease. In addition, the observation of the stepwise decrease in resistivity (curve Ia (for 270—300 K) appears to be inconsistent with the above explanation based on the *breaks* in the *blocks*. Probably, the resistivity jumps are associated with crystal blocks passing through the transition between a high-conductive state and a low-conductive state separately.[2] The series of transitions appears to indicate that the phase transition is affected by the shape and size of each *block*.

Note Added in Proof. After the completion of this paper, investigations of the electronic and structural properties of $(TTF)(SCN)_x$ and $(TTF)(SeCN)_x$ were reported by Wudl *et al.*[13] and Somoano *et al.*[14] As shown in Table 3, the crystallographic data given in their papers do not agree with those reported here. It is therefore, appropriate to briefly mention the reason for these discrepancies.

(1) Repeated elemental analysis by Wudl *et al.* results in the formula, $(TTF)_{11}(SCN)_6$ (*i.e.*, $(TTF)(SCN)_{0.545}$), whereas the formula of Somoano *et al.* is $(TTF)_{12}(SCN)_7$ (*i.e.*, $(TTF)(SCN)_{0.583}$), which was determined on the basis of the ratio of the TTF sublattice spacing to the SCN sublattice spacing. Although, in the present work, the samples were prepared according to the method of Wudl, the formula, $(TTF)(SCN)_{0.57\pm0.03}$, obtained on the basis of the measured density (1.756±0.015) agrees rather well with that of Somoano *et al.* The crystal structure of $(TTF)(SCN)_x$ was refined for several x-values. For $0.50<x<0.70$, the final structures as well as the temperature factor for SCN, are essentially identical to each other. For $x=0.60$, the lowest R-value, 0.045, and the corresponding final atomic parameters listed in Table 1 were obtained.

(2) The lattice constants of the TTF sublattice of Somoano *et al.* agree well with those presented here, whereas the values of Wudl *et al.* appear to differ from the other two, by more than the experimental error.

(3) For the crystals used here, the atomic positions of the S, C, and N atoms are one-dimensionally disordered along the c direction and no indication of the existence of the two sublattices of the TTF and SCN compound were obtained from X-ray diffraction. However, the X-ray examination of Somoano *et al.* revealed the existence of the two spacings, 3.61 Å for TTF and 6.15 Å for SCN, *i.e.*, in their crystals, the translational symmetry of the SCN arrangement is different from that for TTF. Considering that the crystals of Somoano *et al.* were grown by the diffusion method from $(CH_3)_4N(SCN)$ and $(TTF)_3(BF_4)_2$, this disagreement appears to be due to the difference in the sample preparation procedures. Some details of the crystal structure of $(TTF)_{11}(SCN)_6$ were reported by Wudl *et al.* The arrangement of TTF is very similar to that determined here, whereas their conclusion of the regular arrangement of SCN is inconsistent with their c-axis lattice constant, because this constant should be larger than the SCN spacing (c/0.545).

In conclusion, the crystals used here appear to be identical with those of Somoano *et al.* except for the orderliness of SCN. The degree of disorder may change according to differences in the procedure of preparation of the crystals. Such disorder has been observed for crystals of *N*-methylphenazinium-TCNQ.[15,16] It is not clear how the crystals of Wudl *et al.* differ from those of Somoano *et al.* and those used in the present experiments.

Conformational Study of Glutathione by NMR

Shizuo FUJIWARA, Grazyna FORMICKA-KOZLOWSKA,* and Henryk KOZLOWSKI*
Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113
**Institute of Chemistry, University of Wrocław, Wrocław, Poland*
(Received March 29, 1977)

Proton NMR spectra of glutathione have been analyzed over the whole pH region. The spectra of the glutamic acid residue are of the ABCDX type at pHs below 2.5, of the AA'BB'X types in the pH region 2.5—9, and of the ABCC'X type at pHs higher than 9. For the cysteine part, spectra of the ABC type have been observed at pHs higher than 8, which change to spectra of the A_2B type at pHs lower than 7. On the basis of these results the conformation of the glutathione molecule in solution has been discussed in detail.

The NMR technique has been successfully used in the conformational study of various amino acids.[1-9] A similar study of more complex molecules like polypeptides is usually complicated by poorly resolved spectra and a large number of coupled protons.

A fundamental and manifold interest in the recognition of the chemical, physical, and biological properties of peptides has occasioned our attempts to establish the structure of glutathione in solution by means of NMR.[10-14] Knowledge of the conformation of glutathione should help us in better understanding some metal-glutathione interaction, which is the further aim of our study.

Experimental

Materials. The glutathione was purchased from Wako Pure Chemical Industries, and the D_2O, from E. Merck. The pHs of the solutions were controlled by adding a concentrated DCl or NaOH solution in D_2O, and measured with a Toa Dempa pH-meter, model HM-5A. The concentration of glutathione in the solutions was 0.1 M. The chemical shifts are reported in Hz relative to internal tetramethylammonium (TMA). The NMR spectra were recorded with a JNM PS-100 spectrometer operating at 100 MHz.

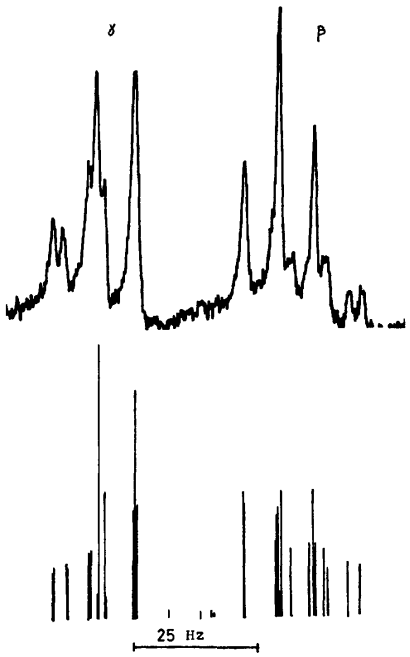

Fig. 1. Experimental and calculated spectra of γ and β protons of the glutamic acid residue at pH 0.7.

Analysis of Spectra. Glutamic Acid Residue Spectra: Five protons of the glutamic-acid part give spectra of the ABCDX type at pH lower than 2 (Fig. 1), of the AA'BB'X type in the pH range of 2.51—8.05 (Fig. 2), and of the ABCC'X type at pH higher than 9 (Fig. 3). Here ABCDX, AA'BB'X, or ABCC'X refers to the β, β', γ, γ', α protons (Fig. 4). In the pH region of 2.5—8.05 the AA'BB' pattern for the β and γ protons was confirmed by the decoupling of the α proton. An analysis of the spectra observed at a certain pH was carefully carried out with a set of input data which had been obtained in the analysis of spectra observed at a slightly different pH. It has been found that, in order to reproduce a calculated spectrum which is in good agreement with the

8.8	123.9	−14.1	7.6	5.0	9.0

All the NMR parameters are given in Hz.

the spectra are very poorly resolved and have to be analysed as the A_2B type. In this pH region, $J_{AC}=J_{BC}=6.3$ Hz. Using the notation "ABC" given in Fig. 6, the NMR parameters are given in Table 2, where the chemical shift of the A proton is taken to be in a higher field than that of the B proton. The pH dependence of the chemical shifts of the C proton of the cysteine and CH_2 protons of the glycine are shown in Fig. 7. The CH_2 protons of the glycine give a singlet line due to the exchange by deuterium of the NH proton of the neighboring peptide nitrogen,** and there is a small difference in the chemical shifts of the two protons. To confirm the pH dependence of the chemical shifts, the microscopic ionization constant (Fig. 8) were calculated using a method described by Rabenstein[10] (Table 3).

Rotational Isomerism. In order to discuss the conformation of the entire glutathione molecule, the populations of the rotamers for cysteine and glutamic acid residues were calculated separately.***

** In the case of the H_2O solution, above pH 7.5 the CH_2 protons of glycine also give a singlet as a result of the averaging of conformations due to the fast exchange of peptide protons.

*** The population of rotational isomers was obtained by following the procedure originally used by Pachler.[1] The scope and limitations of this method, especially in the case of simple amino acids, have been discussed previously.[2]

Rotamers for Glutamic Acid Residue. In this part of glutathione, nine rotamers have to be considered (Fig. 9). From the experimental data, $J_{\alpha\gamma}\cong 0$. Thus, it is not possible to find the relative conformations of the α and γ protons from the J value. We will calculate the populations of the I, II, and III rotamers (Fig. 10a) and, independently, the populations of 1, 2, and 3 rotamers (Fig. 10b).

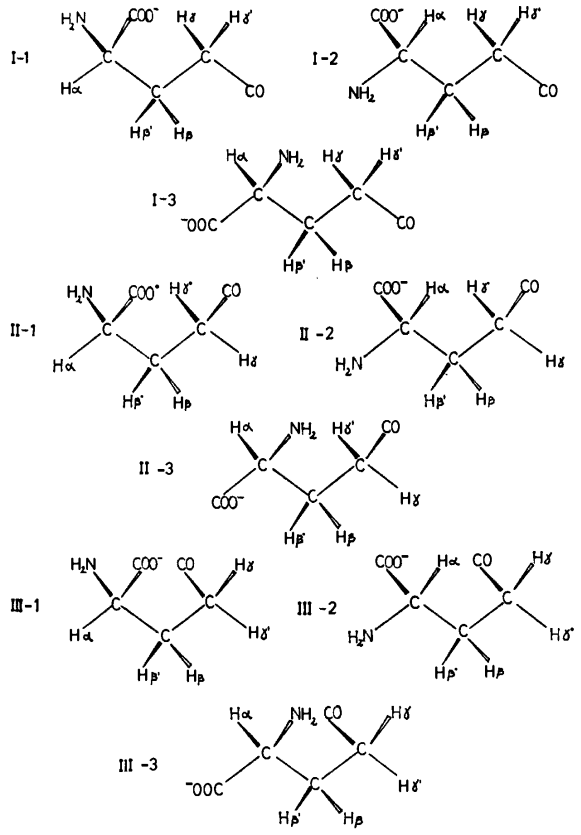

Fig. 9. Nine rotational isomers of the glutamic acid residue.

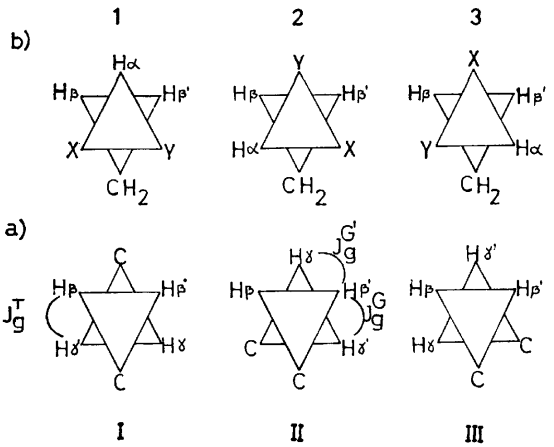

Fig. 10. The partial rotamers of glutamic acid:
a) for β and γ carbons
b) for α and β carbons.
X and Y are the carboxyl and amino groups, respectively.

Rotamers I, II, and III. We will approximate this unit in the glutamic residue as a substituted ethane. For the estimation of an average vicinal coupling constant, it may be possible to use the Abraham and Pachler empirical equation;[16]

$$J_{av} = 17.96 - 0.796 \sum_{i=1}^{6} E_i \qquad (1)$$

where E_i is the Huggins electronegativity of atoms attached to the ethyl carbons. From this equation, $J_{av}\cong 7.1$. Equation 1, however, is only a general expression for the relation between the electronegativity and J_{vic}, and it seems more reasonable to use the experimental data for the estimation of J_{av}. At pH 0.7, all four J values are almost equal to each other within the limits of experimental error, and $J_{av}=7.41$. Because there are two different sets of J values, we rewrite: $J_{\beta\gamma}=J_{\beta'\gamma'}=J'$ and $J_{\beta\gamma'}=J_{\beta'\gamma}=J$, and, if $N=J+J'$ and $L=J-J'$, we obtain another expression for the J_{av};

$$\begin{aligned} J_{av} &= 1/3(3/2N+1/2L) \\ &= 1/3(2J+J') \\ &= 1/3(J_t+2J_g) \end{aligned} \qquad (1')$$

and $J_{av}=7.43$ Hz if $(3/2N+1/2L)=22.3$. For further discussion, $J_{av}=7.4$ Hz will be used. The vicinal coupling constants, $J_{\beta\gamma}$, $J_{\beta\gamma'}$, $J_{\beta'\gamma}$, and $J_{\beta'\gamma'}$ for this system (Fig. 10a) are given by the following equations:

$$\begin{aligned} J_{\beta\gamma} &= p_I J_t + p_{II} J_g^{\,G} + p_{III} J_g^{\,G} \\ J_{\beta'\gamma'} &= p_I J_t + p_{II} J_g^{\,G} + p_{III} J_g^{\,G} \\ J_{\beta\gamma'} &= p_I J_g^{\,T} + p_{II} J_t + p_{III} J_g^{\,G'} \\ J_{\beta'\gamma} &= p_I J_g^{\,T} + p_{II} J_g^{\,G'} + p_{III} J_t, \end{aligned} \qquad (2)$$

where p_I, p_{II}, and p_{III} are the populations of the I, II, and III rotamers and $J_g^{\,T}$, $J_g^{\,G}$, and $J_g^{\,G'}$ are as defined in Fig. 10a. From the Eq. 2 one can see directly that, for any values of p_I, p_{II}, and p_{III}, $J_{\beta\gamma}=J_{\beta'\gamma'}$. This results is in agreement with the results of the analysis. Also from these results, $J_{\beta\gamma'}=J_{\beta'\gamma}$; hence, $p_{II}=p_{III}$. The fact that the populations of both rotamers of the gauche form are equal to each other agrees with the results obtained for simple 1,2-disubstituted ethanes.[17,18] This appears to justify our assumption that the $-CH_2-CH_2-$ unit in glutamic acid can be considered as a substituted ethane.

Equation 2 may be simplified to this form:

$$J' = J_{\beta\gamma} = J_{\beta'\gamma'} = p_{\mathrm{I}}J_{\mathrm{t}} + 2p_{\mathrm{II}}J_{\mathrm{g}}^{\mathrm{G}}$$
$$J = J_{\beta\gamma'} = J_{\beta'\gamma} = p_{\mathrm{I}}J_{\mathrm{g}}^{\mathrm{T}} + p_{\mathrm{II}}(J_{\mathrm{g}}^{\mathrm{G}'} + J_{\mathrm{t}}) \quad (2')$$

To estimate populations, it is necessary to have the values of $J_{\mathrm{g}}^{\mathrm{T}}$, $J_{\mathrm{g}'}^{\mathrm{G}}$ and $J_{\mathrm{g}}^{\mathrm{G}'}$ ($J_{\mathrm{g}}^{\mathrm{T}} > J_{\mathrm{g}}^{\mathrm{G}} > J_{\mathrm{g}}^{\mathrm{G}'}$ [17]).

Table 4. Populations of the I, II, and III rotamers of the glutamic acid residue

pH	$\bar{p}_{\mathrm{I}}$	$\bar{p}_{\mathrm{II}}$	Δp_{II}	$3/2N+1/2L$
2 M NaOH	0.60	0.20	0.01	21.60
12.8	0.59	0.20	0.01	21.77
9.58	0.48	0.26	0	22.11
9.1	0.42	0.29	0	22.56
8.05	0.40	0.30	0.01	22.78
7.75	0.40	0.30	0	22.53
4.5	0.40	0.30	0.01	22.58
2.95	0.39	0.30	0.01	22.86
2.51	0.39	0.30	0.01	22.58
2.02	0.36	0.32	0.01	22.64
1.2	0.34	0.33	0	22.25
0.7	0.34	0.33	0	22.20
6 M DCl	0.34	0.33	0	22.32

From Table 4 it can be seen that, with an increase in pH, the J' value also increases. According to Equations 2', this result implies that there is an increase in the population of a trans isomers (p_{I}). Thus, if the $J_{\mathrm{g}}^{\mathrm{T}}$ values is sufficiently higher than that of $J_{\mathrm{g}}^{\mathrm{G}}$ and $J_{\mathrm{g}'}^{\mathrm{G}'}$ the values $(3/2N+1/2L)=(J'+2J)$ should steadily increase with an increase in p_{I}. In the present case, these values are almost constant at all pH values, equal to 22.2 ± 0.6 Hz. The deviation may be attributed to the experimental error. However, the deviation of this range may be caused by a small cahnge in the nature of the medium, such as the dielectric field in the solution, or the dissociation of functional groups of the glutathione. $J_{\mathrm{g}'}^{\mathrm{T}}$, $J_{\mathrm{g}'}^{\mathrm{G}}$, or $J_{\mathrm{g}}^{\mathrm{G}}$ should be constant throughout the pH rang examined. Therefore, it seems reasonable to put one J_{g} value into Eq. 2'. By combining Eqs. 2' and 3:

$$p_{\mathrm{I}} + 2p_{\mathrm{II}} = 1 \quad (3)$$

the following expressions can be obtained:

$$\text{from } J': \quad p_{\mathrm{I}} = (J'-J_{\mathrm{g}})/(J_{\mathrm{t}}-J_{\mathrm{g}}), \quad p_{\mathrm{II}} = 1/2(J_{\mathrm{t}}-J')/(J_{\mathrm{t}}-J_{\mathrm{g}}), \quad (4)$$

$$\text{from } J': \quad p_{\mathrm{I}} = (J_{\mathrm{t}}+J_{\mathrm{g}}-2J)/(J_{\mathrm{t}}-J_{\mathrm{g}}), \quad p_{\mathrm{II}} = (J-J_{\mathrm{g}})/(J_{\mathrm{t}}-J_{\mathrm{g}}). \quad (4')$$

In order to determine J_{t} and J_{g} in addition to J_{av}, it is necessary to assume the $J_{\mathrm{t}}/J_{\mathrm{g}}$ ratio, for which we will take a common value of 5.2[1,2,9,20] ($J_{\mathrm{t}}/J_{\mathrm{g}}=5.6$ for pure ethane[19]) for all α-amino acids. The result is that $J_{\mathrm{t}}=16.03$ Hz and $J_{\mathrm{g}}=3.08$ Hz. From Eqs. 4 and 4' we can determine two sets of p_{I} and p_{II} values, using the J' or J spin-coupling constant. The very good agreement between the two sets of p_{I} and p_{II} populations confirms that, at least for a qualitative discussion, the present assumptions are sufficiently correct. The average values, $\bar{p}_{\mathrm{I}}$ and $\bar{p}_{\mathrm{II}}$, and the deviation of $\bar{p}_{\mathrm{II}}$ from the values obtained using Figs. 4 and 4' are given in Table 4.† $J_{\alpha\beta}$ changes only slightly from about 6.3 Hz in the pH range 2.9—8.05 to about 6.6 Hz for pH values lower than 0.7 and higher than 11. Using the J_{t} and J_{g} values estimated for simple amino acids,[1,2,9] it is easy to find that, in the region of pH 2.9—8.05, all three rotamers, 1, 2, and 3 (Fig. 10b), have the same population. In other pH regions there is some excess of the 2 and 3 rotamers over the 1 rotamer, the populations being 0.36, 0.36, and 0.28. The 2 and 3 rotamers cannot be distinguished from one another because the observed spectrum is of the A_2X type. (We can determine only the average value of $J_{\alpha\beta}$).

Cysteine Residue. Using $J_{\mathrm{g}}=2.6$ Hz, $J_{\mathrm{t}}=13.6$ Hz, and $J_{\mathrm{av}}=6.3$ Hz, the populations of the three *a*, *b*, and *c* rotamers (Fig. 6) can be obtained (Table 5). However, it is not possible to distinguish the A and B protons in this experiment. Furthermore it is not certain which rotamer, *b* or *c*, is more stable. In the pH region where poorly resolved spectra are observed, $J_{\mathrm{AC}}=J_{\mathrm{BC}}=6.3$ Hz and $a=b=c=1/3$.

Discussion

Glutamic Acid Residue. The I-1, 2, and 3 rotamers appear to be stable with respect to the interaction of the two terminal functional groups of this residue with the peptide linkage between glutamic and cysteine parts. In gauche isomers (II, III), the II-1 rotamer appears to be the least stable because of the electrostatic interaction of the carboxyl and ammonium group with the peptide backbone, especially with the carbonyl group. For a similar reason, the III-2 isomer seems to be less stable. At pH<2, the total population of the gauche form is large in comparison to the trans one (I), and this interaction with the peptide-bond group induces an observable difference in the populations of the 1, and 2, and 3 rotamers. It is also likely that there exists some difference in population of the II-2 and II-3 rotamers, and so on, but the fast interconversion between the two isomers of the gauche form (II and III) (*e.g.*, II-2—III-2) makes it impossible to distinguish them.††

The dissociation of the COOH group to COO^- which occurs between pH 0.7—2.95 makes this interaction stronger because of the excessive negative charge on the carboxyl group, and some increase in the population of the trans (I) form has been observed. In the pH range of 8—11, where the dissociation of the NH_3^+ group occurs, an additional negative charge on the glutamic terminal causes an other increase in the population of the trans (I) isomer, for the same reason. The rotamers stable at pH values higher than 11 are I-1, 2, and 3, and the gauche forms, II-2 and III-3. The least stable should be II-1 and III-1.

At pHs below 2.5 and pHs higher than 9, the unequal populations of the 1, 2, and 3 rotamers distinguish the chemical shifts of β and β', while at pHs below 2.5 the chemical shifts for γ and γ' protons can be differentiated. The interaction of the carboxyl and the ammonium groups with the γ and γ' protons is more effective in the gauche form of the unit considered, and at high pHs probably a smaller population of this form causes $\Delta_{\gamma\gamma'}$, to equal 0. To explain this, more accurate populations of the particular rotamers, II-1—III-3, have to be known.

Cysteine. Below pH 8, $a=b=c=1/3$. When the

† The $\bar{p}$ values are the average values of the populations obtained from Eqs. 4 and 4'.

†† In this case, a more complex intercoversion between the 1, 2, 3 and I, II, III rotamers should be considered.

Table 5. Populations of the cysteine residue rotamers

pH	a	b(or c)	c (or b)
2 M NaOH	0.29	0.48	0.23
12.95	0.29	0.50	0.21
12.8	0.30	0.48	0.22
12.4	0.29	0.50	0.21
10.9	0.30	0.49	0.21
9.5	0.30	0.49	0.21
9.1	0.31	0.48	0.21
8.8	0.32	0.46	0.22
<8	$a \cong b \cong c \cong 0.33$		

SH group dissociates to S^-, the spectra are better resolved (ABC type) and a more detailed population of the three rotamers (a, b, and c) can be found (Table 5, Fig. 6). The smallest change of the population is observed for the a rotamer, where the population is decreased from 0.33 to about 0.29. This result means that the most stable rotamer after the dissociation of the SH group is the one in which the position of S is trans to the cysteine peptide nitrogen or the carbonyl peptide group.

From all these considerations it seems that a peptide linkage between glutamic acid and cysteine, and the interaction of the carbonyl group in the peptide linkage with the changes in the functional groups of the glutamic residue are important for the conformational equilibrium in solution. Thus, the most stable conformer after the complete dissociation of the peptide molecule is the one in which the COO^- and NH_2 groups of the glutamic acid residue are far from the peptide backbone of the glutathione.

We wish to thank Dr. Yoji Arata, Dr. Hidehiro Ishizuka and Dr. Akira Yamasaki for their helpful discussion and help during the analysis of the NMR spectra.

Nuclear Quadrupole Resonances of $AlBr_3 \cdot SbBr_3$, $AlI_3 \cdot SbI_3$, and $AlBr_3 \cdot BiBr_3$

Tsutomu OKUDA, Koji YAMADA, Hideta ISHIHARA, and Hisao NEGITA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730

(Received May 30, 1977)

The quadrupole coupling constants (e^2Qq/h) and the principal axes of electric field gradient (efg) at ^{81}Br, ^{127}I, ^{27}Al, ^{121}Sb, and ^{209}Bi in $AlBr_3 \cdot SbBr_3$, $AlI_3 \cdot SbI_3$, and $AlBr_3 \cdot BiBr_3$ were determined by means of NQR or NMR, in order to clarify the structures and chemical bonds of these compounds. The NQR spectra of $AlBr_3 \cdot SbBr_3$ and $AlI_3 \cdot SbI_3$ resemble each other and these two compounds consist of V-shaped SbX_2^+ and distorted tetrahedral AlX_4^- ions (X=Br and I). However, there are weak bonds between the Sb atom in SbX_2^+ and the halogens in AlX_4^- ion. The V-shaped SbX_2^+ has the bond angle 97.3° for the bromide and 99.0° for the iodide. The orientation of the efg axes at the ^{121}Sb atom suggests that the antimony atom has a lone pair of electrons in the opposite direction to the bisector of the two Sb–X bonds. On the other hand, only one terminal bromine atom bonded to the Bi atom was found for $AlBr_3 \cdot BiBr_3$.

The formation of the 1:1 adducts between trihalides of the metals of group III and V such as $AlX_3 \cdot SbX_3$ or $GaX_3 \cdot SbX_3$ (X=Cl, Br, or I) has been reported in the literature.[1-3] According to the electron diffraction study, $AlBr_3 \cdot SbBr_3$ has an ethane-like structure (Br_3Sb–$AlBr_3$) in the gaseous state.[4] In the solid state, however, no crystal structure for these compounds has been reported so far. Recently, Chemouni and Potier studied vibrational spectra of the $GaX_3 \cdot SbX_3$ (X=Cl, Br, or I) compounds in the solid state and concluded that the bridging structure (X_2Sb–X–GaX_3) is more probable than the ethane-like structure (X_3Sb–GaX_3).[5]

In the present investigation we discuss the structure and chemical bonds for the adducts $AlBr_3 \cdot SbBr_3$, $AlI_3 \cdot SbI_3$, and $AlBr_3 \cdot BiBr_3$, on the basis of the quadrupole coupling constants and the orientation of the principal axes of the electric field gradient (efg). A part of this work has already been reported elsewhere.[6]

Experimental

Adducts $AlBr_3 \cdot SbBr_3$, $AlI_3 \cdot SbI_3$, and $AlBr_3 \cdot BiBr_3$ were prepared from the stoichiometric mixture of the relevant halides in a sealed tube and crystallized slowly from the melt. The single crystals of these compounds were grown by the Bridgman-Stockbarger method. The NQR spectrometer was a super-regenerative type, and signals were observed on an oscilloscope. The Zeeman effect on the NQR was examined by means of the zero-splitting cone method.[7] The quadrupole coupling constants of ^{27}Al were determined by use of a broad line NMR spectrometer operated at 13.000 MHz. Using single crystals of these compounds, the shift of the central line ($-1/2 \leftrightarrow +1/2$) due to the second order quadrupole effect were observed and analyzed by the Volkoff method.[8,9]

TABLE 1. NQR PARAMETERS OF $AlBr_3 \cdot SbBr_3$, $AlI_3 \cdot SbI_3$, AND $AlBr_3 \cdot BiBr_3$ (296 K)

Compound		ν_1/MHz	ν_2/MHz	ν_3/MHz	ν_4/MHz	$\eta^{a)}$	$\eta^{b)}$	e^2Qq/h/MHz

	Br(6)	148.30				0.027		296.6

a) These values were determined by Zeeman effect experiments.

b) These values were determined by the use of frequency ratios, ν_1/ν_2.

Results and Discussion

Tables 1 and 2 show the quadrupole coupling constants (e^2Qq/h) and the asymmetry parameter (η) of the efg tensors observed for ^{81}Br, ^{121}Sb, ^{127}I, ^{209}Bi, and ^{27}Al. These parameters were determined by NQR or NMR experiments using single crystals. The NQR lines of ^{79}Br and ^{123}Sb were also observed at the frequencies expected from the quadrupole moment ratios, $Q(^{79}Br)/Q(^{81}Br)=1.1971$ and $Q(^{123}Sb)/Q(^{121}Sb)=1.2748$.

Table 2. Quadrupole coupling constants for ^{27}Al

Compound	e^2Qq/h/MHz	η	Temp/K
$AlBr_3 \cdot SbBr_3$	7.2±0.1	0.56±0.03	295
$AlI_3 \cdot SbI_3$	5.7±0.1	0.55±0.03	285

$AlBr_3 \cdot SbBr_3$. It is apparent from Table 1 that the bromine atoms are divided into two groups. The first group contains Br(1), Br(2), Br(3), and Br(4), and the second group Br(5) and Br(6). Bromine atoms in the first group have large η values and their e^2Qq/h values are approximately the same as those of $AlBr_4^-$ in $MAlBr_4$ (M=Li, Na, or Cs).[9] These four Br atoms can be assigned to $AlBr_4^-$ ions in the present compound, although most of them have strong interactions with neighboring atoms. Bromine atoms in the second group have very small η values and slightly higher quadrupole coupling constants than those due to the bromines in $SbBr_3$.[10] On the basis of these parameters, Br(5) and Br(6) are considered to form bonds with an antimony atom and they have no interactions with other neighboring atoms, thus differing from the Br atoms in the $SbBr_3$ crystal. Figure 1 shows the zero-splitting patterns which are considered to arise from the Sb and Br atoms in one $SbBr_2$ unit. In practice, however, a pair of zero-splitting patterns was observed for each resonance line; these patterns were symmetrical with respect to the b-axis because of the monoclinic system. It is reasonable to assume that the efg z-axis of the Br(5) or Br(6) atom lies along its Br–Sb bond because of the small η. The bond angle $\angle$BrSbBr determined in this way is 97.3°, which is nearly equal to that of the $SbBr_3$ crystal. In the case of ^{121}Sb ($I=5/2$), the locus of the zero-splitting for ν_1 is formed around

Table 3. NQR parameters of $SbBr_3$, SbI_3, and $BiBr_3$

	^{209}Bi	82.8	266.6	289	18

a) Averaged values of three resonance lines.

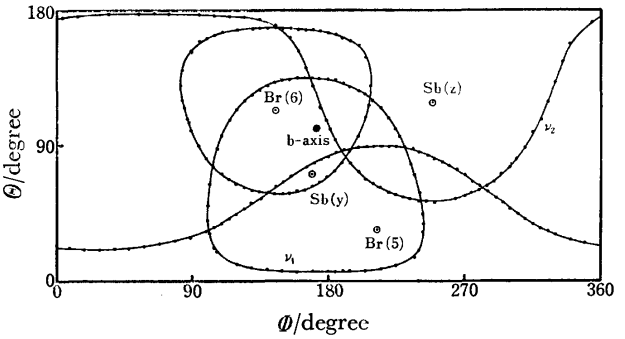

Fig. 1. Zero-splitting loci for the $^{81}Br(5)$, $^{81}Br(6)$, $^{121}Sb(\pm1/2\leftrightarrow\pm3/2)$, and $^{121}Sb(\pm3/2\leftrightarrow\pm5/2)$ lines in the $AlBr_3 \cdot SbBr_3$ crystal at room tempreature. In practice a pair of zero-splitting patterns was observed for each resonance line symmetrically with respect to the b-axis because of the monoclinic system. ⊙: efg axis.

the y-axis of the efg tensor and that of ν_2 is formed around the z-axis when η is greater than 41.2%.[11,12] Therefore, it is apparent from Fig. 1 that the z-axis of this antimony atom is almost perpendicular to the Br–Sb–Br plane and the y-axis is parallel to the bisector of the two Sb–Br bonds. Table 4 shows the angles between their efg axes determined by the Zeeman effect of NQR. Furthermore, the large values of η and e^2Qq/h of the antimony atom also support the existence of the V-shaped $SbBr_2$ unit. Figure 2 shows the orientation of the efg axes of this antimony atom as compared with that of the bridging Br atom existing in Al_2Br_6[13] or KAl_2Br_7.[9] This figure shows that the x-axis and y-axis of these two bridging atoms are reversed, although their bond angles are nearly equal to each other. The efg axes for the bridging Br atom have been explained by assuming that the Br atom forms sp^3 hybridized orbitals with two lone pair orbitals.[14,15] On the other hand, in order to explain the reversed orientation of the x- and y-axes at the Sb atom, sp^2 hybridized orbitals

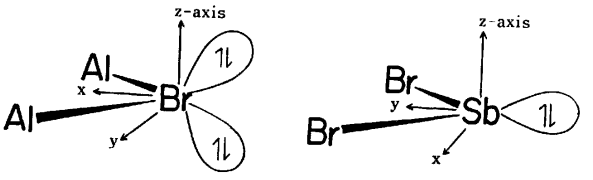

Fig. 2. efg axes with respect to the bridging plane. (a) Bridging Br atom in the Al_2Br_6 crystal and (b) antimony in the $SbBr_2^+$ ion.

with C_{2v} symmetry are adopted by assuming no hybridization of the d orbitals. The orthonormal orbitals at the Sb atom are expressed as follows:

$$\phi_1 = \psi_z,$$
$$\phi_2 = \alpha\psi_s - (1-\alpha^2)^{1/2}\psi_y,$$
$$\phi_3 = (2)^{-1/2}\{(1-\alpha^2)\psi_s + \alpha\psi_y - \psi_x\},$$
$$\phi_4 = (2)^{-1/2}\{(1-\alpha^2)\psi_s + \alpha\psi_y + \psi_x\},$$

with $$\alpha = \cot 2\gamma,$$

where ψ_s, ψ_x, ψ_y, and ψ_z are the 5s, $5p_x$, $5p_y$, and $5p_z$ orbitals of the antimony atom and 2γ is the bond angle ∠BrSbBr. The ∠BrSbBr angle was determined to be 97.3° by measuring the ^{81}Br Zeeman effect. The lone pair orbital ϕ_2 contains two electrons and has a large portion of s orbital; the electrons can be regarded as an inert pair of the Sb atom. The sigma-bonding orbitals ϕ_3 and ϕ_4 are used to form bonds with two Br atoms. The populations of these orbitals are roughly estimated to be 0.55 from the ionic character of the Sb–Br bond, which was determined by the NQR parameters of ^{81}Br by assuming 15% s-electron character for the bonding orbital of the Br atom. Then, the populations of the orbitals ϕ_1, ϕ_2, and ϕ_3 $(=\phi_4)$ are

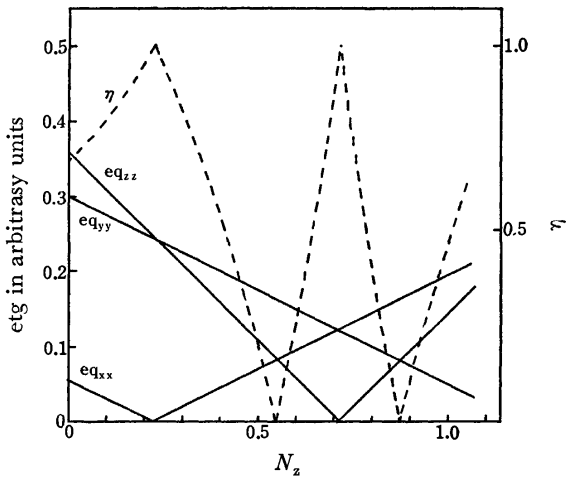

Fig. 3. Dependence of the efg at the Sb site on the population of the ϕ_1 orbital. If the population is smaller than 0.23, the observed orientation of the efg axes is consistent with this calculation.

assumed to be N_z, 2, and 0.55, respectively. Using the Townes-Dailey theory, the efg at the Sb site can be expressed as a function of N_z, where x-, y-, and z-axes are chosen as shown in Fig. 2. At N_z=0.11, the observed asymmetry parameter and the orientation of the efg tensor could be explained satisfactorily. This electronic configuration is consistent with that expected from the $SbBr_2^+$ ion, because the outer electron configuration of the Sb^+ ion is $5s^25p^2$. Further calculation is obstracted because of the lack of accurate information on the crystal structure and the quadrupole coupling constant for a 5p electron of antimony.

Figure 4 shows the zero-splitting patterns of the Br(1)—Br(4). The angles between their z-axes are distributed from 103.9 to 118.1°. This fact suggests the existence of a distorted tetrahedral $AlBr_4^-$ ion, although their efg z-axes somewhat deviate from the Br–Al bond axes because of the large η value. Figure 5

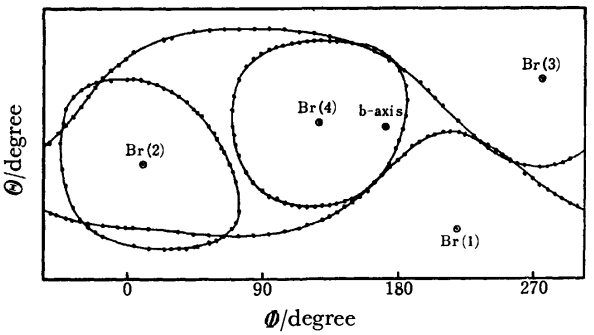

Fig. 4. Zero-splitting loci for the ^{81}Br(1)—Br(4) lines in the $AlBr_3 \cdot SbBr_3$ crystal. In practice a pair of zero-splitting patterns was observed for each resonance line symmetrically with respect to the b-axis. ⊙: efg axis.

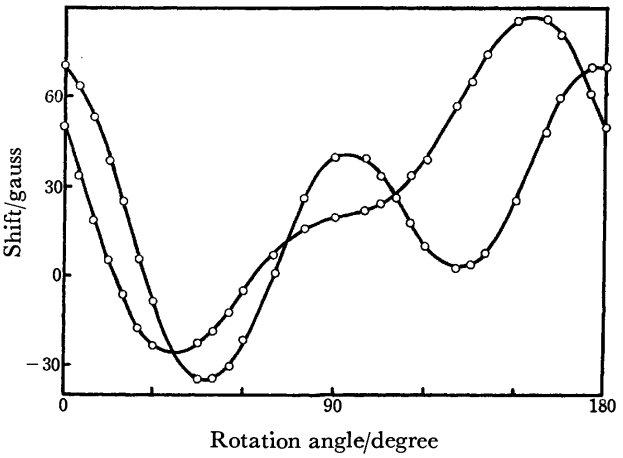

Fig. 5. The second order quadrupole effect in ^{27}Al NMR for the $AlBr_3 \cdot SbBr_3$ crystal.

shows the ^{27}Al NMR rotation pattern of the central line $(-1/2 \leftrightarrow +1/2)$, and in this case the rotation axis was arbitrarily chosen. Because of the monoclinic system, two central lines corresponding to different orientations of their efg tensors were observed. The e^2Qq/h and η thus obtained also support the distortion of the $AlBr_4^-$ ion from the regular tetrahedron, but the e^2Qq/h value is smaller than that of tetrahedrally bonded aluminum in the Al_2Br_6[14] or KAl_2Br_7[9] crystal.

From these findings it seems reasonable to propose that the $AlBr_3 \cdot SbBr_3$ crystal consists of the $SbBr_2^+$ and $AlBr_4^-$ ions and these ions are linked together by weak bonds between the Sb atom in $SbBr_2^+$ and the Br atom in $AlBr_4^-$. The lower population for the ϕ_1 orbital than ϕ_3 or ϕ_4 may suggest the existence of a weak bond between the Sb atom and the Br atom of the $AlBr_4^-$ ion. According to X-ray crystal analysis, similar structures are reported for $AlCl_3 \cdot ICl_3$,[16] $SbCl_5 \cdot ICl_3$,[16] and $AlCl_3 \cdot TeCl_4$.[17] These crystals consist of ion pairs, $AlCl_4^-ICl_2^+$, $SbCl_6^-ICl_2^+$, and $AlCl_4^-TeCl_3^+$, in which cations and anions are linked by weak bonds through the Cl atoms of the anions.

$AlI_3 \cdot SbI_3$. In the case of ^{127}I and ^{121}Sb (both I=5/2), a pair of NQR lines, $\nu_1(\pm 1/2 \leftrightarrow \pm 3/2)$ and $\nu_2(\pm 3/2 \leftrightarrow \pm 5/2)$, were observed. Zero-splitting patterns were observed for the six ν_1 transitions of the ^{127}I nuclei and for the ν_1 and ν_2 transitions of the ^{121}Sb nuclei.

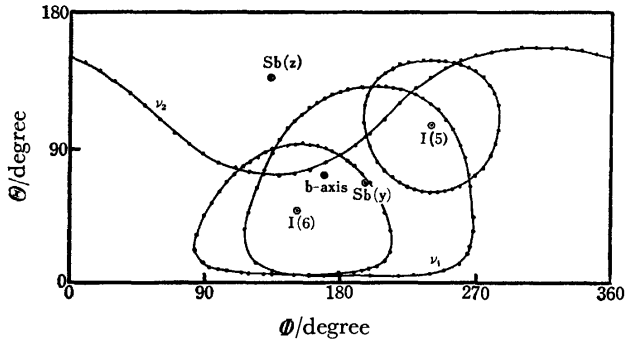

Fig. 6. Zero-splitting loci for the $^{127}I(5)$, $^{127}I(6)$, $^{121}Sb(\pm 1/2 \leftrightarrow \pm 3/2)$, and $^{121}Sb(\pm 3/2 \leftrightarrow \pm 5/2)$ lines in the $AlI_3 \cdot SbI_3$ crystal at room temperature. In practice a pair of zero-splitting patterns was observed for each resonance line symmetrically with respect to the b-axis because of the monoclinic system. ⊙: efg axis.

Therefore, the assignment of the pair ν_1 and ν_2 can be determined on the basis of the asymmetry parameter from the zero-splitting pattern. For the ^{127}I and ^{121}Sb nuclei the two values of the asymmetry parameter were independently calculated from the results of the Zeeman effect and from the frequency ratio of the pair, as shown in Table 1. The NQR parameters of this compounds are similar to that of the $AlBr_3 \cdot SbBr_3$ crystal, *i.e.*, this compound is expected to consist of the ion pair of SbI_2^+ and AlI_4^-. Figure 6 shows the zero-splitting patterns of $^{121}Sb(\pm 1/2 \leftrightarrow \pm 3/2)$, $^{121}Sb(\pm 3/2 \leftrightarrow \pm 5/2)$, $^{127}I(5)(\pm 1/2 \leftrightarrow \pm 3/2)$, and $^{127}I(6)(\pm 1/2 \leftrightarrow \pm 3/2)$, which arise from one SbI_2 unit. From the orientations of the efg tensors, the V-shaped SbI_2 unit has the geometry shown in Table 4. The z-axis of the Sb atom is almost perpendicular to the I–Sb–I plane, whereas the y-axis deviates about 7 degrees from the bisector of the two Sb–I bonds to the z-axis of the I(6) atom within the ISbI plane. This may be due to the fact that the two Sb–I bonds somewhat differ from each other, as is obvious from the e^2Qq/h of the I(5) and I(6) atoms.

$AlBr_3 \cdot BiBr_3$. The NQR spectra for this compound are different from those of the former compounds in the following points. (1) The asymmetry parameter of the ^{209}Bi atom is relatively small. (2) Only the Br(6) atom can be regarded as a terminal atom bonded to the Bi atom. (3) The Br(5) atom yields a somewhat smaller

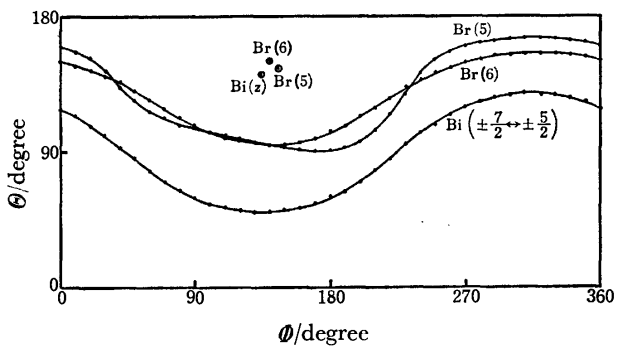

Fig. 7. Zero-splitting loci for the $^{81}Br(5)$, $^{81}Br(6)$, and ^{209}Bi $(\pm 5/2 \leftrightarrow \pm 7/2)$ lines in the $AlBr_3 \cdot BiBr_3$ crystal. ⊙: efg axis.

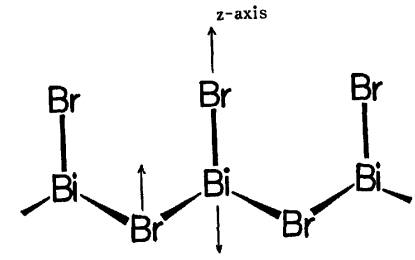

Fig. 8. Proposed structure for the $BiBr_2^+$ ion. The arrows indicate efg z-axes.

e^2Qq/h value compared with that of $BiBr_3$,[18] so that it must form a bridging bond of the type Bi–Br–Bi because of its large η.

Figure 7 shows the zero-splitting patterns of the ^{209}Bi $(\pm 7/2 \leftrightarrow \pm 9/2)$, $^{81}Br(5)$, and $^{81}Br(6)$ resonance lines. Each resonance line yields only one zero-splitting pattern. This fact suggests that the crystal belongs to a triclinic system. As is obvious from this figure, the z-axes of the three atoms are nearly parallel, within 9 degrees. On the basis of these findings, it is supposed that the $BiBr_2^+$ ions form a chain-like structure such as is shown in Fig. 8.

Polarized Absorption Spectra and Configuration Analyses of Xanthene and Xanthone

Tsuneyuki MINEGISHI, Toshihiko HOSHI,* Hiroshi HIRATSUKA, and Yoshie TANIZAKI

Department of Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo 152
** Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo 157*

(Received April 1, 1977)

The polarized absorption sepctra of xanthene and xanthone were measured in stretched poly(vinyl alcohol) films, and the polarization direction of each electronic transition was determined. It was confirmed that xanthone has the short molecular-axis polarized bands ($^1A_1 \leftarrow {}^1A_1$) at 343, 260, and 226 nm, and the long molecular-axis polarized ones ($^1B_2 \leftarrow {}^1A_1$) at 290, 266, and 242 nm. The electronic transitions of xanthone are discussed in connection with those of xanthene by use of the configuration analysis. For the 266 and 260 nm bands, the contributions of the intramolecular charge transfer character from the xanthene skeleton to the carbonyl group are considerable.

Derivatives of xanthone have been found as plant pigments and have received considerable attention because of their anomalous emission behavior. From lifetime and polarization measurements, it has been indicated that the configuration of the lowest triplet state of xanthone is $^3(n, \pi^*)$ type in a nonpolar solvent (3-methylpentane) but $^3(\pi, \pi^*)$ in a polar solvent.[1] The electronic absorption spectra of xanthone and its derivatives have been studied by several investigators,[1-3] but their assignments of the individual bands are different. For instance, Pownall and Huber[1] measured absorption and polarized phosphorescence spectra of xanthone, and they found five electronic bands at 364, 335, 282, 256, and 234 nm. The five bands were assigned to $^1A_2(n, \pi^*) \leftarrow {}^1A_1$, $^1A_1 \leftarrow {}^1A_1$, $^1B_2 \leftarrow {}^1A_1$, $^1A_1$-(CT)$\leftarrow {}^1A_1$, and $^1A_1 \leftarrow {}^1A_1$ transitions in order of increasing energy. From the measurements of absorption and fluorescence spectra and PPP calculations, Mizutani *et al.*[2] have also discussed the electronic structure of xanthone and its hydroxy and methoxy derivatives, and reported that there are a few discrepancies between their results and the above-mentioned ones.[1]

In this paper, measurements of polarized absorption spectra using stretched poly(vinyl alcohol) films and PPP calculations for xanthene and xanthone have been performed, and the electronic spectrum of xanthone is analyzed in connection with that of xanthene by use of the method of configuration analysis developed by Baba *et al.*[4]

Experimental

Materials. Commercially available (Tokyo Kasei Co., Ltd.) xanthene and xanthone were purified by repeated recrystallizations from ethanol. The melting point of xanthene was 99—100.2 °C (lit,[9] 99 °C) and that of xanthone 173.6 °C (lit,[9] 174 °C).

Measurements and Notations Used. The polarized absorption spectra were measured with a Shimadzu QV-50 spectrophotometer.[5-7]

The notations used in the figures of the polarized absorption spectra are as follows: R_s is a ratio of stretching,[5] $D_{//}$ and $D_\perp$ are absorbances for the light polarized parallel to and perpendicular to the stretched direction of the film, respectively, and R_d is the ratio of the optical densities ($R_d = D_{//}/D_\perp$).

In the case of planar molecules belonging to the point group C_{2v}, D_2, D_{2h} *etc.*, we can obtain a reduced polarization spectrum using the above-mentioned R_s and R_d values, *i.e.*, the absorption spectrum in a non-stretched polymer film can be reduced into two component spectra which are polarized parallel (D_z) to and perpendicular (D_y) to the principal symmetry axis (z).

Calculations

In the MO calculations, a modified PPP method developed by Nishimoto and Förster[8] was employed. The valence state ionization potentials ($I_p(r)$) and electron affinities ($E_a(r)$) used are as follows: $I_p(C) = 11.42$, $E_a(C) = 0.58$, $I_p(-O-) = 32.9$, $E_a(-O-) = 13.37$, $I_p(=O) = 23.7$, and $E_a(=O) = 2.47$ eV. The resonance integrals (β_{rs}) were adjusted at every iteration of the SCF calculations by the equations[8]

$$\beta_{CC} = -0.51 p_{CC} - 1.84,$$
$$\beta_{CO} = -0.56 p_{CO} - 2.20.$$

Here, p_{rs} is a π-bond order between the atoms r and s. In the CI calculations, all the one-electron excited configurations among the upper five occupied and lower five unoccupied SCF orbitals were taken into account.

It is very interesting for chemists to know the origin of the elctronic transitions more quantitatively. The configuration analysis developed by Baba and his coworkers[4] may be one of the most useful methods for this purpose. According to their method, any state function Ψ can be developed in terms of reference wavefunctions (Ψ°) appropriately chosen,

$$\Psi = \Psi^\circ M,$$

where M is a transformation matrix and the square of the matrix element (M_{ji}) of M represents the degree of contribution of a reference wavefunction Ψ_i° to the resultant wavefunction Ψ_j under consideration.

Results and Discussion

Figure 1 shows the polarized absorption spectrum of xanthene in the stretched poly(vinyl alcohol) film. The absorption spectrum ($D_{//}$ or $D_\perp$ curve) of this compound consists of three apparent bands at 294, 252, and ≈215 nm. The R_d values for the 252 nm band are large compared with those of the 294 nm band. This indicates that the relatively intense 252 nm band is polarized along the long molecular-axis (y-axis) and 294 nm

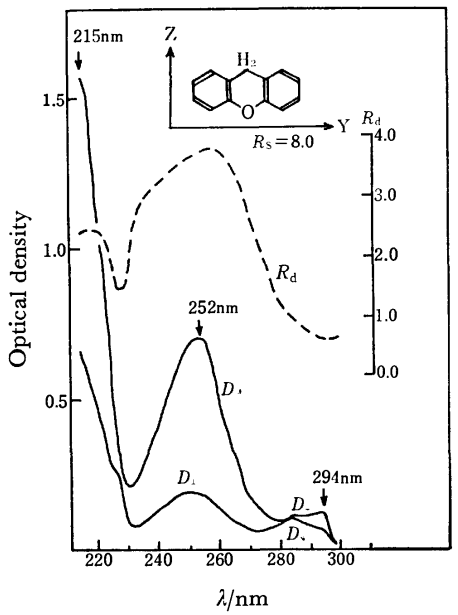

Fig. 1. The polarized absorption spectrum of xanthene in the stretched poly(vinyl alcohol) film.

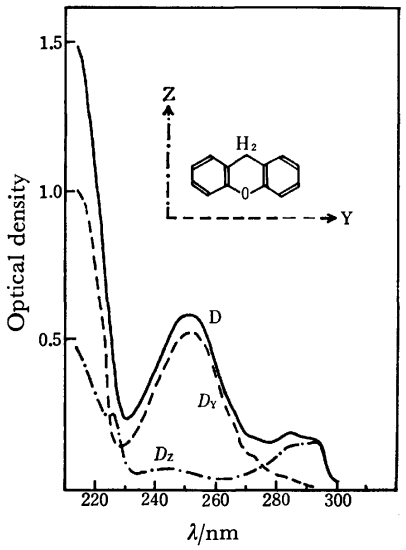

Fig. 2. The reduced polarized absorption spectrum of xanthene. D: The absorption spectrum in the non-stretched poly(vinyl alcohol) film. D_y and D_z: The reduced polarization spectrum.

band along the short-axis (z). The behavior of the R_d curve suggests the presence of additional weak bands at 285 and 226 nm, that is, the R_d values are steeply increased with decreasing wavelength around 285 nm and a distinct minimum is found at 226 nm. To determine in more detail the locations of these hidden bands, we obtained the reduced polarization spectrum, which is shown in Fig. 2. From this figure, it is clearly seen that the z-axis polarized bands are at 294 and 226 nm and the y-axis polarized ones are at 285, 252, and around 215 nm.

The above experimental results are compared with calculated ones in Table 1. From this table, it is clear that the observed 294 and 226 nm bands can be assigned

Table 1. Comparison of the observed and calculated transition energies, intensities, and polarizations for xanthene

Symmetry	Transition energy (nm) Calcd	Obsd[a]	Intensity Calcd(f)	Obsd(ε)[b]	Polarization Calcd	Obsd
I A_1	287	294	0.016	1900	z	z

to $^1A_1 \leftarrow {}^1A_1$ transitions and the observed 285 and 252 nm bands to $^1B_2 \leftarrow {}^1A_1$.

Figure 3 shows the polarized absorption spectrum of xanthone. The spectrum of this compound is very complex, *i.e.*, four apparent peaks are found at 343, 290, 266, and 242 nm besides a shoulder around 235 nm. The R_d curve shows clear maxima at 290 and 242 nm and a shoulder at 266 nm, indicating that the 290, 266, and 242 nm bands are polarized along the long molecular-axis (y). On the other hand, the 343 nm band is polarized along the short molecular-axis (z), because the R_d values for this band are the smallest in the observed wavelength region. The R_d values decrease steeply on both sides of the intense 242 nm band and a clear minimum is found around 254 nm. This indicates that weak bands polarized along the short molecular-axis are hidden at about 254 and 220 nm.

Figure 4 shows the reduced polarization spectrum of xanthone. From this figure the location of each band including above-mentioned hidden bands can be clearly seen. That is, the long molecular-axis polarized bands

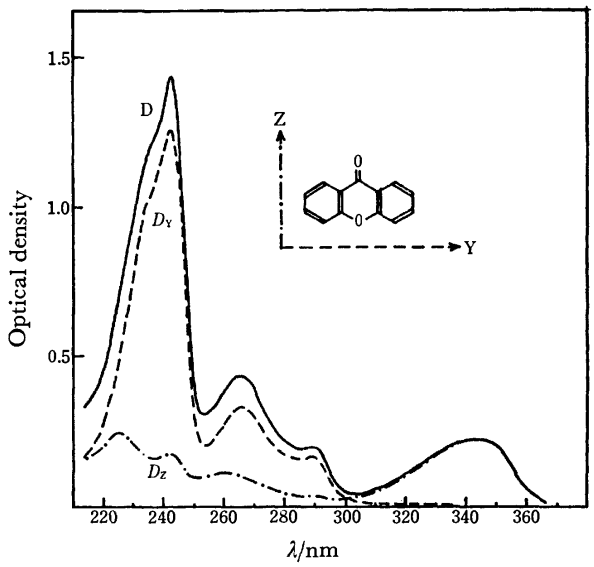

Fig. 4. The reduced polarized absorption spectrum of xanthone. Notations used: *cf.* Fig. 2.

are found at 290, 266, and 242 nm, and the short molecular-axis polarized ones at 343, 260, and 226 nm. From the above experimental results, the z-axis polarized 343 and 260 nm bands can be assigned to the $^1A_1 \leftarrow {}^1A_1$ transitions, and the y-axis polarized 290, 266, and 242 nm bands to $^1B_2 \leftarrow {}^1A_1$, as shown in Table 2. This assignment is not always consistent with the previously reported assignments.[1] For instance, the relatively intense 266 and 242 nm bands were earlier assigned to $^1A_1 \leftarrow {}^1A_1$ transitions.[1]

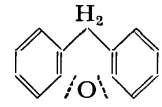
Configuration Analysis. State wavefunctions of a molecule can be developed in terms of wavefunctions of an appropriately chosen reference molecule. In the case of xanthene, we have chosen the structure of the reference molecule as



The results of the configuration analysis are shown in Fig. 5. From this figure, it is clear that the state wave-

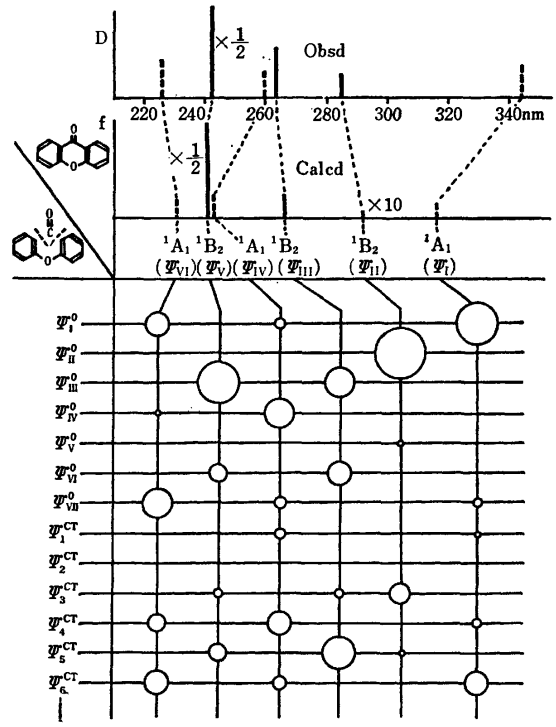


Fig. 6. Results of the configuration analysis of xanthone. See the explanation of Fig. 5, where Ψ_i^{CT} stands for wavefunction for the charge transfer state from xanthene skeleton to the carbonyl group.

functions Ψ_{I}, Ψ_{II}, Ψ_{III}, and Ψ_{IV} are approximately represented by the state functions Ψ_{I}°, Ψ_{II}°, Ψ_{III}°, and Ψ_{IV}° of the reference molecule, respectively. That is, it may be considered that the first two transitions ($\Psi_{I}\leftarrow\Psi_{0}$ and $\Psi_{II}\leftarrow\Psi_{0}$) arise from the interaction between the $^{1}L_{b}$ states of the two benzene rings and the next two transitions ($\Psi_{III}\leftarrow\Psi_{0}$ and $\Psi_{IV}\leftarrow\Psi_{0}$) from the two $^{1}L_{a}$ states.

As for xanthone, the excited state wavefunctions were developed in terms of the wavefunctions of xanthene (reference molecule) as shown in Fig. 6. The transitions I(Ψ_{I}), II(Ψ_{II}), and V(Ψ_{V}) of xanthone are approximately represented by the transitions I(Ψ_{I}°), II(Ψ_{II}°), and III(Ψ_{III}°), respectively. Transition III(Ψ_{III}) is considered to be due to the interaction of Ψ_{III}°, Ψ_{VI}°, and Ψ_{CT5}°, and transition IV(Ψ_{IV}) due to the interaction of Ψ_{IV}° and Ψ_{CT4}°, where Ψ_{CT}°'s represent the charge transfer configuration from the xanthene skeleton to the carbonyl group. Transitions III and IV of xanthone observed at 266 and 260 nm may be considered to be charge transfer bands. As for this molecule, charge transfer configurations from the C=O group to the xanthene skeleton can also be considered, but the contributions of these configurations are negligibly small.

Kinetic Studies on Double Relaxation of Surfactant Solutions Using a Capillary Wave Method

Minoru SASAKI, Tatsuya YASUNAGA, Shigemi SATAKE, and Minoru ASHIDA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received May 4, 1977)

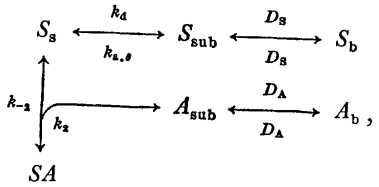
The frequency dependence of the damping coefficient of a capillary wave was measured in decylamine hydrochloride solutions. The observed relaxations were well expressed by the double-relaxation equations. From the concentration dependence of the relaxation parameters obtained, the relaxations at low and high frequencies were attributed to the adsorption-desorption and ion-pair formation reactions on the surface, respectively. Furthermore, the adsorption rate constants are related to the hydrophobic and hydrophilic properties of the surfactants.

Very recently, adsorption-desorption phenomena on the surface of sodium dodecyl sulfate (SDS), dodecylamine hydrochloride (DAC), and octylamine hydrochloride (OAC) solutions have been investigated theoretically and experimentally by means of the capillary wave method.[1,2] Similar studies on a homologous series of alkylamine hydrochloride solutions would give valuable information about the relationship between the dynamic behavior and the structure of the surfactant molecules.

The purpose of this paper is to study the adsorption-desorption phenomena by measuring the frequency dependence of the damping coefficient of the capillary wave on the surface of decylamine hydrochloride (DeAC) solutions as an extension of previous studies.

Theoretical

Let us consider the following scheme, which is a combination of adsorption-desorption and ion-pair formation reactions on the surface of a surfactant solution:[1]



where

$$K = \frac{k_2}{k_{-2}},$$

S, A, and SA are the surfactant ion, counter ion, and ion-pair on the surface, subscripts s, sub, and b refer to the surface, subsurface and bulk phase, $k_{a,\theta}$ and k_d are the adsorption and desorption rate constants defined in a previous paper,[1] k_2 and k_{-2} are the association and dissociation rate constants, D_S and D_A are the diffusion coefficients for S and A, respectively, and K is the equilibrium constant.

The following rate and diffusion equations are given for the two processes:[1]

For the diffusion processes ($y \leqslant -d_{sub}$),

$$\frac{dc_i}{dt} = D_i\left(\frac{\partial^2 c_i}{\partial x^2} + \frac{\partial^2 c_i}{\partial y^2}\right)$$

$$(c_i = c_{S,b},\ c_{A,b} \text{ and } D_i = D_S,\ D_A), \qquad (1)$$

and for the (Langmuir-type) adsorption-desorption and ion-pair formation processes ($0 \geqslant y \geqslant -d_{sub}$),

$$\frac{d\theta_1}{dt} = k_{a,\theta}(1-\theta_1-\theta_2)c_{S,sub} - k_d\theta_1 - k_2\theta_1 c_{A,sub} + k_{-2}\theta_2 \qquad (2)$$

and

$$\frac{d\theta_2}{dt} = k_2\theta_1 c_{A,sub} - k_{-2}\theta_2,$$

where x and y are the rectangular coordinates normal and tangent to the surface at rest, $c_{S,sub}$, $c_{A,sub}$, $c_{S,b}$, and $c_{A,b}$ are the molar concentrations of S_{sub}, A_{sub}, S_b, and A_b, t is the time, d_{sub} is the thickness of the subsurface layer, and θ_1 and θ_2 are the fractions of sites occupied by S and SA, respectively. The changes in the concentrations are given by:

$$c_j = \bar{c}_j + \Delta c_j \exp\{i(\omega' t + \kappa x)\}$$

$$(c_j = c_i,\ c_{S,sub},\ c_{A,sub}) \qquad (3)$$

and

$$\theta_k = \bar{\theta}_k + \Delta\theta_k \exp\{i(\omega' t + \kappa x)\} \quad (k = 1, 2),$$

where

$$\omega' = 4\pi f, \quad \kappa = 2k,$$

with ω' and κ being the angular frequency and wavenumber of the perturbed variables, f and k the frequency and wavenumber, respectively, and with the bar denoting the equilibrium state. The solution of Eq. 1 gives:[1,3,4]

$$\Delta c_i = E_i \exp(n_i y)$$

$$(E_i = E_S,\ E_A \text{ and } n_i = n_S,\ n_A), \qquad (4)$$

where

$$n_i = \left(\kappa^2 + \frac{i\omega'}{D_i}\right)^{1/2} = \beta_{11} + i\omega'\beta_{12},$$

E_i is a constant and n_i are the parameters related to the thickness of the bulk phase concerned with the diffusion process. On the other hand, the laws of conservation of mass give two independent relations for the concentration changes of the surfactant and counter ions:[1]

$$F(\Delta\theta_1 + \Delta\theta_2) + \int_{-\infty}^{-d_{sub}} E_S \exp(n_S y)dy = F(\Delta\theta_1 + \Delta\theta_2) + \frac{\Delta c_{S,sub}}{n_S} = 0 \qquad (5)$$

and

$$F\Delta\theta_2 + \int_{-\infty}^{-d_{sub}} E_A \exp(n_A y)dy = F\Delta\theta_2 + \frac{\Delta c_{A,sub}}{n_A} = 0,$$

where

$$F = 10^3\Gamma_{max},$$

and Γ_{max} is the maximum value of the surface excess. A combination of Eqs. 2—5 gives:

$$\begin{aligned} i\omega'\{1+k_{a,\theta}(1-\bar{\theta}_1-\bar{\theta}_2)F\beta_{S2}\}\Delta\theta_1 \\ +i\omega'F\{k_{a,\theta}(1-\bar{\theta}_1-\bar{\theta}_2)\beta_{S2}+k_2\bar{\theta}_1\beta_{A2}\}\Delta\theta_2 \\ = -[k_{a,\theta}\{\bar{c}_{S,sub}+(1-\bar{\theta}_1-\bar{\theta}_2)F\beta_{S1} \\ +k_d+k_2\bar{c}_{A,sub}]\Delta\theta_1-[k_{a,\theta}\{\bar{c}_{S,sub} \\ +(1-\bar{\theta}_1-\bar{\theta}_2)F\beta_{S1}\}+Fk_2\bar{\theta}_1\beta_{A1}-k_{-2}]\Delta\theta_2 \end{aligned} \quad (6)$$

and

$$\begin{aligned} i\omega'(1+k_2F\bar{\theta}_1\beta_{A2})\Delta\theta_2 \\ = k_2\bar{c}_{A,sub}\Delta\theta_1-(k_2F\bar{\theta}_1\beta_{A1}+k_{-2})\Delta\theta_2. \end{aligned}$$

For relatively concentrated surfactant solutions near the CMC, these equations are simplified in the cases of c_0 (the initial concentration)$>10^{-3}$ mol dm^{-3}, $k_2<5\times10^4$ mol^{-1} dm^3 s^{-1}, and $K<10^4$ mol^{-1} dm^3 (with $D_S\approx10^{-6}$ cm^2 s^{-1}, $D_A\approx10^{-5}$ cm^2 s^{-1}, and $\bar{c}_{S,sub},\approx\bar{c}_{A,sub}\approx c_0$)[1] to

$$\begin{aligned} i\omega'\Delta\theta_1 &= -a_{11}-a_{12} \\ \text{and} \\ i\omega'\Delta\theta_2 &= -a_{21}-a_{22}, \end{aligned} \quad (7)$$

where

$$a_{11} = k_{a,\theta}c_0+k_d+k_2c_0, \quad a_{12} = k_{a,\theta}c_0-k_{-2},$$
$$a_{21} = -k_2c_0, \quad a_{22} = k_{-2}.$$

Solving Eq. 7, one obtains the following equation for the relaxation times, τ:[5]

$$\tau_{I,II}^{-1} = \frac{1}{2}(a_{11}+a_{22})\left[1\pm\left\{1-\frac{4(a_{11}a_{22}-a_{12}a_{21})}{(a_{11}-a_{22})^2}\right\}^{1/2}\right]. \quad (8)$$

This equation is easily simplified by the conditions $a_{11}\gg a_{22}$ and $a_{22}\gg a_{11}$ to the following forms:[5]

For $a_{11}\gg a_{22}$ ($\tau_I^{-1}\gg\tau_{II}^{-1}$),

$$\begin{aligned} \tau_I^{-1} &= a_{11} = k_{a,\theta}c_0 + k_d + k_2c_0 \\ \text{and} \\ \tau_{II}^{-1} &= a_{22} - \frac{a_{12}a_{21}}{a_{11}} = k_{-2} + \frac{k_2c_0(k_{a,\theta}c_0-k_{-2})}{k_{a,\theta}c_0+k_d+k_2c_0}, \end{aligned} \quad (9a)$$

and for $a_{22}\gg a_{11}$ ($\tau_{II}^{-1}\gg\tau_I^{-1}$),

$$\begin{aligned} \tau_I^{-1} &= a_{11} - \frac{a_{12}a_{21}}{a_{22}} = k_{a,\theta}(1+Kc_0)c_0 + k_d \\ \text{and} \\ \tau_{II}^{-1} &= a_{22} = k_{-2}. \end{aligned} \quad (9b)$$

The apparent relaxation strengths, δ', for two-step reactions on the surface are given by the following equations on the basis of two-dimensional relaxation theory[1] and of the theory for ultrasonic absorption[5] at constant activity:

$$\delta_I' = \frac{(W\Delta\gamma_1+X\Delta\gamma_2)^2}{\gamma RT}\left(W^2\Sigma\frac{\nu_{i1}^2}{c_i}+2XW\Sigma\frac{\nu_{i1}\nu_{i2}}{c_i}+X^2\Sigma\frac{\nu_{i2}^2}{c_i}\right)^{-1}$$

and

$$\delta_{II}' = \frac{(Y\Delta\gamma_1+Z\Delta\gamma_2)^2}{\gamma RT}\left(Y^2\Sigma\frac{\nu_{i1}^2}{c_i}+2YZ\Sigma\frac{\nu_{i1}\nu_{i2}}{c_i}+Z^2\Sigma\frac{\nu_{i2}^2}{c_i}\right)^{-1},$$

where

$$\begin{pmatrix} W & Y \\ X & Z \end{pmatrix} = \begin{pmatrix} 1 & a_{12}/(a_{22}-\tau_I^{-1}) \\ a_{21}/(a_{11}-\tau_{II}^{-1}) & 1 \end{pmatrix},$$

γ is the surface tension, $\Delta\gamma$ is the standard surface tension change defined in a previous paper,[1] R is the universal gas constant, T is the temperature, ν is the stoichiometric coefficient, and subscripts 1 and 2 denote the adsorption-desorption and ion-pair formation processes, respectively. The conditions $a_{11}\gg a_{22}$ and $a_{22}\gg a_{11}$ then lead to:[1,5] for $a_{11}\gg a_{22}$:

$$\delta_I' = \frac{(\Delta\gamma_1)^2}{\gamma RT}\left(\frac{1}{\Gamma_{max}\bar{\theta}_1}+\frac{3}{2}\times10^2N^{1/3}c_0^{-2/3}\right)^{-1}$$

and

$$\begin{aligned} \delta_{II}' = \frac{(Y\Delta\gamma_1+\Delta\gamma_2)^2}{\gamma RT}\left\{\frac{1-2Y-Y^2}{\Gamma_{max}\bar{\theta}_2}+\frac{1}{\Gamma_{max}\bar{\theta}_2}\right. \\ \left.+\frac{3}{2}\times10^2(1+Y^2)N^{1/3}c_0^{-2/3}\right\}^{-1}, \end{aligned} \quad (10a)$$

where

$$\begin{pmatrix} W & Y \\ X & Z \end{pmatrix} = \begin{pmatrix} 1 & -a_{12}/a_{11} \\ 0 & 1 \end{pmatrix},$$

and for $a_{22}\gg a_{11}$,

$$\begin{aligned} \delta_I' = \frac{(\Delta\gamma_1+X\Delta\gamma_2)^2}{\gamma RT}\left\{\frac{1-2X+X^2}{\Gamma_{max}\bar{\theta}_1}+\frac{X^2}{\Gamma_{max}\bar{\theta}_2}\right. \\ \left.+\frac{3}{2}\times10^2(1+X^2)N^{1/3}c_0^{-2/3}\right\}^{-1} \end{aligned}$$

and

$$\delta_{II}' = \frac{(\Delta\gamma_2)^2}{\gamma RT}\left(\frac{1}{\Gamma_{max}\bar{\theta}_1}+\frac{1}{\Gamma_{max}\bar{\theta}_2}+\frac{3}{2}\times10^2N^{1/3}c_0^{-2/3}\right)^{-1}, \quad (10b)$$

where

$$\begin{pmatrix} W & Y \\ X & Z \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ -a_{21}/a_{22} & 1 \end{pmatrix}.$$

Experimental

The apparatus employed was the same as that reported in a previous paper.[2]

Decylamine (Schuchardt, purity; 90%) was distilled twice and the purity of the distillate was confirmed to be 99.8% using gas chromatography. Decylamine was neutralized by hydrochloric acid in a butanol solution and was then recrystallized four times from the butanol solution and finally washed with petroleum ether. The value of the CMC was determined to be 62.5 mM* using the electric conductivity method at 25 °C.

The measurements of the damping coefficient of the capillary wave were carried out from 40 to 700 Hz on the surface of concentrated DeAC solutions below the CMC at 25± 0.4 °C.

Results and Discussion

The frequency dependence of the damping coefficient, α, is shown in Fig. 1. As seen from this figure, the experimental values of α/f are greater than the theoretical results of α_d/f, where α_d refers to the damping coefficient resulting only from diffusion between the surface and the bulk phase.[1,3,4] This difference cannot be expressed by a single relaxation equation as was done in a previous paper.[2] In order to interpret the experimental results, let us consider multiple-step reactions on the surface. The equation for the damping coefficient derived in previously[2] is generalized to the mutiple relaxations, as follows:

$$\frac{3\rho c^3}{2\pi\gamma k}\left(\frac{\alpha}{f}-\frac{\alpha_d}{f}\right) = \sum_{i=1}^{N}\frac{\omega'\tau_i\delta_i'}{1+\omega'^2\tau_i^2}, \quad (11)$$

* Throughout this paper, 1 M=1 mol dm^{-3}.

where ρ is the density, c is the propagation velocity, and N is the number of reaction steps. The frequency dependence of the left hand side of Eq. 11 is shown in Fig. 2. The experimental results can be satisfactorily represented by the right hand side of Eq. 11 in the case of $N=2$; thus, the existance of double relaxations was confirmed. The relaxation parameters obtained are listed in Table 1, where subscripts 1 and 2 refer to the relaxations at lower and higher frequencies, respectively.

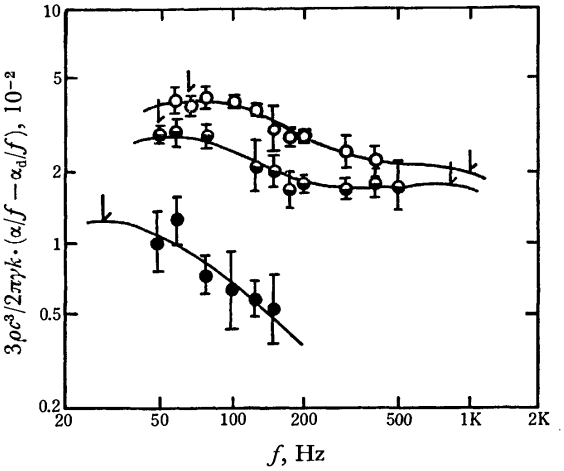

Fig. 3. The relaxation absorption spectra in the purified OAC solutions.
○: 115 mM, ◒: 76.9 mM, ●: 46.1 mM.

These facts lead to a new problem: why was only a single relaxation observed for the SDS, DAC, and OAC solutions reported in Ref. 2. Before this problem could be clarified, the experimental results for the OAC solutions stimulated a reexamination of the purified OAC solutions, since the OAC contained a minute amount of DeAC (content; 2.3%). The OAC was prepared by neutralizing octylamine (the purity of which was verified to be 99.9% using gas chromatography) with hydrochloric acid. The experimental results for the purified OAC solutions are shown in Fig. 3. As seen from this figure, double relaxations are observed and the relaxation parameters obtained are listed in Table 1 together with those for the DeAC solutions. The concentration dependence of the relaxation parameters is the same as that for the DeAC solutions. This suggests that the relaxation phenomena in both solutions are caused by perturbation of the same process. In a series of studies on relaxation phenomena on the surface of surfactant solutions,[2] double relaxations were observed in the DeAC and OAC solutions but were not observed in the SDS and DAC solutions. The concentration dependence of τ_2^{-1} for the former solutions differs from that of the reciprocal relaxation time for the latter solutions. Moreover, the τ_2^{-1} for the DeAC solution is larger than that for the OAC solution. Since the SDS and DAC hydrocarbon chain lengths are longer than those for DeAC and OAC, the above-mentioned facts suggest that the relaxations at the higher frequency in the SDS and DAC solutions may be located outside the measured frequency range.

a) Ref. 2.

The new experimental results described above prompted a modification of the adsorption-desorption mechanism model proposed in a previous paper.[1] The concentration dependence of τ_1^{-1} listed in Table 1 is similar to that for the relaxation times reported previously.[2] This fact suggests that the relaxation at lower frequency may be due to the adsorption-desorption process of the surfactants. On the other hand, the τ_2^{-1} values were independent of the surfactant concentration as seen from Table 1. Various reactions on the surface are considered, *e.g.*, an ion-pair formation reaction, a monomer-dimer reaction, and a conformational change reaction. Of these, the ion-pair formation reactions between halide and dodecylpyridinium ions and between the various anions and polysoap on the surface have been studied under static conditions by Parreira[6] and Plaisance and Ter-Minassian-Saraga,[7] respectively. Thus, the model of the adsorption-desorption mechanism presented in a previous paper[1] was modified in the manner expressed by the scheme given in the theoretical section. Since the τ_1^{-1} values are an order of magnitude smaller than the τ_2^{-1} values, *i.e.*, $a_{22} \gg a_{11}$ (see Eq. 9b), the equations for the relaxation times and the apparent relaxation strengths are given by Eq. 9b ($\tau_I=\tau_1$ and $\tau_{II}=\tau_2$) and by the following equation, respectively:

$$\delta'_{1,2} = \frac{(\Delta\gamma)^2}{\gamma RT} \cdot f_{1,2}(\gamma, c_1), \tag{12}$$

where

$$f_1(\gamma, c_1) = (1+Kc_0)^2 \left\{ \frac{1-2Kc_0+K^2c_0^2}{\Gamma_{max}\bar{\theta}_1} + \frac{K^2c_0^2}{\Gamma_{max}\bar{\theta}_2} + \frac{3}{2} \times 10^2 (1+K^2c_0^2) N^{1/3} c_0^{-2/3} \right\}^{-1},$$

$$f_2(\gamma, c_1) = \left(\frac{1}{\Gamma_{max}\bar{\theta}_1} + \frac{1}{\Gamma_{max}\bar{\theta}_2} + \frac{3}{2} \times 10^2 N^{1/3} c_0^{-2/3} \right)^{-1},$$

under the assumption that $\Delta\gamma_1$ in Eqs. 10a and 10b is approximately equal to $\Delta\gamma_2$, since the counter ion may associate in the immediate proximity of the surface.

The K values in Eq. 12 were determined so as to give straight lines for the plots of $\delta'_{1,2}$ *vs.* $f_{1,2}$ (γ, c_1). As is shown in Fig. 4, the experimental values fall on the theoretical straight lines in the cases of $K=4$ and 5 for the DeAC and OAC solutions, respectively. With the K values obtained, the equations for the relaxation times were applied to the experimental results listed in Table 1. As seen from Figs. 5 and 6, the experimental values fall on the straight lines. The linearities of these plots confirm the validity of the scheme. The values of $\Delta\gamma$, $k_{a,\theta}$ k_d, and k_{-2} were obtained from the slopes and intercepts in Figs. 4, 5, and 6, respectively and are listed in Tables 2 and 3. The k_2 values listed in Table 2 were calculated using the values of K and k_{-2}. The values of the adsorption rate constant, k_a,[1] and the adsorption energy, ΔG,[2] were calculated and are also listed in Tables 2 and 3. The K and k_2 values listed in Table 2 satisfy the conditions for the simplification of Eq. 6. In the present work, other plausible processes, a monomer-dimer reaction and a conformational change reaction on the surface, were also examined, but no results were obtained.

Table 3. Thermodynamic parameters in various surfactant solutions at 25 °C

	ΔG ($-RT$)		$\Delta\gamma$ (10^{10} dyn cm mol^{-1})[d]	
SDS[a]	6.1	6.8[b]	10	6[c]
DAC[a]	5.9	6.3[b]	8	7[c]
DeAC	5.1	4.6[b]	2	7[c]
OAC	4.4	4.5[b]	2	7[c]

a) Ref. 2. b) These values were calculated using the Szyszkowski equation. c) These values were estimated using $(\gamma_{water}-\gamma_{CMC})/\Gamma_{max}$. d) 1 dyn=$10^{-5}$ N.

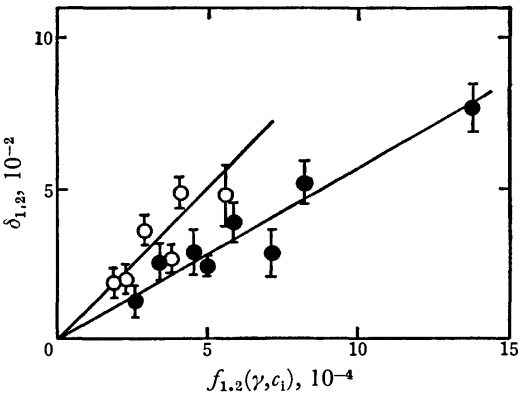

Fig. 4. The plots of $\delta'_{1,2}$ *vs.* $f_{1,2}$ (γ,c_1) in the DeAC (open circles) and OAC (closed circles) solutions. The values of $f_{1,2}$ (γ,c_1) were calculated using $K=4$ and 5 in the DeAC and OAC solutions, respectively.

Among the kinetic parameters concerned with the adsorption-desorption process listed in Table 2, $k_{a,\theta}$ and k_a are inversely proportional to the CMC, as seen in Fig. 7 but k_a is independent of the CMC. Since the logarithm of the CMC bears a linear relation to the hydrophile-liophile balance (HLB) value,[8,9] $k_{a,\theta}$ and k_a can be related to the HLB values as follows:

$$\log k_{a,\theta} = (0.30\pm0.06)HLB + (0.5\pm0.6)$$

and

$$\log k_a = (0.25\pm0.05)HLB + (1.8\pm0.6). \tag{14}$$

These relations indicate that the adsorption rate

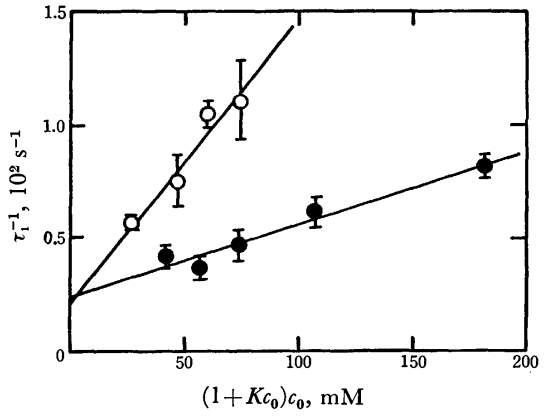

Fig. 5. The plots of τ_1^{-1} *vs.* $(1+Kc_0)c_0$ in the DeAC (open circles) and OAC (closed circles) solutions.

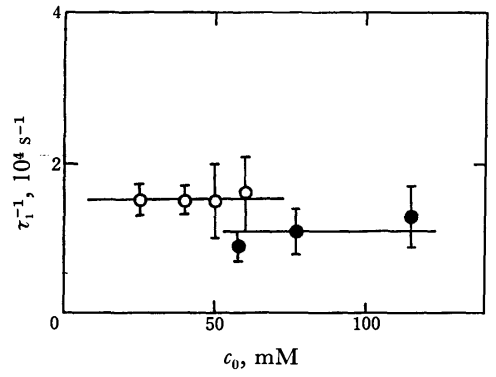

Fig. 6. The plots of τ_2^{-1} *vs.* c_0 in the DeAC (open circles) and OAC (closed circles) solutions.

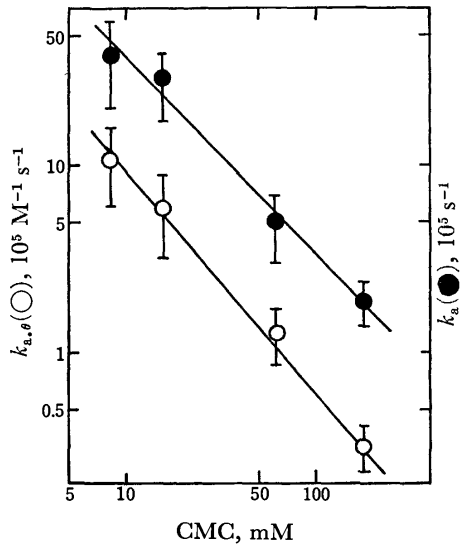

Fig. 7. The plots of $k_{a,\theta}$ (open circles) and k_a (closed circles) *vs.* CMC.

constants are influenced considerably by the instability of the surfactants in the bulk phase. In the alkylamine hydrochloride solutions, moreover, k_a also involves the number of $-CH_2-$ groups, n, as follows:

$$\ln k_a = (0.7\pm0.1)n + (4\pm1). \quad (15)$$

This equation indicates that the activation adsorption energy per $-CH_2-$ group is 0.4 kcal at 25 °C. On the other hand, the ΔG values are in good agreement with the theoretical results calculated using the Szyszkowski equation, as can be seen from Table 3. The $\Delta\gamma$ values are also in orderly agreement with those estimated using $(\gamma_{water}-\gamma_{CMC})/\Gamma_{max}$.[2]

As seen in Table 2, the kinetic parameters involving the ion-pair formation process are appreciably independent of the hydrocarbon chain length. This suggests that the interaction between the surfactant and counter ions may be governed by that between a hydrophilic group and Cl^- ions. Since the interaction energy between Na^+ and the anionic surfactant is smaller than that between Cl^- and the cationic surfactant,[10] however, SDS will scarcely associate on the surface and the relaxation concerned with the ion-pair formation should not be observed even outside the measured frequency range.

The remarkable difference between the relaxations observed for the OAC solutions in the present work and those of previous work[2] implies that the relaxation phenomena on the surface of surfactant solutions are sensitive to impurities in the surfactants. In a subsequent paper, the experimental results for the effect of additives on the relaxation of DeAC solutions, which are homologous to the OAC solutions, will be reported.

Finally, it can now be asserted that the capillary wave method is a powerful tool for analyzing reactions at the gas-liquid interface.

Crystal and Molecular Structure of α-Form of 2,4,6-Trimethyl-1,3,5-trithiane*

Kiyotane SEKIDO, Haruaki ONO,** Teruo NOGUCHI,** and Sakutaro HIROKAWA

Department of Chemistry, The National Defense Academy, Hashirimizu, Yokosuka 239

***Koa Oil Co., Ltd., Ōtemachi, Tokyo 100*

(Received May 10, 1977)

The crystal structure of α-form of 2,4,6-trimethyl-1,3,5-trithiane (α-TTA) has been determined by the X-ray method. The crystal data are $a=9.768$, $b=12.306$, $c=8.521$ Å, and $\beta=116.33$ °. The space group is Cc with four molecules in a unit cell. The structure was deduced from interpretation of the 3D-Patterson series, and refined by 3D-Fourier and least-squares method to the final R factor of 0.040 for 1371 reflections. The molecule has a six-membered ring where three sulfur atoms and three carbon atoms are linked alternatively, forming a chair-form. Two methyl groups are in the equatorial positions and one methyl group in the axial. The mean values of the bond distances are 1.818 Å for S–C and 1.519 Å for C–C_{eq}. The distance is 1.541 Å for C–C_{ax}. The mean values of the bond angles are 101.89° for C–S–C, 107.60° for S–C–C_{eq}, 113.25° for S–C–C_{ax}, and 112.92° for S–C–S.

Studies on organic synthesis show that TTA has two isomers. One isomer is called the α-form (mp 102 °C), where two methyl groups are in the equatorial positions and a third one is axial. The other is called the β-form (mp 126 °C), where all the methyl groups are equatorial.

The crystal structure of the β-form has been reported by Valle *et al.*[1] and Hirokawa *et al.*,[2] but not that of the α-form. We have determined the crystal and molecular structure of the α-form from the viewpoint of molecular geometry or the packing of molecules in the crystal. The results are given below.

Experimental

Colorless prisms elongated along the a-axis were obtained by slow evaporation of α-TTA from acetone solution. The crystals are built upon a monoclinic unit cell.

Crystal Data. The cell dimensions were determined by the least-squares method using various sets of high angle reflections on a diffractometer. Systematic absence, $h+k$ odd in hkl and l odd in $h0l$, restricted the possible space group to either Cc or C2/c. Consideration on the number of molecules in the unit cell and the symmetric feature of the molecule favored the former. This was supported by the statistical test of intensity-distribution, and confirmed by the packing of the molecules. The crystal data are given in Table 1.

TABLE 1. CRYSTAL DATA
The experimental errors, given in parentheses, refer to the last figures.

Molecular formula	$C_6H_{12}S_3$
Formula weight	180.4
Mp	102 °C
Crystal system	Monoclinic
a	9.768 (4) Å
b	12.306 (7)
c	8.521 (4)
β	116.33(3)°
Systematic absences	hkl, $h+k=2n$
	$h0l$, $l=2n$
Space group	Cc
V	918.0(3) Å^3
Z	4
D_m	1.299 g cm^{-3}
D_x	1.305
μ (Mo $K\alpha$)	7.31 cm^{-1}
Crystal dimension	0.5 mm $\phi\times$0.8 mm
λ (Mo $K\alpha$)	0.7107 Å

Intensity Data. A prismatic crystal was ground to a cylinder of 0.5 mm in diameter and 0.8 mm in length. It was mounted on a four-circle diffractometer (Rigaku AFC-III) with Mo $K\alpha$ from a graphite monochrometer, and intensities were collected for the independent 1403 reflections within $2\theta<60°$, using the ω-2θ scan technique with a scanning speed of 4° min^{-1} in 2θ. Thirty-two reflections whose $|F|$'s were less than $2\sigma(|F|)$ were designated unobserved, where $\sigma(|F|)$ is the standard deviation of $|F|$ due to counting statistics. After corrections for background and Lorentz-polarization factor, the intensities were reduced to structure amplitudes. No corrections were made for absorption or extinction.

Structure Determination

The location of three sulfur atoms in the general positions was derived from synthesized 3D-Patterson series. The first 3D-Fourier series were synthesized, using phases determined by the atomic coordinates of the three sulfur atoms. The synthesized electron-density maps showed extra peaks in addition to the peaks due to the three sulfur atoms. Some of these extra peaks were considered to be significant as the constituent-atoms of the molecule. These were added to the successive Fourier-works. After three cycles of the procedure, the location of all the carbon atoms was determined. The possibility of centrosymmetric arrangement was discarded because of the mode of the packing of the molecules in the unit cell.

The structure was refined by syntheses of 3D-Fourier and 3D-difference series, where structure factors were calculated with isotropic B values for all the atoms. Location of the hydrogen atoms was roughly obtained from the 3D-difference maps. They were refined after the heavier atoms were fixed, assuming the tetrahedral angle for each carbon atom and a bond length of 1.09 Å for each C–H bond. Further refinements were made with a block-diagonal least-squares program on a computer CDC-6600 in Century Research Center Co.,

* A preliminary report was presented at the 30th National Meeting of the Chemical Society of Japan, Osaka, April 1974.

Tokyo, using anisotropic thermal parameters for the non-hydrogen atoms with B values of the hydrogen atoms fixed at isotropic values. After six cycles of this procedure convergence was attained with R=0.040. The final parameters with standard deviations resulting from the procedure are given in Tables 2 and 3.***

Discussion

Molecular Geometry and Conformation. The structural and conformational features are shown in Fig. 1, together with atomic numbering and thermal vibration ellipsoids[3] scaled to 50% probability, excluding the hydrogen atoms. Intramolecular interatomic distances and angles involving the non-hydrogen atoms are given in Table 4, being also shown in Fig. 2(a) and (b). The standard deviations of these measurements are 0.001 Å for distances and 0.01—0.05° for angles. S–C lengths are in the range 1.810—1.824 Å with a mean of 1.818 Å, showing a slight alternative shortening along the sides of the six-membered ring. These values together with the bond angles of the sulfur atoms (101.89° as a mean) are comparable to those for organic compounds which have ring-membered sulfur atoms.[1,2,4-7]

*** The complete F_o-F_c data are deposited as Document No. 7722 at the Office of the Editor of the Bulletin of the Chemical Society of Japan.

A significant difference can be seen between the lengths of C–C_{eq} (from a ring-membered carbon to a methyl carbon in the equatorial position) and C–C_{ax} (axial); a mean of 1.519 Å is given to C–C_{eq} and 1.541 Å to C–C_{ax}. This might correspond to the difference in the bond angles for the ring-membered carbon atoms; a mean of 107.60° for S–C–C_{eq} and a mean of 113.25° for S–C–C_{ax}. A similar difference can be seen in the distance from a sulfur atom to a ring-membered carbon atom which is in a diagonal position of the ring; a mean of 3.431 Å for S···C whose carbon atom is linked with the equatorial methyl group, and 3.466 Å for S···C where the carbon atom is linked with the axial methyl group. The conformation of a methyl group may affect the molecular dimensions of a ring-membered carbon atom linked with it.

TABLE 4. INTRAMOLECULAR INTERATOMIC DISTANCES (l) AND ANGLES (ϕ) INVOLVING THE NON-HYDROGEN ATOMS
Estimated standard deviations are given in parentheses.

	l/Å		ϕ/°

Table 5. Torsion angles (ϕ)
Torsion angle A(i)–A(j)–A(k)–A(l) is viewed down A(j)–A(k) with a clockwise rotation of A(i) to A(l) taken to be positive.

Ring torsion angles	ϕ/°
C(6)–S(1)–C(4)–S(2)	−65.4
C(5)–S(2)–C(4)–S(1)	67.0
C(4)–S(2)–C(5)–S(3)	−67.0
C(6)–S(3)–C(5)–S(2)	65.6
C(5)–S(3)–C(6)–S(1)	−62.2
C(4)–S(1)–C(6)–S(3)	62.4
Mean (absolute value)	64.9
Exocyclic torsion angles	
C(6)–S(1)–C(4)–C(7)	176.3
C(5)–S(2)–C(4)–C(7)	−174.0
C(4)–S(2)–C(5)–C(8)	174.4
C(6)–S(3)–C(5)–C(8)	−176.2
Mean (absolute value)	175.2
C(5)–S(3)–C(6)–C(9)	68.2
C(4)–S(1)–C(6)–C(9)	−68.5
Mean (absolute value)	68.3

The triangle formed by these three sulfur atoms is regular, the averaged length being 3.029 (±0.006) Å and the averaged apex angle 60.00 (±0.12)°. Another triangle formed by three ring-membered carbon atoms is also regular, with length 2.822 (±0.031) Å and angle 60.00 (±1.07)°. These triangles are approximately parallel to each other, showing that the ring has a chair-form. Shifts of three sulfur atoms from the plane containing three ring-membered carbon atoms are −0.635 Å for S(1), −0.712 Å for S(2), and −0.637 Å for S(3), where signs indicate whether or not the atoms are on the same side of the plane.

A torsion angle of these two triangles is calculated to be 60.4° (from S(1) to C(6)), which is given as a dihedral

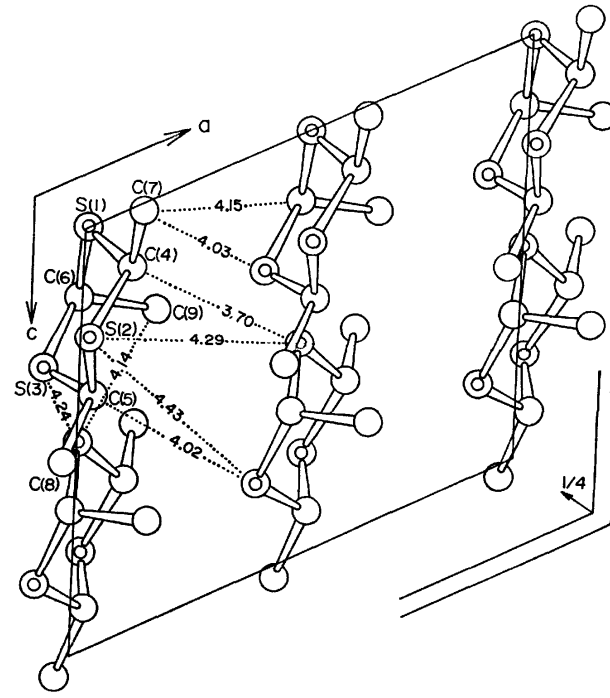

Fig. 3. The molecular packing viewed down b, showing all intermolecular distances (the non-hydrogen atoms) of less than 4.50 Å.

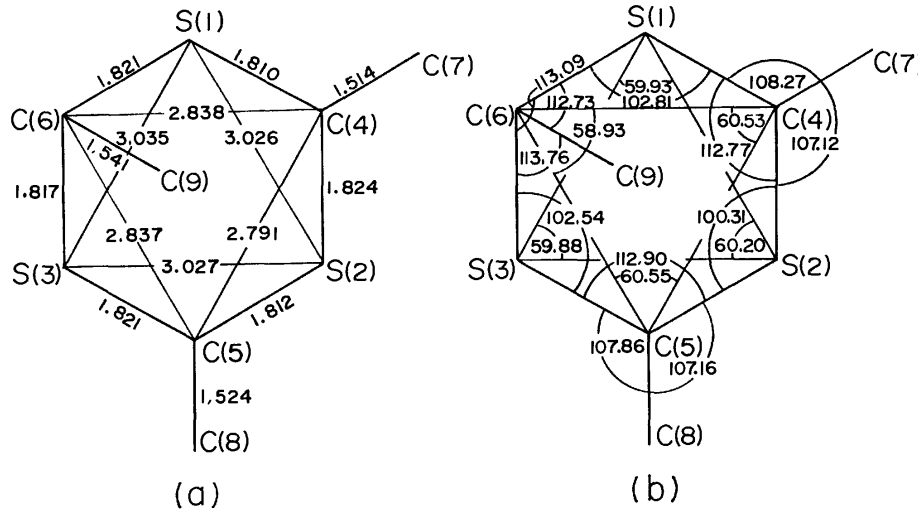

Fig. 2. Intramolecular interatomic distances (a) and angles (b).

angle around the line connecting the centers of the triangles.

Shifts of the three methyl carbon atoms from the plane formed by the three ring-membered carbon atoms are −0.283 Å for C(7), −0.389 Å for C(8), and +1.531 Å for C(9), showing that C(7) and C(8) are equatorial and C(9) is axial.

Torsion angles in the molecule are given in Table 5, where an angle for A(i)–A(j)–A(k)–A(l) is viewed down A(j)–A(k) with a clockwise rotation of A(i) to A(l) to be positive. The conformation of the chair-form is clearly seen from the alternative change of sign assigned to each torsion angle. The averaged value of the endocyclic torsion angles is 64.9° in absolute value.

The conformation of each methyl group is also clear; a mean of 175.2° for C···C_{eq} and a mean of 68.3° for C···C_{ax} rotation.

Molecular Packing. The molecular packing in the unit cell together with intermolecular interatomic distances less than 4.50 Å are shown in Fig. 3. The shortest contact of 3.70 Å is seen between C(4) and S(1) operated by the n-glide plane. No significant contact other than this can be seen. The molecules are held together in the crystal by the weak van der Waals contacts, corresponding to a low melting point.

Solid-State Anodic Oxidation of Aluminum with Organic-Conductor Counterelectrode

Susumu YOSHIMURA and Mutsuaki MURAKAMI
Matsushita Research Institute Tokyo, Inc., Ikuta, Tama-ku, Kawasaki 214
(Received May 18, 1977)

Solid-state anodic oxidation of aluminum contacted to a pellet of various organic conductors based on 7,7,8,8-tetracyanoquinodimethane was observed. A typical passivation curve was observed in the current-voltage characteristics for the anodic polarization of the metal. Along with impedance measurements on the electrode system, it was proved that the passivation is due partly to a thermal transformation in the organic conductor and partly to a solid-state anodization of aluminum, the latter being conditioned by the former through the formation of an electrolyte layer *in situ*. The current efficiency of anodization was estimated by a linear voltage sweep method to be as high as 2%, depending on the ambient moisture. The high efficiency explains the prominent self-healing action of a new type of solid electrolytic capacitor in which manganese dioxide is replaced by an organic-conductor counterelectrode.

The solid electrolytic capacitor was developed in 1956,[1] but little experimental information on the anodic oxidation of valve metals with a solid electrolyte has been given since then. Smith[2] studied the electrical properties of a tantalum electrode pressed on a surface of manganese dioxide, MnO_2, and claimed that the tantalum oxide is anodically formed at the expense of the local oxygen content of MnO_2. There is, however, another theory according to which the counterelectrode functions in the capacitor self healing; a thermally induced transition of the oxide to insulating lower oxides.[3] Smith did not exclude the thermal reduction of MnO_2 but rather credited it with the appearance of a high electric field appropriate to the ionic conduction.[2]

Recently a new type of aluminum solid electrolytic capacitor, in which MnO_2 is replaced by organic conductor, OC, was developed.[4] Highly conductive organic salts based on 7,7,8,8-tetracyanoquinodimethane, TCNQ,[5] were adopted, because of their prominent effect on the capacitor self healing. The capacitor was featured by stable high frequency characteristics[6] and a very low leakage current density. In this paper we wish to report on the electrical properties of an Al/OC electrode system, showing that the solid state anodic oxidation proceeds at an efficiency of up to 2%, considerably higher than that with MnO_2. The current-voltage and impedance characteristics of the electrode system, are presented with a discussion on the mechanism of anodic oxidation.

Experimental

Materials. Typical molecular compounds of TCNQ, including non-ionic change transfer complexes and less conductive ion-radical salts with metallic cations were examined. We report herewith on highly conductive salts which might have significance in capacitor application. The effects of resistivity, thermal stability and stoichiometry on the solid state reaction were studied for the compounds, quinolinium-$(TCNQ)_2$, $Q(TCNQ)_2$, *N*-methylquinolinium$(TCNQ)_{2.2}$, $(NMQ)(TCNQ)_{2.2}$, *N*-propylquinolinium$(TCNQ)_2$, $(NPQ)(TCNQ)_2$, *N*-methylacridinium$(TCNQ)_2$, $(NMA)(TCNQ)_2$, and *N*-methylphenazinium(TCNQ), (NMP)(TCNQ). $(NMQ)(TCNQ)_{2.2}$ and (NMP)(TCNQ) were a metastable, highly conductive modification,[7] the former sample being used to examine the contribution of the thermal transformation of the solid counterelectrode. Results on the salts with metallic cations will be referred to as regards the discussion of the reaction mechanism.

Electrode System. The TCNQ compounds were compressed under a pressure of *ca.* 2000 kg/cm^2 into a pellet of 13 mm in diameter and *ca.* 0.8 mm in thickness. A 99.999% hard aluminum bar, 0.5 mm diam., was used as an electrode metal. This was degreased with 10% NaOH and rinsed with deionized water and acetone. The bar was truncated immediately before measurement and the fresh surface was pressed on the OC pellet. It was extremely difficult to obtain a reproducible contact between Al and OC. The dominant factors for the reproducibility were the nature of the surfaces of both solids, contact pressure and the water content of the pellet. Figure 1 shows a test jig for the Al/OC electrode system, with which a pressure as high as 100 kg/cm^2 could be applied to the contact without any deformation of the bar. Since the glossy surface of the OC pellet did not give a reproducible result, it was rubbed with emery paper and lapped with cotton gauze.

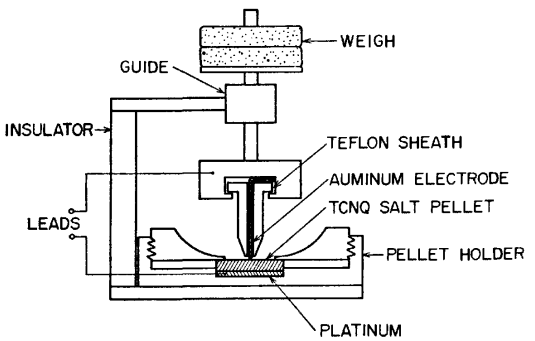

Fig. 1. Sketch of a constant-pressure, point-contact electrode system.

Apparatus. The current-voltage characteristics were measured by the constant-rate-of-voltage-increase (CRVI) method first adopted by Dignam[8] for the anodic oxidation of Al in a liquid electrolyte. Since a very low rate of voltage increase with a very low noise level is required to meet the supposed low efficiency of the solid state reaction,[2] we constructed a Miller integrator with operational amplifiers and a 500 μF slug tantalum electrolytic capacitor. Measurements with stepwise application of constant voltage were found to be inappropriate for the OC system, for it was not possible to distinguish between the anodic and the cathodic reactions especially

when the thermal transformation of OC took part in the reaction. The impedance of the Al/OC system was measured as a function of the applied voltage with a Yokogawa BV-Z 13A universal bridge at a frequency of 1 kHz. Measurements of the equivalent series capacitance, C_s, and resistance, R_s, were made after the current had reached a steady state for each applied voltage.

Results

Current-Voltage Characteristics. The *I-V* characteristics measured by the CRVI method for three Al/OC systems, shown in Fig. 2, are typical data for a humidity of 50% RH and a voltage rise rate of 1/24 V/s. For the anodic polarization (*e.g.* when Al was anodically polarized), all the electrode systems exhibited a well-known passivation curve with a current peak, V_p^+, between 2.5 and 4.7 V, the current following as low as 10^{-5} A for higher voltages. The curves are very smooth with no discontinuity below *ca.* 15 V, at which the current suddenly diverges resulting in decomposition in OC at the contact point. For the cathodic polarization, there are more than one current peaks, the current making an oscillatory growth. The first peak appears, in all cases, at a lower voltage than the anodic peak. The anodic and cathodic peak voltages and powers ($W_p^+ = V_p^+ I_p^+$) along with the specific resistivity of compactions[9] for the OC's examined are summarized in Table 1. The superlinear curve in the anodic direction results from a contact resistance at voltages lower than 1 V and the Joule heat above 1 V. In the underlinear and decreasing regions, the change in the electrode resistance is irreversible; the resistance is not restored by the application of cathodic voltage. In the cathodic direction, however, an reversible increase in the electrode resistance takes place from *ca.* 0.1 V, for the resistance is restored by the anodic polarization, provided that the cathodic electrification does not exceed the voltage of the first peak. The difference in the *I-V* characteristics between the anodic and cathodic directions strongly suggests that the passivations are due to electrochemical reactions.

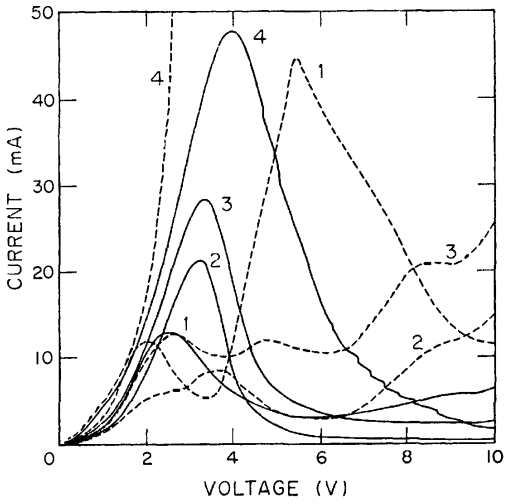

Fig. 2. Current-voltage characteristics at 1/24 V/s and 50% RH of an Al electrode system for anodic (solid lines) and cathodic (dotted lines) polarizations. 1. Q-(TCNQ)$_2$, 2. (NPQ)(TCNQ)$_2$, 3. (NMA)(TCNQ)$_2$, 4. MnO_2.

Table 1. Peak voltage $V_p^{\pm}$ and power $W_p^{\pm}$ of passivation curves

Compound	V_p^+ (V)	W_p^+ (mW)	V_p^- (V)	W_p^- (mW)	ρ (Ω cm)
Q(TCNQ)$_2$	2.5	32.5	2.0	23.6	0.6
(NMQ)(TCNQ)$_{2.2}$	3.3	64.4	2.5	20.0	1.0
(NPQ)(TCNQ)$_2$	3.0—3.2	74.5	2.3	12.7	3.6
(NMA)(TCNQ)$_2$	3.1—3.3	89.1	2.6	33.3	1.3
(NMP)(TCNQ)	4.7	91.2	4.2	52.5	7.8
MnO_2	3.8—4.0	568	—	—	5

The results for an Al/MnO_2 systems are also shown in Fig. 2. MnO_2 was obtained by thermal decomposition of a 50% $Mn(NO_3)_2$ solution in the form of a block which was cut and lapped into nearly the same shape as that of the OC pellet. The MnO_2 system exhibited essentially the same anodic curves as the OC system, though there were a number of discontinuous falls in current at $V > V_p^+$, indicating thermal transformation in MnO_2. The cathodic current, however, increased to infinity (over 200 mA) at *ca.* 2.5 V.

Thermal Transformation in OC. We measured the *I-V* characteristics using Ta and noble metals, Pt and Au. All the electrodes exhibited a large passivation peak similar to those shown in Fig. 2. However, in the case of the noble metal, there was no difference in the *I-V* curves between the anodic and cathodic polarizations. This indicates that, although the anodic passivation in the Al/OC system is peculiar to the valve metal and is of electrochemical nature, it was initiated by some kind of thermal transformation in OC. Figure 3 shows the current and temperature-voltage characteristics of a chromel-almel, Al/OC system, where the current was passed through the thermocouple, 0.5 mm in diameter (Omega Engineering, Inc.), which was pressed on the OC pellet with a Pt bar. The figure illustrates not only the existence of the passivation peak for the non-valve metal system but also the correspondence of the current to the electrode temperature. A current peak appeared at 2.5 and 4.7 V for Q(TCNQ)$_2$

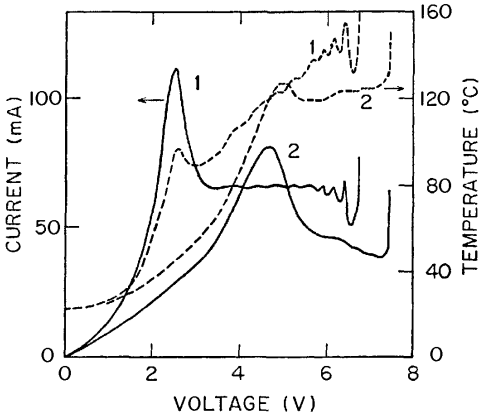

Fig. 3. Current (solid lines)- and temperature (dotted lines)- voltage characteristics at 1/24 V/s and 50% RH of chromel-almel/organic systems.
1. Q(TCNQ)$_2$, 2. (NPQ)(TCNQ)$_2$.

and $(NPQ)(TCNQ)_2$, respectively, and the corresponding temperature peak appeared at 95.7 and 126.4 °C for the former and the latter, respectively. The peak temperatures are considerably lower than the decomposition temperatures of these compounds.[5,10] However, the resistivity of the highly conductive TCNQ salts frequently increases irreversibly at these temperatures.[11] This seems to be due to the dissociation of the neutral TCNQ from the salts.[12] The difference in the position of the current peak or the electric power of the peak (Table 1) between compounds is understandable on the basis of the thermal stability against the dissociation of the compounds.

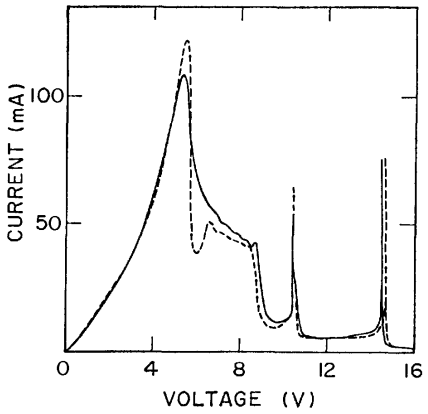

Fig. 4. Current-voltage characteristics at 1/24 V/s of a $Pt/(NMQ)(TCNQ)_{2.2}$ system. —anodic, ···cathodic.

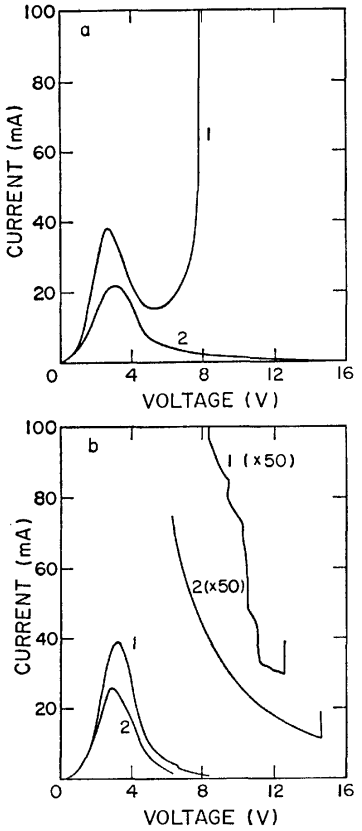

Fig. 5. Effect of humidity on the current-voltage characteristics of $Al/Q(TCNQ)_2$ (a) and $Al/(NMA)(TCNQ)_2$ (b) systems. 1: 20%RH, 2: 98%RH.

Figure 4 shows the *I-V* curves of a $Pt/(NMQ)(TCNQ)_{2.2}$ system forming a single exception in the non-valve metal system. This system displayed drastic decay and spikes in the current starting from *ca.* 8.5 V in addition to the above mentioned passivation at 5.3 V. The metastable modification of $(NMQ)(TCNQ)_{2.2}$ undergoes a monotropic phase transition and the resistivity increases by a factor of 80.[13] The drastic decay (Fig. 4) is undoubtedly due to the phase transition in the bulk of the OC. That the *I-V* curves of $Al/(NMQ)(TCNQ)_{2.2}$ showed no discontinuity implies that the thermal transformation does not dominate at higher voltage ($V \gg V_p^+$).

Effect of Ambient Moisture. The *I-V* characteristics measured at various relative humidities are shown in Fig. 5. The *I-V* curves in the higher voltage region are severely altered by the ambient moisture. At a relative humidity of 98%RH, the current declines to about an order of magnitude lower than those at 50%RH. In dry air, on the contrary, it increases to infinity with $Q(TCNQ)_2$ or shows lots of jumps with $(NMA)(TCNQ)_2$ at higher anodic voltages. The discontinuous falls for the $(NMA)(TCNQ)_2$ system are strikingly similar to those for the MnO_2 system (Fig. 2), indicating that a thermal transformation proceeds locally in the OC. In the case of $Q(TCNQ)_2$, however,

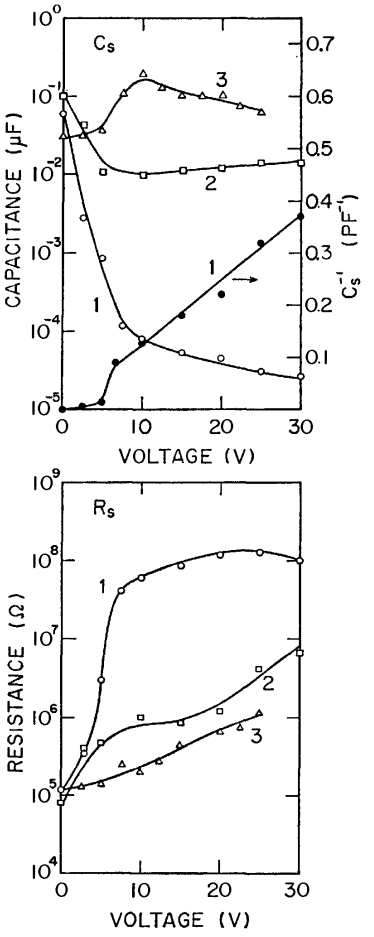

Fig. 6. Equivalent series capacitance and resistance of an $Al/Q(TCNQ)_2$ system. 1: Anodic polarization in the room air (about 70 %RH), 2: anodic polarization in dry oxygen, 3: cathodic polarization in the room air.

the *I-V* curve and the appearance of the Al contact indicate carbonization in the OC. This seems to be due to the low thermal stability of $Q(TCNQ)_2$. In any case, the results confirm that the anodic passivation should be ascribed to two mechanisms, each being replaced by the other at a voltage of *ca.* $2V_p^+$ in the presence of water. The cathodic *I-V* curves and the curves obtained using the non-valve metal electrodes are not largely altered by the relative humidity.

Impedance Characteristics. Figure 6 shows C_s and R_s at 1 kHz of the Al/$Q(TCNQ)_2$ system measured under three typical conditions. For the anodic polarization in humid air (about 70%RH), C_s decreases and R_s increases markedly with increasing voltage. The inverse of C_s shows a linear dependence on the voltage at voltages in excess of *ca.* 6 V, the voltage roughly corresponding to that at which the CRVI curve reaches a steady state (Fig. 2). This strongly indicates the formation of the anodic oxide on Al. The very high electrode resistance, R_s, may also be evidence for the anodization, since the thermal transformation alone cannot yield such a high resistance as suggested by curve 2. Curves marked 2 give the result of measurements in dry oxygen. They have almost the same features as those of the non-valve metal systems, so that the measured impedance is thought to be that of the transformed OC alone. It should be noted that the R_s measured at higher RH decreased again at higher voltages; in the case of $(NMQ)(TCNQ)_{2.2}$, for example, R_s decreased to the same value as the initial R_s. The decrease can be explained by the formation of a very high resistance connected in parallel with the anodic capacitor. The cathodic reaction causes an increase in C_s with a slight increase in R_s, indicating that the cathodic passivation is not dominated by the thermal transformation of OC either.

Discussion

Anodic Oxidation. The experimental results on the electrical properties of the Al/OC electrode system as a whole confirm the solid-state anodic oxidation of Al, though no direct evidence for the material transport or the existence of Al_2O_3 was found. One possible objection may be that there might be an electrochemical reaction of the TCNQ salts followed by a disproportionation reaction with water or *vice versa* at high electric fields. However, if such reaction could take place, the strict relation C_sV=constant (Fig. 6) would be too accidental, since the electrification period was not made constant for each applied voltage. Assuming the electrode area as 2×10^{-3} cm^2, we obtain C_sV=0.44 μF·V/cm^2, which is to be compared with $C\cdot V$=6.45 μF·V/cm^2 for the ideal anodization in a boric acid-borate solution.[14] Coincidence between experiment and theory is considered to be good in view of various factors through which the capacitance is lowered; namely, 1) reduction of the contact area arising from the roughness of the surface, 2) a series capacitance due to the thermally transformed OC, and 3) a low efficiency of the solid-state reaction.

The CRVI method, which was originally introduced for the analysis of the anodic oxidation in the liquid electrolyte,[8] is useful and powerful for the solid state reaction. The anodic and the cathodic reactions are discriminated and different reactions depending upon the voltage are manifested. Let us calculate the current efficiency of the anodic oxidation using the CRVI results.[15] When the ionic current I_i flows through the oxide of thickness x, the equation for an oxide growth rate dx/dt is given by Faraday's law,

$$dx/dt = \Omega I_i \quad (1)$$

where Ω is 5.55 A s^{-1} mA^{-1} cm^2 for Al_2O_3. Then the potential across the oxide V_{ox} increases as follows,

$$dV_{ox}/dt = E_v dx/dt \quad (2)$$

where E_v is the Maxwell field strength which depends on the rate of voltage increase v. If we assume

$$dV_{ox}/dt = dV_a/dt = v \quad (3)$$

where V_a is the applied voltage and define the ionic current efficiency η with respect to the total current I through the electrode system as

$$I_i = \eta I, \quad (4)$$

then we obtain from Eqs. 1 through 4,

$$\eta = v/\Omega E_v I. \quad (5)$$

Since Eq. 3 holds for $V_a \gg V_p^+$ or for I_i=constant, η can be calculated using the experimental data on I in Fig. 2. The results for a relative humidity of 50%RH are shown in Table 2, where E_v was obtained by Dunn[15]

Table 2. Current efficiency of anodic oxidation, η (%), at 50% RH

Compound	η (Voltage, V)
$Q(TCNQ)_2$	0.053 (6)
$(NMQ)(TCNQ)_{2.2}$	1.68 (13)
$(NPQ)(TCNQ)_2$	0.62 (13)
$(NMA)(TCNQ)_2$	0.10 (13)
(NMP)(TCNQ)	0.21 (16)

as $E_v=8\times10^6$ V/cm for v=1/24 V/s. The efficiency was found to be 0.05 to 1.7%, considerably higher than the published data on the Ta/MnO_2 system (0.01 to 0.001%).[2] At higher relative humidities, the efficiency was higher; 2.1% for $Q(TCNQ)_2$ and 1.5% for (NMA)-$(TCNQ)_2$ at 98%RH. The efficiency for the MnO_2 system cannot be obtained, since the discontinuous falls in the *I-V* curves do not allow us to assume Eq. 3. An apparent efficiency was calculated to be 0.93% at 14 V, which is thought to be an overestimate by about two orders of magnitude over a true value if we take the amount of the discrete jumps in current into account.

Reaction Mechanism. The anodic oxidation necessitates both an ionically conducting layer which prevents the short circuiting of the electrode system and ionogens which may serve as an oxygen source of Al_2O_3. The TCNQ salts are known as an electronic conductor. The idea of Gutmann *et al.*[16] that $Mg(TCNQ)_2$ behaves as a solid electrolyte has been vitiated by Friedel[17] and Weidenthaler and Pelinka.[18] We postulate that the initial passivation at relatively low voltages (V_p^+) produces an ionically conducting layer between Al and OC. Since the transformed layer has a higher resistivity, the applied voltage may be absorbed by this thin layer,

resulting in a high electric field effective to the ionic conduction. The TCNQ salts we examined meet the requirement for the anodizing electrolyte postulated by Smith.[2] The transformed OC was dissolved in acetonitrile and the composition was determined spectroscopically.[7] It was shown that the layer contains an excess of neutral TCNQ molecules over a stoichiometric composition; *e.g.*, TCNQ/cation=2.11 for the transformed NPQ salt. The resulting nonstoichiometric compound is very advantageous for anodic oxidation. First, the disordered structure may give a good chance for the ionic conduction as in the case of inorganic materials.[19,20] Second, the OC layer with excess TCNQ molecules may behave as a p-type conductor,[21] to facilitate rectification of a junction $Al/Al_2O_3/OC$.[22]

It was assumed in the above discussion that the existence of neutral TCNQ is essential for anodization. For the sake of comparison simple salts with metallic cations, such as Li, Na, K, Mg, Ca, Ba, Mn(II), Fe(II), Ni(II), and Cu(I) were examined. However, they were not anodizing electrolytes for the valve metals. The only metallic salt which exhibits both a passivation curve in the CRVI experiment and a remarkable decrease in C_s in the impedance measurement is $Cu(TCNQ)_2$. An X-ray photoemission study[23] and IR study have shown that $Cu(TCNQ)_2$ is not a simple salt but is composed of Cu(I)(TCNQ) and $TCNQ^0$ as a formulation of $Cu^+(TCNQ^-)(TCNQ^0)$ or $(Cu^+)_2(TCNQ^-)_2(TCNQ^0)_2$,[5] providing another support for our model. The anodizing ability of the simple salt (NMP)(TCNQ) is not counterevidence either. A recent examination has revealed a partial charge transfer between NMP and TCNQ,[24] suggesting the existence of $TCNQ^0$. This may explain the striking difference in the anodizing ability between (NMP)(TCNQ) and alkali-TCNQ's, the charge transfer being complete in the latter.[24] The results and those with $(NMQ)(TCNQ)_{2.2}$ suggest that nonstoichiometric salts having higher contents of TCNQ[25] may be a more efficient anodizing electrolyte.

Since the TCNQ salts we examined have no oxygen in their composition, water should be the oxygen source. It is not unreasonable because water is, with a few exceptions,[26] the oxygen source in most of the anodic oxidation in liquid electrolyte. The findings of Weidenthaler and Pelinka[18] that the presence of water is essential for the electromotive force to be observed in a cell, metal/TCNQ-salt solution/Pt, should also be considered. Smith's claim that water is a catalyst in the anodic oxidation of the Ta/MnO_2 system cannot be accepted. The major electrochemical reactions are the dissociation of water and/or the oxidation of Al, and the efficiency may vary with the catalytic activity of $TCNQ^0$ in the electron transfer processes. In fact, the formation of an ion pair Al···TCNQ with the aid of water has been known[27] and a slowly decreasing electromotive force was generated in a cell Al/OC/Pt with Al negative.

Conclusion

The experimental results as a whole support the anodic oxidation of Al with the OC functioning as a solid electrolyte *in situ*. The material criteria for the anodizing electrolyte are that the existence of neutral TCNQ molecules in the salt is essential and the disordered structure is favored. The high efficiency of anodization explains the prominent self-healing action of a new type of solid electrolytic capacitor in which MnO_2 is replaced by an OC counterelectrode.[4]

The authors wish to express their sincere gratitude to Dr. Katsue Hasegawa for his continuous encouragement. They are also indebted to Shirow Asakawa and Dr. Shigeo Kondo for various valuable discussions on the electrochemical properties of the TCNQ salts and water.

Kinetic Studies of Spin-trapping Reactions. I. The Trapping of the *t*-Butyl Radical Generated by the Photodissociation of 2-Methyl-2-nitrosopropane by Several Spin-trapping Agents

Takahisa DOBA, Tsuneki ICHIKAWA, and Hiroshi YOSHIDA
Faculty of Engineering, Hokkaido University, Kita-ku, Sapporo 060
(Received May 20, 1977)

The photochemical reaction of 2-methyl-2-nitrosopropane (a spin-trapping agent) in benzene was studied at 299 K by monitoring the optical absorption intensity of the spin-trapping agent and the ESR signal intensity of the spin-adduct radical (di-*t*-butyl nitroxide). The observed kinetic feature was interpreted in terms of three elementary processes; the photodissociation of the spin-trapping agent giving a *t*-butyl radical, the spin trapping of the *t*-butyl radical by the trapping agent giving the spin adduct radical, and the reaction of the spin-adduct radical with the *t*-butyl radical giving diamagnetic products. The rate constant of the last process was found to be 10 times as large as that of the spin-trapping process, which was determined to be 3.3×10^{6} mol^{-1} dm^{3} s^{-1} based on the reported rate constant for the scavenging of the *t*-butyl radical by tributylstannane. The relative spin-trapping rate constants toward the *t*-butyl radical were also determined to be 0.07, 1.0, 41, 63, and much higher than 50 for 2,4,6-tri-*t*-butylnitrosobenzene, 2-methyl-2-nitrosopropane, pentamethylnitrosobenzene, nitrosodurene and nitrosobenzene, respectively. *C*-phenyl-*N*-*t*-butylnitrone was found to be much less reactive by a factor of less than 0.003.

The reaction of several nitroso compounds with short-lived free radicals giving stable nitroxide radicals (or anilino-type radicals) provides an indirect but convenient technique for detecting the short-lived free radicals by the conventional electron spin resonance (ESR) method.[1,2] This spin-trapping technique has been widely used in recent years to study radical intermediates in photochemical, radiation chemical, and even thermal reaction systems.[3–5] 2-Methyl-2-nitrosopropane, like nitrosobenzene derivatives, has been used very often as a spin-trapping agent because it gives an ESR spectrum of spin-adduct radicals (products of spin-trapping reactions) with a better-resolved hyperfine structure, facilitating the identification of the trapped radicals. However, one drawback of this spin-trapping agent is that it decomposes readily to give a *t*-butyl radical when irradiated by light.[2,6]

Naturally the observed yield of the spin-adduct radicals depends not only on the concentration of the trapped radicals in the reaction systems, but also on the rate constant of the spin-trapping process. The stability of the spin-adduct radicals is another factor determining the observed yield if they are unstable either in decomposing by themselves or in reacting with other radical entities. No quantitative information can, therefore, be drawn from spin-trapping experiments without knowing the kinetic features involved. However, there have been only a limited number of reports on the kinetic study of spin-trapping reaction systems. Although the figures available for the spin-trapping rate constant of the nitroso compounds have been very scanty,[7,8] it appears that the spin trapping is a comparatively slow process, and that it cannot always be the main reaction pathway of the short-lived free radicals. The accumulation of rate data on the spin-trapping is, therefore, desirable in order to extend the utility of this technique and to correlate more firmly the spin-adduct radicals with the actual reaction intermediates.

In the present study, the photochemical processes of 2-methyl-2-nitrosopropane in benzene were investigated mechanistically and kinetically. This photochemical reaction system was then used to determine the reaction rate constants of several spin trapping agents toward the *t*-butyl radical.

Experimental

Benzene and tributylstannane of analytical grade were used as received, without further purification. The benzene solvent was degassed by the freeze-pump-thaw technique, mixed with a spin-trapping agent (or agents) through a break seal under a vacuum of about 10^{-5} Torr in the dark, and sealed in a glass tube with a quartz-tip portion for ESR measurements at one end and a quartz optical-absorption cell at the other. The concentration of spin-trapping agents were usually from 0.01 to 0.1 mol dm^{-3}.

The trapping agents used were 2-methyl-2-nitrosopropane (BNO), nitrosobenzene, nitrosodurene, pentamethylnitrosobenzene, 2,4,6-tri-*t*-butylnitrosobenzene, and *C*-phenyl-*N*-*t*-butylnitrone (*N*-*t*-butyl-α-toluenimine *N*-oxide). The BNO and nitrosobenzene were commercially purchased from the Aldrich Chem. Co., Inc., and Nakarai Chem., Ltd., and were used without further purification. The pentamethylnitrosobenzene was synthesized[9–11] and recrystallized from an acetone solution. The nitrosodurene, tri-*t*-butylnitrosobenzene, and *C*-phenyl-*N*-*t*-butylnitrone were kindly supplied by R. Konaka of Shionogi Pharm. Co., Ltd., M. Tabata of Hokkaido University, and K. Kuwata of Osaka University.

The solution was photolyzed with light from a Xe lamp through a band-pass filter (transmission maximum at 690 nm). The concentration of the spin-adduct radicals was monitored by means of an X-band ESR spectrometer (JEOL, JES-ME-2X), and that of BNO, by measuring its absorption at 680 nm by means of a recording spectrophotometer (Hitachi, EPS-3T). The photolysis and measurements were carried out 299 K.

Results and Discussion

Optical Absorption and Photodecomposition of BNO. The BNO solution in benzene shows, immediately after its preparation, an intense optical-absorption band with a maximum at 295 nm and a weak absorption band with a maximum at 680 nm, as is shown in Fig. 1. The latter band is attributed to the $\pi^{*}\leftarrow$n transition of

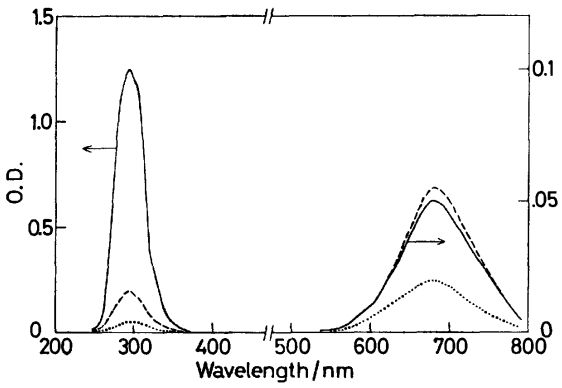

Fig. 1. The optical absorption spectra of BNO at 299 K (solid curves) immediately after dissolving it in benzene, (dashed curves) after 90 minutes when the monomer-dimer equilibrium was reached, and (dotted curves) after the photolysis for 200 minutes.

monomeric BNO, which is red-shifted by 15 nm compared with the band observed in the polar solvent of acetone.[12] The former band was found to decrease gradually in its intensity concomitantly with the increase in the band of monomeric BNO in the dark, as is shown in Fig. 1. Therefore, it is attributable to dimeric BNO. The monomer-dimer equilibrium was reached very slowly (in an hour) and was found to be shifted almost completely over to the monomer. Photoirradiation at the dimer band enhanced the dissociation of the dimer into the monomer.

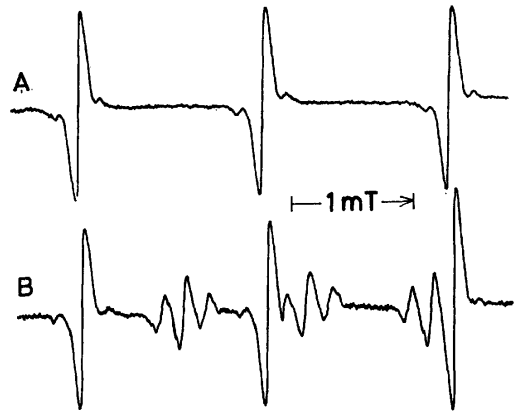

Fig. 2. The ESR spectra observed after the photolysis of BNO at 299 K. The upper spectrum was recorded from the benzene solution of BNO and is due to the di-*t*-butyl nitroxide formed by the spin trapping of *t*-butyl radical by BNO, and the bottom spectrum recorded from the benzene solution containing BNO and 2,4,6-tri-*t*-butylnitrosobenzene is due to both the di-*t*-butyl nitroxide and *N*-*t*-butoxy-2,4,6-tri-*t*-butylanilino radical formed from these two spin trapping agents.

On irradiating the solution at the monomer band, the BNO disappeared gradually, while an ESR spectrum with the hyperfine splitting due to a nitrogen nucleus (1.57 mT) developed, as is shown in Fig. 2. The ESR spectrum is attributed to the di-*t*-butyl nitroxide radical, the spin-adduct radical of the *t*-butyl radical resulting from the photodissociation of the spin-trapping agent itself,[1,2]

$$(t\text{-Bu})\text{NO} \xrightarrow{h\nu} t\text{-Bu}\cdot + \text{NO} \quad (1)$$

$$t\text{-Bu}\cdot + (t\text{-Bu})\text{NO} \xrightarrow{k_2} (t\text{-Bu})_2\text{NO}\cdot \quad (2)$$

No other ESR spectrum was observed. No optical absorption other than that of the BNO was recorded down to 260 nm, either. The spin-adduct radical was found stable in the dark at room temperature.

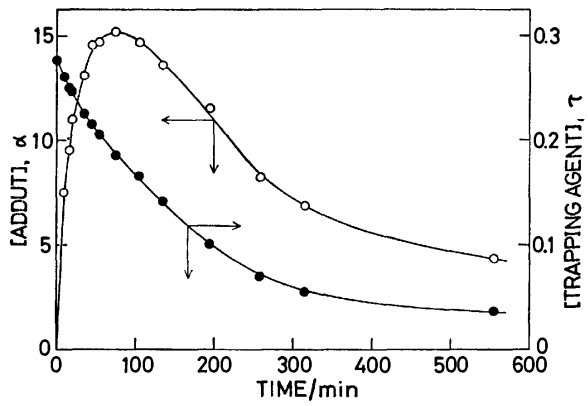

Fig. 3. The change in (●) the concentration of the spin trapping agent, BNO and (○) that of the spin adduct radical, di-*t*-butyl nitroxide, during the photolysis of BNO (2.7×10^{-2} mol dm^{-3}) in benzene at 299 K. The arbitrary units, α and τ are given in the text.

The change in the concentrations of the BNO and the spin adduct radical were followed by means of optical absorption and ESR measurements during the photolysis. The results are shown in Fig. 3. The spin-adduct radical initially increased in its intensity, reached a maximum, and then decreased gradually. By examining the effect of the initial BNO concentration, no indication was observed of the involvement of a second-order process with respect to the short-lived intermediates, such as a combination between the *t*-butyl radicals. The decay of the spin-adduct radical is, therefore, attributed to its reaction with the *t*-butyl radical, giving a diamagnetic product (or products) as:

$$(t\text{-Bu})_2\text{NO}\cdot + t\text{-Bu}\cdot \xrightarrow{k_3} (t\text{-Bu})_2\text{NO}(t\text{-Bu}). \quad (3)$$

The reaction between di-*t*-butyl nitroxide and the *t*-butyl radical was inferred to occur in the gas-phase reaction in pyrolyzing BNO.[13] The photodecomposition of the spin-adduct radical is not expected to occur, because the photolysis was carried out with light of selected wavelengths. The adduct radicals do not combine with themselves,[14] and so such a combination reaction cannot be a reason for their decay either.

Kinetic Features of the Photochemical Reaction of BNO. Based on the three elementary processes, Reactions 1 to 3, the photochemical reaction of the BNO can be totally described by the following rate equations:

$$\frac{d[T]}{dt} = -I\phi - k_2[T][R] \quad (4)$$

$$\frac{d[R]}{dt} = I\phi - k_2[T][R] - k_3[A][R] \quad (5)$$

$$\frac{d[A]}{dt} = k_2[T][R] - k_3[A][R] \quad (6)$$

where T, R, and A stand for the spin trapping-agent (BNO), the *t*-butyl radical, and the spin adduct radical (di-*t*-butyl nitroxide) respectively. In principle, the ratio of the rate constants, k_3/k_2, can readily be determined as $k_3/k_2=[T]/[A]$ at the time when [A] reaches the maximum. The assumption of the steady-state for [R] leads to:

$$\frac{d[A]}{d[T]} = \frac{(k_3/k_2)[A]-[T]}{(k_3/k_2)[A]+2[T]}, \quad (7)$$

which tests the validity of the presumed reaction mechanism by using the observed changes of [A] and [T] and the determined value of k_3/k_2.

However, it is a difficult task to determine precisely enough the absolute values of [A] by means of the ESR method. Therefore, the values were determined only relatively in the present experiment. Using the instrumental constants of a and b, [A] and [T] are expressed as $[A]=a\alpha$ and $[T]=b\tau$ respectively, α and τ being the recorded intensity of the ESR spectra of the spin-adduct radical and that of the optical-absorption spectra of the spin-trapping agent. Then, at the maximum α, this relationship:

$$(\tau/\alpha) = (k_3/k_2)(a/b) \quad (8)$$

is obtained. The results shown in Fig. 3 gave the value of 0.0123 for $(k_3/k_2)(a/b)$. Equation 7 is transformed as:

$$\frac{d\alpha}{d\tau} = \frac{b}{a}\cdot\frac{(k_3/k_2)(a/b)\alpha-\tau}{(k_3/k_2)(a/b)\alpha+2\tau}. \quad (9)$$

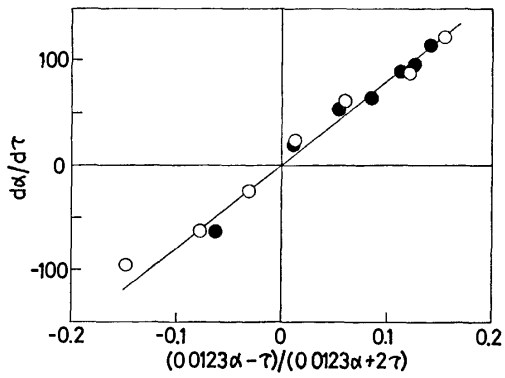

Fig. 4. The relationship between the ratio of the changing rate of the concentration of the spin trapping agent to that of the concentration of the spin adduct radical, $d\alpha/d\tau$, and the concentrations of the spin trapping agent and the spin adduct radical, $(0.0123\alpha-\tau)/(0.0123\alpha+2\tau)$, during the photolysis of (○) 2.7×10^{-2} mol dm^{-3} or (●) 1.2×10^{-2} mol dm^{-3} of BNO in benzene. The slope gives the value of 820 for b/a and, in turn, the value of 10 for k_3/k_2. See also the text.

The results in Fig. 3 are replotted in Fig. 4, where the expected linear relationship is observed between $d\alpha/d\tau$ and $(0.0123\alpha-\tau)/(0.0123\alpha+2\tau)$, and the slope gives the value of 820 for b/a. It turns out that $k_3/k_2=10$. The observed linear relationship gives a support to the presumed reaction mechanism comprised of Reactions 1, 2, and 3. Using the reported extinction coefficient of the monomer band[12] and the determined value of b/a, the concentration of the spin-adduct radical is found to have reached its maximum value of 1.8×10^{-3} mol dm^{-3} when the BNO concentration decreased to 1.9×10^{-2} mol dm^{-3} from its initial value of 2.7×10^{-2} mol dm^{-3} (*cf.* Fig. 3).

Equation 7 shows that d[A]/d[T] (or $d\alpha/d\tau$) is independent of the initial concentration of the spin-trapping agent. As a matter of fact, the data obtained for the initial BNO concentration half as much fall on the same straight line in Fig. 4. This result gives evidence that the second-order reaction with respect to the *t*-butyl radical concentration is effectively absent.

Although the available data on the rate constant of radical scavengers against the *t*-butyl radical has been very little, tributylstannane has been reported to react with the *t*-butyl radical at the constant of 7.4×10^5 mol^{-1} dm^3 s^{-1} in cyclohexane at 298 K.[15] If the radical scavenger is present in the solution, the radical-scavenging reaction:

$$t\text{-Bu}\cdot + (t\text{-Bu})_3\text{SnH} \xrightarrow{k_{10}} t\text{-BuH} + (t\text{-Bu})_3\text{Sn}\cdot \quad (10)$$

competes with Reaction 2 in the early period of the photolysis when Reaction 3 is effectively absent. An example of the observed scavenger effect is shown in Fig. 5. The linear increase of [A] is reduced in the presence of the radical scavenger. The reduction of the spin-adduct formation depends on the concentration of the radical scavenger, [S], as is shown in Fig. 6, and agrees with the normal competition kinetics:

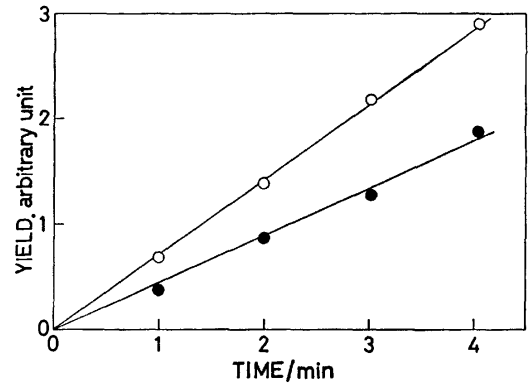

Fig. 5. The yield of the spin adduct radical in the benzene solution at 299 K as a function of the photolysis time, (○) in the presence of only 0.19 mol dm^{-3} BNO and (●) in the presence of 0.19 mol dm^{-3} BNO and 0.56 mol dm^{-3} tributylstannane.

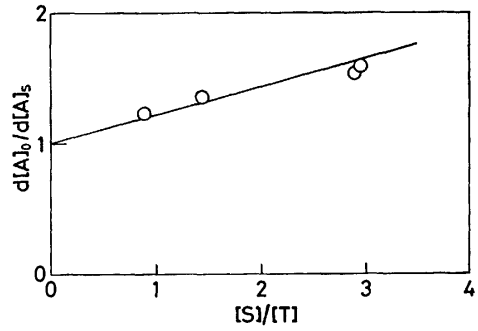

Fig. 6. The dependence of the rate of the spin adduct formation on the concentration of radical scavenger, tributylstannane, during the photolysis of BNO in benzene at 299 K.

$$\frac{d[A]_0}{d[A]_s} = 1 + \frac{k_{10}[S]}{k_2[T]}. \quad (11)$$

On the basis of the reported k_{10},[15] k_2 is determined to be 3.3×10^6 mol^{-1} dm^3 s^{-1}.

Spin-trapping Rate Constants of Several Spin-trapping Agents. When BNO and another spin trapping agent (RNO) are present in the solution, and when the former is selectively photolyzed to generate the *t*-butyl radical, the spin-trapping rate constant of the latter can be determined relative to that of the former by the conventional treatment of competition reactions. As has been shown in the preceeding section, only the reaction:

$$t\text{-Bu}\cdot + \text{RNO} \xrightarrow{k_{12}} \text{RN}(t\text{-Bu})\text{O}\cdot \text{ or } \text{R}\dot{\text{N}}\text{O}(t\text{-Bu}) \quad (12)$$

competes with Reaction 2 against the *t*-butyl radical in the initial period of the photolysis. The rate constant, k_{12}, can readily be determined from this relationship:

$$\frac{d[A']}{d[A]} = \frac{k_{12}[T']}{k_2[T]}, \quad (13)$$

and the observed intensities of ESR spectra due to two kinds of spin-adduct radicals in the short photolysis time when they are increasing linearly. T′ stands for the second spin trapping-agent, from which the spin-adduct radical, A′, is generated.

Figure 2B shows the ESR signal observed from the solution of BNO and 2,4,6-tri-*t*-butylnitrosobenzene. The *t*-butyl radical is added to the oxygen atom of tri-*t*-butylnitrosobenzene to form an anilino-type spin-adduct radical,[16] whose ESR spectrum is distinguished from that of the spin-adduct radical from BNO. Even when the nitroxide-type spin-adduct radical was generated from either the nitrosobenzene, nitrosodurene, or

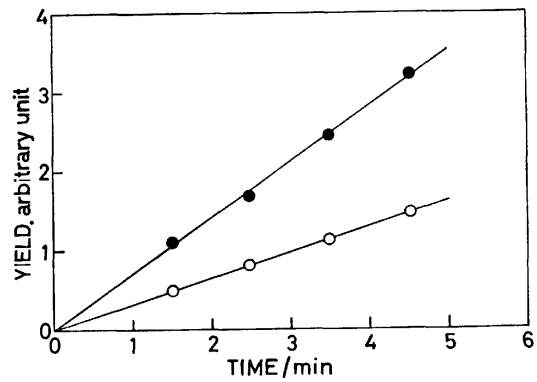

Fig. 7. The yields of the *t*-butyl radical adducts competitively formed (○) from 2.3×10^{-2} mol dm^{-3} BNO and (●) from 1.0×10^{-2} mol dm^{-3} nitrosodurene during the photolysis of BNO in the benzene solution at 299 K.

pentamethylnitrosobenzene coexisting with BNO in the solution, the ESR spectra of the two kinds of nitroxide radicals could readily be distinguished and their intensities determined relative to each other. In the presence of BNO and nitrosodurene in the solution, for instance, the concentration of the spin-adduct radicals increased linearly, as is shown in Fig. 7. The relative spin-trapping efficiency, k_{12}/k_2, was determined to be 63 from the observed slopes of the linear increases and the concentrations of the two spin-trapping agents dissolved in the solution. This shows that the spin-trapping rate constant of nitrosodurene is 2.0×10^8 mol^{-1} dm^3 s^{-1} toward the *t*-butyl radical. The spin-trapping rate constants were determined in the same manner for pentamethylnitrosobenzene,[11] tri-*t*-butylnitrosobenzene,

Table 1. The rate constants of the trapping *t*-butyl radical and the dimerization equilibrium constants of several spin-trapping agents at 299 K in benzene

		Relative rate constant k_{12}/k_2	Rate constant[a] (mol^{-1} dm^3 s^{-1})	Equilibrium constant, K (mol dm^{-3})	Monomer fraction[c]
2-Methyl-2-nitroso-propane		1.0	3.3×10^6	1.92[b]	0.99
Nitrosobenzene		>50	$>2.0\times10^8$	—	1.0
Nitrosodurene		63	2.0×10^8	1.6×10^{-4}	0.086
Pentamethylnitroso-benzene		41	1.4×10^8	3.6×10^{-4}	0.13
2,4,6-Tri-*t*-butyl-nitrosobenzene		0.07	2.3×10^5	—	1.0
Phenyl-*N*-*t*-butyl-nitrone		<0.003	$<1.0\times10^4$	—	1.0

a) The absolute values were determined with an experimental uncertainty of ±10%. b) From Ref. 21, the value determined at 299.5 K. c) The monomer fraction for 0.01 mol dm^{-3} of the total concentration based on the monomeric form.

and nitrosodurene, as is shown in Table 1. Nitrosobenzene was found to be too reactive toward the *t*-butyl radical for the rate constant to be determined precisely. The rate constants in Table 1 may include an experimental uncertainty, at the most, of 10% caused mainly in measuring the ESR intensities and in weighing the small amounts of spin-trapping agents.

The only data available to be compared with these results are those for BNO: the spin-trapping rate constant is 1.1×10^{6} mol^{-1} dm^{3} s^{-1} at 317 K toward the *t*-butoxycarbonyl radical[7] and 1.3×10^{8} mol^{-1} dm^{3} s^{-1} at 228 K toward the methoxyl radical.[8] The reactivity of BNO depends very much on the free radicals trapped, and the rate constant toward the *t*-butyl radical reasonably falls in between. The rate constant depends also very much on the spin-trapping agents used. Although tri-*t*-butylnitrosobenzene is exceptionally unreactive toward the *t*-butyl radical (it gives an anilino-type spin-adduct radical) because of the steric hindrance due to the ring substitution with bulky *t*-butyl groups, aromatic nitroso compounds are generally more reactive than BNO, the nitrosoalkane examined.

C-phenyl-*N*-*t*-butylnitrone, one of the most commonly used spin-trapping agents, was also examined in the same way. However, its concentration 30 times as high as the BNO concentration gave no detectable ESR spectrum of the spin-adduct radical from it in the competition reaction experiment. Thus, *C*-phenyl-*N*-*t*-butylnitrone was found to be less reactive than BNO by a factor of less than 0.003 toward the *t*-butyl radical. It turns out that the spin-trapping rate constant is as small as 1×10^{4} mol^{-1} dm^{3} s^{-1} or less. This is much smaller than the spin-trapping rate constants previously reported for *C*-phenyl-*N*-*t*-butylnitrone: 4×10^{5} mol^{-1} dm^{3} s^{-1} toward the benzyloxyl radical at room temperature,[17] 5.5×10^{6} mol^{-1} dm^{3} s^{-1} toward the *t*-butoxyl radical at 298 K,[18] and 1.2×10^{7} mol^{-1} dm^{3} s^{-1} toward the phenyl radical at 298 K.[19] This trapping agent seems to be exceptionally unreactive toward the *t*-butyl radical.

Monomer-Dimer Equilibrium of Spin-trapping Agents. Nitroso compounds are often present in solutions in the dimeric form, which is inactive in trapping free radicals. Therefore, the dissociation constant, K (=[monomer]^2/[dimer]), of the spin-trapping agent used is an important parameter in the quantitative application of the spin-trapping technique.

Nitrosodurene showed optical absorption bands at 800 and 320 nm, the former being due to the monomer, and the latter, to the dimer. According to the well-known relationship between the total concentration of nitrosodurene, c, and the optical density of the monomer band:

$$\frac{c}{\mathrm{OD}}=\frac{1}{2\varepsilon}+\frac{1}{K\varepsilon^{2}}\mathrm{OD}, \qquad (14)$$

the dissociation constant was determined to be 7.5×10^{-5} mol dm^{-3} at 298 K in benzene. It turns out that only 8% of the nitrosodurene is present in the monomeric form at the total concentration usually occurring in the spin-trapping experiments, 10 mmol dm^{-3}. The temperature dependence of K was also studied in the 293—313 K range, as is shown in Fig. 8, which gives the

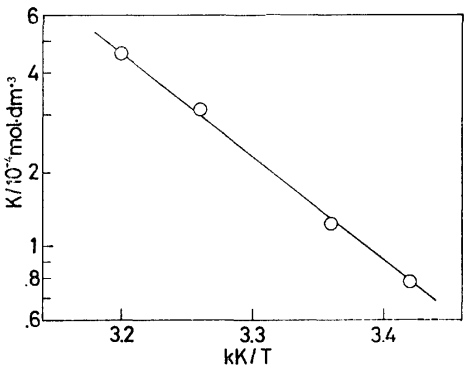

Fig. 8. The dependence of the monomer-dimer equilibrium constant of nitrosodurene in benzene on the reciprocal temperature.

Arrhenius expression of $K=10^{6.80}\exp(-61/RT)$ in kJ/mol unit. The molar extinction coefficient, ε, was found to be 91 mol^{-1} dm^{3} cm^{-1}, almost unchanged in the temperature range examined.

For pentamethylnitrosobenzene, K was determined in the same way to be $10^{5.26}\exp(-50/RT)$, as has been reported previously.[11] Stowell reported the monomer-dimer equilibria for BNO at 288 and 298 K,[20] which were confirmed by the present observation that K is 1.31 at 290 K. Nitrosobenzene and tri-*t*-butylnitrosobenzene are already known to be totally monomeric in solutions.[21,22] *C*-phenyl-*N*-*t*-butylnitrone does not form the dimer at all, either.

The spin-trapping rate constants, k_{12}, shown in the preceeding section were determined on the basis of the monomer concentration calculated by using the dissociation constants obtained here. The dissociation constants used in the calculation and the monomer fractions for the total concentration of 10^{-2} mol dm^{-3} are also shown in Table 1.

In a practical sense, the efficiency of spin-trapping agents may be given by the product of the spin-trapping rate constant and the monomer fraction. Even though nitrosodurene and pentamethylnitrosobenzene are mostly in the dimeric form in benzene, they are more efficient in trapping the *t*-butyl radical than are BNO and tri-*t*-butylnitrosobenzene. Nitrosobenzene is an extremely efficient spin-trapping agent, though it gives a complicated hyperfine structure of the ESR spectrum of the spin-adduct radical.

Summary and Conclusion

The most significant results in the present investigation may be summarized as follows: (1) The *t*-butyl radical reacts with its spin-adduct radical formed from BNO more readily than with BNO itself, so that the yield of the spin-adduct radical cannot go above a certain level. (2) The spin-trapping rate constant depends very much on the nitroso compounds used as the spin-trapping agents; it varies from 2.3×10^{5} to 2.0×10^{7} or more toward the *t*-butyl radical in benzene at 299 K. Aromatic nitroso compounds are generally more efficient in trapping the *t*-butyl radical than the nitrosoalkane. *C*-phenyl-*N*-*t*-butylnitrone is less efficient

in trapping the *t*-butyl radical than the nitroso compounds. (3) In some cases, the monomer-dimer equilibrium shifts well over to the dimer and reduces the practical effectiveness of the spin-trapping agents. Furthermore, the equilibrium was found to be reached extremely slowly (in about an hour) after mixing the spin-trapping agents with a benzene solvent.

These results are believed to give a clue to developing a quantitative utilization of the spin-trapping technique in the study of free radical reaction intermediates.

The authors wish to express their thanks to Professor Keiji Kuwata of Osaka University, Dr. Ryusei Konaka of Shionogi Pharm. Co., Ltd., and Dr. Masayoshi Tabata of Hokkaido University for kindly supplying some of the spin-trapping agents used here. This work was supported by a Science Grant from the Japanese Ministry of Education (No. 085010, 1975).

(Received June 20, 1977)

The spontaneous degradation of penicillin G in aqueous solution has been studied using NMR and thin layer chromatography. Correlation NMR spectroscopy was used to follow products which appear at the early stage of degradation. It has been found that in 0.3 M phosphate buffer (pH 7.0, 30 °C) a successive first order degradation

$$\text{penicillin G} \xrightarrow{k_1} \text{penicilloic acid} \xrightarrow{k_2} \text{secondary product}$$

is dominant with kinetic constants of $k_1 = 0.7 \times 10^{-2}$ h^{-1} and $k_2 = 6 \times 10^{-2}$ h^{-1}.

It is well known that penicillin G is labile in aqueous solution, and degraded to give a number of products. Several pathways of degradations have already been proposed.[1] However, until now kinetic studies of the degradation of penicillin G[2-4] have been based on the observation of a decreasing time-course of undegraded penicillin G, and information from a number of degradation products has never been used quantitatively; only an overall rate of degradation of penicillin G was reported, which actually consists of several consecutive steps.

In the present work, in order to clarify the elementary process of degradation of penicillin G, a degradation product such as penicilloic acid has been followed quantitatively using NMR spectroscopy. Correlation NMR spectroscopy[5] was employed to follow products which appear at the early stage of degradation.

Experimental

Penicillin G potassium salt for injection (Takeda Chemical Industries, Lot No. 0021) and penicillinase (Calbiochem., Lot No. 400960) were used without further purification. All other reagents are of analytical grade. The concentration of penicillin G is 10 mg/ml which is approximately equal to that used for intramuscular injection. Penicillin G was dissolved in 0.3 M deuterated phosphate buffer (pH 7.0). The sample temperature was maintained at 30 °C throughout the experiments.

NMR measurements were performed using a JEOL PS-100 spectrometer. Chemical shift values reported are from external TMS (10% (v/v) in CCl_4). The concentrations of penicillin G and its degradation products were determined by comparing the peak height of each signal with that of TMS sealed in a coaxial tube. Correlation NMR technique was employed to follow degradation products which give small signals near the strong HDO peak.[5]

Degradation of penicillin G was also monitored by thin layer chromatography (TLC), the procedure of Vandamme and Voets[1] being followed with a slight modification. TLC plates are Merck $60F_{254}$ (5×20 cm with a thickness of 250 μ). 5—6 μl of penicillin G solution (4 mg/ml, 10 mg/ml) was applied and developed at 21 °C using an 85% aqueous solution of acetone. The solvent was allowed to rise to a height of 17 cm. Each TLC plate was sprayed consecutively with 2 M NaOH, 1% starch gel and iodine azide reagent. The R_f values of degradation products were standardized by that of penicillin G.

Results and Discussion

First, a decreasing time-course of degradation of penicillin G was followed using NMR spectroscopy. Figure 1 shows a time change in the NMR peak intensity of α-methyl, $-CH_2-$ and 3-H of penicillin G dissolved in 0.3 M phosphate buffer (pH 7.0). This result indicates that the overall degradation process of penicillin G is of a pseudo-first order reaction with a half life of 85 h. From this result the kinetic constant of overall degradation process, $k_{overall}$, can be estimated at 0.8×10^{-2} h^{-1} at 30 °C in the phosphate buffer solution. A kinetic constant of 1.4×10^{-3} h^{-1} has been reported at 35 °C, pH 7.0 using UV spectroscopy and other methods.[2,3] The phosphate buffer solution used in the present experiment is known to accelerate the degradation of penicillin G.[4] In view of this, the kinetic constant obtained using NMR is consistent with the previously known value.

However, the result of TLC indicates that the process of spontaneous degradation of penicillin G is actually not so simple as described above. The R_f values of degradation products at several different stages are

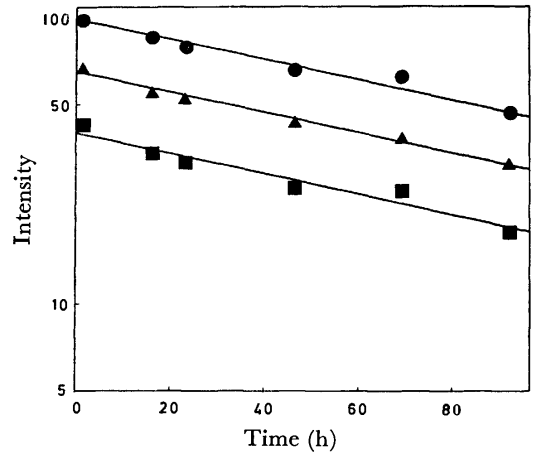

Fig. 1. Semilog plots of intensity of α-CH_3 ●, $-CH_2-$ ▲ and 3-H ■ of penicillin G *vs.* time at 30 °C in the phosphate buffer solution (pH 7.0). Initial value of α-CH_3 intensity of penicillin G is arbitrarily taken to 100.

Table 1. R_f values ($\times 100$) of degradation products of penicillin G at several different stages in the phosphate buffer solution

Penicillin G was used as a standard.

Time(h)	0	2.5	7	17	30	70	118	240	Product
	56	56	56	56	56	56	56	56	Penicillin G
						49			
					37	40	43	40	
R_f values $\times 100$			31	32	27	31	33	32	Secondary product
		16	17	17	15	15	17	14	Penicilloic acid

summarized in Table 1. Only one species of degradation products can be observed at 2.5 h after penicillin G is dissolved. After 7 h, the second species becomes observable, and more than three species can be observed after 17 h. This result indicates that from the observation of the decreasing time-course of penicillin G, only an overall degradation rate of penicillin G can be obtained. Therefore, in order to study the actual complicated process of degradation of penicillin G, the formation process of the degradation products was followed quantitatively.

In order to identify the initial product of spontaneous degradation using NMR, the chemical shift values of the initial product were compared with those of penicillinase-degraded products.[6] This result clearly indicates that the initial product is penicilloic acid.

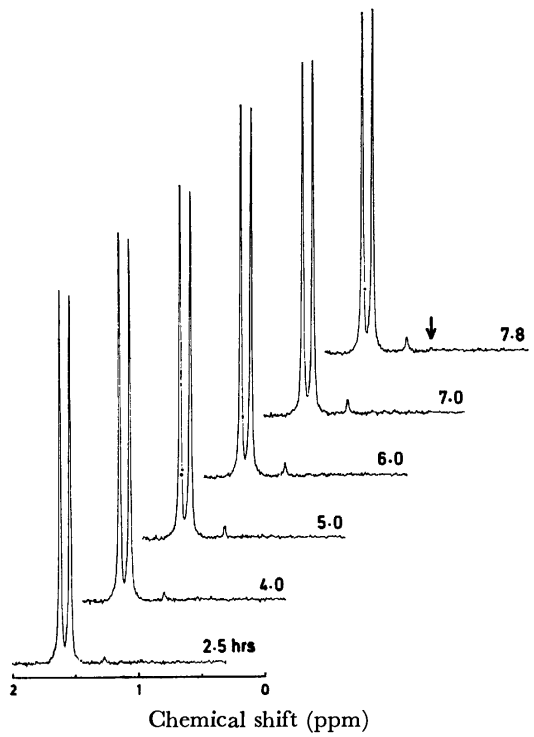

Fig. 2. Correlation NMR spectra of methyl region of penicillin G and penicilloic acid at early stages of degradation. Number of accumulations: 128. Two large peaks at $\delta=1.54$ and 1.62 ppm result from penicillin G and a small peak at $\delta=1.27$ ppm results from penicilloic acid. The signal due to the secondary product ($\delta=1.07$ ppm) is marked by an arrow.

In order to follow the formation of penicilloic acid at the early stage, 32—128 accumulations were performed in the correlation mode. Each accumulation was completed within 10 min. Figure 2 gives NMR spectra of the methyl region of penicillin G and penicilloic acid at the early stage of degradation. The α-methyl peak of penicilloic acid appears at $\delta=1.27$ ppm. Although NMR is less sensitive than TLC, a signal due to the secondary product ($\delta=1.07$ ppm) can be clearly seen in Fig. 2, where the signal is marked by an arrow. This signal becomes much stronger at a later stage of degradation. An aqueous solution containing only penicilloic acid also gives a product which is identical with this secondary product. This result demonstrates that the secondary product is produced from penicillin G through penicilloic acid, *i.e.* the process of formation of penicilloic acid and the secondary product is a successive degradation reaction. When pH is not regulated, penicilloic acid is known to undergo degradation forming penilloic acid by decarboxylation.[1] In the present experiment, the secondary product is presumably penilloic acid, judging from the formation of bubbles in the solution during the course of incubation. No attempt has been made to identify this product. The order of appearance of the degradation products observed by the correlation NMR method is consistent with that observed by TLC; as shown in Table 1, penicilloic acid with an R_f value of 0.15 appears first, followed by the secondary product which gives an R_f value of 0.3. Products whose R_f values are 0.4 and 0.49 cannot be assigned to any distinct NMR peaks due to a low concentration of these products.

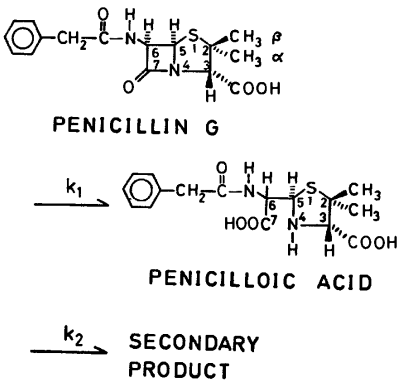

Fig. 3. A degradation process of penicillin G.

A computer simulation of the process of formation of penicilloic acid and the secondary product was performed by assuming that the reaction is successive first order reaction. The result is illustrated in Fig. 3. For the simulation, the yields for these products observed within 17 h after the addition of penicillin G were used; no other products exist during this period judging from the TLC result. The computer simulation gives kinetic constants of $k_1=0.7\times10^{-2}\,h^{-1}$ and $k_2=6\times10^{-2}\,h^{-1}$. Figure 4 illustrates observed and calculated formation processes for penicilloic acid and the secondary product. In the case of penicilloic acid the calculated curve is in good agreement with the observed yield over the entire range of the reaction. On the other hand, the observed

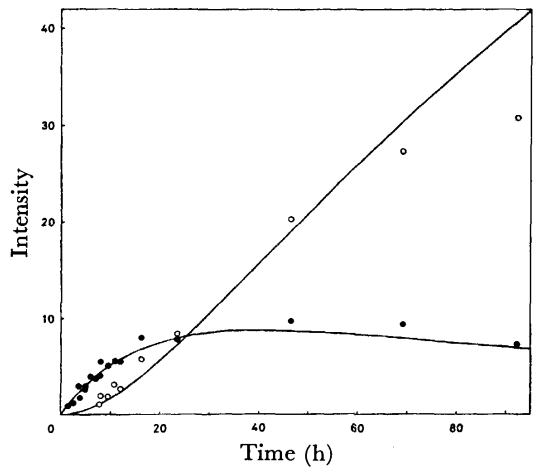

Fig. 4. Plots of intensity of the methyl group of penicilloic acid ● and the secondary product ○ *vs.* time at 30 °C in the phosphate buffer solution. Solid lines indicate the calculated values. Initial value of α-CH_3 intensity of penicillin G is arbitrarily taken to 100.

value for the secondary product does not agree well with the calculated value at a later stage of the reaction. This suggests that the secondary product is labile and further degraded.

A kinetic constant of the first step, k_1 obtained here is in good agreement with $k_{overall}$ which is obtained from the decreasing time-course of penicillin G. From this result it was found that the successive first order reaction given in Fig. 3 is dominant in 0.3 M phosphate buffer solution (pH 7.0) at 30 °C with kinetic constants of $k_1=0.7\times10^{-2}$ h^{-1}, $k_2=6\times10^{-2}$ h^{-1}.

The Crystal Structures of Tin(II) Chloride Dihydrate in High- and Low-Temperature Phases as Studied by Neutron and X-Ray Diffractions

Katsuki KITAHAMA and Hideko KIRIYAMA

The Institute of Scientific and Industrial Research, Osaka University, Yamadakami, Suita, Osaka 565

(Received June 27, 1977)

The neutron-diffraction results for deuterated single crystals have shown definitely that the phase transition is ascribable to the ordering of the hydrogen atoms. The ordered arrangement below the transition temperature (T_t= 234 K) agrees well with the NMR results. No doubling of the unit cell or loss of the center of symmetry can be detected. In the disordered phase above T_t, four deuterons of two non-equivalent water molecules are distributed into seven sites. The occupancy factors of the individual sites have been refined by least-squares methods under different constraints. Bernal and Fowler's ice rule is obeyed in the H-bonded water layers, and the water molecules of crystallization scarcely dissociate at all. The crystal structure has been redetermined by the X-ray diffraction method at 209 and 223 K, using an $SnCl_2 \cdot 2H_2O$ single crystal. No distinct change in the structure of non-hydrogen atoms has been disclosed on passing through the transition point (T_t=218 K). However, in the close vicinity of T_t, the *a* and *c* lattice parameters and the three H-bonded O···O distances steeply change in association with the ordering of the hydrogen atoms.

Crystals of $SnCl_2 \cdot 2H_2O$ exhibit a phase transition accompanied by a characteristic dielectric anomaly at 218 K (at 234 K for its deuterated analogue).[1] Successive studies of proton (PMR) and deuteron (DMR) magnetic resonance,[2,3] X-ray diffraction,[4] and Raman scattering[5] have shown that the phase transition should be ascribed to the ordering of hydrogen atoms in H-bonded water layers without another distinct change in the crystal structure. Furthermore, the critical phenomena of the phase transition have been studied by other approaches, such as specific heat,[6,7] and dielectric measurements.[8] On the other hand, the theory of the phase transition[9] and the explanation of the dielectric behavior[10] have been developed in cooperation with these experiments.

This study was performed to elucidate more directly the hydrogen arrangement in the H-bonded network below and above the phase-transition temperature, T_t. Some of the neutron-diffraction (ND) results have been given previously.[11] Additionally, the crystal structures at 209 and 223 K as well as the lattice parameters in the 93—293 K range were determined by X-rays in order to make sure whether or not the hydrogen-ordering is associated with structural changes in other atoms.

Neutron-diffraction Experiments

Samples. Deuterated single crystals, $SnCl_2 \cdot 2D_2O$, were used for the present ND study, because X-ray photographs taken at both 293 and 93 K had shown no change in the crystal structure on deuteration. Single crystals were grown from a deuterated hydrochloric acid solution saturated with anhydrous tin(II) chloride. A large single crystal was cut into three cylindrical pieces, weighing 0.8957, 0.9282, and 1.2361 g. The smallest one has dimensions of 5.5, 6.0, and 7.5 mm along the a, c, and b axes respectively, and it was mainly used. Another crystal, weighing 12.3 g, was also used at the initial stage of the experiment. These four crystals are labeled S1, S2, S3, and S4 in increasing order of weight. Since this compound is sensitive to moisture, many sorts of organic adhesives, and metals, each single-crystal sample was wrapped with Teflon tape and then placed in an aluminium capsule.

Intensity Data Collection. All the ND measurements were carried out with the KUR-1 reactor of the Research Reactor Institute, Kyoto University. The intensity data of Bragg reflections were collected on a Rigaku neutron four-circle diffractometer at 297 and 88 K. The neutron flux had a density of 7×10^4 n cm^{-2}·s^{-1} at the specimen and a wavelength of 0.994 Å. The reflections were measured within $\sin\theta/\lambda$ of 0.72 Å^{-1}. The 2θ-ω step-scan technique was used with the step size of $\Delta 2\theta = 0.1°$. The scan range for each reflection was adjusted so as to include at least five background points on both sides of the peak. The counting time was controlled by monitoring the intensity of an incident neutron beam. A graphical method was used for integrating the observed intensity and for correcting the background. No correction for absorption was made because of the small linear absorption coefficient (μ= 0.255 cm^{-1}). The standard intensity was monitored every 25 reflections. There was no significant change in the intensity of the standard reflection throughout the data collection.

At room temperature (297 K) the *hk*0 and 0*kl* intensity data were collected with the biggest crystal, S4, while 0*kl*, *h*0*l*, and *hkh̄* were measured with the smallest, S1. For the measurement at 88 K, a ten-liter Dewar vessel containing liquid nitrogen was attached on the ϕ table of the four-circle diffractometer to cool the specimen down to 88 K by a conduction method. Because this arrangement limited the tilting angle of the χ-circle to the range of $-20° < \chi < 20°$, three crystals, S1, S2, and S3, were mounted with b, a, and c axes respectively along the ϕ-axis of the goniostat.

Some forbidden reflections for the $P2_1/c$ space group, as determined by X-rays, were carefully checked, but their intensities did not exceed more than one half of the background level. Thus, no evidence was found to suggest that the low-temperature phase is either antiferroelectric or ferroelectric.

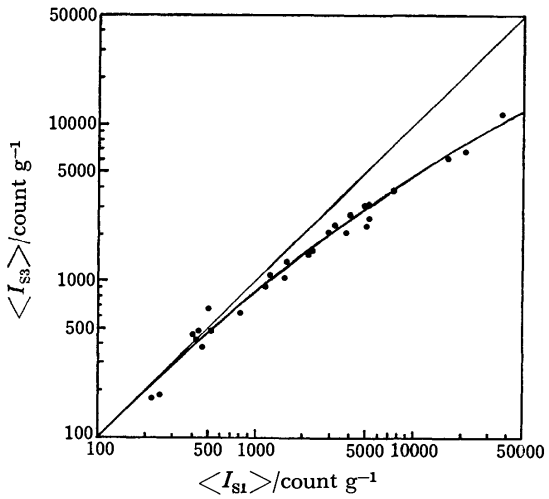

Fig. 1. The extinction effect observed in the ND experiment of $SnCl_2 \cdot 2D_2O$. The reduced intensity of a bigger crystal S3 is plotted against that of a smaller crystal S1, both on logarithm scale. Deviation from the line with a slope of unity reflects the extinction effect.

Extinction Correction. In the early stage of least-squares refinements, it became apparent that the intensities were affected by severe extinction and that the data required adequate corrections. Two kinds of isotropic corrections were attempted, for simplicity neglecting the dependence of the extinction on the Bragg angles. One was an exponential type with a single parameter, such as $I_o = I_c \exp(-kI_c)$. This type of correction was unsuccessful, probably because the I_o/I_c ratio was less than 0.7, as was suggested by Hamilton.[12] The other was based on the reduced intensity, $\langle I \rangle$, which was a quotient of the observed intensity divided by the crystal weight. The reduced intensity of a bigger crystal, $\langle I_b \rangle$ was plotted against that of a smaller crystal, $\langle I_s \rangle$, both on the logarithm scale. The difference in these reduced intensities, $\Delta\langle I \rangle$ $(=\langle I_s \rangle - \langle I_b \rangle)$, was evaluated from the smoothed curve shown in Fig. 1. Thus, the intensity data were corrected by extrapolating the $\langle I \rangle$ to an infinitesimally small weight, using either of the following two equations:

$$\langle I_{corr} \rangle = \langle I_b \rangle + \frac{W_b}{W_b - W_s} \Delta\langle I \rangle$$
$$= \langle I_s \rangle + \frac{W_s}{W_b - W_s} \Delta\langle I \rangle$$

where W_b and W_s are the weights of a bigger and a smaller crystal, respectively. This type of correction was effective in avoiding negative temperature factors and in lowering the R-value by more than 2%. However, this correction seemed to be not enough for the biggest crystal, S4; therefore its intensity data were excluded from the final least-squares refinement.

X-Ray-diffraction Experiments

A single crystal of $SnCl_2 \cdot 2H_2O$, with dimensions of $0.08 \times 0.1 \times 0.32$ mm^3 and sealed in a Lindemann-glass capilary, was used throughout the X-ray work. This crystal was mounted on a Rigaku four-circle diffractometer, with its c-axis along the ϕ-axis of the goniostat. The crystal was cooled by blowing a stream of cold nitrogen, using an X-ray low-temperature device manufactured by the Rigaku Denki Co. The reflection intensities at 209 and 223 K, and monoclinic cell dimensions (space group; $P2_1/c$) from 93 to 293 K were measured with an Mo $K\alpha$ radiation monochromatized by pyrolytic graphite. The temperatures were controlled within ± 0.5 K during each measurement of the lattice parameters, and within ± 1.0 K throughout each collection of the intensity data. The cell dimensions at a given temperature were refined by a least-squares method using 21 reflections with 2θ between 40 and 65°. They are summarized in Table 1. All the intensity data were collected by means of the 2θ-ω scan technique. No correction was made for absorption ($\mu = 54.9$ cm^{-1}).

Space group; $P2_1/c$ (throught the temperature range), $Z=4$, F.W. 225.63 g mol^{-1}, $\rho_{obsd}=2.710$,[19] $\rho_{calcd\,(293\ K)} = 2.724$ g cm^{-3}, μ(Mo $K\alpha$)$=54.85$ cm^{-1}. E.s.d.'s are given in parentheses.

Structure Analyses and Refinements

Structure at 88 K by Neutron Diffraction. The approximate positions of deuterons were easily determined from the Fourier projections of nuclear-scattering density along the a and c axes; the signs were based on the heavy-atom coordinates from a previous X-ray study.[4] No evidence was found for any disordering of the deuteron positions. The extinction correction described above was made prior to the refinement. In order to check whether or not the deuterium substitution was complete, the neutron-scattering length of deuteron was refined, as well as the positional and isotropic thermal parameters for all the atoms and a scale factor, in the full-matrix least-squares refinement. The obtained scattering length was $b_D = (0.605 \pm 0.018) \times 10^{-12}$ cm, indicating that the unsubstituted hydrogen was negligibly small. The scattering lengths used were $b_{Sn}=0.610$, $b_{Cl}=0.961$, $b_O=0.577$, and $b_D=0.612$ in units of 10^{-12} cm from Neutron Diffraction Commission, 1969.[13]

The refinement was performed by a block-diagonal least-squares method with 814 reflections, in which positional and anisotropic thermal parameters for all the atoms, an overall temperature factor, and a scale factor (a total of 65 parameters) were varied until the maximum shift in any parameter was less than one-fourth of its e.s.d. The quantity minimized in this

refinement was $\Sigma w(|F_o|-|F_c|)^2$, with a unit weight for all reflections. The final $R[=\Sigma||F_o|-|F_c||/\Sigma|F_o|]$ was 0.081 for all reflections and 0.078 for non-zero reflections. The final F_c and F_o, with the extinction corrections, are given in Table 2. The final positional and thermal parameters are listed in Table 3, where the anisotropic temperature factors are shown in Å^2 for comparison with the isotropic ones at 297 K.

Structure at 297 K by ND. The difference Fourier projections of the nuclear-scattering density along the a and c axes and [101] direction were calculated using the heavy-atom positions from the X-ray study.[4] The maps revealed that the four deuterons scatter in seven sites of the asymmetric unit, providing direct evidence for the disordering of deuteron positions in the high-temperature phase. Moreover, the heights of the deuteron peaks were considerably different from one another. Accordingly, the occupancy factors of the individual deuteron sites should be adjusted as well as the positional and thermal parameters in the least-squares refinement.

A full-matrix least-squares refinement based on 311

a) $F_{ND}(000)=24.683$ cm^{-12} cell^{-1}. b) Extinction corrections have been applied.

independent reflections (obtained by use of the S1 sample) was initiated with the heavy-atom positions from the X-ray study[4] and the deuteron positions postulated just above. In the early stage of the refinement, the occupancy factors of the deuteron positions were fixed at values of 1/3, 2/3, 1/3, 2/3, 1/3, 2/3, and 1.0 for D(1), D(2),···, D(7) in the same order, according to the suggestion from the DMR study.[2,3] After the stage of $R=0.121$, several kinds of full-matrix least-squares refinements were carried out under appropriate constraints, because of the occupancy factors strongly correlate with the temperature factors; these were labeled A, B, C, D, and E as follows.

Refinement A: All the occupancy and temperature factors for the deuteron positions were refined at the same time with no constraint.

Refinement B: The sum of the occupancy factors of the two deuteron positions in each H-bond was fixed at unity.

Refinement C: The occupancy and temperature factors of deuteron were refined alternately every four cycles. This procedure yielded the lowest R_0 (R for non-zero reflections), the minimum standard deviation of observation, and the uniform temperature factors.

Refinement D: The occupancy and temperature factors were varied in alternate cycles. All the occupancy factors were adjusted after every cycle of their refinement

Table 5. Final positional parameters (10^4x_j), thermal parameters ($10^2B/Å^2$), and site occupancy factors (W) in the high-temperature phase at 297 K
Estimated standard deviations are given in parentheses. The isotropic temperature factors are of the form: $T=\exp(-B\sin^2\theta/\lambda^2)$.

a) Estimated standard deviations are given in parentheses. The anisotropic thermal factors are given by the same expression as in Table 3.

in such a way that an oxygen atom always has a total of two nearest deuterons to constitute a water molecule.

Refinement E: The strong constraint of so-called ice rules was imposed on the refinement. Since each oxygen has a total of two nearest deuterons, and since each H-bond involves one deuteron, only two occupancy factors, such as D(4)'s and D(6)'s, need to be refined. This refinement converged only slightly, and it was far from satisfactory (see Table 6).

No positional parameters of any of the atoms differed by more than their associated e.s.d.'s among these refinements. Therefore, only the final F_c, the F_o after the extinction correction, and the final positional parameters in the C refinement are presented in Tables 4 and 5. The occupancy factor, W_j, and the isotropic temperature factor, B_j, for the j-th deuteron position are compared in Table 6. The extinction correction described above was made before any refinement, and the weighting scheme used throughout the refinement was

$$w = I_o/I_e, \quad \text{if } I_o > 4I_{min},$$
$$w = (I_o+I_{min})/5I_{min}, \quad \text{if } I_o < 4I_{min},$$

where I_o and I_e were the integrated intensities before and after the extinction correction respectively, and where I_{min} was the averaged background intensity. The quantity minimized in all least-squares refinements was $\Sigma w(|F_o|-|F_c|)^2$.

Structure at 209 and 223 K by X-Ray Diffraction. The procedure used was almost the same as in the previous study.[4] The structure was refined by a block-diagonal least-squares method, with 1582 and 1589 independent reflections at 209 and 223 K respectively. For comparison, the structure at 293 K was refined again including anomalous dispersion corrections for Sn and Cl. In these calculations, the atomic scattering factors for Sn^{2+}, Cl^-, and O^- and anomalous dispersion corrections, f' and f'' for Sn and Cl were taken from the International Tables for X-Ray Crystallography, Vol. IV.[14] The values of R and R_0 at each temperature are [given as T/K, R, R_0]: 209, 0.053, 0.047; 223, 0.045, 0.038; and 293, 0.045, 0.043. The final positional and thermal parameters at 209, 223, and 293 K are summarized in Table 7, together with those at 88 K obtained from the neutron study. A list of the observed and calculated structure factors at 209 and 223 K has been deposited with the Chemical Society of Japan (Document No. 7723).

Computation. All the computations in this study were made on the NEAC 2200/700 at the Computer Center, Osaka University, using local modifications of the RSFLS, RSSFR-5, HBLS-V, and RSDA-4 in the UNICS program system[15] and the stereoscopic drawing program ORTEP.[16]

Results and Discussion

Crystal Structure Except for Hydrogens. The crystal contains two kinds of water molecules. The first, $H_2O(1)$, is coordinated to a tin atom to form a trigonal pyramidal dichloroaquatin(II) comples, $SnCl_2 \cdot OH_2$, whereas the second, $H_2O(2)$, does not. These two are H-bonded to each other to construct a puckered water-layer, which extends along the (100) plane. Tin and Cl atoms form double layers parallel to (100), also. Between these Cl/Sn double layers, the water layer intervenes (Fig. 2).

The Sn–Cl(2) bond length is significantly longer (by 0.06 Å) than Sn–Cl(1). This is consistent with the facts that Cl(2) is close to two Sn atoms of different pyramids

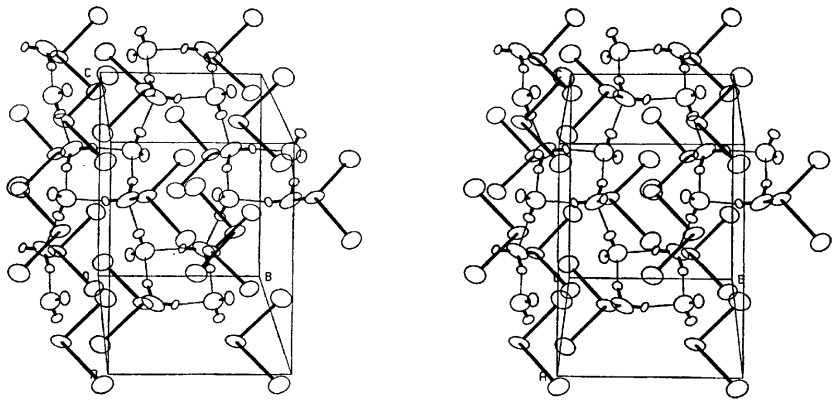

Fig. 2. View of the whole cell in $SnCl_2 \cdot 2D_2O$ determined by ND at 88 K. The c axis is vertical and the b axis is horizontal on the page.

at distances of 3.22 and 3.33 Å, while Cl(1) has two Sn neighbors with much longer separations of 3.41 and 3.65 Å. Such a difference in the nature of the chemical bonds should reflect on the quadrupole resonance (NQR) frequences of the ^{35}Cl nuclei. Recently Trontelj and Pirnat have detected two NQR frequencies of 8.656 and 8.511 MHz at 300 K.[17] The former can be assigned to Cl(1), and the latter, to Cl(2), because Cl(1) is less ionic than Cl(2) in view of the interatomic distances. Further details with regard to the arrangement of non-hydrogen atoms have already been described in a previous paper.[4]

Hydrogen-ordered Structure at 88 K. The positions and site-occupancy factors of hydrogen atoms are of much interest, because they play a dominant role in the phase transition. The unit cell of the hydrogen-ordered structure is shown in Fig. 2; it was determined by neutron diffraction at 88 K. It was confirmed from these results that the configuration of $D_2O(1)$ is Type H, while that of $D_2O(2)$ is Type E, according to the classification of Chidambaram *et al.*[18] In the former, one of the lone pairs of oxygen O(1) is directed toward a tin atom, and the other, toward an H-bond-donor oxygen O(2). On the other hand, two lone pairs of oxygen O(2) are directed toward two H-bond-donor oxygens, O(1) and $O(1^{iii})$. Thus, the three deuterons, D(2) and D(4) of the coordinated water molecule and D(5) of the non-coordinated one, form three normal O–D···O hydrogen bonds. The remaining one, D(7), of $D_2O(2)$ does not participate in any H-bond, but is directed toward one Cl atom rather than two; the separations of $D(7)\cdots Cl(1^{iv})$ and $D(7)\cdots Cl(2^{iv})$ are 2.43 and 2.78 Å respectively at 88 K. These ordered, non-centric hydrogen positions are consistent with our PMR and DMR results.[2,3]

Mognaschi *et al.* have revealed, from their dielectric measurement, that a weak but significant, antiferroelectric interaction develops between the H-bonded

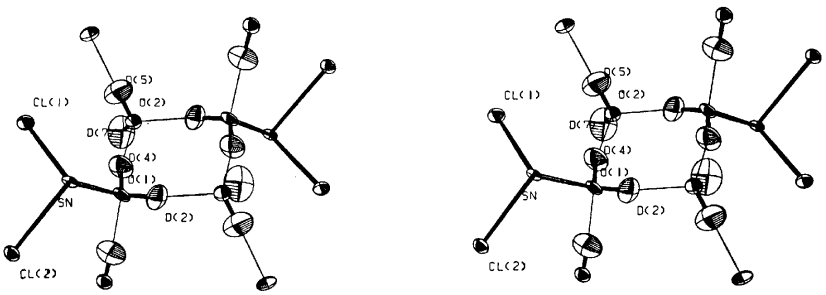

Fig. 3. Stereoscopic drawings of the ordered-arrangement of deuterons with thermal ellipsoids at 50% probability.

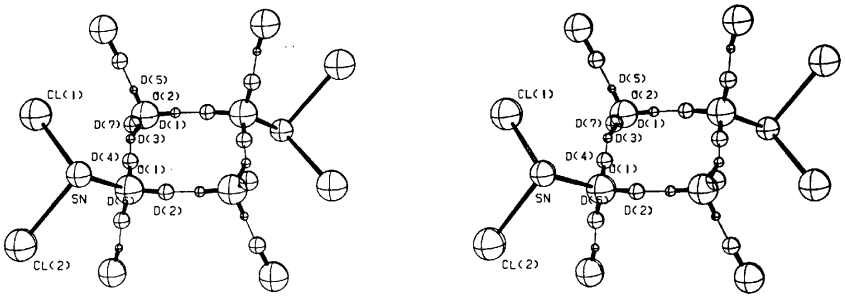

Fig. 4. Stereoscopic view of the disordered-arrangement of deuterons at 297 K. Each occupancy factor given in Table 5 is represented by a size of sphere.

water layers, in addition to the ferroelectric interaction within the layer, as the temperature approaches T_t very closely.[8] They explained the anomalous behavior of the dielectric constant and of the spin-lattice relaxation rate of protons near T_t in terms of a "critical slowing down" of the electric polarization, as in many ferroelectric and antiferroelectric substances. However, as has been described earlier, our examinations by both X-ray and neutron-diffraction methods showed that no superstructure reflection indicating the doubling of [100] or any lowering of the crystal symmetry appears in the low-temperature phase.

Hydrogen-disordered Structure at 297 K. This compound undergoes the phase transition at 218 K (the deuterated analogue does at 234 K), above which the reorientation rates of both water molecules are high enough to affect the NMR spectra. The deuteron arrangements in the H-bonded layer at 88 and 297 K are compared in Figs. 3 and 4.

In the high-temperature phase, two deuterons of $D_2O(1)$ are distributed among three sites, D(2), D(4), and D(6). In contrast with this, only one deuteron of $D_2O(2)$ is dispersed among the D(1), D(3), and D(5) sites, while the other remains at the fixed position of D(7). This striking feature, together with the DMR results,[3] suggests that $D_2O(1)$ and $D_2O(2)$ reorient about Sn–O(1) and O(2)–D(7) bonds respectively, with a nearly three-fold symmetry. If this is the case, the deuteron occupancy factors, W_j, would be 2/3 for D(2), D(4), D(6), and 1/3 for D(1), D(3), D(5). The ND results of the various least-squares refinements given in Table 6 are in fair agreement with the above picture, at least in regard to W_1, W_2, W_3, W_4, and W_7.

It is noteworthy, however, that the occupancy factors, W_5 and W_6, deviate from the expected values by more than three times their e.s.d.'s in all the refinements. This indicates that the H-bond involving D(5) and D(6) is closely associated with the phase transition, as was suggested in a previous paper.[11] Salinas and Nagle have calculated, using statistical mechanics, the site occupancy of D(5) as a function of the temperature and have pointed out that its value should be less than 1/3 at high temperatures ($\lim_{T\to\infty} W_5=0.119$).[9] At room temperature, the theoretical value of W_5 is 0.34, which is larger by 0.1 than the experimental one (0.21 in the C refinement). However, in view of the approximation of the theory and the uncertainty in the experimental occupancy factor, the agreement between these values seems satisfactory. In summary, it may be said that the ND results support the mechanism of the phase transition proposed by Salinas and Nagle.

The results of the least-squares refinements show that each oxygen atom has a total of approximately two deuteron neighbors and that the sum of the two occupancy factors on each H-bond amounts to unity. It can, therefore, be concluded that Bernal and Fowler's ice rules are obeyed in this two-dimensional H-bonded network; hence, scarcely no partial dossociation water molecules occurs.[11]

The bond angle of $D_2O(1)$ in the low-temperature phase is typical of a water molecule of crystallization, in spite of a considerably narrow acceptor-angle, O(2)···

ii	x, 1/2−y,	−1/2+z		v	1−x, 1−y, 1−z

O(1)···O(2^{ii}) (90.2°). On the other hand, some H–O–H angles in the high-temperature phase deviate from the tetrahedral angle or the typical value of 105°, but these deviations are of no significance, because of the large number of refined parameters relative to the number of the intensity data. Some interatomic distances and angles based on the neutron data at 88 and 297 K are compared in Table 8.

Change in the Crystal Structure with the Temperature. In order to make clear whether or not the ordering of the hydrogen atoms is accompanied by any displacement of other atoms, especially in the vicinity of the transition point, T_t, the crystal structure was analyzed by means of X-ray diffraction at 209 and 223 K, a little below and above T_t.

The structures obtained at both temperatures were almost the same as those previously determined by X-rays at 293 K and by neutron diffraction at 88 K (Table 7), except, of course, for the hydrogen atoms. Only a slight, but, significant change was found in the H-bonded net work. The O···O distances of the three non-equivalent H-bonds vary with the temperature in complicated ways (Fig. 5). In Fig. 5 the H-bonds are designated as d_{12}, d_{34}, and d_{56}, according to the numbering of the deuterons (or protons) involved; the temperature dependence of an Sn···Cl separation between adjacent layers is also included for comparison. It is noteworthy again that the H-bond d_{56} differs from the other two in their features; the former distance decreases with an increase in the temperature, whereas those of the other two increase normally. As the temperature approaches T_t from below, these H-bond distances change drastically; one of them contracts and the others elongate, and then just above T_t all three become nearly equal. As a result, the volume change of the unit cell occurring at T_t is quite small, and the single crystal does not shatter nor become opaque on passing through the phase transition.

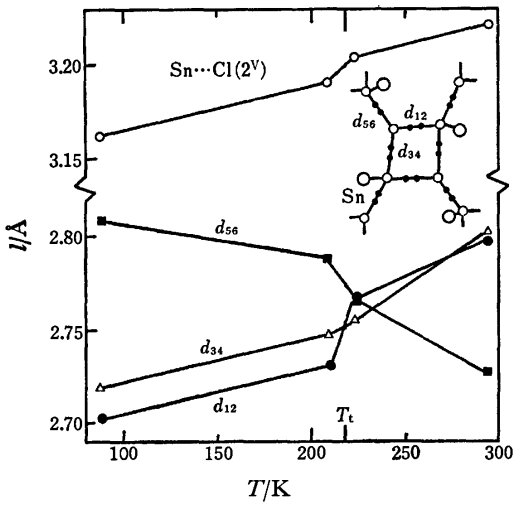

Fig. 5. Plot of three H-bonded O···O distances and an Sn···O distance against temperature. The results at 88 K come from ND, and the others from X-ray diffraction.

Thermal Expansion. The high-resolution heat-capacity measurements by Matsuo *et al.* showed that the phase transition is of a quasi-first-order type.[7] No hysteresis was detected on the curve of any lattice parameter or of the unit-cell volume near T_t, within ±0.5 K. The anomaly of the linear and volume expansion-coefficients extends over a much wider temperature range than that of the heat capacity. In particular, the volume expansion-coefficient swings in a complicated manner around the phase transition. Figure 6 shows the results deduced by numeric point-by-point differentiation from the lattice parameters at various temperatures. The remarkable elongation of the a-axis about T_t corresponds to an abrupt expansion of the separation between adjacent double layers of Cl and Sn atoms. The anomalous expansion-coefficient along the c-axis reflects the change in the $d_{34}+d_{56}$ with the temperature. On the other hand, the elongation of d_{12} is partly canceled by the contraction of d_{56}, resulting in a monotonic elongation along the b direction. A steep variation near T_t was also found in the monoclinic β angle.

The line profiles of all (h00) reflections checked by X-rays are often broadened in both 2θ-ω and ω scans in the low-temperature phase; their half-widths are more than twice the corresponding ones in the high-temperature phase. They can, however, be sharpened by annealing for 24 h 20 K below T_t.

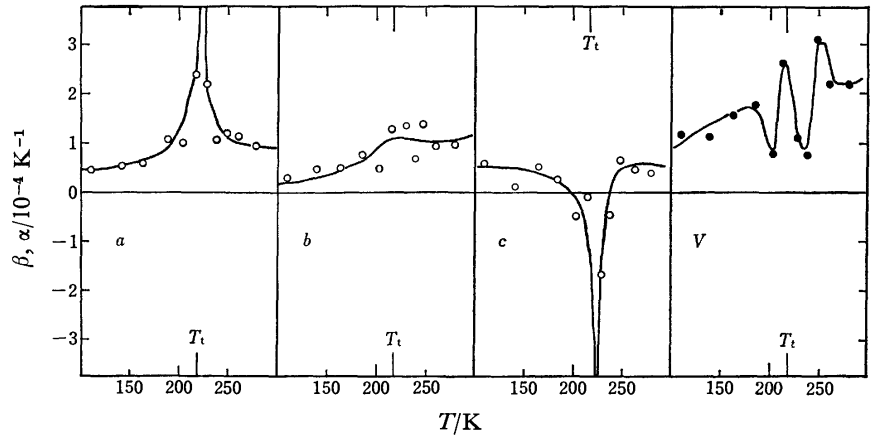

Fig. 6. Temperature dependences of thermal expansion-coefficents. Linear and volume expansion-coefficients are defined as $\beta = 1/l \cdot dl/dT$ and $\alpha = 1/V \cdot dV/dT$, respectively.

The authors are greatly indebted to Professor Iwao Shibuya for his guidance and assistance in this ND work at the Research Reactor Institute, Kyoto University. The authors are also grateful to Professor Emeritus Ryôiti Kiriyama for his continued interest and encouragement throughout the present study and to Dr. Takeshi Asai for his careful reading of the manuscript.

The Crystal and Molecular Structure of Dichloro [*N*, *N*-dimethyl-*α*-methyl-*o*-(butylphenylphosphino)benzylamine] palladium(II)

Akio TAKENAKA, Yoshio SASADA, Keiji YAMAMOTO, and Jiro TSUJI

Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received June 30, 1977)

The crystal structure of dichloro[*N*,*N*-dimethyl-α-methyl-*o*-(butylphenylphosphino)benzylamine]palladium-(II) has been determined from Mo*K*α diffraction data. The space group is $P2_1$ with $Z=2$, $a=9.255(2)$, $b=14.372$ (3), $c=8.584(1)$ Å, and $\beta=105.99(1)°$. The final R became 0.034 by least-squares refinement. The Pd atom has a square planar coordination of N, P, and two Cl atoms, which is considerably distorted by the intramolecular atomic repulsions. The Pd–N distance, 2.134(4) Å, which is longer than those found so far, is accompanied by a short distance 2.285(1) Å of trans Pd–Cl. A plot of Pd–Cl distance *versus* trans Pd–N distance in several Pd complexes, in which the nitrogen atom is not π-acceptor, shows a linear relationship with the correlation factor of −0.28(4).

N,*N*-Dimethyl-α-methyl-*o*-(butylphenylphosphino)-benzylamine, $(C_6H_5)P(C_4H_9)C_6H_4CH(CH_3)N(CH_3)_2$, prepared from (*S*)-α-methylbenzylamine, is a diastereomeric bidentate ligand. The rhodium complexes with the optically resolved ligand catalyze hydrogenation of certain olefins; the preferred configuration of the products depends primarily upon the chirality of the ligand.[1] To determine the absolute configuration of the ligand, the title Pd complex was synthesized and its crystal structure was analyzed by the X-ray diffraction method.

Experimental

$Pd(C_6H_5CN)_2Cl_2$ (156 mg, 0.4 mmol) and $C_6H_5P(C_4H_9)C_6H_4CH(CH_3)N(CH_3)_2$ (124 mg, 0.4 mmol), a pure epimer, were dissolved in 15 ml of dry benzene. After 2 h stirring in N_2 atmosphere, deep yellow precipitates, 150 mg, were collected by filtration and recrystallized from a hexane–CH_2Cl_2 (1:2) solution. Calcd for $C_{20}H_{28}Cl_2NPPd$: C, 48.95; H, 5.75; N, 2.85%. Found: C, 48.41; H, 5.86; N, 2.84%; mp 196—197 °C (dec); $[\alpha]_D^{20}$ −202° (in CH_2Cl_2).

Table 1. Crystal data

$Pd[C_6H_5P(C_4H_9)C_6H_4CH(CH_3)N(CH_3)_2]Cl_2$	
F.W. 490.7

$a=9.255(2)$ Å	$Z=2$
$b=14.372(3)$	$D_m=1.48$ g cm^{-3} (by flotation)
$c=8.584(1)$	$D_x=1.485$ g cm^{-3}
$\beta=105.99(1)°$	μ (Mo*K*α) $=12.4$ cm^{-1}

A crystal, 0.15×0.3×0.5 mm in size, was used for data collection on a Rigaku computer-controlled four-circle diffractometer, using graphite-monochromated Mo*K*α radiation ($\lambda=0.71069$ Å). The cell parameters were obtained by least-squares calculation with 22 high-angle reflexions. The crystal data are summarized in Table 1. Intensities were measured in ω-2θ scan mode with scan width of 1.5° (in 2θ) plus α_1-α_2 divergence at scan speed 4° (in 2θ) min^{-1}, using a large receiving slit 5.5×5.5 mm. By this scan technique, intensity profile of each reflexion showed a single peak, although the specimen gave twinned spots on Weissenberg photographs owing to a crack within it. Five reference reflexions, monitored after every 50 reflexions, indicated no significant intensity variations throughout the experiment. Out of 2616 independent reflexions in the range $2\leq 2\theta\leq 55°$, 88 weak reflexions which gave the counts under background were considered as zero-reflexions. The data were corrected for Lorentz and polarization factors but not for absorption effects. Bijvoet pairs of reflexions were collected on Weissenberg photographs using Cu*K*α radiation.

Structure Determination

The structure was solved by the heavy-atom method and its atomic parameters were refined by block-diagonal least-squares technique. All the hydrogen atoms, found on a difference map, were included. The quantity minimized was $\Sigma w(|F_o|-|F_c|)^2$, with $w=1/(\sigma_p^2+qF_o^2)$, where σ_p is due to counting statistics and q is 1.02×10^{-5} derived from the variation of the monitored reflexions.[2] The zero-reflexions were included in least-squares calculation by assuming $F_o=F_{lim}$ and $w=w(F_{lim})$, where F_{lim} is 3.198, an observational threshold value, but those for which $|F_c|<F_{lim}$ were omitted. The final R value was 0.034; the maximum shift of coordinates in the last cycle was 0.10σ for Pd, Cl, and P, 0.15σ for N, 0.44σ for C, and 1σ for H atoms. The absolute configuration was determined from a comparison of intensities of 22 Bijvoet pairs. Atomic parameters are listed in Table 2.[3] A stereoscopic view of the molecule is shown in Fig. 1, and bond distances and angles in Fig. 2. Atomic scattering factors used were taken from International Tables for X-Ray Crystallography.[4]

Results and Discussion

As shown in Fig. 1, the Pd atom has a considerably distorted square planar coordination of the N, P, and two Cl atoms. The chlorine atoms are cis as required by the geometry of the bidentate chelating ligand. The absolute configuration of C(7) is sinister (*S*) and that of P is rectus (*R*). The methyl group C(9) and the butyl group are located above the coordination plane, while the methyl group C(8) lies below it. If the rhodium complexes[1] take the same structure, such an arrangement might furnish the structural basis for the mechanism of the asymmetric hydrogenation. When the prochiral substrate approaches Rh above or below the coordination plane to form a π-complex, the steric constraint could determine the preferable enantiotropic face of the substrate.

The two Pd–Cl bond distances differ significantly to

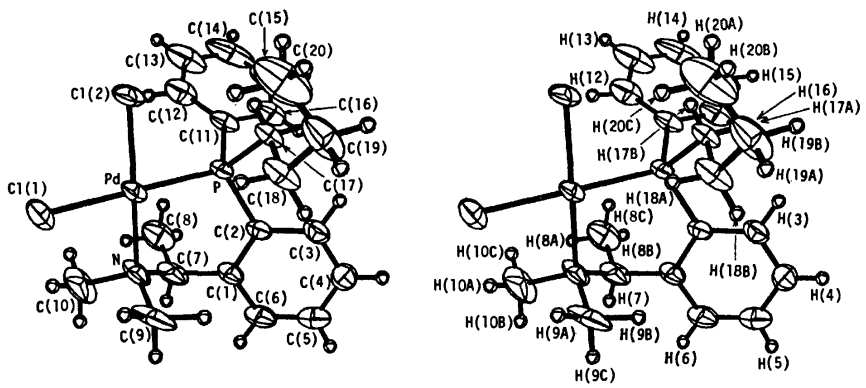

Fig. 1. Stereoscopic drawing of the molecule of dichloro[*N*,*N*-dimethyl-α-methyl-*o*-(butylphenylphosphino)benzylamine]palladium(II). The non-hydrogen atoms are represented by their thermal ellipsoids with 50% probability, while the hydrogen atoms are represented by arbitrary spheres.

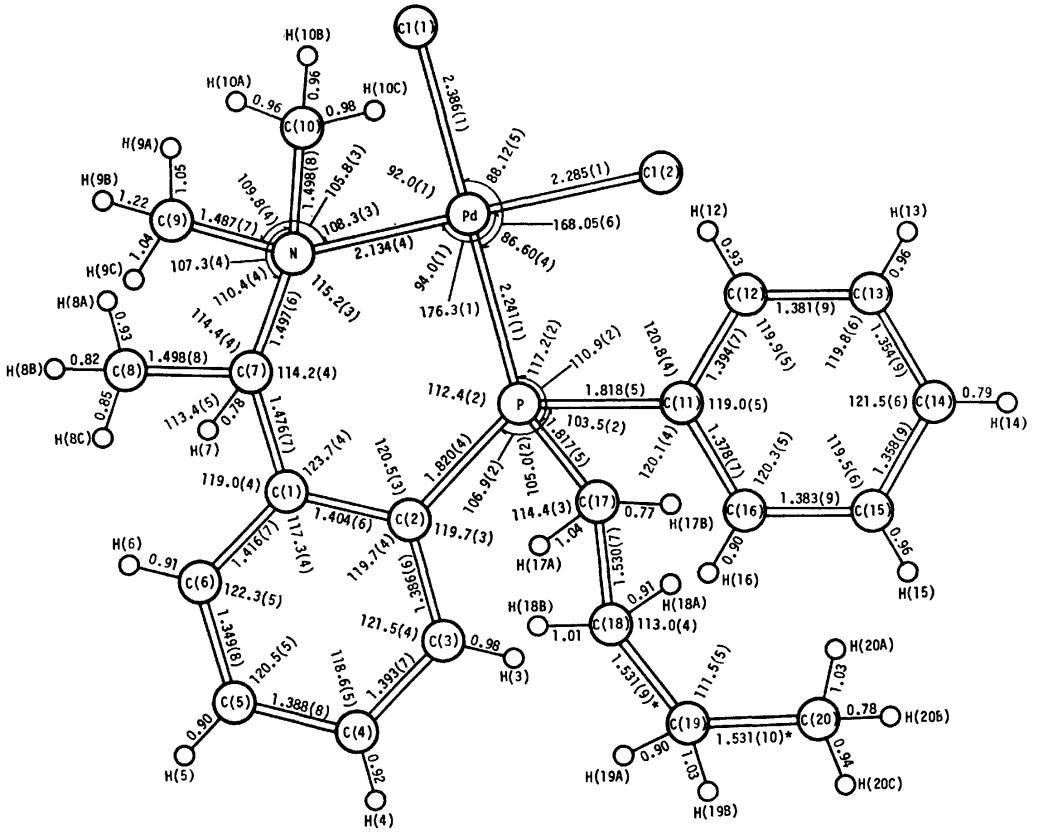

Fig. 2. Bond distances (l/Å) and bond angles (ϕ/°), with their e.s.d.'s in parentheses. Starred values are corrected for riding motion. Standard deviations of C–H bonds are 0.06 Å, and bond angles involving hydrogen atom are nearly tetrahedral or trigonal angle.

each other. The greater length of Pd–Cl(1) (trans to Pd–P) than Pd–Cl(2) (trans to Pd–N) is consistent with the observation that the Pd–Cl bond length decreases as the electronegativity of the trans atom increases.[5] The Pd–Cl(1) distance, 2.386(1) Å, is in the range expected for a Pd–Cl bond trans to Pd–P. On the other hand, the Pd–Cl(2) distance, 2.285(1) Å, is shorter and the Pd–N distance, 2.134(4) Å, is longer than those found so far in Cl–Pd–N systems. Figure 3 shows a plot of Pd–Cl distance *versus* trans Pd–N distance for several Pd complexes, in which the nitrogen atom is not a π-acceptor. Except for $Pd(NH_2CH_2CH_2NH_2)Cl_2$, a linear relationship is observed, the correlation factor is −0.28(4). This observation could be explained in terms of electrostatic interaction, as proposed for Cl–Pt–C system by Manojlović-Muir and Muir.[11] The present Pd–N bond is lengthened by the geometrical constraints mentioned later. The "bend" deformation of the metal d_π orbital by electrostatic repulsion from the σ orbital of Pd–N bond would be small, so that the trans Cl(2) could approach the metal. The value of the correlation factor may be reasonable, since the repulsions from the deformed d_π is mitigated at a long distance of Pd–Cl(2).

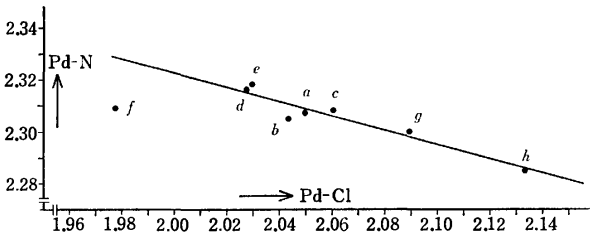

Fig. 3. A plot of Pd–Cl distance *versus* trans Pd–N distance. *a*: $PdCl_2$(*S*-methyl-L-cysteine)H_2O Ref. 6, *b*: *idem*, *c*: $PdCl_2$(D,L-methionine) Ref. 7, *d*: $PdCl_2$(*meso*-2,3-diaminobutane) Ref. 8, *e*: *idem*, *f*: $PdCl_2$(ethylenediamine) Ref. 9, *g*: $PdCl_2$(tetrahydrogen-ethylenediaminetetraacetate)$5H_2O$ Ref. 10, *h*: present work.

The geometrical constaint is indicated by the deviations of atoms from the mean plane through the four coordinating atoms, Pd −0.172, P 0.044, Cl(1) 0.056, Cl(2) −0.050, and N −0.423 Å. The deviation of P is due to repulsions from C(7) and C(8), and that of Cl(1) is caused by C(10); the close contacts are given in Fig. 4. At the same time these repulsions make the N–Pd–Cl(1) and N–Pd–P angles expand, so that P–Pd–Cl(1) deviates from a line. In addition the bond angles involving C(8), C(8)–C(7)–N and C(8)–C(7)–C(1), expand owing to the close contact between P and C(8). The 6-membered chelate ring is also constrained to enlarge the angles, P–Pd–N, Pd–N–C(7), N–C(7)–C(1), C(7)–C(1)–C(2), and Pd–P–C(2), from their normal values. The torsion angles about the C(17)–C(18) and C(18)–C(19) bonds are 186.8(4) and 70.8(6)°, respectively. The three P–C bond distances are 1.817—1.820 Å. The C–N bond distance is 1.494 Å in average. The bond lengths are apparently shortened.

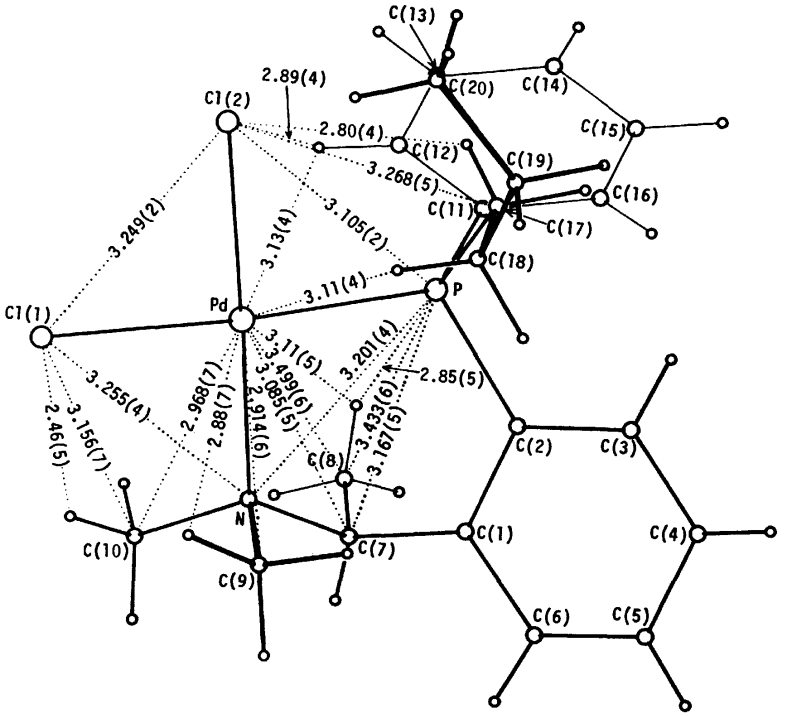

Fig. 4. Close contacts (in Å) around the palladium atom.

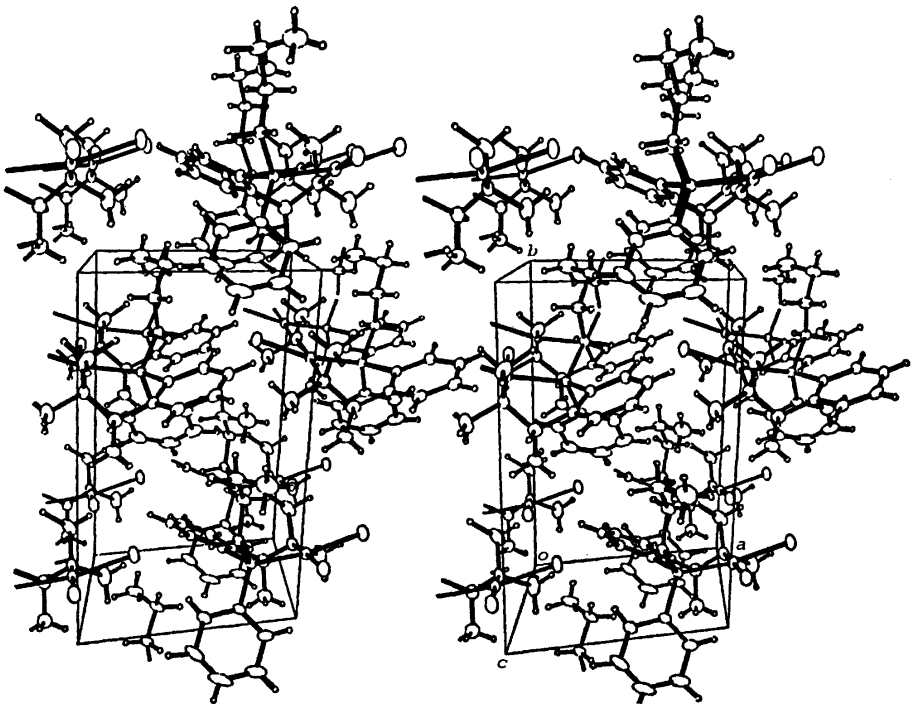

Fig. 5. Stereoscopic diagram showing the molecular packing.

at the periphery of the molecule by the large thermal motions.

As shown in Fig. 5, the complex molecules are packed by van der Waals interactions. A survey of the intermolecular distances indicates no abnormal contacts.

The authors thank Prof. T. Shimanouchi for permitting the use of the TOOL-IR system, by which the data of palladium complexes were looked up in the Cambridge Crystallographic Files.

The Crystal and Molecular Structure of Dimethyl *m*-Phenylenediacrylate

Hachiro NAKANISHI and Yoshio SASADA*

Research Institute for Polymers and Textiles, Sawatari, Kanagawa-ku, Yokohama 221
**Faculty of Science, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152*

(Received June 30, 1977)

Photooligomerizable crystals of dimethyl *m*-phenylenediacrylate are orthorhombic, $Pmn2_1$, with $a=26.419(8)$, $b=3.960(1)$, $c=5.935(2)$ Å, and $Z=2$. The structure was solved by the direct method and refined by the block-diagonal least-squares calculation to the R value of 0.042 for 617 observed reflections. The molecule is nearly planar and V-shaped with a mirror symmetry. A parallel plane-to-plane stack is found along the short b-axis. The molecules in the stack overlap completely, in contrast with the half-molecule overlap in the photopolymerizable crystals of this kind. The length of the b-axis is just the shortest intermolecular distance between reactive double bonds, indicating that the double bonds related by the b-translation would react to form a cyclobutane ring with a mirror symmetry.

Many diolefinic compounds undergo the four-center type photopolymerization in the crystalline state.[1] In the serial studies on the photopolymerizable crystals,[2] we have shown that all the photopolymerizable diolefins with *p*-phenylene moiety change, under the strict control of monomer crystal lattice, into crystalline polymers containing cyclobutane rings with the center of symmetry.

In contrast, dimethyl *m*-phenylenediacrylate (*m*-PDAMe) has been found to give amorphous oligomer having more than two kinds of cyclobutane rings with respect to steric configuration, by prolonged irradiation. At the lower reaction temperature, the dimer with a regular conformation of cyclobutane ring is formed in better yield.[3] From such results, a two-step reaction mechanism, *i.e.*, topochemical dimer formation in a regular crystal lattice and subsequent random cycloaddition in a disordered crystal lattice, was proposed previously.[3] The present crystal structure analysis has been undertaken in order to clarify the mechanism of such characteristic oligomer formation.

Experimental

m-PDAMe was synthesized according to the method described in the previous paper.[4] Plate-shaped crystals were grown from a methanol solution by slow evaporation. The specimen used was a fragment of a plate, $0.15\times0.15\times0.10$ mm in size. The space group was determined from photographs. The precise lattice constants and intensity data were obtained from measurements on a Rigaku computer-controlled four-circle diffractometer, with graphite-monochromatized Cu $K\alpha$ radiation. All reflections within the range of $2\theta<150°$ were collected by use of 2θ-ω scan mode with the scanning rate of 4° min^{-1}. Stationary background counts were accumulated for 10 s before and after each scan. Out of 681 reflections, 617 were greater than $3\sigma(|F_o|)$ and were used for structure determination. No correction was made for absorption. Crystallographic data of *m*-PDAMe are: $C_{14}H_{14}O_4$, *M. W.* 246.3. Orthorhombic, $Pmn2_1$, $a=26.419(8)$, $b=3.960(1)$, $c=5.935(2)$ Å, $U=620.9$ Å^3. $Z=2$, $Dx=1.318$, $Dm=1.320$ g cm^{-3}. μ(Cu $K\alpha$)$=9.30$ cm^{-1}.

* A list of structure factors is deposited as Document No. 7725 at the Office of the Editor of the Bulletin of the Chemical Society of Japan, 1-5, Kanda-Surugadai, Chiyoda-ku, Tokyo 101.

Determination and Refinement of the Structure

The space group and Z indicated that the molecule has a mirror symmetry. The structure was solved by the direct method with MULTAN.[5] All the non-hydrogen atoms were clearly located in the E map computed with the best set of phases. The parameters were refined by the block-diagonal least-squares method using $\omega=0.5$ for $|F_o|\leq1.0$, 1.0 for $|F_o|>1.0$. Isotropic hydrogen atoms were first located geometrically and then refined. The final R value was 0.042.* Atomic scattering factors were taken from International Tables for X-Ray Crystallography (1962). Final atomic coordinates and thermal parameters are given in Table 1.

Results and Discussion

Bond Lengths and Angles. The molecular structure and the numbering system used are shown in Fig. 1. The structure is compared with those of related compounds[6–10] in Table 2, where abbreviations of the compounds are also given.

Close resemblance is found among the molecular dimensions of *m*-PDAMe, *p*-phenylenediacrylic acid (*p*-PDA) derivatives and the corresponding half of

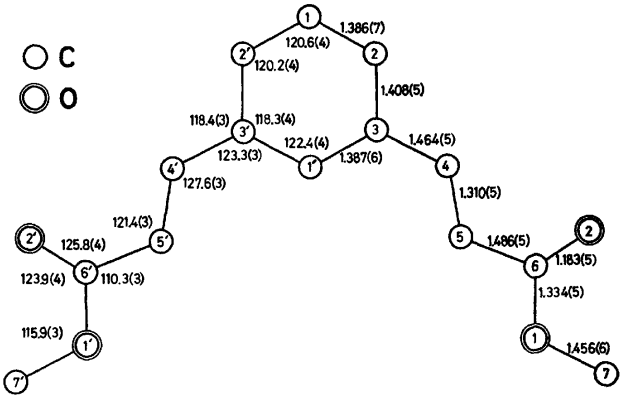

Fig. 1. Bond lengths (Å) and angles (°). The estimated standard deviations are in parentheses.

a) For these planes, the equivalent atoms which are related by the mirror symmetry have also been included in the plane evaluation. b) The atoms are not included in the plane evaluation.

CVCCMe: all the bond lengths and angles other than the double bond lengths of six esters in Table 2 are nearly identical within 3σ.

Planarity and Conformation. The equations of mean planes and the displacements of atoms from each plane are given in Table 3. The benzene ring, ethylene and carbonyl groups are planar. Referring to the benzene ring, the ethylenic plane rotates by 3.4° (θ_1 in Table 2) about C(3)–C(4), and the carbonyl by 3.5° (θ_2) about C(5)–C(6) in the same direction. The methyl group rotates by only 1.5° (θ_3) about O(1)–C(7). Thus, the molecule as a whole is nearly planar within the deviation of 0.127 Å from the mean plane; the maximum deviation is found at O(2).

The carbonyl oxygen atom with lone pair electrons is situated at the same side as the ethylenic double bond with respect to the intervening single bond C(5)–C(6), so that the lone pair electrons extend parallel to the double bond. This is also the case of photopolymerizable diolefins,[7] and suggests that the electronic interaction between lone pair and π electrons (especially of ethylenic double bond) is operative for taking the present conformation in preference to the alternative one where the carbonyl group is at the opposite side.

According to the discussion in the previous paper,[7] the internal rotation (θ_2) around C(5)–C(6) should be near 10° in this type of conjugated system. However, θ_2 of *m*-PDAMe is considerably small compared with those of the photopolymerizable diolefins. Such small θ_2 is also found in CVCCMe and HNCMe (Table 2). This may be due to intermolecular repulsion, since molecules in these three crystals are piled up along the short crystal axis as will be described below.

Crystal Structure and Reaction Mechanism. The crystal structure viewed along the b-axis is shown in Fig. 2. The molecules are piled up along the shortest

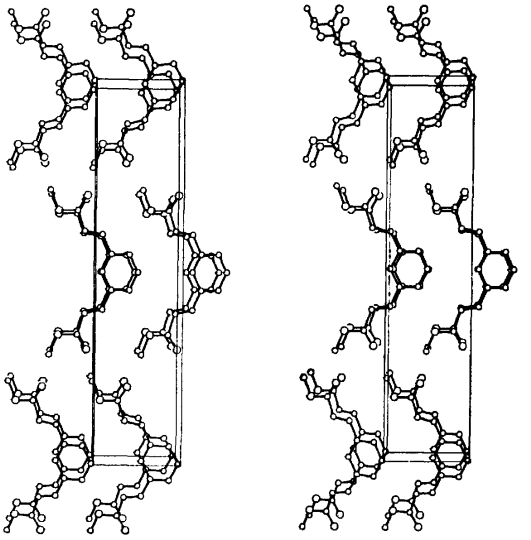

Fig. 2. A stereoview of the crystal structure viewed along the b-axis.

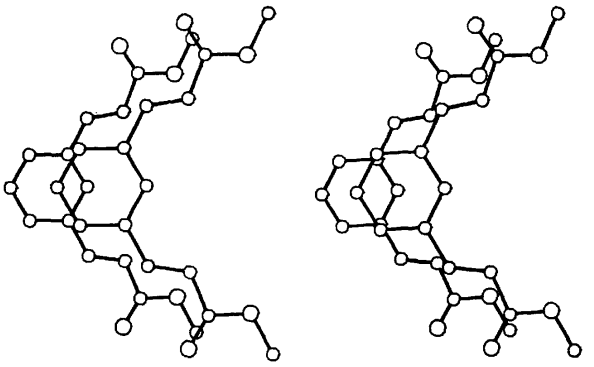

Fig. 3. A stereoview of the overlapping of molecules to react, viewed along the normal of the mean plane of the molecule.

crystal axis (b-axis) to form a parallel plane-to-plane stack. As seen from Fig. 3, the adjacent molecules in the stack overlap completely to each other. The same type of stack is also found in CVCCMe, another photo-oligomerizable crystal having the shortest crystal axis of 3.956 Å.[10] This stack is quite different from that in the photopolymerizable crystals where molecules are piled up along about 7 Å axis, displaced by half a molecule in the direction of the molecular long axis,[7] and also from the layer-type packing of the photostable modification of 2,5-distyrylpyrazine where molecules in the adjacent layers do not overlap at all.[11]

The length of the b-axis is just the shortest intermolecular distance between reactive double bonds, which is very close to those found in the photopolymerizable crystals (3.94 Å on the average). The second shortest distance, longer than 5 Å, is found between the molecules in different stacks (related by the two-fold screw axis) (Table 4).

The most plausible explanation for the reaction behavior,[3] on the basis of the crystal structure, is as follows. At the initial stage of photoirradiation, the molecules related by the b-translation react topo-

chemically to form the dimer having a cyclobutane ring with a mirror symmetry. The cyclobutane ring formation in one wing of the molecular pair makes large the distance between the double bonds in the other wing. The dimerization of this type probably destroys the regular arrangement of surrounding monomers. The subsequent reaction between the dimer and its neighbor in the disordered crystal lattice results in amorphous oligomer having more than two kinds of cyclobutane rings. The rate of the reaction should be smaller than that of the initial dimerization with topochemical assistance. Such reaction in the disordered lattice will be more favorable at higher temperature. Thus, the reaction mechanism proposed previously[3] is supported by the present structural study.

The authors are grateful to Dr. Masaki Hasegawa and Dr. Fusae Nakanishi of the Research Institute for Polymers and Textiles for their valuable suggestion and encouragement. The authors also thank Messrs. Katsuhiko Ueno and Kazuaki Harata for their assistance through this work.

(Received July 4, 1977)

The garnet $Mn_3Fe_2Si_3O_{12}$ with $a_0=11.821$ Å was synthesized at high pressure and temperature. Infrared and Mössbauer spectra of the synthetic garnets $A_3Fe_2Si_3O_{12}$ (A: Mn, Cd, Ca) suggest that the distortion of SiO_4 tetrahedra in these garnets increases and that of FeO_6 octahedra decreases with increase in the radius of eight fold coordinated cation.

The garnets, general formula $A_3B_2C_3O_{12}$, contain metal ions in eight, six and four coordinated sites, affording a fruitful field for investigation of the influence of ionic substitution and excellent models for crystal chemical studies.

Infrared absorption spectra of garnet group minerals $A_3B_2Si_3O_{12}$ were studied by Wickersheim and Tarte.[1-4] They found that the major absorption bands for 800 to 1100 cm^{-1} arise from the site group splitting of ν_3 due to the distortion of the isolated SiO_4 tetrahedron. Moor and White[5] explained the distortion of tetrahedra in the crystal lattice of natural garnet series by using group theory.

Recently considerable attention has been paid to the chemical application of the Mössbauer effect. The two parameters, the chemical shift and the electric quadrupole splitting obtained from Mössbauer spectra, vary not only with oxidation state and electronic configuration and coordination number of iron atoms in crystal structure, but also with marked changes in geometry of the ligand environment.

We have measured infrared and Mössbauer spectra for synthetic garnet series $A_3Fe_2Si_3O_{12}$ (A: Mn, Cd, Ca). The effects of the substitution of ions in the eight coordinated site on the geometry of SiO_4 tetrahedra and FeO_6 octahedra are discussed.

Experimental

For the synthesis of $A_3Fe_2Si_3O_{12}$ (A: Mn, Cd, Ca), starting materials were prepared by mixing oxides, nitrates or carbonates of the cations with colloidal silica in stoichiometric proportions. They were then dried and heated at 750 °C in most cases for at least four hours. The temperature was varied somewhat with material since it had to be high enough to decompose the starting material without causing any volatilization. After the heating, the starting materials were ground and mixed.

Piston-cylinder type and cubic type apparatus were used for high temperature and pressure experiments. The starting materials were packed into a platinum capsule and compressed. After treatment at 10—60 kbar and 1000—1200 °C for one hour, the samples were rapidly cooled to room temperature and the pressure was released. The product was identified by X-ray powder diffraction and optical microscopy.

The Mössbauer spectra were measured at room temperature using radiation from ^{57}Co in Pd, with a 400 channel multichannel analyzer. Velocity scale was calibrated with iron foil as a standard absorber. Infrared spectra were obtained using a Hitachi Model 225 Spectrophotometer and the Nujol mull technique.

Results

Single phases of garnets $Ca_3Fe_2Si_3O_{12}$ and $Cd_3Fe_2Si_3O_{12}$ were synthesized at 15 kbar and 1000 °C. They have a cubic structure with $a_0=12.06$ and 12.01 Å, respectively. Geller and Miller[6] attempted to synthesize the solid solution of $Mn_3(Al_{1-x}Fe_x)_2Si_3O_{12}$ in air and succeeded in synthesizing garnets containing up to 20 per cent of Fe^{3+}. High pressure was necessary to synthesize the single phase of garnet $Mn_3Fe_2Si_3O_{12}$ which is the last member in the above solid solution series. The products synthesized below 35 kbar at 1000 °C consist of mixtures of two or more phases such as $(Mn, Fe)_2O_3$, spinel phases and SiO_2 (quartz or coesite). Even under high pressure conditions of 40 kbar, traces of these phases were found when the temperature was above 1100 °C. The single phase garnet $Mn_3Fe_2Si_3O_{12}$ was synthesized under the conditions of 1000 °C and 60 kbar. No evidence was found for the other phases mentioned above by means of X-ray data. The garnet $Mn_3Fe_2Si_3O_{12}$ obtained has a cubic structure with $a_0=11.821$ Å. X-Ray diffraction data are given in Table 1.

a) Indexed on the basis of $a_0=11.821$ Å.

The relation between lattice constants and the ionic radii of eight fold coordinated cations in the synthetic garnets are shown in Fig. 1 on the basis of Shannon and Prewitt's effective radii.[7] The same relationship for the pyralspite series $A_3Al_2Si_3O_{12}$ was also found.[8] Parallelism was found in both garnet series.

The infrared spectra for the synthetic garnets are

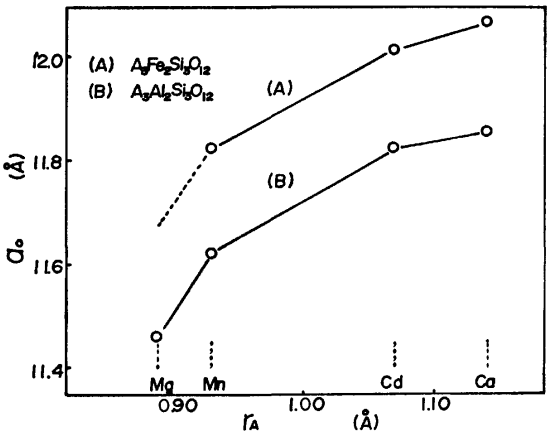

Fig. 1. Lattice constants a_0 *vs.* ionic radii of divalent dodecahedrally coordinated cations.

	ν/cm^{-1}			
	1	2	3	4
$Ca_3Fe_2Si_3O_{12}$		889	833	814
$Cd_3Fe_2Si_3O_{12}$		889	835	810
$Mn_3Fe_2Si_3O_{12}$	949	913	848	822

qualitatively similar in the region 800—1000 cm^{-1}. There are three strong and sharp bands (2, 3, 4 in curve c) with almost equal intensity (Fig. 2). The band frequencies decrease almost linearly with increase of a_0. They are assigned to the ν_3 vibration of SiO_4. Splitting of ν_3 vibration into three bands due to the distortion of SiO_4 tetrahedron in the garnet structure is in line with the results of site group and factor group analyses.[5] The origin of band 1 is not clear but it may result from a combination of internal and/or external mode.[10] The magnitude of band splitting of ν_3, Band 2—(Band 3—Band 4)/2, is known to be correlated with the distortion of SiO_4 tetrahedron.[11] From the band splitting of

$Mn_3Fe_2Si_3O_{12}$	0.344	0.385

ν_3, the distortion of SiO_4 tetrahedron seems to increase with decrease in the radius of eight fold coordinated cation.

Figure 3 shows the Mössbauer spectra of synthetic garnets at room temperature. All the spectra are resolved symmetric doublets. The garnets are paramagnetic at room temperature and there is no hyperfine magnetic splitting. The doublet lines arise from the quadrupole interaction of the ^{57}Fe nuclei with the inhomogeneous electric field in the crystal. Table 3 shows the Mössbauer parameters for all the garnets synthesized. The values of the isomer shifts for all the garnets lie in the range characteristic of the trivalent high spin state of iron ion. The parameters indicate little contribution of covalent forces to the ionic chemical bond of iron with oxygen in the octahedral coordination. The quadrupole splitting due to the electric field gradient decrease with decrease in the radius of eight fold coordinated cation. This shows that the trivalent high spin state of iron ions in the garnet $Mn_3Fe_2Si_3O_{12}$ is in the most symmetrical octahedral environment.

Discussion

$Mn_3Fe_2Si_3O_{12}$ with a cubic garnet structure was synthesized under high temperature and high pressure conditions. The reason for the synthetic conditions under high pressure for $Mn_3Fe_2Si_3O_{12}$ being influenced

by temperature thought to be due to the instability of Mn^{2+} ions in a high pressure vessel at elevated temperature. The parameter values of Mössbauer spectra for iron ions are typical for the trivalent high spin state of iron ions in an octahedral site. It is concluded that all manganese ions are divalent in the dodecahedral site and all iron ions are trivalent in the octahedral site. Although Mason reported the natural occurrence of a garnet with a probable composition of $Mg_3Fe_2Si_3O_{12}$, this compound could not be prepared under the experimental conditions employed in this study. From the similarity of both curves in Fig. 1, the lattice constant of $Mg_3Fe_2Si_3O_{12}$ is predicted to be 11.656 Å, which is a little higher than 11.515 Å reported by Mason.[9] Some of the Si^{4+} ions are presumed to be substituted for Fe^{3+} ions in the octahedral site of natural garnet $Mg_3Fe_2Si_3O_{12}$.

Usually, but not always, increase in the regularity of SiO_4 tetrahedron should allow the sp^3 hybrid orbitals on oxygen to be in a position for a more favorable overlap with those of Si, suggesting a decrease in the Si–O bond length. Novak showed by comparison of the refined structures of eight natural garnets that the Si–O bond length actually increases, as SiO_4 tetrahedron in pyralspite garnet series $A_3Al_2Si_3O_{12}$ (A: Ca, Mn, Fe, Mg) becomes more regular.[12] From the infrared spectra of synthetic garnets $A_3Fe_2Si_3O_{12}$, it seems that the regularity of SiO_4 tetrahedron also increases as the Si–O bond length increases due to a simple stretching of the $Fe_2Si_3O_{12}$ framework in response to the increase of radius of eight fold coordinated cation.

In pyralspite $A_3Al_2Si_3O_{12}$, the octahedral edge shared with triangular dodecahedron AO_8 is longer than the octahedron's unshared edge in A^{2+} ion's radius longer than 1.01 Å by weakening repulsive forces between A^{2+} and Al^{3+} (0.53 Å) cations. In the garnets $A_3Fe_2Si_3O_{12}$ with Fe^{3+} (0.645 Å) cations in octahedral site, the effect appears when the radius of A^{2+} ion is smaller than 1.01 Å. When the radius of the ion is near that of Mn^{2+} ion, shared and unshared octahedral edge lengths are statistically identical. $Mn_3Fe_2Si_3O_{12}$ garnet is thus considered to have an almost regular octahedron in line with the result of Mössbauer spectra.

The authors express their thanks to Drs. Nobukazu Kinomura, and Shoichi Kume, Osaka University. The study was partly defrayed by a Scientific Grant from the Ministry of Education.

A Selectivity Study on Liquid Anion Exchange Membranes*

Nobuo YOSHIDA** and Nobuhiko ISHIBASHI

Department of Applied Analytical Chemistry, Faculty of Engineering, Kyushu University, Fukuoka 812

(Received July 7, 1977)

The selectivity of liquid anion exchange membranes consisting of a perchlorate, thiocyanate, or iodide salt of Crystal Violet dissolved in nitrobenzene was studied by measuring membrane potentials. In bi-ionic systems the selectivity coefficient was observed to vary with the concentrations of aqueous solutions and of the ion exchanger in the membrane. This was attributed mainly to the ionic composition at the membrane-solution interface differing from that in the bulk solution. However, when the concentration of the aqueous solutions was sufficiently high in comparison with that of the ion exchanger, a selectivity coefficient intrinsic to a pair of counter ions was obtained. This selectivity coefficient was also applicable to mixed electrolyte systems and was shown to be consistent with the Conti-Eisenman theory on the relation between the selectivity coefficient and ionic parameters.

The potentials measured with liquid membrane electrodes in solutions containing a number of species of univalent ions to which the electrode responds, have been found to obey the following empirical equation:[1,2]

$$E = \text{const} - \frac{RT}{F} \ln (a_i + \sum_j K_{i,j}^{pot} a_j). \quad (1)$$

Here a_i and a_j are activities of the primary ion i and any other ion j. $K_{i,j}^{pot}$ is the potentiometric selectivity coefficient of ion j over the primary ion. The selectivity coefficient calculated by means of Eq. 1, however, has generally been observed to vary with solution concentration, composition, and ion exchanger concentration in the membrane. Such variations of the selectivity coefficient have been considered to be due to the changes of the ion-exchange selectivity coefficient with solution concentration[2,3] and of the physical properties of the membrane with ion exchanger concentration.[4]

In the present work, the selectivity of liquid anion exchange membranes consisting of a perchlorate, thiocyanate, or iodide salt of Crystal Violet dissolved in nitrobenzene was studied. The variation of the selectivity coefficient is explained in terms of the change of ionic composition at the membrane-solution interface and a selectivity coefficient intrinsic to a pair of counter ions is introduced. This selectivity coefficient is compared with that expected from a theory of a liquid ion exchange membrane.

Experimental

Reagents and Liquid Membranes. All reagents used in this study were of analytical reagent grade. A Crystal Violet salt of anion X (CV-X, where X=ClO_4^-, SCN^-, or I^-) was prepared by dissolving Crystal Violet (obtained as a chloride salt from Kishida Kagaku Co.) in hot water and precipitation with aqueous NaX at the same temperature. The precipitate was washed with demineralized water and dried in vacuum. Liquid membranes were prepared by dissolving a known amount of the Crystal Violet salt in nitrobenzene.

Measurement of Membrane Potentials. Membrane potentials were measured by means of the cell

SCE/KCl-agar bridge/Solution(′)/Liquid membrane/Solution(″)/KCl-agar bridge/SCE. (2)

Here the symbols (′) and (″) are used to designate the solutions on both sides of the membrane. In cells with solutions containing perchlorate ion, NH_4Cl-agar bridges were used in place of KCl-agar bridges. The experimental cell used was a U-shaped glass tube with 12 cm^3 of the membrane phase at the bottom and 10 cm^3 of each aqueous solution above. The aqueous and the membrane phases were not stirred unless differently indicated. In most experiments, the concentration ranges of the aqueous solutions and of the ion exchanger (the Crystal Violet salt) in the membrane were chosen so as not to cause the elution of the ion exchanger into the adjacent aqueous solutions. All membrane potentials were measured with a Takeda Riken Electrometer TR 8651 at room temperature (23±3 °C), after the cells had been constructed.

Determination of Composition Changes in Aqueous Solutions. Cells of the type: 0.1 M† NaI (′)/CV-I in nitrobenzene/0.1 M NaX (″) (where X=NO_3^- or ClO_4^-) were used to examine composition changes in aqueous solutions which may be caused by ion exchange during the measurement of membrane potentials. About 30 min after the construction of the cell, the concentration of iodide ion in solution (″) was determined by using an iodide ion-selective electrode (Toa Denpa Kogyo Co., Model I-125).

Determination of Distribution Coefficients. A nitrobenzene solution of a Fuchsine Basic salt of anion X (X=ClO_4^-, SCN^-, or I^-) was prepared by extraction from a mixture of Fuchsine Basic (obtained as a chloride salt from Kishida Kagaku Co.) and NaX in water. The concentration of the Fuchsine Basic salt in the nitrobenzene solution was of the order of 10^{-4} M. Ten cm^3 of the solution was vigorously agitated with 10 cm^3 of water. The system was maintained overnight in a thermostated water bath (25.0±0.1 °C). After complete separation of the phases the salt concentration in the aqueous phase was determined by measuring the absorbance at 542 nm. Next, the distribution coefficient of the salt was calculated.

Results and Discussion

In order to evaluate the ratios of the activity coefficients (concentration basis) of thiocyanate and perchlorate ions, $y(SCN^-)/y(ClO_4^-)$, at high concentrations (necessary in the following calculation of the selectivity coefficient), concentration potentials were first measured for aqueous NaSCN and $NaClO_4$ solutions. Figure 1 shows the observed potentials as a function of the ion exchanger concentration. In this figure the concentration potentials which are independent of the exchanger concentration (horizontal parts of the curves) may be

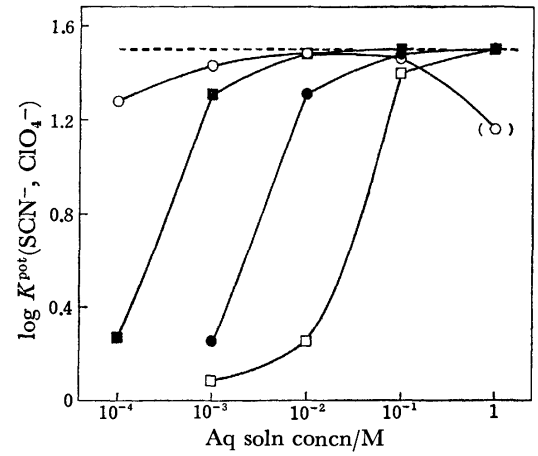

Fig. 2. Variation of the selectivity coefficient with concentrations of aqueous solution and of ion exchanger in the bi-ionic system NaSCN–$NaClO_4$. Membrane solvent: nitrobenzene. Concentrations of ion exchanger (CV–SCN): ○, 5×10^{-5} M; ■, 5×10^{-4} M; ●, 5×10^{-3} M; □, 5×10^{-2} M.

considered to be ideal; the decrement of the potentials at the low exchanger concentrations is presumably due to the incomplete exclusion of the co-ion (sodium ion) from the membrane. By application of the Nernst equation to the former potentials, the values of $\log\{y(SCN^-)/y(ClO_4^-)\}$ in 0.1- and 1-M solutions were estimated to be 0.02 and 0.09, respectively, where the ratio $y(SCN^-)/y(ClO_4^-)$ was assumed to be unity below 10^{-2} M. These results were used for the calculation of the selectivity coefficient in the bi-ionic system NaSCN–$NaClO_4$ presented below.[5]

In the case of two univalent counter ions (anions) X and Y, the membrane potential, E_M, in cell (2) may be expressed by

$$E_M = \frac{RT}{F}\ln\frac{a''_X + K^{pot}_{X,Y}a''_Y}{a'_X + K^{pot}_{X,Y}a'_Y}. \quad (3)$$

Here the sign of the potential refers to solution (″). For cells in which solution (′) contains only ion X and solution (″) only ion Y, Eq. 3 reduces to

$$E_M = \frac{RT}{F}\ln\frac{K^{pot}_{X,Y}a''_Y}{a'_X}. \quad (4)$$

Figure 2 shows the selectivity coefficient $K^{pot}(SCN^-, ClO_4^-)$ for the bi-ionic system NaSCN–$NaClO_4$ in which the membrane (CV–SCN in nitrobenzene) is interposed between solutions of NaSCN (′) and of $NaClO_4$ (″) of the same concentration. The selectivity coefficient was calculated from the measured potential by the use of Eq. 4. (Such a selectivity coefficient is an "apparent" one described below). It is observed that the selectivity coefficient varies with the concentrations of the ion exchanger in the membrane and of the aqueous solutions. However, with membranes having a given concentration of the exchanger, the selectivity coefficient approaches a limiting value (indicated by the dashed line in the figure) with the increasing concentration of the aqueous solutions. With solutions having a given concentration of the electrolytes, the selectivity coefficient also tends toward the same limiting value as the exchanger concentration decreases. As in the case of the concentration potentials described above, the deviation of the parenthesized value from the limiting one is attributed to the incomplete exclusion of the co-ion (sodium ion) from the membrane. Similar results were obtained with the bi-ionic systems NaI–$NaClO_4$ and NaI–NaSCN by the use of nitrobenzene solutions of CV–I as the liquid membranes.[6]

The variation of the selectivity coefficient may be understood from the following argument. In the bi-ionic cell used here, before the aqueous solutions and the liquid membrane are in contact with each other, solution (′) and the membrane contain the same counter ion X, whereas solution (″) contains a different counter ion Y. When the cell is assembled, an exchange of the counter ions occurs between solution (″) and the membrane. Therefore, the ionic composition at the membrane-solution (″) interface is generally different from that in the bulk of solution (″) since a diffusion layer (through which the transport of ions can occur by diffusion only) exists adjacent to the interface. (In experiments of short duration, such a change of ionic composition would be negligible at the membrane-solution (′) interface).

Such a cell is not a true bi-ionic cell and, taking account of the composition change at the interface, we must express the membrane potential of the cell as

$$E_M = \frac{RT}{F}\ln\frac{a^*_X + K^{pot}_{X,Y}a^*_Y}{a'_X} + (\phi'' - \phi^*), \quad (5)$$

where the asterisks refer to the interface inside solution (″) and ϕ is the electric potential. As shown in Appendix, since the mobilities of the counter ions used (ClO_4^-, SCN^-, and I^-) are nearly equal in the aqueous solution,[7] the second term in Eq. 5 becomes negligible and $c^*_X + c^*_Y \approx c''_Y \approx c'_X$ (c: concentration). We then obtain (assuming, for simplicity, activities to be equal to concentrations)

$$E_M \approx \frac{RT}{F}\ln\left\{K^{pot}_{X,Y} + (1 - K^{pot}_{X,Y})\frac{c^*_X}{c'_X}\right\}, \quad (6)$$

from which an "apparent" selectivity coefficient, $K^{pot}_{X,Y}$(app), (obtained from the straightforward application of Eq. 4 to the cell) is given by

$$K^{pot}_{X,Y}(app) \approx K^{pot}_{X,Y} + (1-K^{pot}_{X,Y})\frac{c^*_X}{c'_X}. \quad (7)$$

The higher the exchanger concentration compared with the solution concentration, the larger will be the value of c^*_X/c'_X. Hence $K^{pot}_{X,Y}$(app) becomes correspondingly smaller when $K^{pot}_{X,Y}>1$ and larger when $K^{pot}_{X,Y}<1$. This indeed the case for the bi-ionic system NaSCN–$NaClO_4$ presented above, where $K^{pot}(SCN^-, ClO_4^-)$ (which is considered to be the limiting value of the selectivity coefficient in this system as described below) is 1.5 on logarithmic scale.

However, in cases where the solution concentration is sufficiently high in comparison with the exchanger concentration, the influence of the composition change at the interface will be negligibly small. The above-mentioned limiting value of the selectivity coefficient (limiting selectivity coefficient) corresponds to such situations of the cell and is considered to be a parameter correctly describing the properties of the membrane.[8]

Table 1. Changes in composition of aqueous solutions in the cell

0.1 M NaI (′)/CV–I in nitrobenzene/0.1 M NaX (″).

Concn of CV–I / M	X	$c''(I^-)$ / M	log $K^{pot}(I^-, X)$ Apparent	Corrected
5×10^{-4}	NO_3^-	4.7×10^{-5}	−1.3	−1.3
5×10^{-3}	NO_3^-	2.6×10^{-4}	−1.2	−1.2
5×10^{-2}	NO_3^-	8.5×10^{-4}	−0.95	−0.98
5×10^{-4}	ClO_4^-	1.1×10^{-4}	1.97	1.97
5×10^{-3}	ClO_4^-	2.9×10^{-4}	1.96	1.96
5×10^{-2}	ClO_4^-	2.0×10^{-3}	1.86	1.86

The variation of the selectivity coefficient may also be attributed partly to the contamination of the bulk solution itself caused by the counter-ion exchange mentioned above. Table 1 shows the composition changes in bulk solutions observed with some bi-ionic cells, together with the apparent selectivity coefficients obtained as before from the measured potentials. In this table $c''(I^-)$ represents the molarity of iodide ions (in solution (″)) which were exchanged for nitrate or perchlorate ions (initially present in solution (″)) during the potential measurement. The selectivity coefficients corrected for the composition change in solution (″) (*i.e.*, calculated by use of Eq. 3 with $a'(NO_3^-)=0$ or $a'(ClO_4^-)=0$) are presented in the last column. As can be seen from the table, however, this correction is small and the selectivity coefficient still shows the variation with the ion exchanger concentration. (Incidentally, the limiting selectivity coefficients $K^{pot}(I^-, NO_3^-)$ and $K^{pot}(I^-, ClO_4^-)$ were found to be −1.3 and 1.97, respectively, on logarithmic scale). The variation of the selectivity coefficient is thus ascribed mainly to the change of ionic composition at the membrane-solution interface.

The limiting selectivity coefficient is also applied to cells in which the two solutions each contain only one of two species of counter ions but at different concentrations, as long as the composition change at the interface is expected to be small. Figures 3 and 4

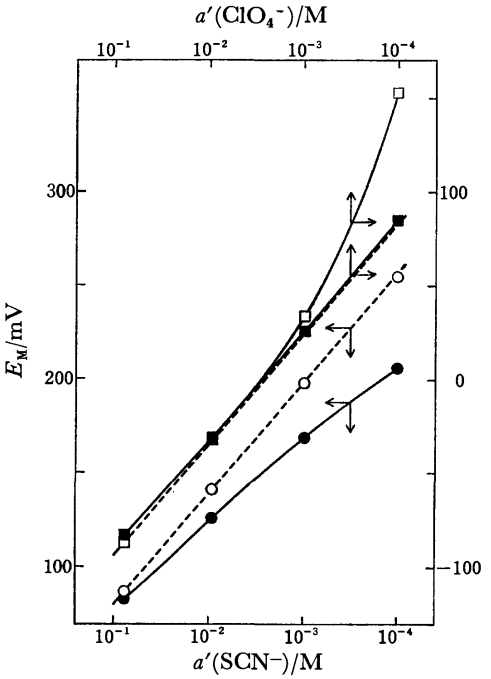

Fig. 3. Membrane potential *vs.* anion activity. Systems: ○, ●, NaSCN with molarity variable (′)–0.1 M $NaClO_4$ (″); □, ■, $NaClO_4$ with molarity variable (′)–0.1 M NaSCN (″). Membrane solvent: nitrobenzene. Ion exchangers: ○, □, 5×10^{-4} M CV-SCN; ●, ■, 5×10^{-4} M CV-ClO_4.

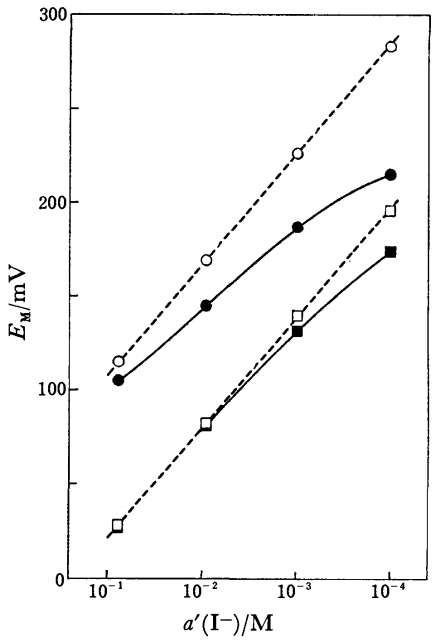

Fig. 4. Membrane potential *vs.* activity of iodide ion. Systems: ○, ●, NaI with molarity variable (′)–0.1 M $NaClO_4$ (″); □, ■, NaI with molarity variable (′)–0.1 M NaSCN (″). Membrane solvent: nitrobenzene. Ion exchangers: ○, □, 5×10^{-4} M CV–I; ●, 5×10^{-4} M CV-ClO_4; ■, 5×10^{-4} M CV-SCN.

show membrane potentials measured with such cells, where ClO_4^-, SCN^-, and I^- are paired against each other. The observed potentials are indicated by points; the dashed lines represent the values calculated from Eq. 4 with the values of the limiting selectivity coefficient obtained in the corresponding bi-ionic systems (see Table 2). (The solid curves merely connect the experimental points). The experimental points can be seen to agree with the calculated lines in cells of the type: NaX with molarity variable (′)/5×10^{-4} M CV–X in nitrobenzene/0.1 M NaY (″) where X=SCN^-, Y=ClO_4^-; X=I^-, Y=ClO_4^-; or X=I^-, Y=SCN^-. Figures 3 and 4 also illustrate the effect on the membrane potential of varying the counter ion species initially present in the membrane. When in the above cells CV–Y is used, instead of CV–X, as the ion exchanger, the measured potentials become lower than the calculated, which is due to the composition change at the membrane-solution (′) interface. In the cell: $NaClO_4$ with molarity variable (′)/5×10^{-4} M CV–ClO_4 in nitrobenzene/0.1 M NaSCN (″), although solution (′) and the membrane contain the same counter ion, perchlorate ion, the experimental points lie slightly above the corresponding calculated line (dashed). This is probably because the concentration of NaSCN in solution (″) (0.1 M) is not high enough to eliminate completely the effect of the composition change at the membrane-solution (″) interface.

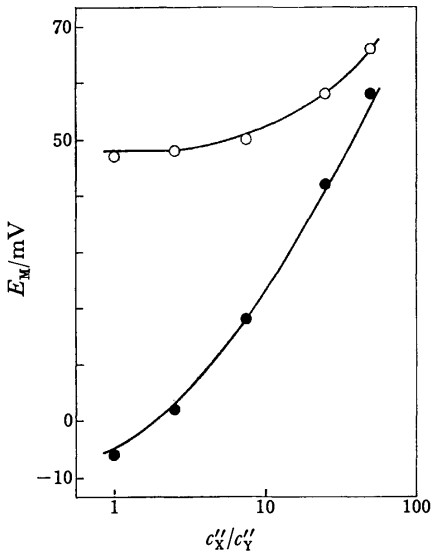

Fig. 5. Comparison of experimental and calculated potentials in the mixed electrolyte system NaX (′)/10^{-4} M CV–X in nitrobenzene/NaX+NaY (″) where $c'_X=10^{-2}$ M, c''_X=variable, and $c''_Y=2\times10^{-3}$ M. ○: X=SCN^-, Y=ClO_4^-; ●: X=I^-, Y=SCN^-.

The limiting selectivity coefficient is further applicable to mixed electrolyte systems. Typical data for such systems are shown in Fig. 5. Circles represent the experimentally observed potentials for mixed solutions containing a pair of counter ions, either SCN^-–ClO_4^- or I^-–SCN^-. The curves were drawn according to Eq. 3 with the values of the limiting selectivity coefficient obtained in the corresponding bi-ionic systems. The agreement between the experimental and calculated potentials is seen to be excellent.

As judged from the association constants of ion pairs in nitrobenzene,[9–11] the degree of ion association in the membrane used here is small and virtually negligible at the low exchanger concentrations. For the case of a liquid ion exchange membrane with negligible association, Conti and Eisenman[12] have shown theoretically that the selectivity coefficient between counter ions X and Y is given by

$$K^{pot}_{X,Y}=\frac{\bar{u}_Y k_Y}{\bar{u}_X k_X}, \tag{8}$$

where $\bar{u}_X$ and $\bar{u}_Y$ are the mobilities of ions X and Y in the membrane, and k_X and k_Y are the single-ion distribution coefficients between the membrane solvent and water. The selectivity coefficient is therefore expected to be nearly independent of solution concentration, composition, and exchanger concentration, which is consistent with the experimental observations described above.

Table 2. Comparison of limiting selectivity coefficients with calculated values

X	Y	$\log K^{pot}_{X,Y}$	
		Limiting	Calcd
I^-	ClO_4^-	1.97	1.94
SCN^-	ClO_4^-	1.5	1.39
I^-	SCN^-	0.47	0.546

For a direct comparison of the limiting selectivity coefficient with that expected from Eq. 8, the parameters controlling the selectivity were evaluated. The distribution coefficients of perchlorate, thiocyanate, and iodide salts of Fuchsine Basic between nitrobenzene and water were found to be 68.1, 13.1, and 7.40, respectively. Here the distribution coefficient is given as the ratio of the salt concentration in the organic phase to that in the aqueous phase. The value of k_Y/k_X was calculated from the square of the ratio of these distribution coefficients. The corresponding value of $\bar{u}_Y/\bar{u}_X$ was obtained from the ratio of the limiting ionic conductances.[11,13] The selectivity coefficients calculated by Eq. 8 from these values are compared with limiting selectivity coefficients[14] in Table 2. The limiting selectivity coefficients can be seen to be in good agreement with the calculated values.

Appendix

The ionic fluxes in the diffusion layer (at the solution side of the membrane-solution interface) may be expressed by the following Nernst-Planck equations:

$$J_X=-u_X c_X\frac{d}{dx}(RT\ln c_X-F\phi), \tag{A-1}$$

$$J_Y=-u_Y c_Y\frac{d}{dx}(RT\ln c_Y-F\phi), \tag{A-2}$$

$$J_{Na}=-u_{Na} c_{Na}\frac{d}{dx}(RT\ln c_{Na}+F\phi), \tag{A-3}$$

where J_X, J_Y, and J_{Na} are the fluxes of counter ions (univalent anions) X and Y and sodium ion (co-ion); u_X, u_Y, and u_{Na}, and c_X, c_Y, and c_{Na} are the corresponding mobilities and concentrations (u_X, u_Y, and u_{Na} are assumed to be constants); ϕ is the electric potential; and x is the space coordinate perpendicular to the membrane-solution interface. The conditions of electroneutrality and absence of electric current lead to

$$c_X + c_Y = c_{Na}, \quad \text{(A-4)}$$

$$J_X + J_Y = J_{Na} = 0, \quad \text{(A-5)}$$

where it has been assumed that the membrane is impermeable to sodium ion. Inserting Eqs. A-1—A-3 into Eq. A-5 and eliminating $d\phi/dx$, we have

$$\frac{d\{c_{Na}(u_X c_X + u_Y c_Y)\}}{dx} = 0. \quad \text{(A-6)}$$

For the case where $u_X = u_Y$, Eq. A-6 becomes with the help of Eq. A-4

$$\frac{dc_{Na}}{dx} = \frac{d(c_X + c_Y)}{dx} = 0. \quad \text{(A-7)}$$

Inserting this result into Eq. A-3 and taking into account Eq. A-5, we obtain

$$\frac{d\phi}{dx} = 0. \quad \text{(A-8)}$$

Thus the total counter-ion concentration and the electric potential are constant throughout the diffusion layer.

5) Except in this system, activity coefficients were obtained from Kielland's table since solution concentrations were all below 0.1 M. J. Kielland, *J. Am. Chem. Soc.*, **59**, 1675 (1937).

6) The limiting value of the selectivity coefficient was found to be more easily obtained in cases where the counter ion less extractable into the membrane was initially present in the membrane. In order to determine the limiting value of K^{pot} (SCN^-, ClO_4^-), for example, the membrane containing the less extractable thiocyanate ion was preferable to the membrane containing perchlorate ion.

7) For these ions, the ratio of the limiting ionic conductances does not exceed 1.2 in water. "Landolt-Börnstein Tabellen," Vol. II, Part 7, 6th ed, Springer-Verlag, Berlin, Göttingen, and Heidelberg (1960), pp. 259, 261.

8) G. Shean and K. Sollner [*J. Membr. Biol.*, **9**, 297 (1972)] have also found that bi-ionic potentials are essentially independent of solution concentration and exchanger concentration, although their experimental conditions are somewhat different from ours.

14) In this case, strictly speaking, the limiting selectivity coefficient must be evaluated under conditions in which a steady state is established across the membrane, since the Conti-Eisenman theory applies only to such experimental conditions. For this purpose membrane potentials were measured by using a cell with a stirred membrane. When the membrane phase is stirred, no concentration gradient of ions exists inside the bulk membrane and a stable concentration gradient will be established in the (unstirred) diffusion layers just internal to each membrane-solution interface. Hence, as far as the membrane potential is concerned, the membrane phase may be regarded as consisting of the two diffusion layers alone where the steady state required by the theory is attained. However, in cells in which the influence of the composition change at the interface (discussed in the text) is negligible, the stirring of the membrane interior had little effect on the membrane potential. Thus the value of the limiting selectivity coefficient was the same with stirred and unstirred membranes.

Electronic States of the Picric Acid Complexes with 1-Methylnicotinamide, Tryptamine, DL-Tryptophan, and Serotonin

Masashi TANAKA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received July 25, 1977)

The polarized reflection spectra of the crystals of the picric acid complexes with 1-methylnicotinamide, tryptamine, DL-tryptophan and serotonin have been measured from 15000 to 40000 cm^{-1} and the molar extinction coefficient of these crystals has been obtained by the Kramers-Kronig transformation. Furthermore, the theoretical calculation of the electronic states of these complexes has been made and compared with the experimental results. This analysis shows that the appearance of the new band in the region of 20000 cm^{-1} is the origin of the reddish color of the crystals of tryptamine picrate, DL-tryptophan picrate, and serotonin picrate; the new band can be assigned to the charge-transfer band from the picrate anion to the indole nucleus.

Indole derivatives are widely distributed through biological systems and form donor-acceptor complexes with a variety of aromatic acceptors. Szent-Gyorgyi and Isenberg[1] reported the formation of colors on mixing electron donors such as indole with certain electron acceptors and further showed that the new band, not present in either component alone, can be assigned to the charge-transfer band.

The charge-transfer interactions were shown to play an important part in such biological processes as the binding of nicotinamide[2-3] and flavin coenzymes[4] to tryptophan residues of enzymes, the interactions of indoles with nucleotides and with nucleic acid,[5] and the binding of serotonin and hallucinogenic tryptamines to synaptic receptor sites.[6]

The simplest of the substituted nicotinamides, 1-methylnicotinamide, forms donor-acceptor complexes with iodide ions.[7] Freeman and Bugg[8] determined the crystal structure of the iodide of 1-methylnicotinamide and compared the interactions and structural features in this iodide salt with the crystal structures of the chloride and picrate salts of 1-methylnicotinamide, where charge-transfer forces are expected to be of little or no importance.

Tryptamine picrate is obtained as a reddish orange salt; DL-tryptophan picrate is prepared as a reddish brown crystal; and serotonin crystallized as a dark red picric salt. Since these amino acids are colorless and the picrate ion is pale yellow, the red color of the picrate salts is unexpected and suggests the formation of a donor-acceptor complex. Thewalt and Buug[9] determined the crystal structure of serotonin picrate monohydrate in order to examine the solid state interactions between serotonin and the picrate ion. Gartland, Freeman, and Bugg[10] described the crystal structures of the picrate complexes of tryptamine and DL-tryptophan in order to obtain information about the structural factors involved in the indole interactions with aromatic acceptors.

The complexes of picric acid with amines revealed that a proton is transferred from picric acid to amine and the interaction between the picrate ion and the amine molecule is capable of producing a charge-transfer absorption band. Matsunaga[11] reported that the picrate anion is as strong as picric acid as an electron acceptor and the indole derivatives are the electron donors and the color of the tryptophan picrate complex aries from the charge-transfer interaction between the nucleus and the picrate anion.

The author undertook the spectroscopic examination of the crystals of the picrate complexes with 1-methylnicotinamide, tryptamine, DL-tryptophan, and serotonin molecules by measuring the microscopic polarized reflection spectra. Furthermore, we studied theoretically the electronic states of these complexes and showed that the new band in the region of 20000 cm^{-1} is the charge-transfer band from the picrate anion to the indole nucleus.

Experimental and Theoretical

Single crystals of the picrate complex with 1-methylnicotinamide, tryptamine, DL-tryptophan, and serotonin were crystallized by the slow evaporation of the solution of the salt.

Reflection spectra at the normal incidence have been measured over a range of 15000—40000 cm^{-1} with a reflection spectrophotometer made in our laboratory and the absorption spectra have been obtained by the Kramers-Kronig transformation.

The electronic states of the molecules are calculated by the Pariser-Parr-Pople[12] SCF method in order to obtain the molecular orbitals and the orbital energies.

The two-center coulomb integrals γ_{pq} are estimated by Nishimoto-Mataga's method.[13] The one-center core coulomb integrals α_p and the two-center core resonance integrals β_{pq} are approximated in the following equations:

$$\alpha_p = -I_p - (n_p-1)\gamma_{pp} - \sum_{r\neq p} n_r\gamma_{pr},$$

$$\beta_{pq} = -K(I_p+I_q)S_{pq},$$

where the constant K is taken to be 0.39. The overlap integrals S_{pq} are calculated between the nearest neighbor atoms by using the Slater type AO's and neglected in other cases. Then, the overlap integrals S_{CN} between the 2pπ AO's of the carbon atom on the benzene ring and the nitrogen atom on the nitro group are estimated by the equation

$$S_{CN} = S^{\circ}_{CN}\cos\theta,$$

where θ is the dihedral angle between the two 2pπ AO's χ_C and χ_N. The overlap integrals S°_{CN} are determined by using the 2pπ AO's χ°_C and χ°_N on the same plane. The values of the first ionization potentials I_P are taken from Pilcher and Skinner's[14] table and the one-center coulomb integrals γ_{PP} are given by the relation $\gamma_{pp}=I_p-A$. These parameters (I_p, γ_{pp}, and n_p) are given in Table 1.

The intermolecular overlap integrals are written as follows:

Table 1. The values of the ionization potentials (I_p in eV), the one-center intergrals (γ_{pp} in eV), and the core charge (n_p) used in the SCF calculation

Atom		I_p	r_{pp}	n_p	Bonding type
Carbon	$t_1t_2t_3z$	−11.22	10.60	1	-CH=CH-
Nitrogen	$t_1^2t_2t_3z$	−14.51	13.31	1	-N=CH-
	$t_1t_2t_3z^2$	−12.26	13.31	2	-NH-, $-NO_2$
Oxygen	sx^2y^2z	−17.76	13.89	1	$-NO_2$
	$t_1^2t_2t_3z^2$	−14.97	14.89	2	-OH
	$t_1^2t_2^2t_3z^2$	−14.97	14.89	1	$-O^-$

$$S_{at,bf} = \int \phi_a^t(1)^* \phi_b^f(1) d\tau = \sum_{p,q} C_{at,p} C_{bf,q} (\chi_p^a | \chi_q^b)$$

where ϕ_a^t is the t-th molecular orbital on the molecule a and ϕ_b^f the f-th molecular orbital on the molecule b. χ_p^a is the $2p\pi$ AO of the p-th atom on the molecule a and χ_q^b the $2p\pi$ AO of the q-th atom on the molecule b. Then, the intermolecular overlap integrals involve the integrals between two $2p\pi$ AO's χ_p^a and χ_q^b at orientations determined by the crystal structure. The line joining the atoms p and q defines the z axis and the y axis may be chosen to be perpendicular to one orbital, defining

$$A = \boldsymbol{n}\cdot\boldsymbol{x}_p, \quad B = \boldsymbol{n}\cdot\boldsymbol{y}_p = 0, \quad C = \boldsymbol{n}\cdot\boldsymbol{z}_p,$$
$$D = \boldsymbol{m}\cdot\boldsymbol{x}_q, \quad E = \boldsymbol{m}\cdot\boldsymbol{y}_q, \quad F = \boldsymbol{m}\cdot\boldsymbol{z}_q,$$

when $\boldsymbol{n}$ and $\boldsymbol{m}$ are unit vectors in the direction of the $2p\pi$ orbitals located on the centers p and q, respectively. Then, the atomic overlap integrals may be expressed as

$$(\chi_p^a | \chi_q^b) = AD(2p\pi_p^a | 2p\pi_q^b) + CF(2p\sigma_p^a | 2p\sigma_q^b).$$

The calculation of the excitation energy of the charge-transfer complex is carried out by the composite molecule method. That is, the matrix elements between the ground configuration Φ_0, the locally excited configuration $\Phi_{at\to af}$, and the charge-transfer configuration $\Phi_{at\to bf}$ are given in the zero-differential overlap approximation as follows.

$$(\Phi_{at\to af}|H|\Phi_{at\to af}) = E_0 + \varepsilon_{af} - \varepsilon_{at} - (\phi_a^t\phi_a^t|\phi_a^f\phi_a^f) + 2(\phi_a^t\phi_a^f|\phi_a^t\phi_a^f)$$
$$(\Phi_{at\to bf}|H|\Phi_{at\to bf}) = E_0 + \varepsilon_{bf} - \varepsilon_{at} - (\phi_a^t\phi_a^t|\phi_b^f\phi_b^f) + P$$
$$(\Phi_{at\to af}|H|\Phi_{ak\to al}) = 2(\phi_a^t\phi_a^f|\phi_a^k\phi_a^l) - (\phi_a^t\phi_a^k|\phi_a^f\phi_a^l)$$
$$(\Phi_{at\to af}|H|\Phi_{bk\to bl}) = 2(\phi_a^t\phi_a^f|\phi_b^k\phi_b^l)$$
$$(\Phi_{at\to bf}|H|\Phi_{ak\to bl}) = -(\phi_a^t\phi_a^k|\phi_b^f\phi_b^l)$$
$$(\Phi_{at\to bf}|H|\Phi_0) = \sqrt{2}K'S_{at,bf}$$
$$(\Phi_{at\to bf}|H|\Phi_{at\to bl}) = K'S_{bf,ql}$$
$$(\Phi_{at\to bf}|H|\Phi_{bk\to bf}) = -K'S_{at,bk}$$
$$(\Phi_0|H|\Phi_{at\to af}) = (\Phi_{at\to af}|H|\Phi_{ak\to bl}) = (\Phi_{at\to bf}|H|\Phi_{bk\to al}) = 0$$

Here P is the term which takes into account the polarization effect and K' is a constant. ε_{at} is the orbital energy of the t-th MO on the molecule a and ε_{bf} the orbital energy of the f-th MO on the molecule b.

In the calculation of the picrate complexes, P is taken to be 0.8 eV and K' given as −15.0 eV. All of the above-mentioned computations were carried out on a FACOM 230-75 computer at the Nagoya University computation center.

Results and Discussion

1-Methylnicotinamide Picrate. The picrate salt of 1-methylnicotinamide was crystallized as yellow prisms by slowly cooling a hot, saturated aqueous solution containing approximately equimolar quantities of 1-methylnicotinamide chloride and of picric acid.[8] The projection onto the ab plane of the picrate salt is shown in Fig. 1. The amino group of 1-methylnicotinamide is hydrogen bonded to the oxygen atom of the C–O^- bond in the picrate anion. The picrate and 1-methylnicotinamide moieties do not overlap and there are no unusually short intermolecular contacts except for the hydrogen-bonded interactions. Therefore, the charge-transfer interactions are probably of little importance in the crystals of 1-methylnicotinamide picrate.

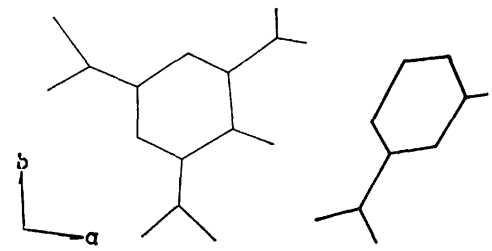

Fig. 1. Projection onto the ab plane of the crystal of 1-methylnicotinamide picrate.

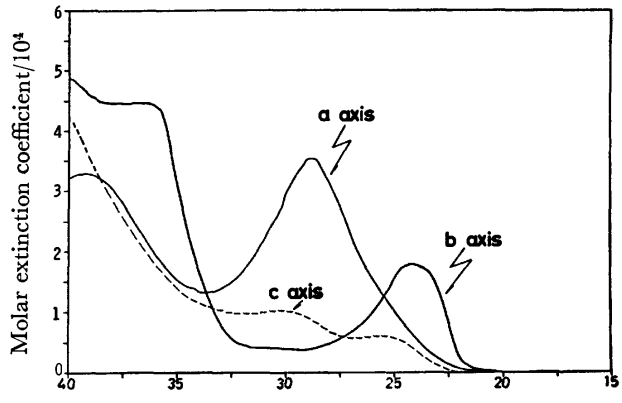

Fig. 2. The polarized absorption spectra of the crystal of 1-methylnicotinamide picrate obtained by the K-K transformation of the reflection spectra.

The absorption spectra transformed from the reflection spectra of the crystal of this salt are depicted in Fig. 2. The 23400 (LE_1) and 28800 (LE_2) cm^{-1} bands can be assigned to the local excitation band of the picrate anion. The LE_1 band is observed in the b axis spectrum and the LE_2 band in the a axis. Therefore, the LE_1 band is allowed for the light polarized perpendicular to the C–O^- bond of the picrate anion and the LE_2 band is active for the light polarized parallel to the C–O^- bond.

Tryptamine Picrate. Tryptamine picrate was obtained as a reddish orange crystal upon mixing aqueous solutions of tryptamine and picric acid. The

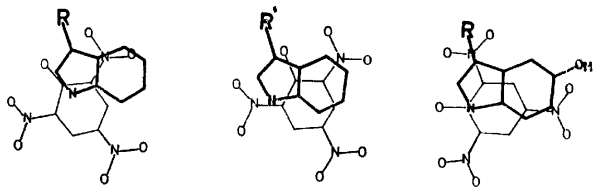

Fig. 3. Stacking patterns in the crystals of tryptamine picrate, DL-tryptophan picrate-methanol and serotonin picrate monohydrorate.

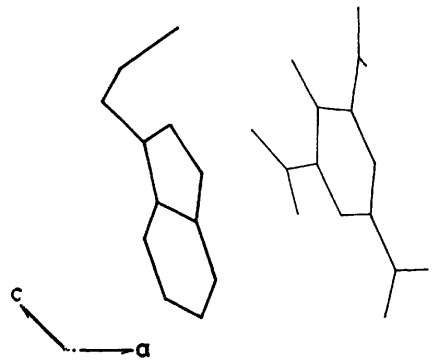

Fig. 4. Projection onto the ac plane of the crystal of tryptamine picrate.

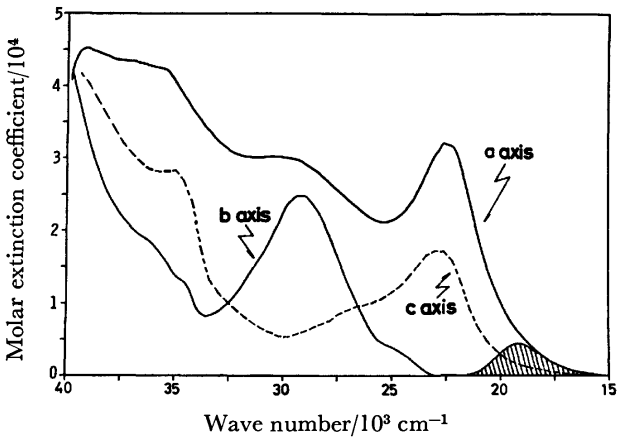

Fig. 5. The polarized absorption spectra of the crystal of tryptamine picrate obtained by the K-K transformation of the reflection spectra.

crystal packing scheme for the tryptamine picrate is described in Fig. 3 and the projection onto the ac plane in Fig. 4.[10]

The absorption spectra transformed from the reflection spectra of the crystal of this complex are shown in Fig. 5. The LE_1 band is observed at 22500 cm^{-1} in the both the a and c axes spectra and the LE_2 band at 28200 cm^{-1} mainly in the b axis spectra, as predicted from the directions of the transition moments of the LE_1 and LE_2 bands. Furthermore, the new, quite diffuse band appears as a long extension on the side of the longer wave length of the LE_1 band in the a axis spectrum. Because of this overlap, the position of the maximum of the new band cannot be known, and so the shaded region may be thought to be a new absorption band which has its peak at 19200 cm^{-1}.

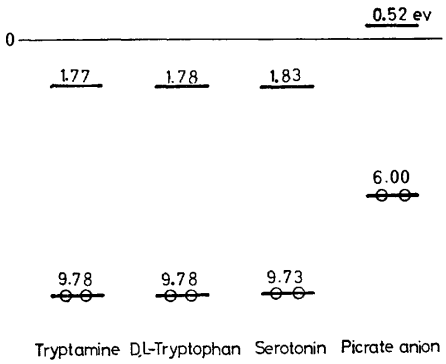

Fig. 6. The orbital energy diagram of the donor and acceptor molecules in the picrate salt system.

In the theoretical calculation, the overlap integral between the HOMO of the indole ring in the tryptamine cation and the LUMO of the picrate anion is 0.0084; the orbital energy diagram of the donor and acceptor molecules is shown in Fig. 6. The calculated excitation energy (E_{CT}) and the wavefunction (Ψ_{CT}) of the lowest excited state are shown as follows.

$$E_{CT} = 20250\ cm^{-1},$$

$$\Psi_{CT} = 0.9769\Phi(\phi_2^{10}\rightarrow\phi_1^6) - 0.1231\Phi(\phi_2^9\rightarrow\phi_1^6) + 0.1019\Phi(\phi_2^{10}\rightarrow\phi_2^{11}) + 0.0929\Phi(\phi_1^5\rightarrow\phi_1^6) + 0.0755\Phi_0.$$

The stabilization energy (ΔE) and the wave function (Ψ_0) of the ground state are written in the following equations:

$$\Delta E = 0.019\ eV,$$

$$\Psi_0 = 0.9966\Phi_0 - 0.0721\Phi(\phi_2^{10}\rightarrow\phi_1^6),$$

where ϕ_1^i is the i-th molecular orbital of the tryptamine molecule and ϕ_2^j the j-th molecular orbital of the picrate anion.

Therefore, the new band at 19200 cm^{-1} can be assigned to the chrage-transfer band from the picrate anion to the indole nucleus.

DL-Tryptophan Picrate–Methanol. Reddish brown crystals of the DL-tryptophan picrate–methanol complex were obtained by slowly evaporating a methanol solution that contained an equimolar mixture of DL-tryptophan and picric acid. The crystal packing scheme for the DL-tryptophan picrtate–methanol is depicted in Fig. 3 and the projection onto the bc plane in Fig. 7.[10]

The absorption spectra transformed from the reflection spectra of the crystal of this complex are shown in Fig. 8. The LE_1 band is observed at 23400 cm^{-1} in the

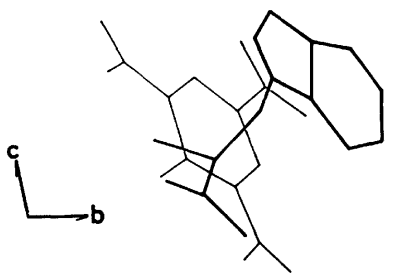

Fig. 7. Projection onto the bc plane of the crystal of DL-tryptophan picrate–methanol.

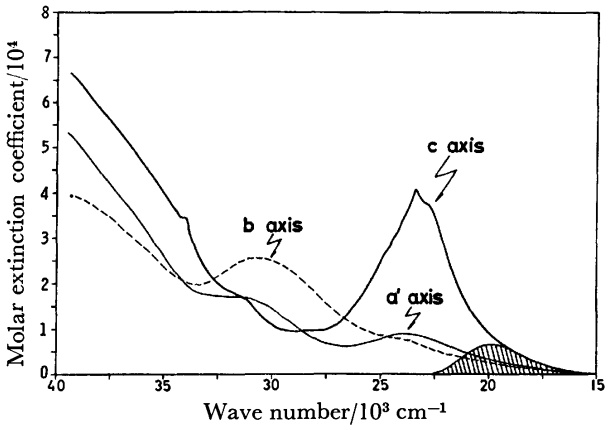

Fig. 8. The polarized absorption spectra of the crystal of DL-tryptophan picrate obtained by the K-K transformation of the reflection spectra.

c axis spectrum and the LE_2 band at 30600 cm^{-1} in the b axis spectrum, as predicted from the directions of the transition moments of the LE_1 and LE_2 bands. Furthermore, the new diffuse band appears as a long extension on the side of the longer wavelength of the LE_1 band in the c, b, and a′ axes spectra. The maximum of the new band cannot be located but the shaded region may be thought to be a new band which has its peak at 19600 cm^{-1}.

In the theoretical calculation, the overlap integral between the HOMO of the indole ring in the tryptophan cation and the LUMO of the picrate anion is 0.0077 and the relation of the orbital energies of the donor and acceptor molecules is shown in Fig. 6. The calculated excitation energy (E_{CT}) and the wavefunction (Ψ_{CT}) of the lowest excited state are expressed as follows:

$$E_{CT} = 19020\,cm^{-1},$$
$$\Psi_{CT} = 0.9918\Phi(\phi_2^{10}\rightarrow\phi_1^6) + 0.0502\Phi(\phi_1^4\rightarrow\phi_1^6) + 0.0443\Phi(\phi_1^5\rightarrow\phi_1^6) + 0.0679\Phi_0.$$

The stabilization energy (ΔE) and the wavefunction (Ψ_0) of the ground state are written in the next equations:

$$\Delta E = 0.024\,eV,$$
$$\Psi_0 = 0.9959\Phi_0 - 0.0692\Phi(\phi_2^{10}\rightarrow\phi_1^6) + 0.0444\Phi(\phi_2^9\rightarrow\phi_1^6),$$

where ϕ_1^i is the i-th molecular orbital of the tryptophan molecule and ϕ_2^j the j-th molecular orbital of the picrate anion.

Accordingly, the new band at 19600 cm^{-1} can be assigned to the charge-transfer band from the picrate anion to the indole nucleus.

Serotonin Picrate Monohydrate. Serotonin picrate monohydrate was crystallized as dark red prisms by slowly evaporating a saturated aqueous solution containing approximately equimolar quantities of serotonin creatinine sulphate and picric acid. The crystal packing for the serotonin picrate monohydrate is shown in Fig. 3 and the projection onto the bc plane in Fig. 9.[9]

The absorption spectra transformed from the reflection spectra of the crystal of this complex are shown in Fig. 10. The LE_1 band is not observed in the b and c axes spectra but the LE_2 band is observed at 27200

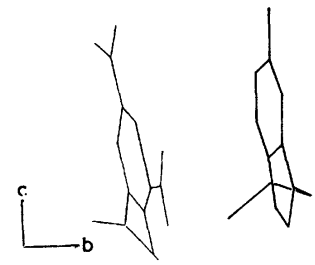

Fig. 9. Projection onto the bc plane of the crystal of serotonin picrate monohydrate.

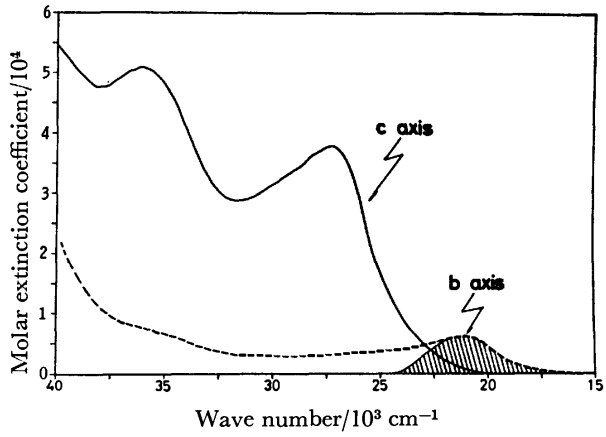

Fig. 10. The polarized absorption spectra of the crystal of serotonin picrate monohydrate.

cm^{-1} in the c axis spectrum, as expected from the direction of the transition moments of the LE_1 and LE_2 bands. Furthermore, the new band appears at 21000 cm^{-1} in the b axis spectrum and the observed transition moment is directed along the intermolecular vector between the hydroxyindole and picrate molecules.

In the theoretical calculation, the overlap integral between the HOMO of the hydroxyindole ring in the serotonin cation and the LUMO of the picrate anion is 0.0059; the diagram of the orbital energies of the donor and acceptor molecules is shown in Fig. 6. The calculated excitation energy (E_{CT}) and the wavefunction (Ψ_{CT}) of the lowest excited state are written as follows.

$$E_{CT} = 20770\,cm^{-1},$$
$$\Psi_{CT} = 0.9678\Phi(\phi_2^{10}\rightarrow\phi_1^7) - 0.1735\Phi(\phi_2^9\rightarrow\phi_1^7) + 0.0640\Phi(\phi_2^{10}\rightarrow\phi_1^8) - 0.0623\Phi(\phi_2^{10}\rightarrow\phi_2^{11}) + 0.1289\Phi(\phi_1^5\rightarrow\phi_1^7) + 0.0533\Phi_0.$$

The stabilization energy (ΔE) and the wavefunction (Ψ_0) of the ground state are given in the following equations:

$$\Delta E = 0.013\,eV,$$
$$\Psi_0 = 0.9978\Phi_0 - 0.0491\Phi(\phi_2^{10}\rightarrow\phi_1^7),$$

where ϕ_1^i is the i-th molecular orbital of the serotonin molecule and ϕ_2^j the j-th molecular orbital of the picrate anion.

Therefore, the new band at 21000 cm^{-1} can be assigned to the charge-transfer band from the picrate anion to the hydroxyindole nucleus.

Studies of Electrode Processes of Oxovanadium(IV). IV. Catalytic Reduction of Acetylacetone Coupled with Cathodic Reduction of Bis(acetylacetonato)oxovanadium(IV)

Mitsutaka KITAMURA, Kazuo SASAKI,* and Hideo IMAI

Faculty of Integrated Arts and Sciences, Hiroshima University, Hiroshima 730
**Faculty of Engineering, Hiroshima University, Hiroshima 730*

(Received February 24, 1977)

Acetylacetone was catalytically reduced in the course of the electrolytic reduction of bis(acetylacetonato)-oxovanadium(IV) at a mercury cathode. In acetonitrile solutions the catalytic reduction proceeded at −2.1 V *vs.* Ag/0.01 mol dm^{-3} $AgClO_4$ electrode and the reduction products were hydrogen and acetylacetonate anion, while by the direct electrolysis of acetylacetone at −2.5 V a product with vicinal hydroxyl groups was formed. A steady-state current was observed in the controlled potential electrolysis. A reaction mechanism involving the regeneration of trivalent vanadium by the coupled chemical reaction of divalent vanadium with acetylacetone is proposed.

The electrochemical or photochemical behavior of oxovanadium(IV) complexes has been reported in previous papers.[1-3] Although in acetonitrile solution containing a large excess of acetylacetone (Hacac) a well-defined polarographic cathodic wave of bis-(acetylacetonato)oxovanadium(IV), $[VO(acac)_2]$, was developed in a single step with two-electron transfer, only trivalent vanadium was detected in the solution subjected to controlled potential electrolysis at −2.1 V *vs.* Ag/0.01 M $AgClO_4$ electrode (M=mol dm^{-3}). The processes involved therein were postulated as follows:

(1) One-electron transfer to break a V-O bond;

$$[VO(acac)_2] + e^- + \text{Hacac} \longrightarrow [V(acac)_3] + OH^-. \quad (1)$$

(2) Further one-electron transfer to form divalent vanadium;

$$[V(acac)_3] + e^- \longrightarrow [V(acac)_3]^-. \quad (2)$$

Reaction 1 proceeded at a more negative potential ($E_1/_2$=−1.93 V) than Reaction 2 ($E_1/_2$=−1.78 V) owing to the strong V-O bond and ligand rearrangement. Reactions 1 and 2 may be followed by the reaction of OH^- with Hacac or of $[V(acac)_3]^-$ with $[VO(acac)_2]$, thus forming $acac^-$ or $[V(acac)_3]$. But, the concentration of $acac^-$ was found to increase even after the vanadyl species was depleted completely in the solution, suggesting another route in the reaction sequence.

The evidence for catalytic regeneration of trivalent vanadium by a coupled chemical reaction of divalent vanadium with Hacac is presented in this paper, and the reaction mechanism is discussed.

Experimental

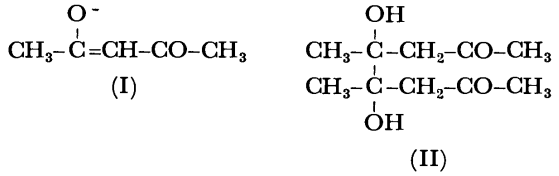
An ordinary polarograph and a potentiostat were used, and the UV and visible absorption spectroscopy and vapor phase chromatography were employed for subsidiary purposes.

For the controlled potential electrolysis a three-compartment cell separated by sintered glass diaphragms was used. A mercury pool cathode was stirred by a magnetic bar, and the solution was agitated by bubbling purified nitrogen through it. For measurements of steady-state current, vigorous agitation was essential in order to obtain reproducible data. The reference electrode was Ag/0.01 M $AgClO_4$ electrode.

Solutions were prepared by using purified acetonitrile, which contained a trace of water. The supporting electrolyte was tetraethylammonium perchlorate (TEAP). The prepared solution was deaerated carefully by bubbling purified nitrogen through it. Experiments were carried out at room temperature.

Results and Discussion

Reduction Mechanism of Acetylacetone. Acetylacetone in an acetonitrile solution containing 0.1 M TEAP developed an irreversible polarographic cathodic wave at about −2.3——2.4 V, the reduction potential being largely shifted with the concentration of Hacac. After the reduction of Hacac by the controlled potential electrolysis at −2.5 V, the polarogram showed an anodic wave at −0.45 V corresponding to the anodic process of $acac^-$. The absorption spectra before and after the electrolysis are shown in Fig. 1. The wavelengths of the absorption maximum, 273 nm for Hacac and 293 nm for $acac^-$, coincide well with Neal and Murray's data.[4] The difference between our results and Neal and Murray's data can be attributed to the difference in reaction mechanisms, as will be described later. Neal and Murray used a thin layer cell for the electrolysis of Hacac in acetonitrile, and confirmed $acac^-$ (I) to be the main reduction product. In addition to $acac^-$, in our case where an ordinary electrolysis cell was used, the existence of vicinal hydroxyl groups was confirmed in the reduction products by means of the periodate titration. It is highly likely that the



(I) (II)

product is 4,5-dihydroxy-4,5-dimethyl-2,7-octanedione (II). This estimate is supported by the formation of pinacol as a dimeric product of the reduction of 1,3-diphenyl-1,3-propanedione in DMSO as reported by Buchta and Evans.[5] Vapor phase chromatography indicated that an ether extract from the electrolyzed solution contained two dominant species which appeared

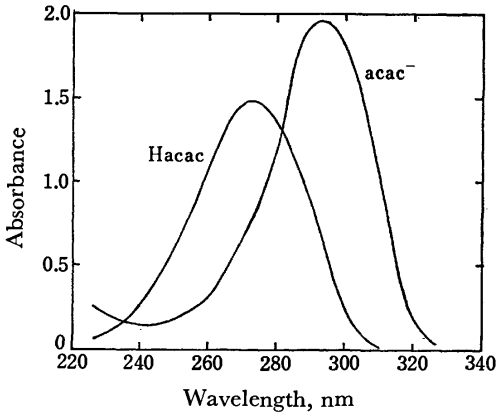


Fig. 1. Absorption spectra of 0.22 mM Hacac in acetonitrile solution before and after controlled potential electrolysis at −2.5 V.

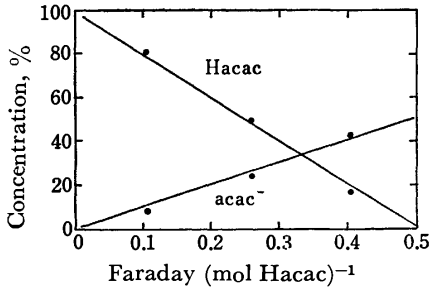

Fig. 2. Relative change in concentrations of Hacac and acac⁻ in the course of controlled potential electrolysis of Hacac at −2.5 V. Solution: 1 mM Hacac in acetonitrile solution containing 0.1 M TEAP.

at far later stages compared with the retention time of pinacol derived from acetone. Unfortunately, the direct confirmation of these compounds was unsuccessful, owing to their extreme instability and rapid decomposition during the isolation procedure.

The relative concentration changes in both Hacac and acac⁻ during the course of the controlled potential electrolysis were monitored by using an ordinary polarograph. The result is shown in Fig. 2, where the ordinate and abscissa are expressed in terms of the concentration ratio in % and electricity consumed in Faraday mol^{-1}, respectively. As is seen in Fig. 2, the descending line intersects the abscissa at about 0.5 Faraday mol^{-1}. This indicates that the number of electrons transferred per molecule (n) is equal to 0.5. The increase of the concentration of acac⁻ was no longer observed after 0.5 Faraday mol^{-1} was consumed. Since the increment of acac⁻ is exactly one half of the decrement of Hacac, it is concluded that one mol of acac⁻ is produced from two mol of Hacac. Taking the product with vicinal hydroxyl groups into consideration, the reaction scheme can be expressed as follows:

$$4\ \text{enol–Hacac} + 2e^- \longrightarrow \text{Dimer} + 2\text{acac}^-. \quad (3)$$

In reaction 3 a proton abstraction by an acetylacetone anion radical from an acetylacetone molecule is assumed to be involved.

This reaction mechanism is consistent with the observed facts, but inconsistent with the result obtained by Neal and Murray,[3] who concluded that the reaction proceeded as follows:

$$\text{Hacac} + e^- \longrightarrow \text{Hacac}^{\cdot} \longrightarrow \frac{1}{2}H_2 + \text{acac}^{\cdot}. \quad (4)$$

According to the reaction mechanism of Eq. 4, the stoichiometric molar ratio of Hacac and acac⁻ is 1 : 1. The difference between Reactions 3 and 4 is clearly shown when we compare the ratio of absorbance of Hacac and acac⁻ in Fig. 1 of this report and Fig. 1 of Ref. 4. The difference in the reaction mechanisms seems to be attributed to the experimental techniques employed. In the thin layer cell used by Neal and Murray, most of the depolarizer undergoes the electrode reaction without any complication such as proton abstraction or dimer formation, and the reaction intermediate seems to decompose directly to hydrogen and acac⁻.

Bis(acetylacetonato)oxovanadium(IV) dissolved in the acetonitrile solution containing an amount of Hacac 20 times excess in molar ratio was reduced at a dropping mercury electrode with the half-wave potential of −2.00 V; the reduction product was divalent vanadium, as shown in Eqs. 1 and 2. In polarograms observed *in situ* in solutions subjected to the controlled potential electrolysis at −2.1 V the same anodic wave was observed at −0.45 V as in the case of the direct electrolytic reduction of Hacac. But in this case no dimeric product with vicinal hydroxyl groups could be detected. The relative concentration changes of Hacac and acac⁻ during the course of the controlled potential electrolysis are shown in Fig. 3. The concentration change of oxovanadium(IV) ions in Fig. 3 was separately measured spectrophotometrically at the wavelength of 700 nm by using 3 mM bis(acetylacetonato)oxovanadium(IV) solution. As shown in Fig. 3, oxovanadium(IV) ions are quickly depleted with a coulombic efficiency of about 1 faraday mol^{-1}. The concentration of acac⁻ increased steadily even after the oxovanadium(IV) ions were depleted completely. The increment of acac⁻ at each quantity of electricity consumed was exactly equal to the decrement of Hacac, as shown in Fig. 3, so that the stoichiometric molar ratio of acac⁻ and Hacac was 1 : 1. The extrapolation of the descending line gives an

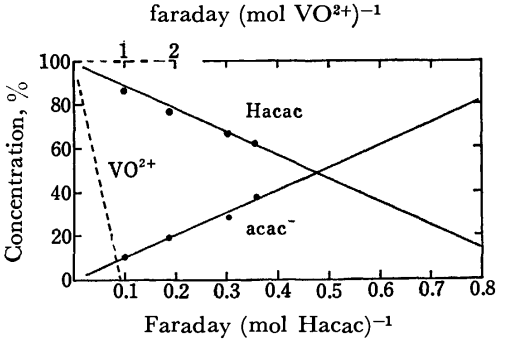

Fig. 3. Relative change in concentrations of VO^{2+}, Hacac and acac⁻ in the course of controlled potential electrolysis of VO^{2+} at −2.1 V. Solution: 1 mM [VO(acac)$_2$] and 20 mM Hacac in acetonitrile solution containing 0.1 M TEAP. (Refer to the text in relation to the concentration change of VO^{2+}.)

intercept at about 1 F mol^{-1}. This result indicates that the value of n is unity. It is noteworthy that this result coincides well with Neal and Murray's result. In view of these findings the following reaction mechanism is deduced:

$$[V(acac)_3]^- + Hacac \longrightarrow [V(acac)_3] + Hacac^{\cdot}, \quad (5)$$

$$Hacac^{\cdot} \longrightarrow \frac{1}{2}H_2 + acac^-. \quad (6)$$

Reaction 2 is coupled with Reaction 5, so that Hacac is catalytically reduced by a regenerative cycle of vanadium(II). This mechanism is also supported by the fact that the limiting current of oxovanadium(IV) ion shows the characteristics of kinetic current, as shown previously in Ref. 2. The formation of a dimeric product by Reaction 3 does not seem to be involved in this case.

Steady-state Current in Controlled Potential Electrolysis. When a solution containing a known quantity of oxovanadium(IV) ion and 20 times excess of Hacac was electrolyzed at −2.1 V, the electrolytic current decreased gradually and attained a steady-state value in a few minutes. The plot of the steady-state current, i_{st}, *versus* the concentration of oxovanadium(IV), C_y, is shown in Fig. 4, where i_{st} is linearly proportional to C_y up to the concentration of 0.6 mM. As described in the previous paper,[2] the color of the electrolyzed solution turned to greenish yellow and finally to dark green. The dark green color indicates the existence of divalent vanadium in the solution bulk, but it promptly fades to yellow on being left to stand in a nitrogen atmosphere. The yellow solution was cathodically reduced to form divalent vanadium at −1.78 V. Therefore, it is concluded that the oxidation of divalent vanadium by Hacac proceeds fairly rapidly, and thus the concentration of trivalent vanadium in the bulk solution is kept practically constant. Under this condition, the electrolytic current flowing through the cell can be expressed by the following equation:

$$i_{st} = nFADC_y/\delta, \quad (7)$$

where A is the surface area of the mercury cathode, the concentration of trivalent vanadium in the bulk solution is practically equal to C_y, δ is the thickness of the diffusion layer, C_y/δ the concentration gradient of trivalent vanadium in the diffusion layer, and the other symbols have their usual meanings. It is noteworthy that in the ordinary case C_y is time deptendent, but in this special case C_y can be treated as a constant.

By introducing numerical data in Eq. 7 ($i_{st}/C_y = 3.5\times10^3$ amp mol^{-1} cm^3, $n=1$, $A=12.6$ cm^2, and $D=6\times10^{-6}$ cm^2 s^{-1}), we obtain the value of δ to be about 3×10^{-3} cm. This value seems to be reasonable in view of the controlled potential electrolysis with vigorous stirring of the solution.

At the final stage of the controlled potential electrolysis at −2.1 V the steady-state current decreased, and the electrolyzed solution gave no more cathodic wave. This indicates that the regenerative cycle of trivalent vanadium by the coupled chemical reaction ceases owing to the depletion of Hacac.

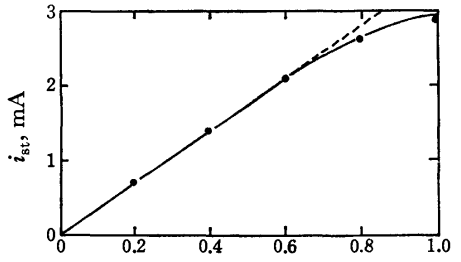

Fig. 4. Dependence of steady-state current on concentration of oxovanadium(IV) ion.

A Spectrophotometric Study of Phosphomolybdenum Blue Formed by the Reaction of Phosphate with a Mixture of Molybdenum(V) ($Mo_2O_4^{2+}$) and Molybdenum(VI) and Application to the Spectrophotometric Determination of Small Amounts of Phosphates

Kousaburo Ohashi, Kumiko Yasu, Choutaro Suzuki, and Katsumi Yamamoto

Department of Chemistry, Faculty of Science, Ibaraki University, Mito 310

(Received March 3, 1977)

The spectrophotometric determination of trace amounts of phosphates, based on the color development of phosphomolybdenum blue formed by the reaction of phosphate with a mixture of molybdenum(V) ($Mo_2O_4^{2+}$) and molybdenum(VI), is described. The rates of formation of phosphomolybdenum blue were measured at 25 °C in a perchloric acid medium. The maximum constant color development was obtained in the perchloric-acid range from 0.20 to 0.41 M under given conditions by warming the solution for 10 min at 80 °C. The method obeys Beer's law in the phosphate-concentration range from 0.08 to 1.16 μg/ml. The molar absorptivity at 840 nm was calculated to be 2.4×10^4 l mol^{-1} cm^{-1}. The rate is inverse fifth-order with respect to the perchloric-acid concentration in the range from 0.20 to 0.41 M and is first-order with respect to the molybdenum(V) concentration. The formation rates increase with the phosphate and molybdenum(VI) concentrations, although the rate dependence on the concentrations of these reactants is complicated. The ratio of P: Mo(V) for phosphomolybdenum blue was determined to be 1: 1 using the molar-ratio method.

Analytical methods for the determination of phosphates are usually based on the formation of molybdophosphoric acid from the reaction between molybdenum(VI) and the phosphate in an acidic solution,[1] and the subsequent reduction to phosphomolybdenum blue.[2-5] Extensive investigations of the analytical methods and their numerous modifications have been carried out.

Lucena-Conde and Prat[6] developed a spectrophotometric determination method for phosphates based on the blue color development of phosphomolybdenum blue formed by the reaction of the phosphate with a mixture of molybdenum(VI) and molybdenum(V). They examined the effect of the ratio Mo(VI): Mo(V) on the color development.

Hosokawa and Ohshima[7] have modified the method established by Lucena-Code and Prat and applied it to the determination of phosphate in sea water. They also examined the effect of hydrogen-ion concentration on the color development.

The present authors found that the rate of formation of phosphomolybdenum blue formed by the reaction of phosphate with a mixture of molybdenum(VI) and molybdenum(V) is notably dependent on the perchloric-acid concentration. Therefore, the phosphomolybdenum blue formation and the spectrophotometric determination of phosphate, based on the color development of phosphomolybdenum blue, were investigated in perchloric-acid media. The effects of various ions on the color development are described. The composition of molybdenum blue was also studied using the molar-ratio method.

Experimental

Materials. A 1.00×10^{-1} M molybdenum(VI) solution was prepared by dissolving 24.196 g of sodium molybdate dihydrate into 1 litre of redistilled water. Working solutions were prepared by dilution with redistilled water to the desired concentrations. A molybdenum(V) ($Mo_2O_4^{2+}$) perchlorate solution was prepared using a method similar to that reported in Ref. 8. The concentration of this molybdenum(V) solution was determined spectrophotometrically at 384 nm (ε= 103).[9] The hydrogen-ion concentration of the molybdenum(V) solution was determined using a cation-exchange resin of hydrogen form. Thus, the hydrogen-ion concentration was established at 2.0 M. The stock solution of molybdenum(V) perchlorate was stored in a refrigerator. A 1.00×10^{-2} M phosphate solution was prepared by dissolving known quantities of sodium dihydrogenphosphate dihydrate or disodium hydrogenphosphate dodecahydrate into redistilled water. All the other chemicals were of analytical grade.

Apparatus. All the absorption spectra and absorbance at the given wavelengths were measured using a Hitachi EPS-3 type automatic recording spectrophotometer. The measurements of absorbances at a fixed wavelength were made on a Hitachi 101 manual spectrophotometer. Cells having a light path length of 1 cm were used in all cases. A Yamato BS-44 type water bath was used for warming the solution.

General Procedure for the Spectrophotometric Determination of Phosphate Content. In each experiment, 5 ml of 1.60×10^{-2} M molybdenum(VI), 2 ml of 2.20×10^{-2} M molybdenum (V), and a given quantity of a phosphate at 4.00×10^{-4} M were pipetted into a 25-ml measuring flask. 3 ml of 1.0 M perchloric acid was added to adjust the final hydrogen-ion concentration to 0.28 M. The final volume was brought to 25 ml by the addition of redistilled water. The solution was warmed for at least 10 min at 80 °C in a thermostatically-controlled water bath. A portion of the solution was then transferred into a cell. The measurements of absorbances were made at 840 nm.

Measurements of the Formation Rate of Phosphomolybdenum Blue. The solutions of molybdenum(VI), molybdenum(V), and sodium dihydrogen phosphate were maintained at 25 °C. In each experiment, portions of these solutions were pipetted into a 25-ml measuring flask, the molybdenum(V) perchlorate solution was added last to the solution containing molybdenum(VI) and phosphate, and the time was measured from its addition. A portion of the solution was transferred into a cell, which was placed in a thermostatically-controlled cell compartment. The kinetic measurements were carried out by recording the change in absorbance at 840 nm as a function of the time. The plots of the absorbance at 840 nm *vs.* time

were linear for at least 15% of the entire reaction. Therefore, the zeroth-order rate constants of the formation of phosphomolybdenum blue were determined from the initial slope of the absorbance *vs.* time plots.

Results and Discussion

Absorption Spectra of Phosphomolybdenum Blue Formed by the Reaction of Molybdenum(V) with Molybdenum(VI). The absorption spectra of a product formed by the reaction of a given concentration of phosphate with a mixture of 1.76×10^{-3} M molybdenum(V) and 3.20×10^{-3} M molybdenum(VI) in 0.28 M perchloric acid are shown in Fig. 1. The absorption spectra coincide with that of phosphomolybdenum blue formed by the reduction of molybdenum(VI) by hydrazinium sulfate in the presence of a phosphate.

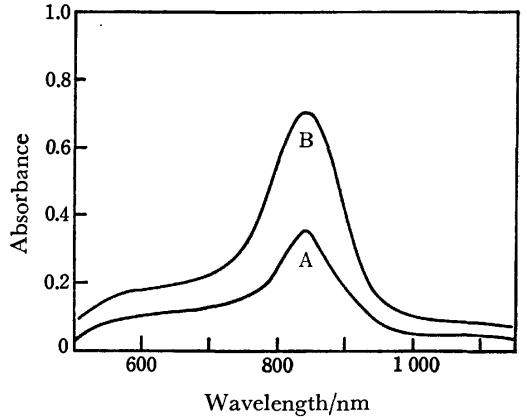

Fig. 1. The absorption spectra of phosphomolybdenum blue formed from the reaction of 1.76×10^{-3} M molybdenum(V) with 3.20×10^{-3} M molybdenum(VI) in the presence of phosphate at 0.28 M perchloric acid. (A): $[NaH_2PO_4]=1.45\times10^{-5}$ M, (B): $[NaH_2PO_4]=2.90\times10^{-5}$ M.

Effects of the Reaction Time and Temperature on the Color Development. The effects of the reaction time at 25 and 80 °C on the color development were examined with 1.76×10^{-3} M Mo(V), 3.20×10^{-3} M Mo(VI), 2.90×10^{-5} M NaH_2PO_4, and 0.28 M $HClO_4$. The results are shown in Fig. 2. The rate at 25 °C is very small, but the formation rate at 80 °C is relatively large. It requires at least 3 min for the color development to proceed completely at 80 °C. The color is quite stable even after standing for 6 h at 80 °C.

Effect of Perchloric-acid Concentration on the Color Development and the Formation Rate of Phosphomolybdenum Blue. The effect of the perchloric-acid concentration on the color development was studied with 2.90×10^{-5} M phosphate, 1.76×10^{-3} M Mo(V), and 3.20×10^{-3} M Mo(VI). The absorbances were measured after warming the solution for 10 min at 80 °C. The results are shown in Fig. 3. The maximum constant absorbance was obtained in the range for perchloric-acid concentration from 0.20 to 0.41 M. Above 0.43 M perchloric acid, the absorbances decrease with increasing perchloric-acid concentration. Below 0.20 M perchloric acid, the reaction of molybdenum(V) with molybdenum(VI)

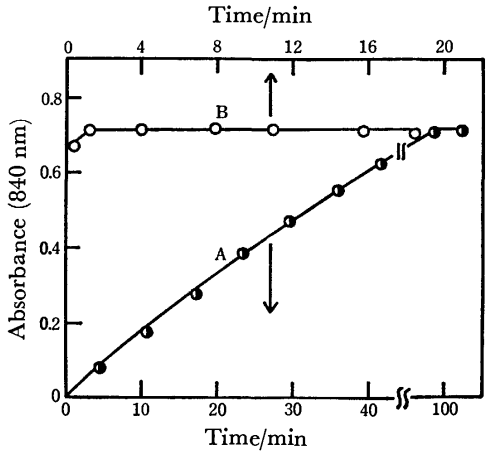

Fig. 2. The Effect of the heating time on the color development. $[Mo(VI)]=3.20\times10^{-3}$ M, $[Mo(V)]=1.76\times10^{-3}$ M, $[NaH_2PO_4]=2.90\times10^{-5}$ M, $[HClO_4]=0.28$ M. (A): 20 °C, (B): 80 °C.

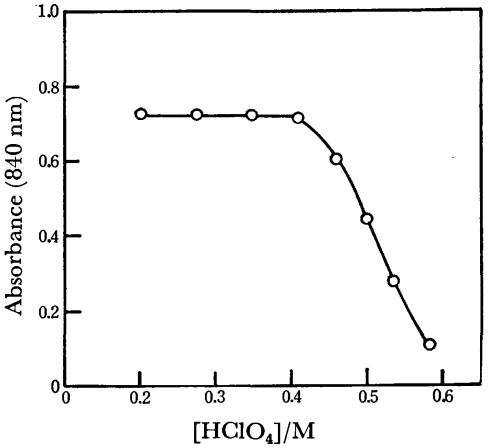

Fig. 3. The effect of the concentration of perchloric acid on the color development. $[Mo(VI)]=3.20\times10^{-3}$ M, $[Mo(V)]=1.76\times10^{-3}$ M, $[NaH_2PO_4]=2.90\times10^{-5}$ M, 10 min, 80 °C.

gives a blue precipitation.

The effect of the perchloric-acid concentration on the rate of formation of phosphomolybdenum blue was examined in the range from 0.20 to 0.55 M for 1.01×10^{-3} M Mo(V), 1.60×10^{-3} M Mo(VI), and 5.80×10^{-5} M NaH_2PO_4 (Fig. 4). The result that the slope of the logarithm of the rate *vs.* pH plot is −5 indicates that the rate of the formation is inversely fifth order with respect to the perchloric-acid concentration in the range from 0.20 to 0.40 M.

Effects of Molybdenum(VI) and Molybdenum(V) Concentrations on the Color Development and the Formation Rate of Phosphomolybdenum Blue. The effect of molybdenum(VI) concentration on the formation of phosphomolybdenum blue was examined under given conditions. The results are shown in Fig. 5. Constant maximum color development was obtained in the range for molybdenum(VI) from 2.30×10^{-3} to 6.40×10^{-3} M with 1.76×10^{-3} M Mo(V), 2.90×10^{-5} M phosphate, and 0.28 M $HClO_4$. In the case of 1.00×10^{-3} M Mo(V), any concentration of molybdenum(VI) greater than 1.50×10^{-3} M results in constant maximum color

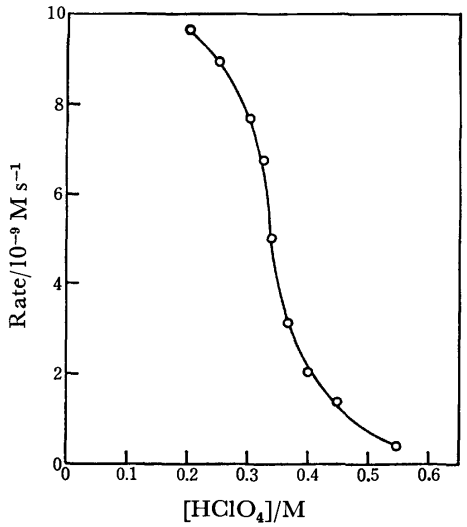

Fig. 4. The relation between the formation rate of phosphomolybdenum blue and the concentration of perchloric acid.
$[Mo(VI)]=1.60\times10^{-3}$ M, $[Mo(V)]=1.01\times10^{-3}$ M, $[NaH_2PO_4]=5.80\times10^{-5}$ M, $I=0.70$ M ($NaClO_4$), 25 °C.

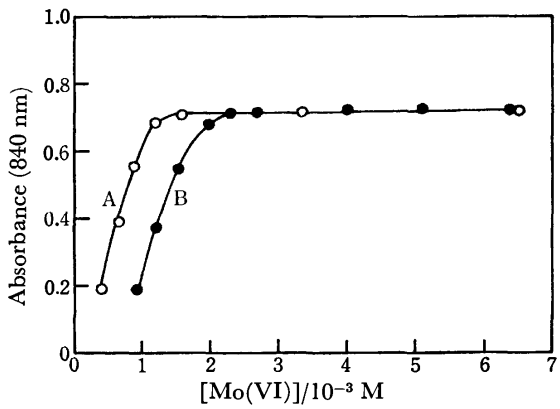

Fig. 5. The effect of the concentrations of molybdenum(VI) on the color development.
$[NaH_2PO_4]=2.90\times10^{-5}$ M, $[HClO_4]=0.28$ M.
(A): $[Mo(V)]=1.00\times10^{-3}$ M, (B): $[Mo(V)]=1.76\times10^{-3}$ M.

development. These results indicate that the color development is significantly affected by the Mo(VI): Mo(V) ratio.

The effect of the molybdenum(VI) concentration on the formation rate of phosphomolybdenum blue was examined for 0.36 M $HClO_4$, 6.76×10^{-4} M Mo(V), and 4.36×10^{-5} M NaH_2PO_4. The results are shown in Fig. 6. At low concentrations of molybdenum(VI), the formation rate is greatly affected by the molybdenum(VI) concentration, but at high concentrations the effect is small.

The effect of molybdenum(V) concentration on the formation of phosphomolybdenum blue was also examined. The rate has a first-order dependence on the molybdenum(V) concentration in the range from 2.00×10^{-4} to 1.76×10^{-3} M for 2.40×10^{-3} M Mo(VI), 5.80×10^{-5} M NaH_2PO_4, and 0.28 M $HClO_4$.

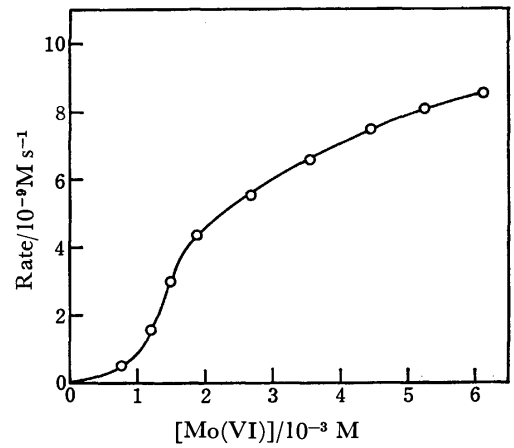

Fig. 6. The relation between the formation rate of phosphomolybdenum blue and the concentration of molybdenum (VI).
$[Mo(V)]=6.76\times10^{-4}$ M, $[NaH_2PO_4]=4.36\times10^{-5}$ M, $[HClO_4]=0.36$ M, $I=0.70$ M ($NaClO_4$), 25 °C.

Determination of Phosphate Concentration. The calibration curve was obtained by the general procedure for the determination of phosphate concentrations. The phosphomolybdenum blue color system obeys Beer's law in the phosphate range from 0.08 to 1.16 μg/ml. Based on the phosphate concentration, the molar absorptivity at 840 nm can be calculated to be 2.4×10^4 l mol^{-1} cm^{-1}. The sensitivity is very high. Standard solutions prepared from Na_2HPO_4 and NaH_2PO_4 give the same result.

Precision and Accuracy. The accuracy of the results is represented in Table 1. An estimate of the

Table 1. Accuracy of the results

Measured absorbance[a] (840 nm)	Amount of phosphate in 25 ml (μg)		
	Taken	Found	Error (%)
0.780	21.7	21.3	−1.84
0.610	15.9	16.4	+3.14
0.453	12.6	12.4	−1.59
0.309	8.0	8.3	+3.75
0.150	4.4	4.3	−2.27

a) $[Mo(VI)]=3.20\times10^{-3}$ M, $[Mo(V)]=1.76\times10^{-3}$ M, $[HClO_4]=0.28$ M.

Table 2. Precision of the results

0.8 μg/ml phosphate Measured absorbance (840 nm)[a]	0.4 μg/ml phosphate
0.696	0.345
0.710	0.342
0.693	0.361
0.701	0.357
0.717	0.359
0.720	0.363
Av. 0.706	0.355

a) $[Mo(VI)]=3.30\times10^{-3}$ M, $[Mo(V)]=1.76\times10^{-3}$ M, $[HClO_4]=0.28$ M.

precision was obtained for the results of replicate samples at two different phosphate concentrations. These results are listed in Table 2.

Effect of Various Ions. The effect of many different ions was examined by the proposed procedure for the determination of 0.8 μg/ml of phosphate. The metal ions, such as Mg^{2+}, Al^{3+}, Ca^{2+}, Cr^{3+}, Mn^{2+}, Fe^{3+}, Co^{2+}, Ni^{2+}, Zn^{2+}, Cd^{2+}, Hg^{2+}, Pb^{2+}, UO_2^{2+}, and SiO_3^{2-} in moderate amounts (4 μg/ml) do not interfere with this determination.

Determination of the P: Mo(V) Molar Ratio in Phosphomolybdenum Blue. There are a few investigations of the formation mechanism and composition of phosphomolybdenum blue. Arnold and Wacker,[10] Baman *et al.*,[11] and Hahn and Schmidt[12] have investigated the composition of phosphomolybdenum blue formed by the reduction of 12-molybdophosphoric acid by reducing agents. Assuming that phosphomolybdenum blue contains the same number of molybdenum atoms as the unreduced 12-molybdophosphoric acid, they proposed that the Mo(VI): Mo(V) ratios in phosphomolybdenum blue are 2: 1 or 5: 1, depending on the type of reducing agents and reduction time.

Recently, Meiklejohn *et al.*[13] isolated $(Bu_4N)_4PMo^{V}Mo^{VI}_{11}O_{40}$, which was prepared by the interaction of $PMo_{11}O_{39}^{7-}$ and $Bu_4N[MoOCl_4]$ in acetonitrile or propylenecarbonate, where Bu_4N represents the tetrabutyl ammonium ion.

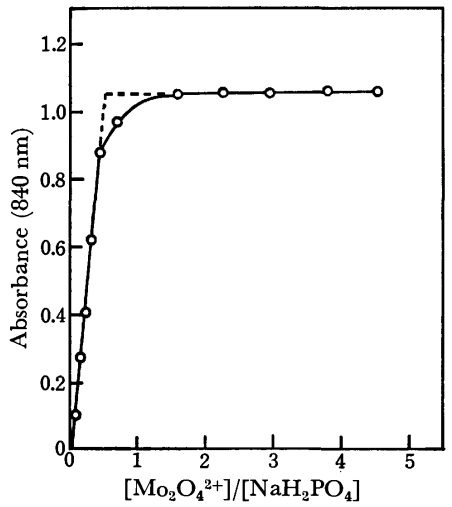

Fig. 7. The determination of molar ratio of P: Mo(V) in phosphomolybdenum blue.
$[Mo(VI)]=2.40\times10^{-3}M$, $[NaH_2PO_4]=4.36\times10^{-5}M$, $[HClO_4]=0.28$ M,

In this work, the P: Mo(V) molar ratio in phosphomolybdenum blue, which was formed by the reaction of molybdenum(V) with molybdenum(VI), was determined by means of the molar-ratio method, under the condition of the presence of amounts of molybdenum(V) small with respect to that of molybdenum(VI). The results are shown in Fig. 7. Since the formation rate of phosphomolybdenum blue is markedly small for these experimental conditions, it requires at least 300 min at 80 °C for the color to completely develop. The results shown in Fig. 7 illustrate that the P: Mo(V) molar ratio (as a monomer) is 1: 1 for 0.28 M $HClO_4$. The same result was obtained with 0.36 M $HClO_4$. A determination of the P: Mo(VI) molar ratio based on the molar-ratio method was unsuccessful.

The formation mechanism of phosphomolybdenum blue determined from this work has not yet been ascertained. The present authors are planning a detailed kinetic treatment of the formation of phosphomolybdenum blue.

Catalytic Decomposition of the Excess Reagent in the Spectrophotometric Determination of Copper(II) with *o,o'*-Dihydroxyazo Compounds

Masao SUGAWARA, Yuh'ichi ROKUGAWA, and Tomihito KAMBARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received April 16, 1977)

A simple and sensitive spectrophotometric method for determination of copper(II) is described. It is based on the reaction of copper(II) with Hydroxynaphthol Blue in the weakly alkaline medium and the decomposition of the unconsumed reagent which shows an intense absorption at the wavelength, 555 nm, of the maximum absorbance of the copper(II) complex. Beer's law is obeyed over the range 0.13—1.27 ppm copper with the molar absorption coefficient of $\varepsilon_{555}=3.01\times10^4$ dm^3 mol^{-1} cm^{-1} (Sandell's sensitivity 2.11×10^{-3} μg/cm^2). A fairly large number of common ions except for nickel(II) do not interfere.

Several *o,o'*-dihydroxyazo reagents have been employed in spectrophotometric determination of metal ions,[1] but in some cases the use of the azo reagent as a spectrophotometric reagent is prevented by similarity in absorption spectrum of the metal complex and the reagent itself. In addition, the color reaction is poor in selectivity. For improving the sensitivity and selectivity of the reaction, extraction of the complex anion formed between a sulfonated azo-dye and a metal ion as an ion-pair with a quaternary ammonium cation has been investigated[2] and applied to the spectrophotometric determination of aluminium,[3] magnesium,[4] and rare earth elements.[5]

In the present paper, a new method for spectrophotometric determination of copper(II) with *o,o'*-dihydroxyazo compounds is described, in which the excess reagent and some of the colored chelates formed by interfering metal ions are decomposed by the use of the manganese(II)-catalysed discoloration reaction.[6,7] The reaction is also utilized in the catalymetric microdetermination of manganese(II) by Yamane and Fukasawa.[8]

Experimental

Reagents. Commercially available 1-(2-hydroxy-4-sulfo-1-naphthylazo)-2-naphthol-3,6-disulfonic acid, trisodium salt (Hydroxynaphthol Blue, abbreviated as HNB), 1-(1-hydroxy-2-naphthylazo)-6-nitro-2-naphthol-4-sulfonic acid, sodium salt (Eriochrome Black T), 1-(2-hydroxy-1-naphthylazo)-2-naphthol-4-sulfonic acid, sodium salt (Calcon) and 1-(2-hydroxy-5-methylphenylazo)-2-naphthol-4-sulfonic acid (Calmagite) were obtained from Dojindo Laboratories Ltd. and used without further purification. The purity of the reagents was checked by the method described below. The solution was daily prepared by dissolving the reagent in water and concentration was corrected.

A 0.01 mol dm^{-3} standard solution of copper(II) was prepared from its sulfate and standardized by the method of the conventional chelatometric titration.

A mixture of 3 (w/w)% hydrogen peroxide and 0.2 mmol·dm^{-3} manganese(II) was freshly prepared before use by mixing the appropriate amounts of 30 (w/w)% hydrogen peroxide and 0.01 mol dm^{-3} manganese(II) chloride solutions and diluting with water.

Sörensen's buffer solution (pH 8.0—11.0), Kolthoff's buffer solution (pH 6.0—7.4) and deionized water were used.

All the chemicals except for the azo reagents used were of analytical grade.

Apparatus. A Hitachi two-wavelength and double-beam spectrophotometer 356 and a Shimadzu spectrophotometer, Model QV-50, with 10-mm glass cells were used for spectrophotometric measurements. A Hitachi-Horiba glass electrode pH-meter, Model F-5, was used for pH measurements.

The Purity of Azo Reagents. The purity of the reagent was evaluated by applying the familiar mole-ratio method to the copper(II)–dye system, where excess reagent is decomposed in the similar manner as described below. After correcting the reagent concentration, a continuous variation method was applied to the calcium(II)- or magnesium(II)–dye system to check the estimated value of the purity. It was found that the molar ratio of the dye to the metal ion is 1:1, in accordance with the results reported by several authors.[9,10] The purity was found to be *ca.* 40% for HNB, 46.5% for Eriochrome Black T, 64% for Calmagite and 45% for Calcon, and the concentration of the reagent was therefore corrected in a suitable manner.

Procedure. In a 50-cm^3 volumetric flask are taken an appropriate volume up to 20 cm^3 of the solution containing less than 63.6 μg of copper(II), 5 cm^3 of 0.4 mmol dm^{-3} HNB solution and 20 cm^3 of the buffer solution (pH 10). The solution is mixed well. After addition of 2 cm^3 of a 3% hydrogen peroxide-0.2 mmol dm^{-3} manganese(II) solution, the mixture is diluted with water to the volume and allowed to stand for 15 min. The absorbance of the solution is measured at 555 nm against water.

The similar procedure is available for preparing the calibration graph with other dyes.

Results and Discussion

Absorption Spectra. The absorption spectra of HNB and its copper(II) complex are shown in Fig. 1. On adding hydrogen peroxide and manganese(II) after the full development of color of copper(II)–HNB complex, the HNB present in excess is rapidly decomposed by the catalytic effect of manganese(II), whereas the red-purple copper(II)–HNB complex, the absorption maximum being 555 nm, remains stable. The addition of hydrogen peroxide alone is not effective for the discoloration of the HNB solution. After standing the solution for 15 min, only approx. 5% decrease in absorbance is observed. Of the azo-dyes used, the decomposition rate of HNB is most rapid and the absorbance of the resulting solution at the wavelength of the maximum absorption of the copper(II) complex is the lowest.

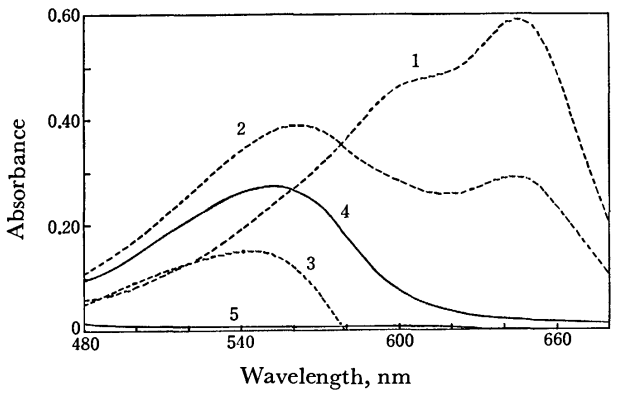

Fig. 1. Absorption spectra of copper-(II)HNB complex and HNB at pH 9.1 in the presence (——) and absence (------) of 0.12% hydrogen peroxide and 4 μmol dm^{-3} manganese (II).
1: HNB 20 μmol dm^{-3}. 2: Cu(II) 10 μmol dm^{-3}, HNB 20 μmol dm^{-3}. 3: Cu(II)-HNB complex measured against the reagent blank solution. 4: Cu(II) 10 μmol dm^{-3}, HNB 20 μmol dm^{-3}, after decomposition of excess reagent by H_2O_2 and Mn(II). 5: The reagent blank solution corresponding to 4. The measurements were carried out after standing for 15 min.

Effect of pH. The extent of the decomposition of azo reagents is dependent on the pH of solution as shown in Fig. 2. In the pH range from 9.3 to 10.5, the reagents are almost completely decomposed after standing the solution longer than 10 min. The absorbance of the copper(II) complexes is constant in the pH range where the decomposition is almost complete.

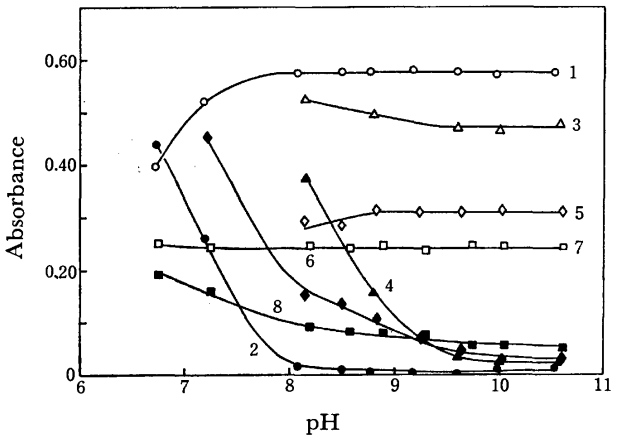

Fig. 2. Effect of pH on the absorbance of the copper(II) complexes and the reagent blank solutions after standing for 15 min in the presence of 0.12% hydrogen peroxide and 16 μmol dm^{-3} manganese (II).
1: HNB 40 μmol dm^{-3}, Cu(II) 20 μmol dm^{-3}, 555 nm. 2: The reagent blank solution corresponding to 1. 3: Calcon 44.5 μmol dm^{-3}, Cu(II) 20 μmol dm^{-3}, 545 nm. 4: The reagent blank solution corresponding to 3. 5: Eriochrome Black T 46.5 μmol dm^{-3}, Cu(II) 20 μmol dm^{-3}, 540 nm. 6: The reagent blank solution corresponding to 5. 7: Calmagite 64.5 μmol dm^{-3}, Cu(II) 12 μmol dm^{-3}, 530 nm. 8: The reagent blank solution corresponding to 7. The absorbance of the complexes was measured against the reagent blank solution.

Effect of Reagent Concentration. It was found that a small excess of the reagent more than the stoichiometrically necessary amount was sufficient to develop fully the color of the copper(II) complex with each dye except for Eriochrome Black T as shown in Fig. 3. The absorbance of the copper(II)-Eriochrome Black T complex was observed to increase notably with increasing concentration of the reagent more than the equivalent amount to copper(II). The composition of the complex formed between copper(II) and the azo-dye is estimated to be 1 : 1 molar ratio for each copper(II)-dye system except for the Eriochrome Black T complex.

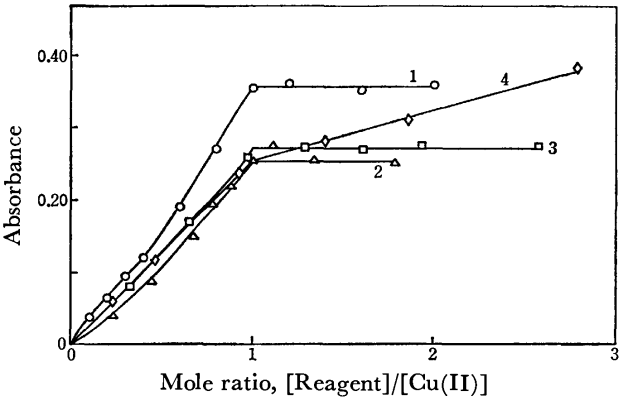

Fig. 3. Effect of the reagent concentration on the absorbance of copper(II) complex measured against water after standing for 15 min. Hydrogen peroxide 0.12%, manganese(II) 16 μmol dm^{-3}.
1: HNB, Cu(II) 12 μmol dm^{-3}, 555 nm, pH 9.1.
2: Calcon, Cu(II) 10 μmol dm^{-3}, 545 nm, pH 10.
3: Calmagite, Cu(II) 12 μmol dm^{-3}, 530 nm, pH 9.9.
4: Eriochrome Black T, Cu(II) 20 μmol dm^{-3}, 540 nm, pH 9.9.

Stability of Copper(II) Complex. The copper(II)-HNB complex after decomposing the excess reagent is sufficiently stable for practical use and the absorbance of the complex is constant at least for one hour as shown in Table 1. The addition of the hydrogen peroxide-manganese(II) solution more than 4 cm^3 is undesirable because the optical measurements are prevented by the occurrence of bubble which is adsorbed onto the wall of cell. The copper(II) complex with Calcon, Calmagite or Eriochrome Black T is somewhat unstable as compared with that of the HNB complex and the absorbance of the complexes at 12 μmol dm^{-3} copper(II) level decreases by 3—7% between 15 and 60 min.

Table 1. Stability of the copper(II)-HNB complex

Cu(II) taken μg/50 cm^3	Amount of {1.5% H_2O_2–0.2 mmol dm^{-3} $MnCl_2$} added cm^3	Absorbance at 555 nm *vs.* water after 15 min	30 min	45 min	60 min
19.0	1.0	0.174	0.173	0.173	0.172
	2.0	0.174	0.173	0.173	0.172
	4.0	0.176	0.176	0.175	0.175

	2.0	0.346	0.347	0.347	0.347
	4.0	0.350	0.350	0.350	0.350

HNB concentration 40 μmol dm^{-3}, pH 9.2.

Calibration Curve and Sensitivity. The copper(II)-HNB system conforms to Beer's law in the range of 0.13 to 1.27 ppm copper with the molar absorption coefficient of 3.01×10^4 dm^3 mol^{-1} cm^{-1} at 555 nm. The molar absorption coefficient of copper(II)-Calcon and -Calmagite system is 2.59×10^4 at 545 nm and 2.04×10^4 at 530 nm, respectively. The copper(II)-Eriochrome Black T system does not obey the Beer's law. The sensitivity of the HNB method is higher than those of cuprizone method (molar absorption coefficient 1.6×10^4),[1] zincon method (2.2×10^4),[11] *N*-[2-(2-pyridylmethyleneamino)ethyl]-*N*-(2-aminoethyl)dithiocarbamic acid method (1.75×10^4),[12] Calcichrome method (8×10^3),[13] Xylenol Orange method (1.25×10^4)[14] and Sarcosine Cresol Red method (2.09×10^4),[15] but lower than those of tetraphenylporphine-trisulfate method (4.8×10^5),[16] Chromazurol S-zephiramine method (4.76×10^4)[17] and 2-bromo-4,5-dihydroxyazobenzene-4'-sulfonate-hexadecyltrimethylammonium chloride method (4.8×10^4).[18]

Effect of Foreign Ions. From the viewpoint of sensitivity and simplicity in the procedure, it seems that the HNB is most preferable among the four reagents examined in the present work. Therefore, the effect of diverse ions on the determination of copper(II) according to the above-mentioned HNB procedure was examined, as tabulated in Table 2. The cations were added as nitrates, chlorides or sulfates and anions as sodium, potassium or ammonium salts. The major interference arises from nickel(II) which reacts with HNB and produces an intense coloration. Magnesium(II), zinc(II), cadmium(II) and thorium(IV) form the similarly colored complexes, but these complexes, being unstable under the given conditions, decompose on the addition of hydrogen peroxide and manganese(II). Aluminium(III) at the 2-fold excess amount and iron(III) at the 4-fold excess amount over copper(II) are easily masked by adding a 20-fold excess amount of fluoride. The four-fold excess amount of cobalt(II) over copper(II) is masked by previously oxidizing it to cobalt(III) with hydrogen peroxide in ammoniacal buffer solution. In Table 3 are given the analytical results of copper(II) in the synthetic sample. Almost satisfactory results were obtained.

TABLE 2. EFFECT OF VARIOUS IONS

(Received April 18, 1977)

All four possible isomers of the bis(ethylenediamine)sarcosinatocobalt(III) ion, $[Co(sar)(en)_2]^{2+}$, were separated chromatographically on the column of an SP-Sephadex cation exchanger, and their absorption, circular dichroism, and ^{13}C NMR spectra were measured. The more stable pair of isomers were identified as Λ-$[Co(S\text{-sar})(en)_2]^{2+}$ and Λ-$[Co(R\text{-sar})(en)_2]^{2+}$, while the less stable pair were Λ-$[Co(R\text{-sar})(en)_2]^{2+}$ and Λ-$[Co(S\text{-sar})(en)_2]^{2+}$. The Λ-$[Co(S\text{-sar})(en)_2]^{2+}$ isomer in an aqueous solution showed mutarotation which can be ascribed to a change in configuration (epimerization) about the sarcosinato nitrogen atom. In equiribrium at 25 °C, the mixture consisted of 84.8% of the $\Lambda(S)$ isomer and 15.2% of the $\Lambda(R)$ isomer. From this result, the free-energy difference between the isomers was estimated to be 4.2_6 kJ mol^{-1}. The presence of the less stable isomers, which were not found by Buckingham *et al.*, was also confirmed by the ^{13}C NMR measurements.

The bis(ethylenediamine)sarcosinatocobalt(III) ion possesses four possible isomers arising from two asymmetric centers, one at the cobalt and the other at the sarcosinato nitrogen atom. Figure 1 shows two of the isomers, $\Lambda(S)$ and $\Lambda(R)$, which are different from each other only with respect to their configurations about the nitrogen atom. The $\Lambda(R)$ configuration appears to be less stable than $\Lambda(S)$ due to nonbonded repulsive interactions between the hydrogen atoms on the methyl group and those on the adjacent ethylenediamine chelate ring.

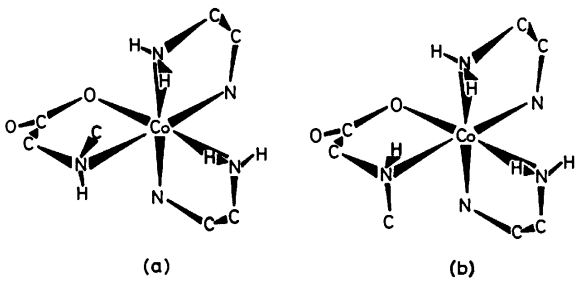

Fig. 1. Structures of Λ-$[Co(S\text{-sar})(en)_2]^{2+}$ (a) and Λ-$[Co(R\text{-sar})(en)_2]^{2+}$ (b) viewed along the pseudo-C_3 axis. Some of hydrogen atoms attached to carbon and nitrogen atoms are omitted.

The first attempt to separate the four isomers was made by Meisenheimer *et al.*,[1] who claimed to have obtained one isomer having high positive rotatory power in the pure state and two having lower rotatory powers of positive and negative signs, at least in an impure state. However, their results have not been reproduced by other investigators.[2]

In a previous paper,[3] the present authors briefly reported that the four isomers were present as a mixture in an aqueous solution and that their less stable enantiomers were completely resolved into optical isomers by a chromatographic technique using an SP-Sephadex column.

The present study was undertaken to obtain all four isomers of the complex in optically pure form, and to characterize them from measurements of the absorption, circular dichroism (CD), and ^{13}C NMR spectra, the mutarotation rate, and the isomer distribution. The results will be discussed from the structural point of view with reference to the available data on X-ray structural analysis[6] and conformational analysis.[9]

Experimental

Synthesis of the Racemic Complex. Bis(ethylenediamine)-sarcosinatocobalt(III) iodide was prepared from *trans*-$[CoCl_2(en)_2]Cl$ and sarcosine according to the procedure described by Liu and Douglas.[4] The iodide obtained was recrystallized twice from slightly alcoholic water and was dried under reduced pressure. Found: C, 16.14; H, 4.26; N, 13.44%. Calcd for $[Co(CH_3NHCH_2COO)(C_2H_8N_2)_2]I_2$: C, 16.55; H, 4.18; N, 13.52%.

Resolution. The method of Buckingham *et al.*[5] for the resolution of $[Co(sar)(en)_2]I_2$ was used with slight modification. A very slight excess of silver (+)-bromocamphorsulfonate,† Ag (+)-BCS, suspended in water was added to a solution of the complex at about 40 °C. After stirring of the mixture for 30 min, the precipitated silver iodide was filtered off and washed with water. The filtrate and washings were combined and evaporated to dryness on a water bath. The resulting (+)-bromocamphorsulfonate, $[Co(sar)(en)_2]\{(+)\text{-BCS}\}_2$, was recrystallized from aqueous ethanol. The crystals showed a negative CD peak in the vicinity of 518 nm and the filtrate showed a positive CD peak in the same region. After repeated fractional recrystallizations, the least soluble fraction gave a $\Delta\varepsilon_{518}/\varepsilon_{495}$ value of -0.014 and the most soluble fraction a value of $+0.015$. The isomers of the complex showing CD signs of $\{-\}_{518}$ and $\{+\}_{518}$ will hereafter be represented by M and P, respectively (see Table 1).

Chromatographic Separation. An aqueous solution containing about 0.2 g of the (+)-bromocamphorsulfonate of the M-complex was poured onto a small column of SP-Sephadex (volume of 5 cm^3) to collect the complex ions. The SP-Sephadex carrying the complex was transferred to the top of another SP-Sephadex column (2.7 diam × 137 cm). Chromatographic elution with 0.12 M (=mol dm^{-3}) sodium (+)-tartratoantimonate(III), $Na_2[Sb_2((+)\text{-}C_4H_2O_6)_2]$, (pH 3.5) gave two bands, denoted by M-I and M-II in order of effluence (Fig. 2). Similar experiments were also made on the P-complex, which gave two bands, P-I and P-II, and,

† In the present paper, (+)-bromocamphorsulfonate denotes (+)-3-bromocamphor-8-sulfonate.

Table 1. Assignments and abbreviations of the isomers

Isomer	Assignment	CD sign[a)]	Abbrev.	Relative stability
P-I	$\Lambda(+)_{589}$[Co(*S*-sar)$(en)_2]^{2+}$	$\{+\}_{518}$	$\Lambda(S)$	less stable
P-II	$\Lambda(+)_{589}$[Co(*R*-sar)$(en)_2]^{2+}$	$\{+\}_{518}$	$\Lambda(R)$	stable
M-I	$\Delta(-)_{589}$[Co(*R*-sar)$(en)_2]^{2+}$	$\{-\}_{518}$	$\Delta(R)$	less stable
M-II	$\Delta(-)_{589}$[Co(*S*-sar)$(en)_2]^{2+}$	$\{-\}_{518}$	$\Delta(S)$	stable

a)The $\{+\}_\lambda$ and $\{-\}_\lambda$ symbols represent the CD sign at λ nm.[7)]

on the racemic complex, which gave three bands, A, B, and C (Fig. 2). The notations, M-I, M-II, P-I, and P-II, will hereafter also be used to designate the isomer contained in each band.

Conversion to the Chloride. The combined eluate of the M-I bands from several elutions was diluted twenty times with water, acidified by a small amount of HCl (pH≈3), to prevent isomerization.†† The complex in the diluted eluate from the M-I band was again collected on a separate SP-Sephadex column. After washing the column with 0.005 M HCl to remove sodium ions, if any, the M-I isomer sorbed was eluted with 0.5 M HCl. The eluate containing the chloride of the M-I isomer was evaporated almost to dryness under reduced pressure. Ethanol, and subsequently ether, were added to precipitate the chloride. The chloride of the M-I isomer obtained was dried under reduced pressure. The chlorides of the M-II, P-I, and P-II isomers were also obtained from the eluates of the corresponding bands by means of similar procedures. M-I (P-I). Found: C, 20.47 (20.51); H, 6.55 (6.33); N, 16.57 (16.57)%. Calcd for [Co(CH_3-$NHCH_2COO$)$(C_2H_8N_2)_2$]$Cl_2\cdot 2H_2O\cdot HCl$: C, 20.47; H, 6.63; N, 17.06%. M-II (P-II). Found: C, 22.24 (22.40); H, 6.33 (5.88); N, 18.15 (18.38)%. Calcd for [Co(CH_3NHCH_2COO) $(C_2H_8N_2)_2$]$Cl_2\cdot 2H_2O$: C, 22.47; H, 5.93; N, 18.72%.

Physical Measurements. Absorption spectra were recorded on a Shimadzu UV 200S spectrophotometer equipped with a 1-cm quartz cell at room temperature. The sample solutions contained complex ions at approximately 4×10^{-3} M in 0.5 M HCl. CD curves were measured for a *ca.* 10^{-3} M solution of each isomer in 0.5 M HCl with a JASCO J-20 CD recorder using a 1-cm cell. The ^{13}C NMR spectra were obtained with a JEOL JNM FX-60 spectrometer at a probe temperature of 35 °C. Dioxane in D_2O in a coaxial inner tube was used as an external reference for all samples. The concentrations of the samples were approximately 0.1 M. Usually, 40000—50000 pulses were accumulated to produce a very clear spectrum.

Equilibration. About 0.02 g of each isomer was dissolved in 10 cm^3 of each solution listed in the first column of Table 4. The slightly alkaline or neutral solution (with added NaOH, if necessary) was allowed to stand at 25 °C for three days and then acidified with 0.5 M HCl. The complex was collected from the solution on a small amount of SP-Sephadex. The collected equilibrium mixture of the complex was subjected to chromatographic separation on an SP-Sephadex column (1.5 diam×87 cm) using 0.12 M $Na_2[Sb_2((+)\text{-}C_4H_2O_6)_2]$ as the eluent. The isomer ratio was obtained from the ratio of the areas of the bands in the elution curve.

Mutarotation. The rate of CD change was measured for a 0.1 M acetate buffer solution (pH 5.66) of each isomer (3.0×10^{-3} M) at 30.0 °C. The change in the CD intensity was observed at 465 nm, the wavelength at which the CD spectra showed a marked difference between the I and II isomers. The reaction was followed for at least three half-lives.

†† Although the elutions were carried out at room temperature (15—20 °C), the eluates were stored in a refrigerator (≈5 °C) to inhibit isomerization.

Results and Discussion

Chromatographic Behavior and Identification. Figure 2 shows the results of chromatographic elutions of the M-, P-, and racemic complexes with 0.12 M sodium (+)-tartratoantimonate(III). The ratios of the areas under the peaks are approximately 1 : 4.5 for (a) and (b), and 1 : 1 : 9 for (c) in Fig. 2. Comparisons of the band positions identified the A, B, and C bands of the racemic complex as the M-I, P-I, and combined P-II and M-II bands, respectively. For the C band, the CD sign at 518 nm was positive at the head of the band and negative at the tail, in agreement with the observation that the P-II isomer was eluted slightly faster than M-II.

The CD spectrum of the M-II isomer (Fig. 4) closely resembles that of $(-)_{589}$[Co(sar)$(en)_2]^{2+}$ obtained by Buckingham *et al.*[5)] On the basis of an X-ray analysis of $(-)_{589}$[Co(sar)$(en)_2]I_2\cdot 2H_2O$,[6)] the M-II isomer is identified as Δ-[Co(*S*-sar)$(en)_2]^{2+}$ (Fig. 1(a)). The P-II isomer can be identified as Λ-[Co(*R*-sar)$(en)_2]^{2+}$ from its enantiomeric relationship to the M-II isomer. Taking account of the isomerization behavior, which is described below, the M-I and P-I isomers are identified as the less stable isomers, Δ-[Co(*R*-sar)$(en)_2]^{2+}$ (Fig.

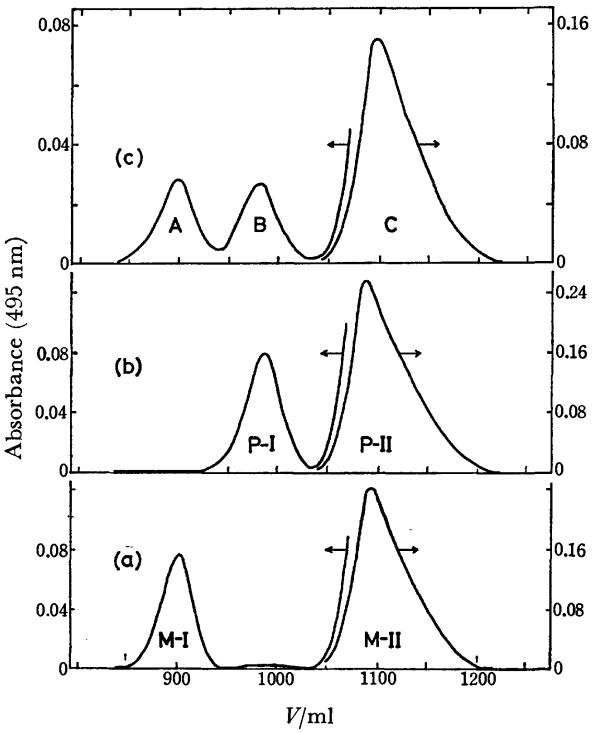

Fig. 2. Elution curves for $\{-\}_{518}$[Co(sar)$(en)_2]^{2+}$ (a), $\{+\}_{518}$[Co(sar)$(en)_2]^{2+}$ (b), and *rac*-[Co(sar)$(en)_2]^{2+}$(c).

1(b)) and *Λ*-$[Co(S\text{-sar})(en)_2]^{2+}$, respectively. The assignments are summarized in Table 1.

The P-I isomer showed no measurable CD change either in 0.12 M $Na_2[Sb_2((+)\text{-}C_4H_2O_6)_2]$ or in acidified water at room temperature over one week. This indicates that epimerization (configuration change) at the nitrogen center of the sarcosinato ligand is very slow in acidic solutions. The (+)-bromocamphorsulfonate of M-complex was dissolved in acidified water (pH≈3), and was subjected to chromatographic separation, as described in the experimental section. The elution curve showed a very small peak corresponding to M-I and a large peak corresponding to M-II, with the area ratio being 1 : 23. This suggests that the recrystallized (+)-bromocamphorsulfonate of the M-complex consists almost solely of the M-II isomer. On the other hand, in a neutral or alkaline solution, epimerization at the nitrogen center occurred to give an equilibrium mixture of M-I and M-II (Fig. 2(a)).

The fact that the less stable isomers, M-I and P-I, are eluted faster than the more stable M-II and P-II (Fig. 2) can be taken as an indication of the former being favored in the interaction with the eluting agent, sodium (+)-tartratoantimonate(III). The stereoselectivity is ascribed to the structural feature of the less stable isomers that each has a set of three N–H hydrogens directed nearly parallel to the pseudo-C_3 axis of the complex (Fig. 1). Further discussion in this connection can be found below.

Absorption (AB) and Circular Dichroism (CD) Spectra. Figures 3 and 4 show the AB and CD spectra of the four isomers, and Table 2 summarizes the numerical data for the M-I and M-II isomers. For the less stable isomer, M-I, both the first and second absorption bands appeared at slightly lower wave numbers than for the more stable isomer, M-II, indicating a slightly weaker ligand field in the M-I isomer. The CD spectra of M-I and P-I (Fig. 3) were mirror images of each other, confirming the enantiomeric relationship deduced from their chromatographic behavior. A similar relationship was observed between M-II and P-II (Fig. 4). The CD spectra of M-I and M-II are similar in that they have a main CD band of negative sign in the $^1T_{1g} \leftarrow {}^1A_{1g}$ (O_h) region, but are different from each other in other respects, as depicted in Figs. 3 and 4.

In Fig. 5, the halved sum of CD curves for P-I and P-II, showing the contribution of the *Λ*-configuration about the cobalt center, is compared with the CD curve for $\Lambda(+)_{546}[Co(gly)(en)_2]I_2$;[4] the latter has a configura-

	2nd band	28.6	111	28.1	+0.13
				30.8	−0.04

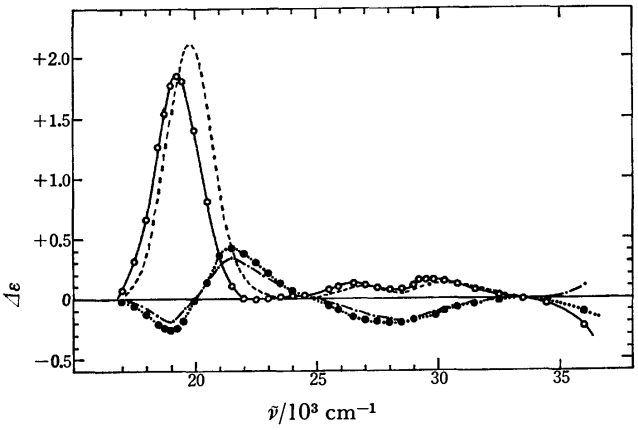

Fig. 5. Configurational and vicinal CD curves of $[Co(sar)(en)_2]^{2+}$: $1/2\times\{(P\text{-}I)+(P\text{-}II)\}$ (-○-) and $1/2\times\{(M\text{-}I)-(M\text{-}II)\}$ (···●···), respectively, compared with the CD spectra of Λ-$[Co(gly)(en)_2]^{2+}$ (------) and $(-)_{436}$-$[Co(R\text{-}sar)(NH_3)_4]^{2+}$ (- · -).

tion similar to that of the P-isomers, but has no asymmetric center at the aminoacidato nitrogen. Figure 5 also shows the halved difference of the CD spectra for M-I and M-II, showing *R*-vicinal contribution of the asymmetric nitrogen. This difference was compared with the CD spectrum for $(-)_{436}[Co(R\text{-}sar)(NH_3)_4](NO_3)_2$,[8] which makes only a vicinal contribution of the sarcosinato nitrogen to the CD spectrum. The similarity of the halved-sum and -difference spectra to those of the reference complexes can be taken as additional evidence for our assignment of the absolute configurations of the isomers; the small difference in the position of the main peak between the halved-sum CD spectrum and the reference spectrum may result from some conformational effect of the ethylenediamine rings.

In an X-ray study of the Λ-$[Co(S\text{-}sar)(en)_2]I_2\cdot 2H_2O$ crystal, the conformation of the ethylenediamine rings was found to be $\delta\lambda$.[6] On the other hand, Buckingham and his coworkers[9] have shown in their strain-energy

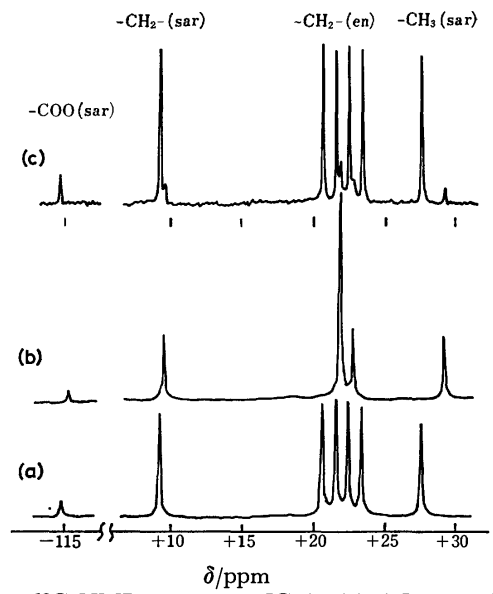

Fig. 6. ^{13}C NMR spectra of $[Co(sar)(en)_2]^{2+}$ in 0.5 M HCl solutions using dioxane as an external standard: P-II, (a); P-I, (b); racemic complex, (c).

calculations that the $\delta\lambda$ and $\lambda\lambda$ conformations would have the same minimum energy for the $\Delta(S)$ ion and that the $\lambda\lambda$ conformation is most stable for the $\Delta(R)$ ion. Thus, it is very probable that the $\Delta(S)$ and $\Delta(R)$ ions have different ring conformations and, therefore, that the halved-sum spectrum of these ions shows a conformational effect in addition to the Δ-configurational effect.

Carbon-13 NMR Spectra. Figure 6 shows the ^{13}C NMR spectra (^1H "noise" decoupled) of P-II, P-I, and the racemic mixture, which was equilibrated in an aqueous solution. All measurements were made in 0.5 M hydrochloric acid solutions to prevent isomerization. A comparison of the spectra shows that the racemic mixture contains II isomers as the major component and I isomers as the minor component.

The $[Co(sar)(en)_2]^{2+}$ ion has seven carbon atoms:

four methylene carbon atoms in the two ethylenediamine ligands, and single methyl, methylene, and carboxyl carbon atoms in the sarcosinato ligand. Correspondingly, the spectrum for P-II shows seven resonance peaks of nearly equal intensity except for the lowest-field peak of low intensity (Fig. 6(a)). The latter was assigned to the carboxyl carbon, which is known to relax slowly and to show a weak resonance peak.[10] Further information was obtained by allowing the ^{13}C nuclei to couple with protons. The resonance peak at the highest field split into a quartet and was readily assigned to the methyl carbon atom of the sarcosinato ligand. The signal of the methylene carbon atom in the sarcosinato ligand was distinguished from those of the methylene carbon atoms in the ethylenediamine ligands, because each of the triplet signals of the latter carbon atoms was broadened due to long-range coupling with the protons of the adjacent methylene and amino groups. However, the resonances of the ethylenediamine carbon atoms were difficult to assign to the individual atoms. The chemical shift data and assignments are summarized in Table 3. The table also gives the data for *rac*-$[Co(gly)(en)_2]Cl_2$ measured under the same conditions.

All the resonance peaks for the carbon atoms in the sarcosinato ligand appeared at a higher field for P-I than P-II. Since the chemical shift difference was the greatest between the methyl carbon signals of the two isomers, the high-field shifts observed for P-I can be ascribed to a distortion of the chelate ring brought about by an increase in the nonbonded repulsive interactions of the methyl group with an adjacent ethylenediamine ring. Such a distortion was also inferred from the low wave-number shift of the absorption spectrum of P-I relative to that of P-II. Concerning the resonance pattern of the four carbon atoms in ethylenediamine ligands, a marked difference was observed between P-I and P-II. Whereas P-II gave four nearly equally spaced peaks (Fig. 6(a)), P-I resulted in a pattern in which three of the four carbon atoms were apparently equivalent (Fig. 6(b)). The reasons for the incidental degeneracy in this nonsymmetric complex are not immediately evident. The ethylenediamine carbon atoms of the corresponding glycinato complex gave four distinct resonance peaks similar to those of P-II, although slight chemical-shift differences were observed among them. Therefore, nonbonded repulsive interactions of methyl group are responsible for the incidental degeneracy of the ethylenediamine carbon signals of P-I.

Mutarotation Rate (Rate of Epimerization at the Nitrogen Center). Figure 7 shows a typical set of CD spectra (480—380 nm) obtained at intervals after the P-I isomer had been dissolved in the acetate buffer solution at 28 °C. The spectra gave an isosbestic point at 403 nm and showed the greatest intensity change at 465 nm. From these observations, it is inferred that the CD change resulted from only one reaction which is epimerization at the nitrogen center yielding the P-II isomer.

The CD change measurements were carried out starting from the P-I and P-II isomers. In each kinetic run, the plot of $\ln|(\Delta\varepsilon)_t-(\Delta\varepsilon)_\infty|$ *vs.* time gave a straight line for at least three half-lives, where $(\Delta\varepsilon)_t$ and $(\Delta\varepsilon)_\infty$ represent the CD intensities at time t and at infinite

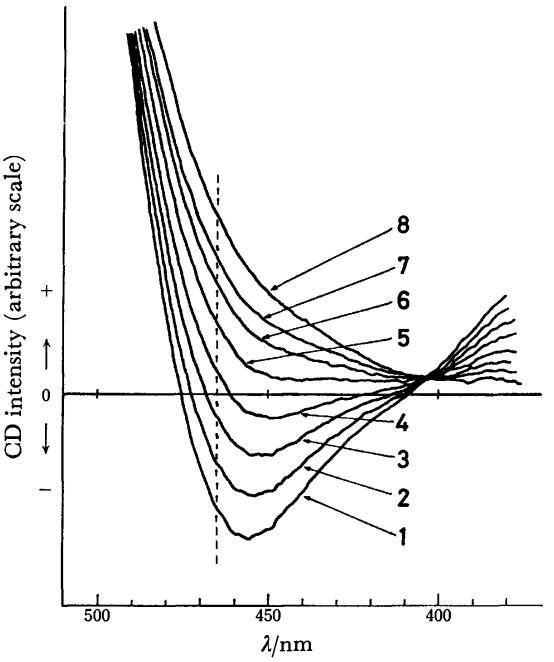

Fig. 7. Change of the CD spectrum with time for the P-I isomer in a 0.1 M acetate buffer at 28 °C. The curves 1—8 show the spectra measured at 5, 30, 60, 90, 130, 170, 215, and >1400 minutes, respectively.

time, respectively, at 465 nm. The slope gave the pseudo first-order rate constant, k_{obsd}. The runs using P-I and P-II as the starting isomers in a 0.1 M acetate buffer solution (pH 5.66) at 30.0 °C gave k_{obsd} values of 3.32×10^{-4} and 3.37×10^{-4} s^{-1}, respectively. They are in good agreement with each other.

For reversible isomerization (epimerization):

$$\text{P-II}(\Lambda(R)) \underset{k_r}{\overset{k_f}{\rightleftharpoons}} \text{P-I}(\Lambda(S))$$

the forward and reverse rate constants, k_f, and k_r, are related to the observed rate constant, k_{obsd}, and to the equilibrium constant, K, as follows:

$$k_{obsd} = k_f + k_r$$
$$K = k_f/k_r.$$

The K values was found to be 0.177 in chromatographic experiments on the equilibrium mixture (Table 4). This leads to k_f and k_r values of 0.50×10^{-4} and 2.85×10^{-4} s^{-1}, respectively. The rate of epimerization is known to be proportional to the hydroxide ion concentration,[8] and the second-order rate constants, k, k_1, and k_2, can be obtained from the corresponding first-order rate constants, k_{obsd}, k_f, and k_r, in terms of the equations:

$$k = k_{obsd}/[OH^-],\ k_1 = k_f/[OH^-],\ \text{and}\ k_2 = k_r/[OH^-].$$

The resulting values are 7.32×10^4, 1.1×10^4, and 6.2×10^4 M^{-1} s^{-1}, respectively. On the other hand, Halpern *et al.*[8] obtained a corresponding rate constant, $k=1.9\times10^4$ M^{-1} s^{-1}, for the racemization of $[Co(sar)(NH_3)_4](NO_3)_2$ dissolved in a 0.1 M acetate buffer at 30.0 °C. This gives $k_1=k_2=1.0\times10^4$ M^{-1} s^{-1}, which can be compared with the k_1 value for $[Co(sar)(en)_2]^{2+}$ of the present study. The several times greater value of k_2 for $[Co(sar)(en)_2]^{2+}$ suggests that some steric

a) Starting substance for equilibration. b) Kinetic run in an acetate buffer at 30.0 °C (see text).

repulsion exists in the $\Lambda(S)$ isomer to result in the acceleration of the $\Lambda(S)$ to $\Lambda(R)$ epimerization.

Equilibrium Isomer Distribution. The complex was equilibrated in various solutions at 25 °C and chromatographically analyzed for the isomer distribution. The results are given in Table 4. No indication was observed of the formation of other isomers and decomposition products in the column-chromatographic procedure.

The runs starting from M-I and from M-II in water gave essentially the same I to II ratios within the experimental error ($\approx\pm3\%$), consistent with the mutarotation experiments. Therefore, other runs were performed with either of the stable isomers (M-II and P-II) as the starting substance. At equilibrium in an aqueous solution, the I to II ratio was 15.2: 84.8 on the average, which gave the equilibrium constant, $K=0.177$, and the free energy difference, $\Delta G=4.2_6$ kJ mol^{-1}, between the I and II isomers. This ΔG value is close to the strain energy difference of 0.9 kcal mol^{-1} (=3.8 kJ mol^{-1}) calculated by Buckingham and his coworkers,[9] who gave minimized strain energies of 3.8 kcal mol^{-1} for the $\delta\lambda$-*S* and $\lambda\lambda$-*S* isomers of the Δ-complex and 4.7 kcal mol^{-1} for the $\lambda\lambda$-*R* isomer of the Δ-complex.†††

The addition of oxo anions effected an increase in the proportion of I isomer. Whereas, in 0.3 M CH_3COONa, this effect was not clearly observable due to the experimental error, a marked effect was found in 0.1 M Na_2SO_4. Sodium (+)-tartrate also showed the effect of increasing the proportion of I isomer, although the abundance of I isomer in 0.1 M $Na_2((+)$-$C_4H_4O_6)$ was not as high as that in 0.1 M Na_2SO_4 (Table 4). It is to be noted that, in 0.3 M $Na_2((+)$-$C_4H_4O_6)$, the M-and P-isomers showed different I/II ratios (Table 4), which is suggestive of stereoselective interactions of the isomers with the (+)-tartrate ion.

Such stereoselectivity was confirmed by the following chromatographic experiment. A slightly acidic (with HCl) aqueous solution of the P-I and M-I isomers mixed in equal amounts was allowed to flow through an SP-Sephadex column (1.5 dia. × 90 cm) and the complex sorbed by the column was eluted with 0.24 M $NaH((+)$-$C_4H_4O_6)$ (pH 3.4). Although the elution curve showed only one band, CD measurements revealed partial resolution of the enantiomers with an elution order P-I ($\Lambda(S)$) and M-I ($\Delta(R)$). This order can be compared with the Λ-Δ order of $[Co(en)_3]^{3+}$ when eluted with a sodium (+)-tartrate solution[11] and also when eluted with a sodium hydrogen-(+)-tartrate solution,[12] although the stereoselectivity was much higher in the $[Co(en)_3]^{3+}$ cases.

The behavior of the I isomer is understandable from the structural point of view. Both P-I and M-I isomers have a set of three N–H bonds (one sarcosinato and two ethylenediamine N–H bonds) aligned approximately parallel to the pseudo-C_3 axis of the complex, if the ethylenediamine ligands assume the *lel* conformation (Fig. 1). In the P-II and M-II isomers, on the other hand, the N–CH_3 bond of the sarcosinato ligand is nearly parallel to the pseudo-C_3 axis. Therefore, I isomers will more favorably interact with sulfate, (+)-tartrate, and hydrogen-(+)-tartrate ions than will II isomers and, thus, the proportion of I isomers in the equilibrated mixture will increase. The greatest effect shown by sulfate ions (Table 4) can be taken as suggesting that sulfate ions have the greatest tendency to form ion pairs with I isomers. This is consistent with the fact that the formation constant for the $[Co(en)_3]^{3+}$–SO_4^{2-} ion pair is approximately twice as large as that for the ion pair with the (+)-tartrate.[13]

The stereoselectivity of the (+)-tartrate ion for the P-I and M-I isomers can be explained in a manner similar to that for the case of stereoselective ion-pair formation between the (+)-tartrate ion and the $[Co(en)_3]^{3+}$ isomers.[14] The lower stereoselectivity for the $[Co(sar)(en)_2]^{2+}$ isomers appears to result mainly from the lower charge of this complex than for $[Co(en)_3]^{3+}$. For $[Co(gly)(en)_2]^{2+}$, (+)-tartrate ions showed little stereoselectivity.

The stereoselectivity shown by (+)-tartratoanti-

††† However, they assumed that the actual ΔG value probably exceeds $\approx$2 kcal mol^{-1}, since their careful ion-exchange chromatographic studies failed to show any isomeric separation.

monate(III) ions is very different from that of (+)-tartrate ions. As illustrated in Fig. 2(c), (+)-tartratoantimonate(III) ions show a high stereoselectivity for $[Co(sar)(en)_2]^{2+}$; however, this selectivity is the reverse of that shown by (+)-tartrate ions. This is in contrast to the case of $[Co(en)_3]^{3+}$, for which (+)-tartratoantimonate(III) ions show a stereoselectivity of the same preference as that shown by (+)-tartrate ions. The formation of the $[Co(sar)(en)_2]^{2+}$–$[Sb_2((+)\text{-}C_4H_2O_6)_2]^{2-}$ ion pair may occur through a mechanism different from that in the ion-pair formation involving (+)- tartrate or hydrogen-(+)-tartrate ions, since the tartrato hydroxyl groups in the (+)-tartratoantimonate(III) ion are bound to antimon(III) ions[15] and not readily available for ion pairing.

Preparation and Stereochemistry of Cobalt(III) Complexes Containing *N*-Methylbis(2-aminoethyl)amine

Masaaki KOJIMA, Masaru IWAGAKI, Yuzo YOSHIKAWA, and Junnosuke FUJITA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received May 10, 1977)

Seven new cobalt(III) complexes containing *N*-methylbis(2-aminoethyl)amine (4-methyldiethylenetriamine, abbreviated as dema) were prepared and their structures were determined by electronic, circular dichroism, and PMR spectroscopy. For the mixed $[Co(dien)(dema)]^{3+}$ complex(dien=diethylenetriamine), three geometric isomers, *s-fac*, *u-fac*, and *mer* were isolated. The $[Co(dema)_2]^{3+}$ complex formed only *s-fac* isomer. A conformational analysis was carried out to compare the stability of these geometric isomers.

Recently three geometric isomers of $[Co(dien)_2]^{3+}$ (dien=diethylenetriamine) were isolated, and the *u-fac* and the *mer* isomers were resolved into optical antipodes.[1,2] The formation ratio in an equilibrium mixture of the bromides (25 °C),[1] *s-fac*: *u-fac*: *mer*= 7: 30: 63 indicates that the *mer* arrangement is preferred over the *fac* one. The absolute configuration of the $(+)_{589}$-*u-fac* isomer assigned on the basis of the circular dichroism spectrum agreed with that determined by X-ray work.[3] For the *mer* isomer, however, the relationship between the circular dichroism spectrum and the absolute configuration is not clear yet.

The same isomerism is expected for the complex ions, $[Co(dien)(dema)]^{3+}$ (dema=*N*-methylbis(2-aminoethyl)amine, 4-methyldiethylenetriamine) and $[Co(dema)_2]^{3+}$. Molecular model studies indicate that the *mer* and the *u-fac* isomers of these complexes involve considerable steric interactions between the methyl group and its surroundings. Accordingly, the distribution of isomers in these complexes will differ from that in $[Co(dien)_2]^{3+}$. It will also be interesting to see how such steric interactions are reflected on the absorption and circular dichroism spectra.

Experimental

Ligands. *N*-Methylbis(2-aminoethyl)amine (dema) and its hydrochloride(dema·3HCl) were prepared by the method of Nakajima *et al.*[4] Diethylenetriamine(dien) was obtained from Tokyo Kasei Co., and used without further purification.

$[Co(NO_2)_3(dema)]$ and $[CoCl_2(H_2O)(dema)]Cl\cdot 0.5H_2O$. $[Co(NO_2)_3(dema)]$ was prepared from $Co(NO_3)_2\cdot 6H_2O$, $NaNO_2$, and dema by a method similar to that for $[Co(NO_2)_3(dien)]$,[5] and recrystallized from water containing a small amount of $NaNO_2$ and a few drops of acetic acid . Orange needle crystals were filtered off, washed with water and air dried, 60% yield. Found: C, 18.93; H, 4.64; N, 26.71%. Calcd for $CoC_5H_{15}N_6O_6=[Co(NO_2)_3(dema)]$: C, 19.12; H, 4.81; N, 26.75%.

$[Co(NO_2)_3(dema)]$(6.8 g, 22 mmol) was gently heated with 70 cm³ of concd HCl until the evolution of nitrogen dioxide ceased. Fine blue crystals which formed on standing the resulting solution overnight at room temperature were filtered off and washed with acetone, 75% yield. Found: C, 19.22; H, 6.13; N, 13.08; H_2O, 8.92%. Calcd for $CoC_5H_{18}N_3O_{0.5}Cl_3=[CoCl_2(H_2O)(dema)]Cl\cdot 0.5H_2O$: C, 19.39; H, 5.86; N, 13.58; H_2O, 8.74%.

s-fac-$[Co(dien)(dema)]Cl_3\cdot H_2O$(Isomer A). To a solution of $CoCl_2\cdot 6H_2O$(0.6 g, 2.5 mmol) in 10 cm³ of water were added a solution of dema (0.4 g, 3.5 mmol) and dien (0.35 g, 3.5 mmol) in 10 cm³ of water, and active charcoal (0.3 g). The mixture was aerated for 6 h at room temperature, and filtered to remove the charcoal. The resulting orange filtrate was diluted with about 1 dm³ of water and passed through an SP-Sephadex column ($\phi 2.5\times 4$ cm). A small portion of the SP-Sephadex charged with the product was poured on the top of the adsorbent layer of an SP-Sephadex column ($\phi 2.7\times 120$ cm) and the adsorbed complexes were eluted with a 0.2 M aqueous solution of Na_2SO_4. Three separate bands were obtained. The first band was *s-fac*-$[Co(dien)_2]^{3+}$, but the second and the third bands were mixtures of *u-fac*-$[Co(dien)_2]^{3+}$ and *s-fac*-$[Co(dien)(dema)]^{3+}$, and *mer*-$[Co(dien)_2]^{3+}$ and *s-fac*-$[Co(dema)_2]^{3+}$, respectively. The effluent of the second band was diluted with water and reloaded on an SP-Sephadex column, and the adsorbed band was eluted with a 0.15 M sodium $(+)_{589}$-tartratoantimonate(III) solution. Three separate bands, II_A, II_B, and II_C which eluted in this order were $(+)_{589}$-*u-fac*-$[Co(dien)_2]^{3+}$, $(-)_{589}$-*u-fac*-$[Co(dien)_2]^{3+}$, and *s-fac*-$[Co(dien)(dema)]^{3+}$, respectively. The third band was rechromatographed by a method similar to that for the second band. The column gave three separate bands, III_A, III_B, and III_C in the order of elution, which were $(+)_{589}$-*mer*-$[Co(dien)_2]^{3+}$, $(-)_{589}$-*mer*-$[Co(dien)_2]^{3+}$, and *s-fac*-$[Co(dema)_2]^{3+}$, respectively. The formation ratio, *s-fac*-$[Co(dien)_2]^{3+}$: *u-fac*-$[Co(dien)_2]^{3+}$: *mer*-$[Co(dien)_2]^{3+}$: *s-fac*-$[Co(dien)(dema)]^{3+}$: *s-fac*-$[Co(dema)_2]^{3+}$ was about 1: 4: 15: 6: 5. The effluent containing *s-fac*-$[Co(dien)(dema)]^{3+}$ was diluted with water and poured again on an SP-Sephadex column ($\phi 1.5\times 3$ cm), the column was washed with a large amount of 10^{-2} M HCl, and then the adsorbed complex was eluted with 1.0 M HCl. Orange crystals were obtained by evaporating the effluent to almost dryness in a vacuum desiccator over NaOH and P_2O_5. Found: C, 26.41; H, 7.40; N, 20.98%. Calcd for $CoC_9H_{30}N_6OCl_3$=*s-fac*-$[Co(dien)(dema)]Cl_3\cdot H_2O$: C, 26.78; H, 7.49; N, 20.82%.

u-fac-*$[Co(dien)(dema)]^{3+}$(Isomer B).* An aqueous solution (50 cm³) of dien·3HCl(0.63 g, 3 mmol) neutralized with $NaHCO_3$ (0.75 g, 9 mmol) was added to a solution of $[CoCl_2(H_2O)(dema)]Cl\cdot 0.5H_2O$(0.9 g, 3 mmol) in 50 cm³ of water. The solution was heated at 50 °C for 40 h, and then diluted with 1 dm³ of water. The solution was poured on an SP-Sephadex column ($\phi 2.5\times 4$ cm), and the adsorbed product was chromatographed by a method similar to that for *s-fac*-$[Co(dien)(dema)]^{3+}$ with a 0.2 M aqueous aolution of Na_2SO_4. The column gave orange, red-violet, and violet bands in the order of elution. The effluent of the first orange band was diluted with water and reloaded on an SP-Sephadex column, and the adsorbed band was eluted with a 0.2 M sodium $(+)_{589}$-tartrate solution. The column showed three yellow-orange bands. The first, the second, and the third bands in the order of elution were *u-fac*-$[Co(dien)(dema)]^{3+}$, *s-fac*-$[Co(dien)(dema)]^{3+}$, and *u-fac*-$[Co(dien)_2]^{3+}$, respectively. The

effluent of *u-fac*-[Co(dien)(dema)]$^{3+}$ was diluted with water and poured again on an SP-Sephadex column (ϕ1.5×3 cm), and the adsorbed complex was eluted with a 1.0 M NaCl solution. The complex was isolated as hexacyanocobaltate(III) salt by adding a $K_3[Co(CN)_6]$ solution to the effluent. Found: C, 33.26; H, 6.28; N, 30.74%. Calcd for $Co_2C_{15}H_{34}N_{12}O_3$= *u-fac*-[Co(dien)(dema)][$Co(CN)_6$]·3H_2O: C, 32.85; H, 6.25; N, 30.64%. The complex hexacyanocobaltate(III) was converted into chloride by use of the anion exchanger, Dowex 1×8 in the chloride form. The complex chloride did not crystallize on the addition of common organic solvents to a concentrate of the chloride solution. Thus, the orange residue obtained by evaporation in a vacuum desiccator was used for measurement.

The complex was resolved by SP-Sephadex column chromatography with a 0.15 M sodium $(+)_{589}$-tartratoantimonate-(III) solution as the eluent. The optically active chloride salt was isolated as an orange residue by a method similar to that for the racemic complex chloride.

mer-[*Co(dien)(dema)*]$^{3+}$*(Isomer C)*. To a suspension of *mer*-[$CoCl_3$(dien)][6] (2.2 g, 8.2 mmol) in 10 cm^3 of *N,N*-dimethylformamide (DMF) was added dema (1.0 g, 8.5 mmol), and the mixture was stirred for 1 h at 50 °C. The resulting orange solution was diluted to 1 dm^3 with water, and poured on SP-Sephadex. The product adsorbed on SP-Sephadex was similarly chromatographed. By elution with 0.15 M sodium $(+)_{589}$-tartratoantimonate (III), the column gave two pairs of enantiomers, the fast-(very small amount) and the slow-moving bands being $(+)_{589}$- and $(-)_{589}$-*mer*-[Co(dien)$_2$]$^{3+}$ and $(-)_{490}$- and $(+)_{490}$-*mer*-[Co(dien)(dema)]$^{3+}$, respectively. The optically active *mer*-[Co(dien)(dema)]$^{3+}$ was isolated as hexacyanocobaltate(III) salt by a method similar to that for *u-fac*-[Co(dien)(dema)]$^{3+}$, and the isolated salt was converted into bromide with the anion exchanger, Dowex 1X 8 in the bromide form. The solution of the complex bromide was evaporated to dryness in a vacuum desiccator to give orange crystals. Found: C, 19.30; H, 5.74; N, 14.82%. Calcd for $CoC_9H_{33}N_6Br_3O_{2.5}$=$(+)_{490}$-*mer*-[Co(dien)(dema)]$Br_3$·2.5-$H_2O$: C, 19.17; H, 5.90; N, 14.89%. The racemic complex was isolated as perchlorate salt by the following method; the effluents containing $(-)_{490}$- and $(+)_{490}$- isomers were combined, diluted with water, and poured on SP-Sephadex. The adsorbed complex was eluted with a 1.5 M $NaClO_4$ solution and the effluent was concentrated in a vacuum desiccator over P_2O_5 to give orange crystals. Found: C, 17.74; H, 5.21; N, 13.70%. Calcd for $CoC_9H_{32}N_6O_{14}Cl_3$=*mer*-[Co(dien)(dema)]$(ClO_4)_3$·2H_2O: C, 17.62; H, 5.26; N, 13.69%.

s-fac-[*Co(dema)*$_2$]$^{3+}$. *Method 1*: A solution of dema·3HCl(5.0 g, 22 mmol) in water (20 cm^3) was neutralized with an aqueous solution (10 cm^3) of NaOH (2.4 g, 60 mmol) or Na_2CO_3(3.2 g, 30 mmol). The solution was added to a solution of $CoCl_2$·6H_2O (2.38 g, 10 mmol) in water (30 cm^3), and then mixed with active charcoal (0.5 g). The mixture was aerated for 12—120 h at room temperature.

Method 2: To a solution of $CoCl_2$·6H_2O (0.24 g, 1 mmol) in 50 cm^3 of water were added a solution of Na_3PO_4·12H_2O (1.9 g, 5 mmol) and dema·3HCl (0.46 g, 2 mmol) in water (10 cm^3), and active charcoal (0.2 g). The cobalt ions were oxidized by bubbling a stream of air through the solution at room temperature for 22 h. The addition of phosphate is known to change the distribution of isomers in the complex formation of [Co(dien)$_2$]$^{3+}$.[7]

Method 3: To a dimethyl sulfoxide (DMSO) solution (20 cm^3) containing $Co(NO_3)_2$·6H_2O(0.29 g, 1 mmol) and dema·3HCl(0.23 g, 1 mmol) were added a solution of dema(0.29 g, 2.5 mmol) in DMSO (10 cm^3), and active charcoal (0.2 g). The oxidation of cobalt ions was carried out under the same conditions as that for Method 2.

Method 4: A solution of dema·3HCl (0.91 g, 4 mmol) in 10 cm^3 of water was neutralized with Na_2CO_3 (0.64 g, 6 mmol). To this solution were added a solution of [$Co(H_2O)$-$(NH_3)_5$]$(ClO_4)_3$(0.46 g, 1 mmol) in water (20 cm^3), and active charcoal (0.2 g). The mixture was heated at 70—80 °C for 2 h.

Method 5: To a solution of [$Co(H_2O)(NH_3)_5$]$(ClO_4)_3$(0.92 g, 2 mmol) in 20 cm^3 of DMSO was added a DMSO solution (10 cm^3) of dema (0.8 g, 7 mmol). The solution was heated at 85 °C for 15 min.

Method 6: To a solution of dema·3HCl (0.68 g, 3 mmol) and sodium methoxide (0.41 g, 7.5 mmol) in methanol (12 cm^3) was added a solution of *trans*-[$CoCl_2(py)_4$]Cl·6H_2O[8] (0.59 g, 1 mmol) in methanol (8 cm^3). The reaction took place immediately to give orange precipitate.

Method 8: This method was the same as Method 7 except that pyridine was used as the solvent instead of methanol.

Method 9: To an ice-cold, stirred solution of $K_3[Co(CO_3)_3]$[9] (2.1 mmol) in water (5 cm^3) was added dropwise a solution of dema·3HCl (1.0 g, 4.4 mmol) in water (5 cm^3). The mixture was heated at 70—80 °C for 6 h until the color of the solution became red. The solution was mixted with acetic acid (50%, 15 cm^3) and heated further 2 h.

Method 10: To a solution of dema (2 g, 17 mmol) in 10 cm^3 of DMF was added [$CoCl_2(H_2O)$(dema)]Cl·0.5H_2O (0.8 g, 2.7 mmol). The mixture was heated at 50 °C for 2 h.

Method 11: This method was the same as Method 1 except that the aeration was carried out at 80 °C for 7 h.

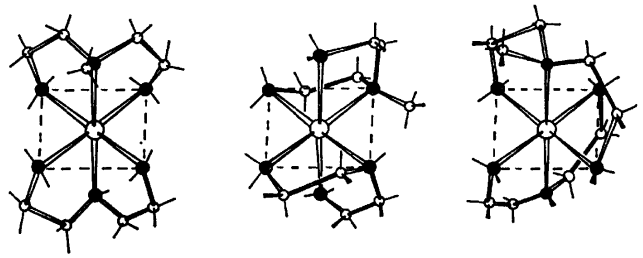
The reaction mixtures were filtered to remove the charcoal if necessary, diluted with water, and then the pH of the solutions were adjusted to 4—6 with HCl. A small amount of each solution was applied to SP-Sephadex column (ϕ2.7 ×120 cm) chromatography. The eluents used were 0.2 M sodium sulfate, 0.2 M sodium $(+)_{589}$-tartrate, or 0.15 M sodium $(+)_{589}$-tartratoantimonate(III) solutions. All the preparative methods except for Method 11 gave only one isomer, *s-fac*-[Co(dema)$_2$]$^{3+}$. No indication for the formation of other isomers was found. The complex was isolated as perchlorate salt by a method similar to that for *mer*-[Co(dien)-(dema)]$(ClO_4)_3$·2H_2O. Found: C, 20.04; H, 5.00; N, 14.12%. Calcd for $CoC_{10}H_{31}N_6O_{12.5}Cl_3$=*s-fac*-[Co(dema)$_2$]$(ClO_4)_3$·0.5 H_2O: C, 20.00; H, 5.20; N, 13.99%. The solution obtained from Method 11 was chromatographed in a manner similar to those for Method 1—10. By elution with a 0.2 M Na_2SO_4 solution, the column gave four yellow-orange bands. The first small band was *s-fac*-[Co(dien)(dema)]$^{3+}$ which may be a demethylated product of *s-fac*-[Co(dema)$_2$]$^{3+}$, and the second main band was *s-fac*-[Co(dema)$_2$]$^{3+}$. Complexes obtained from the third and the fourth bands gave analytical results which do not correspond to the dien or dema complexes, and were not characterized.

Measurements. Absorption and diffuse reflectance spectra were recorded on a Hitachi 323 spectrophotometer, and circular dichroism spectra on a JASCO model J-20 spectropolarimeter. PMR spectra were recorded on a JEOL PMX-60 spectrometer at 60 MHz in DMSO-d_6 with TMS as the internal reference.

Results and Discussion

Preparation and Characterization of the Isomers. (i) [*Co(NO$_2$)$_3$(dema)*], [*CoCl$_2$(H$_2$O)(dema)*]$^+$, *and* [*CoCl$_3$-(dema)*]: The [$Co(NO_2)_3$(dien)] complex has been determined to be *mer* configuration by X-ray analysis.[10] By heating this complex with concd hydrochloric acid,

brown crystals of $[CoCl_3(dien)]$ are obtained.[7] It gives only *mer* isomer of $[Co(dien)(dema)]^{3+}$ by reacting with dema in DMF. On the other hand, the reaction of $[Co(NO_2)_3(dema)]$ with concd hydrochloric acid yields blue crystals of $[CoCl_2(H_2O)(dema)]Cl\cdot 0.5H_2O$, which turn green $[CoCl_3(dema)]$ by heating at 110 °C for 1 h *in vacuo*. These chlorodema complexes give only *s-fac*-$[Co(dema)_2]^{3+}$ by the reaction with dema. These results and the diffuse reflectance spectra of the tri-chloro complexes (*vide post*) indicate that the dien and the dema ligands in the present nitro and chloro complexes have *mer* and *fac* configurations, respectively. Two geometric isomers are possible for *fac*-$[CoCl_2(H_2O)(dema)]^+$. However, the structure of the present blue complex could not be assigned by PMR and absorption spectroscopy.



(a) *s-fac* (b) *u-fac* (c) *mer*

Fig. 1. Three geometric isomers of $[Co(dien)(dema)]^{3+}$.

(ii) $[Co(dien)(dema)]^{3+}$: As Fig. 1 shows, the *s-fac* isomer is achiral, while both the *u-fac* and the *mer* isomers are chiral and exist each in a pair of enantiomers. The *mer* isomer is expected to be optically stable only in acidic solution as has been observed for *mer*-$[Co(dien)_2]^{3+}$.[1,2] The isomer A can be assigned to the *s-fac* isomer, since it is not resolved, while the other two isomers (the isomers B and C) are completely resolved. The resolved isomer C loses rapidly its optical activity in alkaline solution, but the isomer B is optically stable under the same condition. Thus the isomers B and C are assigned to the *u-fac* and the *mer* isomers, respectively. As described in Experimental part, only the *s-fac* isomer of $[Co(dien)(dema)]^{3+}$ was isolated from the product obtained by the reaction in the presence of active charcoal, although the product contained three isomers of $[Co(dien)_2]^{3+}$ and *s-fac*-$[Co(dema)_2]^{3+}$. Strain energy minimization calculation reveals that the *u-fac* and the *mer* isomers are less stable than the *s-fac* isomer by 22.1 and 6.1 $kJ\cdot mol^{-1}$, respectively (*vide post*).

The *u-fac* isomer was obtained by the reaction of *fac*-$[CoCl_2(H_2O)(dema)]Cl\cdot 0.5H_2O$ with dien in water without the addition of active charcoal. The *mer* isomer was prepared similarly from *mer*-$[CoCl_3(dien)]$ and dema in DMF, as stated previously. The triamine ligands in the starting complexes seem to retain the arrangement in these substitution reactions.

(iii) $[Co(dema)_2]^{3+}$: All the preparative methods give a single geometric isomer as evidenced by column chromatography. The PMR spectrum of $[Co(dema)_2](ClO_4)_3\cdot 0.5H_2O$ in DMSO-d_6 exhibits only one kind of the NH_2 group, (δ=5.1 ppm). In the *s-fac* isomer, the NH_2 groups should be equivalent, while the other two isomers have two nonequivalent sets of NH_2 groups (Fig. 1). Thus, the complex can be assigned to the *s-fac* isomer. Conformational analysis also indicates that the *s-fac* isomer is the most stable (*vide post*).

Very recently, Searle and Larsen[11] reported the PMR data for the *u-fac* isomer, but did not describe the preparative method.

Absorption and Circular Dichroism Spectra. Figure 2 and Table 1 compare the absorption spectra of the *s-fac* isomers of $[Co(dema)_2]^{3+}$, $[Co(dien)(dema)]^{3+}$, and $[Co(dien)_2]^{3+}$. All of the absorption bands shift to longer wavelengths as the number of the dema ligand increases. A similar shift is observed for a series of complexes of the type $[Co(en)_x(N\text{-meen})_{3-x}]^{3+}$ (x= 0—3, N-meen=N-methylethylenediamine).[12] The differences in the absorption maxima of the first absorption bands amount to 480 cm^{-1} between $[Co(dien)_2]^{3+}$ and $[Co(dien)(dema)]^{3+}$ and 490 cm^{-1} between $[Co(dien)(dema)]^{3+}$ and $[Co(dema)_2]^{3+}$. Therefore, it is concluded that dema is located at a lower position than dien in the spectrochemical series. Both *s-fac*-[Co-

(dien)(dema)]$^{3+}$ and *s-fac*-[Co(dema)$_2$]$^{3+}$ exhibit shoulders at a longer wavelength side of the charge transfer bands. These shoulders may correspond to the charge transfer transitions from the tertiary nitrogen atom of the dema ligand to the central cobalt ion. The absorption bands of the *u-fac* and the *mer* isomers of [Co(dien)(dema)]$^{3+}$ are also at a longer wavelength side than those of the corresponding isomers of [Co(dien)$_2$]$^{3+}$

(Figs. 3 and 4, and Table 1). The first absorption bands of the isomers of $[Co(dien)(dema)]^{3+}$ shift to longer wavelengths in the order of *s-fac*, *mer*, and *u-fac* isomers, the same order being observed in the isomers of $[Co(dien)_2]^{3+}$.[1]

Figure 5 shows the absorption spectra of *mer*-$[Co(NO_2)_3(dien)]$ and $[Co(NO_2)_3(dema)]$ which was assigned to the *fac* configuration as stated previously. The former has a pair of nitrite ions in the *trans* positions. It is known that the so-called nitro specific band ($\approx$30000 cm^{-1}) of a *trans*-dinitrocobalt(III) complex is located at a longer wavelength than that of the corresponding *cis* complex. However, the present nitro complexes give their nitro specific bands at nearly the same position.

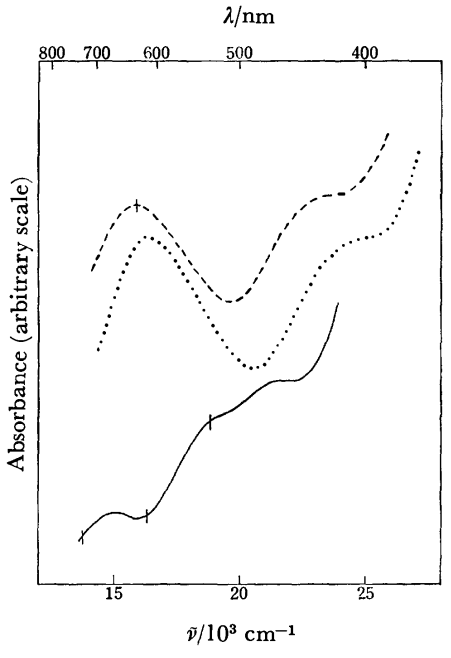

Fig. 6. Diffuse reflectance spectra of *mer*-$[CoCl_3(dien)]$ (——), *fac*-$[CoCl_3(dema)]$(——), and *fac*-$[CoCl_2(H_2O)(dema)]Cl\cdot 0.5H_2O$ (……). Short vertical lines show the calculated band positions.

Figure 6 compares the diffuse reflectance spectra of $[CoCl_3(dien)]$ and $[CoCl_3(dema)]$, which have been assigned previously to the *mer* and the *fac* configurations, respectively. These tri-chloro complexes are hardly soluble in common organic solvents and aquate rapidly in water. From Yamatera's theory,[13] the first absorption band of *mer*-$[CoCl_3(dien)]$ is expected to split into three components, and their positions can also be predicted. Since the first absorption maximum (21.5×10^3 cm^{-1}) of *mer*-$[Co(dien)_2]^{3+}$ is at nearly the same position as that of $[Co(en)_3]^{3+}$ (21.4×10^3 cm^{-1}), the values of parameters, δ(N) and δ(Cl) for *mer*-$[CoCl_3(dien)]$ may be approximated to those obtained from $[Co(en)_3]^{3+}$ and *trans*-$[CoCl_2(en)_2]^{+}$[14] (21.6, 16.2×10^3 cm^{-1}). The predicted positions of the three components of *mer*-$[CoCl_3(dien)]$ are 18.85, 16.3, and 13.75×10^3 cm^{-1}. On the other hand, no splitting is expected for the first absorption band of *fac*-$[CoCl_3(dema)]$. The first absorption band of *s-fac*-$[Co(dema)_2]^{3+}$ (20.8×10^3 cm^{-1}) is at nearly the same position as that of $[Co(NH_3)_6]^{3+}$ (21.0×10^3 cm^{-1}). Thus, the first absorption band of *fac*-$[CoCl_3(dema)]$ is similarly predicted at *ca.* 15.9×10^3 cm^{-1} with reference to the maximum positions of *trans*-$[CoCl_2(NH_3)_4]^{+}$[15] (21.0 and 15.9×10^3 cm^{-1}). The predicted values for both the tri-chloro complexes satisfy the observed spectra as marked on the curves in Fig. 6. These results will support the previous assignment for the structures of *mer*-$[CoCl_3(dien)]$ and *fac*-$[CoCl_3(dema)]$. The first absorption band of *fac*-$[CoCl_2(H_2O)(dema)]Cl\cdot 0.5H_2O$ is at a shorter wavelength (610 nm) than that of *fac*-$[CoCl_3(dema)]$ (630 nm) in accordance with the order of the spectrochemical series of H_2O and Cl^-, indicating that the water molecule coordinates to the cobalt ion.

In Fig. 3 the absorption and CD spectra of $(+)_{589}$-*u-fac*-$[Co(dien)(dema)]^{3+}$ are shown. It exhibits a CD spectrum similar to that of Λ-$(+)_{589}$-*u-fac*-$[Co(dien)_2]^{3+}$[3] over the entire region. The effect of sulfate ions on the CD spectrum of $(+)_{589}$-*u-fac*-$[Co(dien)(dema)]^{3+}$ is also similar to that of the corresponding bis-dien complex. Thus, the absolute configuration of $(+)_{589}$-*u-fac*-$[Co(dien)(dema)]^{3+}$ can be assingned to Λ.

As Fig. 1 shows, *mer*-$[Co(dien)(dema)]^{3+}$ has an equal number of Δ and Λ ring-pairs, and of δ and λ conformers. Hence, the chiral contributions from the configurational and the conformational effects may be canceled out as in the case of *mer*-$[Co(dien)_2]^{3+}$. The chirality in the *mer*-$[Co(dien)(dema)]^{3+}$ isomer should come from the stereochemical relationship between the N–H bond of the secondary nitrogen atom in the dien ligand and the N-CH_3 bond in the dema ligand. The CD spectrum of $(-)_{490}$-*mer*-$[Co(dien)(dema)]^{3+}$ is shown in Fig. 4. The pattern and magnitude of the CD spectrum of this isomer, and the changes in the CD band area on the addition of sulfate are all similar to those of $(+)_{589}$-*mer*-$[Co(dien)_2]^{3+}$. Therefore, it can be concluded that these two isomers have the same absolute configuration. However, the relationship between the CD sign and the absolute configuration for complexes of this type still remains unknown.

The active *mer*-$[Co(dien)(dema)]^{3+}$ isomer is optically stable over one year in acidic water (*ca.* pH 2) at room temperature (*ca.* 25 °C), but racemizes immediately on raising the pH to 12 by adding a NaOH solution.

Conformational Analysis. The strain energies of the isomers of $[Co(dien)(dema)]^{3+}$ and $[Co(dema)_2]^{3+}$ were calculated by the previously reported method,[16] the force field in which includes the contributions from bond stretching, nonbonded interactions, angle bending, and tortional potentials. The initial molecular structures of the isomers were the same as those of the final results obtained previously for the corresponding $[Co(dien)_2]^{3+}$ isomers,[16] except that the N–C(H_3) bond of 1.5 Å was taken for the dema ligand instead of the N–H (secondary amine) bond of dien. When the dema ligand coordinates to the Co(III) ion, the Co–N(CH_3) (tertiary amine) distance lengthens (1.99—2.02 Å) compared with the Co–N(H) (secondary amine) distance (1.94—1.97 Å), and the $\angle$CoNC (of the methyl group) angle becomes much larger (117—120°) than the normal tetrahedral angle. Similar results are also obtained for the

TABLE 2. FINAL ENERGY TERMS FOR THE ISOMERS OF $[Co(dien)(dema)]^{3+}$ AND $[Co(dema)_2]^{3+}$

Isomer	Bond	Nonbond	Angle	Torsion	Total
$[Co(dien)(dema)]^{3+}$					
s-fac	6.42	34.10	16.28	31.17	89.58 kJ·mol^{-1}
u-fac[a]	8.74	41.29	20.22	41.39	111.64
mer	7.62	35.64	25.77	26.63	95.65
$[Co(dema)_2]^{3+}$					
s-fac	11.16	47.08	23.91	31.37	113.53
u-fac[a]	14.06	51.86	36.90	32.55	134.38
mer	11.97	53.09	27.71	30.79	123.56

a) This isomer corresponds to the *u-fac*-1 isomer in the preceding paper.[16] The *u-fac*-2 isomer has the more strained structure.

N-methylethylenediamine[17] and sarcosinato[18] complexes of Co(III). Table 2 shows the minimized energy terms of all the isomers of $[Co(dien)(dema)]^{3+}$ and $[Co(dema)_2]^{3+}$. In contrast to the case of $[Co(dien)_2]^{3+}$, of which the energies of the isomers are calculated to be *mer*≲*s-fac*≲*u-fac*,[16] both the dema complexes have the lowest and the highest energies in the *s-fac* and the *u-fac* isomers, respectively. As stated in Experimental part, the reaction of $CoCl_2 \cdot 6H_2O$ with a mixture of dien and dema (1 : 1) in the presence of active charcoal produced only the *s-fac* isomers of $[Co(dien)(dema)]^{3+}$ and $[Co(dema)_2]^{3+}$, together with the three isomers of the bis-dien complex. The other isomers of $[Co(dien)(dema)]^{3+}$ were not detected in SP-Sephadex column chromatography, although the energy difference between the *s-fac* and the *mer* isomers was calculated to be 6.1 kJ·mol^{-1}. The *u-fac* and the *mer* isomers of $[Co(dien)(dema)]^{3+}$ were prepared from *fac*-$[CoCl_2(H_2O)(dema)]^+$ and *mer*-$[CoCl_3(dien)]$, respectively in the absence of active charcoal. All the preparative methods for $[Co(dema)_2]^{3+}$ gave always only the *s-fac* isomer. If the calculated energy differences among the isomers of this complex were correct, the formation of other isomers than the *s-fac* would almost be zero. Thus, the experimental results agree with those obtained by the energy minimization calculation; each complex of $[Co(dien)(dema)]^{3+}$ and $[Co(dema)_2]^{3+}$ is the most stable in the *s-fac* isomer.

The Crystal and Molecular Structure of the Aquabis(cyclo-L-histidyl-L-histidylato)dicopper(II) Perchlorate Hydrate $[H_2O\ Cu_2(C_{12}H_{13}N_6O_2)_2](ClO_4)_2 \cdot 3.5H_2O$

Yoshitane KOJIMA, Ken HIROTSU, and Keiji MATSUMOTO

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received May 28, 1977)

The crystal structure of the title compound has been determined by a three-dimensional X-ray structure analysis, using 4563 counter intensity data. The crystals are monoclinic, with $a=22.97(2)$, $b=15.89(1)$, $c=10.00(1)$ Å, $\beta=100.1(1)°$, space group $P2_1$, and $Z=4$. The structure was solved by the Patterson and Fourier technique and was refined by the block-diagonal least-squares method to $R=0.061$. The unit cell contains two crystallographically independent complex cations, the structure of which are very similar to each other. The complex cation is dimeric; there are two Cu atoms, and each of the two cyclo-L-histidyl-L-histidylato ligands bridges two metal atoms. Except for the aqua ligand, the main body of the complex has an approximate twofold axis which passes through the two metal atoms and relates the ligands to each other. The two Cu atoms have different coordination geometries. One Cu atom has a flattened tetrahedral coordination by 4N atoms, whereas the other is surrounded by 2N and 3O atoms and is intermediate between the square pyramid and the trigonal bipyramid.

There has been considerable interest in the structures of the metal chelates of amino acid anhydride as simple model compounds for the biomolecules.[1] Although some infrared and visible spectral studies have been made of these complexes,[2] the stereochemical details of the complexes have not yet been elucidated. Since no X-ray structure has been reported as yet, we wish to report here the preparation and X-ray structure of the title compound. A preliminary communication on the structure of the complex has already been published.[3]

Experimental

Preparation of the Complex. $HISH_2$[$HISH_2$=cyclo(L-histidyl-L-histidyl)] was prepared following the procedure of Abderhalden *et al.*[4] A suspension of equimolar amounts of $HISH_2$(0.585g, 2 mmol) and copper(II) perchlorate hexahydrate (0.741 g, 2 mmol) in hot methanol was stirred until both substances had been completely dissolved. Lithium hydroxide monohydrate (0.084 g, 2 mmol) was then added, and the resultant solution was allowed to stand for one day at room temperature. The blue crystals were separated out. The square prisms were obtained upon recrystallization from a hot aqueous solution. Yield, 0.393 g (41.2%).

Found: C, 30.26; H, 3.63; N, 17.68%. Calcd for $[H_2O\ Cu_2(C_{12}H_{13}N_6O_2)_2](ClO_4)_2 \cdot 3.5H_2O$: C, 30.23; H, 3.70; N, 17.63%.

X-Ray Data Collection. The specimen employed for data collection had dimensions of $0.22 \times 0.25 \times 0.28$mm. Preliminary X-ray photographic studies, using oscillation, Weissenberg, and precession techniques, revealed the approximate unit-cell dimensions, the Laue symmetry of $2/m$, and the systematic absences of $0k0$ for $k=2n+1$. These extinctions indicate that the space group is $P2_1$, since the compound is optically active.

Crystal Data: $Cu_2(C_{12}H_{13}N_6O_2)_2(ClO_4)_2(H_2O)_{4.5}$, $a=22.97(2)$, $b=15.89(1)$, $c=10.00(1)$Å, $\beta=100.1(1)°$, $U=3596.3$Å^3, $Z=4$, $D_x=1.76$, $D_m=1.74$ g cm^{-3}, space group $P2_1$, λ(Mo$K\alpha$)$=0.7107$Å, μ(Mo$K\alpha$)$=78.0$ cm^{-1}.

The cell dimensions were determined by the least-squares treatment using 48 θ values measured accurately on a Philips PW1100 diffractometer. Intensity data with $3° \leqq 2\theta \leqq 50°$ were collected at room temperature by the use of graphite-monochromated Mo$K\alpha$ radiation. The ω-2θ scan technique was employed. The scan range was $(0.9+0.3\tan\theta)°$, and the scan speed, 2°/min; the background was counted for 15 s at each end of the scan. The three standard reflections, 080, 900, and 004, measured every 150 min, showed no appreciable decay. A total of 4563 intensities with $I_{top} - 2\sqrt{I_{top}} > I_{back}$ were classified as observed, where I_{top} is the intensity (count/s) measured at the top of the peak and I_{back} is the mean background intensity (count/s), obtained from the preliminary background measurements for 5 s on each side of the peak. The Lorentz-poralization corrections were made, and relative structure factors were derived.[5] No absorption correction was applied.

Structure Determination and Refinement. The four copper stoms were located from a three-dimensional Patterson map, and the positions of the remaining non-hydrogen atoms were determined by successive Fourier syntheses. The structure was initially refined by the isotropic block-diagonal least-squares method. In the course of refinement, it was found that the 15O atoms of perchlorate ions and all the water molecules of crystallization were somewhat disordered. Therefore, isotropic temperature factors were assigned to them throughout the refinement. Six cycles of the anisotropic least-squares refinement resulted in convergence at $R=0.061$. No parameter was observed to shift by $>0.1\,\sigma$. The function minimized was $\sum w(F_o - |F_c|)^2$, with $w=1/\sigma(F_o)^2$ being used. The scattering factors for the neutral Cu, Cl, O, N, and C atoms were taken from Ref. 6. No attempt was made to locate the hydrogen atoms. The absolute crystal structure was determined on the basis of the known configuration of the cyclo-L-histidyl-L-histidilato ligand. The final atomic coordinates which give the absolute crystal structure are presented in Table 1, along with their temperature factors. The observed and calculated structure factors have been deposited at the Chemical Society of Japan (Document No. 7721). All the calculations were performed on a FACOM 270-30 computer at Osaka City University. The programs used included a local version of the UNICS.[7]

Results and Discussion

The structural formula of cyclo-L-histidyl-L-histidyl ($HISH_2$) is shown in Fig. 1. The middle 2,5-piperadinedione moiety ($DKPH_2$) takes a planar structure. Since the C(5) and C(7) atoms have an S absolute configuration, both the C(4) and C(9) atoms lie on one side of the ring plane of the $DKPH_2$. The $HISH_2$ molecule

TABLE 1. FRACTIONAL POSITIONAL PARAMETERS ($\times 10^4$) AND ANISOTROPIC TEMPERATURE FACTORS ($\times 10^4$), WITH e.s.d.'s IN PARENTHESES

The temperature factors are of the form: $\exp[-(h^2B_{11}+k^2B_{22}+l^2B_{33}+hkB_{12}+hlB_{13}+klB_{23})]$.

a) Isotropic temperature factors ($\times 10^2$) with e.s.d.'s in parentheses.

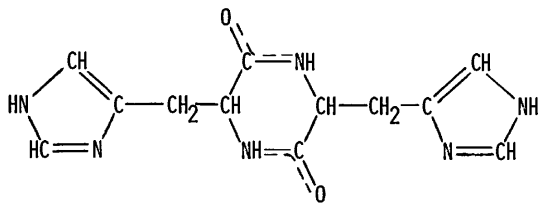

Fig. 1. The schematic drawing of cyclo(L-histidyl-L-histidyl)

has four donor atoms: two N atoms of the respective imidazole groups (Im) and two O atoms in the $DKPH_2$. In the cyclo-L-histidyl-L-histidylato ligand ($HISH^-$) of the present complex, one of the NH groups in the $DKPH_2$ is deprotonated; the resulting "anionic" N atom also coordinates to the Cu atom.

There are two crystallographically independent complex cations in the unit cell; a stereoscopic view of them is given in Fig. 2, where the atom numbering

scheme is also given. Both of the complex cations can be represented by the same formula, $[Cu(HISH)_2Cu(H_2O)]^{2+}$. The four $HISH^-$ ligands in the two complex cations are crystallographically independent of each other. The atom-numbering scheme for the $HISH^-$ is shown in Fig. 2; the same numbering was used for these four ligands, but primes are utilized in order to distinguish between these ligands. The bond lengths and angles are listed in Tables 2 and 3 respectively.

The two complexes have a close resemblance in

structure, but the values of a number of bond angles in one complex are somewhat different from those of the corresponding ones in the other. Furthermore, some of the corresponding bonds show a slight but, in view of a statistical significant test, significant differences in length. However, the "significant differences" may be ascribed to the underestimation of standard deviation. On the other hand, the bond angle will vary with the packing. Therefore, the two complex cations should be considered to be chemically identical. Since the difference between the equivalent structural parameters including the equivalent bond angles is small, we will use the mean values of the respective parameters in the following description, unless we state otherwise, and make use of one of the two complex cations for illustration.

Figures 3(a) and (b) show the elevation perpendicular to a plane through Cu(A), Cu(B), N(1), and N′(1), and the projection along the Cu(A)···Cu(B) axis, respectively. The complex cation is dimeric, with two Cu atoms of different coordination modes. In case the ligating water molecule [O(3W)] is excluded from the complex, the remaining part has a pseudo twofold axis which passes through the two Cu atoms. The structural parameters related by this axis are almost identical except for the Cu(A)–O(1) and Cu(A)–O′(1) bond lengths. The average bond lengths are shown in Fig. 4.

The Cu(B) atom has a flattened tetrahedral coordination by the N(5) atom of the Im group and the anionic N(4) atom of the $DKPH^-$ moiety of one ligand, and the chemically equivalent N′(5) and N′(4) atoms of the other [Cu–N=1.97 Å]. The average value of the chelate bite angles at the Cu(B) is 91.7°. The dihedral angle between the N(4), Cu(B), and N(5) plane and the N′(4), Cu(B), N′(5) plane is 50.0°, which is comparable to the value (53.6°) in bis(*N*-*t*-butylsalicylideneaminato)copper(II).[8] The tetrahedral coordination of bivalent copper is rather unusual. The dimerization

and strong affinity of Cu(II) for N atoms may be responsible for such a coordination in the present complex.

The coordination geometry of Cu(A) atom seems to be intermediate between the square pyramid and the trigonal bipyramid (Fig. 3). From the square-pyramidal viewpoint, the apical position is occupied by the O(1) atom, whereas the basal plane is defined by the O(3W) (oxygen of ligating water molecule), N(1), O'(1), and N'(1) atoms. The disposition of the four basal atoms is not planar, the maximum deviation of the atom from the plane being 0.38 Å. The Cu–O(1) apical bond is longer than the four basal bonds ($Cu–O(1)_{apex}=2.21$, $Cu–O_{base}=2.04$, $Cu–N_{base}=1.97$ Å). The N(1)–Cu(A)–N'(1) angle is close to 180°, which is suggestive of the trigonal-bipyramidal coordination. In the trigonal bipyramidal approximation, the N(1) and N'(1) atoms occupy the axial positions. The Cu(A) atom is displaced 0.13 Å toward N'(1) from the equatorial

where X, Y, and Z are coordinates in Å units relative to the a, b, and c^* axes respectively.

plane defined by the O(1), O′(1), and O(3W) atoms. One of the equatorial bonds is longer than the other two, and the O–Cu–O angles in the equatorial plane are 103.6, 106.5, and 149.7°. The Cu(B) atom is distant from O(1) and O′(1) by 2.81(1) and 2.80(1) Å respectively, and the interatomic distance, Cu(A)··· Cu(B), is 3.570(3) Å.

All the $HISH^-$ ligands assume a similar, asymmetric conformation; the C(4)–Im and C(9)–Im fragments are rotated respectively about the C(4)–C(5) and C(7)–C(9) bonds in such a way that the donor atoms in the Im groups are favorably located for coordination to the Cu(A) and Cu(B) atoms. The average bond lengths in the $HISH^-$ ligand are also shown in Fig. 4. Each Im group is planar within 0.02 Å, and the bond lengths and angles are in agreement with the corresponding ones in the bis(histidino)-nickel(II) and -cobalt(II).[9] The leastsquares planes of various parts of the complex and the dihedral angles between them are listed in Table 4. The $DKPH^-$ ring is nearly planar, and the torsional angles in the ring (IUPAC-IUB conventions)[10] are presented in Table 5. In the two C=O bonds, the one whose O atom participates in the coordination is longer than the other. In the peptide-bondings, N(4)–C(6)–O(1) and N(3)–C(8)–O(2), a short N–C bond length indicated the delocalization of π electrons over this bonding.

The $DKPH_2$ can be regarded as a kind of secondary

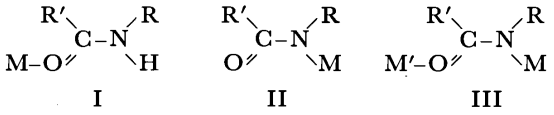
a) The conventions of the IUPAC-IVB Commission are followed.[b] b) See also Ref. 10.



I II III

amide group which is capable of ligating in three ways:[11] I is most usual, whereas II and III are uncommon and deprotonation is necessary prior to complex formation. The coordination mode of the "amide group" in the present DKPH$^-$ group can be classified as III. In μ-formamide-bis[pentaamminecobalt(III)] pentachloride monohydrate, which is known as the sole example of III, the M′–O bond is nearly coplanar with the plane of the amide group, the M′–O–C bond angle being 126°.[12] However, in the present complex the Cu(A)–O′(1) bond is not coplanar with the [N′(4), C′(6), O′(1)] "amide plane," but makes an angle of 59.3° with this plane. Similarly, the Cu(A)–O(1) bond intersects the [N(4), C(6), O(1)] "amide plane" in an angles of 61.7°.

a) Numerals refer to the following equivalent positions: 1 (x,y,z), 2 $(x,y,-1+z)$, 3 $(-1+x,y,-1+z)$, 4 $(1-x,-1/2+y,1-z)$, 5 $(1-x,-1/2+y,2-z)$, 6 $(2-x,-1/2+y,2-z)$.

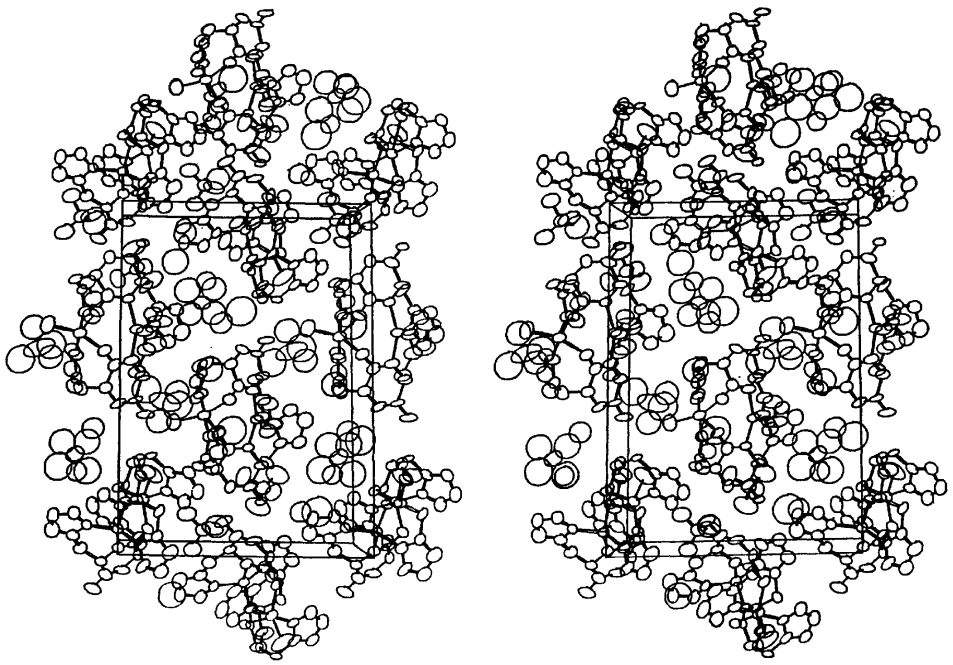

Fig. 5. Stereoview of crystal structure of aquabis(cyclo-L-histidyl-L-histidylato)dicopper(II) perchlorate hydrate along the c axis.

Both of the 6-membered chelate rings, B[N(4), Cu(B), N(5), C(10), C(9), C(7)] and B'[N'(4), Cu(B), N'(5), C'(10), C'(9), C'(7)], which are related mutually by the pseudo twofold axis, assume an envelope form; the five atoms in each chelate ring are planar within 0.13 Å, whereas C(7) in B and C'(7) in B' deviate by 0.65 and 0.66 Å from the respective least-squares planes defined by the five atoms. The 7-membered ring A[Cu(A), O(1), C(6), C(5), C(3), C(4), N(1)] and the A' related with A by the pseudo twofold axis have a boat form. Although the 7-membered ring has been thought generally to be unstable compared with 5- and 6- membered ones, and although, moreover, the ligating ability of the oxygen in an amide group toward metal is not strong, the formation of the 7-membered ring in the present complex presumably results from the dimerization and migration of the negative charge to the O atom from the adjacent "anionic" N atom.

Figure 5 shows the stereoview of the crystal structure along the c axis. The data concerning hydrogen bonds are presented in Table 6. The perchlorate anions and uncoordinated water molecules participate in the O–H···O, N–H···O, and O–H···N hydrogen bonds. The N(3) atom in the complex which involves unprimed Cu atoms has short contacts of N(3)···O'(5) (3.03 Å) and N(3)—O''(2)(2.97 Å). These contacts suggest that the H atom linked to N(3) takes part in the bifurcated hydrogen bonding.

A Re-investigation of the Dimer ESR Spectra in Several Quadridentate Schiff Base Complexes of Copper(II)

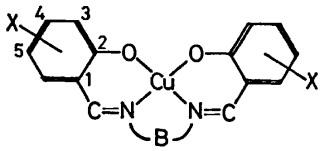
Makoto CHIKIRA and Hiroshi YOKOI

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira, Sendai 980

(Received June 1, 1977)

The angle between the $g_{//}$ axis and the copper-copper axis in most parallel planar dimers of the quadridentate salicylaldehyde Schiff base complexes of copper(II) in toluene or xylene has been reconfirmed to be not $\approx$35°, but $\approx$17°, by a computer simulation of the dimer ESR spectra at both the K and X-bands. In order to remedy the shortcomings of the so-called point-dipole approximation generally used in the simulation, a delocalization model, in which the delocalization of each unpaired electron on the copper atom and its surrounding four ligand atoms is explicitly taken into consideration, has been discussed in some detail. The delocalization effect has been proven to be highly significant in estimating dimeric structures reliably. An application of this model to the structural estimation of several dimers in solutions has also been made.

A number of mono-nuclear planar copper(II) complexes have been found to exist as dimers in crystals[1–4] and in solutions.[5–11] The structures of dimers in solutions have been estimated by the computer simulation of the dimer ESR spectra.[6–11,13–16] We have previously reported that many quadridentate salicylaldehyde Schiff base complexes of copper(II) (hereafter abbreviated as Cu(nX-SalB), Fig. 1) in toluene form dimers with almost coaxial g and fine-structure tensors,[12] together with the fact that the dimeric structures of Cu(SalB) in solution are markedly different from those of Cu(3NO$_2$-SalB).[13]



Cu(nX-SalB)

Fig. 1. Quadridentate salicylaldehyde Schiff base complexes of copper(II).
Abbreviations: Me=$-CH_3$, en=$-CH_2CH_2-$, pn=$-CH(CH_3)CH_2-$, ibn=$-C(CH_3)_2CH_2-$, MeO=$-OCH_3$, tn=$-CH_2CH_2CH_2-$.

Recently, Cookson *et al.* have reported that the angle, ξ, between the $g_{//}$ axis and the copper-copper axis in the dimers of Cu(nX-SalB) (nX=H or 3MeO and B=pn or tn) in frozen xylene is estimated to be 35° by the computer simulation of the X-band ESR spectra, suggesting that these dimers are similar in structure to that of Cu(Salen) in crystals.[2,14] This value, however, is very different from the value (15°) we ourselves previously estimated for similar systems.[12] More reliable information on the mutual orientation of these axes can often be obtained by investigating simultaneously the dimer ESR spectra at different microwave frequencies. In this study, therefore, the dimeric structures for Cu(3Me-Salpn) in toluene, Cu(Salpn) in xylene, and Cu(3NO$_2$-Salibn) in nitroethane were examined by the computer simulation of the K-band ESR spectra as well as the X-band ones.

In most studies so far reported on the computer simulation of dimer ESR spectra, the magnetic dipole interaction has been calculated using the so-called point-dipole approximation.[6,15,16] Actually, however, each unpaired electron in a dimer is delocalized on the copper atom and its surrounding ligand atoms. It has been suggested that there is a tendency for the Cu–Cu distance, r, and the ξ value in the dimer to be over- and under-estimated respectively by the use of the point-dipole approximation.[17,18] A notable example of the delocalization effect has recently been presented for the dimer of bis(dialkyldithiocarbamato)copper(II) (Cu(dtc)$_2$) by Van Rens and De Boer.[19] By calculating the fine-structure tensor of the dimer from the results of extended Hückel molecular orbital calculations, they have indicated that the delocalization reduces the dipolar interaction by a factor of two, and that one of the principal axes of the fine-structure tensor bisects the angle between the $g_{//}$ and Cu–Cu axes.

Although the metal-ligand bondings of Cu(dtc)$_2$ are strongly covalent,[20] the question still comes to our minds whether or not the delocalization effect can be neglected in many other cases. In order to obtain detailed information on errors inherent in the point-dipole approximation, a delocalization model was discussed and checked by applying the model to two dimeric systems of known structures in the title complexes. Using the results, an attempt was made to reestimate the structures of several dimers in solution more reliably.

Experimental

All the quadridentate salicylaldehyde Schiff base complexes of copper(II) used here had been prepared and purified in previous works.[12,13] The Cu(Salen)·$CHCl_3$ was prepared by the recrystallization of Cu(Salen) from chloroform.[21] The sample of Cu(Salen) diluted in the nickel complex was prepared by the recrystallization of a 5:1 mixture of Ni(Salen) and Cu(Salen) from nitrobenzene, and the Ni(Salen) was prepared by the same method. All the solvents used were purified by the usual methods.[22]

The ESR spectra at 77 K were recorded on Hitachi 771 X-band and MES-4001 K-band ESR spectrometers and analyzed by computer simulation. All the calculations in the simulation were carried out at the Computer Center of Tohoku University on a NEAC 2200 computer, using fundamentally the same program as in previous works,[7,13] except that the delocalization of each unpaired electron was taken into consideration, as will be described later. The co-ordinate system for the present dimers is shown in Fig. 2.

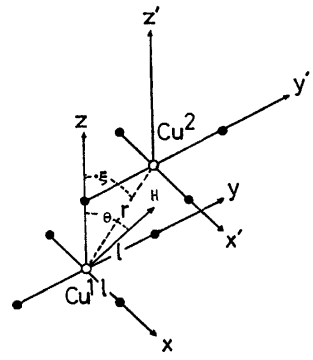


Fig. 2. Co-ordinate system for the dimers.

Results and Discussion

Combined Use of K and X-Band ESR Spectral Simulations. The observed ESR spectra of Cu(3Me-Salpn) in toluene at X and K-bands and of Cu(Salpn) in xylene at K-band are shown in Figs. 3, 4, and 5 respectively, together with the calculated spectra. The $\Delta M=2$ transition probability is inversely proportional to the square of microwave frequency,[15] so that, unfortunately, we have not observed any well-defined $\Delta M=2$ spectra at K-band with our spectrometer because of the low signal-to-noise ratios. The observed X-band and K-band dimer ESR spectra of Cu(3Me-Salpn) in toluene were almost the same as those of Cu(Salpn) in xylene, so their dimeric structures are similar. In this section, only the magnetic and structural parameters estimated by the computer simulation of the dimer ESR spectra using the point-dipole approximation will be discussed.

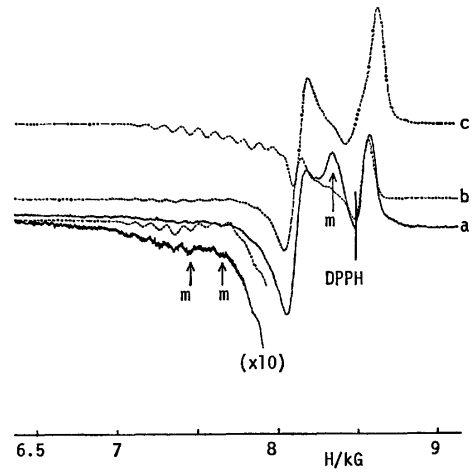

Fig. 5. K-Band ESR spectra of Cu(Salpn): a (solid lines), observed in xylene at 77 K; b and c, computer simulated with the parameters, (b) $g_{//}=2.19$, $g_{\perp}=2.045$, $|A_{//}|=0.0100$ cm^{-1}, $|A_{\perp}|=0.0015$ cm^{-1}, $r=4.05$ Å, $\xi=15°$, $\Delta H=25$ Gauss, and (c) $g_{//}=2.18$, $g_{\perp}=2.03$, $|2A_{//}|=0.0225$ cm^{-1}, $|2A_{\perp}|=0.0010$ cm^{-1}, $r=3.95$ Å, $\xi=35°$, $\Delta H=30$ G m represents absorption line due to monomers.

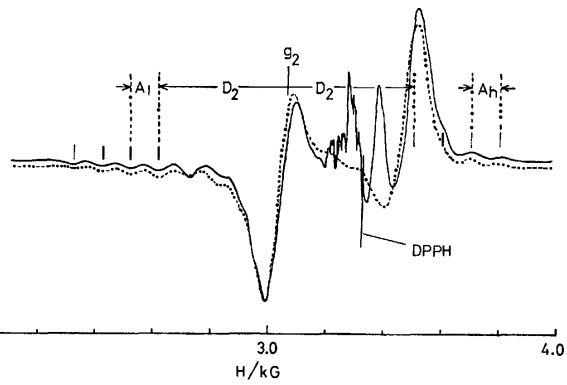

Fig. 3. X-Band ESR spectra of Cu(3Me-Salpn): (——), observed in toluene at 77K; (------), computer simulated with the parameters, $g_{//}=2.19$, $g_{\perp}=2.045$, $|A_{//}|=0.0100$ cm^{-1}, $|A_{\perp}|=0.0015$ cm^{-1}, $r=4.04$ Å, $\xi=15°$, and $\Delta H=25$ G (Gaussian linewidth).

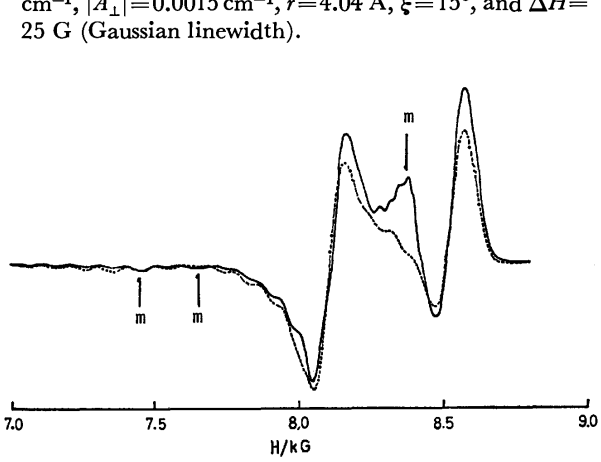

Fig. 4. K-Band ESR spectra of Cu(3M-Salpn): (——), observed in toluene at 77 K; (------), computer simulated with the parameters, $g_{//}=2.19$, $g_{\perp}=2.045$, $|A_{//}|=0.0100$ cm^{-1}, $|A_{\perp}|=0.0015$ cm^{-1}, $r=4.04$ Å, $\xi=15°$, and $\Delta H=30$ G. m represents absorption line due to monomers.

The parameters of (b) and (c) in Fig. 5, which have been estimated from the X-band spectra by us and by Cookson *et al.* respectively for the dimer of Cu(Salpn), are considerably different, especially in ξ. On the basis of the fact that both the A_1 and A_h values and the g_2 value are almost equal to the monomer's $A_{//}/2$ and $g_{//}$ values respectively in many quadridentate Schiff base complexes, we have previously concluded that the $g_{//}$ and Cu–Cu axes in these complexes almost coincide; namely, the ξ value is close to 0°,[6,12,13] where the parameters of A_1, A_h, and g_2 are as defined in Fig. 3. Two calculated $\Delta M=1$ spectra (b and c) of Cu(Salpn) at K-band, which we obtained with their respective sets of parameters, are shown in Fig. 5, together with the observed one. It should be noted that no complicated progression of the hyperfine structure in the 7.5—8 kG range (1 G=10^{-4} T) can be seen in the observed K-band spectra of either Cu(3Me-Salpn) in toluene or of Cu(Salpn) in xylene, but such a progression can be seen in the calculated spectrum of c. The appearance of such a hyperfine structure, therefore, was found to be characteristic of non-coaxial g and fine-structure tensors. In addition, the calculated spectrum of c as a whole is shifted to a little higher magnetic field than the observed one. As one can see in Fig. 5, a much better fit between the calculated and observed spectva at K-band is obtained with the parameters of (b) than with those of (c). We may conclude, therefore, that the ξ value of

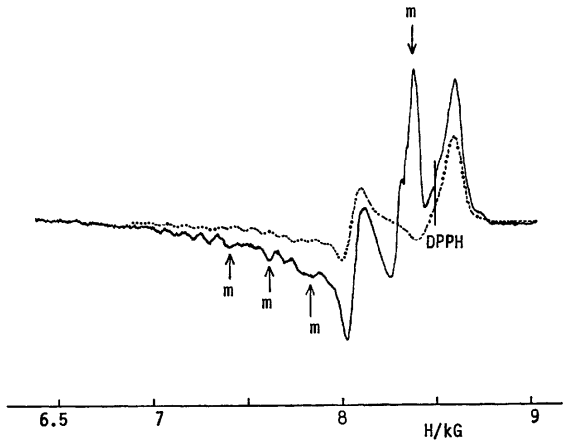

Fig. 6. K-Band ESR spectra of Cu(3NO$_2$-Salibn): (——), observed in nitroethane at 77 K; (------), computer simulated with the parameters, $g_{//}=2.20$, $g_{\perp}=2.045$, $|A_{//}|=0.0100$ cm^{-1}, $|A_{\perp}|=0.0010$ cm^{-1}, $r=3.8$ Å, $\xi=35°$, $\Delta H=30$ G. m represents absorption line due to monomers.

35° is too large for the present dimer, as far as the point-dipole approximation is concerned.

On the other hand, the dimer of Cu(3NO$_2$-Salibn) in nitroethane is a typical dimer with a larger ξ value. The observed and calculated K-band spectra of this dimer are shown in Fig. 6, in which the parameters used in the calculation were the same as those previously chosen for the X-band spectrum ($\xi=35°$).[13] Although the hyperfine structures due to the monomer were also simultaneously observed in the 7—8 kG range, every peak in the range can be well assigned by comparison with the simulated spectrum. Accordingly, we are led to the conclusion that the dimeric structure of Cu(3NO$_2$-Salibn) in nitroethane is remarkably different from those of many other quadridentate salicylaldehyde Schiff base complexes in toluene.

Errors Inherent in the Point-dipole Approximation. In order to obtain information on errors inherent in the point-dipole approximation, we first simulated the ESR spectra for the dimers of a known structure. The observed X-band spectrum of Cu(Salen)·CHCl$_3$ in the powder state at 77 K is shown in Fig. 7. This spectrum is obviously due to typical $\Delta M=1$ transitions in copper(II) pairs, although no hyperfine structure was observed in it. According to Baker *et al.*,[21] the molecules of Cu(Salen) in Cu(Salen)·CHCl$_3$ crystals exist as dimers with $r=3.37$ Å and $\xi=34°$. The best calculated spectrum, which is also shown in Fig. 7, was obtained with the parameters listed there, in which the g and A values were taken from the monomer spectrum of Cu(Salen) in chloroform and in which the ξ value mentioned above was adopted. The difference of 0.28 Å between the true and estimated r values is probably responsible for the point-dipole approximation used.[17,18]

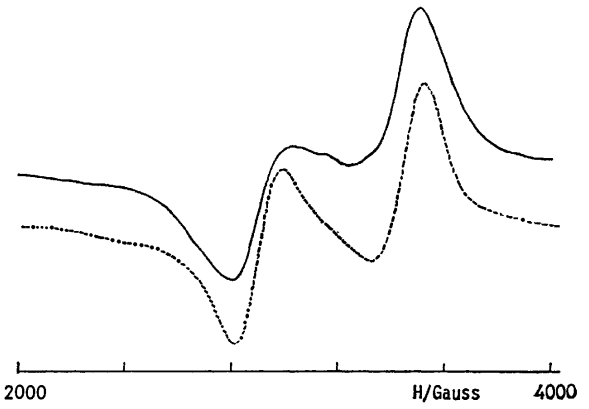

Fig. 7. X-Band powder ESR spectra of Cu(Salen)·CHCl$_3$: (——), observed at 77 K; (------), computer simulated with the parameters, $g_{//}=2.19$, $g_{\perp}=2.04$, $|A_{//}|=0.0100$ cm^{-1}, $|A_{\perp}|=0.0010$ cm^{-1}, $r=3.65$ Å, $\xi=34°$, and $\Delta H=60$ G.

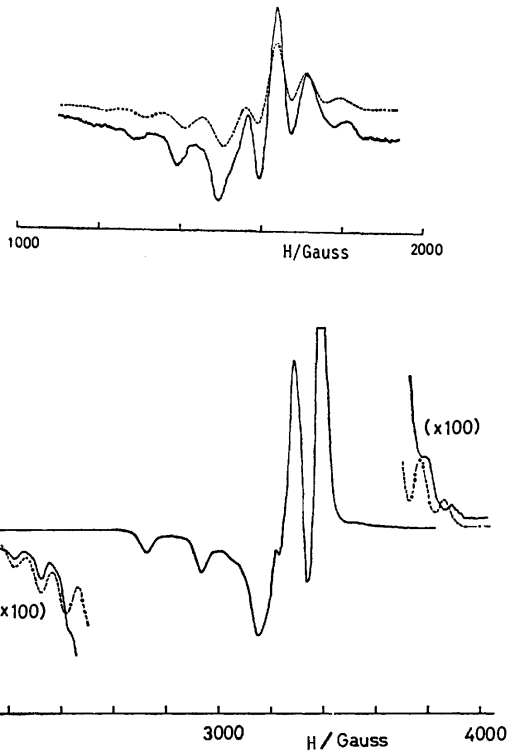

Fig. 8. X-Band powder ESR spectra of Cu(Salen) in Ni(Salen) crystals: (——), observed at 77 K; (------), computer simulated with the parameters, $g_{//}=2.19$, $g_{\perp}=2.04$, $|A_{//}|=0.0100$ cm^{-1}, $|A_{\perp}|=0.0010$ cm^{-1}, $r=3.8$ Å, $\xi=15°$, and $\Delta H=25$ G.

The powder X-band ESR spectra of Cu(Salen) doped in a high concentration in Ni(Salen) crystals are shown in Fig. 8. According to Shkol'nikova *et al.*,[23] the Ni(Salen) molecules in crystals are also present as dimers with $r=3.22$ Å and $\xi=15°$. This ξ value is much closer to those estimated for the dimers of Cu(Salpn) and Cu(3Me-Salpn) in frozen solutions than those for Cu(Salen) in crystals of Cu(Salen) itself ($\xi=40°$) and Cu(Salen)·CHCl$_3$. In the $\Delta M=1$ spectrum shown in Fig. 8, it is noteworthy that the hyperfine splittings at both edges are equal ($\approx$100 G), being the same as one half of the monomer's $|A_{//}|$ value. This fact indicates that the principal axes of the g and fine-structure tensors are almost coincident and, therefore, that the dimeric structure of Cu(Salen) in Ni(Salen) crystals is similar to that of the host nickel complex. The best fit for the $\Delta M=1$ spectrum at both sides and for the $\Delta M=2$

spectrum was obtained with the same g and A values as in Fig. 7 and with $r=3.80$ Å and $\xi=15°$. The difference of 0.58 Å between the true and estimated r values for the dimer of Cu(Salen) in Ni(Salen) crystals is larger than that in Cu(Salen)·$CHCl_3$ crystals. This fact suggests that the error in r inherent in the point-dipole approximation depends upon both r and ξ. Such might also be the case with the error in ξ.

In order to check these errors more systematically, we calculated the fine-structure splittings in the $\Delta M=1$ spectra, assuming that, in each of the monomeric halves in the dimers, the fractions of the unpaired electron on the copper atom and on each of its four coordinating ligand atoms are given by α^2 and $(1-\alpha^2)/4$ respectively, where α^2 is a covalency parameter which has its usual meaning in the metal-ligand bondings.[24,25] As may be seen in Fig. 2, the x′ and y′ axes are parallel to the x and y axes respectively, and the Cu^2 atom is located on the xz plane. It is obvious from a symmetry consideration of the dimer that the maximum principal value axis of the fine-structure tensor is on the xz plane. We calculated the fine-structure splitting D, setting the static magnetic field on the xz plane and changing θ from 0 to 90° at intervals of 1°. The maximum principal value, D_H, and the direction, θ_{max}, of the D tensor were determined graphically from the plots of D against θ.[26]

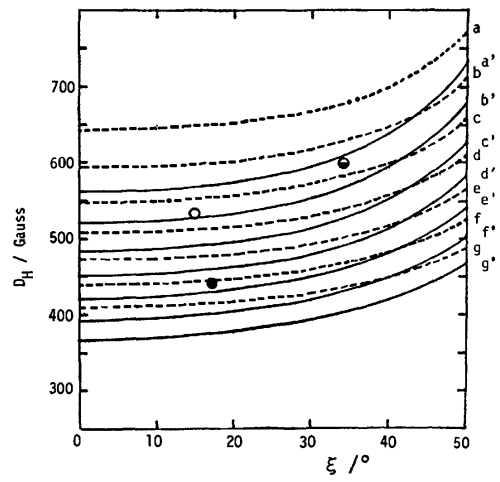

Fig. 9. Dependence of D_H on ξ and r: (——), $\alpha^2=0.65$; (------), $\alpha^2=0.75$.
a and a′, $r=3.2$ Å, b and b′, $r=3.3$ Å; c and c′, $r=3.4$ Å; d and d′, $r=3.5$ Å; e and e′, $r=3.6$ Å; f and f′, $r=3.7$ Å; g and g′, $r=3.8$ Å. D_H was calculated for $g_{//}=2.19$, $g_\perp=2.045$, and microwave frequency=9.23 GHz. ○, Cu(Salen) in Ni(Salen) crystals; ◒, Cu(Salen) in Cu(Salen)·$CHCl_3$ crystals; ●, Cu(3Me-Salpn) in toluene.

Figure 9 shows the dependence of D_H on ξ and r for $\alpha^2=0.65$ and 0.75. This figure clearly indicates that D_H increases with ξ and α^2, and that the increment of D_H *vs.* α^2 decreases with an increase of r. These results are in agreement with the intuitively acceptable fact that the point-dipole approximation becomes a better one as α^2 or r increases. This figure also explains why the error in r inherent in the point-dipole approximation is smaller for the dimer of Cu(Salen) in Cu(Salen)·$CHCl_3$ crystals than for the one in Ni(Salen) crystals.

The open and half-darkened circles shown in Fig. 9 are for the dimers of Cu(Salen) in Ni(Salen) and Cu(Salen)·$CHCl_3$, to which the D_H values estimated and the ξ values taken from the crystal data were assigned, respectively. A closer inspection of these circles with regard to r indicates that the above-mentioned dimers can have their actual r value when $\alpha^2=\approx0.65$ and 0.75 respectively are assumed for them. Both of the α^2 values are smaller than 0.82,[27] which was calculated from the monomer's ESR parameters by the usual method.[25] These small inconsistencies in α^2, however, do not seem significant because all the procedures involved are originally rough. We would like to emphasize here that, in order to get more fruitful results from the dimer ESR spectra, an explicit consideration of the delocalization effect in the simulation is necessary.

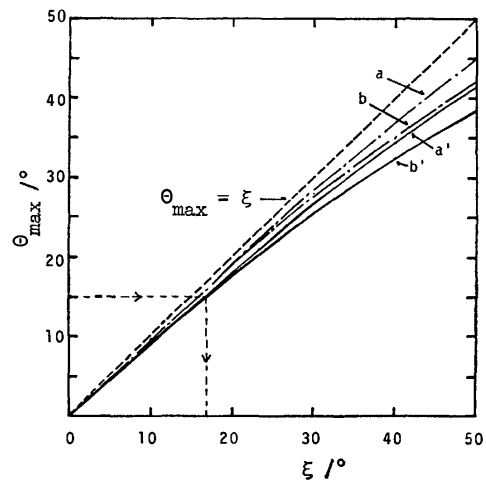

Fig. 10. Dependence of θ_{max} on ξ for $g_{//}=2.19$ and $g_\perp=2.045$.
a, $r=3.8$ Å and $\alpha^2=0.75$; b, $r=3.2$ Å and $\alpha^2=0.75$; a′, $r=3.8$ Å and $\alpha^2=0.65$; b′, $r=3.2$ Å and $\alpha^2=0.65$.

Figure 10 shows the dependence of θ_{max} on ξ, r, and α^2. Apparently, the value of $\Delta\xi=\xi-\theta_{max}$ increases with ξ and decreases with increases in α^2 and r. When each unpaired electron is completely localized on the copper nucleus, θ_{max} is equal to ξ. For a dimer with a considerable delocalization of the unpaired electron, therefore, the ξ value estimated by the use of the point-dipole approximation should approach the θ_{max} value rather than the actual ξ one. As has been described above, the ξ ($\simeq\theta_{max}$) values for the dimers of Cu(Salpn) in xylene and of Cu(3Me-Salpn) in toluene have been estimated to be 15° using the point-dipole approximation. These results suggest that their dimeric structures are similar to that of Cu(Salen) in Ni(Salen) crystals, in which the D_H value has been satisfactorily explained on the assumption of $\alpha^2=0.65$. By applying the case of $\theta_{max}=15°$ and $\alpha^2=0.65$ to Fig. 10, we can estimate $\xi=17°$ for these dimers in solution. Furthermore, by re-plotting their estimated D_H values at $\xi=17°$ as darkened circles in Fig. 9, we can estimate their r values more reliably as ≈3.55 Å. In the same way, $r=\approx3.50$ Å and $\xi=\approx38.5°$ have been estimated for the dimer of Cu(3NO_2-Salibn) in nitroethane. The result of $\xi=17°$ thus re-estimated for the dimers of Cu(Salpn) in xylene

and of Cu(3Me-Salpn) in toluene supports our previous conclusion that these dimers are remarkably different in structure from that of Cu(Salen) in crystals.

The authors are grateful to Professor Masamoto Iwaizumi for his encouragement throughout this work.

26) The approximate determination of D_H begins by plotting the resonance magnetic field for $\Delta M=1$ transitions against θ. Since $2D_H$ is defined as the maximum difference between two resonance fields at the same θ value, θ_{max}, D_H is graphically determined from the plot. D_2 is generally different from D_H, because $2D_2$ is defined as the difference between the maximum and minimum magnetic fields at different θ values (see Ref. 6).
27) The value of 0.82 is likely to decrease slightly if we regard the α^2 value as the metal orbital population in the anti-bonding molecular orbital occupied by an unpaired electron. See R. S. Mulliken, *J. Chem. Phys.*, **23**, 1833 (1955).

Preparation and Spectroscopic Studies of Four Stereoisomers of Tris[(*S*)-1,3-butanediamine]cobalt(III) Complex

Masaaki KOJIMA and Junnosuke FUJITA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received June 3, 1977)

Four stereoisomers, *mer*-Δ, *mer*-Λ, *fac*-Δ, and *fac*-Λ, of the tris[(*S*)-1,3-butanediamine]cobalt(III) complex were obtained, and their absorption and circular dichroism spectra were recorded in water in the absence or presence of sulfate ions. The shift of absorption bands and the variation of circular dichroism spectra caused by the addition of sulfate ions seem to be correlated with the conformational instability of six-membered (*S*)-1,3-butanediamine chelate rings in the complexes.

Experimental observations[1-4] indicate that the most stable conformation of the (*S*)(or (*R*))-1,3-butanediamine(*S*(or *R*)-bn) chelate ring is the chair form with an equatorially disposed methyl group. However, a six-membered chelate ring is known to be conformationally flexible and to interchange easily its conformation between two forms, the chair and the skew depending on environment. The *S*(or *R*)-bn chelate ring in the δ(or λ)-skew conformation also has the methyl group in equatorial orientation (see Fig. 2). In a previous paper,[5] we have suggested that the variation of circular dichroism spectra of some cobalt(III) complexes containing (*R*,*R*)-2,4-pentanediamine (*RR*-ptn) in various solvents is closely related with such conformational instability of the six-membered *RR*-ptn chelate ring. The most stable conformation of the *RR*-ptn chelate ring is the λ-skew form in which the two methyl groups are equatorially disposed. In order to compare the effects of a methyl group on the conformational instability of six-membered chelate rings, this paper reports the preparation of four stereoisomers of the $[Co(S\text{-bn})_3]^{3+}$ complex and their absorption and circular dichroism spectra in the absence or presence of sulfate ions. The circular dichroism spectrum of $[Co(NH_3)_4(S\text{-bn})]^{3+}$ is also recorded.

Experimental

Ligand. 1,3-Butanediamine (bn) was prepared by the method of Strack *et al.*[6] and resolved by the method of Balieu *et al.*[7] The $(+)_{589}$-isomer is known to have the *S*-configuration,[7] and its dihydrochloride salt (*S*-bn·2HCl) was used to prepare cobalt(III) complexes.

[Co(NH$_3$)$_4$(S-bn)](ClO$_4$)$_3$. This complex was prepared from $[Co(H_2O)(NH_3)_5](ClO_4)_3$ and *S*-bn·2HCl by a method similar to that for the corresponding (*R*,*R*)-2,4-pentanediamine (*RR*-ptn) complex.[5]

trans-[CoCl$_2$(S-bn)$_2$]Cl. An aqueous solution (50 cm^3) of *S*-bn·2HCl (4.8 g, 30 mmol) was neutralized with Na_2CO_3 (3.1 g, 30 mmol). To this solution was added a solution of $Na_3[Co(NO_2)_6]$ (6.1 g, 15 mmol) in water (40 cm^3), and the mixture was heated at 70 °C for 3 h. The resulting yellow solution was mixed with concd HCl (50 cm^3), and heated at 70 °C for 2 h with occasional stirring to give a reddish violet solution. Green crystals which formed by concentrating the solution to a small volume in a rotary evaporator were filtered off and washed with ethanol. Yield: *ca.* 30%.

Tris(S-bn)cobalt(III) Complex. A suspension of *S*-bn·2HCl (0.4 g, 2.5 mmol) and sodium methoxide (0.22 g, 4 mmol) in methanol (3 cm^3) was added to a solution of *trans*-$[CoCl_2(S\text{-bn})_2]Cl$ (0.69 g, 2 mmol) in DMSO (30 cm^3). The mixture was stirred for a day at room temperature, then diluted with 1 dm^3 of water and passed through an SP-Sephadex column (ϕ 2.7×5 cm). A small portion of the Sephadex charged with the product was loaded on the top of adsorbent layer of an SP-Sephadex column (ϕ 2.7×120 cm), and the adsorbed complexes were developed with a 0.2 M aqueous solution of sodium $(+)_{589}$-tartratoantimonate(III). The column gave three separate bands, I, II, and III in the order of elution, which were *mer*-Δ, *fac*-Δ, and a mixture of *mer*-Λ and *fac*-Λ isomers, respectively. The effluent of the band III was diluted with water and loaded again on an SP-Sephadex column, and the adsorbed band was eluted with a 0.2 M sodium sulfate solution. Two isomers, *fac*-Λ(IIIA) and *mer*-Λ(IIIB) were eluted separately from the column in this order. The formation ratio, *mer*-Δ(I): *fac*-Δ(II): *fac*-Λ(IIIA): *mer*-Λ(IIIB) was 2:1:1:2. Each effluent was reloaded on SP-Sephadex and the isomers were isolated by the following methods.

$(-)_{546}$-mer-Δ-[Co(S-bn)$_3$]Cl$_3$·3H$_2$O and $(-)_{470}$-fac-Λ-[Co(Sbn)$_3$]Cl$_3$·2H$_2$O. The complex adsorbed on SP-Sephadex was eluted with 1.0 M HCl. The effluent was evaporated to

almost dryness in a vacuum desiccator over P_2O_5 and NaOH. Orange crystals which formed by the addition of ethanol were filtered off and washed with ethanol.

(+)$_{546}$-mer-Λ-[*Co(*S-*bn)*$_3$]$Cl_3 \cdot 2H_2O$. This complex was obtained in a similar way to that for the *mer-Δ* or the *fac-Λ* isomer except that methanol was used for crystallization instead of ethanol.

(+)$_{470}$-fac-Δ-[*Co(*S-*bn)*$_3$]$Cl_3 \cdot 3.5H_2O$. This complex did not crystallize on the addition of common organic solvents to a concentrate of the effluent. Thus the orange residue obtained by evaporating the effluent in a vacuum desiccator was used for measurements.

mer-Δ-, fac-Δ-, *and* mer-Λ-[*Co(*S-*bn)*$_3$]$(ClO_4)_3 \cdot 2H_2O$ *and* fac-Λ-[*Co(*S-*bn)*$_3$]$(ClO_4)_3 \cdot H_2O$. The adsorbed complex was eluted with a 1.5 M sodium perchlorate solution and the effluent was concentrated to a small volume in a rotary evaporator. Orange crystals which formed on cooling the concentrate were filtered off and washed with ethanol.

Other complexes, *mer-* and *fac-*[Co(*meso*-ptn)$_3$]$^{3+}$ were prepared and resolved by the method reported previously.[8]

Table 1 shows the results of chemical analysis.

Measurements. Absorption and circular dichroism spectra were recorded on a Hitachi 323 spectrophotometer, and a JASCO model J-20 spectropolarimeter, respectively. PMR spectra were recorded on a JEOL C-60H spectrometer in D_2O–DCl with DSS (sodium 2,2-dimethyl-2-silapentane-5-sulfonate) as the internal reference.

Results and Discussion

*1. Tetraammine(*S-*bn)cobalt(III) Complex.* As Fig. 1 shows, [Co$(NH_3)_4$(*S*-bn)]$(ClO_4)_3$ in water exhibits extremely weak CD in the region of the d-d absorption bands. Hawkins and Lawrance[2] reported that [Co$(NH_3)_4$(*S*-bn)]$(NO_3)_3 \cdot H_2O$ shows no measurable CD in this region. In general, a tetraammine complex containing an optically active diamine chelate exhibits CD much stronger than that of the *S*-bn complex in the region of the first absorption band, and the sign of a main CD band depends on the conformational chirality of a diamine chelate ring. For example, [Co$(NH_3)_4$(*R*-pn)]$^{3+}$ (*R*-pn=*R*-propylenediamine) gives a positive CD band ($\Delta\varepsilon = +0.33$) at 461 nm, and the *R*-pn chelate ring is assigned to the λ-gauche conformation.[9] The main CD band of [Co$(NH_3)_4$(*RR*-ptn)]$^{3+}$ is rather weak ($\Delta\varepsilon = +0.10$, 490 nm), and the *RR*-ptn chelate ring is suggested to be in equilibrium between the λ-skew and the chair conformations.[5] Accordingly, the weak CD of the *S*-bn complex in water may indicate that the *S*-bn chelate ring exists predominantly in the achiral chair conformation with the equatorial methyl group as suggested by Hawkins and Lawrance.[2] Energy minimization calculation on a hypothetical complex, [$CoCl_4$(*S*-bn)]$^-$ shows that the predominant conformer of the *S*-bn chelate ring is the same chair form.[10]

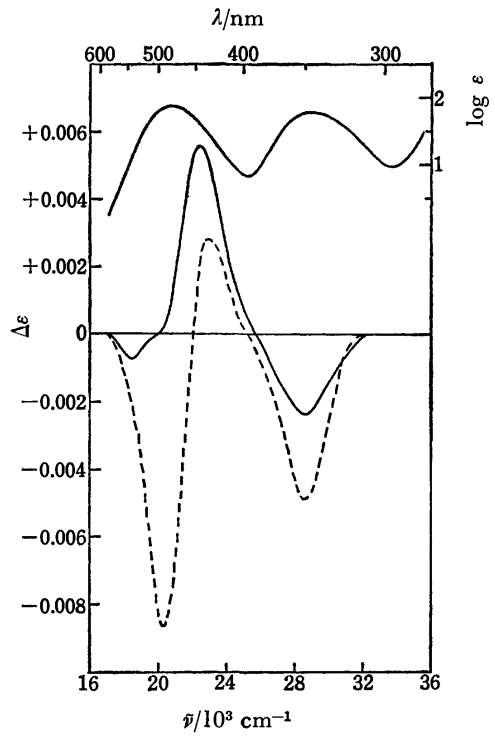

Fig. 1. Absorption and CD spectra of [Co$(NH_3)_4$(*S*-bn)]$(ClO_4)_3$ in water (——) and CD spectrum in 0.2 M Na_2SO_4 (------).

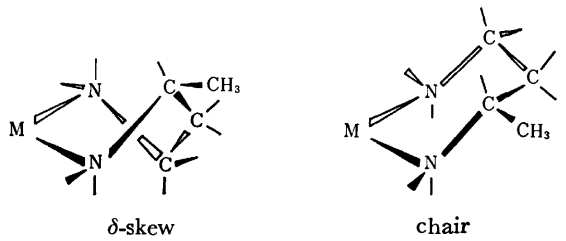

Fig. 2. Possible conformations of six-membered *S*-bn chelate.

The CD spectrum of [Co$(NH_3)_4$(*S*-bn)]$^{3+}$ in water changes remarkably on the addition of Na_2SO_4, as shown in Fig. 1. The sign of the main CD band in the region of the first absorption band is reversed, and the spectral pattern is almost mirror image of that of [Co$(NH_3)_4$(*RR*-ptn)]$^{3+}$ in which the *RR*-ptn chelate ring will be in equilibrium between the λ-skew and the chair conformations as stated previously. Thus, it is suggested that the δ-skew conformation of the *S*-bn chelate ring is stabilized by the addition of Na_2SO_4. Both the chair and the δ-skew conformations have the equatorially disposed methyl group, as shown in Fig. 2. However, the strength of the CD bands is still very weak in the presence of Na_2SO_4. The *S*-bn chelate ring will also exist predominantly in the chair conformation in this solution.

*2. Tris(*S-*bn)cobalt(III) Complexes. a) Characterization of the Isomers*: The tris(*S*-bn)cobalt(III) complex exists in four stereoisomers, *mer-Δ*, *mer-Λ*, *fac-Δ*, and *fac-Λ* (Fig. 3). As Fig. 4 shows, the PMR spectra of the isomers, II and IIIA show only one kind of doublet signal due to the methyl protons, while those of the isomers, I and IIIB give signals indicating the presence of nonequivalent methyl groups. From symmetry argument (*fac*(C_3), *mer*(C_1)), therefore, the isomers, I, II, IIIA, and IIIB can be assigned to *mer*, *fac*, *fac*, and *mer* configurations, respectively.

Figures 5—8 show the CD spectra of all the isomers in water and in 0.2 M Na_2SO_4 solutions. In the region of

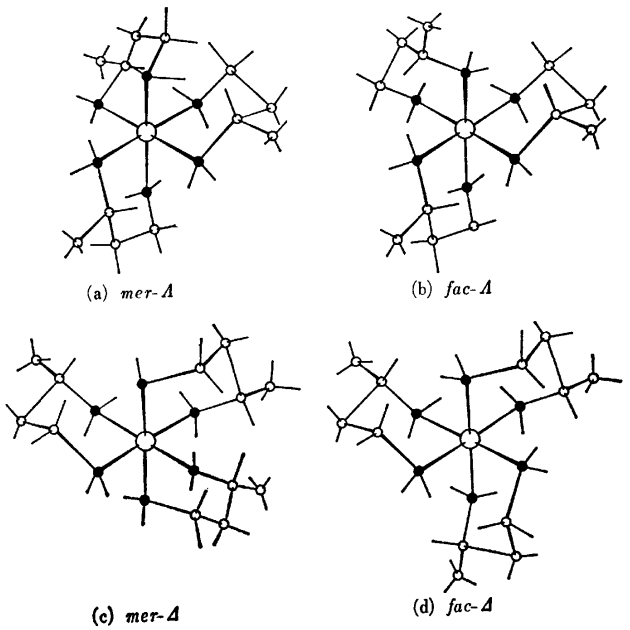

Fig. 3. Schematic structure of tris(*S*-bn)cobalt(III) ions in the chair$_3$ conformer.

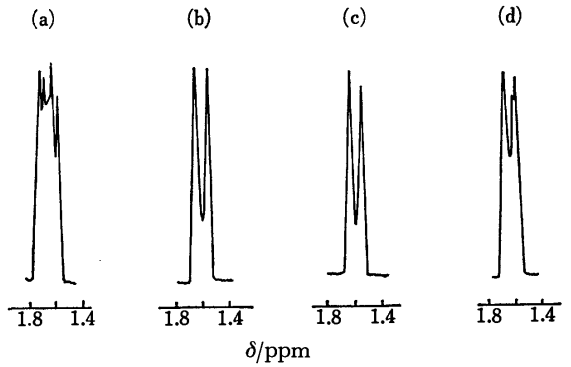

Fig. 4. PMR spectra of the isomers, (a) I(*mer*-Δ), (b) II(*fac*-Δ), (c) IIIA(*fac*-Λ), and (d) IIIB(*mer*-Λ).

the first absorption band, the main CD bands of the isomers, I(*mer*) and II(*fac*) in water have negative sign, while those of the isomers, IIIA(*fac*) and IIIB(*mer*) positive sign. Thus, the former two and the latter two are suggested to have the Δ and Λ configurations, respectively. In the charge transfer region, the isomers, I(*mer*) and II(*fac*) exhibit three CD bands with positive, negative, and positive signs from longer to shorter wavelengths. This pattern coincides with that of Δ-$[Co(tn)_3]^{3+}$ (tn=trimethylenediamine), whose absolute configuration has been determined by X-ray work[11] (Fig. 9). The other isomers, IIIA(*fac*) and IIIB(*mer*) show the same CD pattern in this region, but the signs are reversed. These results lead to the conclusion that the isomers, I, II, IIIA, and IIIB are *mer*-Δ, *fac*-Δ, *fac*-Λ, and *mer*-Λ configurations, respectively. The effect of sulfate ions on the CD spectra will be described later.

b) Absorption Spectra: Table 2 shows that the maxima of the first absorption bands of the four isomers are in the range of 489.5 (20430) to 491 nm (20370

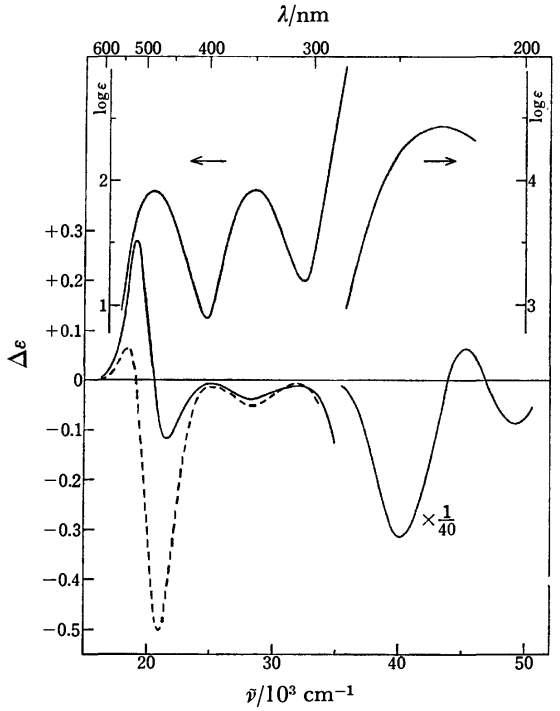

Fig. 5. Absorption and CD spectra of IIIA: *fac*-Λ-[Co(*S*-bn)$_3$]$(ClO_4)_3 \cdot H_2O$; 3.06×10^{-3} M in visible region and 1.88×10^{-4} M in UV region in water (——), and 3.06×10^{-3} M in 0.2 M Na_2SO_4 (------).

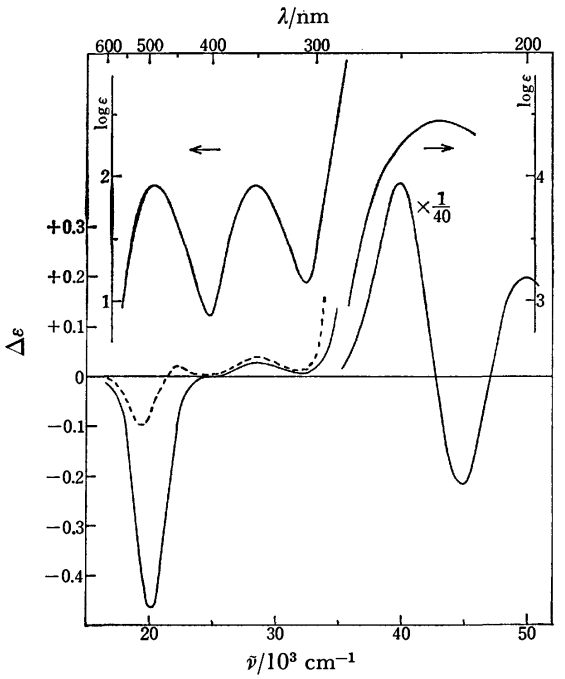

Fig. 6. Absorption and CD spectra of II: *fac*-Δ-[Co(*S*-bn)$_3$]$(ClO_4)_3 \cdot 2H_2O$; 4.02×10^{-3} M in visible region and 1.90×10^{-4} M in UV region in water (——), and 4.02×10^{-3} M in 0.2 M Na_2SO_4 (------).

cm^{-1}). For a complex of six-membered 1,3-diamine, maximum position of the first absorption band seems to depend on the conformation of the diamine; a diamine complex in the skew conformation gives the first absorp-

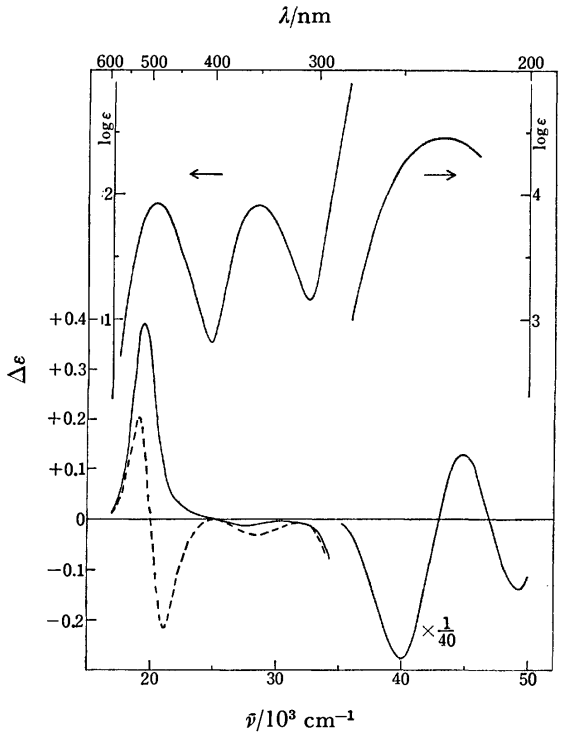

Fig. 7. Absorption and CD spectra of IIIB: *mer*-*Λ*-[Co(*S*-bn)$_3$](ClO$_4$)$_3$·2H$_2$O; 3.08×10^{-3} M in visible region and 1.23×10^{-4} M in UV region in water (——), and 3.08×10^{-3} M in 0.2 M Na_2SO_4 (------).

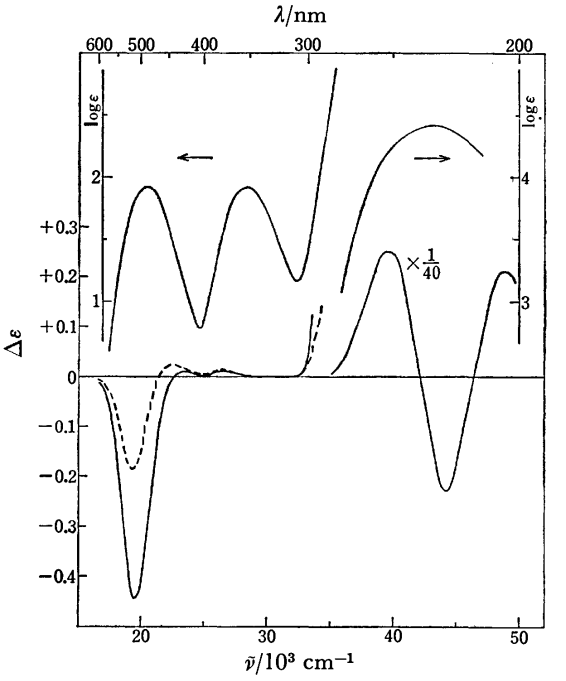

Fig. 8. Absorption and CD spectra of I: *mer*-*Λ*-[Co(*S*-bn)$_3$](ClO$_4$)$_3$·2H$_2$O; 2.82×10^{-3} M in visible region and 1.13×10^{-4} M in UV region in water (——), and 2.82×10^{-3} M in 0.2 M Na_2SO_4 (------).

tion band at a shorter wavelength than that in the chair conformation. For example, *Λ*-[Co(*RR*-ptn)$_3$]$^{3+}$ of which the most stable conformation is the *λ*-skew form exhibits the first absorption band at 482 nm (20750

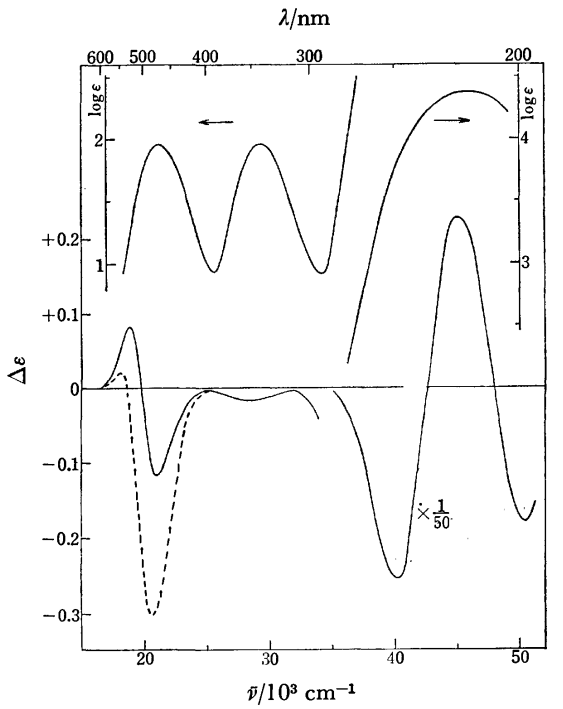

Fig. 9. Absorption and CD spectra of *Λ*-[Co(tn)$_3$](ClO$_4$)$_3$; 5.68×10^{-3} M in visible region and 2.27×10^{-4} M in UV region in water (——), and 5.68×10^{-3} M in 0.2 M Na_2SO_4 (------).

cm^{-1}), while those of *fac*-[Co(*meso*-ptn)$_3$]$^{3+}$ and [Co(tn)$_3$]$^{3+}$ in which the chelate ligands take predominantly the chair conformation are at 491(20370) and 490 nm (20410 cm^{-1}), respectively. Therefore, it is suggested that the *S*-bn chelate rings in all the [Co(*S*-bn)$_3$]$^{3+}$ isomers are intrinsically the most stable in the chair conformation.

The first absorption band of the *fac*-*Λ* isomer (489.5 nm, 20430 cm^{-1}) is a little at a shorter wavelength than that of the *fac*-*Δ* isomer (490.5 nm, 20390 cm^{-1}). It is observed that for a pair of diastereomers, the d-d absorption bands of the one involving more steric interactions lie at longer wavelengths than those of the other.[12] In contrast to such observations, molecular models show that the structure of the *fac*-*Λ* isomer (489.5 nm) seems to be a little more crowded than that of the *fac*-*Δ* isomer (490.5 nm), because the three methyl groups of the former in the chair conformation are disposed so as to concentrate around the C_3 axis of the complex ion (Fig. 3). The observed difference in the peak positions between the two *fac* isomers may be related with conformational instability of the chelate rings in solution. As stated previously, the *δ*-skew conformation of a *S*-bn chelate ring also has the equatorially disposed methyl group. When the *S*-bn chelate ring forms the *δ*-skew conformation, the *fac*-*Λ* isomer results in the *lel*$_3$(*Λ*(*δδδ*)) structure, while the *fac*-*Δ* isomer the *ob*$_3$(*Δ*(*δδδ*)) one. Since the *ob*$_3$ conformer has been calculated by conformational analysis to have a substantially higher energy,[13] the chelate rings in only the *fac*-*Λ* isomer could interchange between the chair and the *δ*-skew conformations, and the complex would be in equilibrium between these two conformers.

The formation of the skew conformer causes shift in the first absorption band to a shorter wavelength as stated previously. The fact that the first absorption band of the more crowded *fac*-*Λ* isomer is at a shorter wavelength than that of the less crowded *fac*-*Δ* isomer may be accounted for by such a conformational equilibrium of the *S*-bn chelate ring.

In the presence of Na_2SO_4 (0.5 M), the first absorption band of the *fac*-*Λ* isomer shifts a little, but more than 1 nm to a shorter wavelength. The *fac*-*Δ* isomer also shows such a band shift toward a shorter wavelength under the same condition, but the magnitude of shift is very small (less than 0.5 nm). In the presence of sulfate ions, the $lel_3(\Lambda(\delta\delta\delta))$ conformer may be stabilized by ion-pair formation between the complex cation and the sulfate ion, and the first absorption band shifts further to a shorter wavelength owing to the increasing amount of the δ-skew conformer. For a tris-diamine

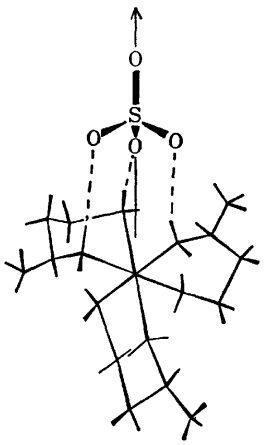

Fig. 10. A proposed structure of the ion-pair between *fac*-Δ(chair$_2\delta$(*ob*))-[Co(*S*-bn)$_3$]$^{3+}$ and SO_4^{2-}.

complex, the *lel*$_3$ conformer is known to have the most effective structure in forming an ion-pair through hydrogen bonding between the amino protons and the sulfate ion.[5] The [Co(tn)$_3$]$^{3+}$ complex of which the conformational behavior is expected to resemble that of the *fac*-Λ isomer also shows a similar shift (*ca.* 1 nm) in the first absorption band on the addition of sulfate ions. The *fac*-Δ isomer could not form the *lel*$_3$(Δ($\lambda\lambda\lambda$)) conformer without difficulty, because the λ-skew conformation has the axial methyl group. However, the first absorption band of this isomer also shifts a little to a shorter wavelength in the presence of sulfate ions. If it is assumed that such a shift is caused by the formation of a certain conformer involving the δ-skew form stabilized by an ion-pair with the sulfate ion, the most probable conformer will be of *fac*-Δ(chair$_2\delta$(*ob*)) form as shown in Fig. 10. This conformer has a set of three N–H bonds provided by two *S*-bn chelate ligands, one being in the chair and the other in the δ-skew conformation. These N–H bonds are parallel to an axis as shown in Fig. 10, and the complex may form an ion-pair in a similar way with the oxoanions such as sulfate ion through hydrogen bonding. The increase in the amount of the *fac*-Δ(chair$_2\delta$(*ob*)) conformer in the presence of sulfate ions may cause shift similarly to a shorter wavelength in the first absorption band of the *fac*-Δ isomer.

The first absorption bands of the *mer*-Δ (491 nm, 20370 cm^{-1}) and the *mer*-Λ (489.5 nm, 20430 cm^{-1}) isomers are at nearly the same wavelengths as those of the corresponding *fac* isomers, respectively (Table 2). If all of the *S*-bn chelate rings adopt the chair conformation, these *mer* isomers will be more crowded and strained than the *fac* isomers, since the two chelate rings in each *mer* isomer approach very close to each other. For [Co(*meso*-ptn)$_3$]$^{3+}$ in which the *meso*-ptn chelate rings are expected to be very stable in the chair conformation, the first absorption band of the more crowded *mer* isomer is at longer wavelengths by 2 nm than that of the less crowded *fac* isomer.[8] The fact that both Δ- and Λ-isomers of the *mer*-[Co(*S*-bn)$_3$]$^{3+}$ complex exhibit the first absorption bands at nearly the same wavelengths as those of the *fac* isomers may indicate that one of the two close *S*-bn chelate ligands in each *mer* isomer prefers to take the δ-skew conformation to reduce interactions between the ligands. The chair$_2\delta$ conformer will give the first absorption band at a shorter wavelength than that expected for the chair$_3$ conformer. The difference in the absorption maxima of the two *mer* isomers may be interpreted by the difference in the structures of the isomers. In the *mer*-Λ isomer, two methyl groups on the two close *S*-bn chelate rings are disposed away from each other (*exo* form), while those in the *mer*-Δ isomer come near to each other (*endo* form) (Fig. 3). The *endo-mer*-Δ isomer should be more crowded, and gives the first absorption band (491 nm) at a longer wavelength compared with that of the other *exo- mer*-Λ isomer (489.5 nm). Furthermore, the latter isomer can also form the *lel*$_3$(Λ($\delta\delta\delta$)) conformer, the first absorption band of which will be at a shorter wavelength than those of the other conformers involving the chair conformation.

On the addition of sulfate ions, the first absorption bands of both the *mer*-Δ and -Λ isomers shift to a shorter wavelength, the latter (*ca.* 1 nm) showing larger shift than the former (*ca.* 0.5 nm). These band shifts may be caused by a mechanism similar to that described for the *fac* isomers. The *mer*-Λ isomer can form the *lel*$_3$(Λ($\delta\delta\delta$)) conformer suitable for ion-pair formation with the sulfate ion. On the other hand, the *mer*-Δ isomer in the Δ(chair$_2\delta$(*ob*)) conformation can provide a set of three N–H bonds in a similar manner to that of the *fac*-Δ isomer in the same conformation. These conformers will be stabilized by ion-pair formation with sulfate ions, and give the first absorption bands at shorter wavelengths than those in the absence of sulfate ions.

c) Circular Dichroism Spectra. The CD patterns of all the isomers of [Co(*S*-bn)$_3$]$^{3+}$ in water satisfy the known relationship between the absolute configuration and the CD sign, if our assignments were correct. However, the additive law for the configurational and the vicinal effects does not hold for the present diastereomeric isomers. For example, the CD spectra of the *fac*-Δ and -Λ isomers are not mirror image of each other, although the CD spectrum of [Co(NH$_3$)$_4$(*S*-bn)]$^{3+}$ shows that the vicinal effect of the *S*-bn chelate ligand is negligible. This result also indicates that the complexes are in equilibrium among some conformers and that the conformational equilibrium of one complex is different from those of the other complexes. In a previous paper,[5] we have reported that the CD spectra of conformationally flexible complexes such as Δ-[Co(*RR*-ptn)$_3$]$^{3+}$ or Δ(or Λ)-[Co(tn)$_3$]$^{3+}$ are remarkably affected by the vicinal effect of chelate rings in a certain conformation stabilized by ion-pair formation between a complex ion and its counter ion. The *fac*-Λ-[Co(*S*-bn)$_3$]$^{3+}$ isomer seems to be the case. In the region of the first absorption band, the CD spectrum of the complex chloride in water shows a clear dependence on the concentration, as shown in Fig. 11. The complex perchlorate exhibits no such dependence in the concentration range of 3.25×10^{-2} to 3.15×10^{-4} M. In the presence of sulfate ions, the negative CD component at a shorter wavelength is considerably enhanced (Fig. 5). Such features quite resemble those observed for Λ-[Co(tn)$_3$]$^{3+}$, indicating that the CD variation is brought about by the vicinal effect of the δ-skew conformer of the *S*-bn chelate ring

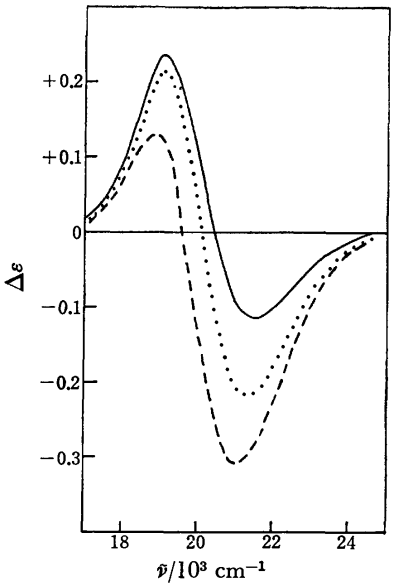

Fig. 11. Dependence of CD of *fac*-*Λ*-[Co(*S*-bn)$_3$]Cl$_3$·2H$_2$O on its concentration in water: 4.21×10^{-4} M (——), 4.18×10^{-3} M (……), and 4.17×10^{-2} M (-----).

stabilized by ion-pair formation. The vicinal effect of the *δ*-skew conformation is known to exhibit negative CD in this region. Therefore, it can be concluded that the *fac*-*Λ* isomer is conformationally flexible and is in equilibrium between the chair$_3$ and the *lel*$_3$(*Λ*(*δδδ*)) conformers. This conclusion coincides with that obtained from the study of absorption spectra.

In contrast to the *fac*-*Λ* isomer, the other three complex chlorides show little dependence on the concentration, the CD patterns in the region of the first absorption band remaining unchanged; *fac*-*Δ*$=-0.37$ (3.54×10^{-4} M)——0.30 (3.66×10^{-2} M): *mer*-*Λ*$=0.38$ (3.13×10^{-4} M)—0.34 (3.12×10^{-2} M): *mer*-*Δ*$=-0.42$ (4.00×10^{-4} M)——0.39 (2.72×10^{-2} M). Since the ability of these isomers to form ion-pairs with chloride ions will not differ greatly from that of the *fac*-*Λ* isomer, the result indicates that these isomers are not stabilized in particular conformers by ion-pair formation with chloride ions. The isomers may be less conformationally flexible than the *fac*-*Λ* isomer as claimed in the previous discussion. In the presence of sulfate ions, however, these three isomers change the CD patterns remarkably (Figs. 6—8). Of these CD changes, that of the *mer*-*Λ* isomer is similar to the CD change of the *fac*-*Λ* isomer. Each of these *Λ* isomers in the presence of sulfate ions gives a strong negative CD band at the expense of the positive CD band. As stated previously, the *mer*-*Λ* isomer could also form the *lel*$_3$(*Λ*(*δδδ*)) conformer. The oxoanions such as sulfate ion may induce the conformational change of rather crowded, rigid chelate rings by forming strong hydrogen bonds with the amino protons of the complex. Thus, the *mer*-*Λ* isomer in the presence of sulfate ions may be stabilized in the *lel*$_3$(*Λ*(*δδδ*)) conformer.

On the other hand, both *mer*- and *fac*-isomers of the *Δ* configuration in the presence of sulfate ions diminish considerably the strength of the main CD bands, but show no marked increase in the CD bands with the reversed sign as observed in the *Λ*-isomers (Figs. 6 and 8). According to the previous discussion, the decrease in the negative CD strength indicates the formation of chelate rings with the *λ*-skew conformation. However, this indication seems to be unlikely, since the *λ*-skew conformer has the axial methyl group. A similar CD variation is seen in the spectra of *mer*- and *fac*-*Λ*(or *Δ*)-[Co(*meso*-ptn)$_3$]$^{3+}$ on the addition of sulfate ions, as shown in Figs. 12 and 13. The conformation of the *meso*-

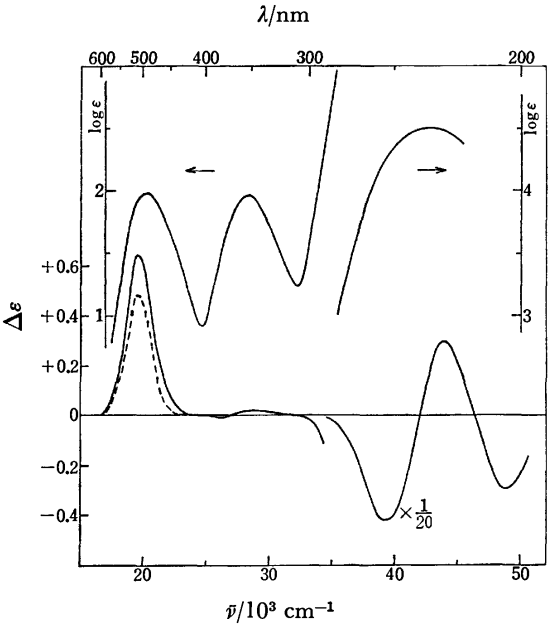

Fig. 12. Absorption and CD spectra of *mer*-*Λ*-[Co(*meso*-ptn)$_3$](ClO$_4$)$_3$·2H$_2$O; 2.89×10^{-3} M in visible region and 1.16×10^{-4} M in UV region in water (——), and 2.89×10^{-3} M in 0.2 M Na$_2$SO$_4$ (------).

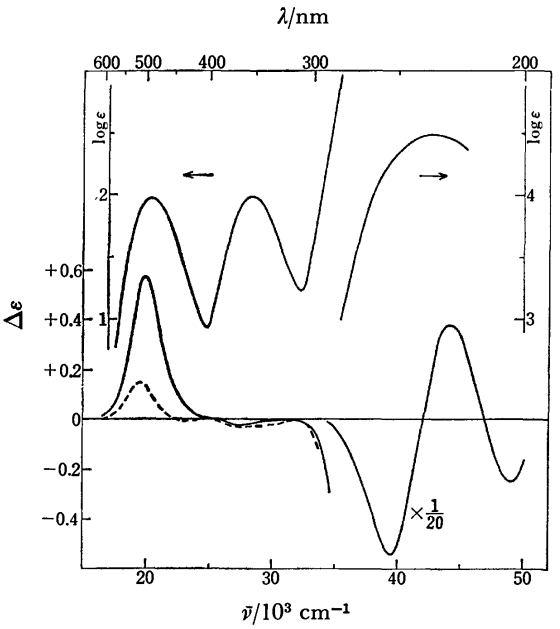

Fig. 13. Absorption and CD spectra of *fac*-*Λ*-[Co(*meso*-ptn)$_3$](ClO$_4$)$_3$·2H$_2$O; 3.11×10^{-3} M in visible region and 3.46×10^{-4} M in UV region in water (——), and 3.11×10^{-3} M in 0.2 M Na$_2$SO$_4$ (------).

ptn chelate ring is expected to be very stable in the chair form. The CD patterns of these *S*-bn and *meso*-ptn complexes in the presence of sulfate ions somewhat differ from those of the *Λ* isomers of *S*-bn and tn complexes in the same condition. In the latter two *Λ* isomers, the enhancement of one CD component seems to be accompanied with the diminution of the other CD component, and the total strength of the two CD components does not seem to change greatly. On the other hand, the former *S*-bn and *meso*-ptn complexes diminish the total CD strength. Such a difference in the CD variations can not be explained at present, but may also be related with the conformational instability of chelate rings in the complexes. The complexes, *mer-Δ*, *fac-Δ*-$[Co(S\text{-bn})_3]^{3+}$, *mer-Λ*-, and *fac-Λ*-$[Co(meso\text{-ptn})_3]^{3+}$ which diminish the total CD strength in the presence of sulfate ions will have more crowded, rigid structures compared with those of *fac-Λ*-$[Co(S\text{-bn})_3]^{3+}$ and *Λ*-$[Co(tn)_3]^{3+}$. For these crowded complexes, the CD variation of the more crowded *mer-Λ*-$[Co(meso\text{-ptn})_3]^{3+}$ is smaller than that of the corresponding less crowded *fac-Λ* isomer. A similar relation is seen between the *mer-Δ* and the *fac-Δ* isomers. The crowded, rigid $\Lambda(ob_3)$-$[Co(RR\text{-ptn})_3]^{3+}$ complex shows little variation in the CD spectra in various solvents.[5] These observations strongly suggest that the CD variations observed for both *Δ*-$[Co(S\text{-bn})_3]^{3+}$ and $[Co(meso\text{-ptn})_3]^{3+}$ are also closely related to the conformational instability of the six-membered chelate rings.

Preparation and Properties of Pd(II) and Pt(II) Complexes of *N*-Picolinoyl-*S*,*S*-tetramethylenesulfilimine, *N*-Trimethylammoniopicolinamidate, and Related Ylides

Hideo KISE, Hiroyuki ENDŌ, and Manabu SENŌ

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received June 11, 1977)

The reactions of *N*-picolinoyl-*S*,*S*-tetramethylenesulfilimine and *N*-trimethylammoniopicolinamidate with dichlorobis(benzonitrile)palladium(II) and dipotassium tetrachloroplatinate(II) afforded chelate complexes of formula MCl_2[Ylide]. The structures of the complexes were examined by IR and NMR spectroscopy, and determined as mononuclear complexes with ligands coordinated through two nitrogen atoms. A reverse relationship between pK_a values of the ylides and C=O stretching band frequency shifts on complex formation was found, and the nature of the coordination *via* ylidic nitrogen was discussed in terms of σ- and π-character of the ligands in the chelate complexes and several related bis-ylide complexes.

Carboxylic acid amides are anbidentate ligands and have potential coordination sites of nitrogen and carbonyl oxygen atoms. In most cases, they form complexes with a variety of Lewis acids *via* carbonyl oxygen in neutral media.[1] In alkaline media, however, amides liberate the hydrogen and form neutral complexes through anionic nitrogen atoms.[2] In the case of picolinamides, both cationic and neutral chelate complexes with transition metals were prepared and characterized;[3] the former has coordination through nitrogen and oxygen atoms, while the latter has coordination through two nitrogen atoms (**1** and **2**).

In this paper we describe a novel type of Pd(II) and Pt(II) complexes of sulfilimine (S–N ylide) and aminimide (N–N ylide) with picolinoyl group on ylidic nitrogen (**3** and **8**). These ylides have a close similarity to picolinamide anions in that they are bidentate *via* nitrogen atom in pyridine ring and anionic nitrogen with charge delocalized over adjacent carbonyl group. In contrast to amide anions, they are stable enough to be prepared and isolated by known procedures, and this would make it possible to elucidate directly the change in electronic state of the ligands upon complex formation. In addition, while each of the ylides has an anionic center, it has ammonium or sulfonium moiety adjacent to the ylidic nitrogen, and hence is a neutral molecule as a whole. The effect of the positively charged group on complex formation would be an interesting problem to examine.

An increasing number of reports have been published on metal–ylide complexes.[4] Many of them describe reactions of metal carbonyl with ylides,[5] and direct formation of metal–carbon bonds by reactions of metal salts with stable[6] and unstable[7] phosphorus and sulfur ylides. Several papers also describe the formation of metal complexes of sulfilimines and aminimides,[8] but chelate complexes of these ylides have not been reported so far except *ortho*-metallated *N*-(1-pyridinio)benzamidate complexes of transition metals.[9]

Results and Discussion

Preparation of Complexes. The complex formation of the ylides **3** and **8** occurred smoothly with dichlorobis(benzonitrile)palladium(II) in ethanol and with dipotassium tetrachloroplatinate(II) in water at room temperature. In all cases, the complexes were isolated as yellow or orange-yellow precipitates. The Pd(II) complexes were also prepared by reactions with disodium tetrachloropalladate(II) in ethanol or with dichloro(1,5-cyclooctadiene)palladium(II) in acetone, giving the same products as described above. The elemental analyses revealed that the complexes have equimolar compositions of MCl_2 (M=Pd or Pt) and ylides (Table 1), suggesting chelate structures for these complexes. *N*-Benzoyl- and *N*-acetylsulfilimines and aminimides formed complexes with two ylide molecules per metal atom (bis-ylide complexes). The thermal stability of the bis-ylide complexes is somewhat lower than that of the chelate complexes.

In the case of bidentate ligands, **3** and **8**, the reactions were carried out at the mole ratio of metal salt to ligand of 1 : 1 and 1 : 2, but no differences in the yield and spectroscopic properties of the products were observed. This indicates that the coordinating nitrogen atoms in the chelate complexes are not replaced by another ligand molecules, suggesting that the chelate formation is favored not only entropically but also energetically, resulting in the formation of stronger coordination bonds than those of bis-ylide complexes.

Structure of Complexes. The sulfilimines and aminimides used as ligands have an ambidentate character with resonance structures such as shown in **3a**—**c** and **8a**—**b**. The difference between a sulfilimine and an aminimide is that the former has dπ-pπ interaction between sulfur and ylide nitrogen, making the S–N bond length shorter than ordinary single bond length,[10] while the latter does not have such interaction; the single bond character of N–N linkage and shortening of N–C(carbonyl) bond have been proved by X-ray analysis.[11] These ylides form stable sulfonium and ammonium salts by treatment with aqueous HCl in acetone except for **3** and **8**, whose HCl salts were not isolated. The IR spectral data of these ylides and salts are collected in Table 2. It is evident that the ylides have large contribution from the enolate form structures such as **3c** and **8b**, as manifested by low carbonyl stretching frequencies similar to those of carboxylate ions. The C=O bands shift as much as 105—160 cm^{-1} to higher frequencies, while the C=N stretching bands shift down from 1290—1350 to 1220—1274 cm^{-1} in going from ylides to their salts,[12] indicating that

protonation occurred at ylidic nitrogen to form salts such as **5** and **10**.

As shown in Table 3, the C=O bands of the ylides shift to higher frequencies on complex formation, and this seems to indicate that coordination to metal occurs through ylidic nitrogen. In view of the Pd–Cl stretching bands of Pd(II) complexes, there seems to be two groups of complexes; one includes **16a—c, 24,** and **25** which have only one Pd–Cl absorption band at 323—345 cm^{-1}, and another one includes **14, 17, 18, 20,** and **21** which have two Pd–Cl bands at 327—331 and 346—368 cm^{-1}. The former is considered to have *trans*-configuration and the latter has *cis*-configuration around the Pd atom.

In the case of picolinoyl ylides **3** and **8**, the absorption bands due to in-plane deformation of pyridine ring[3f] appear at 615 and 623 cm^{-1} respectively, and these bands shift to higher frequencies (655—665 cm^{-1}) on complex formation. Furthermore, the lack of IR bands characteristic of the bridging M–Cl–M stretching mode that would be expected below 300 cm^{-1} rules out binuclear structures.[13] These and analogous considerations on the Pt(II) complexes, **15** and **19**, lead to the conclusion that the structures of **14, 15, 18,** and **19** are best represented by **A** and **B** in Fig. 1. In the NMR spectrum of **18**, protons of the pyridine ring, as well as protons of methyl groups, show down field shift in comparison with the free ligand **8**, and this also implies the chelate ring formation through two nitrogen atoms.

One of the structurally related Pd(II) complexes of picolinamides is shown in Fig. 1 (**C**).[3f] In this case, the amide groups coordinate to metal *via* anionic nitrogens, forming a 1 : 2 metal-amide complex. The C=O band of the complex **C** appears at 1625 cm^{-1} which

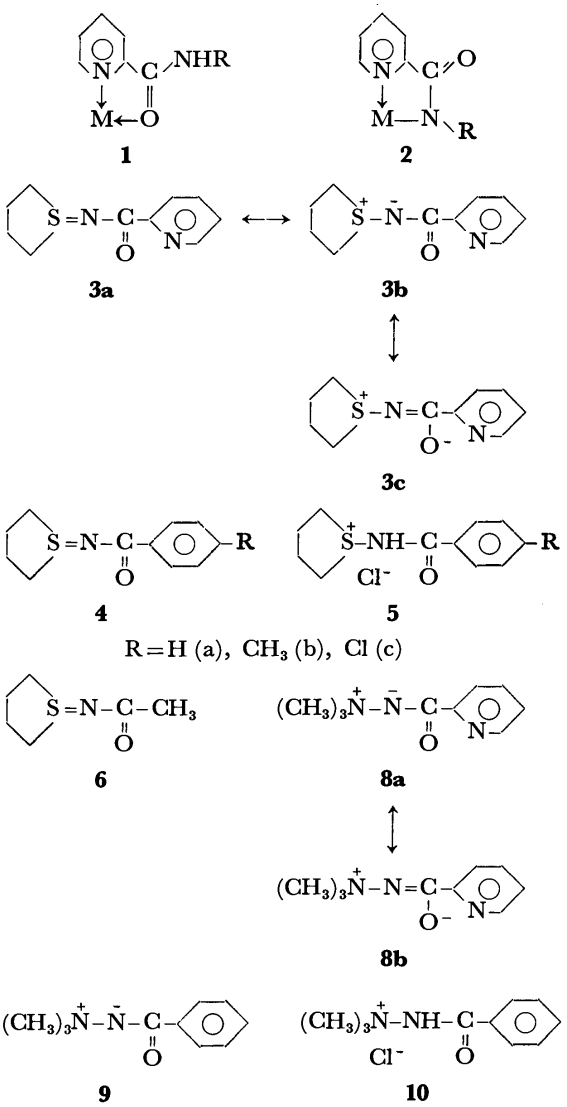
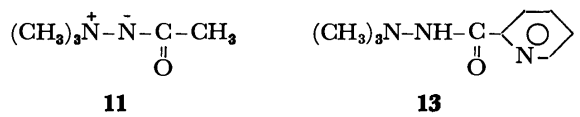
a) Δ_1 and Δ_2 are C=O frequency differences between salts and complexes, and between complexes and ylides, respectively. Δ% is $\Delta_2/(\Delta_1+\Delta_2)\times 100$. b) Pyridine in plane deformation band.[3f] In free ligands this bands appear near 615 cm^{-1}. c) Values of Δ were calculated using $\nu_{C=O}=1694\ cm^{-1}$ for the salt of **3**. d) Values of Δ were calculated using $\nu_{C=O}=1692\ cm^{-1}$ for the salt of **8**. e) Two absorption bands of almost equal intensities were observed. f) $PdCl_2[(C_6H_5)_3P{=}CHCOC_6H_5]_2$, Ref. 6a. g) $PdCl_2[(CH_3)_2S{=}CHCOC_6H_5]_2$, Ref. 6c.





is the same frequency as the C=O band of **16a**. Considering that the basicity of the anionic ligand and hence the strength of metal–ligand bonding is thought to be much higher in the former complex than the latter, it is obvious that the metal–ligand bond strength can not be estimated by the observed C=O band shift. In fact, including a hydrazide complex **D** (*vide infra*), the order of basicity (pK_a of the corresponding amide hydrogens) of the anionic nitrogens is expected to be **C>D>B>A**, while the C=O frequency is in the order **C<D<B<A.**

The degree of higher shift of C=O band on complex

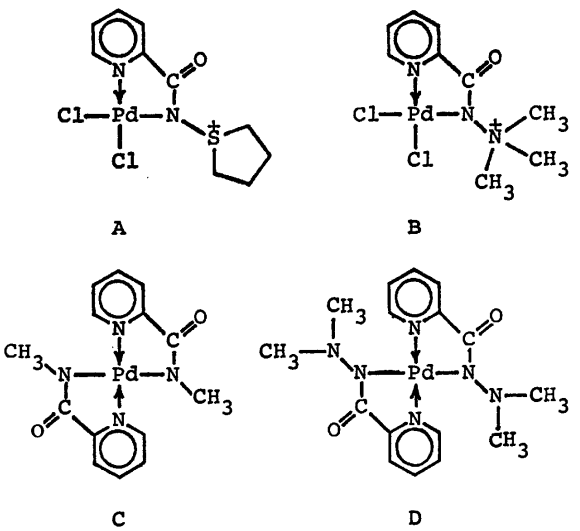


Fig. 1. Structures of chelate complexes.

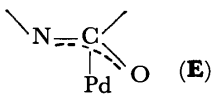
formation is quite different between the aminimides and the sulfilimines, and among the ylides with different substituents on the carbonyl group. In order to visualize these structural effects, the C=O frequency differences between the salts and the complexes (Δ_1), and those between the complexes and the ylides (Δ_2) are summerized in Table 3, together with the percentages of $\Delta\% = \Delta_2/(\Delta_1+\Delta_2)$ ($\Delta_1+\Delta_2$ equal to the frequency differences between the ylides and the salts). Since the attempted preparations of the salts of the picolonoyl ylides, **3** and **8**, were unsuccessful, the values of Δ_1 and $\Delta\%$ of **14**, **15**, **18**, and **19** were calculated using hypothetical values of 1694 and 1692 cm^{-1} for the salts of **3** and **8**, respectively. These values were calculated on assumption that the values of $\Delta_1+\Delta_2$ of the *N*-picolinoyl compounds are equal to those of *N*-benzoyl compounds. Table 3 also includes the values for the P–C and S–C ylides calculated from the reported data and the pK_a values of the salts of the ylides. The value of $\Delta\%$ is considered to be a measure of degree of σ-bonding between dsp^2 hybridized orbital of the metal ion and sp^2 orbital of the ylidic nitrogen.

There is a tendency that the sulfilimine complexes have somewhat higher values of $\Delta\%$ than the aminimide complexes with the same substituents on the carbonyl carbon. This may indicate that the latter has smaller σ-bond character than the former. In the case of carboxylate complexes such as metal complexes of amino acids, the stretching frequency of the coordinated carboxyl group becomes higher as the metal–oxygen bond becomes stronger.[14] Therefore, it may be considered that the coordination in the sulfilimine complexes is stronger than that in the aminimide analogs. However, the conclusion is somewhat dubious, because the observed basicity of the sulfilimines is lower than the aminimides, and hence the latter is expected to have stronger electrostatic interactions with metal ions.

An alternative explanation for these results is that the metal-ylide coordination is appreciably of ionic character with π-electron delocalized over N–C–O atoms (**E**).



(**E**)

Chelate complexes cannot have a coordination like **E**. A similar complex of an anionic ligand, acetamidopentaamminecobalt(III) perchlorate $[Co(NHCOCH_3)(NH_3)_5](ClO_4)_2$, has been reported by Schneider *et al.*[2b] The complex has C=O stretching band at 1560 cm^{-1}, and X-ray analysis revealed that C=O bond length is longer than ordinary double bonds, indicating electron delocalization over N–C–O atoms.

It should be noted that the chelate complexes have larger σ-bond character than the bis-ylide complexes as seen in Table 3, and that the complexes of *N*-acetyl ylides have remarkably larger ionic character; the C=O bands appear closer to those of free ylides rather than salts.

One of the distinguishable characteristics of ylide ligands is that they have a positively charged group adjacent to the coordination site. In order to evaluate the effect of the charged group, a complex of 2′, 2′-dimethylpicolinohydrazide (**13**) was prepared by the reaction with disodium tetrachloropalladate(II) in an alkaline medium. The proposed structure of the complex (**22**) is shown in Fig. 1 (**D**), and the comparison of C=O bands of **B** and **D** (Table 3) suggests that the latter has a little larger ionic character. It is interesting that by complex formation the NMR bands of methyl and pyridine-6-CH protons of 2′,2′-dimethylpicolinohydrazide show down field shift by 0.25 and 1.36 ppm, respectively. The magnitude of the shift of pyridine-6-CH protons is larger than that expected from the electronic deshielding by coordination of pyridine N atom, and this was ascribed to the van der Waal's interaction with methyl groups of another ligand in the complex.

Ligand Exchange Reactions. The complexes prepared in the present study have relatively low solubilities in water and ordinary organic solvents, making it difficult to study the reactions in solution. However, it was found that the NMR spectra of bis-ylide complexes **16** in DMSO-d_6 were essentially the same with those of free ligands, suggesting that the ligands in these complexes were readily replaced by the solvent molecules. On the contrary, the spectra of the chelate complexes **18** and **22** observed under the same condition were unchanged for more than one week.

The heterogeneous reaction of the complexes with equimolar triphenylphosphine were carried out in refluxing acetonitrile. The bis-sulfilimine Pd(II) complexes **16a** and **17** afforded monosubstituted complexes $PdCl_2(Ylide)PPh_3$ in 76 and 60% yields, respectively, while the chelate complexes did not give monsubstituted complexes, but mixtures of $PdCl_2(PPh_3)_2$ and unreacted complexes were obtained together with small amounts of unidentified products.

Experimental

Melting points are uncorrected. IR spectra were taken on JASCO IRA-2 and DS-403G spectrometer, and NMR spectra were recorded on a Hitachi R-20A spectrometer (60 MHz) using TMS as an internal standard. Elemental analyses were performed on a Perkin Elmer 240 analyzer.

Preparation of Sulfilimines, Aminimides, and Their Salts.

N-Picolinoyl-S,S-tetramethylenesulfilimine (3): To a solution of 4.59 ml (0.052 mol) of tetrahydrothiophen in 30 ml of methanol was added dropwise 5.62 ml (0.050 mol) of *t*-butyl hypochlorite at −50—−45 °C. To the resulting mixture a solution of 6.10 g (0.050 mol) of picolinamide and 1.20 g (0.054 mol) of sodium in 40 ml of methanol was added dropwise keeping the temperature between −55 and −45 °C.[15] After 3 h reaction, the mixture was allowed to warm up to room temperature, evaporated by a rotary evaporator under vacuum, and the residue was extracted by 60 ml of dichloromethane. By evaporation of dichloromethane, crude **3** was obtained in 90% yield. Pure **3** was obtained by recrystallization from a mixture of benzene and petroleum ether. Mp 78—80 °C. Found: C, 57.29; H, 5.97; N, 13.44%. Calcd for $C_{10}H_{12}N_2OS$: C, 57.66; H, 5.82; N, 13.45%. N-Benzoyl- and N-(p-Substituted Benzoyl)-S,S-tetramethylenesul-

filimines (4a—c): These sulfilimines were prepared and purified by similar methods to that described above. Analytical and NMR data are shown: **4a**, mp 116—117 °C. Found: C, 64.03; H, 6.71; N, 6.71%. Calcd for $C_{11}H_{13}NOS$: C, 63.73; H, 6.33; N, 6.76%. NMR ($CDCl_3$) δ=1.7—2.7 (4H, m, C-CH_2-C), 3.25 (4H, br. t, J=8 Hz, CH_2S), 7.37 (3H, t, J=3 Hz, *m*- and *p*-CH), 7.9—8.2 (2H, m, *o*-CH). **4b**, mp 99—100 °C. Found: C, 65.61; H, 6.92; N, 6.40%. Calcd for $C_{12}H_{15}NOS$: C, 65.11; H, 6.85; N, 6.33%. NMR ($CDCl_3$) δ=1.7—2.5 (4H, m, C-CH_2-C), 2.35 (3H, s, CH_3), 3.25 (4H, br. t, J=8 Hz, CH_2S), 7.12 (2H, d, J=8 Hz, *m*-CH), 7.93 (2H, d, J=8 Hz, *o*-CH). **4c**, mp 106—108 °C. Found: C, 54.46; H, 5.14; N, 6.04%. Calcd for $C_{11}H_{12}NOSCl$: C, 54.65; H, 5.01; N, 5.80%. NMR ($CDCl_3$) δ=1.7—2.6 (4H, m, C-CH_2-C), 3.25 (4H, br. t, J=7 Hz, CH_2S), 7.28 (2H, d, J=8 Hz, *m*-CH), 7.97 (2H, d, J=8 Hz, *o*-CH).

1-(Benzoylamino and p-Substituted Benzoylamino)thiolanium Chlorides (5a—c): These sulfonium chlorides were prepared by the method reported previously.[16]

N-Acetyl-S,S-tetramethylenesulfilimine (6) and 1-Acetylaminothiolanium Bromide (7): These compounds were also reported in a literature.[17]

N-Trimethylammoniopicolinamidate (Trimethylamine-picolinimide) (8): A modified method of McKillip and Slagel[18] was employed for the syntheses of aminimides **8**, **9**, and **11**. Thus, a mixture of 10.43 g (0.0516 mol) of 1,1,1-trimethylhydrazinium iodide, 7.08 g (0.0516 mol) of methyl picolinate, and 6.02 g (0.0536 mol) of potassium *t*-butoxide in 60 ml of *t*-butyl alcohol was heated with stirring at 60—65 °C for 4.5 h. The precipitate was separated by filtration and the filtrate was evaporated to dryness under vacuum. The residue was recrystallized from ethyl acetate, and a hygroscopic solid was obtained which was identified as **8** by IR and NMR. Yield 70%, mp 148—149 °C. NMR ($CDCl_3$) δ=3.56 (9H, s, CH_3), 7.1—7.5 (1H, m, Py-4-CH), 7.75 (1H, t, J=7 Hz, Py-5-CH), 8.11 (1H, d, J=8 Hz, Py-3-CH), 8.66 (1H, d, J=5 Hz, Py-6-CH).

N-Trimethylammoniobenzamidate (**9**), mp 167—168 °C, (lit,[19] 168—169 °C), and *N*-trimethylammonioacetamidate (**11**), mp 124—126 °C (lit,[20] 122.5—123 °C), were prepared in similar manners and converted to hydrochloric acid salts. **9**; Found: C, 67.49; H, 7.93; N, 15.22%. Calcd for $C_{10}H_{14}N_2O$: C, 67.37; H, 7.93; N, 15.72%. NMR ($CDCl_3$) δ=3.42 (9H, s, CH_3), 7.2—7.5 (3H, m, *m*- and *p*-CH), 7.8—8.1 (2H, m, *o*-CH). **10**; mp 178—179 °C. Found: C, 56.32; H, 7.15; N, 13.11%. Calcd for $C_{10}H_{15}N_2OCl$: C, 55.93; H, 7.06; N, 13.05%. NMR (DMSO-d_6) δ=3.80 (9H, s, CH_3), 7.4—7.7 (3H, m, *m*- and *p*-CH), 7.8—8.1 (2H, m, *o*-CH). Ylide **11** was very hygroscopic and could not analyzed. NMR ($CDCl_3$) δ=1.79 (3H, s, C-CH_3), 3.36 (9H, s, N-CH_3). **12**, mp 198—199 °C. Found: C, 39.17; H, 8.54; N, 18.18%. Calcd for $C_5H_{13}N_2OCl$: C, 39.49; H, 8.60; N, 18.34%. NMR (DMSO-d_6) δ=2.02 (3H, s, C-CH_3), 3.63 (9H, s, N-CH_3).

2',2'-Dimethylpicolinohydrazide (13): This compound was prepared by the reaction of 1,1-dimethylhydrazine with picolinic acid in the presence of dicyclohexylcarbodiimide in dichloromethane.[21] Picolinic acid (4.9 g, 0.04 mol) was added to a solution of 8.2 g (0.04 mol) of dicyclohexylcarbodiimide and 2.4 g (0.04 mol) of 1,1-dimethylhydrazine in 160 ml of dichloromethane, and the solution was stirred at room temperature for 2 h. The precipitate was removed by filtration, and the filtrate was extracted by three portions of 50 ml of 3 M HCl. After the extract was neutralized by sodium carbonate, the product was extracted by chloroform and dried over anhydrous sodium sulfate. The evaporation of chloroform gave crude **13** in 78% yield. After several recrystallization from benzene-hexane or cyclohexane, pure **13** was obtained, mp 67—68 °C. Found: C, 57.79; H, 6.75; N, 24.92%. Calcd for $C_8H_{11}N_3O$: C, 58.15; H, 6.72; N, 25.44%. NMR ($CDCl_3$) δ=2.72 (6H, s, CH_3), 7.25—7.50 (1H, m, Py-4-CH), 7.80 (1H, t, J=7 Hz, Py-5-CH), 8.18 (1H, d, J=7 Hz, Py-3-CH), 8.45 (1H, d, J=4 Hz, Py-6-CH), 8.65 (1H, br. s, NH).

Preparation of Complexes. Dichloro(N-picolinoyl-S,S-tetramethylenesulfilimine)palladium(II) (14): To a solution of 0.763 g (3.66 mmol) of **3** in 60 ml of benzene 1.26 g (3.29 mmol) of dichlorobis(benzonitrile)palladium(II) was added. After overnight reaction with stirring, an orange-yellow precipitate was separated and dried *in vacuo*. Crude **14** (93% yield) was purified by recrystallization from DMSO. Alternative procedures for the preparation of **14** are the reaction of **3** with disodium tetrachloropalladate(II) in ethanol or with dichloro-(1,5-cyclooctadiene) palladium(II) in acetone. In both cases the products were obtained as precipitates and identified as **14**.

Dichloro(N-picolinoyl-S,S-tetramethylenesulfilimine)platinum(II) (15): A solution of 0.514 g (2.47 mmol) of **3** in 5 ml of water was added dropwise to a solution of 0.257 g (0.618 mmol) of dipotassium tetrachloroplatinate(II) in 5 ml of water. After 3 h reaction at room temperature, an orangered precipitate was separated, washed with water, and dried *in vacuo*; yield 66%.

Dichlorobis(N-benzoyl-S,S-tetramethylenesulfilimine)palladium(II) (16a): A solution of 0.447 g (2.15 mmol) of **4a** in 5 ml of ethanol was added dropwise at room temperature to a solution of 0.376 g (1.08 mmol) of disodium tetrachloropalladate (II) in 25 ml of ethanol. The orange precipitate formed was filtered, washed with ethanol-water, and dried *in vacuo*; yield 95%. *p*-Methyl- and *p*-chlorobenzoylsulfilimine complexes of palladium(II) were prepared by similar methods. The NMR spectra of **15a—c** in DMSO-d_6 were essentially the same with those of **4a—c** respectively, indicating that the ylide ligands were replaced by the solvent. The complex **17** was prepared in tha same way.

Dichloro(N-trimethylammoniopicolinamidate)palladium(II) (18): A solution of 0.555 g (3.09 mmol) of **8** in 5 ml of ethanol was added at room temperature to a solution of 0.598 g (1.56 mmol) of dichlorobis(benzonitrile)palladium(II) in 30 ml of ethanol. A brownish precipitate formed immediately. After 1 h reaction, the precipitate was separated, washed with ethanol, and dried *in vacuo*; yield 74%. NMR (DMSO-d_6) δ=3.68 (9H, s, CH_3), 7.4—8.4 (3H, m, Py-3,4,5-CH), 8.90 (1H, d, J=6 Hz, Py-6-CH). No significant change was observed in the spectrum of **18** in DMSO-d_6 after 1 week, indicating that the aminimide ligand was not displaced by the solvent. The reactions of **8** with disodium tetrachloropalladate(II) in ethanol and with dichloro(1,5-cyclooctadiene)-palladium(II) in acetone also gave **18** in almost quantitative yields.

Dichloro(N-trimethylammoniopicolinamidate)platinum(II) (19): A solution of 0.289 g (1.61 mmol) of **8** in 5 ml of water was added at room temperature to a solution of dipotassium tetrachloroplatinate(II) (0.666 g, 1.60 mmol) in 10 ml of water. After 6 h reaction, the precipitate was separated, washed with water, and dried *in vacuo*; yield 49%.

Dichlorobis(N-trimethylammoniobenzamidate)palladium(II) (20) and Dichlorobis(N-trimethylammonioacetamidate)palladium(II) (21): These complexes were prepared by the reactions of disodium tetrachloropalladate(II) with two equivalents of the aminimides **9** and **11** in ethanol. Yields were 95 and 73%, respectively.

Bis(2',2'-dimethyl-1'-picolinoyl-1'-hydrazino)palladium(II) (22): A solution of 0.712 g (4.31 mmol) of **13** and 0.172 g (4.31 mmol) of sodium hydroxide in 8 ml of ethanol was added dropwise to a solution of disodium tetrachloropalladate(II) (0.635 g, 2.16 mmol) in 30 ml of ethanol. After 2 h reaction

at room temperature, the precipitate was separated by filtration, the filtrate was concentrated, and the solution was poured into 200 ml of water. After standing in a refrigerator overnight, the yellow crystal was filtered and dried *in vacuo*. Yield 83%. NMR ($CDCl_3$) δ=2.97 (6H, s, CH_3), 7.40—7.65 (1H, m, Py-4-CH), 8.02 (2H, d, J=4 Hz, Py-3- and -5-CH), 9.84 (1H, d, J=5 Hz, Py-6-CH).

Reactions of Pd (II) Complexes with Triphenylphosphine. A mixture of 0.228 g (0.591 mmol) of **14** and equimolar amount of triphenylphosphine in 15 ml of acetonitrile was refluxed for 4 h. The precipitate was separated by filtration and it was found to be a mixture of **14** and dichlorobis(triphenylphosphine)palladium(II) (**23**). The reaction of **18** with triphenylphosphine was also carried out in a similar way, and **23** was isolated in 40% yield. In the case of bis-sulfilimine complexes, **16a** and **17**, monosubstituted complexes, $PdCl_2[(CH_2)_4S{=}NC{-}OC_6H_5](PPh_3)$ (**24**) and $PdCl_2[(CH_2)_4S{=}NCOCH_3](PPh_3)$ (**25**) were obtained as orange precipitates by cooling the reaction mixtures in 76 and 60% yields, respectively.

pK_a Measurement of Aminosulfonium and Aminoammonium Chlorides. pK_a values of the salts **5** and **7** were reported in a previous paper,[16] and those of **10** and **12** were measure by a similar method.

The Consitution of $NaPO_3$-GeO_2 Melts

Makoto WATANABE, Masao ITO, Shoji SATO, and Tamotsu YAMADA

Department of Industrial Chemistry, Chubu Institute of Technology, Matsumoto-cho, Kasugai-shi, Aichi 487

(Received June 13, 1977)

The glassy and crystalline thermal products were prepared by heating a mixture of sodium phosphate glass and germanium dioxide with P/Ge ratios of 1.0—300 at 1000 °C for 3 h in a platinum crucible, and by then rapidly quenching the resulting melt. The thermal products with P/Ge ratios larger than 50 were glassy. The products with P/Ge ratios smaller than 30 were a mixture of glassy and crystalline substances, and the quantity of the glassy substance in the mixture increased with an increase in the P/Ge ratio. The crystalline substance was insoluble in water. From the results of the distribution and the average chain length of the condensed phosphates present in the glassy thermal products, it was concluded that the glass has P–O–Ge linkages and that the most reasonable chemical structure of the glass is $Ge\text{-}(\text{-}O\text{-}\underset{\underset{|}{O}}{P}\text{-})_4$. The colorimetric determination of the phosphorus and germanium contained in the crystalline thermal product showed that the P/Ge ratio of the crystalline substance is 1.3. The value of the P/Ge ratio corresponds to that of $Ge_3(PO_4)_4$.

Studies of the reaction of phosphate glass with the oxides or oxoacid salts of some elements other than phosphorus at moderately high temperatures have been carried out by several research workers. The systems studied were arsenate–phosphates,[1] silicate–phosphates,[2] vanadate–phosphates,[3] and borate–phosphates.[4,5] It was found, as a result, that the thermal products of these systems have P–O–As, P–O–Si, P–O–V, and P–O–B linkages respectively. The authors also studied the constitution of thermal products in the systems of antimonate–phosphates,[6–8] molybdate–phosphates,[9] tungstate–Phosphates,[9] aluminate–phosphates,[10] and chromate–phosphates.[11] It was concluded that they have P–O–Sb, P–O–Mo, P–O–W, P–O–Al, and P–O–Cr linkages respectively. In the present work, the glassy and crystalline thermal products in the system of $NaPO_3$–GeO_2 were investigated to obtain some information concerning the reactivity of $NaPO_3$ glass with germanium dioxide at a moderately high temperature and the structures of the thermal products.

Experimental

Preparation of the Thermal Products. A mixture of sodium phosphate glass (Graham's salt) and germanium dioxide with P/Ge ratios from 1.0 to 300 was heated in a platinum crucible at 1000 °C for 3 h. The resulting melts were quenched rapidly by placing the crucible in ice water. Sodium phosphate glass was made by heating sodium dihydrogenorthophosphate in a platinum crucible at 1000 °C for 3 h and by then quenching the melt by the same method described above.

The Solubility of the Products. About two grams of the thermal products were stirred in about 100 ml of water for 30 min at room temperature. The water-insoluble parts were then filtered off, dried, and weighed.

Paper Chromatography. The compositions of the phosphate species contained in the water-soluble part of the thermal product were determined by using one-dimensional paper chromatography. Acidic and basic developing solvents were used to separate chain phosphates (ortho-, pyro-, tri-, and high-polyphosphates) and small-ring phosphates (*cyclo*-tri- and *cyclo*-tetraphosphates) respectively.[12] About 5 μl of the mother liquor obtained by the measurement of the solubility of the thermal product was spotted onto a Toyo No. 51A filter paper (2 by 50 cm). The development was achieved at 5 °C for about 50 h. Then the filter paper was heated at 75 °C for more than 30 min in an air bath and a perchloric acid–molybdate solution was sprayed on. After drying, the paper was exposed to ultraviolet rays until blue spots appeared. The identification of each spots on the chromatograms was done by referring the spots to those of known phosphates. When the acidic developing solvent was used, the germanate ions contained in the water-soluble part of the thermal product were separated from the phosphate ions.

Colorimetric Measurement of Phosphates. Phosphates contained in the paper chromatograms were extracted with 0.1 M aqueous ammonia and determined colorimetrically by the method described in a previous paper.[6]

The Determination of the Phosphorus and Germanium Present in the Water-insoluble Thermal Product. About 0.5 g of the water-insoluble part of the thermal product was mixed with about 1.0 g of sodium carbonate, and the mixture was heated at 1000 °C for 1 h in a platinum crucible. The resulting melt was cooled rapidly in a desiccator and dissolved in 50 ml of water. About 5 μl of the sample solution was placed on a Toyo No. 51A filter paper (2 by 50 cm) and developed at room temperature for 2 days by using the acidic solvent described above. The paper was dried and sprayed a perchloric acid–molybdate solution. Then the paper was dried again and exposed to ultraviolet rays until blue spots appeared. The blue spots of phosphate and germanate were cut at the demarcation line and soaked in 10 ml of 0.1 M aqueous ammonia for 1 h. The determination of the phosphorus present in the extracting solution was made by the same method as that of a previous paper.[6] The germanium present in the extracting solution was determined colorimetrically (phenylfluorone method).

X-Ray Diffractometry. The samples were ground with an agate mortar until they could pass through a 150-mesh screen. Their X-ray diffraction diagrams were recorded on a Toshiba X-ray diffractometer, ADG-102, by means of a powder method.

Infrared Spectral Measurement. The IR spectra of the thermal products were measured with a JASCO infrared spectrophotometer, model IR-G, by using a KBr tablet method.

The Average Chain Length of Phosphates. The average chain length of phosphates present in the glassy thermal products was measured by the pH-titration method.[13,14] The effect of a germanate ion on the titration was nagligibly small.

Results and Discussion

Solubility and X-Ray Diffraction Diagrams of the Thermal Products. Table 1 shows the amount (%) of the

TABLE 1. AMOUNT OF WATER-SOLUBLE PARTS OF THE PRODUCTS AND IDENTIFICATION OF THE CRYSTALLINE PRODUCTS BY X-RAY DIFFRACTOMETRY

P/Ge	X-Ray diffraction	Water-soluble parts (%)
1.0	GeO_2, $Ge_3(PO_4)_4$	69
2.0—30	$Ge_3(PO_4)_4$	83—99
50—300	Glassy	100

water-soluble part of the thermal product and the results of the identification of crystalline thermal products by means of their X-ray diffraction patterns. The amount of the water-soluble part increased with an increase in the P/Ge ratio. The thermal products with P/Ge ratios larger than 50 were completely dissolved in water. The thermal products with P/Ge ratios from 1.0 to 30 contained crystalline substances. By referring the X-ray diffraction diagrams of the thermal products to those of ASTM cards, it was found that the thermal product with the P/Ge ratio of 1.0 contains germanium dioxide and an unknown crystalline substance, while those with the P/Ge ratios from 2.0 to 30 contain only an unknown crystalline substance. The intensity of the diffraction peaks of the products decreased with an increase in the P/Ge ratio, and the thermal products with P/Ge ratios of 20 and 30 showed only one or two weak peeks. The unknown crystalline substance was insoluble in water. According to the quantitative analysis of the phosphorus and germanium contained in the unknown crystalline substance, the P/Ge ratio of the crystal was 1.3. This value corresponds to the P/Ge ratio of germanium orthophosphate, $Ge_3(PO_4)_4$. This crystalline substance can be made by the method to be described below. The pH of an aqueous solution of sodium dihydrogenorthophosphate (30%) was adjusted to 5—7 with aqueous ammonia or aqueous sodium hydroxide, and then, under vigorous stirring, about 5 g of germanium tetrachloride was added to about 50 ml of the orthophosphate solution. The resulting precipitate was filtered off and heated at 1000 °C for 3 h in a platinum crucible. This substance gave the same X-ray diffraction diagram and P/Ge ratio as those of the unknown crystalline thermal product. Therefore, the crystalline substance may be germanium orthophosphate, $Ge_3(PO_4)_4$. The X-ray diffraction pattern of the crystalline substance is shown in Fig. 1.

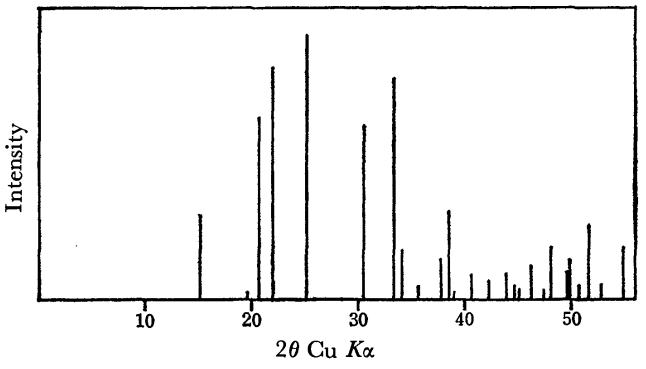

Fig. 1. X-Ray diffraction diagram of $Ge_3(PO_4)_4$.

TABLE 2. DISTRIBUTION OF PHOSPHATES OF WATER-SOLUBLE PARTS IN THE PRODUCTS

P/Ge	Ortho	Pyro	Tri	*cyclo*-Tri	*cyclo*-Tetra	Higher
1.0	42.3	45.1	9.4			3.2
2.0	44.1	45.8	7.1			3.0
3.0	19.3	61.3	10.9			8.4
5.0	3.1	47.2	3.6	2.4		43.7
7.0	1.4	30.4	6.8	2.2	1.1	58.1
10	0.4	17.8	5.0	2.8	2.1	71.9
15	0.9	11.8	3.4	3.3	2.5	78.1

100		0.8	0.9	3.6	2.4	92.3
150		0.8	0.8	3.9	3.3	91.2
200		0.4	0.4	4.2	2.7	92.3
300		0.1	0.1	4.5	2.9	92.4

Distribution of Phosphates. The results of the colorimetric determination of the phosphates (P%) contained in the water-soluble thermal products with P/Ge ratios from 1.0 to 300 are listed in Table 2. The orthophosphate content decreases with an increase in the P/Ge ratio. The pyro- and triphosphate contents show the largest value at the P/Ge ratio of 3.0 and decrease with an increase in the P/Ge ratio from 3.0 to 300. *cyclo*-Tri- and *cyclo*-tetraphosphates were usually not contained in the thermal products with P/Ge ratios of 1.0—3.0 and 1.0—5.0 respectively; if they were present, the contents of those phosphates amounted to a small percentage. The quantity of long-chain phosphates increased with an increase in the P/Ge ratio. The spot of germanate ion also appeared on the chromatograms of the sample solutions of P/Ge ratios from 1.0 to 300. The R_f value of a germanate ion was 0.50. Accordingly, the reaction of germanium dioxide with sodium phosphate glass at 1000 °C produces germanium orthophosphate and a glassy substance. In the glassy product, it could be concluded that germanium dioxide is a network-former and makes a P–O–Ge linkage. The P–O–Ge linkage may be readily hydrolyzed in a water solution to form phosphate and germanate ions, because the chain length of the phosphates contained in glassy products increases with an increase in the P/Ge ratio.

Average Chain Length of Phosphates and the Chemical Structure of Glassy Products. As is shown in Fig. 2, the average chain length of the polyphosphates of glassy products increased with an increase in the P/Ge ratio. The result is in good accordance with that of distribution of phosphates. Therefore, it can be said that the result also supports the presence of a P–O–Ge linkage in glassy products and the rapid hydrolysis of the P–O–Ge linkage in a water solution. According to the method described in previous papers,[2,6–11] the chemical structure of the glassy thermal products can be discussed by examining the relation between the average chain length of polyphosphates contained in the glassy products and the P/Ge ratio. The average chain length, $\bar{n}$, of the polyphosphates in the glass of the $NaPO_3$–GeO_2

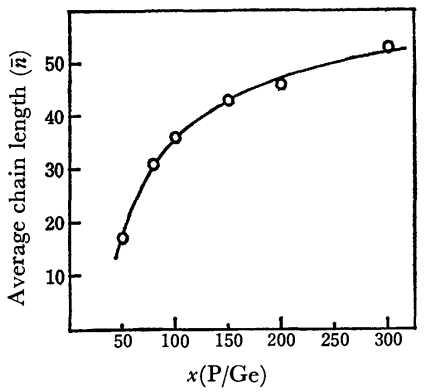

Fig. 2. Variation of average chain length of polyphosphates in the glassy thermal products with P/Ge ratios larger than 50.

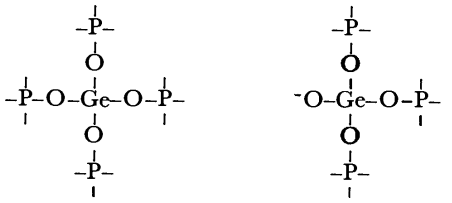
system is given by the following equation:

$$(\bar{n}+2)/\bar{n} = (x+y-z+fx)/x, \quad (1)$$

where x, y, and z stand for, respectively, the number of phosphorus atoms, the P–O–Ge linkages, and the Ge–O^- linkages per atom of germanium and where f is the factor shortning the chain length of the polyphos phates, given with respect to an atom of phosphorus. The f value of sodium phosphate glass was given by the following equation:

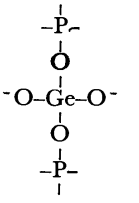
$$(\bar{n}+2)/\bar{n} = (1+f)/1. \quad (2)$$

Since the average chain length of sodium phosphate glass was 77 under the experimental conditions employed, the f value is 0.026. These four chemical structures with P–O–Ge and Ge–O^- linkages may be considered:

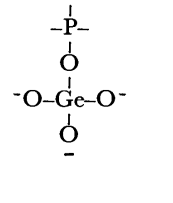


Structure A

Structure B



Structure C



Structure D

For each chemical structure, one can calculate the average chain length of polyphosphates present in the glass of this system by using Eq. 1. The measured and calculated average chain lengths of polyphosphates contained in the glassy products are listed in Table 3. The most reasonable chemical structure of the glassy product is Structure A, because the measured $\bar{n}$ value agrees well with the calculated one throughout the P/Ge range of 50—300.

Infrared Spectral Measurement. The infrared spectra of the starting materials and the thermal products are shown in Fig. 3. The infrared spectra of the thermal products with P/Ge ratios larger than 20 are not shown because the spectra are the same as that of sodium phosphate glass. As the P/Ge ratio becomes larger, the infrared spectrum of the thermal product gradually becomes similar to that of sodium phosphate glass. The infrared spectra of the thermal products with P/Ge

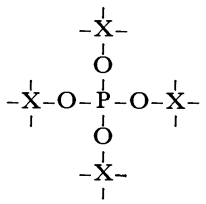
ratios of 1.0—5.0 show absorptions (1110, 1070, and 680 cm^{-1}) attributable to germanium orthophosphate (water-insoluble part of thermal products); the absorptions are ambiguous because, as is shown in Table 1, the quantity of the water-insoluble part of the thermal products with P/Ge ratios of 1.0—5.0 is small. According to Corbridge and Lowe,[15] the absorption of sodium phosphate glass at 1270 cm^{-1} is due to P=O stretching. This absorption of thermal products gradually shifts to a lower wave number as the P/Ge ratio changes to a smaller value. It could be considered that the shift is caused by the decrease in the P=O bond strength. This could be explained as the P=O bond in sodium phosphate glass being transferred to the P⋯O⋯Ge bond by the coordination of a germanium atom. Therefore, it could be concluded that the glassy product has a four-way branching as follows:



where X stands for phosphorus or germanium. This phenomenon was also observed in the infrared spectra of the thermal products of the $NaPO_3$–Al_2O_3 system.[10]

The Disproportionation Constants of Mercury(I) in Dilute Solutions

Isao SANEMASA and Tsutomu HIRATA

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami-machi, Kumamoto 860

(Received July 5, 1977)

The disproportionation constants for the $Hg_2^{2+} \rightleftarrows Hg(aq) + Hg^{2+}$ reaction have been measured in dilute mercury(I) perchlorate solutions over the temperature range from 15 to 30 °C. The technique was based on a simple kinetic method which made use of a characteristic property of the elemental mercury in aqueous solutions. The disproportionation constant at 25 °C and $\mu=0.1$ was found to be $1.1\pm0.1\times10^{-8}$ M, and the associated thermodynamic parameters were $\Delta H=13.2\pm0.2$ kcal/mol and $\Delta S=8.0\pm0.8$ e.u. The reliability of the method was discussed with relation to the reported values in the literature.

It is widely accepted that mercury(I) ions in aqueous solutions exist in the dimeric form and are in equilibrium with dissolved mercury atoms and mercury(II) ions, and that the equilibrium is rapidly established:[1,2]

$$Hg_2^{2+} \rightleftarrows Hg(aq) + Hg^{2+}. \quad (1)$$

The equilibrium constant, K_d, can be expressed by $K_d=[Hg^{2+}]f_2\cdot[Hg(aq)]f_0/[Hg_2^{2+}]f_1$, where the brackets indicate molarities and where the f values are activty coefficients for the corresponding species. It has been common practice to assume that $f_0=1$ and that $f_2=f_1$, an approximation which is reasonable at low ionic strengths. Therefore, the equilibrium constant can be expressed more conveniently by

$$K_d = [Hg^{2+}][Hg(aq)]/[Hg_2^{2+}]. \quad (2)$$

Kinetic and thermodynamic studies of the reactions concerned with mercury(I) require accurate knowledge of the disproportionation constant.[2-7] Potentiometric studies of $[Hg^{2+}]/[Hg_2^{2+}]$ ratios have been reported in the literature by many investigators.[8-11] However, there have been few studies of the equilibrium constant involving the [Hg(aq)] term, K_d. The first and the only attempt to determine the K_d was made by Moser and Voigt.[12] They made use of the extraction of free mercury into non-polar solvents to measure the extent of the disproportionation of mercury(I) and estimated K_d by using the solubilities of Hg^0 in an aqueous solution and organic solvents. The technique they used was, however, troublesome, and their data were limited to those at 25 °C.

This paper will describe a simple technique that might allow an estimation of the disproportionation constant of mercury(I) in dilute aqueous solutions. It makes use of the fact that elemental mercury in the aqueous phase is readily carried by an air-stream into the gaseous phase:

$$Hg(aq) \xrightarrow{k} Hg(gas), \quad (3)$$

where k is the rate constant associated with the Hg^0 phase-transfer. When a nitrogen gas is made to flow through a solution containing Hg_2^{2+}, the dispropotionation of mercury(I) may occur according to Reaction 1. Considering Process 3 to be a rate-controlling step, the rate of the disproportionation of mercury(I) can be expressed by:

$$-d[Hg_2^{2+}]/dt = kK_d[Hg_2^{2+}]/[Hg^{2+}]. \quad (4)$$

The initial concentration of Hg^{2+} in equilibrium with Hg_2^{2+} is sufficiently low, and $[Hg^{2+}]=[Hg^{2+}]_0+[Hg_2^{2+}]_0-[Hg_2^{2+}]=[Hg^{2+}]_0-[Hg_2^{2+}]$. Then, Eq. 4 becomes, on integration

$$[Hg_2^{2+}]_0 \log [Hg_2^{2+}] - [Hg_2^{2+}]/2.303 = -kK_dt/2.303 + [Hg_2^{2+}]_0 \log [Hg_2^{2+}]_0 - [Hg_2^{2+}]_0/2.303, \quad (5)$$

where the subscript 0 denotes the initial concentration. The rate constant, k, can be determined by a separate experiment. Nitrogen gas is passed through a solution containing a known concentration of elemental mercury, which can be prepared by saturating mercury vapor in an aqueous solution.[13] Then, Reaction 3 proceeds; its rate can be expressed by

$$-d[Hg(aq)]/dt = k[Hg(aq)], \quad (6)$$

which becomes, on integration

$$\log [Hg(aq)] - \log [Hg(aq)]_0 = -kt/2.303. \quad (7)$$

Eqs. 5 and 7 enable us to determine kK_d and k respectively, from which we can determine K_d.

Experimental

Reagents. Doubly distilled water was used throughout this work. All the chemicals were of an analytical reagent grade. The metallic mercury was purified in the usual manner.[13] The sodium perchlorate solutions to maitain a constant ionic strength were obtained by mixing sodium carbonate solutions and perchloric acid. The preparation and standardization of mercury(I) perchlorate solutions were all done in the way described in a previous paper.[3] Saturated solutions of elemental mercury of a constant ionic strength adjusted with $NaClO_4$ were prepared using a mercury-vapor solubility apparatus as has been described in a previous paper,[13] with a modification of its gas-inlet-type adaptor. A fritted disk was employed in place of the inlet glass tube in order to attain equilibrium within a shorter time. As a result of this modification, a time of 10 min was found to be sufficient to attain the solubility equilibrium.

Apparatus and Procedure. Two separate measurements were made: atomic absorption spectrophotometric measurements of elemental mercury, which lead to k values (*Procedure A*), and spectrophotometric measurements of mercury (I), which lead to kK_d values (*Procedure B*). Several Pyrex Erlenmeyer flasks of a 100-ml capacity and of the same size and form were used as reaction vessels in both *Procedures A* and *B*. The reaction vessel was connected at the ground-glass joint to a gas-washing-type adaptor. The adaptor was equipped with a fine tip of a glass tube *ca.* 1 mm i.d., and the front was positioned centrally 1 cm above the bottom of the reaction vessel. The reaction vessel containing the sample solution was immersed in a constant bath thermostated to within 0.05 °C.

Procedure A: A 40-ml portion of a saturated mercury solution was introduced into the reaction vessel. Then, nitrogen gas was immediately dispersed at a constant flow rate through the solution by means of the fine tip. The resulting mercury vapor was carried with the nitrogen stream through a 10-cm-path-length absorption cell with quartz windows, where it was detected by a Hitachi Model 508 atomic absorption spectrophotometer. In order to catch water droplets, an empty trap immersed in an ice-cooled bath was inserted between the reaction vessel and the cell. The absorption peaks of mercury were recorded on a Hitachi Model 108 recorder with a chart speed of 40 mm/min.

Procedure B: A 500-ml mercury(I) perchlorate solution was prepared by diluting a 10^{-3} M mercury(I) stock solution with 0.05 M $HClO_4$ and by adding a suitable volume of a 1 M $NaClO_4$ solution. This solution was then divided into 40-ml portions in separate reaction vessels which had been stoppered until used. Nitrogen gas was then passed through the solution under the same conditions as in *Procedure A*. After a fixed time, the reaction vassel was placed by another one. The solutions were measured by means of a Hitachi Model 181 spectrophotometer at 236.5 nm, and the concentrations of Hg_2^{2+} were determined based on a calibration curve.[14]

Results

Some typical results of atomic absorption monitoring of the elemental mercury carried with nitrogen gas at a constant flow rate are shown in Fig. 1. The ordinate is an arbitrary unit represented by the height on the recorder chart. The total peak area from zero to infinity time corresponds to the initial amount of mercury present in the solution, and is related to $[Hg(aq)]_0$, which can be predicted from the solubility study.[13] Then, we can estimate [Hg(aq)] at any time, t, by subtracting the peak area from zero to time t from the total peak area. As a matter of convenience, the summation of all the individual peak heights read every 1 mm on the abscissa is employed instead of the peak area. The plots of log[Hg(aq)] *vs.* t were found to be linear for at least 3 half-lives, as predicted from

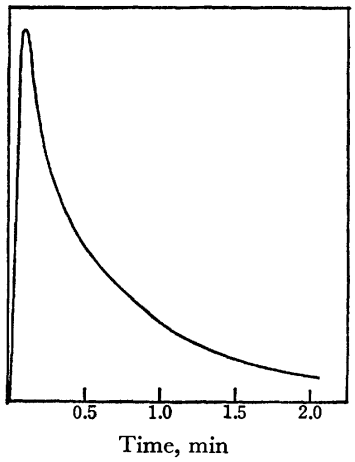

Fig. 1. Typical result of monitoring Hg° by atomic absorption spectrophotometry. The ordinate is an arbitrary unit represented by the recorder chart height. $[Hg(aq)]_0$; 1.75×10^{-7} M, temp; 15 °C, μ; 0.1, N_2 flow rate; 2.0 l/min.

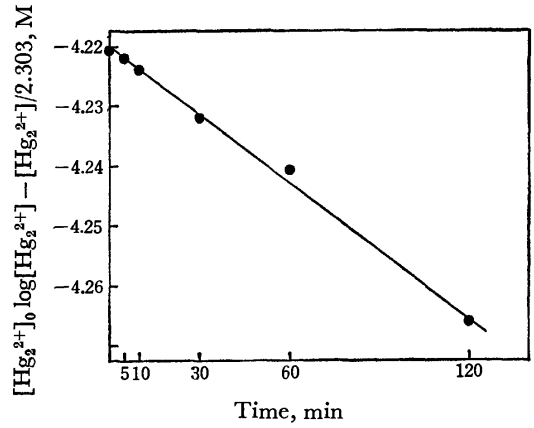

Fig. 3. Plot according to Eq. 5. $[Hg_2^{2+}]_0$; 0.76×10^{-5} M, temp; 15 °C, μ; 0.1, N_2 flow rate; 2.0 l/min.

Eq. 7 in the range of the nitrogen flow rate from 1.5 to 2.5 l/min. A typical result is shown in Fig. 2. From the slope of the straight line, k was obtained. According to Eq. 5, the concentrations of Hg_2^{2+} were plotted against time t. The results are shown in Fig. 3. From the slope of the straight line, we can estimate the kK_d value.

The conditions under which some typical runs were made and their results are given in Table 1. The disproportionation constants of mercury(I) over the temperature range of 15 to 35 °C were determined under such conditions that μ=0.1, nitrogen flow rate= 2.0 l/min, $[Hg_2^{2+}]_0=0.76\times10^{-5}$ M, and $[Hg(aq)]_0$= saturated at each temperature under study. The results are listed in Table 2. The thermodynamic parameters associated with K_d are calculated from Table 2 by the least-squares method, $\Delta H=13.2\pm0.2$ kcal/mol and $\Delta S=8.0\pm0.8$ e.u.

Discussion

The method described here to determine the disproportionation constant of mercury(I) is essentially the

same as those used in the kinetic studies of oxidation reactions of mercury(I) with inorganic oxidants.[5)] According to Sykes and his co-workers,[6,15)] for two-equivalent oxidants with relatively low oxidation potentials, the general rate law is expressed satisfactorily by

$$-d[Hg_2^{2+}]/dt = k_1K_d[Hg_2^{2+}][Oxidant]/[Hg^{2+}]. \quad (8)$$

The mechanism has been explained as involving the following paths:

$$Hg_2^{2+} \overset{K_d}{\rightleftharpoons} Hg(aq) + Hg^{2+}, \text{ fast}$$

$$Hg(aq) + Oxidant(2e^-) \overset{k_1}{\longrightarrow} Hg^{2+}$$

It is usually difficult to determine k_1 independently because of the limited solubility of elemental mercury in an aqueous solution. Therefore, the rate constant of the rate-controlling step, k_1, has been estimated by combining the observed rate constant and the K_d value.[5)] In the present study, Hg(aq), which is in equilibrium with Hg^{2+} and Hg_2^{2+}, was removed from the aqueous phase by the use of an inert gas instead of oxidants. In such a treatment, the reaction system is very much simplified, and, moreover, the rate constant in the rate-controlling step can be determined independently by the use of a highly sensitive atomic-absorption technique. The rate of Hg^0 transfer from the aqueous to the gaseous phase was taken to be the rate-controlling step because the disproportionation equilibrium is rapidly established. In such a heterogeneous system, the rate constant, k, must be a function of the surface area of the gaseous phase in contact with a solution, which depends on many factors, such as the shape of the nitrogen-inducing tube and the reaction vessel, the flow rate of the nitrogen gas, and the size of the sample solutions. However, the k required for the present purpose is not an inherent value, but a relative value sensitive only to the solution temperature. It is absolutely essential to carry out independent determinations of k under the same conditions as the determinations of kK_d. Under the present experimental conditions, N_2 flow rates in the range from 1.5 to 2.5 l/min were suitable for the determinations of k. Deviations from linear plots according to Eq. 7 were observed both at lower and higher flow rates than this range. These deviations are probably because a lower flow rate may result in an insufficient stirring of the aqueous phase, while a higher flow rate may result in the disturbance of a regular stream of the gaseous phase along the path from the reaction vessel and in the measuring cell. The variations in the initial concentrations of Hg_2^{2+}, 1.52×10^{-5} to 0.38×10^{-5} M, and Hg(aq), 3.2×10^{-7} to 1.1×10^{-7} M, have little effect on kK_d and k respectively, as may be seen from Table 1. This appears to support the rate laws expressed by Eqs. 4 and 6.

The present method is very similar to that by Moser and Voigt,[12)] though different experimental approaches are employed, that is, a kinetic and a static method respectively. The latter requires accurate solubility data of elemental mercury in water and organic solvents, while the present kinetic method does not require the absolute values of $[Hg_2^{2+}]$ and [Hg(aq)], since they have no effects on the slopes of the rate plots obtained by means of Eqs. 5 and 7. The K_d value at 25 °C determined in the present study is about two times larger than that reported by Moser and Voigt, 5.5×10^{-9} M. The discrepancy, however, seems to be small when we consider the different experimental approaches employed in the two studies.

The thermodynamic principles underlying the Hg(0)/Hg(I)/Hg(II) equilibria are quite well understood. The equilibrium constant, $K=[Hg^{2+}]/[Hg_2^{2+}]$, can be calculated from the formal potentials of the Hg(I)-Hg(0) and Hg(II)-Hg(I) couples reported in the literature, ranging from 0.006 to 0.012.[7,12,16] The product of K and the mercury solubility, 3.2×10^{-7} M,[13] comes to be from 1.9×10^{-9} to 3.8×10^{-9} M. The potentiometric method may give a reliable K value in the presence of liquid mercury. However, it appears extremely doubtful that the product of K and the mercury solubility should be taken as K_d. The solubility of mercury cited in the literature might be unsuitable for predicting [Hg(aq)] under relatively high mercury(I) concentrations and in the presence of liquid mercury because of the formation of the colloidal mercury.[17] If the colloidal mercury could take part in the disproportionation equilibrium, Reaction 1 should be shifted to the left, leading to a lower apparent K_d. In the studies of reactions concerned with dilute mercury(I) ions in which mercury atoms are present in equilibrium with Hg_2^{2+} and Hg^{2+} and are not in excess, the K_d value should be adopted as the equilibrium constant.

Schwarzenbach and Anderegg have reported that, for the $Hg(l)+Hg^{2+}\rightleftharpoons Hg_2^{2+}$ reaction, $\Delta H^\circ=-0.820$ kcal/mol, $\Delta S^\circ=6.0$ e.u., and $\Delta G^\circ=-2.62$ kcal/mol.[10] In the present study, $\Delta H^\circ=13.2$ kcal/mol, $\Delta S^\circ=8.0$ e.u., and $\Delta G^\circ=10.8$ kcal/mol were obtained for the $Hg_2^{2+}\rightleftharpoons Hg(aq)+Hg^{2+}$ reaction. When these two reactions are compared, it follows that $\Delta G^\circ=8.19$ kcal/mol for the $Hg(l)\rightleftharpoons Hg(aq)$ equilibrium. A termodynamic datum for this equilibrium has been published: $\Delta G^\circ=9.4$ kcal/mol.[18] The discrepancy between these two values may be partly due to the experimental errors.

In his spectrophotometric study Higginson suggested a homolytic dissociation, $Hg_2^{2+}\rightleftharpoons 2\,Hg^+$, in dilute mercury(I) solutions and reported a value of $k_{diss}=[Hg^+]^2/[Hg_2^{2+}]$ within the limits of 10^{-8} and 10^{-6} M.[14] However, such a dissociation constant was not taken into consideration in the present work for the following reasons, as suggested by other investigators: (1) a deviation from Beer's law in dilute mercury(I) solutions was not observed by another investigator;[19] (2) a K_{diss} value as large as 10^{-7} M is shown by the extraction technique to be highly unlikely[12] and (3) the evidence for a contribution from $[Hg_2^{2+}]^{1/2}$ instead of $[Hg_2^{2+}]$ has not been observed in kinetic studies of the reactions in which mercury(I) ions are concerned.[6]

The authors wish to express their thanks to Professor Hideo Nagai and Dr. Toshio Deguchi of Kumamoto University for their encouragement and discussions. They also wish to thank Dr. Kenzo Kitayama of the Tokyo Institute of Technology for his helpful discussions on the thermodynamic interpretation.

Synthesis and Properties of Cobalt(II), Nickel(II), and Copper(II) Complexes with Acetaldehyde Oxime and Benzaldehyde Oxime

Hideaki TANAKA, Hiro KUMA, and Shoichiro YAMADA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received July 20, 1977)

Cobalt(II), nickel(II), and copper(II) complexes with acetaldehyde oxime and benzaldehyde oxime have been prepared and characterized by vibrational and electronic spectroscopy, magnetism, and other methods. The cobalt(II) and nickel(II) complexes isolated are of the general formulae: (A) $MX_2(oxime)_4$ (X=Cl, Br, I, NO_3, NCS and CH_3COO); (B) $M(NCS)_2(oxime)_2$; (C) $MSO_4(oxime)_3 \cdot 3H_2O$. They are all six-coordinate, and the complexes (B) are probably multinuclear. Copper(II) forms complexes of the formulae: (A) $CuX_2(oxime)_4$ (X=Cl, Br), (B) $CuX_2(oxime)_2$ (X=Cl, Br, NCS); (C) $CuSO_4(oxime)_4 \cdot H_2O$. Possible structures for these copper(II) complexes are also discussed. Acetaldehyde oxime and benzaldehyde oxime are unidentates in all these complexes, being coordinated through their nitrogen atom.

Some complexes of cobalt, nickel, and copper with acetaldehyde oxime and benzaldehyde oxime were prepared fifty years ago.[1] However, little work has been done on the more detailed examination of their stereochemistries based upon physicochemical measurements.[2,3] Such studies are thought to be highly desirable in order to elucidate the nature of interaction between the oximes and transition metal ions.

In the present work cobalt(II), nickel(II), and copper(II) complexes with acetaldehyde oxime and benzaldehyde oxime, including previously reported ones, have been synthesized and their stereochemistries have been examined on the basis of vibrational and electronic spectra, magnetism, conductivities, and powder X-ray diffraction patterns. Acetaldehyde oxime and benzaldehyde oxime are abbreviated in the present paper as acox and bzox, respectively.

Experimental

Materials. Acetaldehyde oxime and benzaldehyde oxime were obtained commercially and used as received.

Analytical data of the metal complexes prepared in the present work are given in Tables 1 and 2.

Dichloro- and Dibromotetrakis(acetaldehyde oxime)nickel(II), $NiX_2(acox)_4$ (X=Cl, Br) were prepared as reported previously.[1]

Diiodotetrakis(acetaldehyde oxime)nickel(II) Hydrate, $NiI_2(acox)_4 \cdot H_2O$. A suspension of $NiI_2 \cdot 6H_2O$ (0.01 mol) in chloroform (50 ml) was heated under stirring at 40 °C for 15 min and acetaldehyde oxime (0.04 mol) was added to the suspension. The mixture was heated at 40 °C for 1 h and filtered. The filtrate was concentrated to 10 ml with a rotary evaporator at 40 °C and allowed to stand in a refrigerator overnight. A crystalline precipitate was collected by filtration and recrystallized from chloroform to yield olive-green, prismatic crystals.

TABLE 1. ANALYTICAL DATA OF NICKEL(II) AND COBALT(II) COMPLEXES WITH ACETALDEHYDE OXIME AND BENZALDEHYDE OXIME

Compound	Found, %			Calcd, %			μ
	C	H	N	C	H	N

Dinitratotetrakis(acetaldehyde oxime)nickel(II) Hydrate, $Ni(NO_3)_2(acex)_4 \cdot H_2O$, was prepared from $Ni(NO_3)_2 \cdot 6H_2O$ (0.01 mol) and acetaldehyde oxime (0.04 mol) in a manner analogous to the diiodo-complex.

$Ni(NCS)_2(acox)_4$ and $Ni(NCS)_2(acox)_2$. A suspension of $Ni(NCS)_2$ (0.01 mol) in ethanol (50 ml) was heated at 60 °C under stirring for 2 h, until the solution turned green, and filtered. To the filtrate was added acetaldehyde oxime (0.04 mol) and stirred for 1 h at room temperature. On evaporating the solution spontaneously, blue crystals of $Ni(NCS)_2(acox)_4$ appeared in the solution. They were collected by filtration and washed with ethanol. The filtrate was heated for 2 h at room temperature. A crystalline powder of $Ni(NCS)_2(acox)_2$ formed in the solution was filtered, washed with ethanol, and dried in a desiccator over silica gel.

$NiSO_4(acox)_3 \cdot 3H_2O$ was prepared as blue microcrystals from $NiSO_4 \cdot 7H_2O$ (0.01 mol) and acetaldehyde oxime (0.04 mol) in a manner analogous to the dinitrato-complex.

Dichloro- and Dibromotetrakis(benzaldehyde oxime)nickel(II), $NiX_2(bzox)_4$ (X=Cl, Br), were prepared by the literature method.[1]

Diiodotetrakis(benzaldehyde oxime)nickel(II) Hydrate, $NiI_2(bzox)_4 \cdot H_2O$, was prepared as olive-green crystals in a manner similar to the corresponding acetaldehyde oxime complex.

Dihalogenotetrakis(acetaldehyde oxime)- and Dihalogenotetrakis(benzaldehyde oxime)cobalt(II), $CoX_2(acox)_4$ and $CoX_2(bzox)_4$ (X=Cl, Br), were prepared as reported previously.[1]

$Co(NCS)_2(acox)_2$. To a suspension of $Co(NCS)_2 \cdot 4H_2O$ (0.01 mol) in chloroform (50 ml) was added acetaldehyde oxime (0.04 mol) at 60 °C, and the mixture was refluxed for 2 h. A pink crystalline precipitate was filtered and washed with chloroform several times.

$Co(NCS)_2(bzox)_2$ was prepared as red-brown crystals in a manner analogous to the corresponding complex with benzaldehyde oxime.

$CoSO_4(acox)_3 \cdot 3H_2O$ was prepared as wine-red crystals from $CoSO_4 \cdot 7H_2O$ (0.01 mol) and acetaldehyde oxime (0.04 mol) in a manner analogous to the corresponding nickel(II) complex.

$CuCl_2(acox)_2$. To a solution of $CuCl_2 \cdot 2H_2O$ (0.015 mol) in ethanol (50 ml) was added acetaldehyde oxime (0.02 mol), and the solution was stirred at room temperature for 3 h. Light-blue flaky crystals of $CuCl_2(acox)_2$ formed in the solution were filtered and washed with ether. The *filtrate* was used for preparing $CuCl_2(acox)_4$. The crystals thus obtained are highly hygroscopic. When left in a desiccator over silica gel for a long time, the blue form of $CuCl_2(acox)_2$ transformed into a green substance of the same composition.

Dichlorotetrakis(acetaldehyde oxime)copper(II), $CuCl_2(acox)_4$. Acetaldehyde oxime (0.05 mol) was added to the *filtrate* obtained in the preparation of $CuCl_2(acox)_2$. Stirring the solution at room temperature for 15 min yielded blue prismatic crystals. They are hygroscopic and are readily decomposed even in the solid state. When kept in a desiccator over silica gel, they gradually lose acetaldehyde oxime, turning green. The composition of the green final product was close to $CuCl_2(acox)_2$.

$CuBr_2(acox)_4$ and *$CuBr_2(acox)_2$* were prepared as blue and yellow-green crystals, respectively, by methods similar to the corresponding dichloro-complexes. They are hygroscopic. When left in a desiccator, $CuBr_2(acox)_4$ loses acetaldehyde oxime to yield $CuBr_2(acox)_2$.

$CuCl_2(bzox)_2$ was prepared as yellow-green crystals by the literature method.[1] Purification was carried out by recrystallization from chloroform or acetone.

$CuBr_2(bzox)_2$ was prepared as brown crystals from $CuBr_2$ and benzaldehyde oxime in a manner analogous to the corresponding dichloro-complex.

$CuSO_4(acox)_4 \cdot H_2O$. To a suspension of $CuSO_4 \cdot 5H_2O$ (0.01 mol) in chloroform was added acetaldehyde oxime (0.06 mol), and the mixture was stirred at room temperature for a few hours. The precipitate was recrystallized from chloroform to yield a blue crystalline powder.

Measurements. Electronic absorption spectra of the complexes in solution and in Nujol were recorded on a Shimadzu MPS-50L spectrophotometer. Infrared spectra were measured as Nujol mulls on a Hitachi EPI-S2 infrared spectrophotometer and a Hitachi 215 infrared spectrophotometer.

Magnetic measurements at room temperature were carried out by the Gouy method using $CoHg(SCN)_4$ as a calibrant.

Powder X-ray diffraction patterns were obtained with a Toshiba DX-103 X-ray diffractometer equipped with a Geiger-Müller counter, using Co $K\alpha$ radiation and an iron filter.

Conductivity measurements were carried out using a calibrated Toa-Electronics CG 201 PL conductivity cell and a Toa-Electronics Model CM-1DB conductivity bridge.

Results and Discussion

Nickel(II) Complexes. The following types of nickel(II) complexes were isolated, L being acox or bzox: (1) NiX_2L_4 (X=Cl, Br, I, NO_3, CH_3COO); (2) $Ni(NCS)_2L_2$; (3) $NiSO_4(acox)_3 \cdot 3H_2O$. All these nickel(II) complexes are paramagnetic with magnetic moments of 3.0—3.2 BM (Table 1). The dichloro- and dibromo-nickel(II) complexes were reported previously by Hieber and Leutert.[1]

All the dihalogeno-complexes are non-electrolytes in nitrobenzene, indicating that the halide ions are bound to the nickel(II) ion. According to a previous X-ray

study,[3] $NiCl_2(acox)_4$ in the crystalline state has a six-coordinate *trans*-dichloro-structure. The acetaldehyde oxime molecules are coordinated to the nickel(II) ion through their nitrogen atom, and the OH group is hydrogen-bonded to Cl. It is presumed that $NiX_2(acox)_4$ (X=Br, I) and $NiX_2(bzox)_4$ (X=Cl, Br, I) also have a six-coordinate *trans*-dihalogeno-structure, since their electronic absorption spectra are similar to that of *trans*-$NiCl_2(acox)_4$. They all show a significantly large tetragonal splitting in the d-d bands. This *trans*-structure is retained in chloroform, since the spectra of the chloroform solutions are essentially the same as the solid state spectra. On the contrary, they undergo decomposition in water, methanol, and ethanol. For instance, the spectra of the ethanolic solutions differ appreciably from the spectra of the chloroform solutions as well as from the solid state spectra.

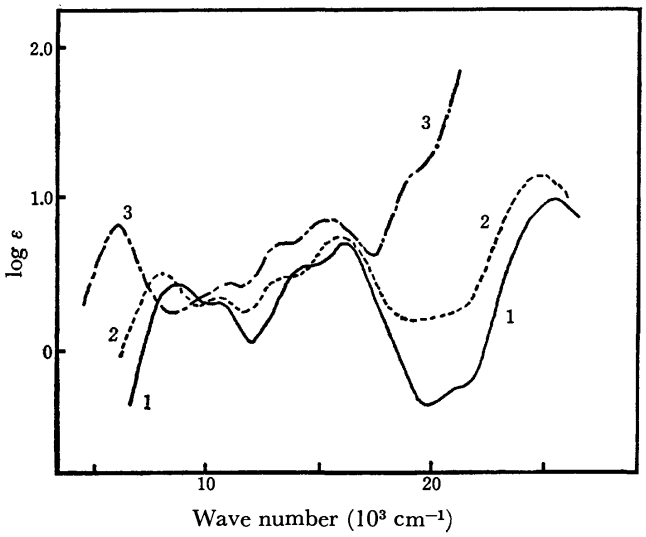

Fig. 1. Electronic absorption spectra of *trans*-dihalogeno-tetrakis(acetaldehyde oxime)nickel(II), *trans*-$NiX_2(acox)_4$, in chloroform: 1, X=Cl; 2, X=Br; 3, X=I.

As representative examples, the spectra of the acetaldehyde oxime complexes are shown in Fig. 1. It is predicted theoretically that regularly octahedral nickel(II) complexes show three spin-allowed d-d bands, each of which is split into two components as the symmetry of the complexes changes from O_h to D_{4h}. If the splitting is considerably large, the components are likely to be well resolved in the observed spectrum. The band splitting in the spectra of the present dihalogeno-complexes is large enough to enable us to resolve the three main d-d bands into their components with reasonable accuracy. The maxima of the components obtained are shown in Table 3. From these data and using expressions derived on the basis of the crystal field approximation,[4] the tetragonal splitting parameters were estimated. The results are shown in Table 3. For *trans*-$NiCl_2(acox)_4$ a similar analysis was made previously using solid state spectrum.[2] The results roughly agree with the present ones. Comparison of the present results with previous studies[4a] on $NiX_2(py)_4$, py being pyridine, gives the following order as to the in-plane crystal field parameter: bzox<acox<py. It is thus found that bzox and acox are close to, though slightly lower than, py in the spectrochemical series.

Table 3. Split components of d-d bands and crystal field parameters in 10^3 cm^{-1} of *trans*-NiX_2L_4

	L=acox (=bzox)

Ds	0.30 (0.48	0.51 0.46	0.66 0.55)

In $Ni(NO_3)_2(acox)_4$ the nitrate ions are not free but coordinated to the nickel(II) ion, since infared bands due to the nitrate ions occur at 1290, and 1495 cm^{-1}.[5] The complex is paramagnetic and its electronic spectrum is typical of the six-coordinate nickel(II) complex (Table 4). The broad d-d bands at about 10 and 17×10^3 cm^{-1} have a shoulder at higher frequencies in the former band and at lower frequencies in the latter, indicating

Table 4. Maxima of main d-d absorption bands of nickel(II) complexes with acetaldehyde oxime and benzaldehyde oxime

$Ni(NCS)_2(bzox)_2$	Nujol	8.5, 10.9 sh	16.2	27.1

ν_1 $^3T_{2g} \leftarrow {}^3A_{2g}$; ν_2 $^3T_{1g} \leftarrow {}^3A_{2g}$; ν_3 $^3T_{1g}(P) \leftarrow {}^3A_{2g}$ or components thereof. sh: shoulder.

an apparent band splitting, in agreement with the model of the six-coordinate *trans*-dinitrato-complex.

The complex $Ni(CH_3COO)_2(acox)_4$ exhibits CO stretching vibrations at 1580 and 1340 cm^{-1}, showing that the acetate ions are not free but coordinated to the nickel(II) ion as unidentate ligands.[5] The complex is paramagnetic and shows an electronic absorption spectrum typical of the six-coordinate nickel(II) complex.

In $NiSO_4(acox)_3 \cdot 3H_2O$, the ν_1 stretching vibration due to the sulfate group appears at 993 cm^{-1} and ν_3 is split into three bands at 1040, 1085, and 1200 cm^{-1}. Based on the criteria proposed previously,[5] these results indicate that the sulfate group in this complex is coordinated as a bidentate ligand to the nickel(II) ion. Its electronic spectrum is typical of the six-coordinate nickel(II) complex (Table 4). It is, therefore, most likely that the nickel(II) ion forms a six-coordinate complex with three acetaldehyde oxime molecules, a bidentate sulfate ion and a water molecule coordinated. A multinuclear structure, however, may not be eliminated.

$Ni(NCS)_2(acox)_4$ is paramagnetic with a moment of about 3 BM, indicative of a six-coordinate structure for this complex. Its Nujol spectrum is similar to the spectrum of its chloroform solution, showing that the configuration in the solid state is retained in the chloroform solution. The spectra are typical of the six-coordinate nickel(II) complex, and resemble that of *trans*-$Ni(NCS)_2(NH_3)_4$,[6] although slightly displaced towards lower frequencies. It is highly probable that $Ni(NCS)_2(acox)_4$ has a similar structure to that of *trans*-$Ni(NCS)_2(NH_3)_4$ with the thiocyanate ions coordinated through their nitrogen atom to the nickel(II) ion. Any appreciable splitting was not observed in the d-d bands for $Ni(NCS)_2(NH_3)_4$ and $Ni(NCS)_2(acox)_4$, possibly because the N-coordinating thiocyanate stands comparatively close to acox and NH_3 in the spectrochemical series.

The complex $Ni(NCS)_2(acox)_4$ undergoes decomposition gradually. Infrared bands due to unidentate N-coordinating thiocyanate ions appear at 2090 and 820 cm^{-1}, but in addition to them another band, probably originating from the decomposition product, appears at 2020 cm^{-1}.

The complexes $Ni(NCS)_2L_2$, L being acox and bzox, are paramagnetic (Table 1) and show electronic absorption spectra typical of the six-coordinate nickel(II) complex (Table 4). They show infrared ν(C–N) and ν(C–S) vibrations at 2115 and 780 cm^{-1} for L=acox and at 2130 and 785 cm^{-1} for L=bzox. The values lie in the range expected for the bridging NCS group.[7] It is highly probable that $Ni(NCS)_2L_2$ are multinuclear with six-coordinate nickel(II) ions and bridging NCS ions, having a similar structure to that of $Ni(NCS)_2(py)_2$.[8]

All the nickel(II) complexes show hydrogen bonded OH stretching vibrations at about 3150—3200 cm^{-1}, except for $Ni(NCS)_2(acox)_2$ and $Ni(NCS)_2(bzox)_2$, which show a sharp band at a much higher frequency, indicative of the presence of the non-hydrogen-bonded NOH group (Table 6).

Cobalt(II) Complexes. The following types of cobalt(II) complexes were isolated, L being acox and bzox: (1) CoX_2L_4 (X=Cl, Br); (2) $Co(NCS)_2L_2$; (3) $CoSO_4(acox)_3 \cdot 3H_2O$. The dichloro- and dibromo-complexes were prepared previously.[1]

The complexes $CoX_2(acox)_4$ and $CoX_2(bzox)_4$ are paramagnetic with magnetic moments of 4.9—5.2 BM, which are in the range expected for six-coordinate cobalt(II) complexes. Their electronic absorption spectra (Table 5) are also typical of the six-coordinate cobalt(II) complexes. Conductivity measurements show that they are non-electrolytes in nitrobenzene. It is most likely that in these cobalt(II) complexes the six-coordination of the cobalt(II) ion is achieved by two halide ions and four oximes, which are unidentate ligands coordinating through the nitrogen atom. In agreement with this, their OH stretching vibrations appear at frequencies close to those of the dihalogeno-nickel(II) complexes, which have been concluded to have a *trans*-configuration. The powder X-ray diffraction patterns of the dichloro-cobalt(II) complexes are similar to those of the dibromo-cobalt(II) complexes. When dissolved in chloroform, the dichloro-cobalt(II) complexes retain the structure existing in the solid state, while the dibromo-cobalt(II) complexes tend to undergo decomposition gradually. Both the dichloro- and the dibromo-complexes are decomposed in methanol, ethanol, and water.

In $CoSO_4(acox)_3 \cdot 3H_2O$, the ν_1 stretching vibration due to the sulfate group appears at 940 cm^{-1} and ν_3 is split into three bands at 1030, 1080, and 1190 cm^{-1}. As discussed in the preceding section of the present paper,

ν: cm^{-1}.

these results indicate that the sulfate group in this complex is coordinated as a bidentate ligand to the cobalt(II) ion. Its electronic spectrum (Table 5) is typical of the six-coordinate cobalt(II) complex, and its magnetic moment (5.15 BM) lies in the range expected for the six-coordinate cobalt(II) complex. The powder X-ray diffraction pattern is very similar to that of the corresponding nickel(II) complex, indicating that these cobalt(II) and nickel(II) complexes have a similar structure.

The complexes $Co(NCS)_2L_2$, L being acox and bzox, are paramagnetic with magnetic moments of 4.86 and 4.93 BM, which are in the range expected for the octahedral cobalt(II) complexes. Their electronic absorption spectra are also typical of the six-coordinate cobalt(II) complexes. They show infrared ν(C–N) and ν(C–S) vibrations at 2100 and 785 cm^{-1} for L=acox and at 2110 and 780 cm^{-1} for L=bzox. In the same way as in $Ni(NCS)_2(bzox)_2$, the infrared data indicate that the NCS groups function as bridging ligands. It is thus most likely that the complexes $Co(NCS)_2L_2$ have a similar multinuclear structure to that of $Ni(NCS)_2L_2$. The powder X-ray diffraction patterns of $Co(NCS)_2L_2$ are almost identical with those of $Ni(NCS)_2L_2$. Exactly like the corresponding nickel(II) compounds, they exhibit a sharp OH band at 3450 and 3425 cm^{-1} typical for the NOH group, which is not involved in hydrogen bonding.

The other cobalt(II) complexes show OH stretching vibrations at about 3150—3200 cm^{-1}.

Copper(II) Complexes. The copper(II) complexes obtained are of the following three types, X being Cl and Br: (1) $CuX_2(acox)_4$; (2) $CuX_2(acox)_2$ and $CuX_2(bzox)_2$; (3) $CuSO_4(acox)_4\cdot H_2O$. The complexes $CuCl_2(acox)_2$ and $CuCl_2(bzox)_2$ were prepared previously.[1]

Since $CuCl_2(acox)_4$ shows a powder X-ray diffraction pattern similar to that of *trans*-$NiCl_2(acox)_4$, it also has a six-coordinate *trans*-dichloro-structure, in which the molecules of acox are bound to the copper(II) ion through the nitrogen atom. The electronic absorption spectrum of $CuBr_2(acox)_4$ is very similar to that of $CuCl_2(acox)_4$. Their d-d band maxima lie at almost equal frequencies (Table 7). It is, therefore, very likely that $CuBr_2(acox)_4$ has a structure similar to that of $CuCl_2(acox)_4$, namely a six-coordinate *trans*-dihalogeno-structure.

Table 7. Maxima of main d-d absorption bands and of some infrared bands of copper(II) complexes with acetaldehyde oxime and benzaldehyde oxime

Compound	d-d band, 10^3 cm^{-1}	Infrared bands, cm^{-1}	
		ν(M-X)	ν(M-L)
$CuCl_2(acox)_2$	14.8	296, 235	272
$CuBr_2(acox)_2$	14.8	243, 208	259
$CuCl_2(bzox)_2$	14.3	295, 224	267
$CuBr_2(bzox)_2$	14.2	235, 210	261
$CuCl_2(acox)_4$	16.5	285	272
$CuBr_2(acox)_4$	16.6	238	271
$CuCl_2(py)_2$*	14.5	294, 235	268
$CuBr_2(py)_2$*	14.6	255, 202	269

* Multinuclear. The data are taken from references 9 and 10 in the text.

In view of the results on the corresponding cobalt(II) and nickel(II) complexes, it may be reasonable to assume that acox and bzox are coordinated through their nitrogen atom in the complexes of the types $CuX_2(acox)_2$ and $CuX_2(bzox)_2$. In agreement with this, they show OH-stretching vibrations at about 3150—3200 cm^{-1}, which lie close to those of $MX_2(acox)_4$ and $MX_2(bzox)_4$. Since acox and bzox lie close to pyridine in the spectrochemical series, it may be pertinent to remember previous studies on the copper(II) pyridine complexes of a similar composition. Billing and Underhill[9] examined correlation between electronic spectra and stereochemistries of complexes of the type CuX_2L_2, L being pyridine and its derivatives. They obtained two types of the complexes. The complexes of one type have a multinuclear structure, in which the copper(II) ion is in a six-coordinate, tetragonally distorted pseudo-octahedral environment, showing a broad d-d band with a maximum at $14—15\times10^3$ cm^{-1}. The d-d band maxima vary considerably, depending upon the extent of the tetragonal distortion. The complexes of the other type have a binuclear structure with square-pyramidal coordination about the copper(II) ion with bridging apical chloride ions and basal pyridine or substituted pyridine molecules. The spectra of the latter complexes have a d-d band at $16—19\times10^3$ cm^{-1} with a shoulder at 13.5×10^3 cm^{-1}. The uninuclear square-pyramidal copper(II) complex would show the corresponding d-d band at a higher frequency.

The complexes $CuX_2(acox)_2$ and $CuX_2(bzox)_2$ obtained in the present work show a broad d-d band at about $14.2—14.8\times10^3$ cm^{-1} (Table 7). According to the criteria derived previously,[9] these copper(II) complexes probably have a multinuclear structure similar to that of $CuX_2(py)_2$; $CuCl_2(py)_2$ and $CuBr_2(py)_2$ show a d-d band at about 14.5 and 14.6×10^3 cm^{-1}, respectively.

Their infrared ν(M-X) and ν(M-L) bands also seem to correspond well to those of multinuclear $CuCl_2(py)_2$ and $CuBr_2(py)_2$ (Table 7).[9,10]

When left in a desiccator for a long period, the blue form of $CuCl_2(acox)_2$ transformed into the green form of the same composition. The green form shows almost the same infrared spectrum as that of the blue form of $CuCl_2(acox)_2$ in the range from 200 to 3500 cm^{-1}. The electronic spectrum of the green substance is similar to that of the blue form, although the green form shows a d-d band at a slightly lower frequency than the blue form (Table 7). From the spectral criteria proposed previously,[9] both the two modifications probably have a similar multinuclear structure. The slight difference in the band maximum between the two may arise from the different extent of the tetragonal distortion.

In $CuSO_4(acox)_4 \cdot H_2O$, the ν_3 stretching vibration due to the sulfate group is split into two bands at 1035 and 1195 cm^{-1}, indicating that the sulfate group in this complex is coordinated as a unidentate ligand to the copper(II) ion.[5] The copper(II) ion probably takes five-coordination with four molecules of acetaldehyde oxime and a unidentate sulfate group.

Its electronic absorption spectrum has a broad d-d band with a maximum at 16.5×10^3 cm^{-1}, being in accordance with the five-coordinate structure.[11] A six-coordinate model with a water molecule as an additional ligand may not be eliminated.

The authors are grateful to Professor Masayoshi Obashi for powder X-ray diffraction patterns.

A Relationship between the Circular Dichroism and the Configuration of Asymmetric Nitrogen in *trans*(*N*,Ethylene)-chloro-L-aminocarboxylato-η^2-ethyleneplatinum(II)

Yoshiro TERAI, Hiroaki KIDO, and Kazuo SAITO

Chemistry Department, Faculty of Science, Tohoku University, Aramaki, Aoba, Sendai 980

(Received July 27, 1977)

The circular dichroism (CD) peaks of *trans*(*N*, ethylene)[PtCl(L-am)(C_2H_4)] (L-am, L-amino carboxylate) in acetonitrile (AN) at 33000 and 37000 cm^{-1} are characteristic of those complexes with asymmetric nitrogen. The CD sign depends on the substituents on the asymmetric nitrogen, and the additivity law holds for methyl and benzyl derivatives of L-prolinato, L-hydroxyprolinato, and L-valinato complexes. The quadrant rule is applicable to the contribution of the substituents on the nitrogen. On the preparation of the benzyl-L-valinato complex from Zeise's salt in a weakly acid medium the nitrogen exhibits a marked stereoselectivity to give *R* configuration.

Optical rotatory dispersion (ORD) and circular dichroism (CD) of asymmetric nitrogen on *N*-alkyl-L-amino carboxylate ligand have been mostly studied with cobalt(III) complexes. The absolute configuration of asymmetric nitrogen of $(+)_{589}$-[Co(sar)$(en)_2]^{2+}$ (sar, sarcosinate; en, ethylenediamine) was determined by X-ray diffraction to be *R*.[1] This complex gives a plus CD peak in 20000 to 25000 cm^{-1} region (first d-d transition band region), which was assigned to the asymmetric nitrogen.[2,3] Crystal structure[4] and CD spectra of copper(II) complexes containing asymmetric nitrogen[5,6] were studied but their relationship has not been discussed.

We have extended CD studies of square planar platinum(II) complexes containing amino carboxylates and η^2-olefins,[7] and synthesized various complexes of the type *trans*(*N*, ethylene)[PtCl(L-am)(C_2H_4)], where L-am stands for amino carboxylates having asymmetric nitrogens. This paper deals with the syntheses and the relationship between CD spectra and absolute configurations of the coordinated asymmetric nitrogens.

Experimental

Materials. Ligands: L-Allohydroxyproline (2*S*, 4*S*) (L-ahyp) was prepared from L-hydroxyproline (L-hyp) by the known method.[8,9] *N*-Methyl- and *N*-benzyl derivatives of L-proline (L-pro), L-hydroxyproline, L-valine (L-val), L-phenylalanine (L-phe), and L-alanine (L-ala) were synthesized by known methods.[10,11] Guaranteed grade L-proline, L-hydroxyproline, L-valine, L-phenylalanine, and L-alanine were used without further purification. (The abbreviations in parentheses indicate their deprotonated forms.)

Complexes. *trans*(*N*,Ethylene)-isomers of various [PtCl(L-am)(C_2H_4)] and *cis*(*N*,ethylene)[PtCl(L-pro)(C_2H_4)] were prepared by the reported methods.[7,12] New *trans*(*N*,ethylene) complexes containing L-hyp, L-ahyp, *N*-me-L-hyp, and *N*-bz-L-val were identified by elemental analysis of carbon, hydrogen, and nitrogen, and ultraviolet (UV) absorption spectra.

Measurements. The UV absorption and CD spectra were recorded in acetonitrile (AN) at room temperature with a Hitachi 323 and a JASCO J-40 Spectrophotometer, respectively.

Results and Discussion

CD Pattern. The UV absorption pattern of all the *trans*(*N*, ethylene) complexes is similar to one another and exemplified in Fig. 1A by *trans*(*N*, ethylene)-[PtCl(L-pro)(C_2H_4)]. The CD spectra of *trans*(*N*, ethylene) complexes containing L-pro, L-hyp, and L-

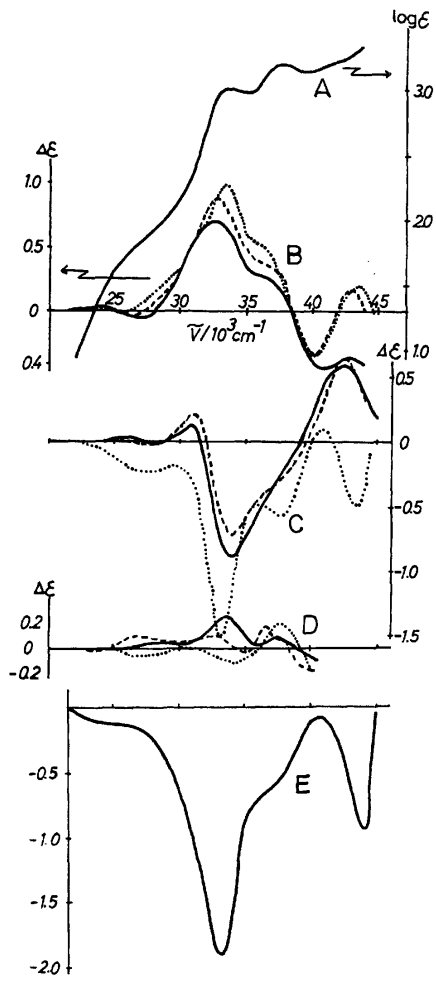

Fig. 1. Ultraviolet absorption and circular dichroism (CD) spectra of *trans*(*N*,ethylene)[PtCl(L-am)(C_2H_4)] in acetonitrile at room temperature. (L-am=L-amino carboxylate).
A: UV absorption of L-prolinato complex.
B: CD of — L-pro, --- L-hyp, and- -- L-ahyp complex.
C: CD of — *N*-me-L-pro, --- *N*-me-L-hyp, and --- *N*-bz-L-pro complex.
D: CD of — L-ala, --- L-phe, and --- L-val complex.
E: CD of *N*-bz-L-val complex.

ahyp have large plus components with $\Delta\varepsilon$ 0.7 to 1.0 in the 33000 cm^{-1} region. (Fig. 1B). In the same region, similar complexes containing substituted L-prolinate, *i.e* *N*-me-L-pro, *N*-me-L-hyp, and *N*-bz-L-pro, have large minus CD peaks with $\Delta\varepsilon$'s -1 to -2. (Fig. 1C). All these complexes have a fixed configuration of the coordinated asymmetric nitrogen. On the other hand, complexes without asymmetric nitrogen, *i.e.* L-ala, L-val, and L-phe complexes fail to show large CD peaks in this region. (Fig. 1D). Hence the characteristics of CD peaks in 33000 cm^{-1} region must depend on the configuration around coordinated asymmetric nitrogen.

These complexes have other absorption peaks in the regions *ca.* 25000, 37000, and 45000 cm^{-1}, and CD peaks are observable in these regions. However, the CD peaks corresponding to the first and the last absorption peak are irregular, and do not seem to be directly related to the coordinated asymmetric nitrogen. The CD peaks in the 37000 cm^{-1} region of the complexes with asymmetric nitrogens are large, and have the same sign as those in the 33000 cm^{-1} region. Hence we consider that these peaks are also related to the asymmetric nitrogen (*vide infra*).

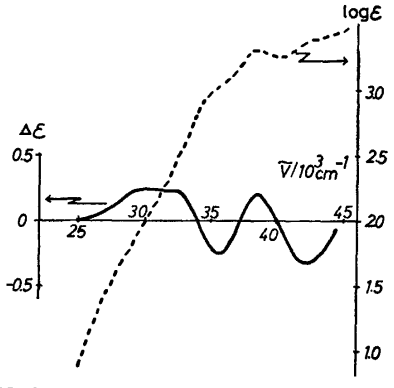

Fig. 2. UV absorption and CD spectra of *cis*(*N*,ethylene)-[PtCl(L-pro)(C_2H_4)] in acetonitrile.

The *cis*(*N*, ethylene) complex gives an absorption peak at *ca.* 38000 cm^{-1} and three shoulders at 28000, 35000, and 42000 cm^{-1}. CD peaks are observed in these regions corresponding to the absorption peak and shoulders. (Fig. 2). The absorption pattern is similar to that of the trans isomer. The CD peaks, however, are not very large and the signs are not equal to those of the *trans*(*N*, ethylene) complexes. Hence no further discussion will be made with the *cis* complex.

Stereoselectivity. The nitrogen of *N*-benzyl-L-valinate can coordinate to a metal ion in either *R* or *S* configuration, and its complex *trans*(*N*, ethylene)[PtCl(*N*-bz-L-val)(C_2H_4)] can exist as a pair of diastereoisomers, *S*(N)*S*(C) and *R*(N)*S*(C). Its CD spectrum is very similar both in location and intensity to that of the *N*-bz-L-pro complex, which can be only in *R*(*N*)*S*(C) configuration. It appears as if the *R*(N)*S*(C) diastereoisomer was obtained almost exclusively, when *N*-benzyl-L-valinate underwent substitution reaction with Zeise's salt in a very wealky acid aqueous solution of pH 5—6.[7] Saburi and Yoshikawa found that *N*-methyl-L-alaninate coordinates to cobalt(III) in a basic solution stereospecifically in *R* form, to give [Co(*R*(N)-*N*-me-L-ala)(NH_3)$_4$]$^{2+}$.[13]

The common preference of *R* configuration around coordinated nitrogen in these complexes may be understood by a molecular model study; *S*-configuration around coordinated nitrogen gives *N*-substituents in *cis* position to the substituents on the asymmetric α-carbon in *S* configuration, to result in large steric hindrance between the substitutents on *S*-nitrogen and *S*-carbon. Thus the *R*(N)*S*(C) configuration should be prefered regardless of the other moieties of the complex.

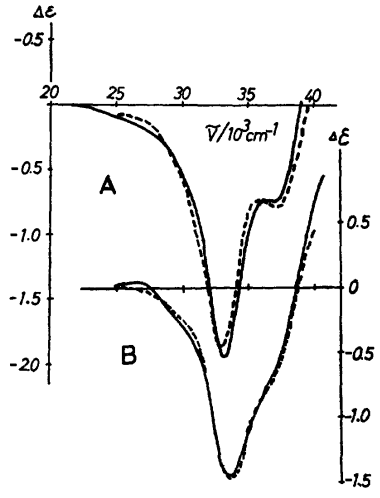

Fig. 3. Difference in CD between two complexes of the type *trans*(*N*,ethylene)[PtCl(L-am)(C_2H_4)] in AN.
A: $\delta\Delta\varepsilon$, — between *N*-bz-L-pro and L-pro, and --- between *N*-bz-L-val and L-val.
B: $\delta\Delta\varepsilon$, — between *N*-me-L-pro and L-pro, and --- between *N*-me-L-hyp and L-hyp.

Additivity of CD. Figure 1B and 1C indicate that the curves in 33000 and 37000 cm^{-1} regions show CD' of reverse signs. In Fig. 3A the differences of CD's between the *N*-benzyl-L-prolinato and L-prolinato, and between *N*-benzyl-L-valinato and L-valinato complexes are plotted against the wave number. Both $\delta\Delta\varepsilon$ curves are very similar to each other. In Fig. 3B similar plots of $\delta\Delta\varepsilon$'s between *N*-methyl-L-hydroxyprolinato and L-hydroxyprolinato, and between *N*-methyl-L-prolinato and L-prolinato complexes are shown. Again both curves are similar to each other. These curves should reflect the contribution of *N*-benzyl and *N*-methyl group upon the asymmetric nitrogen, the $\delta\Delta\varepsilon$ being -1.9 and -1.5, respectively. Hence additivity law should hold between the contribution of *N*-substituent and the L-prolinato moiety. The contribution of the former should be independent of the amino carboxylate framework.

Application of Quadrant Rule. Scott and Wrixon found an empirical rule between the absolute configuration of asymmetrically coordinated prochiral η^2-olefins and the CD sign of their platinum(II) complexes in 25000 cm^{-1} region, and interpreted the results on the basis of quadrant rule.[14] We have applied this rule to the interpretation of the CD spectra coming from asymmetric nitrogen. A projection of *trans*(*N*, ethylene)-

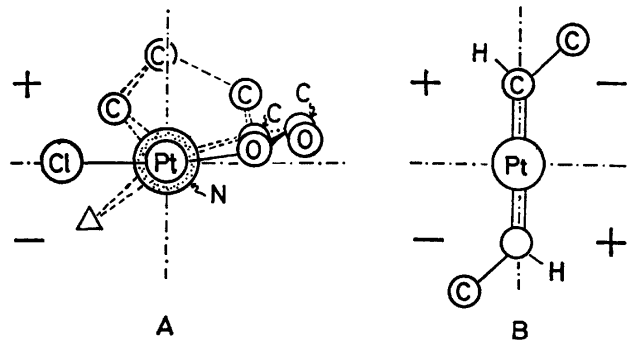

Fig. 4. Projection of the square planar complexes.
A: *N*-substituted-L-am moiety, the Pt–N bond is perpendicular to the paper and N is beneath Pt.
B: *trans*-2-butene moiety, the C–C axis is across the square plane of the Pt(II) complex behind the paper, and Pt-olefin bond is perpendicular to the paper.

[PtCl(*N*-alkyl-L-pro)(C_2H_4)] is shown in Fig. 4A. The square plane of the complex is represented by the horizontal line, and the Pt–N bond is perpendicular to the paper plane. The asymmetric nitrogen is beneath the platinum(II) and shown by a large dotted circle. When the quadrant rule is to be applied on the basis of this projection, the contribution of the minus quadrant at below left side behind the paper should depend on the size of the moiety, shown by a triangle on Fig. 4A. The larger the size of this substituent (benzyl, methyl, or hydrogen), the greater the contribution of the minus component. The substitution of benzyl or methyl for the hydrogen on the asymmetric nitrogen gives a large minus contribution. The apparently reverse CD sign in these regions in Fig. 1B and 1C and the additivity law are thus accounted for.

The UV absorption of all the present complexes shows peaks with log ε *ca.* 3 from 31000 to 45000 cm^{-1} region. Denning, Hartley, and Venanzi assigned the absorption bands of Zeise's salt in these regions to that d-π^* (ethylene) transition.[15] We have observed CD peaks at *ca.* 35000 and 39500 cm^{-1} with $\Delta\varepsilon$'s -1.3 and $+3.3$, respectively, for the tetraphenylphosphonium salt of [$PtCl_3$(${}^2S$,${}^3S$-*trans*-2-butene)]$^-$ in AN.[16] The absorption peak at 35000 cm^{-1} must correspond to the same transition to which the main CD of Fig. 3 owes.[17] In Fig. 4B a similar projection of this Zeise-type complex is shown, the C–C moiety being placed across the square plane of platinum(II) behind the paper surface. Application of the quadrant rule discloses that the contribution of the same minus regions behind the paper predominates for the Zeise- type complex, as it does to the present complexes with asymmetric nitrogens. It is thus suggested that the d-π^*(ethylene) transition is perturbed by the asymmetric nitrogen trans to the ethylene, so that a remarkable CD appears in this region.

Sydnones. Synthesis and Photochromic Behavior of 3-(3-Pyridyl)sydnone Derivatives and a 4-Alkenyl-3-phenylsydnone

Shinichi INOUE, Nobuyoshi ASAI,* Gorou YASUDA, and Takuya HORI

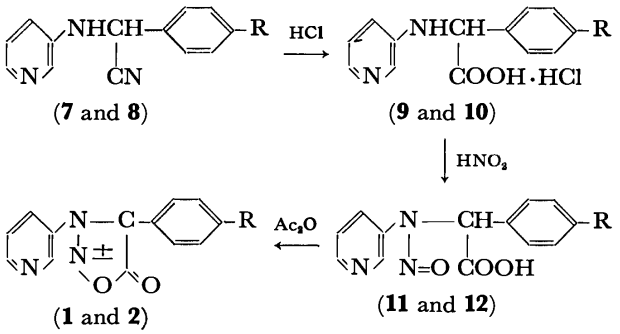
Department of Applied Chemistry, Aichi Institute of Technology, Yagusa-cho, Toyoda-shi, Aichi 470-03

(Received January 18, 1977)

Six new sydnones [3-(3-pyridyl)-4-(*p*-chlorophenyl)sydnone (**1**), 3-(3-pyridyl)-4-(*p*-tolyl)sydnone (**2**), 3-(3-pyridyl)-4-(*p*-nitrophenyl)sydnone (**3**), 3-(3-pyridyl)-4-(*p*-aminophenyl)sydnone (**4**), 3-(3-pyridyl)-4-(*p*-acetamidophenyl)sydnone (**5**), and 3-phenyl-4-(α-phenylstyryl)sydnone (**6**)] were synthesized and examined for photochromic behavior. Sydnone **2** exhibited photochromism in the solid state upon UV irradiation (230—580 nm).

Photochromic 3-(3-pyridyl)sydnone was synthesized for the first time by Tien and Hunsberger. Later, several investigators prepared 3-(3-pyridyl)sydnone derivatives[1,2] and examined the effect of substituents on pyridylsydnone photochromism. However, none of the prepared sydnones exhibited photochromic behavior. Recently, several photochromic 4-alkenyl-3-phenylsydnones were synthesized by several groups[3-7] and investigated for photochromic properties. Here, the synthesis of new sydnones and their photochromic behavior is reported.

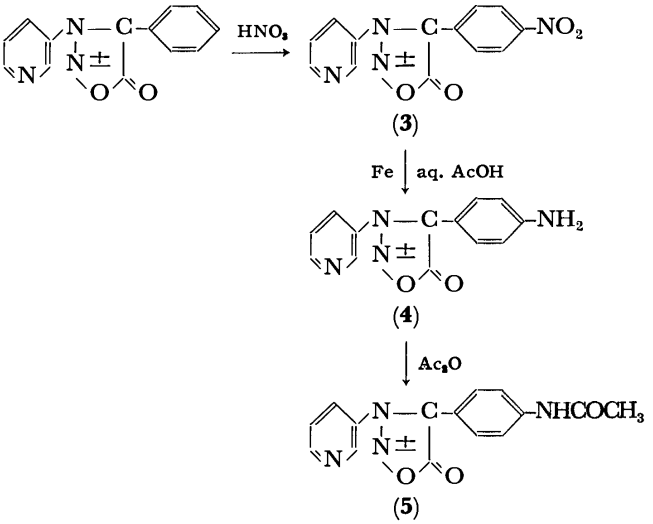
When *p*-chlorophenyl-(3-pyridylamino)acetonitrile (**7**) and *p*-tolyl-(3-pyridylamino)acetonitrile (**8**), which were easily obtained from the reaction of 3-aminopyridine with *p*-substituted benzaldehydes and potassium cyanide, were hydrolyzed with hydrochloric acid, *N*-(3-pyridyl)-*p*-chlorophenylglycine hydrochloride (**9**) and *N*-(3-pyridyl)-*p*-tolylglycine hydrochloride (**10**) were obtained. Compounds **9** and **10** easily reacted with sodium nitrite to afford *N*-nitroso-*N*-(3-pyridyl)-*p*-chlorophenylglycine (**11**) and *N*-nitroso-*N*-(3-pyridyl)-*p*-tolylglycine (**12**), which were then cyclized with acetic anhydride to give **1** and **2** in 50—70% yields.



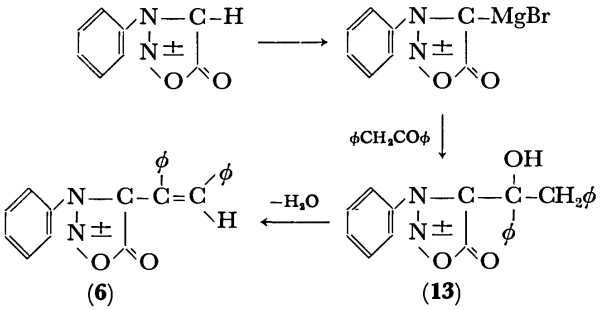
(**7** and **8**) (**9** and **10**) (**1** and **2**) (**11** and **12**)

(**1**), (**7**), (**9**), and (**11**): R=Cl;
(**2**), (**8**), (**10**), and (**12**): R=CH_3

In order to obtain 4-(*p*-nitrophenyl)derivative **3**, the nitration of 3-(3-pyridyl)-4-phenylsydnone was examined. The nitration was accomplished in the following manner. Treatment of 3-(3-pyridyl)-4-phenylsydnone with fuming nitric acid at −5 °C afforded **3** in a moderate yield (52%). Compound **3** was readily reduced with iron powder in acetic acid at 90 °C to give 4-(*p*-aminophenyl)derivative **4** in a 45% yield. **4** underwent acetylation to give 4-(*p*-acetamidophenyl)-derivative **5** in an excellent yield (82%).



The reaction of 3-phenylsydnone with butylmagnesium bromide in THF at 2 °C gave the corresponding Grignard compound, which then reacted with deoxybenzoin to give 4-(1-hydroxy-1,2-diphenylethyl)-3-phenylsydnone (**13**) in a 54% yield. 3-Phenylsydnone derivative **13** was dehydrated by means of phosphoryl chloride and acetic anhydride to give 3-phenyl-4-(α-phenylstyryl)sydnone **6**, in an 88% yield.



The structures of the new sydnones (**1**—**6**) were assigned on the basis of their IR, NMR, mass, and UV spectra, and elemental analysis.

In the solid state, each of the new sydnones was exposed to ultraviolet radiation (230—580 nm). Sydnone **2** exhibited photochromism, with no other sydnones, however, exhibiting this behavior.

Sydnone **2** is a pale yellow compound, stable in air at room temperature if stored in the dark. **2** turned blue upon irradiation with ultraviolet light for a period of 3 to 5 min. This photochromic change was reversible; **2** returned to its original state after storage in the dark for several days. A more rapid recovery of **2** can be

* Present address: Institute of Chemistry, The University of Tsukuba, Niihari-gun, Ibaraki 300-31.

induced by heating at 80 °C for 30 min. After repeated exposures to ultraviolet radiation, **2** showed a delay in returning to its original state. The photochromic change was restricted to the crystalline state at room temperature; no such phenomenon was observed in solution.

An infrared spectrum of **2** was obtained and compared with that taken after a 5 min irradiation with ultraviolet light. The two spectra were essentially identical. The similarity between the infrared spectra of **2** before and after ultraviolet irradiation is an indication that there is no structural alternation associated with the photochromic change.

A conclusion drawn from these observations gives support to the proposition of Greco and O'Reilly[4] that the mesoionic ring may be a necessary, but not a sufficient, structural feature for photochromism. At present, the effect of molecular modification on the photochromism of compound **2** is being examined in order to elucidate the photochromic mechanism.

Finally, it should be noted that the new sydnones are comparatively stable even at high temperature.

Experimental

The IR spectra were recorded with a Hitachi Model 215 spectrophotometer and the UV spectra with a Hitachi Model EPS-3T spectrophotometer. The NMR spectra were obtained on a JEOL JNM-C-60H spectrometer, with tetramethylsilane as the internal reference. The mass spectra were determined on a Hitachi RMU-6E spectrometer. The melting points are uncorrected.

Materials. *p*-Chlorophenyl- and *p*-tolyl(3-pyridyl)acetonitriles (**7** and **8**) were prepared by the reaction of 3-aminopyridine with *p*-substituted benzaldehydes and potassium cyanide. **7**, mp 152—153 °C. Found: C, 64.12; H, 4.10; N, 17.21%. Calcd for $C_{13}H_{10}N_3Cl$: C, 64.07; H, 4.14; N, 17.24 %. **8**, mp 145.5—146.5 °C. Found: C, 75.30; H, 5.81; N, 18.77%. Calcd for $C_{14}H_{13}N_3$: C, 75.31; H, 5.87; N, 18.82%.

3-(3-Pyridyl)-4-phenylsydnone was prepared using the method of Ohta and Masaki.[1]

3-Phenylsydnone was also prepared by cyclization of *N*-nitroso-*N*-phenylglycine using the usual procedure.[8]

Hydrolysis of p-*Substituted Phenyl(3-pyridylamino)acetonitrile. Preparation of* N-*(3-Pyridyl)*-p-*chlorophenylglycine Hydrochloride(**9**) and* N-*(3-Pyridyl)*-p-*tolylglycine Hydrochloride (**10**)*: A mixture of **7** (2.0 g, 8 mmol) and concentrated HCl (18 ml) was stirred for 2 h under reflux. After cooling for 3 h at 0 °C, the resulting ammonium chloride was filtered, the solvent was distilled and the residue was heated with concentrated HCl for 15 min. After washing with concentrated HCl and recrystallization from concentrated HCl, pure **9** (2.1 g, 85%) was obtained.

The same procedure starting with acetonitrile (**8**) gave product **10** in a yield of 88%.

*Glycine Hydrochloride (**9**)*, mp 223—227 °C. Found: C, 52.17; H, 4.01; N, 9.40%. Calcd for $C_{13}H_{12}N_2O_2Cl_2$: C, 52.19; H, 4.05; N, 9.37%.

*Glycine Hydrochloride (**10**)*, mp 224—228 °C. Found: C, 60.34; H, 5.40; N, 9.99%. Calcd for $C_{14}H_{15}N_2O_2Cl$: C, 60.32; H, 5.43; N, 10.05%.

Nitrosation of Glycine Hydrochloride. Preparation of N-*Nitroso*-N-*(3-pyridyl)*-p-*chlorophenylglycine (**11**) and* N-*Nitroso*-N-*(3-pyridyl)*-p-*tolylglycine (**12**)*: To a suspension of **9** (4.4 g, 15 mmol) in water (45 ml) was added a 20% aqueous sodium hydroxide solution until compound **9** was completely dissolved. Sodium nitrite (1.2 g, 17 mmol) was added and concentrated HCl was then added at 0 °C until the solution showed acidity (pH 2) and then the reaction mixture was stirred for 30 min. After standing overnight at −2 °C, the deposited crystals were collected by filtration. Upon washing with cold water, pure **11** (3.4 g, 79%) was obtained.

Application of the same procedure to glycine hydrochloride (**10**) led to product **12** in a yield of 89%.

*Nitrosoglycine (**11**)*, mp 140—141 °C (dec). Found: C, 53.51; H, 3.45; N, 14.42%. Calcd for $C_{13}H_{10}N_3O_3Cl$: C, 53.53; H,3.46; N, 14.41%.

*Nitrosoglycine (**12**)*, mp 145.5—146.5 °C (dec). Found: C, 61.96; H, 4.82; N, 15.45%. Calcd for $C_{14}H_{13}N_3O_3$: C, 61.99; H, 4.83; N, 15.49%.

*3-(3-Pyridyl)-4-(*p-*chlorophenyl)sydnone (**1**)*. A mixture of **11** (1.0 g, 3 mmol) and acetic anhydride (20 ml) was stirred for 2 h at room temperature. After heating for 5 min at 50 °C, the solvent was removed under reduced pressure in a nitrogen atmosphere. To the residual oil was added 50% ethanol and the mixture was then allowed to stand for a few minutes. The resulting crystals were filtered off and the residue was washed with ethanol and recrystallized from ethanol to give 0.6 g (64%) of sydnone **1** as pale yellow needles; mp 141—142 °C. IR (KBr): 1752 (C=O) and 1735 cm^{-1} (C=O); NMR ($CDCl_3$): δ 9.10—7.60 (4H, m, py) and 7.37 (4H, m, C_6H_4); UV (MeOH) max: 254 (ε 12400) and 340 nm (10500); MS *m/e* (%): 273 (M^+, 57), 215 (100), and 78 (58). Found: C, 57.25; H, 2.78; N, 15.13%. Calcd for $C_{13}H_8N_3O_2Cl$: C, 57.05; H, 2.95; N, 15.35%.

*3-(3-Pyridyl)-4-(*p-*tolyl)sydnone (**2**)*. A mixture of **12** (1.0 g, 4 mmol) and acetic anhydride (10 ml) was stirred for 3 h at room temperature. After heating for 5 min at 70 °C, the mixture was worked up using the same method as described above to give 0.52 g (56%) of sydnone **2** as pale yellow needles; mp 142—143 °C. IR (KBr): 1745 cm^{-1} (C=O); NMR ($CDCl_3$): δ 9.05—7.50 (4H, m, py), 7.22 (4H, m, C_6H_4), and 2.64 (3H, s, CH_3); UV (MeOH) max: 251 (ε 7950) and 341 nm (6170); MS *m/e* (%): 253 (M^+, 60), 195 (100), and 78 (26). Found: C, 66.34; H, 4.17; N, 16.59%. Calcd for $C_{14}H_{11}N_3O_2$: C, 66.39; H, 4.37; N, 16.59%.

*3-(3-Pyridyl)-4-(*p-*nitrophenyl)sydnone (**3**)*. To fuming nitric acid (10 ml) was slowly added 3-(3-pyridyl)-4-phenylsydnone (2.0 g, 8 mmol) at −5 °C which was then stirred for 20 min. The reaction mixture was poured into ice water. The resulting crystals were filtered off and washed several times with cold water and then crystallized from 60% ethanol to give 1.2 g (52%) of synone **3** as yellow needles; mp 162—163 °C. IR (KBr): 1770 (C=O), 1750 (C=O), 1520 (NO_2), 1353 (NO_2), and 856 cm^{-1}; NMR (DMSO-d_6): δ 9.10—7.84 (8H, m, py and C_6H_4); UV (MeOH) max: 262 (ε 7080) and 362 nm (17000); MS *m/e* (%): 284 (M^+, 63), 226 (100), 180 (38), and 78 (66). Found: C, 55.03; H, 2.67; N, 19.71%. Calcd for $C_{13}H_8N_4O_4$: C, 54.93; H, 2.83; N, 19.71%.

*3-(3-Pyridyl)-4-(*p-*aminophenyl)sydnone (**4**)*. To a suspension of **3** (3.5 g, 12 mmol) in hot water were added iron powder (8 g) and acetic acid (10 ml) and then the mixture was stirred for 20 min at 95 °C. After cooling, the reaction mixture was neutralized with $NaHCO_3$. The precipitate was filtered and washed several times with cold water. After drying, the residue was extracted with THF (100 ml) three times, and then the solvent was concentrated under reduced pressure in a nitrogen atmosphere. Petroleum ether (40 ml) was added and the mixture was coold. The resulting crystals were collected by filtration and then washed with petroleum ether. Recrystallization from absolute ethanol afforded 1.4 g (45%) of pure **4** as pale yellow needles; mp 194.5—196 °C. IR (KBr): 3425 (NH_2), 3342 (NH_2), and 1735 cm^{-1} (C=O); NMR (py-d_5): δ

9.02—7.40 (4H, m, py), 7.36—6.65 (4H, m, C_6H_4), and 5.35 (2H, s, NH_2); UV (MeOH) max: 266 (ε 13200) and 378 nm (6760); MS *m/e* (%): 254 (M^+, 27) and 196 (100). Found: C, 61.28; H, 3.80; N, 21.96%. Calcd for $C_{13}H_{10}N_4O_2$: C, 61.41; H, 3.96; N, 22.04%.

*3-(3-Pyridyl)-4-(*p*-acetamidophenyl)sydnone (**5**).* A mixture of **4** (0.20 g, 0.78 mmol), acetic anhydride (1.5 ml), and acetic acid (5 ml) was stirred for 20 min at 80 °C. The solvent was removed under reduced pressure in a nitrogen atmosphere. To the residual oil ethanol (2 ml) was added. The resulting crystals were collected by filtration. Recrystallization from 50% ethanol afforded 0.19 g (82%) of pure **5** as yellow needles; mp 242—244 °C. IR (KBr): 3300 (NH), 1720 (C=O), and 1678 cm^{-1} (CH_3C=O); NMR (DMSO-d_6): δ 9.00—7.80 (4H, m, py), 7.75—7.15 (4H, m, C_6H_4), 3.56 (1H, s, NHC=O), and 3.15 (3H, s, CH_3C=O); UV (MeOH) max: 269 (ε 8710) and 351 nm (6760). Found: C, 60.82; H, 4.01; N, 18.88%. Calcd for $C_{15}H_{12}N_4O_3$: C, 60.80; H, 4.09; N, 18.91%.

*Grignard Reaction. Preparation of 4-(1-Hydroxy-1,2-diphenylethyl)-3-phenylsydnone (**13**)*: To butylmagnesium bromide (30 ml, 50 mmol)[9] was added a solution of 3-phenylsydnone (3.2 g, 20 mmol) in THF (80 ml) at 2—3 °C which was then stirred for 1 h. To this was added a solution of deoxybenzoin (10.0 g, 50 mmol) in THF (10 ml) at 5 °C and this mixture was then stirred for 2 h and poured into dilute acetic acid. The reaction mixture was extracted with benzene (100 ml) three times. The extract, after washing with water (50 ml) three times and drying over anhydrous magnesium sulfate, was concentrated in a nitrogen atmosphere. The residue was purified by washing with benzene–hexane (1: 1) to give **13** (3.8 g, 54%).

*Sydnone (**13**)*; mp 130—131 °C. Found: C, 73.65; H, 5.12; N, 7.84%. Calcd for $C_{22}H_{18}N_2O_3$: C, 73.72; H, 5.07; N, 7.81%.

*Dehydration of 4-(1-Hydroxy-1,2-diphenylethyl)-3-phenylsydnone. Preparation of 3-Phenyl-4-(α-phenylstyryl)sydnone (**6**)*: To a solution of **13** (0.5 g, 0.14 mmol) in pyridine (10 ml) was added phosphoryl chloride (2 ml) at −5 °C. After standing for 12h at room temperature, the mixture was heated for 2 h and then poured into ice water. The resulting crystals were collected by filtration. Recrystallization from 50% ethanol afforded 0.22 g (47%) of pure **6** as pale yellow needles; mp 172—174 °C. IR (KBr): 1735 (C=O) and 818 cm^{-1} (C=CHR); NMR ($CDCl_3$): δ 7.56—7.12 (15H, m, C_6H_5) and 6.32 (1H, s, CHR); UV (MeOH) max: 231 (ε 11220) and 351 nm (8320); MS *m/e* (%): 330 (M^+, 18) and 272 (100). Found: C, 77.60; H, 4.76; N, 8.20%. Calcd for $C_{22}H_{16}N_2O_2$: C, 77.63; H, 4.74; N, 8.23%.

A New Type of Iminocarbonylaton of Diols, Mercaptoalkanol, and Dithiol *via* Their Dibutylstannyl Derivatives

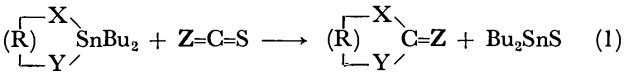
Shizuyoshi SAKAI,* Hiroji NIIMI, Yoshihiro KOBAYASHI, and Yoshio ISHII

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya 464

(Received January 24, 1977)

Reactions of phenyl isothiocyanate with cyclic and acyclic dibutylstannyl dialkoxides derived from several alcohols, such as 1,2- and 1,3-diols and methanol, afforded quantitatively phenyliminocarbonate derivatives with the elimination of dibutylstannyl sulfide. Cyclic organostannyl sulfides, such as 2,2-dibutyl-1,3,2-oxathiastannolane and -dithiastannolane, reacted with phenyl or alkyl isothiocyanate to give 2-imino-oxathiolane (**10**) and -dithiolane (**14**), respectively. At higher reaction temperatures, rearrengment and decomposition of products **10** and **14** occurred.

The usual method for the preparation of iminocarbonates utilizes isocyanide dichloride, $RN{=}CCl_2$, as a reactant.[1] The major disadvantage of this method is that only a limited number of the reagent is available because of their toxicities. The present study is aimed at an application of organostannyl derivatives to the iminocarbonylation of alkanol and diols, mercaptoalkanols, and dithiols with various isothiocyanates (Reaction 1).



$$(R)\begin{matrix}X\\Y\end{matrix}SnBu_2 + Z{=}C{=}S \longrightarrow (R)\begin{matrix}X\\Y\end{matrix}C{=}Z + Bu_2SnS \quad (1)$$

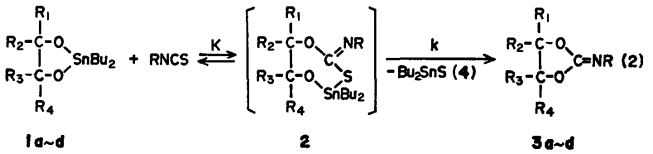
X, Y=O, S; Z=NR

Reactions anologously to Reaction 1 using bis(tributylstannyl) derivatives of HX(R)YH have already been reported previously which dealt with the thiocarbonylation (X, Y=NMe or O; Z=S), iminocarbonylation (X, Y=NMe or O; Z=NPh),[2] and preparation of orthocarbonates.[3] However, this method appeares to be more suit for a new type of iminocarbonylation of diols, mercaptoalkanols and dithiols, because the corresponding dibutylstannyl compounds can be easily prepared from commercially available dibutylstannyl chloride or oxide, and are less toxic than tributylstannyl compounds.

Results and Discussion

The appropriate dibutylstannyl compounds were readily prepared and these starting materials were allowed to react with isothiocyanates is in a nitrogen atmosphere to afford cyclic iminocarbonylated products (X, Y=O or S in Reaction 1).

The reaction of some 2,2-dibutyl-1,3,2-dioxastannolanes (**1a**—**c**) with phenyl isothiocyanate for 2 h in 1,2-dichloroethane at 55 °C afforded the corresponding 2-phenylimino-1,3-dioxolanes (**3a**—**c**) and dibutylstannyl sulfide (**4**)[4] in quantitative yields (Reaction 2). However, a tetra-substituted derivative, dioxastannolane **1d** in Table 1, did not react with phenyl isothiocyanate under the same coditions, *i.e.*, more severe reaction conditions were required to complete the reaction, as is seen in Table 1. This fact suggests a large steric effect in the reactions with organostannyl compounds.



The intermediate (**2**) was not detected, even by IR and NMR measurements of the reaction mixture. However, it appears probable that the reaction proceeds *via* the addition of phenyl isothiocyanate to the tin-oxygen bond, followed by the elimination of a stable organostannyl sulfide (**4**), anologously to the case of the reactions of the compounds **5** and **8** mentioned below.

A six-membered ring compound, 2,2-dibutyl-1,3,2-dioxastannin (**1e**), was also allowed to react with phenyl isothiocyanate for 2 h at 55 °C to give 2-phenylimino-1,3-dioxane (**3e**) in a 60% yield (Reaction 3). On the other hand, the reaction of the seven-membered ring compound, 2,2-dibutyl-1,3,2-dioxoastannepane (**1f**), with phenyl isothiocyanate to form **3f** was unsuccessful, because of the instability of the product (**3f**). The instability is probably due to transfer polymerization of

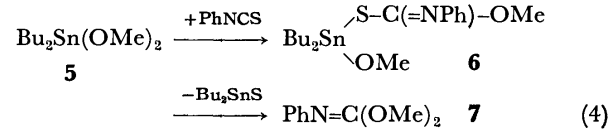
An acyclic organostannyl compound, **5**, was also submitted to the reaction with phenyl isothiocyanate in dichloroethane at 55 °C, affording only the 1 : 1 adduct (**6**) reported by Davies and Harrison.[5] However, under more severe conditions such as 70 °C for 16 h in 1,2-dichloroethane, the adduct (**6**) was converted to phenyl isocyanide dimethoxide (**7**) in a 96% yield (Reaction 4).



An aliphatic isothiocyanate, MeNCS, was also allowed to react with **1a**, and 2-methylimino-1,3-dioxolane was obtained in a moderate yield (70%).

In general, addition reactions of heterocumulenes to the tin-oxygen bond occur easily,[5] while heterocumulenes scarcely react with the tin-sulfur bond. Here, the reaction of an isothiocyanate with equimolar 2,2-dibutyl-1,2,3-oxathiastannolane (**8**), which was readily prepared from mercaptoethanol and dibutyltin oxide or chloride, was examined. For example, an equimolar mixture of phenyl isothiocyanate and **8** was heated for 2 h in dry 1,2-dichloroethane at 55 °C to afford 2-phenylimino-1,3-oxathiolane (**10**;R=Ph) and dibutylstannyl sulfide (Reaction 5). Alkyl isothiocyanates were also used in the reaction, the results of which are shown in Tables 2 and 3. The product (**10**) from the alkyl isothiocyanates were thermally unstable, and some parts decomposed to give alkyl isocyanates and thiirane.[6] Because of such thermal instability of the products, the reactions were carried out at relatively low temperatures such as 40 °C, even though alkyl isocyanates were less reactive than phenyl isothiocyanate.

a) In 1,2-dichloroethane. b) Dibutylstannyl sulfide was obtained in a quantitative yield. c) Accompanied by unreacted **8** (11%). d) The unreacted **8** was recovered in a quantitative yield. e) Ethylene sulfide and isocyanate were detected.

From the results in Table 2, the apparent order of the reactivities is as follows: PhNCS>MeNCS,EtNCS,PrNCS,BuNCS≫*i*-PrNCS,*cyclo*-C_6H_{11}≫Me_3CNCS. This order suggests that the reactivity of an isothiocyanate in the insertion across the tin-oxygen bond of **8** is affected by both the electronic nature and the bulkiness of the isothiocyanate substituent.

It is reasonable to assume that the reaction course forming **10** is an addition-elimination process (**8**→**9**→**10**): the formation of the intermediate (**9**) is strongly suggested on the basis of the fact that the C=N stretching band ascribable to **9** is observed at 1500—1530 cm^{-1} in

the IR spectrum of the reaction mixture in the initial stage of the reaction at 40 °C. At elevated reaction temperatures (80 °C), **10** was partially rearranged to N-substituted thiazolidin-2-one (**11**). No such rearrangement was observed in the reaction of **8** with phenyl isothiocyanate.[7]

Finally, 2,2-dibutyl-1,3,2-dithiostannolane was allowed to react with sulfur-containing heterocumulene for several days at 40—80 °C to give a dithio-carbonate derivative (**14**) and dibutylstannyl sulfide. The results are tabulated in Table 4. Although no intermediate adduct (**13**) was detected, the reaction course may be depicted analogously to reaction scheme (5).

a) A trace amount of ethylene sulfide was detected by NMR measurements. b) Yield (%) of *N*-methylthiazolidin-2-thione. c) In 1,2-dichloroethane.

At elevated temperatures, 1-methylthiazolidine-2-thione (**15**) was obtained. Thus it is suggested that thermal rearrangement of **14** to **15** occured, as has been reported by Ueno *et al.*[6]

Organostannyl sulfides are known to be stable in ordinary reactions.[8] However, it is interesting to note that dibutylstannyl sulfide (**12**) is moderately reactive in reaction with methyl isothiocyanate. From a comparison of the result in Table 2 with that in Table 3, it is seen that methyl isothiocyanate is less reactive in reaction with **8** than is phenyl isothiocyanate, although the former is more reactive in reaction with **12** than is the latter. Moreover, carbon disulfide reacts with **12** to afford ethylene trithiocarbonate, but did not react with **8**, even in a mixture of **8** and carbon disulfide that was heated for nine days at 40 °C. These results cannot be explained by the usual rate order observed in reaction of simple organostannyl compounds, *i.e.*, Sn–N>Sn–O> Sn–S.[8,9] Therefore, the difference in the degree of association between **1a—d** or **8** (dimer) and **12** (monomer) and in the co-ordinating power of heterocumulene molecules to tin atom in these organostannyl compounds may affect their reactivities. A detailed discussion of the reaction rate and mechanism will be published elsewhere.[11]

Experimental

All melting and boiling points are uncorrected. The IR spectra were obtained on a Nippon-Binko DS-403G and IR-S spectrometers. The NMR spectra were recorded on a Japan Electron Optics Model C-60HL spectrometer with TMS as the internal standard. A Japan Electron Optics Model JMS-OISG mass spectrometer and a Yanagimoto Model GCG-220 gas chromatograph (Silicone DC-200, 25%) were also used. Analyses were performed in the laboratories of Professor Sasaki and of the Toa-gosei Co. All reactions and measurements were carried out using dry solvents.

All isothiocyanates (RNCS) were prepared using a reported method;[12] bp 117—119 (R=Me), 132—135 (Et), 153—154 (Pr), 170—175 (Bu), 137—142 (*i*-Pr), 120 (*cyclo*-C_6H_{11}) °C and 131—133 °C/10 mmHg (Me_3C). All solvents were dried over P_2O_5 and distilled before use. Mercaptoethanol and ethane-1,2-dithiol were obtained commercially and distilled in nitrogen; bp 55—58 °C/15 mmHg and 70—73 °C/50 mmHg, respectively. The dioxastannolanes (**1a—f**) were prepared from diol, Bu_2SnCl_2 and Na_2CO_3, or from diol and Bu_2SnO,[13] and stored in a dessicator containing blue silica gel.

Preparation of 2,2-Dibutyl-1,3,2-oxathiastannolane (8). (A) Mercaptoethanol (15.6 g, 200 mmol), dibutyltin dichloride (60.4 g, 200 mmol), and sodium carbonate (60 g) were heated under reflux in toluene (150 cm^3) in an atmosphere of nitrogen for 10 h in a flask equipped with a Dean-Stark water-separater, a condensor, and a stirrer. The hot reaction mixture was filtered, and evaporated to recover the toluene used. The residue was distilled in a vacuum to give crude **8** in a 90% yield (52.8 g). Redistillation afforded white solid **8**; bp 173—176 °C/0.4 mmHg; mp 92—93.5 °C (Ref.[10,14] 89—90 °C). The IR and NMR spectra coincided well with those previously reported.[1,14]

(B) Mercaptoethanol (15.6 g, 200 mmol) and Bu_2SnO (48 g, 200 mmol) were allowed to react under reflux in toluene and were treated as mentioned above, to afford **8** in a 92% (54 g) yield.

Preparation of 2,2-Dibutyl-1,3,2-dithiastannolane (12). A mixture of ethane-1,2-dithiol (18.2 g, 200 mmol), Bu_2SnCl_2 (60.4 g, 200 mmol), and Na_2CO_3 (65 g) was heated for 10 h in refluxing toluene (200 cm^{-1}) in an atmosphere of nitrogen, and treated as mentioned above to give **12** in a 77% yield; bp 127—129 °C/0.1 mmHg; mp 57—58 °C (Ref.[15] 59—60 °C); NMR (CCl_4) δ 2.93 (s, 4H, CH_2S) and 0.7—1.7 ppm (br., 18H, SnBu); IR (CCl_4) 1285, 1245, 925, and 845 cm^{-1}. The dithiastannolanes **12** was also prepared in a 86% yield (53 g) from Bu_2SnO instead of Bu_2SnCl_2 and Na_2CO_3.

The Reaction of 2,2-Dibutyl-1,2,3-dioxastannolane (1a) with PhNCS. To a solution of **1a** (5.8 g, 20 mmol) in dry 1,2-dichloroethane (40 cm^3) in a flask equipped with a condenser and a drying tube, PhNCS (2.8 g, 21 mmol) was added and the mixture was heated with stirring for 2 h at 55 °C. Then, the solvent was evaporated, and the residue was distilled in a vacuum to give 2-phenylimino-1,3-dioxolane (**3a**) in a 98% yield (3.2 g, 19.6 mmol); bp 148—150 °C/15mmHg; mp (recrystallized from toluene) 72—72.5 °C (Ref.[16] 74—75 °C); NMR δ 4.43 (s, 4H, CH_2O) and 6.8—7.3 ppm (m, 5H, Ph); IR ($CHCl_3$) 1721 ($\nu_{C=N}$) and 1056 cm^{-1}. The spectral data were the same as those of an authentic sample. The pot residue showed the same IR spectrum that of the authentic Bu_2SnS (ν_{SnSSn} at 360 cm^{-1}); yield 91% (4.9 g).

The Reaction of 2,2-Dibutyl-4-methyl-1,3,2-dioxastannolane (1b) with PhNCS. The stannolane **1b** was allowed to react with PhNCS for 2 h at 55 °C, and was treated as mentioned above; yield 95%; bp 131—132 °C/1 mmHg; NMR (CCl_4)

δ 1.23 (d, J=5.1 Hz, 3H, CH_3), 3.5—4.8 ($ABCX_3$-pattern, 3H,CH_2CH), and 6.8—7.3 ppm (m, 5H, Ph); IR ($CHCl_3$) 1708 ($\nu_{C=N}$) and 1040 (ν_{C-O}) cm^{-1}; Found C, 67.55; H, 6.37; N, 7.88%. Calcd for $C_{10}H_{11}ON$: C, 67.78; H, 6.29; N, 7.90%.

Dibutylstannyl sulfide was obtained as a pot residue in a 95% yield.

The Reaction of 2,2-Dibutyl-4,5-dimethyl-1,3,2-dioxastannolane (1c) with PhNCS. This compound (**1c**) was allowed to react with PhNCS for 5 h in 1,2-dichloroethane at 55 °C and was treated as described above to give **3c** (95% yield; bp 120—122 °C/0.4 mmHg). The IR and NMR spectra coincided well with those of an authentic sample.[16]

Reaction of Dimethoxydibutylstannane (5) with PhNCS. To a solution of **5** (5.9 g, 20 mmol) in 1,2-dichloroethane, PhNCS (2.7 g, 20 mmol) was added dropwise and the reaction mixture showed δ_{CH_3-O} at 3.93 and 3.51 ppm in the NMR spectrum and $\nu_{C=N}$ band at 1630 cm^{-1} in the IR spectrum, which are the same as those reported for the 1:1 adduct (**6**).[5] This adduct (**6**) was heated for 16 h at 70 °C, and distilled to give phenyl isocyanide dimethoxide **7** in a 96% yield; bp 60—62 °C/0.3 mmHg; NMR ($CDCl_3$) δ 3.17 (s, 6H, CH_3) and 6.7—7.3 ppm (m, 5H, Ph); IR ($CHCl_3$) 1677 ($\nu_{C=N}$) cm^{-1}. Those spectral data coincided well with those of a commercial sample.

The Reaction of 2,2-Dibutyl-1,3,2-dioxastannoxane (1e) with PhNCS. Compound **1e** was allowed to react with PhNCS in 1,2-dichloroethane as in the case of **1a**. The reaction mixture was fractionally distilled to afford 2-phenylimino-1,3-dioxacyclohexane **3e** in a 60% yield; bp 136—139 °C/0.2 mmHg; NMR ($CDCl_3$) δ 4.25 (t, J=5.5 Hz, 4H, CH_2O), $\approx$1.9 (m, 2H, CCH_2C), and 6.8—7.3 ppm (m, 5H, Ph); IR ($CHCl_3$) 1690 and 1100 cm^{-1}. Found: C, 67.48; H, 5.98; N, 7.75%. Calcd for $C_{10}H_{11}O_2N$: C, 67.78; H, 6.26; N, 7.90%.

The Reaction of 2,2-Dibutyl-1,3,2-dioxastannaepane (1f) with PhNCS. Compound **1f** was allowed to react with an equimolar amount of PhNCS for 20 h in 1,2-dichloroethane at 70 °C, to give a mixture which showed the characteristic $\nu_{C=N}$ band ascribable to 2-phenylimino-1,3-dioxepane (**3f**) at 1690 cm^{-1}, but distillation gave a resinous product having an IR band at 1680 cm^{-1}.

The Reaction of 1a with MeNCS. This compound (**1a**) was allowed to react with MeNCS for 16 h in dry 1,2-dichloroethane at 70 °C, to give 2-methylimino-1,3-dioxolane in a 70% yield; bp 98—100 °C/25 mmHg, NMR ($CDCl_3$) δ 2.99 (s, 3H, CH_3) and 4.38 ppm (s, 4H, CH_2); IR ($CHCl_3$) 1740 cm^{-1}. Found: C, 47.83; H, 7.12; N, 13.59%. Calcd for $C_4H_4O_2N$; C, 47.52; H, 6.98; N, 13.86%.

Reaction of 2,2-Dibutyl-1,3,2-oxathiostannolane (8) with PhNCS. An equimolar mixture of **8** and PhNCS was heated for 2 h in dry 1,2-dichloroethane at 55 °C. The reaction mixture was concentrated in vacuum and cooled to precipitate crude crystal of 2-phenylimino-1,3-oxathiolane (**10**, R=Ph) in a 95% yield; mp (recrystallized from a toluene–hexane (1:1) mixture) 65.0—65.5 °C; NMR ($CDCl_3$) δ 3.35 (t, J=6.3 Hz, 2H, CH_2S), 4.66 (t, J=6.3 Hz, 2H, CH_2O), and 6.8—7.3 ppm (m, 5H, Ph); IR ($CHCl_3$) 1658 ($\nu_{C=N}$) 1113, and 1038 (ν_{C-O}) cm^{-1}. Found: C, 60.10; H, 5.11; N, 7.80%. Calcd for C_9H_9ONS: C, 60.31; H, 5.06; N, 7.81%. The parent solution contained Bu_2SnS (97% yield).

Reaction of 8 with Some Alkyl Isothiocyanates. A typical example is as follows: the oxathiostannolane **8** and MeNCS (each 25 mmol) were heated for three days at 40 °C in dry dichloromethane in a flask equipped with a condensor and a drying tube. During the course of the reaction, the mixture showed the $\nu_{C=N}$ band of the 1:1 adduct at 1610 cm^{-1} in the IR spectrum. After the reaction, the solvent and the low boiling by-product were recovered in a cold trap by distillation at atmospheric pressure, and the residue was distilled in a vacuum, to afford 2-methylimino-1,3-oxathiolane (**10**;R=Me) in a 59% yield; bp 117—118 °C/20 mmHg. The identification of **10** was performed using IR and NMR spectroscopies and elemental analysis. It was confirmed by VPC and NMR measurements that the trapped mixture comprised the solvent, thiirane (3%), MeNCO (2%), and MeNCS (1%).

Bu_2SnS was obtained as a residue in an almost quantitative yield.

The results of the reactions of **8** with other alkyl isothiocyanates are summerized in Tables 2 and 3.

Picrate Formation of 10. Compound **10** (R=Me and Et) was added to a solution of picric acid in EtOH at room temperature, and cooled at 0 °C to precipitate the picrate crystals. The picrate of **10** (R=Me): mp (EtOH) 143—144 °C; IR (KBr) 1628, 1609, 1551, 1367, and 1268 cm^{1-}; Found: C, 34.69; H, 2.91; N, 16.18%. Calcd for $C_{10}H_{10}O_8S$: C, 34.57; H, 3.14; N, 16.26%. The picrate of **10** (R=Et): mp (EtOH) 80—82 °C; IR (KBr) 1660, 1615 (br.), 1368, and 1275 cm^{-1}; Found: C, 36.34; H, 3.64; N, 15.15%. Calcd for $C_{11}H_{12}O_8N_4S$: C, 36.67; H, 3.36; N, 15.15%.

The Rearrangement of 10 to 11 (R=Me). Compound **10** prepared *in situ* from **8** and MeNCS (25 mmol each) was heated under reflux for four days in 1,2-dichloroethane, and the reaction mixture was distilled to afford **11** (R=Me) in a 46% yield; bp 73—75 °C/0.2 mmHg (Ref.[6] 84—86 °C/0.2 mmHg); IR ($CHCl_3$) 1689 cm^{-1} (Ref.[6] 1685 cm^{-1}). Under the same reaction conditions, **10** (R=Ph) was not rearranged and recovered by distillation in an almost quantitative yield.

The Reactions of 2,2-Dibutyl-1,3,2-dithiostannolane (12) with MeNCS and PhNCS. This compound (**12**) was allowed to react with an equimolar amount of MeNCS for five days in dry dichloromethane under reflux, and was distilled to give 2-methylimino-1,3-dithiolane (**14**; Z=NMe) in a 76% yield; bp 64—68 °C/0.3 mmHg (Ref.[6] 79—81 °C/0.45 mmHg); the IR and NMR spectra coincided well with those prepared by a published method.[16] The trapped distillate contained only a trace amount of thiirane.

The reaction of **8** with MeNCS was carried out for one day in refluxing 1,2-dichloroethane, and the reaction mixture showed the characteristic C=N stretching band of **14** (Z=NMe) at 1614 cm^{-1}. The reaction was further continued for three days at 80 °C. Then, the solvent was evaporated, and the residual solid was recrystallized from CCl_4 to give 1-methylthiazolidine-2-thione (**15**) in a 64% yield; mp 68—69 °C (Ref.[6] 68—69 °C); NMR (CCl_4) δ 2.37 (t, J=7.3 Hz, 2H, CH_2N) and 4.08 (t, J=7.3 Hz, 2H, CH_2S); IR (CCl_4) 1308 cm^{-1}. These spectral data are the same as those prepared by a published method.[16]

The Reaction of the Dithiostannolane (12) with CS_2. An equimolar mixture of **12** and CS_2 was allowed to react for nine days in 1,2-dichloroethane at 40 °C, and the reaction mixture was submitted to column chromatography on silica gel (Wakogel C-100; CCl_4–$CHCl_3$) to give ethylene trithiocarbonate **14** (Z=S, 39% yield), dibutylstannyl sulfide (35%), and the unreacted **12** (65%). The IR ($\nu_{C=S}$ 1080 cm^{-1}) and NMR (δ_{CH_2} 3.92 ppm) spectra coincided well with those of a commercial sample.

Synthesis and Hydrolysis of 4-Acetoxymethylbenzimidazoles. Effects of Freezing an Internal Rotation on Intramolecular Catalysis by a Benzimidazolyl Group

Masanori UTAKA, Masahisa TAKATSU,* and Akira TAKEDA

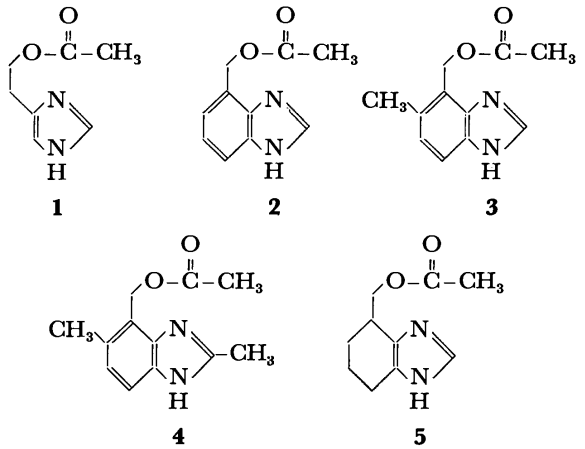
Department of Synthetics Chemistry, School of Engineering, Okayama University, Tsushima, Okayama 700

(Received January 24, 1977)

As models for acetyl-α-chymotrypsin, 4-acetoxymethylbenzimidazole (**2**), its 5-methyl derivative **3** and 2,5-dimethyl derivative **4** were synthesized from *o*-toluidine in moderate yields. Their hydrolytic reactivities were determined in water at 50 °C in comparison with their open-chain analog, 4-(acetoxyethyl)imidazole(**1**). The rate constant (k_1) for intramolecular general base catalysis by the imidazolyl group of **2** was 1.6 times larger than k_1 for **1**. A corrected relative rate of 4.1 is obtained by correcting the basicity difference and the polar substituent effect. The value of 4.1 is an expected magnitude of the effect of freezing an internal rotation as reported for 4,5-(1-acetoxymethyltetramethylene)imidazole. The 5-methyl group of **3** enhances the k_1 value 1.4 times as large as that for **2**. The enhancement can be attributed to restriction of the second internal rotation. The hydrolytic reactivity of **4** is discussed.

In a previous paper[1] we reported that intramolecular general base catalysis in the hydrolysis of acetate **5** by its imidazolyl group is 2.6 times more effective than the catalysis in acetate **1**. It was concluded that this enhancement of 2.6 can be rationalized from the entropy effect of freezing an internal rotation. This suggests that, even if the three remaining internal rotations in the acetoxymethyl group were frozen in **5**, the total enhancement would be a factor of about 50 at the highest, and that there remains a factor of about 500 to attain the deacylation rate constant of acetyl-α-chymotrypsin. This deficiency might possibly be provided by the presence of a carboxylate group which affords the so-called "charger-relay" system[2] in the enzyme, but such a large factor using a model system[3] has never been realized. Thus it is important to estimate the rate enhancement caused by freezing an internal rotation. In order to examine further the enhancement caused by the freezing, we have synthesized three new models **2**—**4** and compared their hydrolytic reactivities with the reactivity of **1** or **5**.

Acetate **2** is an unsaturated analog of acetate **5**. The former has a planar skeleton of benzene which is more rigid than that of cyclohexene in the latter.



1 **2** **3** **4** **5**

* Present address: Nissei Kagaku Kogyo Co., Ltd., Fukumachi, Nishiyodogawa-ku, Osaka 555.

Moreover, **2** has a slightly shorter distance between the carbonyl carbon and the imidazolyl nitrogen than **5**. It seems interesting to show the effect of these factors on the reactivity. The 5-methyl derivative **3** was designed to investigate the rate enhancement caused by restricting the second internal rotation by the methyl group. The dimethyl derivative **4** was prepared as a modification of **3**.

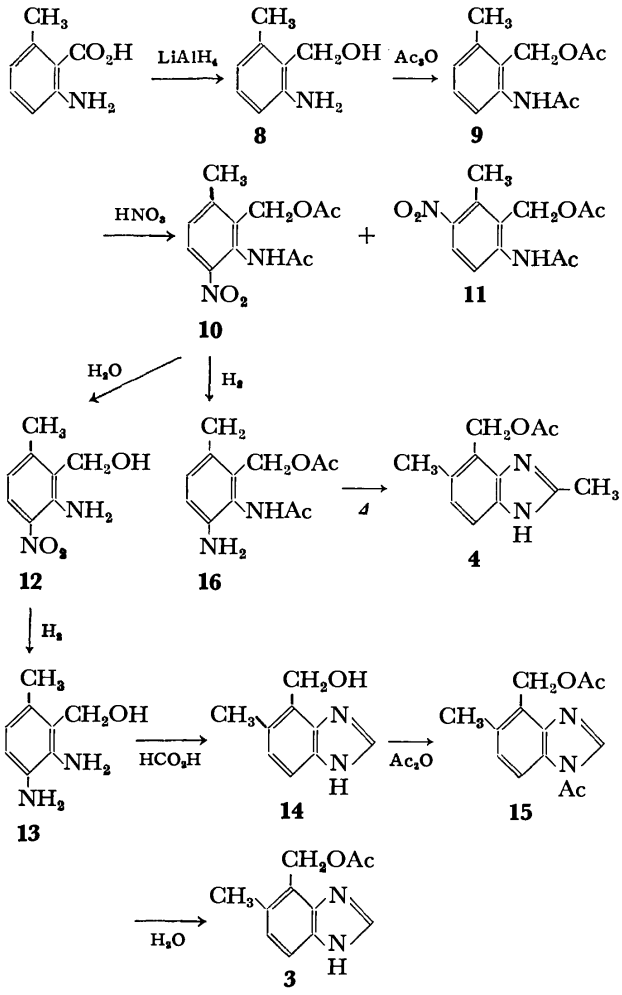
Results and Discussion

Synthesis. Acetate **2** was obtained by reduction and subsequent acetylation of methyl 4-benzimidazolecarboxylate prepared from *o*-toluidine according to the method of Williams and Salvadori.[4]

The 5-methyl derivative **3** was prepared as outlined in Scheme 1. Reduction of 2-amino-6-methylbenzoic acid with lithium aluminum hydride gave **8** in 73% yield, which, after acetylation, was nitrated with 70% nitric acid in acetic anhydride to give a 2:1 to 3:1 mixture of **10** and **11** in 79% yield. The isomer **10** crystallized with ease from the oily layer in the aqueous reaction mixture. Another isomer **11** was isolated by column chromatography. From their NMR spectra showing an AX pattern in the aromatic region with an intensity of two protons, 1,2,3,4-tetrasubstitution was evident for their benzene rings. Although it was not possible to distinguish **10** from **11** using their NMR and IR spectra, the former was distinguishable from the latter since only **10** could provide the benzimidazole derivative **14**.

Reduction of **12** with Urushibara nickel A[5] gave the expected diamino derivative **13** in 99% yield. To prevent coloration of **13**, the reaction mixture was worked up in a nitrogen atmosphere and the product was used immediately for formation of the benzimidazole ring. Use of tin and concd hydrochloric acid reduced not only the nitro group but also the hydroxyl group in 74% yield. The product was confirmed by the formation of 4,5-dimethylbenzimidazole.[6] Reduction with tin(II) chloride and hydrochloric acid[7] gave **13** in a yield of less than 10%.

The benzimidazole derivative **14** was prepared



Scheme 1.

conveniently by heating **13** with 80% formic acid[8] in an about 40% yield. Although acetylation of **14** was accompanied by unavoidable *N*-acetylation, model **3** was obtained in a good yield after selective hydrolysis of the *N*-acetyl group.

Reduction of **10** with Urushibara nickel A also gave the corresponding amine quantitatively. By refluxing **16** in xylene[9] and cooling for deposition, model **4** was obtained in 87% yield. Its NMR spectrum showed no signal near δ 8.0 for the hydrogen attached to the C-2 carbon, but indicated the presence of the 2-methyl group by a singlet at δ 2.55.

Kinetics. In Table 1 are given k_1 (min^{-1}) for intramolecular catalysis of the acetate hydrolysis by an imidazolyl or a benzimidazolyl group and k_{OH} (M^{-1} min^{-1}) for bimolecular hydroxide ion attack for **1**—**5**. These rate constants were derived from the observed pseudo-first-order rate constant k_{obsd} using the equation

$$k_{obsd} = \alpha k_1 + k_{OH}[OH^-],$$

where α is the mole fraction of the neutral imidazole. To calculate the concentration of OH^-, the ionization constant of water was taken as $10^{-13.2617}$ at 50 °C.[10] The plots of log k_{obsd} *vs.* pH for acetates **2** and **3** are given in Fig. 1. The curves in Fig. 1 were drawn using the above equation and the rate constants and pK_a values given in Table 1. For comparison the rate constants for **1** and **5** taken from the previous paper[1] are included in Table 1 and the relative rates corrected for the basicity and the polar substituent effect are also given.

Table 1. Hydrolytic rate constants of acetates **1**—**5** and pK_a values of their benzimidazolyl or imidazolyl groups in water[a]

	1[b]	**2**	**3**	**4**	**5**[b]
pK_a[c]	6.50	4.57	4.85	5.62	6.90
$k_{OH}\times10^{-2}$ (M^{-1} min^{-1})	0.63	2.0	1.95	1.8	0.54
Rel rate	1	3.2 (1)	(0.97)	(0.90)	0.86
$k_1\times10^4$ (min^{-1})	1.00	1.6	3.1	2.9	2.6
Rel rate	1	1.6 (1)	(1.9)	(1.8)	2.6
Corrected rel k_1					
For basicity[d]	1	13 (1)	(1.4)	(0.58)	1.7
For polarity[e]	1	4.1			

a) At 50±0.1 °C, 0.1 M KCl. k_1 and k_{OH}, ±5%; pK_a, ±0.02. b) Taken from Ref. 1. c) For comparison the pK_a value for benzimidazole was determined to be 5.16 under the same conditions. d) Corrected for ΔpK_a using the Brönsted exponent β=0.47. e) Corrected for polar effects using the relative rate for k_{OH}.

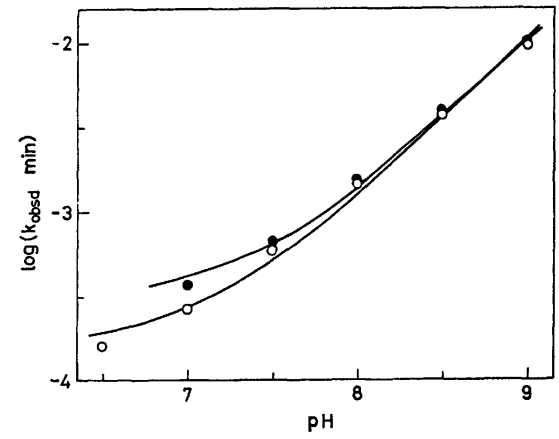


Fig. 1. Plots of log k_{obsd} *vs.* pH for the hydrolyses of **2** (○) and **3** (●) in water at 50 °C, 0.1 M KCl. The points are experimental and the lines theoretical using the equation $k_{obsd}=\alpha k_1+k_{OH}[OH^-]$ and the constants listed in Table 1.

pK_a *Values.* As seen from Table 1 the pK_a value (4.57) for **2** is 0.59 pK_a units smaller than that (5.16) for benzimidazole. This magnitude of a base-weakening effect of an acetoxymethyl group attached to the C-4 position coincides with that for the saturated analog **5** (pK_a 6.90) and 4,5-tetramethyleneimidazole (pK_a 7.50).[1] This suggests that the acetoxymethyl group exerts its effect on the imidazolyl nitrogen through space or sterically. The pK_a value for **3** is 0.28 pK_a units larger than that for **2** and this increment is comparable to 0.33 pK_a units reported for 5-methylbenzimidazole (pK_a 5.81) and benzimidazole (pK_a 5.48) in water at 25 °C.[11] We find an additivity of the substituent effect on the pK_a value (5.62) for **4** as shown by the fact that

the increment (1.05) for the two methyl groups in **4** is equal to the sum of the increments (0.33 and 0.71) for the 5- and 2-methyl[11] groups, no anomaly being found in the pK_a values for **2**, **3**, and **4**.

Effects of Freezing an Internal Rotation. Acetate **2** can be characterized by the rigidity of its structure. It has one internal rotation frozen between the imidazolyl nitrogen and the carbonyl carbon in comparison with acetate **1**. As reported the hydrolysis of **1** is catalyzed by its intramolecular imidazolyl group as general base.[1] The catalytic activity is enhanced in the acetate **5** by a factor of 2.6 mainly because of the rigidity in structure. Thus we can except acetate **2** to show a similar enhancement in the catalysis.

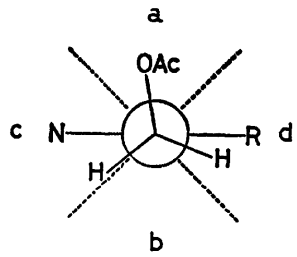
The catalytic rate constant k_1 for **2** was found to be 1.6 times as large as that for **1** (Table 1). This rate factor of 1.6 must be corrected for the basicity and polarity differences between **1** and **2**. Since **2** is less basic than **1** by 1.93 pK_a units, the general base catalysis in **2** is expected to decrease by a factor of 8.07 when we use the Brönsted exponent $\beta=0.47$ for the general base-catalyzed hydrolysis of ethyl dichloroacetate.[1,12] The correction gives a rate factor of 13 for **2**. A correction factor of 3.2 for the polarity difference was adopted from the relative rate for the hydroxide-ion hydrolysis. Although the polar substituent constants (σ^*) for the two alkoxyl groups in **1** and **2** have not been estimated, the observed rate factor of 3.2 seems reasonable as judged from the polar effect of ethyl and benzyl groups.[13]

Thus we obtain a rate factor of 4.1 for freezing an internal rotation in **2**. The value is about twice as large as the factor of 1.7 for **5**. However, the doubled factor is what had been expected previously.[1] In the imidazolyl group-catalyzed hydrolysis of **1** or **2**, two transition states, which are mirror images of each other and identical energetically, may take place during the imidazolyl residue rotation about the methylene-imidazolyl residue bond. But for **5**, since the acetoxymethyl group is expected to take a preferred pseudo-equatorial position, only one transition state can be realized.

We can thus concluded that the rigid structure of benzene in **2** gives rise to almost the same rate factor by freezing an internal rotation as the flexible structure of cyclohexene in **5**, and that the difference in the spatial alignments of the imidazolyl nitrogen and the carbonyl carbon between **2** and **5** is not critical for the intramolecular catalysis. These two conclusions are consistent with the looseness of the transition state in general base catalysis.[1]

Restriction of the Second Internal Rotation. The rate enhancement in k_1 by the 4-methyl group seems to be properly estimated using the concept of rotamer population.

Figure 2 shows the Newman projection for **2** and **3**, in which the horizontal line represents the benzimidazole plane. The projection formula indicates the existence of four rotamers **a**, **b**, **c**, and **d** with the acetoxyl group in a, b, c, and d regions, respectively. Rotamers **a** and **b** are considered to be active catalytically; rotamer **c** is thought to be inactive owing to the crowded and less



2 R=H
3 R=CH_3

Fig. 2. The projection formula for **2** and **3**. The horizontal line represents the benzimidazole plane.

favorable alignment of the acetoxyl group and rotamer **d** to be inactive because of the incorrect orientation of the acetoxyl group. Since the rotation about the carbon-carbon bond is expected to be essentially free for **2**, the four rotamer populations can be taken to be roughly equal to each other if the active region is accepted as shown in Fig. 2. Then the fraction of the active rotamer population is 2/4. If rotamer **c** is negligible owing to the steric repulsion between the nitrogen and the oxygen, the fraction will be 2/3.

On the other hand, rotamer **d** must be absent for the 4-methyl derivative **3**, whereas the remaining three rotamers are similar to the corresponding ones for **2**. Then the fraction of the active rotamer population is 2/3 or 2/2 for **3**. Thus we obtain a relative rate of 1.33—1.5 for the expected enhancement in k_1. Actually, the value of 1.4 was obtained for **3** after the correction for basicity (Table 1).

Effects of the 2-Methyl Group. Acetate **4** shows deceleration of the hydrolyses. A larger deceleration factor of 2.4 (=1.4/0.58) is obtained for k_1 in comparison with the small factor of 1.1 for k_{OH}, but the deceleration is not so large when compared with the deceleration factor of 92 reported for the intramolecular nucleophilic catalysis by 2-methylbenzimidazole of the hydrolysis of *p*-nitrophenyl acetate.[14]

Experimental

All melting points are uncorrected. Elemental analyses were carried out by Mr. E. Amano of our laboratory. ^1H NMR spectra were recorded at 60 MHz on a Hitachi Model R-24 spectrometer. Tetramethylsilane was used as internal standard unless otherwise noted.

Materials. Potassium chloride and benzimidazole of reagent grade were used after recrystallization. Hydrochloric acid, sodium hydroxide, and standard buffer solutions were obtained from Nakarai Chemicals (Kyoto). Deionized water was used in all kinetic runs.

4-Hydroxymethylbenzimidazole (6). Reduction of methyl 4-benzimidazolecarboxylate with lithium aluminum hydride in THF, prepared according to the method of Williams and Salvadori[4] from *o*-toluidine, gave crude yellow crystals of **6** in 74% yield. The crude crystals were recrystallized from hot water after treating with carbon, giving colorless needles: mp 140—144 °C; IR (KBr) 3400—2200 (OH and NH), 1620 (benzimidazole ring), and 1005 cm^{-1} (C–O); NMR (DMSO-d_6) δ (solvent peak as internal standard, δ 2.50) 8.22 (s, 1, N–CH=N), 7.7—7.1 (m, 3, benzene ring), 6.5 (s, NH and OH), and 4.92 ppm (s, 2, CH_2–O).

N-Acetyl-4-acetoxymethylbenzimidazole (7). In acetic anhydride **6** was heated at 70 °C for 1 h with stirring. The excess anhydride was distilled under reduced pressure, leaving white crystals of **7**. Recrystallization from carbon tetrachloride gave pure crystals in 95% yield: mp 96.0—97.5 °C; IR (KBr) 1730, 1725 (ester and amide C=O), 1600 (benzimidazole ring), and 1235 cm^{-1} (C–O); NMR ($CDCl_3$) δ 8.33 (s, 1, N–CH=N), 8.2—7.2 (m, 3, benzene ring), 5.53 (s, 2, CH_2–O), 2.71 (s, 3, N–$COCH_3$), and 2.10 ppm (s, 3, O–$COCH_3$).

4-Acetoxymethylbenzimidazole (2). In dil hydrochloric acid **7** was dissolved at 50 °C with stirring over a 50-min period. The solution was filtered and neutralized with aq potassium hydrogen carbonate. The neutral solution was extracted with chloroform, and the solvent was evaporated after drying over magnesium sulfate to leave white crystals of **2** in 94% yield. Recrystalliztion from chloroform gave a pure sample: mp 169.5—170.5 °C; IR (KBr) 3200—2200 (NH), 1723 (C=O), 1620—1605 (benzimidazole ring), 1242 (C–O), and 754, 715 cm^{-1} (1,2,3-trisubstituted benzene); NMR ($CDCl_3$) δ 8.06 (s, 1, N–CH=N), 7.9—7.1 (m, 3, benzene ring), 7.1 (s, 1, NH), 5.45 (s, 2, CH_2–O), and 2.08 ppm (s, 3, $COCH_3$). Found: C, 63.47; H, 5.50; N, 14.78%. Calcd for $C_{10}H_{10}N_2O_2$: C, 63.15; 5.30; N, 14.73%.

2-Amino-6-methylbenzyl Alcohol (8). 2-Amino-6-methylbenzoic acid[15] prepared from *o*-toluidine was reduced with lithium aluminum hydride in ether at room temperature. The excess hydride was decomposed with water and the resulting mixture was filtered. The white solid was washed with ether repeatedly. The filtrate and washings were combined, the solvent being removed to leave white crystals of **8** in 73% yield. Recrystallization from carbon tetrachloride gave white needless: IR (KBr) 3400—2400 (NH_2 and OH), 1600 (NH_2), 1000 (C–O), and 785, 745 cm^{-1} (1,2,3-trisubstituted benzene).

2-Acetylamino-6-methylbenzyl Acetate (9). In excess acetic anhydride **8** was heated at 70 °C for 2 h with stirring. The excess anhydride was removed under reduced pressure to leave **9** in a quantitative yield. Recrystallization from carbon tetrachloride gave colorless needles: mp 118—118.5 °C; IR (KBr) 3250 (NH), 1735 (ester C=O), 1650 (amide C=O), and 790, 750 cm^{-1} (1,2,3-trisubstituted benzene); NMR ($CDCl_3$) δ 9.05 (s, 1, NH), 7.8—6.8 (m, 3, benzene ring), 5.12 (s, 2, CH_2–O), 2.41 (s, 3, CH_3), 2.19 (s, 3, N–$COCH_3$), and 2.05 ppm (s, 3, O–$COCH_3$). Found: C, 64.87; H, 6.59%. Calcd for $C_{12}H_{15}NO_3$: C, 65.14; H, 6.83%.

2-Acetylamino-3-nitro-6-methylbenzyl Acetate (10). To a solution of 5.0 g (21.6 mmol) of **9** in 25 ml of acetic anhydride was added 4 ml of 70% nitric acid dropwise with stirring at 19—20 °C. After the addition was completed, the mixture was stirred for 1 h at the same temperature. The mixture was poured into 300 ml of cold water with stirring. Colorless needles separated were collected and recrystallized from ethanol to give pure **10** in 38% yield: mp 147—148 °C; IR (KBr) 3250 (NH), 1740 (ester C=O), 1655 (amide C=O), and 1510, 1355 cm^{-1} (NO_2); NMR ($CDCl_3$) δ 8.9 (s, 1, NH), 7.81 (d, 1, J=9 Hz, H_4), 7.19 (d, 1, J=9 Hz, H_5), 5.15 (s, 2, CH_2–O), 2.50 (s, 3, CH_3), 2.19 (s, 3, N–$COCH_3$), and 2.08 ppm (s, 3, O–$COCH_3$). Found: C, 53.86; H, 5.07%. Calcd for $C_{12}H_{14}N_2O_5$: C, 54.13; H, 5.30%.

From the mother liquor a mixture of **10** and **11** was recovered, giving a 79% yield for the nitration. The isomer **11** was separated by column chromatography using silica gel (Wakogel C-200) and dichloromethane, and recrystallized from carbon tetrachloride: mp 227—230 °C; IR (KBr) 3350 (NH), 1712 (ester C=O), 1688 (amide C=O), and 1520, 1350 cm^{-1} (NO_2); NMR ($CDCl_3$) δ 9.5 (s, 1, NH), 8.03 (d, 1, J=9 Hz, H_4), 7.78 (d, 1, J=9 Hz, H_3), 5.20 (s, 2, CH_2–O), 2.58 (s, 3, CH_3), 2.25 (s, 3, N–$COCH_3$), and 2.12 ppm (s, 3, O–$COCH_3$).

2-Amino-3-nitro-6-methylbenzyl Alcohol (12). In aq methanol **10** was dissolved and hydrolyzed for 3 h at 60 °C after addition of aq sodium hydroxide. The solution was neutralized with hydrochloric acid and extracted four times with chloroform. After drying over magnesium sulfate, the solvent was removed to give orange crystals of **12** in 99% yield. Recrystallization from ethanol gave a pure sample: mp 135—136 °C; IR (KBr) 3460, 3350 (NH_2 and OH), 1636 (NH_2), 1498, 1321 (NO_2), and 816 cm^{-1} (1,2,3,4-tetrasubstituted benzene); NMR ($CDCl_3$) δ 7.89 (d, 1, J=9 Hz, H_4), 6.48 (d, 1, J=9 Hz, H_5), 4.76 (s, NH_2 and OH), 4.70 (s, 2, CH_2–O), and 2.35 ppm (s, 3, CH_3). Found: C, 52.45; H, 5.41%. Calcd for $C_8H_{10}N_2O_3$: C, 52.74; H, 5.53%.

2,3-Diamino-6-methylbenzyl Alcohol (13). One hundred mg of **12** was dissolved in 5 ml of ethanol and reduced with hydrogen (1 atm) using about 20 mg of Urushibara nickel A.[5] Absorption of hydrogen ceased after the theoretical volume of hydrogen was taken up. The yellow solution was gradually decolorized as the hydrogen was absorbed. To dissolve a white precipitate 10 ml of hot ethanol was added and the reaction mixture was filtered with a glass filter with suction. Removal of ethanol gave 88 mg (99%) of white needles of **13**. The reaction mixture was worked up in a nitrogen atmosphere and **13** thus prepared was used immediately for the next step: mp 181—182 °C; IR (KBr) 3450—2400 (NH_2 and OH), 1660—1550 (NH_2), and 802 cm^{-1} (1,2,3,4-tetrasubstituted benzene); NMR (DMSO-d_6) δ 6.44 (d, 1, J=8 Hz, H_4 or H_5), 6.24 (d, 1, J=8 Hz, H_5 or H_4), 4.46 (s, 2, CH_2–O), and 2.16 ppm (s, 3, CH_3).

4-Hydroxymethyl-5-methylbenzimidazole (14). In 15 ml of 80% formic acid was dissolved 428 mg of freshly prepared **13**, and the solution was heated at 100 °C for 1 h with stirring. The resulting red solution was neutralized with concd aq sodium hydroxide to separate a red oil on the bottom. The decolorized supernatant solution was decanted and concentrated under reduced pressure to precipitate white needles. The needles were collected, washed with cold water, and dried, giving 171 mg (37%) of **14**: mp 205—205.5 °C; IR (KBr) 3300—2200 (NH and OH), 1590 (benzimidazole ring), and 811 cm^{-1} (1,2,3,4-tetrasubstituted benzene); NMR ($CDCl_3$) δ 8.00 (N–CH=N), 7.42 (d, 1, J=8 Hz, $H_{7(4)}$), 7.03 (d, 1, J=8 Hz, $H_{4(7)}$), 4.97 (s, 2, CH_2–O), and 2.45 ppm (s, 3, CH_3).

N-Acetyl-4-acetoxymethyl-5-methylbenzimidazole (15). Acetylation of **14** in the same way as for **6** gave crude **15**, which was recrystallized from carbon tetrachloride to give white needles in 80% yield: mp 156—157 °C; IR (KBr) 1725 (ester and amide C=O), 1595 (benzimidazole ring), and 817 cm^{-1} (1,2,3,4-tetrasubstituted benzene); NMR ($CDCl_3$) δ 8.32 (s, 1, N–CH=N), 8.06 (d, 1, J=9 Hz, H_7), 7.24 (d, 1, J=9 Hz, H_6), 5.59 (s, 2, CH_2–O), 2.71 (s, 3, N–$COCH_3$), 2.48 (s, 3, CH_3), and 2.07 ppm (s, 3, O–$COCH_3$).

4-Acetoxymethyl-5-methylbenzimidazole (3). Partial hydrolysis of **15** in the same way as for **7** gave white crystals of **3** in 83% yield after recrystallization from chloroform. The analytical and kinetic sample was purified further by sublimation *in vacuo*: mp 229—229.5 °C; IR (KBr) 3200—2400 (NH) 1720 (C=O), 1625, 1595 (benzimidazole ring), 1240 (C–O), and 820 cm^{-1} (1,2,3,4-tetrasubstituted benzene); NMR (CD_3OD) δ 8.02 (s, 1, N–CH=N), 7.46 (d, 1, J=9 Hz, $H_{7(4)}$), 7.05 (d, 1, J=9 Hz, $H_{6(5)}$), 5.42 (s, 2, CH_2–O), 4.74 (s, NH), 2.44 (s, 3, CH_3), and 2.02 ppm (s, 3, $COCH_3$). Found: C, 64.88; H, 5.98; N, 13.78%. Calcd for $C_{11}H_{12}N_2O_2$: C, 64.69; H, 5.92; N, 13.72%.

2-Acetylamino-3-amino-6-methylbenzyl Acetate (16). Using

the Urushibara nickel catalyst **10** was reduced with hydrogen in the same way as for **12**. White crystals of **16** were obtained in 100% yield: mp 149—151 °C; IR (KBr) 3390, 3230 (NH_2 and NH), 1732 (ester C=O), and 1650 cm^{-1} (amide C=O); NMR ($CDCl_3$) δ 8.8 (s, 1, NH), 6.90 (d, 1, J=8 Hz), 6.60 (d, 1, J=8 Hz), 5.07 (s, 2, CH_2-O), 2.30 (s, 3, CH_3), 2.20 (s, 3, N-$COCH_3$), and 2.01 ppm (s, 3, O-$COCH_3$).

4-Acetoxymethyl-2,5-dimethylbenzimidazole (4). A mixture of 2 ml of dry xylene and 50 mg of **16** was heated at 135 °C for 5 h with stirring. The reaction mixture was cooled to precipitate colorless needles, which were collected and washed with ether to give 40 mg (87%) of **4**. This was purified by recrystallization from carbon tetrachloride–chloroform and subsequent sublimation *in vacuo*: mp 220—221 °C; IR (KBr) 3500—2300 (NH), 1725 (C=O), 1625, 1595 (benzimidazole ring), 1235 (C-O), and 820 cm^{-1} (1,2,3,4-tetrasubstituted benzene); NMR (CD_3OD) δ 7.37 (d, 1, J=9 Hz, $H_{7(4)}$), 7.02 (d, 1, J=9 Hz, $H_{6(5)}$), 5.42 (s, 2, CH_2-O), 4.8 (s, NH), 2.55 (s, 3, CH_3), 2.44 (s, 3, CH_3), and 2.04 ppm (s, 3, $COCH_3$). Found: C, 65.94; H, 6.67; N, 13.12%. Calcd for $C_{12}H_{14}N_2O_4$: C, 66.04; H, 6.47; N, 12.84%.

Reduction of 12 with Tin and Hydrochloric Acid. To a mixture of 102 mg of **12** and 400 mg of tin was added 2.5 ml of concd hydrochloric acid, and the mixture was heated at 70 °C for 30 min. Then it was made basic (pH 11) by addition of 5 ml of 5 M sodium hydroxide and heated at 100 °C for a while. Extraction with chloroform gave 56 mg of white needles in 74% yield, which was identified as 3,4-*o*-xylenediamine: IR (KBr) 3400—3150 (NH_2), 1625 cm^{-1} (NH_2); NMR (CD_3OD) δ 6.45 (t, 2, CH=CH), 4.63 (s, 4, NH_2), 2.14 (s, 3, CH_3), and 2.03 ppm (s, 3, CH_3).

Kinetics. All kinetic measurements for hydrolysis were made at 50±0.1 °C (0.1 M KCl) in water by the titration of liberated acid with the titration assembly.[1] The initial concentration of acetate **2** was 0.0025 and 0.005 M. However, only 0.0025 M was used for **3** and **4** owing to their solbilities. Hydrolysis of the acetates were followed to 3 (at pH 6.5)—50 % (at pH 9.0) completion for **2**, to 2.4 (at pH 7.0)—47% (at pH 9.0) for **3**, and to 6.9 (at pH 6.5)—15% (at pH 9.0) for **4**. Deposition of **3** from the kinetic solution after 1 h or so from the start of kinetic run allowed only 2—3% completion for **3** at pH 6.5—7.0, although **3** could be dissolved initially in the acidic solution. All runs followed first-order kinetics. Values of k_{obsd} were reproduced within±5%.

pK_a *Determinations.* Values of pK_a were determined according to the method of Albert and Serjeant[16] using the apparatus for kinetics under the same conditions as for kinetics.

13) R. W. Taft, Jr., "Steric Effects in Organic Chemistry," ed by M. S. Newman, Wiley, New York (1965), Chap. 13, pp. 619, 644—645. For the alkaline hydrolysis of ethyl and benzyl acetates, a rate factor of 2.93 can be calculated using σ^* values −0.100 and 0.215 for C_2H_5 and $C_6H_5CH_2$, respectively, and a ρ^* value of 1.465. The steric effect of the two substituents is calculated to give a factor of 1.09 using E_s values −0.09 and −0.22 for C_2H_5 and i-C_4H_9, respectively, and a δ value 0.301 for the alkaline hydrolysis of $ROCOCH_3$. Here the value for i-C_4H_9 is used instead of that for $C_6H_5CH_2$ since the latter is not known yet. The E_s values for C_2H_5 and $C_6H_5CH_2$ in the acyl component, however, are reported to be −0.07 and −0.38, respectively. With these we obtain the factor of 1.24. The steric effect on the relative rate is very small as compared with the polar effect.

Photochemistry of Heterocyclic Compounds. VII.[1] Photochemical Reaction of 2,5-Diphenyl-1,3,4-oxadiazole with Benzo[*b*]thiophenes

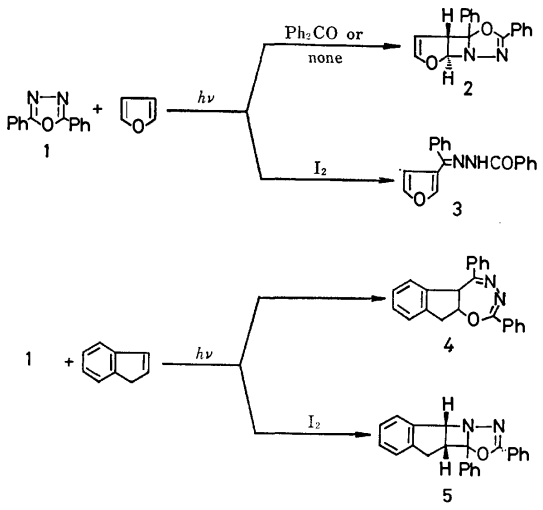
Kōji Oe, Masashi Tashiro, and Otohiko Tsuge*

Research Institute of Industrial Science, Kyushu University 86, Hakozaki, Higashi-ku, Fukuoka 812

(Received February 19, 1977)

Irradiation of 2,5-diphenyloxadiazole **1** with benzothiophene **6a** gives 3-benzoylbenzothiophene **7**, its benzoylhydrazone **8**, and/or the oxadiazepine **9**; the yields depended on the nature of solvents. With benzophenone as a sensitizer, the photochemical reaction of **1** with **6a** forms the [2+2] cycloadduct **12**. It is found that **9** is photochemically dissociated to **1** and **6a**. In the case of 2-methylbenzothiophene **6b**, 3-benzoyl-2-methylbenzothiophene benzoylhydrazone **18** is formed, and with benzophenone as a sensitizer the [2+2] cycloadduct **19** is obtained. In the absence or presence of benzophenone, however, irradiation of **1** with 3-methylbenzothiophene **6c** gives the [2+2] cycloadduct **20**. The photochemical reaction of **1** with **6a** or **6b** in the presence of iodine gives the corresponding 3-benzoylbenzothiophene, **7** or **21**, and benzoylhydrazone, **8** or **18**, respectively. In the case of **6c**, however, the [2+2] cycloadduct **23** is formed, together with 2-benzoyl-3-methylbenzothiophene **22**. Mechanistic considerations of these reactions are also described.

Although [2+2] photocycloadditions of olefins to other olefins[2] and to ketones[3] are well characterized, only a few examples of similar photocycloadditions to the carbon-nitrogen double bonds appeared in the literature.[4-8] Previously, we reported some novel photoproducts from the photochemical reactions of 2,5-diphenyl-1,3,4-oxadiazole (**1**) with furan[4] and indene[5] in the absence or presence of iodine as depicted in Scheme 1. The [2+2] cycloadduct **2** is formed *via* the interation between a triplet excited state of **1** and furan, and the formation of the benzoylhydrazone **3** is attributable to the reaction of **1** with cyclobutadiene oxide (probably its iodine complex) produced from the photochemical interaction between furan and iodine. On the other hand, the reaction to afford the oxadiazepine **4** starts with a singlet excited state of indene, and the [2+2] cycloadduct **5** is produced *via* the photochemical reaction of **1** with σ-complex between indene and iodine.



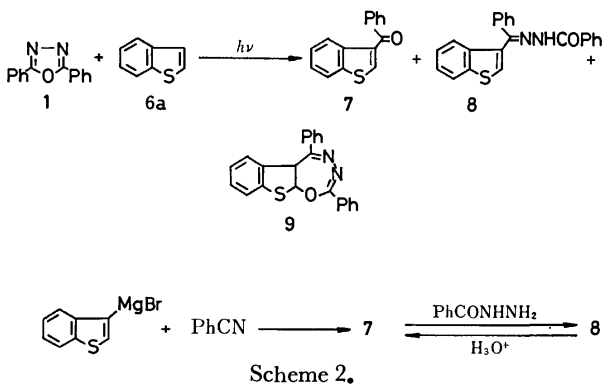
Scheme 1.

It has been reported that upon irradiation with olefins[9] and acetylenes[10] benzo[*b*]thiophene gave the cycloadducts. Thus we were interested in the photochemical reaction of **1** with benzo[*b*]thiophene. We now report here on the photochemical reactions of **1** with benzo[*b*]thiophene and its methyl derivatives under various conditions.

* To whom correspondences should be addressed.

Results and Discussion

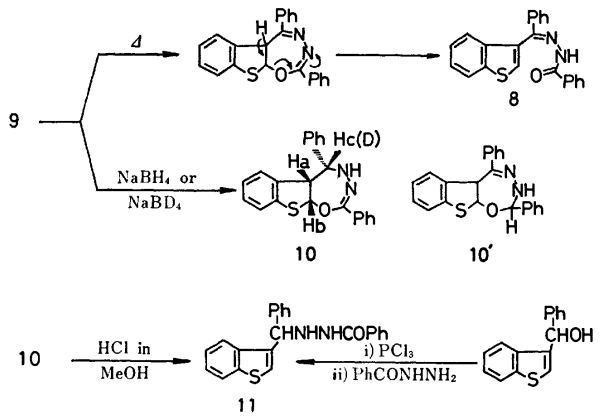
Photochemical Reaction in the Absence of Iodine. Irradiation of a solution of the oxadiazole **1** and benzo[*b*]thiophene (**6a**) in benzene below 15 °C afforded 3-benzoylbenzo[*b*]thiophene (**7**), its benzoylhydrazone **8**, and the 1 : 1 cycloadduct **9**. The results in various solvents are shown in Table 1; the yields of the products depended on the nature of solvent. Structural elucidation of **7** and **8** was accomplished on the basis of their spectral data as well as of identification with authentic samples prepared by the routes depicted in Scheme 2.



Scheme 2.

From the following evidence, the 1 : 1 adduct **9** was assigned to be 2,5-diphenyl-5a,10a-dihydro[1]benzothieno[3,2-*f*][1,3,4]oxadiazepine whose ring system is the same as that of **4**. The IR spectrum and chemical behavior of **9** are similar to those of the oxadiazepine **4**. The 1 : 1 adduct **9** is thermally labile and on being heated readily isomerized to the benzoylhydrazone **8** in benzene. Reduction of **9** with sodium borohydride afforded the dihydro compound whose structure was assigned to be 2,5-diphenyl-4,5,5a,10a-tetrahydro[1]-benzothieno[3,2-*f*][1,3,4]oxadiazepine (**10**), but not the 2,3,5a,10a-tetrahydro compound **10'**. The NMR spectrum of **10** exhibits methine proton signals at δ 4.67

(H_a, t, J=8 Hz), 6.23 (H_b, d, J=8 Hz) and 6.32 (H_c, d, J=8 Hz), besides aromatic and NH proton signals. In the NMR spectrum of **10**-d_1 which was prepared by reduction of **9** with sodium borohydride-d_4, the doublet at δ 6.32 does not appear, and two doubles (J=8 Hz) are displayed at δ 4.67 and 6.25. On treatment with hydrochloric acid in methanol at room temperature, **10** was converted into 1-benzoyl-2-[α-(3-benzo[*b*]thienyl)-benzyl]hydrazine (**11**), which was identical with an authentic sample (Scheme 3).



Scheme 3.

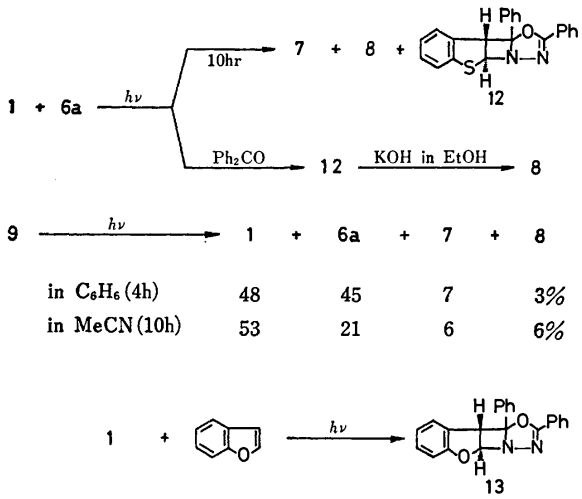
Previously,[5] we have reported that the oxadiazepine **4** is the *cis*-fused adduct, and that three methine hydrogens in the dihydro compound of **4** are situated *cis* each other. Although the NMR spectrum of **9** could not be measured owing to its insolubility in solvents and to its lability, it was deduced that **9** would be also the *cis*-fused adduct on the basis of stereochemistry of **10**. In analogy with the dihydro compound of **4**, we assumed that the moiety –N–N=C(O)Ph in the seven-membered cyclic ring of **10** is coplanar. An inspection of the Dreiding models of **10** indicates that the dihedral angles, θ_{ab} between H_a and H_b, and θ_{ac} between H_a and H_c, are *ca.* 25° respectively, when the hydrogens H_a, H_b, and H_c are situated *cis* each other. The observed J_{ab} and J_{ac} values are 8 Hz which is compatible with the calculated value (6.7 Hz) when θ is 25°.[11]

Table 1. Photochemical reaction of **1** with **6a** in various solvents

Solvent	Irradiation time, h	Products, %		
		7	**8**	**9**
Hexane	1	trace	—	69
Dioxane	1	6	—	21
Benzene	1	5	trace	24
Diethyl ether	1	2	—	47
Tetrahydrofuran	1	4	—	21
Acetonitrile	1	1	3	—
Acetonitrile	10	2	5	—

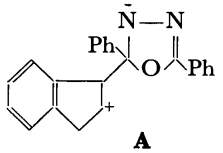
Irradiation of **1** with **6a** in benzene for 10 h did not give the oxadiazepine **9**, but instead a new 1 : 1 adduct **12** was obtained in 8% yield, together with small quantities of **7** and **8** and with recovery of **1** and **6a**. Photolysis of the oxadiazepine **9** in benzene or acetonitrile afforded the oxadiazole **1**, benzothiophene **6a**, benzoylbenzothiophene **7**, and 1 : 1 adduct **12** (Scheme 4). Thus, it can be concluded that the oxadiazepine **9** is photochemically dissociated to the starting materials **1** and **6a**, along with a partial isomerization to **8**. On treatment with ethanolic potassium hydroxide, the 1 : 1 adduct **12** isomerized to **8**. On the basis of the above fact and spectral data, **12** was assigned to be the *trans* [2+2] cycloadduct, 4,4a,9b,9c-tetrahydro-2,9c-diphenyl[1]benzothieno[3',2': 3,4]azetidino[2,1-*b*][1,3,4]oxadiazole.

In the benzophenone photosensitized reaction of **1** with **6a**, the [2+2] cycloadduct **12** was formed as the sole product. Both electronic absorption spectra of **1** and **6a** show absorptions around 310 nm, while that of benzo[*b*]furan displays no appreciable absorption above 290 nm. When a solution of **1** and benzo[*b*]-furan in benzene was irradiated with a high-pressure mercury lamp or with monochromatic light (313 nm), the *trans* [2+2] cycloadduct **13** was obtained. Thus, it may concluded that the reaction for the formation of **12** starts with a triplet excited state of **1**.



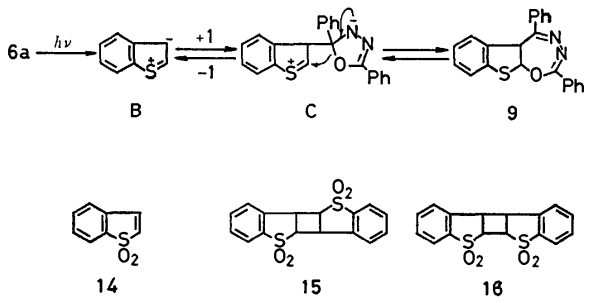
Scheme 4.

In a previous paper[5] we suggested that the reaction producing the oxadiazepine **4** starts with a singlet state of indene, and the subsequent interaction with **1** forms the betaine intermediate **A** which gives **4**. The plausible



A

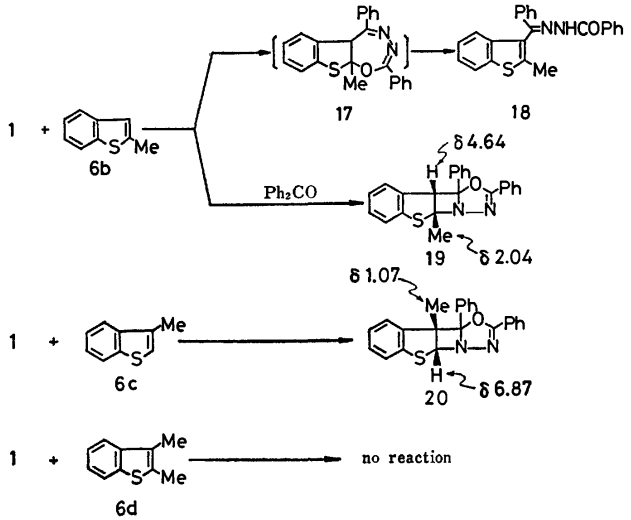
pathway for the formation of **9** is outlined in Scheme 5. By the absorption of light **6a** is excited to the polar species **B** proposed in the photochemical reaction of **6a**.[10] This is followed by interaction with **1** to give the betaine intermediate **C** like **A**, and subsequent ring opening of **C** with concurrent ring closure affords **9**.



Scheme 5.

The following result suggests a significant contribution of **B** to the formation of **9**. Benzo[*b*]thiophene 1,1-dioxide (**14**) cannot form an excited species such as **B**. The 1,1-dioxide **14** failed to add **1**, but instead underwent a cinnamic acid type dimerization to give a mixture of two isomeric dimers **15** and **16**.

Although the photochemical reaction of **1** with **6a** in acetonitrile did not give the oxadiazepine **9** (Table 1), irradiation in ethyl ether containing acetonitrile (5 mol to **6a**) afforded the oxadiazepine **9** in 38% yield; this fact indicates that acetonitrile does not act as an inhibitor for the formation of **9**. Thus it may be viewed that the primary photoadduct **9** is readily dissociated to the starting materials in a polar solvent such as acetonitrile.



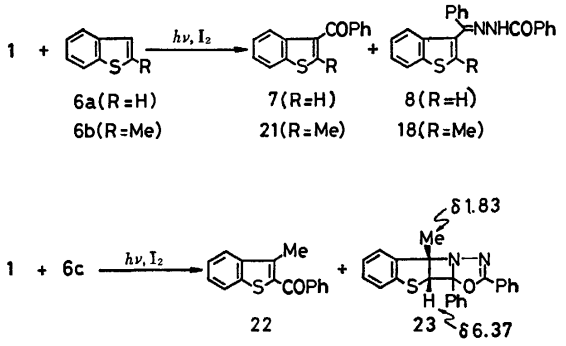
Scheme 6.

Next, we investigated the photochemical reaction between **1** and methylbenzo[*b*]thiophenes. Without or with benzophenone as the sesitizer, irradiation of **1** with 2-methylbenzo[*b*]thiophene (**6b**) afforded 3-benzoyl-2-methylbenzo[*b*]thiophene benzoylhydrazone (**18**) or [2+2] cycloadduct **19**, respectively. The benzoylhydrazone **18** might be interpreted as arising *via* the oxadiazepine **17**, but no **17** was detected in the reaction mixture. On the other hand, the photochemical reaction of **1** with 3-methylbenzo[*b*]thiophene (**6c**) did not give the corresponding oxadiazepine nor benzoylhydrazone, but instead the [2+2] cycloadduct **20** was formed in 13% yield; this fact means that the polarized species of **6c** such as **B** does not contribute to the reaction, because of the electron-donating 3-methyl group. With benzophenone as the sesitizer, the [2+2] cycloadduct **20** was obtained in 33% yield. Upon irradiation, however, 2,3-dimethylbenzo[*b*]thiophene (**6d**) did not react with **1** (Scheme 6). Structures of the photoproducts, **18**—**20**, were established by the spectral data. The stereochemistry of **19** and **20** will be described later.

It is reasonable to conclude that the reactions producing the [2+2] cycloadducts **19** and **20**, as well as the [2+2] cycloadduct **12**, start with a triplet excited state of **1**.

Photochemical Reaction in the Presence of Iodine. Irradiation of **1** with **6a** or **6b** in the presence of iodine (20 mol % to **1**) in benzene afforded the corresponding 3-benzoylbenzothiophene **7** (16%) or **21** (1%), and benzoylhydrazone **8** (50%) or **18** (15%), respectively. These results appear to be similar to that of the reaction with furan in the presence of iodine (Scheme 1). In the reaction of **1** with **6c** under similar conditions, however, a new [2+2] cycloadduct **23** was obtained, together with 2-benzoyl-3-methylbenzo[*b*]thiophene (**22**) (Scheme 7). The benzoyl compounds **21** and **22** were identical with the respective authentic samples prepared from the Friedel-Crafts benzoylation of **6b** and **6c**.

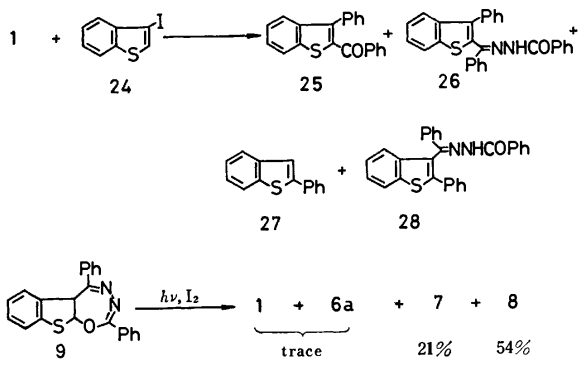
On the basis of the following spectral data, **23** was assigned to be 4,4a,9a,9b-tetrahydro-2,9b-diphenyl-4a-methyl[1]benzothieno[2′,3′: 3,4]azetidino[2,1-*b*][1,3,4]-oxadiazole, whose structure corresponds to the reversed adduct of **20**. The IR spectrum of **23** is very similar to that of **20**. The chemical shift of methine proton in **23** is comparable to that (δ 6.45) of the methine adjacent to the nitrogen atom in the [2+2] cycloadduct **5**, but not compatible with that in **20**. The methyl proton signal in **23** appears at a higher field than that in **19**, but at a lower field than that in **20**. The stereochemistry of **23** will be also described later.



Scheme 7

It is known that **6a** undergoes electrophilic substitution with bromine to yield 3-bromobenzo[*b*]thiophene.[12] Thus, we investigated the possibility of the formation of **8** from the photochemical reaction of **1** with 3-iodobenzo[*b*]thiophene (**24**). As shown in Scheme 8, irradiation of **1** with **24** in benzene gave 2-benzoyl-3-phenylbenzo[*b*]thiophene (**25**), its benzoylhydrazone **26**, 2-phenylbenzo[*b*]thiophene (**27**), and 3-benzoyl-2-phenylbenzo[*b*]thiophene (**28**); no **7** and **8** were formed. The benzoylhydrazone **26** may be interpreted as arising *via* interaction between **1** and 3-phenylbenzo[*b*]thiophene which formed from the pho-

tochemical reaction of **24** with the solvent (benzene). It has been reported that the treatment of 3-phenylbenzothiophene with iodine does not give the 2-isomer **27**,[13] but with hydrogen fluoride 3-phenyl derivative isomerizes to **27**.[14] The formation of **27** seems to be attributable to the isomerization of 3-phenyl derivative with hydrogen iodide generated *in situ*.



Scheme 8.

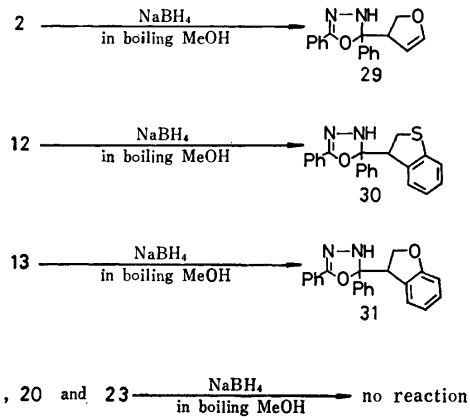
As mentioned above, the oxadiazepine **9** is photochemically dissociated to the starting materials. However, we found that iodine inhibited the photochemical dissociation of **9**. Irradiation of **9** in the presence of iodine afforded 3-benzoylbenzothiophene **7** and its benzoylhydrazone **8**, together with traces of **1** and **6a** (Scheme 8). It is noteworthy that the yields of **7** and **8** are almost equal to those in the direct irradiation of **1** with **6a** in the presence of iodine. In addition, upon irradiation of **9** in the presence of 2,5-di(*p*-tolyl)-1,3,4-oxadiazole **7** and **8** were formed in 18 and 50% yields respectively, but no 3-(*p*-toluoyl)benzothiophene and its *p*-toluoylhydrazone were formed. Thus, the formation of **8** in the direct irradiation of **1** with **6a** in the presence of iodine may be interpreted as arising *via* isomerization of the primary adduct **9** with iodine.[15]

The photochemical reaction of **1** with **6c** in the presence of iodine is comparable to that of **1** with indene producing the [2+2] cycloadduct **5**. Although mechanistic considerations are still speculative, a potential pathway for the formation of **23** is outlined in Scheme 9, which is similar to that previously proposed for the formation of **5**.[5] The photochemical reaction of **6c** with iodine yields the complex **E** *via* **D**. Subsequent interaction between **E** and **1** forms the intermediate **F**, which undergoes ring closure with loss of iodine to produce the [2+2] cycloadduct **23**.

*Stereochemistry of [2+2] Cycloadducts **19**, **20**, and **23**.* It is difficult to learn the stereochemistry of [2+2] cycloadducts **19**, **20**, and **23** from inspection of their NMR spectra. We have inadvertently found that the reduction of [2+2] cycloadducts with sodium borohydride can be used to distinguish between the *cis*- and *trans*-adducts.

Reduction of the *trans* [2+2] cycloadduct **2** with sodium borohydride in boiling methanol gave the corresponding dihydro compound, 2-(2,3-dihydro-3-furyl)-2,5-diphenyl-2,3-dihydro-1,3,4-oxadiazole (**29**).

Similarly, *trans* [2+2] cycloadducts, **12** and **13**, afforded the corresponding dihydro compounds, **30** and **31**, respectively. However, the *cis* [2+2] cycloadduct **5** remarkably resisted toward reduction under similar conditions; **5** was recovered quantitatively.



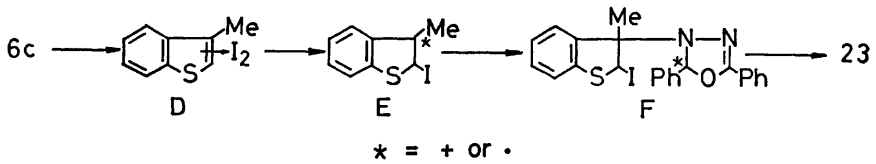
Scheme 10.

The above facts indicate that *trans* [2+2] cycloadducts, **2**, **12**, and **13**, are susceptible to reductive cleavage with sodium borohydride owing to their ring strain, and that this method can be used to diagnose the stereochemistry of [2+2] cycloadducts, **19**, **20**, and **23**. The cycloadducts, **19**, **20**, and **23**, as well as **5**, did not undergo reductive cleavage with sodium borohydride (Scheme 10). Thus, **19**, **20**, and **23** may be assigned to the corresponding *cis*-adducts respectively.

Experimental

All melting and boiling points are uncorrected. The IR spectra were measured in KBr disks, and NMR spectra were determined at 60 MHz with a Hitachi R-20 NMR spectrometer with TMS as an internal reference. The mass spectra were obtained on a Hitachi RMS-4 mass spectrometer, using a direct inlet and an ionization energy of 70 eV. Unless otherwise stated, irradiations were performed with Pyrex-filtered light from a 300-W high-pressure mercury lamp (Taika HLV-B) below 15 °C in a nitrogen atmosphere. Irradiation with monochromatic light (313 nm) was performed with a 100-W high-pressure mercury lamp (Riko UVL-100P) utilizing the potassium biphthalate aqueous solution[16] as a filter.

*Photochemical Reaction of 2,5-Diphenyl-1,3,4-oxadiazole (**1**) with Benzo[b]thiophene (**6a**).* A solution of 1.11 g (5×10^{-3} mol) of **1** and 2.01 g (1.5×10^{-2} mol) of **6a**[17] in 250 ml of benzene was irradiated for 1 h. The solvent from the



Scheme 9.

mixture was removed *in vacuo* to afford a residue, which was triturated with 30 ml of diethyl ether giving pale yellow needles. Filtration gave 0.43 g (24%) of oxadiazepine **9**, mp 172—173 °C, which was subjected to microanalysis without further purification. IR 1607, 1560 cm^{-1} ($\nu_{C=N}$); mass spectrum *m/e* 356 (M^+), 253 (M^+-PhCN), 251 (M^+-PhCO), 236 ($M^+-PhCONH$), 223, 222, 221, 189, 121, 105, 77. Found: C, 73.88; H, 4.43; N, 7.70%. Calcd for $C_{22}H_{16}N_2OS$: C, 74.14; H, 4.53; N, 7.86%.

The ether filtrate was evaporated *in vacuo*, and the residue was chromatographed on alumina using hexane and benzene as eluents. From the hexane elution 1.76 g (88%) of **6a**, and from the hexane–benzene (1: 1) elution 60 mg (5%) of 3-benzoylbenzo[*b*]thiophene (**7**) and traces of the benzoylhydrazone **8** were obtained respectively. The benzene elution gave 0.48 g (43%) of **1**.

7: yellow oil; IR (neat) 1645 cm^{-1} ($\nu_{C=O}$). This compound was identical with an authentic sample prepared by the reaction described below.

8: colorless needles, mp 172—173 °C; IR 3340 (ν_{NH}), 1640 cm^{-1} ($\nu_{C=O}$); NMR ($CDCl_3$) δ 7—8 (15H, m, aromatic protons), 9.05 (1H, br, N**H**); mass spectrum *m/e* 356 (M^+), 251 (M^+-PhCO), 236 ($M^+-PhCONH$), 233 ($PhO{\equiv}\overset{+}{N}NH-COPh$), 222, 221, 181, 121 ($[PhCO-NH_2]^+$), 105, 77. Found: C, 74.18; H, 4.36; N, 7.73%. Calcd for $C_{22}H_{16}N_2OS$: C, 74.14; H, 4.53; N, 7.86%. This compound was identical with an authentic sample prepared from **7** and benzoylhydrazine.

Similar photochemical reactions were carried out in various solvents, and the results are given in Table 1.

3-Benzoylbenzo[b]*thiophene (7).* A solution of 2.0 g of benzonitrile in 20 ml of diethyl ether was added to a solution of 3-benzo[*b*]thienylmagnesium bromide which was prepared *in situ* from 3-bromobenzo[*b*]thiophene[12] (3.3 g) and metallic magnesium (0.55 g) in 20 ml of diethyl ether, at 0 °C. The reaction mixture was stirred at room temperature for 1 h, and then refluxed for 30 min. After the mixture was stirred with 1 ml of concd hydrochloric acid, the ether layer was evaporated *in vacuo*, and the residue was chromatographed on alumina using benzene as an eluent to give 0.4 g (11%) of **7**.

Isomerization of Oxadiazepine 9. A suspension of 0.3 g of **9** in 30 ml of benzene was refluxed for 3 h. The solvent from the mixture was removed *in vacuo*, and the residue was triturated with small amounts of diethyl ether to give 0.29 g (97%) of benzoylhydrazone **8**.

Reduction of Oxadiazepine 9 with Sodium Borohydride. A suspension of 0.2 g of **9** in 40 ml of methanol was stirred with 0.1 g of sodium borohydride at room temperature for 1 h. The reaction mixture was poured into 100 ml of water, giving 0.2 g (*ca.* 100%) of crystals. Recrystallization from methanol afforded the dihydro compound **10**, mp 187—188 °C, as colorless needles. IR 3320 (ν_{NH}), 1650 cm^{-1} ($\nu_{C=N}$); NMR ($CDCl_3$) δ 4.67 (1H, t, >C**H**, J=8 Hz), 6.23, 6.32 (each 1H, d, >C**H**, J=8 Hz), 6.5—7.8 (14H, m, aromatic protons), 8.0 (1H, br, N**H**); mass spectrum *m/e* 358 (M^+), 356 (M^+-H_2), 224 ($[PhCH{=}NNHCOPh]^+$), 223, 147 (224—Ph), 134, 121 ($[PhCONH_2]^+$), 105, 91, 89, 77. Found: C, 73.75; H, 4.86; N, 7.80%. Calcd for $C_{22}H_{18}N_2OS$: C, 73.77; H, 5.06; N, 7.82%.

Similarly, reduction of **9** with sodium borohydride-d_4 in methanol-d_1, and recrystallization of the product from methanol afforded the dihydro compound **10**-d_1, mp 184—185 °C, as colorless needles. NMR ($CDCl_3$) δ 4.67, 6.25 (each 1H, d, >C**H**, J=8 Hz), 6.5—7.8 (14H, m, aromatic protons), 8.1 (1H, br, N**H**); mass spectrum *m/e* 359 (M^+), 358, 357 (M^+-H_2), 356, 225 ($[PhCD{=}NNHCOPh]^+$), 224, 148 (225^+-Ph), 134, 121, 105, 92, 90.

1-Benzoyl-2-[α-(3-benzo[b]*thienyl)benzyl]hydrazine (11).*

i) A solution of 1.35 g of **10** in 20 ml of methanol was stirred with 2 ml of concd hydrochloric acid at room temperature for 10 h. The reaction mixture was evaporated *in vacuo*, and the residue was triturated with 20 ml of diethyl ether, giving 0.95 g (70%) of crystals. Recrystallization from methanol afforded the hydrazine **11**, mp 165—166 °C, as colorless prisms. IR 3300, 3240 (ν_{NH}), 1650 cm^{-1} ($\nu_{C=O}$); NMR ($CDCl_3$) δ 4.74, 8.0 (each 1H, br, N**H**), 5.75 (1H, s, >C**H**), 7.0—8.0 (15H, m, aromatic protons); mass spectrum *m/e* 358 (M^+), 237 ($M^+-PhCONH_2$), 208 ($[PhCH{=}N{-}N{=}CH-Ph]^+$), 189, 178, 134, 121, 105, 91, 89, 77. Found: C, 73.60; H, 4.87; N, 7.87%. Calcd for $C_{22}H_{18}N_2OS$: C, 73.77; H, 5.06; N, 7.82%.

A similar treatment of the dihydro compound **10**-d_1 afforded the hydrazine **11**-d_1, mp 164—166 °C, in 80% yield. NMR ($CDCl_3$) δ 4.74, 8.0 (each 1H, br, N**H**), 7.0—8.0 (15H, m, aromatic protons); mass spectrum *m/e* 359 (M^+), 237, 236, 225, 224, 209, 190, 180, 178, 148, 134, 122, 105, 92, 77.

ii) A solution of 0.14 g of 3-benzoylbenzothiophene **7** in 20 ml of methanol was stirred with 50 mg of sodium borohydride at room temperature for 30 min. The reaction mixture was poured into 50 ml of water, and the aqueous solution was acidified with hydrochloric acid, and then extracted with chloroform. The extract was concentrated *in vacuo*, and the residue was chromatographed on silica gel using chloroform as an eluent to give 90 mg (64%) of 3-benzo[*b*]thienylphenylmethanol as pale yellow oil. IR (neat) 3300—3400 cm^{-1} (ν_{OH}); NMR (CCl_4) δ 3.75 (1H, br, O**H**), 5.62 (1H, s, >C**H**), 6.9—7.8 (10H, m, aromatic protons); mass spectrum *m/e* 240 (M^+), 233 (M^+-OH), 221, 163 (M^+-Ph), 161, 135, 105, 77.

After 70 mg of the alcohol was heated with 2 ml of phosphorus trichloride under reflux for 1 h, excess phosphorus trichloride from the mixture was removed *in vacuo*. The residue was treated with 0.1 g of benzoylhydrazine to give crystals, which on recrystallization from methanol gave 10 mg of the hydrazine **11**, mp 165—166 °C.

Irradiation of Oxadiazepine 9. A suspension of 1.0 g of **9** in 250 ml of benzene was irradiated for 4 h. The solvent from the mixture was removed *in vacuo*, and the residue was chromatographed on alumina. From the hexane elution 0.17 g (45%) of benzothiophene **6a**, and from the hexane–benzene (1: 1) 50 mg (7%) of benzoylbenzothiophene **7** were obtained respectively. Finally, 30 mg (3%) of the [2+2] cycloadduct **12** and 0.3 g (48%) of oxadiazole **1** were separated from the benzene elution.

12: colorless prisms, mp 187—188 °C. IR 1645 cm^{-1} ($\nu_{C=N}$); NMR ($CDCl_3$) δ 4.85, 6.97 (each $1H^2$ d, >C**H**, J= 2.5 Hz), 7.1—8.0 (14H, m, aromatic protons); mass spectrum *m/e* 356 (M^+), 253 (M^+-PhCN), 251 (M^+-PhCO), 237 ($M^+-PhCNO$), 210, 164, 134, 121, 105, 77. Found: C, 74.05; H, 4.31; N, 7.71%. Calcd for $C_{22}H_{16}N_2OS$: C, 74.14; H, 4.53; N, 7.86%.

A similar irradiation of **9** was performed in acetonitrile for 10 h, and the yields of products are given in Scheme 4.

Isomerization of the [2+2] Cycloadduct 12. A solution of 0.2 g of **12** in 30 ml of ethanol was stirred with 0.1 g of potassium hydroxide at 60—70 °C for 1 h. The reaction mixture was poured into 50 ml of water, and neutralized with 10% hydrochloric acid to give crystals. Recrystallization from methanol afforded 20 mg (10%) of the benzoylhydrazone **8**.

Photochemical Reaction of Oxadiazole 1 with Benzothiophene 6a in the Presence of Benzophenone. A solution of 1.11 g (5×10^{-3} mol) of **1**, 2.01 g (1.5×10^{-2} mol) of **6a**, and 0.45 g (2.5×10^{-3} mol) of benzophenone in 250 ml of benzene was irradiated for 10 h. The solvent from the mixture was removed *in*

vacuo, and the residue was chromatographed on silica gel using benzene and then chloroform as eluents. The first elution gave 1.25 g of a mixture of **6a** and benzophenone. From the second and third elutions, 0.25 g (14%) of the [2+2] cycloadduct **12**, and 0.65 g (59%) of 1 were isolated respectively.

*Photochemical Reaction of Oxadiazole **1** with Benzo*[b]*furan.* *i)* A solution of 1.11 g (5×10^{-3} mol) of **1** and 1.77 g (1.5×10^{-2} mol) of benzofuran[18] in 250 ml of benzene was irradiated for 10 h. The solvent from the mixture was removed *in vacuo*, and the residue was chromatographed on alumina using benzene as an eluent, giving 0.93 g (53%) of benzofuran, 0.22 g (13%) of the [2+2] cycloadduct **13**, and 0.85 g (77%) of **1**.

13: colorless prisms, mp 216—218 °C. IR 1670 cm^{-1} ($\nu_{C=N}$); NMR ($CDCl_3$) δ 4.68 (1H, m, >C**H**), 7.03 (1H, d, >C**H**, J=1.0 Hz), 6.8—7.9 (14H, m, aromatic protons); mass spectrum *m/e* 340 (M^+), 312 (M^+-CO), 311, 237 ($M^+-PhCNO$), 207 (312^+-PhCO), 194, 178, 118, 105, 77. Found: C, 77.63; H, 4.67; N, 8.26%. Calcd for $C_{22}H_{16}N_2O$: C, 77.63; H, 4.74; N, 8.23%.

A similar photochemical reaction in diethyl ether for 10 h afforded 0.15 g (9%) of **13**, together with recovery of **1** (47%) and benzofuran (56%).

ii) A solution of 1.11 g of **1** and 1.77 g of benzofuran in 600 ml of benzene was irradiated with monochromatic light (313 nm) for 30 h. A similar treatment afforded 50 mg (3%) of **13**, together with 0.82 g (74%) of **1** and 1.2 g (68%) of benzofuran.

Irradiation of Benzo[b]*thiophene 1,1-Dioxide (**14**) in the Presence of Oxadiazole **1**.* A solution of 1.9 g (1.1×10^{-2} mol) of **14**[19] and 1.11 g (5×10^{-3} mol) of **1** in 250 ml of diethyl ether was irradiated for 10 h. Filtration gave 0.74 g (39%) of crystals. Recrystallization from chloroform gave colorless needles, mp>300 °C, which were a mixture of the head to tail dimer **15**[20] and head to head dimer **16**[20] by inspection of the IR spectrum.

The filtrate was evaporated *in vacuo* to afford 1.92 g of a mixture of **1** and the dimers.

*Photochemical Reaction of Oxadiazole **1** with 2-Methylbenzo*[b]*thiophene (**6b**).* *i) Without Benzophenone*: A solution of 1.11 g (5×10^{-3} mol) of **1** and 2.22 g (1.5×10^{-2} mol) of **6b**[21] in 250 ml of diethyl ether was irradiated for 10 h. The solvent from the mixture was removed *in vacuo*, and the residue was chromatographed on alumina using benzene and then chloroform. From the benzene elution, 0.97 g (44%) of **6b**, and 0.61 g (55%) of **1** were recovered. The benzene–chloroform elution afforded 0.29 g (16%) of 3-benzoyl-2-methylbenzo[*b*]thiophene benzoylhydrazone (**18**), mp 125—126 °C, as colorless prisms. IR 3240 (ν_{NH}), 1675 cm^{-1} ($\nu_{C=O}$), NMR ($CDCl_3$) δ 2.40 (3H, s, C**H**$_3$), 7.0—8.2 (14H, m, aromatic protons), 9.0 (1H, br, N**H**); mass spectrum *m/e* 370 (M^+), 265 (M^+-PhCO), 250 ($M^+-PhCONH$), 249, 235 ($M^+-PhCONHNH$), 234, 223 ($PhC\equiv\overset{+}{N}NHCOPh$), 221, 147, 105, 77. Found: C, 74.47; H, 5.01; N, 7.33%. Calcd for $C_{23}H_{18}N_2OS$: C, 74.58; H, 4.90; N, 7.56%.

ii) With Benzophenone: A solution of 1.11 g of **1**, 2.22 g of **6b**, and 0.275 g (1.5×10^{-3} mol) of benzophenone in 250 ml of benzene was irradiated for 10 h. The solvent from the mixture was removed *in vacuo*, and the residue was chromatographed on alumina. From the benzene elution, 1.40 g of a mixture of **6b** and benzophenone, and 0.1 g (5%) of the [2+2] cycloadduct **19** were isolated, and the chloroform elution gave 0.67 g (60%) of **1**.

19: colorless prisms, mp 204—205 °C. IR 1645 cm^{-1} ($\nu_{C=N}$); NMR ($CDCl_3$) δ 2.04 (3H, s, C**H**$_3$), 4.64 (1H, s, >C**H**), 7.0—8.0 (14H, m, aromatic protons); mass spectrum *m/e* 370 (M^+), 267 (M^+-PhCN), 265 (M^+-PhCO), 237 (265^+-N_2), 235, 223, 221, 148, 105, 77. Found: C, 74.52; H, 4.75; N, 7.71%. Calcd for $C_{23}H_{18}N_2OS$: C, 74.58; H, 4.90; N, 7.56%.

*Photochemical Reaction of Oxadiazole **1** with 3-Methylbenzo*[b]*thiophene (**6c**).* *i) Without Benzophenone*: A solution of 2.22 g (10^{-2} mol) of **1** and 4.44 g (3×10^{-2} mol) of **6c**[22] in 250 ml of diethyl ether was irradiated for 10 h. The reaction mixture was concentrated *in vacuo*, and the residue was chromatographed on alumina using benzene and benzene–chloroform as eluents. From the benzene elution, 2.7 g (61%) of **6c** and 65 mg (2%) of the [2+2] cycloadduct **20** were isolated, and the benzene–chloroform elution gave 0.68 g (31%) of **1**.

20: colorless prisms, mp 267—268 °C. IR 1645 cm^{-1} ($\nu_{C=N}$); NMR ($CDCl_3$) δ 1.07 (3H, s, C**H**$_3$), 6.87 (1H, s, >C**H**), 7.0—8.1 (14H, m, aromatic protons); mass spectrum *m/e* 370 (M^+), 267 (M^+-PhCN), 265 (M^+-PhCO), 237 (265^+-N_2), 224, 221, 147, 105, 77. Found: C, 74.43; H, 4.87; N, 7.57%. Calcd for $C_{23}H_{18}N_2OS$: C, 74.58; H, 4.90; N, 7.56%.

A similar photochemical reaction in benzene affords the [2+2] cycloadduct **20** in 13% yield.

ii) With Benzophenone: A solution of 1.11 g (5×10^{-3} mol) of **1**, 2.22 g (1.5×10^{-2} mol) of **6c**, and 0.28 g (1.5×10^{-3} mol) of benzophenone in 250 ml of benzene was irradiated for 10 h. A similar work-up afforded 1.17 g of a mixture of **6c** and benzophenone, 0.61 g (33%) of **20**, and 0.52 g (47%) of **1**.

Photochemical Reaction in the Presence of Iodine. *i) Reaction with Benzothiophene **6a***: A solution of 2.0 g (9×10^{-3} mol) of oxadiazole **1**, 4.0 (3×10^{-2} mol) of **6a**, and 0.46 g (1.8×10^{-3} mol) of iodine in 500 ml of benzene was irradiated for 20 h. The solvent from the mixture was removed *in vacuo*, and chromatographic separation of the residue on alumina using benzene and then chloroform as eluents afforded 2.9 g (73%) of **6a**, 0.35 g (16%) of 3-benzoylbenzothiophene **7**, 0.21 g (11%) of **1** (from the benzene elution), and 1.59 g (50%) of the benzoylhydrazone **8** (from the benzene–chloroform elution).

*ii) Reaction with 2-Methylbenzothiophene **6b***: A solution of 1.11 g (5×10^{-3} mol) of **1**, 2.22 g (1.5×10^{-2} mol) of **6b**, and 0.25 g (10^{-3} mol) of iodine in 250 ml of benzene was irradiated for 10 h. A similar work-up afforded 15 mg (1%) of 3-benzoyl-2-methylbenzo[*b*]thiophene (**21**) and 0.28 g (15%) of the benzoylhydrazone **18**, together with recovery of 0.6 g (54%) of **1** and 1.05 g (47%) of **6b**.

The compound **21**, mp 73—74 °C, was identical with an authentic sample prepared from the Friedel-Crafts benzoylation of **6b**.

*iii) Reaction with 3-Methylbenzothiophene **6c***: A solution of 1.11 g of **1**, 2.22 g of **6c**, and 0.25 g of iodine in 250 ml of benzene irradiated for 10 h. A similar work-up afforded 75 mg (6%) of 2-benzoyl-3-methylbenzo[*b*]thiophene (**22**) and 0.15 g (8%) of the [2+2] cycloadduct **23**, together with recovery of 0.98 g (44%) of **6c** and 0.21 g (19%) of **1**. The compound **22**, mp 67—68 °C, was identical with an authentic sample prepared from the Friedel-Crafts benzoylation of **6c**.

23: colorless prisms, mp 152—153 °C; IR 1640 cm^{-1} ($\nu_{C=N}$); NMR ($CDCl_3$) δ 1.83 (3H, s, C**H**$_3$), 6.37 (1H, s, >C**H**), 6.9—8.1 (14H, m, aromatic protons); mass spectrum *m/e* 370 (M^+), 267 (M^+-PhCN), 265 (M^+-PhCO), 237 (265^+-N_2), 224, 223, 222, 165, 149, 148, 105, 77. Found C, 74.23; H, 4.56; N, 7.36%. Calcd for $C_{23}H_{18}N_2OS$: C: 74.58; H, 4.90; N, 7.56%.

*Photochemical Reaction of Oxadiazole **1** with 3-Iodobenzo*[b]*thiophene (**24**).* A solution of 1.11 g (5×10^{-3} mol) of **1** and 0.73 g (2.8×10^{-3} mol) of **24**[23] in 250 ml of benzene was irradiated for 10 h. The solvent from the mixture was removed *in vacuo*, and the residue was chromatographed on alumina using hexane, benzene, and then chloroform as eluents. From the hexane elution, 0.15 g (21%) of **24** and

40 mg (7%) of 2-phenylbenzo[*b*]thiophene (**27**) were obtained. From the benzene elution, 65 mg (7%) of 2-benzoyl-3-phenylbenzo[*b*]thiophene (**25**) and 0.59 g (53%) of **1** were isolated, and finally the chloroform elution gave 15 mg (1%) of 3-benzoyl-2-phenylbenzo[*b*]thiophene benzoylhydrazone (**28**) and 0.22 g (18%) of 2-benzoyl-3-phenylbenzo[*b*]thiophene benzoylhydrazone (**26**).

25: colorless prisms, mp 105—106 °C; IR 1630 cm^{-1} ($\nu_{C=O}$); mass spectrum *m/e* 314 (M^+), 286 (M^+-CO), 237 (M^+-Ph), 209 (M^+-PhCO), 165 ($M^+-PhCOS$), 105, 77. Found: C, 80.20; H, 4.50%. Calcd for $C_{21}H_{14}OS$: C, 80.24; H, 4.49%. This compound was identical with an authentic sample prepared from the Friedel-Crafts benzoylation of 3-phenylbenzo[*b*]thiophene.[14]

26: colorless prisms, mp 177—178 °C; IR 3160 (ν_{NH}), 1660 cm^{-1} ($\nu_{C=O}$); NMR ($CDCl_3$) δ 7.0—8.2 (19H, m, aromatic protons), 8.5 (1H, br, N**H**); mass spectrum *m/e* 432 (M^+), 327 (M^+-PhCO), 311 ($M^+-PhCONH_2$), 297 ($M^+-PhCONHNH$), 223 ($PhC{\equiv}\overset{+}{N}NHCOPh$), 105, 77. Found: C, 77.62; H, 4.63; N, 6.42%. Calcd for $C_{28}H_{20}N_2OS$: C, 77.76; H, 4.66; N, 6.48%. Hydrolysis of **26** with hydrochloric acid in boiling ethanol for 1 h afforded **25** in 28% yield.

27: colorless needles, mp 177—178 °C (lit,[14] mp 174—175 °C); IR 1600, 1480, 1440, 1420 cm^{-1}; mass spectrum *m/e* 178 (M^+-S), 176, 165 (M^+-CHS), 134, 92, 77.

28: colorless needles, mp 183—184 °C; IR 3360 (ν_{NH}), 1690 cm^{-1} ($\nu_{C=O}$); mass spectrum *m/e* 432 (M^+), 327 (M^+-PhCO), 311 ($M^+-PhCONH_2$), 297 ($M^+-PhCONHNH$), 223, 105, 77. Found: C, 77.29; H, 4.59; N, 6.49%. Calcd for $C_{28}H_{20}N_2OS$: C, 77.76; H, 4.66; N, 6.48%.

*Irradiation of Oxadiazepine **9** in the Presence of Iodine.* *i)* A suspension of 0.5 g (1.4×10^{-3} mol) of **9** in 250 ml of benzene was irradiated with 0.107 g (30 mol% to **9**) for 3 h. The solvent from the mixture was removed *in vacuo*, and chromatographic separation afforded traces of **6a**, 70 mg (21%) of **7** (from the benzene elution), traces of **1** and 0.27 g (54%) of **8** (from the chloroform elution).

ii) A suspension of 0.5 g of **9** in 250 ml of benzene irradiated in the presence of 0.107 g of iodine and 0.7 g (2.8×10^{-3} mol) of 2,5-di(*p*-tolyl)-1,3,4-oxadiazole for 3 h. A similar work-up afforded 60 mg (18%) of **7** and 0.25 g (50%) of **8**, together with recovery of 0.62 g (89%) of ditolyloxadiazole.

Reduction of the [2+2] Cycloadducts with Sodium Borohydride. A solution of 0.2 g of the [2+2] cycloadduct **2** in 20 ml of methanol was refluxed with 0.1 g of sodium borohydride for 3 h. The solvent from the mixture was removed *in vacuo*, and 30 ml of water was added to the residue to give crystals, which on recrystallization from methanol afforded 30 mg (15%) of the dihydro compound **29**, mp 142—143 °C, as colorless prisms. IR 3240 (ν_{NH}), 1620 cm^{-1} ($\nu_{C=N}$); NMR ($CDCl_3$) δ 2.9—3.9 (3H, m, C**H**$_2$ and N**H**), 4.8, 6.7 (each 1H, m, =C**H**), 5.1 (1H, m, $\rangle$C**H**), 6.9—7.9 (10H m, aromatic protons); mass spectrum *m/e* 292 (M^+), 290, 263 (M^+-CHO), 261, 187 (M^+-PhCO), 185, 170, 159, 157, 145, 128, 115, 105, 77. Found: C, 74.11; H, 5.48; N, 9.30%. Calcd for $C_{18}H_{16}N_2O_2$: C, 73.95; H, 5.52; N, 9.58%.

Similar reductions of the [2+2] cycloadducts **12** and **13** with sodium borohydride in boiling methanol for 1 h afforded the corresponding dihydro compounds **30** and **31** in 28 and 40% yields respectively.

30: colorless prisms, mp 152—153 °C; IR 3260 (ν_{NH}), 1620 cm^{-1} ($\nu_{C=N}$); NMR ($CDCl_3$) δ 3.20 (1H, dd, H**C**H, J=6, 12 Hz), 3.6 (1H, br, N**H**), 3.70 (1H, dd, HC**H**, J=7, 12 Hz), 4.18 (1H, dd, $\rangle$C**H**, J=6, 7 Hz), 7.0—8.0 (14H, m, aromatic protons); mass spectrum *m/e* 358 (M^+), 356, 253 (M^+-PhCO), 212, 211, 210, 165, 121, 105, 77. Found: C, 73.76; H, 5.04; N, 7.93%. Calcd for $C_{22}H_{18}N_2OS$: C, 73.73; H, 5.06; N, 7.82%.

31: colorless prisms, mp 182—183 °C; IR 3220 (ν_{NH}), 1660 cm^{-1} ($\nu_{C=O}$); NMR ($CDCl_3$) δ 3.25 (1H, dd, **H**CH, J=4, 12 Hz, when exchanged with D_2O, this signal changed to a doublet with J=12 Hz), 3.74 (1H, dd, HC**H**, J=6, 12 Hz), 4.10 (1H, d, $\rangle$C**H**, J=6 Hz), 4.6 (1H, m, N**H**), 6.7—7.9 (14H, m, aromatic protons); mass spectrum *m/e* 342 (M^+), 340, 237 (M^+-PhCO), 222, 220, 207, 194, 165, 105, 77. Found: C, 77.13; H, 5.17; N, 8.16%. Calcd for $C_{22}H_{18}N_2O_2$: C, 77.17; H, 5.30; N, 8.18%.

The [2+2] cycloadducts, **5**, **19**, **20**, and **23**, were inert with similar reduction.

Stereoselective Monoalkylation of α-Halocyclopropyllithiums. A Versatile Method for the Synthesis of α-Alkylcyclopropyl Acetates and Alkylidenecyclopropanes

Katuzi KITATANI, Tamejiro HIYAMA, and Hitosi NOZAKI
Department of Industrial Chemistry, Kyoto University, Yoshida, Kyoto 606
(Received March 10, 1977)

The title carbenoids (**7** and **8**) prepared by the action of butyllithium on dihalocyclopropanes are smoothly methylated with methyl iodide. The product ratio of *cis*-methylated product (**3**)/*trans*-methylated one (**4**) (or *endo*-methylated product (**5**)/*exo*-methylated one (**6**) is found to depend on the aging period of the carbenoids; thermodynamic equilibration gives almost **3** or **5**. This procedure has been extended to general alkylation by utilizing HMPA co-solvent. The resulting α-alkylated cyclopropyl halides are converted into allylic acetates or cyclopropyl acetates upon acetolysis and also into alkylidenecyclopropanes upon base treatment. The protonolysis of **8** gives *trans*- or *exo*-bromocyclopropanes stereoselectively.

Halogen-metal exchange of *gem*-dihalo compounds with alkyllithium occurs easily to give lithium carbenoids which are generally nucleophilic enough to react with various electrophiles at low temperatures.[1] The title carbenoids derived from olefin-dihalocarbene adducts are thermally labile and decompose above −50 °C.[2] This instability has restricted their synthetic use only to such intramolecular process leading to allene and/or bicyclobutane formation.[3] As lithiation of *gem*-dihalocyclopropanes proceeds rapidly even at sufficiently low temperature (*e.g.* −110 °C) and the resulting carbenoids are stable for several hours to exist as such at −95 °C,[4] we have studied to utilize the reactive intermediates for synthetic purpose and found these species can actually add to carbonyl compounds, affording cyclopropyl ketones, cyclobutanones or 1,1-cyclopropanedicarboxylates.[5] This article describes alkylation of the carbenoids and several transformations of the resulting α-alkylcyclopropyl halides.[6]

Alkylation of α-Halocycloprophyllithiums. The carbenoids generated by lithiation of *gem*-dibromocyclopropanes (**1** or **2**) at −95 °C with butyllithium were converted into α-alkylcyclopropyl bromides in good yields upon treatment with excess alkyl halides. Methylation was scrutinized first in the hope that the present reaction would provide a short-cut methodology to construct a methyl substituted cyclopropane moiety commonly found among various natural products.[7] The results are summarized in Table 1. Addition of methyl iodide after 10 minutes' aging of the carbenoids (conditions A) resulted in the exclusive or at least predominant formation of *cis*-methylated products **3** or *endo*-methylated ones **5**. This might be ascribed to the thermodynamically preferred configuration of the carbenoid. When methyl iodide is present at the stage of lithium-halogen exchange, the resulting carbenoid should be methylated spontaneously before the configurational isomerization of the carbenoid (conditions B). The experiments showed a little increase of *trans*-methylated isomers **4** or *exo*-methylated ones **6**. Furthermore, the use of hexamethylphosphoric triamide (HMPA) co-solvent is expected to prompt the alkylation (conditions C). These conditions may reflect to some extent the susceptibility of each geminal bromine atom to the lithium-bromine exchange. The products were obtained in better yields with almost the same isomer ratio as conditions B, in general, with the exception of the reaction of **1a**, which yielded the otherwise less favored isomer **4a** now predominantly.

These observations can be understood by the Scheme 1. Less hindered bromine atom is preferentially lithiated to give a carbenoid **7** which isomerizes to thermodynamically more stable isomer **8**.[8] Subsequent methylation of **8** and **7** proceeds with retention of configuration to yield **3** (or **5**) and **4** (or **6**) respectively. The exclusive formation of **3** or **5** under the conditions A may be attributed to complete isomerization of **7** to **8**. The exclusive formation of **3c** from **1c** is particularly attributable to the ethereal substituent.[9]

In contrast, however, methylation of 1,1-dichloro-2-phenylcyclopropane (**1d**) afforded **3f** and **4f** with 12: 88 ratio under the conditions A, possibly due to slow configurational isomerization of the intermediary car-

Table 1. Yield (%) of the products in the methylation of 1,1-dibromocyclopropanes and the product ratios (**3**: **4** or **5**: **6**)

Dibromocyclopropane	Products	Conditions[a] A	B	C

benoids.[10]

Alkylation with ethyl iodide or allyl bromide required modification of the reaction conditions. Both halides turned out to react sluggishly. The use of HMPA co-solvent was found indispensable in order to eliminate the possible decomposition of carbenoids during the long reaction time. Another complicating side reaction was elimination of hydrogen halide from alkyl halides having β-hydrogen. This was, however, successfully suppressed by the addition of copper(I) salt such as copper(I) iodide or phenylacetylide.[11] Thus, **1a** was converted to **3d** and **4d** (89: 11, 59% yield) and to **3e** and **4e** (94: 6, 54% yield) respectively in the presence of Cu(I). Noteworthy is the alkylation of 7,7-dibromonorcarane with allyl bromide or 3-methyl-2-butenyl bromide; *endo*-alkylated product **5c** (87%) or **5d** (77%) was obtained exclusively. It should be noted that the coupling of 3-methyl-2-butenyl bromide with the carbenoid occurred at the α-position and no trace of S_N2' product was detected.

Stereoselective Reduction of gem-*Dihalocyclopropanes.* Protonolysis of the carbenoids, prepared as above, is expected to give monohalocyclopropanes[12] with high degree of stereoselectivity. Thus, production of the carbenoids according to the conditions A and the successive workup with ethanol at low temperature afforded monohalocyclopropanes (Table 2), the stereoselectivity being comparable with the above alkylation.

Table 2. Stereoselective reduction of 1,1-dihalocyclopropanes

Dihalocyclopropane	Products (yield, %)[a]	Product ratio[b] (**3**: **4** or **5**: **6**)
1a	**3g**(87)	100: 0
1b	**3h**+**4h**(75)	81:19
1c	**3i**(83)	100: 0
1d	**3j**+**4j**(82)	26:74
2a	**5e**(90)	100: 0
2b	**5f**+**6f**(74)	92: 8

a) Isolated yield after short-path distillation. b) The isomer ratio was calculated by GLC or NMR assay.

Acetolysis of α-Alkylcyclopropyl Bromides. The well-known conversion of monohalocyclopropanes into allyl cations obeys the orbital symmetry rule.[13] Therefore, α-alkylcyclopropyl halides obtained selectively should be utilized for selective olefin synthesis. We have attempted the acetolysis of **3** and **5** by heating in acetic acid in the presence of silver acetate and a catalytic amount of silver tetrafluoroborate. The bromocyclopropane **3a** gave 2-methyl-3-phenyl-2-propen-1-yl acetate (**9a**) in 74% yield and no regioisomer **10a**. In contrast **3b** produced two isomeric acetates **9b** (32%) and **10b** (43%), while **3c** gave **9c** (30%) and **10c** (28%). The trisubstituted ethylenes **9a**—**c** were found to have E configuration and this was attributed to the energetically favorable W-form of cations **11**.

The *endo*-alkylated bromonorcaranes **5** unexpectedly underwent acetolysis and the products were proved to be 7-acetoxy-7-alkylnorcaranes **12**. The *exo* configuration of 7-acetoxyl group is based on the assumed S_N1 type reaction involving **13**, which is stabilized by 7-alkyl group and do not rearrange into the strained cycloheptenyl cation **14**, and also based on the approach control. Similar stabilization has been recorded by Ledlie *et al.*[14]

Alkylidenecyclopropane Synthesis. The 1-alkyl-1-bromocyclopropanes **3a**—**c**, **5a** and **5c** were easily

transformed into alkylidenecyclopropanes **15a—c** and **16a, b** in good yields by means of potassium *t*-butoxide in dimethyl sulfoxide. The rather mild reaction conditions prevent the subsequent thermal isomerization of the products. Consequently the alkylation of carbenoids **7** and **8** followed by dehydrobromination provides a variety of alkylidenecyclopropanes[15] which are otherwise difficultly accessible.

Stereochemistry of 3, 4, 5 and 6. The configurational assignment of monoalkylated products was based on PMR spectra (see the Experimental). Methyl substituent *cis* to phenyl group on cyclopropane ring (*e.g.* **3a**, δ 1.43) appeared at higher field than its *trans* isomer (**4a**, δ 1.93).[16] This applies to other isomers **3d**, **4d**; **3f**, **4f**. The bridge head protons of **5a** *cis* to halogen atom and *trans* to alkyl group on cyclopropane ring appeared at lower field than that of its isomer **6a**. The latter criterion is principally based on the deshielding effect[17] of the *trans* alkyl group and of the vicinal bromine atom as well. This assignment is also ascertained by the reactivity of each isomer under solvolytic conditions. Thus, 7-*exo*-bromo isomer **5a** was solvolyzed into **12a**, while the isomer **6a** was susceptible to ring opening.

Experimental

All the temperatures are uncorrected. The IR spectra were obtained on a Shimadzu spectrometer 27-G, MS on a Hitachi RMU-6L, and PMR on JEOL JNM-PMX 60, Varian EM-360, or Varian HA-100D spectrometers. Butyllithium was purchased from Aldrich Co., Ltd. Commercial copper(I) iodide was purified according to the literature.[18] Copper(I) phenylacetylide was prepared by the Castro's method[19] and vacuum dried before use. Tetrahydrofuran (THF) was dried on lithium aluminum hydride and freshly distilled before use. HMPA was dried on calcium hydride and distilled. The cold bath of −95 °C was prepared by mixing liquid nitrogen and toluene (freezing point of toluene). All the reactions were carried out under a nitrogen atmosphere.

gem-Dihalocyclopropanes. Dibromocarbene adducts were prepared by the reaction of bromoform and *t*-BuOK with the corresponding olefins. 1,1-Dichloro-2-phenylcyclopropane was obtained by the phase transfer method ($CHCl_3$/NaOH, hexadecyltrimethylammonium bromide). A typical procedure is given for the synthesis of **1c**.

1,1-Dibromo-2-(benzyloxymethyl)cyclopropane (1c). A suspension of *t*-BuOK (60 g, 0.45 mol, containing 26% of *t*-BuOH) in dry hexane (100 ml) was cooled to 0 °C and mixed with benzyl allyl ether (43 g, 0.36 mol). A solution of $CHBr_3$ (91 g, 0.36 mol) in hexane (50 ml) was added at such a rate as to maintain the temp. below 10 °C (*ca.* 2 h). After the addition was complete, stirring was continued for 14 h at room temp. The reaction mixture was then treated with water (100 ml) and extracted with four 200 ml portions of hexane. The combined organic layer was washed with three 100 ml portions of brine, dried (Na_2SO_4) and concentrated. The oily residue was fractionated through a 15 cm Vigreux column under reduced pressure. The product **1c** was collected at 120—129 °C/0.28 mmHg (18 g, 20% yield). Analytically pure sample was obtained by preparative TLC (silica gel, hexane–ether 10: 1, R_f 0.6—0.7). IR (neat): 3090, 3060, 3030, 2850, 1495, 1455, 1366, 1108, 730, 691, 676 cm^{-1}; MS: *m/e* (%), 322 (M^++4, 0.08), 320 (M^++2, 0.16), 318 (M^+, 0.08), 91 (100); PMR (CCl_4): δ 1.1—2.1 (m, 3H), 3.50 (d, J=6 Hz, 2H, $OC\underline{H}_2C$), 4.46 (s, 2H, $PhC\underline{H}_2$), 7.1—7.5 (m, 5H, Ph). Found: C, 41.5; H, 3.7%. Calcd for $C_{11}H_{12}Br_2O$: C, 41.3; H, 3.8%.

1-Bromo-1-methyl-2-phenylcyclopropanes (3a and 4a). The procedure exemplifies the preparation and alkylation of α-halocyclopropyllithiums.

Conditions A. A magnetically stirred solution containing 1.4 g (5.0 mmol) of **1a** in 10 ml of THF was cooled to −95 °C and maintained approximately at this temp. during the addition (5 min) of a solution of *n*-BuLi in hexane (4.3 ml of 1.17 M solution, 5.0 mmol). The reaction mixture was stirred at −95 °C for 10 min, treated with MeI (1.0 ml, *ca.* 3 eq) over 5 min, allowed to warm to room temp. in 2 h and quenched with water. Workup and distillation at 70—80 °C/4 mmHg of the oily residue gave 0.74 g (70% yield) of *r*-1-bromo-1-methyl-*t*-2-phenylcyclopropane (**3a**): bp 70—71 °C/4 mmHg; IR (neat): 1608, 1583, 1500, 1451, 1387, 1157, 1090, 770, 735, 700, 605 cm^{-1}; MS: *m/e* (%), 212 (M^++2, 2), 210 (M^+, 2), 131 (100), 117 (8), 91 (42); PMR (CCl_4): δ 1.17 (t, J=7 Hz, 1H), 1.43 (s, 3H, Me), 1.55 (dd, J=7, 10 Hz, 1H), 2.74 (dd, J=7, 10 Hz, 1H, $PhC\underline{H}$), 6.8—7.5 (m, 5H, Ph). Found: C, 56.9; H, 5.4%. Calcd for $C_{10}H_{11}Br$: C, 56.9; H, 5.3%.

Conditions B. A magnetically stirred solution containing 0.28 g (1.0 mmol) of **1a** and 0.5 ml of MeI in 5 ml of THF was cooled to −95 °C and maintained approximately at this temp. during the addition of *n*-BuLi (1.1 mmol, 1.00 M in hexane) over a 5 min period. Stirring was continued at −95 °C for 30 min and the temp. was raised gradually to room temp. in 2 h. After aqueous workup short-path distillation at 72—82 °C/4 mmHg gave an isomeric mixture of 1-bromo-1-methyl-2-phenylcyclopropanes (see Table 1). Each isomer was separated by preparative GLC on a 1 m stainless steel column packed with 20% Silicone HV grease coated Celite 545 (column temp 150 °C; carrier gas, He; 1.0 kg/cm^2; R_t 20 min for *trans* isomer and 21 min for *cis* one).

r-1-Bromo-1-methyl-c-2-phenylcyclopropane (4a): bp 58—61 °C/3 mmHg; IR (neat): 1605, 1582, 1499, 1450, 1260, 1167, 760, 730, 695 cm^{-1}; MS: *m/e* (%), 212 (M^++2, 2), 210 (M^+, 2), 131 (100), 117 (21), 91 (41); PMR (CCl_4): δ 1.25 (dd, J=7, 10 Hz, 1H), 1.50 (t, J=7 Hz, 1H), 1.93 (s, 3H, Me), 1.96 (dd, J=7, 10 Hz, 1H, $PhC\underline{H}$), 7.0—7.4 (m, 5H, Ph). Found: C, 56.7; H, 5.3%. Calcd for $C_{10}H_{11}Br$: C, 56.9; H, 5.3%.

Conditions C. A magnetically stirred solution containing 0.28 g (1.0 mmol) of **1a**, 1 ml of HMPA, and 0.5 ml of MeI in THF (10 ml) was cooled to −95 °C. The same operation as the conditions B, followed by short-path distillation at 70—80 °C/4 mmHg, gave a mixture of **3a** and **4a** (Table 1).

r-1-Bromo-1-methyl-t-2-hexylcyclopropane (3b): bp 50—51 °C/3 mmHg; IR (neat): 3080, 1470, 1380, 1154, 1032, 729 cm^{-1}; MS: *m/e* (%), 220 (M^+ 2, 0,9), 218 (M^+, 0.9), 139 (3), 97 (25), 83 (58), 69 (61), 55 (100), 41 (100); PMR (CCl_4): δ 0.2—0.5 (m, 1H), 0.7—1.7 (m, 15H), 1.70 (s, 3H, Me). Found: C, 54.6; H, 8.9%. Calcd for $C_{10}H_{19}Br$: C, 54.8; H,

8.7%.

r-*1-Bromo-1-methyl*-c-*2-hexylcyclopropane* (**4b**): bp 55—65 °C (bath temp)/3 mmHg; IR (neat): 3060, 1440, 1369, 1165, 1020 cm^{-1}; MS: *m/e* (%), 220 (M^++2, 0.9), 218 (M^+, 0.9), 139 (3), 97 (28), 83 (63), 69 (65), 55 (98), 41 (100); PMR (CCl_4): δ 0.6—0.8 (m, 2H), 0.8—1.7 (m, 14H), 1.73 (s, 3H, Me). Found: C, 55.0; H, 8.7%. Calcd for $C_{10}H_{19}Br$: C, 54.8; H, 8.7%.

r-*1-Bromo-1-methyl*-t-*2-(benzyloxymethyl)cyclopropane* (**3c**): bp 87—93 °C (bath temp)/0.1 mmHg; IR (neat): 3080, 3050, 1605, 1585, 1496, 1451, 1375, 1165, 1145, 1095, 1025, 733, 695 cm^{-1}; MS: *m/e* (%), 256 (M^++2, 0.07), 254 (M^+, 0.07), 145 (7), 105 (5), 91 (100), 77 (5); PMR (CCl_4): δ 0.58 (t, J= 6 Hz, 1H), 1.0—1.5 (m, 2H), 1.72 (s, 3H, Me), 3.1—3.7 (m, 2H, OCH_2), 4.43 (s, 2H, $PhC\underline{H}_2$), 7.1—7.5 (m, 5H, Ph). Found: C, 56.4; H, 5.9%. Calcd for $C_{12}H_{15}BrO$: C, 56.5; H, 5.9%.

r-*1-Bromo-1-methyl*-c-*2-(benzyloxymethyl)cyclopropane* (**4c**): bp 95—105 °C (bath temp)/0.06 mmHg; IR (neat): 3030, 1494, 1451, 1370, 1168, 1090, 1026, 739, 700 cm^{-1}; MS: *m/e* (%), 256 (M^++2, 0.1), 254 (M^+, 0.1), 91 (100); PMR (CCl_4): δ 0.8—1.4 (m, 3H), 1.77 (s, 3H, Me), 3.2—3.8 (m, 2H, OCH_2), 4.49 (s, 2H, $PhC\underline{H}_2$), 7.1—7.6 (m, 5H, Ph). 1-Allyl-1-bromo-2-phenylcyclopropanes. A solution of *n*-BuLi in hexane (1.7 ml of 1.17 M solution, 2.0 mmol) was added to a cooled (−95 °C) solution of **1a** (0.55 g, 2.0 mmol) in THF (10 ml) over a 5 min period. After 30 min copper(I) iodide (0.19 g, 1.0 mmol) was added and 30 min thereafter allyl bromide (0.26 g, 2.0 mmol) diluted with HMPA (1 ml) was added. Stirring for 4 h and subsequent workup gave a mixture of **3d** and **4d** (0.28 g, 59% yield, bp 85—95 °C/4 mmHg). Each isomer was separated by preparative GLC (Silicone HV grease, similar condition as described in conditions B).

1-Allyl-r-*1-bromo*-t-*2-phenylcyclopropane* (**3d**): bp 90—95 °C/4 mmHg; IR (neat): 1644, 1606, 1500, 1452, 1429, 1238, 1202, 1150, 918, 772, 738, 700 cm^{-1}; MS: *m/e* (%), 238 (M^++2, 1), 236 (M^+, 1), 157 (48), 129 (52), 115 (95), 91 (100); PMR (CCl_4): δ 1.2—2.4 (m, 4H), 2.81 (dd, J=7, 10 Hz, 1H, PhC$\underline{H}$), 4.7—5.9 (m, 3H), 7.1—7.3 (m, 5H, Ph). Found: C, 60.5; H, 5.4%. Calcd for $C_{12}H_{13}Br$: C, 60.8; H, 5.5%.

1-Allyl-r-*1-bromo*-c-*2-phenylcyclopropane* (**4d**): bp 84—94 °C (bath temp)/4 mmHg; IR (neat): 1640, 1603, 1582, 1499, 1450, 1430, 1266, 1150, 1043, 998, 920, 764, 732, 698 cm^{-1}; MS: *m/e* (%), 238 (M^++2, 1), 236 (M^+, 1), 157 (55), 129 (55), 115 (100), 91 (95); PMR (CCl_4): δ 1.2—1.6 (m, 2H), 2.01 (dd, J=7, 10 Hz, 1H, PhC$\underline{H}$), 2.2—3.0 (m, 2H), 4.9—6.3 (m, 3H), 6.8—7.3 (m, 5H, Ph). Found: C, 60.7; H, 5.5%. Calcd for $C_{12}H_{13}Br$: C, 60.8; H, 5.5%.

1-Bromo-1-ethyl-2-phenylcyclopropanes (**3e** *and* **4e**). A magnetically stirred suspension of copper(I) phenylacetylide (0.17 g, 1.0 mmol) in THF (5 ml) containing **1a** (0.28 g, 1.0 mmol) was cooled to −95 °C and the whole was maintained approximately at this temperature during the addition of *n*-BuLi in hexane (0.8 ml of 1.25 M solution, 1.0 mmol) over 5 min. Five min after the addition ethyl iodide (0.10 ml, *ca.* 1.2 mmol) and 15 min thereafter HMPA (1 ml) were added. The mixture was maintained at −95 °C for successive 5 h and warmed gradually to room temp (14 h). Workup and short-path distillation of the crude product at 60—80 °C/3 mmHg gave an isomeric mixture of **3e** and **4e** (0.12 g, 54% yield). Each isomer was separated by preparative GLC (Silicone HV grease, see conditions B).

r-*1-Bromo-1-ethyl*-t-*2-phenylcyclopropane* (**3e**): R_t 23 min; bp 72—74 °C/4 mmHg; IR (neat): 1603, 1580, 1497, 1454, 1140, 804, 770, 733, 699 cm^{-1}; MS: *m/e* (%), 226 (M^++2, 0.8), 224 (M^+, 0.8), 145 (100), 130 (14), 117 (31). 91 (32); PMR (CCl_4): δ 0.7—1.7 (m, 7H), 2.78 (dd, J=7, 10 Hz, 1H, PhC$\underline{H}$), 7.0—7.3 (m, 5H, Ph). Found: C, 58.6; H, 5.7%. Calcd for $C_{11}H_{13}Br$: C, 58.7; H, 5.8%.

r-*1-Bromo-1-ethyl*-c-*2-phenylcyclopropane* (**4e**): R_t 25 min; bp 99—103 °C (bath temp)/4 mmHg; IR (neat): 1602, 1580, 1496, 1450, 1370, 1157, 1025, 824, 752, 730, 694 cm^{-1}; MS: *m/e* (%), 226 (M^++2, 0.7), 224 (M^+, 0.7), 145 (100), 130 (14), 117 (50), 91 (42); PMR (CCl_4): δ 1.0—2.1 (m, 8H), 7.0—7.3 (m, 5H, Ph). Found: C, 58.6; H, 5.9%. Calcd for $C_{11}H_{13}Br$: C, 58.7; H, 5.8%.

endo-*7-Allyl-7-bromonorcarane* (**5c**). A suspension of copper(I) iodide (0.48 g, 2.5 mmol) in THF (15 ml) containing **2a** (1.3 g, 5.0 mmol) was cooled to −95 °C and a solution of *n*-BuLi in hexane (2.7 ml of 2.0 M solution, 5.5 mmol) was added to this suspension during the period of 5 min. After 10 min allyl bromide (1.0 ml) was added and stirring was continued for 4 h. The mixture was gradually warmed up to room temp in 2 h and quenched with water. Workup and extraction with ether followed by distillation at 80—90 °C/2 mmHg gave **5c** (0.94 g, 87% yield). Preparative GLC (Silicone HV grease, 120 °C, 1.0 kg/cm^2, R_t 15 min) gave the analytically pure sample. Bp 77—80 °C/2 mmHg; IR (neat): 3090, 3010, 1643, 1470, 1452, 1426, 1224, 1168, 1115, 1049, 980, 910, 835 cm^{-1}; MS *m/e*: (%), 216 (M^++2, 2), 214 (M^+, 2), 172 (2), 135 (77), 93 (78), 79 (66), 67 (100); PMR (CCl_4): δ 0.9—2.2 (m, 10H), 2.57 (dt, J=6.2, 1 Hz, 2H, CH_2=

$CHC\underline{H}_2$), 4.9—6.3 (m, 3H). Found: C, 55.8; H, 7.2%. Calcd for $C_{10}H_{15}Br$: C, 55.8; H, 7.0%.

exo-7-Bromo-7-(3-methyl-2-butenyl)norcarane (5d). A magnetically stirred solution containing **2a** (0.51 g, 2.0 mmol) in THF (10 ml) was cooled to −95 °C and maintained at this temp during the dropwise addition of a solution of *n*-BuLi (1.0 ml of 2.1 M hexane solution, 2.2 mmol) over a 5 min period. The reaction mixture was stirred at −95 °C for 10 min and 3-methyl-2-butenyl bromide (0.35 g, 2.4 mmol) diluted with HMPA (1 ml) was added at −95 °C over 5 min. The reaction mixture was allowed to warm to −78 °C in 2 h and quenched with ethanol (1 ml). Workup and preparative TLC (silica gel, hexane, R_f 0.7) gave pure **5d** (0.37 g, 77% yield). Bp 100—103 °C/4 mmHg; IR (neat): 3030, 1670, 1470, 1445, 1370, 1170, 1115, 1095, 1045, 805 cm^{-1}; MS: *m/e* (%), 244 (M^++2, 0.9), 242 (M^+, 0.9), 227 (0.5), 199 (12), 186 (24), 163 (54), 107 (99), 41 (100); PMR (CCl_4): δ 0.9—2.3 (m, 16H), 2.47 (d, J=6 Hz, 2H), 5.0—5.5 (m, 1H). Found: C, 59.1; H, 8.0%. Calcd for $C_{12}H_{19}Br$: C, 59.3; H, 7.9%.

trans-1-Bromo-2-phenylcyclopropane (3g).[12a] According to the procedure of conditions A the carbenoids were generated and quenched with ethanol (2 ml) instead of MeI, and the reaction mixture was warmed up to room temp. Workup and distillation at 109—113 °C/19 mmHg gave 87% yield of **3g**. IR (neat): 3030, 1600, 1498, 1229, 758, 700, 620 cm^{-1}; MS: *m/e* (%), 198 (M^++2, 0.5), 196 (M^+, 0.5), 195 (0.5), 117 (100), 115 (47), 91 (23); PMR: (CCl_4) δ 1.2—1.6 (m, 2H), 2.1—2.5 (m, 1H), 2.7—3.1 (m, 1H), 6.7—7.5 (m, 5H, Ph).

trans-1-Bromo-2-hexylcyclopropane (3h)[12g] *with Concomitant 4h (19%):* Bp 77—80 °C/19 mmHg; IR (neat): 3060, 1470, 1375, 1236, 1034, 920 cm^{-1}; MS: *m/e* (%), 206 (M^++2, 0.3), 204 (M^+, 0.3), 162 (2), 148 (4), 83 (49), 69 (100), 55 (88); PMR (CCl_4): δ 0.6—1.8 (m, 16H), 2.4—2.7 (m, 1H, CHBr).

trans-2-(Benzyloxymethyl)-1-bromocyclopropane (3i): Bp 90—98 °C (bath temp)/0.07 mmHg; IR (neat): 3040, 1600, 1493, 1450, 1090, 740, 700 cm^{-1}; MS: *m/e* (%), 242 (M^++2, 0.9), 240 (M^+, 0.9), 210 (0.8), 161 (1.5), 131 (11), 91 (100); PMR (CCl_4): δ 0.8—1.8 (m, 3H), 2.5—2.9 (m, 1H, CHBr), 3.1—3.6 (m, 2H, OCH_2), 4.42 (s, 2H, $PhC\underline{H}_2$), 7.1—7.4 (m, 5H, Ph). Found: C, 55.1; H, 5.3%. Calcd for $C_{11}H_{13}BrO$: C, 54.8; H, 5.4%.

trans-1-Chloro-2-phenylcyclopropane (3j):[20] bp 90—100 °C (bath temp)/19 mmHg; IR (neat): 3040, 1605, 1499, 1450, 1253, 940, 888, 760, 700, 680 cm^{-1}; MS: *m/e* (%), 154 (M^++2, 3), 152 (M^+, 8), 117 (100), 115 (43), 91 (18); PMR (CCl_4): δ 1.2—1.6 (m, 2H), 2.1—2.5 (m, 1H), 2.9—3.3 (m, 1H, CHCl), 6.9—7.5 (m, 5H, Ph).

cis-1-Chloro-2-phenylcyclopropane (4j):[20] Bp 89—95 °C (bath temp)/19 mmHg; IR (neat): 3030, 1600, 1495, 1450, 1278, 1078, 917, 812, 767, 730, 700, 658, 591 cm^{-1}; MS: *m/e* (%), 154 (M^++2, 3), 152 (M^+, 8), 117 (100), 115 (46), 91 (9); PMR (CCl_4): δ 1.0—1.6 (m, 2H), 2.0—2.5 (m, 1H), 3.1—3.4 (m, 1H, CHCl), 7.0—7.5 (m, 5H, Ph).

exo-7-Bromonorcarane (5e):[12a] Bp 63—68 °C (bath temp)/18 mmHg; IR (neat): 3010 1448 1330 1215 1006 760 685 cm^{-1}; MS: *m/e* (%) 176 (M^++2, 7) 174 (M^+, 7) 132 (16) 95 (100), 67 (54); PMR (CCl_4): δ 0.7—2.3 (m, 10H), 2.50 (t, J=3.5 Hz, CHBr).

exo-7-Bromo-1-methylnorcarane (5f):[21] Bp 55—59 °C (bath temp)/1 mmHg; IR (neat): 1450, 1375, 1231, 700 cm^{-1}; MS: *m/e* (%), 190 (M^++2, 0.4), 188 (M^+, 0.4), 173 (0.8), 109 (100), 93 (12), 81 (24), 67 (96), 55 (36); PMR (CCl_4): δ 0.8—2.2 (m, 9H), 1.25 (s, 3H, Me), 2.70 (d, J=4 Hz, CHBr). (Found: C, 51.1; H, 7.1%).

(E)-β-Methylcinnamyl Acetate (9a). A suspension of silver acetate (87 mg, 0.52 mmol) and silver tetrafluoroborate (15 mg, 0.07 mmol) in a solution of **3a** (0.11 g, 0.52 mmol) and acetic acid (1.0 ml) was stirred at 75 °C for 22 h. Workup, followed by preparative TLC (silica gel, benzene, R_f 0.6), gave **9a** (74 mg, 74% yield). Bp 70—77 °C (bath temp)/3 mmHg; IR (neat): 3080, 3050, 1740, 1660, 1600, 1580, 1493, 1445, 1370, 1230, 1120, 745, 700 cm^{-1}; MS: *m/e* (%), 190 (M^+, 21), 148 (37), 130 (74), 115 (59), 77 (13), 43 (100); PMR (CCl_4): δ 1.87 (s, 3H, Me), 2.04 (s, 3H, OAc), 4.57 (s, 2H, CH_2O), 6.47 (s, 1H, $PhC\underline{H}$), 7.1—7.4 (m, 5H, Ph). Found: C, 75.6; H, 7.5%. Calcd for $C_{12}H_{14}O_2$: C, 75.8; H, 7.4%.

Solvolysis of 3b. A mixture of **9b** and **10b** was obtained and each isomer was separated by preparative GLC (Silicone HV grease, 130 °C, 1.0 kg/cm^2).

(E)-2-Methyl-2-nonen-1-yl Acetate (9b): R_t 10 min; bp 64—72 °C (bath temp)/3 mmHg; IR (neat): 1736, 1464, 1370, 1225, 1015 cm^{-1}; MS: *m/e* (%), 198 (M^+, 0.3), 156 (6), 138 (14), 95 (23), 68 (41), 43 (100),; PMR (CCl_4): δ 0.7—1.5 (m, 13H), 1.63 (s, 3H, Me), 1.98 (s, 3H, OAc), 4.37 (s, 2H), 5.42 (t, J=7 Hz, 1H). Found: C, 72.8; H, 11.4%. Calcd for $C_{12}H_{22}O_2$: C, 72.7; H, 11.2%.

2-Methyl-1-nonen-3-yl acetate (10b): R_t 8 min; bp 53—64 °C (bath temp)/1.5 mmHg; IR (neat): 3080, 1730, 1650, 1235, 1020, 900 cm^{-1}; MS: *m/e* (%), 156 (M^+−42, 8), 138 (8), 113 (8), 95 (16), 82 (15), 68 (25), 43 (100); PMR (CCl_4): δ 0.7—2.3 (m, 13H), 1.68 (s, 3H, Me), 1.95 (s, 3H, OAc), 4.7—5.2 (m, 3H); Found: C, 72.4; H, 11.1%. Calcd for $C_{12}H_{22}O_2$: C, 72.7; H, 11.2%.

Solvolysis of 3c. A mixture of 4-benzyloxy-2-methyl-2-buten-1-yl acetate (**9c**) and 1-benzyloxy-3-methyl-3-buten-2-yl acetate (**10c**) was obtained and separated by preparative TLC (silica gel, hexane–ether 5: 1).

9c: R_f 0.3—0.4; bp 87—93 °C (bath temp)/1 mmHg; IR (neat): 3050, 3020, 1730, 1490, 1450, 1360, 1220, 1065, 1020, 737, 700 cm^{-1}; MS: *m/e* (%), 174 (M^+−60, 3), 159 (3), 105 (11), 91 (100), 43 (72); PMR (CCl_4): δ 1.63 (s, 3H, Me), 2.00 (s, 3H, OAc), 4.00 (d, J=6.5 Hz, 2H), 4.41 (s, 4H), 5.4—5.9 (m, 1H), 7.0—7.5 (m, 5H). Found: C, 72.0; H, 7.7%. Calcd for $C_{14}H_{18}O_3$: C, 71.8; H, 7.7%. The geometry of double bond is assumed to be (E) on the analogy of the solvolysis of **3a** to **9a**.

10c: R_f 0.4—0.5; bp 85—95 °C (bath temp)/1 mmHg; IR (neat): 3030, 1732, 1650, 1494, 1450, 1362, 1230, 1095, 1025, 905, 740, 700 cm^{-1}; MS: *m/e* (%), 234 (M^+, 0.01), 174 (2), 91 (78), 65 (43), 43 (100); PMR (CCl_4): δ 1.73 (s, 3H, Me), 2.00 (s, 3H, OAc), 3.45 (d, J=6 Hz, 2H), 4.45 (s, 2H), 4.8—5.1 (m, 2H), 5.31 (t, J=6 Hz, 1H), 7.0—7.5 (m, 5H, Ph). Found: C, 72.0; H, 8.0%. Calcd for $C_{14}H_{18}O_3$: C, 71.8; H, 7.7%.

Hydrolysis of 9b. One drop of sodium methoxide in methanol (1 M) was added to a solution of **9b** (7.5 mg, 0.04 mmol) in CH_2Cl_2 (1 ml). After stirring at room temp for 1 h the reaction mixture was worked up. Preparative TLC (silica gel, hexane–ether (2: 1. R_f 0.4—0.5) afforded *(E)*-2-methyl-2-nonen-1-ol (5.4 mg, quantitative yield). Bp 93—100 °C (bath temp)/20 mmHg; IR (neat): 3360, 1640, 1480, 1380, 1265, 1010 cm^{-1}; MS: *m/e* (%), 156 (M^+, 6), 138 (4), 109 (4), 95 (9), 83 (12), 71 (46), 55 (27), 40 (100); PMR (CCl_4): δ 0.6—2.2 (m, 14H), 1.63 (s, 3H, Me), 3.88 (s, 2H, CH_2O), 5.2—5.5 (m, 1H). The methyl signal of this alcohol is strictly different from that of (*Z*) isomer (δ 1.71).[22]

Hydrolysis of 9a. This reaction afforded *(E)*-β-methylcinnamyl alcohol in 65% yield. Bp 88—95 °C (bath temp)/3 mmHg; IR (neat): 3300, 3070, 3050, 3020, 1664, 1600, 1575, 1493, 1443, 1074, 1008, 739, 695 cm^{-1}; MS: *m/e* (%), 148 (M^+, 51), 133 (28), 115 (49), 105 (46), 91 (100); PMR (CCl_4): δ 1.84 (br s, 4H, Me and OH), 4.08 (br s, 2H, CH_2O),

6.4—6.6 (m, 1H), 7.0—7.5 (m, 5H, Ph). The product was identical in all respects with the authentic sample prepared from lithium aluminum hydride reduction of (*E*)-β-methylcinnamaldehyde.[23]

exo-*7-Acetoxy-7-methylnorcarane (**12a**)*. A solution of **5a** (0.15 g, 0.80 mmol) in acetic acid (1 ml) was added to a suspension of silver acetate (0.13 g, 0.80 mmol) and silver tetrafluoroborate (16 mg, 0.08 mmol) in acetic acid (2 ml). After stirring for 2 h at 75 °C the reaction mixture was neutralized by the addition of saturated sodium hydrogencarbonate aq solution and extracted with ether. The organic layer was dried over sodium sulfate and evaporated *in vacuo*. The crude product was purified by preparative TLC (silica gel, hexane–ether 4: 1, R_f 0.5). **12a** was obtained in 63% yield (85 mg). Bp 62—72 °C (bath temp)/4 mmHg; IR (neat): 3050, 1745, 1450, 1370, 1240, 1189, 1113, 1020, 893 cm^{-1}; MS: *m/e* (%), 126 (M^+−42, 13), 111 (15), 44 (85), 43 (100); PMR (CCl_4): δ 0.9—2.2 (m, 10H), 1.38 (s, 3H, Me), 1.85 (s, 3H, OAc). Found: C, 71.2; H, 9.9%. Calcd for $C_{10}H_{16}O_2$: C, 71.4; H, 9.6%.

exo-*7-Acetoxy-7-allylnorcarane (**12c**)*: Bp 72—82 °C (bath temp)/3 mmHg; IR (neat): 3070, 3000, 1735,1637, 1449, 1361, 1220, 1175, 910, 790 cm^{-1}; MS: *m/e* (%), 194 (M^+, 0.2), 153 (14), 111 (17), 67 (23), 43 (100), 41 (41); PMR (CCl_4): δ 0.6—2.4 (m, 10H), 1.85 (s, 3H, Me), 2.57 (d, J= 6 Hz, 2H), 4.9—6.2 (m, 3H). Found: C, 73.9; H, 9.4%. Calcd for $C_{12}H_{18}O_2$: C, 74.2; H, 9.3%.

exo-*7-Acetoxy-7-(3-methyl-2-butenyl)norcarane (**12d**)*: Bp 66—76 °C (bath temp)/2 mmHg; IR (neat): 3000, 1735, 1460, 1445, 1360, 1230, 1063, 1048 cm^{-1}; MS: *m/e* (%), 222 (M^+, 0.1), 180 (10), 162 (21), 147 (62), 43 (100); PMR (CCl_4): δ 0.5—2.3 (m, 12H), 0.83 (s, 6H, Me_2C), 1.98 (s, 3H, OAc), 4.67 (t, J=7 Hz, 1H). Found: C, 75.7; H 10.1%. Calcd for $C_{14}H_{22}O_2$: C, 75.6; H, 10.0%.

exo-*7-Acetoxy-1,7-dimethylnorcarane (**12b**)*: Bp 61—69 °C (bath temp)/4 mmHg; IR (neat): 1740, 1445, 1369, 1250, 1232, 1190, 1120, 1020, 790 cm^{-1}; MS: *m/e* (%), 182 (M^+, 0.2), 167 (0.3), 140 (12), 125 (26), 95 (10), 43 (100); PMR (CCl_4): δ 0.5—0.8 (m, 1H), 0.9—2.2 (m, 8H), 1.07 (s, 3H, Me), 1.38 (s, 3H, Me), 1.90 (s, 3H, OAc). Found: C, 72.2; H, 10.1%. Calcd for $C_{11}H_{18}O_2$: C, 72.5; H, 10.0%.

*Acetolysis of a Mixture of **5a** and **6a**.* A mixture of **5a** and **6a** (36: 64) (0.19 g, 1.0 mmol) dissolved in acetic acid (1 ml) was treated with silver salts as above affording an inseparable mixture of **12a** and 2-methyl-2-cyclohepten-1-yl acetate (93 mg, **12a**/ring opened isomer 59: 41) in 55% yield. The ratio was estimated by its PMR (δ 1.37 (s, Me), 1.85 (s, OAc) for **12a**; δ 1.98 (s, AOc), 5.2—5.8 (m, CHOAc and olefinic proton) for its isomer).

*2-Phenyl-1-methylenecyclopropane (**15a**)*.[24] A solution of **3a** (50 mg, 0.24 mmol) in dimethyl sulfoxide (0.5 ml) was added to a solution of *t*-BuOK (42 mg, containing 26% of *t*-BuOH, 0.30 mmol) in DMSO (3 ml) at room temp. After stirring for 1 h the reaction mixture was quenched with water and extracted with pentane. The yield was estimated by GLC (Silicone SE-30, indane as an internal standard). The pure sample was obtained by short-path distillation (50—58 °C/10 mmHg). IR (neat): 3080, 1745, 1603, 1496, 1452, 1198, 1118, 1014, 890, 743, 695 cm^{-1}; MS: *m/e* (%), 130 (M^+, 70), 129 (100), 128 (60), 115 (66); PMR (CCl_4): δ 1.0—1.9 (m, 2H), 2.4—2.8 (m, 1H), 5.5—5.8 (m, 2H), 7.0—7.5 (m, 5H, Ph).

*2-Hexyl-1-methylenecyclopropane (**15b**)*:[24] Bp 53—63 °C (bath temp)/20 mmHg; IR (neat): 3060, 3040, 1740, 1460, 1016, 885 cm^{-1}; MS: *m/e* (%), 138 (M^+, 3), 123 (16), 109 (18), 95 (37), 81 (100), 67 (88), 55 (80), 41 (70); PMR (CCl_4): δ 0.6—2.0 (m, 16H), 5.2—5.6 (m, 2H).

*2-(Benzyloxymethyl)-1-methylenecyclopropane (**15c**)*: Bp 65—75 °C (bath temp)/3 mmHg; IR (neat): 3060, 3040, 1735, 1600, 1580, 1492, 1450, 1350, 1080, 1021, 885, 735, 700 cm^{-1}; MS: *m/e* (%), 174 (M^+, 0.05), 129 (4), 107 (6), 91 (100), 65 (10); PMR (CCl_4): δ 0.7—2.0 (m, 3H), 3.0—3.6 (m, 2H), 4.45 (s, 2H), 5.3—5.6 (m, 2H), 7.1—7.5 (m, 5H). Found: C, 82.6; H, 8.3%. Calcd for $C_{12}H_{14}O$: C, 82.7; H, 8.1%.

*7-Methylenenorcarane (**16a**)*:[15f] Bp 65—75 °C (bath temp)/130 mmHg; IR (neat): 3060, 2970, 2700, 1749, 1452, 1351, 1331, 1140, 882, 848, 710 cm^{-1}; MS: *m/e* (%), 108 (M^+, 15), 107 (25), 93 (77), 91 (83), 79 (100), 55 (56); PMR (CCl_4): δ 0.8—2.1 (m, 10H), 5.2—5.4 (m, 2H).

Substituent Effects on Tautomerism of 4-Pyridinethiones

Hiromichi BESSO,* Kimiaki IMAFUKU, and Hisashi MATSUMURA

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami, Kumamoto 860

(Received March 25, 1977)

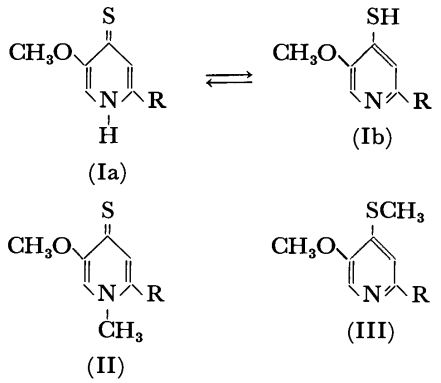
The tautomeric constants K_t of several 4-pyridinethiones were determined by measurement of pK_a values. For 2-substituted 5-methoxy-4-pyridinethiones, the K_t values are correlated to the substituent constants σ, by the equation $\log K_t = 4.00 + 3.99\sigma_m - 7.33\sigma_o$.

Two tautomers, enethiol and thione forms, are possible for the tautomerism of 4-pyridinethiones. Ross[1] found by means of UV spectra that 4-pyridinethione exists predominantly in the thione form in ethanolic solution. Jones and Katritzky,[2] and Albert and Barlin[3] concluded by measurement of pK_a values that the thione form predominates in aqueous solution by factors of *ca.* 10^4 by comparative studies of 4-pyridinethione and both alkylated compounds. It was shown by means of IR,[4] NMR,[5] and UV[6] that polyhalogenated 4-pyridinethiones exist mostly in the enethiol form.

In the previous paper, we reported the substituent effects of 2-substituted 5-methoxy-4-pyridones in aqueous solution on tautomerism.[7] We hereby report the tautomerism of 2-substituted-5-methoxy-4-pyridinethiones by a similar treatment to that of 2-substituted 5-methoxy-4-pyridones.

Results and Discussion

Dissociation Constants. The dissociation constants of 4-pyridinethiones (I), *N*-methyl-4-pyridinethiones (II), and 4-methylthiopyridines (III) were determined spectrophotometrically in water at 25 °C. The results are summarized in Table 1, where pK_1 represents the first dissociation constants for 4-pyridinethiones (I), pK_{NCH_3} and pK_{SCH_3} corresponding to the dissociation constants for *N*-methyl-4-pyridinethiones (II) and 4-methylthiopyridines (III), respectively.



Since activity coefficients were not introduced into the calculation, the dissociation constants do not represent thermodynamic terms, giving only a relative measure of base strength.

The pK_a values of 4-pyridinethiones (I) and *N*-methyl-4-pyridinethiones (II) are smaller than those of 4-pyridones and *N*-methyl-4-pyridones, since electronegativity of sulfur atom is smaller than that of oxygen atom. The pK_a values of I, II, and III decrease by electron-withdrawing groups attached to 2-position similarly to those of 4-pyridones.

Table 1. Dissociation constants

Substituent	pK_1	pK_{NCH_3}	pK_{SCH_3}
CH_3	1.90	1.82	6.50
H	1.69		
CH_2OH	1.64	1.53	5.38
CH_2OCH_3		1.44	
CHO			3.86

Tautomeric Ratio. The tautomeric constants K_t which represent the ratio of NH-form (Ia) to SH-form (Ib), are given by the following equation:[8] (Table 2).

$$\log K_t = pK_{SCH_3} - pK_{NCH_3} \quad (1)$$

Table 2. Tautomeric constants

Substituent	$\log K_t$	
	4-Pyridinethiones	4-Pyridones
CH_3	4.7	3.7
CH_2OH	3.9	2.8

The K_t values for 4-pyridinethiones are affected by the substituents in the 2-position, decreasing by electron-withdrawing groups. It is concluded that the thione forms predominate in aqueous solution by factors of *ca.* 10^5 for 5-methoxy-2-methyl-4-pyridinethione and *ca.* 10^4 for 5-methoxy-2-hydroxymethyl-4-pyridinethione.

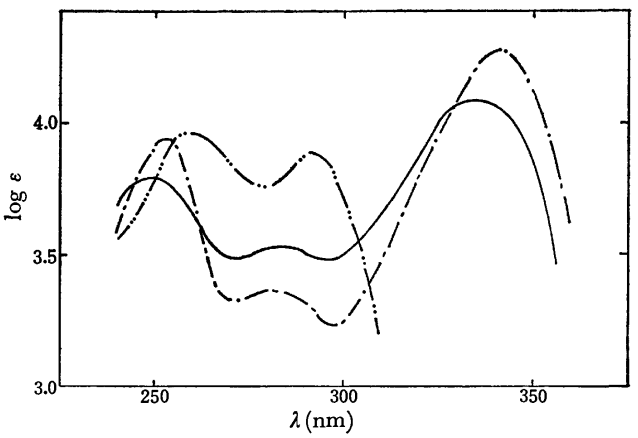


Fig. 1. The UV spectra of the neutral species of 5-methoxy-2-hydroxymethyl-4-pyridinethione series
—— 5-methoxy-2-hydroxymethyl-4-pyridinethione;
–·– 5-methoxy-2-hydroxymethyl-1-methyl-4-pyridinethione;–··– 5-methoxy-2-hydroxymethyl-4-methylthiopyridine.

* Present address: Wakunaga Pharmaceutical Co., Ltd., Koda-machi, Takata-gun, Hiroshima 729-64.

UV Spectra. The UV spectra of the neutral species of 5-methoxy-4-pyridinethiones (I) having the methyl and hydroxymethyl group in the 2-position are similar to those of their *N*-methyl derivatives (II), but differ a great deal from those of their *S*-methyl derivatives (III). Figure 1 shows the UV spectra of the neutral species of 5-methoxy-2-hydroxymethyl-4-pyridinethione series, the thione form being seen to exist predominantly.

Substituent Effects. Clark and Perrin[9] obtained the substituent constants σ_o for ortho-substituted pyridines from their dissociation constants. We also obtained the substituent constants σ_o and σ_m for the hydroxymethyl group.[7] When the pK_a values of 2-substituted 5-methoxy-4-pyridinethiones (I), pK_1, are plotted against the substituent constants σ_m,[10,11] a straight line is obtained, giving the following equation by the least-square methods:

$$pK_1 = 1.68 - 3.16\sigma_m \quad (r=0.998). \tag{2}$$

For the proton gain of 2-substituted 5-methoxy-1-methyl-4-pyridinethiones (II) and the proton loss of 2-substituted 5-methoxy-4-methylthiopyridines (III), Eqs. 3 and 4, respectively, are obtained.

$$pK_{NCH_3} = 1.54 - 3.99\sigma_m \quad (r=0.992), \tag{3}$$

$$pK_{SCH_3} = 5.54 - 7.33\sigma_o \quad (r=0.999). \tag{4}$$

When Eqs. 3 and 4 are substituted into Eq. 1, we have

$$\log K_t = 4.00 + 3.99\sigma_m - 7.33\sigma_o. \tag{5}$$

We have obtained a similar equation for 2-substituted 5-methoxy-4-pyridones:[7]

$$\log K_t = 2.98 + 2.93\sigma_m - 6.18\sigma_o. \tag{6}$$

The ρ-value 2.93 for the substituent constants σ_m indicates the decrease of the hydroxy form by electron-withdrawing groups in the 2-position. In contrast, the ρ-value -6.18 for the substituent constants σ_o shows that the ratio of the hydroxy form increases electron-withdrawing group in the 2-position. It is possible to explain the tautomerism of 2-substituted 5-methoxy-4-pyridinethiones in a similar manner to that above. In Eq. 5, the ρ-value 3.99 for σ_m indicates the decrease of the enethiol form (Ib) by the electron-withdrawing group in the 2-position. In contrast, the ρ-value -7.33 for σ_o shows that the ratio of (Ib) increases with electron-withdrawing group in the 2-position. The substituent effects on the tautomerism of 2-substituted 5-methoxy-4-pyridinethiones are similar to those of 2-substituted 5-methoxy-4-pyridones.

It is concluded that the thione forms for 4-pyridinethione-4-mercaptopyridine tautomerism predominate by factors of *ca.* 10 the keto forms for 4-pyridone-4-hydroxypyridine tautomerism.

Experimental

All the melting points were measured on a Yanagimoto micromelting point apparatus and are uncorrected. The IR spectra were taken on a JASCO IRA-1 spectrophotometer, and the NMR spectra on a Hitachi-Perkin-Elmer R-24 spectrometer (60 MHz) with tetramethylsilane as an internal reference.

The pK_a values of 4-pyridinethiones (I), *N*-methyl-4-pyridinethiones (II), and 4-(methylthio)pyridines (III) were measured spectrophotometrically in water at 25 °C by the method of Albert and Serjeant.[12] The absorption spectra were taken on a Hitachi EPS-3T spectrophotometer, while the pH values were measured with a Hitachi-Horiba F-7 pH meter.

Materials. 4-Pyridinethiones (I) and *N*-methyl-4-pyridinethiones (II) were obtained by the reaction of 4-pyranthiones with ammonia and methylamine. All 4-pyranthiones were prepared by the reaction of the corresponding 4-pyrones with phosphorus pentasulfide in dry benzene.

3-Methoxy-4-pyranthione: Yield, 36%; mp 110—114 °C (from carbon tetrachloride); IR (KBr) 1604 cm^{-1}; NMR ($CDCl_3$) δ: 7.45 (d, 1H, J=4.7 Hz), 7.45 (s, 1H), 7.26 (d, 1H, J=4.7 Hz), 3.83 (s, 3H). Found: C, 50.49; H, 4.26%. Calcd for $C_6H_6O_2S$: C, 50.71; H, 4.26%.

5-Methoxy-2-methyl-4-pyranthione: Yield, 40%; mp 98.5—100 °C (from carbon tetrachloride); IR (KBr) 1615 cm^{-1}; NMR ($CDCl_3$) δ: 7.43 (s, 1H), 7.22 (s, 1H), 3.82 (s, 3H), 2.24 (s, 3H). Found: C, 53.55; H, 5.06%. Calcd for $C_7H_8O_2S$: C, 53.82; H, 5.17%.

5-Methoxy-2-acetoxymethyl-4-pyranthione: Yield, 54%; mp 152.5—153.5 °C (from benzene); IR (KBr) 1750, 1630 cm^{-1}; NMR ($CDCl_3$) δ: 7.45 (s, 1H), 7.32 (s, 1H), 4.88 (s, 2H), 3.85 (s, 3H), 2.15 (s, 3H). Found: C, 50.40; H, 4.60%. Calcd for $C_9H_{10}O_4S$: C, 50.47; H, 4.67%.

5-Methoxy-2-methoxymethyl-4-pyranthione: Yield, 37%; mp 56—56.5 °C (from benzene–petroleum ether); IR (KBr) 1635 cm^{-1}; NMR ($CDCl_3$) δ: 7.43 (s, 1H), 7.36 (s, 1H), 4.24 (s, 2H), 3.86 (s, 3H), 3.46 (s, 3H). Found: C, 51.48; H, 5.33%. Calcd for $C_8H_{10}O_3S$: C, 51.59; H, 5.42%.

3-Methoxy-4-pyridinethione: Yield, 44%; mp 149—152 °C (from methanol); IR (KBr) 3160, 2800, 1602 cm^{-1}; NMR (CF_3COOH) δ: 8.3—7.7 (m, 3H), 4.20 (s, 3H). Found: C, 50.80; H, 5.02; N, 9.94%. Calcd for C_6H_7NOS: C, 51.06; H, 5.02; N, 9.93%.

5-Methoxy-2-methyl-4-pyridinethione: Yield, 66%; mp 156—158 °C (from ethyl acetate); IR (KBr) 3245, 2800, 1615 cm^{-1}; NMR (CF_3COOH) δ: 7.9—7.5 (m, 2H), 4.15 (s, 3H), 2.69 (s, 3H). Found: C, 54.04; H, 5.78; N, 8.90%. Calcd for C_7H_9NOS: C, 54.19; H, 5.81; N, 9.03%.

5-Methoxy-1,2-dimethyl-4-pyridinethione: Yield, 60%; mp 200—202 °C (dec) (from methanol); IR (KBr) 3450, 3370, 1615 cm^{-1}; NMR (CF_3COOH) δ: 7.92 (s, 1H), 7.64 (s, 1H), 4.17 (s, 3H), 4.12 (s, 3H), 2.69 (s, 3H). Found: C, 56.66; H, 6.53; N, 8.25%. Calcd for $C_8H_{11}NOS$: C, 56.79; H, 6.55; N, 8.28%.

5-Methoxy-2-hydroxymethyl-4-pyridinethione was obtained by the reaction of 5-methoxy-2-acetoxymethyl-4-pyranthione with ammonia: Yield, 41%; mp 154—156 °C (from methanol); IR (KBr) 3210, 1600, 1585 cm^{-1}; NMR (CF_3COOH) δ: 8.2—7.6 (m, 2H), 5.13 (s, 2H), 4.18 (s, 3H). Found: C, 48.78; H, 5.35; N, 8.08%. Calcd for $C_7H_9NO_2S$: C, 49.08; H, 5.30; N, 8.19%.

5-Methoxy-2-hydroxymethyl-1-methyl-4-pyridinethione was obtained by the reaction of 5-methoxy-2-acetoxymethyl-4-pyranthione with methylamine: Yield, 65%; mp 199.5—201.5 °C (from methanol); IR (KBr) 3300, 1615 cm^{-1}; NMR (CF_3COOH) δ: 7.99 (br, s, 2H), 5.14 (s, 2H), 4.27 (s, 3H), 4.16 (s, 3H). Found: C, 51.29; H, 6.07; N, 7.58%. Calcd for $C_8H_{11}NO_2S$: C, 51.85; H, 5.98; N, 7.57%.

5-Methoxy-2-methoxymethyl-1-methyl-4-pyridinethione: Yield, 70%; mp 166—168 °C (dec) (from methanol); IR (KBr) 1615 cm^{-1}; NMR (CF_3COOH) δ: 8.00 (s, 1H), 7.86 (s, 1H), 4.78 (s, 2H), 4.26 (s, 3H), 4.16 (s, 3H), 3.65 (s, 3H). Found: C, 54.08; H, 6.58; N, 7.01%. Calcd for $C_9H_{13}NO_2S$: C, 54.26; H, 6.58; N, 7.03%.

5-Methoxy-2-methyl-4-(methylthio)pyridine was obtained by the

methylation of 5-methoxy-2-methyl-4-pyridinethione with methyl iodide: Yield, 54%; mp 58—59 °C (from petroleum ether); IR (KBr) 1575 cm^{-1}; NMR (CCl_4) δ: 7.75 (s, 1H), 6.66 (s, 1H), 3.85 (s, 3H), 2.37 (s, 3H), 2.31 (s, 3H). Found: C, 56.79; H, 6.62; N, 8.30%. Calcd for $C_8H_{11}NOS$: C, 56.79; H, 6.55; N, 8.28%.

5-Methoxy-2-hydroxymethyl-4-methylthiopyridine was obtained by the methylation of 5-methoxy-2-hydroxymethyl-4-pyridinethione with methyl iodide: Yield, 53%; mp 108 °C (from carbon tetrachloride); IR (KBr) 3200, 1580 cm^{-1}; NMR ($CDCl_3$) δ: 7.97 (s, 1H), 7.02 (s, 1H), 4.69 (s, 2H), 3.95 (s, 3H), 2.43 (s, 3H), 4.3—3.3 (br, 1H). Found: C, 51.44; H, 5.95; N, 7.67%. Calcd for $C_8H_{11}NO_2S$: C, 51.85; H, 5.98; N, 7.57%.

5-Methoxy-2-formyl-4-(methylthio)pyridine was obtained by manganese dioxide oxidation of 5-methoxy-2-hydroxymethyl-4-methylthiopyridine: Yield, 62%; mp 116—117 °C (from petroleum ether); IR (KBr) 1720, 1550 cm^{-1}; NMR ($CDCl_3$) δ: 9.96 (s, 1H), 8.19 (s, 1H), 7.73 (s, 1H), 4.06 (s, 3H), 2.51 (s, 3H). Found: C, 52.35; H, 5.03; N, 7.55%. Calcd for $C_8H_9NO_2S$: C, 52.46; H, 4.95; N, 7.65%.

A New Synthesis of Flavones by the Reaction of 2-Phenyl-2*H*-1-benzopyrans with Potassium Permanganate

Yoshihiro ASHIHARA, Yasuyuki NAGATA,* and Kazu KUROSAWA

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami, Kumamoto 860

(Received April 11, 1977)

The oxidation of ten 2-phenyl-2*H*-1-benzopyrans with potassium permanganate in acetone has been found to give the corresponding flavones in 8—73% yields. The reaction mechanism is discussed on the basis of the substituent effect and the oxidations of related compounds.

Flavones can be synthesized from 2'-hydroxychalcones[1] or from flavanones[2] or they can be synthesized from *o*-benzoyloxyacetophenones by the Baker-Venkataraman rearrangement followed by cyclization[3] or from *o*-hydroxyacetophenones and aromatic acids by the Allan-Robinson condensation.[4] We have investigated the possibility of transforming 2-phenyl-2*H*-1-benzopyrans into flavones; this could be accomplished by the oxidation of the former with potassium permanganate. The procedure is very simple and can be utilized as an easy preparation method for flavones when 2-phenyl-2*H*-1-benzopyrans are readily available.

The 2-phenyl-2*H*-1-benzopyrans (IIa—IIj) were prepared from the corresponding 2'-hydroxychalcones (Ia—Ij) by sodium borohydride reduction, followed by treatment with aqueous acetic acid. The structures of the new 2-phenyl-2*H*-1-benzopyrans were confirmed by examining their NMR spectra and by elemental analyses.

When the 2-phenyl-2*H*-1-benzopyrans (IIa—IIj) were oxidized with potassium permanganate in a molar ratio of 1 : 4 in acetone, flavones (IIIa—IIIj) were obtained in 8—73% yields; they were identified by comparing their melting points with those reported and by examining their NMR spectra. When the reaction was carried out with potassium permanganate as an oxidizing reagent in a molar ratio less than 1 : 4 (Table 1, entries 5 and 12) or more than 1 : 4 (entries 9 and 24), it gave a rather poor yield because of the presence of some unchanged II or of tarry products. The change in the reaction time did not alter the yield significantly (entries 6, 7, and 8). However, 2-phenyl-2*H*-1-benzopyran (IIa) and 7-methoxy-2-phenyl-2*H*-1-benzopyran (IIb) had longer reaction times, 16 h (entry 2) and 12 h (entry 4), respectively, and the yields after 4 h were much lower (entries 1 and 3). It is thus considered that the 4'-methoxyl group and two methoxyl groups in the ring A may accelerate the reaction rate. The yield of 2',3',4',7-tetramethoxyflavone (IIIe) is extremely low (entry 16). This may indicate that the 2'-methoxyl group has a steric hindrance towards potassium permanganate which attacks the hydrogen at C(2)-position. There were many unidentified products in this case. When the reaction was conducted in pyridine in place of acetone, the yields and the reaction times were not affected (entries 14 and 21). The reaction in acetic acid, on the other hand, gave the lowest figure (entry 22). The change of the oxidizing reagent from potassium permanganate to chromium trioxide-pyridine complex[5] caused a decrease in the yield of III (entry 11).

In order to explain the above observations, we assumed three probable reaction mechanisms. The reaction may proceed through a cyclic intermediate (V) which is known to be involved in the reaction of olefins with potassium permanganate to give α-diols or α-ketols[6] (pathway a). The reaction could be of an ionic nature and proceed *via* flavylium cation (VI) (pathway b). Or the reaction may proceed *via* radical intermediate (VII) (pathway c).

Pathway a is not attractive since it fails to explain the facts that the reaction rate was enhanced by the 4'-methoxyl group and that the steric hindrance was exercised by the 2'-methoxyl group which is located far from the ethylenic double bond in IIe. Pathway a is completely excluded for the case when 7-methoxy-2-(*p*-methoxyphenyl)-4*H*-1-benzopyran (IV) was readily oxidized to give IIId in a yield comparable to that obtained in the oxidation of IId. Isomerization of IId to IV is not likely to occur in the reaction conditions, as IId was stable in 0.75% potassium hydroxide-moist acetone-d_6 even after 24 h, as observed by NMR spectra. The fact that the reaction time of IV (2.5 h) was shorter than that of IId (4 h) also argues against the pathway IV→IId→V (R=CH_3O–, Ar=*p*-CH_3O-C_6H_4–)→IIId.

Pathway b seemed to be consistent with all our observations. The electron-donating group, such as the methoxyl group in the rings A and B, would make the hydrogen at C(2)-position easier to be removed by an oxidant, and the methoxyl group at C(2')-position would hinder the approach of the oxidant by steric reasons. The fact that the oxidation of IV also yielded IIId may indicate that 4',7-dimethoxyflavylium ion (VI; R=CH_3O–, Ar=*p*-CH_3O-C_6H_4–) could be an intermediate. However, when we examined the oxidation of VI (R=CH_3O–, Ar=*p*-CH_3O-C_6H_4–) under similar conditions, it gave a complex mixture of products in which IIId was not found. This suggests that pathway b should also be eliminated.

Pathway c will account for the substituent effects due to the methoxyl groups in rings A and B, and for the identical results of the oxidations of 2-phenyl-2*H*-1-benzopyrans (II) and 2-phenyl-4*H*-1-benzopyran. When the reaction was carried out in the presence of 2,6-di-*t*-butylphenol (entry 15) in the hope of trapping the radical intermediate (VII), whose presence has been successfully demonstrated in the reaction of 2'-hydroxychalcone with lead tetraacetate using 3,5-dimethoxy-

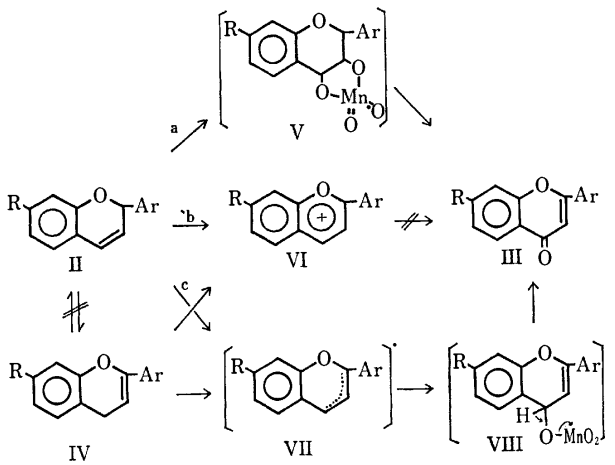
Scheme 1.

phenol,[7] it caused a decrease in the yield but no adduct was obtained. The reaction, carried out under nitrogen atmosphere, gave a flavone in a similar yield as well as in the same reaction time (entry 10).



Scheme 2. The possible reaction pathways of the oxidations of 2-phenyl-2*H*-1-benzopyrans and 2-phenyl-4*H*-1-benzopyran.

Nevertheless, it is likely that the oxidation of II and IV may proceed through the hydrogen abstraction at the C(2)-position in the case of II and at the C(4)-position in the case of IV giving the identical radical (VII), and that the attack of the permanganate ion to VII at the C(4)-position gave VIII and the elimination of reduced manganese species in VIII would give III.

The oxidations of the 2-phenyl-2*H*-1-benzopyrans are also interesting in connection with their biogenetic transformations into 3-flavanols,[8,9] 4-flavanols,[10,11] 3,4-flavandiols,[9,10] and 3,4-epoxyflavans.[9]

Experimental

All ^{1}H NMR spectra were recorded with a Hitachi R 24 NMR spectrometer with TMS as an internal standard, while the IR spectrum was recorded with a JASCO IRA-1 grating spectrometer. Melting points were determined on a Yanagimoto micro hot-stage and were uncorrected.

*Preparations of 2-Phenyl-2*H*-1-benzopyrans (IIb, IIe, IIf, and IIh).* A mixture of 2'-hydroxychalcone (6 mmol), sodium borohydride (12 mmol), and ethanol (100 ml) was stirred for 3 h at room temperature. After the removal of the ethanol, the resulting solid was treated with 10% aqueous acetic acid (100 ml) and then extracted with benzene. The benzene solution was separated and evaporated under reduced pressure. The resulting liquid was purified on a silica gel column (Wakogel C 100, 100 g) by eluting with benzene and by recrystallization or by distillation.

*7-Methoxy-2-phenyl-2*H*-1-benzopyran (IIb)*: $Bp_{0.02}$ 180 °C (bath temp), 35% yield, NMR (CCl_4) δ=3.66 (3H, s, OCH_3), 5.57 (1H, dd, J=9.6, 3.6 Hz, $H_{(3)}$), 5.83 (1H, dd, J=3.6, 1.6 Hz, $H_{(2)}$), 6.3—6.6 (3H, m), 6.85 (1H, m, $H_{(5)}$), and 7.1—7.6 (5H, m, Ph). Found: C, 80.37; H, 5.81%. Calcd for $C_{16}H_{14}O_2$: C, 80.64; H, 5.92%.

*7-Methoxy-2-(2,3,4-trimethoxyphenyl)-2*H*-1-benzopyran (IIe)*: $Bp_{0.02}$ 200 °C (bath temp), 41% yield, NMR (CCl_4) δ= 3.65 (3H, s, OCH_3), 3.75 (3H, s, OCH_3), 3.75 (3H, s, OCH_3), 3.92 (3H, s, OCH_3), 5.48 (1H, dd, J=9.0, 3.3 Hz, $H_{(3)}$), 6.10 (1H, dd, J=3.3, 1.7 Hz, $H_{(2)}$), 6.22—6.5 (3H, m), 6.40 (1H, d, J=10.0 Hz, $H_{(5')}$), 6.78 (1H, m, $H_{(5)}$), and 7.02 (1H, d, J=10.0 Hz, $H_{(6')}$). Found: C, 69.35; H, 6.17%. Calcd for $C_{19}H_{20}O_5$: C, 69.50; H, 6.14%.

*6,7-Dimethoxy-2-phenyl-2*H*-1-benzopyran (IIf)*: Mp 79—80 °C (light petroleum), 67% yield, NMR (CCl_4) δ=3.62 (6H, s, 2×OCH_3), 5.47 (1H, dd, J=10.0, 3.5 Hz, $H_{(3)}$), 5.67 (1H, dd, J=3.5, 1.8 Hz, $H_{(2)}$), 6.30, (1H, dd, J=10.0, 1.8 Hz, $H_{(4)}$), 6.21 (1H, s, $H_{(8)}$), 6.37 (1H, s, $H_{(5)}$), and 7.20 (5H, m, Ph). Found: C, 75.95; H, 6.09%. Calcd for $C_{17}H_{16}O_3$: C, 76.10; H, 6.01%.

*7,8-Dimethoxy-2-phenyl-2*H*-1-benzopyran (IIh)*: Mp 60—61 °C (MeOH), 53% yield, NMR (CCl_4) δ=3.63 (3H, s, OCH_3), 3.77 (3H, s, OCH_3), 5.64 (1H, dd, J=9.7, 3.5 Hz, $H_{(3)}$), 5.81 (1H, dd, J=3.5, 1.8 Hz, $H_{(2)}$), 6.28 (1H, d, $H_{(6)}$), and 6.56 (1H, d, $H_{(5)}$) (AB system, J_{AB}=8.0 Hz), 6.40 (1H, $H_{(4)}$, coincided with a part of the AB system), and 7.2—7.5 (5H, m, Ph). Found: C, 75.93; H, 6.01%. Calcd for $C_{17}H_{16}O_3$: C, 76.10; H, 6.01%.

4',7-Dimethoxyflavylium Perchlorate (VI). Through a mixture of *p*-methoxyacetophenone (2.0 g), 2-hydroxy-4-methoxybenzaldehyde (2.5 g), and 85% formic acid (30 ml) was passed dry hydrogen chloride for 2.5 h at room temperature. 20% perchloric acid (27 ml) was added to the cooled reaction mixture, which was then left overnight. The precipitates were collected by filtration, giving a dark red powder, mp 265 °C (lit,[14] mp 270 °C) (3.05 g, 61%).

*7-Methoxy-2-(*p*-methoxyphenyl)-4*H*-1-benzopyran (IV).* 4',7-Dimethoxyflavylium perchlorate (1.83 g) in ethanol (50 ml) was reduced with sodium borohydride (51 mg) at 0 °C for 1 h. After the removal of the ethanol, the resulting solid was washed with ether. The ether was evaporated and the resulting substance was recrystallized to give colorless prisms, mp 137—139 °C (EtOH) (0.46 g, 35%).

*Oxidation of 2-Phenyl-2*H*-1-benzopyrans (IIa—IIj) with Potassium Permanganate.* A mixture of a 2-phenyl-2*H*-1-benzopyran (1 mmol), potassium permanganate (3—5 mmol), and a solvent (50 ml) was stirred at room temperature until all of II was consumed (the period of time is shown in the Table). The solvent was evaporated, and the resulting mixture was treated with 5% aqueous sodium hydrogen sulfite (20 ml) and acidified with concd sulfuric acid. The precipitates were collected and purified on a silica gel column by eluting with chloroform and by recrystallization to give II. In the case of IIe, the reaction mixture was filtered and the manganese dioxide was washed with chloroform. The combined filtrate was then evaporated, and the product was purified on TLC and by recrystallization. IIIa, mp 97 °C (MeOH) (lit,[15] mp 97 °C); IIIb, mp 107—108 °C (MeOH) (lit,[16] mp 110—111 °C); IIIc, mp 155—156 °C (MeOH) (lit,[17] mp 157—158 °C); IIId, mp 146—147 °C (MeOH) (lit,[18] mp 143—144 °C); IIIe. mp 164—165 °C (MeOH), IR ($CHCl_3$) 1635 cm^{-1} (C=O), NMR ($CDCl_3$) δ=3.87 (6H, s, 2×OCH_3), 3.88 (3H, s, OCH_3), 3.90 (3H, s, OCH_3), 6.78 (1H, d, J=8.1 Hz, $H_{(5')}$), 6.90 (1H, s, $H_{(3)}$), 6.85—7.05 (2H, m, $H_{(6)}$ and $H_{(8)}$), 7.49 (1H, d, J=8.1 Hz, $H_{(6')}$), and 8.09 (1H, m, $H_{(5)}$) [Found: C, 66.43; H, 5.36%. Calcd for $C_{19}H_{18}O_6$: C, 66.66; H, 5.30%.]; IIIf, mp 189—190 °C (MeOH) (lit,[18] mp 189 °C); IIIg, mp 181—182 °C (MeOH) (lit,[19] mp 184—185 °C); IIIh, mp 147—148 °C (MeOH) (lit,[20] mp 151 °C); IIIi, mp 192—194 °C (MeOH) (lit,[21] mp 189—190 °C); IIIj, mp 203—204 °C (MeOH) (lit,[21] mp 200 °C).

*Oxidation of 7-Methoxy-2-(*p*-methoxyphenyl)-4*H*-1-benzopyran (IV) with Potassium Permanganate.* The reaction was carried out in a manner similar to the above, giving IIId, mp 146—147 °C.

*Oxidation of 2-(*p*-Methoxyphenyl)-2*H*-1-benzopyran (IIc) with Chromium Trioxide–Pyridine Complex.* A mixture of IIc (1 mmol), chromium trioxide–pyridine complex[5] (8 mmol), and dichloromethane (30 ml) was stirred at room temperature under nitrogen atmosphere for 24 h. 5% aqueous sodium hydrogen sulfite (20 ml) and concd sulfuric acid (1 ml) were added to the reaction mixture, which was extracted with chloroform. The organic layer was separated, dried, and evaporated to dryness. The resulting solid was purified in a manner similar to the above, giving IIIc, mp 155—156 °C.

*Oxidation of 7-Methoxy-2-(*p*-methoxyphenyl)-4*H*-1-benzopyran (IV) with Chromium Trioxide–Pyridine Complex.* IV was oxidized with the reagent to give IIId, mp 146—147 °C.

The Reaction of *N*-Imidoylsulfimides with Carbon Disulfide

Hiroshi YOSHIDA, Tsuyoshi OGATA, and Saburo INOKAWA

Department of Synthetic Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu 432

(Received April 15, 1977)

The reaction of *S,S*-diphenyl- and *S,S*-dimethyl-*N*-imidoylsulfimides (**1** and **2**) with carbon disulfide was studied. **1** yielded nitrile, isothiocyanate, diphenyl sulfide, and sulfur, whereas **2** gave *N*-thiocarbonyl-*S,S*-dimethylsulfimide together with isothiocyanate. Kinetic studies indicate that the reaction proceeds *via* a [2+2]cycloaddition mechnism, as is shown by the small effects of the solvents and the substitutent on the rate.

A number of recent works[1] on sulfimides have shown their importance in organic synthesis. Some interesting reactions of *N*-imidoyl-[2] and *N*-thiocarbonylsulfimides[3] have also been reported.

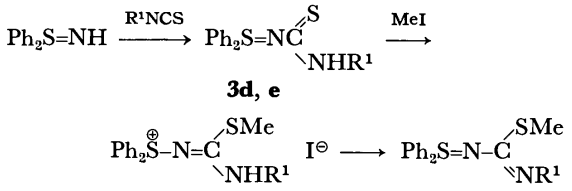
In continuation of our previous studies to explore the physical and chemical properties of *P*- and *S*-ylides and imides,[3] we have found an interesting reaction of the *S,S*-diphenyl- and *S,S*-dimethyl-*N*-imidoylsulfimides **1** and **2** with carbon disulfide.

Results and Discussion

Preparation. The *N*-imidoylsulfimides, **1a**—**c** and **2a**—**f** (Table 1), were prepared by the reaction of benzimidoyl chlorides with free *S,S*-diphenylsulfimide $Ph_2S{=}NH$ or *N*-haloamidines with dimethyl sulfide,

1 **2**

modifying the reported methods.[2a] The *N*-[(methythio)carbonimidoyl]sulfimides, **1d** and **e** were prepared by the reaction of the *N*-thiocarbamoylsulfimides, **3d** and **e** with methyl iodide, followed by treatment with a base.



3d, e **4d, e** **1d, e**

d: R^1=Ph **e**: R^1=Me

The physical properties of **1** and **2** are collected in Table 1.

The Reaction of 1 and 2 with Carbon Disulfide. The **1b**, **2b**, and **c** sulfimides were shown to be stable up to 150 °C.[2a] On the other hand, the **1** and **2** sulfimides showed high reactivities with carbon disulfide even at room temperature. The products in the reaction of *S,S*-diphenylsulfimides **1a**—**e** with carbon disulfide were confirmed to be isothiocyanates, nitriles, diphenyl sulfide, and sulfur by comparing their IR and GLC with those of authentic samples.

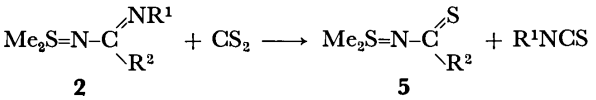
a) The phenyl-ring protons appeared at δ 7—8 as multiplets.

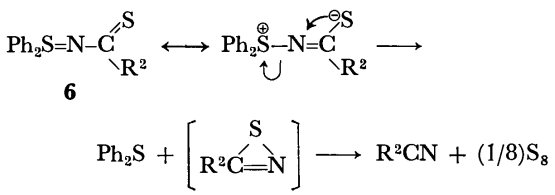
S,S-Dimethylsulfimides **2a—f** also reacted easily with carbon disulfide at room temperature yielding the *N*-thiocarbonyl-*S,S*-dimethylsulfimides together with the isothiocyanates.



2 **5**

The structure of **5** was confirmed on the basis of their NMR, MS, and elemental analyses. These results are shown in Tables 2 and 3.

In a previous paper[3] we have shown that the thermal decomposition of *N*-thiocarbonyl-*S,S*-diphenylsulfimides **6**, proceeds *via*



the nucleophilic attack of thiocarbonyl sulfur at the nitrogen atom, yielding thiazirine and diphenyl sulfide. On the other hand, **5** were stable under heating at 50 °C for a long time. We believe **6** to be the initial products of the reaction of **1** with carbon disulfide. The marked difference in thermal stability between **5** and **6** may be attributed to the electron-attracting power of the groups on the sulfide sulfur. The phenyl groups of **6** may facilitate the nucleophilic attack of the thiocarbonyl sulfur on the nitrogen in the transition state.

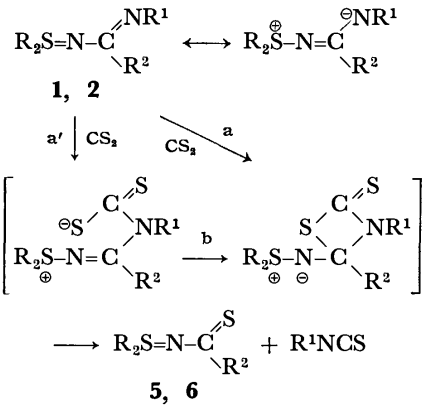
The *N*-imidoylsulfimides **1** and **2** reacted easily with carbon disulfide under mild conditions. Meanwhile, the action of hydrogen sulfide on amidines represents a useful route to thioamides.[4] In an old article,[5] it was reported that *N,N'*-diphenylbenzamidine reacts with carbon disulfide under drastic conditions (130—140 °C) to yield thiobenzanilide and phenyl isothiocyanate. We have performed kinetic experiments in order to find a reasonable mechanism for the reaction of **1** and **2** with carbon disulfide. The reaction gave good second-order rate constants (k_2), which were first-order with **1** or **2** and carbon disulfide respectively, when the reaction was followed by NMR spectroscopy. The results are listed in Tables 4 and 5, which indicate small effects of solvents and substituents on rate and negative entropies for the reaction. These observations indicate that the mechanism for the formation of 1,3-thiazetidine-2-thione *via* a rate-determining electrophilic attack on iminonitrogen, followed by ring closure (Routes a' and b), can be ruled out. The reaction of **1** or **2** with carbon disulfide seems to be a typical [2+2]cycloaddition reaction.[6] The mechanism we suggest is shown is Scheme 1, which involves the initial formation of 1,3-



Scheme 1.

thiazetidine-2-thione *via* cycloaddition (Route a), followed by a rapid ring cleavage to yield **5** or **6** and isothiocyanate.

Experimental

Preparation of ***1a—c.*** Free *S,S*-diphenylsulfimide was prepared according to the literature.[7] The general procedure for the preparation of **1a—c** is as follows: to a solution of *S,S*-diphenylsulfimide (2.01 g, 0.01 mol) in 50 ml of dry benzene we added a solution of imidoyl chloride (5 mmol) in 10 ml of dry benzene in one portion. After 30 min the liquid layer was condensed *in vacuo* to give a crystalline mass, which afforded needles, **1a—c**, from chloroform–hexane. The results are shown in Table 1.

Preparation of ***1d and 1e.*** *N*-Thiocarbamoyl-*S,S*-diphenylsulfimides, **3d**, and **e** were prepared according to the literature.[3,8] To a solution of **3d** (0.01 mol) in chloroform we added methyl iodide (0.02 mol) in one portion. The resulting solution was kept standing at room temperature for 12 h. Then the solution was dried *in vacuo* to give a crystalline mass. We then added a solution of sodium ethoxide in ethanol [from sodium (0.015 mol) and ethanol (30 ml)] to the mass, portion by portion, under vigorous stirring. The mixture was stirred for 5 min and then poured into 100 ml of ice water. The product was extracted with chloroform, and crystallized from chloroform–hexane.

1e was prepared similarly; the results are shown in Table 1.

Preparation of ***2a—f.*** **2** were prepared according to the literature.[9] The yields (based on amidines used) and physical properties are shown in Table 1.

The Reaction of ***1a—e*** *with Carbon Disulfide.* A solution of **1a—e** (1 mmol) and carbon disulfide (10 mmol) in 20 ml of chloroform was kept standing for a day at room temperature. After the reaction, the mixture was dried *in vacuo* and separated into petroleum ether-soluble and insoluble parts. The former part was analyzed by GLC (silicone grease on celite) and found to be a mixture of diphenyl sulfide, isothiocyanate, and nitrile. The petroleum ether-insoluble part was sulfur. The results are shown in Table 2.

The Reaction of ***2a—f*** *with Carbon Disulfide.* A solution of **2a—f** (1 mmol) and carbon disulfide (10 mmol) in 20 ml of chloroform was kept standing at room temperature for 2 days. After drying the solvent *in vacuo*, the residue was separated into petroleum ether-soluble and insoluble parts. The former part was isothiocyanate, which was confirmed by comparing their IR and GLC with those of the known sample. The latter part was *N*-thiocarbonyl-*S,S*-dimethylsulfimide, **5**. The results are collected in Tables 2 and 3.

Kinetic Studies. A solution of **1** or **2** (0.05—0.3 mol/l) and carbon disulfide (0.4—0.8 mol/l) in chloroform-*d* (or other solvents) was sealed in an NMR sample tube; the rate was followed at suitable time intervals by analyzing the NMR signals of the methyl groups of **1a** or **2** and the products. The results are shown in Tables 4 and 5.

Aminosugars. XXVIII. A Facile Synthesis of Benzyl α- and β-Kasugaminides *via* the Corresponding Abequosides[1]

Juji YOSHIMURA, Ken-ichi SATO, Hironobu HASHIMOTO, and Kuniaki SHIMIZU

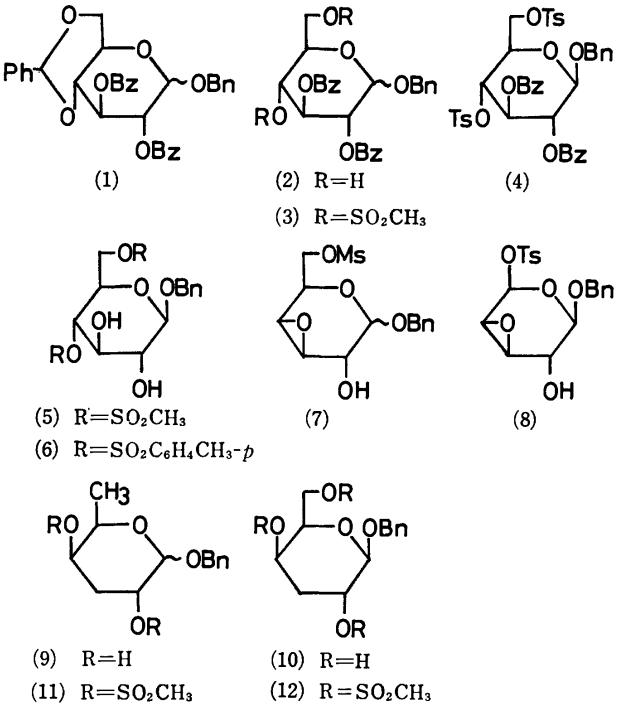
Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received April 19, 1977)

Synthesis of benzyl α- and β-kasugaminides (benzyl 2,4-diamino-2,3,4,6-tetradeoxy-α- and β-D-*arabino*-hexopyranosides) was carried out by the simultaneous substitution at 2,4-positions of 2,4-di-*O*-mesyl-abequosides (3,6-dideoxy-2,4-di-*O*-mesyl-α- and β-D-*xylo*-hexopyranosides) with sodium azide followed by hydrogenation. The substitution in *N,N*-dimethylformamide at higher temperature gave the elimination products (4-azido-2,3-unsaturated derivatives) and the subsequently rearranged products (3,4-unsaturated 2-azido derivatives), but, that in hexamethylphosphoric triamide at lower temperature gave the desired compounds in fairly good yields.

In connection with synthetic studies on kasugamycin[2,3] a few reports on the synthesis of racemic[4,5] and optically active[6] methyl α-kasugaminide (methyl 2,4-diamino-2,3,4,6-tetradeoxy-α-D-*arabino*-hexopyranoside) have been published. The necessity of the resolution of a racemate is a shortcoming in the former synthesis, whereas the stepwise conversion in the latter takes longer steps, and consequently gives a lower overall yield.

In order to study the relationship between the configuration of aminosugar moiety in kasugamycin and the biological activity, we intended to develope a better pathway for synthesis of optically active kasugaminide and its diastereomers. In this paper, a facile synthesis of benzyl α- and β-kasugaminides *via* the simultaneous S_N2-substitution at 2,4-positions of the corresponding abequosides (benzyl 3,6-dideoxy-α- and β-D-*xylo*-hexopyranosides) is descrided. As methyl α-abequoside[7-9] is known to be synthesized by the simultaneous deoxygenation of 3,6-positions of methyl 3,4-anhydro-6-*O*-*p*-tolylsulfonyl-α-D-galactopyranoside obtainable from D-glucose, the pathway offered here is advantageous.

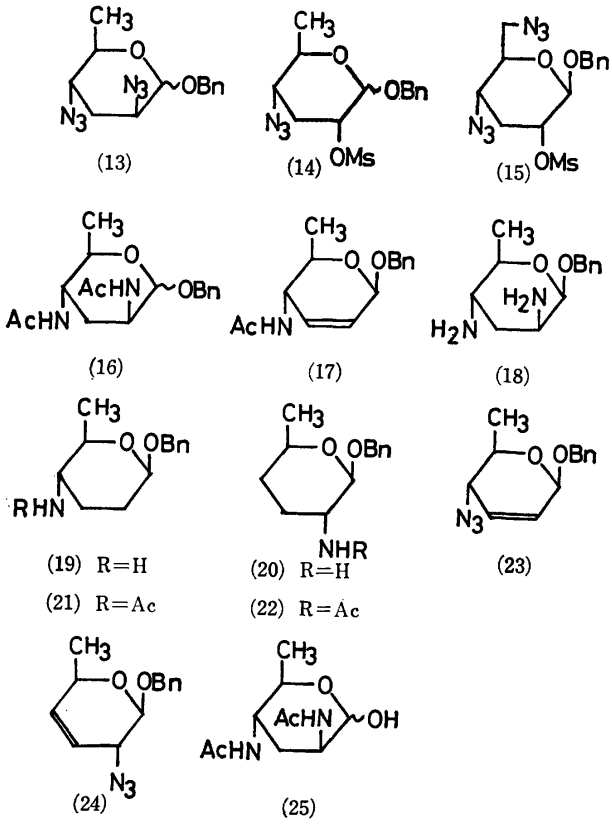


Results and Discussion

According to the method of Siewert and Westphal,[7] benzyl α- and β-abequosides were newly prepared. Benzoylation of benzyl 4,6-*O*-benzylidene-α-[10] and β-D-glucopyranosides[11] in the usual manner gave the 2,3-di-*O*-benzoates (**1α** and **1β**) in good yields, respectively. Partial hydrolysis of the 4,6-*O*-benzylidene group in **1α** and **1β** proceeded quantitatively in 70% acetic acid at 90—95 °C to give **2α** and **2β**, respectively. Mesylation of **2α** and **2β** in the usual manner gave the corresponding 4,6-di-*O*-mesylates (**3α** and **3β**) in good yields, respectively. Benzyl 2,3-di-*O*-benzoyl-4,6-di-*O*-*p*-tolylsulfonyl-β-D-glucopyranoside (**4**) was also prepared from **2β** in a similar manner.

Examination of the conversion of **3β** in dichloromethane or chloroform into the corresponding epoxide (**7β**) by treatment with sodium methoxide in methanol indicated that **3β** was once changed into an intermediate (**5**) within 6 h and then gradually converted into **7β**.

In fact, **5** deposited from the reaction mixture, when the amount of solvents (especially methanol) was not enough. This conversion proceeded slower than that of the corresponding methyl glucoside,[7] and the use of a little excess (1.3—1.4 mol) sodium methoxide gave a better result. Thus, **7α** and **7β** were obtained in 64 and 75% yields, respectively. In a similar way, tosylated intermediate (**6**) and tosylated epoxide (**8**) were obtained from **4**. It was characteristic that NMR spectra of these epoxides showed a coupling between OH and H_2 and a AB-quartet of H_3 and H_4. Reduction of **7α**, **7β**, and **8** in tetrahydrofuran (THF) with 3 mol of lithium aluminium hydride (LAH) gave sirupy benzyl abequosides (**9α** and **9β**), respectively. When 1.5 mol of LAH were used in one instance, crystalline benzyl 3-deoxy-β-D-*xylo*-hexopyranoside (**10**) was separated on a silica gel column in 22% yield, indicating that the epoxide ring was more reducible than the 6-*O*-sulfonate group. Excepting the last step in the synthesis of **9α** and **9β**, the purification of the product in each reaction was not always necessary, and both α- and β-abequosides could be actually obtained in *ca.* 20% overall yield from D-glucose. Mesylation of **9α** or **9β** and **10** gave the corresponding 2,4-di-*O*-mesylates (**11α** or **11β**) and 2,4,6-tri-*O*-mesylate (**12**) in good yields, respectively.



The simultaneous substitution at 2,4-positions of mesylates mentioned above with sodium azide was unexpectedly accompanied with the formation of unsaturated products. Reaction of **11**β in *N*,*N*-dimethylformamide (DMF) with 3 mol of sodium azide at 120 °C overnight was incomplete, and two spots other than a small amount of the starting material were detected on TLC. Separation of the products on a silica gel column gave one monoazide (**14**β) in pure state, but the NMR spectrum of another fraction indicated the presence of unsaturated compounds. Reaction of **12** under the same condition gave also the corresponding 4,6-diazide (**15**) in a low yield. Even after the reaction of **11**β was continued at 160—165 °C[6] until **14**β disappeared, the mixture of products could not be separated by repeating column chromatography. Therefore, the separation was tried after hydrogenation of the products with LAH in THF followed by *N*-acetylation. Thus, benzyl *N*,*N'*-diacetyl-β-kasugaminide (**16**β) and benzyl 4-acetamido-2,3,4,6-tetradeoxy-β-D-*erythro*-hex-2-enopyranoside (**17**) could be isolated in 12 and 19% yields, respectively. When the hydrogenation was carried out in the presence of Raney nickel, the corresponding saturated amino derivatives could be separated by column chromatography into three sirupy products (**19**, **20**, and **18**) in 8, 19, and 42% yields, respectively. These compounds were characterized after quantitative conversion into *N*-acetyl derivatives (**21**, **22**, and **16**β). The first-order analysis of the NMR spectrum of **16**β (*cf.* Experimental) completely proved the allocated structure, and $J_{1,2}$ values of **21** ($J_{1,2e}$=2.4, $J_{1,2a}$=8.0) and **22** ($J_{1,2}$=8.2) supported them. It will be noteworthy that **19** is a glycoside of the enantiomer of natural L-tolyposamine.[12,13]

The results mentioned above suggest that the second substitution at *C*-2 of the initial product (**14**β) gives 2,4-diazide (**13**β), but the substitution is followed by the elimination of axial C_2-azido group to give benzyl 4-azido-2,3,4,6-tetradeoxy-β-D-*erythro*-hex-2-enopyranoside (**23**), which subsequently rearranges to the corresponding 2-azido-3-enopyranoside (**24**). Recently, several papers have been published on the thermal rearrangement of 2,3-unsaturated 4-azido- and 4-thiocyanatoglycopyranosides to 3,4-unsaturated sugars having nitrogen function at *C*-2.[14–16] These conversions were explained as a [3,3]-sigmatropic rearrangement of cyclic allylic systems in which the asymmetry at the initial allylic centre is transmitted to the new centre by the suprafacial migration.[14] Although the formation of a small amount of unsaturated product in the substitution of equatorial C_4-sulfonyloxy group attached to 3-deoxy-hexopyranoside-ring with sodium azide in DMF has been reported,[10] the question whether the formation of **23** is initiated from the equatorial C_2-sulfonyloxy group of **14**β or from axial C_2-azido group of **13**β was remained ambiguous.

TABLE 1. SUBSTITUTION OF **11**α AND **11**β WITH SODIUM AZIDE IN HMPA

	Conditions		Products (%)		
	Temp (°C)	Time (h)	**14**	**13**	Unsaturated products
11α	80	20	86	—	—
11α	120	42	—	69	12[a]
11β	80	20	81	—	—
11β	100	5	78	—	—
11β	120	18	—	55	31[a]

a) Yields were estimated from the weight of crude products and the intensity ratio of olefinic proton and others in NMR spectra.

In order to prevent the formation of unsaturated compounds, the same substitution of **11**α and **11**β was examined at a lower temperature, using hexamethylphosphoric triamide (HMPA) as a solvent. As shown in Table 1, the reaction at 80 °C gave exclusively monosubstituted **14** in good yields. The continuation of the reaction at 120 °C until **14** disappeared also resulted in the formation of unsaturated compounds, but the yields of the desired diazides (**13**) were improved. Actually, **16**α and **16**β were obtained from the crude products in 60 and 46% yields, respectively, by subsequent hydrogenation and *N*-acetylation. The structure of **16**α and **16**β was further confirmed by respective hydrogenation into known *N*,*N'*-diacetyl-kasugamine (**25**).[17] It has been reported that the substitution of methyl 4,6-*O*-isopropylidene-3-*O*-methyl-2-*O*-methylsulfonyl-β-D-gluco- and D-mannopyranoside with potassium benzoate in DMF proceeded smoothly, whereas that of α-anomers did not occur.[18] Slower but steady substitution of the α-anomer in this experiment will be attributed to the absence of substituent at *C*-3 and to the flexibility of **11**α.

Experimental

All melting points are uncorrected. The solutions were evaporated under diminished pressure at a bath temperature not exceeding 45 °C. Specific rotations were measured in a 0.5-dm tube, with a Carl Zeiss LEP-Al polarimeter. The IR spectra were recorded with a Hitachi Model EPI-G2 spectrometer. The NMR spectra were taken with a JEOL-4H-100 MHz spectrometer using tetramethylsilane as an internal standard, in deuteriochloroform unless otherwise stated. Chemical shifts and coupling constants were recorded in δ and Hz units, and IR frequencies in cm^{-1}.

*Benzyl 2,3-Di-O-benzoyl-4,6-O-benzylidene-α- and β-D-glucopyranosides (**1α** and **1β**).* Benzyl 4,6-*O*-benzylidene-β-D-glucopyranoside[11] was benzoylated with benzoyl chloride in benzene. A usual work up and recrystallization of the product from ethanol gave pure **1β** in 90.5% yield. Mp 167—168.5 °C; $[\alpha]_D^{22}$ −19.9° (*c* 0.5, $CHCl_3$). IR: 1728 (ester), 1600 and 1490 (Ph); NMR: 7.90 and 7.60—7.00 (Ph; m), 5.73 (H_3: t, $J_{3,4}$=9.2), 5.52 (H_2: q, $J_{2,3}$=8.8), 5.51 (CH: s), 4.79 (H_1: d, $J_{1,2}$=7.4), 4.87 and 4.62 (CH_2: ABq, J_{AB}=12.5), 4.41 (H_{6e}: q, $J_{6e,6a}$=10.0), 3.93 (H_4: t, $J_{4,5}$=8.8), 3.87 (H_{6a}: t, $J_{5,6a}$=9.8), 3.72 (H_5: m, $J_{5,6e}$=5.0). Found: C, 72.02; H, 5.34%. Calcd for $C_{34}H_{30}O_8$: C, 72.07; H, 5.34%.

Similarly, benzoylation of benzyl 4,6-*O*-benzylidene-α-D-glucopyranoside[10] gave **1α** in 93% yield. Mp 134—136 °C; $[\alpha]_D^{22}$ +123.2° (*c* 0.35, $CHCl_3$). IR: 1700 (ester), 1600 (Ph); NMR: 7.95 and 7.50—7.10 (Ph; m), 6.10 (H_3: t, $J_{2,3}=J_{3,4}$=9.3), 5.51 (CH: s), 5.28 (H_1: broad s), 5.23 (H_2: q, $J_{1,2}$=3.3), 4.72 and 4.53 (CH_2: ABq, J_{AB}=13.0), 4.33—3.75 (H_4, H_5, H_6, and $H_{6'}$: m). Found: C, 72.34; H, 5.77%. Calcd for $C_{34}H_{30}O_8$: C, 72.07; H, 5.34%.

*Benzyl 2,3-Di-O-benzoyl-α- and β-D-glucopyranosides (**2α** and **2β**).* A suspension of **2β** (30 g) in 70% acetic acid–ethanol–acetone (300 ml, 150 ml, and 90 ml) was heated for 2 h at 90—95 °C until **2β** disappeared on TLC, and then evaporated to give a sirup which was crystallized from benzene. Yield, 24 g (94%); mp 157—158 °C; $[\alpha]_D^{22}$ +65.1° (*c* 1.2, $CHCl_3$); IR: 3460 (OH), 1725 and 1710 (ester), 1603 and 1495 (Ph). Found: C, 67.93; H, 5.56%. Calcd for $C_{27}H_{26}O_8$: C, 67.77; H, 5.48%.

In a similar manner, 4,6-*O*-benzylidene group of **1α** was hydrolyzed to give **2α** quantitatively. Mp 125—126 °C; $[\alpha]_D^{22}$ +175.2° (*c* 0.5, $CHCl_3$). IR: 3500 and 3380 (OH), 1730 and 1705 (ester), 1600 and 1490 (Ph). Found: C, 67.53; H, 5.57%. Calcd for $C_{27}H_{26}O_8$: C, 67.77; H, 5.48%.

*Benzyl 2,3-Di-O-benzoyl-4,6-di-O-methylsulfonyl-α- and β-D-glucopyranosides (**3α** and **3β**).* Mesylation of **2β** with methanesulfonyl chloride in the usual manner, and crystallization of the product from chloroform–ethanol (1: 1) gave pure **3β** in 90% yield. Mp 165—166 °C; $[\alpha]_D^{22}$ +43.7° (*c* 1.0, MeOH). IR: 1710 and 1733 (ester), 1595 and 1490 (Ph), 1345 and 1175 (sulfate); NMR: 8.02—7.08 (Ph: m), 5.70 (H_3: t, $J_{2,3}=J_{3,4}$=9.0), 5.46 (H_2: q), 4.98 (H_4: t, $J_{4,5}$=9.0), 4.83 and 4.69 (CH_2: ABq, J_{AB}=12.0), 4.70 (H_1: d, $J_{1,2}$=8.1), 4.63 (H_6: q, $J_{5,6}$=2.0), 4.44 ($H_{6'}$: q, $J_{5,6'}$=4.7, $J_{6,6'}$=10.8), 3.93 (H_5: m), 2.86 and 3.08 (OSO_2CH_3). Found: C, 55.10; H, 4.84; S, 9.72%. Calcd for $C_{29}H_{30}O_{12}S_2$: C, 54.88; H, 4.76; S, 10.10%.

Similarly, **2α** was mesylated to give the 4,6-di-*O*-mesylate in 93% yield. Mp 182—183 °C, $[\alpha]_D^{22}$ +137° (*c* 0.6, $CHCl_3$). IR: 1720 (ester), 1595 and 1490 (Ph), 1350 and 1180 (sulfate); NMR: 7.93 and 7.58—7.12 (Ph: m), 6.08 (H_3: t, $J_{2,3}=J_{3,4}$=10.0), 5.32 (H_1: d, $J_{1,2}$=3.8), 5.15 (H_2: q), 4.98 (H_4: t, $J_{4,5}$=9.5), 4.71 and 4.58 (CH_2: ABq, J_{AB}=11.5), 4.50—4.10 (H_5, H_6, and $H_{6'}$: m), 3.05 and 2.86 (OSO_2CH_3). Found: C, 54.62; H, 4.68; S, 10.00%. Calcd for $C_{29}H_{30}O_{12}S_2$: C, 54.88; H, 4.76; S, 10.10%.

*Benzyl 2,3-Di-O-benzoyl-4,6-O-p-tolylsulfonyl-β-D-glucopyranoside (**4**).* Reaction of **2β** and *p*-toluenesulfonyl chloride in pyridine in the usual manner gave **4** in 67% yield. Mp 125—126 °C; $[\alpha]_D^{22}$ +13.9° (*c* 1.0, $CHCl_3$). Found: C, 62.55; H, 4.81; S, 8.02%. Calcd for $C_{41}H_{38}O_{12}S_2$: C, 62.58; H, 4.87; S, 8.15%.

*Benzyl 3,4-Anhydro-6-O-methylsulfonyl-α- and β-D-glucopyranosides (**7α** and **7β**).* To a solution of **3β** (14.8 g, 124 mmol) in chloroform (150 ml) was added a methanol solution (100 ml) of sodium methoxide (0.56 g, 1.2 equivalent of sodium) and then kept in a refrigerator overnight. The reaction mixture was diluted with chloroform (100 ml), and then washed three times with water. The chloroform layer was dried and evaporated to give a sirup which was crystallized from benzene–petroleum ether. Yield 5.8 g (75%); mp 77—78 °C; $[\alpha]_D^{22}$ −108.3° (*c* 1.0, $CHCl_3$). IR: 3400 (OH), 1490 (Ph), 1350 and 1190 (sulfate), 930 (epoxide); NMR: 7.30 (Ph: s), 4.80 and 4.53 (CH_2: ABq, J_{AB}=11.5), 4.42—4.30 (H_6 and $H_{6'}$: m), 4.22 (H_1: d, $J_{1,2}$=7.0), 4.19 (H_5: t, $J_{5,6}=J_{5,6'}$=5.7), 3.68 (H_2: q, $J_{2,OH}$=3.8), 3.21 and 3.12 (H_3 and H_4: each d, $J_{3,4}$=3.8), 2.99 (OSO_2CH_3), 2.66 (OH: d). Found: C, 51.38; H, 5.42; S, 9.41%. Calcd for $C_{14}H_{18}O_7S$: C, 50.90; H, 5.49; S, 9.71%.

When the amount of solvents or the reaction time in the above reaction was not enough, the intermediate, benzyl 4,6-di-*O*-methylsulfonyl-β-D-glucopyranoside (**5**) deposited from the reaction mixture or from the chloroform layer during the washing with water. It was characterized as follows; mp 101—103 °C; $[\alpha]_D^{22}$ −41.8° (*c* 0.86, MeOH); IR: 3400 (OH), 1490 (Ph), 1350 and 1190 (sulfate). Found: C, 42.12; H, 5.39; S, 14.74%. Calcd for $C_{15}H_{22}O_{10}S_2$: C, 42.24; H, 5.20; S, 15.04%.

Similarly, **3α** was converted into **7α** in 64% yield. Mp 73—74 °C (from ethanol–hexane); $[\alpha]_D^{24}$ +42.4° (*c* 0.5, $CHCl_3$), IR: 3350 (OH), 1495 (Ph), 1350 and 1190 (sulfate); NMR: 7.40 (Ph, s), 4.94 (H_1: d, $J_{1,2}$=4.8), 4.84 and 4.60 (CH_2: ABq, J_{AB}=11.5), 4.45—4.30 (H_6 and $H_{6'}$: m), 3.85 (H_2: q, $J_{2,OH}$=10.5), 3.30 and 3.24 (H_3 and H_4: ABq, $J_{3,4}$=2.6), 3.07 (OSO_2CH_3), 2.50 (OH: d). Found: C, 50.62; H, 5.56; S, 9.53%. Calcd for $C_{14}H_{18}O_7S$: C, 50.90; H, 5.49; S, 9.71%.

*Benzyl 3,4-Anhydro-6-O-p-tolylsulfonyl-β-D-glucopyranoside (**8**) and Benzyl 4,6-Di-O-p-tolylsulfonyl-β-D-glucopyranoside (**6**).* Epoxidation of **4** in the same manner as above, and separation of the product on a silica gel column gave **8** (sirup) and **6** (mp 110—112 °C) in 48.4% and 25% yields, respectively.

8: $[\alpha]_D^{22}$ −93.4° (*c* 0.9, $CHCl_3$); NMR: 7.85—7.15 (Ph: m), 4.71 and 4.45 (CH_2: ABq, J_{AB}=14.0), 4.25—4.02 (H_5, H_6, and $H_{6'}$: m), 3.61 (H_2: broad d), 3.13 and 3.02 (H_3 and H_4: ABq, J_{AB}=4.4), 2.88 (OH: broad s), 2.37 (CH_3: s). Found: C, 59.26; H, 5.59; S, 7.76%. Calcd for $C_{20}H_{22}O_7S$: C, 59.10; H, 5.46; S, 7.89%.

6: $[\alpha]_D^{22}$ −37.7° (*c* 1.0, MeOH). Found: C, 57.21; H, 5.35; S, 10.51%. Calcd for $C_{28}H_{30}O_{10}S_2$: C, 56.93; H, 5.12; S, 10.86%.

*Benzyl 3,6-Dideoxy-α- and β-D-xylo-hexopyranosides (**9α** and **9β**).* To a suspension of lithium aluminium hydride (LAH, 2.4 g, 63 mmol) in tetrahydrofuran (THF, 100 ml) was added dropwise a solution of **7β** (8 g, 18 mmol) in THF (70 ml) with stirring. The reaction mixture was refluxed for 5 h, and a mixed solution of water and ethyl acetate was added to decompose excess LAH. After bubbling carbon dioxide into the reaction mixture, it was filtered, and the filtered mass was washed with methanol–water (1: 1). The filtrate and

washings were evaporated, and the residue was dissolved in water. Sodium periodate (2 g, 7.5 mmol) was added to the aqueous solution and kept in a refrigerator overnight. After addition of hydrogen peroxide (30%, 3 ml), the mixture was reduced with excess sodium thiosulfate, evaporated, and an aqueous solution of the residue was extracted with chloroform. Evaporation of the extracts gave a sirup (3.8 g) which was fractionated on a silica gel column (ethanol: benzene=1: 9) to give pure **9**β (3.0 g, 52%) as a sirup, $[\alpha]_D^{22}$ −107° (*c* 0.5, $CHCl_3$). Found: C, 65.81; H, 7.72%. Calcd for $C_{13}H_{18}O_4$: C, 65.53; H, 7.61%.

The same compound was also obtained from **8** in 48.5% yield. In a similar manner mentioned above, **9**α was obtained from **7**α in 53% yield as a sirup. $[\alpha]_D^{22}$ +119° (*c* 0.8, $CHCl_3$). Found: C, 64.98; H, 7.38%. Calcd for $C_{13}H_{18}O_4$: C, 65.53; H, 7.61%.

In case of 1.5 mol of LAH were used for hydrogenation of **7**β, fractionation of the product gave benzyl 3-deoxy-β-D-*xylo*-hexopyranoside (**10**) in 22% yield. Mp 95—95.5 °C; $[\alpha]_D^{22}$ −50.9° (*c* 1.1, MeOH). Found: C, 61.17; H, 7.08%. Calcd for $C_{13}H_{18}O_5$: C, 61.40; H, 7.14%.

*Benzyl 3,6-Dideoxy-2,4-di-O-methylsulfonyl-α- and β-D-xylo-hexopyranosides (**11**α and **11**β).* Mesylation of **9**β in the usual manner, and crystallization of the product from ethanol gave **11**β in 77% yield. Mp 104—105 °C; $[\alpha]_{22}^{D}$ −64° (*c* 1.0, $CHCl_3$). IR: 1360 and 1170 (sulfate); NMR: 7.32 (Ph, s), 4.92 and 4.58 (CH_2: ABq, J_{AB}=12.0), 4.23 (H_4: m), 4.68—4.50 (H_1 and H_2: m), 3.80 (H_5: octet, $J_{4,5}$=1.5), 2.91 and 3.08 (2×OSO_2CH_3), 2.71 (H_{3e}: m, J_{gem}=12.7), 2.04 (H_{3a}: m), 1.35 (CH_3: d, $J_{CH_3,5}$=6.3). Found: C, 45.91; H, 5.68; S, 16.28%. Calcd for $C_{15}H_{22}O_8S_2$: C, 45.67; H, 5.62; S, 16.26%.

Similarly, **9**α was mesylated to give **11**α quantitatively. Mp 92—93 °C (from ethanol–hexane); $[\alpha]_D^{22}$ +95.2° (*c* 0.6, $CHCl_3$); IR: 1340 and 1175 (sulfate). Found: C, 45.86; H, 5.69; S, 16.31%. Calcd for $C_{15}H_{22}O_8S_2$: C, 45.67; H, 5.62; S, 16.26%.

*Benzyl 3-Deoxy-2,3,6-tri-O-methylsulfonyl-β-O-xylo-hexopyranoside (**12**).* Mesylation of **10** in pyridine with methanesulfonyl chloride gave the tri-*O*-mesylate in 76% yield. Mp 123—126 °C; $[\alpha]_D^{22}$ −59.6° (*c* 1.0, $CHCl_3$); IR: 1350 and 1180 (sulfate); NMR: 7.32 (Ph: s), 4.97 (H_4: m), 4.90 and 4.65 (CH_2: ABq, J_{AB}=12.0), 4.67—4.56 (H_1 and H_2: m), 4.40—4.25 (H_6 and H_6': m), 4.00 (H_5: sex, $J_{4,5}$=1.0, $J_{CH_3,5}$=7.9), 3.11, 3.04 and 2.93 (3×OSO_2CH_3), 2.81 (H_{3e}: sex, J_{gem}=14.3, $J_{2,3e}$, $J_{3e,4}$=3.5), 2.04 (H_{3a}: m, $J_{2,3a}$=9.0, $J_{3a,4}$=4.0). Found: C, 39.61: H, 4.91; S, 19.63%. Calcd for $C_{16}H_{24}O_{11}S_3$: C, 39.33; H, 4.95; S, 19.69%.

*Benzyl 4-Azido-3,4,6-trideoxy-2-O-methylsulfonyl-α- and β-D-ribo-hexopyranosides (**14**α and **14**β).* i) Reaction in *N,N*-dimethylformamide (DMF). A suspension of **11**β (600 mg, 1.52 mmol) and sodium azide (500 mg, 7.69 mmol) in DMF (10 ml) was stirred at 120 °C overnight, filtered, and the filtrate was evaporated to give a sirup (450 mg) which showed two spots other than **11**β. The sirup was fractionated on a silica gel column (benzene: ethanol=10: 1). The first fraction (140 mg, 31.9%) was a mixture of **11**β and other products, and the second fraction was **14**β. Yield, 50 mg (9.6%); $[\alpha]_D^{22}$ −44.4° (*c* 0.4, $CHCl_3$); mp 76—78 °C (from ethanol). IR: 2120 (N_3), 1365 and 1180 (sulfate); NMR: 7.30 (Ph; s), 4.84 and 4.55 (CH_2: ABq, J_{AB}=11.5), 4.46 (H_1: d, $J_{1,2}$=7.0), 4.33 (H_2: dt, $J_{2,3a}$=8.0, $J_{2,3e}$=5.2), 3.27 (H_5: dq, $J_{4,5}$=9.6), 3.14 (H_4: sex, $J_{4,3a}$=9.6, $J_{4,3e}$=4.5), 2.87 (OSO_2CH_3), 2.58 (H_{3e}: dt, J_{gem}=12.0), 1.76 (H_{3a}: broad q), 1.31 (CH_3: d, J_{5,CH_3}=7,0). Found: C, 49.50; H, 5.61; N, 12.46; S, 9.21%. Calcd for $C_{14}H_{19}N_3O_5S$: C, 49.25; H, 5.61; N, 12.31; S, 9.39%. ii) Reaction in hexamethylphosphoric triamide (HMPA). A suspension of **11**β (1.2 g) and sodium azide (1 g) in HMPA (5 ml) was stirred at 80 °C for 20 h, and then poured into water (30 ml). The resulting solution was extracted with ether. The ether solution was washed with water, dried, and then evaporated to give a hard sirup (**14**β) which was crystallized from ethanol–hexane. Yield, 0.84 g (81%). The physical constants of this product were identical with those mentioned above.

The reaction of **11**α with sodium azide in the same manner gave sirupy **14**α in 86% yield. $[\alpha]_D^{22}$ +114.2° (*c* 0.76, $CHCl_3$); IR: 2100 (N_3), 1360 and 1180 (sulfate); NMR: 7.38 (Ph, s), 5.00 (H_1: d, $J_{1,2}$=3.4), 4.76 and 4.62 (CH_2: ABq, J_{AB}=12.0), 4.80—4.60 (H_2: m), 3.68 (H_5: dq, $J_{4,5}$=10.0, J_{5,CH_3}=6.3), 3.14 (H_4: sextet, $J_{3a,4}$=10.0, $J_{3e,4}$=5.3), 2.95 (OSO_2-CH_3), 2.35 (H_{3e}: $J_{2,3e}$=5.6, J_{gem}=11.6), 2.18 (H_{3a}: q, $J_{2,3a}$=11.0), 1.22 (CH_3: d). Found: C, 49.45; H, 5.51; N, 12.18; S, 9.45%. Calcd for $C_{14}H_{19}N_3O_5S$: C, 49.25; H, 5.61; N, 12.31; S, 9.39%.

*Benzyl 4,6-Diazido-3,4,6-trideoxy-2-O-methylsulfonyl-β-D-ribo-hexopyranoside (**15**).* A suspension of **12** (980 mg, 2 mmol) and sodium azide (780 mg, 12 mmol) in DMF (13 ml) was stirred at 120 °C overnight, filtered, and the filtrate was evaporated. A usual extraction gave a sirup which showed two spots other than **12** on TLC. Separation of the sirup on a silica gel column (benzene: ethanol=10: 1) gave two main fractions of which the first fraction (230 mg, 35%) showed no absorption of a sulfonyloxy group, but the second fraction (110 mg, 14.3%) showed the mesyl signal in the NMR spectrum. The former was rechromatographed, but it could not be purified. The latter fraction crystallized on standing, and recrystallized from benzene–petroleum ether. Mp 78—80 °C; $[\alpha]_D^{22}$ −25.2° (*c* 0.6, $CHCl_3$); IR: 2100 (N_3), 1365 and 1180 (sulfate); NMR: 7.30 (Ph, s), 4.88 and 4.58 (CH_2: ABq, J_{AB}=11.5), 4.51 (H_1: d, $J_{1,2}$=7.0), 4.37 (H_2: dt, $J_{2,3e}$=5.3), 3.41 (H_4, H_5, H_6, and H_6': broad s), 2.90 (OSO_2-CH_3), 2.67 (H_{3e}: dt, $J_{3e,4}$=4.2), 1.81 (H_{3a}: broad q, J_{gem}=$J_{3a,4}$=$J_{3a,2}$=11.0). Found: C, 44.26; H, 4.65; N, 22.33; S, 7.99%. Calcd for $C_{14}H_{18}N_6O_5S$: C, 43.97; H, 4.74; N, 21.98; S, 8.39%.

*Benzyl 2,4-Diacetamido-2,3,4,6-tetradeoxy-β-D-arabino-hexopyranoside (**16**β) and Benzyl 4-Acetamido-2,3,4,6-tetradeoxy-β-D-erythro-hex-2-enopyranoside (**17**).* A suspension of **11**β (800 mg, 2 mmol) and sodium azide (700 mg, 10.8 mmol) in DMF (15 ml) and water (1.5 ml) was stirred at 120 °C for one day, and then at 160—165 °C until the initial product **14**β disappeared (8 h). Treatment of the reaction mixture in the usual way and purified on a silica gel column gave a sirup (450 mg). A suspension of this sirup (350 mg) and LAH (380 mg, 10 mmol) in THF was refluxed on a oil-bath for 3 h, and a small amount of water containing ethyl acetate was added to decompose excess LAH, and then filtered. After neutralization of the filtrate, it was evaporated. The residue was dried, and then acetylated in the usual manner to give a sirup which contained two main components. The two products were isolated in pure state by column chromatography repeated twice. Thus, the first fraction **16**β and the second **17** were obtained in 50 mg (12%) and 80 mg (19.4%) yields, respectively.

16β: Mp 146—147.5 °C; $[\alpha]_D^{22}$ −45.2° (*c* 1.0, $CHCl_3$); IR: 3270 (NH); 1650 and 1550 (amide); NMR: 7.29 (Ph: s), 4.80 and 4.55 (CH_2: ABq, J_{AB}=12.0), 4.54 (H_1: d, $J_{1,2}$=2.5), 4.14 (H_2: broad s), 3.83 (H_4: m), 3.43 (H_5: dq, $J_{4,5}$=8.2), 2.18 (H_{3e}: dt, $J_{3e,4}$=$J_{3e,2}$=4.7, J_{gem}=13.5), 1.93 and 1.96 (2×NAc), 1.53 (H_{3a}: octet, $J_{3a,4}$=10.0, $J_{3a,2}$=4.0), 1.29 (CH_3: d, $J_{CH_3,5}$=7.0). Found: C, 64.03; H, 7.62; N, 8.73%.

Calcd for $C_{17}H_{24}N_2O_4$: C, 63.73; H, 7.55; N, 8.74%.

17: Mp 162—164 °C; $[\alpha]_D^{22}$ −249° (*c* 0.2, $CHCl_3$); IR: 3270 (NH), 1640 and 1550 (amide); NMR: 7.30 (Ph, s), *ca.* 5.7 (olefinic H, m), 4.83 and 4.57 (CH_2: ABq, J_{AB}=12.0), 4.63 (H_1: d, $J_{1,2}$=4.5), 4.5—4.2 (H_4 and H_5: m), 1.91 (NAc), 1.33 (CH_3: d, $J_{CH_3,5}$=7.0). Found: C, 69.23; H, 7.29; N, 5.52%. Calcd for $C_{15}H_{19}NO_3$: C, 68.94; H, 7.33; N, 5.36%.

*Preparation of Benzyl β-Kasugaminide (**18**), Benzyl 4-Amino-2,3,4,6-tetradeoxy-β-*D-erythro-*hexopyranoside (**19**), Benzyl 2-Amino-2,3,4,6-tetradeoxy-β-*D-erythro-*hexopyranoside (**20**), and Their Conversion into the Corresponding* N*-Acetates (**16β**, **21**, and **22**).*

In the same manner mentioned above, the reaction of **11β** (7.5 g) with sodium azide was carried out, and the crude product was hydrogenated in the presence of Raney nickel at 50 °C for 5 h under 50 atm hydrogen gas to give a sirup which showed three spots on TLC. The sirup on a silica gel (80 g Wakogel C-200) column was eluted with benzene–ethanol [in turn 7:1 (500 ml), 5:1 (500 ml), and 1:1 (300 ml)] to give **20** (0.8 g, 19.0%), **19** (0.34 g, 8.1%), and **18** (1.82 g, 41.9%) as a sirup, respectively. Each sirup was acetylated with acetic anhydride and pyridine. The reaction mixture was directly evaporated to dryness, and the product was purified by column chromatography if necessary. Each acetate obtained in almost quantitative yield was characterized with NMR spectrum, respectively.

Compound **20** was not characterized.

22: mp 161.5—162 °C; $[\alpha]_D^{22}$ −90.4° (*c* 0.6, $CHCl_3$); IR: 3280 (NH), 1635 and 1550 (amide); NMR: 7.35 (Ph, s), 4.88 and 4.58 (CH_2: ABq, J_{AB}=12.0), 4.36 (H_1: d, $J_{1,2}$=8.2), 3.82—3.40 (H_2 and H_5: m), 2.3—1.3 (H_{3a}, H_{3e}, H_{4a}, and H_{4e}: m), 1.90 (NAc), 1.26 (CH_3: d, $J_{CH_3,5}$=6.5). Found: C, 68.72; H, 8.30; N, 5.60%. Calcd for $C_{15}H_{21}NO_3$: C, 68.41; H, 8.04; N, 5.32%.

19: $[\alpha]_D^{22}$ −70.8° (*c* 1.1, $CHCl_3$). Found: C, 69.95; H, 8.88; N, 6.32%. Calcd for $C_{13}H_{20}NO_2$: C, 70.55; H, 8.65; N, 6.33%.

21: mp 165—167° (admixture with **22** showed mp of 137—146 °C); $[\alpha]_D^{22}$ −89.8° (*c* 0.5, $CHCl_3$); IR: 3270 (NH), 1635 and 1545 (amide); NMR: 7.35 (Ph, s), 4.90 and 4.58 (CH_2: ABq, J_{AB}=12.0), 4.51 (H_1: q, $J_{1,2e}$=2.4, $J_{1,2a}$=8.0), 3.70 (H_4: dt, $J_{4,5}$=$J_{3a,4}$=10.0, $J_{3e,4}$=4.4), 3.36 (H_5: dq, J_{5,CH_3}=6.0), 1.98 (NAc), 2.22—1.38 (H_{2a}, H_{2e}, H_{3a}, and H_{3e}: m), 1.28 (CH_3). Found: C, 68.82; H, 8.20; N, 5.37%. Calcd for $C_{15}H_{21}NO_3$: C, 68.41; H, 8.04; N, 5.32%.

18: $[\alpha]_D^{22}$ −92.4° (*c* 0.4, $CHCl_3$). Found: C, 65.76; H, 8.95; N, 11.58%. Calcd for $C_{13}H_{20}N_2O_2$: C, 66.07; H, 8.53; N, 11.86%.

Physical properties of *N,N'*-diacetate of **18** were identical with **16β**.

*Benzyl 2,4-Diacetamido-2,3,4,6-tetradeoxy-α-*D-arabino-*hexopyranoside (**16α**).* A suspension of **11α** (2.4 g, 6.08 mmol) and sodium azide (2 g, 28.8 mmol) in HMPA (10 ml) was stirred at 120 °C for 42 h until the initial product (**14α**) disappeared on TLC, and the subsequent hydrogenation with LAH and *N*-acetylation of the product were carried out as mentioned before to give a sirup which showed three spots on TLC. The main spot was separated by a silica gel column chromatography to give crystals which were recrystallized from ethanol–hexane. Yield, 1.17 g (60%); mp 95—98 °C; $[\alpha]_D^{22}$ +77.9° (*c* 0.6, $CHCl_3$). IR: 3260 (NH), 1645 and 1545 (amide); NMR (D_2O exchanged): 7.32 (Ph, s), 4.68 (H_1: broad s, $J_{1,2}$=<1.5), 4.66 and 4.52 (CH_2: ABq, J_{AB}=11.5), 4.18 (H_2: broad t), 3.95 (H_4: q, $J_{4,3a}$=8.0, $J_{4,5}$=10.0), 3.64 (H_5: dq, J_{5,CH_3}=6.0), 1.98 and 1.95 (2×NAc), 2.05—1.72 (H_{3e} and H_{3a}: m), 1.20 (CH_3: d). Found: C, 63.25; H, 7.31; N, 8.29%. Calcd for $C_{17}H_{24}N_2O_4$: C, 63.73; H, 7.55; N, 8.74%.

N,N'-*Diacetylkasugamine (**25**).* A solution of **16β** (0.84 g, 2.62 mmol) in methanol–50% acetic acid (1:1, 10 ml) was hydrogenolyzed in the presence of palladium–charcoal (5%, 0.5 g), filtered, and then the filtrate was evaporated to give a sirup which was crystallized from ethanol–hexane. Yield, 0.46 g (76%); mp 124—126 °C; $[\alpha]_D^{22}$ +65° (*c* 0.8, H_2O), [lit,[17] mp 123—125 °C; $[\alpha]_D^{20}$ +67° (*c* 1.0, H_2O)]. Found: C, 52.52; H, 8.02; N, 11.95%. Calcd for $C_{10}H_{18}N_2O_4$: C, 52.16; H, 7.88; N, 12.17%.

The same compound was also obtained from **16α** by hydrogenolysis in 80% yield.

The authors are indebted to the members of the Laboratory of Organic Analysis for microanalysis and to Mr. H. Matsumoto for NMR measurements.

Layered Compounds. XLIV.[1] Transannular π-π Interactions in Tetracyanoethylene Complexes of [*m.n*]Paracyclophadiynes and the Related Cyclic Acetylenes

Takahiro KANEDA and Soichi MISUMI

The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka 565

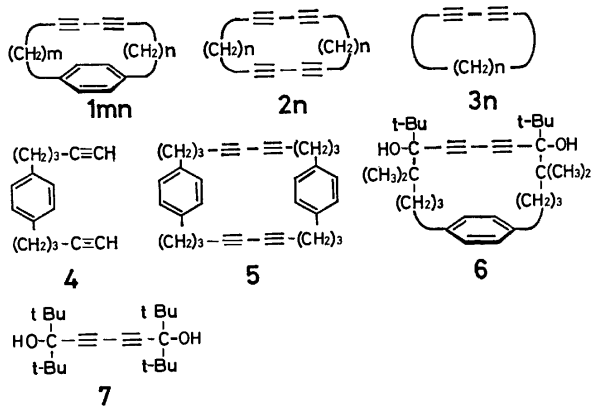
(Received April 21, 1977)

The electronic spectra of TCNE complexes of acyclic and cyclic diacetylenes and cyclic tetraacetylenes were measured. They show a maximum in the narrow region 423—431 nm regardless of ring strain in the donor molecules and proximity of two diacetylene groups. Crystalline two-to-one TCNE complexes of [*m.n*]paracyclophadiynes were prepared, the formation of one-to-one TCNE complexes in solution being established by means of the Benesi-Hildebrand plots using various molar ratios of the two components. The electronic spectra of some 1 : 1 [*m.n*]paracyclophadiyne–TCNE complexes were measured. The spectra suggest that the complexes are equilibrium mixtures consisting of three isomeric complexes, *i.e.*, a diacetylene-site complex and two pseudo-conformers of benzene-site complex. The longer wavelength band of [*m.n*]paracyclophadiyne complexes shows a marked red-shift as compared with the other bands. This is interpreted in terms of transannular π-π interaction between the diacetylene group and the benzene ring fixed closely with each other by shortening of methylene bridges. The contribution of the three isomeric complexes on the red-shift is discussed.

In previous papers of this series[2,3] reports were given on the syntheses and spectra of [*n*]paracyclophadiynes or [*m.n*]paracyclophadiynes $\mathbf{1}_{mn}$ where *m* and *n* are the numbers of bridging methylenes inserted between a benzene ring and a diacetylene group. Thermal and photochemical cycloadditions[4] and ^{13}C-NMR spectra[5] of $\mathbf{1}_{mn}$ and related cyclic diacetylenes were also investigated. The unusual reactions and spectral properties have been interpreted in terms of proximity interactions between the diacetylene group and the aromatic ring placed close to each other in a molecule.

Tetracyanoethylene (TCNE) complexes have often been used in studies on the relative π-base strength of various methyl-substituted benzenes[6] and transannular π-π interactions in donor molecules, *e.g.*, [*m.n*]paracyclophanes,[7] [2.2]metacyclophanes,[8] multilayered [2.2]paracyclophanes,[9] and multilayered [2.2]paracycloheterophanes.[10] The π-basicity of the donor molecules increases with an increase in the number of substituted methyl groups and/or stacking benzene rings and an increase in the face-to-face overlapping between aromatic nuclei. In contrast to the cyclophanes having symmetric donor-sites, unsymmetric cyclophanes containing non-equivalent donor sites such as 4-acetyl- and 4-methoxy-[2.2]paracyclophanes[7b] can be expected to form two isomeric one-to-one complexes with TCNE, *i.e.*, pseudo-configurational isomers. An important factor for determining which isomeric complex is more predominant or exclusive is the magnitude of ionization potentials of the constituent donor moieties. The relative orientation between an acceptor and a donor, or pseudo-conformation, is the second factor to affect transition energy of charge transfer (CT) complexes. Two pseudo-conformers were assumed for one-to-one *p*-substituted benzene–TCNE complexes and were investigated experimentally and theoretically.[11]

Since dialkyldiacetylenes have also been proved to form CT complexes with TCNE in the present study, paracyclophadiynes $\mathbf{1}_{mn}$ can be regarded as unsymmetric donor molecules having two possible donor sites. In the present work the transannular π-π interactions in $\mathbf{1}_{mn}$ and cyclic tetraacetylenes $\mathbf{2}_n$, where a suffix *n* is the number of bridging methylenes, are discussed considering geometrical effect with the aid of their TCNE complexes.



Results and Discussion

Charge Transfer Complexes of Alkadiyne and Alkynes with TCNE. The π-donation of triple bonds have been observed in some examples,[12] *e.g.*, in the formation of hydrogen bond with hydroxylic protons[13] and of molecular complex with hydrogen chloride,[14] but not in TCNE complex. Thus we first examined alkadiyne- and alkyne–TCNE complexes in connection with the study of paracyclophadiyne–TCNE complexes.

The equilibrium constants of 5-decyne- and 5,7-dodecadiyne–TCNE complexes were determined at 25°C in dichloromethane with the Benesi-Hildebrand equation[15]

$$\frac{(A)l}{\log I_0/I} = \frac{1}{K\varepsilon}\cdot\frac{1}{[D]} + \frac{1}{\varepsilon} \qquad (1)$$

where (A), *l*, [D], ε, and *K* are molar concentration of TCNE, light path length, mole fraction of the alkyne, apparent molar extinction coefficient, and the equilibrium constant, respectively. Plots of $(A)l/(\log I_0/I)$ against 1/[D] give straight lines for both complexes, demonstrating that a 1 : 1 complex is formed between

Table 1. Absorption maxima and equilibrium constants of alkyne–TCNE complexes (CH_2Cl_2, 25 °C)

Alkyne	λ (nm)	K (ε)
5,7-Dodecadiyne	424	7.0(1100)
5-Decyne	370	3.9(500)
3-Octyne	367	—

the alkyne and TCNE in the solution. The observed values of λ_{mn} and K given in Table 1 indicate 5,7-dodecadiyne to be a much stronger π-base to TCNE than 5-decyne.

Electronic Spectra of Cyclic Di- and Tetraacetylene–TCNE Complexes. The electronic spectra of $\mathbf{2}_n$– and $\mathbf{3}_n$–TCNE complexes exhibit absorption bands with a maximum in the narrow region 423—431 nm as well as the one-to-one 5,7-dodecadiyne–TCNE complex, suggesting that each spectrum is associated with the transition of one-to-one complex.

The TCNE complexes of two cyclic diacetylenes, strained $\mathbf{3}_9$ and $\mathbf{3}_{10}$, show the absorption maxima at the same position. This suggests a slight strain effect on the CT-transition of diacetylene–TCNE complexes. The cyclic tetraacetylene $\mathbf{2}_3$ in which a pair of diacetylene groups are closely fixed shows an abnormal spectrum[20b] due to transannular electronic interaction as compared with the other homologs $\mathbf{2}_n$. Thus, the $\mathbf{2}_3$–TCNE complex is also expected to exhibit transannular π-π electronic interaction differing from the other $\mathbf{2}_n$-TCNE complexes. However, it reveals a spectrum similar to those of the others, indicating that the proximity of the two diacetylene groups is not important for CT-transition energy of cyclic tetraacetylene–TCNE complexes.

Composition and Geometry of Paracyclophadiyne–TCNE Complexes. Crystalline TCNE complexes of both $\mathbf{1}_{34}$ and $\mathbf{1}_{44}$ were isolated and confirmed to consist of two moles of donors and one mole of TCNE. Harata *et al.* reported the crystal structure of the latter complex, where a TCNE molecule is sandwiched between the two benzene rings of two $\mathbf{1}_{44}$ molecules but not complexed with diacetylene group-site (Fig. 1).[16]

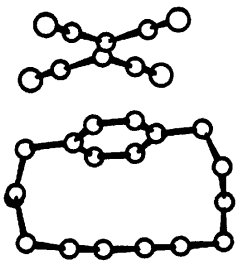


Fig. 1. Crystal structure of two-to-one [4.4]paracyclophadiyne–TCNE complex.[16]

In solution, on the other hand, [m.n]paracyclophadiynes $\mathbf{1}_{mn}$ are found to form one-to-one TCNE complex by the following experiments. When molar ratios of $\mathbf{1}_{33}$ and $\mathbf{1}_{44}$ *vs.* TCNE in dichloromethane are changed in the ranges 16—1/19 and 12—1/13, respectively, the position of absorption maximum and the shape of absorption curve remain unchanged for both

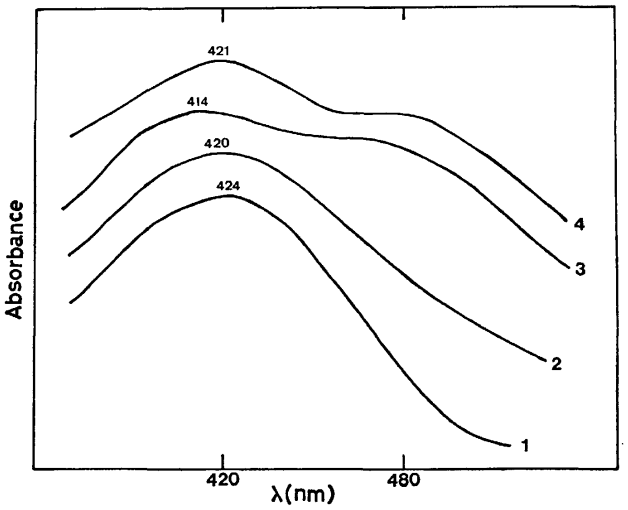

Fig. 2. Electronic spectra of TCNE complexes (CH_2Cl_2, room temp): curve 1, 5,7-dodecadiyne; 2, a 1:6:6 mixture of TCNE, **4**, and 5,7-dodecadiyne; 3, **4**; 4, **6**. * λ_{max} in nm.

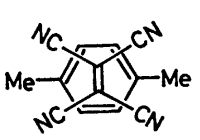
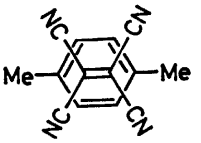
the complex solution.

Two possible pseudo-configurational isomers are expected for the one-to-one complex of $\mathbf{1}_{mn}$, *viz.*, a diacetylene-site complex $\mathbf{10}_{mn}$ and a benzene-site complex for which two conformational isomers $\mathbf{11}_{mn}$ and $\mathbf{12}_{mn}$ are theoretically anticipated for *p*-xylene–TCNE complex.[11c,17]

In studying the electronic spectra of $\mathbf{1}_{mn}$–TCNE complexes, it is advantageous to examine those of TCNE complexes of *p*-di(4-pentynyl)benzene **4** and [5.5]-paracyclophadiyne derivative **6** bearing bulky groups at the propargyl positions. The spectra are shown in Fig. 2. A mixture of TCNE and 1-alkyne or 1,1,6,6-tetra-*t*-butyl-2,4-hexadiyne-1,6-diol **7** having similar bulky groups at the propargyl positions exhibits no band in the visible region. Complexing with TCNE is considered to be difficult owing to steric hindrance of the bulky groups in the latter case. Thus the observed CT-bands of **4**– and **6**–TCNE complexes should be attributed to the benzene-site complex, but not to the diacetylene-site one. The shorter- and longer-wavelength bands of these complexes are assigned to "perpendicular" and "parallel" complexes, respectively, according to the assignment (**8** and **9**)[11c] for *p*-xylene–

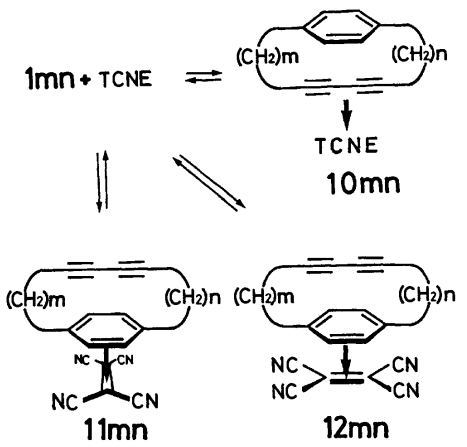


8



9

TCNE complex. As seen in Fig. 2, a mixture of TCNE, **4**, and 5,7-dodecadiyne of a 1:6:6 ratio shows a spectrum which is characterized as a superposition of the spectra due to the two independent complexes. It is quite reasonable that there are three isomeric complexes $\mathbf{10}_{mn}$—$\mathbf{12}_{mn}$ in the equilibrium mixture of $\mathbf{1}_{mn}$–TCNE complex (Scheme 1).



Scheme 1.

Electronic Spectra of Paracyclophadiyne–TCNE Complexes. The absorption curves and their apparent maxima of $\mathbf{1}_{mn}$– and **5**–TCNE complexes are given in Fig. 3 and Table 2. All the complexes show a maximum in the narrow region 425—431 nm, $\mathbf{1}_{33}$–TCNE complex exhibiting an additional, strong maximum at 555 nm. The other curves are unsymmetric, suggesting an additional band submerged in longer wavelength region. We have resolved the curves into two components on the assumption that they consist approximately of two CT-bands, since the shorter wavelength band (λ_{max} *p*-xylene 415 nm;[6] [*m.n*]paracyclophane 416—430 nm)[7a] of the two maxima of *p*-xylene derivative–TCNE complexes and the absorption band (421—431 nm) of diacetylene–TCNE complex appear at nearly the same position. The results of curve analyses are given in Table 2. The $\mathbf{1}_{24}$–, $\mathbf{1}_{44}$–, and $\mathbf{1}_{55}$–TCNE complexes exhibit a longer wavelength band at 470 or 480 nm in addition to a shorter wavelength band. From the fact that the absorption curves of these complexes are very similar to curve 2 in Fig. 2, one may reason as follows: the shorter wavelength band is possibly attributed both to the diacetylene-site complex $\mathbf{10}_{mn}$ and the benzene-site "perpendicular" complex $\mathbf{11}_{mn}$, and the longer wavelength band to the "parallel" complex $\mathbf{12}_{mn}$. It is also shown that in the cases of the three $\mathbf{1}_{mn}$–TCNE complexes, there is no appreciable transannular π-π interaction between the two chromophores in the donor molecules.

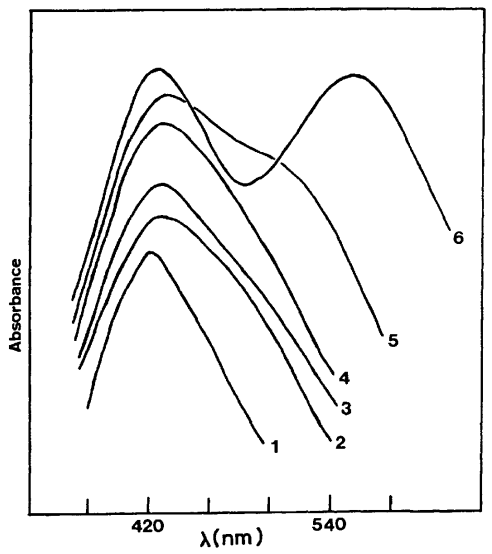


Fig. 3. Electronic spectra of [*m.n*]paracyclophadiyne–TCNE complexes (CH_2Cl_2, room temp): curve 1, **5**; 2, $\mathbf{1}_{24}$; 3, $\mathbf{1}_{55}$; 4, $\mathbf{1}_{44}$; 5, $\mathbf{1}_{34}$; 6, $\mathbf{1}_{33}$.

TABLE 2. CT-BAND POSITIONS OF CYCLOPHANE– AND *p*-XYLENE–TCNE COMPLEXES(CH_2Cl_2, ROOM TEMP)

Donor	λ_{max} (nm)[a]	
$\mathbf{1}_{33}$	427 (425)	555 (555)
$\mathbf{1}_{34}$	431 (415)	(510)
$\mathbf{1}_{24}$	430 (402)	(470)
$\mathbf{1}_{44}$	429 (410)	(480)

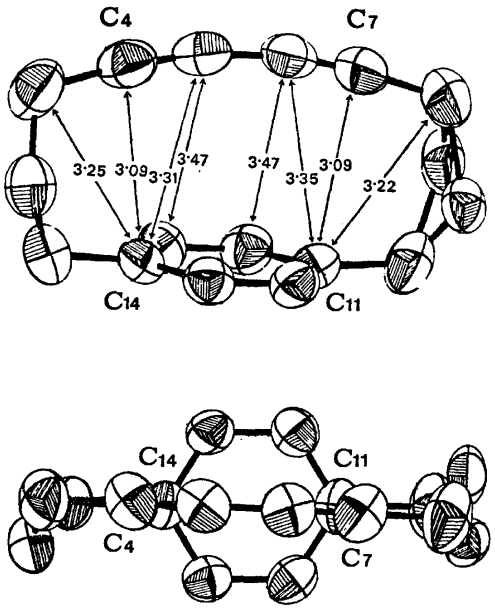

Fig. 4. Crystal structure of [3.3]paracyclophadiyne.[18]

The longer wavelength band of $\mathbf{1}_{33}$–TCNE complex appears with a red-shift of 75 nm as compared to those of complexes of $\mathbf{1}_{44}$ and $\mathbf{1}_{55}$. The crystal structure of $\mathbf{1}_{33}$ shows a remarkable distortion of the diacetylene group and a slight bending of the benzene ring from their normal arrangements as seen in Fig. 4.[18] Since the positions of CT-absorption maxima are little affected by such distortions of benzene ring[7a,b] and of diacetylene group as described for $\mathbf{3}_9$ and $\mathbf{3}_{10}$, the marked red-shift of $\mathbf{1}_{33}$–TCNE complex should be interpreted in terms of considerable transannular π-electron donation from the non-complexed diacetylene group to the complexed benzene ring in the parallel complex $\mathbf{12}_{33}$. On the other hand, the shorter wavelength band can be assigned

to the complex $\mathbf{10}_{33}$ and $\mathbf{11}_{33}$, provided that both complexes are in an equilibrium as shown in Scheme 1. Since the maximum of this band appears at nearly the same position as the corresponding maxima of the other complexes $\mathbf{10}_{mn}$ and $\mathbf{11}_{mn}$ having different number of bridged methylene, it is suggested that the transannular π-π interaction does not make a very important contribution to the CT-tansitions of both complexes $\mathbf{10}_{33}$ and $\mathbf{11}_{33}$.

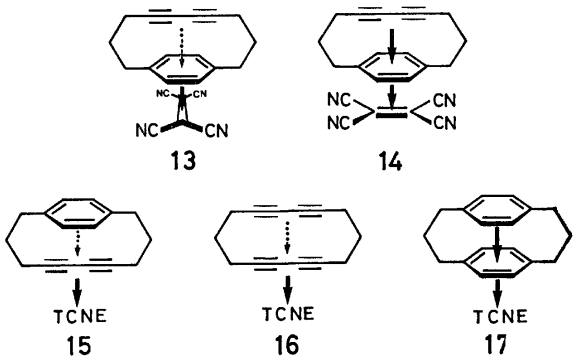

Fig. 5. Transannular π-π interaction in cyclic donor–TCNE complexes; thick and dotted arrows in the donor molecules indicate effective and unobserved interactions, respectively.

The complex of $\mathbf{1}_{34}$ shows an intermediate spectral feature between those of its homologs $\mathbf{1}_{33}$ and $\mathbf{1}_{m=n>3}$. The argument described for $\mathbf{1}_{33}$ seems to be also applicable to this complex.

Geometrical Effect of TCNE Complexes on Transannular π-π Interaction. A different π-donating character of the diacetylene group was observed between two pseudo-conformer $\mathbf{11}_{33}$ and $\mathbf{12}_{33}$ (or **13** and **14** in Fig. 5). The difference can be qualitatively accounted for according to the discussion for the spectra of two isomeric complexes of *p*-disubstituted benzenes.[11a,c] The molecular orbitals that take part in allowed CT-transitions are depicted as **18** for **13** and as **19** for **14**. In **19**, the large π-electron density at C_4, C_7, C_{11}, and C_{14} causes facile overlapping between the three chromophores as expected from the crystal structure in Fig. 4, making the charge delocalization favorable. In the alternative pseudo-conformer **18**, the π-π interaction is not favorable because of the existence of a nodal plane passing through C_4, C_7, C_{11}, and C_{14} (Fig. 6). Two bands of TCNE complexes of [3.4]paracyclophadiyne $\mathbf{1}_{34}$ and [3.3]paracyclophane[7a] are similarly explained in terms of two pseudo-conformers.

It is noteworthy that there is no appreciable transannular delocalization in the diacetylene-site complexes, **15** and **16**, and the benzene-site perpendicular complex **13** in contrast to marked delocalization in the parallel complex **14**. Unusual thermal cycloaddition reactions of [m.n]paracyclophadiynes with TCNE were observed to proceed *via* the complex $\mathbf{10}_{mn}$ and not *via* the more stable $\mathbf{12}_{mn}$.

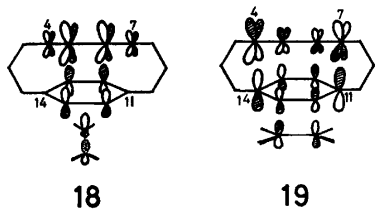

Fig. 6. Orbital sets of [3.3]paracyclophadiyne–TCNE complex.

Experimental

Materials. Five [m.n]paracyclophadiynes $\mathbf{1}_{mn}$, cyclic tetraacetylenes $\mathbf{2}_n$ (n=9 and 10), cyclic diacetylenes $\mathbf{3}_n$, diethynyl compound **4**, and paracyclophatetrayne **5** were prepared previously.[2] The diacetylene derivatives having bulky group at propargyl positions **6** and **7**,[19] cyclic tetraacetylenes $\mathbf{2}_n$ (n=3 and 4),[20] 5,7-dodecadiyne,[21] 5-decyne, and 3-octyne[22] were synthesized respectively according to the corresponding methods.

Tetracyanoethylene was recrystallized from chlorobenzene and sublimed twice at 125 °C/1 mmHg. TCNE was dissolved without coloration in dichloromethane (E. Merck Co. spectrograde) used as a solvent.

Electronic Spectra and Determination of Equilibrium Constants. All the spectra were measured on a Hitachi EPS-3T autorecording spectrophotometer using a 10 mm cell at room temperature within a few minutes after preparation of the solution.

Dichloromethane solutions of $\mathbf{1}_{mn}$- and **5**–TCNE complexes were prepared by a method similar to that for [m.n]paracyclophane–TCNE complexes.[7a] The observed maximum absorbances were 0.57—0.72 for $\mathbf{1}_{mn}$-complexes and 0.36 for **5**-complex. From the solutions of $\mathbf{1}_{33}$- and $\mathbf{1}_{44}$-complexes the donors were recovered by chromatography on alumina using hexane–ether (2: 1) as an eluent.

The spectra of $\mathbf{2}_n$- and $\mathbf{3}_n$–TCNE complexes were measured as follows: concentration of donor, 0.005—0.022 M; concentration of TCNE, 0.022—0.032 M; molar concentration ratio, 0.3—0.9. The observed maximum absorbances were in the range 0.20—0.42.

The Benesi-Hildebrand method[19] was used to determine the molar extinction coefficients and equilibrium constants for 5,7-dodecadiyne- and 5-decyne–TCNE complexes in dichloromethane at 25 °C. In these determinations the mole fraction of the donors was varied from 0.018 to 0.044, while the concentration of TCNE was held between 0.007 and 0.011 M. A straight line was obtained through the four measured points for each complex. The values of K and ε in Table 1 were calculated by the least-squares method.

Preparation of Crystalline Paracyclophadiyne–TCNE Complexes. The two-to-one complexes of [3.4]- and [4.4]-paracyclophadiynes over TCNE were prepared as follows.

A mixture of 0.1 g of $\mathbf{1}_{34}$ and 0.03 g of TCNE was dissolved in 0.5 ml of ethyl acetate, and then 3 ml of pentane was added. The solution was cooled to −20 °C to yield dark-red rhombic plates, which were collected and dried. $\mathbf{1}_{34}$–TCNE 2: 1 complex, mp 96—102 °C. Found: C, 83.84; H, 6.37; N, 9.69%. Calcd for $C_{40}H_{36}N_4$: C, 83.88; H, 6.34; N, 9.78%.

A solution of $\mathbf{1}_{44}$ (0.1 g) and TCNE (0.02 g) in 0.5 ml of ethyl acetate was cooled to −20 °C to give red crystals. The crystals were dissolved in a minimum amount of ethyl acetate, and the solution was allowed to stand overnight at room temperature. During this period the solvent was nearly completely evaporated to give reddish-orange rhombic plates, which were collected, washed quickly with petroleum ether containing a small amount of ethyl acetate, and dried. $\mathbf{1}_{44}$–TCNE 2: 1 complex, mp 117—128 °C. Found: C, 83.88; H, 6.71; N, 9.42%. Calcd for $C_{42}H_{40}N_4$: C, 83.96; H, 6.71;

N, 9.33%.

The infrared spectra of these crystalline complexes were illustrated as a superposition of those due to the two components.

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

The Structure and Reactions of Imidoyl Triphenylphosphonium Methylides

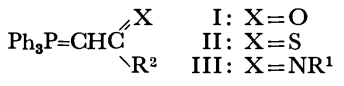
Hiroshi YOSHIDA, Tsuyoshi OGATA, and Saburo INOKAWA

Department of Synthetic Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu 432

(Received April 22, 1977)

Twenty-five imidoyl triphenylphosphonium methylides III were prepared from triphenylphosphonium methylide and imidoyl chlorides or imidates in moderate yields. The configration of these ylides was assigned on the basis of NMR spectroscopic studies. *N*-Tosyl substituted ylides showed no reactivity toward aldehydes, whereas *N*-aryl substituted ylides could be converted easily into α,β-unsaturated ketimines in good yields. The reaction of III with carbon disulfide was also studied.

In recent years a number of phosphonium ylides stabilized by adjacent groups, such as carbonyl, thiocarbonyl, sulfonyl, and cyano, have been isolated, and their physical and chemical properties have been documented.[1]

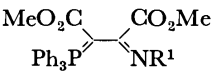


I: X=O
II: X=S
III: X=NR¹

In the course of our studies of *P*- and *S*-ylides and imides,[2,3] we have found a useful method for the preparation of imidoyl-stabilized phosphonium ylides, III. Here we will report on the structure and reactions of III.

Results and Discussion

Preparation of Imidoyl Triphenylphosphonium Methylides III. Some imidoyl-substituted ylides III have been reported.[4–6] The addition of phenylethynylphosphonium salt to aniline gives IIIp.[4] The thioimidate-type ylide IIIk is prepared by the alkylation of thiocarbamoyl triphenylphosphonium methylide with methyl iodide, followed by treatment with a base.[5] (This route seems to be a good method for the preparation of alkylthiocarbonimidoyl ylides). The addition of phosphinimine with dimethyl acetylenedicarboxylate gives α-imidoyl ylide IV.[6]



IV

These reported methods seems to have a limited application for the preparation of III with various substituents. We found that imidates, thioimidates, and imidoyl chlorides were good reagents for the preparation of imidoyl triphenylphosphonium methylides. The results are shown in Table 1.

$$2Ph_3P{=}CH_2 + R^1N{=}C(R^2)X \longrightarrow Ph_3P{=}CHC(NR^1)R^2 + Ph_3\overset{\oplus}{P}Me\ \overset{\ominus}{X}$$

V III

The structure of the products were confirmed by the NMR, IR, and elemental analyses.

Although the reaction of V(R^1=Ph, R^2=H, X=OEt; R^1=Ph, R^2=Me, X=Cl; R^1=Me, R^2=Ph, X=Cl) with phosphonium methylide proceeded vigorously, the isolation of the corresponding ylides III(R^1=Ph, R^2=H; R^1=Ph, R^2=Me; R^1=Me, R^2=Ph) failed, yielding only a brown oil. This result suggests that strong electron-withdrawing groups, such as tosyl, *p*-nitrophenyl for the R^1 and/or R^2 of III, stabilize ylides III.

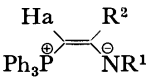
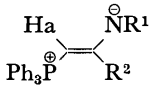
Structure of III Ylides. Evidence for the resonance interaction of the ylide carbanion with the imino group can be obtained by an examination of the infrared spectra of the imidoyl ylides, III. The C=N stretching frequencies of III occurred at around 1500 cm^{-1} (Table 2). Considering the frequencies of the model compounds[7] [ketimines (−1650 cm^{-1}), imidates (−1650 cm^{-1}), and thioimidates (−1610 cm^{-1})], the shifts of 100—150 cm^{-1} for III may be attributed to the increased single-bond character and to the delocalization of the carbanion electrons through the imino groups (*i.e.*, such betain forms as III_E and III_Z).



III_Z



III_E

The structure of the ylide was confirmed on the basis of NMR spectroscopic studies.[10] The results obtained are collected in Tables 3 and 4.

The NMR spectra of ester-stabilized ylides, I and II(R^2=*O*-Alkyl), have been shown to be mixtures of *E* and *Z* isomers;[8] however, the carbonyl-stabilized ylides, I and II(R^2=Alkyl or Aryl), are only *Z* isomers.[9]

The aldimino-type ylides, IIIa, u, v, and w existed as mixtures of *E* and *Z* isomers in benzene, nitrobenzene, and chloroform, and the *E*/*Z* ratios increased in accordance with the solvent polarity (benzene–nitrobenzene). The hydrogen-bonding interaction between chloroform and a negative oxygen or sulfur atom[2,8] is not as important a factor for IIIa, u, v, and w (Table 3) as for II(R^2=H). This result reveals that the strong electron-withdrawing effect of the R^1 substituent would stabilize both betain forms, III_E and III_Z.

As is shown in Table 4, two kinds of methyl signals due to ethyl or isopropyl groups of alkoxycarbonimidoyl or alkylthiocarbonimidoyl ylides III(R^2=*O*-Alkyl or *S*-Alkyl) appeared at δ 0.5—0.8 and 1.2—1.4 respectively. The stereochemistry of these methyl groups was assigned on the assumptions that protons of the R^2 group, neighbouring *cis* to the phosphorus, are shielded by the phenyl groups and that they appear at a higher field than that of the *trans* isomer.[2] The IIIc, d, e, f, and g ylides were also considered to be mixtures of *E* and *Z* isomers. The *N*-phenyl-substituted ylides, IIIl, m and IIIn, o were only *Z* and/or *E* isomers respectively (Table 4).

The coupling constants, J_{PCH_a}, for the alkoxycarbonimidoyl, alkylthiocarbonimidoyl, and formimidoyl ylides III(R^2=*O*-Alkyl, *S*-Alkyl, and H) show that the constants for the *Z* isomers are larger than those for the

E isomers (24—25 and 18—20 Hz respectively). This result suggests that the structures of the ketimino-type ylides, IIIh, i, j, p, q, r, s, and t may be considered to be Z isomers on the basis of their coupling constants J_{PCHa} (23—28 Hz).

The Reaction of III with Carbon Disulfide. The electrophilic attack of carbon disulfide on phosphonium methylides[1] occurred at the ylide carbanions. The ylides III(R^1=Aryl) can react easily with carbon disulfide, as is shown in Table 5. The reaction of the alkylthiocarbonimidoyl ylides, IIIk and l with carbon disulfide gave the thiocarbonyl ylides, IIb and c (R^2= SMe and SEt), and phenyl isothiocyanate in good yields. The products were identified by comparing their NMR and mps with those of authentic samples.[2]

$Ph_3P{=}CHC(=S)R^2$ (II)

IIa: R^2=Ph
IIb: R^2=SMe
IIc: R^2=SEt
IId: R^2=OMe

The ketimino ylides, IIIp and r also showed a high reactivity toward carbon disulfide. The NMR spectroscopic study of this reaction seems to be interesting. To a solution of IIIr in chloroform-d we added a large excess amount of carbon disulfide in one portion, yielding a red solution within a minute. The NMR spectrum of this reaction mixture showed two new, nearly equivalent methyl signals of p-tolyl groups at δ 2.11 and 2.33, whose original signals appeared at 2.19. On standing at 40 °C for 2 days or heating at 70 °C for 12 h the higher-field signal disappeared almost entirely. The reaction products were triphenylphosphonium thiobenzoylmethylide, IIa, and p-tolyl isothiocyanate. To find the initial reaction products, controlled experiment was undertaken. IIIr (1 mmol) was dissolved in 3 ml of carbon disulfide. Three minutes later, to the resulting red mixture we added methyl iodide (0.66 mmol) in one portion and stirred the mixture well. Then all the liquid was removed *in vacuo*, and the benzene-soluble part was separated. Concentration and crystallization from chloroform–hexane yielded triphenylphosphonium[(methylthio)thiocarbonyl](*N*-p-tolylbenzimidoyl)methylide VIb (R^1=p-Tol, R^2=Ph) in a 19% yield. The structure of VIb was confirmed on the basis of NMR, MS, and a methylation reaction, yielding VIIb (R^1=p-Tol, R^2=Ph). A similar treatment of IIIp with carbon disulfide yielded VIa (R^1=R^2=Ph) in a 23% yield.

On the other hand, the reaction of IIIn with carbon disulfide proceeded slowly to give not IId,[2] but VIII, as an isolable product in a 76% yield (based on the methyl groups). The structure of VIII was confirmed on the basis of NMR (SMe and OMe groups), MS, and methylation with methyl iodide to yield IX.

The marked difference in the reactivity of these ylides III with carbon disulfide may be attributed to the pK_a values of the conjugate acids of the ylide carbanions.

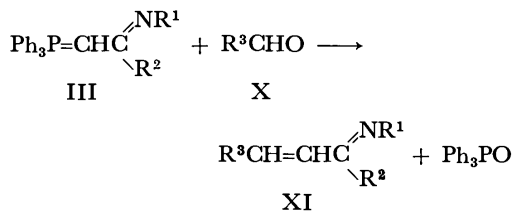
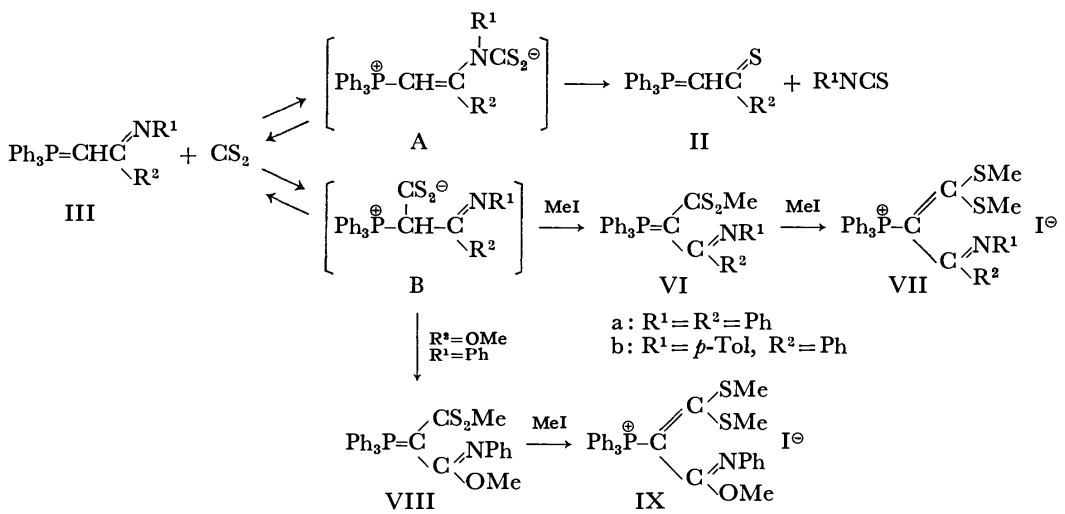
a) Protons due to the phenyl and vinyl groups appeared at 6.5—8.0 as multiplets.

The reactivity decreases with the decrease in pK_a values (Tables 2 and 5). Considering the results obtained, we assumed equilibria between III, A, and B, followed by the kinetically controlled decomposition of A and B, depending on the nature of the substituents, R^1 and R^2 (Scheme 1). The A formed from IIIk, l, p, and r and carbon disulfide gave II and isothiocyanate, while the B from IIIp, r gave VIa and b in the presence of methyl iodide. On the other hand, IIIn reacted slowly with carbon disulfide to give the product, VIII, from B *via* the intermolecular nucleophilic attack of the thiolate anion on the methyl group of IIIn. The thiocarbonyl ylides, VI and VIII, can be easily identified because of their high reactivity with methyl iodide to yield two *S*-methylation products, VII and IX, as was observed for the II ylides.[2]

The Reaction of III with Aldehydes, X. The Wittig reaction of III with the aldehydes, X, gave α,β-unsaturated ketimines, XI, in fairly good yields (Table 6). The products were confirmed by MS, NMR, and acid hydrolysis. XI (R^1=R^2=R^3=Ph) and XI (R^1=*p*-Tol, R^2=R^3=Ph) gave chalcone on hydrolysis with 1M-HCl in 30% aqueous ethanol. Although the NMR spectra of XI (Table 6) showed the presence of stereo isomers, no effort was made to effect their isolation at this stage.



α,β-Unsaturated aldimines can be easily prepared by the condensation of unsaturated aldehydes and amines.[11] On the contrary, α,β-unsaturated ketones can react



Scheme 1.

with amines to give not imines, but β-amino ketones.[12] The Wittig reaction of III seems to be a useful method for the preparation of α,β-unsaturated ketimines, XI.

N-Tosyl-substituted ylides IIIb and h showed no reactivity toward aldehydes even when heated at 80 °C for 10 h in benzene or chloroform.

Experimental

Preparation of Imidoyl Chlorides, Imidates, and Thioimidates. The formimidates, Va, u, v, and w were prepared by the condensation of ethyl orthoformate and amide or amine according to the literature.[13,14] The new compound, Vu, had a mp of 84—85 °C (ethanol); M^+, 255.

The other imidoyl chlorides and imidates were prepared by the known methods shown in the literature.[15] New compounds were checked by MS. Vd: mp 62—63 °C (ethanol); M^+, 363. Vf: mp 84—85 °C (ethanol); M^+, 273. Vg: mp 76 °C (ethanol); M^+, 287. Vi: mp 60—62 °C (ethanol); M^+, 272. Vl: bp 110—113 °C/3mmHg; M^+, 225. Vm: bp 136—138 °C/3 mmHg; M^+, 253.

Preparation of III. A suspension of triphenylmethylphosphonium bromide (5.0 g, 14 mmol) and sodium amide (1.5 g) in 50 ml of dry benzene was stirred for 12 h in a stoppered flask at room temperature. After the separation of the precipitate, the ammonia was removed *in vacuo* to give a yellow solution of triphenylphosphonium methylide. To the solution we added imidoyl chloride (6 mmol) in 10 ml of benzene in one portion. The mixture was then allowed to stand for 1 h at room temperature and subsequently treated with charcoal (phosphonium chloride also separated) and condensed *in vacuo* to give a crystalline mass. Crystallization from appropriate solvents yielded III. The results are shown in Table 1.

Determination of pK_a of Ylides, III. The pK_a values were measured in 20% aqueous ethanol according to the literature.[16] The results are given in Table 2.

The Reaction of III with Carbon Disulfide. To a solution of IIIk, l, p, and r (1 mmol) in 20 ml of chloroform we added 1 ml of carbon disulfide in one portion. The resulting solution was heated at 40 °C or at room temperature for 1—2 day, and condensed *in vacuo*, thus separating the petroleum ether-soluble and -insoluble parts. The latter part gave triphenylphosphonium thiocarbonylmethylides, IIa, b, and c, whose physical properties have been previously reported by the present authors.[2]

IIIp (1 mmol) was dissolved in 3 ml of carbon disulfide. Three minutes later methyl iodide (0.66 mmol) was added to the resulting red mixture. Then all the liquid was removed *in vacuo*, and a benzene-soluble product was separated. Crystallization from chloroform–hexane yielded VIa (R^1=R^2=Ph): mp 235—237 °C; NMR ($CDCl_3$) δ=2.64 (3H, s, SMe), 6.8—8.0 (25H, m, Harom). Found: C, 74.51; H, 5.42; N, 2.44%; M^+, 545. Calcd for $C_{34}H_{28}NPS_2$: C, 74.83; H, 5.17; N, 2.57%; M, 545. The methylation of VIa with methyl iodide in chloroform yielded VIIa (R^1=R^2=Ph) in a quantitative yield. VIIa: mp 162—164 °C; NMR ($CDCl_3$) δ=1.87 and 2.00 (3H, s, 1:2, SMe), 2.69 and 2.82 (3H, s, 1:2, SMe), and 6.9—8.2 (25H, m, Harom). In the similar treatment of IIIr with carbon disulfide, VIb (R^1=*p*-Tol, R^2=Ph) was obtained in a 19% yield. VIb: mp 228—229 °C; NMR ($CDCl_3$) δ=2.38 (3H, s, $C\underline{H}_3C_6H_4$), 2.58 (3H, s, SMe), and 6.8—8.0 (24H, m, Harom). Found: C, 75.28; H, 5.24; N, 2.39%; M^+, 559. Calcd for $C_{35}H_{30}NPS_2$: C, 75.10; H, 5.40; N, 2.50%; M, 559. VIIb (R^1=*p*-Tol, R^2=Ph): mp 193—194 °C; NMR ($CDCl_3$) δ=1.90 and 2.02 (3H, s, 1:2, SMe), 2.27 and 2.61 (3H, s, 1:2, $C\underline{H}_3C_6H_4$), 2.71 and 2.84 (3H, s, 1:2, SMe), and 6.8—8.0 (24H, m, Harom).

The reaction of IIIn with carbon disulfide was run similarly to give VIII in a 75% yield. VIII: mp 242—245 °C (ethyl acetate–hexane); NMR ($CDCl_3$) δ=2.62 (3H, s, SMe), 3.63 (3H, s, OMe), and 6.7—8.0 (20H, m, Harom). Found: C, 69.72; H, 5.33; N, 2.94%; M^+, 497. Calcd for $C_{29}H_{26}NOPS_2$: C, 70.00; H, 5.27; N, 2.81%; M, 497. IX: oil; NMR ($CDCl_3$) δ=1.82 (3H, s, SMe), 2.73 (3H, s, SMe), 3.56 (3H, s, OMe), and 6.7—8.0 (20H, m, Harom).

The Reaction of III with Aldehydes X. To a solution of III (1 mmol) in 10 ml of chloroform we added an equimolar amount of aldehyde, X. After 5 min the solution was condensed *in vacuo*, and the petroleum ether-soluble part (XI) and -insoluble part (phosphine oxide) were separated. By crystallization from ethanol XI substances were obtained in good yields (Table 6).

Hydrolysis of XI (R^1=R^2=R^3=Ph) and XI (R^1=p-Tol, R^2=R^3=Ph). A solution of XI (1 mmol) in 15 ml of 1M-HCl 30% aqueous ethanol was kept standing at room temperature for 12 h. The solution was quenched in 30 ml of water, yielding precipitates which, on crystallization from ethanol, gave chalcone in 70—80% yields.

The Components of *Petasites japonicus* Maxim. IV.[1] The Structure of Petasitin

Ichiro TAKAGI,* Yasuhito TAZUKE, and Keizo NAYA

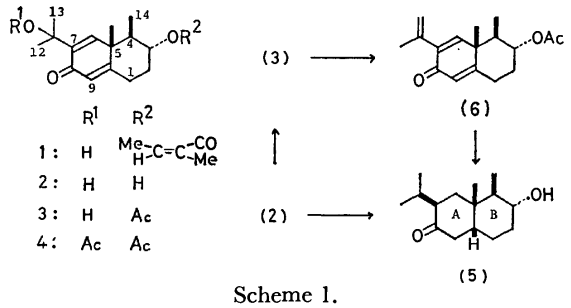
Department of Chemistry, Faculty of Science, Kwansei Gakuin University, Uegahara, Nishinomiya, Hyogo 662

(Received April 30, 1977)

Petasitin, a component isolated from a wild variety of *Petasites japonicus* Maxim., has been shown to be 3α-[(*Z*)-2-methyl-2-butenoyloxy]-11-hydroxyeremophila-6,9-dien-8-one, and has been synthesized from the known isopetasin by photosensitized oxygenation.

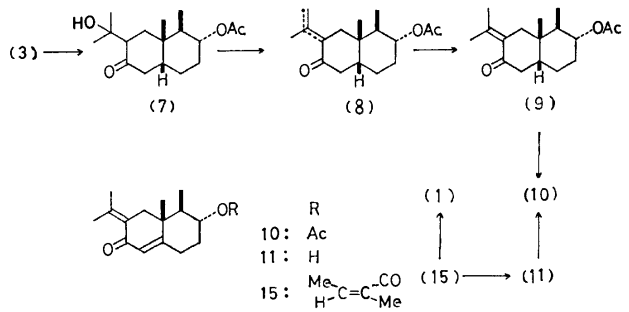
In an earlier communication,[2] we reported the structural proof of petasitin (**1**) isolated from the wild plant of *Petasites japonicus* Maxim. ("Fuki" in Japanese). We wish now to describe its isolation and structural determination, and also the synthesis of **1** from a known isopetasin (**15**).[3]

A methanol extract of the dried flower stalks of the plant was chromatographed repeatedly on alumina and silica gel, and from the polar part a component named petasitin (**1**) was obtained.



Scheme 1.

Petasitin (**1**), $C_{20}H_{28}O_4$ (bp 167.0—170 °C/2×10^{-4} mmHg, $[\alpha]_D$ −26.2°), is a colorless, highly viscous oil. Its IR and UV spectra show the presence of α,β-unsaturated carbonyl systems— a ketone (1665 cm^{-1} and λ_{max} 235 nm (ε, 14200)) and an ester (1710 and 1235 cm^{-1}). The spectral data also indicated that the fourth oxygen atom seemed to be a tertiary alcohol (3460 cm^{-1}) attached to the carbon atom bearing two methyls (δ 1.50, s, 6H). The existence of a (*Z*)-2-methyl-2-butenoate moiety as the ester group in petasitin, **1**, was inferred from the NMR signals, by analogy with those of the constituents[3-5] isolated from the same plant. In fact, the alkaline hydrolysis of **1** afforded (*Z*)-2-methyl-2-butenoic acid (angelic acid), accompanied by a small amount of the isomerization product, that is, the corresponding (*E*)-isomer (tiglic acid) and a diol, named petasitol (**2**), $C_{15}H_{22}O_3$ (mp 110.0—113.0 °C). In the UV spectrum of **2**, the intensity of the maximum at 244 nm (ε, 12700) suggests the presence of a cross-conjugated dienone system, and the IR spectrum exhibits bands at 3340 (hydroxyl), 1655 (α,β-unsaturated ketone), and 1610 cm^{-1} (double bond). In the NMR spectrum, petasitol, **2**, showed the signals due to four methyls, two vinyl protons (δ 6.12, t, J=1.0 Hz, 1H and 6.92, s, 1H), and a proton (δ 3.70, m, $W_{1/2}$=14 Hz) attached to a carbon atom carrying a newly appeared hydroxyl group. The acetylation of **2** with acetic anhydride–pyridine at room temperature gave a monoacetate (**3**) (mp 80.0—82.0 °C), which showed IR bands at 3420 (hydroxyl), 1735, 1240 (acetate), 1660 and 1610 cm^{-1} (α,β-unsaturated ketone), while acetylation with acetic anhydride–sodium acetate under reflux gave a mixture of monoacetate, **3**, and diacetate (**4**). The hydrogenation of **2** with 10% palladium charcoal in ethanol, followed by treatment with a catalytic amount of sodium methoxide in methanol, gave a dehydroxy-tetrahydro compound (**5**), $C_{15}H_{26}O_2$ (mp 103.0—103.5 °C), which was found to be identical with the known tetrahydroisopetasol (**5**)[3] (mp 103.0—104.0 °C), by a mixed-melting-point determination and a comparison of the spectral data. Thus, the one hydroxyl group lost by hydrogenolysis can be placed at an allylic position. This hydroxyl group in petasitol monoacetate, **3**, was readily dehydrated with phosphoryl chloride–pyridine to afford an anhydro derivative (**6**), whose spectra showed the NMR signals due to an *endo*-methylene group bearing a methyl (δ 5.11, d with allylic splittings, J=7.0 Hz, 2H and 1.97, d, J=1.0 Hz, 3H) and IR bands (3080, 920 cm^{-1}) attributable to the *exo*-methylene group. Tetrahydroisopetasol, **5**, was also obtained from the anhydro derivative, **6**, by hydrogenation with 10% palladium charcoal in ethanol, followed by stabilization in a basic medium. Thus, the **1** structure was assumed for petasitin on the basis of the above results.



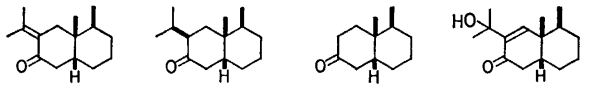
Scheme 2.

Furthermore, the location of a tertiary hydroxyl group was also confirmed by the following chemical reaction sequence— that is, by the conversion from petasitol monoacetate, **3**, to the known isopetasol acetate (**10**). The hydrogenation of **3** with Adams' catalyst in ethyl ether afforded a tetrahydroacetate (**7**),

* Present address: Department of Chemistry, Wakayama University, Masagocho, Wakayama 640.

$C_{17}H_{28}O_4$ (mp 92.0—95.0 °C), without the loss of a hydroxyl group. Compound **7** was dehydrated with phosphoryl chloride–pyridine to give a mixture of olefinic isomers (**8**), which were isomerized to an α,β-unsaturated ketone (**9**) by column chromatography over alumina. The dehydrogenation of **9** with DDQ afforded isopetasol acetate (**10**), $C_{17}H_{24}O_3$ (mp 82.0—85.0 °C), which was identified by a mixed-melting-point determination and by a comparison of the spectra.

The steric course of the hydrogenation for the cross-conjugated dienone system in isopetasol (**11**) has already been clarified by the stereochemical correlation between isopetasol, **11**, and fukinone (**12**).[3] Therefore, the hydrogenation of petasitol, **2**, and the monoacetate, **3**, with another type of dienone system also proceeds predominantly to furnish two steroidal A/B *cis*-fused compounds, **5** and **7**. The above results clearly indicate that the stereochemical course of the hydrogenation of the α,β-α',β'-unsaturated dienone system in a neutral medium must be influenced by the presence of the C-7 substituent; this must be compared with the earlier generalization, based on the hydrogenation of Δ^4-3-keto steroid-type compounds,[6] that the product compositions with *cis*- and *trans*-fused A/B rings were approximately equal.



(12) (13) (14) (16)

In a previous paper,[2] we reported that tetrahydroisopetasol, **5** (mp 103.0—103.5 °C), derived from petasitol, **2**, showed a negative RD Cotton effect on the basis of the close resemblance to the RD curves of dihydro- (**13**) and desisopropylidene fukinone (**14**).[3] On the other hand, the pure tetrahydroisopetasol, **5**, has always been obtained as crystals after the crude hydrogenation product (**5a**) of isopetasol, **11**, has been subjected to isomerization with sodium methoxide–methanol or potassium hydroxide–methanol, that is, immediately after the hydrogenation product, **5a**, a viscous oil, showed a strong negative extreme, $[\theta]_{292}$ −1920, in the CD curve (Fig. 1). After all, the crystalline tetrahydroisopetasol, **5** (mp 103.0—104.0 °C), converted from isopetasol, **11**, has been found to show a weak positive Cotton effect, $[\theta]_{280}$ +460, by the reinvestigation of a part of the CD study of the eremophilan-8-one derivatives[7] (Fig. 1).

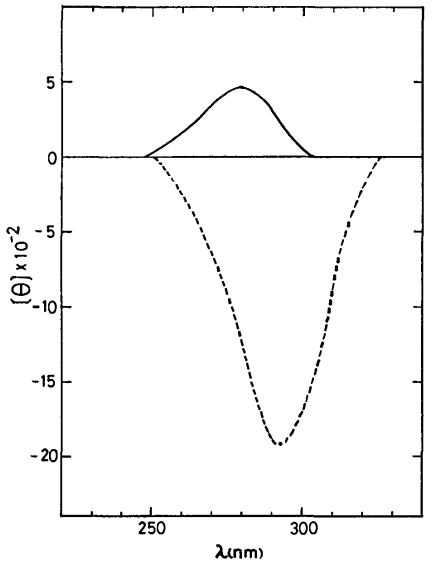


Fig. 1. CD curves of tetrahydroisopetasol: **5a** (an oily compd before isomerization; a dotted line) and **5** (a cryst compd after isomerization; a full line).

The final evidence for the stereochemistry of petasitin, **1**, was provided by the conversion of the known isopetasin (**15**) to **1** by means of photosensitized oxygenation in a manner similar to that in the case of the synthesis of petasitolone (**16**).[8]

Experimental

All the melting and boiling points are uncorrected. The IR, UV, ORD-CD, and mass spectra were taken with Jasco DS-402G, Cary Model 14, Jasco Model ORD-5, and Hitachi RMU-6 spectrophotometers respectively. The NMR spectra were recorded with JEOL C-60 and Hitachi R-20B (60 MHz) spectrophotometers, and the chemical shifts are reported in δ-values, with TMS as the internal reference. The optical rotations were measured with a Perkin-Elmer 141 polarimeter. The TLC were run on Kieselgel G (Merck). The analytical and preparative GLC were performed with a Shimadzu GC-1C apparatus on a stainless steel column (ϕ= 3 mm). The microanalyses were carried out in the microanalytical section of the Shionogi Research Laboratory, Shionogi and Co., Ltd.

Isolation of Petasitin (1). Dried flower stalks (34 kg) of *P. japonicus* Maxim. collected at Mt. Ioh in Ishikawa Prefecture, were extracted with methanol at room temperature. The extract was evaporated *in vacuo*, and the residue was dissolved in benzene. The benzene solution was washed with a saturated sodium hydrogencarbonate solution, dried over anhydrous sodium sulfate, and evaporated *in vacuo* to afford a dark green oil (2.4 kg). This oil was once chromatographed on alumina, and then repeatedly on silica gel. Subsequent elution with benzene–ethyl acetate (50: 1), gave petasitin (**1**) as a viscous oil (6.7 g) and almost a single spot on TLC (R_f, 0.2; benzene–ethyl acetate, 10: 1). This oil was purified by vacuum distillation and GLC for an analytical sample; bp 167.0—170.0 °C/2×10^{-4} mmHg; GLC: SF-96, 2 m, 60 ml/min H_2; column temperature, 240 °C; retention time, 16 min; $[\alpha]_D^{22}$ −26.2° (*c*, 1.0, MeOH); MS: *m/e* 332 M^+; IR (film): 3460, 1710, 1665, 1632, 1617, 1235 cm^{-1}; UV: λ_{max}^{EtOH} 235 nm (ε, 14200); NMR ($CDCl_3$): 6.93 (s, 6-H), 6.15 (t, J=1.0 Hz, 9-H), 6.13 (q, J=7.0 Hz, 3-H in an ester part), 4.95 (m, $W_{1/2}$=14 Hz, 3-H), 2.05 (d, J=7.0 Hz, 3-Me in an ester part), 1.90 (s, 2-Me in an ester part), 1.50 (s, 12- and 13-Me), 1.25 (s, 15-Me), 1.16 (d, J=7.0 Hz, 14-Me).

Found: C, 72.63; H, 8.56%. Calcd for $C_{20}H_{28}O_4$: C, 72.26; H, 8.56%.

Alkaline Hydrolysis of Petasitin (1). A solution of petasitin, **1** (1.26 g), in 5% ethanolic potassium hydroxide (20 ml) was allowed to stand at room temperature for 2 days. After the removal of the solvent, the aqueous solution of the residue was extracted with ether. The extract was washed with water and dried over anhydrous sodium sulfate. The evaporation of the solvent gave petasitol (**2**) (760 mg) as a semisolid, which was then crystallized from ethyl acetate–

light petroleum as colorless prisms; mp 110.0—113.0 °C, $[\alpha]_D^{21}$ −1.2 ° (*c*, 1.1, $CHCl_3$); $[\alpha]_D^{21}$ −5.5 ° (*c*, 1.0, MeOH); MS: *m/e* 250 M^+; IR (KBr): 3340, 1655, 1610 cm^{-1}; UV: λ_{max}^{EtOH} 244 nm (ε, 12700); NMR ($CDCl_3$): 6.92 (s, 6-H), 6.12 (t, J=1.0 Hz, 9-H), 3.70 (m, $W_{1/2}$=14 Hz, 3-H), 1.50 (s, 12- and 13-Me), 1.18—1.30 (partly superimposed two methyls).

Found: C, 67.01; H, 8.97%. Calcd for $C_{15}H_{22}O_3 \cdot H_2O$: C, 67.13; H, 9.09%.

The 2,4-dinitrophenylhydrazone was prepared as usual and crystallized from ethanol as red needles; mp 230.0—232.0 °C (dec).

Found: C, 58.71; H, 6.10; N, 13.24%. Calcd for $C_{21}H_{26}O_6N_4$: C, 58.59; H, 6.06; N, 13.02%.

The above alkaline solution was acidified with 3 M sulfuric acid and extracted with ether. The ethereal extract was washed with water and dried. The solvent was removed to give a crude acidic part (310 mg); IR (film): 3500—2400 (broad), 1685, 1655 cm^{-1}. The above residue was transformed to the *p*-phenylphenacyl ester in the usual manner, using *p*-phenylphenacyl bromide. The product (550 mg) was chromatographed with light petroleum–benzene (10: 1) on silica gel (10 g) to give *p*-phenylphenacyl (*Z*)-2-methyl-2-butenoate (220 mg), which was crystallized from methanol as colorless prisms; mp 88.0—89.5 °C.

Found: C, 77.54; H, 6.20%. Calcd for $C_{19}H_{18}O_3$: C, 77.53; H, 6.16%.

The subsequent elution on the above chromatography gave *p*-phenylphenacyl (*E*)-2-methyl-2-butenoate (30 mg), which was crystallized from methanol as colorless prisms (mp 104.5—106.5 °C). The two esters were identified by a mixed-melting-point determination with authentic samples.

Acetylation of Petasitol (2). a) A solution of petasitol, **2** (510 mg), in pyridine (2 ml) and acetic anhydride (2 ml) was left at room temperature for 20 h. The reaction mixture was then worked up in the usual manner to afford a crude monoacetate (**3**) as a solid, which was subsequently crystallized from acetone–light petroleum as prisms; mp 80.0—82.0 °C, $[\alpha]_D^{21}$ −17.9 ° (*c*, 1.0, $CHCl_3$), $[\alpha]_D^{21}$ −12.9 ° (*c*, 1.0, MeOH); MS: *m/e* 292 M^+; IR (KBr): 3420, 1735, 1660, 1616, 1240 cm^{-1}; UV: λ_{max}^{EtOH} 242 nm (ε, 14700); NMR ($CDCl_3$): 6.88 (s, 6-H), 6.10 (t, J=1.0 Hz, 9-H), 4.90 (m, $W_{1/2}$=14 Hz, 3-H), 2.06 (s, AcO), 1.48 (s, 12- and 13-Me), 1.20 (s, 15-Me), 1.10 (d, J=7.0 Hz, 14-Me).

Found: C, 65.79; H, 8.45%. Calcd for $C_{17}H_{24}O_4 \cdot H_2O$: C, 65.78; H, 8.44%.

b) A mixture of petasitol, **2** (44 mg), acetic anhydride (1.5 ml), and sodium acetate (70 mg) was refluxed for 8 h. Working-up as usual gave a crude product (63 mg), which was subsequently chromatographed on silica gel (5 g); elution with benzene–ethyl acetate (30: 1) then afforded diacetate (**4**) as a viscous oil (18 mg); MS: *m/e* 334 M^+, *m/e* 274 M^+ −60, *m/e* 214 M^+ −120, *m/e* 59 base peak; IR (film): 1735—1725, 1660, 1240 cm^{-1}.

Further elution with the same solvent gave monoacetate, **3** (20 mg), which was crystallized as has been described above and identified with the above monoacetate by a mixed-melting-point determination.

Hydrogenation of Petasitol (2). Petasitol, **2** (95 mg), was hydrogenated with 10% palladium charcoal (40 mg) in ethanol (3 ml). After the hydrogen-uptake (2 mol, 1 h) had ceased, the filtrate was evaporated *in vacuo* to furnish an oil (93 mg). The residue was chromatographed on silica gel (10 g), after which elution with benzene–ethyl acetate (15: 1) gave a viscous oil (74 mg) as a single spot on TLC (R_f, 0.56; benzene–ethyl acetate, 5: 1).

The above oil (60 mg) was refluxed with a catalytic amount of sodium under a nitrogen atmosphere in methanol for 2.5 h. After working-up as usual, the crystalline product (**5**) (63 mg) was crystallized from light petrolcum as leaflets; mp 103.0—103.5 °C, $[\alpha]_D^{22}$ +39.2 ° (*c*, 2.56, MeOH).

Found: C, 75.50; H, 11.05%. Calcd for $C_{15}H_{26}O_2$: C, 75.58; H, 11.00%.

The 2,4-dinitrophenylhydrazone was prepared in the usual manner and then crystallized from ethanol as yellow needles; mp 165.5—167.0 °C.

Found: C, 60.18; H, 7.14; N, 13.48%. Calcd for $C_{21}H_{30}O_5N_4$: C, 60.27; H, 7.23; N, 13.39%.

The semicarbazone was prepared in the usual manner and crystallized from methanol as needles; mp 188.0—189.5 °C.

Found: C, 65.06; H, 10.00; N, 13.95%. Calcd for $C_{16}H_{29}O_2N_3$: C, 65.05; H, 9.90; N, 14.23%.

The above substance and its derivatives were found by a mixed-melting-point determination and a comparison of the spectra, to be identical in all respects with those[3] of tetrahydroisopetasol (**5**) obtained from isopetasin (**12**).

Dehydration of Monoacetate (3). Monoacetate, **3** (550 mg), in pyridine (10 ml) was treated with phosphoryl chloride (10 ml) at room temperature for 44 h. The reaction mixture was then poured onto ice and extracted with ether. The extract was washed successively with a saturated sodium hydrogencarbonate solution and water. The dried solvent was removed to give a crude product (330 mg), which was then chromatographed on silica gel (30 g). Elution with benzene–ethyl acetate (50: 1) afforded the anhydro derivative (**6**) (145 mg) as an oil; MS: *m/e* 274 M^+, *m/e* 84 base peak; IR (film): 3080, 3040, 1737, 1664, 1637, 1242, 920 cm^{-1}; UV: λ_{max}^{EtOH} 240 nm (ε, 12500), ε, 9800/220 nm; NMR ($CDCl_3$): 6.82 (s, 6-H), 6.04 (t, J=1.0 Hz, 9-H), 5.11 (d, J=7.0 Hz, 12-C=CH_2), 4.87 (m, $W_{1/2}$=14 Hz, 3-H), 2.06 (s, AcO), 1.97 (d, J=1.0 Hz, 13-Me), 1.22 (s, 15-Me), 1.10 (d, J=7.0 Hz, 14-Me).

Hydrogenation of Anhydromonoacetate (6). Anhydroacetate, **6** (122 mg), in ethanol (3 ml) was hydrogenated with 10% palladium charcoal (23 mg). Hydrogen-uptake ceased after 10 h. The filtrate was evaporated *in vacuo* to leave an oil (137 mg). The residue (103 mg) was refluxed in methanol (4 ml) with sodium metal (28 mg) under a nitrogen atmosphere for 3 h. Working-up as usual gave a product (94 mg) which was chromatographed on silica gel (6 g) with benzene–ethyl acetate (5: 1) and then crystallized from aqueous ethanol as leaflets (mp 101.0—103.0 °C). This was found to be identical with tetrahydroisopetasol (**5**) by a mixed-melting-point determination and a comparison of the IR spectra.

Isomerization of Tetrahydroisopetasol (5) with a Base. Isopetasol, **11** (3.03 g), in ethanol (45 ml) was hydrogenated with 10% palladium charcoal (600 mg) at room temperature for 6 h. The subsequent working-up as usual gave a viscous oil, which was then chromatographed on silica gel (64 g). Elution with benzene–ethyl acetate (20: 1) gave tetrahydroisopetasol (**5a**) (3.01 g) as a colorless oil; $[\alpha]_D^{24}$ −19.1° (*c*, 1.26, MeOH); IR (film): 3380, 1695, 1380, 1360, 1020 cm^{-1}; ORD (*c*, 0.1025, MeOH): $[\phi]_{391}$ 0, $[\phi]_{325}$ −600, $[\phi]_{307}$ −1160 (trough), $[\phi]_{289}$ 0, $[\phi]_{265}$ +1330; CD (*c*, 0.1025, MeOH): Fig. 1; NMR ($CDCl_3$): 3.58 (m, $W_{1/2}$=18 Hz, 3-H), 1.08 (s, 15-Me), 0.98 and 0.88 (each d, J=7.0 Hz, 12- and 13-Me), 0.82 (d, J=6.5 Hz, 14-Me).

The above product (3.01 g) was dissolved in methanol (10 ml) and refluxed with 0.2 M potassium hydroxide–methanol (40 ml) under a nitrogen atmosphere for 5 h. The subsequent working-up as noted above gave a partially crystallized product, which was crystallized from ethyl acetate to afford tetrahydroisopetasol (**5**)[3] as leaflets; mp 103.0—104.0

°C, $[\alpha]_D^{25}$ +34.3° (*c*, 1.01, MeOH); IR (CCl_4): 3610, 3450, 1720, 1390, 1375, 1035 cm^{-1}; ORD (*c*, 0.0937, MeOH): $[\phi]_{375}$ +200, $[\phi]_{325}$ +330, $[\phi]_{288}$ +710, $[\phi]_{275}$ +530, $[\phi]_{258}$ +380, $[\phi]_{225}$ +1040; CD (*c*, 0.0937, MeOH): Fig. 1; NMR ($CDCl_3$): 3.53 (m, $W_{1/2}$=18 Hz, 3-H), 1.01 and 0.83 (each d, J=7.0 Hz, 12- and 13-Me), 0.93 (s, 15-Me), 0.91 (d, J=6.0 Hz, 14-Me).

Hydrogenation of Monoacetate (3). Monoacetate, **3** (1.03 g), was dissolved in ether (30 ml) and hydrogenated with Adams' catalyst (111 mg). Hydrogen-uptake (2.2 mol) ceased after 30 min. Working-up as usual gave a crude product, which was chromatographed on silica gel (22 g) with benzene–ethyl acetate (10: 1) to afford the tetrahydro compound (**7**) (687 mg) (mp 92.0—95.0 °C) as needles (from light petroleum); IR (KBr): 3490, 1710, 1263 cm^{-1}; IR (CCl_4): 3500, 1735, 1700, 1240 cm^{-1}; NMR ($CDCl_3$): 4.81 (m, 3-H), 4.28 (br s, OH), 2.05 (s, AcO), 1.23 (s, 12- and 13-Me), 1.18 (s, 15-Me), 0.95 (d, J=7.0 Hz, 14-Me).

Found: C, 68.89; H, 9.57%. Calcd for $C_{17}H_{28}O_4$: C, 68.89; H, 9.52%.

Dehydration of Tetrahydromonoacetate (7). The above product, **7** (565 mg), was treated with pyridine (8 ml) and phosphoryl chloride (6.5 ml) at room temperature for 20 h. Working-up as usual gave a mixture of a dehydration product (**8**) (438 mg); IR (film): 1735, 1717 (sh), 1687 (sh), 1645, 1633, 1245 cm^{-1}.

The above product, **8** (430 mg), was chromatographed on alumina (10 g); subsequent elution with light petroleum–ethyl acetate (50: 1) gave a sole product (**9**) (360 mg); IR (film): 1735, 1682, 1630, 1240 cm^{-1}; UV: λ_{max}^{EtOH} 251 nm (ε, 5160); NMR ($CDCl_3$): 4.80 (m, 3-H), 2.05 (s, AcO), 1.98 and 1.81 (each s, 12- and 13-Me), 1.04 (s, 15-Me), 0.90 (d, J=7.0 Hz, 14-Me).

The 2,4-dinitrophenylhydrazone was prepared as usual and crystallized from ethanol (mp 168 °C) as deep red needles.

Found: N, 12.54%. Calcd for $C_{23}H_{30}O_6N_4$: N, 12.22%.

Dehydrogenation of Unsaturated Monoacetate (9). Into a stirred solution of the acetate, **9** (320 mg), and DDQ (2,3-dichloro-5,6-dicyano-*p*-benzoquinone) (292 mg) in dry dioxane (4 ml) anhydrous hydrogen chloride was bubbled at room temperature over a 30-s period. After further stirring for 40 min, crystals were separated, after which the stirring was continued for 8 h. After subsequent filtration and concentration, the residue was diluted with ether, washed successively with a 1% aqueous sodium hydroxide solution and water, and dried over anhydrous sodium sulfate. The removal of the solvent gave a product (290 mg) which was later chromatographed on silica gel (8 g). Elution with benzene gave a fraction (R_f, 0.35; benzene–ethyl acetate, 10: 1) which was subsequently crystallized from aqueous methanol to afford a pure acetate (**10**) as prisms; mp 82.0—85.0 °C; IR (Nujol): 1735, 1662, 1630, 1245 cm^{-1}; IR (CCl_4): 1740, 1666, 1631, 1244 cm^{-1}; UV: λ_{max}^{EtOH} 242 nm (ε, 7550), 278 (sh) nm (ε, 2900). This was found to be identical with the isopetasol acetate (**10**) converted from isopetasol (**11**) by a mixed-melting-point determination and a comparison of the IR spectra.

Acetylation of Isopetasol (11).[3] Isopetasol, **11** (106 mg), was acetylated with pyridine (1 ml) and acetic anhydride (0.5 ml). A subsequent working-up in the usual manner afforded the acetate (**10**) (98 mg), which was subsequently crystallized from aqueous methanol as prisms; mp 86.0—87.0 °C, $[\alpha]_D^{25}$ +80° (*c*, 0.97, $CHCl_3$); IR (KBr): 1735, 1660, 1630, 1245 cm^{-1}; IR (CCl_4): 1740, 1660, 1630, 1245 cm^{-1}; UV: λ_{max}^{EtOH} 243 nm (ε, 8400), 278 (sh) nm (ε, 3100); NMR (CCl_4): 5.65 (d, J=1.0 Hz, 9-H), 4.76 (sex, J=12.0, 10.0, and 5.0 Hz, $W_{1/2}$=16 Hz, 3-H), 2.04 (s, 12-Me), 2.01 (s, AcO), 1.83 (s, 13-Me), 1.04 (s, 15-Me), 0.95 (d, J=6.0 Hz, 14-Me).

Found: C, 73.70; H, 8.79%. Calcd for $C_{17}H_{24}O_3$: C, 73.88; H, 8.75%.

Preparation of Petasitin (1). A stirred solution of isopetasin (**15**)[3] (1.0 g) and Rose Bengal (5 mg) in absolute methanol was irradiated with a circular fluorescent lamp (30 watt) for 36 h under the bubbling of air. The reaction mixture was then stirred with a solution of sodium sulfite (2.5 g) in water (15 ml) for 3 h. After the removal of the solvent, the residue was extracted with ether. The subsequent working-up in the usual manner gave a crude product, which was chromatographed over silica gel (20 g). Elution with benzene afforded petasitin (**1**) (430 mg), which was found to be identical with the natural specimen by a comparison of the spectral data (IR and NMR) and by GLC analysis under the conditions described above. The other products were not investigated further.

The authors wish to thank the staff of the Shionogi Research Laboratory, Shionogi and Co., Ltd., for the microanalysis and the Institute of Food Chemistry for the measurement of the MS and NMR spectra. The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Nucleophilic Behavior of the Phenyl Radical in the Hydrogen Abstraction Reaction from Substituted Toluenes. A Contribution to the Study of the Phenyldiazenyl Radical

Tadashi SUEHIRO, Akira SUZUKI, Yasuyoshi TSUCHIDA, and Junji YAMAZAKI

Department of Chemistry, Faculty of Sciences, Gakushuin University, Mejiro, Toshimaku, Tokyo 171

(Received May 6, 1977)

Phenyl radicals derived from benzoyl peroxide (BPO) showed nucleophilic behavior, rho=+0.18 (meta-series) for the hydrogen abstraction reaction from substituted toluenes at 80 °C, and a kinetic deuterium isotope effect, $k_H/k_D=3.73\pm0.2$, was found for toluene. Comparison of these results with those for the phenyl radicals from phenylazotriphenylmethane (PAT) leads to the suggestion that the phenyldiazenyl radicals derived from PAT abstract hydrogen from toluene to yield benzene, which should amount to about 50% of the total benzene formed.

Phenyl radicals have been reported to be electrophilic in hydrogen abstraction reactions based on the results of investigations using phenylazotriphenylmethane (PAT) as the source of the phenyl radicals.[1,2] The phenyl radicals derived from PAT behave, however, differently from those generated from benzoyl peroxide (BPO), as revealed by the fact that the yields of benzene in the thermolysis of PAT in toluene at 60—70 °C, 50—58% per mole PAT,[3,4] are markedly larger than that of BPO, 32% per mole phenyl radicals,[4] in contrast to the very similar yields of methylbiphenyls in both cases, 25% for PAT and 23% for BPO.[4] Appreciable amounts of phenyl radicals from BPO are transformed into esters and quarterphenyls, which are not accounted for in the above measurements. This does not, however, affect the conclusion that the "phenyl" radicals from PAT produce much more benzene in toluene than do those from BPO.

In the thermolysis of PAT, the triphenylmethyl-nitrogen bond dissociates at first to give triphenylmethyl and phenyldiazenyl radicals in a cage.[5] Although the reaction of phenyldiazenyl radicals out of the "cage" is not clear as yet, the hydrogen abstraction reaction of the radicals from toluenes would lead to phenyldiazene, which is known to produce benzene in good yields upon thermal decomposition.[6] PAT could thus receive the cooperation of phenyldiazenyl radicals in the formation of benzene. When the reactions of phenyldiazenyl radicals proceed, the polarity of the "phenyl" radical deduced from the experiments on PAT should be different from that obtained from reactions using BPO, because in the latter studies the precursors of phenyl radicals, benzoyloxy radicals, are converted into benzoic acid upon hydrogen abstraction and can be separated completely from benzene. The intrinsic behavior of the phenyl radicals in the hydrogen abstraction reaction can only be determined using BPO as the radical source.

Results and Discussion

The polar nature of phenyl radicals was determined by the reactivities of substituted toluenes toward phenyl radicals. For the measurement of the reactivities of toluenes, competitive reactions of BPO (4.13 mmol) were carried out at 80 °C between each 100 mmol of a substituted toluene and carbon tetrachloride in a nitrogen atmosphere. Relative rate constants, k_H/k_{Cl}, of Reactions 1 and 2,

$$ArCH_3 + Ph\cdot \xrightarrow{k_H} PhH + ArCH_2\cdot, \quad (1)$$

$$CCl_4 + Ph\cdot \xrightarrow{k_{Cl}} PhCl + Cl_3C\cdot, \quad (2)$$

were calculated from the yields of benzene and chlorobenzene with proper corrections, as described below. Duplicate runs afforded the rate ratios listed in Table 1 and the Hammett plot shown in Fig. 1.

Table 1. Rates of hydrogen abstraction from toluenes relative to chlorine abstraction from carbon tetrachloride at 80 °C

$XC_6H_4CH_3$ X=	k_H/k_{Cl}	$XC_6H_4CH_3$ X=	k_H/k_{Cl}
m-$(CH_3)_2$	0.214±0.046	*p*-CH_3O	0.389±0.09
H	0.210±0.055	*p*-CH_3	0.270±0.035
m-Cl	0.288±0.055	*p*-Cl	0.277±0.054
m-CN	0.220±0.042	*p*-CN	0.265±0.051
m-NO_2	0.332±0.075	*p*-NO_2	0.646±0.11

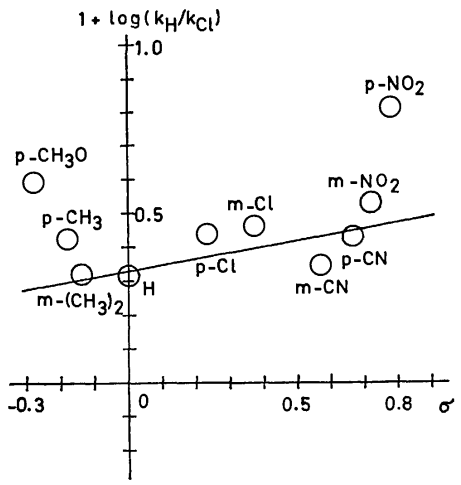

Fig. 1. Hammett plot of rates of hydrogen abstraction by phenyl radicals from toluenes relative to rates of chlorine abstraction from carbon tetrachloride.

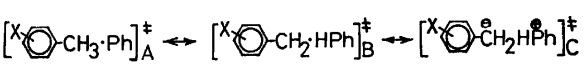
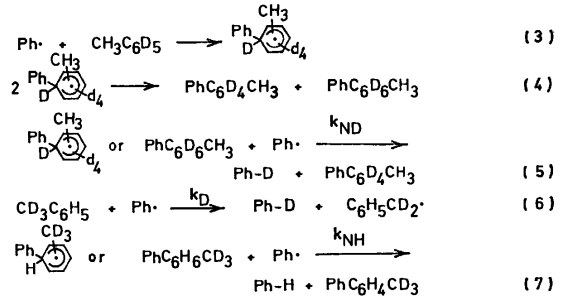
The polar character of the phenyl radicals obtained from the results of meta-substituted toluenes was slightly nucleophilic, rho=+0.18, in contrast to the results of earlier reports, −0.1,[1] −0.4,[2] and −0.5.[7] The reactivities of para-substituted toluenes are larger than the values expected from the rates of the meta-series. Definite extra resonances are operative in the transition

state of the hydrogen abstraction reaction and they are especially effective in the cases of *p*-nitro- and *p*-methoxytoluenes. The effect of the extra resonances play an important role in the manifestation of B.



In the calculation of the rate ratios, the following were taken into consideration. Phenyl radicals from BPO can also take up hydrogen from the aromatic ring of a substrate molecule during the course of homolytic phenylation. Because the homolytic phenylation by BPO proceeds by means of the disproportionation reaction *via* substituted phenylcyclohexadienyl radicals,[8] and an appreciable amount of dihydrobiaryls are formed, phenyl radicals can abstract hydrogen from the cyclohexadienyl radicals and from dihydrobiaryls.



The extent of Reactions 5 and 7 can be estimated by examining benzene and deuteriobenzene formed from experiments using toluene-nuclear-d_5 and toluene-α-s_3 as the substrate, together with rate ratios ($k_{\text{total benzene}}/k_{\text{Cl}}$) for the toluene–carbon tetrachloride and toluene-α-d_3–carbon tetrachloride systems.[9]

From the reaction using toluene-d_5 (d_5-fraction 90.3 %), the ratio C_6H_6: C_6H_5D=93.8: 6.2 was obtained for the benzene formed. For the benzene formed from toluene-α-d_3 (d_3-fraction 90.0%), the ratio C_6H_6: C_6H_5D =54.5: 45.5 was found. The kinetic deuterium isotope effect for Reactions 7 and 5 ($k_{\text{NH}}/k_{\text{ND}}$) was calculated to be 2.97, and the hydrogen abstraction reaction at the nuclear positions (k_{NH}) contributes *ca.* 10% of the total formation of benzene.

It is tentatively assumed, that the participation of nuclear hydrogen in the formation of benzene in the system containing substituted toluenes is proportional to the rates of phenylation of the substituted toluenes, and that the rates of phenylation can be estimated using partial rate factors for phenylation.[10] The rates of phenylation of substituted toluenes (R_X) relative to that of toluene were calculated to be as follows:

R_X:	*p*-MeO	1.13	*p*-Me	1.01	*m*-Me 1.01
	p-Cl	1.19	*m*-Cl	1.03	*p*-CN 1.96
	m-CN	2.04	*p*-NO_2	2.02	*m*-NO_2 2.13

Measurements on benzene using GLPC for competitive reactions were corrected by substracting from them the amounts of benzene formed from the nuclear hydrogen by phenyl radicals:

$$(\text{benzene})_{\text{corr}} = (\text{benzene})_{\text{total}} \cdot (1 - \text{Corr})$$

$$\text{Corr}_{\text{toluene}} = 0.10.$$

Similarly, the corrections for X-substituted toluenes are

$$\text{Corr}_{\text{X-toluene}} = R_X \cdot \text{Corr}_{\text{toluene}} = 0.10 \cdot R_X.$$

The values in Table 1 have been corrected in this manner.

The effect of the methoxyl substituent of methoxytoluene in the formation of benzene was checked using the isotope tracer technique with *p*-deuteriomethoxytoluene as the substrate. For the benzene formed, a molar ratio C_6H_6: C_6H_5D of 92.3: 7.7 was found. The corrected value is listed in the table. The benzene from the methoxyl group amounts to about 33% of the total benzene formed.

The difference in the polar nature of the phenyl radical found here (+0.18) from that of Trosman and Bagdasar'yan[7] (−0.5) arises from different experimental conditions. The determination of benzene separately from one by-product, chloroform, is one of the key points in the present study. The column used by Bridger and Russell[1] was found to be unsuccessful in this laboratory. A 2-m column of ODPN (20% on C-22 AW), in combination with a 1-m column of Apiezon Grease L (25% on C-22 AW) was used at 80 °C with helium as the carrier gas. Much more chloroform was formed than benzene, when toluenes with electron-donating groups were used as the substrate. The rate ratios $k_{\text{H}}/k_{\text{Cl}}$ found for nitrotoluene by Trosman and Bagdasar'yan[7] 0.80 for para- and 0.475 for meta-compounds, gave 0.64 and 0.36 after the correction described above, which are in good accord with the present values of 0.646 and 0.332. Their values of the rate ratios for toluene and xylenes are by far larger than the present values.

The slightly nucleophilic nature of the phenyl radical for the hydrogen abstraction reaction in the present findings is in very good agreement with the results reported by Ito *et al.* for homolytic phenylation (rho= +0.05),[10] and with the results reported by Migita *et al.* for bromine abstraction from substituted benzyl bromides (rho=+0.15 for meta-series).[11] Thus, a parallel relationship in the polar nature of phenyl radicals was established between the addition reaction to benzene nuclei and the abstraction reaction from benzylic compounds.

The kinetic deuterium isotope effect was found to be 3.73±0.2. This is a little smaller than the value, 4.5± 0.5, found by Bridger and Russell.[1]

The nucleophilic nature of phenyl radicals from BPO for the hydrogen abstraction reaction contrary to the electrophilic radicals from PAT, suggests the coexistence of phenyldiazenyl radicals together with phenyl radicals in the thermolysis of PAT. In measuring the electrophilicity of phenyldiazenyl radicals, amino radicals should be taken as a reference. For example dimethylamino radicals are reported to be electrophilic for hydrogen abstraction from toluenes: rho=−1.08 (sigma plus) and $k_{\text{H}}/k_{\text{D}}$=4.0 at 130 °C.[12] Diphenylmethyleneamino radicals were also found to be electrophilic (rho=*ca.* −2.5).[13] Phenyldiazenyl radicals are, therefore, probably electrophilic in the abstraction of hydrogen from toluenes. Based on these assumptions, the results of Bridger and Russell[1] and Pryor *et al.*[2] appear to be explainable.

Another electrophilic property of particular radicals, X·, derived from PAT were also found for hydrogen abstraction from solvent molecule toluenes giving benzyl radicals during the thermolysis of PAT. The relative rates of formation of benzyl and substituted benzyl radicals, $k_{ArCH_2\cdot}/k_{PhCH_2\cdot}$, were measured by determining the amount of 1-aryl-2,2,2-triphenylethane, which was isolated by column chromatography in a 66% yield per mole of benzene as determined by GLPC. Because a fairly large amount of triphenylmethyl radicals were present in solution during the PAT thermolysis, it appears plausible to assume that the radical-scavenging step is effective, so that hydrogen abstraction is rate determining in the reaction,

$$ArCH_3 \xrightarrow{X\cdot} ArCH_2\cdot \xrightarrow{Ph_3C\cdot} ArCH_2CPh_3. \quad (8)$$

A mixture of aryltriphenylethanes from a competitive reaction mixture was obtained by column chromatography and analyzed using NMR or the ^{14}C-tracer technique. The rate ratios, $k_{ArCH_2\cdot}/k_{PhCH_2\cdot}$, are listed in Table 2. A Hammett plot is shown in Fig. 2. The polar nature of particular free radicals, X·, derived from PAT in the formation of benzyl radicals at 50 °C was electrophilic (rho=−0.49 (sigma plus)). The results are in good accord with those of Pryor *et al.* for the hydrogen abstraction reaction.[2)]

TABLE 2. RELATIVE RATE OF FORMATION OF SUBSTITUTED BENZYL RADICALS, $k_{ArCH_2\cdot}/k_{PhCH_2\cdot}$, BY PAT AT 50 °C

Substrate	Chemical shift of CH_2 in $ArCH_2CPh_3$ in pyridine (δ)	$k_{ArCH_2\cdot}/k_{PhCH_2\cdot}$
p-Methoxytoluene[a)]	4.05	3.52
p-Xylene	4.05	1.46[b)]
Toluene	4.05	1.00
p-Chlorotoluene	4.10	0.67
m-Chlorotoluene	3.98	0.79
p-Nitrotoluene	4.10	0.65

a) Measured by the ^{14}C-tracer technique. b) Corrected per methyl group.

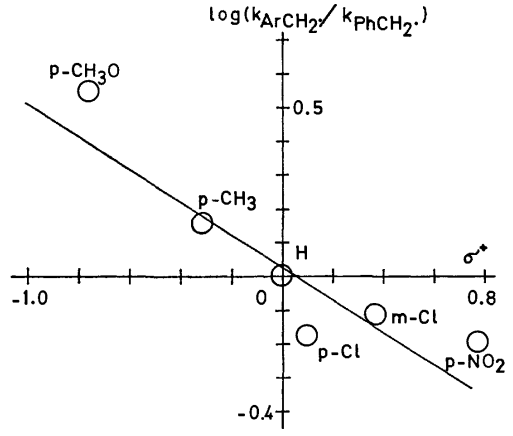


Fig. 2. Hammett plot (against sigma plus) of formation of substituted benzyl radicals from toluenes through hydrogen abstraction by particular radicals derived from PAT.

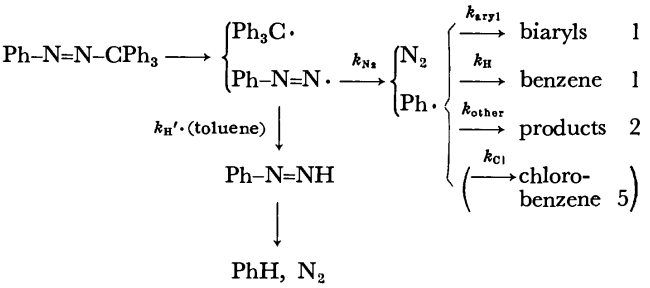
Assuming the phenyldiazenyl radical as the intermediate, the reaction scheme for thermolysis of PAT in toluene at 60 °C can be formulated as follows:



Scheme 1.

The reactions of phenyl radicals (k_{aryl}, k_H, and k_{other}) should be referred to the results of BPO, *i.e.*, the rate ratios with respect to each other are *ca.* 1 : 1 : 2 at 80 °C, and k_{N_2} is rate-determining. Because the benzene yield per mole of PAT is about twice that of BPO (Table 4), the rate, k_{N_2}, is about four times as large as the rate of hydrogen abstraction of phenyldiazenyl radicals, k_H'· (toluene). This gives $k_{N_2}=40\cdot k_H'$, using a toluene concentration of 10 M. When carbon tetrachloride is present as a co-solvent, k_{Cl} should also be taken into consideration and was about five times as large as k_H, because the k_H/k_{Cl} found was 0.210.

TABLE 3. CALCULATED RATE RATIOS, $k_{benzene}/k_{Cl}$ FOR THERMOLYSIS OF PAT IN TOLUENE–CARBON TETRACHLORIDE

Substrate	$k_{benzene}/k_{Cl}$
p-Methoxytoluene	2.80
p-Xylene	1.36
Toluene	1.00
p-Chlorotoluene	0.75
p-Cyanotoluene	0.68
p-Nitrotoluene	0.68

Based on this scheme, setting k_{N_2}, k_{Cl}, and k_{other} constant, the rho value for k_H to +0.18, the rho for k_H' to −2.5,[13)] and k_{aryl} proportional to R_x, as described previously, we can estimate the rate ratios, $k_{benzene}/k_{Cl}$, as shown in Table 3. These results are in very good agreement with the results shown in Table 2 and also with the results of Bridger and Russell[1)] and of Pryor *et al.*[2)] The data for PAT may thus be interpreted in terms of phenyldiazenyl and phenyl radicals.

Experimental

Gas Chromatographic Determination of Benzene and Chlorobenzene. Benzene and chlorobenzene were measured with apparatus of the KGL-2A (HITACHI) and JGC-1100 (JEOL) types using a 2-m column of ODPN (20% on C-22 AW) connected to a 1-m column of Apiezon Grease L (25% on C-22 AW), with the He carrier gas flowing at a rate of 90 ml/min at 80 °C. For the determination of chlorobenzene, only a 2-m column of ODPN was used with He at a flow rate of 150 ml/min at 80 °C. Their internal standard was selected from toluene, *p*-xylene, and *o*-xylene according to the reaction mixture.

Yields of Benzene and Methylbiphenyls. The benzene and methylbiphenyls yields from the thermolysis of PAT and BPO in toluene were determined by GLPC (Table 4).

Competitive Reactions in the Substituted Toluene–Carbon Tetrachloride System. Benzoyl peroxide (4.13 mmol) was dissolved in a mixture of 100 mmol each of carbon tetrachloride and substituted toluene in a nitrogen atmosphere and heated for 42 h at 80±1.0 °C.

The reaction mixture was distilled with steam after a certain amount of mesitylene had been added to the mixture to assure the separation of chlorobenzene from high-boiling products. When nitrotoluenes were subjected to competitive reactions, the distillate was treated with a stannous chloride-concd. hydrochloric acid mixture to remove the nitro-compound. The purified distillates were subjected to GLPC determinations of benzene and chlorobenzene.

GC-MS Spectrometry. Mass spectrometric measurements were made on an apparatus of the LKB-9000 (SHIMADZU) type for a) the deuterated benzene formed, b) toluene-α-d_3, c) toluene-d_5, and d) *p*-deuteriomethoxytoluene.

a) The determination of the deuteriobenzene formed from the substrates, deuteriotoluene and deuteriomethoxytoluene, was made at 14 eV using a 3-m column of Apiezon Grease L on Chromosorb W (AW) at 42 °C. The He flow rate was 60 ml/min.

b) Toluene-α-d_3 was prepared by reduction of benzylidyne trichloride with a zinc dust–acetic acid-*d* solution according to the method of Renaud and Leitch.[14] The fraction of toluene-α-d_3 was found to be 90.0% at 12 eV.

c) Toluene-d_5 from Merk, Sharp and Dohme, Canada, Ltd., was used for the studies. The sample contained a 90.3% fraction of toluene-d_5 measured at 12 eV. Toluene-d_6 was present in a 2.3% fraction.

d) *p*-Methoxy-d_3-toluene was prepared from *p*-cresol and dimethyl-d_6 sulfate. Its boiling point was 80.5 °C at 37 Torr. The fraction of trideuteriomethoxytoluene was determined at 12 eV to be 98.1%.

Evaluation of Kinetic Deuterium Isotope Effects on Hydrogen Abstraction from the Methyl Group of Toluene, the Fraction of Hydrogen Abstraction from the Nuclear Position of Toluene, and the Fraction of Hydrogen Abstraction from the Methoxyl Group of p-*Methoxytoluene.* Kinetic deuterium isotope effect, (k_H/k_D), the relative rate of abstraction from the nuclear position, (k_{NH}/k_H) ((nuclear-H)/(toluene)), and the relative rate of abstraction from the methoxyl group of *p*-methoxytoluene, (k_{O-CH_3}/k_H), were evaluated using the following equations:

$$\frac{k_H(CH_3)+k_{NH}(n\text{-}H)}{k_D(CD_3)+k_{ND}(n\text{-}D)} = \frac{93.8}{6.2} \quad (9)$$

for benzene from toluene-d_5,

$$\frac{k_H(CH_3)+k_{NH}(n\text{-}H)}{k_D(CD_3)} = \frac{54.5}{45.5} \quad (10)$$

for benzene from toluene-d_3,

$$\frac{k_H(CH_3)+k_{NH}(n\text{-}H)}{k_D(CD_3)+k_{NH}(n\text{-}H)+k_H(CH_3)} = 2.91, \quad (11)$$

for the ratio of the rate ratios, $k_{toluene}/k_{Cl}$ and $k_{toluene\text{-}d_3}/k_{Cl}$,

$$\frac{k_H(CH_3)+k_{NH}(n\text{-}H)+k_{O\text{-}CH_3}(O\text{–}CH_3)}{k_{O\text{-}CD_3}(O\text{–}CD_3)} = \frac{92.3}{7.7}, \quad (12)$$

for benzene from methoxy-d_3-toluene, and

$$\frac{k_H(CH_3)+k_{NH}(n\text{-}H)+k_{O\text{-}CH_3}(O\text{–}CH_3)}{k_H(CH_3)+k_{NH}(n\text{-}H)+k_{O\text{-}CH_3}(O\text{–}CH_3)+k_{O\text{-}CD_3}(O\text{–}CD_3)} = 1.35, \quad (13)$$

for the ratio of the rate ratios, $k_{methoxytoluene}/k_{Cl}$ and $k_{methoxy\text{-}d_3\text{-}toluene}/k_{Cl}$,

here (CH_3), (CD_3), (n-H), (n-D), $(O\text{–}CH_3)$, and $(O\text{–}CD_3)$ denote the concentrations for the CH_3 and CD_3 groups of toluene or methoxytoluene, the nuclear-hydrogen and nuclear deuterium atoms of toluene or methoxytoluene, and the methoxyl group and deuteriomethoxyl groups of methoxytoluene, respectively. k_x represents the rate constants for hydrogen abstraction from the corresponding groups. The nuclear hydrogen concentrations were expressed by the yields of the biaryls formed during the thermolysis of BPO (4 mmol) in 200 mmol of toluene, *i.e.*, 1.43 mmol (n-H) in 200 mmol of toluene.

We obtain from Eqs. 9, 10, and 11, the following results:

$$k_H/k_D = 3.73\pm0.2, \quad k_{NH}/k_H = 17.6.$$

Using the same k_{NH} for Eqs. 12 and 13, as for Eqs. 9—11, we obtain

$$k_H/k_{O\text{-}CH_3} = 2.07\pm0.02.$$

The participation of the nuclear hydrogen of toluene in the hydrogen abstraction reaction was found from (k_{NH}/k_H) ((n-H)/(CH_3)) to be 0.125, *i.e.*, about 10% of the benzene was formed from nuclear hydrogen. The participation of the methoxyl group of methoxytoluene in the benzene formation is about 33%.

^{14}C-Tracer Experiments. Triphenylmethanol-α-^{14}C was prepared from benzoate-carbonyl-^{14}C by the Grignard reaction and its specific activity was measured. ^{14}C-PAT was derived from triphenylmethanol-^{14}C and used for thermolysis without dilution.

^{14}C-PAT (13.5 mmol) was heated to 50 °C in nitrogen in a mixture of toluene and *p*-methoxytoluene (a) 1: 1, b) 2: 1, total 3.0 mmol) and treated according to the standard dilution method.

a) The reaction mixture was divided into two equal parts and to each of them was added 1.00 g of unlabelled $PhCH_2CPh_3$ or $CH_3OC_6H_4CH_2CPh_3$.

b) The reaction mixture was divided into two parts in a 2: 1 volume ratio, and to each was added 1.00 g of unlabelled $PhCH_2CPh_3$ or $CH_3OC_6H_4CH_2CPh_3$. The results were as follows:

Radioactivity (dpm/mg)

	Starting Ph_3COH	Isolated $CH_3OC_6H_4$-CH_2CPh_3	Isolated $PhCH_2CPh_3$	k_{ArCH_3}/k_{PhCH_3}
a)	4080	559.5	191.8	3.48
b)	4080	313.3	357.8	3.56
			av.	3.52

The radioactivity was measured using a scintillation counter of the Beckman LS-200 type. The NMR spectra were recorded on Varian A-60 instrument, with TMS as the internal standard.

For the radio assay, we are grateful to Dr. N. Morikawa of the University of Tokyo.

Phenanthro[4,5-*bcd*]furan Derivatives. IV. A Synthesis of Phenanthro[4,5-*bcd*]furan

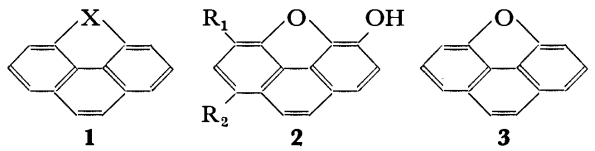
Takaaki HORAGUCHI

Department of Chemistry, Faculty of Science, Niigata University, Ikarashi, Niigata 950-21

(Received May 6, 1977)

Phenanthro[4,5-*bcd*]furan was synthesized from 1,2,3,8,9,9a-hexahydrophenanthro[4,5-*bcd*]furan-3-ol by dehydrogenation with palladium–charcoal. Some chemical reactivities and spectral properties of phenanthro[4,5-*bcd*]furan were investigated and compared with those of phenantherene and dibenzofuran. The results suggest that phenanthro[4,5-*bcd*]furan has the chemical properties of both phenanthrene and dibenzofuran, and does not have a large strain in the fused-ring system. Also, the reactivities of 1,2,3,8,9,9a-hexahydrophenanthro[4,5-*bcd*]furan-3-one were explored.

Compounds such as Formula **1** have bridged atoms (C, N, S, O) which link the 4 and 5-positions in phenanthrene. The synthetic methods of these compounds except for X=O were early reported in the literature.



1 **2** **3**

1a: X=C
1b: X=N
1c: X=S
1d: X=O(**3**)

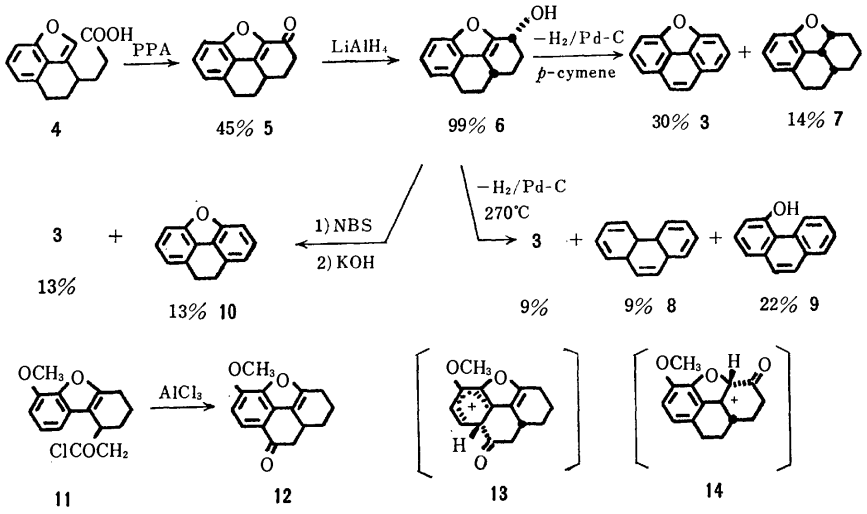
For example, phenanthro[4,5-*bcd*]thiophene (**1c**; X=S)[1] was prepared by heating phenanthrene with hydrogen sulfide at 630 °C in the presence of an alumina–chromia–magnesia catalyst. Also, phenanthro[4,5-*bcd*]-pyrrole (**1b**; X=N)[2] was similarly obtained from 4-phenanthrylamine. On the other hand, when X was a carbon atom 4*H*-cyclopenta[*def*]phenanthrene (**1a**; X=C)[3] was synthesized by the intramolecular cyclization of 3-(1-acenaphthenyl)propionic acid, followed by the reduction of the carbonyl group and then dehydrogenation. In the case of X=O, Compound **3** is termed phenanthro[4,5-*bcd*]furan and is a fundamental skeleton of morphine. Though the syntheses of **2** ($R_1=R_2=H$; $R_1=OCH_3$, $R_2=H$; $R_1=H$, $R_2=OCH_3$)[4-6] have already reported by us, the fundamental skeleton (**3**) has not yet been synthesized. It is said that the ring system of **3** has an inherent strain because of ether linkage between the 4 and 5-positions in phenanthrene. Therefore, we attempted to prepare phenanthro[4,5-*bcd*]furan (**3**) and discussed the strain in the phenanthro-[4,5-*bcd*]furan ring by comparing the chemical reactivities and physical properties of **3** with those of phenanthrene, dibenzofuran, and other related compounds.

Results and Discussion

The synthesis of phenanthro[4,5-*bcd*]furan (**3**) was attempted in three ways; the routes are shown in Scheme 1. For the synthesis of **3** 1,2,3,8,9,9a-hexahydrophenanthro[4,5-*bcd*]furan-3-one (**5**)[4] was employed as an important intermediate. When **5** was reduced with lithium aluminum hydride, only one product, 1,2,3,8,-9,9a-hexahydrophenanthro[4,5-*bcd*]furan-3-ol (**6**), was obtained. Although the formation of diastereoisomers is possible by the attack of lithium aluminum hydride on the carbonyl group from both sides, it seems that only one-sided attack from the less hindered face occurred preferentially because of steric requirements. A similar asymmetric synthesis has been reported[7] in the reduction of 1-bromocodeine to codeine with lithium aluminum hydride. It appears that the structure of the alcohol is as is shown in Formula **6** judging from the molecular model and the NMR spectrum. The methine proton on a carbon atom at the 3-position of **6** has absorptions (multiplet) at δ 4.85—5.06, and the coupling pattern is similar to that of the methine proton on a carbon atom at the 3-position of **16** (*vide infra*). This suggests that the configurations of the two methine protons of **6** and **16** are the same.

By the dehydrogenation of **6** with palladium–charcoal in *p*-cymene, the desired phenanthro[4,5-*bcd*]furan (**3**) was obtained in a 30% yield, along with 1,2,3,3a,8,9,-9a,9b-octahydrophenanthro[4,5-*bcd*]furan (**7**; 14% yield). The structure of **3** was confirmed by the elemental analysis and by its spectral properties (see Experimental). When **6** was heated with palladium-charcoal without a solvent at 270 °C, three kinds of products were obtained; phenanthro[4,5-*bcd*]furan (**3**; 9%), phenanthrene (**8**; 9%), and 4-phenanthrol (**9**; 22%). As the separation of **3** and **8** was fairly difficult, the ratio was determined by gas chromatography. This suggests that the ether bridge is easy to cleave at a high temperature. The reaction of **6** with *N*-bromosuccinimide gave a mixture of two products after the elimination of hydrogen bromide with potassium hydroxide. The NMR spectrum of the mixture showed that it consisted of phenanthro[4,5-*bcd*]furan (**3**; 13% yield) and 8,9-dihydrophenanthro[4,5-*bcd*]furan (**10**; 13% yield). Therefore, in all three methods the yield of the aromatization of **6** was the best when it was carried out in *p*-cymene.

Dendy *et al.*[8] attempted to cyclize **11** to a phenanthro-[4,5-*bcd*]furan derivative (**12**) by means of a Friedel-Crafts reaction. However, the yields was very low, and so they abandoned the subsequent synthesis of morphenol (**2**; $R_1=R_2=H$). In the case of naphtho[1,8-*bc*]furan derivatives (**4**), the cyclization occurred easily to give **5** in good yields.[4] The structure of **5** and **12** are similar to each other; therefore, the ring strains of the two compounds seem almost the same, if present at all. In the Friedel-Crafts reaction (**11**→**12**) an sp^2

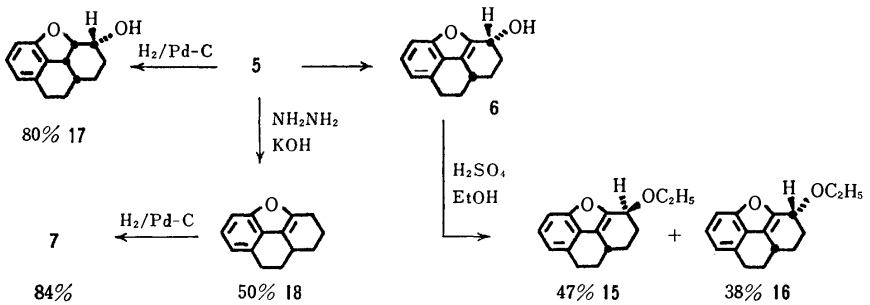


Scheme 1.

hybrid orbital of a carbon atom in the benzene ring must be changed to an sp^3 hybrid orbital in an intermediate, as is shown in Formula **13**. The consideration of a molecular model suggests that the conformation of the intermediate **13** must be cup-shaped and have a strain. On the other hand, in the case of **4** the cyclization occurs without a large deformation of the **4** molecule because the side chain of propionic acid is situated at a very favorable position for the cyclization reaction. From these consideration, it seems that the low yield of **12** is due to the strain in the intermediate, **13**, rather than to that in the product, **12**. If the carbon-carbon double bond in the furan ring of **11** is hydrogenated, the cyclization would become easy, for the side chain of acetic acid could closely approach the benzene ring.

Some chemical reactivities on **5** are shown in Scheme 2. Compound **6** dissolved in ethanol was converted to two products (**15** and **16**) by the action of sulfuric acid. The two products are diastereoisomers to each other, and the yields are 47 and 38% respectively. The structures of **15** and **16** were confirmed by comparing the NMR spectra with that of **6**. The catalytic hydrogenation of **5** with palladium–charcoal gave 1,2,3,3a,-8,9,9a,9b-octahydrophenanthro[4,5-*bcd*]furan-3-ol (**17**) in an 81% yield. The infrared spectrum of **17** shows an absorption due to a monomeric hydroxyl group at 3580 cm^{-1}. This suggests that a hydroxyl group is present in the cup-shaped molecule and that the juncture is all *cis*, as is shown in Formula **17**. By the Wolff-Kishner reduction of **5**, 1,2,3,8,9,9a-hexahydrophenanthro[4,5-*bcd*]furan (**18**) was obtained in a 50% yield. Compound **18** was hydrogenated with palladium–charcoal to give 1,2,3,3a,8,9,9a-octahydrophenanthro-[4,5-*bcd*]furan (**7**) in an 84% yield. The structure of **7** must be a *cis-cis* juncture, as is shown in Formula **7**, because **18** is easy to approach from the less-hindered face to the catalyst and the NMR spectrum of **7** is similar to that of **17**.

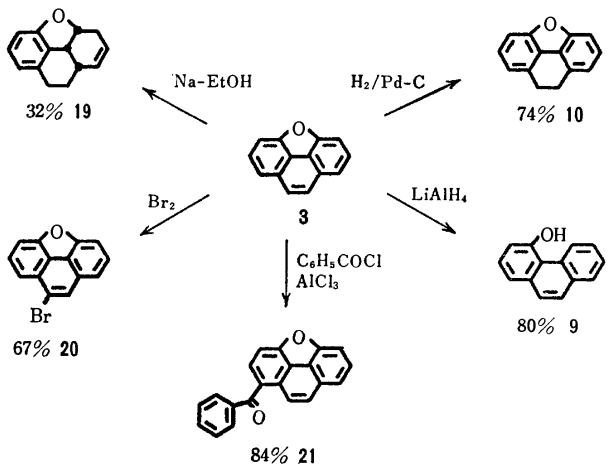
Some chemical reactivities of phenanthro[4,5-*bcd*]-furan (**3**) were investigated and compared with those of phenanthrene and dibenzofuran. The results are shown in Scheme 3. The catalytic hydrogenation of **3** with palladium–charcoal gave 8,9-dihydrophenanthro[4,5-*bcd*]furan (**10**) in a 74% yield. Under the same conditions, phenanthrene was not reduced, but it was hydrogenated to 9,10-dihydrophenanthrene under more drastic conditions (copper chromium oxide, 150—200 atm, 180 °C).[9] By the bromination of **3** with bromine, 8-bromophenanthro[4,5-*bcd*]furan (**20**) was obtained in a 67% yield. Also, phenanthrene was brominated to 9-bromophenanthrene.[12] However, the bromination of dibenzofuran gave 2-bromodibenzofuran.[13] These findings suggest that the 8,9-double bond of **3** has a considerable olefinic character and is more reactive than that in phenanthrene. When Compound **3** was heated with sodium and ethanol, 3,3a,8,9,9a,9b-hexahydrophenanthro[4,5-*bcd*]furan (**19**) was obtained in a 32% yield. Under these conditions dibenzofuran was reduced to 1,2,3,4-tetrahydrodibenzofuran,[10] but phenanthrene was not converted to 9,10-dihydro-



Scheme 2.

phenanthrene without the employment of sodium and 1-pentanol.[11] By the Friedel-Crafts reaction of **3** and benzoyl chloride with anhydrous aluminum chloride 1-benzoylphenanthro[4,5-*bcd*]furan (**21**) was obtained in an 84% yield. Under similar conditions, dibenzofuran also reacted with benzoyl chloride to give 2-benzoyldibenzofuran.[16] When **3** was treated with lithium aluminum hydride in dry ether, 4-phenanthrol (**9**) was obtained in an 80% yield. As the ether bridge in a five-membered ring is difficult to cleave with lithium aluminum hydride, the facile cleavage of the ether bridge may due to an inherent strain in the fused-ring system of **3**. In fact, dibenzofuran is not reduced under these conditions.

From these experimental results, it appears that phenanthro[4,5-*bcd*]furan has the character of both phenanthrene and dibenzofuran and is more reactive because of the ether bridge in the fused-ring system of **3**.



Scheme 3.

The ultraviolet spectrum of phenanthro[4,5-*bcd*]furan (**3**) is shown, along with that of pyrene[1] in Fig. 1. The shapes of the spectra of **3** and pyrene are very similar to each other, but the region of absorption for **3** is shifted to a shorter wavelength than that of pyrene. It is thus apparent that a non-bonding pair of electrons on the oxygen atom functions as part of the overall chromophoric π-system in phenanthro[4,5-*bcd*]furan. Also, the ultraviolet spectra of phenanthro[4,5-*bcd*]furan (**1d**; X=O), phenanthro[4,5-*bcd*]thiophene (**1c**; X=S),[1] and phenanthro[4,5-*bcd*]pyrrole (**1b**; X=N)[2,15] are shown in Fig. 2. The shapes of the three spectra are similar to one another, and in all the regions of absorptions shift to longer wavelengths as X changes from a oxygen atom to a sulfur or a nitrogen atom. This shows that interaction between the non-bonding pair of electrons on the oxygen atom and the π-electrons on the phenanthrene ring is weak in phenanthro[4,5-*bcd*]furan. In the case of X=N, the interaction is strong, while it is medium when X is a sulfur atom with *d*-orbitals. Moreover, the spectrum of pyrene is superimposable on that of phenanthro[4,5-*bcd*]thiophene.[1] The ultraviolet spectra of 8,9-dihydrophenanthro[4,5-*bcd*]furan and dibenzofuran are shown in Fig. 3. The shapes of the spectra of the corresponding pair of compounds are similar to each other. These spectral properties suggest that phenanthro[4,5-*bcd*]furan does not have a large strain in the fused-ring system.

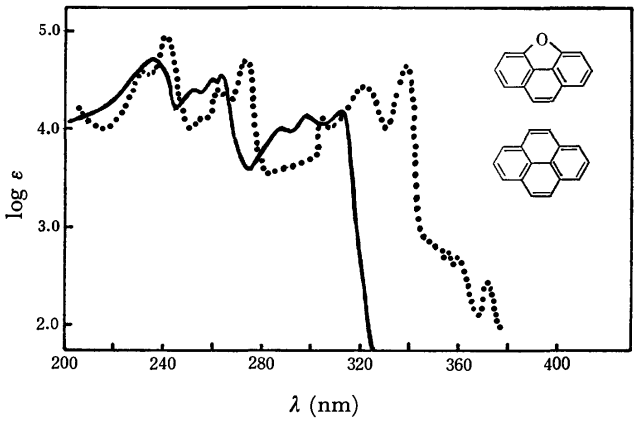


Fig. 1. Ultraviolet spectra for **3** (solid line) and pyrene (dotted line) in ethanol.

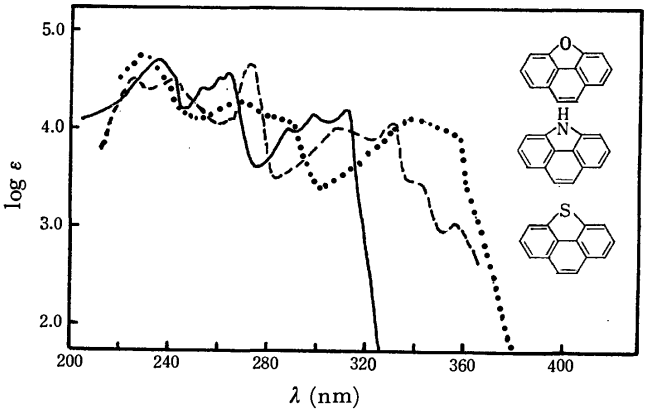

Fig. 2. Ultraviolet spectra for **3** (solid line), **1b** (X=N; dotted line), and **1c** (X=S; broken line) in ethanol.

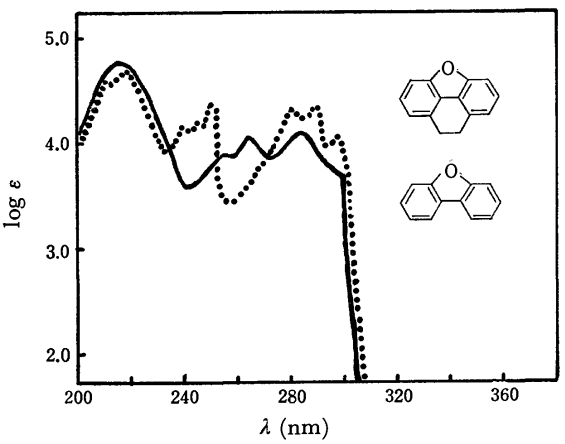

Fig. 3. Ultraviolet spectra for **10** (solid line) and dibenzofuran (dotted line) in ethanol.

Experimental

All the melting points are uncorrected. The column chromatography was performed on silica gel (WAKOGEL C-200).

Unless otherwise stated, anhydrous sodium sulfate was employed as the drying agent. The infrared absorption spectra were determined with a JASCO Model DS 402 G infrared spectrophotometer. The ultraviolet absorption spectra were determined with a Shimadzu Model UV-200 spectrophotometer. The nuclear magnetic resonance spectra were determined at 100 MHz with a JEOL Model 4H-100 NMR spectrometer, using tetramethylsilane as the internal standard.

*1,2,3,8,9,9a-Hexahydrophenanthro[4,5-*bcd*]furan-3-ol (6).* A mixture of **5** (2.0 g), lithium aluminum hydride (0.3 g), and dry ether (40 ml) was refluxed for 4 h. After the reaction, the excess lithium aluminum hydride was decomposed with ethyl acetate. The mixture was poured into ice water, acidified with 6 M hydrochloric acid, and extracted with ether. The ethereal layer was washed with water, dried, and then evaporated to give 2.0 g (99%) of **6** as crystals. Recrystallization from benzene gave colorless needles; mp 122—123 °C. IR (KBr): ν_{max} 746, 758, 775, 948, 996, 1023, 1052, 1075, 1240, 1350, 1635, 3300 cm^{-1}. NMR ($CDCl_3$): δ 1.02—1.43 (m, 2H, $-CH_2-$), 1.70—2.60 (m, 4H, $-CH_2-$ + $-CH_2-$), 2.46 (s, 1H, OH), 2.70—2.96 (m, 3H, $-CH_2-$ + =CH–), 4.85—5.06 (m, 1H, =CHO–), 6.90—7.23 (m, 3H, Ar–H). UV (EtOH): λ_{max} (ε) 210^{sh} (19500), 216 (21000), 257 (12700), 288 nm (900).

Found: C, 78.23; H, 6.71%. Calcd for $C_{14}H_{14}O_2$: C, 78.48; H, 6.59%.

*Phenanthro[4,5-*bcd*]furan (3) and 1,2,3,3a,8,9,9a,9b-Octahydrophenanthro[4,5-*bcd*]furan (7).* A mixture of **6** (3.6 g), 8% palladium–charcoal (1.0 g), and *p*-cymene (30 ml) was heated at 195 °C for 6 h under a nitrogen atmosphere. The initially produced water was removed at the first stage of the reaction. After the removal of the catalyst by filtration, the *p*-cymene was removed under reduced pressure to give an oil. The oil was chromatographed over silica gel and eluted with benzene(1)–hexane(9). From the first fraction we obtained 810 mg (30%) of **3** as crystals. Recrystallization from methanol gave colorless plates; mp 90—91 °C. IR (KBr): ν_{max} 709, 754, 816, 825, 993, 1030, 1218, 1240, 1312, 1355, 1420, 1440, 1500, 1590, 3080 cm^{-1}. NMR ($CDCl_3$): δ 7.53—7.77 (m, 6H, Ar–H), 7.92 (s, 2H, Ar–H). UV (EtOH): λ_{max} (ε) 236 (56700), 253 (26300), 260^{sh} (31000), 263 (34200), 288^{sh} (8100), 299 (12500), 313 nm (14500).

Found: C, 87.25; H, 4.27%. Calcd for $C_{11}H_8O$: C, 87.48; H, 4.20%.

By further elution with benzene(1)–hexane(1), 380 mg (14%) of **7** were obtained as crystals. Recrystallization from methanol gave colorless needles; mp 79.5—80.5 °C. IR (KBr): ν_{max} 743, 763, 855, 876, 915, 967, 1005, 1080, 1210, 1230, 1243, 1455, 1610, 1630, 2880, 2960, 3080 cm^{-1}. NMR ($CDCl_3$): δ 0.95—1.20 (m, 3H, $-CH_2-$ + $-CH_2-$), 1.35—1.70 (m, 2H, $-CH_2-$), 1.78—2.00 (m, 3H, $-CH_2-$ + $-CH_2-$), 2.05—2.39 (m, 1H, =CH–), 2.64 (d,d, J=6 and 10 Hz, 2H, $-CH_2-$), 3.35 (t, J=6 Hz, 1H, Ar–CH=), 4.91 (t, J=8 Hz, 1H, =CHO–), 6.56 (d, J=8 Hz, 1H, Ar–H), 6.62 (d, J=8 Hz, 1H, Ar–H), 7.00 (t, J=8 Hz, 1H, Ar–H). UV (EtOH): λ_{max} (ε) 208 (29200), 232^{sh} (4000), 275—285 nm (1600).

Found: C, 83.82; H, 8.06%. Calcd for $C_{14}H_{16}O$: C, 83.96; H, 8.05%.

Dehydrogenation of 6 without a Solvent. A mixture of **6** (1.0 g) and 8% palladium–charcoal (0.1 g) was heated at 275 °C for 1 h under a nitrogen atmosphere. After the reaction, benzene was added to the mixture and the catalyst was removed by filtration. The benzene was evaporated to give an oil. The oil was chromatographed over silica gel and eluted with benzene(1)–hexane(9). The first fraction gave 160 mg of crystals. It was composed of phenanthro[4,5-*bcd*]furan (**3**) and phenanthrene (**8**), and the **3**/**8** ratio was found to be 1 by gas chromatography. By the fractional recrystallization of the mixture from ethanol, a few of individual components were obtained in a pure state. However, the separation of **3** and **8** was generally difficult.

By further elution with benzene, 220 mg (22%) of 4-phenanthrol (**9**) were obtained as crystals. Recrystallization from benzene–hexane gave colorless needles; mp 112—113 °C. (lit,[14] mp 113 °C). IR (KBr): ν_{max} 716, 743, 800, 830, 1004, 1225, 1290, 1313, 1345, 1420, 1445, 1580, 3085, 3555 cm^{-1}. NMR ($CDCl_3$): δ 5.57 (s, 1H, OH), 6.81 (d,d, J=2 and 8 Hz, 1H, Ar–H), 7.17—7.90 (m, 6H, Ar–H), 7.65 (s, 2H, Ar–H). UV (EtOH): λ_{max} (ε) 213 (25000), 226 (23700), 244 (49500), 249^{sh} (44100), 275 (20900), 295^{sh} (9000), 302^{sh} (7700), 323 (2000), 338 (3300), 355 nm (4100).

Found: C, 86.32; H, 5.20%. Calcd for $C_{14}H_{10}O$: C, 86.57; H, 5.19%.

Reaction of 6 with N-Bromosuccinimide. A mixture of **6** (0.5 g), *N*-bromosuccinimide (1.0 g), and carbon tetrachloride (10 ml) was refluxed for 1 h. After the removal of the insoluble materials by filtration, the carbon tetrachloride was evaporated. To the residue potassium hydroxide (3.0 g) and ethanol (20 ml) was added, after which the mixture was refluxed for 3 h. The mixture was then poured into ice water, acidified with 6 M hydrochloric acid, and extracted with ether. The ethereal layer was washed with water, dried, and then evaporated. The resulting oil was chromatographed over silica gel and eluted with benzene(1)–hexane(9). The first fraction gave 120 mg (26%) of an oil which partially solidified. It consisted of phenanthro[4,5-*bcd*]furan (**3**) and 8,9-dihydrophenanthro[4,5-*bcd*]furan (**10**), and the **3**/**10** ratio was found to be 1 by a study of the NMR spectrum. The partially solidified oil was washed with methanol, and the resulting solid was recrystallized from methanol to give 10 mg (2%) of **3** as colorless plates; mp 90—91 °C.

*3-Ethoxy-1,2,3,8,9,9a-hexahydro[4,5-*bcd*]furan (15 and 16).* Sulfuric acid (3.0 g) was added, drop by drop, to **6** (1.5 g) in ethanol (15 ml) under cooling with ice water, after which the mixture was stirred for 3 h at 0 °C. The mixture was then poured into ice water and extracted with ether. The ethereal layer was washed with water, dried, and then evaporated to give an oil. The oil was chromatographed over silica gel and eluted with benzene. The first fraction gave 800 mg (47%) of **15** as a colorless oil. IR (neat); ν_{max} 753, 770, 780, 935, 995, 1015, 1070, 1090, 1120, 1150, 1205, 1235, 1340, 1360, 1405, 1435, 1450, 1465, 1635, 2890, 2960, 3005 cm^{-1}. NMR ($CDCl_3$): δ 1.07—1.63 (m, 2H, $-CH_2-$), 1.22 (t, J=7 Hz, 3H, $-CH_3$), 1.78—2.37 (m, 4H, $-CH_2-$ + $-CH_2-$), 2.56—3.00 (m, 3H, $-CH_2-$ + =CH–), 3.60—3.90 (m, 2H, $-OCH_2-$), 4.51—4.59 (m, 1H, –OCH=), 6.90—7.29 (m, 3H, Ar–H). UV (EtOH): λ_{max} (ε) 216 (23000), 256 (13100), 287 nm (1100).

Found: C, 79.10; H, 7.37%. Calcd for $C_{16}H_{18}O_2$: C, 79.31; H, 7.49%.

From the second fraction, 650 mg (38%) of **16** were obtained as crystals. Recrystallization from ethanol gave colorless needles; mp 85—86 °C. IR (KBr): ν_{max} 750, 760, 773, 1092, 1120, 1245, 1350, 1400, 1465, 2890, 2970, 3005 cm^{-1}. NMR ($CDCl_3$): δ 1.06—1.48 (m, 2H, $-CH_2-$), 3.31 (t, J= 8 Hz, 3H, $-CH_3$), 1.55—2.55 (m, 4H, $-CH_2-$ + $-CH_2-$), 2.67—3.07 (m, 3H, $-CH_2-$ + =CH–), 3.63—4.14 (m, 2H, $-OCH_2-$), 4.59—4.77 (m, 1H, –OCH=), 6.90—7.28 (m, 3H, Ar–H). UV (EtOH): λ_{max} (ε) 216 (21800), 257 (14200), 287 nm (1000).

Found: C, 79.06; H, 7.56%. Calcd for $C_{16}H_{18}O_2$: C, 79.31; H, 7.49%.

*1,2,3,3a,8,9,9a,9b-Octahydrophenanthro[4,5-*bcd*]furan-3-ol (17).* A mixture of **5** (1.0 g), 8% palladium–charcoal (0.3 g), and

ethanol (50 ml) was shaken for 10 h at room temperature under a hydrogen atmosphere. After the removal of the catalyst by filtration, the ethanol was evaporated under reduced pressure. The resulting oil was chromatographed over silica gel and eluted with benzene(8)–ether(2) to give 0.81 g (80%) of **17** as crystals. The crystals were dissolved in hexane and recrystallized after the removal of the insoluble materials to give colorless needles; mp 74.5—76 °C. IR (KBr): ν_{max} 534, 640, 765, 800, 838, 930, 956, 970, 1005, 1054, 1213, 1236, 1293, 1300, 1345, 1460, 1610, 1630, 2880, 2970, 3580 cm^{-1}. NMR ($CDCl_3$): δ 1.20—1.51 (m, 2H, $-CH_2-$), 1.63—2.03 (m, 2H, $-CH_2-$), 1.79 (s, 1H, OH), 2.66 (t, J=7 Hz, 2H, $-CH_2-$), 3.45 (t, J=7 Hz, 1H, Ar–CH=), 3.99—4.10 (m, 1H, –OCH=), 4.86 (d,d, J=6 and 8 Hz, 1H, –OCH=), 6.58 (d, J=8 Hz, 1H, Ar–H), 6.64 (d, J=8 Hz, 1H, Ar–H), 7.01 (t, J=8 Hz, 1H, Ar–H). UV (EtOH): λ_{max} (ε) 208 (28500), 276—286 nm (1600).

Found: C, 77.79; H, 7.45%. Calcd for $C_{14}H_{16}O_2$: C, 77.75; H, 7.46%.

*1,2,3,8,9,9a-Hexahydrophenanthro[4,5-*bcd*]furan (**18**).* A mixture of **5** (2.0 g), hydrazine hydrate (80%; 15 g), potassium hydroxide (28 g), and triethylene glycol (80 ml) was heated for 2 h at 140 °C and for 3.5 h at 190 °C. During the reaction, the distilled liquid was removed. After the reaction, the mixture was poured into ice water, acidified with 6 M hydrochloric acid, and extracted with ether. The ethereal layer was washed with water, dried, and then evaporated. The resulting oil was chromatographed over silica gel and eluted with benzene(1)–hexane(1) to give 0.93 g (50%) of **18** as crystals. Recrystallization from methanol gave colorless plates; mp 46—47 °C. IR (KBr): ν_{max} 758, 777, 822, 956, 1012, 1110, 1188, 1210, 1222, 1240, 1335, 1450, 1465, 1500, 1630, 1675, 2870, 2960, 3080 cm^{-1}. NMR ($CDCl_3$): δ 0.80—1.45 (m, 2H, $-CH_2-$), 1.70—2.34 (m, 4H, $-CH_2-$ + $-CH_2-$), 2.40—3.15 (m, 5H, $-CH_2-$ + $-CH_2-$ + =CH–), 6.85—7.20 (m, 3H, Ar–H). UV (EtOH): λ_{max} (ε) 217 (22900), 257 (12100), 288 nm (1000).

Found: C, 84.65; H, 7.15%. Calcd for $C_{14}H_{14}O$: C, 84.81; H, 7.12%.

*1,2,3,3a,8,9,9a,9b-Octahydrophenanthro[4,5-*bcd*]furan (**7**).* A mixture of **18** (0.4 g), 8% palladium–charcoal (0.3 g), and ethanol (20 ml) was shaken for 6 h at room temperature under a hydrogen atmosphere. After the removal of the catalyst by filtration, the ethanol was evaporated under reduced pressure. The resulting crystals were chromatographed over silica gel and eluted with benzene(6)–hexane(4) to give 0.34 g (84%) of **7** as crystals. Recrystallization from methanol gave colorless needles; mp 79.5—80.5 °C.

*8,9-Dihydrophenanthro[4,5-*bcd*]furan (**10**).* A mixture of **3** (0.35 g), 8% palladium–charcoal (0.3 g), and ethanol (30 ml) was shaken for 15 h at room temperature under a hydrogen atmosphere. After the removal of the catalyst by filtration, the ethanol was evaporated under reduced pressure. The resulting oil was chromatographed over silica gel and eluted with benzene(1)–hexane(9) to give 0.26 g (74%) of **10** as crystals. Recrystallization from methanol gave colorless leaflets; mp 41—42 °C. IR (KBr): ν_{max} 773, 982, 1015, 1194, 1238, 1435, 1450, 1595, 1630, 1660, 3065, 3090 cm^{-1}. NMR ($CDCl_3$): δ 3.28 (s, 4H, $-CH_2-$ + $-CH_2-$), 7.02—7.31 (m, 6H, Ar–H). UV (EtOH): λ_{max} (ε) 214 (49400), 227 (26300), 255^{sh} (8000), 264 (12000), 285 (11200), 294^{sh} (8600), 297^{sh} nm (8000).

Found: C, 86.38; H, 5.18%. Calcd for $C_{14}H_{10}O$: C, 86.57; H, 5.19%.

*4-Phenanthrol (**9**).* A mixture of **3** (0.1 g), lithium aluminum hydride (0.1 g), and dry ether (20 ml) was refluxed for 25 h. The excess lithium aluminum hydride was then decomposed with ethyl acetate, and the mixture was poured into ice water and acidified with 6 M hydrochloric acid. The mixture was subsequently extracted with ether. The ethereal layer was washed with water, dried, and then evaporated to give an oil. The oil was chromatographed over silica gel and eluted with benzene(1)–hexane(9). The first fraction gave 50 mg (50%) of the starting material (**3**). From the second fraction we obtained 40 mg (80%) of **9** as colorless leaflets. The IR spectrum of the product was in according with that of 4-phenanthrol (**9**) obtained by the dehydrogenation of **6** without a solvent.

*8-Bromophenanthro[4,5-*bcd*]furan (**20**).* To **3** (0.2 g) in carbon tetrachloride (10 ml) we added 1.2 mol of bromine in carbon tetrachloride (10 ml), after which the mixture was stirred for 2 h at room temperature. It was then heated at 70 °C for 30 min to eliminate the hydrogen bromide. After the evaporation of carbon tetrachloride, the resulting crystals were chromatographed over silica gel and eluted with benzene(1)–hexane(9) to give 0.21 g (67%) of **20** as crystals. Recrystallization from ethanol gave colorless needles; mp 144—145 °C. IR (KBr): ν_{max} 712, 770, 830, 866, 1036, 1188, 1235, 1300, 1345, 1420, 1465, 1505, 1590 cm^{-1}. NMR ($CDCl_3$): δ 7.53—7.88 (m, 6H, Ar–H), 8.16 (s, 1H, Ar–H). UV (EtOH): λ_{max} (ε) 222 (28100), 237 (45600), 258 (29600), 265 (34500), 308 (13100), 319 (13300), 337 (1900), 353 nm (200).

Found: C, 61.76; H, 2.73%. Calcd for $C_{14}H_7OBr$: C, 62.02; H, 2.60%.

*3,3a,8,9,9a,9b-Hexahydrophenanthro[4,5-*bcd*]furan (**19**).* Compound **3** (0.3 g) was dissolved in ethanol (20 ml), and the solution was heated under reflux. To the solution sodium (4.0 g) was added in limited amounts. When precipitates of sodium ethoxide were produced, additional ethanol (20 ml) was introduced into the solution and residual sodium was added. After the sodium had disappeared (1.5 h), the mixture was poured into ice water, acidified with 6 M hydrochloric acid, and extracted with ether. The ethereal layer was washed with water, dried, and then evaporated. The resulting oil was chromatographed over silica gel and eluted with benzene(1)–hexane(1) to give 0.1 g (32%) of **19** as a colorless oil. IR (neat): ν_{max} 740, 770, 810, 864, 880, 926, 1023, 1042, 1220, 1235, 1244, 1465, 1615, 1635, 2890, 2960, 3060 cm^{-1}. NMR ($CDCl_3$): δ 1.38—1.69 (m, 1H, $-CH_2-$), 1.80—2.12 (m, 2H, $-CH_2-$), 2.17—2.31 (m, 1H, $-CH_2-$), 2.39—2.65 (m, 2H, $-CH_2-$), 2.71—2.96 (m, 1H, =CH–), 3.56 (t, J= 8 Hz, 1H, Ar–CH=), 4.96—5.17 (m, 1H, –OCH=), 5.65 (s, 2H, CH=CH), 6.57 (d, J=8 Hz, 1H, Ar–H), 6.61 (d, J= 8 Hz, 1H, Ar–H), 6.98 (t, J=8 Hz, 1H, Ar–H). UV (EtOH): λ_{max} (ε) 207 (26800), 275—284 nm (1900).

Found: C, 84.56; H, 6.98%. Calcd for $C_{14}H_{14}O$: C, 84.81; H, 7.12%.

*1-Benzoylphenanthro[4,5-*bcd*]furan (**21**).* To a solution of **3** (100 mg) and benzoyl chloride (110 mg) dissolved in carbon disulfide (5 ml) we added anhydrous aluminum chloride (100 mg). The mixture was then stirred for 6 h at room temperature, decomposed with dilute hydrochloric acid, and extracted with ether. The ethereal layer was washed with water, dried, and then evaporated. The resulting oil was chromatographed over silica gel and eluted with benzene(8)–hexane(2). The first fraction gave 130 mg (84%) of **21** as crystals. Recrystallization from methanol gave colorless needles; mp 126—127 °C. IR (KBr): 660, 702, 733, 756, 792, 960, 1028, 1215, 1232, 1270, 1325, 1400, 1505, 1590, 1650 cm^{-1}. NMR ($CDCl_3$): δ 7.38—7.89 (m, 9H, Ar–H), 7.99 (d, J=9 Hz, 1H, Ar–H), 8.06 (d, J=8 Hz, 1H, Ar–H), 8.41 (d, J=9 Hz, 1H, Ar–H). UV (EtOH): λ_{max} (ε) 207 (36200), 238 (52500), 255 (40300), 278^{sh} (19500), 329 (19500).

Found: C, 84.89; H, 4.14%. Calcd for $C_{21}H_{12}O_2$: C, 85.12; H, 4.08%.

The author wishes to thank Mr. Yoshiaki Takahashi for the elemental analyses and Mr. Takao Oono for the nuclear magnetic resonance analyses.

1,3-Dipolar Cycloadditions to Bicyclic Olefins. II. The Effects of Non-aromatic Polar Solvents on the *exo/endo* Product Ratios in 1,3-Dipolar Cycloadditions to Norbornadienes[1,2]

Hisaji TANIGUCHI, Yoshihiro YOSHIDA, and Eiji IMOTO

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Mozu-Umemachi, Sakai, Osaka 591

(Received May 10, 1977)

The *exo/endo* product ratios for three types of 1,3-dipolar cycloadditions of phenylglyoxylonitrile oxide(**1**) to 2,3-bis(methoxycarbonyl)norbornadiene(**2a**), norbornadiene, and 2,3-dicyanonorbornadiene decrease with increasing E_T value of the non-aromatic polar solvent used. The *exo/endo* ratio in the reaction of **1** with **2a** is larger than unity, but the value of $\Delta H^{\ddagger}_{exo} - \Delta H^{\ddagger}_{endo}$ is nevertheless positive. This phenomenon is attributed to the relatively large positive value of $\Delta S^{\ddagger}_{exo} - \Delta S^{\ddagger}_{endo}$, that is, $\Delta G^{\ddagger}_{exo} - \Delta G^{\ddagger}_{endo} < 0$ at ordinary temperatures. On the basis of these results, the conditions, under which the *exo/endo* ratio in the reaction of **1** with **2a** is smaller than unity, were determined. The results can be reasonably explained by the assumption that the dipole moment of the *endo*-form in the transition state is greater than that of the *exo*-form.

In a previous paper, it was reported that various 1,3-dipolar cycloadditions to norbornadienes gave exo-adducts together with small amounts of endo-adducts.[2] Now, the *exo/endo* product ratios for the Diels-Alder reactions of cyclopentadiene with dienophiles, such as methyl acrylate, methyl methacrylate, and methyl *trans*-crotonate, decrease with increasing Ω value of the solvent used.[3] This fact suggests that the stereoselectivity of the 1,3-dipolar cycloadditions to norbornadienes may also depend on the solvent, because the 1,3-dipolar cycloadditions are mechanisms analogous to Diels-Alder reactions. Therefore, the effects of the solvents on the stereoselectivity of the cyloadditions of phenylglyoxylonitrile oxide (**1**) to 2,3-bis(methoxycarbonyl)norbornadiene (**2a**), norbornadiene (**2b**), and 2,3-dicyanonorbornadiene (**2c**), which have been shown to be kinetically controlled,[2] were studied and it was found that the *exo/endo* product ratios decrease with increasing E_T value[4] of the non-aromatic polar solvent. In addition, it was found that these ratios depend on the reaction temperature.

Experimental

Solvents. THF was dried over NaOH for one week and distilled over $LiAlH_4$; bp 66 °C. Ethyl acetate was dried over $CaCl_2$ for a few days and distilled; 77 °C. Chloroform was shaken together with concd sufuric acid, washed with distilled water, dried over $CaCl_2$, and distilled; bp 61 °C. Dichloromethane was dried over $CaCl_2$ and distilled; bp 40 °C. Acetone was dried over $MgSO_4$ and distilled; 56.5 °C. 2-Propanol was dried over CaO and distilled; bp 82.5 °C. Ethanol was refluxed over CaO for 12 h and distilled; bp 78.5 °C. Methanol was prepared by distilling commercial methanol over CaO; bp 64.5 °C.

Materials. Dipolarophiles, **2a**[5] and **2c**,[2] were prepared by methods descrived in the literature. Norbornadiene was purchased and distilled before use. α-Chloro-α-hydroxyiminoacetophenone (**9**), which is a precursor of **1**, was prepared by a method described in the literature.[6] All of the cycloadducts (**3a**, **3b**, **3c**, **4a**, **4b**, and **4c**) produced by the cycloadditions of **1** to **2a**, **2b**, and **2c** have been characterized in previous work.[2]

General Procedure for 1,3-Dipolar Cycloadditions. a) The reaction of **1** with **2a**: A mixture of **9** (460 mg, 2.50 mmol) and **2a** (520 mg, 2.50 mmol) was dissolved in an appropriate solvent (40 cm^3). Then, the solution was maintained at a given temperature (Which was controlled to within ±0.1 °C). A solution of triethylamine (330 mg, 3.26 mmol) in the same solvent (10 cm^3) as that used above was added dropwise over 1 h. After additional stirring for 1 h, the triethylammonium chloride obtained was removed by filtration. The filtrate was evaporated under reduced pressure to give a mixture of the *exo*- and *endo*-adducts. This mixture was submitted to a measurement of the *exo/endo* product ratio by the NMR technique (*vide infra*). (When the ammonium salt was soluble in the solvent, the solvent was evaporated and then the cycloadducts were extracted with benzene.)

b) The reactions of **1** with **2b** and **2c**: Two molar equivalents of **2b** or **2c** with respect to **1** were taken. In the case of the reaction of **1** with **2b**, a small amount of bisadducts was produced in addition to a mixture of the *exo*- and *endo*-monoadducts. The monoadducts were separated from the bisadducts using column chromatography on silica gel.

Measurement of the exo/endo *Product Ratios.* Quantitative analysis of the *exo/endo* product ratios was carried out using NMR spectra (recorded on a Hitachi NMR R-24A spectrometer at 60 MHz.) The ratios were determined by measuring the area ratios of the signals of the *endo*- and *exo*-protons attached on each 2-carbon atom of the *exo*- and *endo*-adducts. These signals were well separated and, moreover, no other signals appeared in the vicinity of these signals.[2]

In order to minimize the error in the measurement of the area integrals, concentrated solutions containing the *exo*- and *endo*- adducts (in 40% $CDCl_3$ solutions) were prepared. The ratio values are subject to an uncertainty of ±0.02.

Results and Discussion

The Linear Relationship between the exo/endo *Product Ratios and the* E_T *Value of the Solvent.* The *exo/endo* product ratios in all three systems were dependent on the kind of the solvent, in the manner shown in Fig. 1. This figure indicates the following.

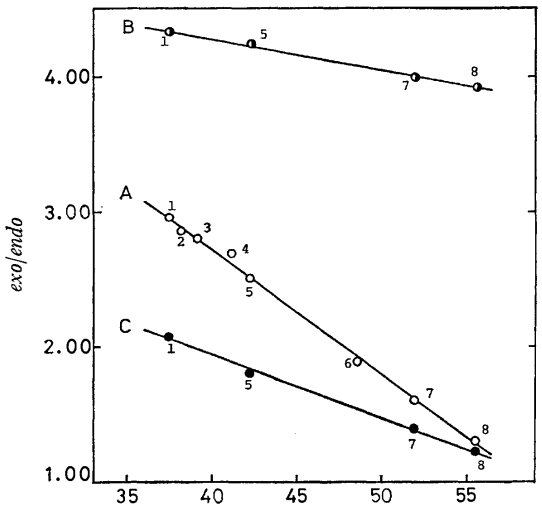

Fig. 1. The linear relationship between the *exo/endo* product ratios (at 0 °C) and $E_{T,30}$ value of the solvent.
A: Reaction of **1** with **2a**, B: reaction of **1** with **2b**, C: reaction of **1** with **2c**, 1; THF, 2; EtOAc, 3; $CHCl_3$, 4; CH_2Cl_2, 5; acetone 6; 2-propanol, 7; EtOH, 8; MeOH.

a) All the *exo/endo* product ratios are greater than unity.

b) The *exo/endo* ratios in each system decrease linearly with increasing E_T value[4] of the solvent.

c) The *exo/endo* ratios for the three systems are in decreasing order, **2b**, **2a**, and **2c**.

The Effect of Temperature on the exo/endo *Product Ratio.* A linear relationship between $1/T$ and the *exo/endo* ratio was observed for the reactions of **1** with **2a** and **2b** carried out in acetone, chloroform, or THF (Fig. 2).

From the results shown in Fig. 2, the differences in activation parameters were calculated (Table 1). Table 1 shows the following.

a) In the reaction of **1** with **2a**,

$$\Delta H^{\ddagger}_{exo} - \Delta H^{\ddagger}_{endo} > 0 \quad (1)$$

and

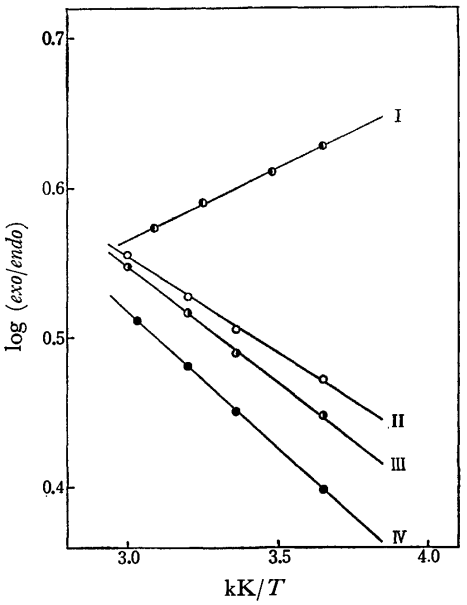

Fig. 2. The linear relationship between $1/T$ and the *exo/endo* product ratio.
I: Reaction of **1** with **2b** in acetone, II: reaction of **1** with **2a** in THF, III: reaction of **1** with **2a** in $CHCl_3$, IV: reaction of **1** with **2a** in acetone.

$$\Delta S^{\ddagger}_{exo} - \Delta S^{\ddagger}_{endo} > 0, \quad (2)$$

and in the reaction of **1** with **2b**,

$$\Delta H^{\ddagger}_{exo} - \Delta H^{\ddagger}_{endo} < 0 \quad (3)$$

and

$$\Delta S^{\ddagger}_{exo} - \Delta S^{\ddagger}_{endo} > 0. \quad (4)$$

If judged only from expression (1) without respect to expression (2), the *exo/endo* ratio should be smaller than unity. Actually, however, the ratio is greater than unity as shown in Fig. 1. This phenonmenon implies that the entropy term of the reaction greatly contributes to the difference in the free energies of activation, that is, the value of $\Delta G^{\ddagger}_{exo} - \Delta G^{\ddagger}_{endo}$ is negative at ordinary temperatures (Table 1).

Expressions of (3) and (4) explain the fact that the *exo/endo* ratio is greater than unity.

b) The value of $\Delta G^{\ddagger}_{exo} - \Delta G^{\ddagger}_{endo}$ for the reaction of **1** with **2a** decreases with increasing E_T value of the solvent.

Conditions Which Give an exo/endo *Product Ratio Smaller than Unity.* The results shown in Fig. 1 suggest that the yield of the *endo*-adduct of the reaction of **1** with **2a** should surpass that of the exo-adduct, if a solvent having a larger E_T value than 58.6 is used as the

reaction solvent. Such a solvent was prepared with the addition of water ($E_{T_{30}}$ value, 63.1) to mathanol ($E_{T_{30}}$ value, 55.5), since water does not dissolve **2a**.[7] In a medium consisting of methanol and water (1: 1, volume ratio), the yield of the *endo*-adduct in the reaction surpassed that of the *exo*-adduct (Table 2).

A Tentative Explanation for the Above Results. The explanation of Berson *et al.* for the *exo/endo* product ratio in the Diels-Alder reaction of cyclopentadiene with methyl acrylate[3] was adopted here.

The permanent dipole moments of the *exo*- and *endo*-forms in the transition states, **5** and **6**, were assumed to be given approximately by the vectorial sum of the dipole moments of the two components, **7** and **8**. The values of the dipole moments of **8a**, **8b**, and **8c** can be estimated using the bond angles and the bond moments shown in the figure (*vide infra*). The bond angles and the bond moments for the transition states were assumed to be equel to those for the cycloadducts produced. The bond angles for the cycloadducts were determined from their molecular models and the values of the bond moments were extracted from the literature.[8–10] The arrows shown for **5**—**8** are directed from the positive toward the negative end of each structure or component. The dihedral angles between the dipoles of the two components, **7** and **8**, were assumed to be 170° for the *exo*-form in the transition state and 55° for the *endo*-form using molecular models of the cycloadducts. The above estimate indicates that the resultant dipole moment of **6** is greater than that of **5**.

When the E_T value of the solvent becomes larger or the solute more polar, the free energy of solvation becomes smaller.[3,11] As described above, the dipole moment of the *endo*-form in the transition state is greater than that of the *exo*-form. Therefore, the change from a small E_T value for the solvent to a large value results in a larger decrease in the free energy of solvation for the *endo*-form in the transition state as compared with that for the *exo*-form. Thus, as the E_T value of the solvent becomes larger, the rate of formation of the *endo*-adduct increases more greatly as compared with that of the *exo*-adduct. This explanation is reasonable on the basis of the present results.

Substituent Effects in the Diels-Alder Reaction of Substituted Benzynes with Hexamethylcyclohexa-2,4-dienone

Akira Oku and Akira Matsui

Department of Chemistry, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606

(Received June 6, 1977)

The Diels-Alder reaction of unsymmetrically substituted benzynes that had been generated from 3-Me-, 4-Me-, 5-Me-, 6-Me-, 3,4-Me_2-, 3-NO_2-, 4-NO_2-, 5-NO_2-, and 3-Cl-benzenediazonium-2-carboxylates, with hexamethylcyclohexa-2,4-dienone gave a mixture of 5- or 6-substituted-1,2,3,4,10,10-hexamethyl-1,4-dihydro-1,4-ethanonaphthalene-9-one (Type **7**) and its 8- or 7-substituted isomer (Type **8**). The **7**/**8** isomer ratios varied from 1.0 to 2.0 depending substantially on the size and the position of substituents of the benzynes and also on the temperature and the solvent. The ratios were the same when two positionally isomeric acids, *i.e.*, 3- and 6-, or 4- and 5-substituted acids, were used as the precursors. Thus, the identity of the benzynes generated from these paired isomeric precursors was proved, ruling out the possibility of an inherent memory effect of the precursors. The factor that controls the isomer ratios is discussed in terms of the steric repulsive interaction between the substituents of benzynes and the *gem*-dimethyl groups of the dienone.

In view of the chemical interest in benzyne chemistry, the structure of benzyne does not seem to have been fully elucidated, particularly with regard to that in the transition state of chemical reactions. Triple-bond (**1a**), biradical (**1b**), and ion-pair (**1c**) structures have most often been proposed and discussed in numerous reactions.[1] Among them, the Diels-Alder-type reactions of benzyne with conjugated dienes, for example, have been considered to proceed mainly by means of the **1a** structure with symmetrical bonding, though there is some possibility of **1b** and **1c**.[2]

In our previous study of the synthesis of polymethylnaphthalenes, the reaction of hexamethylcyclohexa-2,4-dienone with unsymmetrically substituted benzynes that were generated from the corresponding benzenediazonium-2-carboxylates has been shown to give two isomeric adducts (Type **7** and Type **8**) in an unequal ratio.[3] Therefore, in the present study, our first interest was focussed on the characterization of the factors controlling the stereoselectivity in the formation of these adducts. We presumed, first of all, that when two different benzenediazonium-2-carboxylates, **2** and **4**, are used as the precursors of an identical benzyne, then the structure of the benzyne adducts may inherit the memory of the ionic structure of the diazonium carboxylates in certain reactions in which a substantial polar reactant interaction exists either prior to the benzyne generation or in the transition state, regardless of the substituent effect of the benzynes. Hexamethylcyclohexa-2,4-dienone (**6**),[4] for instance, seems to be a suitable dipolar diene for examining this memory effect. On the other hand, if this memory effect does not operate, then the reaction will be controlled by the benzyne structure, **1a** (or **1b**) or **1c**, only when there is a polar effect of the benzyne substituents. In this case, the isomer ratio, **7**/**8**, obtained from the reaction of **2** with **6** (Eq. 1) should be the same as that of **4** with **6** (Eq. 2), and the substituent effect that determines the **7**/**8** isomer ratio, will be either a steric effect, an inductive effect, or a dipole-dipole interaction between reactants.

In the present study, the reactions of hexamethylcyclohexa-2,4-dienone (**6**) with several unsymmetrically substituted benzynes that are generated from the corresponding arenediazonium-2-carboxylates (**2** and **4**, where X and Y are H, CH_3, Cl, or/and NO_2) are carried out under controlled conditions, and a qualitative diagnosis of the substituent effects in the transition state is deduced from the isomer ratios of the adducts.

Results and Discussion

Substituted benzenediazonium-2-carboxylates, as the aryne precursors, were prepared in the form of hydrochlorides from the corresponding anthranilic acids. They can be handled safely in the dried-powder state, except for the nitro derivatives, which are detonated by heat or impact. Most anthranilic acids were synthesized, after testing several procedures, *via* the corresponding isatines,[5] except in the case of nitroanthranilic acids, which were synthesized from the corresponding nitrophthalamic acids.

The reactions of unsymmetrically substituted benzenediazonium-2-carboxylate hydrochlorides (**2** and **4**) with hexamethylcyclohexa-2,4-dienone (**6**) were carried out under controlled conditions—constant rate of rising

temperatures and a constant concentration of reagents. The product analysis of these reactions, mainly by means of NMR, proved that the products were mixtures of two structurally isomeric adducts, **7** and **8**. Their NMR assignments were performed as follows (see Table 1).

The Assignment of Adduct Structures and the Determination of Isomer Ratios. The NMR spectrum of the adduct obtained from the reaction of **2a** with **6** was identical with that obtained from the reaction of **4a** with **6**, and it has been clarified that the adduct consisted of two structural isomers, **7a** and **8a**.[6,7] These isomers could not be separated, but their spectral assignment was achieved by a means analogous to that employed in the assignment of **7f** and **8f**, which was carried out with the aid of a lanthanoid shift reagent, $Eu(fod)_3$.[3] The **7a**/**8a** isomer ratio was determined mainly by the comparison of the NMR integration of the geminate methyl groups that are at the 9-position of the 1,4-dihydro-1,4-ethanonaphthalene ring and oriented *syn* to the benzene ring, since the difference in chemical shifts between the *syn*-methyls of **7a** and **8a** ($\Delta\delta$=0.07 ppm) is large enough to discriminate the two isomers. The ratios obtained from **2a** and **4a** are 1.73 and 1.75 respectively.

The same mixtures of isomeric adducts, **7b** and **8b**, were obtained from both benzyne precursors, **2b** and **4b**. The VPC separation of these two isomers was unsuccessful, and the NMR chemical shifts of the *syn-gem*-methyl groups were almost identical and undiscriminative. Fortunately, however, the chemical shifts of aryl methyl groups were slightly different between **7b** and **8b** ($\Delta\delta$= 0.02 ppm), and this difference could be enlarged clearly enough to distinguish the two isomers by the aid of the lanthanoid shift reagent, $Eu(fod)_3$ (0.30 mol equivalent). The isomer ratios obtained from **2b** and **4b** are 1.01 and 1.00 respectively. The assignment of NMR spectra to these isomers is based on the assumption that the aryl methyl group situated farther from the carbonyl group shows a lower field absorption than the one situated closer to the carbonyl group, which is analogous to the finding in the cases of **7a** and **8a**.

The reaction of 3-nitrobenzenediazonium-2-carboxylate hydrochloride (**4c**) with **6** gave a mixture of **7c** and **8c**. The NMR spectra of this mixture showed a clear difference in the chemical shift of the *syn* methyl group between the two isomers, **7c** and **8c** ($\Delta\delta$=0.11 ppm). The assignment of the chemical shifts to each isomer is based upon the assumption that the *syn* methyl group with the closer nitro substituent (isomer **8c**) will suffer a more shielding effect than that in the other isomer, **7c**. The ratio, thus determined by NMR, is 1.44 (by VPC, the ratio is 1.50). The same adducts were not obtained from the reaction of **2c**[8] because the diazotization of the corresponding 3-nitroanthranilic acid by isopentyl nitrite in the presence of hydrochloric acid caused an unusual nucleophilic substitution of the nitro group[9] by the chloride anion to produce 6-chlorobenzenediazonium-2-carboxylate (**2e**).

The assignment of the NMR spectra of the isomers, **7d** and **8d**, which were obtained as mixtures from both precursors, **2d** and **4d**, was carried out by the aid of the lanthanoid-shift reagent. The reagent facilitated the separation of the chemical shifts of the aromatic protons situated beta to the nitro substituent, *i.e.*, β_7-H in **7d** and β_8-H in **8d**. Here, the principal assumption is that β_8-H, that locates in closer proximity to the carbonyl group, is shifted to a lower field than β_7-H because of the complexation of the shift reagent with the carbonyl group.[10] The isomer ratio, **7d**/**8d**, determined therefrom, are 0.99 in the reaction of **2d** and 1.00 in that of **4d**. The ratios determined by a VPC analysis are 1.07 in both reactions. These two isomers, **7d** and **8d**, were separated by recrystallization from methanol; **7d**, with a less crowded structure, has a higher mp (158.5—159.5 °C) than that of **8d** (126—128 °C).

The two isomeric adducts, **7e** and **8e**, that were obtained from **2e**, can be separated; the isomer with a higher mp (107—108 °C) was assigned to **7e**, while the one with a lower mp (93—94 °C) to **8e**, on the basis of the mp as well as of the NMR chemical shift of the *syn-gem*-methyl groups. The isomer ratio (**7e**/**8e**) determined from the NMR integrations of *syn*-methyls ($\Delta\delta$=0.10 ppm) is 1.09, while it is 1.11 when determined by VPC.

In the adducts mentioned above, it is anticipated that the isomer with an intramolecularly more crowded

Table 2. Melting points of some benzyne-adducts (°C)

Substituents		Adducts	
o-	*m*-	Type **7**	Type **8**

Cl	H	107—108	93—94
CH_3	CH_3	154—156.5	127—130

structure will have a lower mp than the one with a less crowded structure. In fact, some isomers which were separated and structurally assigned support this hypothesis (see Table 2). This finding must be useful for the structure assignment of isomeric benzyne-adducts by a comparison of their melting points.

Table 3. Substituent effects on the isomer ratios **7**/**8**[a)]

a) The numbers in parentheses are the ratios determined by VPC.

The Interrelation between Substituent Effects and the Structure of Arynes. The isomer ratios (**7**/**8**) in the addition products are listed in Table 3. There it is evident that the isomer ratios are the same in both adducts obtained from the precursors of Type **2** and Type **4**, though the dispositions of their ion-pairs are inverse to each other. Thus, the identity of the arynes generated from both precursors is established, ruling out any possibility of intervening ionic memory effect inheritable from the starting-diazonium salts. The reason for the predominant formation of the isomer of Type **7** over **8** will be presented below.

In the general reaction procedure, 1,2-dichloroethane was employed as the solvent. This solvent, however, is non-polar and shows a poor dissolving power to benzenediazonium-2-carboxylate hydrochlorides. In this solvent the polar interaction, if any, between dienone **6** and aryne precursors (**2** and **4**) in or prior to the transition state will be exerted less than that in polar solvents. Therefore, the effect of the increasing solubility of **2** and **4** in such polar solvents as acetonitrile, *N*-methylformamide, and dienone itself, in which all reactants are soluble, was examined. The results are shown in Table 4. No appreciable difference was observed in the **7a**/**8a** isomer ratio between the starting compounds **2** and **4**, although, in polar solvents, the ratios are inclined to increase somewhat more than those in less polar solvents. Thus again, the memory effect was not observed even in these polar solvents. The increased isomer ratio observed in polar solvents seems to be ascribable mainly to the lower temperature of the decomposition of the aryne precursors in these solvents.

Table 4. Isomer ratios **7a**/**8a** in various solvents

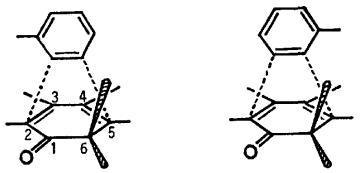
60		1.70
50	1.77	1.79
40	1.76	1.80

a) Butene-1-oxide was used instead of PO.

The effect of the reaction temperature on the isomer ratios was also examined, especially in an attempt to know whether it is different between the two starting compounds (**2** and **4**). It has been calculated that the ion-pair structure, **1c**, has a higher free energy than that of **1a** or **1b**,[2)] hence, a temperature effect will be anticipated if any function of **1c** is involved in or prior to the transition state. The results in Table 5, however, give a negative evidence to this hypothesis, because no appreciable difference is observable in the isomer ratios obtained from the two aryne precursors, **2** and **4**. The slightly enhanced formation of the **7a** isomer over **8a** at lower temperatures, as shown in this table, seems to indicate that the energy of activation for the formation of **7** is slightly lower than that for **8**. This difference, $\Delta E_a = E_a(\mathbf{8a}) - E_a(\mathbf{7a})$, was determined by the Arrhenius plotting of the isomer ratios in Table 5. Thus, we found that $\Delta E_a = 0.26 \pm 0.04$ kcal/mol, and $A(\mathbf{7a})/A(\mathbf{8a}) = 1.18 \pm 0.07$.

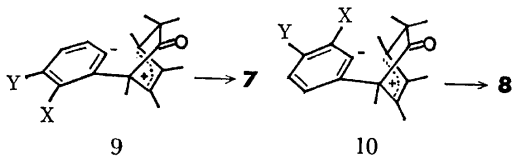
Although the possibility of the participation of the memory effect was thus completely ruled out, the substituent effects that determine the isomer ratios in the benzyne adducts still remain unclarified. Table 3 clearly indicates that the steric interaction between the *gem*-dimethyl groups of **6** and the substituent, X, in the transition state seems to be the sole factor controlling the isomer ratios. Thus, the ratios decrease as the Van-der-Waals radius of the X substituent diminishes, and accordingly, the effect of the β-substituent, Y, is negligible.[11)] In the case of 3-methylbenzyne, that gave the largest isomer ratio (1.7—1.8) among those examined, the difference in kinetic parameters between the two sterically different transition states, *i.e.*, $\Delta E_a = 0.26$ kcal/mol, and especially the ratio of the frequency factors $A(\mathbf{7a})/A(\mathbf{8a}) = 1.18$, indicates that the steric course leading to the adduct of Type **7** is slightly, but apparently, favored over that of Type **8**. A framework diagnosis

of possible transition states (*e.g.*, **A** and **B**) also supports this. These framework are constructed on the supposition that benzyne approaches vertically to the 2- and 5-positions of the planar dienone, keeping the two bonding distances equal. Then, when Type **B** is concerned, the overlapping of Var-der-Waals radii between *gem*-dimethyl and aryne methyl groups becomes substantial in the range of bonding distances shorter than 2.8 Å, about twice the bond length in the adduct.



(The interaction between the aryne methyl and 5- methyl of the dienone in Type **B** is also substantial, but is cancelled out by the similar interaction in Type **A** between aryne methyl and 2-methyl of the dienone when **A**/**B** is considered).

Other substituent effects that seem to be involved in determining the isomer ratio are: *a*) the dipole-dipole interaction between the carbonyl group of the **6** dienone and the X substituent, or/and *b*) the inductive effect of X. In the case of nitrobenzynes, if the former effect operates between the nitro group and the carbonyl group, then the product, **8c** (or **8d**), should be the predominant product in Run 2 (or Run 5) in Table 3. However, the ratios are **7c**/**8c**=1.44 and **7d**/**8d**=1.00; thus, the possibility of *a* is ruled out. As for the latter effect, *b*, if it contributes to the polar structure of arynes, then the adduct of Type **8** should favorably be formed in Runs 1, 4, and 6, and Type **7**, in Runs 2, 3, and 5.



Alternatively, recent studies of aryne reactions[12] have led us to suspect that the inductive effect of the X substituent (or/and Y) operates in the transition state of a two-stage addition reaction, so that a zwitter-ion, **9** or **10**, can be stabilized. According to this hypothesis, the adduct of Type 7 should be obtained predominantly from methyl-substituted benzynes, and Type **8**, from nitro- or chloro-benzynes. However, this was not the case. Therefore, the inductive effect is not likely to be involved, and, even when be involved, its magnitude is too small to overcome the steric effects.

Recently, Newman and Kannan reported that, in the reaction of 2-substituted furans with the aryne precursors analogous to Types **2a** and **4a**, where the steric interaction was expected to be more substantial than in our system, the isomer ratios found were smaller than 1.8.[19] Comparing our results with those, it should be noticed that the interaction of the X substituent with the *gem*-methyl group of **6** that is located at the 5-position of a cyclic 1,3-diene is almost as large as that of X with the substituent at the 1- or 4-position.

Experimental

General. The NMR spectra were measured in CCl_4 solutions, and the chemical shifts are given in δ-units. The VPC analyses were performed on a chromatograph equipped with a FID. Below, the experimental description will be divided into three sections: 1) methylbenzynes, 2) nitrobenzynes, and 3) chlorobenzyne. The combustion analysis was performed by the Elemental Analysis Laboratory of the Institute for Chemical Research of Kyoto University. The analyses of isomeric mixtures of benzyne-adducts agreed well (within an error of 0.30%) with the corresponding calculated values for the methylbenzyne- and nitrobenzyne adducts, and fairly well (within an error of 0.80%) for the chlorobenzyne adduct.

1. Preparation and Reaction of Methylbenzynes. 1-a) 6-Methylbenzenediazonium-2-carboxylate Hydrochloride (2a): This compound, **2a**, was prepared from 3-methylanthranilic acid (**11**)[5] by a procedure analogous to that previously reported.[13] Yield, 97%; mp 112.5—113.5 °C (dec); IR ν(N≡N) 2230 cm^{-1} (Nujol).

1-a') Free 6-Methylbenzenediazonium-2-carboxylate (2a'): Compound *2a'* was prepared by a procedure analogous to that employed above (see *1-a*), except that HCl was not added to the initial ethanolic solution. Yield, 43%; mp 98—99 °C; IR ν(N≡N) 2230 cm^{-1}.

1-b) 1,2,3,4,6,10,10-Heptamethyl-1,4-dihydro-1,4-ethanonaphthalene-9-one (7a) and Its 1,2,3,4,7,10,10-Heptamethyl Isomer (8a) by the Reaction of 2a with 2,3,4,5,6,6-Hexamethylcyclohexa-2,4-dien-1-one (6): The experimental conditions of seven runs are tabulated below. The first three runs were carried out in order to examine the solvent effects, and the last four runs, to examine the temperature effects. For the isomer ratios, see Tables 3,4, and 5. The experimental procedure for Run 1 is described below as the standard procedure, which will be refered to in the procedures following.

Run	Base	Solvent	Temp (°C)	Time (min)	Yield (%)
1	PO	CH_2ClCH_2Cl	60	70	95
2	PO	CH_3CN	60	70	26
3	PO	CH_3NHCHO	60	70	17
4	EB	CH_2ClCH_2Cl	40	480	100
5	EB	CH_2ClCH_2Cl	50	180	100
6	EB	CH_2ClCH_2Cl	70	60	100
7	EB	CH_2ClCH_2Cl	80	60	100

EB: 1,2-epoxybutane.

Run 1. Into a suspension of **2a** (0.50 g, 2.5 mmol) in 1,2-dichloroethane (6.3 ml), **6** (0.45 g, 2.5 mmol) and propylene oxide (0.8 ml, abbreviated as PO) were added. The mixture was then immediately heated under the standard conditions; *i.e.*, the temperature was raised at the rate of 2.5 °C/min from 25 to 60 °C. After additional stirring at 60 °C for 70 min, the dark brown solution was cooled. (These conditions were employed in the other runs that were carried out with the purpose of obtaining the adduct-isomer ratios.) After a vacuum evaporation, the residue was redissolved in Et_2O, and the solution was washed four times with 5 ml of 5% aq NaOH and again four times with water, and then dried ($MgSO_4$). The subsequent evaporation of the solvent gave a mixture of **7a** and **8a**; 0.64 g (95%). These isomers could

not be separated satisfactorily by column chromatography ($CHCl_3$, silica gel). NMR **7a**: *gem*-Me 0.54 and 1.02 (3H each; Me's *syn* and *anti* to the benzene ring respectively), Ar–Me 2.47 (3H), allylic Me 1.65—1.75 (6H), bridge-head Me 1.55 and 1.78 (3H each), Ar–H 6.7—7.1 (3H) ppm. **8a**: *gem*-Me 0.61 and 0.99 (3H each; Me's *syn* and *anti* to the benzene ring respectively), Ar–Me 2.52 (3H), allylic Me 1.65—1.75 (6H), bridge-head Me 1.55 and 1.78 (3H each), Ar–H 6.7—7.1 (3H) ppm; $P^+(m/e)$ 268. The isomer ratio, **7a**/**8a**, determined by a comparison of the NMR-integration, was 1.73. A VPC analysis (PEG-succinate, 2 m at 175 °C), though not achieving a satisfactory isomer separation, also gave the isomer ratio of 2.03.

Runs 4—7. Instead of PO, 1,2-epoxybutane (0.44 ml; abbreviated as EB) was added to a mixture of **2a** and **6** in 1,2-dichloroethane; the mixture was immediately heated at 80-, 70-, 50-, or 40±0.2 °C for the periods listed in the table. For the work-up, see the details in Run 1. Yield (**7a**+**8a**), *ca.* 100% in all runs. For the isomer ratios, see Table 5.

1-c) 7a and 8a by the Reaction of 2a′ with 6: Two runs were performed in order to examine the effect of free diazonium carboxylate, **2a′**, on the isomer ratio: Run 1, without PO in CH_2ClCH_2Cl; yield, 37%; Run 2, without PO, but in an excess amount of **6**; yield, 54%. The other reaction conditions were the same as in *1-b*. For the isomer ratios, see Table 4.

1-d) 3-Methylbenzenediazonium-2-carboxylate Hydrochloride (4a). From 6-Mcthylanthranilic Acid (12): For the preparative procedure, see *1-a*. Yield, 84%; mp 110.5—111 °C (dec); IR ν(N≡N) 2210 cm^{-1} (Nujol).

1-e) 3-Methylbenzenediazonium-2-carboxylate (4a′): See the procedure *1-a′*. Yield 4%; mp 68—70 °C (dec); IR ν(N≡N) 2250 cm^{-1}.

1-f) 7a and 8a by the Reaction of 4a with 6: For the procedure, see *1-b*. The reaction conditions and the results of eight runs are tabulated below. The first three runs were carried out in order to examine the solvent effects, and the last five runs, to examine the temperature effects. For the isomer ratios, see Tables 3, 4, and 5.

Run	Base	Solvent	Temp (°C)	Time (min)	Yield (%)
1	PO	CH_2ClCH_2Cl	60	70	83
2	PO	CH_3CN	60	70	13
3	PO	CH_3NHCHO	60	70	13
4	EB	CH_2ClCH_2Cl	40	560	100
5	EB	CH_2ClCH_2Cl	50	180	98
6	EB	CH_2ClCH_2Cl	60	70	100
7	EB	CH_2ClCH_2Cl	70	60	98
8	EB	CH_2ClCH_2Cl	80	60	100

1-g) 7a and 8a by the Reaction of 4a′ with 6: Refer to the *1-c* procedure. See also Table 4. Yield (**7a**+**8a**), 36%.

1-h) 5- and 4-Methylbenzenediazonium-2-carboxylate Hydrochloride (2b and 4b): Diazonium salts, **2b** and **4b**, were prepared from the corresponding anthranilic acids by the same method as in *1-a*. Yields, 89% (**2b**) and 84% (**4b**).

1-i) 1,2,3,4,6,10,10-Heptamethyl-1,4-dihydro-1,4-ethanonaphthalen-9-one (7b) and Its 1,2,3,4,7,10,10-Heptamethyl Isomer (8b): See the *1-b* procedure, Run 1. The same mixture of the **7b**+**8b** adducts were obtained from either precursor **2b** or **4b**. Yields, 75—77%. The isomers could not be separated. $P^+(m/e)$ 268; NMR **7b**: *gem*-Me 0.48 and 1.03 (3H each, Me's *syn* and *anti* to the benzene ring respectively), Ar–Me 2.29 (3H), allylic Me 1.65—1.76 (6H), bridgehead Me 1.56 (6H), Ar–H 6.85—7.1 (3H) ppm. **8b**: all the chemical shifts, except that of Ar–Me at 2.31, are the same as those of **7b**. The **7b**/**8b** isomer ratios determined by the NMR integration (see the text) were 1.01 and 1.00 from **2b** and **4b** respectively.

2. Preparation and Reactions of Nitrobenzynes. The procedure reported in old literature[14–16] on the preparation of nitroanthranilic acids was insufficient to reproduce the same results reported therein. The present authors employed the following modified procedure, that gave the acids in better yields than those previously reported.

2-a) 6-Nitroanthranilic Acid (14) from 6-Nitrophthalamic Acid (13): Acid **13** (5.69 g, 27.1 mmol)[15] was slowly added to a NaOCl solution which had been prepared by mixing 17.6 g of a commercial grade NaOCl-solution containing 10% active Cl, 2.0 g of NaOH, and 10 ml water at 0 °C. The mixture was warmed at 82 °C for 30 min (gas evolution was observed), cooled, and acidified with HCl. "After removing the solids that precipitated at pH 4, the filtrate was evaporated. The residue was extracted with Et_2O to give **14**. The extraction residue was redissolved in dil NaOH, and the solution was acidified." The above procedure in quotation marks "—" was repeated three times. Yield, 1.68 g (34%); mp 185.5—189.5 °C.[17]

2-b) 3-Nitrobenzenediazonium-2-carboxylate Hydrochloride (4c) from 14: See the *1-a* procedure. **4c**: yellow-orange powder; yield, 69%; mp 110.5—111 °C (dec); IR ν(N≡N) 2190 cm^{-1} (Nujol). Avoid unnecessary impact by hammering or heating; otherwise, it detonates!

2-c) 1,2,3,4,10,10-Hexamethyl-5-nitro-1,4-dihydro-1,4-ethanonaphthalen-9-one (7c) and Its 8-Nitro Isomer (8c): See the *1-b* procedure. A mixture of **7c** and **8c** was obtained. They were purified through a silica gel column (benzene), but could not be separated. NMR **7c**: *gem*-Me 0.68 and 1.04 (3H each, Me's *syn* and *anti* to the benzene ring respectively), Ar–H 6.91—7.38 (3H), bridge-head Me 1.59 and 1.62 (3H each), allylic Me 1.71—1.84 (6H) ppm. **8c**: *gem*-Me 0.57 and 1.08 (3H each, Me's *syn* and *anti* to the benzene ring respectively), Ar–H 6.91—7.38 (3H), bridge-head Me 1.54 and 1.64 (3H each), allylic Me 1.71—1.84 (6H) ppm. **7c**/**8c** isomer ratio = 1.44 (NMR), 1.50 (VPC). $P^+(m/e)$ 299; IR ν(C=O) 1730 and (NO_2) 1355 cm^{-1} (for both isomers in CCl_4); yield, 1.69 g (44%) after column chromatography.

2-d) 4-Nitro- and 5-Nitroanthranilic Acid (17 and 18): A mixture of 4- and 5-nitrophthalamic acid (**15** and **16**)[14] was treated with the NaOCl solution by the same method as in *2-a*. Cooling the reaction mixture separated needle-like precipitates. They were dissolved in water and acidified with HCl to pH 3—4, and the separated solid was washed with water, dried, and extracted with xylene by means of a Soxhlet apparatus for two days. The insoluble residue was recrystallized from aq EtOH ($EtOH/H_2O$ = 1.0 v/v) to give glistening yellow-green needles of **18** (48%): mp 275—283 °C (dec). The xylene solution was then evaporated to give **17** (32%) contaminated by **18**.

2-e) 5-Nitrobenzenediazonium-2-carboxylate Hydrochloride (2d): See the *2-b* procedure. Commercially available acid **17** was used. Here also caution should be taken when handling the dried powder of **2d**: yield, 90%; mp 128—130 °C (dec); IR ν(N≡N) 2230 cm^{-1}.

2-f) 1,2,3,4,10,10-Hexamethyl-6-nitro-1,4-dihydro-1,4-ethanonaphthalen-9-one (7d) and Its 7-Nitro Isomer (8d): See the *1-b* procedure. Yield (**7d**+**8d**), 61% after recrystallization from MeOH. The two isomers were separated mannually by the aid of a magnifying glass and recrystallized independently. **7d**: mp 158.5—159.5 °C; NMR *gem* Me 0.52 and 1.10 (3H each, Me's *syn* and *anti* to the benzene ring respectively), Ar–H 7.90—8.12 (2H, α to NO_2) 7.29 (H, β to NO_2), other Me's 1.64—1.80 (12H) ppm; IR ν(C=O, NO_2) 1730

and 1355 cm^{-1} (CCl_4); $P^+(m/e)$ 299. **8d**: mp 126—128 °C; NMR *gem*-Me 0.53 and 1.10 (3H each, Me's *syn* and *anti* to the benzene ring respectively), Ar–H 7.90—8.12 (2H, α to NO_2), 7.26 (H, β to NO_2), other Me's 1.64—1.80 (12H) ppm; the IR and $P^+(m/e)$ were the same as those of **7d**. For the isomer ratio, see Table 3.

2-g) 4-Nitrobenzenediazonium-2-carboxylate Hydrochloride (4d): See *1-b*. Caution should be taken when handling *4d*. Yield, 67%; mp 119.5—120 °C (dec); IR ν(N≡N) 2210 cm^{-1}(Nujol).

2-h) 7d and 8d by the Reaction of 4d with 6: See *1-b*, Run 1. Yield (**7d**+**8d**), 69%. For the isomer ratio, see Table 3.

3. Preparation and Reaction of 3-Chlorobenzyne.

3-a) 6-Chlorobenzenediazonium-2-carboxylate Hydrochloride (2e) from 3-Chloroanthranilic Acid (19): Acid **19** was prepared from *o*-chloroaniline.[18,5] For the preparation of the diazonium salt **2e**, see *1-a*, Run 1. Yield, 92%; mp 146—148 °C; IR ν(N≡N) 2230 cm^{-1}.

3-b) 1,2,3,4,10,10-Hexamethyl-5-chloro-1,4-dihydro-1,4-ethanonaphthalen-9-one (7e) and Its 8-Chloro Isomer (8e): A mixture of **7e** and **8e** was obtained by the method described in *1-b*. The two isomers were separated by column chromatography (silica gel; cyclohexane for **7e** and benzene for **8e**). The separated isomers were recrystallized independently from MeOH (the rate of crystallization of **8e** was slower than that of **7e**). Yield (**7e**+**8e**), 89%; isomer ratio, see Table 3. **7e**: mp 107—108 °C; NMR *gem*-Me 0.67 and 1.03 (3H each, Me's *syn* and *anti* to the benzene ring respectively), Ar–H 7.00—7.15 (3H), allylic Me 1.7—1.9 (6H), bridge-head Me 1.59 and 1.98 (3H each) ppm; $P^+(m/e)$ 289; IR ν(C=O) 1725 cm^{-1} (CCl_4). **8e**: mp 93—94 °C; NMR *gem*-Me 0.57 and 1.06 (3H each, Me's *syn* and *anti* to the benzene ring respectively), Ar–H 7.0—7.15 (3H), allylic Me 1.77 (6H), bridge-head Me 1.59 and 1.91 (3H each) ppm; the $P^+(m/e)$ and IR were the same as those of **7e**.

Solid-Phase Syntheses of $Glu_{20}Ala_{20}Phe$ and $Ala_{20}Glu_{20}Phe$ by the Step-by-step Coupling of Dipeptide and Tetrapeptide[1]

Sho TAKAHASHI

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received June 13, 1977)

$Glu_{20}Ala_{20}Phe$, (I), and $Ala_{20}Glu_{20}Phe$, (II), were synthesized by the step-by-step coupling of N^{α}-*t*-butoxycarbonyl (BOC-) derivatives of Ala–Ala and (γ-benzyl–Glu)$_4$ to phenylalanyl-1% crosslinked polystyrene resin using dicyclohexylcarbodiimide. The products were cleaved from the resin with hydrogen bromide in acetic acid and purified by gel filtration, followed by DEAE-cellulose chromatography, with yields of approximately 10% for both of the hentetracontapeptides. The optical purities of the glutamic acid and alanine incorporated in the peptides, I and II, were estimated as 1 and 5% respectively from the analysis of the diastereomeric mixture of dipeptides derived from the reaction between the total acid hydrolyzate of I or II with the *N*-hydroxysuccinimidyl ester of BOC–L-Leu.

The problem that an α-helix, one of the most important ordered secondary structure of a polypeptide chain, is uncoiled from one side, either the N- or the C-terminal, has not yet been studied experimentally. The available works on the problem have been limited to a few theoretical treatments.[2,3] The study of the effects exerted by the secondary structures of neighboring moieties in a polypeptide chain on a local α-helix has importance, especially in comprehending the stability of proteins, in which secondary structures are sequenced.

Block copolypeptides will serve as a good model to study the effects of a local conformation of a polypeptide chain on other parts of the chain. Previously we attempted to synthesize and to study the stability of the local α-helical conformation in two kinds of block copolypeptides, $Glu_{20}Ala_{20}$ and $Ala_{20}Glu_{20}$, in solution. The number of residues in a block, 20, was chosen as a compromise between the need for a stable α-helix and ease of syntheses. However, as has already been reported,[3] the attempted solid-phase peptide synthesis of these block copolypeptides by a step-by-step coupling of *t*-butoxycarbonyl-(BOC-)glutamic acid or -alanine was shown to be impractical due to the poor yield of the desired peptides. Furthermore, the difficulties in the solid-phase peptide synthesis of glutamyl peptides (including γ-peptides) have been well documented.[4–7] On the other hand, the coupling reactions of oligopeptides on a solid support have found their successful applications in syntheses of sequential peptides,[8,9] physiologically active peptides,[10–16] and some miscellaneous peptides.[17–19] We also tried a condensation of oligopeptides on a solid support as an alternative route to synthesizing $Glu_{20}Ala_{20}$ and $Ala_{20}Glu_{20}$ and obtained a satisfactory result, as will be described in this paper.

Results and Discussion

The synthesis of oligoglutamyl peptides by conventional solid-phase peptide synthesis has caused much trouble, as was initially documented by Bonora *et al.*[4] The yield of the desired peptide was drastically decreased with an increase in the number of residues, n, on their attempted synthesis of $(Glu)_n$, and the synthesis failed when n reached 5, where the desired peptide could not be isolated at all. As has also been reported previously,[3] we also attempted solid-phase syntheses of $(Glu)_n$ and $(Ala)_n$ by the step-by-step coupling of BOC-glutamic acid or -alanine. For both $(Glu)_n$ and $(Ala)_n$, it was observed that the elongation of a peptide chain proceeded smoothly with each cycle of the solid-phase synthesis if n was below about 5; then it became gradually sluggish and apparently stopped when n reached around 10. The failure of the syntheses might be ascribed to something other than the cleavage process of peptides from peptide-resin, because the yield of peptides was based on the incorporation of amino acids (glutamic acid or alanine), which was evaluated on the basis of the amino-acid analyses of hydrolyzates of peptide-resin. Some of the reasons for the failure of the synthesis by Bonora *et al.*[4] might be attributed to undesired side reactions of a glutamyl side chain which occurred during a cleavage reaction of peptides from peptide-resin, as has been reported by Sano and Kawanishi[5] and Feinberg and Merrifield,[6] but there seem to be other reasons inherent in the method itself in the case of solid-phase peptide syntheses of homologous peptides with enough residues to form a regular secondary structure.[3]

Although we are not yet aware of the exact reasons for the difficulties encountered in the solid-phase peptide synthetic approaches to some of the homologous peptides, one way devoid of difficulties would be a modification of the solid-phase method to incorporate a coupling reaction using oligopeptides instead of amino acids. The advantages would be as follows: (1) an improvement in the yield of the final product because of the smaller number of steps, (2) discrete distribution of the residues, which promises an easy purification of the reaction products, and (3) the possibility that the reactivity of a growing peptide chain on a solid matrix is critically dependent on the chain length due to interaction between the reactive center of a chain and a supporting matrix, especially if a stable secondary structure is present in that chain. Interactions of that kind seem likely for solid-phase syntheses of homologous peptides because a unique secondary structure is to be expected. The use of oligopeptides instead of amino acids as the unit in the syntheses may surpass the critical chain length.

Syntheses. Taking these points into account, we attempted solid-phase syntheses of $Glu_{20}Ala_{20}Phe$, (I), and $Ala_{20}Glu_{20}Phe$, (II), using oligopeptides as the

Table 1. A cycle of solid-phase peptide synthesis for the addition of one oligopeptide[a)]

	Function	Solvent or reagent	Time (min)	Number of applications
(1)	wash	CH_2Cl_2	2	3

a) The amount was for 5 g of resin containing 0.825 mmol of a reactive amino group. Volume of solvent, 60 ml. b) In the case of glutamyl peptide, these procedures were omitted and Step (5) was repeated. c) *N*,*N*-dimethylformamide. d) 3.3 mmol of oligopeptide in 25 ml of the solvent. e) 3.3 mmol of DCC in 5 ml of the solvent.

condensing unit. First, phenylalanine was anchored to resin as an internal marker. 1% cross-linked polystyrene resin was used, for its porosity is higher than that of the usual 2% cross-linked resin. BOC–(γ-benzyl–Glu)$_4$, (III), and BOC–$(Ala)_2$, (IV), were used as units for the syntheses of a Glu_{20}– and an $(Ala)_{20}$–block respectively. We attempted to use BOC–Ala_4 as a condensing unit, but the poor solubility of the tetrapeptide in most solvents made the attempt impractical.

All the peptides used for solid-phase synthesis were synthesized by the method of Anderson *et al.*[20] The reaction of the BOC-alanine *N*-hydroxysuccinimidyl-(–OSu) ester with alanine gave IV. The optical purity of the purified IV which was used in the solid-phase syntheses was shown, by an analysis to be described in a later section, to be 97% in the L-configuration. The γ-benzyl(γ-Bzl–) ester of BOC–Glu–OSu, (V), was reacted with γ-Bzl-glutamate to give BOC–(γ-Bzl–Glu)$_2$, (VI), a half of which was then converted into its *N*-hydroxysuccinimidyl ester, (VII), and the other half to (γ-Bzl–Glu)$_2$, (VIII). A reaction between VII and VIII gave the desired tetrapeptide, III, and the peptide was purified *via* its salt with dicyclohexylamine (DCHA). The optical purity of I that was used in the following solid-phase synthesis was greater than 99% in the L-configuration.

Solid-phase peptide syntheses were carried out using a cycle summarized in Table 1. After each cycle had finished, an aliquot of peptide resin was hydrolyzed with acid and analyzed for its amino-acid composition. The results are shown in Fig. 1, where a tendency for the yield of peptide-chain elongation to decrease was observed when the number of residues reached about 10. Even under the assumption that the yield of a reaction needed to extend one oligopeptide unit is uniformly α, irrespective of the length of the peptide chain, there are two extreme possibilities. (1) At the one extreme, α is considered simply as the possibility of a reaction occurring at a reactive center, and the unreacted peptide fraction (1-α) remains reactive and will react with the same probability in the next reaction cycle (for instance, an incomplete removal of the BOC group, *etc.*). The total amount of alanine and glutamic acid incorporated

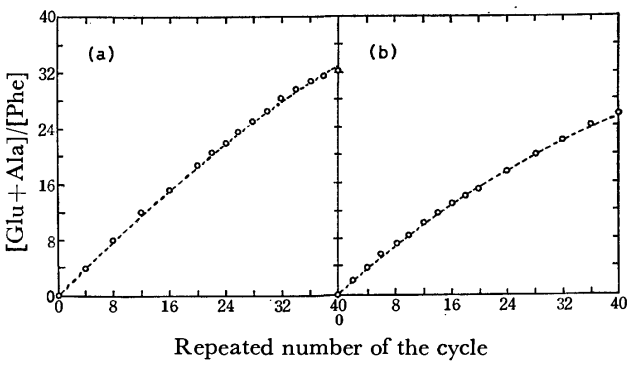

Fig. 1. The amount of amino acids incorporated with the progress of solid-phase peptide syntheses of: (a) $Ala_{20}Glu_{20}Phe$, and (b) $Glu_{20}Ala_{20}Phe$. The ordinate is the total amount of glutamic acid and alanine per mol of phenylalanine, and the abscissa is the repeated number of cycles of solid-phase synthesis. Circles represent the observed values and dotted curves for the calculation based on the dead-end products assumption. α(see text) was chosen as 0.97 for (a) and 0.95 for (b).

in the products will be linearly proportional to α. (2) At the other extreme, the peptide fraction, α, is considered living and reactive, and the fraction, (1-α), is a dead-end product which is no more reactive. In this case, if we start from 1 mol of phenylalanyl resin, the amount of such a dead-end product, $Glu_{4i}Ala_{2j}$, will be given by $\alpha^{i+j}(1-\alpha)$ moles, and the amounts of alanine and glutamic acid incorporated after m times coupling of IV and n times coupling of III are given by $2\sum_{i=1}^{m}\alpha^i$ and $4\sum_{i=1}^{n}\alpha^i$ moles respectively (after 10 times coupling of IV, followed by 5 times coupling of III, the number is $2\sum_{i=1}^{10}\alpha^i+4\alpha^{10}\sum_{i=1}^{5}\alpha^i$). The actual amounts of glutamic acid and alanine found in the acid-hydrolyzates of peptide resin with the progress of the number of coupling reactions (Fig. 1) deviate from a line, thus showing the (1) assumption to be unlikely. For a comparison, theoretical curves were calculated under the (2) assumption and for various values of α. α=0.97 and 0.95 for the

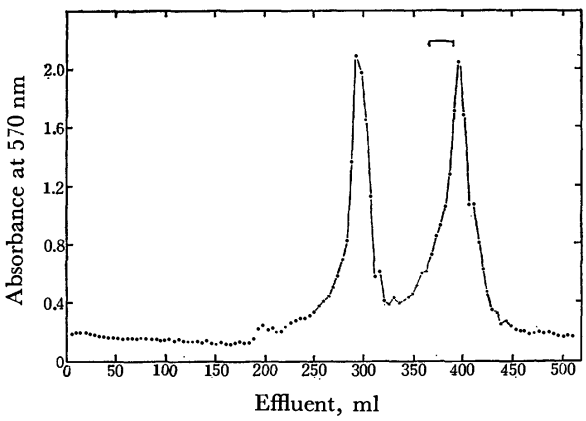

Fig. 2. Sephadex G-50 gel filtration of the product of solid-phase synthesis of $Glu_{20}Ala_{20}Phe$. The ordinate is absorption at 570 nm after the ninhydrin reaction of alkaline hydrolyzates of 0.01 ml aliquots from chromatographic fractions. The inserted bar shows the position of fractions which gave the amino acid composition was Glu: Ala: Phe= >19: >19: 1.

syntheses of Ala_mGlu_nPhe and Glu_mAla_nPhe respectively gave the best fit with the experimentally observed values, as shown in Fig. 1. Although the efficiency of a real peptide coupling reaction might depend on the length of the peptide chain, the comparison of the experimentally obtained plot and the theoretical ones for the extreme cases suggests that the experiments support, rather, the dead-end product assumption.

The peptides were cleaved from the resin by a conventional method, using hydrogen bromide in a mixture of acetic acid and trifluoroacetic acid. The products, (IX) and (X), obtained from the syntheses of I and II respectively were treated with aq. sodium hydrogencarbonate, and a fraction soluble in hydrogencarbonate solution was chromatographed on Sephadex G-50 (Figure 2 shows the results for IX). A fast eluting component appeared for both IX and X; it is considered to consist of peptide aggregates which are composed of alanine-rich peptides, as shown by their amino-acid analyses. All the chromatographic fractions were analyzed for their amino-acid compositions: the fractions containing Glu: Ala: phe=>19:>19: 1 were collected, desalted on a column Sephadex G-10, and lyophilized. The lyophilized material was chromatographed on DEAE-cellulose, and the fractions which gave the amino acid composition of: Glu: Ala: Phe= >19: >19: 1 were considered to be the final product, I or II (Fig. 3). These final products were analyzed by means of 2,4-dinitrophenylation for their free amino groups. The yield of 92—94% 2,4-dinitrophenylalanine or -glutamic acid suggested that only small amounts of pyroglutamate and/or other N-blocked products were present. The final yields of I and II were 9 and 11% respectively.

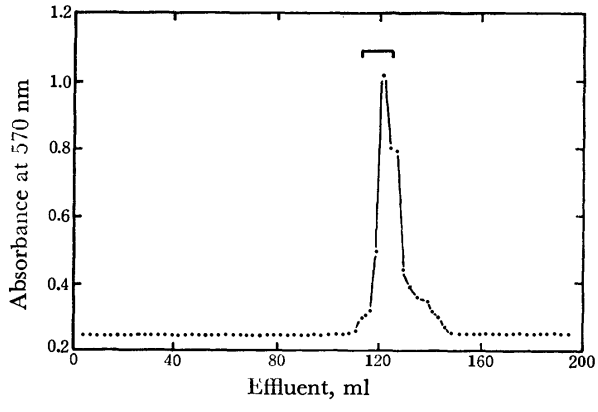

Fig. 3. DEAE-cellulose chromatography of $Glu_{20}Ala_{20}$-Phe. Aliquot of 0.025 ml from each fraction was alkaline hydrolyzed and absorbance at 570 nm was recorded after the ninhydrin reaction. The inserted bar has the same meaning as used in Fig. 2.

Degree of Racemization in the Products. The chromatographically purified products, I and II, were analyzed for their degrees of racemization caused by the peptide-coupling reactions. The racemization detection method by Manning[21] was modified and used. The peptide hydrolyzates, which were obtained by the treatment of the peptides with 6 M hydrochloric acid at 110 °C for 24 h, were reacted with BOC-L-Leu-OSu in the presence of sodium hydrogencarbonate. The products, after an acid treatment to remove the BOC group, were analyzed with an amino-acid analyzer. The authentic samples of D,L-glutamic acid and D,L-alanine were reacted with BOC-L-Leu-OSu under the same conditions and the ninhydrin colour value for each dipeptide separated on an amino-acid analyzer was used as the reference standard. The overall (because they included the difference in the reactivities of L- or D-amino acids towrd BOC-L-Leu-OSu) average ratio of ninhydrin colour values obtained from several experiments were: (L-Leu-D-Ala)/(L-Leu-L-Ala)=0.74, (L-Leu-D-Glu)/(L-Leu-L-Glu)=0.60, starting from a racemic mixture. The authentic samples of each dipeptide were also synthesized and used to identify the peaks in the chromatograms. These analyses showed the amounts of D-glutamic acid and D-alanine present in the hydrolyzate of the peptide I to be less than 1 and 5% respectively. The peptide II gave the same values.

The starting materials, III and IV, for the solid-phase syntheses were also tested for their degrees of racemization by the same method. The content of D-glutamic acid in III was shown to be less than 1%, and that of D-alanine in IV, to be 3%. Unfortunately, the original L-alanine used in the syntheses was found to contain 3% D-alanine. A comparison of the ORD curves of the hydrolyzate of IV and another sample of pure L-alanine confirmed the result ($[\alpha]_{230}$ were 1750° and 1860° (1%, 1 M HCl) for the hydrolyzate of IV and pure L-alanine respectively). Recrystallization seemed not to be able to separate a diastereomeric mixture, and the origin of a half of the D-alanine found in I and II was explained from the purity of the starting material. Therefore, the racemization accompanied by one step of the peptide-coupling reaction was about 0.3% or lower for the coupling of BOC-$(Ala)_2$ or BOC-$(\gamma$-Bzl-Glu$)_4$ respectively.

Experimental

The melting points were determined on a micro hot plate and are uncorrected. The elementary analyses were carried

out in the elementary analysis section in the Institute for Chemical Research, Kyoto University. The amino-acid analyses were carried out with a JEOL liquid chromatographic system under the conditions of Spackman *et al.*[22] A JASCO J-20 spectropolarimeter was used to measure the optical rotations. The BOC-hydrazide, trifluoroacetic acid, dicyclohexylcarbodiimide (DCC), and HOSu were purchased from the Protein Research Foundation, Osaka, Japan. The polystyrene beads (SX-1) were products of BioRad, Calif., U.S.A. The amino acids and other reagents were purchased from Nakarai Chemical Co., Kyoto, Japan. Reagent-grade dichloromethane was stored over sodium hydrogencarbonate, dried over molecular sieves (Type 4A, Linde), and distilled before use. The *N,N*-dimethylformamide was passed through a freshly packed column of silica gel G, dried over a molecular sieve (Type 4A, Linde), and distilled *in vacuo*. The trifluoroacetic acid was used after distillation over P_2O_5. The triethylamine was treated with 2,4-dinitrofluorobenzene and distilled over sodium.

N$^{\alpha}$-t-Butoxycarbonyl-L-alanyl-L-alanine, (IV). The dipeptide was synthesized from 143 g of BOC–Ala–OSu,[20] 53.5 g of alanine, and 50.5 g of $NaHCO_3$ in a mixture of 900 ml of tetrahydrofuran and 600 ml of water, according to the general method of Anderson *et al.*[20] Yield, 123 g (95%); mp 128—129 °C in a sealed tube (lit mp 85.5—87 °C,[23] 132—133 °C[24]). The compound could not be distinguished in melting point or infrared spectrum from the specimen obtained by the coupling of BOC-alanine with methyl alaninate employing isobutoxycarbonyl chloride, followed by saponification.[24] IV was hydrolyzed in 6M HCl at 110 °C for 24 h, and the hydrolyzate was submitted to measurements of the optical rotation and the racemization-detection reaction.

N$^{\alpha}$-t-Butoxycarbonyl-γ-benzyl-L-glutamic Acid, N-Hydroxysuccinimidyl Ester (V). 90 g of BOC–(γ-Bzl–Glu)[25] was allowed to react with 19.9 g of HOSu and 39.2 g of DCC at −8 °C in a mixture of 600 ml of ethyl acetate and 100 ml of tetrahydrofuran. Yield of V after recrystallization from 2-propanol, 68.3 g (91%); mp 106 °C (lit mp 100—101 °C[26]).

N$^{\alpha}$-t-Butoxycarbonyl-γ-benzyl-L-glutamyl-γ-benzyl-L-glutamic Acid (VI), and Its Dicyclohexylammonium Salt (VIa). 71.7 g of V, 59 g of γ-benzyl-L-glutamate, and 34.6 ml of triethylamine were stirred in 600 ml of *N,N*-dimethylformamide at room temperature for 10 h. Oily VI, obtained by the evaporation of the solvent *in vacuo*, was treated with 30 g of DCHA to give VIa, which was then recrystallized from ethyl acetate-cyclohexane. The VIa had a mp of 108—109 °C. Found: C, 66.65; H, 8.27; N, 5.72%. Calcd for $C_{41}H_{59}O_9N_3$ (VIa): C, 66.73; H, 8.06; N, 5.69%. VI has been known as oil.[26]

N-Hydroxysuccinimidyl Ester of VI(VII). 100 g of VIa was suspended in 400 ml of ethyl acetate and washed with 20% citric acid to convert the VIa into VI. The VI was reacted with 18.7 g of HOSu and 33.4 g of DCC at −8 °C for 10 h, and then at 5 °C for 25 h. The product, VII, was recrystallized from 2-propanol. Yield, 81 g (91%); mp 112—114 °C. Found: C, 60.88; H, 6.18; N, 6.42%. Calcd for $C_{33}H_{39}O_{11}N_3$: C, 60.63; H, 6.01; N, 6.43%.

γ-Benzyl-L-glutamyl-γ-benzyl-L-glutamic Acid(VIII). A 5.1-g portion of VIa was dissolved in 20 ml of dichloromethane and washed with 20% citric acid. The organic phase was washed with H_2O, dried over drierite, and then added to 10 ml of trifluoroacetic acid. The mixture was kept at room temperature for 1 h and then evaporated *in vacuo*. The residue was treated with 3% aq $NaHCO_3$ to crystallize the dipeptide acid VIII, which was subsequently recrystallized from ethanol. Yield, 2.1 g (65%); mp 124—125 °C. Found: C, 62.99; H, 6.22; N, 5.92%. Calcd for $C_{24}H_{28}O_7N_2$: C, 63.14; H, 6.18; N, 6.14%. The washing procedure with citric acid could be eliminated without any trouble. In that case, the amount of dichloromethane was reduced to 10 ml.

N$^{\alpha}$-t-Butoxycarbonyl-(γ-benzyl-L-glutamyl-)$_3$-γ-benzyl-L-glutamic-Acid, (III), and Its Dicyclohexylammonium Salt(IIIa). 52 g of VIII, 74 g of VII, 22.8 g of triethylamine, and 500 ml of *N,N*-dimethylformamide were mixed and stirred at room temperature for 24 h. The residues which were obtained after the evaporation of the solvent *in vacuo* were dissolved in ethyl acetate and washed thoroughly with 3% aq $NaHCO_3$. In the washing procedure, the sodium salt of tetrapeptide acid, III, was not transferred to the aqueous phase, but remained in the organic phase. The organic layer was washed with 5% citric acid and then with water, and dried over Na_2SO_4. A 20.4-g portion of DCHA was added to convert the III into IIIa, which was recrystallized several times from ethyl acetate. Yield, 105 g (79%); mp 129—130 °C. Found: 66.06; H, 7.24; N, 5.90%. Calcd for $C_{65}H_{85}O_{15}N_5$: C, 66.36; H, 7.28; N, 5.95%.

Solid-phase Peptide Synthesis. Polystyrene beads (BioBeads SX-1) which had been crosslinked with 1% divinylbenzene were chloromethylated[27] to a substitution level of 0.18 mmol Cl/g resin. The chloromethylated resin was reacted with BOC-phenylalanine to give the starting resin, BOC–Phe-resin. Acid hydrolysis, followed by amino-acid analysis, showed that 0.165 mmol of phenylalanine was incorporated per g of resin. 15 cycles of solid-phase peptide synthesis (the cycle is summarized in Table 1) were manually performed with a home-made shaker, starting with 5 g of BOC–Phe-resin for each block copolypeptide. After Step (11) in Table 1, an aliquot of peptide resin was removed, acid-hydrolyzed and analyzed for its amino-acid composition. Hydrolyses of the resin-bound peptides were carried out in a mixture of propionic acid and concd HCl (1: 1) or, for alanine-rich peptide-resin, in 95% trifluoroacetic acid, both in a sealed and evacuated tube at 110 °C for 24 h.

Cleavage of Peptide from Peptide-resin and Gel Chromatography of Peptides. A 20-ml portions of 20% HBr in acetic acid was added to 3 g of peptide-resin suspended in 10 ml of trifluoroacetic acid. The mixture was kept at room temperature for 1 h and then filtered to separate the resin. The resin was washed with a 1: 1 mixture of acetic acid and trifluoroacetic acid, and the combined filtrate was evaporated *in vacuo*. The residue was thoroughly washed with ether and dissolved in aq hydrogencarbonate solution. The peptides precipitated by acidification with HCl were redissolved in a small amount of aq $NaHCO_3$, and chromatographed on Sephadex G-50 (medium, 2.8×130 cm). Elution was achieved with 0.1 M NaCl–0.05M $NaHCO_3$–0.005M Na_2CO_3, and each fraction was analyzed for its peptide content by ninhydrin analysis after alkaline hydrolysis[28] or by UV absorption at 230—240 nm. An aliquot from each peptide-containing fraction was acid-hydrolyzed and analyzed for its amino-acid composition. Fractions containing a peptide whose amino acid composition was Glu: Ala: Phe= >19: >19: 1 were pooled and lyophilized. The lyophilized material was then dissolved in 2 ml of H_2O and placed on a column (1.5×130 cm) of Sephadex G-10. Elution was achieved with H_2O, and the peptide-containing fractions were combined and lyophilized.

$Glu_{20}Ala_{20}Phe$, (I). The yield of the material obtained after a gel filtration was 280 mg from 3 g of peptide-resin (14%). A 40-mg portion of the lyophilized sample was chromatographed on a DEAE-cellulose (Whatman DE-32) column (1.3×17 cm). The linear gradient of the concentration from 0M to 1M (in a 0.05M Na-phosphate buffer at pH 6.67) was applied for elution (total 200 ml). Each fraction was analyzed by ninhydrin analysis after alkaline hydrolysis,[28] and the peptide-containing fractions were analyzed for

their amino-acid compositions after total hydrolysis. Peptide-containing fractions, for which the amino-acid composition after total hydrolysis was given as Glu: Ala: Phe= >19: >19: 1, were pooled, desalted by Sephadex G-10, and lyophilized. Yield, 26 mg (the total yield was calculated as 306 mg (9%) starting from 5 g of BOC–Phe-resin).

$Ala_{20}Glu_{20}Phe$, (II). The gel-filtrated material was chromatographed on DEAE-cellulose and analyzed in a way similar to that described for I.

N-Terminal Analysis. Aliquots from I and II were 2,4-dinitrophenylated, hydrolyzed in 6M HCl at 110 °C for 18 h, and analyzed for the yield of 2,4-dinitrophenyl(DNP-)alanine or DNP-glutamic acid. After the necessary correction for the loss of DNP-amino acids during the acid hydrolysis, the yields of DNP-glutamic acid from I and DNP-alanine from II were found to be 92% and 94% respectively. No other DNP spots were detected on a TLC plate.

Detection of Racemization. The peptides in question (2 to 5 mg) were hydrolyzed in 2 ml of 6M HCl at 110 °C for 24 h. The hydrolyzates, which were completely free from acid by drying over KOH *in vacuo*, were dissolved in a mixture of 1 ml of H_2O and $NaHCO_3$ (5 equivalents for amino acids). 5 equivalents of BOC-L-Leu-OSu in 0.5 ml of acetonitrile were added to the mixture, and the reaction was carried out at room temperature for 1 h under shaking. The reaction mixture was then washed with ethyl acetate several times and evaporated to dryness. The residue was treated with a mixture of 1 ml of acetic acid and 1 ml of trifluoroacetic acid at room temperature 1 h, and then evaporated to afford a mixture of dipeptides, excess leucine, and some unreacted amino acids. The mixture was dissolved in a 0.2M sodium citrate buffer at pH 2.2 and placed in a 50-cm column of an amino-acid analyzer operated at 55 °C. A 0.2M sodium citrate buffer which had been adjusted to pH 3.10 by adding concd HCl to the regular pH 3.35 sodium citrate (0.2M) buffer[29] was used to separate L-Leu-D-Glu (425 min), L-Leu-L-Glu (488 min), and leucine (545 min), while the regular pH 4.25 buffer (0.2M sodium citrate)[29] was used to separete L-Leu-D-Ala (130 min) and L-Leu-L-Ala (157 min). The retention times are shown in parentheses. For the reference standard, authentic D,L-amino acids were treated under the same conditions. The product, the diastereomeric dipeptide mixture, was analyzed with an amino-acid analyzer to give the standard ratio of the ninhydrin colour values. The positions of the peptides were determined by the analysis of authentic peptides which had been synthesized from BOC-L-Leu-OSu and D- or L-amino acids. BOC-L-Leu-D-Ala (mp 166—168 °C from methanol. Found: C, 55.57; H, 8.67; N, 9.19%. Calcd for $C_{14}H_{26}O_5N_2$: C, 55.61; H, 8.67; N, 9.27%.) and BOC-L-Leu-L-Ala·DCHA (crystallized from ethyl acetate, mp 159—162 °C; the crystals turn unclear at 105—110 °C, presumably because of a loss of solvent for crystallization. Found: C, 63.71; H, 10.22; N, 7.78%. Calcd for $C_{26}H_{49}O_5N_3 \cdot 1/2CH_3CO_2C_2H_5$: C, 63.72; H, 10.12; N, 7.96%) were obtained as crystals, but the corresponding glutamyl peptides were oils.

The Reaction of Dammarane Derivatives: Reactions Involving C-20 Carbonium Ions

Motoo Tori, Takahiko Tsuyuki, and Takeyoshi Takahashi

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received June 23, 1977)

In order to investigate the reaction involving C-20 cation in dammarane derivatives, following reactions were examined: a) (20*S*)- and (20*R*)-dammaran-20-ols (**13** and **14**) with acids. b) dammar-20(22)-en-23-one (**15**) with hydrochloric acid, c) 20,21- and 20,22-epoxydammaranes (**16** and **17**) with boron trifluoride etherate, and d) hexanor- and pentanordammaran-20-ols (**18** and **19**) with phosphoryl chloride and with boron trifluoride etherate, *etc.*, and 20ξ-tosyloxyhexanordammarane (**46**) with silica gel. Either formation of a double bond in the framework or in the side chain (in the cases of **13**, **14**, **18**, **19**, and **46**), deconjugation of the double bond (in the case of **15**), or formation of a carbonyl group in the side chain (in the cases of **16** and **17**) was observed. However, D-homoannulation reaction was not observed in all cases.

The biogenetic pathway of triterpenes proposed by Ruzicka *et al.*[1] strongly suggests an intermediacy of a tetracyclic cation (**1**) with a dammarane-type skeleton as a primary cyclization product from squalene. The cation (**1**) is also suggested to be transformed into various triterpenes depending on characteristic enzyme action *in vivo*. For example, a $C_{(16)}$–$C_{(17)}$ bond migration to C-20 causes a formation of a baccharane skeleton (**2**) with the cation at C-20, which will be further derived into baccharis oxide (**3**) or shionone (**4**).

4

In the field of steroid chemistry, a number of investigations on backbone rearrangement and D-homoannulation reactions have been reported.[2] Among them, D-homoannulation of 20-tosylates has been shown to depend on the configuration at C-20 and also on the solvolytic conditions. For example, 3β-acetoxy-17α-hydroxy-5α-pregnan-20β-yl tosylate (**5**), on treatment with potassium acetate in aqueous acetone or with sodium iodide in acetone, gave 3β-acetoxy-17α-methyl-D-homo-5α-androstan-17a-one (**6**) as a principal product. While the epimeric 20α-tosylate (**7**) yielded 3β-acetoxy-17aα-methyl-D-homo-5α-androstan-17-one (**8**).[3] A solvolysis of 5α-pregnan-20β-yl tosylate (**9**) gave 17α-methyl-D-homo-5α-androstan-17aβ-yl tosylate (**10**) in a high yield.[4] The formolysis of 3β-acetoxy-5α-pregnan-20α-yl tosylate (**11**), however, proceeds predominantly without enlargement of the D-ring to afford 17β-methyl-18-nor-5α,17α-pregn-13-en-3β-yl acetate (**12**) as a main product.[2d]

a variety of investigations on the reactions of dammarane derivatives have so far been carried out.[6,7] In order to examine the reaction of dammarane derivatives having a cationic center at C-20, following reactions have now been investigated: a) (20*S*)- and (20*R*)-dammaran-20-ols (**13** and **14**) with acids, b) dammar-20(22)-en-23-one (**15**) with hydrochloric acid, c) 20,21- and 20,22-epoxydammaranes (**16** and **17**) with boron trifluoride etherate, and d) hexanor- and pentanordammaran-20-ols (**18** and **19**) with phosphoryl chloride.

a) Reaction of (20S)- and (20R)-Dammaran-20-ols (13 and 14) with Acids. Although (20*S*)-dammaran-20-ol (**13**)[8] was easily prepared by Huang-Minlon reduction of (20*S*)-20-hydroxydammaran-3-one (**20**)[5b] derived from dipterocarpol (**21**),[5,6a–d] the epimeric (20*R*)-alcohol (**14**) was synthesized from **13** *via* hexanordammaran-20-one (**22**) or nordammaran-20-one (**23**).[9]

(20*S*)-Dammaran-20-ol (**13**) was treated with phosphoryl chloride in pyridine to afford an olefin mixture, which was subjected to separation by silver nitrate-impregnated silica gel TLC to give a mixture (*ca.* 1 : 1) of (20*R*)- and (20*S*)-dammar-13(17)-enes (**24a** and **24b**; yield 3%), a mixture of (*E*)- and (*Z*)-dammar-20(22)-enes (**25a** and **25b**; y. 65%), and dammar-20-ene (**26**; y. 25%). The structure of the former (**24**) was discussed below and those of the latter two (**25** and **26**) were determined by spectral data (*cf.* Experimental) and by their transformation into **22** and **23**, respectively. The olefin mixture, without separation, was subjected to ozonolysis and the resulting mixture was separated by chromatography to afford hexanordammaran-20-one

(**22**; 40%)[8,10] and nordammaran-20-one (**23**; 22%), together with 13α*H*-octanordammaran-17-one[11] (**27**; 0.4%) and octanordammaran-17-one[11] (**28**; 1.7%). It was therefore suggested that dammar-17(20)-enes (**29a** and/or **29b**) had also been present in a very small amount in the above olefin mixture.[7]

The structure of nordammaran-20-one (**23**) was confirmed by its conversion into dammaran-20-ols (**13** and **14**). Nordammaran-20-one (**23**) was treated with methylmagnesium iodide in ether to give a mixture of the epimeric alcohols (**13** and **14**) in a ratio of 1 : 2, while the Grignard reaction of hexanordammaran-20-one (**22**) with 1-bromo-4-methylpentane in tetrahydrofuran gave the same mixture in a ratio of 11 : 8.

The stereochemistry of the addition reaction of Grignard reagents to 20-keto steroids has been investigated. For example,[12] the addition of methylmagnesium bromide to 3β-acetoxy-21-nor-5α-cholestan-20-one (**30**) gave exclusively the corresponding (20*R*)-alcohol (**31**). On the contrary, the (20*S*)-epimeric alcohol (**32**) was obtained by addition of 4-methylpentylmagnesium bromide to 3β-acetoxy-5α-pregnan-20-one (**33**). The selectivity in these reactions seems to be attributable to the presence of the 13β-methyl group in the steroid skeleton. The lower selectivity to form the (20*S*)- or (20*R*)-alcohol in the case of the dammarane derivatives, compared with the reaction of 20-keto steroids, could be explained by the absence of the 13β-methyl group in the dammarane skeleton.[9]

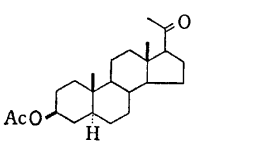
32



33

Mills showed that dammaranediol-II monoacetate (**34**) gave a mixture of isoeuphenyl acetate (**35a**) and isotirucallenyl acetate (**35b**) on treatment with 1 M sulfuric acid.[5b] Tanaka *et al.*[6e,13] reported acid treatments of (20*S*)-dammaran-20-ol (**13**), (20*S*)-dammar-24-en-20-ol, and of the corresponding 12-hydroxylated compounds to examine the epimerization at C-20.

Dehydration reaction of the epimeric (20*S*)- and (20*R*)-dammaran-20-ols (**13** and **14**) catalyzed by various acids has now been investigated under various conditions. i) Treatment of (20*S*)-dammaran-20-ol (**13**) in benzene with boron trifluoride etherate gave a hydrocarbon as a main product. This hydrocarbon was shown to be a mixture (*ca.* 1 : 1) of (20*R*)- and (20*S*)-dammar-13(17)-enes (**24a** and **24b**) by the following evidence. A mixture of euphol (**36a**) and tirucallol (**36b**), extracted from *Euphorbia kansui* Liou.,[14] was acetylated, hydrogenated, and then treated with hydrochloric acid in acetic acid according to the procedures described by Arigoni *et al.*,[15] to yield a mixture of isoeuphenyl acetate (**35a**) and isotirucallenyl acetate (**35b**).[15] This mixture (**35a** and **35b**) was subjected successively to alkaline hydrolysis, Jones oxidation, and Huang-Minlon reduction to afford a mixture of (20*R*)- and (20*S*)-dammar-13(17)-enes (**24a** and **24b**), which was found to be identical with the hydrocarbon obtained by boron trifluoride etherate treatment of **13**. The ratio (*ca.* 1 : 1) of **24a** and **24b** in the olefin mixture (**24**) was estimated from peak heights of the C-21 methyl signals (**24a**, δ 0.94; **24b**, δ 0.90)[16] and by gas chromatographic analysis. When (20*R*)-dammaran-20-ol (**14**) was treated with boron trifluoride etherate in benzene, the same mixture (**24a** and **24b**; *ca.* 1 : 1) was formed.

(20*S*)-Dammaran-20-ol (**13**) was then treated with the following conditions: ii) boron trifluoride etherate in dichloromethane at room temperature, iii) boron trifluoride etherate in acetic acid, iv) stannic chloride in benzene, v) picric acid in nitromethane,[17] vi) 1 M sulfuric acid in acetic acid under reflux according to Mills' procedure,[5b] and vii) formic acid in acetone under reflux. Treatment of (20*R*)-dammaran-20-ol (**14**) with i) boron trifluoride etherate in benzene, ii) boron trifluoride etherate in dichloromethane, or with iii) trifluoroacetic acid, was also examined. In each case, the same reaction products (**24a** and **24b**) were obtained. When protic acids were used, the formation of **25** and **26** was also observed. However, Lewis acid treatment afforded **24** as major products.

Removal of the hydroxyl group at C-20 of **13** or **14** by an acid catalyst may produce a cation at C-20. As this type of cation has rather a long life time, the hydrogen atom at C-17α can undergo 1,2-shift from both the back and the front sides of the cation, resulting in the formation of the epimeric mixtures at the C-20 carbon atom. A C-13β hydrogen atom is then removed to provide an unsaturated double bond $C_{(13)}$–$C_{(17)}$, the position of which is considered to be the most stable one in the dammarane skeleton.

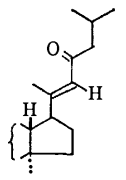
b) Synthesis of Dammar-20(22)-en-23-one (15) and Reaction with Hydrochloric Acid. It was unsuccessful to build up the side chain of **15** directly by the Wittig reaction of hexanordammaran-20-one (**22**) with dimethyl 4-methyl-2-oxopentylphosphonate;[18] an anion derived from the phosphonate was unreactive with the ketone (**22**) in dimethyl sulfoxide or in dimethoxyethane under reflux. Hexanordammaran-20-one (**22**), however, reacted with diethyl cyanomethylphosphonate in dimethoxyethane using sodium hydride as a base. The reaction proceeded quantitatively to yield pentanordammar-20(22)-ene-22-carbonitrile (**37**). Recrystallization from petroleum ether-ether furnished a major isomer, mp 179—180 °C, which was shown to be an (*E*)-isomer (**37a**) from the proton NMR[19] (*cf.* Experimental) and the ^{13}C-NMR spectral data (Table 1). An examination of the mother liquor showed also the presence of the (*Z*)-isomer (**37b**).

The structure of the α,β-unsaturated carbonitrile (**37**) was also supported by its conversion into the α,β-unsaturated ester (**38**). The (*E*)-isomer of the carbonitrile (**37a**) was treated with potassium hydroxide in boiling ethylene glycol followed by methylation with diazomethane to give a mixture of methyl (*E*)- and (*Z*)-tetranordammar-20(22)-en-23-oates (**38a** and **38b**), which was separated by TLC into each isomer.

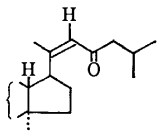
The residual C-4 unit was then introduced to the tetranordammarane skeleton (**37a**). Treatment of **37a** with isobutylmagnesium bromide gave an imine, which was hydrolyzed *in situ* with aqueous ammonium chloride.[20] The resulting products, consisting of (*E*)- and (*Z*)-dammar-20(22)-en-23-ones (**15a** and **15b**), were separated into each isomer by preparative TLC. Assignment of the geometry of the double bonds in **15a**

and **15b** was easily accomplished by NMR measurement.[21,22] The methyl group attached to an olefinic carbon atom at C-20 of the less polar (on TLC) isomer resonates at δ 1.79 (d, J=1.5 Hz) and that of the more polar one at δ 2.05 (d, J=1 Hz). The methyl group resonating in the lower field can be assigned as that of the (*E*)-isomer (**15a**).

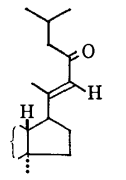
The conformation of each enone (**15a** and **15b**) was also inferred by the solvent effect on the chemical shifts of the proton NMR spectrum.[21a,23] In benzene-d_6, the chemical shift of the $C_{(21)}$-Me of the (*E*)-isomer (**15a**) was observed in the lower field ($\delta_{CDCl_3}-\delta_{C_6D_6}=-0.14$), although the olefinic proton resonated in the higher field ($\delta_{CDCl_3}-\delta_{C_6D_6}=+0.03$). As for the (*Z*)-isomer (**15b**), both of the signals suffered appreciable upfield shifts ($\delta_{CDCl_3}-\delta_{C_6D_6}=+0.15$ for the methyl and +0.12 for the olefinic proton signals). These spectral data suggest the conformation depicted as in **15a**-1 and **15b**-1 (not as in **15a**-2 and **15b**-2) for **15a** and **15b**, respectively, in the solution.



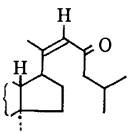
15a-1



15b-1



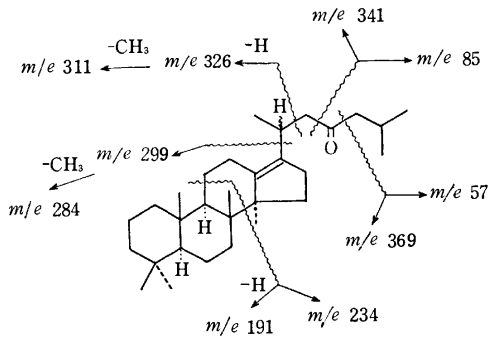
15a-2



15b-2

Treatment of the (*E*)-isomer (**15a**) with *p*-toluenesulfonic acid in ether gave a mixture of the (*E*)- and (*Z*)-isomers (**15a** and **15b**). The (*Z*)-isomer (**15b**) also afforded the same mixture on the same treatment. Similar results were obtained upon treatment with boron trifluoride etherate.

The (*E*)-isomer (**15a**) was refluxed with concd hydrochloric acid in ethanol. Two products were obtained in about equal amounts. The IR spectrum of the less polar product (on TLC) shows bands at 1700 and 1600 cm^{-1} and that of the more polar one at 1705 cm^{-1}. Mass spectra of both compounds closely resemble each other. These observations suggest the similarity of the whole structure of both compounds having a deconjugated double bond. Since NMR spectra show no olefinic proton, the presence of a tetrasubstituted double bond is suggestive. A carbonyl function at C-23 is indicated by fragment peaks at *m/e* 369 and *m/e* 57 and also at *m/e* 341 and *m/e* 85. The location of the tetrasubstituted double bond is also suggested by the mass spectrum (*cf.* **39**). The structure of the two products are therefore considered to be ($20\xi_1$)- and ($20\xi_2$)-dammar-13(17)-en-23-ones (**39**).



39

Protonation at $C_{(23)}$-O function of **15a** provokes of a generation of a cationic center at C-20. Successive 1,2-shift of a hydride from the C-17α to the C-20 carbon atom and deprotonation of $C_{(13\beta)}$-H, or a mechanism involving 1,3-shift, would give rise to a tetrasubstituted double bond between C-13 and C-17. Direct protonation at the double bond of **15a** could also illustrate the formation of the cationic center at C-20.

*c) Synthesis of 20,21- and 20,22-Epoxydammaranes (**16** and **17**) and Reaction with Boron Trifluoride Etherate.* Epoxidation of dammar-20-ene (**26**) with *m*-chloroperbenzoic acid in dichloromethane gave an epoxide (**16**). A signal due to two protons of the epoxide ring terminus appeared at δ 2.59 (br. s, $W_{1/2}$ 2 Hz). As this epoxide was thought to be a mixture of (20*S*)- and (20*R*)-configurations, it was reduced with lithium aluminium hydride in ether. (20*S*)-Dammaran-20-ol (**13**) and (20*R*)-dammaran-20-ol (**14**) were obtained in a ratio of 2: 3. No formation of other alcohols was detected. Consequently, the epoxide mixture was suggested to consist of the (20*S*)- and (20*R*)-20,21-epoxydammaranes (**16**) in a ratio of *ca.* 2: 3. Further separation was not attempted.

Treatment of this mixture of epoxide (**16**) with boron trifluoride etherate in benzene at room temperature for 10 min gave an aldehyde (**40**). Its IR (2680 and 1720 cm^{-1}) and NMR [δ 9.55 and 9.68 (each *ca.* 0.5H, d, J=3 Hz)] spectra suggested the presence of an aldehyde group attached to a secondary carbon atom. And the NMR spectrum also indicated the presence of a pair of C-20 isomeric aldehydes.

Epoxidation of the mixture of dammar-20(22)-enes (**25a** and **25b**) gave an epoxide mixture (**17**). An HPLC examination of **17** suggested the presence of four possible stereoisomers, one of which was the major. The mixture of the epoxides (**17**) including four stereoisomers was treated with boron trifluoride etherate in benzene at room temperature for 20 min. Three products were obtained after usual work-up. The least polar product (on TLC) showed bands at 2660 and 1720 cm^{-1} in its IR spectrum. Its mass spectrum showed peaks at *m/e* 428 (M^+), 399 (M−CHO), 357 ($M-C_5H_{11}$), and 301 ($M-C_8H_{15}O$). These observations suggest the presence of a tertiary aldehyde function and lead to the structure of ($20\xi_1$)-26,27-dinor-20,24-dimethyldammaran-21-al [($20\xi_1$)-**41**] for this product. The spectral data of the second product [($20\xi_2$)-**41**] were

very similar to those of the first one. This fact indicates that these two products are epimers at C-20 each other. However, the configuration of each compound has been left undetermined. The most polar product showed a band at 1710 cm^{-1} and peaks at *m/e* 428 (M^+), 357 ($M-C_5H_{11}$), and 329 ($M-C_6H_{11}O$). This product can be formulated as (20ξ)-dammaran-22-one (**42**) by these spectral data and mechanistic consideration.

An attack of boron trifluoride etherate to the oxygen atom of the epoxide and subsequent ring opening by the $C_{(20)}$–O bond cleavage may generate the cationic center at C-20. In the former (**16**) case, a hydride at C-21 migrates to the C-20 carbon atom to afford the aldehyde (**40**). The configuration at C-20 must be determined by the original configuration of the epoxide: *i.e.*, the hydride which migrates is considered to be introduced from the back side of the oxygen atom of the epoxide. In the latter (**17**) case, there are two possible migrating group, *i.e.*, a hydrogen atom and an isopentyl group on the C-22 carbon atom. When the hydrogen atom migrates to C-20, it may result in formation of the ketone (**42**), while the aldehyde (**41**) may be obtained when the isopentyl group undergoes a 1,2-shift to C-20. Neither hydride shift from C-17α to C-20 nor $C_{(17)}$–$C_{(13 \text{ or } 16)}$ bond migration was observed. A factor of stabilization for the formation of a carbonyl group seems to be larger than that for an en-ol structure. Recently, similar results using cholestane derivatives have been reported by Ikekawa et al.[24] and others.[25,26] All the isomers of the 20(22)-epoxides were synthesized independently and their chemical reactions were discussed.

d) *Reaction of Hexanor- and Pentanordammarane Derivatives.* Hexanordammaran-20-one (**22**) was reduced with sodium borohydride in ethanol to yield a mixture of alcohols (**18**) which could not be separated. This secondary alcohol (**18**) was dehydrated with phosphoryl chloride in pyridine to afford a mixture, which showed two spots on TLC of silica gel. The more polar product (on TLC) was shown to be a mixture of (20*S*)- and (20*R*)-20-chlorohexanordammarane (**43**) (*cf.* Experimental). The less polar part (hydrocarbon) showed one major peak along with two minor ones on GLC analysis. A signal due to an olefinic proton was observed around δ 5.0 ppm (diffused). In order to determine the exact position of the double bond, a solution of this hydrocarbon mixture in carbon tetrachloride was treated with ruthenium tetraoxide in the same solvent at room temperature. On separation by preparative TLC, octanordammaran-17-one (**28**) was obtained, which was identical with an authentic sample.[11] A solution of the hydrocarbon mixture in dry tetrahydrofuran was subjected to hydroboration-oxidation to yield hexanordammaran-20-ol (**18**). The formation of hexadammar-17(20)-enes (**44**) and of **43** from **18** was therefore shown.

Treatment of hexanordammaran-20-ol (**18**) with *p*-toluenesulfonyl chloride in pyridine gave a tosylate (**46**). The tosylate (**46**) was passed through a column of silica gel to give a single product (**45**), mp 104—106 °C, after recrystallization from methanol–chloroform. The elemental analysis and mass spectrum showed a molecular formula, $C_{24}H_{40}$, for this compound. The NMR spectrum showed the presence of an ethyl group and the absence of olefinic proton. In view of the above facts the most reasonable structure of this olefin is hexanordammar-13(17)-ene (**45**).

Hexanordammaran-20-one (**22**) was methylated with methylmagnesium iodide in ether to give a tertiary alcohol (**19**). The alcohol (**19**) was dehydrated with phosphoryl chloride in pyridine to afford two hydrocarbons, which were separated by preparative TLC on silver nitrate-impregnated silica gel. The less polar product could be formulated as pentanordammar-17(20)-ene (**47**) from its NMR spectrum showing the presence of an isopropylidene group. The NMR spectrum of the more polar product indicated the presence of an isopropenyl group; this led to the structure of pentanordammar-20-ene (**48**) for this hydrocarbon.

Treatment of the alcohol (**19**) with boron trifluoride etherate in benzene at room temperature for 1 h furnished two products. The more polar product (on TLC) was identical with **48**. The NMR spectrum of the less polar product showed the presence of an isopropyl group and the absence of olefinic proton; the structure of pentanordammar-13(17)-ene (**49**) was suggested for this product.

These characteristic dehydration reactions are mainly dependent on both of the acids and the solvents used. When a base such as pyridine is present in the reaction system, a proton adjacent to a hydroxyl group is easy to be abstracted. It is known that dammarane-type triterpenes having a normal side chain produce 20(22)- and 20-enes as major products[5] (*vide supra*). However, when the side chain is small, a base such as pyridine can abstract the hydrogen atom at C-17α to afford a 17(20)-ene. This is the remarkable difference between the two. In the case of boron trifluoride etherate, a hydride shift and a subsequent deprotonation can occur to yield the more stable 13(17)-ene, as the life time of the cationic center is longer.

Although all the reactions were attempted for aiming at the chemically induced rearrangements of the C-20 cation of the dammarane-type into baccharane-type skeleton, neither tertiary cation nor secondary cation at C-20 underwent such rearrangement.

^{13}C-NMR Spectra. Recently, O. Tanaka and his co-workers reported the assignments of carbon signals of dammarane-type triterpenes and discussed the chemical shift difference between (20*S*)- and (20*R*)-dammarane-12,20-diol derivatives.[27,28] Remarkable differences were observed owing to a hydrogen bonding between $C_{(12)}$–OH and $C_{(20)}$–OH groups.

We examined the ^{13}C-NMR spectra of some dammarane derivatives without $C_{(3)}$–oxygen function. The assignment of carbon signals of dipterocarpol (**21**) by O. Tanaka et al.[28] made it possible to assign the $C_{(24)}$ and $C_{(25)}$ carbon atoms of dihydrodipterocarpol (**20**; (20*S*)-20-hydroxydammaran-3-one). The accuracy of the assignment was confirmed by the hexanor derivative (**22**). Signals due to $C_{(1)}$—$C_{(6)}$, $C_{(28)}$, and $C_{(29)}$ of (20*S*)- and (20*R*)-dammaran-20-ols (**13** and **14**) were easily assigned by considering the additivity and the effects of substituents and also from comparison of the spectra from compound to compound.

Table 1. ^{13}C-NMR chemical shifts, δ_C, of some derivatives of dammarane-type in $CDCl_3$[1]

a,b,c,d) Assignments may be reversed in each vertical column. 1) FT measurement conditions were as follows: spectral width, 4000 Hz; acquisition time, 1.0 s; number of data points, 8192; pulse width, 3 μs. 2) Ref. 28. 3) Difference of the chemical shift values (δ_C) between (20*S*)-dammaran-20-ol (**13**) and (20*R*)-dammaran-2-ol (**14**).

The unsaturated carbonitrile (**37a**) was deduced to be pure (*vide supra*), showing 26 peaks.

The chemical shift difference between the (20*S*)- and (20*R*)-isomers was very small except for $C_{(21)}$ and $C_{(22)}$ carbon atoms as described by O. Tanaka *et al.*[28] (Table 1).

Experimental

General Procedures. All melting points were measured on a Mel-temp capillary melting point apparatus (Laboratory Devices) and uncorrected. Optical rotations were determined in chloroform solutions on a JASCO polarimeter DIP-SL. Ultraviolet absorption (UV) spectra and infrared (IR) spectra were measured on a Hitachi EPS-2 and a Hitachi EPI-G2 spectrometer, respectively. Mass (MS) spectra were run on a Hitachi RMU-6-Tokugata mass spectrometer and high resolution mass spectra on a Hitachi RMH-2 mass spectrometer operating at 70 eV with a direct inlet system. The relative intensity was expressed in % in the parentheses. Proton nuclear magnetic resonance (NMR) spectra were taken in deuteriochloroform ($CDCl_3$) using a Hitachi R-20B (60 MHz), a JEOL JNM PS-100 (100 MHz), or a JEOL JNM FX-60 spectrometer. Chemical shifts were expressed in ppm downfield from tetramethylsilane (TMS) as an internal standard (δ value) and coupling constants in Hz. ^{13}C NMR spectra were recorded on a JEOL JNM FX-60 FT NMR spectrometer at 15.04 MHz in $CDCl_3$ with TMS as an internal reference (δ_C O) in 8-mm spinning tube. Gas chromatography (GLC) was carried out using Shimadzu 4A-PF or CG-2C equipped with a hydrogen flame ionization detector. Liquid Chromatograph Model ALC/GPC 202/401 (Waters Assoc.) was used for high performance liquid chromatography (HPLC); Column: μ-PORASIL 1/8 (inch) × 1 (foot); Solvent system: 1 or 10% ether–hexane; Flow rate: 1.0 or 1.2 ml/min; Pressure: *ca.* 500 psi; with an RI or UV detector at room temperature. Thin layer chromatography (TLC) was carried out on Kieselgel PF_{254} (E. Merck) or Wako Alumina B-10F (Wako) in 0.25 or 0.5 mm thickness. Wakogel C-200 (Wako) was used for column chromatography.

(20S)-Dammaran-20-ol (13). A mixture of (20*S*)-20-hydroxydammaran-3-one[5b] (**20**; 8 g), potassium hydroxide (4 g), hydrazine hydrate (*ca.* 100%; 3.5 g), and diethylene glycol (60 ml) was refluxed for 1.5 h. After removal of excess hydrazine and water, the reaction mixture was heated under reflux for 4 h. It was poured into water and extracted with chloroform five times. The extracts were combined, washed with water and brine, dried over magnesium sulfate, and evaporated to give a residue. The residue was crystallized from methanol to furnish *(20S)-dammaran-20-ol* (**13**; 5.5 g) as

white crystals; mp 86—87 °C (lit,[8] 85 °C); $[\alpha]_D$ +36° (*c* 1.4) (lit,[8] +34.6°); IR (KBr) 3570 and 3450 cm^{-1}; NMR δ 0.81—0.97 (7×Me) and 1.14 (3H, s, $C_{(20)}$-Me); MS *m/e* 415 (M−15; 2), 412 (M−18; 5), 397 (6), 345 (21), 327 (6), 302 (30), 287 (15), 231 (17), and 191 (100); Found: C, 83.39; H, 12.49%. Calcd for $C_{30}H_{54}O$: C, 83.65; H, 12.64%.

Dehydration of (20S)-Dammaran-20-ol (13). Phosphoryl chloride (2 ml) was added portionwise to a solution of (20*S*)-dammaran-20-ol (**13**; 574 mg) in pyridine (20 ml) at 0 °C. After standing overnight at room temperature, the reaction mixture was poured into ice–water and extracted with petroleum ether five times. The combined extracts were washed with 2M hydrochloric acid, water, and with brine, dried over magnesium sulfate, evaporated, and passed through a short column of silica gel to give a residue (511 mg; y. 93%); IR (film) 1630 and 885 cm^{-1}; NMR δ 1.52 (Me–C=CH–), 4.68 (H_2C=C–), and 5.10 (Me–C=CH–).

The residue was chromatographed on a column of silica gel (60 g) impregnated with silver nitrate (10 g) and eluted with petroleum ether (each 50 ml). Frs. 3—6 afforded a mixture (*ca.* 1:1) of (20*R*)- and (20*S*)-dammar-13(17)-enes (**24a** and **24b**; 17 mg, y. 3%; spectral data are registered later), frs. 8—20 a mixture of (*E*)- and (*Z*)-dammar-20(22)-enes (**25a** and **25b**; 357 mg, y. 65%, after crystallization from pentane), and frs. 26—61 gave dammar-20-ene (**26**; 135 mg, y. 25%). *Mixture of (E)- and (Z)-dammar-20(22)-enes (25)*: amorphous solid, IR (film) 1650 and 860 cm^{-1}; NMR δ 1.53 (3H, br. s, Me–C=CH–) and 5.10 (1H, t, J=*ca.* 6 Hz; Me–C=CH–); MS *m/e* 412 (M^+; 17), 397 (5), 380 (4), 328 (21), 313 (8), 299 (8), 286 (21), 273 (12), 259 (25), 231 (46), and 191 (100); MW Found: 412.4216. Calcd for $C_{30}H_{52}$: 412.4066. This mixture was inferred to consist of the (*E*)- and (*Z*)-isomers[29] by silver nitrate-impregnated silica gel TLC examination. However separation into each isomer was unsuccessful. *Dammar-20-ene (26)*: an oil, IR (film) 3060, 1635, and 885 cm^{-1}; NMR δ 0.84—1.00 (7×Me) and 4.70 (2H, br. s, $W_{1/2}$ 3 Hz; H_2C=C–); MS *m/e* 412 (M^+; 14), 397 (6), 380 (2), 342 (8), 327 (4), 300 (6), 299 (6), 286 (9), 259 (7), 239 (6), 231 (42), and 191 (100).

Nordammaran-20-one (23) and Hexanordammaran-20-one (22). The reaction mixture, obtained by dehydration of (20*S*)-dammaran-20-ol (**13**; 11.5 g) was dissolved in dichloromethane (300 ml) and a slow stream of ozone was bubbled through the solution kept at −78 °C for 2.5 h. After standing at room temperature for 1 h, acetic acid (200 ml) and zinc dust (5 g) were added under cooling. The solution was allowed to stand overnight at room temperature, concentrated to half volume, poured into water, and was extracted with ether. Usual work-up furnished a residue (*ca.* 10 g), which was chromatographed on a column of silica gel (950 g) and eluted with the following solvent system: frs. 1—29, petroleum ether; frs. 30—35, petroleum ether–benzene (20:1); frs. 36—69, (15:1); frs. 70—107, (5:1). From frs. 41—68 nordammaran-20-one (**23**; 2.4 g, y. 22%) was eluted and from frs. 72—94 hexanordammaran-20-one (**22**; 3.7 g, y. 40%, after crystallization from methanol) was obtained. 13α*H*-Octanordammaran-17-one[11] (**27**; 32 mg, y. 0.4%) and octanordammaran-17-one[11] (**28**; 155 mg, y. 1.7%) were eluted from frs. 95—100 and frs. 101—107, respectively. *Nordammaran-20-one (23)*: gum, $[\alpha]_D$ +65° (*c* 0.81); IR (film) 1700 cm^{-1}; NMR δ 0.81—1.00 (7×Me); MS *m/e* 414 (M^+; 8), 399 (6), 329 (3), 301 (42), and 191 (100); MW Found: 414.3739. Calcd for $C_{29}H_{50}O$: 414.3858. *Hexanordammaran-20-one (22)*: mp 130—131 °C (lit,[8] 110—130 °C; lit,[10] 121—132 °C); $[\alpha]_D$ +60° (*c* 1.3) (lit,[8] +61.7°; lit.[10] +60°); IR (KBr) 1705 and 1165 cm^{-1}: NMR δ 0.82, 0.87, 0.87, 0.90, and 1.00 (each 3H, s, *t*-Me) and 2.16 (3H, s, -COMe); MS *m/e* 344 (M^+; 7), 329 (9), 305 (60), 231 (4), 219 (9), 205 (13), and 191 (100); Found: C, 83.66; H, 11.90%. Calcd for $C_{24}H_{40}O$: C, 83.65; H, 11.70%.

Grignard Reaction of Nordammaran-20-one (23) with Methyl Iodide. An ethereal solution of methylmagnesium iodide was prepared from magnesium (300 mg) and methyl iodide (1.5 g) in dry ether under a nitrogen atmosphere. To this solution was added at room temperature a solution of nordammaran-20-one (**20**; 466 mg) in ether (8 ml). The mixture was stirred at reflux temperature for 1 h and then at room temperature for 2 h. After decomposition by addition of saturated ammonium chloride solution, the reaction product was extracted with ether. The organic solution was washed with water, 5% sodium hydrogencarbonate solution and then with brine and dried over magnesium sulfate. The solvent was removed to give a residue, which was chromatographed over silica gel. On elution with petroleum ether–benzene (5:1), (20*S*)-dammaran-20-ol (**13**; 106 mg) and (20*R*)-dammaran-20-ol (**14**; 233 mg) were obtained.

Grignard Reaction of Hexanordammaran-20-one (22) with 4-Methylpentyl Bromide. To the Grignard reagent prepared from 4-methylpentyl bromide (bp 146—149 °C; 1.5 g) and magnesium in dry tetrahydrofuran was added hexanordammaran-20-one (**22**; 340 mg) in tetrahydrofuran. The whole was heated under reflux for 30 min and stirred 3 h at room temperature. The same treatment as mentioned above afforded (20*S*)-dammaran-20-ol (**13**; 108 mg) and (20*R*)-dammaran-20-ol (**14**; 80 mg), together with the starting material (**22**; 13 mg) and an unidentified olfin mixture (114 mg). *(20S)-Dammaran-20-ol (13)*: mp 86—87 °C. Other physical and spectral data are given above. *(20R)-Dammaran-20-ol (14)*: Amorphous solid, $[\alpha]_D$ +32° (*c* 2.0); IR (KBr) 3600 and 3460 (br) cm^{-1}; NMR δ 0.80—0.96 (7×Me) and 1.11 (3H, s, $C_{(20)}$-Me); MS *m/e* 412 (M—18) and 191 (base peak); High resolution MS *m/e* 412.3978. Calcd for $C_{30}H_{52}$ ($M-H_2O$): 412.4066.

Acid-catalyzed Dehydration of (20S)-Dammaran-20-ol (13).

i) With Boron Trifluoride Etherate in Benzene: To a solution of (20*S*)-dammaran-20-ol (**13**; 10 mg) in anhydrous benzene (0.5 ml), boron trifluoride etherate (1 ml) was added at room temperature with stirring. After 15 min, 10% sodium hydrogencarbonate solution was added to the reaction mixture, which was extracted with benzene. The benzene extract was washed with 10% sodium carbonate solution, water, and then with brine and evaporated after drying over magnesium sulfate. The residue was subjected to separation by preparative TLC (SiO_2–$AgNO_3$; developed with petroleum ether) to give a mixture (10.3 mg; R_f *ca.* 0.7) of (20*R*)- and (20*S*)-dammar-13(17)-enes (**24a** and **24b**) as a main product. *(20R)- and (20S)-Dammar-13(17)-enes (24a and 24b)*: an oil; IR (film) 1460, 1380, and 1360 cm^{-1}; NMR δ 0.80—0.88 (6×Me), 0.90 (*ca.* 1.5H, d, J=7 Hz; $C_{(20)}$-Me of **24b**)[16], 0.94 (*ca.* 1.5H, d, J=7 Hz; $C_{(20)}$-Me of **24a**)[16], and 1.08 (3H, s, *t*-Me), neither olefinic proton nor olefinic methyl signal was observed; MS *m/e* 412 (M^+), 397, 327, 299, 220, 205, and 191 (base peak); and GLC examination showed that the mixture consisted of **24a** (R_t 4.8 min) and **24b** (R_t 5.2 min) in a ratio of *ca.* 1:1 [column: SE 30 (0.7 %), 1.5 m; column temperature: 250 °C; carrier gas flow rate: N_2, 27 ml/min].

ii) With Boron Trifluoride Etherate in Dichloromethane: A solution of **13** (19 mg) in dichloromethane (3 ml; purified by passing through a column of Al_2O_3) was treated with boron trifluoride etherate (1 ml) at room temperature for 15 min with agitation. Usual treatment gave the same mixture (**24a** and **24b**; 11 mg), whose IR and NMR spectra were identical with those of the specimen above obtained.

iii) With Boron Trifluoride Etherate in Acetic Acid: A solution of **13** (9.5 mg) in acetic acid (2 ml) was treated with boron trifiuoride etherate (0.7 ml) at room temperature for 15 min with stirring. The same reaction products (**24a** and **24b**) were obtained quantitatively after usual treatment.

iv) With Stannic Chloride in Benzene: To a solution of **13** (10.8 mg) in anhydrous benzene (1 ml) was added anhydrous stannic chloride (*ca.* 0.3 ml) with stirring at room temperature for 20 min. After the same treatment, the same reaction mixture (**24a** and **24b**; 9.7 mg) was obtained.

v) With Picric Acid in Nitromethane: To a solution of **13** (11 mg) in nitromethane (1 ml; dried over calcium chloride) containing 5 drops of dichloromethane, was added a solution of picric acid (12.8 mg) in nitromethane (1 ml) with stirring at room temperature for 8 days. Usual treatment gave a residue, which was chromatographed over silica gel. Fractions eluted with petroleum ether were combined and subjected to separation by preparative TLC (SiO_2–$AgNO_3$; developed with petroleum ether). As amain product the same hydrocarbon mixture (**24a** and **24b**; 5.1 mg) was obtained. The formation of dammar-20-ene (**26**) and dammar-20(22)-ene (**25**) was also shown by TLC.

vi) With Sulfuric Acid in Acetic Acid. A solution of **13** (13.1 mg) in glacial acetic acid (2 ml) containing sulfuric acid (1M; 0.2 ml) was heated under reflux for 2 h. After cooling, the reaction mixture was poured into ice–water and extracted with petroleum ether. The organic layer was worked up in a usual manner to yield the same reaction product (**24a** and **24b**). The formation of **25** and **26** was also observed.

vii) With Formic Acid in Acetone. A solution of **13** (6.1 mg) in acetone (3 ml) containing formic acid (99%, 0.5 ml) was heated under reflux for 17 h. The reaction mixture was treated as usual to give a residue, which was subjected to separation by preparative TLC (SiO_2–$AgNO_3$). A mixture of (20*R*)- and (20*S*)-dammar-13(17)-enes (**24a** and **24b**; 1.2 mg), dammar-20(22)-ene (**25**; 2.1 mg), and dammar-20-ene (**26**; 0.3 mg) were isolated.

Acid-catalized Dehydration of (20R)-Dammaran-20-ol (14). (20*R*)-Dammaran-20-ol (**14**) was treated with acids at room temperature under conditions described below and the reaction mixture was worked up as in the case of **13**. In each case, a mixture of (20*R*)- and (20*S*)-dammar-13(17)-enes (**24a** and **24b**) was obtained as a main product: i) A solution of **14** (15.7 mg) in anhydrous benzene (0.5 ml) with boron trifluoride etherate (1 ml) for 15 min; ii) A solution of **14** (12.2 mg) in dichloromethane (2 ml) with boron trifluoride etherate (1 ml) for 15 min; iii) **14** (7.7 mg) with trifluoroacetic acid (1 ml) for 20 min.

Mixture of (20R)- and (20S)-Dammar-13(17)-enes (24a and 24b). A mixture of isoeuphenyl acetate (**35a** and isotirucallenyl acetate (**35b**) was prepared from a mixture of euphol (**36a**) and tirucallol (**36b**) according to the known procedures.[15] Alkaline hydrolysis, Jones oxidation, and successive Huang-Minlon reduction of this mixture (**35a** and **35b**; 36 mg) by the usual manner gave a mixture (*ca.* 1: 1) of (20*R*)- and (20*S*)-dammar-13(17)-enes (**24a** and **24b**; 5.5 mg), which was identical (IR, MS, and TLC) with a specimen (*vide supra*) obtained by acid-catalyzed rearrangement of (20*S*)- and (20*R*)-dammaran-20-ols (**13** and **14**). The NMR spectra of these specimens (derived from **35**, **13**, and **14**) were virtually identical in respect to numbers of signals and their δ-values except their relative intensities.

Pentanordammar-20(22)-ene-22-carbonitrile (37). Sodium hydride (50%; 297 mg) and dry dimethoxyethane (*ca.* 10 ml) were placed in a flask and diethyl cyanomethylphosphonate (624 mg) was added with stirring at room temperature under a nitrogen atmosphere. After 30 min hexanordammaran-20-one (**22**; 493 mg) in dry dimethoxyethane (*ca.* 5 ml) was added to the solution of the anion and stirring was continued for 18 h. The reaction mixture was poured into water and extracted with ether five times. The organic layer was washed with 2M hydrochloric acid, water, and brine. After drying over magnesium sulfate, the solvent was removed to give a residue, which was crystallized from petroleum ether–ether to yield a white crystalline product (164 mg) of (*E*)-pentanordammar-20(22)-ene-22-carbonitrile (**37a**). The mother liquor was subjected to separation by column chromatography on silica gel (100 g; elution with benzene) and by preparative TLC to furnish the additional (*E*)-isomer (**37a**; 315 mg, recrystallized from petroleum ether; total 479 mg, y. 91%) and (*Z*)-isomer (**37b**). *(E)-Pentanordammar-20(22)-ene-22-carbonitrile (37a)*: mp 179—180 °C; IR (KBr) 2200, 1615, and 815 cm^{-1}; NMR δ 1.99 (3H, d, J=1 Hz; Me–C=CHCN) and 5.09 (1H, br. s, $W_{1/2}$ 3 Hz; Me–C=CHCN)[19]; MS *m/e* 367 (M^+; 68), 352 (45), 231 (37), 191 (100), and 137 (92); Found: C, 84.77; H, 11.04; N, 3.79%. Calcd for $C_{26}H_{41}N$: C, 84.95; H, 11.24; N, 3.81%. *(Z)-Pentanordammar-20(22)ene-22-carbonitrile (37b)*: amorphous solid; NMR δ 1.82 (3H, d, J=1 Hz, Me–C=CHCN) and 5.09 (1H, br. s, $W_{1/2}$ 3 Hz; Me–C=CHCN).[19]

Methyl (E)- and (Z)-Tetranordammar-20(22)-en-23-oates (38a and 38b). (*E*)-Pentanordammar-20(22)-ene-22-carbonitrile (**37a**; 315 mg) and potassium hydroxide (2 g) in ethylene glycol (80 ml) were refluxed under a nitrogen atmosphere for 6.5 h. The reaction mixture was poured into ice-water and extracted with chloroform four times. After usual work-up, a residue, without purification, was dissolved in ether and treated with diazomethane at 0 °C for 4 h. Usual work-up gave a residue, which was chromatographed on a column of silica gel (100 g). Solvent system (petroleum ether–benzene, 10: 1—10: 2) was used for elution (each 50 ml). Frs. 21—30 gave an (*E*)- and (*Z*)-mixture (195 mg) and frs. 31—40 afforded the (*E*)-isomer (16 mg). The mixture was further separated by preparative TLC into each isomer. The (*E*)-isomer was combined with the crops (16 mg) above obtained, and recrystallized from methanol to give *methyl (E)-tetranordammar-20(22)-en-23-oate* (**38a**; 41 mg), mp 87.5—88 °C; IR (film) 1720, 1635, and 860 cm^{-1}; NMR δ 2.10 (3H, d, J=1 Hz; Me–C=CH–), 3.68 (3H, s, –COOMe), and 5.67 (1H, br. s, $W_{1/2}$ 3H; Me–C=CH–); MS *m/e* 400 (M^+; 7), 385 (4), 369 (3), 231 (32), and 191 (100); Found: C, 80.75; H, 11.35%. Calcd for $C_{27}H_{44}O_2$: C, 80.94; H, 11.07%. The (*Z*)-isomer fraction was crystallized from methanol to afford 41 mg of *methyl (Z)-tetranordammar-20(22)-en-23-oate (38b)*; mp 174—174.5 °C; IR (KBr) 1720, 1630, and 855 cm^{-1}; NMR δ 1.82 (3H, d, J=1 Hz; Me–C=CH–), 3.66 (3H, s, –COOMe), and 5.69 (1H, q-like, J=1 Hz; Me–C=CH–); MS *m/e* 400 (M^+; 36), 385 (9), 369 (5), 368 (7), 231 (48), and 191 (100); Found: C, 81.00; H, 11.36%. Calcd for $C_{27}H_{44}O_2$: C, 80.94; H, 11.07%.

(E)- and (Z)-Dammar-20(22)-en-23-ones (15a and 15b). Magnesium powder (150 mg) and dry ether (*ca.* 1 ml) were placed in a flask under nitrogen atmosphere. Isobutyl bromide (809 mg) was added with stirring carefully so that the reaction proceeded smoothly at room temperature. After 1 h, ether was distilled off and anhydrous benzene (*ca.* 10 ml) was poured into the Grignard reagent. The (*E*)-α,β-unsaturated carbonitrile (**37a**; 24 mg) in anhydrous benzene (*ca.* 1 ml) was added portionwise to the Grignard solution and stirred at room temperature for 45 min. The solution was refluxed for 6 h and allowed to stand at room temperature overnight. The reaction mixture was poured into a mixture of ice and saturated aqueous ammonium chloride solution, and extracted

with ether three times. The organic layer was washed with water and brine, dried over magnesium sulfate, and evaporated to dryness. The residue was separated by preparative TLC to give (*Z*)-dammar-20(22)-en-23-one (**15b**; 4 mg, y. 14%) and (*E*)-dammar-20(22)-en-23-one (**15a**; 11 mg, y. 40%), respectively. *(Z)-Dammar-20(22)-en-23-one (15b)*: an oil, IR (film) 1685, 1610, and 980 cm^{-1}; NMR δ 1.79 (3H, d, J=1.5 Hz; Me–C=CH–), 2.22 (2H, d, J=2 Hz, –CO–CH_2–CH), and 6.03 (1H, q-like, J=1.5 Hz; Me–C=CH–CO–); MS *m/e* 426 (M^+; 95), 411 (5), 369 (9), 314 (6), 300 (11), 299 (11), 205 (51), 191 (63), 153 (51), and 95 (100); MW Found: 426.3808. Calcd for $C_{30}H_{50}O$: 426.2858. *(E)-Dammar-20(22)-en-23-one (15a)*: an oil, IR (film) 1680 and 1605 cm^{-1}; NMR δ 2.05 (3H, d, J=1 Hz; Me–C=CH–), 2.23 (2H, d, J=1.5 Hz; –CO–CH_2–CH–), and 6.02 (1H, br. s, $W_{1/2}$ 3 Hz; Me–C=CH–CO–); MS *m/e* 426 (M^+; 15), 411 (2), 369 (13), 341 (3), 326 (2), 274 (2), 259 (3), 191 (55), 153 (88), and 95 (100); *MW* Found: 426.3806. Calcd for $C_{30}H_{50}O$: 426.3858.

Acid Treatment of (E)-Dammar-20(22)-en-23-one (15a). To a solution of (*E*)-dammar-20(22)-en-23-one (**15a**; 23 mg) in ethanol (5 ml) was added 8M hydrochloric acid (0.5 ml) and the whole was refluxed for 18 h. The reaction mixture was poured into ice–water and extracted with ether three times. Usual work-up gave a residue, which was separated by preparative TLC to afford (20ξ_1)-dammar-13(17)-en-23-one [(20ξ_1)-**39**; 7 mg] and (20ξ_2)-dammar-13(17)-en-23-one [(20ξ_2)-**39**; 7 mg] as major products. *(20ξ_1)-Dammar-13(17)-en-23-one* [*(20ξ_1)-39*]: an oil, IR (film) 1700 and 1600 cm^{-1}; NMR δ 0.92 (3H, d, J=7 Hz) and 3.06 (1H, m); MS *m/e* 426 (M^+; 11), 411 (3), 341 (8), 326 (34), 311 (6), 299 (10), 297 (11), 284 (31), 245 (7), 234 (26), 221 (42), 191 (100), 121 (85), 85 (57), and 57 (63). *(20ξ_2)-Dammar-13(17)-en-23-one* [*(20ξ_2)-39*]: an oil, IR (film) 1705 cm^{-1}; NMR δ 0.96 (3H, d, J=7 Hz) and 3.03 (1H, m); MS *m/e* 426 (M^+; 9), 411 (2), 341 (9), 326 (26), 311 (5), 299 (6), 297 (8), 284 (21), 245 (6), 234 (28), 221 (42), 191 (100), 121 (82), 85 (64), and 57 (76).

20,21-Epoxydammarane (16). To a solution of dammar-20-ene (**26**; 163 mg) in dichloromathane (10 ml), *m*-chloroperbenzoic acid (214 mg) in dichloromethane (10 ml) was added at 0 °C and the reaction mixture was stirred for 1 h. After 10% aqueous sodium sulfite (3 ml) was added, the mixture was extracted with ether and the organic layer was washed with 10% aqueous sodium carbonate and brine, and dried over magnesium sulfate. The solvent was removed to afford an epoxide (178 mg). This epoxide is extraordinary labile and easily decomposed during storage. *20,21-Epoxydammarane (16)*: an oil, IR (film) 1080, 1040, and 855 cm^{-1}; NMR δ 0.82—0.97 (7×Me) and 2.59 (2H, br. s, $W_{1/2}$ 2 Hz; $C_{(21)}$–H); MS *m/e* 428 (M^+; 20), 413 (5), 410 (12), 395 (5), 380 (7), 343 (6), 300 (27), 205 (31), 192 (62), and 191 (100); MW Found: 428.3969. Calcd for $C_{30}H_{52}O$: 428.4015.

Reduction of 20,21-Epoxydammarane (16) with Lithium Aluminium Hydride. 20,21-Epoxydammarane (**16**; 3.1 mg) was reduced with lithium aluminium hydride in ether under reflux for 1.5 h and left at room temperature overnight. Usual work-up and preparative TLC furnished (20*R*)-dammaran-20-ol (**14**; 1.8 mg) and (20*S*)-dammaran-20-ol (**13**; 1.2 mg).

Dammaran-21-al (40). A solution of 20,21-epoxydammarane (**16**; 25 mg) in dry benzene (5 ml) was treated with boron trifluoride etherate (1 drop) at room temperature for 10 min. After addition of 10% aqueous sodium hydrogencarbonate, usual work-up furnished dammaran-21-al (**40**) as an oil. This aldehyde was also labile. *Dammaran-21-al (40)*: IR (film) 2680 and 1720 cm^{-1}; NMR δ 0.82—0.94 (7×Me), 9.55 and 9.68 (each *ca.* 0.5H, d, J=3 Hz); MS *m/e* 428 (M^+; 2), 413 (3), 300 (32), 285 (6), 205 (15), and 191 (100); *MW* Found: 428.4000. Calcd for $C_{30}H_{52}O$: 428.4015.

20,22-Epoxydammarane (17). To a solution of dammar-20(22)-ene (**25**; 74 mg) in dichloromethane (15 ml), *m*-chloroperbenzoic acid (81 mg) in dichloromethane (10 ml) was added at 0 °C. After stirring for 30 min at 0 °C, 10% aqueous sodium sulfite (10 ml) was added. Extraction with dichloromethane and usual work-up gave an epoxide (75 mg). *20,22-Epoxydammarane (17)*: an oil. IR (film) 980, 880, and 790 cm^{-1}; NMR δ 1.19 ($C_{(20)}$–Me) and *ca.* 2.6 (m, $C_{(22)}$–H); MS *m/e* 428 (M^+; 25), 413 (3), 410 (3), 399 (3), 395 (2), 385 (1), 357 (3), 325 (5), 311 (5), 300 (25), 299 (27), 285 (12), 231 (10), 205 (31), and 191 (100); *MW* Found: 428.4046. Calcd for $C_{30}H_{52}O$: 428.4016. An examination by HPLC revealed that this epoxide consisted of four isomers, one (t_R 11.8 min) of which was the major product (HPLC: μ-PORASIL, 1% ether–hexane, 1.0 ml/min; t_R 9.0, 10.8, 11.8, and 13.7 min).

Treatment of 20, 22-Epoxydammarane (17) with Boron Trifluoride Etherate. 20,22 Epoxydammarane (**17**; 73 mg) in dry benzen (7 ml) was treated with boron trifluoride etherate (0.5 ml) at room temperature for 20 min. The solution was poured into water and extracted with ether. After usual work-up a residue (65 mg) was obtained, which was separated by preparative TLC to afford (20ξ_1)-26,27-dinor-20,24-dimethyldammarane-21-al [(20ξ_1)-**41**; 6 mg], (20ξ_2)-26,27-dinor-20,24-dimethyldammaran-21-al [(20ξ_2)-**41**; 3 mg], and (20ξ)-dammaran-22-one (**42**; 25 mg), together with a small quantity of hydrocarbons. *(20ξ_1)-26,27-Dinor-20,24-dimethyldammaran-21-al* [*(20ξ_1)-41*]: an oil, IR (film) 2660 and 1720 cm^{-1}; NMR δ 9.41 (1H, s, –CHO); MS *m/e* 428 (M^+; 3), 413 (3), 399 (5), 385 (2), 357 (2), 329 (2), 301 (20), 300 (22), 285 (10), 205 (22), 192 (51), and 191 (100); *MW* Found: 428.3951. Calcd for $C_{30}H_{52}O$: 428.4014. *(20ξ_2)-26,27-Dinor-20,24-dimethyldammaran-21-al* [*(20ξ_2)-41*]: an oil, IR (film) 2660 and 1720 cm^{-1}; NMR δ 9.41 (1H, s, –CHO); MS *m/e* 428 (M^+). *(20ξ)-Dammaran-22-one (42)*: an oil, IR (film) 1710 cm^{-1}; NMR δ 0.82—0.95 (7×Me), 1.07 (3H, d, J=7 Hz), and 2.41 (3H, m); MS *m/e* 428 (M^+; 2), 413 (3), 357 (1), 329 (2), 300 (46), 285 (16), 205 (53), 192 (100), and 191 (76); *MW* Found: 428.3942. Calcd for $C_{30}H_{52}O$: 428.4015.

Hexanordammaran-20-ol (18). Hexanordammaran-20-one (**22**; 230 mg) in ethanol was treated with sodium borohydride (107 mg) and allowed to stand at room temperature for 4 h. The excess of the reagent was decomposed by addition of acetic acid, and the reaction mixture was extracted with ether. After usual work-up, the residue was crystallized from ethanol to furnish *a mixture of hexanordammaran-20-ols (18*; 207 mg), mp 116—118.5 °C; IR (film) 3350 (br) cm^{-1}; NMR δ 0.81—0.98 (5×Me), 1.11 and 1.21 (each *ca.* 1.5H, s; $C_{(20)}$-Me), and 3.70 (1H, m, $C_{(20)}$–H); MS *m/e* 346 (M^+; 8), 331 (5), 328 (4), 313 (6), 301 (35), 191 (88), and 109 (100); Found: C, 83.29; H, 12.02%. Calcd for $C_{24}H_{42}O$: C, 83.17; H, 12.22%. This mixture was inferred to consist of the (20*S*)- and (20*R*)-isomers from the NMR data. However, separation into each isomer was unsuccessful.

Dehydration of Hexanordammaran-20-ol (18) with Phosphoryl Chloride. To a solution of hexanordammaran-20-ol (**18**; 36 mg) in pyridine (3 ml), phosphoryl chloride (0.3 ml) was added portionwise at 0 °C. After stirring for 4 h, the solution was poured into ice–water and extracted with ether three times. Usual work-up and separation by preparative TLC gave crude hydrocarbon (**44**; 17 mg) and a chloride mixture (**43**; 10 mg). *Mixture of (20S)- and (20R)-20-Chlorohexanordammaranes (43)*: mp 114—115 °C (crystallized from CH_2Cl_2–MeOH), IR (KBr) 645 cm^{-1}; NMR δ 1.48 (3H, d,

J=7 Hz; $C_{(20)}$–Me) and 3.46 and 4.17 (each *ca.* 0.5H, q-like, J=7 Hz; $C_{(20)}$–H); *MW* Found: 364.3002 and 366.2898 (in a ratio of *ca.* 3:1). Calcd for $C_{24}H_{41}Cl$: 364.2895 and 366.2866. *Crude Hydrocarbon (44)*: an oil, IR (film) 1635, 840, 820, and 810 cm^{-1}; NMR δ *ca.* 5.0 (1H); MS *m/e* 328 (M^+; 28), 313 (13), 299 (8), 205 (44), 192 (77), and 191 (100). This crude hydrocarbon showed one major peak (R_t 4.1 min) accompanied by two minor peaks in GLC analysis (SE-30, 0.7%; 200 °C; N_2 flow rate: 55 ml/min). Crude **44**, without further separation, was subjected to the following reactions.

Oxidation of the Crude Hydrocarbon (44) with Ruthenium Tetraoxide. A solution of the crude hydrocarbon (**44**; 16 mg) in carbon tetrachloride was added to a solution of ruthenium tetraoxide (10 mg) in carbon tetrachloride with stirring and the stirring was continued for 2 h at room temperature. After addition of isopropyl alcohol (0.5 ml), ruthenium dioxide was filtered off and the filtrate was evaporated. The residue was separated by preparative TLC to afford octanordammaran-17-one[11] (**28**; 3.4 mg) as a major product.

Hydroboration of the Crude Hydrocarbon (44). A solution of the crude hydrocarbon (**44**; 7 mg) in dry tetrahydrofuran (2 ml) was treated with diborane in tetrahydrofuran at 0 °C for 40 min and then at room temperature for 30 min. After 10% aqueous sodium hydroxide solution (6 ml) and 30% hydrogen peroxide (3 ml) were added, the solution was allowed to stand at 60 °C for 1 h. Usual treatment gave hexanordammaran-20-ol (**18**) (*vide supra*).

Tosylation of Hexanordammaran-20-ol (18). A solution of hexanordammaran-20-ol (**18**; 422 mg) and *p*-toluenesulfonyl chloride (540 mg) in pyridine (10 ml) was stored in a refrigerator for 20 days. The solution was poured into ice–water and extracted with ether. Usual work-up furnished a residue, which was crystallized from pentane to give *a tosylate* (**46**) as an oil, IR (film) 1190, 1180, 900, 810, and 655 cm^{-1}; NMR δ 2.42 and 2.47 (total 3H, each s, $-OSO_2-C_6H_4Me$), *ca.* 4.26 (1H, dq, J=12 and 6 Hz; Me–CH–OTs), and 7.28 and 7.72; 7.34 and 7.86 (total 4H, each ABq, J=8 Hz; $-OSO_2-C_6H_4Me$).

Treatment of the Tosylate (46) with Silica Gel. The tosylate (**46**) prepared from hexanordammaran-20-ol (**18**; 84 mg) and *p*-toluenesulfonyl chloride (96 mg) in pyridine was passed through a column of silica gel (10 g). Elution with petroleum ether–benzene (10:1) and crystallization from methanol–chloroform gave *hexanordammar-13(17)-ene (45*; 40 mg*)* as a sole product; mp 104—106 °C, IR (KBr) 1630 cm^{-1}; NMR δ 0.93 (3H, t, J=7 Hz; $C_{(21)}$–H) and 1.08 (3H, s, $C_{(14\alpha)}$–Me); MS *m/e* 328 (M^+; 51), 313 (16), 299 (12), 273 (5), 260 (7), 205 (54), 192 (79), and 191 (100); Found: C, 87.66; H, 12.19%. Calcd for $C_{24}H_{40}$: C, 87.73; H, 12.27%.

Pentanordammaran-20-ol (19). To a solution of methylmagnesium iodide prepared from magnesium powder (94 mg) and methyl iodide (400 mg) in dry ether, hexanordammaran-20-one (**22**; 88 mg) was added at room temperature with stirring. After refluxing for 2 h, the reaction mixture was poured into a mixture of ice and saturated aqueous ammonium chloride, and extracted with ether three times. Washing with water and brine, drying over magnesium sulfate, and evaporation gave a residue (73 mg) of *pentanordammaran-20-ol (19)*, mp 138—138.5 °C (crystallized from MeOH), IR (KBr) 3450 cm^{-1}; NMR δ 0.83, 0.86, 0.86, 0.91, and 0.99 (each 3H, s, *t*-Me) and 1.19 (6H, s, Me_2C–OH); MS *m/e* 360 (M^+; trace), 345 (1), 342 (6), 327 (4), 302 (11), 287 (5), 191 (100), and 95 (93); Found: C, 81.08; H, 12.80%. Calcd for $C_{25}H_{44}O \cdot 1/2\ H_2O$: C, 81.23; H, 12.27%.

Dehydration of Pentanordammaran-20-ol (19) with Phosphoryl Chloride. To a solution of pentanordammaran-20-ol (**19**; 19 mg) in pyridine, phosphoryl chloride (27 drops) was added at 0 °C. After stirring at room temperature for 4 h, the solution was poured into ice–water and extracted with ether three times. Usual treatment and separation by preparative TLC (SiO_2–$AgNO_3$) furnished pentanordammar-17(20)-ene (**47**; 11 mg) and pentanordammar-20-ene (**48**; 8 mg). *Pentanordammar-17(20)-ene (47)*: amorphous solid, IR (KBr) 1630 cm^{-1}; NMR δ 0.83, 0.88 (each 6H, s, *t*-Me), 1.00 (3H, s, *t*-Me), and 1.58 (6H, br. s, $Me_2C{=}C-$); MS *m/e* 342 (M^+; 17), 327 (3), 299 (11), 273 (8), 192 (31), 191 (37), 121 (83), and 95 (100); *MW* Found: 342.3285. Calcd for $C_{25}H_{42}$: 342.3284. *Pentanordammar-20-ene (48)*: amorphous solid, IR (KBr) 3060, 1635, and 885 cm^{-1}; NMR δ 0.81, 0.89, 0.99 (each 3H, s, *t*-Me), 0.86 (6H, s, *t*-Me), 1.67 (3H, d, J=1 Hz; Me–C=CH_2), and 4.65 (2H, d, J=1 Hz; Me–C=CH_2); MS *m/e* 342 (M^+; 7), 327 (4), 299 (3), 231 (31), 191 (100), and 95 (65); *MW* Found: 342.3285. Calcd for $C_{25}H_{42}$: 342.3284.

Treatment of Pentanordammaran-20-ol (19) with Boron Trifluoride Etherate. A solution of pentanordammaran-20-ol (**19**: 22 mg) in benzene (3 ml) was treated with boron trifluoride etherate (0.6 ml) at room temperature for 1 h. To the solution was added 10% aqueous sodium hydrogencarbonate solution and the reaction mixture was extracted with ether three times. After usual treatment and separation by preparative TLC (SiO_2–$AgNO_3$), pentanordammar-13(17)-ene (**49**; 9 mg) and pentanordammar-20-ene (**48**; 11 mg) were obtained. *Pentanordammar-13(17)-ene (49)*: amorphous solid, IR (KBr) 1630 cm^{-1}; NMR δ 0.81 (6H, s, *t*-Me), 0.86, 0.87 (each 3H, s, *t*-Me), 0.93, 0.98 (each 3H, d, J=7 Hz; Me_2CH–C=C–), and 1.09 (3H, s, $C_{(14\alpha)}$–Me); MS *m/e* 341 (M^+; 32), 327 (5), 299 (23), 205 (41), 191 (67), 121 (89), and 95 (100); *MW* Found: 342.3432. Calcd for $C_{25}H_{42}$: 342.3284.

The authors wish to thank Professor G. Ourisson, Université Louis Pasteur, Strasbourg, for a generous gift of dipterocarpol, and Professor Y. Hirata and Dr. D. Uemura, Nagoya University, for a kind supply of extracts from *Euphorbia kansui* Liou. The authors are also grateful to Dr. N. Nakamura, the University of Tokyo, for ^{13}C-NMR measurement.

The Mechanism of NAD(P)H Reduction Reactions

Satoshi INAGAKI and Yoshio HIRABAYASHI

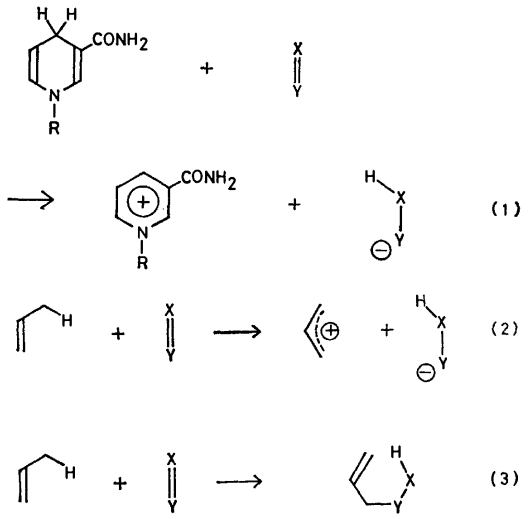
Department of Synthetic Chemistry, Faculty of Engineering, Gifu University, Kakamigahara, Gifu 504

(Received June 25, 1977)

The mechanism of reduction reactions by 1,4-dihydronicotinamides is investigated from the theoretical point of view of the electron configuration and orbital interactions for many systems. The following conclusions are drawn: (1) The reactions are situated near the one-electron-transfer region in the mechanistic spectra dependent on the donor-acceptor property of the reactants; (2) the hydride-equivalent transfers involved, whether concerted or not, proceed more or less in accordance with the nature of the sequential electron-proton-electron shift rather than *via* direct hydride-ion transfer; (3) the paradoxical frontier orbital interaction between the σ-LUMO of C_4–H of 1,4-dihydronicotinamides and the LUMO of substrates is significantly involved in the transfer of the protonic entity. Pseudoexcitation is classified into Type I, where the normal HOMO-LUMO interaction remains important in addition to the LUMO-LUMO and HOMO-HOMO interactions, and Type II, where the HOMO-LUMO interaction contributes little. The NAD(P)H reduction reactions are predicted to belong to Type II.

The roles of nicotinamide-adenine dinucleotide (NAD$^+$) and its phosphoric acid derivative (NADP$^+$), and their reduced form (NAD(P)H) in enzymic oxidation-reduction reactions have been interesting subjects not only in biochemistry, but also in organic chemistry.[1] These coenzymes catalyze similar reactions. Here they can be considered together. The enzymic reactions involve the transfer of a hydride equivalent between the pyridine nucleus in the coenzymes and substrates, generally formulated as in Eq. 1. The reduction reaction is regarded as a special case of further simplified process in which a hydride equivalent is transferred from an allylic position of one molecule to an unsaturated atom of another molecule (Eq. 2).

Theoretically of interest are the fact that no bonds form between the usually very reactive π bonds of 1,4-dihydronicotinamide groups and unsaturated substrates, and the nature of the hydride-equivalent shift. In this paper we shall present a qualitative molecular orbital argument to disclose underlying factors which differentiate the hydride-equivalent shift from the ene reaction (Eq. 3). The mechanism of NAD(P)H reduction reactions is inferred from the theoretical results.



(1)

(2)

(3)

Theoretical

The reaction we are interested in is a bimolecular reaction between electron-donating unsaturated compounds with a reactive σ bond at the allylic position and electron-accepting unsaturated compounds. The weak interaction between the σ bond (M) and the π bond (D) in the donor allows us to suppose our reaction to be a termolecular interaction of M, D, and the acceptor π bond (A).[2,3]

Let the ground-state wavefunction, Ψ, be a linear combination of the electron configurations, Φ_K's, constructed by using the molecular orbitals of each system, *i.e.*,

$$\Psi = \sum_K C_K \Phi_K. \tag{4}$$

The electron density, $\rho(1)$, is then given by

$$\rho(1) = \sum_K C_K^2 \rho_{K,K}(1) + 2\sum_{K>L} C_K C_L \rho_{K,L}(1), \tag{5}$$

$$\rho_{K,K}(1) = n\int \Phi_K^2 dv_2 \cdots dv_n d\sigma_1 \cdots d\sigma_n,$$

$$\rho_{K,L}(1) = n\int \Phi_K \Phi_L dv_2 \cdots dv_n d\sigma_1 \cdots d\sigma_n.$$

Electron delocalization, responsible for the formation of covalent bonds, comes from the HOMO-LUMO interaction or from the mixing of the electron-transferred configuration, D^+A^-, into the initial configuration, DA.[4] The frontier orbital interaction contributes both to stabilizing the system and to accumulating electrons in the intermolecular region where bonds occur.[5] It may be a good approximation in our qualitative arguments to take into consideration the reorganization of the electronic structure due to electron transfer or promotion from HOMO to LUMO.

A further selection of configurations is possible from the point of view of intermolecular electron density. The density fraction, $\rho_{K,K}$, is approximated as the sum of the squares of the occupied orbitals in Φ_K. This term has little to do with the intermolecular electron density. Some $\rho_{K,L}$'s contain a product of two orbitals which belong to different molecules. These terms contribute significantly to the intermolecular density. Such a pair of configurations, K and L, should be obtained from each other by shifting an electron from one molecule to another. Figure 1 displays the configuration pairs (see Appendix).

Suppose that the donor-acceptor property of D and A is less significant. The ground-state wavefunction can then be approximated as a linear combination of

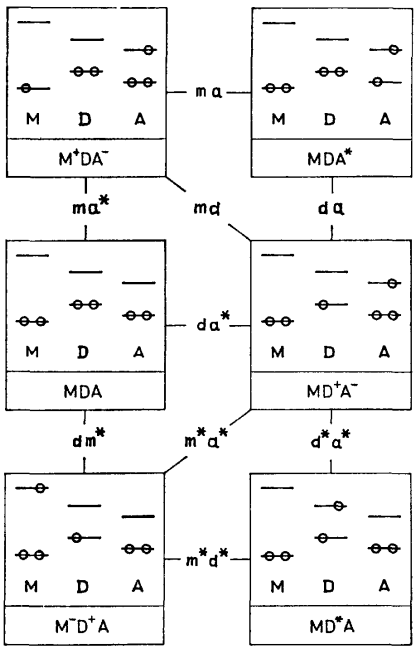


Fig. 1. Electron configuration pairs responsible for intermolecular electron density.

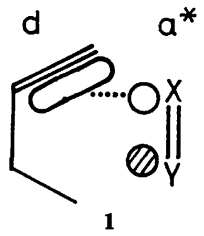
MDA and MD^+A^- (Eq. 6),

$$\Psi \simeq C_{MDA}\Phi_{MDA} + C_{MD^+A^-}\Phi_{MD^+A^-}, (C_{MDA} > C_{MD^+A^-}). \quad (6)$$

The intermolecular density is due to the orbital overlap between d and a*, *i.e.*, the first term in ρ_{MDA,MD^+A^-} (Eq. A7). For this donor-acceptor relation, bond formation neither between M and D nor between M and A is expected, while an attractive interaction gives rise to the association of D and A. The geometrical structure favoring the d-a* interaction was previously shown to be a three-centered interaction such as **1**.[6-8] No reactions of interest are likely to occur.



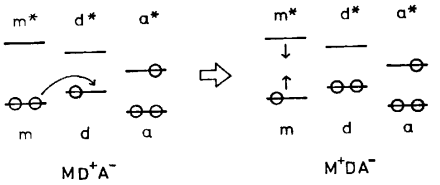
1

Second, let the power of A increase. The energy level of MD^+A^- then lowers and approaches that of MDA so closely that both configurations contribute comparably to the ground-state wavefunction. The comparable contribution of MD^+A^- accompanies an appreciable mixing-in of K's which have a large matrix element with MD^+A^-.[9] The M^+DA^-, M^-D^+A, MD*A, and MDA* configurations are here taken into consideration. The mixing-in of ditransferred configurations, $M^+D^+A^{--}$, $MD^{++}A^{--}$, and $M^-D^{++}A^-$, may be negligible because of the large energetical separation from MDA and MD^+A^-. The ground-state wavefunction is then approximated to be

$$\Psi \simeq C_{MDA}\Phi_{MDA} + C_{MD^+A^-}\Phi_{MD^+A^-} + C_{M^+DA^-}\Phi_{M^+DA^-} + C_{M^-D^+A}\Phi_{M^-D^+A} + C_{MD^*A}\Phi_{MD^*A} + C_{MDA^*}\Phi_{MDA^*}, \quad (7)$$
$$(C_{MDA} \simeq C_{MD^+A^-} > C_{M^+DA^-} \simeq C_{M^-D^+A} \simeq C_{MD^*A} \simeq C_{MDA^*}).$$

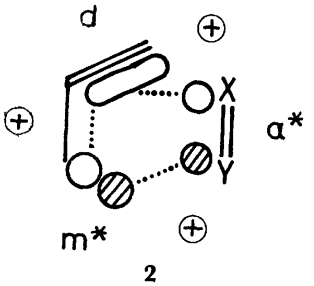
The coefficients, C_{MDA} and $C_{MD^+A^-}$, are larger than any others. Of primary concern are the configurations which contribute to the intermolecular density by means of the interactions with MDA or MD^+A^- (Eqs. A7—A13).

The most important interaction remains the one between MDA and MD^+A^- or between d and a*. A favorable geometry must resemble **1**, although the additional interactions singled out above may modify it. Most interesting is the interaction between MD^+A^- and M^+DA^-, since the weights of both configurations increase to a greater extent as the energy levels lower with an increase in the electron-acceptability of A. This interaction delocalizes the electrons from M to D through the m-d overlap (Eq. A10). The removal of the bonding electrons from m results in a weakening of the σ bond. The concurrent bond-lengthening lowers the m* level, increasing the ability of M to accept electrons



Scheme 1.

(Scheme 1). The M^-D^+A configuration is then allowed to mix effectively. The interaction of M^-D^+A with MD^+A^-, involving the m*-a* overlap (Eq. A11), leads to the structural change from **1** to a transient six-membered-ring state, **2**. As a result, the key orbital interaction occurs among d, a*, and m*. Ene reactions (Eq. 3) take place in this donor-acceptor region.[3]



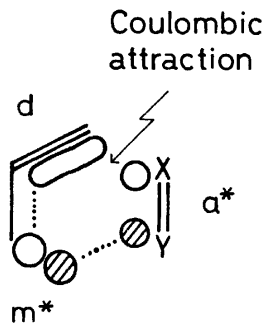
2

Finally, let us discuss the nature of the interaction with the more powerful A. The weights of MD^+A^- and M^+DA^- increase further while the weight of MDA decreases. Consequently, the M^-D^+A configuration contributes to a greater extent. The ground-state wavefunction is then approximated as

$$\Psi \simeq C_{MD^+A^-}\Phi_{MD^+A^-} + C_{M^+DA^-}\Phi_{M^+DA^-} + C_{M^-D^+A}\Phi_{M^-D^+A}, \quad (8)$$
$$(C_{MD^+A^-} > C_{M^+DA^-} \simeq C_{M^-D^+A}).$$

The main configuration is MD^+A^-. The significant interactions are those with MD^+A^-, *i.e.*, the MD^+A^--M^-D^+A and MD^+A^--M^+DA^- interactions. The m*-a* orbital overlap involved in the MD^+A^--

M^-D^+A interaction (Eq. A11) is responsible for the hydride-equivalent transfer, while the d-m orbital overlap involved in the MD^+A^--M^+DA^- interaction (Eq. A10) contributes to π-bond formation between D and M. It should be noted that the ρ_{MDA,MD^+A^-} term predominantly responsible for D-A bonding disappears, since $C_{MDA} \simeq 0$. The extreme stabilization of MD^+A^- disfavors the bond formation between D and A, although D and A are presumably bound through the Coulombic attraction. This difference from the preceding cases characterizes the reactions of powerful A's. The key orbital interaction is illustrated in **3**. The reactions for this donor-acceptor region take place *via* an almost one-electron transfer prior to the transfer of H as a protonic entity, with no σ-bond formation between the π bonds of the reactants.



3

It was proposed that the chemical processes significantly involving the HOMO-HOMO (D^+A^--DA*) and/or LUMO-LUMO (D^+A^--D*A) interactions(s) even on the ground-state potential energy surface be termed "pseudoexcitation."[9] Attention was not paid to whether or not the HOMO-LUMO interaction remains important in addition to the HOMO-HOMO and LUMO-LUMO interactions. The pseudoexcitation is here proposed to be classified into Types I and II. Type I involves the HOMO-LUMO interaction significantly, while Type II does not (Fig. 2). The hydride-equivalent shift belongs to Type II (see **3**), while the ene reaction belongs to Type I (see **2**).

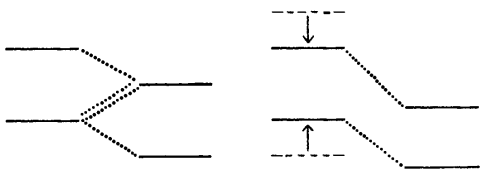


Fig. 2. Pseudoexcitation.

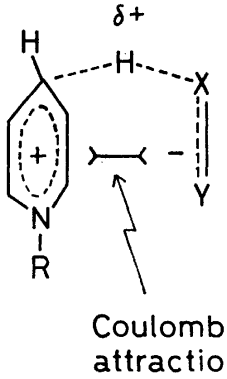
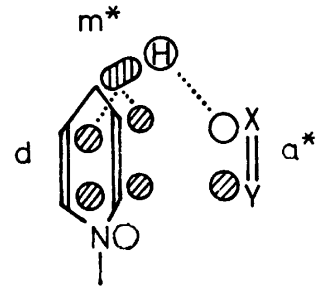
Discussion

From the preceding theoretical arguments on the prototype reaction, it can be suggested that the reduction of unsaturated bonds by 1,4-dihydronicotinamides occurs more or less in accordance with the nature of the sequential electron-proton-electron shift. The hydride-equivalent shift is likely to occur in a concerted manner if the reaction is favored by the donor-acceptor property and other properties. In the transition state, hydrogen migrates as a protonic entity from the cationic dihydronicotinamides to the anionic substrates (**4** and **5**), but not as a hydride anion, as was proposed by Westheimer *et al.*[10]

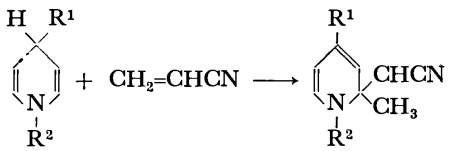


4

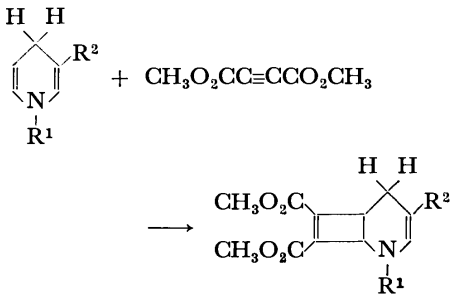


5

When substrates are not such powerful acceptors as to induce the Type II pseudoexcitation, the reactions fall in the Type I pseudoexcitation region. At least one bond forms between the π bonds of dihydronicotinamides and substrates. In fact, acrylonitrile reacts with 1,4-dihydropyridines to give the ene reaction product (Eq. 9),[11] while alkylidene- and arylmethylene-malononitriles are reduced.[12] Another example of the bond formation between the π bonds is the 2+2 cycloaddition reaction with dimethyl acetylenedicarboxylate (Eq. 10).[13]

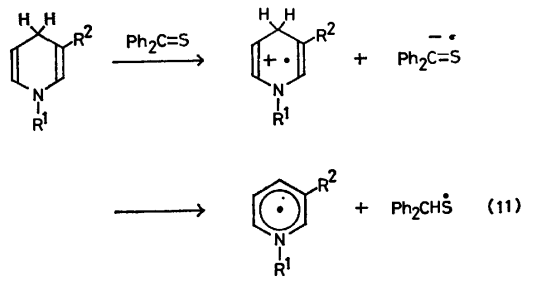


(9)



(10)

The hydride-equivalent shift may be intercepted or retarded by a radical ion-pair intermediate when more powerful acceptors are employed, or when reaction conditions—for example, the temperature and solvent, favor the formation and existence of the intermediate. Ohno and Kito[14] employed the ESR spectroscopic technique to demonstrate the nature of the sequential electron-proton-electron shift in the reduction of thiobenzophenone by 1,4-dihydronicotinamide. The ESR signal of the thiobenzophenone anion radical was detected at a low temperature (77K); the signal faded on warming to room temperature, giving rise to a new signal ascribable to the thiyl radical (Eq. 11). The competition between the reduction and the radical

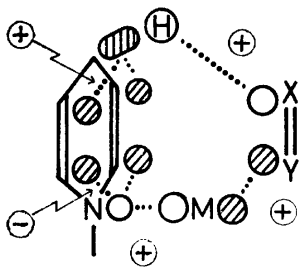


reaction observed by Dittmer and Fouty[15] is understood in terms of two mechanisms near the one-electron transfer region. At least one kinetically important intermediate suggested recently[16,17] is likely to be an ion-radical-pair complex.

Catalysts may affect the reaction course and the efficiency through changing the donor-acceptor property. For example, Lewis acids enhance the electron acceptability of carbonyl compounds by coordination to the carbonyl oxygen. Metal cations were found to assist the reduction of carbonyl compounds.[18-20] This may be explained in terms of the π^* orbital of the carbonyl function being energetically lowered by the positive charge of metal cations.[21] A similar positive-charge effect may also be responsible for the enhanced reactivity of carbonyl groups with an intramolecular hydrogen bond.[10,20,22] The phenolic proton involved provides the carbonyl oxygen with the electrostatic field. In contrast, 1-benzyl-1,4-dihydropyridines were found to be activated by an anionic group in the ortho position of the 1-benzyl substituent.[23] The negative charge may elevate the π-HOMO of the dihydropyridines.

Metal cations can catalyze the reduction reaction in another way, in which the cations are involved in cyclic interaction with dihydronicotinamides and substrates (**6**). In the cyclic interaction the lone-pair orbital on the nitrogen and the C=C bond of dihydronicotinamides are electron-donors, while the C_4–H bond, the unsaturated bond of substrates, and metal cations are acceptors. The orbital-phase requirements for stabilization[2,3] are satisfied if the metal cation provides the cyclic interaction with a low-lying vacant p- or d-orbital. The catalytic reduction should be carefully investigated with this possibility in mind.[24]

Other possible effects of catalysts should also be noted. Some reactions, favored by the donor-acceptor property under uncatalyzed conditions, may be retarded or inhibited if the optimum D-A relation is destroyed by added metal cations which coordinate onto 1,4-dihydronicotinamides or substrates.[25]



6

The theoretical results suggest that the mechanistic features of the reactions of dihydronicotinamides with unsaturated molecules change from one to another. The reduction mechanism can be predicted to be situated near the one-electron transfer region (Type II pseudo-excitation). Consequently, photochemical and catalytic reactions are expected to be of synthetic utility. A useful acceptor of hydride equivalents, 2,3-dichloro-5,6-dicyano-*p*-benzoquinone,[26] is now available to us. The reagents which are more electron-donating than 1,4-dihydronicotinamides and which are similar in structure are promissing candidates as effective donors of hydride equivalents.

The authors wish to express their thanks to Professor Kenichi Fukui of Kyoto University for his helpful discussion, and to Professor Atsuyoshi Ohno of Kyoto University for his stimulating discussion and for the personal communication of his results prior to publication. The present work was partially supported by a Grant-in-Aid from the Ministry of Education (No. 139012).

Appendix

The configuration functions in Fig. 1 and the electron-density fractions are as follows. The letters, m, d, and a, are used to denote the HOMO's of M, D, and A. The asterisk stand for the LUMO of each system.

$$\Phi_{MDA} = \frac{1}{\sqrt{6!}}|m(1)\bar{m}(2)d(3)d(4)a(5)\bar{a}(6)| \quad (A1)$$

$$\Phi_{MD^+A^-} = \frac{1}{\sqrt{2}\sqrt{6!}}\{|m(1)\bar{m}(2)a^*(3)d(4)a(5)\bar{a}(6)| + |m(1)\bar{m}(2)d(3)\bar{a}^*(4)a(5)\bar{a}(6)|\} \quad (A2)$$

$$\Phi_{M^+DA^-} = \frac{1}{\sqrt{2}\sqrt{6!}}\{|a^*(1)\bar{m}(2)d(3)d(4)a(5)\bar{a}(6)| + |m(1)\bar{a}^*(2)d(3)\bar{d}(4)a(5)\bar{a}(6)|\} \quad (A3)$$

$$\Phi_{M^-D^+A} = \frac{1}{\sqrt{2}\sqrt{6!}}\{|m(1)\bar{m}(2)m^*(3)d(4)a(5)\bar{a}(6)| + |m(1)\bar{m}(2)d(3)\bar{m}^*(4)a(5)\bar{a}(6)|\} \quad (A4)$$

$$\Phi_{MD^*A} = \frac{1}{\sqrt{2}\sqrt{6!}}\{|m(1)\bar{m}(2)d^*(3)d(4)a(5)\bar{a}(6)| + |m(1)\bar{m}(2)d(3)d^*(4)a(5)\bar{a}(6)|\} \quad (A5)$$

$$\Phi_{MDA^*} = \frac{1}{\sqrt{2}\sqrt{6!}}\{|m(1)\bar{m}(2)d(3)d(4)a^*(5)\bar{a}(6)| + |m(1)\bar{m}(2)d(3)d(4)a(5)\bar{a}^*(6)|\} \quad (A6)$$

$$\rho_{MDA,MD^+A^-} = \sqrt{2}\,[da^* + (2m^2+d^2+2a^2)s_{da^*} - ma^*s_{md} - mds_{ma^*} - aa^*s_{da}] + \quad (A7)$$

$$\rho_{MDA,M^+DA^-} = \sqrt{2}\,[ma^* + (m^2+2d^2+2a^2)s_{ma^*} - da^*s_{md} - mds_{da^*} - aa^*s_{ma}] + \quad (A8)$$

$$\rho_{MDA,M^-D^+A} = \sqrt{2}\,[m^*d + (2m^2+d^2+2a^2)s_{m^*d} - m^*as_{da} - das_{m^*a} - mm^*s_{md}] + \quad (A9)$$

$$\rho_{MD^+A^-,M^+DA^-} = -[md + (m^2+d^2+2a^2+a^{*2})s_{md} - 2ma^*s_{da^*} - 2da^*s_{ma^*} - mas_{da} - das_{ma}] + \quad (A10)$$

$$\rho_{MD^+A^-,M^-D^+A} = m^*a^* + (2m^2+d^2+2a^2)s_{m^*a^*} - mm^*s_{ma^*} - aa^*s_{m^*a} + m^*ds_{da^*} + da^*s_{m^*d} \quad (A11)$$

$$\rho_{MD^+A^-,MD^*A} = d^*a^* + (2m^2 + d^2 + 2a^2)s_{d^*a^*} - md^*s_{ma^*} - ma^*s_{md^*} + dd^*s_{da^*} - aa^*s_{d^*a} \quad \text{(A12)}$$

$$\rho_{MD^+A^-,MDA^*} = -[da + (2m^2 + d^2 + a^2 + a^{*2})s_{da} - mds_{ma} - mas_{md} - 2aa^*s_{da^*}] \quad \text{(A13)}$$

A Macrocyclic Enzyme Model System. Deacylation of *p*-Nitrophenyl Carboxylates as Effected by a [20]Paracyclophane Bearing an Imidazole Group†

Yukito MURAKAMI,* Yasuhiro AOYAMA, Masaaki KIDA, and Akio NAKANO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received July 5, 1977)

The kinetic effect of a [20]paracyclophane bearing an imidazole moiety (**1**) on the deacylation of various *p*-nitrophenyl carboxylates was investigated in 10.9%(v/v) ethanol–1.0%(v/v) dioxane–water of μ 0.10 (KCl) at 40.0±0.1 °C. The facile reaction of **1** with a hydrophobic ester resulted in the accumulation of the N^{Im}-acyl derivative of **1** along the progress of reaction, and the rate of regeneration of **1** (turnover) was negligibly small under present experimental conditions compared to the corresponding acylation rate. The overall feature for deacylation reactions of *p*-nitrophenyl carboxylates bearing a hydrophobic acyl moiety in the presence of **1** is consistent with the reaction scheme which involves the reactions of the monomeric and aggregated forms of **1** with substrate esters. The second-order rate constants for reactions of the monomeric species of **1** with relatively hydrophobic esters exceed considerably the corresponding second-order rate constants for imidazole-catalyzed reactions, suggesting the significant hydrophobic interaction between **1** and each hydrophobic ester. The binding constants (K) for complex formation of a micelle (aggregation number, N) with significantly hydrophobic substrates are greater than 10^5 M^{-1}. The second-order rate constants (k_mK/N) for reactions of the imidazole group of **1** with the long-chain carboxylates in micellar phase are the largest ever achieved for reactions of synthetic 4-substituted imidazoles with *p*-nitrophenyl esters.

Our recent studies have characterized the catalytic functions of [20]paracyclophanes bearing an oxime nucleophile in ester hydrolyses.[1-5] The novel and highly efficient catalysis played by those macrocycles have been attributed to their marked hydrophobic effect, which gives out the proximity effect through formation of a substrate-paracyclophane complex, and nucleophilic-electrostatic bifunctional character acted on the incorporated substrate. In this study, we have prepared an imidazole derivative of [20]paracyclophane (**1**) and investigated its esterase-like activity. Since the present paracyclophane is catalytically active in its neutral form, the aggregation behavior in a mixed aqueous-organic solvent system and its kinetic consequences in deacylation of various *p*-nitrophenyl carboxylates have been clarified.

Experimental

Vibrational spectra were measured with a JASCO DS-403G grating spectrophotometer. ^{1}H NMR spectra were obtained with either a Varian A-60 or a Bruker WH-90 FT spectrometer and tetramethylsilane (TMS) was used as an internal reference. Fluorescence spectra were recorded on a Shimadzu spectrofluorophotometer RF-500. High speed liquid chromatography for preparative purpose was performed on a Hitachi 635 liquid chromatograph with Hitachi gel 3019. Gel filtration was carried out on a column packed with Sephadex LH-20. Methanol was used as eluant and components eluted were detected by UV absorption at either 254 or 265 nm for both chromatographic techniques.

N-*(Imidazol-4-ylethyl)-10(11)-oxo*[*20*]*paracyclophane-22-carboxamide (1)*. A mixture of 10(11)-oxo[20]paracyclophane-22-carboxylic acid[6] (70 mg) and thionyl chloride (3 ml) was stirred at room temperature for 2 h. Excess thionyl chloride was removed *in vacuo* from the reaction mixture, into which a small amount of dry tetrahydrofuran was added subsequently with stirring. The mixture was evaporated *in vacuo* to give the acid chloride. A tetrahydrofuran solution (15 ml) of the acid chloride was added at room temperature in a period of 1 h to a mixture of histamine dihydrochloride (300 mg) and sodium hydroxide (500 mg) in water (20 ml) with vigorous stirring, and stirring was continued for another 6.5 h. Then, the mixture was poured into water (50 ml) and extracted with ether (50 ml×6). The ether extract was washed with 50 ml of water, dried over sodium sulfate and evaporated. The crude product was extracted with methanol, and then purified by means of repeated preparative liquid chromatography and gel filtration chromatography to afford **1** as an oil; yield 25%. IR (neat): 1718 (ketone C=O str.), 1640 (amide C=O str.), and 1530 cm^{-1} (NH bend. and C–N str.). NMR (CD_3OD, TMS): δ 7.71 and 6.98 (both s, H's on imidazole ring), 7.18 (s, meta and para H's relative to the amide substituent on benzene ring), 7.13 (s, H ortho to the amide on benzene ring), 3.62 (t J=7 Hz, $C\underline{H}_2CH_2NHCO$ or $CH_2C\underline{H}_2NHCO$), 3.1—2.1 (complex m, CH_2CO, benzyl protons, and $CH_2C\underline{H}_2NHCO$ or $C\underline{H}_2CH_2NHCO$), and 1.8—1.2 (m, methylene protons). Found: C, 75.02; H, 9.64; N, 7.87%. Calcd for $C_{32}H_{48}N_3O_2$: C, 75.69; H, 9.73; N, 8.27%.

p-*Nitrophenyl Carboxylates*. *p*-Nitrophenyl acetate (**2**), hexanoate (**3**), decanoate (**4**), dodecanoate (**5**), hexadecanoate (**6**), phenylacetate (**12**), and α-naphthoate (**13**) were prepared by condensation of commercially available carboxylic acids or acid chlorides with *p*-nitrophenol. The esters were identified by elemental analyses and spectral measurements before use.

(a) p-*Nitrophenyl Cyclohexanecarboxylate (7)*: A mixture of cyclohexanecarbonyl chloride (6.5 g) and *p*-nitrophenol (5.0 g), magnesium ribbon (45 mg), and a small amount of iodine in dry benzene (20 ml) was refluxed for 4 h. After cooling down to room temperature, the organic layer was

† Contribution No. 440 from this Department.

* To whom correspondence should be addressed.

separated, washed successively with cold water, saturated aqueous sodium bicarbonate, and cold water, and dried over sodium sulfate. The organic layer was then evaporated *in vacuo* and the residue was distilled; bp 174 °C/0.7 mmHg, yield 6.8 g (62%). NMR ($CDCl_3$, TMS): δ 8.21 and 7.21 (ABq J=9 Hz, aromatic H's), and 2.85—1.00 (m, H's on cyclohexane ring). Found: C, 62.75; H, 6.16; N, 5.40%. Calcd for $C_{13}H_{15}NO_4$: C, 62.64; H, 6.06; N, 5.61%.

(b) p-*Nitrophenyl Cyclohexylacetate (8)*: The ester was prepared in a similar manner from cyclohexylacetyl chloride; yield 57%. NMR ($CDCl_3$, TMS): δ 8.23 and 7.23 (ABq J=9 Hz, aromatic H's), 2.46 (distorted d J=7 Hz, CH_2CO), and 1.70, 1.29, and 1.15 (m, H's on cyclohexane ring). Found: C, 63.77; H, 6.51; N, 5.34%. Calcd for $C_{14}H_{17}NO_4$: C, 63.86; H, 6.50; N, 5.32%.

(c) p-*Nitrophenyl α-Cyclohexylpropionate (9)*: The Reformatsky reaction of cyclohexanone (4.0 g) with methyl α-bromopropionate (6.0 g), which has been carried out under standard conditions,[7] gave *1-(1-methoxycarbonylethyl)cyclohexan-1-ol* (**14**; R^1=CH_3, R^2=H, n=6); bp 78—81 °C/2 mmHg, yield 52%. NMR ($CDCl_3$, TMS): δ 3.68 (s, OCH_3), 2.50 (q J=7 Hz, methine proton), 2.17—1.24 (broad s centered at 1.47, H's on cyclohexane ring and OH), and 1.17 (d J=7 Hz, $CHC\underline{H}_3$). The hydroxy ester was then dehydrated to give the unsaturated ester. The hydroxy ester (20 g) was added to a cold solution of thionyl chloride (30 ml) in benzene (50 ml) containing pyridine (15 ml) at 0 °C. The mixture was allowed to stand at room temperature for a half hour and poured into ice water (200 ml). The organic layer was separated, washed with water, dried over sodium sulfate, and evaporated *in vacuo*, and then the residue was distilled to afford *methyl α-(1-cyclohexenyl) propionate* (**15**; R^1=CH_3, R^2=H, n=6); bp 56.5 °C/1 mmHg, yield 80%. NMR ($CDCl_3$, TMS): δ 5.52 (broad s, CH=C), 3.62 (s, OCH_3), 3.01 (distorted q J=7 Hz, methine proton), 1.95 and 1.56 (m, H's on cyclohexane ring), and 1.22 (d J=7 Hz, $CHC\underline{H}_3$). Methyl α-(1-cyclohexenyl)propionate (14.6 g) in ethyl acetate (100 ml) was hydrogenated in an autoclave at 28 °C with 10% palladium carbon (2.0 g) as catalyst, initial hydrogen pressure being adjusted at 50 kg/cm². The catalyst was removed by filtration through celite 545 (Wako Pure Chemicals, Ltd.). The solvent was removed *in vacuo* and the residue was distilled to afford *methyl α-cyclohexylpropionate* (**17**; R^1=CH_3, R^2=H, n=6); bp 93—96 °C/15 mmHg, yield 69%. NMR ($CDCl_3$, TMS): δ 3.65 (s, OCH_3), 2.22 (distorted q J=7 Hz, methine proton), 1.65 and 1.11 (m, H's on cyclohexane ring), and 1.12 (d J=7 Hz, $CHC\underline{H}_3$). The methyl ester (10.0 g) was saponified with sodium hydroxide (15.0 g) in 50%(v/v) aqueous methanol (40 ml) to give *α-cyclohexylpropionic acid*, and recrystallized from ethyl acetate, mp 60.5—62.5 °C, yield 95%. Found: C, 69.14; H, 10.32%. Calcd for $C_9H_{16}O_2$: C, 69.19; H, 10.29%. The acid was treated with thionyl chloride to give the acid chloride (bp 84—86 °C/9 mmHg, yield 70%), which was converted to the corresponding *p*-nitrophenyl ester (**9**) in a manner as described above; bp 130 °C/0.05 mmHg, yield 57%. NMR ($CDCl_3$, TMS): δ 8.25 and 7.25 (ABq J=9 Hz, aromatic H's), 2.48 (distorted q J=7 Hz, $C\underline{H}CH_3$), 1.70 (m, H's on cyclohexane ring), and 1.26 (d J=7 Hz, $CHC\underline{H}_3$). Found: C, 65.13; H, 6.96; N, 4.96%. Calcd for $C_{15}H_{19}NO_4$: C, 64.96; H, 6.90; N, 5.05%.

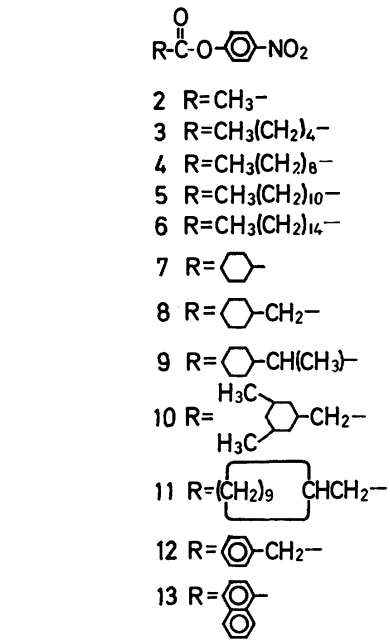
(d) p-*Nitrophenyl 3,5-Dimethylcyclohexylacetate (10)*: The ester was obtained by a preparative procedure similar to that described for **9**. The Reformatsky reaction of ethyl bromoacetate with 3,5-dimethylcyclohexanone obtained by oxidation of 3,5-dimethylcyclohexanol with sodium dichromate afforded the corresponding hydroxy ester (**14**; R^1=H, R^2=CH_3, n=6); bp 92—95 °C/0.5 mmHg yield 32%. NMR (CCl_4, TMS): δ 4.12 (q J=7 Hz, $C\underline{H}_2CH_3$), 3.29 (s, OH), 2.45 and 2.33 (both s, CH_2CO), 1.76 and 1.59 (m, H's on cyclohexane ring), 1.27 (t J=7 Hz, $CH_2C\underline{H}_3$), and 0.86 (distorted d J=6.5 Hz, CH_3's on cyclohexane ring). Found: C, 67.22; H, 10.27%. Calcd for $C_{12}H_{20}O_3$: C, 67.24; H, 10.37%. The hydroxy ester was dehydrated to give *3,5-dimethyl-1-ethoxycarbonylmethyl-1-cyclohexene* (**15**; R^1=H, R^2=CH_3, n=6) and *ethyl 3,5-dimethylcyclohexylideneacetate* (**16**; R^1=H, R^2=CH_3, n=6) in a ratio of 1.6: 1 as judged by the NMR spectrum; bp 92—94 °C/4.5 mmHg, total yield 87%. NMR (CCl_4, TMS): δ 5.47 (s, C=CH–CO for **16**), 5.27 (broad s, CH=C for **15**), 4.06 (q J=7 Hz, $C\underline{H}_2CH)_3$, 2.80 (s, CH_2CO for **15**), 2.12 and 1.72 (m, H's on cyclohexane ring), 1.24 (t J=7 Hz, $CH_2C\underline{H}_3$), and 0.96 (distorted d J=6 Hz, CH_3's on cyclohexane ring). The mixture of unsaturated esters was hydrogenated in ethanol over either 10% palladium carbon or 5% rhodium carbon for 10 h at 80—100 °C and at the initial hydrogen pressure of 100 kg/cm² to give *ethyl 3,5-dimethylcyclohexylacetate* (**17**; R^1=H, R^2=CH_3, n=6), yield 85%. NMR (CCl_4, TMS): δ 4.07 (q J=7 Hz, $C\underline{H}_2CH_3$), 2.30 and 2.05 (both s, CH_2CO), 1.77 and 1.58 (m, H's on cyclohexane ring), 1.25 (t J=7 Hz, $CH_2C\underline{H}_3$), and 0.89 (double d J=2 and 7 Hz, CH_3's on cyclohexane ring). The ester was saponified and treated with thionyl chloride. The resulting acid chloride underwent reaction with *p*-nitrophenol to afford the *p*-nitrophenyl ester (**10**); bp 140 °C/0.2 mmHg, yield (from **17**) 42%. NMR (CCl_4, TMS): δ 8.21 and 7.21 (ABq J=9 Hz, aromatic H's), 2.34 with additional peaks at 2.43 and 2.55 (each s, CH_2CO), 1.97 and 1.63 (m, H's on cyclohexane ring), and 0.90 (d J=6 Hz, CH_3's on cyclohexane ring). Found: C, 65.89; H, 7.31; N, 4.75%. Calcd for $C_{16}H_{21}NO_4$: C, 65.95; H, 7.28; N, 4.80%.

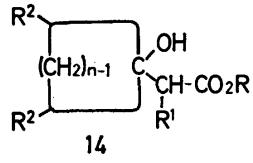
(e) p-*Nitrophenyl Cyclodecylacetate (11)*: The ester was prepared from cyclodecanone[8] in a manner similar to those, described for **8**, **9**, and **10**. NMR (CCl_4, TMS): δ 8.20 and 7.20 (ABq J=9 Hz, aromatic H's), 2.38 (distorted s, CH_2CO), and 1.54 (s, H's on cyclodecane ring). Found: C, 67.43; H, 7.85; N, 4.42%. Calcd for $C_{18}H_{25}NO_4$: C, 67.67; H, 7.90; N, 4.38%. The intermediates obtained in this synthesis were identified as follows. *1-Ethoxycarbonylmethylcyclodecan-1-ol* (**14**; R^1=R^2=H, n=10); bp 125 °C/0.35 mmHg, yield 38%. NMR (CCl_4, TMS): δ 4.18 (q J=7 Hz, $C\underline{H}_2CH_3$), 3.15 (broad s, OH), 2.37 (s, CH_2CO), 1.58 (m, H's on cyclodecane ring), and 1.33 (t J=7 Hz, $CH_2C\underline{H}_3$). *1-Ethoxycarbonylmethyl-1-cyclodecene* (**15**; R^1= R^2=H, n=10) and *ethyl cyclodecylideneacetate* (**16**; R^1= R^2=H, n=10) in a ratio of 3: 1; bp 102—110 °C/7.5 mmHg, total yield 87%. NMR (CCl_4, TMS): δ 5.60 (broad s, C=CH–CO for **16**), 5.26 (t J=8 Hz, CH=C for **15**), 4.06 (q J=7 Hz, $C\underline{H}_2CH_3$), 2.87 (s, CH_2CO for **15**), 2.5—2.0 (m, H_2C–C=C), 1.40 (m, H's on cyclodecane ring), and 1.23 (t J=7 Hz, $CH_2C\underline{H}_3$). Found: C, 73.48; H, 11.54%. Calcd for $C_{14}H_{24}O_2$: C, 74.27; H, 11.60%. *Ethyl cyclodecylacetate* (**17**; R^1= R^2=H, n=10). NMR (CCl_4, TMS): δ 4.07 (q J=7 Hz, $C\underline{H}_2CH_3$), 2.12 (broad s, CH_2CO), 1.51 (s, H's on cyclodecane ring), and 1.23 (t J=7 Hz, $CH_2C\underline{H}_3$).

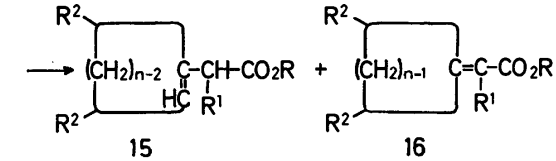
Kinetic Measurements. Rates of *p*-nitrophenol liberation from *p*-nitrophenyl esters were measured at 400 nm with a Union Giken high sensitive spectrophotometer SM-401 under instrumental conditions; response 2 s and sensitivity 0.02 OD/full scale. Each run was initiated by adding a dioxane solution (30 μl) of *p*-nitrophenyl ester (7.0×10^{-5} M) to a reaction medium (3.0 ml) which was pre-equilibrated at 40.0±0.1 °C in a thermostatted cell set in the spectrophotometer. The reaction medium was prepared by mixing a buffer solution (2.7 ml, buffer concentration 0.01 M) and ethanol (0.3 ml) containing an appropriate amount of **1**. The

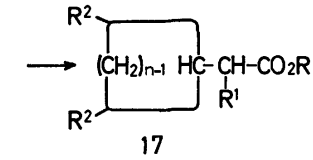
ionic strength of kinetic solutions was maintained at 0.10 with KCl.

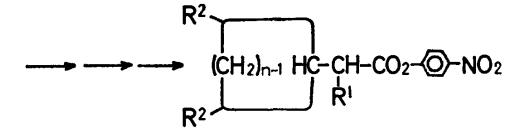
pH Measurements. pH Measurements were carried out with a Beckman expandomatic SS-2 pH meter equipped with a Metrohm EA-125 combined electrode after calibration with a combination of appropriate aqueous standard buffers.











Results and Discussion

The kinetic effect of a [20]paracyclophane bearing an imidazole moiety (**1**) on the deacylation of various *p*-nitrophenyl carboxylates was investigated in 10.9%-(v/v)ethanol-1.0%(v/v)dioxane-water of μ 0.10 (KCl) at 40.0±0.1 °C. Since it is now well known that *p*-nitrophenyl carboxylates bearing a long alkyl chain tend to aggregate above the critical concentrations[9,10] (*e.g.*, 2.0×10^{-6} M for decanoate in 1.0%(v/v) aqueous dioxane at 40 °C),[10] the initial substrate concentrations were adjusted at 7.0×10^{-7} M for most kinetic runs. Although the present paracyclophane is not so much soluble in the above kinetic solvent system, the 5.0×10^{-6} M solution was confirmed to be completely homogeneous in the pH 7—10 range. *p*-Nitrophenyl esters of the present study may be classified into four categories in reference to the extent of rate acceleration brought about by **1** (5.0×10^{-6} M) at pH 8.33 (see Table 1):

Table 1. Pseudo-first-order rate constants for deacylation of *p*-nitrophenyl carboxylates in the absence (k_{hyd}) and presence (k_{obsd}) of **1**[a]

Substrate ester	$k_{hyd}\times10^5/s^{-1}$	$k_{obsd}\times10^4/s^{-1}$	k_{obsd}/k_{hyd}
2	7.8	8.2	1.0
3	3.2	20	6.2
4	2.0	480	240
5	1.4	590	420
6	0.73	680	930
7	1.5	8.3	5.5
8	2.1	9.7	4.6
9	0.18[b]	3.7	20
10	2.0	69	35
11	1.0	170	170
12	17.3	24	1.4
13	1.0	7.9	7.9

a) At 40.0±0.1 °C, pH 8.33 (6.3×10^{-3} M KH_2PO_4—3.7×10^{-3} M $Na_2B_4O_7$), and μ 0.10 (KCl) in 10.9%(v/v) ethanol–1.0%(v/v) dioxane–water; initial substrate concentration, 7.0×10^{-7} M unless otherwise stated; initial concentration of **1**, 5.0×10^{-6} M. b) Initial substrate concentration, 1.0×10^{-5} M.

those having a long alkyl chain (**4**, **5**, and **6**), more than 240-fold acceleration; those having a cyclodecyl moiety or a cyclohexyl moiety with an additional methyl substituent or substituents (**9**, **10**, and **11**), 20—170-fold acceleration; those having a less hydrophobic acyl portion (**3**, **7**, **8**, and**13**), 4—8-fold acceleration; acetate (**2**) and phenylacetate (**12**), the catalytic effect was fairly detected. Thus, the hydrophobic interaction of **1** with an acyl portion of each substrate ester seems to be responsible for the catalytic efficiency. This is evidenced by the effect of ethanol content on the catalytic activity of **1**. As the ethanol content is raised the hydrophobic interaction between **1** and the substrate would be progressively reduced, and consequently the catalytic efficiency of **1** would be lowered. This is what is observed in the deacylation of decanoate (7.0×10^{-7} M) as effected by 5.0×10^{-6} M of **1**: apparent second-order rate constants; 970 in 10%(v/v), 123 in 15%(v/v), 20 in 20%(v/v), and 11 $M^{-1}\,s^{-1}$ in 30%(v/v) aqueous ethanol. Similar effects have been noted elsewhere.[1,10]

The kinetic pK_a value for the deacylation of decanoate (1.0×10^{-6} M) as effected by **1** (5.0×10^{-6} M) was estimated graphically as 6.8 from the pH-rate profile (Fig. 1), which is referred to the acid dissociation of the catalytically active group, imidazole. The facile reaction of **1** with a hydrophobic ester resulted in the

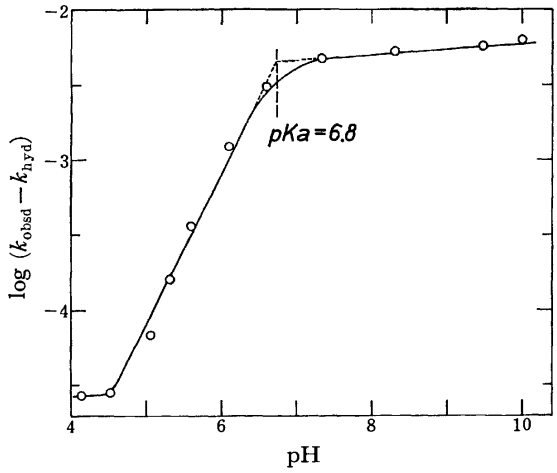


Fig. 1. pH-Rate profile for the deacylation of **4** in the presence of **1** (5.0×10^{-6} M) at 40.0±0.1 °C and μ 0.10 (KCl) in 10.9%(v/v) ethanol–1.0%(v/v) dioxane–water; initial concentration of **4**, 1.0×10^{-6} M. Both k_{obsd} and k_{hyd} are in s^{-1}.

accumulation of the N^{Im}-acyl derivative of **1** along the progress of reaction. The rate of regeneration of **1** (turnover) upon deacylation of the N^{Im}-acyl derivative was negligibly small under present experimental conditions compared to the corresponding acylation rate. With excess substrate ester, the amount of *p*-nitrophenol liberated in the course of reaction increased until it reached a maximal accumulation which exactly corresponds to the amount of **1** used.

Aggregation Behavior. The pseudo-first-order rate constants at pH 8.33 for deacylation of *active esters* are graphically shown in Figs. 2, 3, and 4 as a function of the initial concentration of **1**. In all cases the overall

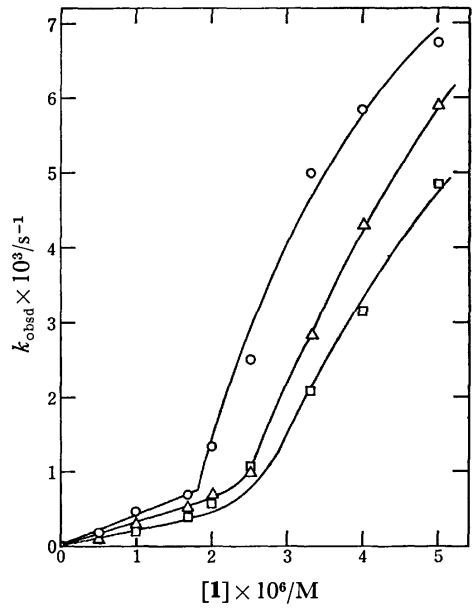

Fig. 2. Correlations of k_{obsd} with the initial concentration of **1** for the deacylation of **4** (□), **5** (△), and **6** (○) at 40.0±0.1 °C, pH 8.33, and μ 0.10 (KCl) in 10.9%-(v/v) ethanol–1.0%(v/v) dioxane–water; initial substrate concentration, 7.0×10^{-7} M.

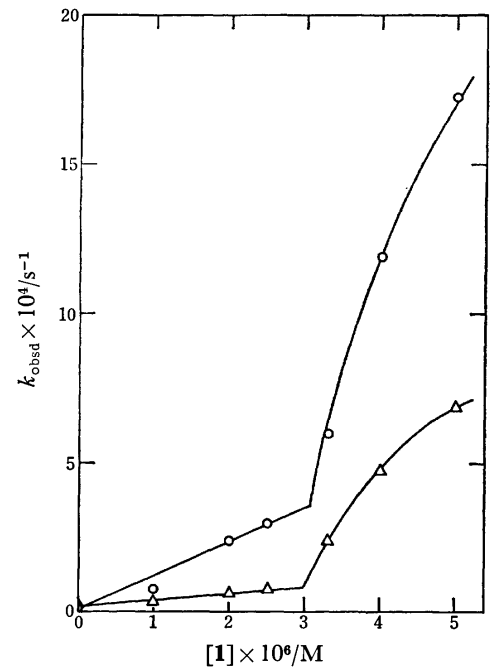

Fig. 3. Correlations of k_{obsd} with the initial concentration of **1** for the deacylation of **10** (△) and **11** (○) at 40.0±0.1 °C, pH 8.33, and μ 0.10 (KC) in 10.9%-(v/v) ethanol–1.0%(v/v) dioxane–water; initial substrate concentration, 7.0×10^{-7} M.

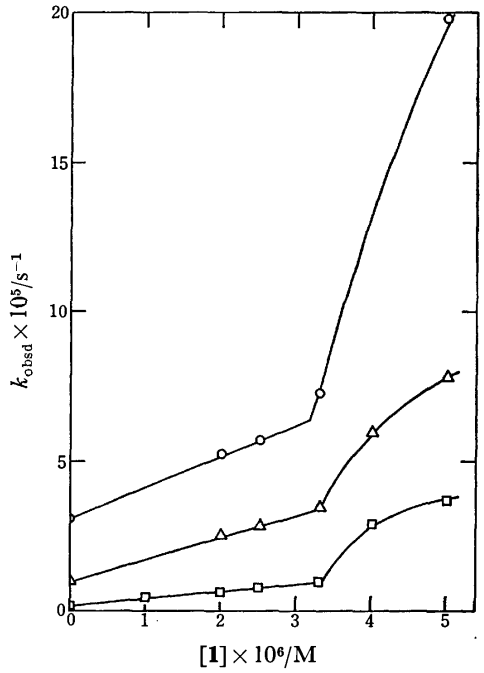

Fig. 4. Correlations of k_{obsd} with the initial concentration of **1** for the deacylation of **3** (○), **9** (□), and **13** (△) at 40.0±0.1 °C, pH 8.33, and μ 0.10 (KCl) in 10.9%(v/v) ethanol–1.0%(v/v) dioxane–water; initial substrate concentration, 7.0×10^{-7} M.

feature is similar to those observed for micelle-catalyzed reactions.[11] The linear portion in a rate-concentration correlation below the break point may correspond to the reaction of the monomeric species of **1**, and a sharp

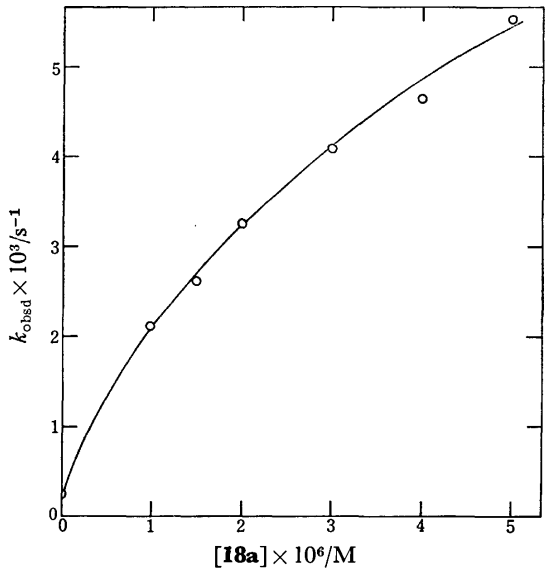

Fig. 5. Saturation-type kinetics for the deacylation of **6** in the presence of **18a** at 40.0±0.1 °C, pH 11.23, and μ 0.10 (KCl) in 10.9%(v/v) ethanol–1.0%(v/v) dioxane–water; initial substrate concentration, 7.0×10^{-7} M.

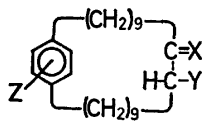
increase in rate above the break point may be due to aggregation or micellization of **1**. In marked contrast to [20]paracyclophane oximes which are believed to be monomeric under similar conditions,[1,2,4] such a kinetic behavior is rather surprising. Since the previous studies with paracyclophane oximes as catalysts in the deacylation reaction were carried out under conditions where the substrate esters were mostly in aggregated forms, we have re-examined the effect of 10-hydroxy-11-hydroxyimino[20]paracyclophane (**18a**) on the deacylation of *p*-nitrophenyl hexadecanoate at pH 11.23 under the same kinetic conditions as employed here; solvent system, temperature, and the initial substrate concentration (7.0×10^{-7} M) as shown in Fig. 5. The rate constant (k_{obsd}) is smoothly correlated with the initial concentration of **18a** without any break point in contrast to the **1**-catalyzed reaction shown in Fig. 2. Furthermore, the plot of $1/(k_{obsd}-k_{hyd})$ *vs.* 1/[**18a**] yielded a straight line in a manner as observed previously.[1,2,4] It may be concluded, therefore, that there is no abrupt change in physical state of **18a** in the concentration range investigated and its critical micelle concentration (CMC), if any, would be greater than 5.0×10^{-6} M. The difference in CMC between the imidazole and oxime derivatives of [20]paracyclophane may arise at least in part from charge difference between the two catalysts: the anionic hydroxyimino group placed in the catalytically active cyclophane raises CMC significantly relative to the imidazole group in neutral form (**1**). It is generally true that the CMC's of ionic surfactants are larger than those of nonionic ones, both types having similar apolar structures. Comparison of the CMC's of surfactants having a dodecyl or dodecanoyl moiety[12] reveals this point: dodecylammonium chloride (cationic), 1.5×10^{-2} M in water at 25 °C; dodecyltrimethylammonium bromide (cationic), 1.5×10^{-2} M in water at 25 °C; sodium dodecanoate



18a X=NOH, Y=OH, Z=H
18b X=O, Y=H, Z=$CH_2N^+(CH_3)_3$ Cl^-

(anionic), 2.4×10^{-2} M in water at 25 °C; polyoxyethylene(6) dodecanol (nonionic), 8.7×10^{-5} M in water at 25 °C; *N,N*-dimethyldodecylamine oxide (nonionic), 2.1×10^{-3} M in water at 27 °C; dodecyldimethylphosphine oxide (nonionic), 5.7×10^{-4} M in water at 30 °C; sucrose dodecanoate (nonionic), 1.9×10^{-4} M in water at 20 °C. Steroid micelles which bear a better resemblance to our paracyclophanes from the structural viewpoint are subject to a charge effect even to a pronounced extent: cholic acid derivatives (anionic), 10^{-3}—10^{-2} M in water at 25 °C;[13-16] and cholesterol (nonionic), $2—4 \times 10^{-8}$ M in water at 25 °C.[17]

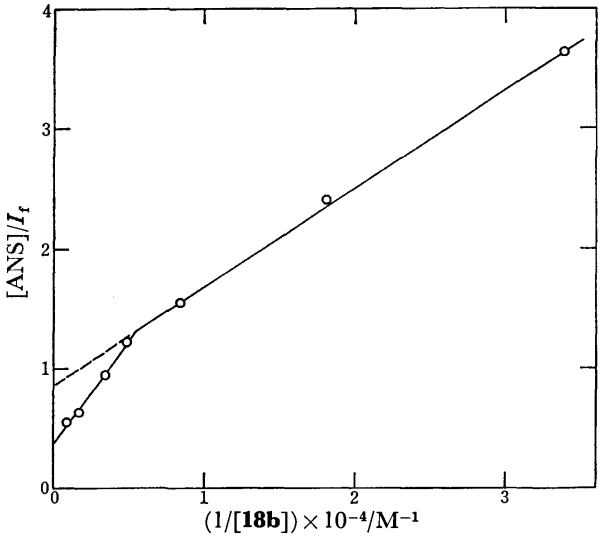


Fig. 6. Analysis of fluorescence spectral data for the interaction of **18b** with ANS (5.0×10^{-5} M) in a buffer solution of pH 8 at 20 °C by means of Eq. 1; I_f, in arbitrary scale.

The proposed charge effect on the CMC's of paracyclophanes is further exemplified by the micellization behavior of the cationic [20]paracyclophane bearing a quaternary ammonium group (**18b**) as investigated by the fluorescence dye technique with 1-anilinonaphthalene-8-sulfonate (ANS) as a probe: concentration of ANS, 5.0×10^{-5} M; excitation wavelength, 384 nm; fluorescence intensity, measured at 468 nm. The relative fluorescence intensity of ANS in a pH 8 buffer at 20 °C increased as the concentration of **18b** was raised in a concentration range of 2.95×10^{-5}—1.18×10^{-3} M. The reciprocal fluorescence intensity ($1/I_f$) is plotted in Fig. 6 as a function of reciprocal concentration of **18b** on the basis of the Benesi-Hildebrand type relationship[18] (Eq. 1) derived under the assumption that only the 1:1 interaction between **18b** and ANS takes place: I_f, observed fluorescence intensity; I_a, fluorescence intensity of ANS bound to the monomeric form of

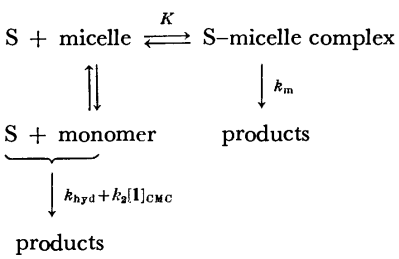
a) At 40.0±0.1 °C, pH 8.33 (6.3×10^{-3} M KH_2PO_4–3.7×10^{-3} M $Na_2B_4O_7$), and μ 0.10 (KCl) in 10.9%(v/v) ethanol–1.0%(v/v) dioxane–water; initial substrate concentration, 7.0×10^{-7} M. b) Values in parentheses, k_{Im} for acetate (**2**) was taken as the reference value. c) Critical micelle concentration of **1**. d) $k_2(\text{app})=(k_{obsd}-k_{hyd})/[\mathbf{1}]$, $[\mathbf{1}]=5.0\times10^{-6}$ M.

18b; K, binding constant for complex formation between the monomeric form of **18b** and ANS.

$$\frac{[\text{ANS}]}{I_f}=\frac{1}{I_a}+\frac{1}{I_aK[\mathbf{18b}]} \quad (1)$$

The break point, which corresponds to the CMC of **18b**, is observed at 1.8×10^{-4} M as shown in Fig. 6. This CMC value is 50—100 times as large as the substrate-dependent CMC's of **1** (Figs. 2, 3, and 4, and Table 2). The binding constant ($K=1.1\times10^{4}$ M^{-1}) is 190 and 7 times as large as those for β-cyclodextrin and a water-soluble heterocyclophane, respectively.[19)]

The overall feature of deacylation reactions of *p*-nitrophenyl carboxylates in the presence of **1** is consistent with reaction pathways shown in Scheme 1.



Scheme 1.

The kinetic parameters can be determined by Eq. 2:[11)] k_{hyd}, rate constant for spontaneous hydrolysis; k_2, second-order rate constant for reaction of an ester with the monomeric form of **1**; k_m, first-order rate constant for reaction of an ester in micellar phase; k_{obsd}, observed pseudo-first-order rate constant; K, association constant for formation of the ester–micelle complex; N, aggregation number of the micelle; [**1**], total concentration of **1**; $[\mathbf{1}]_{CMC}$, CMC of **1** which is dependent on the nature of a particular substrate used. The kinetic data for reactions of **4**, **5**, **6**, **10**, and **11** were analyzed by the aid of Eq. 2. Because of the limited solubilities of the reactants as well as relatively higher kinetic CMC's of **1**, the critical evaluation of k_m and K/N values were not performed for reactions of **3**, **9**, and **13** and the apparent second-order rate constants per mole of **1** forming micelles (k_mK/N) were obtained from the rate profiles shown in Fig. 4 by the aid of Eq. 2. For esters **2**, **7**, **8**, and **12** which showed the least affinity with **1**, the apparent second-order rate constants defined by $k_2(\text{app})=(k_{obsd}-k_{hyd})/[\mathbf{1}]$ were evaluated for the purpose of comparison of reactivity with other esters. All the kinetic parameters are summarized in Table 2 along with the second-order rate constants for reactions of the esters with imidazole as a reference.

$$\frac{1}{k_{obsd}-(k_{hyd}+k_2[\mathbf{1}]_{CMC})}=\frac{1}{k_m-(k_{hyd}+k_2[\mathbf{1}]_{CMC})}\times\left\{1+\frac{N}{K([\mathbf{1}]-[\mathbf{1}]_{CMC})}\right\} \quad (2)$$

Catalytic Efficiency. All the esters except acetate (**2**) are subject to profound catalysis by **1**. The second-order rate constants (k_2) for reactions of the monomeric species of **1** with relatively hydrophobic esters exceed considerably the corresponding second-order rate constants for imidazole-catalyzed reactions (k_{Im}), suggesting the significant hydrophobic interaction between **1** and each hydrophobic ester. The k_2/k_{Im} value may be referred to a measure of the extent of hydrophobic interaction. Care should be exercised for the long-chain esters. The hydrophobic coiling of the alkyl chain, which results in masking of the ester carbonyl against an attacking nucleophile,[10)] seems to be responsible for the decrease in k_{Im} in going from decanoate through hexadecanoate. The geometry of the hydrophobic interaction between each of these esters and the monomeric species of **1** is not known at present. If the intramolecular coiling were retained in the transition state of acyl transfer from the ester to **1**, the k_2/k_{Im} values would provide a meaningful comparison of relative catalytic efficiency. However, the esters most plausibly undergo decoiling or elongation before the transition state is reached.[1-5)] The k_{Im} value for acetate which

is free from the coiling effect may be cited as the plausible reference for the evaluation of catalytic efficiency of the monomeric form of **1** as shown in parentheses in Table 2. As expected from the viewpoint of hydrophobic affinity, the k_2/k_{1m} value increases as the alkyl chain of ester is lengthened (**3**<**4**<**5**<**6**). This value also increases in the order **9**<**10**<**11**. This fact may allow to draw the following conclusion; the extent of hydrophobic interaction between the monomeric species of **1** and an ester having an aliphatic ring moiety in its acyl portion may be primarily governed by the surface area[20] or more simply by the number of carbon atoms in the acyl portion of the ester concerned. The aromatic ester, α-naphthoate (**13**), seems less hydrophobic relative to **10** and **11** in the light of k_2/k_{1m} values even though all three esters have comparable number of carbon atoms.

The binding constants for micellar complex formation with **4**—**6**, **10**, and **11** are greater than $10^5\ M^{-1}$. It may be a surprise to see the decrease in K/N in going from **10** to **11** since **11** is expected to be more hydrophobic than **10** judging from the k_2/k_{1m} values for the two esters. This would be cited as an example of substrate selectivity for the binding process. However, we are not certain whether or not the micelle of **1** has the same aggregation number (N) for different substrates. It is reasonable to assume that N is relatively small for hydrophobic macrocycles in a manner as observed for cholic acid derivatives (N=5—22).[16] Under such circumstances, the aggregation number as well as CMC may be significantly dependent on the nature of a particular substrate employed.

The product of micellar reaction rate and binding constants (k_mK) is referred to the second-order rate constant for reaction of a substrate and a micelle, and consequently the k_mK/N value corresponds to the second-order rate constant for the same reaction as evaluated per mole of **1** forming micelles. There is indeed a wide variation in k_mK/N as can be seen in Table 2, and the long-chain carboxylates (**4**—**6**) show the highest values in the 2000—3000 $M^{-1}\ s^{-1}$ range. These values are the largest ever achieved for reactions of synthetic 4-substituted imidazoles with *p*-nitrophenyl esters,[21] and may be comparable to or greater than the second-order rate constant for the acylation of chymotrypsin with *p*-nitrophenyl acetate (410 $M^{-1}\ s^{-1}$ at 25 °C and pH 7.75).[22] The profound catalytic activity of **1** is due primarily to its large binding ability toward the substrates ($K>10^5\ M^{-1}$), since the micellar rate constant (k_m=0.02 s^{-1}) is less than one hundredth of the corresponding rate constant for acylation of the enzyme with the bound acetate (k_m=3.15 s^{-1} at 25 °C).

The authors are grateful to Professor Taku Matsuo and Mr. Satoru Mihara of our Department for measurements of the fluorescence spectra. This work was supported in part by a Scientific Research Grant (No. 147076) from the Ministry of Education.

Chemical Studies on Tuberactinomycin. XII.[1] Syntheses and Antimicrobial Activities of [Ala^3, Ala^4]-, [Ala^3]-, and [Ala^4]-Tuberactinomycin O[2]

Tadashi TESHIMA, Shinya NOMOTO, Tateaki WAKAMIYA, and Tetsuo SHIBA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received July 8, 1977)

Total syntheses of [Ala^3, Ala^4]-, [Ala^3]-, and [Ala^4]-tuberactinomycin O corresponding to deoxy analogs of natural antibiotic tuberactinomycin O were achieved for the purpose of elucidation of relationship between chemical structure and biological activity. Cyclization of the pentapeptide intermediates at two different positions was investigated. Minimum inhibitory concentrations of the synthetic analogs against *Mycobacterium* or *Corynebacterium* indicated that both hydroxy groups of two serine residues of tuberactinomycins are not required for antibacterial activity, nor participated to drug-resistancy of bacilli. These analogs were found to have the same conformations in solution as those of natural antibiotic from the results of NMR, ORD, and CD measurements.

Chemical structures of tuberactinomycins (Tum),[3] antituberculous peptides isolated from *Streptomyces griseoverticillatus* var. *tuberacticus*,[4] were determined by X-ray analysis as well as chemical degradations in our previous investigations (Fig. 1).[5] Exhaustive study on proton magnetic resonance of tuberactinomycin family added one successful example to conformational analysis of cyclic peptides.[6] Total synthesis of one congener, Tum O, in our recent work contributed to unambiguous establishment of the structures of Tum.[7]

B	H	OH
N	OH	H
O	H	H

Fig. 1. Chemical structure of tuberactinomycins.

For the purpose of thorough elucidation of the structure-antibacterial activity relation of this antibiotic, we planned to exchange each amino acid residue in tuberactinomycins with others by full utilization of either semi-synthesis, total synthesis or chemical modification. In the first experiment, the branched part, *i.e.*, γ-Hy-β-Lys[3] in Tum N was replaced by many different acyl groups semi-synthetically.[1,8] From results of this study, it was concluded that the branched part is not necessarily required for the antibacterial activity but has an auxiliary role for enhancement of the activity.[1]

Therefore, in the present investigation, replacement of amino acid residues inside the cyclic moiety of Tum was so designed as to clarify the more significant site than branched part for the biological activity. Since two hydroxy groups of serine residues are common to all the Tum congeners, it seems to be important to see the effect of elimination of these functional groups from the molecule on antibacterial activity. Thus, we carried out the total syntheses of three deoxy analogs, *i.e.*, [Ala^3, Ala^4]-, [Ala^3]-, and [Ala^4]-Tum O.

In our synthetic strategy, prior to completion of the required amino acid sequence, the cyclic peptide moiety was first synthesized, and then β-Lys was introduced to the branched position as in the semi-synthesis of Tum O[8] from tuberactinamine (Tua) N.[3] In this synthetic plan, possible difficulties arising from extremely labile character of β-ureidodehydroalanine (Uda) residue must be overcome by some device. β,β-Diethoxyalanine (Dea) was chosen as a latent form of Uda,[3] so that Uda structure could be recovered at any synthetic step. A durability of Dea[3] residue during the entire course of this peptide synthesis was assured by preliminary experiments using model compounds.

In order to minimize a racemization at the C-terminal residue in the peptide cyclization reaction, Dea (route A) or A_2pr[3] (route B) was chosen as the C-terminal amino acid of the open chain pentapeptide, since Dea is to be converted to achiral Uda residue in the final synthetic step and α-amino group of A_2pr is not participated in the peptide linkage in the cyclic moiety but is able to be protected by Boc[3] group of urethane form.

In the preparations of [Ala^3, Ala^4]-Tum O, we compared both routes each other for relative advantages. However, the results showed no difference between them in respect of yield for the cyclization reaction. Therefore, route A was adopted for the syntheses of [Ala^3]- and [Ala^4]-Tum O.

Synthesis of [Ala^3, Ala^4]-Tum O. The Protected Cyclic Pentapeptide: *Route A*: H-Dea-OEt[9] and H-A_2pr(Z)-OH[10] were prepared according to the literatures. Capreomycidine (Cpd) was obtained from hydrolyzate of the natural Tum N. Whole synthetic scheme *via* route A was shown in Fig. 2. α-Amino group of Cpd was blocked by Nps[3] protecting group, since selective deprotection from Boc group is required prior to the cyclization. Nps-Cpd(NO_2)-OH (**6**) was coupled with a debenzyloxycarbonylated tetrapeptide, which was obtained by hydrogenolysis of **4**, to give a pentapeptide (**7a**). Saponification of **7a** followed by active esterification by means of DCC-HONSu[3] method to afford the pentapeptide active ester (**9a**). After removal of Nps group from **9a** by means of hydrogen chloride in THF, it was then cyclized under high-dilution conditions in pyridine to **10a** in 35% yield. Molecular weight of **10a** was measured to be 743

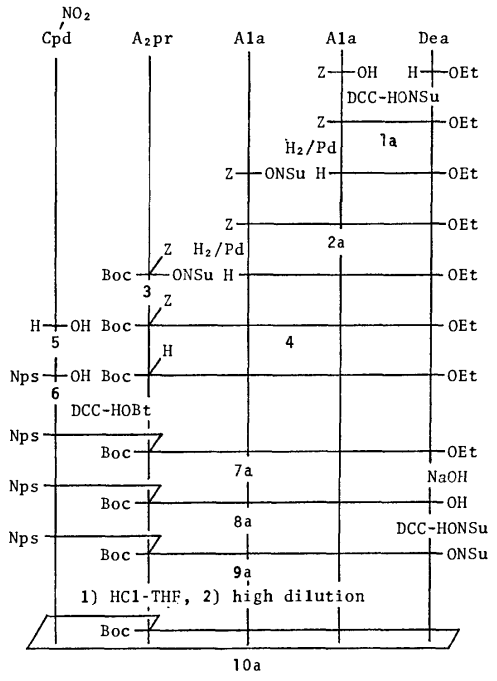

Fig. 2. Synthetic scheme for protected cyclic peptide (**10a**) *via* route A.

(Calcd for $C_{24}H_{46}O_{11}N_{10}\cdot 3/2H_2O$: 714) by means of vapor pressure osmometry, indicating formation of a cyclic monomer.

Route B: Synthetic scheme *via* route B was depicted in Fig. 3. The Nps group of the protected dipeptide (**12**) was selectively cleaved by hydrogen chloride in THF, and then coupled with the protected tripeptide (**14**) by DCC–HOBt[3] method to give the pentapeptide (**15**). This peptide (**15**) was converted into the 1-succinimidyl ester (**17**) after saponification. The active ester (**17**) was treated with hydrogen chloride in THF to remove the Nps group selectively, and then cyclized in pyridine under high-dilution condition in 38% yield. The cyclic peptide (**10a**) thus obtained was identical with the product *via* route A in thin-layer chromatography, high-pressure liquid chromatography, and NMR spectrum.

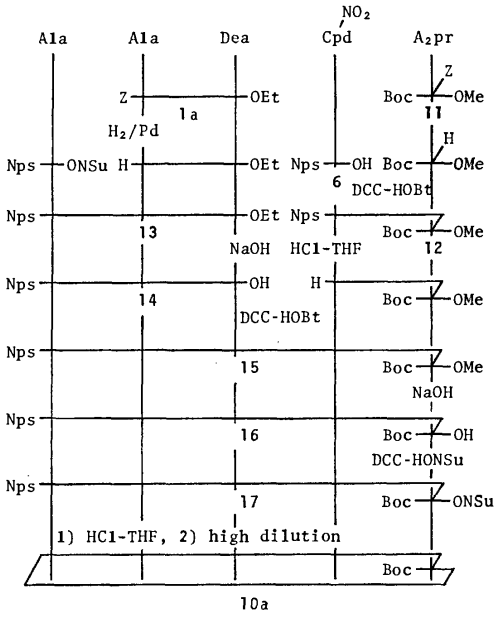

Fig. 3. Synthetic scheme for protected cyclic peptide (**10a**) *via* route B.

A Conversion to [Ala³, Ala⁴]-Tum O: A conversion of Dea residue in **10a** to Uda residue, being a key step throughout this synthesis, was carried out as follows. The deprotected product obtained by hydrogenolysis of **10a** was heated in acetone–1 M hydrochloric acid (1 : 1) under reflux for 8—10 min, and then excess of urea was added. By this procedure, the cyclic Uda peptide (**18a**) was obtained in a good yield, whose structure was confirmed by NMR (olefinic proton: δ 8.0(s) in D_2O) and UV spectra (λ_{max}: 268 nm (neutral or acidic medium), 286 (basic medium)). At the final step of the synthesis, introduction of Boc–β-Lys(Boc)–ONSu to the amino group of **18a** followed by deprotection gave the expected product, [Ala³, Ala⁴]-Tum O (**19a**) in a satisfactory yield (Fig. 4).

Synthesis of [Ala³]- and [Ala⁴]-Tum O. [Ala³]- and [Ala⁴]-Tum O were synthesized according to the route A for [Ala³, Ala⁴]-Tum O. Cyclization reaction

was carried out between the carboxyl group of Dea and the amino group of Cpd. The synthetic scheme for these analogs is shown in Fig. 5.

Tripeptides (**2b**, **c**) were prepared by stepwise elongation method from their C-terminal residue using the *t*-Bu group for protection of hydroxyl group of Ser. Dipeptide (**20**) was coupled with either of deprotected tripeptides obtained from **2b** and **2c** by DCC–HOBt method to give a pentapeptide (**7b**) or (**7c**). These ethyl esters (**7b**, **c**) were converted to their 1-succinimidyl esters (**9b**, **c**) *via* free carboxylic acids respectively. Each active ester was treated with hydrogen chloride in THF to remove Nps group selectively and then cyclized in pyridine under high dilution method to give **10b** in 32% or **10c** in 31% yield. Molecular weights of these peptides (**10b**, **c**) measured by means of vapour pressure osmometry (844 and 811 respectively, calcd for $C_{31}H_{54}N_{10}O_{12}\cdot H_2O$: 777) indicated that a cyclic monomer was formed in both cases. Removal of all protecting groups and conversion of Dea to Uda residue in cyclic peptides (**10b**, **c**) were performed. Resulting Uda peptides (**18b**, **c**) were coupled with Boc–β-Lys(Boc)–ONSu and the products were deblocked to give desired compounds, [Ala^3]- and [Ala^4]-Tum O (**19b**, **c**) (Fig. 6).

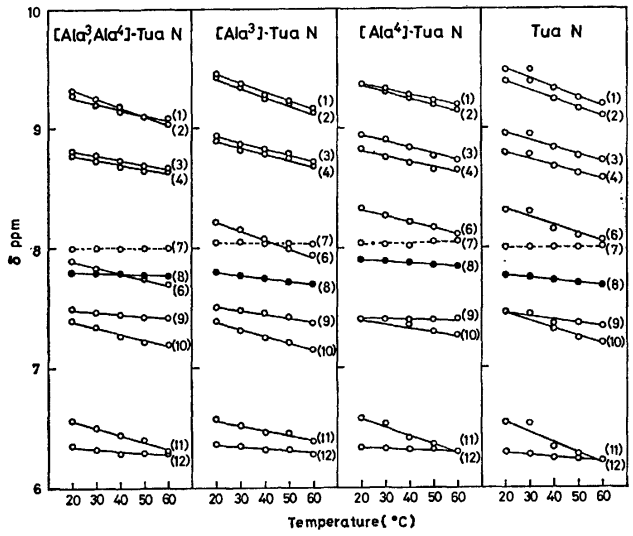

Fig. 8. Temperature dependence of chemical shifts in low-field region of NMR of **18a**, **18b**, and **18c**, as measured in H_2O at pH 2.5. o---o: olefinic proton, •—•: α-amide proton of Cpd, o—o: other NH protons.

decoupling method and comparison with natural ones[6] as shown in Table 1, 2, and Fig. 7. These assignments are very consistent with those for natural Tums, and rather abnormal differences in chemical shifts of α-CH or α-NH in Ser³ and Ser⁴ residues of natural sample were reconfirmed by this study.

Temperature dependence of chemical shifts as depicted in the Fig. 8 suggested that amide proton of Cpd may be participated to an intramolecular hydrogen bond as in natural tuberactinomycins.[6] Slower rate in deuterium exchange of the amide proton of Cpd compared to other protons, supported the existence of an intramolecular hydrogen bond mentioned above, too. Furthermore, for comparison between the synthetic and the natural peptides in terms of the conformation of whole molecules, ORD and CD curves were measured. Cyclic peptide moieties, *i.e.* **18a**—**c** which were synthesized in this study, showed principally the same patterns as that of Tua N. Similarly, ORD and CD curves of Tum O analogs resemble those of natural Tums as shown in Fig. 9. Therefore, it could be concluded that all cyclic peptides prepared here have the same conformations as the natural one including the intramolecular hydrogen bond.

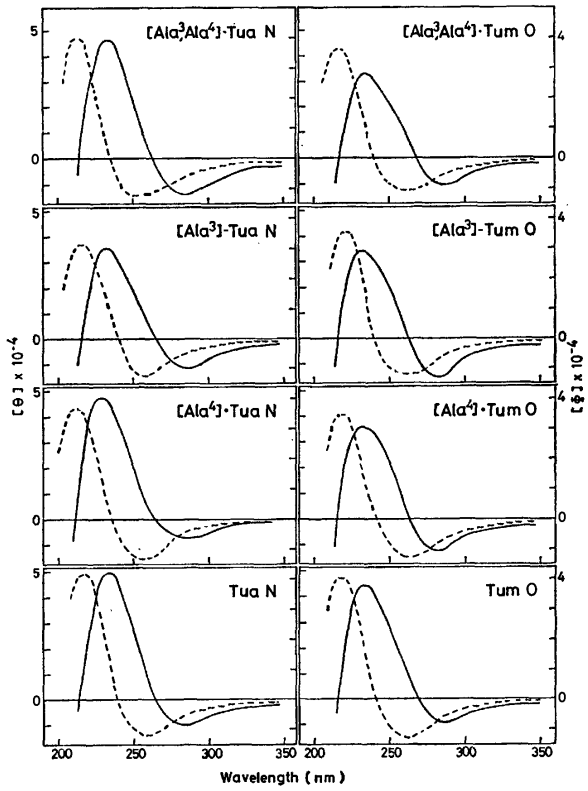

Fig. 9. ORD and CD curves of Tua N and O analogs. ——: ORD, ------: CD.

Antimicrobial Activities. Minimum inhibitory concentrations of [Ala³, Ala⁴]-, [Ala³]-, and [Ala⁴]-Tum O (**19a**—**c**) were listed in Table 3. Spectral patterns in their antibacterial activities of all these analogs were very similar to those of Tum N. It should be noted that [Ala⁴]-Tum O (**19c**) manifested even stronger activities than those of natural Tum N against some of test organisms, *i.e.*, *Bacillus subtilis*, *Salmonella paratyphi*, and *Salmonella enteritidis*, whereas [Ala³, Ala⁴]-Tum O (**19a**) was slightly weaker than natural antibiotics. Although

Human tubercule bacillus	12.5	<12.5	<12.5	<12.5
Human tubercule bacillus (100 μg-resistant to Tum B)	>100	>100	100	100
BCG (100 μg-resistant to Tum N)	>100	>100	>100	>100

a) μg/ml.

these synthetic analogs were also quite active against sensitive species of human tubercule bacillus, they showed no significant activity to Tum-resistant species of human tubercule bacillus and BCG. (Table 4).

Relationship between Structure and Activities. From all results of comparisons in biological activities of the synthetic peptides, it could be emphasized conclusively that both hydroxyl groups at Ser[3] and Ser[4] residues are not necessarily required for antibacterial activity of Tums, although the presence of these hydroxyl groups seemed to strengthen the activities, especially the hydroxyl group of Ser[3] playing more important role than that of Ser[4]. However, it is apparent that these hydroxyl groups may not be concerned with the drug resistancy of human tubercule bacilli.

Experimental

All melting points are uncorrected. NMR spectra were obtained with a Varian XL-100-15 spectrometer using sodium dimethylsilapentanesulfonate as an internal standard. ORD and CD spectra were obtained with a JASCO Model ORD/UV-5 in water. The specific rotations were obtained with a Perkin-Elmer 141 Polarimeter. Molecular weights were obtained with a Knauer vapor pressure osmometer using methanol as a solvent. UV spectra were recorded on a Hitachi 124 Spectrophotometer. TLC was carried out by the ascending method on silica gel G using a developing solvent chloroform–methanol (7: 1).

*Z–Ala–Dea–OEt (**1a**).* To a solution of Z–Ala–OH (14.6 g, 65.2 mmol) and H–Dea–OEt[9] (13.4 g, 65.2 mmol) in ethyl acetate (40 ml), a solution of HONSu[3] (9.01 g, 78.2 mmol) in dioxane (30 ml) and then DCC (14.8 g, 71.7 mmol) were added under stirring in an ice bath. Stirring was continued at 0 °C for 2 h, thereafter at room temperature overnight. After the addition of acetic acid (500 mg, 8.30 mmol), *N,N'*-dicyclohexylurea was filtered off and filtrate was concentrated *in vacuo*. A solution of the residue in ethyl acetate was washed with saturated aqueous sodium hydrogencarbonate and water. Organic layer was dried over anhydrous sodium sulfate and concentrated *in vacuo* to yield an oily product, yield 24.9 g (92.9%).

For characterization a portion of **1a** was converted into the crystalline hydrazide. Thus, to a solution of **1a** (1.40 g, 3.41 mmol) in DMF (20 ml), hydrazine hydrate (3.42 g, 68.3 mmol) was added. The mixture was allowed to stand for two days at room temperature and then concentrated *in vacuo*. The residue was triturated with water, and a crystalline product was filtered off, yield 0.920 g (68.1%). It was recrystallized from ethanol–ether–hexane, mp 208—209 °C (dec), $[\alpha]_D^{29}$ −1.2 °C (*c* 1.0, DMF).[12] Found: C, 54.21; H, 7.17; N, 14.19%. Calcd for $C_{18}H_{28}N_4O_6$: C, 54.53; H, 7.12; N, 14.13%.

*Z–Ala–Ala–Dea–OEt (**2a**).* Into a solution of **1a** (11.5 g, 28.0 mmol) and acetic acid (3.36 g, 56.0 mmol) in ethanol (200 ml), hydrogen was bubbled in the presence of palladium black. After debenzyloxycarbonylation had been completed, catalyst was filtered off and the filtrate was concentrated *in vacuo*. To a solution of the residue in ethyl acetate, triethylamine (3.30 g, 30.0 mmol) and Z–Ala–ONSu (8.96, 28.0 mmol) were added with stirring at 0 °C. The mixture was stirred at 0 °C for 1 h, thereafter at room temperature overnight. The reaction mixture was concentrated *in vacuo* and the residue was dissolved in chloroform. The organic solution was washed with saturated aqueous sodium hydrogencarbonate and water, and then dried over anhydrous sodium sulfate. A crystalline residue obtained after concentration *in vacuo* was recrystallized from chloroform–ethyl acetate, yield 11.7 g (86.8%), mp 186—188 °C. $[\alpha]_D^{28}$ −5.6 ° (*c* 0.9, DMF). Found: C, 57.32; H, 7.37; N, 8.94%. Calcd for $C_{23}H_{35}N_3O_8$: C, 57.37; H, 7.33; N, 8.73%.

*Boc–A$_2$pr(Z)–ONSu (**3**).* To a suspension of H–A$_2$pr(Z)–OH[10] (2.38 g, 10.0 mmol) in water (20 ml), triethylamine (2.1 ml, 15 mmol) and *t*-butyl 4,6-dimethylpyrimidyl-2-thiolcarbonate (2.64 g, 11.0 mmol)[13] in dioxane (6 ml) were added. The reaction mixture was stirred for 20 h. After addition of saturated aqueous sodium hydrogencarbonate, the solution was washed with ethyl acetate. The aqueous layer was acidified with citric acid and the product was transferred to ethyl acetate. The organic layer was washed with water, and then dried over anhydrous sodium sulfate, and then concentrated *in vacuo* to give an oily residue. To its solution in THF (30 ml), HONSu (1.15 g, 10.0 mmol) and DCC (2.06 g, 10.0 mmol) were added with stirring at 0 °C. The mixture was stirred at 0 °C for 2 h, and then at room temperature overnight. The *N,N'*-dicyclohexylurea formed was filtered off and the filtrate was concentrated *in vacuo*. Oily residue was triturated with hexane, and the crystalline product thus obtained (3.71 g, 85.2%) was recrye stallized from dioxane–hexane, yield 2.77 g (63.6%), mp 90—92 °C, $[\alpha]_D^{29}$ −30.7 ° (*c* 1.9, DMF). Found: C, 54.78; H, 5.80; N, 9.68%. Calcd for $C_{20}H_{25}N_3O_8$: C, 55.17; H, 5.79; N, 9.65%.

*Boc–A$_2$pr(Z)–Ala–Ala–Dea–OEt (**4**).* Hydrogenolysis of **2a** (7.00 g, 14.5 mmol) was carried out with addition of acetic acid (1.75 g, 29.1 mmol) in ethanol–dioxane (250 ml) as in the preparation of **2a** from **1a**. To a solution of the residual oil of $CH_3COOH \cdot$H–Ala–Dea–OEt and **3** (6.33 g, 14.5 mmol) in ethyl acetate (200 ml) *N*-methylmorpholine (2.94 g, 29.1 mmol) was added with stirring at 0 °C. The mixture was stirred at 0 °C for 2 h and then at room temperature overnight. The residue obtained after concentration *in vacuo* was dissolved in chloroform, and washed with 10% aqueous citric acid, saturated aqueous sodium hydrogencarbonate, and brine. The organic layer was dried over anhydrous sodium sulfate and concentrated *in vacuo*. The crystalline residue was recrystallized from chloroform–ethyl acetate–ether, yield 16.9 g (87.2%), mp 187—191 °C, $[\alpha]_D^{29}$ −9.2 ° (*c* 2.1, DMF). Found: C, 55.60; H, 7.41; N, 10.55%. Calcd for $C_{31}H_{49}N_5O_{11}$: C, 55.76; H, 7.40; N, 10.49%.

*H–Cpd(NO$_2$)–OH (**5**).* To a mixture of fuming nitric acid (*d*=1.52) (1.5 ml) and 50% fuming sulfuric acid (1.2 ml), H–Cpd–OH·HCl[14] (740 mg, 3.55 mmol) was added portionwise over 30 min with stirring at −20 °C, and then concentated

sulfuric acid (1 ml) was added. The mixture was stirred under the same conditions for 45 min, thereafter poured onto ice. On neutralization of the solution with sodium hydrogencarbonate, a crystalline product was separated out, yield 540 mg (70.0%). It was recrystallized from water, yield 535 mg (69.3%), mp 250 °C (dec), $[\alpha]_D^{29}$ +28.0° (*c* 1.0, 6 M HCl). Found: C, 32.82; H, 5.25; N, 32.22%. Calcd for $C_6H_{11}N_5O_4$: C, 33.18; H, 5.11; N, 32.25%.

Nps-Cpd(NO₂)-OH (6). To a solution of **5** (2.00 g, 9.21 mmol) in 1 M aqueous sodium hydroxide (10.1 ml) and dioxane (40 ml), Nps-Cl (1.92 g, 1.01 mmol) and 1 M aqueous sodium hydroxide (10.1 ml) were added over 15 min simultaneously. The solution was diluted with water, and acidified with citric acid. A yellow crystalline product separated out was filtered off. A small amount of the product was recovered from the filtrate by extraction with ethyl acetate. Both crops were combined and recrystallized from acetone–hexane, yield 2.55 g (74.7%), mp 180—181 °C (dec), $[\alpha]_D^{29}$ +31.3° (*c* 2.0, DMF). Found: C, 38.91; H, 3.94; N, 22.56; S, 8.56%. Calcd for $C_{12}H_{14}N_6O_6S$: C, 38.92; H, 3.81; N, 22.69; S, 8.66%.

Boc-A₂pr(Nps-Cpd(NO₂))-Ala-Ala-Dea-OEt (7a). To a solution of **4** (700 mg, 1.05 mmol) in DMF (10 ml), hydrogen was bubbled in the presence of palladium black. After completion of hydrogenolysis, the catalyst was filtered off. To the filtrate, **6** (383 mg, 1.05 mmol), HOBt (180 mg, 1.33 mmol) and then DCC (236 mg, 1.14 mmol) were added with stirring at 0 °C. The stirring was continued at 0 °C for 2 h and then at room temperature overnight. After addition of acetic acid (20 mg, 0.33 mmol), *N,N'*-dicyclohexylurea was filtered off. The filtrate was concentrated *in vacuo*, and a solution of the residue in ethyl acetate was washed with 10% aqueous citric acid, saturated aqueous sodium hydrogencarbonate and brine. The organic layer was dried over anhydrous sodium sulfate and concentrated *in vacuo*. The yellow solid obtained was reprecipitated from dioxane–ether, yield 760 mg (90.0%), mp 152—165 °C (dec), $[\alpha]_D^{27}$ +40.5° (*c* 2.2, DMF). Found: C, 47.80; H, 6.40; N, 16.80; S, 3.45%. Calcd for $C_{35}H_{55}N_{11}O_{14}S \cdot 1/2C_4H_8O_2$: C, 47.78; H, 6.39; N, 16.57; S, 3.45%.

Boc-A₂pr(Nps-Cpd(NO₂))-Ala-Ala-Dea-OH (8a). To a suspension of **7a** (1.73 g, 1.95 mmol) in ethanol (2 ml), 2 M aqueous sodium hydroxide (1.47 ml, 2.94 mmol) was added with stirring at room temperature and the stirring was continued for 1 h. After the solution was diluted with water (15 ml), it was washed with ethyl acetate, acidified with citric acid, and then extracted with ethyl acetate. The organic layer was washed with water, and dried over anhydrous sodium sulfate. The residue obtained after concentration *in vacuo* was reprecipitated with dioxane–ether, yield 1.46 g (87.0%), mp 154—166° (dec), $[\alpha]_D^{27}$ +39.4° (*c* 1.9, DMF). Found: C, 45.24; H, 5.86; N, 17.66; S, 3.88%. Calcd for $C_{33}H_{51}N_{11}O_{14}S \cdot H_2O$: C, 45.25; H, 6.10; N, 17.59; S, 3.66%.

Boc-A₂pr(Nps-Cpd(NO₂))-Ala-Ala-Dea-ONSu (9a). To a solution of **8a** (960 mg, 1.12 mmol) and HONSu (150 mg, 1.34 mmol) in dioxane (20 ml), DCC (280 mg, 1.34 mmol) was added with stirring at 0 °C. The mixture was stirred at 0 °C for 2 h and then at room temperature for 6 h. After addition of acetic acid (20 mg, 0.33 mmol), *N,N'*-dicyclohexylurea was filtered off. The filtrate was concentrated *in vacuo*, and the residue was reprecipitated from dioxane–ether, yield 920 mg (86.0%), mp 159—160 °C (dec), $[\alpha]_D^{27}$ +39.5° (*c* 2.0, DMF). Found: C, 45.63; H, 5.69; N, 17.39; S, 3.26%. Calcd for $C_{37}H_{54}N_{12}O_{16}S \cdot H_2O$: C, 45.67; H, 5.80; N, 17.27; S, 3.30%.

Cyclo[Boc-A₂pr-Ala-Ala-Dea-Cpd(NO₂)] (10a) via *Route A.* To a solution of **9a** (880 mg, 0.921 mmol) in THF (10 ml), 0.28 M hydrogen chloride in THF (9.86 ml, 2.76 mmol) was added dropwise over 15 min, and the stirring was continued for 30 min. Anhydrous ether was added to the mixture to obtain a precipitate of the free amino active ester, yield 730 mg (94.8%). It was immediately cyclized without purification. Thus, a solution of the product in DMF (100 ml) was added slowly into pyridine (800 ml) by use of high-dilution apparatus over 72 h at 55 °C with stirring. After stirring was continued for additional 24 h, the reaction mixture was concentrated *in vacuo*, and the residue was purified by silica gel chromatography. From the eluate with chloroform–methanol, a white solid was obtained [R_f 0.70 on TLC, ninhydrin negative], yield 212 mg (33.5%). For elemental analysis, the product thus obtained was reprecipitated from ethyl acetate, mp >250 °C, $[\alpha]_D^{19}$ −26.0° (*c* 0.94, DMF). Found: C, 45.81; H, 6.75; N, 19.52%, mol wt, 743. Calcd for $C_{27}H_{46}N_{10}O_{11} \cdot 3/2H_2O$: C, 45.43; H, 6.92; N, 19.63%, mol wt, 714.

Boc-A₂pr(Z)-OMe (11). To a solution of Boc-A₂pr-(Z)-OH, which was prepared from H-A₂pr(Z)-OH (13.77 g, 57.9 mmol) according to the method described for **3**, in ethyl acetate (100 ml), an ethereal solution of diazomethane was added, until yellow color remained. After excess diazomethane was decomposed with acetic acid, the mixture was concentrated *in vacuo*. The trituration of the oily residue with hexane in an ice–salt bath gave crystalline product, yield 18.47 g (90.5%). For elemental analysis, it was recrystallized from hexane. mp 50—52 °C $[\alpha]_D^{14}$ −8.8° (*c* 1.0, DMF). Found: C, 58.02; H, 6.92; N, 7.90%. Calcd for $C_{17}H_{24}N_2O_6$: C, 57.94; H, 6.87; N, 7.95%.

Boc-A₂pr(Nps-Cpd(NO₂))-OMe (12). Compound **11** (4.75 g, 13.5 mmol) was hydrogenolyzed over palladium black in DMF (30 ml). To the filtrate from the catalyst, **6** (5.00 g, 13.5 mmol), HOBt (2.03 g, 15.0 mmol), and then DCC (3.10 g, 15.0 mmol) were added with stirring at 0 °C. The stirring was continued at 0 °C for 2 h and then at room temperature overnight. The reaction mixture was concentrated *in vacuo*, and the residue was dissolved in ethyl acetate. Insoluble material was filtered off and the filtrate was washed with 10% aqueous citric acid, saturated aqueous sodium hydrogencarbonate and brine. The organic layer was dried over anhydrous sodium sulfate and concentrated *in vacuo*. The yellow solid was recrystallized from acetone–hexane, yield, 6.33 g (82.2%), mp 155—160 °C, $[\alpha]_D^{28}$ +89.8° (*c* 1.0, DMF). Found: C, 42.71; H, 5.37; N, 18.73; S, 5.47%. Calcd for $C_{21}H_{30}N_8O_9S \cdot H_2O$: C, 42.85; H, 5.48; N, 19.04; S, 5.45%.

Nps-Ala-Ala-Dea-OEt (13). As in the preparation of **2a**, **13** was synthesized from Z-Ala-Dea-OEt (1.00 g, 2.44 mmol) and Nps-Ala-ONSu (828 mg, 2.44 mmol). The yellow oily product was triturated with hexane to yield crystalline product (962 mg, 78.7%), which was recrystallized from ethyl acetate–hexane, yield 768 mg (62.7%). mp 128—131 °C, $[\alpha]_D^{29}$ −29.3° (*c* 1.0, DMF). Found: C, 50.33; H, 6.49; N, 11.08; S, 6.34%. Calcd for $C_{21}H_{32}N_4O_8S$: C, 50.39; H, 6.44; N, 11.19; S, 6.41%.

Nps-Ala-Ala-Dea-OH (14). To a suspension of **13** (750 mg, 1.50 mmol) in ethanol (5 ml), 1 M aqueous sodium hydroxide was added for saponification. The subsequent procedure was practically the same as that for **8a**. Trituration of the residual product with hexane gave a yellow solid, yield 699 mg, (98.7%). For elemental analysis, the solid was reprecipitated from ethyl acetate–hexane, mp 148—149 °C (dec), $[\alpha]_D^{28}$ −32.0° (*c* 1.0, DMF). Found: C, 47.93; H, 5.99; N, 11.51; S, 6.60%. Calcd for $C_{19}H_{28}N_4O_8S$: C, 48.29; H, 5.97; N, 11.86; S, 6.79%.

Boc-A₂pr(Nps-Ala-Ala-Dea-Cpd(NO₂))-OMe (15). To a suspension of **12** (500 mg, 0.876 mmol) in methanol (10

ml), 0.2 M hydrogen chloride in THF (4.5 ml, 0.90 mmol) was added with stirring at room temperature. After 45 min, additional 0.2 M hydrogen chloride in THF (1.0 ml, 0.20 mmol) was added, and the solution was stirred for additional 15 min. Addition of ether and hexane to the reaction mixture gave a white precipitate, yield 339 mg (85.3%). To a solution of this solid, **14** (353 mg, 0.747 mmol) and HOBt (111 mg, 0.822 mmol) in chloroform (25 ml), triethylamine (76 mg, 0.747 mmol) and DCC (170 mg, 0.822 mmol) were added with stirring at 0 °C. Afterwards, the reaction mixture was treated as in the preparation of **7a**. The solid obtained (565 mg, 74.0%) was reprecipitated from dioxane–ether, yield 382 mg (50.0%). mp 203—204 °C (dec), $[\alpha]_D^{28}$ −33.5° (*c* 1.0, DMF). Found: C, 47.02; H, 6.23; N, 16.77; S, 3.92%. Calcd for $C_{34}H_{53}N_{11}O_{14}S \cdot 1/2C_4H_8O_2$: C, 47.20; H, 6.27; N, 16.82; S, 3.50%.

*Boc–A_2pr(Nps–Ala–Ala–Dea–Cpd(NO_2))–OH (**16**).* The methyl ester **15** (900 mg, 1.03 mmol) was saponified with 1 M aqueous sodium hydroxide (1.13 ml, 1.13 mmol) in ethanol (9 ml) at room temperature for 2 h according to the usual procedure like in the preparation of **8a**. Yield 810 mg (93.9 %). For elemental analysis, it was recrystallized from dioxane–ether, mp 173—174 °C (dec), $[\alpha]_D^{28}$ −32.4° (*c* 1.0, DMF). Found: C, 46.37; H, 6.34; N, 16.72; S, 3.77%. Calcd for $C_{33}H_{51}N_{11}O_{14}S \cdot 1/2C_4H_8O_2$: C, 46.60; H, 6.15; N, 17.08; S, 3.56%.

*Boc–A_2pr(Nps–Ala–Ala–Dea–Cpd(NO_2))–ONSu (**17**).* The acid **16** (1.00 g, 1.17 mmol) was converted to **17** with HONSu (150 mg, 1.28 mmol) and DCC (260 mg, 1.28 mmol) in THF (50 ml) as in the synthesis of **9a**, A yellow solid was obtained, yield 960 mg (86.3%). For elemental analysis, this solid was reprecipitated from dioxane–hexane, mp 162—163 °C (dec), $[\alpha]_D^{23}$ −31.7° (*c* 1.0, DMF). Found: C, 46.90; H, 6.04; N, 16.81; S, 3.44%. Calcd for $C_{37}H_{54}N_{12}O_{16}S \cdot 1/2C_4H_8O_2$: C, 46.89; H, 5.85; N, 16.82; S, 3.21%.

*Cyclo[Boc–A_2pr–Ala–Ala–Dea–Cpd(NO_2)] (**10a**)* via *Route B.* To a solution of **17** (960 mg, 1.01 mmol) in THF (100 ml), 0.194 M hydrogen chloride in THF (11.4 ml, 2.21 mmol) was added with stirring at room temperature. After 1 h, the solution was concentrated *in vacuo* and trituration of the residue with anhydrous ether gave a solid, yield 810 mg (95.7%). The product thus obtained, was immediately cyclized without purification. The cyclization procedure was the same as that for **10a** *via* route A except for the use of the reaction conditions at 60 °C for 55 h. Purification by silica gel chromatography gave a white solid [R_f 0.70 on TLC ninhydrin negative], yield 251 mg (36.1%). For elemental analysis, the product thus obtained was reprecipitated from ethyl acetate, mp >250 °C, $[\alpha]_D^{29}$ −31.2° (*c* 0.94, DMF). Found: C, 45.49; H, 6.70; N, 19.67%. Calcd for $C_{27}H_{46}N_{10}O_{11} \cdot 3/2H_2O$: C, 45.43; H, 6.92; N, 19.63%.

*[Ala³, Ala⁴]-Tua N·2HCl (**18a**).* To a solution of **10a**, obtained either by route A or B (300 mg, 0.427 mmol) and acetic acid (0.2 ml) in a mixture of ethanol (50 ml) and water (15 ml), hydrogen was bubbled in the presence of palladium black for removal of the nitro group. The filtrate from catalyst was concentrated *in vacuo*, a solution of the residue in acetone–1 M hydrochloric acid (1: 1) (10 ml) was heated under reflux for 8 min. After cooling, the solution was allowed to stand with addition of urea (600 mg, 10.0 mmol) at room temperature overnight. The mixture was concentrated *in vacuo*, trituration of the residue with ethanol–ether gave a precipitate (207 mg, 81.3%). This precipitate was recrystallized from water–methanol, yield 126 mg (49.5%). mp >250 °C $[\alpha]_D^{28}$ −23.8° (*c* 1.0, H_2O). λ_{max}; 268 nm (H_2O, ε 25 700), 267 nm (0.1 M HCl, ε 25 400), 301 nm (1 M NaOH, ε 18 400). Found: C, 38.03; H, 5.97; N, 25.86; Cl, 11.68%. Calcd for $C_{19}H_{33}N_{11}O_6Cl_2 \cdot H_2O$: C, 38.00; H, 5.87; N, 25.66; Cl, 11.81%.

*[Ala³, Ala⁴]-Tum O·3HCl (**19a**).* To a suspension of **18a** (50 mg, 0.0858 mmol) in DMF (3 ml), Boc–β-Lys(Boc)–ONSu[8,15] (46 mg, 0.103 mmol) and triethylamine (10.4 mg, 0.103 mmol) were added with stirring at room temperature, and stirring was continued overnight. The solution was concentrated *in vacuo*. Trituration of the residue with THF gave a gelatinous solid, which was collected by centrifugation. The precipitate thus obtained was dissolved in water and washed with ethyl acetate. The aqueous layer was concentrated *in vacuo*. For deprotection, the residue was dissolved in 6 M hydrochloric acid (1 ml) and allowed to stand for 30 min. Addition of ethanol and ether to the mixture gave a white precipitate (58 mg, 91%), which was recrystallized from water–methanol, yield 40 mg (62.4%), mp 250 °C (dec), $[\alpha]_D^{22}$ −25.4° (*c* 0.52, H_2O), λ_{max}; 268 nm (H_2O, ε 23 400), 267 nm (0.1 M HCl, ε 22 500), 295 nm (1 M NaOH, ε 16 700). Found: C, 39.26; H, 6.29; N, 23.62; Cl, 13.72%. Calcd for $C_{25}H_{46}N_{13}O_7Cl_3 \cdot H_2O$: C, 39.24; H, 6.32; N, 23.80; Cl, 13.90%.

*Z–Ser(t-Bu)–Dea–OEt (**1b**).* Coupling of Z–Ser(*t*-Bu)–OH (13.2 g, 44.7 mmol) and H–Dea–OEt (9.17 g, 44.7 mmol) in a manner similar to that for **1a** gave an oily product **1b**, yield 20.8 g (96.5%).

For characterization a portion of **1b** was converted into the crystalline hydrazide as in the case of **1a**, mp 136—144 °C, $[\alpha]_D^{14}$ +10.3° (*c* 1.0, DMF).[12] Found: C, 56.31; H, 7.93; N, 12.00%. Calcd for $C_{22}H_{36}N_4O_7$: C, 56.39; H, 7.74; N, 11.96%.

*Z–Ala–Ser(t-Bu)–Dea–OEt (**2b**).* Hydrogenolysis of **1b** (10.0 g, 20.7 mmol) in DMF (40 ml), and coupling of its product with Z–Ala–OH (4.26 g, 20.7 mmol) by the succinimidyl ester method was performed in a similar manner to that for preparation of **2a**. Acetic acid (242 mg, 4.20 mmol) and *N*-(2-aminoethyl)-piperazine (1.00 g, 7.75 mmol) were used to destroy unreacted DCC and the succinimidyl ester respectively. Yield 8.90 g (77.4%). For elemental analysis, the product thus obtained was recrystallized from ethyl acetate–hexane, mp 104—109 °C, $[\alpha]_D^{19}$ +8.22° (*c* 2.13, DMF). Found: C, 58.16; H, 7.81; N, 7.55%. Calcd for $C_{27}H_{43}N_3O_9$: C, 58.57; H, 7.83; N, 7.59%.

*Z–Ser(t-Bu)–Ala–Dea–OEt (**2c**).* Z–Ser(*t*-Bu)–OH (10.0 g, 33.9 mmol) was coupled with $CH_3COOH \cdot$H–Ala–Dea–OEt prepared from **1c** (13.9 g, 33.9 mmol) by the succinimidyl ester method using *N*-methylmorpholine (6.85 g, 67.7 mmol). Yield 13.5 g (72.0%). For elemental analysis, the product thus obtained was recrystallized from ethyl acetate–hexane, mp 131—145 °C, $[\alpha]_D^{19}$ +5.55° (*c* 2.11, DMF). Found: C, 58.78; H, 7.95; N, 7.80%. Calcd for $C_{27}H_{43}N_3O_9$: C, 58.57; H, 7.83; N, 7.59%.

*Boc–A_2pr(Nps–Cpd(NO_2))–OH (**20**).* Saponification of **12** (3.00 g, 5.26 mmol) in a similar manner to that for **8a** gave a yellow solid, yield 2.49 g (85.0%). For elemental analysis, it was converted to a dicyclohexylammonium salt, and recrystallized from methanol–ether, mp 213—214 °C (dec), $[\alpha]_D^{23}$ +63.8° (*c* 1.0, DMF). Found: C, 51.57; H, 6.96; N, 16.79; S, 4.40%. Calcd for $C_{32}H_{51}N_9O_9S \cdot 1/2CH_3OH$: C, 51.77; H, 7.09; N, 16.72; S, 4.25%.

*Boc–A_2pr(Nps–Cpd(NO_2))–Ala–Ser(t-Bu)–Dea–OEt (**7b**).* Coupling of **20** (3.00 g, 5.39 mmol) and the debenzyloxycarbonylation product of **2b** (2.98 g, 5.39 mmol) in a similar manner as in the preparation of **7a** gave a yellow solid, yield 4.67 g (90.5%), mp 154—164°, $[\alpha]_D^{19}$ +48.6° (*c* 1.9, DMF). Found: C, 48.46; H, 6.58; N, 15.95; S, 3.28%. Calcd for $C_{39}H_{63}N_{11}O_{15}S$: C, 48.89; H, 6.63; N, 16.08; S, 3.35%.

*Boc–A_2pr(Nps–Cpd(NO_2))–Ser(t-Bu)–Ala–Dea–OEt (**7c**).*

Similarly, **20** (3.00 g, 5.39 mmol) was coupled with the deprotected product of **2c** (2.98 g, 5.39 mmol) to give a yellow solid, yield 4.63 g (89.7%), mp 143—153°, $[\alpha]_D^{19}$ +51.6° (*c* 1.9, DMF). Found: C, 48.14; H, 6.54; N, 15.81; S, 3.43%. Calcd for $C_{39}H_{63}N_{11}O_{15}S \cdot H_2O$: C, 47.99; H, 6.71; N, 15.79; S, 3.29%.

*Boc-A_2pr(Nps-Cpd(NO_2))-Ala-Ser(t-Bu)-Dea-OH (**8b**).* Saponification of **7b** (3.17 g, 3.31 mmol) gave a yellow solid in a similar manner as in the preparation of **8a**, yield 2.72 g (88.3%), mp 143 °C (dec), $[\alpha]_D^{19}$ +53.6° (*c* 1.6, DMF). Found: C, 46.74; H, 6.37; N, 16.17; S, 3.22%. Calcd for $C_{37}H_{59}N_{11}O_{15}S \cdot H_2O$: C, 46.88; H, 6.49; N, 16.25; S, 3.38%.

*Boc-A_2pr(Nps-Cpd(NO_2))-Ser(t-Bu)-Ala-Dea-OH (**8c**).* Similarly, saponification of **7c** (4.62 g, 4.82 mmol) gave a yellow solid, yield 3.98 g (88.8%), mp 140—141 °C (dec), $[\alpha]_D^{19}$ +49.2° (*c* 2.0, DMF). Found: C, 46.70; H, 6.40; N, 16.18; S, 3.33%. Calcd for $C_{37}H_{59}N_{11}O_{15}S \cdot H_2O$: C, 46.88; H, 6.49; N, 16.25; S, 3.38%.

*Boc-A_2pr-(Nps-Cpd(NO_2))-Ala-Ser(t-Bu)-Dea-ONSu (**9b**).* The free acid **8b** (2.98 g, 3.20 mmol) was converted to 1-succinimidyl ester as in the preparation of **9a**, yield 3.13 g (95.1%), mp 141—150 °C (dec), $[\alpha]_D^{19}$ +42.6° (*c* 1.1, DMF). Found: C, 46.84; H, 6.01; N, 15.90; S, 2.92%. Calcd for $C_{41}H_{62}N_{12}O_{17}S \cdot H_2O$: C, 47.12; H, 6.17; N, 16.08; S, 3.07%.

*Boc-A_2pr-(Nps-Cpd(NO_2))-Ser(t-Bu)-Ala-Dea-ONSu (**9c**).* Compound **8c** (4.30 g, 4.62 mmol) was changed to 1-succinimidyl ester as in the preparation of **9a**; yield 4.55 g (95.8 %), mp 145—155 °C (dec), $[\alpha]_D^{19}$ +49.5° (*c* 1.8, DMF). Found: C, 47.21; H, 6.10; N, 16.18; S, 3.02%. Calcd for $C_{41}H_{62}N_{12}O_{17}S \cdot H_2O$: C, 47.12; H, 6.17; N, 16.08; S, 3.07%.

*Cyclo[Boc-A_2pr-Ala-Ser(t-Bu)-Dea-Cpd(NO_2)] (**10b**).* Cleavage of the Nps group of **9b** (1.50 g, 1.46 mmol) and the subsequent cyclization were carried out like in the preparation of **10a**, yield 335 mg (30.2%), mp >250 °C, $[\alpha]_D^{17}$ −18.2° (*c* 1.2, DMF). Found: C, 48.21; H, 7.11; N, 18.01% mol wt, 844. Calcd for $C_{31}H_{54}N_{10}O_{12} \cdot H_2O$: C, 47.93; H, 7.27; N, 18.03%, mol wt, 777.

*Cyclo[Boc-A_2pr-Ser(t-Bu)-Ala-Dea-Cpd(NO_2)] (**10c**).* The cyclic peptide, **10c** was synthesized from **9c** (4.40 g, 4.28 mmol) as in the preparation of **10b**, yield 985 mg (30.3%), mp >250 °C, $[\alpha]_D^{17}$ −29.4° (*c* 1.1, DMF). Found: C, 48.13; H, 7.15; N, 18.17%, mol wt, 811. Calcd for $C_{31}H_{54}N_{10}O_{13} \cdot H_2O$: C, 47.93; H, 7.27; N, 18.03%, M. W., 777.

*[Ala³]—Tua N·2HCl (**18b**).* Deprotection of **10b** (370 mg, 0.488 mmol) and conversion of Dea to Uda residue were carried out as in the preparation of **18a**, yield 238 mg (81.5%), mp >250 °C, $[\alpha]_D^{14}$ −16.6° (*c* 0.56, H_2O). λ_{max}; 268 nm (H_2O, ε 20 600), 268 nm (0.1 M HCl, ε 22 100), 290 nm (1 M NaOH, ε 14 800). Found: C, 37.95; H, 5.64; N, 25.43; Cl, 11.62%. Calcd for $C_{19}H_{33}N_{11}O_7Cl_2 \cdot 1/2H_2O$: C, 37.57; H, 5.64; N, 25.37; Cl, 11.67%.

*[Ala⁴]—Tua N·2HCl (**18c**).* This crystalline compound was prepared from **10c** (300 mg, 0.395 mmol) was preapred in a manner similar to that for **18a**, yield 198 mg (83.5%), mp >250 °C, $[\alpha]_D^{14}$ +35.0° (*c* 0.59, H_2O). λ_{max}; 268 nm (H_2O, ε 23 300), 268 nm (0.1 M HCl, ε 24 700), 290 nm (1 M NaOH, ε 17 600). Found: C, 38.07; H, 5.62; N, 25.37; Cl, 11.78%. Calcd for $C_{19}H_{33}N_{11}O_7Cl_2$: C, 38.13; H, 5.56; N, 25.75; Cl, 11.85%.

*[Ala³]—Tum O·3HCl (**19b**).* Boc-β-Lys(Boc)-ONSu (267 mg, 0.602 mmol) was coupled with the free amino group of **18b** (240 mg, 0.401 mmol) followed by deprotection as in the preparation of **19a** to give colorless crystals, yield 250 mg, mp >250 °C, $[\alpha]_D^{14}$ −36.1° (*c* 0.52, H_2O). λ_{max}; 268 nm (H_2O, ε 23 800), 268 nm (0.1 M HCl, ε 24 100), 290 nm (1 M NaOH, ε 16 400). Found: C, 39.12; H, 6.36; N, 22.92; Cl, 13.47%. Calcd for $C_{25}H_{46}N_{13}O_8Cl_3 \cdot 1/2C_2H_5OH \cdot 1/2H_2O$: C, 39.27; H, 6.34; N, 22.90; Cl, 13.38%.

*[Ala⁴]—Tum O·3HCl (**19c**).* Similarly, coupling of Boc-β-Lys(Boc)-ONSu (130 mg, 0.293 mmol) with **18c** (117 mg, 0.196 mmol) and then deprotection gave colorless crystals, yield 124 mg (83.2%), mp 255 °C (dec), $[\alpha]_D^{14}$ −16.4° (*c* 0.53, H_2O). λ_{max}; 268 nm (H_2O, ε 20 300), 268 nm (0.1 M HCl, ε 21 600), 290 nm (1 M NaOH, ε 15 200). Found: C, 39.73; H, 6.39; N, 22.77; Cl, 13.31%. Calcd for $C_{25}H_{46}N_{13}O_8Cl_3 \cdot C_2H_5OH$: C, 40.08; H, 6.48; N, 22.50; Cl, 13.15%.

Authors are deeply indebted to the research laboratories, Toyo Jozo Co., Ltd. for supplying tuberactinomycins and measurements of antibacterial activities, and also to Dr. Masayasu Yamazaki, National Sanatorium, Toneyama Hospital for measurements of biological activities against human tubercule bacilli. We also wish to thank to Dr. Kenji Okawa and his coworkers to give a facility for the vapor pressure osmometer. This work was partially supported by a Grant-in-Aid for Scientific Research from Ministry of Education.

Backbone Rearrangement of 3β,4β-Epoxyfriedelane. A Formation of Germanicol and Solvent Effects[1]

Motoo Tori, Takahiko Tsuyuki, and Takeyoshi Takahashi

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received July 12, 1977)

In the reaction of 3β,4β-epoxyfriedelane with boron trifluoride etherate in benzene, a backbone rearragement proceeds up to D/E rings, giving germanicol as the main product, together with D:B-friedo-olean-5(10)-en-3β-ol, D:B-friedo-olean-5-en-3β-ol, and β-amyrin. The reaction product ratio of this reaction in various solvents was examined by HPLC.

It has been reported that a treatment of 3α,4α-epoxyfriedelane with tin(IV) chloride[2a] or with boron trifluoride etherate[2b] gives D: B-friedo-olean-5(10)-en-3α-ol,[2] olean-12-en-3α-ol,[2b] 18αH-olean-12-en-3α-ol,[2b] olean-13(18)-en-3α-ol,[2b] and 18αH-A-neo-oleana-3(5), 12-diene.[2b] In connection with the synthesis of dendropanoxide (**1**), we previously investigated the boron trifluoride etherate-catalyzed backbone rearrangement of 3β,4β-epoxyfriedelane (**2**) in ether, and reported the formation of dendropanoxide (**1**), 4α-fluorofriedelan-3β-ol (**3**), D: B-friedo-olean-5(10)-en-3β-ol (**4**), D: B-friedo-olean-5-en-3β-ol (**5**), and β-amyrin (**6**), together with an unidentified alcohol in a minute quantity.[3] It has been also reported that the rearrangement reaction of 3β,4β-epoxyshionane with boron trifluoride etherate remarkably depends on the nature of solvents used.[4] The present paper describes the isolation and characterization of germanicol (**7**) in the reaction of 3β,4β-epoxyfriedelane (**2**) with boron trifluoride etherate in benzene and reports solvent effects on the reaction.

Treatment of 3β,4β-epoxyfriedelane (**2**) in benzene with boron trifluoride etherate at room temperature for 10 min gave a mixture of products, which proved by high performance liquid chromatography (HPLC) to consist of the unidentified alcohol[3] (45%), besides the known rearranged products:[3] D: B-friedo-olean-5(10)-en-3β-ol (**4**; 15%), D: B-friedo-olean-5-en-3β-ol (**5**; 15 %), and β-amyrin (**6**; 25%). This mixture was subjected to separation by column chromatography on silica gel and then by preparative HPLC to give the alcohol as crude crystals, which was recrystallized from chloroform–methanol. The alcohol was inferred to be germanicol (**7**)[5] by the following evidence. The alcohol showed mp 177—178.5 °C[5] and a molecular ion peak at *m/e* 426 together with prominent peaks at *m/e* 204, 189, and 177 typical of Δ^{18}-oleanenes.[6] The IR and NMR spectra indicated the presence of a secondary hydroxyl group, a trisubstituted double bond, and of eight tertiary methyl groups (*cf.* Experimental). In the NMR spectrum, the signal due to the olefinic proton resonating at δ 4.85 is characteristic of germanicol and its derivatives [*dl*-germanicol[5b] (δ 4.85, s), the acetate[7] (δ 4.88, d, J=2 Hz), and the butyrate[8] (δ 4.88, s)] and is different from those of taraxerol[9] (**8**; 5.54, 1H, dd, J=8 and 4 Hz, $C_{(15)}$–H), β-amyrin[3] (**6**; δ 5.20, 1H, t, J=4 Hz, $C_{(12)}$–H), 18αH-β-amyrin[10] (**9**; δ 5.15, 1H, m, $C_{(12)}$–H), D: B-friedo-olean-5-en-3β-ol[3] (**5**; δ 5.63, 1H, dd, J=4 and 1.8 Hz, $C_{(6)}$–H), walsurenol[11] (**10**; δ 5.62, 1H, m, $C_{(11)}$–H), or multiflorenol (**11**) derivatives[12] (δ 5.24—5.55, m, $C_{(7)}$–H). The structure (**7**) of this alcohol was confirmed by the following conversion. The alcohol (**7**) in anhydrous benzene was treated with potassium and methyl iodide.[13] Recrystallization of the product from acetone–benzene gave miliacin (**12**), which was found to be identical with an authentic specimen isolated from *Panicum miliaceum* L.[14]

Solvent effects on the formation of products in the reaction were then investigated. The small scale reaction using 3β,4β-epoxyfriedelane (1—3 mg) and boron trifluoride etherate in various solvents was carried out, and the products were examined by HPLC. The results are summarized in Table 1.

The attack of boron trifluoride etherate to the oxygen atom of the epoxide (**2**) gives rise to a cationic center at C-4 (or its equivalent species). A sequence of 1,2-shifts of methyl group(s) and hydride(s) would then be followed to give cations in various rearrangement stages, which after deprotonation afford the rearranged alcohols (**4**, **5**, **6**, and **7**). When the reaction was carried out in a solvent (such as DME, THF, or ether) apt to coordinate with a cation, the reaction was interrupted in early stages to give D: B-friedo-oleanene derivatives[3] (**1**, **4**, and **5**) together with the fluorohydrin[3] (**3**) and friedelin[3] (**13**). The rearrangement in solvents with low nucleophilicity (such as toluene, benzene, and

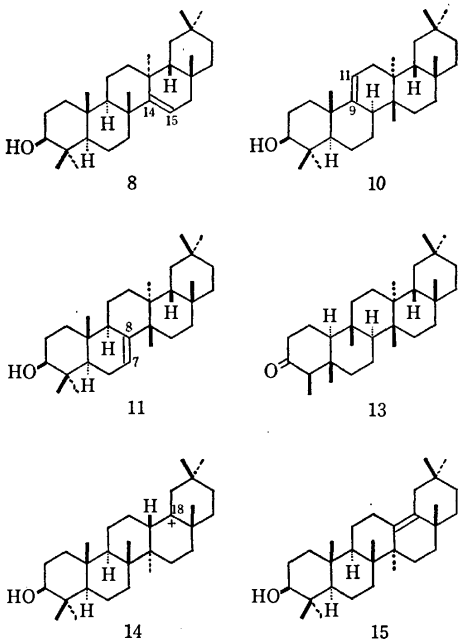
a) Relative yields were determined by HPLC. Measurements were carried out at room temperature using a Liquid Chromatograph Model ALC/GPC 202/401 (Waters Assoc.) with an RI detector; column: μ-PORASIL 1/8 (inch) × 1 (foot); solvent system: 10% ether–hexane; flow rate: 0.8 ml/min; pressure: *ca.* 450 psi. Even if HPLC analyses were carried out under these conditions, the retention times were variable. Mean values of their retention times were 5.1, 5.7, 6.9, 13.2, 14.5, 19.3, 21.2, and 21.8 min for **1**, **2**, **12**, **3**, **5**, **4**, **7**, and **6**, respectively. b) Errors are relatively large owing to the proximity of both retention times. c) Room temperature (r.t.) refers to a temperature range between 20 and 28 °C.



dichloromethane *etc.*) proceeded up to D/E rings to give germanicol (**7**; main product) and β-amyrin (**6**), besides **4** and **5**, as the cationic center survives longer in these solvents. Germanicol (**7**) could be derived from a cation (**14**; or its equivalent species);[15] olean-13(18)-en-3β-ol (**15**) which might be also derived from **14** was not detectable in the reaction mixture. These results (Table 1) shown above are parallel to those observed for the solvent effects on the reaction of 3β,4β-epoxyshionane.[4]

Driving force to provoke backbone rearrangement in the rigid polycyclic ring is considered to be a release[16] of intercyclic tension due to 1,3-diaxial interactions among the alkyl substituents (especially between the side chain and the 13α-methyl group in shionane series) and due to *cis*-fused D/E rings (in friedelane series). Thus, the acid-catalyzed backbone rearrangement of friedelane derivatives proceeds from ring A towards ring E, and constitutes a reversal of the biogenesis[17] of friedelin (**13**) from β-amyrin-type intermediate.[15] In the rearrangement of 3β,4β-epoxyshionane the formation of D: C-friedo-bacchar-7-en-3β-ol and D: C-friedo-bacchar-8-en-3β-ol was observed,[4] while the corresponding 7- and 8-enes were undetected in the product mixture from **2**. This is considered to be a structure difference between the two skeletons of friedelane and shionane. The acid-catalyzed backbone rearrangements hitherto reported for derivatives of friedelane,[2,3,18] alnusane (glutinane),[19] multiflorane,[20] and of taraxane[21] are limited to proceed up to C/D rings. Germanicol is the first example of product in which the backbone rearrangement of friedelane-oleanane-type effected up to E-ring.

Experimental

General procedures and preparation of 3β,4β-epoxyfriedelane (**2**) were the same as described in a previous paper.[3]

Isolation and Characterization of Germanicol (7). A solution of 3β,4β-epoxyfriedelane[3] (**2**; 175 mg) in anhydrous benzene (150 ml) was treated with boron trifluoride etherate (1 ml) at room temperature for 10 min and usual work-up gave a residue (*ca.* 170 mg). The residue was shown by HPLC examination to consist of germanicol[5] (**7**; 45%), D: B-friedo-

olean-5(10)-en-3β-ol[3,19] (**4**; 15%), D: B-friedo-olean-5-en-3β-ol[3,19] (**5**; 15%), and β-amyrin[3] (**6**; 25%). This residue was dissolved in benzene, passed through a column of silica gel (30 g), and eluted with the same solvent (each fraction 50 ml). Fractions 6—14, containing β-amyrin (**6**) and germanicol (**7**), were combined (*ca.* 133 mg) and subjected to preparative HPLC separation to afford about 30 mg of germanicol (**7**). The isolation yield of germanicol (**7**) was very poor, because the separation of **6** and **7** by HPLC was carried out with much difficulity owing to the proximity of their retention times (21.2 and 21.8 min for **7** and **6**, respectively). Recrystallization from chloroform–methanol gave pure germanicol (**7**; 10 mg), mp 177—178.5 °C, (lit, 176—177 °C,[5a] 173—175 °C,[5b] 179 °C,[5c] 176.5—177 °C,[5d] 180 °C,[5e] and synthetic *dl*-germanicol, 220—223 °C,[5f]); IR (KBr) 3450, 1630, and 840 cm^{-1}; NMR ($CDCl_3$) δ 0.74, 0.78, 0.89, 0.98, 1.02, 1.09 (each 3H, s, *t*-Me), 0.94 (6H, s, 2×*t*-Me), 3.20 (1H, dd, $J_{2\beta,3\alpha}=10$ and $J_{2\alpha,3\alpha}=5$ Hz, $C_{(3\alpha)}$–H), and 4.85 (1H, d, $J=1.5$ Hz, $C_{(19)}$–H); MS *m/e* (%) 426 (M^+; 50), 411 (31), 204 (100), 189 (83), and 177 (83).

Methylation of Germanicol (7). Potassium (100 mg) was added to a solution of germanicol (**7**; 5.7 mg) in anhydeous benzene (10 ml) and the mixture was refluxed for 2 h under a nitrogen atmosphere. A solution of methyl iodide (2 ml) in benzene (10 ml) was added and heating was continued for 4 h under reflux. After addition of methanol (2 ml) and benzene (10 ml), the organic solution was washed with water, 2M hydrochloric acid, and then with brine, dried over magnesium sulfate, and evaporated to afford a residue (7 mg). The residue was crystallized from acetone–benzene to give miliacin (**8**; 2.7 mg), mp 280—281.5 °C, (lit, 283 °C[14]); IR (KBr) 1635, 1180, 1110, 860, and 850 cm^{-1}; NMR ($CDCl_3$) δ 0.76 (6H, s, 2×*t*-Me), 0.89, 1.02, 1.08 (each 3H, s, *t*-Me), 0.95 (9H, s, 3×*t*-Me), 3.35 (3H, s, -OMe), and 4.85 (1H, d, $J=1.5$ Hz, $C_{(19)}$–H); MS *m/e* (%) 440 (M^+; 44), 425 (23), 393 (5), 204 (100), 189 (75), and 177 (63). Identification of this compound with an authentic sample (mp 282.5—283 °C) of miliacin[14] was effected on mixed mp (280—283 °C), TLC, IR, NMR, and on mass spectra.

Reaction of 3β,4β-Epoxyfriedelane (2) with Boron Trifluoride Etherate in Various Solvents. Examination of the Products by HPLC. 3β,4β-Epoxyfriedelane (**2**; 1—3 mg) dissolved in a solvent (2—10 ml) was treated with boron trifluoride etherate (2 drops) at −5 °C or at room temperature. After usual treatment, the reaction mixture was extracted with ether to give a residue on evaporation of the solvent. The residue was subjected to examination by HPLC. The results are listed in Table 1. Authentic samples (**1**, **3**—**6**, and **12**) used for an identification of the products are the compounds obtained in the previous work.[3]

Silyl Radicals. XV. Stereochemical Course of Chlorine Abstraction by 1-Methyl-4-*t*-butyl-1-silacyclohexyl Radicals from Polychloroalkane*

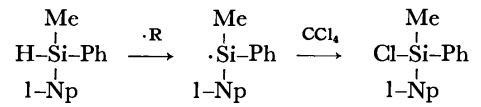
Hideki SAKURAI and Masashi MURAKAMI

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

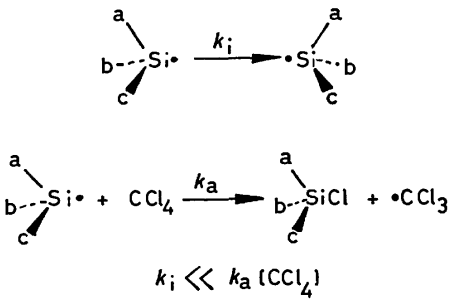
(Received July 11, 1977)

The isomerically pure *cis* and *trans* 1-methyl-4-*t*-butyl-1-silacyclohexane were subjected to the free radical chlorination with carbon tetrachloride in the presence of a catalytic amount of benzoyl peroxide under UV irradiation at 0 °C, affording the corresponding chlorosilanes with retention of configuration. With less reactive polyhalocarbons, however, less stereospecific products were obtained. A mechanism that inversion of silyl radicals competes with chlorine abstraction is proposed. Relative rates of each reaction were analyzed with a steady-state assumption.

During the course of the study on the Group IVB free radicals,[2] we have found that the silyl radical produced from an optically active hydrosilane undergoes chlorine-abstraction reaction mostly with retention of configuration.[3] The chiral silyl radical exists in a pyramidal form with considerable configurational stability, and retains the asymmetry prior to the abstraction of chloride from carbon tetrachloride.



This observation has been amply supported by both other chemical[4-6] and ESR studies.[7-12] The inversion process must be slow, relative to the abstraction process, for retention of configuration to be observed.



The reactivity of each enantiomeric radical generated from optically active compounds is energetically identical, because both steric and electronic environments around the radical center are equal in each enantiomeric radical. On the contrary, when a cyclic radical such as a silacyclohexyl radical is produced, it should exist as an equilibrium mixture of conformers and then reacts through energetically different pathways. Introduction of a *t*-butyl group on the ring prevents the ring inversion, then two steric courses of the reaction, *i.e.* axial and equatorial approaches to the radical become distinguishable if inversion around the radical center on silicon is slow enough for product-forming chlorine abstraction.

In this paper stereochemical course of the chlorine abstraction from polychloroalkanes by silyl radicals, which were generated from conformationally stable hydrosilanes, is discussed.

Results and Discussion

The reaction of *cis*- or *trans*-4-*t*-butyl-1-methyl-1-silacyclohexane** (Ia, Ib)[13,14] with carbon tetrachloride in the presence of dibenzoyl peroxide under UV irradiation at 0 °C proceeded stoichiometrically to give the corresponding chlorosilanes. Interestingly as observed in the chlorination of the optically active hydrosilane, the configuration of the hydrosilanes was retained in resulting 4-*t*-butyl-1-methyl-1-chloro-1-silacyclohexane

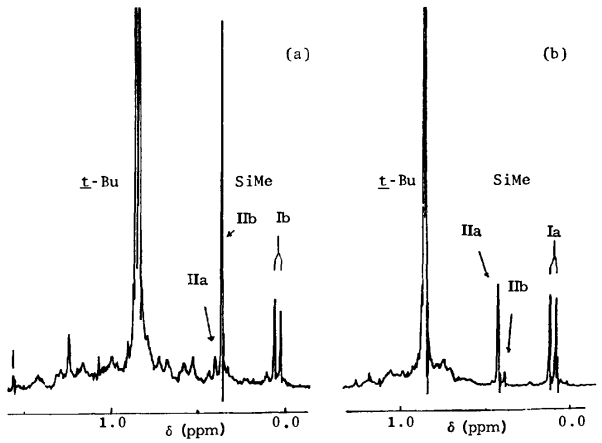


Fig. 1. NMR spectra of the reaction mixture of (a) the chlorination of (Ib) with CCl_4 and (b) the chlorination of (Ia) with CCl_4.

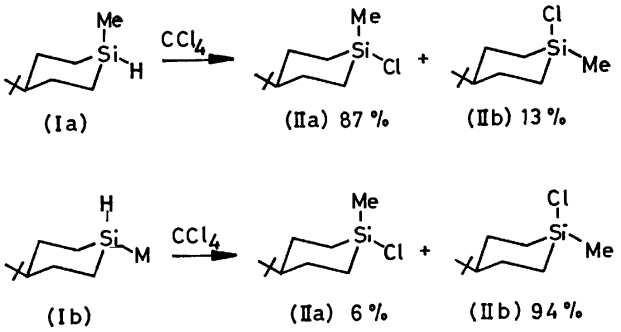
(II) as evidenced by NMR spectra. Figure 1 (a) shows the NMR spectra of the reaction mixture derived from the *trans*-hydrosilane (Ib). Thus, two methyl signals corresponding to *trans*- and *cis*-chlorosilane (IIb and IIa) appeared at δ 0.38 (singlet) and 0.42 (singlet), respectively, in a ratio of 94/6 in addition to the methyl signal of the unreacted *trans*-hydrosilane (Ib) at δ 0.07 (doublet). This means that the reaction proceeds with 94% retention of configuration. The *cis*-hydrosilane (Ia) gave a similar result but slightly less stereospecifically

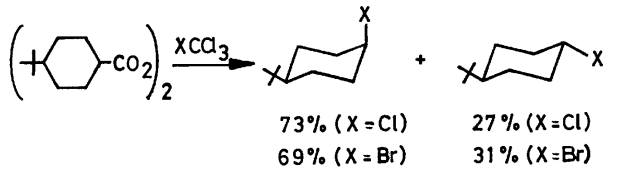
* For part XIV, see Ref. 1.

** Throughout the paper, *cis* and *trans* are defined with respect to 4-*t*-butyl and 1-methyl groups. Suffix a is added to the *cis* compounds and b to the *trans*.

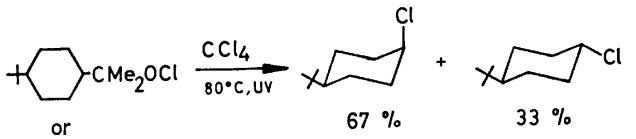
(87%), as seen in Fig. 1(b). Namely, the silyl radical obtained from (Ia) or (Ib) exists in pyramidal form and retains mostly its configuration prior to the abstraction of chlorine from carbon tetrachloride as in the case of the chiral silyl radical obtained from optically active hydrosilane[3,6] and acylsilane.[4]



These results are in striking contrast to those observed for cyclohexyl radical.[15] Thus, *cis*- and *trans*-4-*t*-butylcyclohexane carbonyl peroxides, decomposed in carbon tetrachloride or bromotrichloromethane at 30 °C, give rise to the same products irrespective of the configuration of the starting materials.[16]



Similar results were reported in the decomposition of 1-(*cis* or *trans*-4-*t*-butylcyclohexyl)-1-methylethyl hypochlorite.[17]



These facts requires the formation of a common intermediate from both starting substances. This is likely to be the 4-*t*-butylcyclohexyl radical which evidently reacts with a halogen donor from the two sides. The reason why the intermediate 4-*t*-butylcyclohexyl radical gives rise to the thermodynamically less favored product is ascribable either to a twist-boat conformation in the transition state[17] or, more likely, to a torsional effect at the product-forming process.[18] In any event, the intermediate cyclohexyl radicals are in a planar form or in a rapidly-equilibrated state.

Similar reactions of (I) were carried out with pentachloroethane ($CHCl_2$–CCl_3), 1,1,1,2-tetrachloroethane (CH_2Cl–CCl_3) and chloroform ($HCCl_3$). The resulting chlorosilane (II) systematically lost its configurational purity in the following order of solvent (reactants), $CCl_4 < CHCl_2CCl_3 < CH_2ClCCl_3 < HCCl_3$. In the case

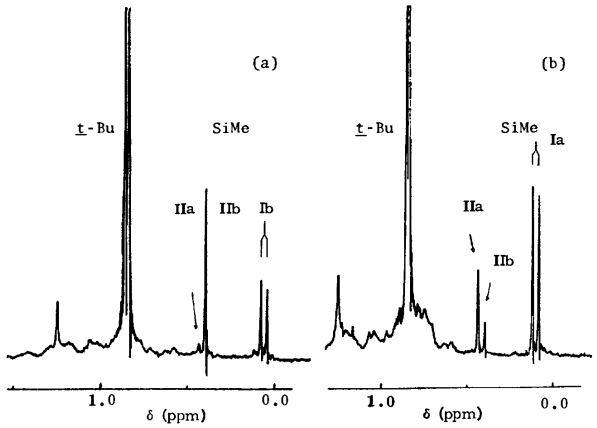


Fig. 2. NMR spectra of the reaction mixture of (a) the chlorination of (Ib) with $CHCl_2CCl_3$ and (b) the chlorination of (Ia) with $CHCl_2CCl_3$.

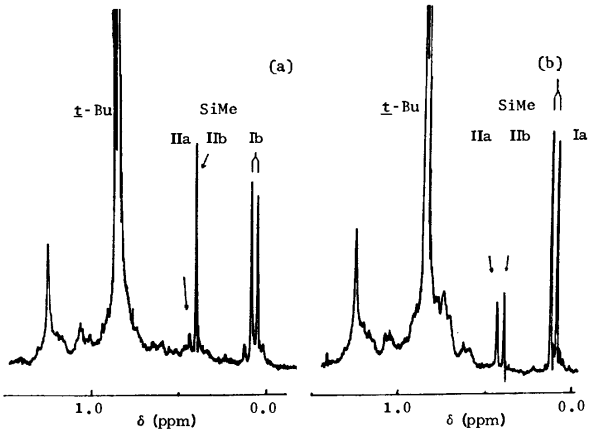

Fig. 3. NMR spectra of the reaction mixture of (a) the chlorination of (Ib) with CH_2ClCCl_3 and (b) chlorination of (Ia) with CH_2ClCCl_3.

Table 1. Reaction of (I) with polyhaloalkanes in the presence of benzoyl peroxide at 0°C

Starting material	Reactant	Reaction time (h)	Conversion (%)	Product(II) *cis*(IIa) : *trans*(IIb)
 (Ia)	Cl–CCl_3	3	41	87 : 13
	$CHCl_2$–CCl_3	4	45	75 : 25
	CH_2Cl–CCl_3	4	23	57 : 43
	H–CCl_3	4.5	28	39 : 61
 (Ib)	Cl–CCl_3	3	55	6 : 94
	$CHCl_2$–CCl_3	4	55	12 : 88
	CH_2Cl–CCl_3	6	24	18 : 82
	H–CCl_3	4	54	25 : 75

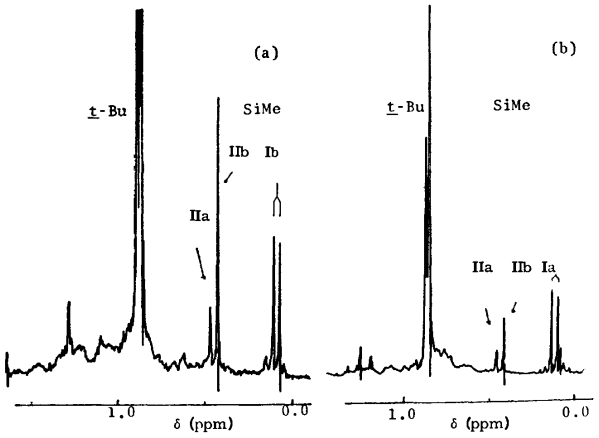

Fig. 4. NMR spectra of the reaction mixture of (a) the chlorination of (Ib) with $ZCHCl_3$ and (b) the chlorination of (Ia) with $CHCl_3$.

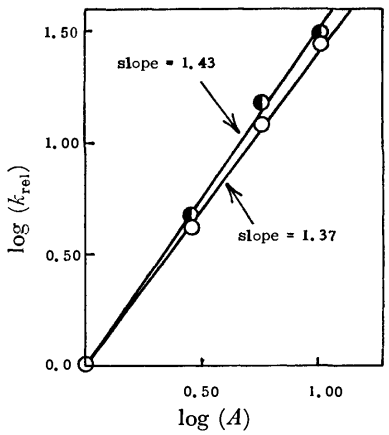

Fig. 5. Correlation between the logarithum of the relative reactivities of both *cis*- (◐) and *trans*- (○) silacyclohexyl radicals (vertical), and logarithum of the relative reactivities of triethylsiyl radicals (horizontal) in chlorine abstraction.

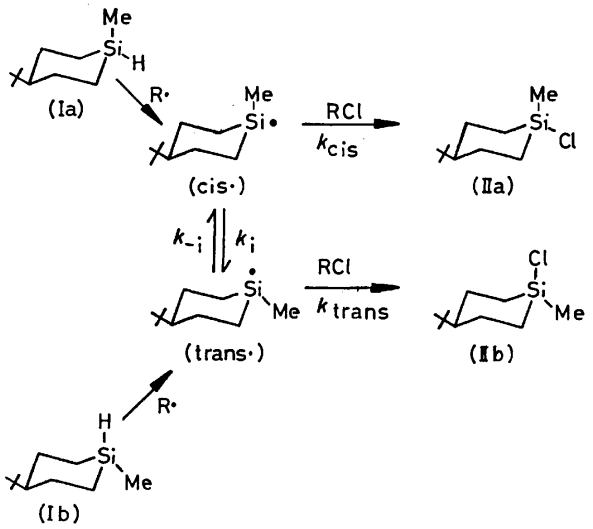
starting from the *cis*-hydrosilane (Ia), intensities of the methyl signal of the *cis*-chlorosilane (IIa) decrease gradually from in carbon tetrachloride to in chloroform. A similar trend can be seen for the case of *trans*-hydrosilane (Ib). These trends can be seen well qualitatively in Figs. 2—5. Quantitative determination of ratios of two isomeric chlorosilanes was performed by integrating the expanded NMR spectra. Generally, it is not easy to get precise integration for two near-by peaks on NMR, although fairly good reproducibility was observed in this particular case (Table 1). Therefore, care must be taken for detailed discussion, but the present data are still pertinent to an approximate kinetic analysis as shown in the next section.

The rate of abstraction of a chlorine atom from carbon tetrachloride is fast compared to the rate of inversion of silyl radicals.[6] On the contrary, the rate of abstraction of a chlorine atom from chloroform may be comparative to the rate of inversion of the same silyl radicals. There fore, net stereochemistry depends on both relative rates of chlorine abstraction and conformational stabilities of silacyclohexyl radicals as shown in the following scheme.



From this scheme using the relevant rate constants shown above, the *cis*/*trans* product ratio (*c*/*t*) can be expressed by the formula

$$(c/t) = (k_{cis}/k_{trans})([cis\cdot]/[trans\cdot]), \quad (1)$$

where [*cis*·] and [*trans*·] are the concentrations of *cis* and *trans* radicals, respectively. The *cis*/*trans* product ratio from *cis* hydrosilane (Ia), $(c/t)_{cis}$, can be derived as follows by assuming the steady-state concentration of the *trans* radical.

$$d[trans\cdot]/dt = k_i[cis\cdot] - k_{-i}[trans\cdot] - k_{trans}[trans\cdot][RCl] = 0, \quad (2)$$

$$[cis\cdot]/[trans\cdot] = (k_{-i}/k_i) + (k_{trans}/k_i)[RCl],$$

$$(c/t)_{cis} = (k_{cis}/k_{trans})(k_{-i}/k_i) + (k_{cis}/k_i)[RCl]. \quad (3)$$

Similarly one can obtain the *trans*/*cis* product ratio from *trans* hydrosilane (Ib), $(t/c)_{trans}$, by assuming the steady-state of the *cis* radical derived from *trans*-hydrosilane (Ib).

$$(t/c)_{trans} = (k_{trans}/k_{cis})(k_i/k_{-i}) + (k_{trans}/k_{-i})[RCl]. \quad (4)$$

Combination of Eqs. 3 and 4 yields

Table 2. Relative rate constants[a]

Reactant	concn (mol/l)	K	k_{trans}/k_{-i}	k_{cis}/k_i	A[b]
$Cl\text{-}CCl_3$	10.6	2.2	1.3(27)	0.59(33)	11.4
$CHCl_2\text{-}CCl_3$	8.31	2.1	0.63(13)	0.30(17)	6.18
$CH_2Cl\text{-}CCl_3$	9.45	2.4	0.23(4.8)	0.096(5.3)	3.07
$H\text{-}CCl_3$	12.4	2.4	0.048(1.0)	0.018(1.0)	1.00
			$\rho^*=0.46$[c]		$\rho^*=0.29$[c]

a) For definition of the symbols, see text. b) Relative reactivities of polyhaloalkanes in the chlorine abstraction by the triethylsilyl radical, see text. c) Reaction constants in the Taft equation.

$$K = (k_{trans}/k_{cis})(k_i/k_{-i}) = \frac{1+(t/c)_{trans}}{1+(c/t)_{cis}}.$$

Then values of $K=(k_{trans}/k_{cis})(k_i/k_{-i})$, (k_{trans}/k_{-i}) and (k_{cis}/k_i) can be calculated from the respective product ratios. These are listed in Table 2. Since it is reasonable to assume that the rate constants of inversion process are invariant regardless of the nature of the solvents used in this study, (k_{trans}/k_{-i}) and (k_{cis}/k_i) indicate the relative reactivities of both *trans* and *cis* radicals toward polyhalomethanes, respectively. These relative reactivities are also listed in parenthases in Table 2. Values of *cis* radicals agree with those of *trans* radicals within a possible experimental error.

Nagai and co-workers[19] reported that the reaction of the triethylsilyl radical with polychloroalkanes, X–CCl_3, where X stands CH_3, H, CH_2Cl, $CHCl_2$, CCl_3, and Cl, proceeded stoichiometrically to give X–CCl_2H, and that the relative reactivities increase in this order. For particular polyhaloalkanes such as $HCCl_3$, CH_2ClCCl_3, $CHCl_2CCl_3$, and CCl_4, they reported values of relative reactivity (k_{X-CCl_3}/k_{HCCl_3}) of chlorine abstraction toward the triethylsilyl radical at 80 °C to be 1.00, 3.07, 6.18 and 11.4, respectively. These relative reactivities derived from competitive experiments were treated by the Taft equation[20] with ρ^* values ranged from 0.26 to 0.29.[19]

The logarithms of relative reactivities toward silacyclohexyl radicals obtained in this study can be correlated strikingly well (correlation coefficient=0.999) with those toward triethylsilyl radicals as shown in Fig. 5. Higher selectivities of silacyclohexyl radicals than triethylsilyl radicals can be attributed to the temperature difference in the extent of 80 °C between two experiments which is reflected in a larger ρ^* value of the Taft equation of 0.46 in the present study.

The K $[K=(k_{trans}/k_{cis})(k_i/k_{-i})]$ values are almost constant irrespective of the solvents, as can be seen in Table 2. Since k_i and k_{-i} are unimolecular rate constants and must be invariant in a series of similar solvents, k_i/k_{-i} should be constant in the present case. Nagai *et al.* have also demonstrated that the reactivity of silyl radicals toward chlorine abstraction is rather insensitive to the structure of the radicals at the fixed condition.[19] Therefore, it seems to be reasonable to get constant K values.

As a conclusion, the remarkable configurational stability of silyl radicals is again demonstrated not only qualitatively but also semi-quantitatively.

Experimental

Materials. The required samples of *cis* and *trans*-4-*t*-butyl-1-methyl-1-silacyclohexane (Ia and Ib), and *cis*- and *trans*-4-*t*-butyl-1-methyl-1-chloro-1-silacyclohexane (IIa and IIb) were prepared as described in the previous paper.[13,14] Pentachloroethane ($CHCl_2$–CCl_3), 1,1,1,2-tetrachloroethane (CH_2Cl–CCl_3) and dibenzoyl peroxide were commercially available materials of the reagent grade.

Reaction of cis- *or* trans-*4-t-Butyl-1-methyl-1-silacyclohexane (Ia or Ib) with Polyhaloalkanes in the Presence of Dibenzoyl Peroxide (BPO).* Appropriate solutions (*ca.* 5%) of (Ia) or (Ib) in polyhaloalkanes (CCl_4, $CHCl_2CCl_3$, CH_2ClCCl_3, and $CHCl_3$) were prepared in NMR tubes. These were bubbled and filled with dry nitrogen and sealed with stoppers. These tubes were irradiated with a high-pressure mercury arc lamp (450 W, with a Pyrex filter) in an ice bath.

The color of the reaction mixtures changed to pale yellow. From the NMR spectra and GLC, the reaction mixture contained only 4-*t*-butyl-1-methyl-1-chloro-1-silacyclohexane (II) as a single product and the unchanged (I) as silicon-containing materials. The product and unchanged silane were identified by the way of NMR spectra and retention times of GLC by comparing with those of authentic samples.

The ratio of (II) and unchanged (I), and the conformational isomer ratio of each material were determined by means of NMR integration of Si–Me signals.

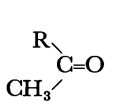
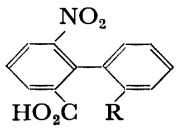
Dioxodioxa[*n*]paracyclophanes which carry two methoxyl, ethoxyl, or propoxyl groups at the aromatic rings were prepared by condensation of α,ω-diols with corresponding 2,5-dialkoxy-1,4-phenylenediacetyl dichlorides under high dilution conditions. Dynamic ^{1}H NMR spectra of these compounds show that barriers to internal rotation of the dialkoxybenzene rings are affected by the chain-length of the alkoxyl groups; the longer the chain length, the higher the barrier.

It has been well documented that the steric hindrance of the alkyl group toward reactivities of organic compounds increases as the chain-length of the alkyl group increases. A typical example is the reactivity of carbonyl groups in alkyl methyl ketones (**1**) toward sodium hydrogen sulfite:[2] the reactivity decreases as the chain-length increases. Likewise, the chain-length of alkyl groups is known to play some role in the internal rotation of molecules. The rates of racemization of 2′-alkoxy-6-nitrobiphenyl-2-carboxylic acids (**2**) are affected by the chain-length of the alkyl group and the half-lives of **2** are 1 : 5 : 9 at *ca.* 18 °C for methyl, ethyl, and propyl compounds, respectively.[3] An apparently reverse



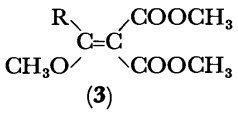
(**1**)

R = CH_3, CH_3CH_2, or $CH_3CH_2CH_2$



(**2**)

R = CH_3, CH_2CH_2, or $CH_3CH_2CH_2$



(**3**)

R = CH_3 or CH_3CH_2

phenomenon is observed in the internal rotation about the C_{sp^2}–R bond of dimethyl 1-methoxyalkylidenemalonates (**3**): the barrier lowers when R changes from methyl to ethyl.[4] This anomaly is, however, attributed to the steric effect which stabilizes the ground state to a greater extent than the transition state for rotation.

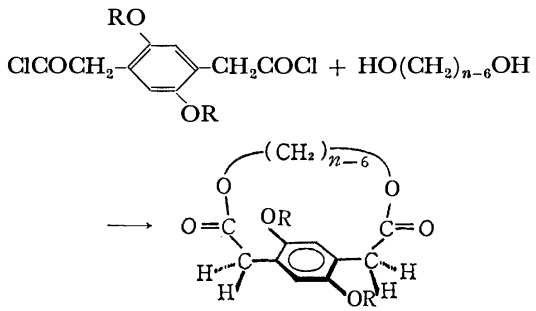
In any event, the change in barriers for internal rotation discussed above is 1 kcal/mol at the most. This small increase may be interpreted as such that the alkyl group takes a conformation, in which the steric effect is given by a first atom or group of the chain and the rest is located far from the site of direct interaction. Evidence for this consideration is found in ultraviolet spectral data which show that 2-alkylbiphenyls, where the alkyl is a straight chain, give absorption at almost the same wavelength.[5] This restriction of conformation, of course, causes the decrease in entropy in the transition state. Indeed, Hall and Harris found that the difference in the free energies of activation for rotation of compounds **2** is attributable to the difference in entropies of activation.[6]

We have briefly reported in a recent paper[7] that the barrier to internal rotation of cyclophanes is greatly influenced by the chain length of the alkoxyl groups which are attached to the benzene ring. The phenomenon was attributed to the fact that the steric hindrance is given not only by an atom or a group which is directly attached to the benzene ring in question but by the group as a whole. The group itself must pass a space provided by the ansa chain and the benzene ring for racemization of the compounds. Then a large difference in barriers is expected on elongating the chain length in contrast to the cases cited above. Our data presented before[7] give only the smallest limit (>1.0 kcal/mol) of difference and more work is needed to find the change in energies by lengthening the alkoxyl chain.

In this paper, we wish to describe the syntheses of dialkoxydioxodioxa[*n*]paracyclophanes, of which the alkoxyl groups are either methoxyl, ethoxyl, or propoxyl, and finding a large change in barriers due to the change in the alkoxyl group, as obtained by the ^{1}H DNMR method.

Experimental

The syntheses of dialkoxydioxodioxa[*n*]paracyclophanes (**4**$_n$, **5**$_n$, and **6**$_n$) were accomplished by condensation of α,ω-diols with 2,5-dialkoxy-1,4-phenylenediacetyl dichlorides under high dilution conditions as reported previously.[8]



4: R = CH_3
5: R = CH_2CH_3
6: R = $CH_2CH_2CH_3$

The diols were of commercial origin except for 1,11-undecanediol which was prepared by lengthening the chain of 1,9-nonanediol. 1,9-Nonanediol was treated with hydrogen bromide followed by sodium cyanide in dimethyl sulfoxide to give undecanedinitrile which was hydrolyzed and esterified to

give the corresponding diester. Lithium aluminium hydride reduction of the ester gave 1,11-undecanediol, mp 57—60 °C (lit,[9] mp 62.0—62.5 °C). IR (KBr) 3300 cm^{-1} (ν_{OH}). Overall yield was *ca.* 50%.

2,5-Dialkoxy-1,4-phenylenediacetyl dichlorides were known compounds[7] except for the 2,5-dipropoxy compound of which synthesis is described below.

1,4-Dipropoxybenzene. To a solution of hydroquinone (11 g, 0.1 mol) and sodium hydroxide (8.8 g, 0.22 mol) in 200 ml of water was added 43 g of propyl tosylate, which was prepared from 1-propanol and *p*-toluenesulfonyl chloride,[10] in small portions. The mixture was heated under reflux for 20 h with stirring. The reaction mixture was extracted with ether and the extract was washed with 6 M hydrochloric acid and then with cold water. After drying over magnesium sulfate, the extract was evaporated to give a pale yellow residue. Recrystallization from CH_2Cl_2–CCl_4 gave 7.0 g (36%) of the desired material, mp 48.0—49.5 °C. IR (KBr) ν_{C-O} 1220, 1025 cm^{-1}. NMR ($CDCl_3$) δ=6.82 (s, 4H), 3.85 (t, J=6.5 Hz, 4H), 1.75 (sestet, J=*ca.* 6.5 Hz, 4H), 1.02 (t, J=*ca.* 6.5 Hz, 6H).

α^1,α^4-Dichloro-2,5-dipropoxy-1,4-xylene. A mixture of 1,4-dipropoxybenzene (7.0 g, 0.035 mol), 37% formalin (6.6 g), concentrated hydrochloric acid (40 ml), and glacial acetic acid (35 ml) was warmed at 50—60 °C for 1.5 h with stirring and introducing dry hydrogen chloride. The resulting solid was collected by filtration and was washed with water. Recrystallization from CH_2Cl_2–CCl_4 gave 8.0 g (78%) of the pure material, mp 79.5—81.0 °C. IR (KBr) ν_{C-O} 1230, 1030 or 1050 cm^{-1}. NMR ($CDCl_3$) δ=6.92 (s, 2H), 4.63 (s, 4H), 3.96 (t, J=6.5 Hz, 4H), 1.84 (sestet, J=*ca.* 6.5 Hz, 4H), 1.08 (t, J=*ca.* 6.5 Hz, 6H).

α^1,α^4-Dicyano-2,5-dipropoxy-1,4-xylene, mp 107.0—108.0 °C (recrystallized from ether–hexane), was prepared from the above dichloride by treatment with sodium cyanide[7] in *ca.* 90% yield. IR (KBr) $\nu_{C\equiv N}$ 2250, ν_{C-O} 1240 and 1030 cm^{-1}. NMR ($CDCl_3$) δ=6.92 (s, 2H), 3.95 (t, J=6.5 Hz, 4H), 3.70 (s, 4H), 1.84 (sestet, J=*ca.* 6.5 Hz, 4H), 1.06 (t, J=*ca.* 6.5 Hz, 6H). Found: C, 70.76; H, 7.52; N, 10.45%. Calcd for $C_{16}H_{20}N_2O_2$: C, 70.56; H, 7.40; N, 10.29%.

2,5-Dipropoxy-1,4-phenylenediacetic Acid. A mixture of the dicyanide (6.5 g, 0.24 mol), ethylene glycol monomethyl ether (50 ml), and sodium hydroxide (5.0 g) in 20 ml of water was refluxed until a homogeneous solution resulted. The reaction mixture was then diluted with 50 ml of cold water, cooled, and poured with stirring into 50 ml of concentrated hydrochloric acid to yield 5.0 g (67%) of a crude product. After purification, the product melted at 200.0—203.0 °C with decomposition. IR (KBr) $\nu_{C=O}$ 1710, ν_{C-O} 1240 and 1030 cm^{-1}.

2,5-Dipropoxy-1,4-phenylenediacetyl dichloride was obtained by a reaction of thionyl chloride with the diacid in dry ether. The yield was 70%. Mp 106.0—107.0 °C (recrystallized from ether). IR (KBr) $\nu_{C=O}$ 1810, ν_{C-O} 1230 and 1000 cm^{-1}. NMR ($CDCl_3$) δ=6.72 (s, 2H), 4.10 (s, 4H), 3.89 (t, J=6.5 Hz, 4H), 1.79 (sestet, J=*ca.* 6.5 Hz, 4H), 1.13 (t, J=*ca.* 6.5 Hz, 6H).

Syntheses of Dialkoxydioxodioxa[n]*paracyclophanes* (**4**$_n$, **5**$_n$, *and* **6**$_n$). The method of syntheses of the paracyclophanes was essentially the same as reported previously.[8] The products were purified by column chromatography on silica gel. Either hexane–benzene or hexane–ether was used for both chromatography and recrystallization. Melting points, analytical data, and solvents of recrystallyzation are summarized in Table 1.

Measurement of Spectra. The infrared spectra were recorded on a Hitachi EPI-G2 spectrometer as KBr discs or neat liquid. The ^1H NMR spectra were measured on a Hitachi R-20B spectrometer with a variable temperature accessory, operating at 60 MHz. The chemical shifts at lower temperatures than 34 °C were recorded with the use of TMS as an internal standard, whereas those at higher temperatures were recorded relative to internal $Cl_2CHCHCl_2$ and converted to the usual δ scale. The temperature reading was calibrated by measuring the chemical shift difference between methyl and hydroxyl protons of methanol at the lower temperatures, whereas the chemical shift difference between methylene and hydroxyl protons of ethylene glycol was used for the higher temperatures. The mass spectra were observed on a Hitachi RMU-6L spectrometer.

Results and Discussion

For the convenience of discussion, compounds are denoted by bold face numbers with suffixes. The suffix corresponds to the length of the ansa chain.

Due to wide variety of coalescence temperatures and solubility, it was not possible to obtain spectra at appropriate temperatures with the use of a single solvent. Although this could cause, in principle, change in barriers, the barrier to rotation is known to be affected by solvent to a small extent expect special cases such as hydrogen bond formation.[11] Thus we discuss the barrier neglecting the solvent effect. Large differences shown below will allow such an approximation.

Heavy overlap of the signals handicapped the total line shape analysis and data so obtained are not expected to be highly reliable. Therefore we limited the investigation to obtaining the free energies. The discussion given below does have drawbacks due to comparison of free energies at different temperatures, yet it is valid because the difference in free energies are large enough to make the contribution of the entropy factor minor.

DNMR Spectra and Rotational Barriers. ^{1}H NMR spectral data of dialkoxydioxodioxa[*n*]paracyclophanes (**4**$_n$, **5**$_n$, and **6**$_n$) at 34 °C are summarized in Table 2. Geminal benzylic protons of **4**$_{15}$, **4**$_{16}$, **5**$_{16}$, **5**$_{17}$, **6**$_{17}$, and **6**$_{18}$ give AB type signals which suggest that the internal rotation of the dialkoxybenzene ring is slow on the NMR time scale. In contrast, those which carry longer ansa chains in the series of **4** and **5** give singlets for benzylic protons to indicate that the internal rotation in these compounds is fast. Thus the temperatures of measurement were varied to see possible coalescence phenomena. By observing coalescence temperature (T_c), difference ($\Delta\delta_{AB}$) in chemical shifts of the AB protons, and the coupling constant (J_{AB}), the barrier to rotation should be obtained by applying the following equation.[12]

$$\Delta G_c^{\neq} = 4.57T_c\{9.97+\log_{10}(T_c/\sqrt{\Delta\delta_{AB}^2+6J_{AB}^2})\}.$$

The line shape of the AB quartets due to benzylic protons of **4**$_{15}$, **5**$_{16}$, and **6**$_{17}$ does not show any essential change on raising the temperature up to 190 °C. The barriers to rotation in these compounds are estimated to be over 23 kcal/mol. In contrast, the AB quartets due to benzylic protons of **4**$_{16}$, **5**$_{17}$, and **6**$_{18}$ coalesce on raising the temperature, as is illustrated in Fig. 1. taking **5**$_{17}$ as an example.

The sharp singlet due to benzylic protons of **4**$_{17}$ broadened considerably on lowering the temperature and finally split into an AB quartet, although the downfield part of the quartet was masked by the signals due to CH_2's alpha to ether oxygens and by that of methoxyl groups. The coalescence temperature of the benzylic methylene signals of **4**$_{17}$ in CS_2–$CDCl_3$ (v/v 3:1) was −52 °C. Likewise the coalescence temperature of signals due to benzylic protons in **5**$_{18}$ was found to be −69 °C.

The AB signals due to benzylic protons of **4**$_{17}$ and **5**$_{18}$ were still dull at the lowest temperature attainable with the instrument. Thus exact values of $\Delta\delta_{AB}$ for both com-

pounds and that of J_{AB} for $\mathbf{5}_{18}$ could not be obtained. Then $\Delta\delta_{AB}$ and J_{AB} of $\mathbf{6}_{17}$ in CS_2 at 34 °C must be diverted to $\mathbf{4}_{17}$ and $\mathbf{5}_{18}$: this operation should not cause serious errors in barriers since the structures of these compounds are alike. The results are summarized in Tables 3 and 4. Data[7] of dialkoxydioxodiaza[*n*]-paracyclophanes (**7** and **8**) and dimethyldioxodioxa[*n*]-paracyclophanes (**9**) are also included for comparison.

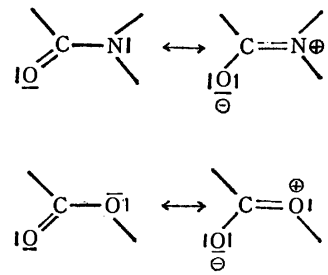
Effect of Rigidity of the Ansa Chain on the Rotational Barriers. It is well known that formal single bonds (C–N and C–O) of amides and ester groups often have considerable double bond character due to delocalization of the lone pair electrons as is visualized by the canonical forms:



Contribution of these canonical forms with a double bond between C and N or between C and O raises the barrier to rotation about the bond in question by lowering the ground state and/or raising the transition state for rotation. Since contribution of the dipolar structure of amides is larger than that of esters, the barriers to internal rotation of amides[13] are usually higher than those of esters.[14] In other words, a chain containing amide groups is considered to be more rigid than that containing ester groups. The cyclophanes dealt with here and elsewhere[7] consitute a series to be compared from the stand point of the rigidity of the chain.

Inspection of Table 4 reveals that an amide with two ethoxyl groups ($\mathbf{8}_{18}$) has a higher barrier to rotation of the diethoxybenzene ring than an ester having the same groups ($\mathbf{5}_{18}$) by 2.1 kcal/mol. Since the coalescence temperature of $\mathbf{8}_{18}$ is higher than that of $\mathbf{5}_{18}$, the difference in enthalpies of activation may be still larger. Similar comparison is made between $\mathbf{7}_{16}$ and $\mathbf{4}_{16}$ to show that the amide gives a higher barrier by at least 0.5 kcal/mol. Thus if we compare the barriers to rotation of the dialkoxybenzene ring in diamides with that in

diesters with the same ansa-chain length, the barriers are always higher in amides. This must be a reflection of the fact that the higher mobility makes it easier for the ansa chain to take a suitable conformation to rotation of the substituted benzene ring.

Effect of the Chain Lengths of Alkoxyl Groups on Rotational Barriers. A recent report from this laboratory has revealed that $\mathbf{4}_{16}$ with two methoxyl groups at the aromatic ring possesses a higher barrier to rotation of the aromatic ring than $\mathbf{9}_{16}$ with two methyl groups by 10.7 kcal/mol.[15] This result was attributed to the steric hindrance of the methoxyl group, given not only by the oxygen atom but by the group as a whole: the methoxyl group must be bulkier than the methyl if the whole group is considered. The phenomenon makes a sharp contrast to the fact that the methoxyl group is generally considered to be of less effective bulkiness than the methyl as is shown by a typical example of barriers to rotation of 2'-substituted 5'-methyl-6-nitrobiphenyl-2-carboxylic acids.[16]

By finding an example of a methoxyl group giving its steric hindrance as a whole, comparison of the steric effect given by a series of straight chain alkyl groups becomes of interest. This is a reason why various dialkoxydioxodioxa[*n*]paracyclophanes were prepared to examine the barriers. Comparison of the data in Table 4 indicates that changing the alkoxyl group from methoxyl to ethoxyl causes the increase in the barrier to rotation by 8.2 kcal/mol in the series of 17-membered ansa chain. Similarly the barrier increases by at least 4.2 kcal/mol on going from ethoxyl to propoxyl in the same series. The same change in the series of 18-membered ansa chain causes the increase of 8.7 kcal/mol. The dramatic change in rotational barriers reflects a fact that the whole substituent must pass through a space, probably as a folded form, provided by the ansa-chain and the benzene ring. In sharp contrast to the fact that the chain-lengthening of the alkyl group usually affects the barriers to rotation to a small extent (1 kcal/mol or less), the steric effect presented here increases by 8—9 kcal/mol by lengthening the chain by but one carbon. This finding is a support for an assumption that the steric effect is often given by the first atom or group in the chain and gives a measure for the bulkiness of the alkoxyl group as a whole.

Effect of the Ansa-Chain Length on the Rotational Barriers. The difference ($\Delta\Delta G^{*}$) in free energies of activation for rotation of the aromatic rings in $\mathbf{9}_{15}$ and $\mathbf{9}_{16}$ with two methyl groups has been reported to be 12.3 kcal/mol.[8] $\Delta\Delta G^{*}$ between $\mathbf{4}_{16}$ and $\mathbf{4}_{17}$ of the dimethoxy series and that between $\mathbf{5}_{17}$ and $\mathbf{5}_{18}$ of the diethoxy series are 10.0 and 9.1 kcal/mol, respectively.

Although it is not possible to compare the whole series to investigate the effect of lengthening the ansa-chain on barriers to rotation, the effect of lengthening the ansa-chain by one on the barriers should become small, in principle, if the ansa-chain length is long enough. The present series represents a part of such tendency. Namely $\Delta\Delta G^{*}$ decreases as follows: $\Delta\Delta G^{*}$ ($\mathbf{9}_{15}$ and $\mathbf{9}_{16}$)$>\Delta\Delta G^{*}$ ($\mathbf{6}_{16}$ and $\mathbf{6}_{17}$)$>\Delta\Delta G^{*}$ ($\mathbf{7}_{17}$ and $\mathbf{7}_{18}$). Extending the chain of the alkoxyl group should provide a method of study on the effect of the ansa-chain length on the rotational barriers.

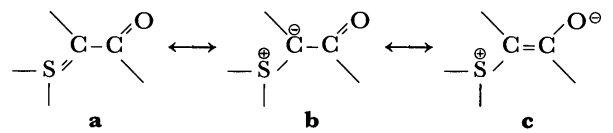
(Received July 23, 1977)

^{13}C chemical shifts and ^{13}C–H spin coupling constants (179.7 Hz) of the ylide carbons of two dialkylsulfonium phenacylides show that the ylide carbons are basically sp^2. Large upfield shifts (−9.5——11.8 ppm) of carbonyl carbon signals (δ_C 181.7 and 179.2) of the ylides from those of the corresponding salts (δ_C 191.2 and 191.0) suggest significant contribution of a betaine structure. The ^{13}C-NMR spectrum of methylisopropylsulfonium phenacylide showed two non-equivalent methyl signals (δ_C 17.9 and 18.4) for the isopropyl group. Steric γ-effects on ylide carbon chemical shifts were observed with several alkylsulfonium bis(methoxycarbonyl)methylides and trialkylsulfonium salts.

The sulfonium ylides containing such electron-withdrawing substituents as carbonyl groups on their negatively charged carbon atoms are described by the canonical structure **a**—**c**.[3] The carbonyl stretching



band of dimethylsulfonium phenacylide (**1a**) is observed at 1520 cm^{-1}, and this suggests that the contribution of **c** is important. In structure **c**, lone-pair electrons on the ylide carbon are considerably delocalized.[4] In fact, **1a** reacted as a zwitter ion and gave *O*-alkylation products.[5]

Recently, we studied the reactions of stable sulfonium ylides containing electron-withdrawing substituents on their ylide carbon atoms (COPh, COMe, COOMe, CN, *etc.*), and large differences were observed in the nucleophilic reactivity of ylide carbanions containing different electron-withdrawing substituents.

Carbon-13 chemical shifts provide some information on the electronic state of carbon atoms in molecules.[6] Some ^{13}C-NMR studies of phosphorus ylides have been reported,[7] but few ^{13}C-NMR studies have been reported on sulfonium ylides.

We measured the ^{13}C-NMR spectra of a series of sulfonium ylides containing electron-withdrawing substituents. The results are described in this paper and the nucleophilicity of these ylides is discussed.

Results and Discussion

sp^2-Carbanion and Betaine Structure. As is shown

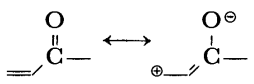
Table 1. Carbon-13 NMR chemical shifts of dimethylsulfonium phenacylide (**1a**) and related compounds[a]

	Compound	$\overset{\ominus}{C}H$ or CH_2	C=O	CH_3–$S^{\oplus}$	1	2 and 3	4	5	6, 7, and 8	Solvent
1a	$(CH_3)_2\overset{\oplus}{S}$–$\overset{\ominus}{C}H$–CO–	53.2 [J_{CH} 179.7]	182.3	28.7 [J_{CH} 142.6]	140.9	126.2; 127.8	129.3			$CDCl_3$
		56.6	180.1	28.4	140.9	125.8; 127.4	128.7			CD_3CN
		60.6	181.7	31.8	143.8	129.0; 130.5	131.8			DMSO-d_6
1b	$(\overset{6}{C}H_3)_2\overset{5}{C}H$, CH_3, $\overset{\oplus}{S}$–$\overset{\ominus}{C}H$–CO–	51.8 [J_{CH} 179.7]	182.3	24.2 [J_{CH} 142.6]	140.9	126.4; 127.8	129.2	46.1 [J_{CH} 144.5]	17.9; 18.4 [J_{CH} 128.9]	$CDCl_3$
		53.4 [J_{CH} 175.8]	179.2	23.9 [J_{CH} 140.7]	141.2	126.0; 127.4 [J_{CH} 160.2]	128.7	46.6	16.5; 17.7	DMSO-d_6
1c	$(CH_3)_2\overset{\oplus}{S}$–$\overset{\ominus}{C}$, CO–, S–	65.1	189.5	27.4	142.2	127.4; 127.7	128.8	140.5	124.2; 125.1	$CDCl_3$
1d	$(CH_3)_2\overset{\oplus}{S}$–$\overset{\ominus}{C}$(CO–)$_2$	88.2	190.9	26.9	141.9	127.4; 128.6	129.7			$CDCl_3$
1a′	$(CH_3)_2\overset{\oplus}{S}$–$CH_2$–CO– $Br^{\ominus}$	52.6 [J_{CH} 146.5]	191.2	24.4 [J_{CH} 146.5]	134.8	128.4; 128.8 [J_{CH} 158.2]	133.8			DMSO-d_6
1b′	$(\overset{6}{C}H_3)_2\overset{5}{C}H$, CH_3, $\overset{\oplus}{S}$–CH_2–CO–, $Br^{\ominus}$	48.8 [J_{CH} 144.5]	191.0	19.7 [J_{CH} 146.5]	134.7	128.8 [J_{CH} 162.1]	133.9	45.2	17.1; 17.5 [J_{CH} 125]	DMSO-d_6
		b)	191.9	19.7 [J_{CH} 146.5]	135.8	129.0; 129.3 [J_{CH} 164.1]	133.5	46.2 [J_{CH} 146.5]	16.8; 17.5 [J_{CH} 123.1]	D_2O

a) δ_C, ppm from TMS(accurate to ±0.13 ppm); J_{CH}, Hz. b) Signal is not observable because of rapid H-D exchange in D_2O.

in Table 1, the ^{13}C–H coupling constant of the ylide carbon atom of dimethylsulfonium phenacylide (**1a**) as 179.7 Hz, and this shows that this carbon uses an sp^2 orbital in bonding with the hydrogen.[8] The coupling constant observed in **1a'** (146.5 Hz) is that expected for sp^3-hybridized carbon bound to a sulfonium sulfur atom.[9] X-Ray studies of various ylides have shown that ylide carbons are basically trigonal planar and therefore sp^2 hybridized.[10]

Large upfield shifts (−9.5—−11.8 ppm) were observed when the carbonyl carbon signals (δ_C 181.7 and 179.2 in DMSO-d_6) of the ylides were compared with those of the corresponding salts (δ_C 191.2 and 191.0 in DMSO-d_6). This suggests an important contribution of betaine structure **c**, since similar upfield shifts were observed when ketones were compared with α,β-unsaturated ketones.[11]



The chemical shifts of the ylide carbon of phenacylide (**1a**), which contains only one electron-withdrawing substituent, is dependent on kinds of solvent (δ_C 53.2 in $CDCl_3$ and 60.6 in DMSO-d_6). This suggests that the electrons are localized on its ylide carbon atom and that large nucleophilicity is expected.[12] The chemical shifts of ylides **1c** and **1d** containing two electron-withdrawing substituents (PhS and COPh) are found at fields lower than those of ylides **1a** and **1b**. Smaller nucleophilicity is expected for **1c** and **1d**.

Nucleophilicity of Disubstituted Sulfonium Ylides.

Nucleophilicity of these disubstituted sulfonium ylides was compared by determining the rates of transylidation[1b,1d] and olefin formation[1c] in the presence of dimethoxy disulfide. The results are shown in Table 2. Clearly, the presence of acetyl groups decreases the reactivity toward both transylidation and olefin formation.

Carbon-13 chemical shifts of acetyl and methoxycarbonyl ylides are listed in Table 3. These chemical shifts are not solvent dependent. When Tables 2 and 3 are compared, it is clear that these order of reactivity of sulfonium ylides are parallel with the order of the chemical shifts of ylide carbon atoms.

Asymmetric Environment about Sulfur of Ylides. The tetrahedral nature of sulfur in disubstituted sulfonium ylides has been shown on the basis of ^1H-NMR spectra.[13] The appearance of the methylene group of the benzyl and ethyl substituents, respectively, as AB patterns in their ^1H-NMR spectra requires an asymmetric environment about sulfur.

TABLE 2. TRANSYLIDATION[1b,1d] AND OLEFIN FORMATION[1c] OF SULFONIUM YLIDES IN THE PRESENCE OF DIMETHOXY DISULFIDE IN $CDCl_3$ AT 35 °C

	Ylide X	Ylide Y	Transylidation[a] half life, $\tau_{1/2}$ (min)	Olefin formation[b] First-order rate constant calculated from $-d[Ylide]/dt = k[Ylide]$ $10^5 \times k$ (s^{-1})
2f	COOMe	COOMe	7	0.8
3b	COMe	COOMe	400	no reaction
4b	COMe	COMe	700[c]	no reaction

a) Mixture consists of ylide (0.5 mmol), Me_2S (0.6—0.8 mmol), and $(MeOS)_2$ (0.2—0.3 mmol), except in the case of **4b**. b) Mixture consists of ylide (0.85 mol/l) and $(MeOS)_2$ (1.36 mol/l). c) Mixture consists of ylide **4b** (0.5 mmol), Me_2S (6.5 mmol), and $(MeOS)_2$ (0.3 mmol).

We examined the ^1H-NMR spectrum of methylisopropylsulfonium penacylide (**1b**), since asymmetric environment of isopropylsulfonium ylides has not been reported in the literature. Two methyl signals were observed at δ_H 1.32 (d, J=6.6 Hz) and 1.36 (d, J=6.6 Hz). The ^{13}C-NMR spectrum of **1b** also showed two methyl signals at δ_C 17.9 and 18.4, and that of **2d** showed two methyl signals at δ_C 18.4 and 18.8 for the isopropyl group.

γ-Effect Observed in Sulfonium Compounds. In the system of sulfonium bis(methoxycarbonyl)methylides (**2a**—**2h**), effects of a bulky substituent on ^{13}C chemical shifts were investigated. The results are listed in Table 4. Clearly, the presence of a bulky substituent on the sulfur atom causes an upfield shift of the ylide carbon signal. This shift is not due to a simple inductive effect but due to steric compression through space (γ-effect).[14] It can be assumed that the inductive effect of the diethyl group of diethyl sulfonium ylide **2g** is similar to that of the pentamethylene group of pentamethylenesulfonium ylide **2h**. However, the chemical shift of the ylide carbon of **2g** was smaller than that of **2h** by −7.0

In the system of sulfonium phenacylides, **1a** and **1b**, a similar γ-effect was observed, which was shown in Table 1.

Table 5 shows the upfield shifts observed for some simple sulfonium salts possessing bulky substituents such as isopropyl and *t*-butyl groups. Such upfield shifts are found even in the sulfonium salts containing the electron-withdrawing phenacyl group (**1a′** and **1b′**), CH_2COPh.

As shown in Tables 4 and 5, large upfield shifts were observed for the ylide and methyl carbon signals when an isopropyl group was the substituent (**2d**, **5b**, **1b′**, and **5e**).

Experimental

Materials. The dimethylsulfonium ylides (**1a**,[4] **1d**,[15] **3a**,[16] and **4a**[16]) were prepared by the methods described in the literature. The phenylmethylsulfonium ylides (**2f**, **3b**, and **4b**) were synthesized by copper-catalyzed decomposition of diazo compounds in large excess sulfides.[17] **1c** was obtained by reaction between **1a** and methyl benzenesulfenate in chloroform at room temperature (75% yield, mp 136—137 °C (lit,[18] 136 °C)).[19] Sulfonium bis(methoxycarbonyl)methylides (**2a**—**c**, **2g**, and **2h**) were prepared by catalytic decomposition of methyl diazomalonate in excess sulfide in the presence of dialkoxy disulfide at room temperature.[1a] **2d** and **2e** were obtained by transylidation between **2f** and methyl isopropyl sulfide (or methyl benzyl sulfide) in chloroform in the presence of dimethoxy dusilfide at room temperature.[1b] **2d**: mp 76—77 °C; IR (KBr), 1640 and 1700 cm^{-1} (ν_{CO}); ^1H-NMR ($CDCl_3$), δ=1.33 (d, J=7.2 Hz), 1.45 (d, J=7.2 Hz) (6H, $(CH_3)_2C$), 2.86 (3H, s, $CH_3-\overset{\oplus}{S}$), 3.78 (6H, s, $COOCH_3$) and 3.90—4.35 (1H, m, CH). Found: C, 49.43; H, 7.34%. Calcd for $C_9H_{16}O_4S$: C, 49.08; H, 7.32%. Methylisopropylsulfonium phenacylide (**1b**) was prepared by deprotonation of salt (**1b′**) with 10% aqueous sodium hydroxide. **1b**: mp 108—109 °C; IR (KBr), 1520 cm^{-1} (ν_{CO}); ^1H-NMR ($CDCl_3$), δ=1.32 (d, J=6.6 Hz), 1.36 (d, J=6.6 Hz) (6H, $(CH_3)_2C$), 2.85 (3H, s, $CH_3-\overset{\oplus}{S}$), 3.8—4.3 (2H, m, CH and $\overset{\ominus}{C}H$) and 7.25—7.86 (5H, m, C_6H_5); ^1H-NMR (DMSO-d_6, δ=1.25 (d, J=6.6 Hz), 1.30 (d, J=6.6 Hz) (6H, $(CH_3)_2C$), 2.71 (3H, s, $CH_3-\overset{\oplus}{S}$), 3.20—3.60 (1H, m, CH), 4.30 (1H, s, $\overset{\ominus}{C}H$) and 7.25—7.80 (5H, m, C_6H_5). Found: C, 68.90; H, 7.77%. Calcd for $C_{12}H_{16}OS$: C, 69.21; H, 7.74%. The sulfonium

a) δ_C, ppm from TMS as external standard in D_2O (accurate to ±0.08 ppm). b) ($\delta_C^{R^1,R^2} - \delta_C^{(CH_3)_2}$).

salts (**1a'** and **1b'**) were prepared by reaction between sulfides and phenacyl bromide in benzene at room temperature. **1b'**: mp 110—111 °C; IR (KBr), 1670 cm^{-1} (ν_{CO}); ^{1}H-NMR (DMSO-d_6), δ=1.55 (6H, d, J=6.6 Hz, $(CH_3)_2C$), 2.99 (3H, s, $CH_3-\overset{\oplus}{S}$), 4.09 (2H, s, CH_2) and 7.50—8.20 (5H, m, C_6H_5). The dialkylmethylsulfonium salts (**5a—e**) were obtained by direct reaction of the alkyl sulfides and methyl iodide. **5e**; ^{1}H-NMR (D_2O), δ=1.57 (d, J=6.6 Hz), 1.61 (d, J=6.6 Hz) (12H, $(CH_3)_2C$), 2.82 (3H, s, $CH_3-\overset{\oplus}{S}$) and 3.90 (2H, m, CH). **5f** was prepared by ethylation of methyl *t*-butyl sulfide with $(C_2H_5)_3O^{\oplus}\,BF_4^{\ominus}$).

Measurement. The ylides were dissolved in $CDCl_3$, CD_3CN and DMSO-d_6 (usually 100—150 mg/cm^3) containing 1—5% tetramethylsilane as reference. The sulfonium salts also were dissolved in D_2O (usually 100—150 mg/cm^3). Solutions were examined in 10-mm tubes using JEOL-FX-60 NMR spectrometer in the Fourier transform mode. Several hundred to several thousand transients were accumulated typically with acquisition times of 1.0 to 5 s, with 3.0 s being normal for coupling constant measurements. Line positions were determined automatically by computer software. The results are listed in Tables 1, 3, 4, and 5.

Transylidation and Olefin Formation. Transylidation and olefin formation of sulfonium ylides (**2f**, **3b**, and **4b**) in the presence of dimethoxy disulfide in $CDCl_3$ at 35 °C are described in the literature.[1b,c] The results are listed in Table 2.

Photo-induced Electricity Generated by Thin-layer Photogalvanic Cells Containing Thionine and Iron(II) Salt

Kiyotaka SHIGEHARA, Masatoshi NISHIMURA, and Eishun TSUCHIDA
Department of Polymer Chemistry, Waseda University, Nishiohkubo, Tokyo 160
(Received March 1, 1977)

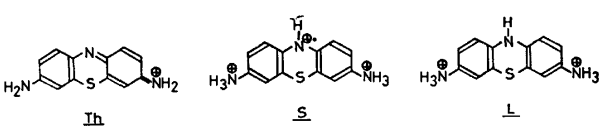
The photogalvanic effects of thionine and Fe(II) salt systems were studied by use of thin-layer photocells. Three systems of the cell components, *i.e.*, SnO_2/thionine–Fe(II) aq/Pt, SnO_2/thionine–Fe(II)-gelatinized reagent/Pt, and SnO_2/polymeric thionine membrane–Fe(II)/Pt, were compared. The photopotential ΔE and the photocurrent I were the largest in the third system. It was concluded that the excellent ability of the polymeric thionine system to generate the photo-induced electricity is due to the strong electrostatic repulsion between Fe^{3+} and the semi-species bound to the cationic polymers, since the repulsion diminished the short-circuit in a solution or the bulk-backward reaction with Fe^{3+}. The electron-recycling in a solution took place not only through the transportation of Fe^{3+} to the cathode, but also through the electron-exchange reaction between Fe^{2+} and Fe^{3+} *via* hydrogen bonds.

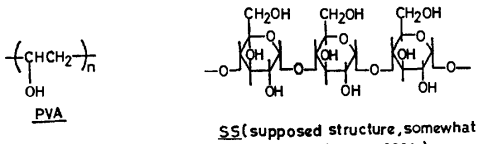
The mechanism of the photogalvanic effect in the photoredox reaction between thionine (thn) and Fe(II) has been studied by many investigators, especially in liquid-phase.[1–6] Few reports, however, describe photogalvanic cells composed of gel or membrane systems, although they are important from the viewpoint of application. We have prepared several types of photocell: (1) a double-Pt photocell containing thn–Fe(II) aq, (2) an SnO_2–Pt photocell of the same size as (1), and (3) a thin-layer type photocell containing thn–Fe(II) aq, thn–Fe(II)-gel (with a semi-permeable membrane), or polymeric thn–Fe(II). The following three points were examined :

(a) the electron-recycling mechanism in solution,
(b) the role of the SnO_2-electrode, and
(c) the factors which influence the photopotential ΔE and the photocurrent I.

Experimental

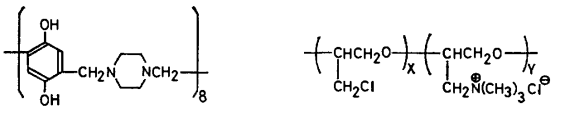
Reagents. Thionine (Tokyo Kasei Co., Ltd., reagent grade, Cl salt) was recrystallized from 50% aqueous ethanol solution before use. Its purity was confirmed by thin-layer chromatography after being eluted with a mixture of 2-propanol (5%) and chloroform. Analytical grade commercial reagents of acids, bases, and iron(II) sulfate containing 0.005% iron(III) were used without further purification. Soluble starch (Wakō Pure Chemical Co., Ltd., reagent grade for medical use) and poly(vinyl alcohol) (degree of polymerization=about 500) of commercial grade were purified by precipitating their hot aqueous solutions from excess methanol. Hydroquinone used as the reductant in the photoredox reaction was recrystallized twice. The formulas of the dyes and the polymers are given below. Thionine and its reduced species (Sthn=semi-thn, Lthn=leuco-thn) at pH 1—4[7,8] are as follows.





Preparation of Polymers. The ternary copolymer composed of hydroquinone, formaldehyde and piperazine residues was prepared by the Mannich-polyaddition-condensation-polymerization.[9] The thn-polymers were prepared by the reaction of poly(epichlorohydrin) (degree of polymerization=170, commercial reagent) with thn under the presence of triethylamine (HCl-remover). First, the prescribed amounts of the polymer and trimethylamine were reacted in an autoclave at 120 °C. The solvent, 50% aqueous *N,N*-dimethylformamide (DMF), was removed from the resulting solution. Solids were then dissolved in absolute methanol and reprecipitated with diethyl ether to yield copoly(epichlorohydrin-glycidyltrimethylammonium chloride) (QE). Next, QE and thn were reacted in absolute DMF at 60 °C in the dark. The solvent of the resulting solution was evaporated, and the product was washed with water until the filtrate showed no color of thn. The thn-polymers (BQEthns) thus obtained was to some extent cross-linked by thn nuclei, which are slightly soluble in methanol. When the reaction of QE and thn is carried out in the molar ratio, [thn]/[$-CH_2Cl$ of QE] $\gg$10, the resulting BQEthn is entirely soluble in water, since the cross-linking by thn nuclei can be avoided.[10] The experimental conditions and results are summarized in Table 1. The structures of the polymers are given below.

Apparatus. The over-all photobleaching rate constant k and the degree of photobleaching Δ% (=([Sthn]+[Lthn]) $\times 100/[\text{thn}]_0$) were measured with a stopped-flow rapid-scanning spectrophotometer (Union Giken Co., Ltd., RA-1300) modified into a cross-illumination system,[11] with a 100 W



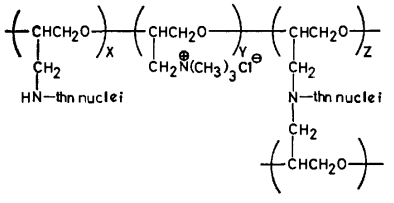


TABLE 1. PREPARATION AND CHARACTERISTICS OF POLYMERS

Pip-2HCl; piperazine·2HCl, TMA; trimethylamine. z% was estimated from the correlation of C%/N% with Cl%.

tungsten illumination light source and a 50 W measureing light source. The intensity of the latter was weakened to 0.03% of the former by use of neutral filters. It was confirmed that the illumination with the latter has little influence on the photoredox reaction. The photopotential ΔE and the photocurrent I of the thn-reductant systems were measured with the photocells illustrated in Figs. 1 (a)—(f), in which the SnO_2 electrode prepared by the usual chemical-vapor-depositing method (about 100 Ω/cm, transparent Nesa glass) was used, with a vibrating reed electrometer (Takeda Riken Co., Ltd., Model TR-84 BS).

Measurements. The prescribed amounts of thn and reductant solutions were bubbled with pure N_2 for 1 h before use, which was completely deoxygenated with use of the alkaline pyrogallol aq, sodium dithionite aq. and chromium-(II) perchlorate aq-zinc amalgam towers. The two reactant solutions were then taken into the syringes of the cross-illumination apparatus separately under N_2 and were rapidly mixed into a 2 mm-flow cell (dead time=450 μs). The rapid spectral changes with time due to the photobleaching of thn were measured. k was determined from the initial section of time-decay curve according to the pseudo-first order plots, and A from the final absorption intensity at a certain photo-equilibrium state. The values of ΔE and I were obtained by use of the photocells under pure N_2 atmosphere in a dry-box, their stationary values being recorded. Unless otherwise stated, the illumination light intensity was adjusted to 10 mW/cm² (>350 nm). The specific viscosity represented by η_{sp} was measured with an Ubbelohde viscometer at 25.0±0.04 °C.

Results and Discussion

Electron-recycling Mechanism. The photocells, one composed of double-Pt electrodes (a), and another of SnO_2–Pt electrodes (b) are shown in Figs. 1(a) and (b), respectively. The two photocells have similar size and surface area of electrodes (2.0 cm²) and also the same distance, 3.5 cm between the two electrodes. In the case of (b), visible light was cast onto both or one of the cell chambers, the light intensity being 10 mW/cm² on the surface of each electrode. The thin-layer photocells composed of a thn–Fe(II) aqueous solution, a gelatinized thn–Fe(II) aqueous system and a membrane-gel system are shown in Figs. 1(c)—(f). The surface area of SnO_2 and Pt electrodes is 3.0 cm² and the distance between the electrodes 2 mm. The visible light of the same intensity as in (a) and (b) was cast through the transparent SnO_2 electrode.

The electron-recycling mechanism proposed for the photogalvanic cells composed of thn–Fe(II) is as follows.[1-6]

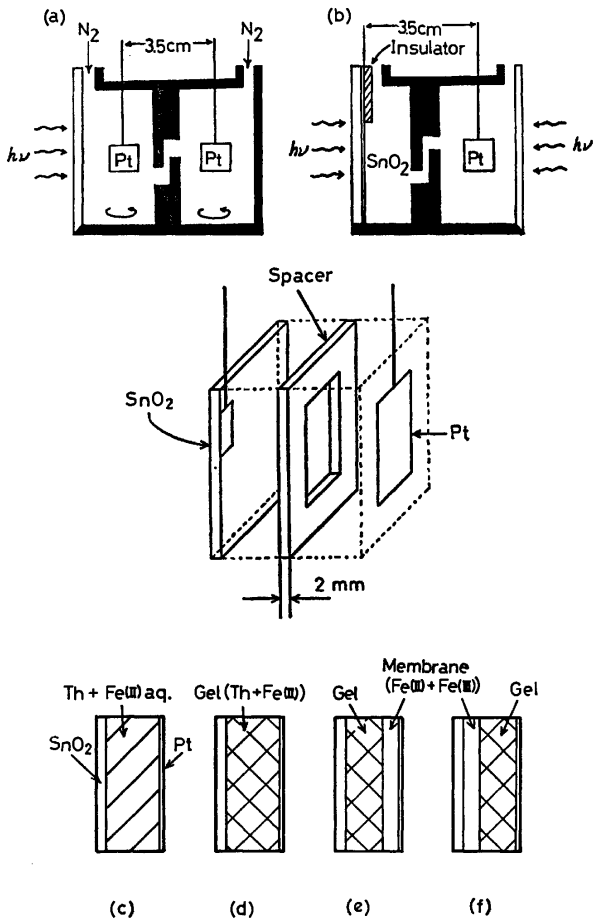

Fig. 1. Photogalvanic cells.
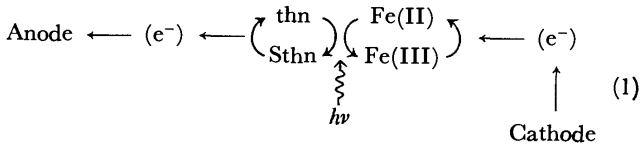
(a); d (distance between two electrodes) =3.5 cm, A (surface area of an electrode) =2.0 cm², (b); d=3.5 cm, A=2.0 cm², (c)—(f); d=2.0 mm adjusted by a spacer, A=3.0 cm². Visible light (>350 nm, 10 mW/cm²) was used, if no captions are given. Visible light can be illuminated onto both the cell-chambers of the photocell (b).



(1)

Only a few investigations have been carried out on the electron-recycling mechanism inside the cell despite its importance. It is doubtful that Fe(III) formed in an illuminated chamber is transported to the cathode *via* infinite pathway in a molecular scale due to diffusion, since the cathodic active species of Fe(III) would disappear by the possible bulk-backward reaction with Sthn or Lthn in the course of transportation. Therefore, another sufficiently fast mechanism should exist in order to cause the electron-recycling in solution.

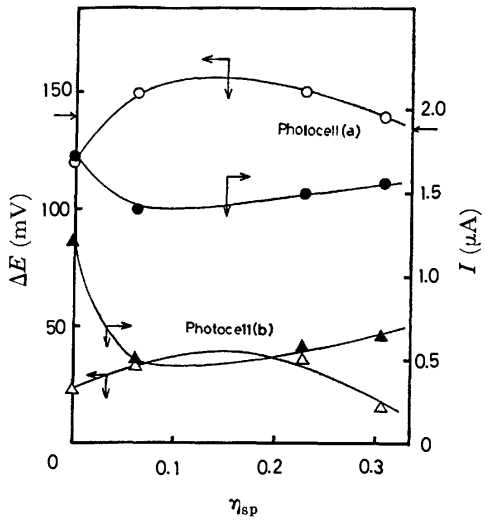


Fig. 2. Effect of added SS on ΔE and I of thn–Fe(II) systems. $[thn]_0=7.17\times10^{-5}$ mol/l, $[Fe(II)SO_4]_0=10^{-2}$ mol/l, $[Fe(III)]_0=5.0\times10^{-7}$ mol/l, pH 2.0-HCl, under N_2, without stirring.
(○,●); photocell (a), (△,▲); photocell (b). The arrows indicate ΔE and I without SS and with the most appropriate stirring of the solution, in photocell (a). η_{sp} indicates the specific viscosity of SS-added solution.

The effect of added SS (soluble starch) on ΔE and I in the thn–Fe(II) aq system is shown in Fig. 2, in which the abscissa indicate the specific viscosity of the solution (η_{sp}). Both ΔE and I measured without stirring of the solution remain almost unchanged with the increase of specific viscosity, which should decrease the transportation of Fe(III) from the illuminated cell-chamber to the cathode. They show the almost constant values of 150 mV and 1.5 μA, respectively, under the given conditions, whereas the effect of added PVA (poly(vinyl alcohol)) (Fig. 3) shows a bell-shaped curve. With increase in PVA concentration, ΔE and I become constant. The anomalous behavior in the PVA system cannot be understood from only the consideration that the electron-recycling in solution proceeds through the Fe(III) transportation.

It is well-kown that there is a very rapid electron-exchange reaction of 10^{-9}—10^{-12} s between Fe(II) and Fe(III) *via* hydrogen bonds in an aqueous solution:[12]

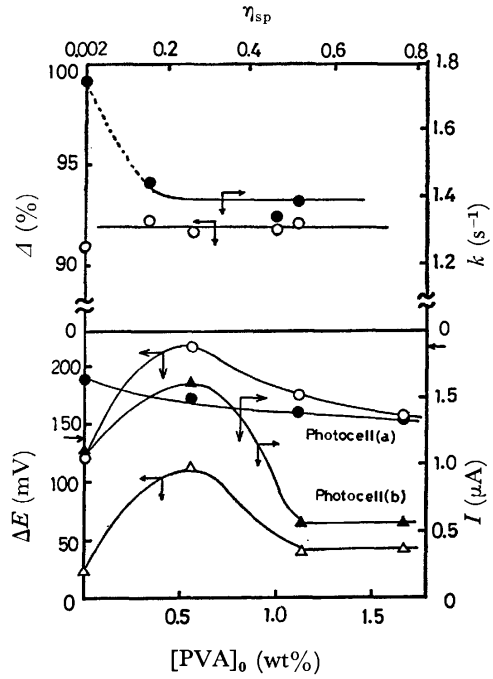

Fig. 3. Effect of added PVA on Δ, k, ΔE and I of thn–Fe(II) systems. The conditions are the same as in Fig. 2.

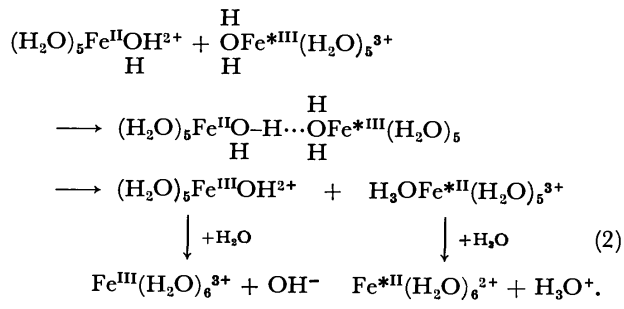
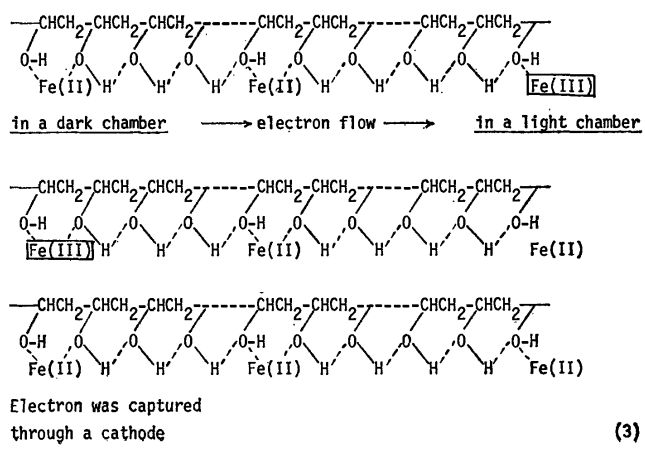


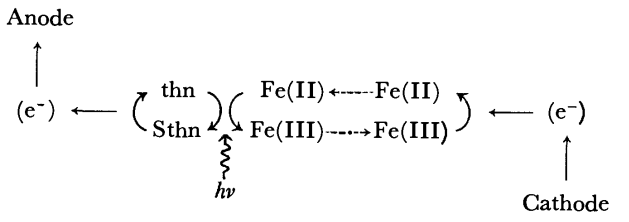
(2)

If this mechanism is valid, the reason for the increase of ΔE and I despite the fact that the values of k and Δ are constant when PVA was added in a small amount can be explained, since PVA forms the intramacromolecular hydrogen bonds which would enhance the electron-exchange reaction between Fe(II) and Fe(III) more easily:



(3)

The value of ΔE and I given in Figs. 2 and 3 were obtained without stirring the solution. Values obtained under appropriate stirring are indicated by arrows at each axis in photocell (a), without addition of SS or PVA. The very small difference between these values and those indicated by circles suggests that stirring of the solution has no remarkable influence on ΔE and I. In other words, the transportation of Fe(III) from the illuminated cell-chamber to the cathode is not the main pathway for the electron-recycling in solution. Thus, the electron-recycling mechanism of the thn-Fe(II) photoredox systems in the aqueous media was considered to be as follows.



Electron-exchange *via* hydrogen bonds and/or ion-transport (4)

The side hydroxyl groups of SS are less effective than those of PVA, probably because they cannot form the polymeric hydrogen bonds intramacromolecularily due to their rigid chain-backbone.

Characteristics of SnO_2 Electrode. The circles and triangles in Figs. 2 and 3 are the values measured with photocells (a) and (b), respectively, where both cell chambers of photocell (b) were illuminated. The values of ΔE and I obtained by use of photocell (b) without stirring are much smaller than those obtained by use of photocell (a). The direction of electron-flow is Pt(L) →Pt(D) in photocell (a), and Pt(L)→SnO_2(L) in photocell (b), where L and D indicate illuminated and dark, respectively. If we consider that SnO_2 is an n-type semiconductor, the direction of electron-flow is irregular in the latter case. SnO_2 seems to select Fe(III) as the electrode-active species, although Sthn also exists (Table 2). Three illumination methods were examined for photocell (b), *i.e.*, visible light cast onto the Pt-camber, onto the SnO_2-chamber and onto both the chambers. As for I and the direction of electron-flow, the systems of Pt(L)–Pt(D) and Pt(L)–SnO_2(D) gave almost the same result. The I values was very small for the SnO_2(L)–Pt(D) in which the direction of electron-flow SnO_2(L)→Pt(D). The I values of SnO_2–Pt(L) system with stirring was the largest, the direction being Pt(L)→SnO_2(L). From the consideration that (1) the effect of stirring is remarkable, (2) the value of I is the largest when the solution is stirred, and (3) the direction is Pt(L)→SnO_2(L) in the SnO_2(L)–Pt(L) system in contrast to the n-type characteristics of SnO_2, there might be some other electrode-reaction differing from the mechanism generally proposed for the case of Pt(L)–Pt(D) systems as given by Eq. 1 or 4.

Clark and Eckert reported that the direction of electron-flow is SnO_2(L)→Pt(L).[14] This cannot explain the results we obtained by use of a thin-layer photocell (Figs. 1(c)—(f)). The distance between the SnO_2 and Pt electrodes is 0.1 mm in Clark and Eckert's cell, but in ours 2.0 mm. The effect of UV light, which might cause distortion of the energy band of SnO_2 as illustrated in Fig. 4(a), is summarized in Table 3. The results indicate that the additional UV-illumination brought about the anodic polarization of SnO_2 to decrease the electron-flow, Pt(L)→SnO_2(L). Hence it is considered that the SnO_2 illuminated by visible light

has a distorted energy-band similar to the cathodic polarization. In order to let the electrons flow from Pt(L) to SnO_2(L), SnO_2, should have the ohmic contact or cathodic polarized state. The former is less probable, since the work-function of Pt is larger than that of SnO_2. There remains possible adsorption of some substances which bring about the cathodic polarization. Figure 5 shows the on-off behavior of ΔE and I in a thin-layer photocell. The electron-flow was SnO_2(L)→Pt(L), indicating that the discharged electrons from Sthn were captured by SnO_2 in the initial stage. The negative values in Fig. 5 represent the electron-flow of SnO_2(L)→Pt(L). The direction of electron-flow then reversed rapidly, *i.e.*, Pt(L)→SnO_2(L), ΔE and I reaching certain stationary values. By cutting off the illumination, ΔE and I increased temporarily toward (+)-side, showing the electron-flow to be Pt(L)→SnO_2(L), and then diminished rapidly. In this on-off behavior, the following should be noted:

1) the magnitude of temporary negative generation toward (−)-side of ΔE and I at on-illumination was larger than that of temporary positive generation toward (+)-side (Fig. 5) at off-illumination,

2) the temporary negative generation at on-illumination was scarecely observed after the second series of on-off recycles,

3) the temporary positive generation at off-illumination did not change with the repeated on-off recycles,

4) thn was strongly chemisorbed on the surface of SnO_2, which was almost constant at any off-illuminated state. The absorbed thn could be washed off with methanol, but not with water,

5) SnO_2 is activated only by UV-light (below 340 nm) to yield the anodic polarization, and is cathodic polarized state with the illumination of visible light, and

6) the SnO_2–Pt thin-layer photocell containing an aqueous solution of thn alone generated no dye-sensitized electricity under the illumination of visible light.

From the results, the reaction mechanism of the thn–Fe(II) system in these thin-layer photocells composed of SnO_2 and Pt is supposed to be as follows.
Firstly, a trivalent cation radical of Sthn at pH 1—4[7,8] encounters the surface of SnO_2, a real n-type semiconductor at this stage, and discharges. This may cause temporary negative generation at the on-illumination. The resulting monovalent cation of thn has smaller solubility than Sthn in water, and it will be adsorbed onto the SnO_2 electrode, which may cause the pseudo-cathodic polarization of SnO_2. However, further adsorption of thn, Sthn, and Lthn dissolved in the aqueous layer may occur on the surface of SnO_2 covered already with the dye (stuff). Thus we cannot determine which of the species thn, Sthn or Lthn covers the SnO_2

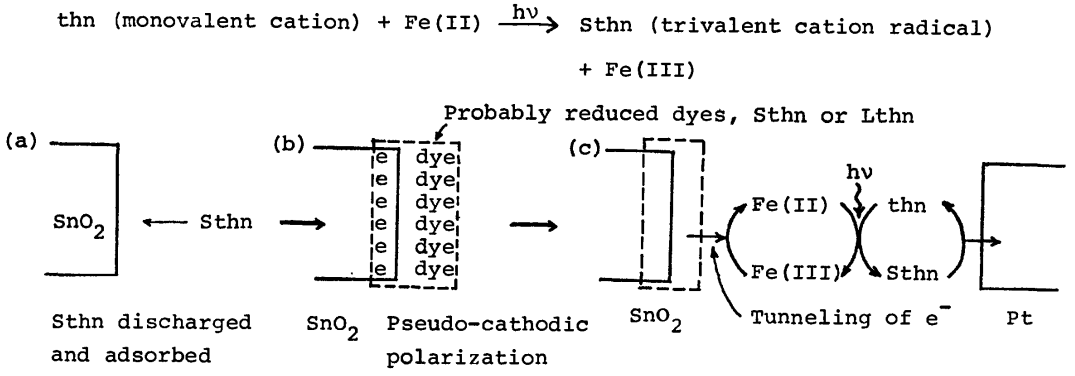

Fig. 6. Schematic representation of the role of SnO_2.

a) Distance between two electrodes.

electrode. When the solution was illuminated, the circuit closed and adsorption of dye (stuff) occurred, the species covering the SnO_2 electrode, formed by the photoredox reaction, was Sthn or Lthn rather than thn. Hence the direction of electron-flow was reversed as shown in Fig. 6(c). If this mechanism is valid, the experimental results 1)—4) and the effect of UV-light are understandable. The temporary negative generation of ΔE and I at the on-illumination in particular would be due to the initial stage of dye adsorption, which occurs only in the first on-off cycle, since the surface of SnO_2 is already covered with the dye (stuff) after the second cycle. The positive generation at off illumination was thus caused by the process of desorption of the dye (stuff) covering excessively the surface of SnO_2.

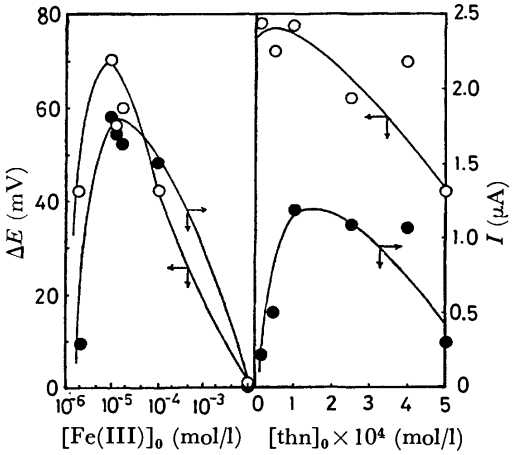

Fig. 7. Effect of $[Fe(III)]_0$ and $[thn]_0$ on ΔE and I of thn-Fe(II) systems. $[thn]_0=5.0\times10^{-4}$ mol/l in (a), $[Fe(OO)SO_4]_0=5.0\times10^{-2}$ mol/l, pH/l, pH 2.0-HCl aq, under N_2. (+) values indicate the electron-flow Pt(L)→SnO_2 (L).

Figure 7 illustrates the effect of $[Fe(III)]_0$ or $[thn]_0$ (subscript 0 indicates the initial concentration) on ΔE and I of the thn-Fe(II) aqueous systems studied by use of the thin-layer photocell (c). The dependence of ΔE and I on $[thn]_0$ is represented by a bell-shaped curve, the Δ values decreasing with $[thn]_0$. Under the conditions employed, $[thn]_0=5.0\times10^{-4}$ mol/l, $[Fe(II)]_0=5.0\times10^{-2}$ mol/l, the Δ value was almost 100%. The excess thn would decrease I due to the excessive adsorption of dye (stuff) onto SnO_2, and also decrease ΔE according to Nernst's equation:*

$$\Delta E = E_0 + 0.0592 \log \{([Sthn]/[thn][H^+])_A \times ([Fe(III)]/[Fe(II)])_C\}, \quad (5)$$

were A and C indicate the anodic and cathodic reactions, respectively. On addition of Fe(III), ΔE and I also showed the behavior represented by bell-shaped curves. At a low $[Fe(III)]_0$, the values increased due to the increased electron-exchange reaction and/or contribution of the $(\ )_C$ term in Eq. 6. The decrease in the values at high $[Fe(III)]_0$ was brought about by the increased short-circuit in solution or the increased bulk-backward reaction, which decreases the concentration of anode-active Sthn, and by the decrease of the dye-adsorption onto SnO_2. The direction of electron-flow reversed when the initial concentration of Fe(III) exceeded 10^{-2} mol/l. No quantitative discussions could be made due to the formation of thn-precipitates.

The experimental results of Clark and Eckert[13] and the present work are compared in Table 4. There is a large difference between the two I values if the direction of electron-flow is not taken into consideration. Since Clark and Eckert gave no details of the experimental procedure, it is difficult to find the reason for the difference. However, from the fact that (A) their I values are extraordinarily large for the thn-Fe(II) photogalvanic cells, and (B) we also observe a short-photocurrent of about 5 μA/cm² (or more) with the direction of SnO_2(L)→Pt(L) (under the conditions given in Table 4), the large I values they presented are considered to be short-photocurrent, or values obtained when the solution was pre-illuminated and the circuit then closed and I was measured. Especially, the phenomenon of (B) can be easily presumed from the on-off behavior shown in Fig. 5, in which the temporary negative generation, *i.e.*, the electron-flow SnO_2(L)→Pt(L), was observed at the on-illumination.

Thin-layer Photocells Composed of Gelatinized Thn-Fe(II) Systems. Since it was found that the electron-recycling in the thn-Fe(II) system mainly proceeds by the possible electron-exchange reaction between Fe(II)

TABLE 5. CORRELATION OF SEVERAL PHOTOGALVANIC CELLS

Systems of photocell	ΔE (mV)	I (μA)
(c) SnO_2/soln/Pt	70	1.82
(d) SnO_2/SS-gel/Pt	20	0.75
(e) SnO_2/SS-gel/membrane/Pt	29	0.30
(e) SnO_2/SS-gel/membrane×2/Pt*	32	0.53
(f) SnO_2/membrane/SS gel/Pt	6	0.23

$[thn]_0=5.0\times10^{-4}$ mol/l, $[Fe(II)SO_4]_0$ both in gel and membrane$=5.0\times10^{-2}$ mol/l, $[Fe(III)]_0$ both in gel and membrane$=2.5\times10^{-6}$ mol/l, *: $[Fe(III)]_0$ in membrane $=1.0\times10^{-5}$ mol/l. pH 2.0-HCl, under N_2. The direction of electron-flow was Pt(L)→SnO_2(L) in all cases.

* Nernst's equation is not correct in order to make quantitative discussions, since the equation does not take the formation of local cells into account. However, the equation is understandable for the qualitative discussions.

and Fe(III), the thin-layer photocells can be converted into some gel systems. Figures 1(c)—(f) illustrate the application of the thin-layer photocells. The results are summarized in Table 5. The semipermeable cellophane membrane having thickness 0.7—0.8 mm and porosity 24 Å was used for a diaphragm through which Fe(II) or Fe(III) permeates but not thn. In practice, thn permeated in a very small amount after 5 h. The most important facts are, (i) ΔE and I are very small in the SnO_2/wet membrane-[Fe(II)+Fe(III)]/gel-[thn+Fe(II)+Fe(III)]/Pt system, and (ii) in some extent larger ΔE and I were observed in the SnO_2/gel-[thn+Fe(II)+Fe(III)]/wet membrane-[Fe(II)+Fe(III)]/Pt system, in which the direction of electron-flow was Pt(L)→SnO_2(L). In the former system, there was no dye around SnO_2, since SnO_2 was attached to the membrane containing no dye. Hence SnO_2 is regarded as the real n-type semiconductor, which has an affinity for Sthn rather than for Fe(III). However, there existed only Fe(III) or Fe(II) around the SnO_2 electrode. Thus the former system is very disadvantageous as seen from the characteristics of SnO_2. In the latter system, SnO_2 can be converted into the pseudo-cathodic polarized state due to the adsorption of the dye (stuff), and consequently the cathodic reaction or the donation of electrons to Fe(III) is favorable on the SnO_2 electrode. However, it is very difficult to consider that Sthn, which cannot permeate to the Pt electrode through the cellophane membrane, discharges throughout the membrane. We consider the electron-recycling mechanism in the SnO_2/membrane/gel/Pt system to be as follows.

$$\underline{SnO_2} \longrightarrow (e^-) \longrightarrow$$

Pseudo-cathodic polarized by the adsorption of dyes.

$$\left(\begin{matrix}Fe(II)\\Fe(III)\end{matrix}\right)\left(\begin{matrix}thn\\Sthn\end{matrix}\right)\left(\begin{matrix}Fe(II)\longrightarrow Fe(II)\\Fe(III)\longleftarrow Fe(III)\end{matrix}\right)$$

$h\nu$ (photoexcitation); Electron-exchange

The reaction in a gel | The reaction in a wet membrane

$$\longrightarrow (e^-) \longrightarrow Pt \qquad (6)$$

As the use of membrane brought about the increase of internal resistivity to yield small ΔE and I values, a single-gel system was examined. Figure 8 illustrates the effect of $[Fe(III)]_0$ or $[thn]_0$ on ΔE and I observed by use of the thin-layer photocell (d) as in the SS (50 wt%)-gel systems. Although, the whole values were smaller than those in Fig. 7, similar bell-shaped curves were obtained. It is important that the dependency of $[Fe(III)]_0$ is more clearly recognized in Fig. 8 than in Fig. 7, *i.e.*, the direction of electron-flow reversed at high $[Fe(III)]_0$ as SnO_2(L)→Pt(L).

Figure 9 shows the effect of $[Fe(III)]_0$ on ΔE and I in the PVA (50 wt%)-gel systems. The values of ΔE and I showed similarly a maximum point of 82 mV at $[Fe(III)]_0=10^{-4}$ mol/l and of 0.85 μA at $[Fe(III)]_0=3.0\times10^{-5}$ mol/l, respectively, which were large enough

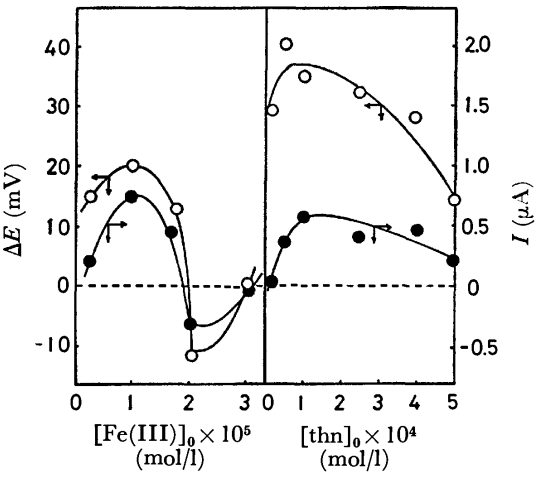

Fig. 8. Effect of $[Fe(III)]_0$ and $[thn]_0$ on ΔE and I of SS(thn-Fe(II))-gel systems. In SS 50 wt% gel, other conditions are the same as in Fig. 7.

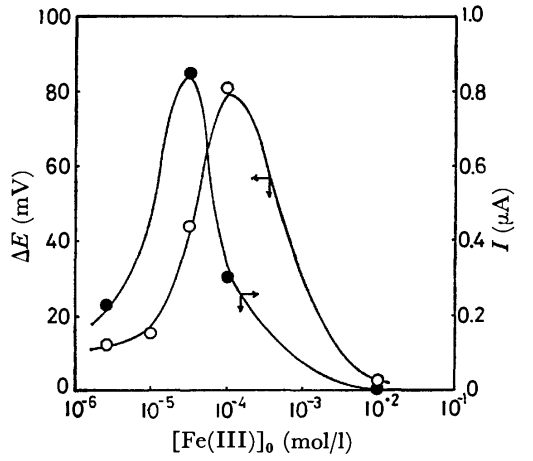

Fig. 9. Effect of $[Fe(III)]_0$ on ΔE and I of PVA(thn-Fe(II))-gel systems. In PVA 50 wt% gel, other conditions are the same as in Fig. 7.

as compared with the corresponding aqueous systems due to the excellent electron-recycling or electron-exchange reaction attributed to the role of the intra-macromolecular hydrogen bonds.

Hydroquinone (H_2Q) is a good reductant in the photoredox reaction with thn. The electrode active species are Sthn (anode) and benzoquinone (BQ) or semi-quinone radical (cathode) in this system. Vigorous stirring of the solution is necessary in order to keep the constant ΔE and I when the double-Pt type photocell as shown in Fig. 1(a) is used. This suggests that the electron-recycling in solution probably proceeds only by the transportation of the cathode active species. Figure 10 illustrates the effect of $[BQ]_0$ on ΔE and I in the SnO_2/thn-PH_2Q-gel/Pt system. The spontaneous decrease in ΔE and I indicates that there is no electron-exchange reaction between PH_2Q and BQ, while ΔE and I increase with $[BQ]_0$ in the SnO_2/thn-PH_2Q-SS-gel/Pt system, when a small amount of BQ is added (Fig. 11). The side hydroxyl groups of SS act the bridging reagent between H_2Q and BQ or semi-quinone residues to increase ΔE and I. PH_2Q is very easily oxidized by molecular oxygen, and the PVA-PH_2Q

system could not be examined.

The ΔE and I values under the most appropriate conditions in all the systems are summarized in Table 6. The ability to generate the photo-induced electricity in the PVA system is remarkable. It is noteworthy that the values and the direction of electron-flow in these thin-layer photocells composed of SnO_2 and Pt are very sensitive toward the experimental conditions, *i.e.*, the ration of $[thn]_0/[Reductant]_0$, or their absolute concentration, *etc.*, being balanced at the very critical and delicate situation.

Thin-layer Photocells Composed of Polymeric Thn-Membrane. A remarkable polymer effect in the photogalvanic property of the cationic thn-polymer-Fe(II) systems has been reported.[12] Large ΔE and I values were obtained due to the prohibition of the short-circuit in solution or the bulk-backward reaction between Sthn and Fe(III). The cationic thn-polymer in a gel or membrane state would generate much larger ΔE and I.

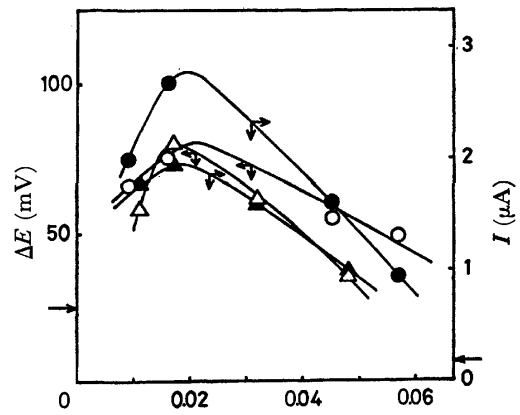

Fig. 12. Relationship between the thickness of BQEthn-film and ΔE, I in thin-layer photocell. (○,●); BQEthn 23%, (△,▲); BQEthn 19%. $[Fe(II)SO_4]_0=5.0\times10^{-2}$ mol/l, $[Fe(III)]_0=2.5\times10^{-6}$ mol/l, pH 2.0-HCl aq, under N_2.

BQEthn of the prescribed structure carrying cationic charges has been prepared, in which it is somewhat crosslinked with thn nuclei and is insoluble in water and soluble in methanol or *N,N*-dimethylformamide, and can thus be cast to a film from a methanol solution. Figure 12 illustrates ΔE and I of the BQEthn-Fe(II) systems cast between SnO_2 and Pt electrodes and swolled by the Fe(II) aqueous solution. Thus, the distance between two electrodes changes with the thickness of the film. The values ΔE and I show maxima at about 0.02 mm thickness of the film, and the direction of electron-flow is also $Pt(L) \rightarrow SnO_2(L)$. The decrease in the values with thicker films is probably due to the potential barrier formed by excess BQEthn. Hence the BQEthn of x (degree of incorporation of thn nuclie, see Experimental) $=23\%$ shows larger values than that of $x=19\%$, since the former requires a smaller amount of polymer than the latter, when the active thn concentration is kept constant. The BQEthn of $x=23\%$ shows absorpbance of about 0.3 at the 0.02 mm thickness, the influence of light-scattering being corrected in the measurement. The ΔE and I values of the thn-Fe(II) aqueous system possessing the same absorbance are also indicated by arrows in Fig. 12. The polymer systems shows much larger values than those of the monomeric solution system.

By utilizing the electron-exchange reaction and several polymer systems, the photogalvanic cells consisting of aqueous solutions could be converted into solid-phase cells without any remarkable decrease of the photo-induced electricity.

The Hydrocracking of a Heavy Anthracene Oil over Molten Salt Catalysts[1)]

Yohji NAKATSUJI, Shigeyuki FUJIOKA, Masakatsu NOMURA, and Shōichi KIKKAWA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received April 25, 1977)

The hydrocracking of a heavy anthracene oil over molten salt catalysts (zinc chloride or a binary mixture of zinc chloride and another metal chloride) at 400 °C for 3 h in a batch autoclave system was carried out, and the products were mainly identified by means of GC-MS. The effects of the hydrogen pressure (60 or 100 kg/cm^2), the quantity of the catalyst, and the addition of metal chloride (potassium chloride or copper(I) chloride) to zinc chloride on the product distribution were examined and discussed. Based on the detailed product analysis, it was found that *cata*-condensed polycyclic aromatic compounds were hydrocracked more efficiently than *peri*-condensed polycyclic aromatic compounds. The $CuCl/ZnCl_2$ molten salt displayed an excellent catalytic activity for the hydrocracking of the heavy anthracene oil.

The ring structures of the constituent units of bituminous coals are highly aromatic, and the average-sized configuration is considered to be three or four rings.[2,3)] In order to obtain a high yield of gasoline from coal, it is necessary to hydrocrack the constituent units to benzene and its derivatives. From this point of view, the hydrocracking of model compounds, which are supposed to be constituent units of coal, has been investigated.[3–12)] Zielke *et al.*[5)] had shown molten zinc chloride to be a superior catalyst for the hydrocracking of pyrene and coal extracts when used in high concentrations. Incidentally, intensive investigations have been under way in our laboratory on the catalytic action of molten salts in several organic reactions.[13)] As a part of this study, this paper will describe the hydrocracking of a heavy anthracene oil, which thus seems to be a kind of model substance. In addition, the change in the hydrocracking activity of zinc chloride by the addition of another metal chloride will be shown in this investigation.

Experimental

The NMR spectra were recorded by means of a JEOL JNM-PS-100 spectrometer, using tetramethylsilane as the internal standard. The GLC analyses were performed on a Shimadzu GC-3AH for gaseous products and on a GC-4BPTF for liquid and solid products. The GC-MS spectra were taken with a Hitachi RMU-6MG spectrometer at 20 eV connected with a Hitachi M 5201 apparatus using a 3 m× 3 mm column of 5% Silicone OV-1 on Uniport KS. The zinc chloride and potassium chloride were obtained from Wako Pure Chemical Industries, Ltd. The copper(I) chloride was obtained from Nakarai Chemicals, Ltd.

Characterization of Feed. A heavy anthracene oil (obtained from Osaka Gas Co., Ltd.; Specific gravity (50/4 °C) 1.142; moisture 0.5%; distillation test (dehydrated sample) 0—360 °C: 28.0%) was separated into three fractions and a residue by means of vacuum distillation. The characterization of these fractions is shown in Tables 1 and 2. Small amounts of heteroaromatics (indole, quinoline, carbazole, benzocarbazoles, and dibenzothiophene) were found in the feed and were identified using GC-MS. The type-analyses undertaken according to the Speight method[14)] (Table 3) gave results in good agreement with the results based on the information obtained from GC-MS.

General Procedure. All the experiments were carried out in a stainless steel (Sus 32) autoclave with a capacity of 500 ml, shaken in a horizontal direction (70 strokes/min). A stainless steel vessel containing feed (about 20 g) and the catalyst were placed in the autoclave. The air in the autoclave was replaced by hydrogen, and then the system was filled with hydrogen to the determined pressure. The rate of the temperature rise was controlled to about 3 °C/min to 400 °C. The temperature was then held at the desired level for 3 h. After the system had been cooled to room temperature, gases were admitted into a gas holder and analyzed by GLC (60—80 mesh Silica gel column 3 m×3 mm). Solid samples from the reaction products were dissolved in a proper solvent and analyzed by GLC (4.5 m×3 mm column packed with 20% SE-30 on Uniport B 60—80 mesh). The liquid products were also analyzed by GLC. The mixture of coke and catalyst obtained after the extraction of the products was washed with water and refluxed in hydrochloric acid to remove the catalyst. The hydrogen sulfide evolved was trapped by the use of an iodine solution, and its quantity was determined by titrating the resulting solution with a sodium

Results and Discussion

Fractions II—IV are especially supposed to be better model substances for the hydrocracking of coals. The results of hydrocracking are shown in Table 5, along with the reaction conditions used. Table 6 describes the composition of the gaseous products (**1**: C_1—C_4 gases).

In the hydrocracking of Fraction II (Runs 1 and 2), the difference in the catalytic activity between zinc chloride and the binary mixture of zinc chloride and

copper(I) chloride was examined. The yield of benzene and its derivatives (**4**) in Run 1 (14.6%) is lower than that in Run 2 (23.3%), and the combined yield of higher aromatics (**7**—**11**) in Run 2 (8.8%) is lower than that in Run 1 (28.7%). This result suggests that the catalytic activity of $ZnCl_2$/CuCl molten salt is superior to that of $ZnCl_2$. Since aromatic-type bonds are not expected to be thermally cleaved at 400 °C, the single C–C bonds of hydroaromatics are considered to be ruptured in the course of this hydrocracking. Therefore, it is necessary that aromatic rings be hydrogenated before they receive catalytic cracking by acidic molten salts. From this standpoint, the capabilities of both hydrogenation and cracking are demanded for the hydrocracking catalyst. On the basis of the product distribution, it is possible to estimate which acts predominantly in this hydrocracking. For example, the ratio of **5**/**6** is supposed to be a measure of the hydrogenating activity of the catalyst. The higher ratio of **5**/**6** in Run 2 than in Run 1 would demonstrate the improvement of its hydrogenating activity upon the addition of copper(I) chloride to zinc chloride. On the other hand, the ratio of isobutane to butane in the gaseous products was found to be not so changed by the addition of copper(I) chloride to zinc chloride. As the ratio of isobutane to butane is supposed to be a measure of the cracking activity of acidic molten salts, this finding shows that the intrinsic cracking activity of zinc chloride according to its Lewis acidity is not so much changed by this addition of copper(I) chloride. Kenney *et al.*[15] demonstrated that the catalytic activity of zinc chloride was lowered by

the addition of metal chlorides, such as KCl, NaCl, and AgCl, in the hydrogen chloride elimination of isopropyl chloride; the principal exception was copper(I) chloride. In addition to the results similar to their findings, an improvement in the hydrogenating activity was found in this investigation. This synergenic effect of the addition of copper(I) chloride to zinc chloride was also found in the hydrocracking of anthracene,[16] phenanthrene, pyrene, fluoranthene, and chrysene.[17]

In the hydrocracking of Fraction III (Runs 3—6), the change in the cracking activity of zinc chloride caused by the addition of potassium chloride and the effect of the initial hydrogen pressure on the hydrocracking were examined. By comparing the result of Run 5 with that of Run 6, the binary mixture of $ZnCl_2$ and KCl was found not to display any appreciable catalytic activity. In the hydrocracking of hydroaromatics in this temperature range, two different reactions can occur.[6] The first of them is thermal cracking under a hydrogen atmosphere, which proceeds by means of a free radical mechanism; the other is catalytic cracking, which proceeds by means of a carbonium ion mechanism. When the hydrocracking proceeds by means of the latter mechanism, the ratio of iso to normal isomers is higher than that in a thermodynamic equilibrium. From this standpoint, the low yield of branched alkanes found in the case of Run 6 describes the lowering of the cracking activity of zinc chloride by the addition of potassium chloride. As the catalytic action of $ZnCl_2$ is attributed to its own molecular character, the formation of ionic complexes (such as K_2ZnCl_4) lowers the intrinsic cracking activity of molten zinc chloride. This is consistent with the result of Kenney *et al.*[15] In the absence of an acidic metal chloride (Run 3), small amounts of gases (most of them are methane and ethane) are obtained, and so the hydrogenation of aromatics is considered to govern this reaction. The effect of the hydrogen pressure is also shown in Runs 4 and 5. At higher hydrogen pressures, the formation of coke is found to be suppressed to a significant extent. This result indicates that the formation of coke may proceed *via* intermolecular dehydrogenation, and that hydrogen may act to capture active intermediates, such as species leading to coke with lesser amounts of hydrogen. The reason for the lowering of cracked products at higher hydrogen pressures may also be attributed to this stabilization.

The quantity of the catalyst is one of the most important factors dominating this hydrocracking (Runs 7 and 8). For example, the change in the conversion according to the quantity of the catalyst is remarkable in the yields of gaseous products. From this finding, the lowering in the cracking activity upon the addition of potassium chloride to zinc chloride mentioned above is attributable to the decrease in the amounts of effective parts of the catalyst.

In all the runs, *cata*-condensed polycyclic aromatics (anthracenes, phenanthrenes and chrysenes) were hydrocracked more efficiently than *peri*-condensed polycyclic aromatics (pyrenes). Therefore, benzopyrenes were hydrocracked to pyrenes, which were relatively resistant to the hydrocracking in the molten salt catalyst. Also, the reactivity of fluoranthenes was found to be fairly high.

In the hydrocracking of Fraction IV with a higher S content, the behavior of S was examined. Most of the S was found in the form of zinc sulfide. Attention was not given to the behavior of N and O, but the contents of hetero atoms in the products were found to be lower than in the feed.

Proton Spin Lattice Relaxation in Blends of Natural Rubber and Polyterpene

Masayoshi Ito and Koji Tanaka

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received May 12, 1977)

Synopsis. NMR measurements were carried out on blends of natural rubber (NR) and polyterpene (PT). The blends of NR and PT are perfectly mixed. The motion of NR chains play a dominant role in the glass transition of the blends. The mobility of NR segments in the blends are constrained by the presence of PT.

Rubbery mixtures of an elastomer and resin are tack, and the tackiness increases with increase in the concentration of resin. Hock[1] found by electron microscopy that the increase of tackiness is due to the development of a second phase, which probably consists of low molecular weight rubber dissolved in the resin. On the other hand, Fukuzawa[2] suggested that the compatibility of elastomer-resin is the most important factor in understanding the increase of tackiness. These different explanations imply that detailed information on the internal structure of the blend materials is necessary to understand the increase of tack.

The application of NMR method to the study of polymer blends is known to offer advantageous information on the microstructure of the blend materials.[3,4]

In the present study, the segmental mobility for the blends of natural rubber and polyterpene was investigated by the NMR method in order to further elucidate the mixing state of the blends.

Experimental

Samples. Unvulcanized natural rubber (Hevea rubber) and polyterpene which is a random copolymer of α-pinene and β-pinene (Sekisui Chemical Industry Co., Ltd.) were used. The number average molecular weight and softening point of polyterpene were 1200 and 100 °C, respectively. X-Ray diffraction patterns indicated that these materials are completely amorphous. The glass transition temperature of natural rubber and polyterpene was determined by DSC to be *ca.* −65 and 70 °C, respectively.

Films containing natural rubber and polyterpene were cast from carbon disulfide solution on glass at room temperature. The ratio of natural rubber to polyterpene is given on a weight basis. The films were dried in a vacuum at room temperature for a week.

Measurements. A pulsed NMR spectrometer similar to the one described by Clark[5] was used. The resonance frequency for protons was 30 MHz. Samples were packed in a glass tube in a vacuum.

Line width was obtained with a JNM W-40 type (resonance frequency for protons was 40 MHz) broad line NMR spectrometer.

Results and Discussion

The temperature dependence of spin-lattice relaxation times (T_1) for natural rubber (NR), polyterpene (PT), and their blends is shown in Fig. 1. T_1 for NR and the four blends shows one T_1 minimum, indicating the presence of a second minimum below the temperature accessible in this study. In NR, the high temperature minimum undoubtedly corresponds to the glass transition, while the low temperature process involves methyl group reorientation.[6] T_1 for PT shows one small minimum at around 150 °C, indicating the presence of two minima below and above the temperature accessible in this study. The low temperature process might be due to the methyl group reorientation as judged from

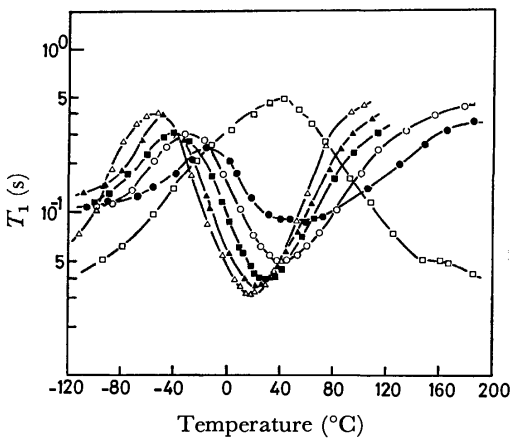

Fig. 1. Temperature dependence of T_1 for NR(△), PT(□), NR–PT=90: 10(▲), NR–PT=70: 30(■), NR–PT=50: 50(○), and NR–PT=30:70(●).

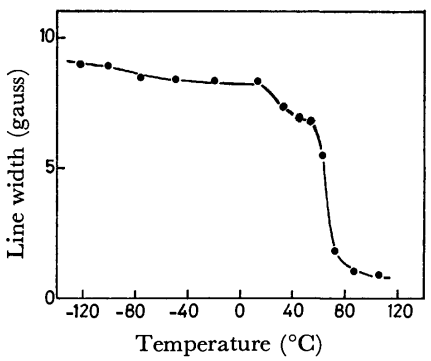

Fig. 2. Temperature dependence of NMR line width of polyterpene.

the very low T_1 minimum temperature and the chemical structure of polyterpene. The line widths for PT obtained from the derivatives of the broad line NMR absorption lines are plotted against temperature in Fig. 2. Two distinct transitions take place. At the first step the narrowing of line width starts at about 20 °C. After the first narrowing the curve enters into the second step of abrupt decrease at *ca.* 70 °C, followed by leveling off. The high temperature transition is consistent with the glass transition temperature of PT. A small decrease of line width at *ca.* 20 °C indicates a small scale segmental motion of PT. From a comparison of the line width data with the T_1 data (Fig. 1), it is postulated for the relaxation mechanisms of PT that the high temperature decrease of T_1 is due to the onset of micro-Brownian motions and the small T_1 minimum at around 150 °C corresponds to the local mode motions. On the basis of the characterization of T_1 minima for NR and PT, it is postulated for the relaxation mechanisms of the blends that the low temperature minimum is due to the reorientation of the methyl group and the high temperature process corresponds to the glass transition. As seen in Fig. 1, all the samples show only one T_1 value in the whole range of temperature. The fact that blends of natural rubber and polyterpene show only one glass transition and T_1 value over the whole range of composition and temperature demonstrates the excellent compatibility of NR and PT.

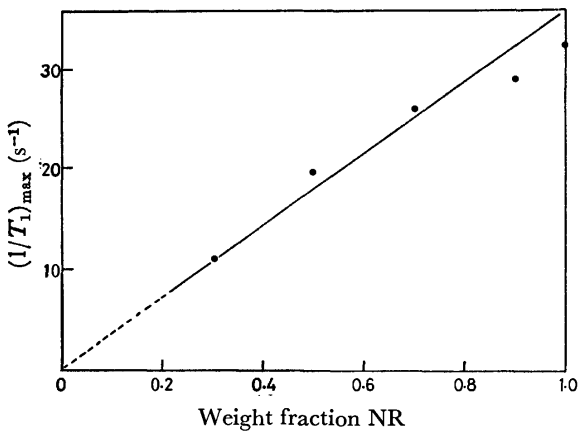

Fig. 3. Natural rubber weight fraction dependence of maximum relaxation rate at the glass transition.

Figure 3 shows the relation between the maximum relaxation rate $(1/T_1)_{max}$ of the blends at the glass transition and the weight fraction of NR. A linear dependence is found. This indicates that the motion of the natural rubber chain plays a dominant role in the mechanisms of glass transition of the blends.

The T_1-temperature curve is gradually broadened at the glass transition and the minimum temperature shifts to the higher temperature side with the increase of PT content (Fig. 1). The broadening of the T_1 minimum indicates that the distribution of correlation times related to the degree of the restriction imposed on the segments is broadened by addition of the PT resin. With the increase of PT content, the intermolecular interaction between NR and PT chains increases and the segmental motion of NR in the blends is constrained and the temperature of the T_1 minimum shifts to the higher temperature side.

In conclusion, blends of natural rubber and polyterpene are perfectly mixed over the whole range of composition. The motion of the natural rubber chain plays a dominant role in the mechanisms of glass transition of the blends and the segmental mobility of natural rubber chains in the blends are greatly constrained by the presence of polyterpene.

The authors wish to express their thanks to Professor M. Takeda for his continuing interest and encouragement during the course of this investigation.

Annihilation of the Catalytic Activity in Butene Isomerization of Porous Vycor Glass by Washing with EDTA Aqueous Solution

Shoji HIRAI,* Akira MORIKAWA, Yoshio ISHINAGA, Kiyoshi OTSUKA, and Yuji WADA

Department of Chemical Engineering, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received June 13, 1977)

Synopsis. The catalytic activity of porous Vycor glass in the isomerization of butenes was eliminated by washing the glass with EDTA aqueous solution, though the contents of Al and Zr in the glass remained unchanged. Destruction by decationation of active sites of silica-alumina character has been suggested.

Porous Vycor glass is one of the most favourable materials for examining molecules bound to the surface by means of spectroscopy. The mechanism of the photoisomerization of butenes was investigated by sensitization of molecules adsorbed on the glass or of the Vycor glass itself.[1-3] However, the glass shows an appreciable thermal catalytic activity in the isomerization,[1,4] occasionally making the experimental results vague.

The minor components of the Vycor glass (96% SiO_2) are mainly alumina, boria, and zirconia. Aluminium forms acid surface sites of a silica-alumina character, with which butene molecules interact to isomerize.[5] Silica-zirconia is also a solid acid.[6] Thus, removal of aluminium or zirconium from the glass might cause annihilation of the thermal catalytic activity of the glass for isomerization. It has been reported that aluminium in zeolites is successfully removed by EDTA treatment.[7] We have applied this technique to porous Vycor glass and suppressed the activity. This paper deals with the results with respect to the change in the isomerization activity and the contents of aluminium and zirconium.

Experimental

A porous Vycor glass plate $30 \times 8 \times 0.9$ mm was calcined at 750 °C in the air for 3 h, washed with 0.01 M neutral aqueous solution of EDTA for an appropriate duration, washed twice with distilled water for 15 min each and dried for 2 h at 400 °C in the air. The glass plate was then placed in a coaxial tubular, quartz-made reactor, calcined at 500 °C for 2 h in a stream of oxygen gas with a pressure of 20 kPa, and degassed for 2 h under a pressure of 7×10^{-3} Pa at the same temperature. At 60 °C a reacting gas, *cis*-2-butene, of pressure 20 kPa was introduced into the reactor, the reaction then proceeding in a closed gas-circulation apparatus with a volume of 190 ml. The products were analyzed by gas chromatography at appropriate intervals. Elements other than Si, B, and O contained in the glass plate were analyzed by means of neutron activation analysis with the GAMA system at Atomic Energy Research Laboratory, Musashi Institute of Technology.

Results and Discussions

The elements present in appreciable amounts were Al, Zr, As, Ti, V, Mn, Fe, Na, and Mg among a large number of elements detected. The amounts of aluminium and zirconium were considerably greater than those of the others.

TABLE 1. *cis*-2-BUTENE ISOMERIZATION ACTIVITY AND CONTENTS OF ALUMINIUM AND ZIRCONIUM

Duration of EDTA washing (h)	0	0.5	1	2	3
Amount of Al (ppm)	2670	3070	2940	2550	3050
Amount of Zr (ppm)	962	960	978	938	852
Catalytic activity (mol s^{-1} g-cat^{-1})	5.1×10^{-9}	trace	none	a)	none

a) Transparency was measured.

The amounts of both aluminium and zirconium in the glass with various durations of EDTA washing are summarized in Table 1. The unwashed glass is denoted by zero duration. No effect of EDTA washing was detected on the contents of the two elements. On the other hand, the catalytic activity was drastically eliminated by only 30 min washing. For the unwashed glass the activities at 60 °C for the isomerization of *cis*-2-butene to 1-butene and *trans*-2-butene are 3.3×10^{-9} and 1.8×10^{-9} mol s^{-1} g-cat^{-1}, respectively, the corresponding apparent activation energies for the isomerization being *ca.* 71 and 83 kJ mol^{-1}, which may be reasonable values for isomerization on the acid sites of a silica-alumina character. For the washed glass, however, even at 80 °C, no activity could be measured.

The results lead us to the following conclusions. (1) Aluminium and zirconium atoms on the surface of the glass, contributing to formation of acid sites, can be removed by EDTA, resulting in annihilation of the catalytic activity for the butene isomerization. (2) Most of the aluminium and zirconium atoms probably entrapped in the silica network of the bulk of glass are resistant to the EDTA washing and inert for the reaction. (3) Such entrapped aluminium or zirconium atoms are immobile under heating at 500 °C for 4 h during the course of pretreatment. If mobile, they may diffuse from the bulk to the surface of the glass, forming acid sites during the course of pretreatment.

The transparency of the washed glass hardly decreased. Only 0.02 increase of absorbance to the light of wavelength 700—400 nm and 0.02—0.15 to 400—250 nm were observed for the 2 h washed glass.

Thus EDTA washing can be utilized for preparing catalytically inert supports of catalysts.

The Preparation of Trivalent Metal Chelates with Some N_3O_3-Type Ligands

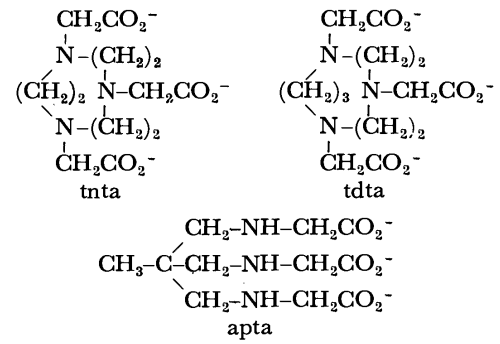
Mariko TAKAHASHI and Susumu TAKAMOTO

Department of Chemistry, Faculty of Sciences, Gakushuin University, Mejiro, Toshima-ku, Tokyo 171

(Received June 6, 1977)

Synopsis. Iron(III), chromium(III), and cobalt(III) chelates with 1,4,7-triazacyclononane-*N,N',N''*-triacetate, 1,4,7-triazacyclodecane-*N,N',N''*-triacetate, and 2-(aminomethyl)-2-methyl-1,3-propanediamine-*N,N',N''*-triacetate were synthesized and characterized by means of the electronic absorption spectra in an aqueous solution. As they are non-charged chelates with a C_3 symmetry, their spectra resemble those of facial tris(glycinato) complexes.

One of the present authors reported earlier that 1,4,7-triazacyclononane formed extremely stable complexes with some hexa-coordinating metal ions,[1] and that the stability constants of divalent metal chelates with its triacetate derivative could be measured polarographically.[2] This complexane-type ligand includes three nitrogen and three oxygen atoms as donors; therefore, a trivalent metal ion can form a non-charged chelate which has a C_3 symmetry. This paper is concerned with the preparation of iron(III), chromium(III), and cobalt(III) chelates with similar tripodal ligands, 1,4,7-triazacyclononane-*N,N',N''*-triacetate (tnta), 1,4,7-triazacyclodecane-*N,N',N''*-triacetate (tdta), and 2-(aminomethyl)-2-methyl-1,3-propanediamine-*N,N',N''*-triacetate (apta).



Experimental

Preparation of Ligands. Each ligand was synthesized by the carboxymethylation of the corresponding triamine, 1,4,7-triazacyclononane,[1,3,4] 1,4,7-triazacyclodecane,[3,4] or 2-(aminomethyl)-2-methyl-1,3-propanediamine,[5,6] which had all been prepared according to the methods in the literature. The procedures of all these carboxymethylations were like those to be described below. Triamine trihydrochloride (40 mmol) and excess chloroacetic acid (140 mmol) were dissolved in water (100 cm³). The mixture was heated to 45 °C, while the pH of the solution was maintained at 10 by adding lithium hydroxide intermittently. After consuming 400 mmol of alkali, the alkaline solution was refluxed for several hours. Then the pH of the solution was adjusted to about 2 with hydrochloric acid, and the mixture was evaporated almost to dryness. After having been washed throughly with methanol, the residue was twice recrystallized from aqueous ethanol. Yields: H_3tnta, 55%; H_3tdta, 35%; H_3apta·HCl, 30%.

Preparation of Chelates. *Iron(III) Chelates*: A solution of $Fe(NO_3)_3 \cdot 9H_2O$ (3.0 mmol in 5 cm³ of water) was added to a warm solution of the ligand (3.3 mmol in 5 cm³ of water). In the case of [Fe^{III}(tnta)], bright yellow needles were deposited almost quantitatively in a few minutes. The crystals were washed with water and ethanol. They were pure enough without further purification. Yield, 85%. [Fe^{III}(tdta)] and [Fe^{III}(apta)] were also obtained in a similar way, but the gentle evaporation of the mixture was needed to form the crystals. These were purified by recrystallization from aqueous ethanol. Yields, 30—50%.

Chromium Chelates: (A) Metallic chromium powder (10 mmol), water (10 cm³), and ligroin (40 cm³) were placed in a conical flask (100 cm³), into which concentrated HCl (3 cm³) was then slowly poured without stirring. After the bubbling reaction had then settled, the flask was put into a warm water bath (50 °C) for 15 min. A ligand solution (5 mmol in 25 cm³ of water) was degassed by boiling and added to the earlier bluish mixture. The excess acid was neutralized with solid $NaHCO_3$, and the ligroin was pipetted out. Then 30% H_2O_2 (2 cm³) was added to the bluish solution, which was heated several minutes. After the chromium hydroxide thus formed was filtered off, the filtrate was ice-cooled for several hours. Deep red crystals were slowly isolated in the case of [Cr^{III}(tnta)], but the tdta or apta chelate was obtained by evaporating the filtrate. The solid product was washed and recrystallized with aqueous ethanol. Yields, 30—50%.

(B) $[Cr^{III}(NH_3)_6]Cl_3$ (3.0 mmol) and the ligand (3.3 mmol) were dissolved in water (30 cm³), after which solution was refluxed for 8 h with stirring (if it did not turn wine red, a few drops of 5% NaOH were added and refluxing was continued). The little chromium hydroxide thus formed was filtered off while hot; then the filtrate was ice-cooled. Deep red crystals of [Cr^{III}(tnta)] were gradually formed, but the concentration of the solution was needed in the case of the tdta or the apta chelates. They were purified in a manner similar to the above. Yields, 30—50%.

Cobalt(III) Chelates: (A) $CoCl_2 \cdot 6H_2O$ (3.0 mmol) and H_3tnta (3.3 mmol) were dissolved in hot water (15 cm³), and 30% H_2O_2 (2 cm³) was added to the solution, which was then warmed for several minutes before being ice-cooled. Wine-red crystals of [Co^{III}(tnta)] were slowly deposited. By the evaporation of the filtrate, more chelate could be recovered. The crude complexes were recrystallized from hot water by adding ethanol and concentrating the solution. The product was washed thoroughly with aqueous ethanol. Yield, 70%. [Co^{III}(tdta)] and [Co^{III}(apta)] could also be prepared by the above procedure except for the addition of a little active charcoal, which had to be removed after the reaction. As these chelates were much more soluble in water than the tnta chelate, the filtrate was evaporated to solidify the complexes. They were recrystallized from aqueous ethanol. Yields, 30—50%.

(B) Cobalt chelates were prepared from the hexaamminecobalt(III) complex in the way that described in (B) for

chromium chelates, however, these reactions were relatively slow compared with that of the corresponding chromium complexes. Yields, 30—50%.

Facial Glycinato (gly) Complexes: [Cr^{III}(gly)$_3$]·3H_2O and [Co^{III}(gly)$_3$]·H_2O were prepared and purified according to the methods of Ley and Winkler[7] and Israily.[8] They were converted into anhydrous complexes by heating *in vacuo* at 130 °C.

Measurements. The electronic absorption spectra of metal chelates were measured on a Hitachi Model 124 recording spectrophotometer using a 10-mm cell. Sample cell of 50 mm or 100 mm was also used to measure the visible spectra of [Cr^{III}(gly)$_3$], [Co^{III}(gly)$_3$], and the iron(III) chelates, which were sparingly soluble in water. The absorption spectra of two glycinato complexes were measured anew under the same conditions, although they had already been reported.[8]

Results and Discussion

All these N_3O_3-type ligands could expel ammonia molecules from hexaamminechromium(III) or -cobalt(III) complexes. The replacement of ammonia with glycine also occurred in the chromium complex, but it was very difficult in the cobalt complex. Although the apta forms six-membered chelate rings upon coordination, it has great chelate effects. This ligand presumably has a very suitable structure for the octahedral coordination. Metal chelates of tnta seem to be the most stable and to have the smallest solubility in water. All these solid chelates were decomposed above 300 °C, leaving metal oxide. A tripodal ligand, apta, which contains three -NH-groups, did not react further with chloroacetate, and only this ligand was obtained as a monohydrochloride. Syntheses of similar triacetate derivatives of 1,4,8-triazacycloundecane and 1,5,9-triazacyclododecane were also attempted, but they failed to isolate any pure solids.

As expected, all the absorption spectra of the chromium(III) and cobalt(III) chelates with these tripodal ligands resemble those of the facial tris(glycinato) complexes. It is of interest that each apta chelate has the first absorption band of the highest energy.

The data of the elemental analysis and the absorption spectra are summarized in Table 1.

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 50 (12), 3415—3416 (1977)

The Formation and Extraction Equilibria of Several Manganese(II) β-Diketonates and Their Trioctyl-Phosphine Oxide Adducts

Tatsuya SEKINE, Ryokichi MURAI, Kazuhiko TAKAHASHI, and Shigehisa IWAHORI

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received July 6, 1977)

Synopsis. From the distribution ratio of manganese(II) between carbon tetrachloride containing various amounts of β-diketone (HA) and trioctylphosphine oxide (TOPO), and an aqueous 1 mol dm^{-3} perchlorate solution at 25 °C, the formation constants for the aqueous chelates and the TOPO adducts of the MnA_2, and the partition constants for the MnA_2 chelates were determined. The constants were then compared with those of other divalent metal ions.

Measurements have previously been made of the solvent extraction equilibria of four divalent metal ions with several β-diketones in carbon tetrachloride and also of the adduct formation equilibria of the extracted chelates with trioctylphosphine oxide (TOPO).[1-4] The present paper will report the results with manganese(II) under identical conditions and will compare the equilibrium constants thus obtained with those for the other divalent metal ions.

Experimental and Statistical

The experiments were performed at 25±0.3 °C in a manner similar to those used previously.[1-4] The initial organic phase was carbon tetrachloride containing various amounts of a certain β-diketone and TOPO, and the initial aqueous phase was a 1 mol dm^{-3} sodium perchlorate solution containing an acetate buffer (less than 0.01 mol dm^{-3}) or no buffer (when the β-diketone buffered) and 2×10^{-6} to 2×10^{-4} mol dm^{-3} of manganese(II). The two phases in a stoppered glass tube were placed on a rotating framework, agitated at 20 r.p.m., and then centrifuged. The metal content in each phase was determined by an atomic absorption method. The hydrogen-ion concentration was determined by potentiometry in stoichiometric units.

The distribution ratio was defined as

$$D = [\mathrm{Mn(II)}]_{\mathrm{org,total}}[\mathrm{Mn(II)}]_{\mathrm{total}}^{-1}, \quad (1)$$

where the subscript "org" and the lack of any subscript denoted those species in the organic and aqueous phases respectively. The β-diketones were denoted by HA and TOPO by L. The equilibrium constants employed were

$$K_a = [\mathrm{H^+}][\mathrm{A^-}][\mathrm{HA}]^{-1}, \quad (2)$$
$$K_d = [\mathrm{HA}]_{\mathrm{org}}[\mathrm{HA}]^{-1}, \quad (3)$$
$$\beta_n = [\mathrm{MnA}_n^{2-n}][\mathrm{Mn^{2+}}]^{-1}[\mathrm{A^-}]^{-n}, \quad (4)$$
$$K_{dm} = [\mathrm{MnA_2}]_{\mathrm{org}}[\mathrm{MnA_2}]^{-1}, \quad (5)$$
$$K_{ex} = [\mathrm{MnA_2}]_{\mathrm{org}}[\mathrm{H^+}]^2[\mathrm{Mn^{2+}}]^{-1}[\mathrm{HA}]_{\mathrm{org}}^{-2} \quad (6)$$
$$= (K_aK_d^{-1})^2K_{dm}\beta_2, \quad (7)$$
$$\beta_{n(\mathrm{org})} = [\mathrm{MnA_2L}_n]_{\mathrm{org}}[\mathrm{MnA_2}]_{\mathrm{org}}^{-1}[\mathrm{L}]_{\mathrm{org}}^{-n}. \quad (8)$$

The distribution ratio in the absence and in the presence of L can generally be written as

$$D_0 = [\mathrm{MnA_2}]_{\mathrm{org}}([\mathrm{Mn^{2+}}]+[\mathrm{MnA^+}]+[\mathrm{MnA_2}])^{-1}$$
$$= [\mathrm{MnA_2}]_{\mathrm{org}}[\mathrm{Mn^{2+}}]^{-1}(1+\sum\beta_n[\mathrm{A^-}]^n)^{-1}, \quad (9)$$
$$D = ([\mathrm{MnA_2}]_{\mathrm{org}}+[\mathrm{MnA_2L}]_{\mathrm{org}}+[\mathrm{MnA_2L_2}]_{\mathrm{org}})$$
$$\times([\mathrm{Mn^{2+}}]+[\mathrm{MnA^+}]+[\mathrm{MnA_2}])^{-1}$$
$$= D_0(1+\sum\beta_{n(\mathrm{org})}[\mathrm{L}]_{\mathrm{org}}^n). \quad (10)$$

The stability constants, β_n, were determined from the data obtained when the $[\mathrm{L}]_{\mathrm{org}}$ was zero or a certain constant value as a function of $[\mathrm{A^-}]$. The adduct formation constants were determined from the data obtained at a certain constant value of $[\mathrm{A^-}]$ as a function of $[\mathrm{L}]_{\mathrm{org}}$. The data were treated by a graphic method previously reported.[1-4] For the determination of the β_1 and β_2 of hexafluoroacetylacetonates, tributyl phosphate was used as the synergist instead of TOPO because TOPO was too effective to achieve suitable conditions.

Results and Discussion

The distribution ratio was measured at various pH values in the absence and in the presence of chromate ions. It was found that the distribution ratio reached a constant value in the absence of chromate if the −log $[\mathrm{H^+}]$ value was lower than 9 and if the agitation interval was shorter than 3 h. This D value was lower than that obtained in the presence of chromate. Thus, the D obtained after an agitation for less than 3 h at −log $[\mathrm{H^+}]$ values lower than 9 was concluded to show the distribution equilibrium of manganese(II) and no extraction of manganese(III).

The extraction curve with benzoylacetone was nearly a straight line with a slope of 2 when the distribution ratio was lower than 10^2; thus, only K_{ex} could be determined form these data. The curve with hexafluoroacetylacetone deviated only slightly from a straight line with a slope of 2 up to its maximum concentration, 0.1 mol dm^{-3}; thus, only K_{ex} and β_1 could be determined.

a) Since these values could not be determined, only the lower limit is assumed. b) Too high to be determined by the present experimental procedures; see text.

Figure 1 shows examples of representative extraction curves.

The extraction with these β-diketones was enhanced very much by TOPO. The adduct formation constants of the benzyltrifluoroacetonate were somewhat inaccurate, and those of the hexafluoroacetylacetonate could not be determined within the limits of experimental error. However, since the constants for the adducts with TBP determined instead of those with TOPO (log $\beta_{1(org)}$ =4.9 and log $\beta_{2(org)}$ =9.4) were rather similar to the corresponding zinc(II) TBP adducts (log $\beta_{1(org)}$ =5.5 and log $\beta_{2(org)}$ =8.5),[2] the values for the TOPO adducts of the manganese(II) hexafluoroacetylacetonate should be similar to those of the zinc(II) chelates.

The constants obtained are given in Table 1, together with the values previously obtained in our laboratory.[1-4]

From these data, it can be concluded that (i) the Irving-Williams natural order is well established among these β-diketonates, (ii) the K_{dm} values (showing the inverse of the aquophilic tendency when the molar volumes are similar[3]) of the manganese(II) chelates are much higher than those of the nickel(II) chelates and lower than those of the copper(II) chelates; they are approximately in the same order as the values of cobalt(II) and zinc(II) chelates, and (iii) the synergic enhancement with TOPO is similar to that of the zinc(II) chelates or greatest among the metal chelates in Table 1.

As is seen from the present results, these manganese(II) extractions, except for that with benzoylacetone, were poor for various practical purposes when the solvent was carbon tetrachloride. However, since the synergic enhancement was very great, the addition of a synergist such as TOPO and TBP or the use of oxygen-containing solvents such as 4-methyl-2-pentanone (MIBK), the extraction of this metal ion should become effective.

There have been reports on the extraction with these β-diketonates of manganese(II) that the extraction was partial with acetylacetone in benzene,[5] but that it was better when using butanol[6] or by the addition of hydrogen peroxide,[7] and that the extraction with benzoylacetone in benzene was more than 90% at pH values higher than 9.[5] Not much has been reported on the stability constants of manganese(II) β-diketonates which can be compared directly with the present results,[9] except that the log β_1 for the acetylacetonate in a 0.1 mol dm^{-3} medium was 4.01.[9]

Reactions of 4-Acyl-2-phenyl-1,3,4-oxadiazoline-5-thiones with Alcohols in the Presence of Metal Ions

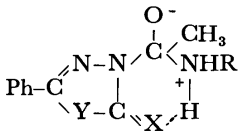
Hiroyuki FUKUDA, Takeshi ENDO, and Makoto OKAWARA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Nagatsuda, Midori-ku, Yokohama 227

(Received February 7, 1977)

Synopsis. 4-Acetyl- and 4-benzoyl-2-phenyl-1,3,4-oxadiazoline-5-thiones reacted with alcohols in the presence of metal ions to give the corresponding esters in good yields.

It is known that metal ions promote some reactions, such as the hydrolysis of α-amino acid esters[1,2] and 8-acyloxy-quinolines,[3,4] the aminolysis of thiol esters,[5] and the alcoholysis of 8-acyloxyquinolines[6] and *S*-(2-pyridyl) thio carboxylates.[7]

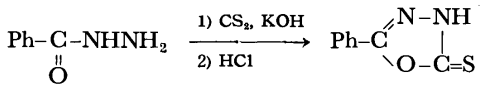


[I]

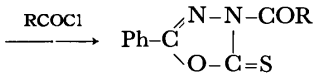
X=O, Y=O or S
X=S, Y=O or S

We have reported that 4-acetyl-2-phenyl-1,3,4-oxa-(thia)diazoline-5-ones(thiones) are 10^2—10^7 times more reactive than *p*-nitrophenyl acetate in the aminolysis by cyclohexylamine, unusually rapid aminolysis being due to the intramolecular base catalyzed reactions as illustrated in I.[8] However, the acetyl derivatives scarcely react with alcohols even under refluxing for several hours. This paper describes the reactions of 4-acyl-2-phenyl-1,3,4-oxadiazoline-5-thiones(IIIa, b) with alcohols in the presence of various metal ions, and with phenylmagnesium bromide.

2-Phenyl-1,3,4-oxadiazoline-5-thione(II), its 4-acetyl compound(IIIa) (yield 78%, mp 115—116 °C), and 4-benzoyl-2-phenyl-1,3,4-oxadiazoline-5-thione(IIIb) (yield 92%, mp 134.5—136 °C) were prepared by the method reported.[8]



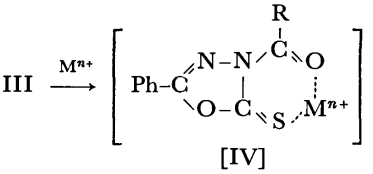
[II]



[IIIa]: R=CH_3 [IIIb]: R=Ph

When 4-acyl-2-phenyl-1,3,4-oxadiazoline-5-thiones-(III) is coordinated with metal ions as shown in IV, it might be subjected to nucleophilic attack on carbonyl carbon atom, as the consequence of activation of carbonyl group by such coordination. This reaction would also be remarkably accelerated if the final product (V) is mercaptide which is an excellent leaving group because of its high stability.

At first, the reactions of 2-phenyl-1,3,4-oxadiazoline-5-thione(II) with various metal ions were examined. Ag^+, Cu^{2+}, Hg^{2+}, and Pb^{2+} formed mercaptides (V) with II, but metal ions, such as Sn^{4+}, Mg^{2+}, Zn^{2+}, and Co^{2+}



[IV]

[V]

gave no mercaptides in methanol or acetonitrile at room temperature. The results are given in Table 1. The mercaptides obtained were confirmed by IR spectra and elemental analyses.

[V]

The reactions of III with alcohols in the presence of metal ions, which form mercaptides with II, were carried out at room temperature for 15 h. A white (mercury(II) salt) precipitate and a dark grey (silver salt) one were formed in a few minutes. In the case of copper(II) chloride, the reaction mixture was heterogeneous during the course of reaction because of the

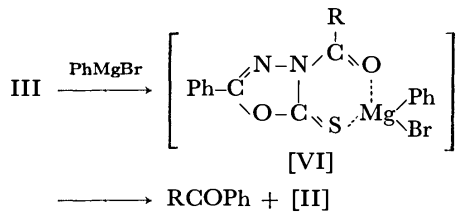
low solubility of copper(II) chloride. As shown in Table 2, all the metal ions, except Pb^{2+}, capable of mercaptide formation, are effective for the acceleration of these reactions, copper(II) chloride being the most remarkable. Lead nitrate did not promote the reaction since it is insoluble in acetonitrile. The precipitates were confirmed to be mercaptides consisting of 1 : 1 molar ratio of II and metal ions by elemental analyses and IR spectra. It was observed that the reactions of IIIa with benzyl alcohol in the presence of metal ions, such as Sn^{4+}, Mg^{2+}, Zn^{2+}, and Co^{2+} which can not form mercaptides with II proceed homogeneously. The results given in Table 3 indicate that tin(IV) salt is very effective for activation of IIIa. Thus, in the deacylation of III with alcohols, the coordination effect of some metal ions on acyl function might be much more important than the increasing stability of the leaving group. If the coordination (IV) assumed above is strong, the shift of C=O and C=S absorption bands of IIIa would be observed in IR spectra. However, no shift of the absorption bands was noted even in the solution of IIIa and Bu_2SnCl_2 or $Mg(ClO_4)_2$. The results indicate that even the weak interaction which can not be observed in IR spectra is also effective for promotion of these reactions.

We have investigated the reactions of III with phenylmagnesium bromide. III was allowed to react with equimolar amount of phenylmagnesium bromide



[VI]

⟶ RCOPh + [II]

in THF at *ca.* −20 °C for 4 h followed by hydrolysis to give the desired ketones. Thus, acetophenone and benzophenone were obtained from IIIa and IIIb in 76 and 78% yields, respectively. This is compatible with the above results.

Experimental

Mercaptides Formation of II with Metal Ions. A mixture of II (0.72 g, 4 mmol) and 4 mmol of metal ions in acetonitrile (30 ml) was stirred for 4 h at room temperature. The mercaptides obtained were filtrated and washed with dry acetonitrile three times, and dried at reduced pressure. The composition of mercaptides (Table 1) was determined by elemental analysis.

Reactions of III with Alcohols in the Presence of Metal Ions. Typical Procedure: A mixture of 0.88 g (4 mmol) of IIIa, 0.43 g (4 mmol) of benzyl alcohol, and 0.59 g (4 mmol) of copper(II) chloride in acetonitrile was stirred for 15 h at room temperature. The reaction mixture was poured into water, and the solution was extracted with ether. The extract was dried over anhydrous magnesium sulfate. After the solvent had been removed in a vacuum, the residue was distilled to afford 0.69 g of benzyl acetate quantitatively.

Reactions of III with Phenylmagnesium Bromide. Typical Procedure: To a solution of IIIa (1.76 g, 8 mmol) in dry THF (20 ml) was added a solution of phenylmagnesium bromide (1.45 g, 8 mmol) in dry THF (20 ml) over 30 min at −20 °C. After the mixture had been stirred at −20 °C for 4 h then at 25 °C for the same period, the reaction mixture was poured into water. The solution was extracted with ether, and the extract was dried over anhydrous magnesium sulfate. After removal of the solvent, the residue was distilled in a vacuum to afford 0.73 g (76%) of acetophenone.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 50 (12), 3419—3420 (1977)

Effect of a Polymer Ligand on Oxidation of Thiophenol Catalyzed by Cobaloximes

Hiroshi NISHIKAWA, Masanori KASAI, Ei-ichi TERADA, and Eishun TSUCHIDA

Department of Polymer Chemistry, Waseda University, Tokyo 160

(Received February 24, 1977)

Synopsis. The oxidation mechanism of thiophenol catalyzed by cobaloximes was deduced by spectroscopic measurement of the oxidation rate at various concentrations of the reactants, the reaction being a Michaelis-Menten type reaction. Addition of polymer ligands such as poly(4-vinylpyridine) and 4-vinylpyridine-styrene copolymer, stabilizing the intermediate similar to a Michaelis complex, resulted in an increase in the oxidation rate under low substrate concentration.

Studies have been reported on the catalytic action of polymer metal complexes,[1] but few detailed investigations have been carried out because of the complicated structure of the complexes and intermediates. Polymer ligands or substrates coordinate with cobaloximes, only in an axial position, making it easy to analyze the reaction mechanism since the structures of the complex coordinated with a polymer ligand or a substrate are confined.

The oxidation reaction of thiophenol catalyzed by cobaloximes is mild and enables us to apply spectroscopic analysis. This report deals with the reaction mechanism as deduced from kinetic studies, discussion being given on the effect of the polymer ligand on the catalytic action of cobaloximes.

Experimental

Materials. Commercial $CoCl_2 \cdot 6H_2O$, $Co(CH_3COO)_2 \cdot 4H_2O$, dimethylglyoxime ($dmgH_2$), pyridine (Py), thiophenol, and NaOH were used without further purification. Poly(4-vinylpyridine) (PVP) and 4-vinylpyridine-styrene copolymer (PPS) (styrene unit content 17%) were obtained by radical polymerization initiated by azobisisobutyronitrile purified by reprecipitation with ethyl acetate. The number-average molecular weights of PVP and PPS determined by the vapor pressure osmometry were 12800 and 18700, respectively. Methanol was distilled before use.

Preparation of Cobaloximes. $CoCl(dmgH)_2(Py)$ was prepared by the conventional method.[2] $CoCl(dmgH)_2(OH_2)$ was obtained through the reaction of 4.2 mmol NaOH in ethanol and aeration, and recrystallized from ethanol. Found: C, 28.0; N, 16.1; H, 4.8%. Calcd for $C_8H_{14}N_4O_4CoH_2OCl$: C, 28.0; N, 16.3; H, 4.7%.

Analysis of Oxidation Reaction. Air oxidation of thiophenol in alkaline methanol solution (containing 3×10^{-4} M NaOH) in the presence of cobaloximes gave diphenyl disulfide (DPS). An increase of absorbance at 310 nm, at which the difference of absorbance between the reactant and product (DPS) was large enough to detect a small change of the concentration of the product, gave the oxidation rate in a steady state under the addition of excess substrate using $CoCl(dmgH)_2(Py)$ as a catalyst. The rate was represented by the concentration of phenylthio radical produced per second. The formation of the Co(II) complex under an atmosphere of nitrogen accompanied by thiophenol oxidation and that of the air oxidation of the Co(II) complex were studied from a visible absorption spectral change. The relationsip between the oxidation rate and the added polymer ligand concentration was derived in a similar way using $CoCl(dmgH)_2(OH_2)$ as a catalyst and Py, PVP, and PPS as an axial ligand respectively. The concentration of the polymer ligand is indicated in 4VP unit mole per liter.

Results and Discussion

Reaction Mechanism of Thiophenol Oxidation. The following mechanisms were postulated for the thiol oxidation catalyzed by metals.[3]

$$M^{n+} + \text{thiophenol}^- \longrightarrow M^{(n-1)+} + \text{thiophenol}^*$$

$$M^{(n-1)+} \xrightarrow{O_2} M^{n+} \qquad 2\text{thiophenol}^* \longrightarrow \text{Pr} \qquad (1)$$

The oxidation rate determined by the measurement of oxygen uptake with Warburg's manometer was in agreement with that determined by spectroscopic measurement. This indicates that thiophenol was converted quantitatively into DPS in the present oxidation system.

The oxidation rate V is proportional to the catalyst concentration. The oxidation rate is proportional to the substrate concentration in the low substrate concentration range, approaching a certain value with increase in concentration (Fig. 1). This can be explained by assuming the existence of the intermediate complex consisting of a catalyst and a substrate. The linear relationship between the reciprocal of the oxidation rate, $1/V$, and that of the substrate concentration, $1/[S]$, suggests the following reaction mechanism, where $(Co)=Co(dmgH)_2XY$.

$$(Co^{III}) + C_6H_5\text{–}S^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} (Co^{III})\,C_6H_5\text{–}S^- \xrightarrow{k_2}$$

$$(Co^{II}) + C_6H_5\text{–}S^*, \qquad (Co^{II}) \xrightarrow{k_3} (Co^{III}),$$

$$2C_6H_5\text{–}S^* \longrightarrow C_6H_5\text{–}S\text{–}S\text{–}C_6H_5 \qquad (2)$$

The change in visible spectra with time after the addition of the substrate to the solution containing $CoCl(dmgH)_2(Py)$ indicates the formation of the Co(II) complex with absorption maximum at 390 nm, reaching equilibrium after *ca.* 30 min. Reaction under nitrogen atmosphere is regarded to turn the Co(III) complex entirely into the Co(II) complex, causing an increase in the absorption at 390 nm about 1.5 times the equilibrium value in the air. The formation rate of Co(II) complex under nitrogen atmosphere at initial stage is proportional to the complex concentration. The decreasing rate in air of excess Co(II) complex formed by the thiophenol oxidation under a nitrogen atmosphere is also proportional to the complex concentration. These results strongly support the reaction mechanism describ-

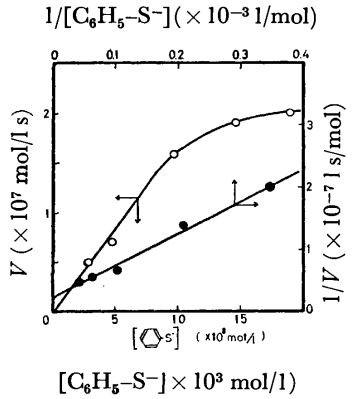

Fig. 1. Relationship between oxidation rate *(V)* and concentration of substrate ([C_6H_5–S^-]). [Co]=3.16×10^{-5} mol/l, [NaOH] =3×10^{-4} mol/l, solvent: methanol, at 22 °C.

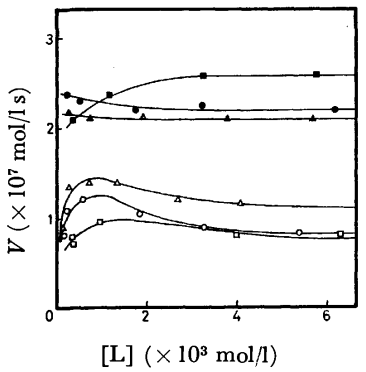

Fig. 2. Relationship between oxidation rate *(V)* and concentration of ligand ([L]). [Co]=3.16×10^{-5} mol/l, [NaOH] =3×10^{-4} mol/l, solvent: methanol, at 15 °C, [C_6H_5–S^-]=3.25×10^{-3} mol/l for ○, △, □, and 3.25×10^{-2} mol/l for ●, ▲, ■, L=Py: □, ■, PVP: △, ▲, and PPS: ○, ●.

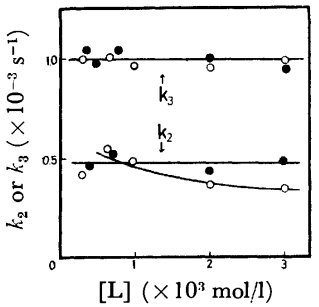

Fig. 3. Values of k_2 and k_3. [Co]=3.16×10^{-5} mol/l, [C_6H_5–S^-]=3.25×10^{-2} mol/l, [NaOH] =3×10^{-4} mol/l, solvent: methanol, at 15 °C, L=Py: ● or PVP: ○.

ed in Eq. 2. Equation 2 leads to the following equation for the oxidation rate at steady state.

$$1/V = [A + B/[C_6H_5\text{–}S^-]]/[Co]$$
$$A = (k_2+k_3)/k_2k_3, \quad B = (k_{-1}+k_2)/k_1k_2,$$
$$V = d[C_6H_5\text{–}S^*]/dt \qquad (3)$$

This equation represents the linear relationship between $1/V$ and $1/[C_6H_5\text{–}S^-]$ as shown in Fig. 1. The rate constants k_2 and k_3 can be determined by spectroscopic measurements of the Co(II) complex formation under nitrogen atmosphere and of the decrease of the Co(II) complex in air, respectively.

Effect of Polymer Ligand. Variations in the thiophenol oxidation rate with the ligand concentration, using $CoCl(dmgH)_2(OH_2)$ as a catalyst and Py, PVP, and PPS as an axial ligand are shown in Fig. 2.

The oxidation rate-ligand concentration curves obtained in lower thiophenol concentration have a maximum. The formation constant K of $CoCl(dmgH)_2(OH_2)$ with PPS is about 1×10^5 in *N,N*-dimethylformamide.[4] If we consider the formation constant in methanol to be almost the same as that in *N,N*-dimethylformamide, almost all the complexes have a ligand at the ligand concentration of the maximum point. The coordination of the axial ligand makes the complex more active as a oxidation catalyst.

The oxidation of thiophenol by $Co\cdot O_2$ complexes scarcely occurs in this system since one axial position of the catalyst,[5] where O_2 should coordinate, is occupied by a ligand such as Py or PVP.

In higher substrate concentration, for which the second term of Eq. 3 is negligible, only the value of A, *i.e.*, $(k_2+k_3)/k_2k_3$, determines the oxidation rate V. Figure 3 shows that the k_2 value of the Py system is larger than that of the polymer system, though k_3 value has almost the same value in both systems. This causes the Py system to have a larger oxidation rate than that of polymer systems. In the polymer system the k_2 value decreases with increase in ligand concentration. This can be explained in terms of steric hindrance by the polymer chain which prevents elimination of the substrates activated by the complex in polymer domain. The decrease in k_2 value with increase in the ligand concentration is in line with the decrease in the oxidation rate of the polymer system shown in Fig. 2.

Under conditions of the lower substrate concentration, where the second term in Eq. 3 is not negligible, the oxidation rate V is affected by the value of B. The faster oxidation rate in the polymer system under the lower substrate concentration indicates that B has a smaller value in the polymer systems than in the Py system. This is because the polymer domain stabilizes the reaction intermediate complex, and prevents the substrate from elimination, thus making k_{-1} value decrease.

It is concluded that the addition of polymer ligands can raise the oxidation activity of the catalyst at a lower substrate concentration region.

Reduction of Selenoxides with Thione Reagents

Seizo TAMAGAKI, Isao HATANAKA, and Seizi KOZUKA

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received March 14, 1977)

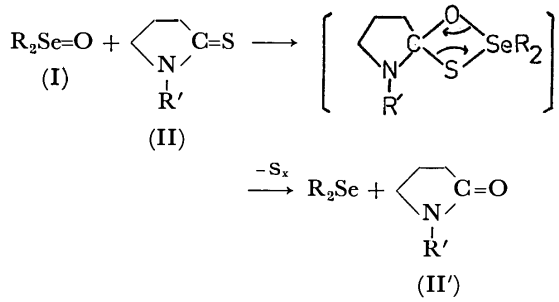
Synopsis. The reaction of selenoxides with various thione compounds such as carbon disulfide, thioamides and thioureas was found to give selenides. The reaction mechanism was discussed.

It is widely known that sulfoxides are deoxygenated by various powerful reducing reagents.[1] Carbon disulfide, a weak reducing reagent, can never deoxygenate dialkyl and diaryl sulfoxides. Selenoxides are more basic and reactive as compared with analogous sulfur compounds due to the more polar nature of the Se=O bonding than the S=O bonding. Thus, diphenyl selenoxide is more basic and readily reducible by phosphines than the most basic sulfoxide, DMSO.[2,3]

However, few reports have been given so far on the chemical behavior of selenoxides toward weak reducing reagents. We report here the results of the reactions of diphenyl and dibenzyl selenoxides with various thione reagents.

Results and Discussion

Diphenyl and dibenzyl selenoxides (I) reacted at room temperature with equimolar amounts of thioamides such as 1-phenyl- and 1-methylpyrrolidine-2-thiones (II-Ph, -Me) and *N,N*-dimethylthioacetamide to give the selenides and the corresponding amides with extrusion of elemental sulfur (Table 1). The results indicate that, in marked contrast to sulfoxides, the oxides undergo a facile deoxygenation even with agents having weak reducing ability.



In a different way, selenoxides were readily reduced with carbon disulfide to give the corresponding selenides and chloroform-insoluble colorless precipitates without deposit of elemental sulfur. The results are summarized in Table 2. The reaction of dibenzyl selenoxide with small amounts of carbon disulfide or phosphorous pentasulfide in chloroform produced dibenzyl selenide

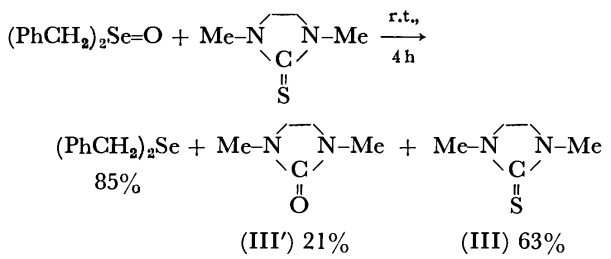
$(Me_2N)_2C=S$	1	10 min	70	0	26[b]

a) [Thione]/[P]. b) Unidentified substances obtained.

and substantial amounts of precipitate, P (dec 115—117 °C). The elemental analysis of the precipitate gave no constant value, within analytical accuracy, with samples taken from different runs, but mostly agreed with a structure carrying five oxygen atoms per one dibenzyl selenide skeleton. This was further supported by the mass spectrum exhibiting the molecular peak at *m/e* 341 arising probably from $(PhCH_2)_2SeO_5$ (33% of base). The detailed structure is still not clear, but it involves $(PhCH_2)_2SeO_5$ as the most important species.

$$(PhCH_2)_2Se{=}O \xrightarrow[P_2S_5]{CS_2 \text{ or}} (PhCH_2)_2Se + \underset{(P)}{(PhCH_2)_2SeO_5}$$

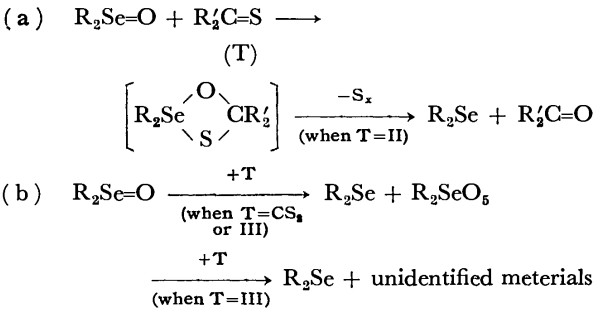
The results given in Table 1 indicate that the reaction of dibenzyl selenoxide with an equimolar amount of thiourea, 1,3-dimethylimidazolidine-2-thione (III), gave only about 20% yield of the corresponding urea derivative (III′) together with the selenide, accompanied by considerable recovery of the starting thione compound (III). The same is true for tetramethylthiourea. The fact that considerable amounts of the thione compounds were recovered unchanged implies that two reactions



take place competitively: one producing dibenzyl selenide and the carbonyl compound, and the other catalytically affording the same selenide and, probably, the precipitate, which then reacts rapidly with the remaining thiourea to give the selenide. The fact, when the precipitate (P) itself was allowed to react with thioureas, dibenzyl selenide and a structure-unidentified product were obtained without being accompanied by the formation of the corresponding carbonyl compounds. The results are given in Table 3.

$$\underset{(P)}{(PhCH_2)_2SeO_5} + III \xrightarrow[10\,min.]{r.t.,} (PhCH_2)_2Se + \text{unidentified product}$$

It thus appears that, with thioamides having a labile thiocarbonyl group, Path a in Scheme 1 shown below is preferable for reduction and Path b, if operative, would be only minor, since the thioamides are almost completely consumed during the course of reaction. On the other hand, with carbon disulfide bearing stable C=S groups, the reaction proceeds mainly *via* Path b where no release of elemental sulfur is observed. The behavior of thioureas is intermediate between that of thioamides and carbon disulfide.



Scheme 1.

Experimental

Reaction of Diphenyl and Dibenzyl Selenoxides with Thione Compounds. A typical experimental procedure is as follows: 1-Phenylpyrrolidine-2-thione (177 mg, 1 mmol) was added at room temperature to a $CHCl_3$ (20 ml) solution of dibenzyl selenoxide (277 mg, 1 mmol). The reaction was followed by TLC. After the reaction was complete, evaporation of the solvent followed by preparative thin-layer chromatography of the residue gave dibenzyl selenide, 1-phenylpyrrolidone and the recovered thione in 92, 82 and 3% yields, respectively.

Some Physical Properties of the Precipitate (P). Mp: 115—117 °C; IR (KBr): 1100 (strong) cm^{-1}; NMR (d_6-DMSO): δ=7.27 (s, 10H), 4.22 (q, 4H) ppm from external TMS; Elemental analysis: Found: (1) C, 49.16; H, 4.58. (2) C, 48.70; H, 4.66. (3) C, 49.83; H, 4.73%. Calcd for $C_{14}H_{14}O_5Se$: C, 49.27; H, 4.13. MS: 342 (M^+), 262. Calcd M: 342 assuming Se=80.

Reaction of Dibenzyl Selenoxide with Carbon Disulfide. Dibenzyl selenoxide was added at room temperature to 20 ml of a $CHCl_3$ solution containing CS_2 (238 mg, 3 mmol). After 12 h, a colorless precipitate was filtered off. The filtrate was concentrated. Preparative TLC of the residue gave dibenzyl selenide in 74% yield.

(Received May 4, 1977)

Synopsis. 2,2′-Anhydro-1-(4′,6′-*O*-benzylidene-3′-*O*-methylsulfonyl-β-D-mannopyranosyl)urasil, prepared smoothly from β-D-glucopyranosyluracil in three steps, was converted into the corresponding unsaturated nucleoside in a good yield by the action of sodium iodide. The unsaturated nucleoside was then debenzylidenated with acid to afford the title compound.

Our recent attention has focussed on the synthesis of unsaturated sugars[1] and nucleosides.[2] In our previous publications,[2] a new synthetic route of the 2′,3′-unsaturation of thymine pyranoside *via* 2,2′-anhydronucleoside has been described, its reaction mechanism has also been discussed. We wish now to report an application of this reaction to the uracil nucleoside series, which can be considered as potent intermediates for the synthesis of such antibiotics[3] as blasticidin S and amicetin.

β-D-Glucopyranosyluracil (I)[4] was converted into the benzylidene derivative (II) in a 68% yield by treatment with benzaldehyde in the presence of zinc chloride. The subsequent sulfonylation of II with methanesulfonyl chloride in pyridine proceeded smoothly to afford a new crystalline product, the 2′,3′-di-*O*-mesyl derivative (III) (89%). Anhydronucleoside (IV) was prepared in an 89% yield by the treatment of III with an equivalent amount of sodium benzoate in *N,N*-dimethylformamide (DMF) at an elevated temperature.

The refluxing of IV with a 20-fold excess of sodium iodide and zinc dust in DMF for 2 h gave the unsaturated nucleoside (V) in a 33% yield. The treatment of IV with a 20-fold excess of sodium iodide in DMF for 1 h under reflux gave V in a 37% yield, along with about a 40% recovery of the starting material. When the reaction time of this reaction was prolonged until 4 h, the unsaturated nucleoside (V) was obtained in a 67% yield. Thus, the unsaturation was performed successfully in the uracil nucleoside series using the anhydronucleoside as a substrate. The structure of V could be easily confirmed by NMR. The vinylic protons at δ 6.50 and 5.70 with the characteristic coupling constant of $J_{2',3'}$= 10 Hz appeared in the spectrum.

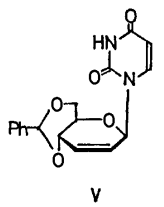
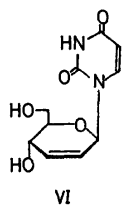
III R=Ms

IV



V



VI

After several screenings, DMF was found to be the most suitable solvent for the elimination reaction.

Compound (V) was treated with 80% aqueous acetic acid for 15 min under reflux to give a new crystalline product, VI, in a 50% yield. The overall yield of VI from I was 18%.

Experimental

All the melting points are uncorrected. The NMR data were recorded at 100 MHz with a JEOL PS-100 instrument.

1-(4′,6′-O-Benzylidene-β-D-glucopyranosyl)uracil (II). A suspension of 4 g of β-D-glucopyranosyluracil (I) and 13 g of freshly melted zinc chloride in 70 ml of benzaldehyde was shaken for 30 h. The resulting clear solution was stirred into ether (500 ml). The precipitate thus formed was filtered and then recrystallized from methanol to afford 3.6 g (68%) of the benzylidene nucleside (II) as colorless needles; mp 278—281 °C (dec);[5] $[\alpha]_D^{22}$ −8° (*c* 1.0 in DMF). Found: C, 55.91; H, 5.07; N, 7.56%. Calcd for $C_{17}H_{18}N_2O_7$: C, 56.35; H, 5.07; N, 7.73%.

1-(4′,6′-O-Benzylidene-2′,3′-di-O-methylsulfonyl-β-D-glucopyranosyl)uracil (III). Into a cooled (0 °C) suspension of the benzylidene nucleoside (II) (11 g) in pyridine (450 ml), we stirred drop by drop methanesulfonyl chloride (8.5 ml). The reaction mixture was kept for 15 h at room temperature. The subsequent addition of the reaction mixture, which had been concentrated to a small volume, into ice water (2 l) with vigorous stirring gave a colored precipitate. The subsequent crystallization of the precipitate from acetone–ethanol afforded 14 g (89%) of III; mp 189—192 °C (dec); $[\alpha]_D^{22}$ −12° (*c* 1.0 in DMF); UV (EtOH) λ_{max} 255 nm (log ε 3.74); NMR [$(CD_3)_2SO$] δ=7.80 (1H, d, $J_{5,6}$= 8.8 Hz, H-6), 7.38 (5H, C_6H_5), 6.20 (1H, broad d, $J_{1',2'}$= 7.5 Hz, H-1′), 5.68 (1H, d, $J_{5,6}$=8.8 Hz, H-5), 5.66 (1H, s, PhCH), 5.15—5.40 (2H, m, H-2′ and -3′), 3.30 (4H, m, H-4′, -5′, -6′, and -6″), 3.16 (3H, s, CH_3SO_2), and 3.10 (3H, s, CH_3SO_2). Found: C, 44.01; H, 4.25; N, 5.41%. Calcd for $C_{19}H_{22}N_2O_{11}S_2$: C, 44.26; H, 4.07; N, 5.33%.

2,2′-Anhydro-1-(4′,6′-O-benzylidene-3′-O-methylsulfonyl-β-D-mannopyranosyl)urasil (IV). A mixture of the methanesulfonylated nucleoside (III) (13.5 g, 26 mmol) and sodium benzoate (4.6 g, 32 mmol) in DMF (500 ml) was heated at 120—130 °C with stirring for 1.5 h. The reaction mixture was then vigorous stirred into ice water (4 l) to give a crystalline product. Recrystallization from acetone afforded 9.8 g (89%) of the anhydronucleoside (IV); mp 215—216 °C (dec); $[\alpha]_D^{22}$ −130° (*c* 0.5 in DMF); UV (EtOH) λ_{max} 225 and 245 nm (log ε 3.90 and 3.89); NMR [$(CD_3)_2SO$]

δ=7.95 (1H, d, $J_{5,6}$=8 Hz, H-6), 7.40 (5H, C_6H_5), 6.13 (1H, $J_{1',2'}$=3 Hz, H-1'), 5.90 (1H, d, $J_{5,6}$=8 Hz, H-5), 5.77 (1H, s, PhCH), 5.55 (1H, q, $J_{2',3'}$=5 Hz, $J_{3',4'}$=10 Hz, H-3'), 5.35 (1H, q, $J_{1',2'}$=3 Hz, $J_{2',3'}$=5 Hz, H-2'), 3.8—4.3 (4H, m, H-4', -5', -6', and -6"), 3.22 (3H, s, CH_3SO_2). Found; C, 50.87; H, 4.26; N, 6.60%. Calcd for $C_{18}H_{18}N_2O_8S$: C, 51.18; H, 4.27; N, 6.64%.

General Procedure for the Unsaturation of the Anhydronucleoside (IV). A mixture of IV (210 mg, 0.5 mmol) and sodium iodide (1.5 g, 10 mmol) in the appropriate solvent (DMF, hexamethylphosphotriamide, or 1,3-dimethyl-2-imidazolidinone,[6] 20 ml) was refluxed for an appropriate time with stirring. The addition of water (30 ml) to the reaction mixture while it was hot gave the crystalline starting material (IV), which was identified by IR. To the filtrate we then added ethyl acetate (50 ml), and the organic layer was washed with thiosulfate and water, dried over Na_2SO_4, and evaporated. The crystals thus obtained were recrystallized from acetone to afford *1-(4',6'-O-benzylidene-2',3'-dideoxy-β-*D-erythro-*hex-2'-enopyranosyl)uracil (V)*; mp 228—230 °C (dec); $[\alpha]_D^{22}$ +32° (*c* 0.75 in DMF); UV (EtOH) λ_{max} 257 nm (log ε 3.75); NMR [$(CD_3)_2SO$] δ=7.45 (1H, d, $J_{5,6}$=8 Hz, H-6), 7.40 (5H, C_6H_5), 6.52 (1H, d, $J_{1',2'}$=3 Hz, H-1'), 6.50 (1H, d, $J_{2',3'}$=10 Hz, H-3'), 5.70 (1H, d, $J_{2',3'}$=10 Hz, H-2'), 5.70 (1H, s, PhCH), 5.65 (1H, d, $J_{5,6}$=8 Hz, H-5), 3.7—4.5 (4H, m, H-4', -5', -6', and -6"). Found: C, 61.24; H, 4.84; N, 8.25%. Calcd for $C_{17}H_{16}N_2O_5 \cdot 1/4H_2O$: C, 61.29; H, 4.96; N, 8.41%.

*1-(2',3'-Dideoxy-β-*D-erythro-*hex-2'-enopyranosyl)uracil (VI).* A mixture of V (140 mg) in 80% aqueous acetic acid (10 ml) was refluxed for 15 min; then, after cooling, the clear solution was evaporated to a syrup. Preparative TLC (silica gel, 10 v/v% EtOH–benzene) of the syrup afforded a pure product (VI) (50 mg, 50%); mp 161—163°; $[\alpha]_D^{22}$ +84° (*c* 0.33 in EtOH); NMR [$(CD_3)_2SO$] δ=7.34 (1H, d, $J_{5,6}$=9 Hz, H-6), 6.28 (1H, q, $J_{1',2'}$=$J_{1',3'}$=2.0 Hz, H-1'), 6.15 (1H, dt, $J_{2',3'}$=10 Hz, $J_{1',3'}$=$J_{3',4'}$=2.0 Hz, H-3'), 5.64 (1H, dt, $J_{2',3'}$=10 Hz, $J_{1',2'}$=$J_{2',4'}$=2.0 Hz, H-2'), 5.62 (1H, d, $J_{5,6}$=9 Hz, H-5), 4.04 (1H, m, H-4'), and 3.2—3.8 (3H, m, H-5', -6', and -6"). Found: C, 50.35; H, 5.05; N, 11.79%. Calcd for $C_{10}H_{12}N_2O_5$: C, 50.0; H, 5.04; N, 11.66%.

The authors wish to thank Professor Sakurai, Tohoku University, for providing the 1,3-dimethyl-2-imidazolidinone.

The Synthesis of the (Diacetylmethyl)tropylium Ion and Its Transformation to the 3-Acetyl-2-methylfurotropylium Ion

Koichi KOMATSU, Satoshi TANAKA, Seiki SAITO,* and Kunio OKAMOTO

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

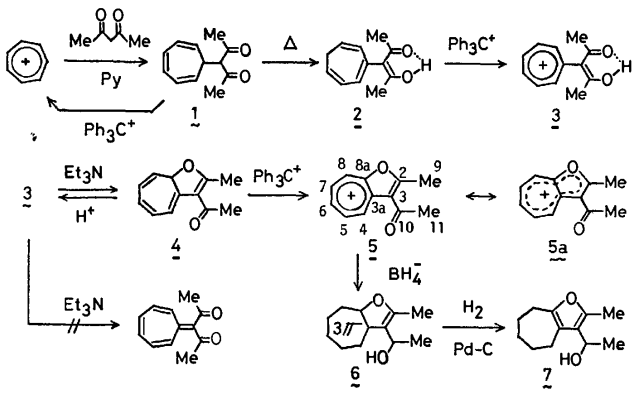
(Received May 17, 1977)

Synopsis. The intramolecularly hydrogen-bonded cation, the (diacetylmethyl)tropylium ion (**3**), has been synthesized. The deprotonation of **3** does not afford 8,8-diacetylheptafulvene, but does give the intramolecularly cyclized cycloheptatriene derivative, which can be transformed to the peripheral ten-π-electron cation, **5**; **5** is characterized by means of ^{13}C NMR spectroscopy.

The deprotonation of substituted tropylium ions is known as the facile method to generate 8-substituted heptafulvenes.[1] Especially, the tropylium ion with an electron-withdrawing group at the α-carbon of the substituent can be regarded as a potential precursor for the stable 8-substituted heptafulvene. Here we wish to report on the synthesis of the (diacetylmethyl)tropylium ion (**3**), the "formal" precursor of 8,8-diacetylheptafulvene, and its transformation to the new ten-π-electron cation, the 3-acetyl-2-methylfurotropylium ion (**5**).

The whole reaction sequence is shown in Scheme 1. The reaction of the trityl cation with the 3-substituted cycloheptatriene, **2**, successfully afforded the **3** cation in a good yield, whereas the reaction with the 7-substituted cycloheptatriene, **1**, was found only to regenerate the unsubstituted tropylium ion in an 81.3% yield. The perchlorate of the **3** cation consists of brownish yellow crystals, stable in air. The IR and NMR spectral data indicated that the diacetylmethyl group of **1** is in the keto form, whereas those of **2** and **3** are in the intramolecularly hydrogen-bonded enol form. The spectrophotometric titration carried out in 23% EtOH indicated the pK_a value for the **3** cation to be 0.72.

As is suggested by the considerable acidity of **3**, a facile deprotonation occurred when **3** was treated with triethylamine in dichloromethane. However, contrary to what was expected, the product (a pale orange oil) was not 8,8-diacetylheptafulvene, but the cycloheptatriene derivative, **4**, that was possibly formed by the intramolecular nucleophilic attack of the enolate anion on the positively charged seven-membered ring.[2] The cyclization product, **4**, is somewhat unstable at room temperature and can be quantitatively reconverted to the **3** cation when treated with proton acids. On the other hand, the hydride abstraction of **4** with the trityl cation gave the perchlorate of the **5** cation as an air-stable, greenish-blue powder.



Scheme 1.

The structure of **5** was confirmed by the chemical transformations (**5**→**6**→**7**) shown in Scheme 1. The hydrogenated product, **7**, exhibited the UV spectrum characteristic of the substituted furans.[3] In the NMR spectrum of **5**, the one-proton multiplet resonating in the lowest field is assigned to H-4, taking into account the diamagnetic anisotropy effect of the acetyl-carbonyl group; therefore, the averaged conformation of the acetyl group appears to be almost coplanar to the molecular plane. The UV-visible spectrum of **5** exhibits the longest wavelength absorption at 634 nm (log ε, 2.46). A comparison of the UV-visible spectrum of **5** with that of 1-acetyl-2-methylazulene[4] suggests the resemblance of the electronic state of **5**, with its furan oxygen donating two unshared 2p electrons to the conjugated π-system, to that of the corresponding azulene derivative. Thus, there seems to be some contribution of the structure, **5a**, to the resonance hybrid of **5**.

Table 1. ^{13}C NMR data for **4** and **5** in CD_3CN

Carbon	δ (ppm from TMS)		Charge density
	4	**5**	**5**
2	178.7 s	176.9 s	+0.2982
3	116.3 s	122.6 s	−0.0834
3a	138.9 s	149.8 s	+0.1029
4	127.2 d	145.9 d	+0.1358
5	132.7 d	147.2 d	+0.1120
6	123.6 d	151.0 d	+0.1307
7	116.7 d	145.4 d	+0.1162
8	111.0 d	136.9 d	+0.1244
8a	84.7 d	165.2 s	+0.1357
9	17.2 q	17.6 q	—
10	194.0 s	194.3 s	+0.4431
11	31.1 q	31.9 q	—

The ^{13}C NMR spectral data for **5** are shown in Table 1, together with those for the neutral compound, **4**. The signal assignment for **5** was made on the basis of the peak multiplicity observed in the off-resonance spectrum and on that of the charge density obtained by the simple HMO calculation using the following parameters: $h_{\dot{O}}=2.0$, $k_{\dot{O}}=\sqrt{2}$; $h_{\ddot{O}}=2.0$, $k_{\ddot{O}}=0.6$. Each carbon in the seven-membered ring as well as the C-3 in the fused furan ring are shown to be definitely shifted to a lower

field upon transformation from **4** to **5**, corresponding to the introduction of the positive charge. Furthermore, it is indicated that the general trend in the π-electron distribution of **5** also resembles that of benzofuran,[5] by a comparison of the ^{13}C chemical shifts observed and reported for these compounds.

Experimental

(Diacetylmethyl)tropylium Perchlorate (3 ClO_4^-). The reaction of tropylium fluoroborate (7.12 g, 40.0 mmol) with acetylacetone (4.00 g, 40.0 mmol) in dry pyridine (80 ml) afforded 7-(diacetylmethyl)cycloheptatriene (**1**)† (7.30 g, 96.0%) as a white powder after a usual work-up; mp 122.1—123.1 °C (from benzene); IR (KBr) 1720 cm^{-1} (C=O); NMR ($CDCl_3$) δ=2.13 (s, 6, CH_3), 2.83 (dt, 1, H^7), 3.91 (d, 1, $CHAc_2$), 5.10 (dd, 2, $H^{1,6}$), 6.20 (m, 2, $H^{2,5}$), and 6.65 ppm (t, 2, $H^{3,4}$). The cycloheptatriene, **1** (2.18 g, 11.5 mmol), was sealed in an ampoule under a vacuum and heated at 155 °C for 2.5 h. Purification by preparative TLC (benzene–ether (97: 3)/SiO_2) and successive vacuum distillation gave 3-(diacetylmethyl)cycloheptatriene (**2**) (1.12 g, 51.4%) as white crystals; bp 89.5 °C/ 0.3 Torr; IR (KBr) 1600 cm^{-1} (C=O···HO); NMR (CCl_4) δ=2.00 (s, 6, CH_3), 2.33 (t, 2, CH_2), 5.38 (dt, 2, $H^{1,6}$), 5.97 (d, 1, H^2), 6.13 (dd, 1, H^5), 6.45 (d, 1, H^4), and 16.50 ppm (s, 1, OH). A mixture of trityl perchlorate (4.38 g, 12.8 mmol) and **2** (2.42 g, 12.7 mmol) in dry acetonitrile (10 ml) was stirred at room temp for 20 min and at 60 °C for 15 min. The addition of ethyl acetate (50 ml) and ether (20 ml) afforded **3** ClO_4^-† (3.14 g, 85.6%); mp 137.1—139.2 °C (dec); UV $\lambda_{max}^{MeCN-10\%HCl(1:1)}$ 222 nm (log ε, 4.42), 263 (3.86), 302 (3.68), and 425 (3.68); IR (KBr) 3200—2800 (O–H···O=C), 1598 (C=O···HO), and 1080 cm^{-1} (ClO_4^-); NMR (CF_3COOH) δ=2.23 (s, 6, CH_3) and 9.28 ppm (s, 6, $C_7H_6^+$). The pK_a value was determined by the spectrophotometric method described previously.[6]

3-Acetyl-2-methylfurotropylium Perchlorate (5 ClO_4^-). The reaction of triethylamine (0.399 g, 3.95 mmol) with **3** ClO_4^- (1.00 g, 3.47 mmol) in dichloromethane (80 ml) for 30 min at room temp and a subsequent work-up yielded **4** (0.705 g, 107%); UV λ_{max}^{MeCN} 229 nm (log ε, 4.22), 286 sh (3.76), and 320 (3.80); IR (neat) 1655 cm^{-1} (conj. C=O); 100 MHz NMR ($CDCl_3$; the numbering is the same as in **5**) δ=2.33 (s, 3, CH_3), 2.41 (s, 3, $COCH_3$), 4.85 (m, 1, >CH–), 5.15 (dd, 1, H^8), 6.00 (ddd, 1, H^7), 6.23 (ddt, 1, H^6), 6.39 (dm, 1, H^4), and 6.58 ppm (ddm, 1, H^5). The reaction of trityl perchlorate (1.43 g, 4.18 mmol) with **4** (0.720 g, 3.81 mmol) in dry acetonitrile (3 ml) for 35 min at room temp gave, after the addition of ethyl acetate and ether, **5** ClO_4^-† (0.907 g, 82.9%) as a greenish blue powder; mp 140.0—141.1 °C (dec); UV λ_{max}^{MeCN} 218 nm (log ε, 4.39), 260 (4.43), 363 (3.85), 590 sh (2.17), and 634 (2.46); IR (KBr) 1660 (conj. C=O) and 1090 cm^{-1} (ClO_4^-); NMR (CF_3COOH) δ=3.00 (s, 3, CH_3), 3.30 (s, 3, $COCH_3$), 9.15 (m, 4, H^{5-8}), and 10.20 ppm (m, 1, H^4).

Reduction of 5. A solution of **5** ClO_4^- (0.848 g, 2.96 mmol) in acetonitrile (50 ml) was added, dropwise, to a stirred suspension of sodium borohydride (0.179 g, 4.73 mmol) in acetonitrile (15 ml). After 1 h at room temp, the orange solution was worked up to give a crude product (0.668 g), from which **6** (0.274 g, 48.7%) was isolated by means of preparative TLC (benzene–ether (4: 1)/SiO_2); IR (neat) 3360 cm^{-1} (OH); NMR (CCl_4) δ=1.37 (br d, 3, CH_3), 2.00 (br s, 1, OH), 2.23 (sx3, 3, >C–CH_3), 3.05 (t, 2, CH_2), 4.73 (qx3, 1, >CH–), and 5.0—6.8 ppm (m, 4, =CH–). Then, **6** (0.151 g, 0.794 mmol) was hydrogenated over palladium–carbon in benzene–ether (3: 1), yielding **7** (0.0671 g, 43.6%) as a colorless oil after purification by preparative TLC (benzene/SiO_2); UV λ_{max}^{EtOH} 217 nm (log ε, 3.82); IR (neat) 3350 cm^{-1} (OH); NMR (CCl_4) δ=1.25 (d, 3, CH_3), 1.61 (br s, 6, $-(CH_2)_3-$), 2.07 (s, 4, >C–CH_3 +OH), 2.44 (br m, 4, >C–CH_2–), and 4.58 ppm (q, 1, >CH–); MS *m/e* 194 (M^+).

† Satisfactory analytical results were obtained.

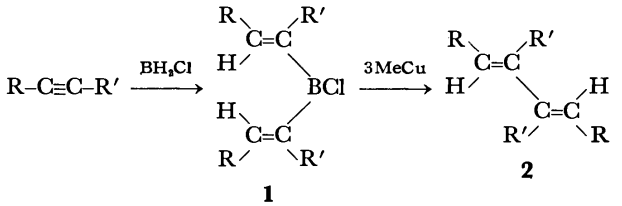
(Received May 18, 1977)

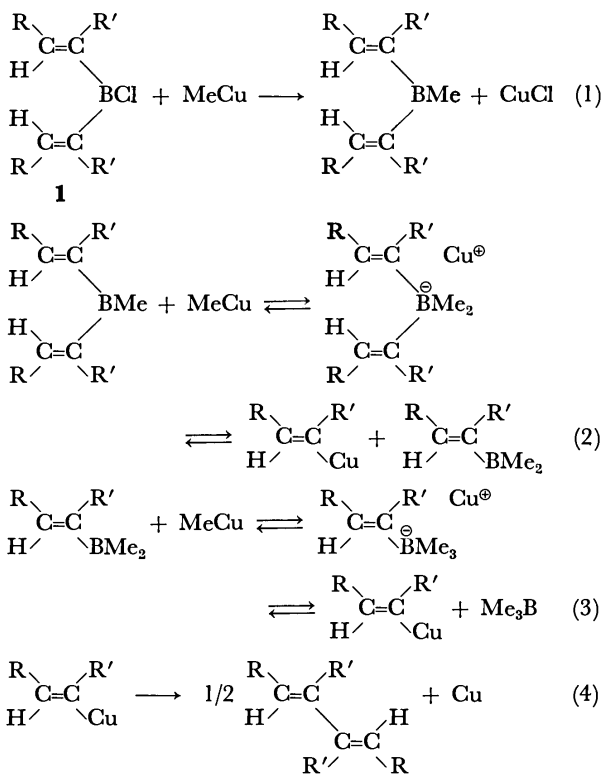
Synopsis. Bis(*trans*-1-hexenyl)methylborane, prepared by the reaction of bis(*trans*-1-hexenyl)chloroborane with methyllithium, was treated with 2 molar equivalents of methylcopper(I) at −78 °C to give (5*E*,7*E*)-5,7-dodecadiene quantitatively. The result indicates the presence of *trans*-1-hexenylcopper(I) intermediate.

It was reported that dialkenylchloroboranes (**1**) react with 3 molar equivalents of methylcopper(I) to give (*E*,*E*)-1,3-dienes (**2**) in a high yield.[1]



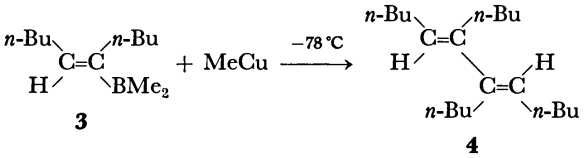
1 **2**

The transformation from **1** to **2** appears to involve the following sequence of reactions (Scheme 1), proceeding through an alkenylcopper(I) intermediate.[2] Actually, the reaction of (1-butyl-1-hexenyl)dimethylborane (**3**) with an equivalent amount of methylcopper(I) gave



Scheme 1. Proposed mechanism.

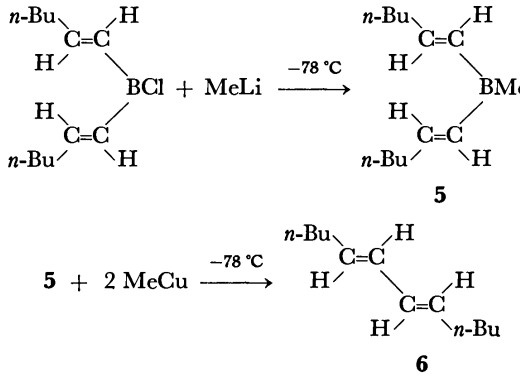
(5*E*,7*E*)-6,7-dibutyl-5,7-dodecadiene (**4**) in *ca.* 100% yield.[2] The result strongly supports the process shown by Eq. 3. However, no verification of Eq. 2 was obtained.[2] We wish to report an experimental evidence, establishing the proposed mechanism in Scheme 1.



3 **4**

Results and Discussion

Bis(*trans*-1-hexenyl)methylborane (**5**) was prepared by the reaction of bis(*trans*-1-hexenyl)chloroborane with an equivalent amount of methyllithium at −78 °C. An ether solution of **5** was slowly added to an ether suspension of 2 molar equivalents of methylcopper(I) at −78 °C. The color immediately changed from yellow to black. GLPC analysis revealed the approximately quantitative formation of (5*E*,7*E*)-5,7-dodecadiene (**6**).



5 **6**

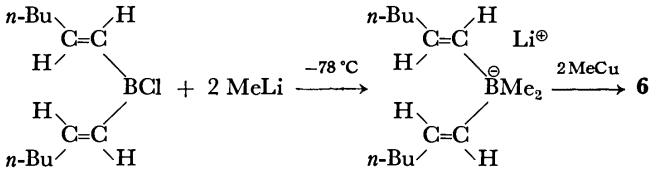
The result indicates that process (2) is involved in the transformation from **1** to **2**. Since an alkenylcopper(I) is far more unstable than methylcopper(I), it dimerizes even at low temperature (probably>−30 °C) (Eq. 4). Consequently, the equilibrium in Eqs. 2 and 3 lies to the right, two molar equivalents of methylcopper(I) being necessary for **5** to complete the reaction.

Process (1) was confirmed by GLPC examination of the borane product; the direct GLPC analysis (SE-30) of the reaction product from bis(*trans*-1-hexenyl)-chloroborane with an equivalent amount of methylcopper(I) at −78 °C revealed the quantitative formation of **5**.

As regards the copper(I) borates in Scheme 1, direct transmetalation from the alkenylboranes to the alkenyl-

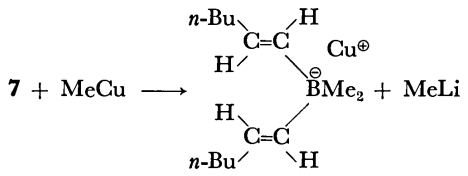
copper(I) without passing through the copper(I) borates can be proposed as an alternative mechanism. So far we have no unambiguous evidence for such copper species. Copper(I) tetraarylborates were prepared by cation exchange reaction.[4] Recently copper(I) tetraalkylborates have been used for organic synthesis.[5] By analogy to these results, it is reasonable to assume the presence of copper(I) dialkenyldimethylborate and copper(I) alkenyltrimethylborate. The present results provide an evidence for the formation of alkenylcopper(I) species, confirming the mechanism in Scheme 1.

The lithium borates (**7**) prepared from bis(*trans*-1-hexenyl)chloroborane and 2 molar equivalents of methyllithium react with 2 molar equivalents of methylcopper(I) to give **6** in 82% yield.[1]



7

The result can be explained according to Scheme 1 by an equilibrium between the lithium borate (**7**) and the copper(I) borate (**8**).[6]



8

Experimental

All temperatures were uncorrected. The NMR spectra were obtained on a Jeol JNM-MH-60 spectrometer, TMS being chosen as an internal standard. GLPC analyses were carried out on a Yanagimoto GCG 550T using a 2 m column packed with SE-30 10 wt% on Celite 545 AW.

Materials. The reagent grade solvent and copper(I) iodide were purified by standard techniques. Commercial 1-hexene was used. $BH_2Cl:OEt_2$[7] and methyllithium[8] were prepared according to the known procedures. The titration of methyllithium was performed according to the method of Watson and Eastham.[9]

Preparation of **5**. To an ether solution of bis(*trans*-1-hexenyl) chloroborane, prepared from the reaction of 1-hexyne with $BH_2Cl:OEt_2$,[7] was added an equivalent amount of methyllithium ether solution at −78 °C. The temperature was regulated to reach room temperature in 1—2 h. Bis(*trans*-1-hexenyl)methylborane was then distilled under reduced pressure; 80—90% yield; bp 65—70 °C/0.5 mmHg NMR(δ in CCl_4, J=Hz) 6.73 (d—t, 2H, J_d=16, J_t=6), 6.16 (d, 2H, J_d=16) 2.44—1.80 (m, 4H), 1.80—1.20 (m, 8H), 0.90 (t, 6H, J_t=6), 0.70 (s, 3H).

Reaction of **5** *with Methyl Copper(I).* The reaction was carried out as described previously.[2] The reaction mixture was analyzed by GLPC with an appropriate internal standard (dodecane). The structure of **6** was assigned by comparison with an authentic sample.[1] Methanol should be produced according to Scheme 1. The peak corresponding to methanol was observed, but its precise yield could not be determined under the present analytical conditions.

*Reaction of the Lithium Borate (***7***).* To an ether solution of bis(*trans*-1-hexenyl) chloroborane was added 2 molar equivalents of methyllithium ether solution at −78 °C. The temperature was regulated to reach 0 °C in 1—2 h. In this case, lithium borate (**7**) was not isolated but directly reacted with methylcopper(I) as described above. The product was analyzed by GLPC with dodecane as an internal standard.

The Photochemical Synthesis of 2-Chloro-3-(2-furyl)-1,4-naphthoquinones

Kazuhiro MARUYAMA and Tetsuo OTSUKI

Department of Chemistry, Faculty of Sciences, Kyoto University, Kyoto 606

(Received May 31, 1977)

Synopsis. Upon the irradiation of a benzene solution of 2,3-dichloro-1,4-naphthoquinone, **1**, and furan derivatives, **2**, 2-chloro-3-(2-furyl)-1,4-naphthoquinones, **3**, were obtained, accompanyed by a liberation of hydrogen chloride. The formation of a CT-complex between **1** and **2** was essential for the progress of the reaction. The ^{1}H-CIDNP signals which were observed during irradiation suggest an intervention of a radical pair in the reaction.

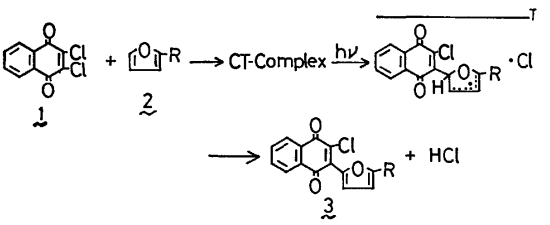
Many workers have reported synthetic methods of a variety of quinones, applying the addition reaction of radicals to quinones,[1] the reaction of organometallic reagents with quinones,[1] and the photochemical reaction of quinones with aldehydes.[2] Here we wish to report on a new photochemical synthetic route to 2-furyl derivatives of 1,4-naphthoquinones.

Results and Discussion

As a typical example the photochemical reaction of 2,3-dichloro-1,4-naphthoquinone, **1**, with the **2a** furan will be illustrated. The irradiation of a benzene solution of **1** and **2a** by a high-pressure Hg arc lamp gave a photo-substitution product, **3a**, as red needles in a yield of 82%, accompanied by the liberation of hydrogen chloride. The hydrogen chloride liberated in the reaction was estimated by titration with a standardized aqueous sodium hydroxide solution; the amount of it reached 84% of that of **3a**. The structure of **3a** was compatible with its spectral data and was further confirmed by its chemical reactions (Scheme 1).[3-5]

When the photochemical reaction was examined by means of the ^{1}H-CIDNP technique, strongly polarized signals were observed during the course of the reaction (Fig. 1). The polarized signals, 1, 2, and 3, were all assignable to furyl-ring protons of **3a**. This suggests that the photo-substitution product, **3a**, is produced *via* a radical pair.

When **2a** was added to a benzene solution of **1** (λ_{max}: 439 nm), a new absorption band (λ_{max}: 465 nm) (shoulder) appeared which was ascribable to the CT-complex between **1** and **2a**.[6,7] When the CT-band was irradiated by the light of a selected wavelengthth (λ_{max}: 488 nm, $\Delta_{1/2}$=20 nm), the product, **3a**, was exclusively produced, the yield being improved to 92%. This result indicates an important contribution of the CT-complex in the initial stage of the reaction (Scheme 2).



R=**a**: H, **b**: CH_3, **c**: CH_2OCH_3, **d**: $CH_2OC_2H_5$, **e**: $CH_2OC_3H_7$, **f**: CH_2O-phytyl **g**: CH_2O-tetra-*O*-acetyl-*β*-D-glycopyranosyl, **h**: CH_2OCOCH_3, **i**: CH_2OCO-CH_2N-phthaloyl.

Scheme 2.

Such furan derivatives as **2a**—**i**, which formed CT-complexes with **1**, behaved similarly in the photochemical reaction and gave photo-products, **3a**—**i**, in fairly good yields (*cf.* Experimental). Thus, the present reaction provides a good method of synthesizing 2-chloro-3-(2-furyl)-1,4-naphthoquinones. During the course of all the reactions, the ring- and α-protons of furyl ring due to the corresponding photo-substitution products, **3a**—**i**, showed polarized ^{1}H-CIDNP signals (Figs. 1—3). In contrast, such furan derivatives as **2j**—**n**, which gave no indication of CT-complex formation with **1**, did not undergo a similar photo-substitution reaction. The importance of the formation of the CT-complex was further supported by the results of the photochemical reactions of other 1,4-naphthoquinones with **2a**. That is, 2,3-dibromo-1,4-naphthoquinone gave a photo-substitution product, **10**, in the reaction with **2a**, but 2-chloro- and 2-bromo-1,4-naphthoquinone gave another types of products.[8]

Experimental

General Procedure. A benzene solution of 2,3-dichloro-1,4-naphthoquinone, **1** (1.5×10^{-3} M), and an excess amount of a furan derivative, **2** (*ca.* 4.5×10^{-2} M), was irradiated by means of a high-pressure Hg arc lamp (300 W) at room temperature. After the complete consumption of **1**, the photosubstitution product, **3**, was isolated using chromatography on silica gel.

Identification of the Products. *2-Chloro-3-(2-furyl)-1,4-naphthoquinone (**3a**)*; red needles, mp 137—138 °C; yield, 82 %. Found: C, 64.95; H, 2.88; Cl, 13.69%. Calcd for $C_{14}H_7O_3Cl$: C, 65.00; H, 2.73; Cl, 13.71%. Mass *m/e*=260, 258 (M^+). IR(KBr) 1680, 1665 cm^{-1}. NMR($CDCl_3$) δ 6.60 (1H, d of d, J=4 and 2Hz), 7.40 (1H, d, J=4 Hz), 7.72 (1H, d, J=2 Hz), 7.6—7.8 (2H, m), 8.0—8.2 (2H, m). UV λ_{max} ($CHCl_3$): 443 nm (ε: 5.5×10^3), 321 (sh) (5.6×10^3), 272 (2.2×10^4). *2-Chloro-3-(5-methyl-2-furyl)-1,4-naphthoquinone (**3b**)*; red crystals, mp 123 °C; yield, 65%. Mass *m/e*=272 (M^+). *2-Chloro-3-(5-methoxymethyl-2-furyl)-1,4-naphthoquinone (**3c**)*; red crystals; mp 107—108 °C; yield, 49%. Mass *m/e*=304, 302 (M^+). *2-Chloro-3-(5-ethoxymethyl-2-furyl)-1,4-naphthoquinone (**3d**)*; red crystals; mp 68 °C; yield, 38%. Mass *m/e*=318, 316 (M^+). *2-Chloro-3-(5-propoxymethyl-2-furyl)-1,4-naphthoquinone (**3e**)*; red crystals; mp 51.5—53.0 °C; yield, 51%. Mass *m/e*=322,330 (M^+). *2-Chloro-3-(5-phytyloxymethyl-2-furyl)-1,4-naphthoquinone (**3f**)*; yellow oil; yield 7%. IR (KBr) 1680 cm^{-1}. NMR($CDCl_3$) δ 0.8—2.2 (36 H, m), 4.10 (2H, d, J=8 Hz), 4.54 (2H, s), 5.36 (1H, t, J=8 Hz), 6.56 (1H, d, J=4 Hz), 7.42 (1H, d, J=4 Hz), 7.7—7.9 (2H, m), 8.0—8.2 (2H, m). *2-Chloro-3-[5-(tetra-O-acetyl-β-D-glucopyranosyloxymethyl)-2-furyl]-1,4-naphthoquinone (**3g**)*; red crystals; mp 160 °C (dec); yield, 22%. (Received June 27, 1977)

Synopsis. The reaction between ethyl propiolate and copper(I) methyltrialkylborates was found to give the corresponding addition products which are converted by hydrolysis into the α,β-unsaturated acid esters in relatively good yields. The α,β-unsaturated esters thus obtained are sclectively *E*-isomers.

Previously, we have reported that copper(I) methyltrialkylborates readily available by the reaction between lithium methyltrialkylborates and copper(I) halides undergo addition reactions to acrylonitrile, ethyl acrylate, and 1-acyl-2-vinylcyclopropanes.[1] These borates also react with alkyl halides such as benzylic,[2] allylic and propargylic halides,[3] and aroyl halides.[4] In the present paper, we wish to report the stereospecific synthesis of (*E*)-α,β-unsaturated carboxylic esters *via* the reaction of copper(I) methyltrialkylborates with ethyl propiolate.

No reaction occurs between ethyl propiolate and lithium methyltrialkylborates at room temperature. However, when copper(I) methyltrialkylborates prepared from lithium methyltrialkylborates and copper(I) halides are used, the reaction proceeds smoothly to give α,β-unsaturated esters together with ethyl 2-butenoate (Eqs. 1 and 2).

$$R_3B + MeLi \longrightarrow [R_3BMe]Li \xrightarrow{CuX} [R_3BMe]Cu \quad (1)$$

$$[R_3BMe]Cu + HC{\equiv}C\text{-}CO_2Et \longrightarrow RCH{=}CHCO_2Et + CH_3CH{=}CHCO_2Et \quad (2)$$

When copper(I) methyltripropylborate obtained from copper(I) bromide and lithium methyltripropylborate was treated with ethyl propiolate at 0 °C in tetrahydrofuran under nitrogen atmosphere, ethyl (*E*)-2-butenoate, ethyl (*E*)-2-hexenoate, and ethyl (*Z*)-2-hexenoate were formed in 32, 37, and 2% yields, respectively. Ethyl 2-butenoate, an undesirable by-product, is considered to be formed by the addition of methyl group of the methyltripropylborate as an alkylating group. It was found that yields and product ratios of the *E*-isomer depend markedly on the copper(I) halides and solvents employed. The reaction using copper(I) iodide as a halide and 1,2-dimethoxyethane (DME) as a solvent was effective for the prevention of formation of a by-product. Under such reaction conditions, the desired (*E*)-α,β-unsaturated acid esters were obtained in good yields from representative organoboranes. The results are summarized in Table 1. The new reaction is applicable to representative primary trialkylboranes such as propyl, butyl, isobutyl, and hexylboranes. Although the reaction mechanism is still unknown, the formation of (*E*)-α,β-unsaturated acid esters as main products seems to suggest that the reaction proceeds through the *cis*-addition process.[5]

Table 1. (*E*)-α,β-Unsaturated acid esters from copper(I) methyltrialkylborates and ethyl propiolate[a]

Organoborane R_3B, R=	CuX X=	Solvent	Reaction time (h)	Yield of products (%)[b] MeCH=CHCO$_2$Et	Yield of products (%)[b] RCH=CHCO$_2$Et (Ratio of *E*-isomer, %)
Propyl	Br	THF	0.5	32	39 (95)
	I	THF	0.5	36	36 (97)
	Br	DME	0.5	18	44 (98)

	I	DME	0.5	5	63 (>99)
Butyl	I	DME	0.5	—	61 (>99)
Isobutyl	I	DME	0.5	—	53 (99)
Hexyl	I	DME	1.0	—	42 (98)

a) All the reactions were carried out by using 20% excess borate complexes. b) Based on ethyl propiolate used. Analyzed by VPC.

The preparation of α,β-unsaturated esters from ethyl propiolate and dialkylboranes was reported by Negishi *et al.*[6] The present reaction, however, provides a more general synthetic method for (*E*)-α,β-unsaturated acid esters from organoboranes.

Experimental

Materials. Commercial copper(I) halides and ethyl propiolate were used. The solvents were purified by distillation before use. Trialkylboranes were prepared by the usual procedure.[7]

The IR and NMR spectra were taken on a Hitachi-Perkin-Elmer Model 125 spectrophotometer and a Hitachi R-22 spectrometer at 90 MHz using tetramethylsilane as an internal standard.

General Procedure. The following procedure for the preparation of ethyl (*E*)-2-hexenoate is representative. A dry 100 ml-flask equipped with a septum inlet and a magnetic stirring bar was flushed with dry nitrogen. The flask was charged with copper(I) iodide (4.68 g, 24 mmol) and dry DME (40 ml). Lithium methyltripropylborate[2] (24 mmol, prepared from equimolar amount of tripropylborane in THF and methyllithium in ether) was added to the solution at 0 °C with stirring. After 5 min, ethyl propiolate (1.9 ml, 20 mmol) was added and the reaction mixture was stirred at 0 °C for 30 min. The residual organoborane was then oxidized with 3 M-aqueous sodium hydroxide (8 ml) and 30% hydrogen peroxide (8 ml) at room temperature for 2 h. The products were extracted with ether and analyzed by VPC. Analysis indicated the presence of 12.6 mmol (63%) of ethyl (*E*)-2-hexenoate and 1.0 mmol (5%) of ethyl (*E*)-2-butenoate. Analytically pure materials were obtained by preparative

Identification of the Products. *Ethyl (E)-2-Hexenoate*: n_D^{23} 1.4371. Found: C, 67.48; H, 9.78%. Calcd for $C_8H_{14}O_2$: C, 67.57; H, 9.93%. Mass: $m/e=142$ (M^+). IR (CCl_4); 1720, 1650, 985 cm^{-1}. NMR (CCl_4); τ, 9.02 (3H, t, $J=7.0$ Hz), 8.71 (3H, t, $J=7.0$ Hz), 8.47 (2H, m), 7.80 (2H, q), 5.84 (2H, q), 4.20 (1H, d, $J_{vinyl}=16.0$ Hz), 3.08 (1H, dt, $J=7.0$ and 7.0 Hz).

Ethyl (E)-2-Heptenoate: n_D^{23} 1.4393 (lit,[8] n_D^{25} 1.4355). Found: C, 69.36; H, 10.38%. Calcd for $C_9H_{16}O_2$: C, 69.19; H, 10.32%. Mass; $m/e=156$ (M^+). IR (CCl_4); 1720, 1650, 985 cm^{-1}. NMR (CCl_4); τ, 9.06 (3H, t, $J=7.0$ Hz), 8.75 (3H, t, $J=7.0$ Hz), 8.57 (4H, m), 7.78 (2H, q), 5.87 (2H, q), 4.23 (1H, d, $J_{vinyl}=16.0$ Hz), 3.10 (1H, dt, $J=7.0$ and 7.0 Hz).

Ethyl (E)-5-Methyl-2-hexenoate: n_D^{21} 1.4362. Found: C, 69.07; H, 10.29%. Calcd for $C_9H_{16}O_2$: C, 69.19; H, 10.32%. Mass; $m/e=156$ (M^+). IR (CCl_4); 1725, 1655, 990 cm^{-1}. NMR (CCl_4); τ, 9.03 (6H, d, $J=6.5$ Hz), 8.82 (3H, t, $J=7.0$ Hz), 8.21 (1H, m), 7.93 (2H, t, $J=7.0$ Hz), 5.86 (2H, q), 4.25 (1H, d, $J_{vinyl}=16.0$ Hz), 3.16 (1H, dt, $J=7.0$ and 7.0 Hz).

Ethyl (E)-2-Nonenoate: n_D^{22} 1.4417. Found: C, 71.50; H, 11.07%. Calcd for $C_{11}H_{20}O_2$: C, 71.69; H, 10.94%. Mass; $m/e=184$ (M^+). IR (CCl_4); 1725, 1655, 985 cm^{-1}. NMR (CCl_4); τ, 9.09 (3H, t, $J=6.0$ Hz), 8.72 (3H, t, $J=6.0$ Hz), 8.64 (8H, s), 7.79 (2H, q), 5.86 (2H, q), 4.43 (1H, d, $J_{vinyl}=16.0$ Hz), 3.10 (1H, dt, $J=6.5$ and 6.5 Hz).
