The *g*-values for the authentically generated semiquinone aions of chloranil, 2,5-, and 2,6-dichloro-*p*-benzoquinones and *p*-benzoquinone have been reported to be 2.00568, 2.00516, 2.00503, and 2.00468 respectively.[18] The spectra assigned to these semiquinone anions in this and previous[12] investigations were all consistent with the reported *g*-values. Evidently the increasing number of chlorine atoms in the semiquinone anions results in an increase in the *g*-value because of the large spin-orbit coupling in the chlorine atom. Keeping in mind the negligible difference in the *g*-value between the *p*-benzosemiquinone anion and the *p*-benzosemiquinone radical, one might be convinced that the shift of the spectra to the higher field (*i.e.*, to the smaller *g*-value) in the solution of chloranil in the highly alkaline ethanol is attributable to the elimination of some of the chlorine atoms by ethoxy-substitution.

Fluoranil in ethanol gave, under the photoillumination, a spectrum with five hyperfine lines of the binomial intensity ratio, just as has been reported previously by Hudson and Lewis.[19] They interpreted this spectrum as being due to a rapid proton transfer between the two oxygen atoms of the semiquinone radical, which was presumed to be the primary intermediate in the photoreduction of fluoranil in ethanol. However, the spectrum was found to decrease in its intensity without changing its shape if the solution was made highly acidic by adding water and sulfuric acid. The interconversion between the semiquinone anion and the radical, which was a part of proposed rapid proton transfer, is believed to be slow for fluoranil, as for *p*-benzoquinone.[12] There is no reason why the observed five-line spectrum cannot be attributed to the fluoranil semiquinone anion generated primarily by the photoinduced one-electron transfer.

No spectrum attributable to the semiquinone radical was observed from either fluoranil or chloranil, even by decreasing the flow rate of solution. In contrast, the superposition of the spectrum of the semiquinone radical on that of the semiquinone anion was observed at a low flow rate for *p*-benzoquinone[12] and dichloro-*p*-benzoquinones. The generation of the *p*-benzosemiquinone radical was found previously to be the result of the hydrogen abstraction of the quinone from hydroquinone, the concentration of which became high enough because of the long photolysis time. The electron affinity increases in the order of *p*-benzoquinone, dichloro-*p*-benzoquinones, fluoranil and chloranil.[20] The photoinduced one-electron transfer is slow for quinones of a low electron affinity, so that the hydrogen abstraction reaction competes. The one-electron transfer for quinones of a high electron affinity, such as fluoranil and chloranil, proceeds so rapidly that their semiquinone anions are exclusively observed by ESR during the photolysis.

Light Scattering by Oligostyrene Solutions

Toshio KAMATA, Hisae NAKAHARA, and Shigeru HATTORI

National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151

(Received March 23, 1977)

Light-scattering photometers were partially modified in order to measure light scattering by low molecular-weight molecules. Corrections to the molecular weights were then theoretically estimated, when the light scattering due to fluid density fluctuations were approximated by that due to the density fluctuations of a pure solvent. The molecular weight of benzene was determined, in an ethyl methyl ketone solvent, using the light-scattering method prior to the determination of the molecular weights of oligostyrene molecules. Measurements of light scattering by oligostyrene molecules with molecular weights from 600 to 20000 were then carried out. The weight-average molecular weight observed by the light-scattering method was compared with the number-average molecular weights which were determined by the vapor-phase osmometric and NMR methods. The molecular-weight heterogeneity of the specimen is discussed. The second virial coefficient, in the ethyl methyl ketone solvent system, was found to change from negative to positive with increasing molecular weight. It is also shown that the molecular optical anisotropy changes markedly in the range of molecular weights between 2000 and 3000, the change being considered to reflect the conformational changes of oligostyrene molecules.

Oligomers are not only useful for practical uses but are also attracting considerable interest in the study of solution properties. It is especially interesting to determine the range of molecular weights in which the recent theory of solutions for high molecular-weight polymers can be applied. For this purpose it is desirable to measure molecular weights in the range from oligomers to high molecular-weight compounds using the same technique, because mean values should be compared on the same basis. The light-scattering method is most suitable for the measurement of molecular weights over such a wide range. There are several technical problems in the measurement of low molecular weights as noted below:

(1) Minute amounts of scattered light must be accurately measured, because the scattering intensity may be very weak.

(2) Scattering due to a fluctuation in the fluid density cannot be approximated by that due to the fluctuation of the solvent density.

(3) The correction to the degree of depolarization of the scattered light due to a fluctuation in the orientation of anisotropic molecules should be made accurately when unpolarized light is used as the incident light.

The method for measuring molecular weights utilizing minute amounts of scattered light has already been reported by Kamata and Nakahara.[1] In the present paper, a method for correcting the observed molecular weights, as the result of density fluctuations and methods for correcting the depolarization are reported. In addition, the characteristic behavior of oligomer molecules in solution are discussed based on the results of light-scattering measurements of oligostyrene.

Experimental

Materials. Polystyrenes, batch 16a, 15a, 12b, 11b, 8b, and 2b, obtained from the Pressure Chemical Co., were used. Dibenzyl of G.R. grade, used as the substance corresponding to the dimer for the measurement of the specific refractive index increment, was obtained from the Tokyo Kasei Kogyo Co. The solvent, ethyl methyl ketone (special grade), was purchased from the Kanto Chemical Co. and used after distillation. The benzene (DOTITE Primazol) used, after distillation, for the calibration of the light-scattering photometers was purchased from the Dojin Chemical Co.

Light-Scattering Measurements. It is difficult to accurately measure the depolarization and the scattered light produced by a solution containing a low molecular-weight substance using a single light-scattering photometer. Thus, the Rayleigh factor and the depolarization were separately measured using two photometers. A light-scattering photometer, Shimadzu Model PG-21, was used for measuring the Rayleigh factor, and a high-gain photomultiplier, Hamamatsu TV. Co. Model R-105 UH, having an anode sensitivity= 1530 μA/μlm, was used for accurately measuring weakly scattered light. A Shimadzu Model DL-10A light scattering photometer was used with some modifications for the depolarization measurements. It is necessary that the zero point be easy to monitor during the experiments and the observed values be stable in order to accurately determine the depolarization of the weakly scattered light. For this purpose, a solenoid shutter was placed in front of the photomultiplier. This shutter can be opened and closed by means of an external switch. The zero point was very easily checked using this shutter, which also rendered the observed values very stable, since there was no need to shut off the power supply for the photomultiplier during the course of the experiments. A Glan-Thompson prism was also used as a polarizer and an analyzer.

The solvents and solutions used were all centrifuged for 1 h at about 60000 g using a Beckman (Spinco) Model L_4 preparative ultracentrifuge, and then directly filtered into the light-scattering cell through a Corning ultrafine glass filter.

The light scattering was measured using mercury radiation at a wavelength of 436 nm in vacuo at room temperature. Calibration of the light-scattering photometer was carried out using the Rayleigh ratio, $R_{90}=45.88\times10^{-6}$ cm^{-1}(20.0 °C), for benzene. Depolarization was measured using the Shimadzu Model DL-10A light-scattering photometer with the cell containing the specimen the same as that used for the Rayleigh factor measurements. The isotropic part was calculated from the Cabannes factor.[2]

The determination of the specific refractive index increment was carried out at room temperature using a Shimadzu differential refractometer.

Measurement of the Number Average Molecular Weight. The number average molecular weight was determined from values of the vapor pressure which was obtained using a

Hitachi-Perkin Elmer Model 115 vapor pressure osmometer and from the NMR spectra obtained in a CCl_4 solvent system using a JEOL Model HL-60 NMR spectrometer.

Gel Permeation Chromatography. Gel permeation chromatography was carried out at 35 °C using a Waters Ana-Prep GPC with four columns (4 feet long with pore sizes of 3×10^5, 10^4, 10^3, and 10^2 nm) connected in series, tetrahydrofuran being used as the solvent.

Results and Discussion

Light Scattering Due to Fluctuations in the Fluid Density and Its Influence on Molecular Weight Determination. The total isotropic light scattering of the binary solution is expressed by

$$R_{is} = R_c + R_d + R^*, \quad (1)$$

where R_c and R_d indicate the scattering intensity due to fluctuations in the densities of solute concentrations and those of the densities of the pure solvent, respectively. R^* is the cross term. The scattering due to fluctuations in the solute concentrations, which is necessary for determining the molecular weight using the light-scattering method, is usually obtained by subtracting the scattering by a pure solvent from that by the solution. As indicated by Eq. 1, the scattering due to fluctuations in the binary solution density is not equal to that due to fluctuations in the pure solvent density. The influence of this difference causes no problem for determining molecular weights larger than 10^4. The determination of low molecular weights, such as those in the range between several tens and several hundreds, however, is considerably affected by this difference.

According to Bullough,[3] when the scattering due to fluctuations in the solution density is approximated by the scattering due to fluctuations in the density of the pure solvent, a correction of the molecular weight obtained by the light-scattering method is given approximately by

$$\Delta M \approx N_A\lambda_0^2(\tau_0\kappa_0kT/8\pi^3)^{1/2}/n_0(dn/dc), \quad (2)$$

where N_A is Avogadro's constant, λ_0 the wavelength of the incident light in vacuo, τ_0 the turbidity, κ_0 the isothermal comressibility, k Boltzmann's constant, T the absolute temperature, n_0 the refractive index of the solvent, and dn/dc the specific refractive index increment. For isotropic molecules, $\tau_0=(16/3)\pi R_{90}$. Therefore, Eq. 2 becomes

$$\Delta M \approx \{(N_A\lambda_0^2/n_0(dn/dc)\}(2R_{90}\kappa_0kT/3\pi^2)^{1/2}. \quad (3)$$

The values of ΔM obtained from measurements at $\lambda_0=436$ nm in several solvents are given in Table 1.

The contribution to the light scattering due to the density fluctuation was found to be rather large when a determination of the molecular weight of benzene was attempted in an ethyl methyl ketone (EMK) solvent using the light-scattering method. The displacement of the estimated molecular weight was up to 13% and was not negligible when the scattering due to fluctuations in the solution density was approximated by that due to fluctuations in the pure solvent density. The influence of such as approximation on estimations of the molecular weights of oligostyrenes, which are larger than 1000, in an EMK solvent using the light-scattering technique, however, was found to be negligible when compared with the experimental errors in the light-scattering measurement.

Measurement of Light Scattering of Benzene in an EMK Solvent. Since styrene polymers contain phenyl groups which are strongly optically anisotropic, it is believed that oligomers may strongly be affected by the phenyl groups and exhibit strong optical anisotropy. It is, therefore, important to correct for the degree of depolarization in the light-scattering measurements of anisotropic molecules using unpolarized incident light. In the present study, as mentioned above, two photometers were used for measurements of the light-scattering intensity and the degree of depolarization. In order to verify the method adopted in this study, a measurement of the molecular weight of benzene dissolved in an EMK solvent was carried out prior to measurements on oligostyrenes.

The equation which is well known for the calculation of molecular weights,

$$Kc/R_\theta = 1/(M_wP(\theta)) + 2A_2c + \cdots, \quad (4)$$

was used. When unpolarized incident light is used, K and $P(\theta)$ are given respectively by

$$K = 2\pi^2n_0^2(dn/dc)^2/(N_A\lambda_0^4) \quad (5)$$

and

$$P(\theta) = 1-(1/3)(4\pi/\lambda)^2R_G^2\sin^2(\theta/2) + \cdots, \quad (6)$$

where R_θ is the isotropic excess light scattering, c the solution concentration (g/cm³), M_w the weight average molecular weight of the solute, A_2 the second virial coefficient and R_G the radius of gyration. R_θ in Eq. 4

was calculated, using the King equation (Eq. 8),[4] from the Rayleigh factor $(R_\theta)_u$, which was measured with unpolarized light,

$$R_\theta = (R_\theta)_u/f_u(\theta) \quad (7)$$

with

$$f_u(\theta) = [6+6\rho_u\{(1-\cos^2\theta)/(1+\cos^2\theta)\}]/(6-7\rho_u), \quad (8)$$

where ρ_u is the degree of depolarization. The scattering diagram for benzene in an EMK solvent is shown in Fig. 1. Since the benzene molecule is optically anisotropic, the curves in Fig. 1 curve downward sharply. A straight line was obtained after correction for depolarization, indicating a proper correction for depolarization. In addition to this, the value of Kc/R_θ in Eq. 4 exhibited no angle dependency and the value of $P(\theta)$ is approximately equal to 1, since the benzene molecule is considerably smaller than the wavelength of the incident light. Thus, the molecular weight of benzene can be calculated from only the 90° scattering.

TABLE 2. MOLECULAR WEIGHT OF BENZENE ESTIMATED FROM LIGHT-SCATTERING MEASUREMENTS

M_{app}	ΔM	M(expt)[a]	M(formula)[b]
88.5	10.1	78.4	78.1

a) $M(\text{expt})=M_{app}-\Delta M$. b) Calculated from molecular formula of benzene.

Since the contribution from the cross term, in Eq. 1, is rather large for the benzene molecule, the molecular weight estimated using the conventional double extrapolation method (Zimm plot) resulted in a considerable deviation from the true value. The measured values of the molecular weight of benzene are shown in Table 2. M_{app} indicates the apparent molecular weights evaluated by the conventional extrapolation method. ΔM gives the correction to the molecular weights, calculated using Eq. 3 and neglecting the cross term in Eq. 1. M is the molecular weight compensated for by the cross term. M(formula) is the molecular weight calculated from the molecular formula of benzene. The corrected molecular weights of benzene agree well with the formula weight of this compound, although Eq. 3 can only give a rough correction. The results given in Table 2, therefore, suggest that molecular weights of low molecular-weight substances may be determined with sufficient accuracy by means of the light-scattering method, if the solvent system is so chosen as to make the molecular weight correction due to the cross term as small as possible.

Light-Scattering Measurements of Oligostyrenes in an EMK Solvent. The scattering diagram of polystyrene (16a) is given in Fig. 2, showing a rather intense optical anisotropy.

The results of measurements on oligostyrene are

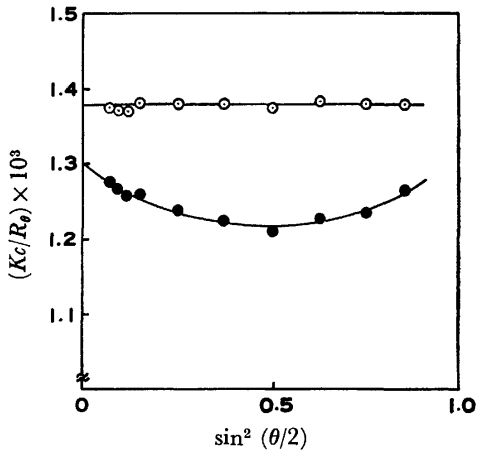

Fig. 2. Light scattering diagram for oligostyrene(16a) in ethyl methyl ketone.

summarized in Table 3. The factor indicating the optical anisotropy, $f_u(90°)$, was calculated with

$$f_u(90°) = [(Kc/R_{90})_u]_{c\to 0}/(Kc/R_{90})_{c\to 0} = [(R_{90})_u/R_{90}]_{c\to 0}, \quad (9)$$

where $(R_{90})_u$ is the excess light scattering observed at an angle of 90°, without correction for depolarization, and R_{90} is the isotropic excess light scattering calculated from the King equation. Values in the "exptl" column for M_w/M_n were calculated from the values obtained using the light-scattering and vapor-pressure measurements. The values under "calcd" in the table indicate the heterogeneity of the molecular weights of polymers calculated, for conditions under which living polymerization would ideally be performed, using

$$M_w/M_n = 1 + 1/P_n, \quad (10)$$

where P_n is the number average polymerization degree. When the observed, reference, and calculated values were compared with each other, the reference value for specimen 16a turned out to be markedly smaller than the calculated value. Since the calculated values were estimated assuming ideal polymerization, the heterogeneity of the molecular weights of real specimens should not be lower than this calculated value. The observed value for specimen 16a, on the other hand, was not in disagreement with the calculated value.

In addition to specimen 16a, there exist considerable discrepancies between the observed values and the reference values for specimens 15a and 11b, the discrepancy being marked for 15a. The heterogeneity of the molecular weights of this specimen is extremely high when compared with other specimens. This appears to be due to incomplete living polymerization. Since the calculated value of the heterogeneity of molecular weights is dependent upon the number average polymerization degree, it is important to accurately measure the number average molecular weight. The number average molecular weight of specimen 16a was estimated from the NMR spectrum of this compound, which is given in Fig. 3. The chemical structure of this substance was thought to contain a terminal butyl group based on its polymerization mechanism. Thus, the degree of polymerization may be estimated by taking the ratio of the H_ϕ contributed by protons in the phenyl group

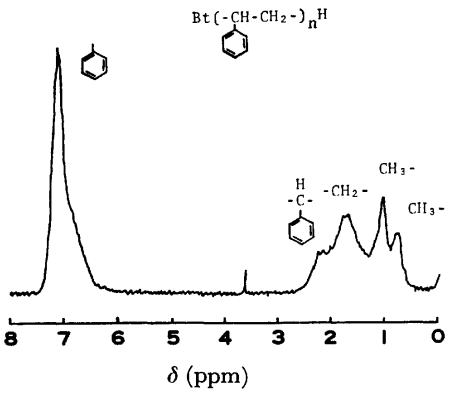

Fig. 3. NMR spectrum of oligostyrene(16a) in carbon tetrachloride.

to that, the H_b, from protons in other groups in the expression

$$H_\phi/H_b = 5P_n/(10+3P_n). \quad (11)$$

The value of H_ϕ/H_b was estimated from the areas occupied by each spectrum and then the value of P_n for oligostyrene was calculated. The P_n value was calculated to be 4.64, and the number average molecular weight estimated from the P_n was found to be 541.

The results obtained for specimen 16a are summarized in Table 4. The values of M_w/M_n were calculated using the number average polymerization degrees obtained from the number average molecular weights observed using various methods and from Eq. 10 on the assumption that living polymerization proceeded under ideal conditions. The values of M_w/M_n are in the range between 1.18 and 1.20. Therefore, the true M_w/M_n value of specimen is thought to be greater than 1.18 and is unlikely to be smaller than 1.10. Although the value of M_w/M_n obtained using the GPC method was slightly higher than those obtained from the light-scattering and VPO methods, it appears to be reasonable judging from the calculated value.

Molecular Optical Anisotropy of Oligostyrene. It is interesting to study the dependency of the molecular optical anisotropy of styrene polymers on their molecular weights because this involves a phenyl group which exhibits strong optical anisotropy. The relation between the molecular optical anisotropies, $f_u(90°)$, and the

molecular weights of oligostyrenes is shown in Fig. 4. Values of $f_u(90°)$ most fluctuated in the range between molecular weights of 2000 and 3000 and became almost constant at about 10000. This tendency has been observed by Nomura and Miyahara[5] who reported the dependency of the partial specific compressibility on the molecular weight. This phenomenon has been considered to reflect the transition process of conformation of the polystyrene molecule from a rod-like rigid form to a random coil caused by internal rotation of the molecular chain.

Dependency of the Specific Refractive Index Increment and the Second Virial Coefficient on Molecular Weight. The data given in Table 3 are plotted in Figs. 5 and 6. The values of dn/dc show considerable fluctuations for molecular weights smaller than 20000. The second virial coefficient of the oligostyrene–EMK solution changed from negative to positive and exhibited a maximum with increasing molecular weight. It has been reported by Outer *et al.*[6] that the second virial coefficient monotonically decreases with increasing molecular weight when light scattering by polystyrenes of molecular weights from 2460 to 1770000 were measured in an EMK solvent. The results obtained in the low molecular-weight range, in the present study, are thus different from their results. Sotobayashi and Ueberreiter[7] have measured the second virial coefficient by means of a cryoscopic method. Nomura and Miyahara[5] have also measured this using vapor-pressure osmometry. They obtained results similar to those reported here. Figure 7 shows the plots of the second virial coefficients against the number average molecular weights, M_n, and also compares the results obtained in the present study with those of Nomura and Miyahara.[5] Since, in the present study, the second virial coefficients were obtained from light-scattering measurements, they could not be compared with those of Nomura and Miyahara[5] because of the influence of the molecular-weight distribution. The overall tendency, however, showing a conversion from negative to positive of the value of A_2 with the molecular weight and the appearance of a maximum, agree well with their results. It has been suggested by Sotobayashi and Ueberreiter,[7] as mentioned above, that this may be due to the transition of the molecular conformation of styrene polymers from rod-like rigid molecules to random coil structures. It appears improper to discuss the nature of this phenomenon in further details, because there is no evidence to prove the homogeneity of the chemical structure of terminal groups and because the heterogeneity of the molecular weights of oligostyrenes are slightly different for each of the specimens used in the present study.

Since the properties of oligomers in solution are greatly influenced by the chemical structure of the terminal groups of the oligomer molecules, it may be necessary, first of all, to prepare specimens with

homogeneous molecular weights and with identical terminal groups in the molecules and then to measure these properties, in order to discuss them in detail over the oligomer molecular-weight range.

The authors wish to express their thanks to Dr. Sueo Nishi for his kind permission to use the vapor pressure osmometer and his helpful advice regarding its operation.

The Molecular Structure of Dimethyl Sulfide*

Takao IIJIMA, Shuzo TSUCHIYA, and Masao KIMURA
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received March 25, 1977)

The gas-phase molecular structure of dimethyl sulfide, $(CH_3)_2S$, has been investigated by means of electron diffraction. By a joint analysis of the diffraction results and the spectroscopic moments of inertia by Pierce and Hayashi, the structure parameters, the distances in r_g and the angles in φ_{a_v}, were determined (with parenthesized limits of error) to be as follows: S–C=1.807(2) Å, C–H=1.116(3) Å, ∠CSC=99.05(4)°, and ∠HCH=109.3(5)°. A tilt of 2.35° and the local C_{3v} symmetry of the methyl groups were assumed. The isotope effects of deuterium substitution were examined, and the DCD angle was found to be larger than HCH in the zero-point average structure.

The present authors have, for some time, been investigating the structures of molecules which contain one or two methyl groups. The combined use of diffraction and spectroscopic data has been successful in obtaining more accurate values of the structure parameters. By this technique, the uncertainties of the hydrogen parameters were especially reduced to ±0.003—6 Å for C–H distances and ±0.5—1.0° for the HCH angles.[1] Furthermore, it was possible in some favourable cases to obtain information on the isotope effects in structure parameters for the deuterium substitution.[2] In the present study, the structure of dimethyl sulfide was determined by applying the technique of the joint analysis.

The microwave spectra of this molecule were extensively studied by Pierce and Hayashi.[3] They measured and analyzed the spectra of several isotopic species as well as the parent species. The spectrum of the parent species was measured also by Rudolph, Dreizler, and Maier.[4] As for the diffraction study, there were the visual works by Brockway and Jenkins[5] and by Schomaker,[6] but no high-precision data have been available.[7] Therefore, the electron-diffraction data were newly obtained in the present study by the sector-microphotometer method. The moments of inertia reported by Pierce and Hayashi were used in the joint analysis.

Experimental

A sample of grade G. R. purchased from Nakarai Chemicals, Ltd., was used without further purification. The diffraction experiments were made by means of the Hokkaido University apparatus[8] at room temperature, using an r^3-sector and two nozzle-to-plate distances, 244.3 and 109.3 mm. The other experimental conditions are as follows: accelerating voltage, 42 kV; beam current, 0.1 μA; exposure times, 100—180 s; and sample pressure, 60—70 Torr (1 Torr=133.322 Pa). The scale factor for $L\lambda$ was calibrated using the diffraction patterns of CS_2 taken in the same sequence of exposures. Data obtained from three selected plates for the long and short camera distances covered the approximate s ranges of 3—17, and 7—40 $Å^{-1}$ respectively.[9]

The theoretical molecular intensities from the best-fit model and the differences (experimental minus theoretical) are shown in Fig. 1.[10] The vertical scale of the difference is four times as large as that of the molecular intensity. The narrower shaded boundaries in the difference correspond to ±2 in the last digit of the digital voltmeter used in photometry, that is the, limit of the detectable changes in the intensity. The outer boundaries, drawn in broken lines, indicate the normally expected range of the random scattering of differences. Some points are outside this boundary for accidental reasons. A least-squares refinement with zero-weights for these points showed that the effects of these extraordinary data on the final parameter-values were negligibly small.

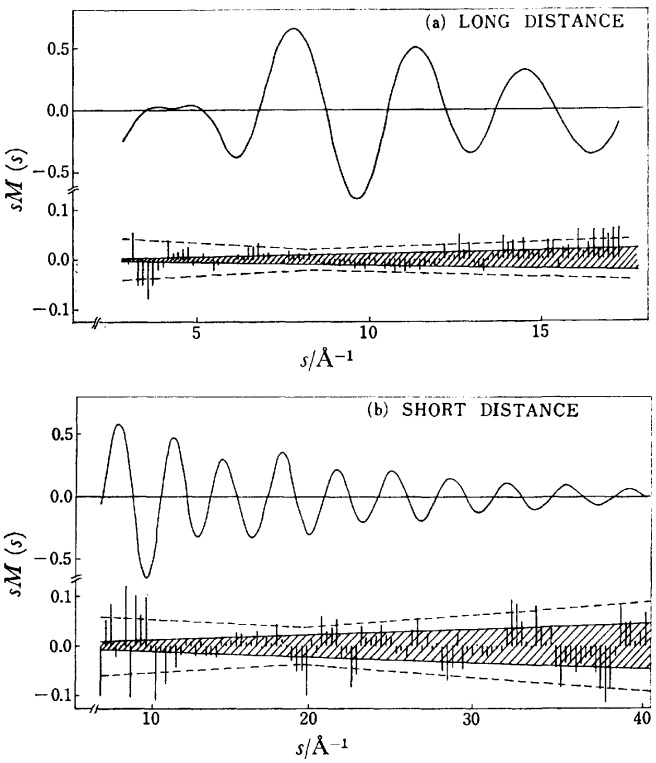

Fig. 1. Theoretical $sM(s)$ from the best-fit model and the differences (experimental minus theoretical) for the long (a) and short (b) camera distances. The vertical scale of the difference is four times as large as that of the $sM(s)$. See text.

Analysis of the Diffraction Data

The skeletal parameters, S–C, S···H, and C···C distances, were determined by the least-squares method.[9] The C–H and H···H r_a distances of the methyl group were fixed at 1.107, and 1.783 Å respectively. The local C_{3v} symmetry of the methyl

* 1 Å=100 pm is used throughout this paper.

group was assumed. The other non-bonded distances were fixed at the values calculated from the reported r_s-structure.[3] The rms amplitudes of vibration were fixed at the values calculated by Gebhardt and Cyvin.[11] The Hartree-Fock elastic scattering factors were generated by a computer program for the partial-waves method.[12] The inelastic scattering factors were taken from the literature.[13] The results of the least-squares procedure are summarized in Table 1.

Table 1. Results of the least-squares analysis of the diffraction data for dimethyl sulfide (in Å units)[a]

	S–C	S···H	C···C
Long camera distance			
r_a	1.8056	2.4098	2.7616
σ_1[b]	8	37	91
σ_2	3	37	64
ε[c]	31	101	243
Short camera distance			
r_a	1.8055	2.3943	2.7567
σ_1	10	91	201
σ_2	3	22	60
ε	33	239	524
Weighted averages			
r_a	1.805_6[d]	2.408_1	2.76_1
ε	2_2	9_3	2_2

a) Index of resolution; 0.82—0.94. b) For the definitions of σ_1 and σ_2, see Ref. 14. c) The limit of error, ε, was estimated from $2.6\sigma_1$ and the systematic error of the scale factor, 0.13% for the long, and 0.11% for the short, camera distance. d) r_g(S–C); 1.806_9 Å.

The r_a values from the data of the long and short camera distances are in good agreement with each other for all three distances. The weighted averages of them give the most probable values of the bond distances as obtained by the diffraction method. For the S–C distance, the long- and short-distance data make nearly equal contributions, while for the S···H and C···C distances, the weights of the long-distance data are much larger than those of the short-distance data.

It is noted that the S–C distance might be affected by the assumed value of the intra-methyl H···H distance, because they are very close to each other. Thus, in the final refinement the value of the H···H was changed to 1.804 Å, a value which was given from the results of the joint analysis, and the least-squares procedure was carried out again. The values of the parameters shifted within only 10% of the standard deviations.

Joint Analysis of the Diffraction Results and the Spectroscopic Moments of Inertia

More detailed structure information was obtained by a joint analysis of the diffraction data and the spectroscopic data on the moments of inertia. Since the data from both methods were combined on the r_z-basis (the zero-point average structure),[15] the vibrational effects of the moments of inertia or the vibrational corrections were calculated by using the force field reported by Gebhardt and Cyvin.[11] The barrier to the internal rotation of the methyl top of this molecule is reported to be about 2.1 kcal/mol.[3] The method of calculating the vibrational corrections for molecules with large-amplitude internal motion was applied.[16,17] The moments of inertia and the vibrational corrections are shown in Table 2.

Table 2. Moments of inertia of dimethyl sulfide (in amu Å^2 units)[a]

	$I^{(0)}$	ΔI	$I^{(z)}$
$(CH_3)_2S$			
a	28.376	0.143(0.143)	28.519
b	66.314	0.209(0.210)	66.522
c	88.387	0.101(0.101)	88.488
γ[b]	(3.262)	0.015(−0.004)	3.277
$(CD_3)SCH_3$			
a	32.646	0.151	32.797
b	76.619	0.227	76.846
c	99.731	0.112	99.843

a) $I^{(0)}$: observed effective values for the ground vibrational state, taken from Ref. 3. The numerical values are, however, slightly different from Ref. 3 because of the use of the conversion factor of 505376 Mc amu Å^2 in this work. ΔI; calculated vibrational corrections. The values in parentheses were obtained by an approximate method. See text. $I^{(z)}$: moments of inertia for the zero-point average structure. b) γ indicates the torsional coordinate of the methyl tops.

For the vibrational correction in the case of a large-amplitude torsional motion, it is necessary to calculate the n_{is} matrix as well as the l_{is} matrix.[16] The n_{is} is the derivative of the l_{is} viewed on the top-fixed axis with respect to the torsional coordinate. The requirement of calculating the n_{is} matrix makes the whole procedure tedious and complicated. If the n_{is} matrix can be neglected, though, the l_{is} matrix may easily be obtained by ordinary normal-cordinate calculations. The vibrational corrections for the parent species calculated by neglecting the n_{is} matrix were found to be good approximations for ΔI except for ΔI_γ, as is shown in the parentheses in Table 2. A similar comparison was made for propane and 2-fluoropropane. The maximum deviation of the approximate value was found to be 0.006 amu Å^2. The vibrational corrections for the CD_3SCH_3 species in Table 2 were calculated by this approximated method.

The r_g(C–S) distance by diffraction, 1.806_9 Å, was converted into r_α^0 ($\approx r_z$), $1.804_8 \pm 0.002$ Å, by the use of anharmonic stretching, 0.0003 Å, the correction for the perpendicular motion, 0.0009 Å, and centrifugal stretching, 0.0009 Å. All these corrections were calculated by the use of the force field by Gebhardt and Cyvin.[11]

As was the case in our previous papers,[1,2] the structure of the molecule including the isotope effects for the deuterium substitution was determined by using the $I^{(z)}$ values of $(CH_3)_2S$ and CD_3SCH_3 species and r_α^0(S–C) from diffraction. The value of r_α^0(S–C) and its limit of error determine the allowable region of the S–C distance. For each S–C value within this region, three

structure parameters, C–H ∠HCH, and ∠CSC, were determined from the three moments of inertia of the parent species, by assuming a local C_{3v} symmetry of the methyl top and a tilt of 2.35°.[18] The equilibrium conformation of the methyl group was determined by the microwave study[3] to be such that one of the C–H bonds lies on the CSC plane in the position trans to the S–C bond.

By using the structure parameters of the parent species, the deuterium-isotope effects were determined from the $I^{(z)}$ values of the d_3-species. The isotope effects in C–D, ∠DCD, and ∠CSC were also taken into consideration. Among them the isotope effect in C–D was estimated by assuming a Morse-type potential and using a diatomic approximation.[19] The values of ∠DCD and ∠CSC were adjusted to give a good fit for the three $I^{(z)}$ values of the d_3-species. It was found that there was no satisfactory solution for them in the r(S–C)<1.803 Å region, just outside the region allowed by the diffraction results. The moments of inertia of the ^{13}C and ^{34}S species were found to be consistent with the parameters of the parent species, in and around the region of the S–C distance examined by the present analysis. The variations of the parameters with the change in the S–C distance are shown in Fig. 2.

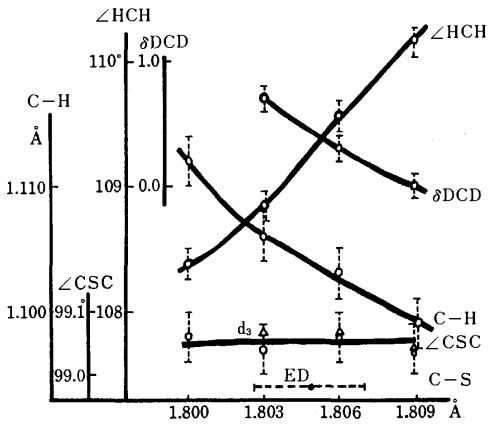

Fig. 2. Variations of structure parameters determined by moments of inertia along the change of the S–C distance. Vertical broken lines show the uncertainties due to ±0.01 amu Å² of $I^{(z)}$. Δ show the CSC angle of d_3-species. The range of S–C allowed by the diffraction result is indicated as ED. No solution was found for ∠DCDh and ∠CSC (d_3) in the region of S–C<1.803.

Table 3. Zero-point average structure of dimethyl sulfide[a]

	r_{av}, ϕ_{av}	ε_1	ε_2	ε_3	ε_4	ε_0
S–C	1.805	0.002	—	—	—	0.002
C–H	1.104	0.002	0.002	—	—	0.003
∠CSC	99.05	0.01	0.04	—	—	0.04
∠HCH	109.30	0.48	0.12	—	0.03	0.50
δ(CSC)[b]	0.01	0.02	0.03	0.01	—	0.04
δ(DCD)[b]	0.40	0.20	0.10	0.08	—	0.25

r_g; S–C 1.807, C–H 1.116

a) The distances are in Å, and the angles, in degree units. ε_1 through ε_4 are uncertainties from various origins, and ε_0 is the estimate of the total uncertainty. See text. b) δ(CSC)=∠CSC(in d_3)−∠CSC(h_6); δ(DCD)=∠DCD−∠HCH.

The structure parameters obtained by the analysis are summarized in Table 3. Uncertainties from various origins were estimated and are also listed in the table. They are: ε_1, from the half-width of the variation of the parameter values in the allowed region; ε_2, from the uncertainties of $I^{(z)}$, assumed to be ±0.01 amu Å²; ε_3, from the uncertainty of the estimated isotope effect in C–D ±0.0015 Å, and ε_4, from the uncertainty in the tilt, ±0.37°.[20] The total estimates of the uncertainty are shown as ε_0, obtained by means of the square-root of the sum of the squares of ε_1 through ε_4.

Discussion

The bond-angles in the zero-point average structure shown in Table 3 are close to the values of the r_s-structure reported by Pierce and Hayashi, while the r_z distances are longer than r_s.[21] The final structure in Table 3 leads to the r_a values of 2.418, 2.748, and 1.804 Å for S···H, C···C, and H···H respectively, neglecting the anharmonicity in bond-angles. The S···H and C···C distances are judged to be consistent with the diffraction results in Table 1. The HCH angle, 109.3(5)°, of this molecule is in the range, 107.9—110.8°, of the HCH angles of acetyl halides,[1] acetone,[2] acetaldehyde,[16] propane,[22] and 2-chloropropane,[23] which were determined by the technique of joint analysis. The C–H distance, 1.116 Å, in r_g is, however, longer than the C–H distances of these molecules, 1.101—1.109 Å. This may be an effect of the neighbouring hetero-atom sulfur, used in place of carbon, on the structure of the methyl group.

A positive isotope effect in the DCD angle (the effect giving a ∠DCD larger than ∠HCH) is similar to that found in acetone and several other molecules. As was discussed in a previous paper on acetone,[2] it may be attributed to the repulsive interaction between the two methyl tops. It is interesting to note that the nearest H···H distance between the two tops is 2.82 Å in acetone and 2.76 Å in dimethyl sulfide. The skeletal bond-distances are very different in the two molecules, but the smaller CSC angle of dimethyl sulfide compensates for the longer S–C distance, and the H···H distance becomes almost the same. Therefore, the effect of the H···H interaction, if any, may be expected to exist to a similar extent.

In the case of acetone, the isotope effect in the CCC angle was found to be 17′(2); that is, the angle for the d_6-species is less than that for the h_6-species. For dimethyl sulfide, however, the isotope effect in the CSC angle of the d_3-species is essentially zero. According to the idea that the isotope effect in the CSC angle is due to the anharmonicity of the symmetric rocking mode of the two methyl groups,[2] the effect in the d_3-species may be roughly estimated to be about one third of what would be observed for the d_6-species. The present result for the d_3-species does not necessarily exclude the possibility of the existence of the isotope effect in the d_6-species of an amount similar to that of acetone. Unfortunately, the spectroscopic data of the d_6-species

are not available.

The authors wish to thank Miss Kumiko Ohtaki for her help in an early stage of this work. The numerical computation was performed on a FACOM 230-75 of the Hokkaido University Computing Center, and also on a FACOM 270-20 in the laboratory of Professor Kimio Ohno, to whom the authors' thanks are due.

Molecular Structure of 2-Chloropropane, as Determined by a Combined Use of the Electron Diffraction Data and the Spectroscopic Moments of Inertia*

Takao IIJIMA, Schigenori SEKI, and Masao KIMURA**

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received March 25, 1977)

The gas-phase molecular structure of 2-chloropropane, $(CH_3)_2CHCl$, has been investigated by means of electron diffraction and by a joint analysis of the diffraction results and the spectroscopic moments of inertia. The structure parameters, distances in r_g and angles in φ_{av}, were determined (with parenthesized limits of error) to be as follows; C–Cl 1.812(1) Å, C–C 1.527(1) Å, C···Cl 2.720(2) Å, C–H 1.104(4) Å, ∠CCC 112.7(4)° and ∠HCH 108.5(8)°. The CCH_{sec} angle was assumed to be 109.8(20)°. The present results, together with the data for other molecules, confirmed a systematic elongation of the C–Cl r_g-distance in the series of methyl, ethyl, isopropyl, and *t*-butyl chlorides.

The systematic elongation of the C–Cl distances in the series of chloroalkanes (*viz.*, methyl, ethyl, isopropyl, and *t*-butyl chlorides) was first pointed out by Lide and Jen.[1] In the corresponding series of fluorides, a similar trend has also been observed.[2,3] These notable appearances of the environment effect on structure parameters are worth careful investigation, perhaps next after the environment effect on carbon-carbon bonds.[4]

For the series of chlorides mentioned above, the r_s-structures were determined by means of microwave spectroscopy. For *t*-butyl chloride, Hilderbrandt and Wieser obtained the r_z- and r_g-structure by an electron-diffraction investigation and a joint analysis of both the diffraction data and the spectroscopic moments of inertia.[5,6] For the other three molecules of the series, there has so far been no high-precision study by gas-electron diffraction. The present paper will report the structure determination of isopropyl chloride, or 2-chloropropane, by means of a joint analysis of the diffraction data and the spectroscopic moments of inertia. A similar study for the structures of ethyl chloride and methyl chloride will be reported in succeeding papers.[7,8]

A brief comment must be added to clarify why we are not content with the r_s-structures which are already available. The r_s-structure is the only existing structural information which can be obtained by making the optimal use of the experimental values of the ground-state rotational constants, without any knowledge of the molecular force field. It is widely accepted that the r_s-structure is useful, not only qualitatively, but, to a considerable extent, quantitatively as well.

In some favorable cases, the r_s-structure can be a good estimate of the r_e-structure. Watson[10] showed that the $I_s=(1/2)(I_e+I_0)$ relation holds for linear, planar, and symmetric top molecules. It is, then, possible to derive the r_e-structure from the r_s-structure and the observed ground-state rotational constants. The relation is theoretically approximate, but it is sufficiently good for molecules which do not contain light atoms, *e.g.*, hydrogen. For the molecules which contain hydrogen atoms, it seems that much is still left to be investigated about the physical nature of the r_s-structure.

In several recent determinations of accurate r_g-distances which were obtained by the combined use of spectroscopic and diffraction information, it was found, contrary to one's expectation, that the differences between r_g and r_s are not necessarily the same for similar bonded distances in different molecules.[11] The C–C distance of *t*-butyl chloride is one such case, the r_g-value being smaller than the r_s-value. This suggests that the r_s-structure (r_0-structure, too) may not be suitable for critical comparison and quantitative discussion of structural parameters.

Table 1. The r_s- and r_g-distances of C–Cl and C–C bonds in the series of chlorides (in Å units)[a]

		C–Cl	C–C	Reference
CH_3Cl	r_s	1.781(1)	—	12
	r_g	1.783(2)	—	8
CH_3CH_2Cl	r_s	1.788(2)	1.520(3)	13
	r_g	1.797(3)	1.526(4)	7
$(CH_3)_2CHCl$	r_s	1.798 (+8, −4)	1.520 (+4, −6)	14, 15
	r_g	1.812(1)	1.527(1)	b)
$(CH_3)_3CCl$	r_s	1.803(2)	1.530(2)	1
	r_g	1.830(5)	1.528(3)	5

a) The uncertainties to be attached to the last significant digit are shown in the parentheses. b) This work.

In the series of chlorides shown in Table 1, the documented r_s-values of C–Cl distances can not clearly establish the longer C–Cl of *t*-butyl chloride as compared with that of isopropyl chloride, if the quoted uncertainties are taken into consideration. In the present study, the uncertainties have been reduced by the use of joint analysis, and the difference in C–Cl distances has been clarified in terms of the r_g-structure, as is summarized in Table 1. The C–C r_g distances are nearly constant in this series of molecules, contrary to the difference observed in the r_s-structure.

Experimental

A guaranteed reagent of the Tokyo Kasei Co., Ltd., was used without further purification. The diffraction photographs were taken at room temperature on a unit with an

* 1Å=100 pm is used throughout this paper.

r^3-sector,[16] under the following conditions: camera length, 109.3 mm; accelerating voltage, 40 kV; beam current, 0.2 μA; exposure time, 1 min; and sample pressure, 60 Torr (1 Torr= 133.322 Pa). The total range of s covered was from 7 to 38 Å^{-1}.

Five sets of plates were taken during a week, each set containing six plates obtained in a sequence of exposures. The first set, like the last, was of the diffraction patterns of carbon disulfide, by which the scale factor was calibrated. The scale factors yielded by the two sets of carbon disulfide patterns agreed with each other within 0.1%. The relative stability of the accelerating voltage was monitored by a digital voltmeter and found to be within 0.05% during the term of a week. The nozzle setting was kept untouched so that the camera length was kept constant. Six plates of 2-chloropropane were selected from eighteen plates and analyzed by the least-squares method.

Analysis of the Diffraction Data

The procedure used to analyze the diffraction data of this molecule was much like that for 2-fluoropropane previously reported.[3] Four distances, C–C, C–Cl, C–H, and C···Cl, were adjusted by the least-squares method for molecular intensity. The remaining eighteen distances were fixed initially at the r_s-values by Tobiason and Schwendeman[14] and finally at values consistent with the converged values of the four adjusted distances, the r_s-values being still used for the parameters which could not be deduced from the four converged values. All the mean amplitudes were fixed at the values calculated by Cyvin and Cyvin.[17] The other details followed the routine procedure described in Ref. 18. The results of the least-squares adjustment are listed in Table 2.

a) Index of resolution: 0.95—1.00 b) For the definitions of σ_1 and σ_2, see Ref. 19. c) Limits of error estimated from $2.5\sigma_1$ and the systematic error originating in the uncertainty of the scale factor.

The best-fit calculated molecular intensity and the residuals of the observed are shown in Fig. 1.[20] The residuals are shown in an enlarged scale, four times as great as that of $sM(s)$ curve. The narrower boundaries with shading correspond to ±2 of the last digit of the digital voltmeter, that is, the limits of detection in the photometry. The outer boundaries (shown by the broken lines) are the estimated limits of error in the intensity measurement; they indicate the normally expected range of scattering in the intensity data. Some of the points exceeded the boundary, more or less for accidental reasons. These points were zero-weighted in the final refinement and are shown by vertical broken lines in Fig. 1. The shifts of the converged values of the parameters caused by the use of the modified weight were within the standard deviations, which were reduced to about two thirds of the standard deviations in the unmodified case.

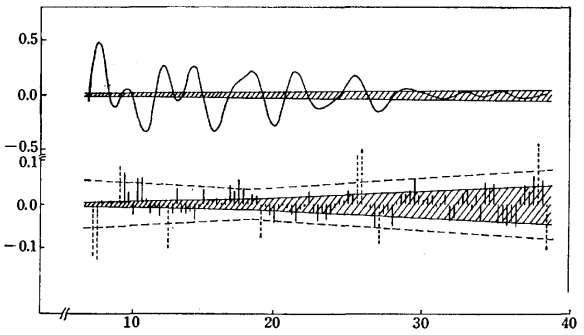

Fig. 1. The best-fit theoretical molecular intensity and the residuals of 2-chloropropane. See text.

Joint Analysis

The effective moments of inertia, as determined by Tobiason and Schwendeman,[14] were corrected for the vibrational effect and converted into $I^{(z)}$, the moments of inertia for the zero-point average structure.[4] The corrections were calculated by the use of the force constants obtained by Cyvin and Cyvin.[17] Since the barrier to the methyl torsion has been reported to be greater than 3.45 kcal/mol,[14] the torsional motions were treated as small amplitude vibrations. The r_g distances of the C–C, C–Cl, and C···Cl atom-pairs determined by electron diffraction were converted into r_α^0 distances[21] by correcting for the anharmonic term, the centrifugal stretching, and the perpendicular vibration. The Morse parameter, a_3, was assumed to be 2.0 Å^{-1} for C–C and C–Cl distances and zero for the non-bonded C···Cl distance. The numerical values of these vibrational corrections are summarized in Table 3.

Table 3. Moments of inertia, vibrational correction, and r_α^0-distances of 2-chloropropane[a]

	$I^{(eff)}$ [b]	ΔI[c]	$I^{(z)}$ (in amu Å^2)

C···Cl	0.0021		2.715_1

a) Similar tables for isotopic species are omitted. b) Calculated from the rotational constants[14] by means of the conversion factor of 505376 Mc amu Å^2. c) Vibrational correction for $I^{(eff)}$. $I^{(z)}=I^{(eff)}+\Delta I$. d) See Ref. 6 for the definition.

The uncertainty of $I^{(z)}$ was assumed to be 0.01 amu Å^2, while that of r_α^0 was taken to be equivalent to the limits of error of the r_a values. The zero-point average

structure (r_{av}-structure)[21] was determined by a joint analysis of the r_α^0 by diffraction and of $I^{(z)}$ by spectroscopy. $(CH_3)_2CH^{35}Cl$, -^{37}Cl, -$D^{35}Cl$, and $(CH_3)(CD_3)$-$CD^{35}Cl$ (the C's are all ^{12}C) were selected for the structure analysis in the present work.

It has been our experience that the moments of inertia of the isotopic species of such heavy atoms as ^{13}C and ^{37}Cl can not give additional information independent of that of the parent species. This comes about for two reasons. First, the range of parameters which can account for the $I^{(z)}$ of both the parent species and the isotopic species is usually rather wide. Thus, the use of $I^{(z)}$ for the isotopic species is of no help in reducing the range of parameters already limited by the results of electron diffraction, if the uncertainties of $I^{(z)}$, which are of the order of 0.01 amu Å^2, are taken into consideration. Secondly, the border between the acceptable region and the unacceptable region of the parameters is very vulnerable to the estimated isotope effects in structure parameters and to the amount of the uncertainty of $I^{(z)}$, for which no quantitative method of estimation has been established.[22]

The deuterated species, on the other hand, can provide independent information. In this case, however, the isotope effect on the structure parameters becomes important. For the bonded distances, the isotope effect may be estimated fairly well by assuming a Morse-type anharmonic potential and using a diatomic approximation.[23] For the bond angles, usually almost nothing is known about the anharmonicity.

It seems to be a sound approach to the problem to let the isotope effects in the bond angles be adjustable and to determine the values from the $I^{(z)}$ of the deuterated species, as has already been attempted in some of the previous studies.[24–26] Fortunately, the deuterated species are very effective in reducing the allowed range of parameters, even if additional freedom is introduced by adjustable isotope effects. Moreover, the discrepancy between the calculated and observed values of $I^{(z)}$ develops markedly with small changes in the parameters, so that the final conclusion for the structure is not sensitive to the estimated amount of the uncertainty in $I^{(z)}$.

Therefore, in the present study, the structure parameters were first determined chiefly by the use of the $I^{(z)}$ of the parent species. The $I^{(z)}$ of the ^{37}Cl species were calculated by the same parameter values only in order to confirm that they were consistent with the observed values. The allowable ranges of the parameters are naturally very wide at this stage, covering an area bounded only by the limits of error in the results of electron diffraction. They were then reduced by the use of the deuterated species. The isotope effects in $\angle ClCD_s$, $\angle DCD$ in the methyl tops and $\angle CCC$ in the D-4 species were adjusted, while the isotope effect in the C–H bond was assumed to be the value calculated by the diatomic approximation, with an estimated uncertainty of ± 0.0015 Å.[27]

The local C_{3v} symmetry was assumed for the methyl tops. The tilting angle was assumed to be zero. The methyl C–H distance and the secondary C–H distance were assumed to be equivalent in their r_g values. Therefore, their difference in r_{av}-structure was fixed at the calculated value, 0.007_5 Å. A pertinent piece of information from the microwave study is that one of the methyl C–H bonds lies on the CCC plane in the trans position to the C–C bond.[14] There are still seven independent structure parameters left, —— C–C, C–Cl, C···Cl, $\angle CCC$, C–H, and $\angle HCH$ in the methyl top and $\angle CCH_s$. For the C–C, C–Cl, and C···Cl distances, the most probable values and the uncertainties by which the parameters may vary have been determined by electron diffraction. Therefore, three more parameters can be determined by the three moments of inertia of the parent species. By considering that the $I^{(z)}$ values are least sensitive to a change in $\angle CCH_s$, it was assumed at the value in the r_s-structure, 109.8°, with an estimated uncertainty of $\pm 2°$.

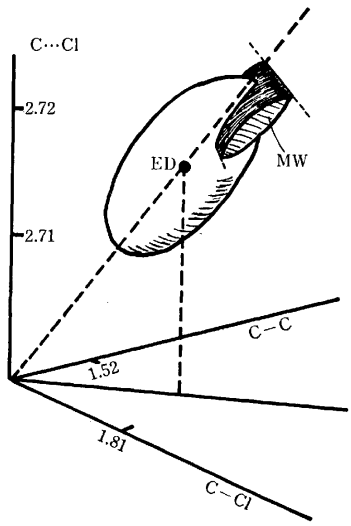

Fig. 2. The allowable range of structure parameters shown in the three-dimensional parameter space. The limits of error of electron diffraction is shown by a boundary like a rugby ball. The region compatible with spectroscopic moments of inertia is shown by the shaded portion of the space, which extends to both sides more than depicted.

The range of parameters compatible with the $I^{(z)}$ of the deuterated species as well as the parent species is shown schematically in Fig. 2; it is denoted as MW, with shading. The most probable values can be determined by the portion of the MW region which is inside the error boundary of electron diffraction. Figure 3 shows the section of Fig. 2 by means of a plane defined by the C···Cl axis and a straight line connecting the origin and the ED point. In the sections parallel to that shown in Fig. 3, the situation is more or less similar.

The results obtained are summarized in Table 4. Uncertainties originating from the several different factors are also shown: ε_1, the half-width of the variation in the parameter value corresponding to the allowed region; ε_2, the uncertainty originating in the uncertainty of $I^{(z)}$, ± 0.01 amu Å^2, although the correlations among the parameters are not shown; ε_3, the uncertainty due to the assumed $\angle CCH_s$, $\pm 2°$; and ε_4, that due to the

uncertainty of the assumed isotope effect in the C–H(D) distance, ±0.0015 Å. The total estimates of uncertainty are then shown in the last column as ε_0.

The parameters of the structure of methyl tops, C–H and HCH, apparently decrease upon averaging over the torsional motion. For comparative purposes, however, it is desirable to get structure parameters which correspond to that of the large-amplitude treatment,[24] or a structure in which the average over the torsional motion is excluded. In the values listed in Table 4, the averaging effect of the torsional motion is eliminated by adding 0.010 Å to the determined C–H distance and 0.17° to the HCH angle. Thes corrections were evaluated from the differences between the present results and those of the large-amplitude treatment.[28] They were also in good agreement with the estimates by a simple model-calculation that the apparent shrinking of the C–H distance is due only to the perpendicular amplitude of the torsional mode and that the decrease in the HCH angle is caused by a slight bending of the shrunken C–H bonds, so that all the hydrogen atoms may lie on the same plane as that in the torsional-equilibrium configuration.

Discussion

The skeletal structure has already been discussed in the introductory part, where it was compared with the structures of other normal alkyl chlorides. The structure of the methyl top of this molecule is much like that of acetone, including a positive isotope effect in the DCD angle, which was interpreted as being due to the repulsive interaction between two methyl tops.[29] The isotope effect in the CCC angle was −0.3° in D-6 acetone, while it is zero in the present case. This is not in perfect conformity with the picture of the repulsive interaction, although the amount of δ(CCC) is expected to be smaller in the present species, for which only one of the two methyl tops is deuterated.

The positive isotope effect in $\angle CCD_s$, obtained as 0.24°, corresponds to a negative one in the $ClCD_s$ angle, −0.5°. This may be manifestation of the anharmonicity due to a repulsive interaction between the chlorine and the secondary hydrogen.

In the present study, the anharmonicity in non-bonded C···Cl was neglected in obtaining r_a^o from r_g. If the Morse-type parameter, a_3, had a non-zero value, the ellipse shown in Fig. 3 by the broken curve would be shifted parallel to the C···Cl axis downwards or upwards, according to whether it has a positive value or a negative one. The overlapping area and, therefore, the structure parameters would be almost the same for a negative value within 0—2 $Å^{-1}$. However, for a positive a_3, the overlapping area would decrease rapidly, and the consistency between the diffraction results and the spectroscopic moments of inertia would diminish. A possibility of a non-bonded anharmonicity which could be expressed by a Morse-type potential with a negative a_3 value has also been found in recent studies of $CHCl_3$[30] and $CHBr_3$[31] molecules.

a) I: the complete r_s-structure; Ref. 14. II: the range of variation in the r_s-structure; Ref. 15. III: the r_{av}-structure of the present study. b) According to Ref. 15. c) Assumed.

Tobiason and Schwendeman determined the complete r_s-structure for this molecule by the use of the species isotopically substituted for all non-equivalent atoms.[14] It is compared in Table 5 with the r_{av}-structure determined in the present study. There also are shown the ranges in the variation of the r_s-values reported by Schwendeman.[15] These variations are what would be caused by different analytical methods as well as by an insufficient number of isotopic species. It may be noted that the complete r_s-structure is in fair agreement with the r_{av}-structure except for the C–Cl distance, and that the maximum deviation of an incomplete r_s-value from the r_{av}-value may be about 2° in bond-angles. It seems, then, appropriate to assume an uncertainty of $\pm 2°$ when some bond angle in the r_s-structure are used as complementary information in determining the r_{av}-structure.

The numerical computations were performed on a FACOM 230-75 of the Hokkaido University Computing Center and on a FACOM 270-20 in the laboratory of Prefessor Kimio Ohno, to whom the authors' thanks are due.

Crystal and Molecular Structure of 3-(Adenin-9-yl)propiontryptamide

Minoru OHKI, Akio TAKENAKA, Hirotaka SHIMANOUCHI, and Yoshio SASADA

Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received March 31, 1977)

The crystal structure of 3-(adenin-9-yl)propiontryptamide (3-(adenin-9-yl)-*N*-[2-(3-indolyl)ethyl]propionamide) has been investigated as a model for adenine-tryptophan interaction. The space group of the crystal is $P2_1/c$, with dimensions $a=8.512(2)$, $b=16.884(3)$, $c=12.405(3)$ Å, $\beta=105.54(2)°$, and $Z=4$. The structure was solved by the direct method and refined by a block-diagonal least-squares method. A slight overlapping between adenine and indole moieties is found, but it may not be sufficient to produce a strong π-π interaction. The adenine base is paired with that related by the centre of symmetry through two N(6)H···N(1) hydrogen bonds, and also with the other centrosymmetrically related adenine base through two N(6)H···N(7) hydrogen bonds. Adenine and indole are bound through a hydrogen bond between N(7) of adenine and imino nitrogen of indole.

Interaction between nucleic acid and protein plays an important role in several biological processes, though the precise molecular mechanism is still unknown. Some elementary binding patterns between amino acid and purine-pyrimidine base, if any, would provide a stereochemical basis for the mechanism of mutual recognition between nucleic acid and protein.

We have reported some common hydrogen bond schemes between cytosine and acidic amino acid through X-ray crystallographic studies of complexes between nucleotide bases and amino acid derivatives.[1-3] The preparation of complex crystals is very difficult owing to the physico-chemical properties of the compounds; only a few complex crystals of restricted combination of components have been obtained. We have tried to use other type of model compounds containing a nucleotide base and a side group of amino acid in a molecule. They might provide interaction modes for any combinations between nucleotide bases and amino acids.

Intermolecular stacking interaction between adenine and tryptophan was suggested from spectroscopic studies.[4-7] On the other hand, in the crystal of 9-ethyladenine–indole complex[8] there is no stacking interaction between the two components. They are bound through a hydrogen bond between N(3) of adenine and imino nitrogen of indole. We have found the same hydrogen bond in the monohydrate crystal[9] of the title compound. In the present paper, we report another mode of hydrogen bond between adenine and indole moieties.

Experimental

3-(Adenin-9-yl)propiontryptamide (3-(adenin-9-yl)-*N*-[2-(3-indolyl)ethyl]propionamide) was synthesized from 9-(β-carboxyethyl)adenine[10] and tryptamine by the dicyclohexylcarbodiimide method. Plate crystals were obtained by evaporating a solution of benzene and methanol (10: 1) at room temperature. Oscillation and Weissenberg photographs showed the space group to be $P2_1/c$ from the systematic absence of reflexions. The density was determined by flotation in a mixture of cyclohexane and carbon tetrachloride. A crystal, $0.2\times0.3\times0.4$ mm, was mounted on a Rigaku four-circle automated diffractometer. Unit-cell parameters were calculated by least-squares refinement of 2θ values for 22 high-angle reflexions (Mo$K\alpha$; $\lambda=0.71069$ Å). Crystallographic data are summarized in Table 1.

Table 1. Crystal data

3-(Adenin-9-yl)propiontryptamide	
$C_{18}H_{19}N_7O$	$F.W.=349.40$
Crystal system: monoclinic	
Systematic absences: $h0l$, $l=2n+1$; $0k0$, $k=2n+1$	
Space group: $P2_1/c$	$Z=4$
$a=8.512(2)$ Å	$D_x=1.350$ g cm^{-3}
$b=16.884(3)$	$D_m=1.34_7$ g cm^{-3}
$c=12.405(3)$	μ(Mo$K\alpha$)
$\beta=105.54(2)°$	$=0.98$ cm^{-1}
$U=1719.6(6)$ Å^3	

Intensity data were collected on the diffractometer by use of graphite-monochromated Mo$K\alpha$ radiation, with a $\omega/2\theta$ scanning technique ($2\theta\leq50°$). Five reference reflexions monitored periodically showed no significant intensity fluctuations during the course of data collection. Corrections were made for the Lorentz and polarization factors, but not for absorption. A total of 3030 independent reflexions were obtained, zero-reflexions ($I\leq\sigma(I)$) numbering 810.

Structure Determination and Refinement

The structure was solved by the symbolic addition procedure.[11] The atomic parameters were refined by the block-diagonal least-squares method; the quantity minimized was $\Sigma\omega(|F_o|-|F_c|)^2$, with $\omega=1/(\sigma^2_p+qF_o^2)$ where σ_p is due to counting statistics and q is 1.25×10^{-5} derived from the intensity variance of the monitored reflexions. In the refinement, the zero-reflexions were included by assuming $|F_o|=F_{lim}$ and $\omega=\omega(F_{lim})$ where F_{lim} is 2.43, an observational threshold value. However, zero-reflexions for which $|F_c|<F_{lim}$ were omitted. When the R value reached 0.11, a difference synthesis revealed all the hydrogen atoms. The refinement was terminated when the maximum shift of parameters for hydrogen was less than 0.49σ. The final R value was 0.088 for 2504 reflexions ($R=0.073$ for $F_o\geq3/\sqrt{\omega}$). Atomic scattering factors were taken from "International Tables for X-Ray Crystallography."[12] A comparison between observed and calculated structure factors is given in Table 2.[13] The final positional and thermal parameters are listed in Table 3.

Table 3. Final positional and thermal parameters

Standard deviations are given in parentheses. The anisotropic temperature factor has the form $\exp[-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{13}hl+B_{23}kl)]$.

Results and Discussion

Molecular Structure. Bond lengths and angles are given in Table 4 and those involving non-hydrogen atoms in Fig. 1. The least-squares planes of adenine, indole and amide moieties are given in Table 5, together with the displacements of atoms from the planes. The molecular structure is shown in Fig. 2, torsion angles being given in Table 6.

The bond lengths and angles of the adenine ring are in good agreement with those found in related compounds.[14] The purine base is highly planar with a maximum shift of 0.011 Å for N(1) from the least-squares plane.

In the six-membered ring of indole, the bond lengths of C(18)–C(19) and C(20)–C(21) are shorter than the others, the bond angle of C(16)–C(21)–C(20) being the smallest. This is a common feature in the related compounds.[15,16] The indole ring is highly planar with a maximum displacement of 0.010 Å for C(20) from the least-squares plane. The exocyclic atom of C(13) significantly deviates from the plane.

As shown in Fig. 2, the molecule is folded as torsions around C(9)–C(10) and C(12)–C(13) are in skew arrangement (Table 6), in contrast to the extended form in its monohydrate crystal.[9] The dihedral angle between the adenine and indole rings in the molecule is 38.3°. The shortest intramolecular contact between the adenine and indole rings is 3.612 Å for C(6)···N(11).

Crystal Structure. The crystal structure viewed along the a axis is shown in Fig. 3, and that along the

projection onto the adenine plane and (b) that onto the indole. These planes make an angle of 18.7°, and the overlapping area is very small, so that there is no strong π-π interaction between them.

The hydrogen bond arrangement is shown in Fig. 6, relevant distances and angles being given in Table 7. The adenine base is paired with that related by the centre of symmetry through two N(6)H···N(1) hydrogen bonds and also with the other centrosymmetrically

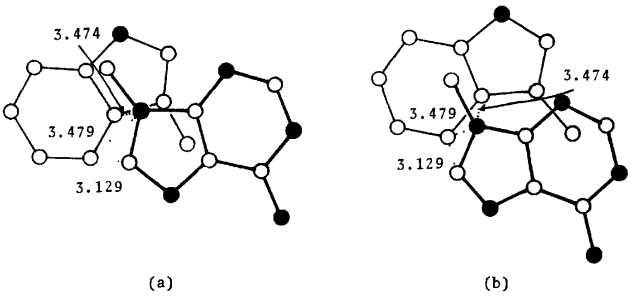

Fig. 5. The stacking geometry of adenine and indole rings. (a) is a projection onto the adenine plane and (b) is that onto the indole.

related adenine bases through two N(6)H···N(7) hydrogen bonds. From a comparison of the hydrogen bond lengths and angles between these two pairing modes (Table 7), it is suggested that the mode by two N(6)H···N(1) hydrogen bonds is more stable than that by two N(6)H···N(7) bonds. This is consistent with the relative stability of these modes calculated by Pullman *et al.*[18] using molecular orbital methods.

N(3) of the adenine ring is hydrogen bonded with N(10) of the amide group in the molecule related by the centre of symmetry. The same kind of hydrogen bonding between nucleotide bases and amide groups is proposed by Gurskii *et al.*[19] as a model of interaction of nucleic acid with regulatory proteins. Furthermore, it is found that N(7) of the adenine ring is hydrogen bonded with N(11) of the indole. Thus N(7) acts as an acceptor

for two hydrogen bonds from N(11) of indole and N(6) of adenine. A similar situation was found for N(1) of adenine in the crystal of *N*-[3(adenin-9-yl)propyl]-3-carbamoylpyridinium bromide.[20] This would be attributable to the large basicity of the nitrogen atoms.[21] Judging from the lengths and angles (Table 7), the N(11)H···N(7) hydrogen bond should be stronger than N(6)H···N(7). The hydrogen bonded adenine and indole rings make an angle of 18.7°.

Interaction Mode between Adenine and Aromatic Moiety of Amino Acid. Crystals of 3-(adenin-9-yl)propiontyramide dihydrate,[22] 3-(adenin-9-yl)propiontryptamide (the present molecule), its monohydrate,[9] and 9-ethyladenine–indole complex[8] are systems in which adenine and aromatic moieties co-exist. Although a π-π interaction between adenine bases in nucleic acid and aromatic side groups in protein is suggested by spectroscopic studies,[4-7] these crystal structures show that there is no stacking between the two components except for the present crystal. Even in the overlapping between adenine and indole rings found in the present crystal (Fig. 5), the relative arrangement may not be sufficient to produce a strong π-π interaction. This is consistent with the calculations of Pullman and Pullman,[23] which indicate both adenine and indole to be π-electron donating. Thus, we consider that hydrogen bonding is more important than the stacking in the system of adenine and the aromatic amino acids.

Two interaction modes between adenine and indole have been found. One is the hydrogen bonding between N(3) of the former and N(11) of the latter found in the crystals of 9-ethyladenine–indole complex[8] and 3-(adenin-9-yl)propiontryptamide monohydrate.[9] The other is the hydrogen bonding between N(7) of the former and N(11) of the latter found in the present crystal. All the adenine bases interacting with indole are paired with other symmetry-related adenines in the crystals. Thus, the hydrogen bonds between adenine and indole provide models of interaction between paired adenine and the side group of tryptophan. We have tried to fit the interaction geometries found in our studies into a double helical nucleic acid (conformation B), atomic coordinates of which are taken from the work of Arnott and Hukins.[24] The indole ring bound to N(7) can be situated in the major groove of DNA without any stereochemical difficulties (Fig. 7); the shortest intermolecular contact is 4.67 Å. On the other hand, the indole ring bound to N(3) in the minor groove gives very short approach to the ribose part, so that some modification of the DNA structure might be required.

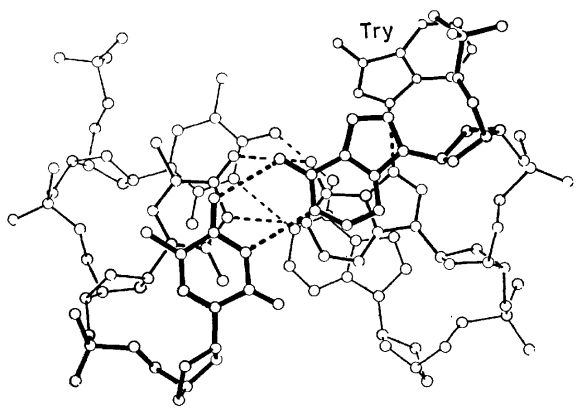

Fig. 7. Indole fitted into a double helical nucleic acid which is constituted with three adenine: thymine base pairs in the B conformation.

Part of the expenses connected with this research was defrayed by grants from the Ministry of Education and from the Kawakami Foundation, to which the authors' thanks are due.

The Oxidation Activity and Acid-base Properties of V_2O_5-based Binary Catalysts

Mamoru Ai

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received April 9, 1977)

The oxidation of *cis*-2-butene, butadiene, and acetic acid was carried out by using a series of V_2O_5–X_nO_m (atomic ratio=9: 1) catalysts with more than twenty metal oxides (X_nO_m). The results were compared with the dehydration activity for isopropyl alcohol (IPA), as a measure of acidity, and with the ratio, dehydrogenation activity for IPA/dehydration activity for IPA, used as a measure of the basicity of catalyst. The activity for the oxidation of butadiene and that for the isomerization of butene are correlated with the acidity, and the activity for the oxidation of acetic acid with the basicity of the catalyst. The selectivity to maleic anhydride from butene and butadiene is scarcely influenced by the introduction of metal oxides. Butene is mainly oxidized to acetic acid as a result of C–C fission. The selectivity to acetic acid is enhanced when the catalyst is highly acidic, decreasing with increase in basicity. It is concluded that the introduction of metal oxides into V_2O_5 modifies the acid-base properties of the catalyst, inducing a change in oxidation activity and selectivity.

Catalysts based on V_2O_5 have been used for a long time in the synthesis of sulfuric acid from sulfur dioxide and of carboxylic acids from aromatic hydrocarbons; they play an important part in the partial oxidation of organic substances. The characteristic feature of these catalysts is their effective specificity in "acid formation."

As a practical catalyst, pure V_2O_5 is rarely used. In most cases V_2O_5 is modified by combining it with oxides of other metals in order to enhance the catalytic action. Attempts have been made to determine the role of the additives as regards the structural,[1–6] electronic,[7–12] and other physico-chemical properties of the catalyst system.[4,13–16] It should be noted that the selectivity of acrolein to acrylic acid is connected with the electronegativity of the metal oxides used as second components added to V_2O_5 catalysts.[17]

The acid-base properties and their correlation with the oxidation activity and selectivity were studied in the case of many MoO_3 and V_2O_5-based binary catalysts, such as MoO_3–P_2O_5,[18] MoO_3–Bi_2O_3–P_2O_5,[19,20] MoO_3–V_2O_5,[21] MoO_3–TiO_2,[22] MoO_3–SnO_2,[23] MoO_3–Fe_2O_3,[24] V_2O_5–P_2O_5,[25] V_2O_5–TiO_2,[22] V_2O_5–SnO_2,[26] and V_2O_5–Fe_2O_3.[24] The catalytic activity for the oxidation of electron-donating (basic) reactants such as olefinic and aromatic hydrocarbons is correlated with the acidic nature of the catalyst surface, and that of acidic reactants such as carboxylic acids with the basic nature of the catalyst. The activity and selectivity in mild oxidations are governed by the acid-base properties of the catalyst and the reactant.[18–26]

The following two functions are required for a catalyst to be active in an oxidation reaction;

(1) activation of oxygen,

(2) activation of reactant molecules.

When a catalyst is potent in the activation of oxygen, *i.e.*, when it has high oxidizing power, the reaction takes place without requiring any activation of the reactant: it proceeds non-selectively toward CO_2 and H_2O. This is the case of deep oxidation.[27] On the other hand, when the oxidizing power of a catalyst is not very high, the reaction requires the activation of the reactant molecule as well as of oxygen. Thus the difference in the mode or degree of this reactant-activation brings about the selectivity of the catalyst.

The acidic sites, probably consisting of metal ions with a particularly high electron affinity, play a role in the electron transfer from reactant to the sites, resulting in the formation of a cationic intermediate and a reduced metal ion;[28–30] the acidic sites contribute to the activation of the elctron-donating (basic) reactants, such as olefins. On the other hand, the basic sites, because of their electron-donating ability, serve to adsorb and activate the acidic reactants such as carboxylic acids.

The fact that V_2O_5 is a typical acidic oxide leads us to the prediction that the addition of metal oxide to V_2O_5 modifies the acid-base properties of the catalyst system, and that this modification, in turn, induces a change in the catalytic behavior.

In the present work, we have attempted to confirm how the addition of a small amount of metal oxide to V_2O_5 modifies the acid-base properties as well as the oxidation activity and selectivity and to find the correlation between the acid-base properties and catalytic behavior.

Experimental

Catalysts. The catalysts used in this study were a series of V_2O_5-based binary oxides, V_2O_5–X_nO_m. As the second component, X_nO_m, more than twenty metal oxides, including almost all those used in practice, were tested. As starting materials, we used nitrates for Al, Sb, Bi, Te, Fe, Ni, Cr, Co, and Zn, ammonium salts of oxo-acid for V, Mo, and W, chlorides (converted into hydroxides with dilute ammonia) for Sn and Ti, hydrates for Ca, Mg, and K, acetate for U, H_2SO_4 for S, and H_3PO_4 for P. The surface area of these catalysts were determined by the BET method, using nitrogen at −196 °C.

Determination of Acidic and Basic Properties. Since the V_2O_5-based mixed oxides are colored and small in surface area, it is not easy to determine their acidity and basicity by the ordinary titration method[31,32] or by studying the adsorption of a basic or acidic molecule in the gas phase. However, from a comparison of the catalytic activities for isopropyl alcohol (IPA) with the acidity-basicity data directly measured on many kinds of mixed catalysts, such as MoO_3–Bi_2O_3–P_2O_5,[20] MoO_3–TiO_2,[22] MoO_3–SnO_2,[23] MoO_3–Fe_2O_3,[24] V_2O_5–TiO_2,[22] V_2O_5–SnO_2,[26] V_2O_5–Fe_2O_3,[24] and TiO_2–

X_nO_m (X_nO_m=various kinds of metal oxides),[33] it has been found that the activity for the dehydration of IPA to propylene (r_p) represents the acidity of the catalyst and that the value of the r_a/r_p ratio, where r_a is the activity for the dehydrogenation of IPA to acetone, is also valid as an index of basicity;

$$\text{acidity} \propto \text{dehydration rate} \quad (1)$$

$$\text{basicity} \propto \frac{\text{dehydrogenation rate}}{\text{dehydration rate}}. \quad (2)$$

The results indicate that acidic and basic sites take part almost equally in the dehydrogenation of IPA;

$$\text{dehydrogenation rate} \propto (\text{acidity})(\text{basicity}). \quad (3)$$

This reaction may proceed by means of a concerted mechanism, *e.g.*,[34]

$$\geq C\text{-}H^{\ominus} \rightarrow \text{acidic site}$$
$$O\text{-}H^{\oplus} \rightarrow \text{basic site}$$

Thus we used the values of r_p and r_a/r_p as measures of the acidity and basicity, respectively, of the catalysts.

Catalytic Activity Measurements. The vapor-phase oxidation of *cis*-2-butene, 1,3-butadiene, and acetic acid, and the dehydration and dehydrogenation of isopropyl alcohol (IPA) were carried out in an ordinary continuous-flow-type reaction system. The concentrations of butene, butadiene, acetic acid, and IPA were 0.67, 0.67, 1.5, and 1.65 mol%, in the air; the total flow rate (at 25 °C) was kept constant at 1.5 l/min, the amout of catalyst used being 2—30 g. The reactor and experimental procedures were the same as those employed in previous works.[18-26]

Results and Discussion

Acidic and Basic Properties. A gaseous mixture of IPA with air was passed through a bed of the catalyst (2—6 g) held at 175 °C. The rates of dehydration (r_p) and dehydrogenation (r_a) [mol/h g-cat], which are known to be almost of zero-order with respect to the IPA concentration,[18-26] were obtained for each catalyst.

The values of r_p together with the surface areas, S (m^2/g) are given in Fig. 1. Introduction of the additives (X_nO_m) causes a remarkable change both in the surface area and the specific acidity (r_p/S) of the catalyst. It should be noted that introduction of TeO_2, K_2SnO_3, and K_2SO_4 into V_2O_5 decreases the acidic property significantly.

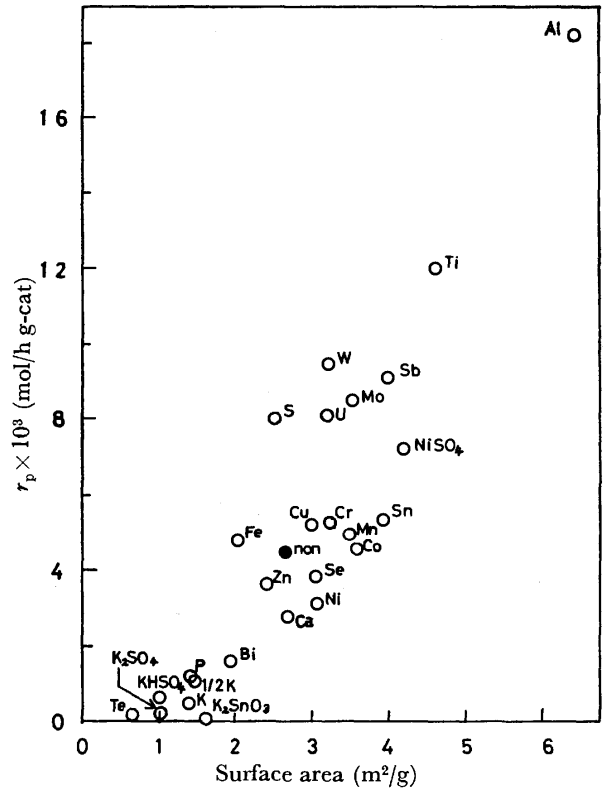

Fig. 1. Influence of the second components (X_nO_m) on the acidity (r_p) and the surface area.

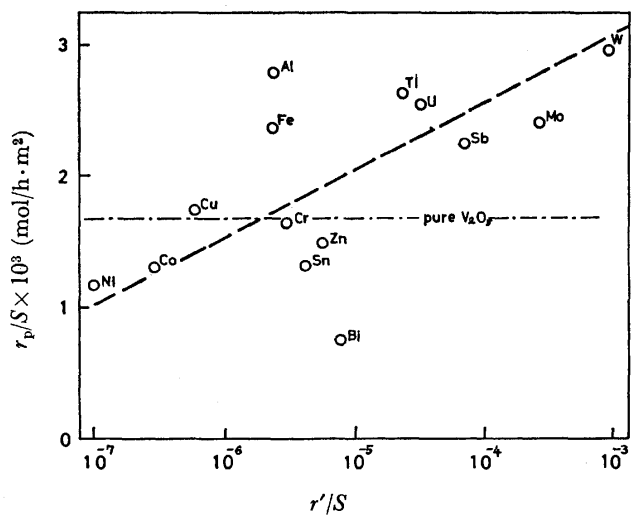

Fig. 2. The specific acidity of the binary system (V_2O_5–X_nO_m), r_p/S, as a function of that of the second component (X_nO_m) alone, r'_p/S.
r_p: The dehydration rate at 175 °C,
r'_p: the dehydration rate at 190 °C.

In Fig. 2 the specific acidity of the binary system, r_p/S, is plotted as a function of that of the second component (X_nO_m) alone, r'_p/S, obtained previously.[35] A rough correlation holds between r_p/S and r'_p/S, though a disparity and some exceptions are found. Addition of such acidic elements as P_2O_5 and TeO_2 decreases the acidity.

Figure 3 shows the relationship between the specific acidity, r_p/S, and the basicity, r_a/r_p. The basicity decreases a great deal with an increase in acidity, as might be expected in the case of a liquid acid-base, except for the cases of P_2O_5 and TeO_2. Introduction of P_2O_5 decreases both the acidity and the basicity.

Isomerization Activity for Butene. The oxidation of butene over a V_2O_5-based catalyst is always accompanied by its isomerization. The influence of the additives on the activity for the isomerization of butene was studied. The experiments were carried out at the *cis*-2-butene concentration of 0.67 mol % in the air, at a total flow rate of 1.5 l/min, and at 220 °C, the catalyst amount being varied in the 2.5—30 g range. The ratio of (*trans*-2-butene + 1-butene)/(*cis*-2-butene + *trans*-2-butene + 1-butene) corresponding to the surface area of 5 m^2, I, which is far from the thermodynamic equilibrium (I_e) of *ca.* 0.65, was adopted as a measure of the specific activity for isomerization. The data are plotted against the value of r_p/S in Fig. 4.

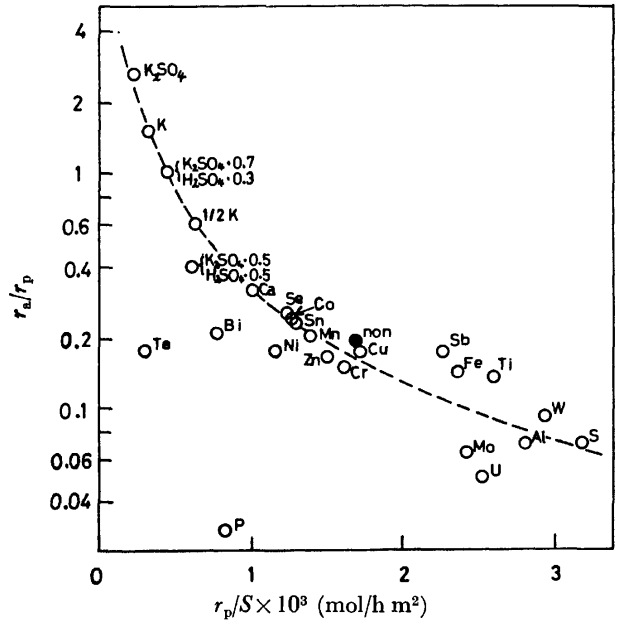

Fig. 3. Relation between the acidity (r_p/S) and the basicity (r_a/r_p).

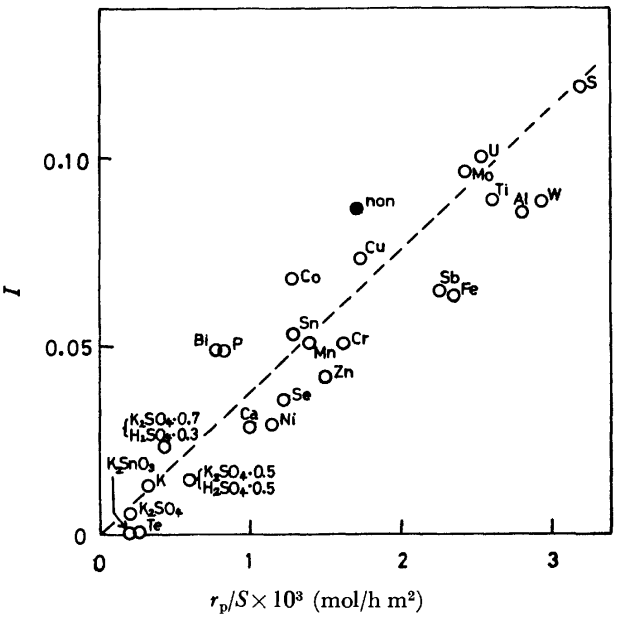

Fig. 4. The isomerization activity (I) against the acidity (r_p/S.)

A linear relationship is obtained between isomerization activity and acidity of the catalyst. This indicates[22,23,26] that, under the circumstances of the oxidation reaction in a flow system, the isomerization is catalyzed only by the acidic sites, and that the basic sites which can also catalyze the isomerization in the absence of oxygen in a closed[36] or pulse-reaction system[37] are poisoned by CO_2 or other acidic products.

Oxidation Activity for Olefin. The promotive effect of the additives on the oxidation activity for such basic reactants as olefins was also examined. The oxidation of 1,3-butadiene was chosen as a model reaction for convenience of experimental procedure. It was carried out over a seires of V_2O_5–X_nO_m catalysts at 285 °C, the amount of the catalyst being varied from 2.5 to 25 g. The initial rate of butadiene disappearance, r_B (mol/h g-cat), was adopted as a measure of activity. The specific activity, r_B/S, is plotted as a function of the specific acidity, r_p/S, in Fig. 5.

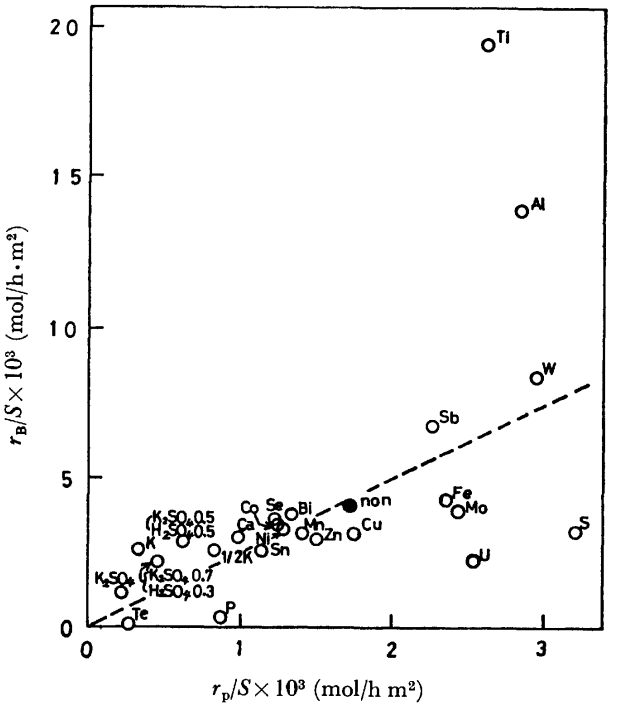

Fig. 5. The oxidation activity for butadiene (r_B/S) as a function of the acidity (r_p/S).

A moderately good correlation is obtained between oxidation activity and acidity, except for several oxides such as TiO_2, Al_2O_3, P_2O_5, SO_3, and U_3O_8. The data are in line with the results obtained previously,[18–26] indicating that the acidic sites play an important role in catalyzing the oxidation of olefin. It seems that the large deviation of V_2O_5–TiO_2 and V_2O_5–Al_2O_3 is connected to their large surface area. When the oxidation activity per unit volume of catalyst is very high, the evolution of heat per unit volume of catalyst becomes great and, the real temperature of the catalyst surface becomes much higher than the measured temperature, which gives rise to a large increase in apparent activity. The disparity of these results may arise in part from the participation of another factor in the catalysis; *e.g.*, the activation of oxygen which seems to be associated with (1) the strength of metal-oxygen bonding and (2) the possibility of incorporation of gaseous oxygen into the crystal lattice oxygen by electron donation from the catalyst.

Oxidation Activity for Acid. The influence of the additives on the oxidation activity for acidic compounds was also examined. Acetic acid was chosen as the reactant. The initial rate of oxidation to CO_2 at 325 °C, r_A (mol/h g-cat), was adopted as a measure of activity.

The specific activity, r_A/S, is plotted as a function of the basicity, r_a/r_p, in Fig. 6. The basic sites of the catalyst are considered to contribute to the activation of acidic compounds.[19–22,24]

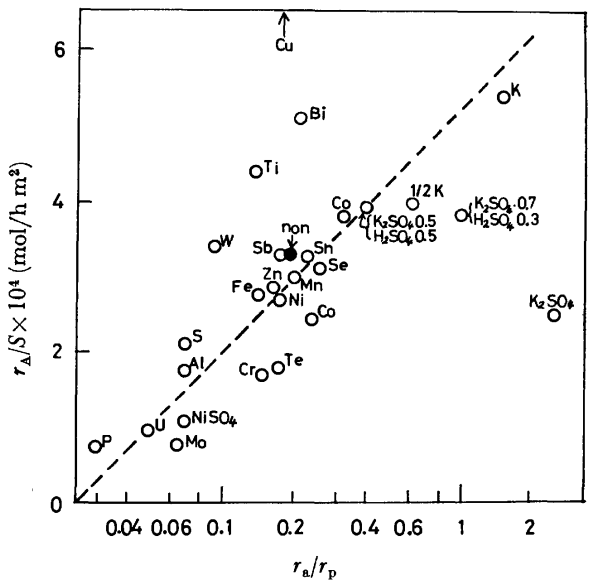

Fig. 6. The oxidation activity for acetic acid (r_A/S) as a function of the basicity (r_a/r_p).

A relatively good correlation is found between r_A/S and r_a/r_p. This supports the validity of the above conception that the basic sites of catalysts contribute to the activation of an acidic compound and oxygen (electron-accepting compound). The large deviation of CuO and K_2SO_4 is supposed to be caused by the strength of metal-oxygen bonding.

Selectivity in Oxidation. The effect of additives on selectivity in the oxidation of olefins was examined. Butadiene was oxidized in the presence of excess air (butadiene=0.67 mol %) over the series of V_2O_5–X_nO_m catalysts with a variety of second components, X_nO_m. At a high conversion of *ca.* 80—95%, the main product, besides CO_2 and CO, was maleic anhydride as in earlier results. The amount of acetic acid was fairly small.

The selectivity of butadiene to maleic anhydride at a conversion of 80—90% is plotted as a function of the basicity of the catalyst, r_a/r_p, in Fig. 7. The selectivity is *ca.* 50 mol % and nearly independent of the additives, except in the cases of K_2SO_4 and K_2SnO_3 where the oxidation activity is extremely low. Since V_2O_5-based catalysts are acidic enough, *viz.*, they are inactive for acidic compounds, the selectivity is not limited by the consecutive decomposition of the maleic anhydride produced, but by the selectivity in the steps from butadiene to maleic anhydride.

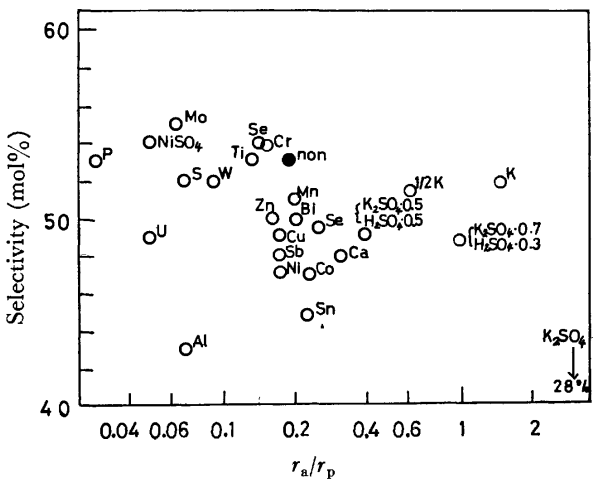

Fig. 7. The selectivity from butadiene to maleic anhydride at a conversion of 80—95% as a function of the basicity of the catalyst (r_a/r_p).

Concerning maleic anhydride formation, the selectivity from butene is fairly small as compared with that from butadiene. A significant amount of acetic acid is formed at the expense of maleic anhydride as has been reported by Brockhaus.[38] The selectivities to maleic anhydride and acetic acid at a 80—95% conversion are plotted as a function of the basicity of the catalyst, r_a/r_p, in Fig. 8.

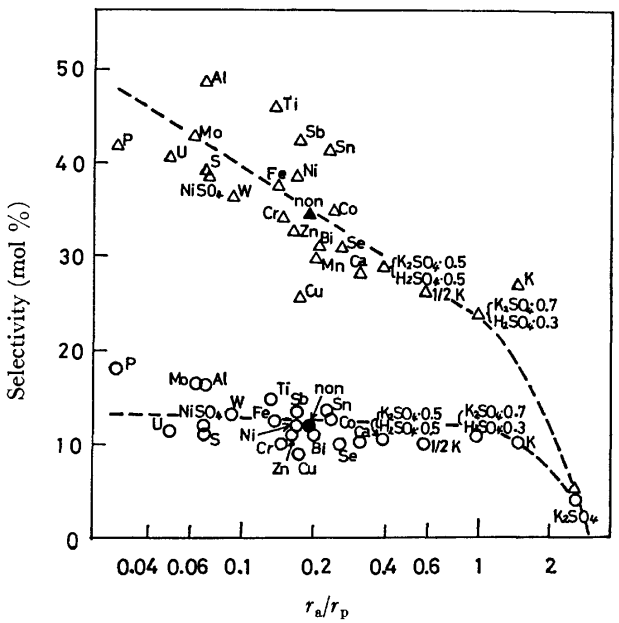

Fig. 8. The selectivity from *cis*-2-butene to maleic anhydride and acetic acid at a conversion of 80—95% as a function of the basicity (r_a/r_p).
○ =Maleic anhydride, △ =acetic acid + maleic anhydride.

The selectivity to maleic anhydride is *ca.* 12 mol % for each catalyst, while selectivity to acetic acid decreases with an increase in the basicity, r_a/r_p. The results in Fig. 8, which coincide with the data of the oxidation activity for acetic acid (Fig. 6), reveal that acetic acid is decomposed more easily than maleic anhydride by means of the basic sites of the catalyst. It is of interest that, in contrast to butadiene, butene is mainly oxidized to acetic acid.

The selectivity to maleic anhydride over V_2O_5-based catalysts not containing a large amount of P_2O_5 is mainly

limilted by the selectivity at the step of allylic oxidation, butene→butadiene.[39] This is because butene is more susceptible to the C–C fission than to the allylic C–H fission.

Thus it can be said that the V_2O_5-based catalysts, if they are highly acidic and moderately basic, are effective for the oxidation of butene to acetic acid.

Conclusion

The introduction of a small amount (10 atom %) of metal oxides into a V_2O_5 catalyst causes a remarkable change in the surface area and the acid-base properties.

The acidity of the binary system, V_2O_5–X_nO_m (9: 1), is roughly correlated to that of the second component, X_nO_m, itself, though there are many exceptions. In general the basicity decreases markedly with acidity.

The activity for the isomerization of 1-butene is proportional to the acidity of catalyst. The oxidation activity for olefin is roughly correlated with the acidity and that for acid is correlated with the basicity of the catalyst.

Since the V_2O_5–X_nO_m (9: 1) catalysts are rather acidic, the selectivity of butadiene to maleic anhydride, which is relatively stable, is *ca.* 50 mol % and is scarcely influenced by the introduction of any metal oxides except for X_nO_m=K_2SO_4 and K_2SnO_3. Over these V_2O_5–X_nO_m catalysts, butene is mainly oxidized to acetic acid as a result of the C–C fission which takes place in preference to the allylic C–H fission, little butadiene being formed from butene. The selectivity to acetic acid decreases with an increase in the basicity of the catalyst, since acetic acid is decomposed easily with the basic sites.

This agrees with the results of our earlier works and leads us to conclude that the introduction of metal oxides into V_2O_5 modifies the acid-base properties of the catalysts, and that this modification induces the main change in oxidation activity and selectivity.

A Study of the Transport of Tetraalkylammonium Ions through Ion-exchange Membranes

Kiyotoshi INENAGA, Akira YAMAUCHI, and Hideo KIMIZUKA
Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka 812
(Received May 6, 1977)

The membrane potential and conductance of the cation-exchange membrane–aqueous quaternary tetraalkylammonium chloride systems have been measured by using NH_4^+, tetramethyl-(Me_4N^+), tetraethyl-(Et_4N^+), tetrapropyl-(Pr_4N^+), and tetrabutylammonium ions (Bu_4N^+). The potential change in the concentration cell with these salts was about 58 mV for a tenfold change of concentration. The membrane conductance in the concentration cell increased with the concentration. The membrane permeability, as estimated from the potential and conductance data, was in the order of $NH_4^+ > Me_4N^+ > Et_4N^+ > Pr_4N^+ > Bu_4N^+$; it is proportional to the geometric mean of the activities of exterior solutions. The effective pore size of the membrane was deduced from the conductance data and found to be *ca.* 10 Å. The selective permeation coefficient has been determined from the potential data of the two- and multi-ionic systems. The selectivity data obtained with the two-ionic system were in agreement with those obtained with the multi-ionic system. The selectivity increased with the chain length of the cation, in contrast to the reversed order of the membrane permeability in the concentration cell. This was attributed to the decreasing mobility with the increasing chain length.

So far, only a few studies of the transport phenomena of organic ions have been reported[1–10] in spite of their importance from the industrial and biological points of view. It is well known that quaternary tetraalkylammonium ions, such as tetramethyl-(Me_4N^+), tetraethyl-(Et_4N^+), tetrapropyl-(Pr_4N^+), and tetrabutylammonium ions (Bu_4N^+), are spherical and that the conductances of these ions in aqueous solutions are generally smaller than those of simple inorganic ions.[12] However, as to the transport of these ions through ion-exchange membranes, it has rarely been reported.[5]

The purpose of this study is to estimate the membrane permeability, the mobility, the selectivity coefficient, and the pore size of the membrane on the basis of measurements of the membrane potential and the membrane conductance of the ion-exchange membrane–organic ion system by using various quaternary ammonium ions and to discuss these physical properties.

Experimental

Materials. The membrane used in this study was a CL-2.5T cation-exchange membrane kindly supplied by the Tokuyama Soda Industry Co., Ltd.; after conditioning it was prepared by immersing the sodium-form membrane in 0.1 M tetraalkylammonium chloride for over a week. The water contents in the membranes of the ammonium and sodium forms were determined from the difference between the weights of the wet and dried membranes. The dried membrane was prepared by heating the wet membrane for a few days at 110 °C until the weight of the membrane attained a constant value. The ion-exchange capacity was measured by means of the back titration of alkali after treating the membrane of the hydrogen form with an excess of a 0.5 M sodium hydroxide solution. The exchange capacity was calculated with respect to the dry weight in the sodium form. The membrane of each form was washed thoroughly with redistilled water and blotted quickly with the filter paper to remove the adhered liquid; its thickness was then measured with the micrometer. The concentration of each counter ion in the wet membrane was calculated on the basis of the exchange capacity and the wet volume of the membrane in the sodium form. The ion-exchange capacity, the water content, and the thickness of the cation-exchange membrane in various forms are summarized in Table 1. The concentrations of the tetraalkylammonium chlorides were determined by the method of Fajans, in which Tween 80 (a nonionic surfactant) was used to decide the end point readily.

TABLE 1. SPECIFIC PROPERTIES OF MEMBRANE[a]

Substance	Thickness × 10^4 / cm	$\bar{C}$[b] / eq/l	Water content / wt %

Pr_4N^+	1.72	1.5	—
Bu_4N^+	1.77	1.4	—

a) Exchange capacity of membrane: 1.70 meq/g.
b) Molarity in membrane.

Membrane Potential and Conductance. The membrane potential and the conductance were measured by the method described in previous papers.[13,14] There are several methods for conductance measurement.[15–17] Lakshminarayanaiah *et al.*[14] have reported that the mercury method yields a steady value of membrane conductance for the range of the frequencies of the applied electric field of 1000—10000 Hz. Thus, this method was employed for the conductance measurement, and values measured with 1000 Hz were taken throughout this study. The area of the membrane for the measurement was 0.785 cm^2. The experiments were carried out at room temperature, 20±0.5 °C.

Mean Activity Coefficient. In order to analyze the experimental results, the mean activity coefficient should be known. Since the mean activity coefficients of tetraalkylammonium ions in concentrations bellow 10^{-1} M have never been reported, they were calculated from the data of the freezing point depression.[18] For concentrations above 10^{-1} M, the values obtained by the gravimetric isopiestic vapor pressure technique[19] were used.

Results and Discussion

Consider the system in which two aqueous phases, I and II, contain electrolytes, M^+X^- and N^+X^-, and in which the aqueous phases are separated by an ion-

exchange membrane. According to earlier papers,[13,14,20] the equations for the membrane potential, V_o, and the membrane conductance, G_m, are expressed by:

$$V_o = \frac{RT}{F} \ln \frac{P_M a_M^I + P_N a_N^I + P_X a_X^{II}}{P_M a_M^{II} + P_N a_N^{II} + P_X a_X^I}, \quad (1)$$

and:

$$G_m = \frac{F^2}{RT}(P_M a_M^{II} + P_N a_N^{II} + P_X a_X^I) \exp\left(\frac{FV_o}{2RT}\right) = \frac{F^2}{RT}(P_M a_M^I + P_N a_N^I + P_X a_X^{II}) \exp\left(-\frac{FV_o}{2RT}\right), \quad (2)$$

respectively. In Eqs. 1 and 2, the superscripts, I and II, refer to the aqueous phases, I and II, respectively, and the subscripts, M, N, and X, the ion M, N, and X, respectively; R denotes the gas constant; T, the absolute temperature; F, the Faraday constant; P_α, the membrane permeability to the ion, α, and a_α, the activity of the ion, α.

When the two phases contain a single electrolyte, M^+X^-, Eqs. 1 and 2 reduce to:

$$V_o = \frac{RT}{F} \ln \frac{P_M a_M^I + P_X a_X^{II}}{P_M a_M^{II} + P_X a_X^I}, \quad (3)$$

and:

$$G_m = \frac{F^2}{RT}(P_M a_M^{II} + P_X a_X^I) \exp\left(\frac{FV_o}{2RT}\right) = \frac{F^2}{RT}(P_M a_M^I + P_X a_X^{II}) \exp\left(-\frac{FV_o}{2RT}\right), \quad (4)$$

respectively.

For the cation-exchange membrane, which is highly permselective to cations, P_X is very small as compared to P_M and P_N. In this case, Eqs. 1—4 can be reduced to:

$$V_o = \frac{RT}{F} \ln \frac{P_M a_M^I + P_N a_N^I}{P_M a_M^{II} + P_N a_N^{II}}, \quad (5)$$

$$G_m = \frac{F^2}{RT}(P_M a_M^I + P_N a_N^I) \exp\left(-\frac{FV_o}{2RT}\right) = \frac{F^2}{RT}(P_M a_M^{II} + P_N a_N^{II}) \exp\left(\frac{FV_o}{2RT}\right), \quad (6)$$

$$V_o = \frac{RT}{F} \ln \frac{a_M^I}{a_M^{II}}, \quad (7)$$

and:

$$G_m = \frac{F^2}{RT} P_M a_M^I \exp\left(-\frac{FV_o}{2RT}\right) = \frac{F^2}{RT} P_M a_M^{II} \exp\left(\frac{FV_o}{2RT}\right), \quad (8)$$

respectively.

When Phase I contains M^+X^- and Phase II, N^+X^-, *i.e.*, when the system is two-ionic, Eqs. 5 and 6 are reduced to:

$$V_o = \frac{RT}{F} \ln \frac{P_M a_M^I}{P_N a_N^{II}}, \quad (9)$$

and:

$$G_m = \frac{F^2}{RT} P_M a_M^I \exp\left(-\frac{FV_o}{2RT}\right) = \frac{F^2}{RT} P_N a_N^{II} \exp\left(\frac{FV_o}{2RT}\right), \quad (10)$$

respectively.

Thus, the membrane permeability can be estimated providing that the potential, the conductance, and the activity data are known.

Concentration Cells. In Fig. 1, the membrane potentials are shown for the concentration cells of Pr_4N^+ and Bu_4N^+ chloride as typical examples. The concentration of the salt in Phase II was kept at 10^{-2} M while that in Phase I was altered. The potential change was about 58 mV for a tenfold change in the concentrations from 10^{-3} to 10^{-1} M and the apparent transference numbers of Pr_4N^+ and Bu_4N^+ were 0.97 or 0.98

▲: NH_4^+, ○: Me_4N^+, △: Et_4N^+, ●: Pr_4N^+, □: Bu_4N^+.

respectively. The same results were also obtained with NH_4^+, Me_4N^+, and Et_4N^+. All the data of membrane conductance are shown in Fig. 2. It has been shown that the membrane conductance becomes larger[16,17,21] as the concentration of the external solution increases except for the case of Et_4NCl. In the case of Et_4NCl, a small decrease in the conductance was observed at higher concentrations. The reason for this decrease is not still clear at present. The order of magnitude of the membrane conductance was $NH_4^+ > Me_4N^+ > Et_4N^+ > Pr_4N^+ > Bu_4N^+$. As has been mentioned previously,[13] the membrane permeability, P_α, was estimated according to Eqs. 7 and 8 by using the experimental results of the membrane potentials and conductances. The membrane permeabilities are plotted against the mean activities in Fig. 3. The results indicate that the membrane permeability decreases with an increase in the concentration and decreases in the order: $NH_4^+ > Me_4N^+ > Et_4N^+ > Pr_4N^+ > Bu_4N^+$.

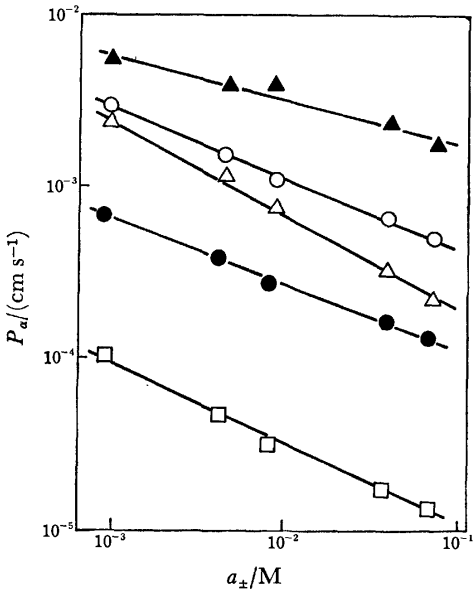

Fig. 3. Permeability *vs.* mean activity diagram for various concentration cells.
▲: NH_4^+, ○: Me_4N^+, △: Et_4N^+, ●: Pr_4N^+, □: Bu_4N^+.

The values of P_{Cl} were found to be very small as compared with those of cations; *i.e.*, P_{Cl}/P_{NH_4} and P_{Cl}/P_{R_4N} were less than 1/100, where R_4N denotes the tetraalkylammonium ion.

According to a previous paper,[20] the membrane permeability is expressed by:

$$P_\alpha = \frac{RT}{|Z_\alpha|F} \frac{\bar{U}_\alpha \bar{C}_\alpha}{\delta (a_\alpha^{\mathrm{I}} \cdot a_\alpha^{\mathrm{II}})^{1/2}}, \qquad (11)$$

provided the membrane is permselective to the ion, α, and the process is membrane-controlling, where Z_α denotes the ionic charge; $\bar{U}_\alpha$, the mobility; $\bar{C}_\alpha$, the concentration of the ion, α, within membranes; δ, the membrane thickness and a_α^{I} and a_α^{II}, the activities of the ion, α, in Phases I and II respectively.

Thus, the permeabilities are plotted against $(a_\alpha^{\mathrm{I}} \cdot a_\alpha^{\mathrm{II}})^{-1/2}$ in Fig. 4. Figure 4 indicates that P_α is

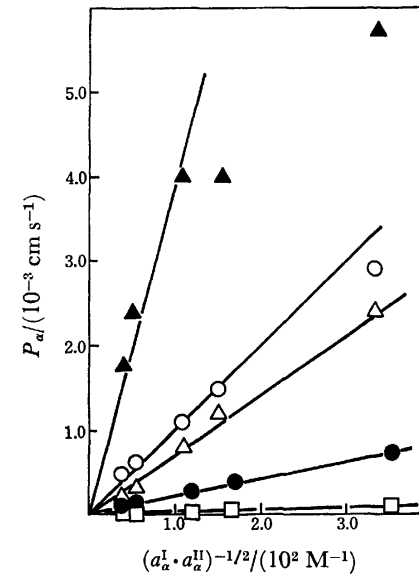

Fig. 4. Permeabilities as functions of the reciprocal of geometric means of the activities of Phase I and Phase II.
▲: NH_4^+, ○: Me_4N^+, △: Et_4N^+, ●: Pr_4N^+, □: Bu_4N^+.

approximately proportional to $(a_\alpha^{\mathrm{I}} \cdot a_\alpha^{\mathrm{II}})^{-1/2}$ for all the systems studied. According to Eq. 11, this implies that $\bar{U}_\alpha \bar{C}_\alpha$ is almost constant. Since the concentration of the cation in the membrane may be regarded as constant within the range of concentrations studied,[22] this means that the mobilities are constant. The mobilities were then evaluated according to Eq. 11; they are summarized, together with the limiting equivalent conductance[11] and ionic radii,[12] in Table 2. The mobility in the membrane in Table 2 are plotted against the limiting equivalent conductance of each ion, λ_α, in Fig. 5.

Table 2. Mobility in the membrane and limiting equivalent conductances in aqueous solution and ionic radii

Substance	$\bar{U}_\alpha$ / $cm^2\ s^{-1}\ V^{-1}$	λ_α / $cm^{-2}\ \Omega^{-1}\ equiv^{-1}$	r_α / Å
NH_4^+	1.4×10^{-5}	73.50	3.31
Me_4N^+	4.2×10^{-6}	44.92	3.67
Et_4N^+	3.0×10^{-6}	32.66	4.00
Pr_4N^+	1.0×10^{-6}	23.42	4.52
Bu_4N^+	1.3×10^{-7}	19.47	4.94

Kawabe *et al.*[5] measured the membrane conductances with the alkali metal cation and tetraalkylammonium ions in order to estimate the effective pore size of the ion-exchange membranes. According to their method, the mean pore size of a membrane was estimated from our experimental results of Et_4N^+, Pr_4N^+, and Bu_4N^+. These quaternary ions may be regarded as indicating that they are not hydrated.[12] By comparing the results of Et_4N^+–Pr_4N^+ and Pr_4N^+–Bu_4N^+, the pore radii of the membrane in this study were found to be 5.4 Å and 5.2 Å respectively. Thus, it can be suggested that the mean effective pore size of the membrane is approximately 10 Å, since the ionic radius of Bu_4N^+ is 4.94 Å and the mobilities of Pr_4N^+ and Bu_4N^+ decrease steeply, as is shown in Fig. 5.

Two-ionic System. The two-ionic membrane potentials for the system expressed by the following scheme were studied.

(II)		(I)
NH_4Cl	Membrane	Tetraalkylammonium chloride
10^{-2} M		10^{-3} M to 10^{-1} M

The concentration of the salt in Phase II was kept at 10^{-2} M NH_4Cl, while that in Phase I was altered from 10^{-3} M to 10^{-1} M. The results are shown in Fig. 6.

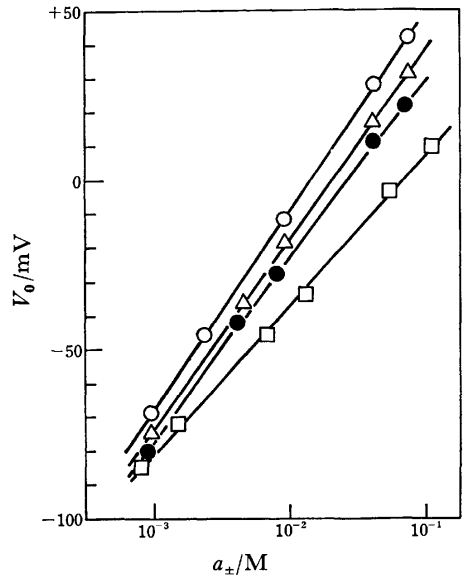

Fig. 6. Membrane potentials as functions of the mean activity of Phase I for two-ionic systems.
○: Me_4N^+, △: Et_4N^+, ●: Pr_4N^+, □: Bu_4N^+.

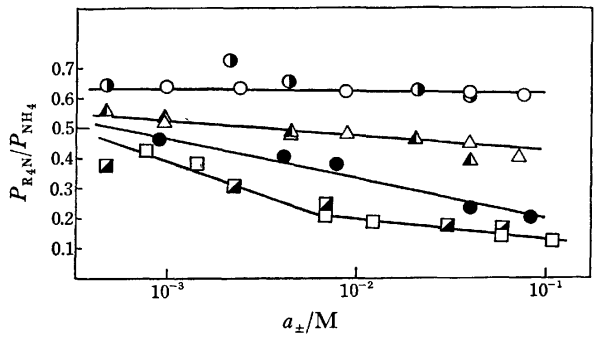

Fig. 7. Permeability ratios as functions of the mean activity of Phase I for two-ionic and multi-ionic systems.
Two-ionic system;
○: Me_4N^+, △: Et_4N^+, ●: Pr_4N^+, □: Bu_4N^+.
Multi-ionic system;
◑: Me_4N^+, ◭: Et_4N^+, ◪: Bu_4N^+.

For the NH_4^+–Me_4N^+ and NH_4^+–Et_4N^+ systems, the plots of the potentials *vs.* the logarithmic activities were found to be linear, with the slope of 58 mV. The results are in agreement with that expected from Eq. 9 provided the membrane permeability ratios are constant. Small deviations from the slope of 58 mV, however, were observed with the NH_4^+–Pr_4N^+ and –Bu_4N^+ systems. The membrane permeability ratios, P_{R_4N}/P_{NH_4}, calculated according to Eq. 9 are shown in Fig. 7. It may be seen in this figure that the longer the chain, the smaller the values of P_{R_4N}/P_{NH_4}, and that the tendency to decrease with the concentration becomes greater as the ionic radius increases. A more detailed study will be required to elucidate the concentration dependence of the permeability ratio.

Multi-ionic System. The multi-ionic potentials of the following system were examined:

(II)		(I)
NH_4Cl	Membrane	$R_4NCl:NH_4Cl=1:1$
10^{-2} M		5×10^{-4} M to 5×10^{-2} M

The concentration of the salt in Phase I, where the concentration ratio of R_4N^+ to NH_4^+ was kept at 1:1, was altered from 5×10^{-4} M to 5×10^{-2} M. Here, the activity coefficient was used without further correction for the mixed electrolyte solutions. The permeability ratio was calculated according to Eq. 5 and shown in Fig. 7. As shown in this figure, P_{R_4N}/P_{NH_4} in the two-ionic system was agreed with that in the multi-ionic system.

According to Eq. 11, $P_\alpha/\bar{U}_\alpha$ may give the measure of the partition of the ion, α, in the membrane; hence:

$$K_{NH_4}^{R_4N} = \frac{P_{R_4N}\bar{U}_{NH_4}}{\bar{U}_{R_4N}P_{NH_4}} \qquad (12)$$

corresponds to the ion-exchange selectivity coefficient. The values of $K_{NH_4}^{R_4N}$ calculated according to Eq. 12 are shown in Table 3. $K_{NH_4}^{R_4N}$ shows an increase with an increase in the alkyl chain length which agrees with the result reported by Kressman and Kitchener.[23,24] At this stage, it is interesting to compare the relative permeabilities, P_{R_4N}/P_{NH_4}, in the two- and multi-ionic systems with those calculated from the permeabilities

TABLE 3. SELECTIVITY COEFFICIENT[a)]

Substance	$K^{R_4N}_{NH_4}$
Me_4N^+	2.2
Et_4N^+	2.2
Pr_4N^+	5.3
Bu_4N^+	19

a) The data were calculated at 10^{-1} M.

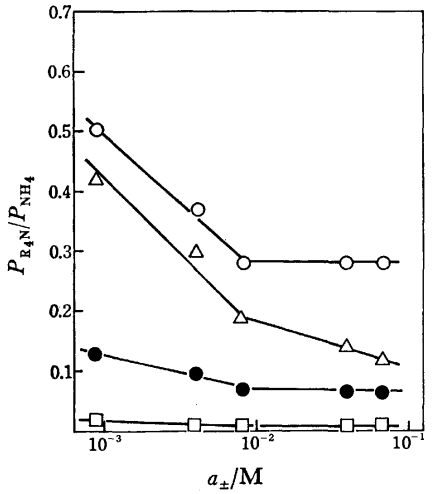

Fig. 8. Permeability ratio, P_{R_4N}/P_{NH_4}, *vs.* mean activity diagram for concentration cells.
○: Me_4N^+, △: Et_4N^+, ●: Pr_4N^+, □: Bu_4N^+.

in the concentration cell given in Fig. 8. Those permeability ratios showed a tendency to decrease against the increase in the concentration of the external solution, *i.e.*, Phase I. However, the values in the concentration cell were found to be much smaller than those in the two- and multi-ionic systems. It is noted that the longer the chain of the organic ion, the smaller the value of P_{R_4N}/P_{NH_4}. This behavior is more or less different from the earlier results in the case of simple inorganic ions.[13,14] These facts imply that the transport phenomena of the organic ions are strongly dependent on the compositions of the ionic species present in the membrane. That is, when only a single species of an ion is present in the membrane, the permeability to the quaternary tetraalkylammonium ion decreases remarkably as their ionic radii increase, as may be seen in Fig. 3. On the other hand, when two species of ions are present together in the membrane, it may be presumed that the relative permeability is governed by the interdiffusion in the membrane and that, therefore, the permeabilities of coexisting ions become closer. However, a more detailed study of the permeability in the two- and multi-ionic systems will be required to confirm the deduction described here.

Structure of Aqueous Isomeric Butyl Alcohols—Sound Velocity Studies

N. Manohara MURTHY and S. V. SUBRAHMANYAM
Department of Physics, Post-Graduate Centre, Anantapur 515003, India

(Received November 1, 1976)

The effect of isomeric butyl alcohols on the temperature of sound velocity maximum in water (TSVM) was studied using a variable path interferometer working at 3 MHz. The structural contribution to the shift in TSVM, $[\Delta T_{str}]_{exp}$, was evaluated for the butyl alcohols and the results are compared with those obtained from studies on the effect of these solutes on the temperature of adiabatic compressibility minimum and density maximum of water. The results indicate that the butyl alcohols enhance the hydrogen-bonded structure of water at low concentrations and at any given concentration, the order of increasing structural contribution to the shift in TSVM being *t*-butyl >*s*-butyl>isobutyl>butyl alcohols. The structural propensities of the butyl alcohols as revealed by TSVM studies are in line with the information obtained from the temperature of adiabatic compressibility minimum and density maximum studies. The results of the present study indicate that TSVM studies are useful in understanding the solution structure in aqueous mixtures.

Many studies have been reported on the solution structure of aqueous alcohols. They mainly deal with the observation of non-ideal thermodynamic behaviour of aqueous mixtures such as viscosity composition,[1] ultrasonic velocity,[2,3] and absorption[4,5] maxima as a function of concentration and negative partial molal volumes.[6,7] At any given temperature water can be considered to consist of essentially two species, one hydrogen bonded and the other non-hydrogen bonded, this being the most common of the many theories.[8] Water exhibits a density maximum at 3.98 °C, adiabatic compressibility minimum at 64 °C and sound velocity maximum at 74 °C. Any parameter which can affect the structural equilibrium of water will also influence the temperature at which the extrema are observed. Hence a study of the effect of non-electrolytes on these physical properties of water helps one to understand the structural propensities of these solutes in water. Wada and Umeda[9] studied the effect of isomeric butyl alcohols on the temperature of density maximum of water. In an earlier communication[10] we reported the effect of these solutes on the temperature corresponding to the adiabatic compressibility minimum of water. Both studies indicate that isomeric butyl alcohols hehave as structure promoters when added in small amounts to water.

According to Eyring and Kincaid[11] a sound wave in a liquid is supposed to travel with infinite velocity within a molecule and with gas kinetic velocity in the intermolecular space. On this assumption, the conversion of hydrogen-bonded into close-packed ones (due to rise in temperature) results in a positive temperature coefficient of sound velocity and the simultaneous volume expansion of both species gives rise to a negative temperature coefficient of velocity. The competition between these two opposing tendencies leads to the sound velocity maximum observed at 74 °C, where thermal expansion balances the effect due to the equilibrium shift. Above 74 °C the structural expansion plays a dominant role and the velocity decreases with increasing temperature.

Any parameter which can affect the structural equilibrium in water would also influence the temperature of sound velocity maximum (TSVM). Hence ultrasonic velocity measurements in aqueous solutions in the vicinity of TSVM are likely to throw some light on the structural effects of different molecules. However, ultrasonic velocity is not generally considered to be a primary thermodynamic quantity. It can be considered to be dependent on density and adiabatic compressibility. Density and adiabatic compressibility of aqueous solutions show a complex temperature dependence, each becoming maxima and minima, respectively, at certain temperatures which are not the same. Under these conditions, we are not certain whether the condition $(du/dt)_{t=TSVM}=0$ can be considered to be a criterion for structure breaking or structure promotion where u denotes ultrasonic velocity and t temperature. The present paper deals with the studies on the effect of isomeric butyl alcohols on the TSVM of water with a view to comparing the results with those obtained from density maximum[9] and adiabatic compressibility minimum[10] studies and thereby evaluate the usefulness of velocity measurements.

Experimental

A. R grade isomeric butyl alcohols were used after purification. Ultrasonic velocity in the pure components and aqueous mixtures was determined using a single crystal variable path interferometer working at 3 MHz with an accuracy of ± 0.003 percent. The details of the experimental technique and the method of measurement of velocity and temperature of liquid were reported.[10]

Solutions of desired concentration were prepared by weighing the samples using triple distilled, degassed water. Ultrasonic velocity in the solutions were determined at $\simeq 2$ °C intervals over a range of 5 °C on either side of TSVM. The velocities were corrected for diffraction effects, following the procedure developed by Subrahmanyam *et al.*[12] At low concentrations of the organic solute, the temperature dependence of sound velocity in the aqueous solutions is parabolic and resembles that of pure water. Hence a transparent template of the curve for pure water was employed to fix TSVM. The accuracy in fixing TSVM is $\pm$ 0.2 °C.

Results

Diffraction corrected ultrasonic velocities in dilute aqueous solutions of isomeric butyl alcohols as a function of temperature at different concentrations are given in Table 1. Some typical results are shown in Fig. 1.

Discussion

In order to understand the structural propensities of solutes in aqueous mixtures from TSVM studies, it is necessary to obtain an expression for the TSVM of the solution in terms of known quantities. For this purpose it is neccessary to express the sound velocity in the mixture in terms of the velocities in the pure components. Since there is no agreed view regarding the method of evaluation of sound velocity in an ideal mixture, we have taken up the additivity of adiabatic compressibility on volume fractions. The adiabatic compressibility of an aqueous solution can be represented by

$$\beta = \phi_1\beta_1 + \phi_2\beta_2 + \beta^E, \quad (1)$$

where β_1, β_2, and ϕ_1, ϕ_2 refer to the adiabatic compressibilities and volume fractions of water and the organic solute, respectively, and β^E represents the excess adiabatic compressibility. Since

$$\beta = \frac{1}{u^2\rho}, \quad (2)$$

where u is the ultrasonic velocity and ρ density, we can rewrite Eq. 1 as

$$\frac{1}{u^2\rho} = \frac{\phi_1}{u_1^2\rho_1} + \frac{\phi_2}{u_2^2\rho_2} + \beta^E. \quad (3)$$

It is not necessary to use $\rho=\phi_1\rho_1+\phi_2\rho_2+\rho^E$ in the above equation since the effect of ρ^E, the excess density, on the velocity of the solution is negligibly small. Hence we can rewrite Eq. 3 as

$$\frac{1}{u^2} = \frac{\phi_1^2}{w_1u_1^2} + \frac{\phi_2^2}{w_2u_2^2} + \rho\beta^E, \quad (4)$$

where w_1 and w_2 refer to the weight fractions of water and the organic solute, respectively, in the solution.

According to Willard[13] the velocity in pure water conforms to the relation

$$u_1 = 1557 - 0.0245(74-t)^2, \quad (5)$$

where t is the temperature in °C. Over a small range of temperature the sound velocity in the organic solute is given by

$$u_2 = u_2^\circ - \alpha_u t, \quad (6)$$

where α_u is the temperature coefficient of sound velocity in the solute and u_2° is the velocity at 0 °C.

By substitution of Eqs. 5 and 6 in Eq. 4, differentiation with respect to temperature, and use of the conditions $(du/dt)_{t=TSVM}=0$, we obtain the following expression for TSVM in the solution:

$$T = 74 - \left(\frac{\phi_2}{\phi_1}\right)^2\left(\frac{w_1}{w_2}\right)\left(\frac{\alpha_u}{0.049}\right)\left(\frac{u_1^3}{u_2^3}\right) - \left(\frac{w_1}{\phi_1^2}\right)\left(\frac{u_1^3}{0.098}\right)\left[\rho\frac{d\beta^E}{dt}+\beta^E\frac{d\rho}{dt}\right]. \quad (7)$$

The shift produced in the TSVM of water due to the presence of the organic solute, ΔT_{obsd}, is given by

$$\Delta T_{obsd} = -\left(\frac{\phi_2}{\phi_1}\right)^2\left(\frac{w_1}{w_2}\right)\left(\frac{\alpha_u}{0.049}\right)\left(\frac{u_1}{u_2}\right)^3 - \left(\frac{w_1}{\phi_1^2}\right)\left(\frac{u_1^3}{0.098}\right)\left[\rho\frac{d\beta^E}{dt}+\beta^E\frac{d\rho}{dt}\right]. \quad (8)$$

ΔT_{obsd} can be thought of as being due to two effects; structural effects caused by interaction of the two molecules and dilution. The effect of dilution is always to lower the TSVM. The first term on the right hand side of Eq. 8 represents the shift which can be called the ideal shift ΔT_{id}. If there is no interaction between the two types of molecules, we have $\Delta T_{obsd}=\Delta T_{id}$. The second term refers to the structural contribution to the shift in TSVM, ΔT_{str}, which can be evaluated either from the values of $d\beta^E/dt$ and $d\rho/dt$ of the solution or by means of the relation

$$[\Delta T_{str}]_{exp} = T_{exp} - T_{id}, \quad (9)$$

where

$$T_{id} = 74 - \left(\frac{\phi_2}{\phi_1}\right)^2\left(\frac{w_1}{w_2}\right)\left(\frac{\alpha_u}{0.049}\right)\left(\frac{u_1}{u_2}\right)^3. \quad (10)$$

T_{id} can be evaluated using α_u, u_1, and u_2 and following the method of successive approximations. The values of u_2° and α_u for the isomeric butyl alcohols evaluated from a study of temperature dependence of ultrasonic velocity are given in Table 2. Since the temperature dependence of ϕ_1 and ϕ_2 is very small, ϕ_1 and ϕ_2 used for determining T_{id} were evaluated at the TSVM of the solution found experimentally.

The values of T_{exp}, T_{id}, and $[\Delta T_{str}]_{exp}$ at different concentrations for the isomeric butyl alcohols are given in Table 3. The variation of T_{exp} with mole fraction

figures are the variation of $[\Delta T'_{str}]_{exp}$ (structural contribution to the shift in the temperature of maximum density of water) and $[\Delta T_{\beta\ str}]_{exp}$ (structural contribution to the shift in the temperature of adiabatic compressibility minimum of water) taken from literature[9,10] to facilitate a comparison of the different studies.

$[\Delta T_{str}]_{exp}$ is positive at low concentrations for *t*-butyl, *s*-butyl, and isobutyl alcohols indicating stabilization of the hydrogen-bonded structure of water. $[\Delta T_{\beta\ str}]_{exp}$ and $[\Delta T'_{str}]_{exp}$ are also positive for these solutes. $[\Delta T_{str}]_{exp}$ and $[\Delta T_{\beta\ str}]_{exp}$ are positive for butyl alcohol though small in magnitude, in the very low concentration range, becoming negative at high concentrations. It is quite possible that the structure stabilizing propensity of this molecule becomes weak at high temperatures. At any given concentration, the structure enhancing efficiency of the butyl alcohols found from TSVM studies is in the order, *t*-butyl>*s*-butyl>isobutyl>butyl alcohol. The same order is found in studies on the effect of these butyl alcohols on the temperature density maximum[9] and adiabatic compressibility minimum[10] of water.

For the butyl alcohols, the optimum concentration at which the quantities $[\Delta T_{str}]_{exp}$, $[\Delta T_{\beta\ str}]_{exp}$, and $[\Delta T'_{str}]_{exp}$ become maxima are not the same (Figs. 3A—3D and Table 4). T_{exp}, $T_{\beta\ exp}$, and T'_{exp} (temperature of maximum density of the solution) for the aqueous isometric butyl alcohols at the optimum concentrations evaluated from the graphs (Fig. 2 and

TABLE 4 $(X_2)_{opt}$ FOR DIFFERENT SOLUTES

Solute	$[\Delta T_{str}]_{exp}$		$[\Delta T_{\beta\ str}]_{exp}$		$[\Delta T_{str}]_{exp}$	
	$(X_2)_{opt}$	T_{exp} (°C)	$(X_2)_{opt}$	$T_{\beta\ exp}$ (°C)	$(X_2)_{opt}$	T' (°C)
t-Butyl alcohol	0.0047	72.4	0.0175	43.5	0.0200	0.87
s-Butyl alcohol	0.0040	69.0	0.0106	52.0	0.0140	2.36
Isobutyl alcohol	0.0038	69.8	0.0092	53.2	0.0124	1.65
Butyl alcohol	0.0027	71.2	0.0090	50.6	0.0090	2.48

literature[9,10]) are also given in Table 4.

The results indicate that the structural effects as revealed from density and adiabatic compressibility measurements have similar concentration dependence. In all cases $[\Delta T_{str}]_{exp}$ becomes maximum at much lower X_2 than either that of $[\Delta T_{\beta\ str}]_{exp}$ or $[\Delta T_{str}]_{exp}$. Even though the concentration at which $[\Delta T_{\beta\ str}]_{exp}$ becomes maximum is less than that at which $[\Delta T_{str}]_{exp}$ becomes maximum, for a given solute, they are close to each other. This indicates that there is a close similarity between the temperature of density maximum and adiabatic compressibility minimum in revealing the structural propensities of solutes in water. However, there is a large difference with respect to the concentration dependence of structural effects as revealed from TSVM studies. This is because $[\Delta T_{str}]_{exp}$ becomes maximum at a lower X_2 as compared to $[\Delta T_{\beta\ str}]_{exp}$ or $[\Delta T'_{str}]_{exp}$ for a given solute. It is difficult to interpret this behaviour from the fact that each study was confined to different temperature (TSVM studies around 74 °C, adiabatic compressibility minimum studies around 64 °C, and density maximum studies around 4 °C). The $(X_2)_{opt}$ of each study is not commensurate to the temperature differences as is clear from Table 4. The occurrance of the maximum in $[\Delta T_{str}]_{exp}$ *versus* X_2 at very low X_2 values as compared to the other two studies may very likely be due to the dependent nature of ultrasonic velocity on density and adiabatic compressibility. However, the TSVM studies, in general, indicate correctly whether a solute behaves as a structure promoter or disrupter.

It is clear that even though ultrasonic velocity is not a primary thermodynamic quantity, TSVM studies could be used to classify the solutes as structure makers or breakers.

Ultraviolet Spectral Study of *o*- and *p*-(Halomercurio)phenols

P. L. YADAV,* N. K. JHA, and V. RAMAKRISHNA**
Department of Chemistry, I. I. T., New Delhi, India
(Received December 13, 1976)

The ultraviolet spectra of *o*- and *p*-(halomercurio)phenols, *o*- and *p*-OHC_6H_4HgX(X=F, Cl, Br, or I) have been recorded in ethanolic solution and λ_{max} and log ε_{max} have been recorded. The spectra of these compounds have been interpreted in terms of the correlation with the spectra of benzene. HgX group is shown to be having electron-withdrawing effect on the benzene ring. Variation in the values of λ_{max} and log ε_{max} on changing from *o*- to *p*-derivative for a particular (halomercurio)phenol and on changing the halogen attached to mercury has been explained.

A very large number of organomercury compounds are known but only a few of them have been subjected to UV spectral study; such a study is specially limited when one considers aromatic organomercurials. Leandri and Tundo[1] have reported and interpreted the UV spectral data (220 to 350 nm) of *p*-XC_6H_4HgCl and $XC_6H_4HgC_6H_4X$ where X=OH, CH_3, Cl, NO_2, and NH_2. Gowenlock and Trotman[2] restudied the *p*-XC_6H_4HgCl compounds in a wider range (200 to 350 nm) and also included compounds where $X=O^-$ or NH_3^+. In addition, they have reported the spectra of some ortho derivatives ($X=O^-$ or OH). Baliah and Subharayan[3] have reported the spectral study of some of the *o*- and *p*- compounds reported earlier and they have enlarged their list to include compounds where $X=(CH_3)_2N$, $(C_2H_5)_2N$, and CH_3O; however, their data were collected upto 220 nm and they have referrred to the work of Leandri and Tundo only but not that of Gowenlock and Trotman.

The spectral study of *o*- and *p*-(halomercurio)phenols reported so far have been confined to the chloromercurio derivatives only. Gowenlock and Trotman[2] predicted from their spectral analysis of *o*- and *p*-chloromercurio derivatives that the spectra of bromo- and iodomercurio derivatives would be more complicated because of the interference from HgBr and HgI groups as observed in the case of HgCl group. In the present work the spectra of *o*- and *p*-OHC_6H_4HgX where X=F, Cl, Br, or I are reported and interpreted.

Experimental

o- and *p*-(Halomercurio)phenols were prepared according to a method reported earlier.[4] The spectral data were recorded using ethanolic solutions of these compounds (ethanol was purified by treating with clean and dry magnesium turnings and a little iodine and refluxing for half an hour; the fraction distilling at 78.3 °C was collected). Solutions of concentration varying from 1×10^{-4} to 7×10^{-5} M were employed. The spectra were recorded on Unicam SP 700 UV and visible spectrophotometer. The spectra are shown in Figs. 1 and 2.

All the eight compounds studied showed three bands in the UV region. λ_{max} was recorded for each band and the corresponding value of log ε_{max} was also calculated. These

values are shown in Table 1. In certain cases, *viz.* *o*-derivatives the band at 225 nm was not distinct, rather observed as an inflection point (Fig. 1).

Discussion

As *o*- and *p*-(halomercurio)phenols are disubstituted benzene derivatives, their spectral data may be correlated with those of benzene. Benzene shows three absorption bands at 256, 203, and 180 nm attributed to $^1B_{2u}\leftarrow{}^1A_{1g}$ $^1B_{1u}\leftarrow{}^1A_{1g}$, and $^1E_{1u}\leftarrow{}^1A_{1g}$ transitions respectively.[5] The 256 and 203 nm bands usually called secondary and primary bands respectively have been studied extensively in benzene derivatives. These bands are usually present in the spectra of substituted benzenes, though shifted due to substitution.[6]

Effect of HgCl Group on the Spectra of Benzene. The two bands of phenylmercury(II) chloride at 210 and 258 nm may be considered as bathochromically shifted primary and secondary bands of benzene.[1-3] It is difficult to assess the amount of shift in the primary band because HgCl group itself absorbs in this region. In fact most of the mercury compounds (though not derivatives of benzene) have absorption bands in this region, *e.g.* $HgCl_2$ 211 nm, $HgBr_2$ 206 and 234 nm, HgI_2 215 and 273 nm,[2] and CH_3HgCl 206 nm.[7] Thus, the bands in the first column of Table 1 may be ascribed to HgX groups and the bands in the second and third columns may be treated as the shifted primary and secondary bands of benzene respectively.

In spite of the overlap of the primary band of C_6H_5-HgCl by that of HgCl group, it is possible to estimate a value of λ_{max} for the former using the observation by Doub and Vandenbelt[6a] that the ratio of λ_{max} (secondary) to λ_{max} (primary) in monosubstituted benzenes is nearly constant, *viz.* 1.19 to 1.28. Taking an average value of 1.23 for this ratio and the known value of λ_{max} (secondary) for C_6H_5HgCl, 258 nm, the value of λ_{max} (primary) for C_6H_5HgCl comes out to be 258/1.23= 210 nm.

Electronic Effect of HgCl Group. It is not possible to conclude from the shifts alone in phenylmercury(II) chloride (203→210 nm, 256→258 nm) whether HgCl group is acting like electron acceptor or electron donor since both electron acceptor and electron donor groups are known to cause shift (bathochromic and hyperchromic) in the primary and secondary bands of benzene.[6,8,9] Gowenlock and Trotman[2] have concluded by comparing the effect of ionization OH→O^- on the secondary band for both *o*- and *p*-substituted phenols that HgCl group is *o*-, *p*-directing. However, their conclusion is not very convincing; for example, for the *p*-substituents SMe, Cl, HgCl, CHO, COMe, and NO_2 the ionization leads to a displacement of λ_{max} to a longer wavelength by 7, 19, 30, 46.5, 49, and 85 nm respectively and from this observation they conclude that HgCl group is similar to Cl group and is *o*-, *p*-directing. However, the value of the shift for HgCl, 30 nm, happens to be between the value for an *o*-, *p*-directing group (Cl, 19 nm) and that for a *m*-directing group (CHO, 46.5 nm) and thus it is not possible to say definitely whether HgCl group is *o*-, *p*-directing or *m*-directing. Unfortunately there is no direct experimental evidence of the *o*-, *p*-directing or *m*-directing nature of HgCl group in literature since most reagents used in substitution in the benzene ring remove the HgCl group from the ring.

Some idea about the electron withdrawing or electron releasing nature of HgCl group may be obtained by using the observation of Doub and Vandenbelt[6] that in a *p*-disubstituted benzene, the shift in the primary band is not much different from the sum of the shifts by

Table 2. Effect of para disubstitution A-C_6H_4-B on the primary band of benzene

A	Shift (nm)[a] for A	B	Shift (nm) for B	Ref.	Shift for *p*-A-C_6H_4-B

a) Calculated from the present work.

the individual substituents (as observed in corresponding monosubstituted derivatives) if the substituents are of the same character (*i.e.* both electron withdrawing or both electron releasing) but the shift is larger than the sum of the two shifts if the substituents are of opposite character. Table 2 shows that when HgCl group is in *p*-position to *o*-, *p*-directing groups (OH, NH_2 *etc.*) the shift is much larger than the sum of the shifts due to two substituents individually. Further when HgCl group is in *p*-position to an electron withdrawing group, namely NO_2, the shift is nearly the same as the sum of the shifts due to NO_2 and HgCl groups individually. These two observations clearly indicate that HgCl group acts like an electron withdrawing group.

The electron withdrawing capacity of Hg group can be ascribed to the fact that mercury has two vacant p orbitals in its valence shell which can accommodate the withdrawn electrons. These must be a conjugative interaction of HgCl group with the electron-releasing group, for example, the following structure would make an important contribution to the excited state of *p*-(halomercurio)phenol:

(I)

which causes a considerable bathochromic shift in the primary band of benzene.

Comparison of the Spectra of o- *and* p-*(Halomercurio)-phenols.* It is observed in Table 1 that the shift in primary band is greater in *p*-compounds than in *o*-compounds and also that the intensities of these bands are greater for *p*-compounds than for *o*-compounds. In fact, for *o*-compounds usually inflection points are observed rather than peaks which are distinct for the *p*-compounds (Figs. 1 and 2). The decrease in the shift and intensity of the primary band in *o*-compounds can be ascribed to the steric interference with coplanarity. The steric overlap between the *o*-substituents sets up appreciable interference which prevents the attainment of uniplanar configuration by the benzene derivatives. Steric inhibition of electronic interaction thus raises the energy level of the ground state but since the phenyl-oxygen and phenyl-mercury links postulated in the excited state contain a larger amount of double bond character and since the interplanar angle cannot from theoretical consideration (Franck-Condon principle) change during transition, the energy level of the excited state will be raised even more than that of the ground state. Thus the transition energy is increased in *o*-compound as compared to *p*-compound resulting in a smaller bathochromic shift and also a reduced transition probability, resulting in a loss of absorption intensity.

In case of secondary bonds *p*-compounds show lesser bathochromic and hyperchromic shifts as compared to *o*-compounds. A reason for such a behaviour is not apparent since one might expect that the secondary bands would be effected in a similar way as the primary bands in changing from a *p*-isomer to *o*-isomer.

Effect of Change in Halogen Atom on the Spectra of o- *and* p-*(Halomercurio)phenols.* It may be noted that the prediction by Gowenlock and Trotman[2] regarding the complex nature of the spectra of bromo and iodo derivatives compared to that of chloro derivatives does not appear to be correct. Table 1 shows that the spectra of all the halo derivatives are similar and there are only three bands in each case.

It is seen in Table 1 that for the *o*-derivatives the intensity of the primary band increases in the order F<Cl<Br<I. The secondary bands behave in a similar way. However, the λ_{max} values for the secondary bands remain nearly constant (282—284 nm) and λ_{max} values for primary bands are also constant except for *o*-iodo derivative which has a longer λ_{max} value than other *o*-halo derivatives. For *p*-derivatives the situation is similar.

The excited state of *p*-(halomercurio)phenol may be represented by the structure I mentioned earlier where HgX group is acting like an electron acceptor. Since the iodo derivative shows the maximum intensity of the primary band, the excited state must be stabilized most in its case and stability of the excited state should decrease in the order I>Br>Cl>F. On the basis of inductive effect of halogen atoms it would appear that the excited state should be most stable in the case of fluoro derivatives (fluorine being the most electronegative amongst the halogens) and the order should be F>Cl>Br>I. Thus, the inductive effect cannot be used to explain the observed order. No other explanation is apparent for the observed order.

(Received May 12, 1975)

The propylene conversion process has been studied in the presence of synthetic zeolites of different types and metal ions. The NiX zeolite is selective for the oligomerization of propylene. On the zeolites of different other metal ions, the hydro-oligomerization process took place. It has been found that the obtained 3-methylpentenes are primary products of the propylene oligomerization. A scheme mechanism has been proposed assuming an intermediate of a cyclobutane derivative. The mechanism explains the formation of all the obtained products of propylene conversion on the synthetic zeolites.

Oligomerization of olefins is one of the most complicated reactions owing to its high exothermic effect. The heat liberated during the reaction accelerates different undesirable side reactions such as cracking, hydrogen transfer, double bond migration, and coke formation.[1-5] It is, therefore, difficult to study either the mechanism or the kinetics of this reaction, especially, on a solid catalyst.

To facilitate this study, two problems had to be solved. The first is the unstability of the temperature during the reaction, and the second is the competition of the side reactions, *i.e.* the selectivity of the used catalyst.

The first problem is solved[6] by making a reactor with a special construction which allows to withdraw the released heat out of the reaction zone and maintains the reaction proceed at constant temperature.

It is of interest to study the propylene oligomerization in the presence of synthetic faujasites of various metal ions for the purpose to obtain a selective catalyst. For this purpose the cations such as cobalt, nickel, manganese, and magnesium were used, the oxides of which possess a high selectivity in the propylene oligomerization.[7-10] Other cations were used for comparison.

Experimental

The various di- and trivalent cationic X and Y zeolites were prepared by exchanging the russian synthetic NaX ($Na_2O \cdot Al_2O_3 \cdot 2.4SiO_2 \cdot nH_2O$) and NaY ($Na_2O \cdot Al_2O_3 \cdot 48SiO_2 \cdot nH_2O$ zeolites).[3] The degree of exchange was maintained at ≈65% for the X Zeolites and ≈85% for the Y Zeolites. A catalyst with 80% of nickel-exchange was also prepared from the NaX zeolite. The ion-exchanged powders were compressed without binders into tablets, 4 mm in diameter and 5—6 mm in thickness.

Propylene conversion activity was measured under atmospheric pressure with 40 ml of catalyst in a fixed bed reactor of conventional design. The catalyst was calcined at 550 °C in a flow of dry air for 4 h and then in a flow of nitrogen for 1 h. After calcination the temperature was adjusted to the desired value. The feed in each run was 4 liters of 100% propylene.

Both gaseous and liquid products were collected separately. Each was analyzed by the gas and liquid chromatography. Liquid products were also analyzed by the infrared spectroscopy. The olefin products were determined quantitatively and separated by the thin layer chromatography using a fluorescene indicator[11]. The total catalytic activity of the catalyst was calculated by the percentage of converted propylene.

The initial temperature was 190 °C, but due to the exothermic behaviour of the studied reaction, it quickly increased by about 20—25 °C depending on the treated zeolite catalyst. For kinetic experiments a reactor of special design[6] was used which allowed to maintain the temperature constant.

The part of liquid products which cannot be obtained by suction after the run, was cracked by raising the temperature slowly to 550 °C. Gases and liquids of C_1—C_8 paraffins were formed and the colour of the catalyst became dark due to the formation of coke. The amount of the latter was determined.

Results and Discussion

Catalytic Activity of Zeolites. The catalytic activity of various ion-exchanged zeolites was tested at an initial temperature of 190 °C and space velocity of propylene 40 ml (ml catalyst)$^{-1}$ h^{-1} (Table 1). The overall order of activity is LaY≃LaX≃CeX≃MgY>NiY>CoY>AlY>MgX>MnY>NiX>CoX>CaX.

When cations are of the same group in the periodic table a certain relation may be obtained.[12] Attempts have failed to correlate the obtained catalytic activities with the ionic radii or ionization potential of the exchanged metal cations of different groups of the periodic table. Thus, each metal ion has its own ability to perform a certain change in the zeolite lattice depending on its own electronic configuration.

Selectivity of Zeolites. Depending on the zeolite form it is possible to obtain liquid products which contain only olefins, paraffins or mixtures of both. In the presence of all the tested zeolites no aromatics are detected by the infrared spectral analysis.

In the cases of CoX, MnX, and MgX, 18.9, 10.1, and 20.2% olefins are, respectively, separated from the liquid products by the thin layer column chromatography. The other products are C_4—C_9 paraffins. The IR spectra of the separated olefins indicate the presence of two bands at 910 and 965 cm^{-1} characteristic for double bonds of the vinyl and transvinyl types.[13] The 890 cm^{-1} band characteristic for the double bond of vinylidene type is absent.

In the presence of all tested zeolites except NiX only paraffinic hydrocarbons are formed, as indicated by both chromatographic and infrared spectral analyses. The composition of these paraffins are presented in

Table 1. Propylene conversion on various zeolite catalysts at 190 °C and 0.025 h

Catalyst	MgY	NiY	CoY	CaY	AlY	LaY	CaY	CeX	LaX
Propylene conversion, wt %	98.7	92.0	90.7	62.4	88.1	98.4	32.6	98.8	98.3

Table 2. Presence of hexane, methylpentanes, and dimethylbutane gives evidence that a hydrodimerization reaction takes place on these zeolites. The C_9 paraffins are formed by hydrotrimerization of propylene. In addition to that, C_2, C_4, C_5, C_7, and C_8 paraffins are formed. This suggests that hydrodimerization of propylene into trimers and tetramers is accompanied by a cracking and then by subsequent hydrogen transfer to the cracking products. The distribution of C_4—C_9 paraffins in the liquid products seems to depend on the exchanged cations (Table 2). The zeolites NiY and LaX give more dimers (47.9, 49.7%), while AlY and CaX give more trimers (16.1; 12.6%). Also the quantity of propylene converted into propane, and the part of the liquid which remained on the zeolite (Table 1) depend on the nature of the exchanged cation and the SiO_2: Al_2O_3 ratio.

The products which remain on the zeolites are probably propylene high oligomers, formed and captured within the pores of zeolites, which on heating crack into C_1—C_8 molecules and pass through the windows of the zeolite pores.

The most interesting zeolite catalyst is the NiX. The reaction products of this catalyst are pure oligomers and 95.49% of which are dimers (Table 3). The calculated octane number of these products is about 94. They contain more than 34% of hexenes which usually[14] do not exceed 10% if an acid catalyst is used. Within the other dimers 3-methylpentenes are present. The presence of these dimers were previously[15] attributed to secondary rearrangement.

In the presence of NiX with a higher degree of nickel ions (80%), C_5, C_7, and C_8 olefins are formed. Thus replacement of the more difficultly exchangeable sodium ions by nickel, enhances the cracking of the formed propylene oligimers.

TABLE. 3. COMPOSITION OF PROPYLENE OLIGOMERS OBTAINED ON NiX AT 190 °C AND 0.025 h

Propylene oligomer	wt %
2-Methyl-2-pentene	27.40
trans-2-Hexene	23.50
trans-3-Methyl-2-pentene + *cis*-2-hexene	11.50
trans- and *cis*-3-hexene	10.24
cis-4-Methyl-2-pentene	1.57
trans-4-Methyl-2-pentene	8.35
2-Methyl-1-pentene + 1-hexene	8.53
cis-4-Meth-l-1-pentene	0.79
cis-3-Methyl-2-pentene	1.26
2,3-Dimethyl-2-butene	1.09
2,3-Dimethyl-1-butene	1.26
Trimers	4.51
Octone number	94

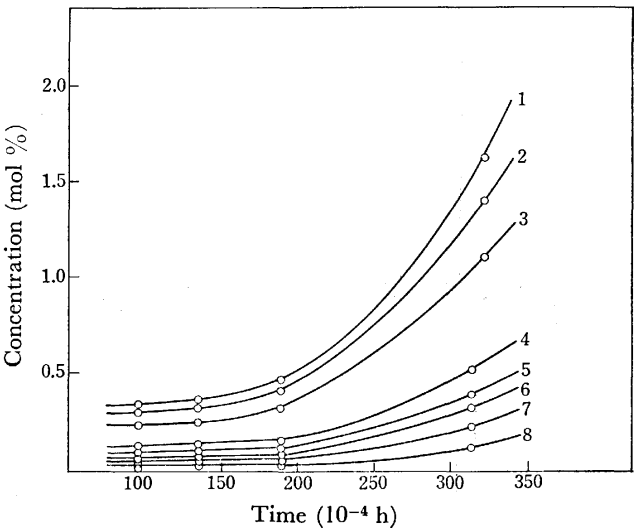

Fig. 1. Distribution of propylene dimers against contact time at a reaction temperature of 225 °C.
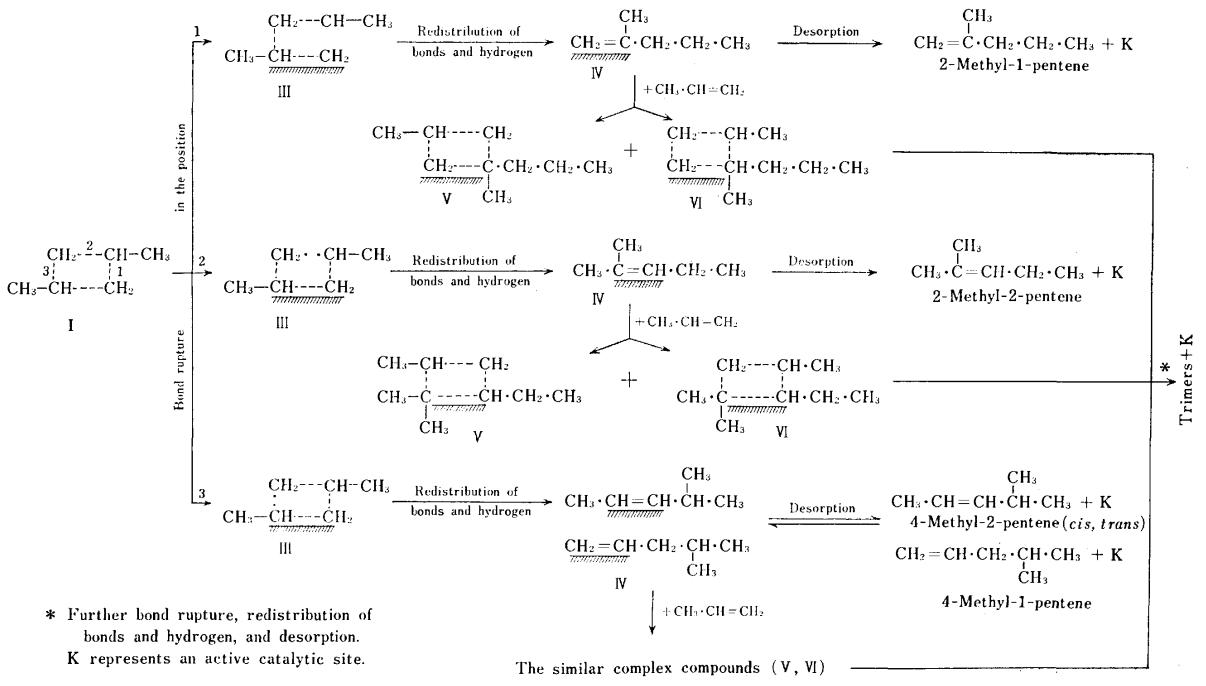
1: 2-Methyl-2-pentene, 2: *trans*-2-hexene, 3: *trans*-3-methyl-2-pentene+*cis*-2-hexene, 4: *trans*- and *cis*-3-hexene, 5: 2-methyl-1-pentene, 6: *trans*-4-methyl-2-pentene+1-hexene, 7: *cis*-3-methyl-2-pentene, 8: 2,3-dimethyl-2-butene.

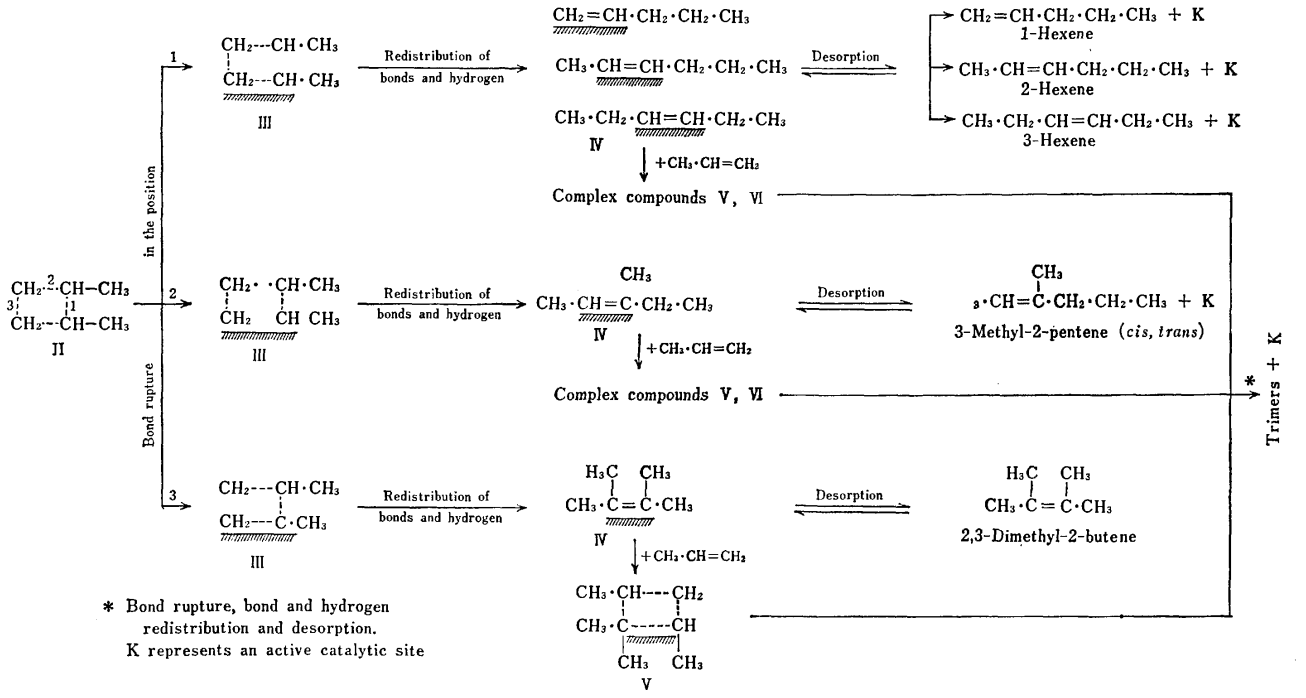
Kinetics of Oligomerization. It is of interest to determine the kinetic curves of the oligomerization to obtain information on the 3-methylpentenes, *i.e.* whether they are secondary products or not. Thus the oligomerization was carried out on the NiX zeolite at different temperatures (190, 205, 217, and 225 °C) and contact times (0.01—0.037 h). Figure 1 reveals a similar character of the decrease of the different dimer contents, as well as that of the 3-methylpentenes with the decrease of the contact time. The same results were obtained at the temperatures of 190, 205, and 217 °C. If 3-methylpentenes are secondary products, then their contents should decrease with a higher degree than the other dimers. With respect to the 3-methylpentane the same results were obtained[16] over the HNaY zeolite as an example of the zeolites over which hydrooligomerization takes place. These experimental facts indicate that the 3-methylpentenes and the 3-methylpentane are primary products of propylene dimerization and hydrodimerization, respectively. They cannot be produced under the used experimental conditions by secondary skeletal isomerization of either hexenes or 2-methylpentenes.

Reaction Mechanism. The 3-methylpentenes cannot be explained as the primary products of propylene dimerization neither by a carbonium-ion mechanism nor by any other mechanism which assumes an open-chain hydrocarbon as the activated intermediate. A mechanism of dimerization has been proposed,[8] over the nickel oxide on silica-alumina catalyst, which



* Further bond rupture, redistribution of bonds and hydrogen, and desorption.
K represents an active catalytic site.

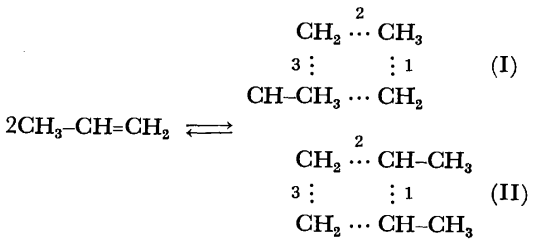
Scheme 1.



Scheme 2.

assumes an intermediate of a cyclobutane derivative. Examination of the present results has shown that the same mechanism may hold for the conversion of propylene on the investigated zeolites.

It is possible that these intermediate compounds can be formed when a propylene molecule reacts with an adsorbed one on the zeolite surface as follows:



The formed dimethylcyclobutanes, I and II, are unstable complexes, and therefore they either converted to the initial molecules or undergo a bond rupture. The latter may take place in the bond 1, 2, or 3. The bond rupture of complex I (Scheme 1) or complex II (Scheme 2) leads to the formation of extremely unstable complexes III, which undergo rearrangement and hydrogen redistribution. As a result, the propylene dimers, II, are formed on the zeolite surface.

Depending on the catalyst selectivity and the experimental conditions the redistribution of hydrogen can lead to the formation of propylene dimers as in the case of NiX zeolite (Table 3) and hydrodimers (paraffins) as in the case of other zeolites (Table 2).

The hydrodimerization leads to the formation of hydrodimers and compounds of poor hydrogen content. Dimers (Table 3) and hydrodimers (Table 2) of different structures are formed due to the rupture of different bonds of I and II. Thus if the rupture occurs at positions 1, 2, or 3, then 4- or 2-methylpentenes are formed in the case of complex I (Scheme 1), and hexenes, 3-methylpentenes or 2,3-dimethylbutenes in the case of complex II (Scheme 2). The formation of 2-methyl-2-pentene and *trans*-2-hexene in large quantities (Table 3, Fig. 1) indicates that the rupture at position 2 (complex I) and position 1 (complex II) occurs much easier than at other positions.

If the rate of desorption is relatively slow, the formed dimers, IV, on the zeolite surface can adsorb another propylene molecule forming the complex V or VI which are unstable as well as complexes I and II. They are converted either to the initial state or undergo bond rupture, bond and hydrogen redistribution and desorption to give propylene trimers or hydrotrimers.

The presence of C_2, C_4, C_5, C_7, and C_8 paraffinic hydrocarbons (Table 2) indicates that bond ruptures may take place for two bonds of complexes V and VI.

Similarly if trimers are not relatively rapidly desorbed they can adsorb another propylene molecules forming, in the same manner, tetramers and so on.

The above mechanism explains the formation of obtained products during the propylene conversion over the zeolites studied. However, the difference in the selectivity of the various cation-exchanged zeolites is not clear. This difference can be explained in view of some recent works[17-20] which reported the existence of two types of active sites with different acidic strengths on faujasite. Barthomeuf and Beaumont[21] reported that weak active sites are related to the cationic sites which are easily exchangeable. Thus, it can be concluded that hydrooligomerization and the accompanied cracking reaction require the stronger active sites compared to the oligomerization. This conclusion is supported by the fact that exchange of the more difficult-

ly exchangable sodium ions by nickel cations, leads to cracking of some of the formed propylene oligomers. On the other hand, it is evident[17,22] that the ratio of strong acidic sites to all the sites on faujasite increases with the increase of the SiO_2: Al_2O_3 ratio. This may explain the reason why the hydrooligomerization takes place on NiY (SiO_2: Al_2O_3=4.8) and oligomerization takes place on NiX (SiO_2: Al_2O_3=2.4). As the conclusion, the difference in selectivity of the various cation-exchanged zeolites in propylene conversion, probably, relates to the change in the acidic strength distribution of the active sites on the zeolite surface, which is due to the SiO_2: Al_2O_3 ratio and the different effect of each cation. However, this conclusion requires further studies on the quantitative basis.

Hydrogen Bonding between Phenols and Nitriles

Inam JAWED*

Institute of Physical Chemistry, Peshawar University, Peshawar, Pakistan

(Received May 16, 1975; in revised form, February 28, 1977)

Hydrogen bonding between a number of para-substituted phenols and nitriles was studied by means of infrared spectroscopy using a longer cell. Thermodynamic quantities were determined and found to be the functions of the electronegativity and inductive effect of the phenol and nitrile substituents respectively except for the complexes of *t*-butyl cyanide for which the $-\Delta H$ values were lower than expected. Some correlations among thermodynamic quantities were also established. Both the sample and the reference cells were heated simultaneously by means of a special heating arrangement which minimized the base line errors and made the intensity measurements more accurate.

Phenol has been one of the most extensively used proton donor molecules in hydrogen bond studies. Systematic data, however, for phenol–nitrile systems are relatively scarce and there are only a few reports available in literature.[1,2] Data on substituted phenols is even more scarce. It was, therefore, considered worthwhile to make a detailed and systematic study of the thermodynamic properties of hydrogen bonds between a number of substituted phenols and nitriles using improved techniques and under more desirable experimental conditions. This study was carried out by means of infrared spectroscopy. The phenols and nitriles were chosen so as to give a rather wide range of acidity and basicity values respectively. Para-substituted phenols were preferred to avoid complications arising from intramolecular associations and steric effects.

Experimental

The infrared spectroscopic measurements were made on a Perkin-Elmer model 125 infrared grating spectrophotometer using an expanded scale (1 cm=5 wave numbers). Quartz cells, 20 mm long, were used. As shown by Russell and Thompson,[3] the slit width should be at least one-fifth of the half width of the absorption band in order to obtain true band intensities. Hence, a slit program was chosen which gave a spectral slit width of about one-seventh of the half width of the hydroxyl stretching vibrational band of phenols, ν_{OH}. Tetrachloroethylene was chosen as the solvent because of its high boiling point (121 °C) to make measurements within a wide range of temperatures, 20 to 65 °C.

A special heating jacket was designed because of the rather large size of the cells. It consisted of two solid brass pieces carefully cut from inside so that when the two pieces were brought together by means of a screw, they formed a round hole in the center of which the cell fitted almost exactly. The brass pieces were fitted through an asbestos insulator onto a brass backing plate. Copper tubes were soldered round the brass pieces through which water could be circulated from a thermostat. By means of this arrangement, it was possible to control the temperature of the cell within ± 1 °C of the desired values for any length of time. Measurements were made at 20, 30, 39.5, 50, and 60 or 61.5 °C. The temperature of the solutions in the cell was measured by means of an iron-constantan thermocouple.

For each phenol, a preliminary investigation was first carried out to determine approximately the maximum concentration at which self-association disappears. Concentrations much lower than this were used keeping the absorption of the bands within 25—60 percent for accurate measurements of the intensities. The following concentrations were used for actual measurements of the thermodynamic parameters:

p-Methoxyphenol and phenol	7.0×10^{-4} M	Cl_3CCN	1.20 M
		C_6H_5CN	0.20 M
		CH_3CN	0.16 M
		$(CH_3)_3CCN$	0.12 M
p-Chlorophenol	7.0×10^{-4} M	Cl_3CCN	0.80 M
		C_6H_5CN	0.12 M
		CH_3CN	0.12 M
		$(CH_3)_3CCN$	0.08 M
p-Cyanophenol and *p*-nitrophenol	4.0×10^{-4} M	Cl_3CCN	1.00 M
		C_6H_5CN	0.06 M
		CH_3CN	0.06 M
		$(CH_3)_3CCN$	0.04 M

The concentrations of the proton donors and acceptors are expected to change as a result of change in solution density with increase in temperature. The correction in the concentration for density changes was made as suggested by Powell and West.[4] Since the densities of the solutions which had quite low concentrations of the proton donors and accep-

$-\Delta S$	16.1	16.4	15.9 (cal/mol/deg)

tors were found to be very similar to that of the solvent. corrections were made using the density of the solvent only.

The phenols and nitriles were purified by the usual methods of drying, recrystallization or fractional distillation. The solvent, tetrachloroethylene, was also dried carefully and fractionally distilled. After purification they were stored in vacuum dessicators or over nitrogen atmosphere in a dry box.

The association constants were calculated using the method described by Lopes and Thompson.[2] Tables 1 and 2 give the typical examples of the measurements of the association constants at different temperatures together with the values of $-\Delta G$, $-\Delta H$, and $-\Delta S$. Three measurements were made for each system at almost the same concentrations of the phenols and nitriles. The thermodynamic quantities were calculated separately and then averaged. Figures 1 and 2 give examples of plot of log *K* *vs.* $1/T$.

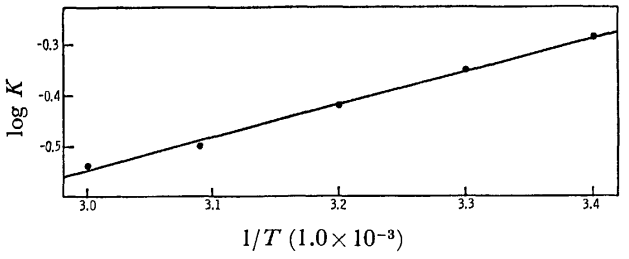

Fig. 1. Plot of log *K* against $1/T$ for *p*-methoxyphenol–Cl_3CCN complex.

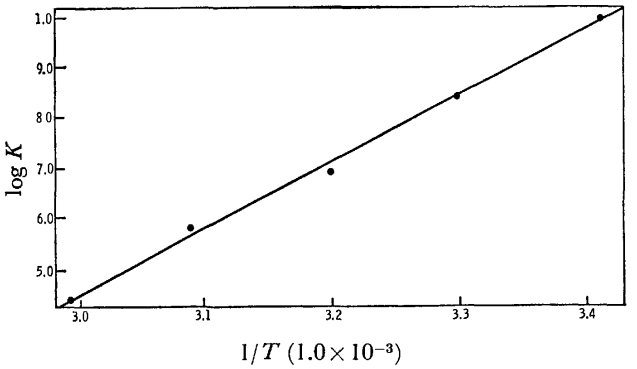

Fig. 2. Plot of log *K* against $1/T$ for *p*-chlorophenol–CH_3CN complex.

Results and Discussion

The values of the thermodynamic quantities of the various systems studied are given in Table 3. As can be seen, for the complexing of any particular nitrile with different phenols, the association constant, and the enthalpy and entropy changes generally follow the same order as the electronegativity of the para-substituents in phenols. For any particular phenol complexing with different nitriles, the association constant follows the same order as the inductive effect of the nitrile substituents. The enthalpy and entropy changes, however, increase from Cl_3CCN to CH_3CN, but, are lower for $(CH_3)_3CCN$ complexes than for CH_3CN complexes although the values of association constants are higher for the complexes of the former. This result was observed for the complexes of $(CH_3)_3CCN$ with every phenols studied, and although the difference is within the error of measurements, repeated measurements confirmed the observed pattern. It seems unlikely that steric hindrance of the bulkier *t*-butyl group plays a significant part here because of the higher values of the association constants and some spectral characteristics like infrared frequency shifts for $(CH_3)_3CCN$ complexes relative to CH_3CN complexes. Solvent effects as suggested by Pullin and co-workers[5] also cannot account for this change as the effect persists even in the gas phase as shown by Thomas[6] in his thermodynamic studies of the hydrogen fluoride–ether complexes in the gas phase. He explains this discrepancy in terms of the heat of conformational rearrangement of the ether molecule on hydrogen bond formation. In

Table 3. Thermodynamic quantities (Solvent: Tetrachloroethylene)

Proton donor	Proton acceptor	*K* (25 °C) l/mol	$-\Delta G$ kcal/mol	$-\Delta H$ kcal/mol	$-\Delta S$ cal/mol/deg

p-Cyanophenol	Cl_3CCN	1.47	0.23	3.48	10.9
	C_6H_5CN	22.3	1.84	5.66	12.8
	CH_3CN	30.0	2.02	6.07	13.6
	$(CH_3)_3CCN$	39.2	2.18	5.89	12.6
p-Nitrophenol	Cl_3CCN	1.20	0.10	4.35	14.2
	C_6H_5CN	27.4	1.96	6.54	15.4
	CH_3CN	33.5	2.08	6.97	16.4
	$(CH_3)_3CCN$	48.2	2.30	6.73	14.9

$\Delta K = \pm 10\%$ (l/mol), $\Delta(\Delta G) = \pm 0.05$ kcal/mol, $\Delta(\Delta H) = \pm 0.2$ kcal/mol, $\Delta(\Delta S) = \pm 1.0$ cal/mol/deg.

the present case, however, *t*-butyl cyanide is likely to have only one conformation common to the free molecule and the complex. Thus, it is unlikely that an explanation of the reduced $-\Delta H$ along the lines of the hydrogen fluoride–ether complexes is possible unless the bonds throughout the molecule are weakened in such a way that the molecule becomes distorted.

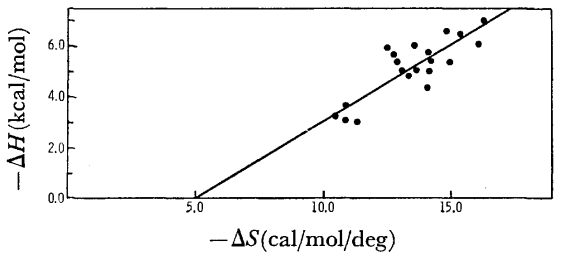

Fig. 3. Plot of $-\Delta H$ against $-\Delta S$ for hydrogen bonds between phenols and nitriles.

The thermodynamic parameters of the hydrogen bonded systems have been reported to show various correlations among themselves. Shepp and Bauer[7] and Person[8] have discussed theoretically the linear relationship between $-\Delta H$ and $-\Delta S$. Several workers have noted this linear relationship.[9–15] The present data for $-\Delta H$ and $-\Delta S$ when subjected to the least squares treatment gave the following equation:

$$-\Delta H\,(\text{kcal/mol}) = -0.60\,\Delta S - 2.97.$$

In view of the considerable scatter (Fig. 3), little meaning can be given to such plots at least for the systems reported here. Person has theoretically predicted a value of 2.0 for the $\Delta H/\Delta S$ slope. The observed value is, however, widely different from this.

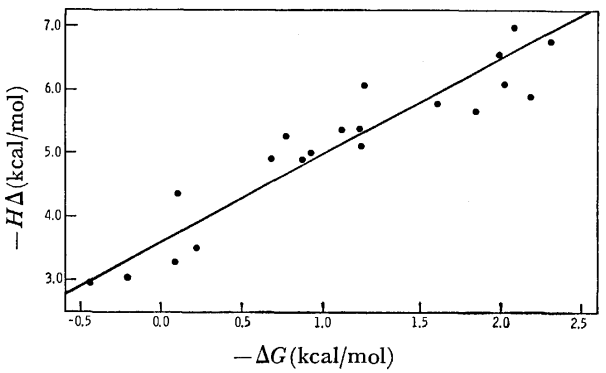

Fig. 4. Plot of $-\Delta H$ against $-\Delta G$ for hydrogen bonds between phenols and nitriles.

All nitriles in the present study show a general increase in $-\Delta H$ with K and hence with $-\Delta G$. The only exception are the complexes of $(CH_3)_3CCN$. These have already been discussed. A least squares treatment of the present data for $-\Delta H$ and $-\Delta G$ gives the following straight line (Fig. 4):

$$-\Delta H\,(\text{kcal/mol}) = -1.38\,\Delta G + 3.6.$$

Several linear correlations have also been reported by other workers.[2,16–18] All these data, however, lead to the conclusion that there is perhaps a more complicated relationship between $-\Delta G$, $-\Delta H$, and $-\Delta S$ than simple equations as shown above and, therefore, not too much weight should be placed on the singificance of these equations.

Before concluding the discussion of the thermodynamic quantities, it is perhaps desirable to make some comments on the difficulties in the interpretation of data from solution phase studies. In fact, no solvent can be regarded as truly inert.[19–21] Jones and Watkinson[22] have shown that there exists an interaction between solvent tetrachloroethylene and phenol molecules. This view seems to be verified from our studies also. Thus, in the course of measurements at various temperatures, we noted that the free or unbonded hydroxyl stretching vibrational frequency shifted to slightly higher values as the temperature raised. The more acidic the phenol, the greater was this shift. This indicates the decrease of a phenol-solvent association by the increase in temperature. Thus the effect of the solvent on the thermodynamic parameters is evident. Moreover, it has been reported that the value of the association constant varies with the concentrations of the proton donor and acceptor molecules.

Figueroa and co-workers,[23] in their studies of association of phenol with sulfoxides, noted that the value of association constant increased with increasing phenol/sulfoxide ratio showing that even in a chosen standard solvent, the concentrations of donor and acceptor molecules may affect the K and $-\Delta H$ values.

Ther are evidences of self-association among nitrile molecules at higher concentrations.[24,25] Such an association would mean that there are less nitrile molecules available to associate with phenol molecules and, consequently, the association constant is lowered. In addition, the heat of formation of hydrogen bond between phenol and nitrile may be partially compensated by the heat of breaking the nitrile-nitrile bond. In the present work, the increased cell thickness enabled us to use very dilute solutions. This, together with the improved heating technique, made the data more reliable.

It is perhaps desirable to include here data on the more accurate values of ν_{OH} obtained by using a longer cell and keeping the temperature more accurate than before. Table 4 gives the values of both the free and bonded ν_{OH} at 20 °C for the phenol–nitrile systems studied.

TABLE 4. FREQUENCIES OF THE FREE AND BONDED ν_{OH} BANDS FOR THE PHENOL–NITRILE SYSTEMS AT 20 °C

Nitrile	ν_{OH} Bonded (cm^{-1})				
	p-Methoxy-phenol	Phenol	*p*-Chloro-phenol	*p*-Cyano-phenol	*p*-Nitro-phenol
Cl_3CCN	3552.5	3544.5	3534.5	3501.5	3494.0
C_6H_5CN	3471.0	3460.0	3442.5	3398.5	3382.5
CH_3CN	3468.0	3456.0	3439.5	3395.0	3380.0
$(CH_3)_3CCN$	3458.0	3445.5	3426.5	3377.0	3363.5
ν_{OH} Free (cm^{-1})	3613.0	3608.0	3605.5	3592.5	3589.5

Accuracy of measurements of the values of $\nu_{OH} = \pm 0.5\ cm^{-1}$. Solvent: tetrachloroethylene. The values of ν_{OH} (bonded) were obtained by extrapolation to infinite dilution of the nitriles.

Table 5. Change in ν_{OH}(Bonded) with concentration of nitriles at 20 °C

Phenol	ν_{OH} Free (cm^{-1})	Nitrile	Nitrile concn mol/l	ν_{OH} Bonded (cm^{-1})
p-Chlorophenol (7.0×10^{-4} M)	3605.5	Cl_3CCN	0.196	3533.5
			1.177	3529.5
		C_6H_5CN	0.041	3441.5
			0.295	3434.0
		CH_3CCN	0.047	3539.0
			0.290	3431.5
		$(CH_3)_3CCN$	0.018	3425.0
			0.126	3420.0
p-Nitrophenol (4.0×10^{-4} M)	3589.5	Cl_3CCN	0.261	3493.0
			1.305	3490.0
		C_6H_5CN	0.028	3381.0
			0.215	3379.0
		CH_3CN	0.032	3381.0
			0.210	3375.5
		$(CH_3)_3CCN$	0.015	3360.0
			0.090	3356.0

Accuracy of measurements of the values of $\nu_{OH}=\pm0.5$ cm^{-1}. Solvent: tetrachloroethylene.

The frequency of the bonded ν_{OH} is also found to depend to some extent on the concentration of the nitrile molecules. Table 5 shows some examples of this concentration dependence. The unbonded or free ν_{OH}, however, remains unchanged.

Multiple Relaxation Processes in Long Chain Molecules at Microwave Frequencies

H. D. PUROHIT and H. S. SHARMA

Microwave Laboratory, Physics Department, University of Jodhpur, Jodhpur, India

(Received January 5, 1977)

The permittivity ε' and dielectric loss ε'' of octanoyl, undecanoyl, and lauroyl chlorides have been measured in benzene for five different concentrations varying from 0.02 to 0.10 wt fraction at three different microwave frequencies, *viz.* 3.31, 9.83, and 26.90 GHz at 35 °C. The static permittivity ε_0 at 100 kHz and the high frequency limiting permittivity ε_∞ have also been measured at the same temperature. The permittivity and dielectric loss at different frequencies have been plotted against concentration and their slopes have been used to draw normalised complex plane plots between $(a'-a_\infty)/(a_0-a_\infty)$ and $a''/(a_0-a_\infty)$ for these compounds. Such plots show a skewed arc dielectric behaviour. The values of distribution parameter β, characteristic relaxation time τ_0, average relaxation time τ_{av}, and dipole moment μ have been reported for the first time. The relaxation mechanism in these three molecules has been explained on the basis of multiple relaxation processes.

Complex plane plots for most of the normal unassociated molecules are semicircular arcs represented by the Debye equation[1] or symmetric Cole-Cole arcs represented by the Cole-Cole equation.[2] However, there are a few exceptions. It has been observed that in case of long chain molecules[3,4] the complex plane plot is a skewed arc and can be represented by the Davidson-Cole equation.[5] Such a behaviour is also exhibited by higher thiols[6] and benzylidyne trifluoride.[7] The present studies have been carried out with three long chain molecules namely octanoyl chloride $CH_3(CH_2)_6COCl$, undecanoyl chloride $CH_3(CH_2)_9COCl$, and lauroyl chloride $CH_3(CH_2)_{10}COCl$ in dilute solutions of benzene.[8] These compounds are highly reactive and when exposed to the atmosphere react with moisture present to form hydrochloric acid. Further in pure liquids the internal field effects[9-11] are pronounced because of large dipolar field. The dielectric behaviour has, therefore, been studied in dilute solutions of benzene so that the solute molecules are in a quasi-isolated state practically unaffected by the dipolar field and solute-solute co-operative phenomenon. These molecules have been chosen because of the likelihood of multiple relaxation mechanism being present in them.

Experimental

Materials. *(a) Solute*: Octanoyl chloride of purum grade (of 98% purity), undecanoyl chloride of purum grade (of 98% purity) and lauroyl chloride of puriss grade (of 99% purity) were obtained from Messrs Fluka, A. G., Switzerland. They were used as such for experimental work.

(b) Solvent: Benzene of A. R. grade was purchased from Messrs British Drug House (India) Ltd. and was dried over sodium and fractionally distilled before use.

Experimental Details. The measurements of permittivity ε' and dielectric loss ε'' for each of the solutes in five dilute solutions of different concentrations (0.02 to 0.10 wt fraction) in benzene were made using the method suggested by Heston *et al.*[12] for low loss liquids and adapted for short circuited termination at three different microwave frequencies *viz.* 3.31, 9.83, and 26.90 GHz. The heterodyne beat method was used for determining the static permittivity ε_0 at 100 kHz. High frequency limiting permittivity ε_∞ was taken as square of the refractive index which was measured by an Abbe's refractometer. All measurements were made at 35 °C and the temperature was maintained within ± 0.5 °C by circulating water from a temperature controlled bath. The values of ε', ε'', ε_0, and ε_∞ thus obtained were plotted against concentration in wt fraction. The slopes a', a'', a_0, and a_∞ are given in Table 1. The accuracy of measurement of a' is ± 1 percent and of a'' is ± 5 percent.

TABLE 1. VALUES OF THE SLOPES OF PLOTS OF ε' AND ε'' *versus* CONCENTRATION

Frequency	a'	a''
(a) Octanoyl chloride		
100 kHz	$a_0=4.58$	—

26.90 GHz	0.40	0.78
Optical	$a_\infty=-0.21$	—

Theory

A system having an asymmetric distribution of relaxation time can be represented by Davidson-Cole type relation.[5] This equation can be modified by substituting a', a'' *etc.* in place of ε', ε'' *etc.* The Davidson-Cole equation can be written for dilute solution as

$$\frac{a^*-a_\infty}{a_0-a_\infty}=\frac{1}{(1+i\omega\tau_0)^\beta}, \qquad (1)$$

where β is a distribution parameter having values between 0 and 1, and τ_0 is the characteristic relaxation time. The average relaxation time τ_{av} is equal to $\beta\tau_0$. Putting the value of $a^*=a'-ia''$ and separating real and imaginary parts, one gets

$$a'-a_\infty = (a_0-a_\infty)(\cos\phi)^\beta \cos\beta\phi, \quad (2)$$

$$a'' = (a_0-a_\infty)(\cos\phi)^\beta \sin\beta\phi, \quad (3)$$

where $\tan\phi = \omega\tau_0$, (4)

hence $$\omega\tau_0 = \tan\left[\frac{1}{\beta}\tan^{-1}\frac{a''}{(a'-a_\infty)}\right]. \quad (5)$$

An approximate value of β can be obtained from the skewed arc in which high frequency side approaches asymptotically a line making an angle $\beta\pi/2$ with real axis of a'. τ_0 can be calculated from Eq. 5 by substituting the measured values of $a''/(a'-a_\infty)$ at a given frequency. The value of β is then adjusted within the experimental range for getting constant value of τ_0 from different frequency data.

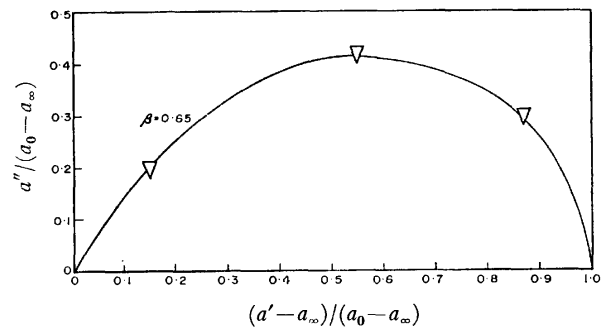

Fig. 1. Normalised plot of $(a'-a_\infty)/(a_0-a_\infty)$ *versus* $a''/(a_0-a_\infty)$ for lauroyl chloride in benzene.

A better method would be to draw curve between $(a'-a_\infty)/(a_0-a_\infty)$ and $a''/(a_0-a_\infty)$ (normalised plots) for different known values of β by varying ϕ by fixed amounts. The values of these quantities obtained experimentally are also plotted on the same graph. The value of β can be found out from the curve which fits the experimental values best. Knowing β, τ_0 can be calculated from Eq. 5 by substituting the measured values of $a''/(a'-a_\infty)$ at a given frequency. A representative normalised plot in case of lauroyl chloride is given in Fig. 1. The normalised maximum loss $a''_m/(a_0-a_\infty)$ which indicates the width of the distribution of relaxation time has also been calculated and reported in Table 2.

Table 2. Values of β, $a''_m/(a_0-a_\infty)$, τ_0, τ_{av}, and μ for octanoyl, undecanoyl and lauroyl chlorides

Compound	β	$a''_m/(a_0-a_\infty)$	τ_0 (ps)	τ_{av} (ps)	μ (D)
Octanoyl chloride	0.75	0.430	18.6	13.6	2.74
Undecanoyl chloride	0.70	0.425	22.3	15.6	2.88
Lauroyl chloride	0.65	0.415	27.3	17.7	2.89

The dipole moments μ of these solute molecules have been calculated by the following equation proposed by Higasi:[13]

$$\mu = A(a_0-a_D)^{1/2} \quad (6)$$

where A is a constant and is given by

$$A = \left[\frac{27kT}{4\pi N}\frac{M_2}{(\varepsilon_1+2)^2 d_1}\right]^{1/2}$$

Here d_1 is the density of the solvent and M_2 is the molecular weight of the solute. The values of μ for all the three solute molecules are reported for the first time and are given in Table 2.

Results and Discussion

The normalised arc plots for all the three solute molecules are skewed arcs which show that there is an asymmetric type of distribution of relaxation time. The value of β increases with the decrease of chain length which means that the distribution of relaxation time decreases with the decrease in chain length. In other words the distribution of relaxation time tends towards a symmetric distribution with decrease in chain length. The width of distribution of relaxation time which is indicated by the normalised maximum loss also increases with the decrease of chain length.

The skewed arc behaviour in liquids has been reported by many workers[14-17] and has been explained in terms of co-operative phenomenon and multiple relaxation processes. In dilute solutions the former possibility is ruled out. The only possible machanism which can explain the asymmetric distribution is due to multiple relaxation processes. This is borne out by the fact that the skewed behaviour increases with the increase in chain length. The molecule becomes less rigid and can relax in more than one way. A particular group or segment of the molecule may rotate, as well as the molecule may rotate as a whole. The former process has a smaller relaxation time as compared to the latter process. These are the limits between which the other relaxation times lie. The orientation of one segment may trigger many other orientations and consequently the rotating group does not relax independently. This intramolecular process has similar effects as intermolecular co-operative phenomenon which has been used to explain the skewed arc behaviour in pure liquids. The decrease in value of β with increase in chain length suggests that the segmental reorientations become increasingly possible with the increase in the number of C–C bonds, whereas with the decrease in chain length or decrease in the number of C–C bonds the segmental reorientation processes are reduced and the distribution becomes symmetric tending towards Cole-Cole behaviour. In the study of such molecules the possibility of solute-solvent interactions can not be ruled out.

The value of dipole moment increases with the increase in chain length. The characteristic relaxation time τ_0 of these compounds in solution increases with the increase in chain length, which is due to the increase in the molecular size. The average relaxation time τ_{av} also increases in the same manner as τ_0.

The authors are indebted to Professor Krishnaji, University of Allahabad, Allahabad for his helpful discussions and for the facilities provided in connection with some measurements. They also wish to thank Prof. A. N. Nigam, Head of Physics Department of this University for providing facilities to continue the present investigations.

The Stereochemistry and Reactivity of Metal-Schiff Base Complexes. II. High Stereoselectivity in (1*S*,2*S*)-*N*,*N*′-1,2-Cyclohexylenebis(salicylideneaminato)(sal$_2$-(*S*,*S*)-chxn) Cobalt(III) Complexes with Amino Acids and the Optical Resolution of Amino Acids with Cobalt(III)-sal$_2$-(*S*,*S*)-chxn*

(Received September 3, 1976)

A series of mixed ligand cobalt(III)–Schiff base complexes with the general formula of [Co(sal$_2$-(*S*,*S*)-chxn)(aa)] (aa=gly$^-$, L- and D-ala$^-$, L- and D-val$^-$, L- and D-leu$^-$, L- and D-thr$^-$, or L- and D-trp$^-$) were newly prepared from [Co(sal$_2$-(*S*,*S*)-chxn)] and amino acids by air oxidation. All the complexes were found to take, stereoselectively, the *Λ-cis-β*$_1$(*fac*)-structure, irrespective of the configuration of the amino acids. On the other hand, the reactions of [Co(sal$_2$-(*S*,*S*)-chxn)] with an excess of DL-amino acids in open air gave [Co(sal$_2$-(*S*,*S*)-chxn) (aa)], in which L-amino acids were selectively coordinated except for proline. These stereospecificities were found from the optical-purity measurement of the unreacted amino acids which had been separated from the reaction solutions by extracting the formed complex with chloroform. The configuration and the optical purities of the unreacted amino acids recovered from 1 : 2 reaction solutions (complex: DL-amino acid) were as follows: ala, (D, 6—10%); leu, (D, 6—8%); met, (D, 6—8%); ser, (D, 10—12%); thr, (D, 27—30%); asp, (D, 16—18%); glu, (D, 6—8%); phe, (D, 29—31%); trp, (D, 41—43%); pro, (L, 48—50%). These stereoselectivities and stereospecificities were explained in terms of the thermodynamic origin and the stereochemical requirement of the complexes.

In recent papers,[1,2] the stereoselectivity in cobalt(III)–Schiff base complexes containing L-amino acids, [Co(sal$_2$en)(L-aa)] and [Co(7,7′-Me-sal$_2$en)(L-aa)], has been reported on. In these complexes, the stereoselectivity was thermodynamic in origin and was well explained in terms of the intramolecular steric repulsion between the alkyl groups of the coordinated amino acids and the H–C=N or CH$_3$–C=N groups of the Schiff base ligands. In this paper, we wish to report on another type of stereoselectivity which comes from a chiral Schiff base ligand in cobalt(III)-sal$_2$-(*S*,*S*)-chxn complexes with amino acids. Also to be reported is a stereospecificity of the cobalt(III)-sal$_2$-(*S*,*S*)-chxn complex to L-amino acids. The study is very interesting because the stereospecificity is thermodynamic in origin and is related to the optical resolution of amino acids with a metal complex[3–13] or to the problem of chiral recognition in metal-coenzyme.[14–19]

Experimental

Preparation of the Complexes. *1)* [*Co(sal$_2$-(S,S)-chxn)*]: This complex was prepared by the method described in Ref. 20 using (1*S*,2*S*)-*N*,*N*′-1,2-cyclohexylenebis(salicylideneamine). The optically active cyclohexanediamine used for the preparation of the optically active Schiff base ligand was resolved by a modification of the literature method.[21] A solution of *d*-tartaric acid (150 g) in 250 ml of water was cooled to about 10 °C. To this solution we then cautiously added 57 g of 1,2-cyclohexanediamine (Tokyo Kasei Co.) in small batches with cooling and stirring, followed by cooling in a refrigerator at about 0 °C for a day. A white powder-like compound was precipitated from the cold solution by scratching the wall of the beaker and subsequently separated by filtration. The white precipitate was the (+)$_D$-component and was recrystallized from a minimum amount of hot water to show a constant optical rotation (5—6 times), $[\alpha]_D$= +27.0°. Yield, 12.5 g. Found: C, 38.68; H, 6.52; N, 6.47%. Calcd for $C_6H_{16}N_2(C_4H_5O_6)_2\cdot H_2O$: C, 38.89; H, 6.53; N, 6.48%. The hydrochloride of the (+)$_D$-component, which was obtained by the usual procedure,[21] showed an $[\alpha]_D$ of +16.0° (lit,[21] +15.8°).

The (−)$_D$-component was obtained as white needles or plates by the slow concentration of the filtrate at room temperature. It was recrystallized from a minimum amount of hot water several times to show a constant optical rotation, $[\alpha]_D$=−12.1° (lit,[22] −12°). Yield, about 7.0 g. Found: C, 44.75; H, 7.65; N, 10.49%. Calcd for $C_6H_{16}N_2(C_4H_4O_6)\cdot 1/4H_2O$: C, 44.69; H, 7.69; N, 10.42%. The hydrochloride showed $[\alpha]_D$ of −16.0°.

The absolute configuration, (1*S*, 2*S*), has been determined for (+)$_D$-chxn by Marumo *et al.* from the X-ray crystal analysis of (−)$_D$-[Co((+)-chxn)$_3$]Cl$_3\cdot$5H$_2$O.[23]

2) [*Co(sal$_2$-(S,S)-chxn)(aa)*]: Since the preparative method is almost the same for all the complexes, only a representative procedure will be described here. The amino acid (1.5×10^{-3} mol) dissolved in 35 ml of water was added to a suspension of [Co(sal$_2$-(*S*,*S*)-chxn)] (0.5 g, 1.3×10^{-3} mol) in 45 ml of methanol. The mixture was stirred vigorously in open air for about 30 min at 60 °C. By this procedure, the complex was dissolved to give green solution. After cooling to room temperature, the solution was concentrated to about 35 ml at room temperature. Chloroform (about 50 ml) was added to extract the formed complex, and the crude product was obtained by evaporating off the chloroform to dryness. It was then recrystallized from methanol (complexes of L-ala, L-thr, D-thr, L-trp, and D-trp) or reprecipitated from chloroform (complexes of gly, D-ala, L-val, D-val, L-leu, and D-leu) by evaporating to dryness. The yields were 80—90%. These complexes can also be prepared from a mixture of a large excess of amino acid (about 1×10^{-2} mol) in 100 ml of water and [Co(sal$_2$-(*S*,*S*)-chxn)(aa)] (1×10^{-3} mol) in 50 ml of methanol, followed by a treatment similar to the method mentioned above. The compounds were identified by their PMR spectra, and their yields were 80—90%. The analytical data are listed in Table 1.

Optical Resolution of Amino Acids. The method for the optical resolution of amino acids is similar for all the amino acids, and so only a representative procedure will be given

* A part of this study was reported in *Chem. Lett.*, **1976**, 745.

here. The molar ratio of the reactants is 1: 2 (Complex: DL-amino acid). DL-Amino acid (2.6×10^{-3} mol), dissolved in 40 ml of water, was added to a suspension of $[Co(sal_2\text{-}(S,S)\text{-chxn})]$ (0.5 g, 1.3×10^{-3} mol) in 60 ml of methanol. The mixture was then stirred vigorously for 30 min at about 60 °C. After cooling, the green complex was extracted into chloroform (50 ml, twice), and the water layer was concentrated to near dryness. The white precipitate thus obtained was washed with methanol; the yields were 90—100% (a half of the used amino acid corresponds to the yield of 100%). The white precipitate in each case was confirmed to be the corresponding amino acid by a study of its IR spectrum. The opical purity of the recovered amino acids was determined by using the method described in Ref. 24.

Measurements. The IR spectra were recorded as KBr pellets with a Hitachi EPI-S2 spectrophotometer. The electronic Absorption spectra were measured with a Hitachi EPS-3 spectrophotometer at 25 °C. The CD spectra were recorded with a JASCO J-20 Automatic Recording Spectropolarimeter at room temperature. The optical rotation at 435 nm was measured with a JASCO DIP-180 Automatic Polarimeter at 25 °C. The PMR spectra were measured with a Hitachi R-20 spectrometer (60 MHz) at 35 °C in CD_3OD using TMS as the internal reference.

Results and Discussion

Stereoselectivity. The data for the electronic absorption spectra (AB) and the circular dichroism spectra (CD) are summarized in Table 2, while some representative AB and CD spectra are shown in Fig. 1 (and Fig. 1 in *Chem. Lett.*, **1976**, 745). The PMR spectral data are listed in Table 3, while some representative PMR spectra are shown in Fig. 2 (and Fig. 2 in *Chem. Lett.*, **1976**, 745.)

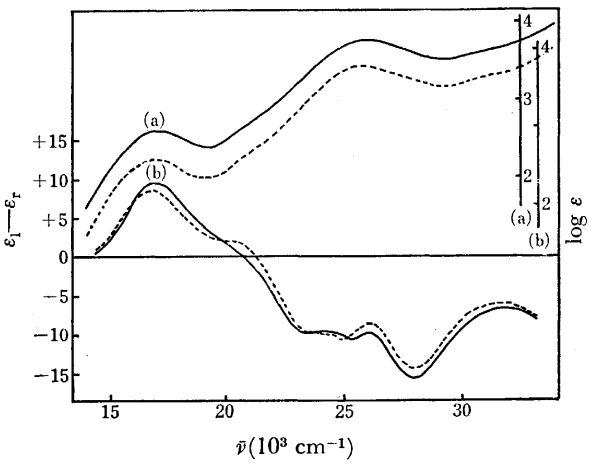

Fig. 1. AB and CD spectra of Λ-$[Co(sal_2\text{-}(S,S)\text{-chxn})(L\text{-val})]$ (——) and Λ-$[Co(sal_2\text{-}(S,S)\text{-chxn})(D\text{-val})]$ (……) in MeOH.

All the complexes exhibit AB and CD spectra which are quite similar to one another. Thus, it is suggested that all the complexes prefer to take the same geometrical structure. All the complexes show CD intensities in the first absorption region (16000—21000 cm^{-1}) as strong as those for optically pure isomers of $[Co(sal_2en)(aa)]$.[2] Thus, it is also suggested that all the complexes prefer to take the same optical form. These speculations are strongly supported by the PMR spectra. All the complexes show almost the same PMR signal for the coordinated $sal_2\text{-}(S,S)$-chxn. Moreover, the PMR signals of the alkyl groups of the coordinated amino acids consist of peaks which correspond to only one isomer. Therefore, it is clear from these data that the

a) Shoulder.

complexes exist as only one diastereoisomer in methanol. As will be mentioned later, six diastereomers are possible for each complex: *Λ*- and *Λ-cis-*β_1, *Λ*- and *Λ-cis-*β_2, and *Λ*- and *Λ-cis-*α. However, all the complexes utilize only one diastereoisomer, and their structures are similar to one another whether the coordinated amino acid is L or D. Thus, it may be concluded that 1) the stereoselectivity in the [Co(sal$_2$-(*S*,*S*)-chxn)(aa)] complex is complete, and 2) the stereoselectivity of the coordinated sal$_2$-(*S*,*S*)-chxn is great enough to assume only one optical form.

Although some differences in CD strengths are observed between the complexes with L- and D-amino acids, this is not due to the poor stereoselectivity but to the vicinal effect of the coordinated amino acids. Since the CD strengths in these Schiff base complexes are 2—3 times greater than those in the usual amino acidato cobalt(III) complexes,[25-28] the vicinal effect may also be somewhat stronger in these complexes. Quite a strong vicinal effect has also been observed for [Co(tfac$_2$en)-(L-aa)] (tfac$_2$en=dianion of *N*,*N*′-ethylenebis(trifluoroacetylacetoneamine); the results will be reported elsewhere.

All the complexes show no time-dependence on their CD and PMR spectra in methanol. Thus, the isomerization reaction such as seen in [Co(sal$_2$en)(L-aa)] and [Co(7,7′-Me-sal$_2$en)(L-aa)] may not occur in these sal$_2$-(*S*,*S*)-chxn-complexes.[2] However, these complexes are substitution-labile for the coordinated amino acid. That is, as has been described in the Experimental section, the reaction of these complexes with an excess of another amino acid (aa′H) proceeds comparatively rapidly to give [Co(sal$_2$-(*S*,*S*)-chxn)(aa′)] with a retention of the configuration. These facts mean that the stereoselectivity of sal$_2$-(*S*,*S*)-chxn-complexes is so high that no conversion of the configuration of the coordinated Schiff base ligand is observed. Since the stereoselectivity in substitution-labile complexes can usually be ascribed to thermodynamic origins,[11-13] the stereoselectivity observed here can also be thought to be thermodynamic in origin.

Structure of the Complexes. All the complexes isolated show ν(COO$^-$) at 1625—1630 cm^{-1}, suggesting the coordination of the carboxylate group of the amino acidato ligand to the central cabolt(III) ion.[29] The elemental analysis suggests that all the amino acids act as bidentate ligands. Since the PMR signal of the H–C=N group of the sal$_2$-(*S*,*S*)-chxn ligand is split into

two peaks of equal intensity, the *cis*-α- and *cis*-β-structures are thought to be possible. However, the *cis*-α-structure is thought to be quite unstable, and such a complex has not yet been reported in cobalt(III)–Schiff base complexes.[30,31] On the other hand, the *cis*-β-structure is well known.[30-34] Since the stereoselectivity in these complexes is thermodymanic in origin, as has been mentioned above, the thermodynamically stable *cis*-β-structure is confidently assigned to the complexes. It is well known that (*S*,*S*)-chxn and its derivatives take the δ-conformation exclusively.[35-37] This is due to the extraordinary stability of the chair form of the cyclohexane ring. Molecular models indicate that the δ-conformation persists in sal$_2$-(*S*,*S*)-chxn and that the Λ-configuration is strain-free in its complex with the *cis*-β form. Therefore, the Λ-configuration is confidently assigned to all the complexes. As will be discussed later, [Co(sal$_2$-(*S*,*S*)-chxn)(L-aa)] is more thermodynamically stable than [Co(sal$_2$-(*S*,*S*)-chxn)-(D-aa)]. This is mainly due to the intramolecular steric repulsion between the alkyl group of the coordinated amino acid and the H–C=N group of the Schiff base ligand. This repulsion is larger in the D-aa-complex than in the L-aa-complex. Molecular models show that the steric repulsion is larger in the Λ_D-*cis*-β_1(*fac*) isomer than in the Λ_L-*cis*-β_1(*fac*) isomer. However, the Λ_L-*cis*-β_2(*mer*) isomer displays somewhat a larger steric repulsion than the Λ_D-*cis*-β_2(*mer*) isomer. Thus, the *cis*-β_1(*fac*)-structure shown in Fig. 3 may be assigned to all the complexes.

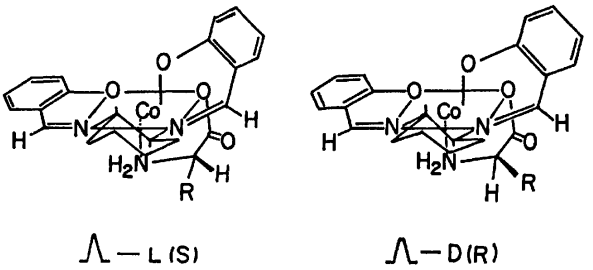

Fig. 3. The proposed structure of [Co(sal$_2$-(*S*,*S*)-chxn)-(aa)].

Stereospecificity. In order to study the stereospecificity of the complexes toward L- or D-amino acids, we examined the reactions of [Co(sal$_2$-(*S*,*S*)-chxn)] with various racemic amino acids in open air. The molar ratio in the reaction was maintained at 1 : 2 (complex: DL-amino acid). The stereospecificity was estimated from the optical purity of the unreacted amino acid which was recovered from the reaction solution by extracting the formed complex with chloroform, followed by the concentration of the amino-acid solution. The optical purities of the unreacted amino acids are sum-

TABLE 4. OPTICAL PURITY OF UNREACTED AMINO ACIDS WHICH WERE RECOVERED FROM THE REACTION SOLUTIONS OF [Co(sal$_2$-(*S*,*S*)-chxn)] AND DL-AMINO ACIDS IN A 1 : 2 MOLAR RATIO

Amino acid	Configuration of unreacted amino acid	Optical purity (%)	Amino acid	Configuration of unreacted amino acid	Optical purity (%)
Ala	D(R)	6—10	Asp	D(R)	16—18
Val	D(R)	6—8	Glu	D(R)	6—8
Leu	D(R)	6—8	Phe	D(R)	29—31
Met	D(R)	6—8	Trp	D(R)	41—43
Ser	D(R)	10—12	Pro	L(S)	48—50
Thr	D(R)	27—30			

marized in Table 4. Since the reaction is stoichiometric, it is written as follows:

$$2[\text{Co(sal}_2\text{-}(S,S)\text{-chxn)}] + 4\text{aaH} + 0.5\text{O}_2 \longrightarrow 2[\text{Co(sal}_2\text{-}(S,S)\text{-chxn)(aa)}] + 2\text{aaH} + \text{H}_2\text{O}. \quad (1)$$

Moreover, since all the complexes are substitution-labile toward the coordinated amino acids, the following equilibrium is also thought to be established in solution:

$$[\text{Co(sal}_2\text{-}(S,S)\text{-chxn)(L-aa)}] + \text{D-aaH} \rightleftarrows [\text{Co(sal}_2\text{-}(S,S)\text{-chxn)(D-aa)}] + \text{L-aaH}. \quad (2)$$

Here, we must consider the possibility of the racemization of amino acids or the assymetric transfer of the coordinated amino acids, but these processes were not observed under our experimental conditions. Therefore, the results in Table 4 indicate that Equilibrium 2 tends to lie toward the left side. Thus, it may be concluded that the cobalt(III)-sal$_2$-(*S*,*S*)-chxn-complex favors L-amino acids more than D-amino acids, with the exception of proline. Since the existence of Equilibrium 2 means that the stereospecificity is thermodynamic in origin, it may be concluded that the L-aa-complex is thermodynamically more stable than the D-aa-complex, again with the exception of proline. In this case, it is known that the stereoselective behavior of proline is markedly different from that of the other amino acids.[1,2]

The stereospecificity increases in the order, ala$\sim$met$\sim$leu$\sim$val$\sim$glu$<$ser$<$asp$<$thr$\lesssim$phe$<$trp$<$pro. This order parallels the increasing order of the stereoselectivity in the [Co(sal$_2$en)(L-aa)] complex and also coincides with the increasing order of the steric crowding of the alkyl group of the amino acid.[2] Therefore, an intramolecular steric repulsion between the alkyl group and the H–C=N group of the Schiff base ligand, such as seen in the [Co(sal$_2$en)(L-aa)] complex,[2] exists in each complex, and it may be larger in the Λ_D-isomer than in the Λ_L-isomer. This is the reason why the L-amino acid is selectively coordinated in the complex. In the case of proline, the molecular model indicates that the steric repulsion is larger in the Λ_L-isomer than in the Λ_D-isomer.

Variation of the Molar Ratio (DL-Amino Acid/Complex) in the Reaction. Figure 4 shows the plots of the optical purity of unreacted amino acid *versus* the molar ratio (m/n) in the reaction of n mol of a complex with $2m$ mol of DL-amino acid. In this figure, the solid lines show the calculated values, and the circles, the observed values. The calculation was carried out by using Eqs. 3 and 4 as derived below. Here, K is the equilibrium constant of Reaction 2 and is equal to

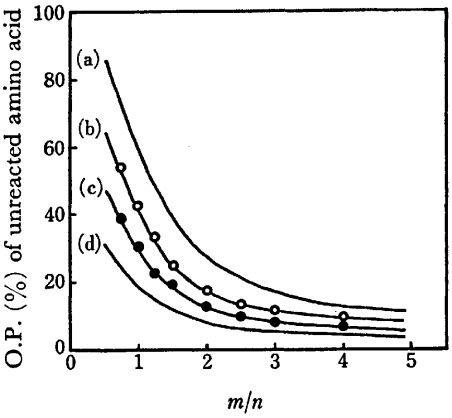

Fig. 4. A plot of optical purity (O.P.) of unreacted amino acid and molar ratio (m/n) in the reaction of n mol of complex with $2m$ mol of DL-amino acid. (a), (b), (c), and (d) are the calculated curve for K=20, K=6.0, K=3.4, and K=2, respectively. ○ and ● are the observed values for tryptophan (○) and phenylalanine (●).

K_L/K_D ($K_L>K_D$ in sal$_2$-(*S*,*S*)-chxn-complex), where K_L and K_D are the stability constants written as follows:

$$K_L = [\text{Co(Y)(L-aa)}]/[\text{Co(Y)}][\text{L-aa}],$$
$$K_D = [\text{Co(Y)(D-aa)}]/[\text{Co(Y)}][\text{D-aa}].$$

Co(Y) indicates the Co(sal$_2$-(*S*,*S*)-chxn)-complex, and the brackets stand for the concentration.

When the reaction of n mol of the complex with $2m$ mol of DL-amino acid ($2m>n$) is considered, the optical purity of the unreacted amino acid is written as follows:

$$\text{O.P. (\%)} = \{[\text{D-aa}]_f - [\text{L-aa}]_f\}/\{[\text{D-aa}]_f + [\text{L-aa}]_f\} \times 100.$$

where $[\text{D-aa}]_f$ and $[\text{L-aa}]_f$ are the concentrations of free D- and L-amino acids respectively. Since the complex formation is quantitative, and if we can neglect the concentration of free complex, [Co(Y)], the O.P.(%) can be written as follows:

$$\text{O.P. (\%)} = \{[\text{D-aa}]_f - (2m-n-[\text{D-aa}]_f)\}/\{[\text{D-aa}]_f + (2m-n-[\text{D-aa}]_f)\} \times 100, \quad (3)$$

where

$$[\text{D-aa}]_f = \{-(3m-n-mK+nK) + [(3m-n-mK+nK)^2 - 4(mn-2m^2)(K-1)]^{1/2}\} \times [2(K-1)]^{-1}. \quad (4)$$

Thus, if K is known, we can estimate the O.P.(%) of the unreacted amino acid by using Eqs. 3 and 4. In Fig. 4, we selected K arbitrarily (K=2 or 20) or as fitted to the

observed values (K=3.4 for phe and K=6.0 for trp).

From these results, it may be seen that the observed values fit the calculated curves quite well at all the reaction molar ratios; the K-values for phe and trp are quite reliable. These K-values are close to the thermodynamic stereoselectivity (Λ_L-*cis*-β_1 isomer/Δ_L-*cis*-β_1 isomer) of the Co(sal$_2$en)-complexes with L-phe and L-trp, respectively (about 4 for phe and 8 for trp).[2] Here, the Λ_L-*cis*-β_1 isomer/Δ_L-*cis*-β_1 isomer ratio is equal to the Λ_L-*cis*-β_1 isomer/Λ_D-*cis*-β_1 isomer ratio; it corresponds to the relative stability constant between the complex with L-aa and that with D-aa. Therefore, these results give strong support for the thermodynamic origin of the stereospecificity.

Finally, it should be pointed out that, although the optical purity at $2m/n$=2 is not very high, it becomes higher as m becomes smaller, and that the use of a chloroform-soluble, non-electrolyte complex is one of the advantages of our method of optical resolution of amino acid, as it provides for the easy separation of the unreacted amino acid and the formed complex by solvent extraction.

The authors wish to express their deep thanks to Professor Y. Yoshino of Tokyo University, and Professor K. Sone and Dr. Y. Fukuda of Ochanomizu University for their kind assistance in the CD spectral measurements. This work was supported in part by a Scientific Research Grant from the Ministry of Education, Japan (No. 154189).

The Synthesis of Greigite from a Polysulfide Solution at about 100 °C

Hiroaki WADA

National Institute for Researches in Inorganic Materials, Kurakake, Sakura-Mura, Nihari-Gun, Ibaraki

(Received October 15, 1976)

Favorable synthesis conditions for greigite are examined in $FeSO_4 \cdot (NH_4)_2SO_4$–$Na_2S$–$Na_2S_x$ systems at about 100 °C. It has been found that greigite formation is influenced by the pH adjustment and by the addition of sulfur. When the final pH is about 6.0 and the dissolved iron concentration is in the 10^{-3}—$10^{-1.5}$ M range, greigite is synthesized as a single phase. The unit-cell dimensions of greigite range from 9.840 to 9.877 Å, corresponding to variations in compositions between 45.4 and 42.9 atomic % Fe. The formula of synthetic greigite is represented as $Fe_{3+x}S_4$ (x=0—0.4).

Many reports have been published on the preparation of greigite, Fe_3S_4, in an aqueous solution.[1-3] However, it is not easy to synthesize greigite as a single phase, because greigite formation depends upon many factors, such as the temperature, the pH, the starting source materials, and the redox conditions.[4,5] Recently, Horiuchi *et al.* studied the reaction of tetragonal FeS (mackinawite) with colloidal sulfur and observed the formation of cubic Fe_3S_4 in the semi-dry system by means of electron diffraction.[6] From the results of this work, it was suggested that amorphous sulfur played an important role in Fe_3S_4 formation.

In an aqueous solution, free sulfur is frequently combined with sulfide ions and so changed into the form of polysulfide ions. Paying special attention to sulfur source materials, the present author attemped to prepare greigite from a polysulfide solution.

Experimental

All the chemicals used were of a guaranteed reagent grade. A polysulfide stock solution was prepared by reacting orthorhombic sulfur with a Na_2S solution in a nitrogen gas atmosphere for 2 h at about 100 °C. After the residual solid sulfur had been taken away by filtration, the polysulfide solution was kept in polyethylene bottles in a cold and dark place. Prior to the experiments, the concentrations of sodium and sulfur were determined by the methods of flame-photometry and conventional gravimetry respectively. 0.20 M $Na_2S_{3.89}$ solution was used in the synthesis of greigite.

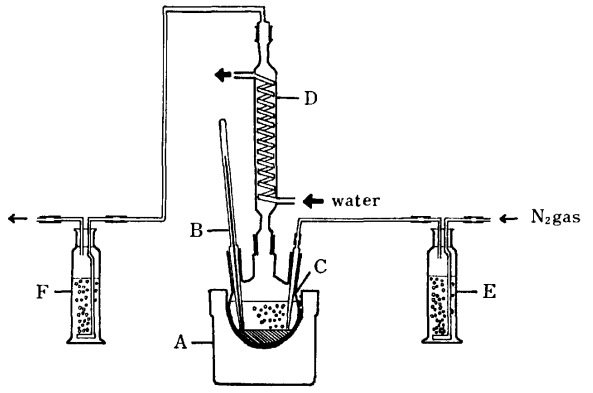

Fig. 1. Schematic diagram of the reaction vessel for synthesis of iron sulfides. A: Heating mantles. B: Mercury thermometer. C: 500 ml of round bottom flask with four necks. D: Dimroth condenser. E and F: Washing gas bottles. E is filled with 40 per cent pyrogallol–NaOH solution to remove oxygen in nitrogen gas. H_2S gas which is expelled from the vessel is absorbed in F, filled with 10 per cent NaOH solution.

$FeSO_4 \cdot (NH_4)_2SO_4$ and Na_2S were dissolved in a proper volume of distilled water in every other experiment. Less than 10 ml of a $Na_2S_{3.89}$ solution was added into large amounts of the Na_2S solution as a part of the sulfur source. Two hundred ml of a 0.0834 ± 0.0006 M $FeSO_4 \cdot (NH_4)_2SO_4$ solution were mixed with 200 ml of a 0.1468 ± 0.0006 M Na_2S solution containing polysufide ions, as is shown in Fig. 1. Purified nitrogen gas was flowed through the solution at the rate of about 170 ml/min in order to avoid the contamination of products by air oxidation. A colloidal suspension of iron sulfides precipitated was heated at the boiling temperature (103 °C) for 15—20 h.

At the termination of each experiment, the final pH of solution was measured by means of a pH meter (TOA Electronics Ltd., HM-7A type). The concentration of ferrous ions in the clear supernatant solution was determined by the titration method using 1.67×10^{-2} M $K_2Cr_2O_7$ or a colorimetric method using 1,10-phenanthroline. The iron sulfide product was separated from the solution by a centrifuge, washed by water, aqueous ammonia, and acetone, dried in a vacuum, and identified by means of X-ray and electron diffraction. An X-ray diffractometer (Shimadzu VDR-11) and an electron microscope (100 kV: Hitachi 11 D) were employed to identify the specimens.

The compositions of the iron sulfide products were determined by the analytical method of Kolthoff and Sandell.[7] About 200-mg portions of the specimens were decomposed into an ionic state on the basis of oxidation in the wet way using bromine with nitric acid. The sulfur was determined gravimetrically as $BaSO_4$. After the dissolved iron had been reduced to Fe^{2+} ions with $NH_2OH \cdot HCl$, the iron content was determined by the spectrophotometric method,[8] using 1,10-phenanthroline.

Results and Discussion

Greigite was obtained under the preferred synthesis conditions, listed in Table 1. Meanwhile, phase transformations were observed in the order of mackinawite, greigite, and pyrite (cubic FeS_2) with an increase in the amounts of the $Na_2S_{3.89}$ solution added. When the $Na_2S_{3.89}$ solution was not added, only mackinawite was formed. Greigite was produced as a single phase by the addition of 3—6 ml of the $Na_2S_{3.89}$ solution. Pyrite was formed together with greigite by the addition of 7—10 ml of the $Na_2S_{3.89}$ solution.

The analytical results of the products showed that the S/Fe atomic ratio of iron sulfides increased linearly with an increase in the amount of polysulfide solution

TABLE 1. EFFECT OF SULFUR FROM A 0.20 M $Na_2S_{3.89}$ SOLUTION UPON PRODUCTS, ON HEATING FOR 15—20 h AT ABOUT 100 °C

Source materials			Final pH	Product
$FeSO_4 \cdot (NH_4)_2SO_4 \cdot 6H_2O$ in g	$Na_2S \cdot 9H_2O$ in g	$Na_2S_{3.89}$ in ml		
6.5401	7.0269	—	6.38	mackinawite

6.6023	7.0279	6	6.03	greigite
6.5211	7.0322	10	6.00	greigite +pyrite

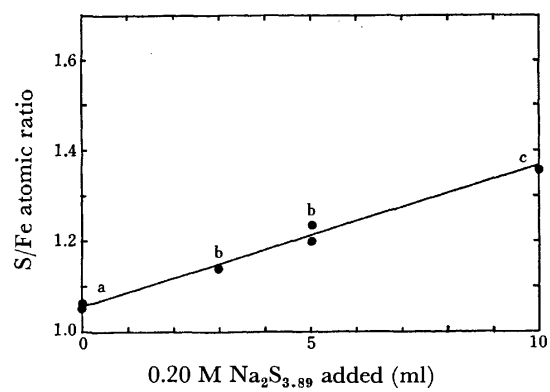

Fig. 2. Relation of S/Fe atomic ratio of products with 0.20 M $Na_2S_{3.89}$ solution added. Products: a=mackinawite, b=greigite, c=greigite+pyrite.

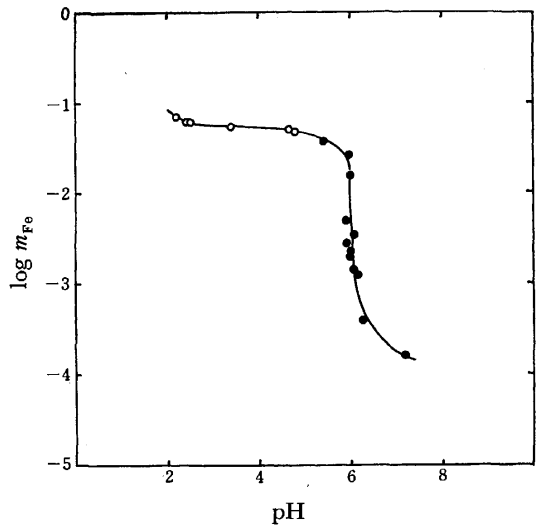

Fig. 3. Relations of the final pH with iron concentration in solutions. The pH is adjusted with variation of mixing ratio of $FeSO_4 \cdot (NH_4)_2SO_4$ and Na_2S (●), and addition of 1.13 M H_2SO_4 (○).

added (Fig. 2). The dissolved iron content in the clear supernatant solution increased by the order of 2.5, from 10^{-4} to $10^{-1.5}$ M/l, corresponding to the pH change from 7 to 5.8 (Fig. 3). The final pH values of the solutions associated with greigite ranged from 5.8 to 6.1. The region of greigite formation was consistent with the conspicuous increase in the solubility of mackinawite. These results indicate that (1) forms of the resulting iron sulfide are controlled systematically by the amounts of sulfur added and by the pH of the solution and (2) the region of greigite formation as a single phase in solutions is restricted to the extremely narrow pH range between 5.8 and 6.1.

It was found that the correct pH adjustment of the solution was important in preparing greigite as a single phase. However, the rapid pH change upon the addition of mineral acids was not suitable for its synthesis. In order to acidify solutions mildly and gradually from the alkaline side in the heating process, proper mixing ratios of $FeSO_4 \cdot (NH_4)_2SO_4$ and Na_2S solutions, described above, were selected. Pure greigite was formed when (1) 2 $m_{SO_4^{2-}} > m_{Na^+}$ and (2) $m_{S^{2-}} + m_{HS^-} > m_{Fe^{2+}}$ (all the iron was transformed initially into the form of precipitated FeS).

After the solution had been dried in a vacuum, synthetic greigite was obtained as a fine sooty black powder with strong magnetic properties. The grain size of greigite was calculated to be 200—300 Å on the basis of the measurement of the half-width of the diffraction peak. Fresh greigite synthesized in acidic solution sometimes showed a pyrophoric property. When exposed to the atmosphere, it was burned with fumes of S_2 and SO_2, being thus completely altered to a mixture of magnetite (Fe_3O_4) and hematite (Fe_2O_3).

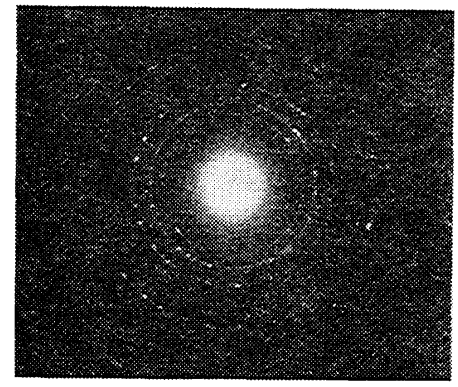

Fig. 4. Electron diffraction pattern of synthetic greigite.

Figure 4 shows a typical electron-diffraction pattern from a synthetic greigite. This pattern contains only the reflections allowed for the spinel structure, with the space group Fd3m. Both the d-spacings and the relative intensities observed are listed in Table 2 in comparison with the X-ray data of natural greigite. There is a close correspondence of d-spacings and intensities between synthetic greigite and the natural mineral.[9]

The product, stable in air was examined by the X-ray powder diffraction method, and its composition was determined by chemical analysis. The compositions of synthetic greigite ranged from 45.4 to 42.9 atomic per cent of iron and explicitly showed a deviation from stoichiometric Fe_3S_4. The chemical formula of synthetic greigite was given by $Fe_{3+x}S_4$ (x=0—0.4). With respect to the compositions, this iron-rich greigite ($Fe_{3+x}S_4$) was analogous to natural iron-rich smythite ($Fe_{3+x}S_4$), which

was found at Silverfields Mine, Cobalt, Ontario.[10)]

The cell edges of synthetic greigite ranged from 9.840 Å to 9.877 Å with corresponding variations in the compositions. They increased with a decrease in the iron content in the compositional range between 45.4 and 42.9 atomic % Fe.

The density determination with a pycnometer was made at 25 °C on synthetic greigite. The specific gravities of $Fe_{3.33}S_4$ and Fe_3S_4 were 4.60 and 4.02 respectively.

The results presented above may be indicative of the possibility that excess iron occupies an interstitial site in the spinel structure. Further detailed researches on the crystal structure are, however, necessary for a better understanding of the nonstoichiometry of greigite.

The author wishes to express his thanks to Dr. Shigeto Yamaguchi for his encouragement and guidance throughout this work and to Dr. Shigeo Horiuchi for his valuable discussions. Thanks are also due to Mr. Kousuke Sakaguchi for his operation of the electron microscope.

Preparation and Properties of the Uni- and Binuclear [Co(III)N_2O_4] Type Complexes Containing (*S*)-2-Amino-1-propanol

Toshikazu NISHIDE and Kazuo SAITO

Chemistry Department, Faculty of Science, Tohoku University, Aramaki, Sendai, 980

(Received November 9, 1977)

Reactions of (*S*)-2-amino-1-propanol (*S*-praH) with the tricarbonatocobaltate(III) solution gave binuclear complexes bridged by carbonates, or carbonate and hydroxide. The carbonate was replaced by oxalate (ox^{2-}) to give binuclear complexes $[(S\text{-praH})_2Co(ox)_2Co(S\text{-praH})_2]^{2+}$ and uninuclear *trans*(*N*)*cis*(*O*)-[Co(ox)(*S*-pra)-(*S*-praH)]. Another uninuclear complex $[Co(ox)(S\text{-praH})_2]^+$ was obtained by direct synthesis from *S*-praH and cobalt(II) acetate by oxidation with lead dioxide. Column chromatography with SP-Sephadex C-25 was useful for separating the geometrical isomers, which were identified by PMR, IR, visible, and UV absorption spectra. Their circular dichroism (CD) spectra changed depending on pH of the aqueous solution. All the *S*-pra$^-$ chelates have δ-conformation, which is characterized by an intensive plus CD component in the 25000 cm^{-1} region, regardless of the skeletal structure of the complexes.

In the previous papers[1,2] we reported the preparation of mixed ligand complexes of the type $[Co^{III}N_5O]$ containing various amino alcohols (amOH), and ammines or diamines. The alcohol protons of coordinated aminoalkanols in complexes of the type $[Co^{III}(amOH)(L)]X_3$ (amOH=2-aminoethanol [etaH], (*S*)-2-amino-1-propanol [*S*-praH] *etc.*; L=$(NH_3)_4$, $(en)_2$, and ((*R*,*R*)-1,2-diaminocyclohexane)$_2$; X=chloride, bromide and perchlorate) were deprotonated easily (p*K* 3 to 3.5 at 25 °C and ionic strength 0.05), and the aminoalkanolato complexes exhibited larger CD components than the protonated did in the first and second absorption band regions. Especially $[Co(S\text{-amO})(L)]^{2+}$ gave characteristic large plus vicinal CD components at *ca.* 25000 cm^{-1} (second band region), which were due to the δ-conformation of the *S*-amO$^-$ chelate.

The study has been extended to related complexes containing two moles of aminoalkanol ligands per cobalt(III), and this paper deals with the preparation of complexes of $[CoN_2O_4]$ type, *i.e.* the uninuclear complexes $[Co(ox)(S\text{-praH})_2]ClO_4$ and *trans*(*N*)*cis*(*O*)-[Co(ox)(*S*-pra)(*S*-praH)], and the binuclear complexes $[(S\text{-pra})_2Co(CO_3,OH)Co(S\text{-pra})(S\text{-praH})]$, $[(S\text{-pra})(S\text{-praH})Co(CO_3)_2Co(S\text{-pra})(S\text{-praH})]$, and $[(S\text{-praH})_2Co(ox)_2Co(S\text{-praH})_2](ClO_4)_2$. Their structure and CD pattern have been discussed with reference to the characteristic nature of the coordinated aminoalkanolato ligand.

Experimental

Material. The *S*-praH ligand was synthesized by Vogl and Pöln's method.[3] The outline of the syntheses is shown in Fig. 1.

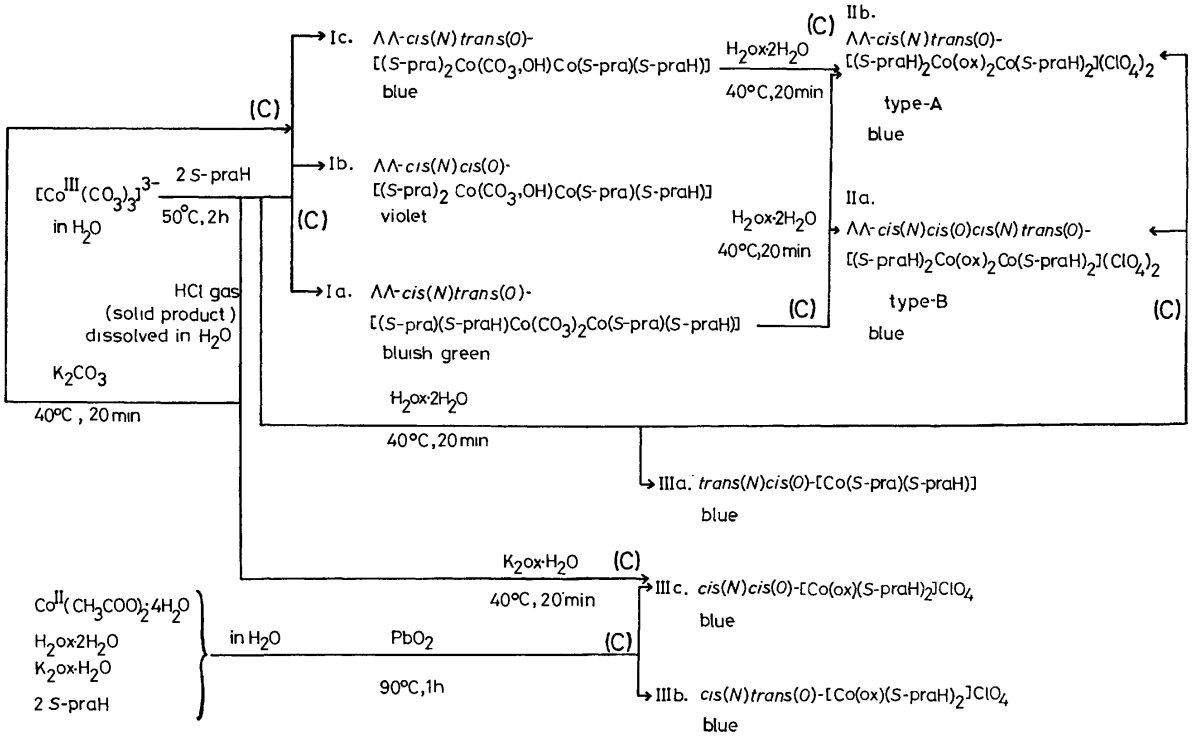

Fig. 1. Outline of the preparation. (C); Column chromatography (see the text).

Syntheses and Separation of μ-Carbonato Complexes: The tricarbonato $[Co(CO_3)_3]^{3-}$ solution (0.042 mol, 50 cm^3)[4] was heated with *S*-praH (0.1 mol) at 60 °C for 2 h and evaporated to dryness under a reduced pressure. The complexes were extracted with ethanol (300 cm^3), the solution was evaporated to dryness and the residue was extracted with a small amount of water. The aqueous solution was poured onto a column (3.5×60 cm) of Dowex 50W-X8 (Na form, 100—200 mesh). The adsorbed band was eluted with water to give three bands. The eluates were collected individually and each was evaporated to dryness under a reduced pressure at 40 °C to give higroscopic powder. The complexes were recrystallized from ethanol and found to have the following formulae. They were named Ia, Ib, and Ic in the order of elution.

Ia: $[(S\text{-pra})(S\text{-praH})Co(CO_3)_2Co(S\text{-pra})(S\text{-praH})]\cdot 2NaHCO_3\cdot 2H_2O$. Found: C, 26.16; H, 5.54; N, 7.06%. Calcd for $Co_2C_{14}H_{34}N_4O_{10}\cdot 2NaHCO_3\cdot 2H_2O$: C, 25.95; H, 5.45; N, 7.57%.

Ib: $[(S\text{-pra})_2Co(CO_3,OH)Co(S\text{-pra})(S\text{-praH})]$. Found: C, 32.18; H, 7.13; N, 11.20%. Calcd for $Co_2C_{13}H_{33}N_4O_8$: C, 31.78; H, 6.77; N, 11.41%.

Ic: $[(S\text{-pra})_2Co(CO_3,OH)Co(S\text{-pra})(S\text{-praH})]\cdot 2H_2O$. Found: C, 29.75; H, 7.36; N, 10.67%. Calcd for $Co_2C_{13}H_{33}N_4O_8\cdot 2H_2O$; C, 29.61: H, 7.07; N, 10.63%.

These complexes were also prepared by the following method. When the residue on the extraction of the initial reaction products with ethanol was treated with hydrogen chloride gas, blue violet hygroscopic powder was obtained with the composition $[CoCl_2(S\text{-praH})_2]Cl$. Reaction of its aqueous solution with potassium carbonate gave a blue solution, which was treated with a similar ion exchange column to that mentioned above for separating Ia, Ib, and Ic from one another.

Syntheses and Separation of μ-Oxalato Complexes: The initial reaction mixture containing the μ-carbonato complexes (0.042 mol) was heated with oxalic acid (6.35 g, 0.05 mol) at 40 °C for 20 min. Blue prisms were filtered off and identified as the uninuclear complex *trans(N)cis(O)*-$[Co(ox)(S\text{-pra})(S\text{-praH})]\cdot 0.5\,H_2O$. (IIIa, *vide infra*) The filtrate was submitted to column (4.5×82 cm) chromatography with SP-Sephadex C-25 and eluted with sodium perchlorate solution (0.2 mol·dm^{-3}). Three bands were observed, of which the first band was too small to be collected. Eluates from the remaining two bands were individually made acid to pH 1 with perchloric acid, and evaporated under a reduced pressure at 40 °C to decrease the volumes to *ca.* 20 cm^3. Both solutions were filtered, made pH 3 with sodium hydroxide solution (1 mol·dm^{-3}) and kept overnight in a refrigerator to give blue crystals. They were filtered off, washed with ethanol, and recrystallized from water, and named IIa and IIb in the order of elution.

IIa: $[(S\text{-praH})_2Co(ox)_2Co(S\text{-praH})_2](ClO_4)_2\cdot 6H_2O$. Found: C, 21.03; H, 5.00; N, 6.05%. Calcd for $Co_2C_{16}H_{36}N_4O_{10}Cl_2\cdot 6H_2O$: C, 21.32; H, 5.37; N, 6.22%.

IIb: $[(S\text{-praH})_2Co(ox)_2Co(S\text{-praH})_2](ClO_4)_2\cdot 2.5H_2O$. Found: C, 23.24; H, 5.38; N, 6.31%. Calcd for $Co_2C_{16}H_{36}N_4O_{10}Cl_2\cdot 2.5H_2O$: C, 22.92; H, 4.93; N, 6.69%.

Reaction of a concentrated aqueous solution of Ia with an equivalent amount of oxalic acid at 40 °C for 20 min gave a blue solution, which was treated with a similar column to that mentioned above to give two bands consisting of IIa and IIb respectively. On the other hand, when a concentrated solution of Ic was caused to react with an equivalent amount of oxalic acid at 40 °C for 20 min, a blue solution was obtained, which gave only one band consisting of IIb on a similar column chromatography.

Preparation of Uninuclear Complexes Containing Oxalate: Among the three geometrical isomers the *trans(N)cis(O)* isomer (IIIa) was obtained as shown before. The other two isomers were synthesized directly as in the following. An aqueous solution of cobalt(II) acetate (0.02 mol) was mixed with oxalic acid (0.024 mol), potassium oxalate (0.016 mol) and *S*-praH (0.048 mol) in water (total 140 cm^3). The solution was oxidized with lead dioxide (5 g) at 80—90 °C for 1 h. The product was filtered and the filtrate was poured into a column (4.5×45 cm) of SP-Sephadex C-25. The adsorbed band was eluted with sodium perchlorate solution (0.2 mol·dm^{-3}). A blue and a violet band were observed in the order of elution. Blue (IIIb) and violet (IIIc) crystals were obtained by treating the respective eluates similarly to those of the μ-oxalato complexes. They were assigned as follows.

IIIa: *trans(N)cis(O)*-$[Co(ox)(S\text{-pra})(S\text{-praH})]\cdot 0.5H_2O$. Found: C, 31.18; H, 6.36; N, 9.22%. Calcd for $CoC_8H_{17}N_2O_6\cdot 0.5H_2O$: C, 31.48; H, 5.95; N, 9.18%.

IIIb: *cis(N)trans(O)*-$[Co(ox)(S\text{-praH})_2]ClO_4\cdot 2.5H_2O$. Found: C, 21.89; H, 5.01; N, 6.53%. Calcd for $CoC_8H_{18}N_2O_{10}Cl\cdot 2.5H_2O$: C, 21.75; H, 5.24; N, 6.34%.

IIIc: *cis(N)cis(O)*-$[Co(ox)(S\text{-praH})_2]ClO_4\cdot H_2O$. Found: C, 23.31; H, 5.13; N, 6.62%. Calcd for $CoC_8H_{18}N_2O_{10}Cl\cdot H_2O$: C, 23.17; H, 4.86; N, 6.76%.

An aqueous solution of the hygroscopic blue violet powder ($[CoCl_2(S\text{-praH})_2]Cl$) was treated with an equivalent amount of potassium oxalate at 40 °C for 20 min to give a blue solution, which was similarly treated with a column containing SP-Sephadex C-25 to give only IIIc isomer.

Measurements. Visible and ultraviolet absorption spectra were recorded with a Hitachi 323 Recording Spectrophotometer. Circular dichroism (CD) spectra were recorded with a JASCO Model ORD/UV-5 Spectrometer with CD attachment. Proton NMR spectra were recorded with Varian T-60 and A-60 Spectrometers. A JASCO IR-A-2S Spectrophotometer was used for the measurement of infrared spectra in KBr disks. The acid dissociation constants of the complexes were determined by the titration with sodium hydroxide solution (0.1 mol·dm^{-3}) with a Metrohm Combi Titrator 3D at 25 °C and ionic strength 0.1. The pH of complex solutions for spectroscopic measurement was adjusted with perchloric acid (0.1 mol·dm^{-3}), sodium hydroxide (0.025 mol·dm^{-3}), or potassium carbonate solution (*ca.* 10^{-2} mol·dm^{-3}).

Results and Discussion

Determination of the Skeletal Structure. The skeletal structure has been identified on the basis of elemental analysis, column chromatography, and infrared (IR) spectroscopy.

Binuclear Complexes with Carbonate Bridges: Each of the complexes Ia, Ib, and Ic in aqueous solution gave an absorption peak in the region from 30000 to 31000 cm^{-1}. Hence they must have bi- or multinuclear structures. They gave antisymmetric stretching absorption of the carbonate ions in the region from 1500 to 1520 cm^{-1} in KBr disks (Fig. 2). Gatehause *et al.*[5] found that the antisymmetric CO stretching absorptions of bi- and unidentate carbonato ligands appeared in higher energy regions than 1520 cm^{-1} and 1493 cm^{-1}, respectively. The uninuclear complex *cisβ*-$[Co(CO_3)(N,N'\text{-}Me_2\text{-}(S,S)\text{-mhydaH})]$ gives the $\bar{\nu}_{as}(CO)$ value 1600 cm^{-1}.[6] The μ-carbonato complex $[(NH_3)_5Co(CO_3)Co(NH_3)_5](SO_4)_2\cdot 4H_2O$ gives the $\bar{\nu}_{as}(CO)$ value 1480 cm^{-1}.[7] Wieghardt prepared various binuclear complexes of the type $[(NH_3)_3Co(OH,OH,RCO_2)Co(NH_3)_3]^{3+}$, and found a linear relationship between the

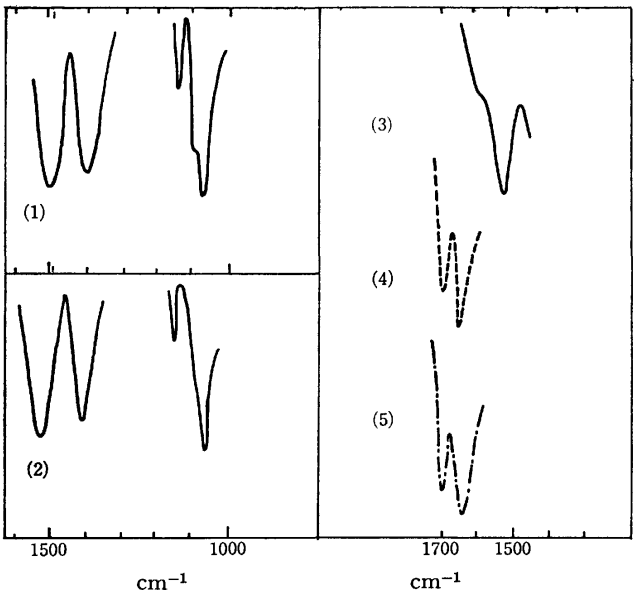

Fig. 2. IR Spectra of the binuclear complexes.
(1) $[(S\text{-pra})_2Co(CO_3,OH)Co(S\text{-pra})(S\text{-praH})]\cdot 2H_2O$ (Ic).
(2) $[(S\text{-pra})(S\text{-praH})Co(CO_3)_2Co(S\text{-pra})(S\text{-praH})]\cdot 2NaHCO_3\cdot 2H_2O$ (Ia).
(3) $[(S\text{-praH})_2Co(ox)_2Co(S\text{-praH})_2](ClO_4)_2\cdot 2.5H_2O$ (——) (IIb).
(4) $[(S\text{-praH})_2Co(ox)_2Co(S\text{-praH})_2](ClO_4)_2\cdot 6H_2O$(----) (IIa).
(5) *trans(N)cis(O)*-$[Co(ox)(S\text{-pra})(S\text{-praH})]\cdot 0.5H_2O$ (—·—) (IIIa).

$\bar{\nu}_{as}(CO)$ in cm^{-1} and the pK_a value of the carboxylic acid.[8] The $\bar{\nu}_{as}(CO)$'s observed for the present binuclear complexes fall on the same line. On the basis of these facts the carbonate ligands in our complexes can be reckoned to bridge two cobalt(III) ions. Reactions with oxalic acid converted all the μ-carbonato complexes into μ-oxalato complexes (Fig. 1). This fact also supports binuclear structure of the carbonato complexes.

Nakamoto *et al.* measured the IR spectrum of the binuclear complex $K_4[(ox)_2Co(OH)_2Co(ox)_2]$, and assigned the band near 1100 cm^{-1} to the Co–O–H bending.[9] Both the complexes Ib and Ic give the same absorption bands. Thus hydroxide ions must bridge two cobalt(III) ions in these complexes. The complex Ia gives no such IR absorption band. On the basis of these data we give the formulae to Ia, Ib, and Ic as mentioned before.

Binuclear Complexes Bridged by Oxalate: Chromatographic behavior of IIa and IIb and the presence of UV absorption bands in 30000—31000 cm^{-1} suggest that they have binuclear structure. The pH titration and IR spectra indicate the absence of unidentate ligands.

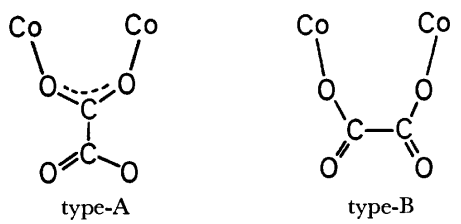

Fig. 3. Types of the bridging oxalate.

Hence these complexes should be doubly bridged.

The oxalate can bridge cobalt(III) in two ways as shown in Fig. 3; *i.e.* by coordinating to two cobalt(III) through two oxygen atoms on one carbon atom (Type-A), or through two oxygens on different carbon atoms (Type-B). IR Spectroscopy was useful for distinguishing these bridges. Scott *et al.* found the $\bar{\nu}(CO)$ of oxalate in the Type-A bridging binuclear complex $[(NH_3)_4Co(NH_2,ox)Co(NH_3)_4]^{3+}$ at 1640 and 1616 cm^{-1} and in $[(NH_3)_3Co(OH,OH,ox)Co(NH_3)_3]^{2+}$ at 1634 and 1600 cm^{-1}.[10] The complex IIb gave $\bar{\nu}(CO)$'s 1620 and 1570 cm^{-1} (Fig. 2). These are slightly lower in wave number than those of Scott *et al*'s complexes. However, such a shift can be caused by the difference in other bridging ligands between ours and theirs. So we conclude that IIb has two bridging oxalates of Type-A.

The complex IIa gave $\bar{\nu}(CO)$ 1700 and 1675 cm^{-1} (Fig. 2). These wave numbers are similar to those of the five-membered oxalate chelate. However, we tend to consider that the oxalates in this complex bridge two cobalt(III) through Type-B by the following reasons. First, the Type-B bridge will have a similar electronic state to chelating oxalate, so that the $\bar{\nu}(CO)$ can be similar to that of chelating oxalate. Scott *et al.* observed four $\bar{\nu}(CO)$'s, 1721, 1701, 1629, and 1670 cm^{-1} for the Type-B binuclear complex $[(NH_3)_5Co(ox)Co(H_2O)(NH_3)_4]^{4+}$.[10] They considered these bands to be the split peaks of the two bands of chelated oxalate at 1696 and 1667 cm^{-1} in $[Co(ox)(NH_3)_4]^+$. IR peaks of our complex fail to show such a splitting, presumably because of the increase in symmetry around the bridging moiety. Second, an alcohol is a weaker ligand than amines and carboxylates toward cobalt(III). If amino alcohols doubly bridged two cobalt(III), the Co–O bonds would be compared to those between Co(III) and (*O*-coordinated) unidentate amino alcohol. Further, each cobalt(III) in such a complex is considered to be chelated by a large chelate ring consisting of two amino alcohols and one cobalt(III). Such a ring may not be stable enough to give a crystalline product. Thus we conclude the structure of IIa and IIb as shown before.

Uninuclear Complexes Containing Oxalates: The complexes IIIa, IIIb, and IIIc gave $\bar{\nu}(CO)$ values of oxalate ligands *ca.* 1700 and 1667 cm^{-1} (Fig. 3). Absence of UV peaks in the 30000 cm^{-1} region, as well as their chromatographic behavior, indicates that these complexes are uninuclear.

Synthetic Method. The tricarbonato method has been recognized as a very useful tool for preparing a variety of uninuclear cobalt(III) complexes containing bidentate carbonate. These products are also useful intermediates for synthesizing further varieties of uninuclear complexes containing other ligands.[4] However, no binuclear complexes have ever been known among the products. We have succeeded in preparing a few binuclear species with carbonate bridges and thus extended the usefulness of this method to the preparation of binuclear complexes.

Reactions of oxalic acid with such binuclear complexes under a mild condition gave binuclear species bridged by oxalate. These reactions appear to involve local substitution of the bridging part.

TABLE. NUMERICAL DATA OF ABSORPTION (AB) AND CD SPECTRA UNINUCLEAR OXALATO COMPLEXES

	Geometrical isomerism		I band		II band	
			AB $\bar{\nu}/10^3$ cm^{-1} (log ε)	CD $\bar{\nu}/10^3$ cm^{-1} ($\Delta\varepsilon$)	AB $\bar{\nu}/10^3$ cm^{-1} (log ε)	CD $\bar{\nu}/10^3$ cm^{-1} ($\Delta\varepsilon$)
IIIa	*trans*(*N*) *cis*(*O*)	a	17.61 (1.81)	16.05 (+1.12)	25.13 (2.12)	27.47 (+0.4)

a: Protonated form $[Co(ox)(S\text{-praH})_2]^+$. b: Deprotonated form $[Co(ox)(S\text{-pra})_2]^-$.

Acid-base Equilibria. The uninuclear complexes IIIb and IIIc were titrated with sodium hydroxide, and their pK_1 and pK_2 values were determined to be *ca.* 3.2 and *ca.* 6, respectively, at 25 °C and ionic strength 0.1. The pK_1 values are similar to the pK_a values of uninuclear complexes containing one amino alcohol.[1,2] The pK_2 values are similar to the pK_a values of aqua ligands in various cobalt(III) complexes. The pK_a values of other complexes were not determined by technical reasons. These data, as well as the pH dependence of the absorption and CD spectra, and the chromatographic behavior, indicate that all the complexes containing oxalate have *S*-praH ligands in protonated form in an aqueous solution of pH≤1, and in completely deprotonated form at pH≥9. μ-Carbonato complexes are only stable in aqueous solutions of pH≥7, so that the amino alcohol logands are in deprotonated forms.

Geometrical Isomerism and Absorption Spectra of the Uninuclear Complexes. Octahedral cobalt(III) complexes containing two *S*-praH and one oxalate exist in three geometrical isomers, *trans*(*N*)*cis*(*O*), *cis*(*N*)*trans*(*O*), and *cis*(*N*)*cis*(*O*), which have C_2, C_2, and C_1 symmetry, respectively. The absorption spectra of protonated and deprotonated forms of IIIa, IIIb, and IIIc are shown in Fig. 4. Change in pH always brings about reversible change of the absorption spectra between the protonated and the deprotonated form. IIIa in the protonated form gives split bands in the first band region and is assigned to *trans*(*N*)*cis*(*O*) isomer. IIIb and IIIc give similar absorption patterns to each other. The IIIc isomer gives more complicated methyl signals in the pmr spectra than the IIIb isomer does, so that they are assinged to *cis*(*N*)*cis*(*O*) and *cis*(*N*)*trans*(*O*) isomer, respectively.

Data of the absorption and CD spectra in the d-d transition region are shown in the Table for both the protonated and the deprotonated form of the complexes. The locations of absorption peaks of the protonated forms are almost equal to those of the corresponding isomers of $[Co(ox)(gly)_2]^-$ (gly=glycinate ion).[11] Hence the alcoholic hydroxyl group has the same position in the spectrochemical series with carboxylates.

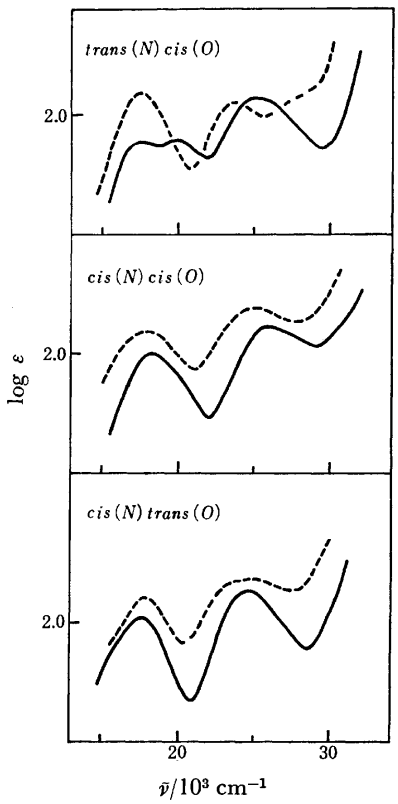

Fig. 4. Absorption spectra of geometrical isomers of $[Co(ox)(S\text{-praH})_2]^+$ (protonated form) (——) and $[Co(ox)(S\text{-pra})_2]^-$ (deprotonated form) (----).

On deprotonation of the hydroxyl groups, peaks in the first band region change in quite characteristic ways depending on the geometrical isomerism. Split peaks of the *trans*(*N*)*cis*(*O*) isomer unite apparently into one peak. The *cis*(*N*)*trans*(*O*) isomer gives blue shift, whereas the *cis*(*N*)*cis*(*O*) isomer red shift. (In the $[CoN_5O]$ type complex containing one (*S*)-2-amino-1-propanol, the peak in the first band region gives blue shift in a basic solution[2]). In the second band region, the peaks of *trans*(*N*)*cis*(*O*) and *cis*(*N*)*trans*(*O*) isomers split on deprotonation. The *cis*(*N*)*cis*(*O*) isomer gives apparently only a broad band. Since all these absorption

bands consist of more than one component, the deprotonation brings about not only splitting but also shift and intensity change of the component peaks. It also causes increase in number of lone pair electrons on coordinating oxygen atoms. These factors give influence in a complicated manner, to result in very diverse change in the absorption pattern.

CD Spectra of the Uninuclear Complexes. Attempts to resolve the isomers were unsuccessful. Intensity of the PMR methyl signals of IIIb and IIIc suggests that these complexes consist of almost equal amounts of *Λ*- and *Δ*-isomers. Hence their CD patterns should reflect the vicinal contribution of *S*-praH and *S*-pra$^-$.

In the first band region, large minus components are commonly seen for both protonated and deprotonated forms of all the geometrical isomers. Such minus components reflect *δ*-conformation of the *S*-praH or *S*-pra$^-$ chelate.[1,2] The $\Delta\varepsilon$ values are large for the deprotonated than for protonated forms. These facts were also seen in $[CoN_5O]$ type complexes with one optically active amino alcohol.[2] The spectral patterns are, however, different among the geometrical isomers. They should be dependent on the symmetry, and related to the change in absorption patterns.

In the second band region, the change of CD pattern with pH is more marked than in the first band region. All the three isomers in the deprotonated form give characteristic large plus components at 23000 to 24000 cm^{-1}. Such a marked plus CD was also observed in the deptonated forms of $[CoN_5O]$ type complexes. We considered that it reflected *δ*-conformation of *S*-pra$^-$ and the unusually large $\Delta\varepsilon$ values in this region were related to the presence of three lone pairs in alcoholate $-O^-$ moiety.[2] The same consideration is

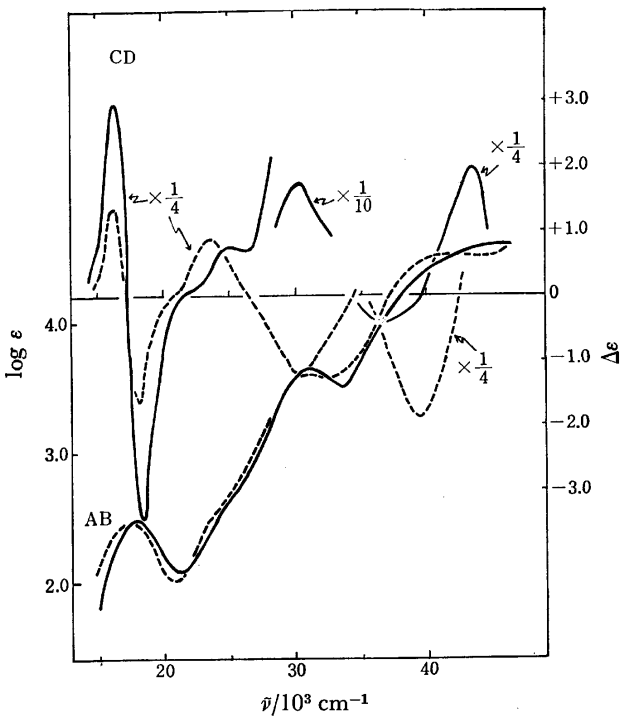

Fig. 5. Absorption and CD spectra of $[(S\text{-praH})_2Co(ox)_2Co(S\text{-praH})_2]^{2+}$ (——) and $[(S\text{-pra})_2Co(ox)_2Co(S\text{-pra})_2]^{2-}$ (------) (IIb).

$[(S\text{-pra})_2Co(CO_3,OH)Co(S\text{-pra})_2]^{-}$ (—·—) (Ib), and
$[(S\text{-pra})_2Co(CO_3,OH)Co(S\text{-pra})_2]^{-}$ (------) (Ic).

applicable to the present complexes containing two *S*-pra$^-$ ligands.

Geometrical Isomerism and CD Spectra of the Binuclear Complexes. A large number of geometrical isomers can exist for such types of binuclear complexes. Only two μ-oxalato complexes and three μ-carbonato complexes have been obtained. Attempts to assign the crystalline products to individual isomers have turned out unsuccessful, because of too complicated absorption and CD patterns.

The CD spectra of μ-oxalato complexes are shown in Figs. 5 and 6, and those of μ-carbonato complexes in Fig. 7. Each of these complexes gives a large plus component in the first band region. It must be due to the $\Lambda\Lambda$-configurational effect around cobalt(III). It appears as if the $\Lambda\Lambda$-isomers were preferentially formed. The reason may be related to the larger stability of lel- than ob-structure, because the chelated *S*-praH ligands give δ-conformation exclusively.

There is one common characteristic pattern in the second band region; *i.e.* the deprotonated forms give remarkable plus CD components. The $\Delta\varepsilon$ values are nearly equal to four times of that of $[Co(S\text{-pra})(NH_3)_4]^{2+}$ ($\Delta\varepsilon=0.85$). The vicinal effect of *S*-pra$^-$ ligand in the second band region does not appear to be much affected by the skeletal structure throughout all the cobalt(III) complexes.

The authors thank the Ministry of Education for financial support.

(Received February 7, 1977)

The *trans* dianiono type complexes of cobalt(III) containing (1*R*,2*R*)-1,2-cyclohexanediamine, *trans*-$[Co(X)_2(R,R\text{-chxn})_2]^+$, and -$[Co(X)(X')(R,R\text{-chxn})_2]^+$ (X and X′=N_3^-, NCS^-, or NO_2^-) were prepared and their circular dichroism (CD) spectra measured in the visible and ultraviolet regions. The CD and absorption behaviors in the so-called specific absorption band region are compared with those of *cis*-type bis(ethylenediamine) complexes and discussed in relation to the origin of the specific band. In addition, three isomers of the $[Co(NCS)(NH_3)(R,R\text{-chxn})_2]^{2+}$ complex are assigned on the basis of their CD spectra.

In a previous paper,[1] circular dichroism (CD) spectra of bis(ethylenediamine) complexes of cobalt(III) with a *cis* configuration were discussed, especially with emphasis on the so-called specific absorption band in the near ultraviolet region. The specific absorption band is moderately intense, and specific for certain aniono ligands, such as azido, isothiocyanato, nitro, and sulfito ligands. The origin of these bands has been attributed to charge-transfer transitions between the aniono ligand and the central metal, or to intraligand transitions. A previous study[1] suggests an interaction between two aniono ligands in the *cis* positions through the central cobalt(III) ion. This kind of electronic interaction between two NCS^-, NO_2^-, or Cl^- ligands have frequently been proposed for complexes which have two aniono ligands in the *trans* positions.[2-6] Thus, the specific band of a *trans* dianiono complex is more bathochromic than that of the corresponding *cis* isomer,[4,5] with some exceptions.[6]

The present paper deals with *trans* dianiono type complexes, including mixed complexes, of cobalt(III) containing (1*R*,2*R*)-1,2-cyclohexanediamine (abbreviated as *R,R*-chxn) for the purpose of studying their CD spectra in the region of the specific absorption bands of azido, isothiocyanato, and nitro ligands.

Experimental

Preparation and Optical Resolution. (1) (1R,2R)-1,2-Cyclohexanediamine: The ligand was optically resolved by the method of Asperger and Liu.[7] The less soluble diastereomer, (*R,R*-chxnH_2) (*d*-tart), showed a constant optical rotation $[\alpha]_{589}=+12.1°$ (*d*-tart denotes the $(+)_{589}$-tartrate(2−) ion). Found: C, 45.18; H, 7.60; N, 10.55%. Calcd for $C_{10}H_{20}N_2O_6$: C, 45.45; H, 7.63; N, 10.60%. For preparative purposes, a stock solution of *R,R*-chxn was conveniently prepared by the addition of a calculated amount of $Ba(OH)_2\cdot 8H_2O$ to a hot suspension of the less soluble diatereomer. After cooling overnight in a refrigerator, the precipitated $BaSO_4$ was removed.

(2) trans-$[CoCl_2(R,R\text{-chxn})_2]Cl\cdot H_2O$: This complex was prepared following exactly the method of Treptow.[8] Found: C, 35.79; H, 7.41; N, 13.60%. Calcd for $[CoCl_2(C_6H_{11}N_2)_2]Cl\cdot H_2O$: C, 35.01; H, 7.35; N, 13.61%.

(3) trans-$[Co(N_3)_2(R,R\text{-chxn})_2]Cl\cdot 0.5H_2O$: The dichloro complex, *trans*-$[CoCl_2(R,R\text{-chxn})_2]Cl\cdot H_2O$ (0.4 g), was dissolved in 20 cm^3 of methanol at 30 °C, and 25 mg of LiN_3 was added with stirring. The azide of the dichloro complex, *trans*-$[CoCl_2(R,R\text{-chxn})_2]N_3\cdot nH_2O$, quickly separated out. The suspension in methanol was vigorously stirred at 30 °C until the azide salt dissolved (about 5 min). Then another 25 mg of LiN_3 was added to the solution and the resulting suspension was further stirred for 15 min. To the resulting blue-violet solution of the azidochloro complex was added 50 mg of LiN_3, and the mixture was heated to 50 °C and stirred for 40 min. This was then cooled in ice to stop the reaction, and concentrated to about 10 cm^3 with a vacuum evaporator. After cooling in a refrigerator overnight, the dark blue-violet crystals that separated out were filtered, washed with ether and air-dried. 110 mg. Recrystallization was performed from methanol by the addition of ether. Found: C, 34.86; H, 6.93; N, 32.78%. Calcd for $[Co(N_3)_2(C_6H_{14}N_2)_2]Cl\cdot 0.5H_2O$: C, 34.66; H, 7.03; N, 33.33%.

(4) trans-$[Co(NCS)_2(R,R\text{-chxn})_2]Cl\cdot H_2O$: To a solution of 0.4 g of the dichloro complex in 20 cm^3 of methanol was added 340 mg of $LiSCN\cdot H_2O$, and the mixture was stirred for 30 min at 65 °C. Then, crystals began to separate out. After further stirring for 15 min, the mixture was ice-cooled for half an hour. The resulting reddish-orange crystals were filtered, washed with ice-cold methanol and ether, and air-dried. 180 mg. Recrystallization was carried out from hot methanol (60 °C, 8 cm^3). Found: C, 36.64; H, 6.66; N, 18.72%. Calcd for $[Co(NCS)_2(C_6H_{14}N_2)_2]Cl\cdot H_2O$: C, 36.80; H, 6.62; N, 18.39%.

(5) trans-$[Co(NO_2)_2(R,R\text{-chxn})_2]Cl\cdot 2.5H_2O$: To a solution of the dichloro complex (0.4 g) in 20 cm^3 of methanol was added 140 mg of $LiNO_2\cdot H_2O$. The mixed solution was stirred at 60 °C for 2 h, and the separated crystals were filtered off. The filtrate was evaporated to 7 cm^3 and stored in a refrigerator overnight. The resulting crystals were filtered off. The yellow-orange lustrous crystals obtained (both the first and second crops) were the *cis*-isomer. The filtrate was evaporated to dryness. The residual solid was suspended in 4 cm^3 of ethanol and filtered. 99 mg. The product was recrystallized from ethanol by the addition of ether, and the resulting fine yellow-orange crystals were filtered, washed with ether, and air-dried. Found: C, 31.75; H, 7.32; N, 18.35%. Calcd for $[Co(NO_2)_2(C_6H_{14}N_2)_2]Cl\cdot 2.5H_2O$: C, 31.35; H, 7.23; N, 18.28%.

(6) trans-$[CoCl(NCS)(R,R\text{-chxn})_2]Cl\cdot 3H_2O$: To a solution of the dichloro complex (0.4 g) in 20 cm^3 of methanol at 30 °C was added 85 mg of $LiSCN\cdot H_2O$. When the mixed solution was stirred for 10 min, the color of the solution changed from green to dark violet. The solution was evaporated to 5 cm^3

* Present address: Osaka Prefectural Industrial Research Institute, Enokojima, Nishi-ku, Osaka 550.

** Present address: Institute of Chemistry, The University of Tsukuba, Ibaraki 300-31.

and stored in a refrigerator overnight. After the removal of the reddish-violet precipitate of the *cis*-chloroisothiocyanato complex, the filtrate was again stored overnight in a refrigerator. The resulting blue-violet precipitate of the desired complex was filtered with suction and washed with ether. 35 mg. The second crop of the blue-violet precipitate was obtained when the filtrate was stored in a refrigerator for further 3 days. 32 mg. The two crops of the crude *trans* complex were combined and reprecipitated from methanol (2 cm^3) by adding ether (8 cm^3). The reprecipitated product was filtered and washed with ether and air-dried. Found: C, 34.51; H, 7.29; N, 14.87%. Calcd for $[CoCl(NCS)(C_6H_{14}N_2)_2]Cl\cdot 3H_2O$: C, 33.19; H, 7.29; N, 14.89%.

(7) trans-$[CoCl(NO_2)(R,R\text{-}chxn)_2]Cl\cdot 1.5H_2O$: The reaction was carried out at 30 °C by adding 70 mg of $LiNO_2\cdot H_2O$ to a solution containing 0.4 g of the dichloro complex in 20 cm^3 of methanol. After stirring for 10 min, the reacted solution of dark orange color was cooled in ice for 2 h. The resulting crystals (the *cis*-chloronitro complex) were removed by filtration, 10 cm^3 of ether was added to the filtrate, and then the mixture was stored in a refrigerator overnight. The second crop of *cis* complex crystals separated out was filtered off, and the filtrate was further cooled for 3 days in a refrigerator. The third crop of crystals yielded in a small quantity, and this was filtered off. The fourth crop, which was obtained upon evaporating the filtrate to about 4 cm^3, was a mixture of *cis* and *trans* complexes. To the filtrate from the fourth crop was added 2 cm^3 of ether, and after a period the *trans* complex separated out. After storage in a refrigerator for 2 h, the crystals were filtered, washed with a little cold methanol and ether, and air-dried. 75 mg. Reddish-orange fine crystals were obtained by recrystallization from methanol (3 cm^3) upon the addition of ether (4 cm^3). Found: C, 33.87; H, 7.31; N, 15.97%. Calcd for $[CoCl(NO_2)(C_6H_{14}N_2)_2]Cl\cdot 1.5H_2O$: C, 33.42; H, 7.25; N, 16.24%.

(8) trans-$[Co(NCS)(NO_2)(R,R\text{-}chxn)_2]Cl\cdot 1.5H_2O$: To a solution of 0.4 g of the dichloro complex in 20 cm^3 of methanol was added 70 mg of $LiNO_2\cdot H_2O$. After the mixture had been stirred for 10 min at 30 °C, 80 mg of $LiSCN\cdot H_2O$ was added to it and the reaction temperature was raised to 60 °C. After stirring for 70 min, the reacted solution was evaporated to dryness. The resulting solid was dissolved in water and the solution was adsorbed on a column (20×220 mm) containing a cation-exchange resin (Dowex 50W×8, K^+ form). The eluting agent, a 0.1 M KCl solution, was made to flow at a rate of 2 cm^3/min. While 6.8—11.5 dm^3 of the eluting agent flowing, the yellow-to-orange colored eluate (4.7 dm^3) was collected in 20-cm^3 portions in a fraction collector. The middle (56—180 th) fractions were confirmed to contain the desired *trans*-isothiocyanatonitro complex by checking the absorption spectra. These were combined and evaporated at 30 °C. After the separated KCl crystals had been removed by filtration several times, the eluate was evaporated to dryness. The complex was extracted from the residual solid using 20 cm^3 of methanol, and the undissolved KCl crystals were filtered off. In order to remove the remaining KCl, careful fractional precipitation was carried out by the addition of ether to the methanol extract. The desired complex obtained as a later fraction was filtered, washed with ether, and air-dried. Found: C, 34.45; H, 6.84; N, 18.66%. Calcd for $[Co(NCS)(NO_2)(C_6H_{14}N_2)_2]Cl\cdot 1.5H_2O$: C, 34.40; H, 6.88; N, 18.52%.

(9) trans-$[Co(N_3)(NCS)(R,R\text{-}chxn)_2]^+$: As in the course of preparing the diazido complex (3), four 25-mg portions of LiN_3 were added over a 30-min period to a stirred solution containing 0.8 g of the dichloro complex in 40 cm^3 of methanol at 30 °C. To the blue-violet reaction mixture (the *cis*- and *trans*-azidochloro complexes) was added 165 mg of $LiSCN\cdot H_2O$, and the solution was heated to 60 °C and stirred for 15 min. The color of the solution turned to red-violet. After the reaction had been stopped by ice-cooling, an equal volume of ether was added to the solution and the resulting mixture was evaporated to dryness with a vacuum evaporator. The solid was dissolved in water and subjected to chromatography on a column containing a cation-exchanger CM-Sephadex C-25 using a 0.1 M NaCl solution as the eluting agent. The earlier eluate contained the desired *trans*-azidoisothiocyanato complex. The isomerization to *cis* occurred even at 25 °C and the *trans* complex could not be isolated in crystal.

(10) trans-$[Co(N_3)(NO_2)(R,R\text{-}chxn)_2]^+$: To a solution of 0.8 g of the dichloro complex in 40 cm^3 of methanol at 30°C was added 140 mg of $LiNO_2\cdot H_2O$ with stirring. This stirring was continued for 10 min. Upon the addition of 100 mg of LiN_3, the azide salt of the dichloro complex separated out. The suspension was heated to 60 °C and stirred for 20 min. The resulting solution was evaporated to dryness, and the solid obtained was dissolved in water and subjected to chromatography on a column (27×980 mm) containing CM-Sephadex C-25 with a 0.1 M NaCl solution at a rate of 0.23 cm^3/min. When 1.5 dm^3 of the eluting agent was passed over the column, the *trans* species reached the bottom of the column. At this time, the eluate began to be collected in 10-cm^3 portions and the 28—38 th fractions were confirmed to contain the desired *trans*-azidonitro complex (the *trans*-dinitro and -diazido complexes were contained in the 1—15 th and 44—50 th fractions, respectively). The isomerization to *cis* occurred rapidly, and isolation of the complex was unsuccessful.

(11) Three Isomers of the $[Co(NCS)(NH_3)(R,R\text{-}chxn)_2]^{2+}$ *Complex*: To a solution containing 0.8 g of the dichloro complex in 40 cm^3 of methanol at 30 °C was added 170 mg of $LiSCN\cdot H_2O$, and the mixed solution was stirred for 10 min. After adding an equal volume of ether, the reaction mixture was evaporated to dryness with a vacuum evaporator. The resulting violet solid was placed in a 250-cm^3 pressure cylinder, which was placed in a dry ice-methanol bath, and ammonia was condensed over the solid. After about 15 cm^3 of ammonia had been condensed, the container was tightly capped and allowed to stand at room temperature (21°C) for about 15 min. The color of the ammonia solution changed to reddish-orange. Then, the cap was removed and the ammonia was evaporated. After the resulting orange product had been dried over P_2O_5 *in vacuo*, it was dissolved in an appropriate amount of water and subjected to chromatography on a cation-exchanger column (CM-Sephadex C-25, 25×850 mm) with a 0.15 M NaCl solution. While 12.4—19.6 dm^3 of the eluting agent was made to flow through the column in one month, the three desired isomers were eluted out in well separated bands. Each of the three eluates was evaporated to dryness on a vacuum evaporator at 30 °C, and the resulting solid was extracted with a minimum amount of methanol and undissolved NaCl was removed by filtration. After evaporating each of the methanol solutions to dryness at 10 °C, the resulting solid (contaminated with a small amount of NaCl) was dissolved in 3 to 4 cm^3 of water.

1) To the aqueous solution obtained from the first eluted band (Fl) was added 0.3 g of NaI with stirring The iodide salt precipitated was filtered, washed with a small amount of ethanol and ether, and air-dried. 100 mg. The iodide dissolved in 15 cm^3 of water, and changed to a chloride solution by employing a cation-exchange resin (Cl^- form). The chloride solution was evaporated to dryness by the freeze-drying method, and the resulting chloride salt was dissolved in 2 cm^3 of water and the solution was evaporated gently to dryness in a vacuum desiccator over P_2O_5. Reddish-orange crystals. 55

mg (Fl). Found: C, 32.39; H, 7.62; N, 17.36%. Calcd for $[Co(NCS)(NH_3)(C_6H_{14}N_2)_2]Cl\cdot 2.5H_2O$: C, 32.34; H, 7.52; N, 17.40%.

2) To the aqueous solutions obtained from the second and third eluted bands (F2 and F3) were added 0.5 and 1.5 g of $LiClO_4\cdot 3H_2O$ with stirring, respectively. The perchlorate salts precipitated were filtered, washed with an ethanol–ether mixture and then ether, and air-dried. 144 mg (F2) and 200 mg (F3). The perchlorate salts were dissolved in an appropriate amount of water, and the solutions were changed to chloride solutions using an ion-exchange method. The chloride solutions were evaporated to dryness by freeze-drying, the resulting powders were dissolved in 3 and 4 cm^3 of water, respectively, and then to the solutions were added 1.0 and 0.75 g of $LiClO_4\cdot 3H_2O$ with stirring. After storage in a refrigerator for 2 days, the perchlorate salts were filtered, washed sufficiently with an ethanol–ether mixture to eliminate the contaminant $LiClO_4\cdot 3H_2O$, then with ether, and air-dried. Reddish-orange crystals. 50 mg (F2) and 73 mg (F3). Found for F2: C, 29.51; H, 5.70; N, 15.70%. Found for F3: C, 29.62; H, 5.89; N, 15.74%. Calcd for $[Co(NCS)(NH_3)(C_6H_{14}N_2)_2](ClO_4)_2$: C, 29.46; H, 5.89; N, 15.85%.

(12) Bis(ethylenediamine) Complexes: The *trans* complexes were prepared according to methods described in the literature, except for the two new complexes, for which the methods will be described below. *Cis* and *trans* isomers of chloronitrobis(ethylenediamine)cobalt(III) chloride were prepared by the method of Werner.[9,10]

trans-$[Co(N_3)(NCS)(en)_2]ClO_4$: To a solution of 12.0 g of *cis*-$[CoCl(NCS)(en)_2]ClO_4$[10] in 75 cm^3 of water (60 °C) was added 2.5 g of NaN_3. The resulting solution was stirred at 60 °C for about 2 h. After diluting with an appropriate amount of water, the solution was subjected to chromatography on a column (26×800 mm, Dowex 50W×8, H^+ form) using a 0.2 M $LiClO_4$ solution as the eluting agent. The elution was continued at a rate of 1.5—2.0 cm^3/min until the first series of bands (containing *trans* complexes) were eluted out. The eluates were fractionated and the intermediate fractions, with the first d-d absorption band at about 528 nm, were combined and evaporated to dryness on a vacuum evaporator below 35 °C. In order to remove the eluting agent, $LiClO_4\cdot 3H_2O$, the solid obtained was suspended in ethanol, filtered, washed sufficiently with ethanol. This was recrystallized from water (55 °C), filtered, washed with water, ethanol, and then ether, and air-dried. Found: C, 15.46; H, 4.21; N, 29.63%. Calcd for $[Co(N_3)(NCS)(C_2H_8N_2)_2]ClO_4$: C, 15.86; H, 4.26; N, 29.59%.

trans-$[Co(N_3)(NO_2)(en)_2]ClO_4$: To a solution containing 4.0 g of *trans*-$[CoCl(NO_2)(en)_2]Cl\cdot H_2O$[9] in 40 cm^3 of water (60 °C) was added 1.0 g of NaN_3. Then the azide salt of chloronitro complex precipitated out. The resulting suspension was stirred at 60 °C for 90 min. After diluting with water, the solution was subjected to chromatography on a column (Dowex 50 W×8, H^+ form) with a 0.1 M LiCl solution. When the elution was continued for 8 days using a 0.1 M LiCl solution of about 25 dm^3, the first series of bands containing *trans* complexes were eluted out. The earlier fractions, which showed the first d-d absorption band at about 481 nm, were combined and evaporated to 20 cm^3 below 35 °C. To the concentrated eluate was added a solution of 2.0 g of $LiClO_4\cdot 3H_2O$ in 4 cm^3 of water. After a period, the perchlorate salt of the desired complex crystallized out. After standing for 1 h, the crystals were filtered (0.8 g), recrystallized from warm water (55 °C), filtered, washed with water, ethanol, and then ether, and air-dried. Lustrous red-orange flakes. 0.5 g. Found: C, 12.92; H, 4.42; N, 30.27%. Calcd for $[Co(N_3)(NO_2)(C_2H_8N_2)_2]ClO_4$: C, 13.11; H, 4.40; N, 30.57%.

Measurements. The absorption spectra were measured using Shimadzu UV-200 and Beckman DU spectrophotometers. The CD spectra were recorded with Jasco ORD/UV-5, J-10, and J-20 spectropolarimeters. The optical rotation was checked using Yanagimoto Model 185 and Jasco ORD/UV-5 spectropolarimeters. The measurements were made at room temperature in aqueous or methanol solutions ranging in concentration from 0.005 to 0.0001 M. The cell lengths were 1, 0.2, and 0.1 cm.

Results and Discussion

Characterization of trans *Dianiono Complexes.* Eight cobalt(III) complexes of *trans*-dianionobis[(1*R*,2*R*)-1,2-cyclohexanediamine] type were derived from *trans*-$[CoCl_2(R,R\text{-chxn})_2]Cl\cdot H_2O$ upon treatment with LiN_3, LiSCN, or $LiNO_2$ in methanol. Only one of these, the *trans*-dinitro complex, is a known complex, which was recently prepared by Brennan and Douglas for the first time.[11] *trans*-to-*cis* isomerization was observed in the isolation procedure of some *trans* complexes containing azido ligand from the eluates, and the azidoisothiocyanato and azidonitro complexes could not be isolated as crystals. The *trans* structures of all the complexes were determined by comparing the visible and ultraviolet absorption bands with those of *cis* and *trans* isomers of the corresponding ethylenediamine complex (Table 1).

Configuration of Three Isomers of the Ammineisothiocyanato Complex. Three isomers are possible for the $[Co(NCS)(NH_3)(R,R\text{-chxn})_2]^{2+}$ ion: one is the *trans* isomer and the other two are the diastereomeric *cis* isomers. All the isomers of the $[Co(NCS)(N)_5]$ type show very similar absorption spectra, and they are indistinguishable on the basis of their absorption spectra. The configurations of the three isomers are assigned, therefore, on the basis of their CD spectra. The *cis* isomers have two kinds of chiralities: one is the "configurational" chirality (Δ or Λ) due to the two chxn chelate rings and the other the "vicinal" chirality due to the asymmetric carbon atom of the *R,R*-diamine (including "conformational" chirality). It has been established that the CD contributions of the two kinds of chiralities are separable and additive in several cobalt(III) complexes containing five-membered chelate rings.[12–15] Thus, for the CD of the diastereomeric *cis* ammineisothiocyanato isomers, ΔRR and ΛRR, the following equations can be written, where *R* represents the *R,R*-chxn ligand,

$$\Delta\varepsilon(\Lambda RR) = \Delta\varepsilon(\Lambda) + 2\Delta\varepsilon(R) \quad (1)$$

and

$$\Delta\varepsilon(\Delta RR) = \Delta\varepsilon(\Delta) + 2\Delta\varepsilon(R). \quad (2)$$

Because $\Delta\varepsilon(\Lambda)$ should be equal to $-\Delta\varepsilon(\Delta)$, one obtains

$$\Delta\varepsilon(\Lambda) = \frac{1}{2}[\Delta\varepsilon(\Lambda RR) - \Delta\varepsilon(\Delta RR)] \quad (3)$$

and

$$\Delta\varepsilon(R) = \frac{1}{4}[\Delta\varepsilon(\Lambda RR) + \Delta\varepsilon(\Delta RR)]. \quad (4)$$

Therefore, if a pair of *cis* isomers can be selected from the three isomers, the configurational CD contribu-

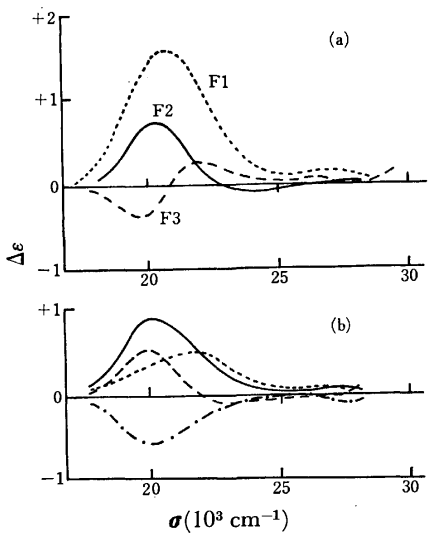

Fig. 1. CD spectra of three isomers of $[Co(NCS)(NH_3)(R,R\text{-chxn})_2]^{2+}$ (a), and calculated curves of (1/2)[Δε(F1) − Δε(F3)] (——), (1/2)[Δε(F2) − Δε(F3)] (------), and (1/2)[Δε(F1) − Δε(F2)] (·····) (b). The CD curve (Δε×2) of $\Delta(-)_{589}$-$[Co(NCS)(NH_3)(en)_2]^{2+}$ is also shown in (b) (-·-·-).

tion can be calculated from their observed CD spectra. The configurational CD curve thus calculated is considered to be similar in shape to the observed CD curve of the corresponding en complex. Fig. 1(a) shows the CD curves in the d-d absorption band region for the three isomers which are designated as F1, F2, and F3 in the order of elution, and Fig. 1(b) shows the calculated curves for (1/2)[Δε(F1) − Δε(F3)], (1/2)[Δε(F2) − Δε(F3)], and (1/2)[Δε(F1) − Δε(F2)] together with the observed CD curve of $\Delta(-)_{589}$-$[Co(NCS)(NH_3)(en)_2]^{2+}$. The calculated (1/2)[Δε(F1) − Δε(F3)] curve is similar in shape to (but reverse in sign to and about twice as intense as) the observed curve of Δ-$[Co(NCS)(NH_3)(en)_2]^{2+}$. It is therefore concluded that F1 and F3 form the *cis* pair and F2 is the *trans* isomer and that F1 is the $\Delta(ob)$ isomer and F3 the $\Delta(lel)$ isomer (this is consistent with the fact that the formation ratio of F1 to F3 is 1: 1.19). Furthermore, if the configurational contribution of the chxn complex is of the same magnitude as that of the en complex, it can be deduced that the optical purity of the $(-)_{589}$-$[Co(NCS)(NH_3)(en)_2]^{2+}$ complex derived from the resolved $[CoCl(NCS)(en)_2]^+$ complex was a little lower than 50% and that its true CD intensity may be about twice the reported value.[1]

CD and Absorption Spectra. It is acceptable, from the first d-d absorption band positions, that the ligand strength of chxn is almost the same as that of en. Two or three CD bands are observed in the first d-d absorption band region (Table 2). Although the *trans*-$[Co(X)_2(R,R\text{-chxn})_2]^+$ complexes are of D_2 symmetry, if they are considered to be of the *trans*-$[Co(X)_2(N)_4]^+$ type, they are approximately of D_{4h} symmetry. Accordingly, the first spin-allowed d-d transition, $^1A_{1g} \rightarrow {}^1T_{1g}$, in O_h is split into the $^1A_{1g} \rightarrow {}^1E_g$ and $^1A_{1g} \rightarrow {}^1A_{2g}$ transitions. Then, the CD bands observed at about 21000 cm^{-1} are considered to correspond to the nondegenerate com-

ponent, $^1A_{1g}\rightarrow{}^1A_{2g}$, and those observed at the lower (X=N_3^- and NCS^-) or higher (X=NO_2^-) energy positions to the degenerate component, $^1A_{1g}\rightarrow{}^1E_g$. In the diazido complex, however, two CD bands corresponding to the $^1A_{1g}\rightarrow{}^1E_g$ component are observed at about 16000 and 18000 cm^{-1} (Fig. 2). This band splitting can be reasonably interpreted by symmetry lowering to D_2. It is remarkable that the CD band assigned to the $^1A_{1g}\rightarrow{}^1A_{2g}$ transition in the diazido complex, which is observed at 21300 cm^{-1} in an aqueous solution, is located just in the trough of the absorption curve. This appears to suggest that, in this complex, the absorption band intensity of this nondegenerate component is very weak and the observed absorption peak corresponds to the degenerate component.

In the diazido complex, two strong CD bands of opposite signs are observed in the specific band region, exactly corresponding to the main absorption peak and the shoulder on its higher energy side (Fig. 2 and Table 3). The two positive CD bands at 24000—26000 cm^{-1} are then thought to belong to the second d-d band which is completely hidden. Also in the diisothiocyanato complex, two CD bands of opposite signs are observed in the specific band region (Fig. 3 and Table 3). In this case, the lower energy band of negative sign is much weaker than the higher energy one of positive sign. The negative band is considered to be partly

a) The $\Delta\varepsilon$ values are estimated by assuming that the molar extinction coefficients of the fisrt d-d absorption band are the same as those of the corresponding en complexes.

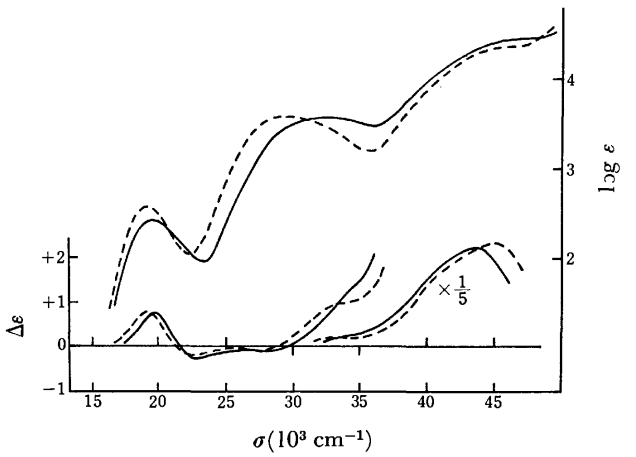

Fig. 3. Absorption and CD spectra of *trans*-$[Co(NCS)_2(R,R\text{-chxn})_2]Cl\cdot H_2O$ in water (——) and in methanol (------).

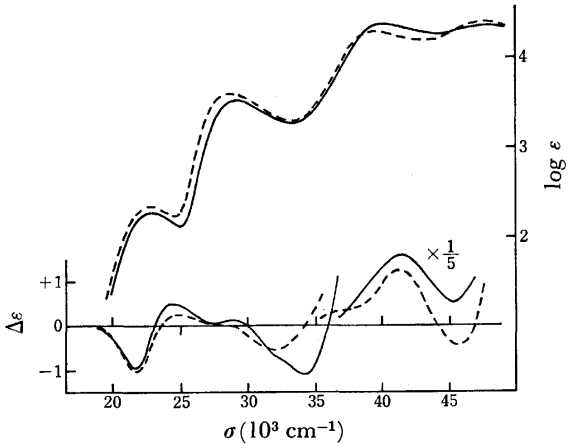

Fig. 4. Absorption and CD spectra of *trans*-$[Co(NO_2)_2(R,R\text{-chxn})_2]Cl\cdot 2.5H_2O$ in water (——) and in methanol (------).

cancelled by the CD bands for the second d-d transition, which probably have a positive net sign like the analogous *trans*-$[Co(X)_2(R,R\text{-chxn})_2]^+$ complexes ($X=F^-$, Cl^-, Br^-,[8] and N_3^-).

In the two pseudohalogeno complexes, a positive CD band is observed in an energy region higher than the specific absorption band.

If the specific absorption bands of the present pseudohalogeno complexes are assigned to the p_π(ligand)→d_{z^2} charge-transfer transitions, the relatively weaker absorption intensity of the higher energy component can be explained by the electric-dipole forbidden character of the p_{π_g}(ligand)→d_{z^2}(e_g→a_{1g} in D_{4h}) transition and the relatively stronger CD intensity of the component can be interpreted by its magnetic-dipole allowed character. Furthermore, the red shift of the specific absorption band of the *trans*-dianiono type complexes (in comparison with the *cis*-dianiono complexes) can be attributed to the relatively stronger absorption intensity of the lower energy electric-dipole allowed component, the p_{π_u}→d_{z^2}(e_u→a_{1g} in D_{4h}) transition. A similar interpretation has been made for the CD spectra of the charge-transfer band region of the halogeno complexes, *trans*-$[Co(X)_2(R,R\text{-chxn})_2]^+$ ($X=Cl^-$ and Br^-), although the signs of these two CD bands are the reverse of the present complexes.[8]

The assignment of the specific bands of the present pseudohalogeno complexes to the p_π→d_{z^2} charge-transfer transitions is consistent with the previous CD study of the *cis*-type bis(ethylenediamine) complexes. The same assignment has also been made in absorption spectral studies of $[Co(X)(NH_3)_5]$ and $[Co(X)(CN)_5]$ complexes[16,17] and a redox study of $[Co(NCS)(NH_3)_5]^{3+}$.[18]

For the corresponding nitro complex (Fig. 4 and Table 2) in aqueous solution, two CD bands of opposite signs are observed under the "nitro-specific band" and the lower energy positive band is weaker than the higher energy negative band. However, the signs of these are reverse to the pseudohalogeno complexes. On the other hand, it has been reported that the analogous $(-)_{589}$-*trans,trans*-$[Co(NO_2)_2(N\text{-Me-en})_2]^+$ complex shows the same CD pattern in this region as that of the present pseudohalogeno complexes.[19]

Concerning the solvent effect on the absorption and CD spectra of the three dianiono complexes, it was found that the specific absorption bands apper at higher energies in water than in methanol; the shift is very wide especially for the isothiocyanato complex (2600 cm^{-1} interval). The shift is in the same direction as that reported for the charge-transfer band in some halogeno complexes.[20]

In a previous paper[1] on the *cis*-type bis(ethylenediamine) complexes, it was found that the dipseudohalogeno complexes show two CD bands in the specific band region, while the amminepseudohalogeno complexes show a single CD band. In Fig. 5, the calculated CD curve of the configurational effect for the *cis*-$[Co(NCS)(NH_3)(R,R\text{-chxn})_2]^{2+}$ complexes and the observed CD curve for the *trans* complex are shown together with their absorption spectra. The configurational CD

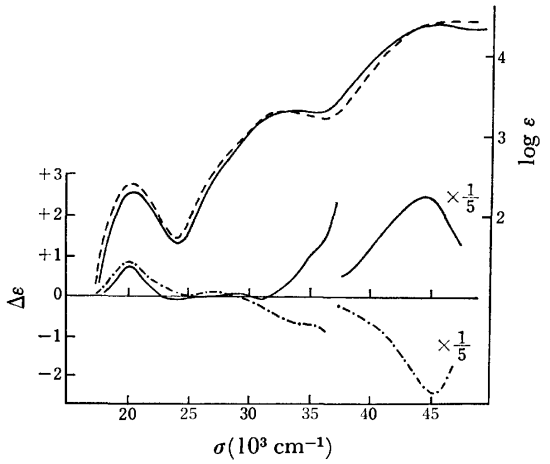

Fig. 5. Absorption and CD spectra of *trans*-$[Co(NCS)(NH_3)(R,R\text{-chxn})_2](ClO_4)_2$ (——) and calculated *Λ* configurational curve of *cis*-$[Co(NCS)(NH_3)(R,R\text{-chxn})_2]^{2+}$ (-·-·-). Absorption spectrum of *Λ*-$[Co(NCS)(NH_3)(R,R\text{-chxn})_2](ClO_4)_2$ is shown in broken line.

curve has the same pattern as the observed CD curve[1] of Δ-$[Co(NCS)(NH_3)(en)_2]^{2+}$ over all the regions, and has a single CD band corresponding to the absorption peak of the specific band. The CD band can be assigned to the degenerate charge-transfer transition, p_π(ligand) $\rightarrow d_{z^2}$($e \rightarrow a_1$ in C_{4v}). However, in the case of the *trans*-$[Co(NCS)(NH_3)(R,R\text{-chxn})_2]^{2+}$ complex which has the same approximate symmetry, C_{4v}, as the *cis* complex, the positive CD band in shoulder and another very weak negative CD band on the lower energy side appear to correspond to the specific absorption band, because the positive shoulder is located rather far from the absorption peak.

The absorption curves in the specific band region of the *trans* mixed complexes $[Co(X)(X')(diamine)_2]^+$ (X and X'=N_3^-, NCS^-, and NO_2^-) are very different

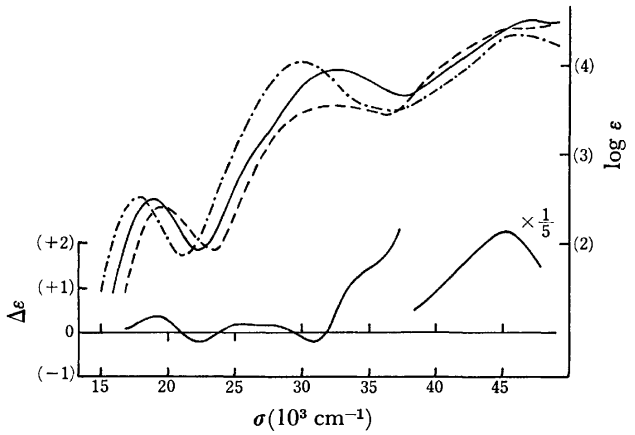

Fig. 6. Absorption and CD spectra of *trans*-$[Co(N_3)(NCS)(R,R\text{-chxn})_2]^+$ eluate (——). (The intensities are estimated by assuming that the molar extinction coefficient of the first d-d band is the same as the corresponding en complex.) Absorption spectra of *trans*-$[Co(N_3)_2(R,R\text{-chxn})_2]Cl \cdot 0.5H_2O$ (-·-·-) and -$[Co(NCS)_2(R,R\text{-chxn})_2]Cl \cdot H_2O$ (------) are shown for comparison.

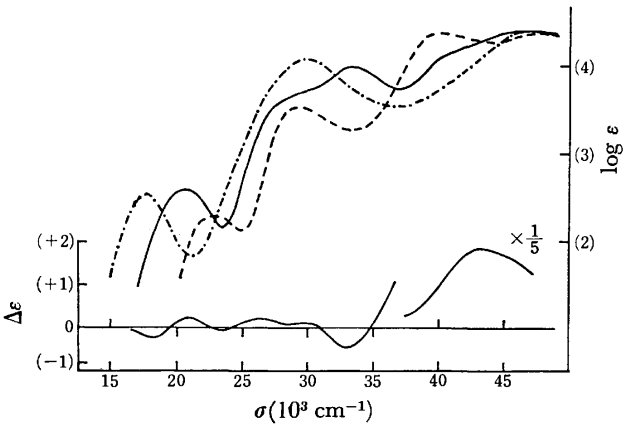

Fig. 7. Absorption and CD spectra of *trans*-$[Co(N_3)(NO_2)(R,R\text{-chxn})_2]^+$ eluate (——). (The intensities are estimated by assuming that the molar extinction coefficient of the first d-d band is the same as the corresponding en complex.) Absorption spectra of *trans*-$[Co(N_3)_2(R,R\text{-chxn})_2]Cl \cdot 0.5H_2O$ (-·-·-) and -$[Co(NO_2)_2(R,R\text{-chxn})_2]Cl \cdot 2.5H_2O$ (------) are shown for comparison.

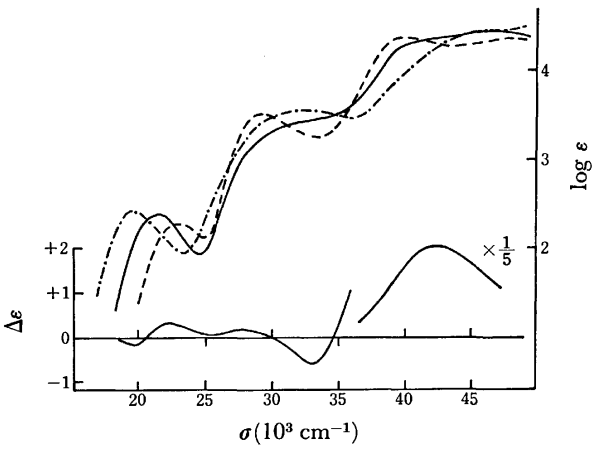

Fig. 8. Absorption and CD spectra of *trans*-$[Co(NCS)(NO_2)(R,R\text{-chxn})_2]Cl \cdot 1.5H_2O$ (——). Absorption spectra of *trans*-$[Co(NCS)_2(R,R\text{-chxn})_2]Cl \cdot H_2O$ (-·-·-) and -$[Co(NO_2)_2(R,R\text{-chxn})_2]Cl \cdot 2.5H_2O$ (------) are shown for comparison.

from the intermediate of the "parent" complexes $[Co(X)_2(diamine)_2]^+$ and $[Co(X')_2(diamine)_2]^+$ (see Figs. 6—8). This absorption behavior suggests that the specific bands are not due to the intraligand transitions and that there is some strong interaction, for example, a p_π-d_π interaction, between the ligands in the *trans* positions through the central cobalt(III) ion. The CD data of the *trans*-$[Co(X)(X')(R,R\text{-chxn})_2]^+$ (X, X'= N_3^-, NCS^-, NO_2^-, and Cl^-) complexes are presented in Tables 2 and 3 and Figs. 6—8. The azidoisothiocyanato complex shows two CD bands under the specific absorption band (Fig. 6): one is the weaker negative CD band of lower energy and the other the stronger positive one of higher energy. The CD behavior is the same as that of the "parent" complexes, *trans*-$[Co(N_3)_2(R,R\text{-chxn})_2]^+$ and -$[Co(NCS)_2(R,R\text{-chxn})_2]^+$. Accordingly, the two CD bands at about 25000 and 28000 cm^{-1} are considered to belong to the second d-d band. The azidonitro complex (Fig. 7) exhibits a very strange absorption spectrum which is remarkably different from the intermediate of the "parent" complexes, and a negative CD band is located under the intense absorption band at 33400 cm^{-1} and two positive CD bands are observed under the shoulder at about 29000 cm^{-1}. It is more probable to consider that the lowest energy CD band corresponds to the second d-d absorption band, which is hidden. Then, the weak positive and strong negative CD bands at 30300 and 33100 cm^{-1} are assigned to the specific absorption band. A single strong positive CD band is observed under another intense absorption band in the higher energy region. In summary, the CD behavior of the mixed complexes in the specific absorption band region is complicated as in the case of the *cis*-type bis(ethylenediamine) complexes, but it seems a common behavior that two CD bands are observed under the specific band, and the higher energy one of which is the stronger.

Finally, the four complexes containing only N_3^- or NCS^-, that is, $(N_3)(N_3)$, $(NCS)(NCS)$, $(N_3)(NCS)$, and $(NCS)(NH_3)$ complexes, exhibit the (—, +) CD pattern under the specific absorption band. The five

complexes containing Cl^- or NO_2^-, namely, $(NO_2)(NO_2)$, $(NCS)(NO_2)$, $(N_3)(NO_2)$, $Cl(NCS)$, and $Cl(NO_2)$ complexes, appear to exhibit the reverse CD pattern, (+, −), under the specific band. Furthermore, the higher energy CD component of the specific band is stronger than the lower energy CD component for all nine complexes. Lastly, it was observed that all the complexes exhibit one strong CD band in the region of 41000—48000 cm^{-1} and that the sign is always positive (Table 3).

The authors are grateful to Dr. Wasuke Mori of Osaka University, and to Dr. Keiji Matsumoto of Osaka City University for their help in the measurements of the CD spectra.

(Received February 7, 1977)

Three geometrical isomers of the bis(β-alaninato)(oxalato)cobaltate(III) and of the (β-alaninato)(glycinato)-(oxalato)cobaltate(III) complexes have been prepared and resolved into their optical isomers. Their structures were assigned on the basis of the electronic absorption, ^1H NMR and ^{13}C NMR spectra. The circular dichroism spectra of these complexes have been measured and compared with those of the bis(glycinato)(oxalato)cobaltate(III) complexes.

Optically active cobalt(III) complexes containing amino acids are important for clarifying the relationships between their electronic absorption and circular dichroism (CD) spectra and the structures of the complexes. A number of investigators have studied α-amino acid–cobalt(III) complexes.[1-8] However, only a few cobalt(III) complexes containing β-alanine have been reported and further investigation is necessary.

β-Alanine can coordinate to a cobalt(III) ion with both carboxyl and amino groups as in the case of α-amino acids. Consequently, in complexes of the type bis(amino acidato)(oxalato)cobaltate(III) anion, β-alanine complexes provide the same geometrical isomers as α-amino acid complexes. However, β-alanine forms a six-membered chelate ring, unlike α-amino acids. It has been pointed out that the difference in size of chelate rings affects the CD spectra.[9,10] Thus, it would be interesting to compare the CD spectra of the complexes which contain β-alanine with those of the complexes containing α-amino acids.

The present paper deals with the separation and optical resolution of the isomers of bis(β-alaninato)-(oxalato)cobaltate(III) and (β-alaninato)(glycinato)-(oxalato)cobaltate(III) complexes and with their electronic absorption and CD spectra. Their spectra are compared with those of optically active bis(glycinato)-(oxalato)cobaltate(III) complexes.

Experimental

Preparation of Complexes. Isomers of Potassium Bis(β-alaninato)-(oxalato)cobaltate(III): A solution of 20 g of cobalt(II) chloride hexahydrate in 20 ml of hot water was added to a solution containing 18.5 g of potassium oxalate monohydrate and 15 g of β-alanine in 80 ml of water. The resulting dark red solution was oxidized with 20 g of lead dioxide at 60 °C for about 22 h. After the mixture had been cooled to room temperature, a large amount of insoluble material was removed by filtration. The filtrate was poured into a column (30 mm × 600 mm) containing an anion exchange resin (Dowex 1×8, 200—400 mesh, acetate form). A small quantity of non-electrolyte complexes was eluted when the column was flushed with water. The adsorbed band was eluted with a 0.05 M aqueous solution of potassium acetate, giving three colored bands. The bands, in the order of elution, were blue-violet, purple and blue. Another blue band remained at the top of the column. The second and third eluted bands were determined from their electronic absorption spectra and column chromatographic behavior to be C_1-*cis*(N)- and C_2-*cis*(N)-$[Co(\beta\text{-ala})_2(ox)]^-$ ions, respectively. The first eluted band was confirmed to be *trans*(N)-$[Co(\beta\text{-ala})_2(ox)]^-$ ion from its absorption spectrum. Each eluted solution was evaporated to a few milliliters in a vacuum evaporator. To each concentrated solution was added a large amount of ethanol. The complex precipitated was washed with methanol. Each complex was recrystallized from hot water by addition of methanol. The yields were 5.0 g for the C_1-*cis*(N) isomer and 1.5 g for the C_2-*cis*(N) isomer. Found: C, 22.77; H, 4.48; N, 6.55%. Calcd for C_1-*cis*(N)-$K[Co(\beta\text{-ala})_2(ox)]\cdot 3.5H_2O$: C, 22.59; H, 4.50; N, 6.59%. Found: C, 23.18; H, 4.22; N, 6.67%. Calcd for C_2-*cis*(N)-$K[Co(\beta\text{-ala})_2(ox)]\cdot 3H_2O$: C, 23.08; H, 4.35; N, 6.73%.

Isomers of Potassium (β-Alaninato)(glycinato)(oxalato)cobaltate-(III): A solution containing 4.5 g of potassium oxalate monohydrate, 1.6 g of glycine and 3.5 g of β-alanine in 20 ml of water (50 °C) was added to a solution containing 4.5 g of cobalt(II) sulfate heptahydrate in 10 ml of water (50 °C). The solution was oxidized with 3 g of lead dioxide. The resulting mixture was stirred at 50 °C for about 30 min. After the mixture had been cooled in an ice bath for about 3 h, a large amount of insoluble material was removed by filtration. The filtrate was poured into a column (35 mm × 900 mm) containing an anion exchange resin (Dowex 1×8, 200—400 mesh, acetate form). After the column had been swept with four liters of water, the adsorbed band was eluted with a 0.04 M aqueous solution of potassium acetate. Ten colored bands were separated: (i) blue-violet, (ii) blue-violet, (iii) violet, (iv) purple, (v) blue, (vi) violet-red, (vii) red-violet, (viii) pale violet, (ix) red-violet and (x) pale blue-violet. The symbols (i)—(x) represent the fractions eluted from each band. The complex/or isomer obtained from each fraction is abbreviated as **1**—**10**. Thus, (i) represents the fraction from the first band and **1** denotes the complex/or isomer from fraction (i), and so on. Each fraction was concentrated in a vacuum evaporator at 35—40 °C. A mixture of a small amount of methanol and a large amount of acetone was added to each concentrated solution to give two liquid layers, a cloudy colorless layer and a clear colored layer. After the cloudy layer was removed by decantation, a mixture of a small amount of methanol and a large amount of acetone was added to the clear layer, and the resulting new cloudy layer was discarded. This procedure was repeated several times, and finally a large amount of ethanol was added to the residual solution. The crude product deposited was filtered and washed with ethanol. Purification of the complex was carried out by addition of ethanol to a concentrated aqueous solution.

The visible absorption and NMR spectra of the isolated complexes indicate that the complexes **1**, **4**, and **5** are three

geometrical isomers of $[Co(\beta\text{-ala})_2(ox)]^-$ and the complexes **3**, **9**, and **10** are those of $[Co(gly)_2(ox)]^-$. The complexes obtained from the (ii), (vi), (vii), and (viii) fractions are the isomers of $[Co(\beta\text{-ala})(gly)(ox)]^-$. The yield of the complex from the band (viii) was so small that we could not isolate complex **8** in pure form. The yields of **2**, **6**, and **7** were 0.15, 0.2, and 0.1 g, respectively. Found for complex **2**: C, 23.31; H, 3.04; N, 7.86%. Calcd for $K[Co(\beta\text{-ala})(gly)(ox)]\cdot 0.5H_2O$: C, 23.54; H,3.10; N, 7.80%. Found for complex **6**: C, 21.85; H, 3.65; N, 7.22%. Calcd for $K[Co(\beta\text{-ala})(gly)(ox)]\cdot 2H_2O$: C, 21.88; H, 3.67; N, 7.29%. Found for complex **7**: C, 22.34; H, 3.50; N, 7.32%. Calcd for $K[Co(\beta\text{-ala})(gly)(ox)]\cdot 1.5H_2O$: C, 22.41; H, 3.49; N, 7.47%.

Optical Resolution of the Complexes. The Second Eluted Isomer of Potassium Bis(β-alaninato)(oxalato)cobaltate(III): A suspension of 2 g of $(+)_{546}$-$[Co(en)_2(ox)]I$ in 14 ml of water was stirred with 0.9 g of silver acetate at 50 °C for about 10 min. The silver iodide precipitated was filtered and washed with a small amount of ice water. To the combined filtrate and washings was added 2 g of C_1-*cis*(N)-$K[Co(\beta\text{-ala})_2(ox)]\cdot 3.5H_2O$ (the second eluted isomer), and the solution was chilled in an ice bath for about 4 h. The red-brown diastereomer which deposited, $(+)_{546}$-$[Co(en)_2(ox)](+)_{546}$-$[Co(\beta\text{-ala})_2(ox)]\cdot 7H_2O$, was filtered, washed with a small amount of ice water, methanol and then ether, and dried in the air. The diastereomer was recrystallized repeatedly from hot water by addition of methanol until no further increase in optical rotation was observed. $[\alpha]_{546}+1490°$. Found: C, 23.38; H, 6.07; N, 11.57%. Calcd for $(+)_{546}$-$[Co(en)_2(ox)](+)_{546}$-$[Co(\beta\text{-ala})_2(ox)]\cdot 7H_2O$: C, 23.47; H, 5.92; N, 11.73%.

A solution containing 0.7 g of the $(+)_{546}$ diastereomer in a small amount of water was passed through a column (20 mm ×200 mm) containing a cation exchange resin (Dowex 50W ×8, 200—400 mesh, potassium form). The complex anion, $(+)_{546}$-$[Co(\beta\text{-ala})_2(ox)]^-$, was eluted when the column was flushed with water, while the resolving agent, $(+)_{546}$-$[Co(en)_2(ox)]^+$, was adsorbed on the top of the column. The eluate (solution) was evaporated to a few milliliters in a vacuum evaporator, methanol being added to the residue. The complex which precipitated was filtered, washed with a water–methanol mixture and then methanol, and dried in the air. The complex was recrystallized from hot water by addition of methanol. $[\alpha]_{546}+1710°$. Found: C, 23.62; H, 4.34; N, 6.80%. Calcd for $(+)_{546}$-$K[Co(\beta\text{-ala})_2(ox)]\cdot 2.5H_2O$: C, 23.59; H, 4.21; N, 6.88%.

The Third Eluted Isomers of Potassium Bis(β-alaninato)(oxalato)cobaltate(III): A suspension containing 1.1 g of $(+)_{546}$-$[Co(en)_2(ox)]I$ in 10 ml of water was stirred with 0.5 g of silver acetate at 50 °C for about 10 min. The silver iodide which precipitated was filtered and washed with a small amount of water. To the combined filtrate and washings was added 1.1 g of C_2-*cis*(N)-$K[Co(\beta\text{-ala})_2(ox)]\cdot 3H_2O$ (the third eluted isomer). A red-brown diastereomer which deposited immediately, $(+)_{546}$-$[Co(en)_2(ox)](+)_{546}$-$[Co(\beta\text{-ala})_2(ox)]\cdot 4H_2O$, was filtered, washed with a small amount of ice water, methanol and then ether, and dried in the air. The diastereomer was recrystallzed repeatedly from hot water by addition of methanol until no further increase in optical rotation was observed. $[\alpha]_{546}+840°$. Found: C, 25.39; H, 5.57; N, 12.61%. Calcd for $(+)_{546}$-$[Co(en)_2(ox)](+)_{546}$-$[Co(\beta\text{-ala})_2(ox)]\cdot 4H_2O$: C, 25.38; H, 5.49; N, 12.69%.

Separation of $(+)_{546}$-$K[Co(\beta\text{-ala})_2(ox)]$ from the diastereomer was carried out by the same method as described for the separation of $(+)_{546}$ isomer from the second eluted band. The complex obtained was recrystallized from hot water by addition of methanol. $[\alpha]_{546}+590°$. Found: C, 24.87; H, 4.16; N, 6.93%. Calcd for $(+)_{546}$-$K[Co(\beta\text{-ala})_2(ox)]\cdot 1.5H_2O$: C, 24.69; H, 3.88; N, 7.19%.

The Potassium Salt of Complex 3: The recemate, (±)-*trans*-(N)-$K[Co(\beta\text{-ala})(gly)(ox)]\cdot 0.5H_2O$ (0.51 g), was dissolved in 70 ml of water, and the solution was treated with a cation exchange resin (Dowex 50W×8, 200—400 mesh, lithium form). The resolving agent, $(+)_{546}$-$[Co(en)_2(ox)]Br\cdot H_2O$ (0.25 g) was dissolved in 200 ml of water, and the solution was treated with an anion exchange resin (Dowex 1×8, 200—400 mesh, acetate form). The two solutions were mixed, the mixture was evaporated to 50 ml, and then 15 ml of ethanol was added to the concentrated solution. The less soluble diastereomer deposited was filtered and washed with warm water. It is sparingly soluble in water. $[\alpha]_{546}+940°$. Found: C, 25.90; H, 4.72; N, 13.94%. Calcd for $(+)_{546}$-$[Co(en)_2(ox)](+)_{546}$-$[Co(\beta\text{-ala})(gly)(ox)]\cdot 1.5H_2O$: C, 25.88; H, 4.85; N, 13.93%.

The cation exchange resin (Dowex 50W×8, 200—400mesh, potassium form) was added to a suspension of the $(+)_{546}$ diastereomer in water. The mixture was stirred for about 1 h and the resin was removed by filtration. The filtrate containing $(+)_{546}$-$K[Co(\beta\text{-ala})(gly)(ox)]$ was concentrated in a vacuum evaporator, ethanol being added to the concentrated solution. The $(+)_{546}$ isomer obtained was reprecipitated repeadedly from aqueous solution by addition of ethanol until optical rotation attained a constant value. The isomer was gelatinous. $[M]_{546}+2040°$ (concentration of the solution was determined from its absorption spectrum).

The Potassium Salt of Complex 6: A 50 ml of aqueous solution of $K[Co(\beta\text{-ala})(gly)(ox)]\cdot 2H_2O$ (obtained from the eluted band (vi), 0.8 g) was treated with a cation exhange resin (lithium form). An aqueous solution of $(+)_{546}$-$[Co(en)_2(ox)]Br\cdot H_2O$ (0.5 g) was passed through an anion exchange resin (acetate form). These two solutions were mixed, the mixture was evaporated to 50 ml in a vacuum evaporator, and then 50 ml of ethanol was added to the concentrated solution. On cooling the solution in an ice bath for 2 h, the less soluble diastereomer precipitated as a red-violet powder. The precipitate was filtered and washed with ethanol. The diastereomer was recrystallized repeatedly from hot water by addition of ethanol until no further increase in optical rotation was observed. $[\alpha]_{546}$ −940°. Found: C, 25.36; H, 4.99; N, 13.57%. Calcd for $(+)_{546}$-$[Co(en)_2(ox)](-)_{546}$-$[Co(\beta\text{-ala})(gly)(ox)]\cdot 2H_2O$: C, 25.50; H, 4.94; N, 13.73%.

The $(-)_{546}$ diastereomer, $(+)_{546}$-$[Co(en)_2(ox)](-)_{546}$-$[Co(\beta\text{-ala})(gly)(ox)]\cdot 2H_2O$, was dissolved in water and the solution was passed through a small column of cation exchange resin (Dowex 50W×8, 200—400 mesh, potassium form). The solution was evaporated to a few milliliters. Violet-red flakes were deposited by adding ethanol to the concentrated solution. The complex was recrystallized from water by addition of ethanol. $[\alpha]_{546}-1830°$. Found: C, 22.25; H, 3.70; N, 7.25%. Calcd for $(-)_{546}$-$K[Co(\beta\text{-ala})(gly)(ox)]\cdot 2H_2O$: C, 21.88; H, 3.67; N, 7.29%.

The Potassium Salt of Complex 7. The complex was resolved in the same way as described for complex **6**. The racemate, $(\pm)$-$K[Co(\beta\text{-ala})(gly)(ox)]\cdot 1.5H_2O$ (obtained from the eluted band (vii), 1.10 g), was dissolved in 50 ml of water, and the solution was treated with a cation exchange resin (Dowex 50W×8, 200—400 mesh, lithium form). The resolving agent, $(+)_{546}$-$[Co(en)_2(ox)]Br\cdot H_2O$ (0.69 g), was dissolved in 60 ml of water at 60 °C, and the solution was treated with an anion exchange resin (Dowex 1×8, 200—400 mesh, acetate form). The two solutions were mixed. The mixture was evaporated to 75 ml in a vacuum evaporator, and then 25 ml of ethanol was added to the concentrated solution. After 1 h, red-violet crystals deposited were filtered and washed with water–ethanol mixture. They were recrystallized from water by addition of

ethanol. $[\alpha]_{546}+980°$. Found: C, 24.48; H, 5.07; N, 13.55%. Calcd for $(+)_{546}$-$[Co(en)_2(ox)](+)_{546}$-$[Co(\beta\text{-ala})(gly)(ox)]\cdot 3H_2O$: C, 24.77; H, 5.11; N, 13.33%.

The $(+)_{546}$ diastereomer was dissolved in water, and the solution was passed through a column of a cation exchange resin (Dowex 50W×8, 200—400 mesh, potassium form) in order to remove the resolving agent. The resulting solution was evaporated to a few milliliters, and then ethanol was added to the concentrated solution. After the solution had been allowed to stand for about 30 min at room temperature, crystalline powder deposited was filtered. It was recrystallized from a mixture of water and ethanol. $[\alpha]_{546}+1210°$. Found: C, 22.81; H, 3.30; N, 7.58%. Calcd for $(+)_{546}$-K-$[Co(\beta\text{-ala})(gly)(ox)]\cdot H_2O$: C, 22.96; H, 3.30; N, 7.65%.

Measurements. The electronic absorption spectra of the complexes were measured with a Hitachi Model EPS-3T spectrophotometer in aqueous solution. The CD spectra were recorded on a JASCO Model MOE-1 spectropolarimeter, the ^1H NMR spectra on a JEOL Model MH-100 spectrometer with DSS as an internal standard, and the ^{13}C NMR spectra on a JEOL Model MFT-100 spectrometer in pulse Fourier transform/proton noise decoupling mode at 25.15 MHz. The ^{13}C chemical shifts were measured relative to external benzene and converted into the chemical shifts from TMS using the relation $\delta_{TMS}=\delta_{benzene}-128.5$ ppm.

Results and Discussion

Both $[Co(gly)_2(ox)]^-$ and $[Co(\beta\text{-ala})_2(ox)]^-$ ions provide three geometrical isomers, *trans*(N), C_1-*cis*(N) and C_2-*cis*(N). On the other hand, the mixed complex ion, $[Co(\beta\text{-ala})(gly)(ox)]^-$, exists in four geometrical isomers of *trans*(N), *cis*(N)*trans*(O_β,N) (O_β represents the coordinating oxygen atom in β-alanine), *cis*(N)*trans*-(O_g,N) (O_g represents the coordinating oxygen atom in glycine) and *cis*(N)*trans*(O_β,O_g) (this isomer has a pseudo C_2 axis, the glycine being regarded as β-alanine; it is therefore referred to as C_2-*cis*(N) in this paper) (Fig. 1).

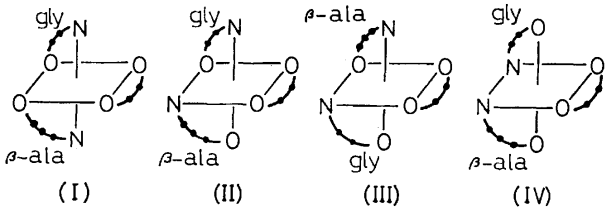

Fig. 1. The geometrical structures of four isomers in the mixed complex ion, $[Co(\beta\text{-ala})(gly)(ox)]^-$.
(I), *trans*(N); (II), *cis*(N)*trans*(O_β,N); (III), *cis*(N)*trans*-(O_g,N); (IV), *cis*(N)*trans*(O_β,O_g) (pseudo C_2 symmetry).

Structural Assignments of the Isomer $[Co(\beta\text{-ala})_2(ox)]^-$. It is generally recognized that the visible absorption band at lower energy side (the so-called first absorption band) of the *trans*(N) isomer of $[Co(N)_2(O)_4]$ type complex shows a more marked split as compared with that of the corresponding *cis*(N) isomer.[12] The $[Co(\beta\text{-ala})_2(ox)]^-$ complex prepared by Hidaka and Shimura[13] has been assigned to *trans*(N) isomer on the basis of the above. A marked split of the first absorption band was also observed for the complex obtained from the first eluted band in the process of separation of $[Co(\beta\text{-ala})_2(ox)]^-$ ion. Thus we conclude that the isomer obtained from the first eluted band has the *trans*(N) configuration. On the other hand, the other two isomers obtained from the second and third eluted bands showed no such marked split in the first absorption band, so that their configurations can be assigned to *cis*(N).

The assignments of the C_1- and C_2-*cis*(N) isomers can be verified by their ^{13}C NMR spectra. Since the chemical environments of the ethylene-carbons of the two β-alanine ligands are equivalent in the C_2-*cis*(N) isomer but not in the C_1-*cis*(N) isomer, two and four resonance lines resulting from ethylene-carbons are expected for the former and the latter, respectively. In addition, one resonance line due to the carboxyl-carbons in the coordinated β-alanines is expected for the C_2-*cis*(N) isomer, and two lines for the C_1-*cis*(N) isomer. The second eluted isomer showed four resonance lines resulting from ethylene-carbons and two resonance lines from carboxyl-carbons (Table 1). On the other hand, the third eluted isomer showed only two resonance lines and one for these carbons. Thus the structures of the second and third eluted isomers can be assigned to C_1-*cis*(N) and C_2-*cis*(N), respectively.

Table 1. ^{13}C CHEMICAL SHIFTS OF THE COORDINATED β-ALANINE

Complex ion	Ethylene-carbons		Carboxyl-carbon
trans(N)-$[Co(\beta\text{-ala})_2(ox)]^-$	33.9 ppm	38.6 ppm	184.4 ppm
C_1-*cis*(N)-$[Co(\beta\text{-ala})_2(ox)]^-$	33.7 (slightly split)	38.0	183.1
		38.6	184.2
C_2-*cis*(N)-$[Co(\beta\text{-ala})_2(ox)]^-$	33.6	38.0	183.3

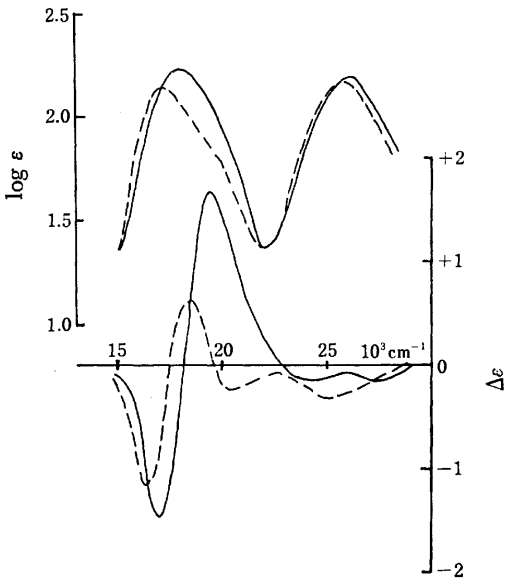

Fig. 2. The absorption and CD spectra of C_1- and C_2-*cis*(N) isomers of $[Co(\beta\text{-ala})_2(ox)]^-$ ion.
—— $(+)_{546}$-C_1-*cis*(N)-$[Co(\beta\text{-ala})_2(ox)]^-$, and
------ $(+)_{546}$-C_2-*cis*(N)-$[Co(\beta\text{-ala})_2(ox)]^-$.

The assignments of the C_1-*cis*(N) and C_2-*cis*(N) isomers can be made also on the basis of the energy difference in the first absorption bands. Matsuoka *et al.*[12] reported three geometrical isomers of a bis(amino acidato)-(oxalato)cobaltate(III) complex, and pointed out that the first absorption maxima of the C_2-*cis*(N) isomers are located in a lower energy region than those of the C_1-*cis*(N) isomers. As shown in Fig. 2, the first absorption maximum (18070 cm^{-1}) of the second eluted isomer was observed in a higher energy region as compared with that (17300 cm^{-1}) of the third eluted isomer. It can be concluded that the second and third eluted isomers take C_1-*cis*(N) and C_2-*cis*(N) structures, respectively. These assignments are in line with those from the ^{13}C NMR data.

Structural Assignments of Four Isomers in [Co(β-ala)(gly)-(ox)]⁻ Ion. Ten chromatographic bands ((i)—(x)) appeared on separation of [Co(β-ala)(gly)(ox)]⁻ (see Experimental). For complexes **3**, **9**, and **10**, the ^1H NMR resonance lines due to only the methylene-protons of the coordinated glycine were observed in the region 3.37—3.67 ppm. On the other hand, for complexes **1**, **4**, and **5**, the resonance lines due to only the ethylene-protons of the coordinated β-alanine were observed in the region 2—3 ppm. However, for complexes **2**, **6**, **7**, and **8**, both signals of the coordinated glycine and β-alanine were observed. The absorption spectra of complexes **1**, **3**, **4**, **5**, **9**, and **10** agree well with those of *trans*(N)-[Co(β-ala)$_2$(ox)]⁻, *trans*(N)-[Co(gly)$_2$(ox)]⁻, C_1-*cis*(N)-[Co(β-ala)$_2$(ox)]⁻, C_2-*cis*(N)-[Co(β-ala)$_2$(ox)]⁻, C_1-*cis*(N)-[Co(gly)$_2$(ox)]⁻, and C_2-*cis*(N)-[Co(gly)$_2$-(ox)]⁻, respectively. It is therefore expected that the remaining complexes, **2**, **6**, **7**, and **8**, are four isomers of the [Co(β-ala)(gly)(ox)]⁻ ion.

Of four isomers of the (β-alaninato)(glycinato)-(oxalato)cobaltate(III) complex, the structure of isomer **2** can be assigned to *trans*(N) since a marked split was observed in the first absorption band, which is characteristic of the complexes of *trans*(N)-[Co(N)$_2$(O)$_4$] type. The other three isomers, **6**, **7**, and **8**, exhibited no such marked split in the first absorption band, and thus would have the *cis*(N) configuration. Of these three *cis*(N) isomers, isomer **8** showed the first absorption band maximum (17670 cm^{-1}) in the lowest energy region (Table 2 and Fig. 3). The absorption maximum of C_2-*cis*(N) isomer was observed in a lower energy region than for the C_1-*cis*(N) isomer in bis(amino acidato)-(oxalato)cobaltate(III) complexes. Isomer **8** is thus expected to take C_2-*cis*(N) structure, as shown in Fig. 1 (IV). The structures of the remaining two isomers **6** and **7** can be assigned to either *cis*(N)*trans*(O_β,N) (Fig. 1 (II)) or *cis*(N)*trans*(O_g,N) (Fig. 1 (III)).

^1H NMR Spectra. The ^1H NMR spectra of the complexes are shown in Fig. 4. The methylene-proton

(1), *trans*(N)-$[Co(\beta\text{-ala})_2(ox)]^-$; (2), *trans*(N)-$[Co(\beta\text{-ala})(gly)(ox)]^-$; (3), *trans*(N)-$[Co(gly)_2(ox)]^-$; (4), C_1-*cis*(N)-$[Co(\beta\text{-ala})_2(ox)]^-$; (5), C_2-*cis*(N)-$[Co(\beta\text{-ala})_2(ox)]^-$; (6), *cis*(N)*trans*($O_\beta$,N)-$[Co(\beta\text{-ala})(gly)(ox)]^-$; (7), *cis*(N)-*trans*($O_g$,N)-$[Co(\beta\text{-ala})(gly)(ox)]^-$; (8), *cis*(N)*trans*($O_\beta$, O_g)-$[Co(\beta\text{-ala})(gly)(ox)]^-$ (pseudo C_2 symmetry, containing some contamination); (9), C_1-*cis*(N)-$[Co(gly)_2(ox)]^-$; and (10) C_2-*cis*(N)-$[Co(gly_2(ox)]^-$.

signals of the chelated glycine appear in the region 3.3—3.7 ppm. The *trans*(N) isomer **3** of the bis(glycinato)(oxalato)cobaltate(III) complex showed a single resonance at 3.67 ppm, and the C_2-*cis*(N) isomer **10** one at 3.52 ppm. However, two different resonance signals (a singlet at 3.52 ppm and a quartet at 3.37 ppm) were observed in the C_1-*cis*(N) isomer **9**. This suggests that the methylene-protons of the two glycines in isomer **9** are present in different chemical environments. Sakaguchi *et al.* pointed out the importance of the effect of magnetic anisotropy which is induced on the central Co(III) chromophore. They applied the anisotropy to the assignments of protons in ethylenediamine-Co(III) complexes[14] and amino acidato-Co(III) complexes.[15] They suggested that, in C_1-*cis*(N)-$[Co(gly)_2(ox)]^-$, the methylene-protons of the chelated glycine located in the plane including N-Co(III)-N would be observed in a lower field than the other methylene-protons of the chelated glycine which is not located in the plane. Thus the singlet at 3.52 ppm can be assigned to H_b and H_b', and the quartet at 3.37 ppm to H_a and H_a' (Fig. 5 (I)).

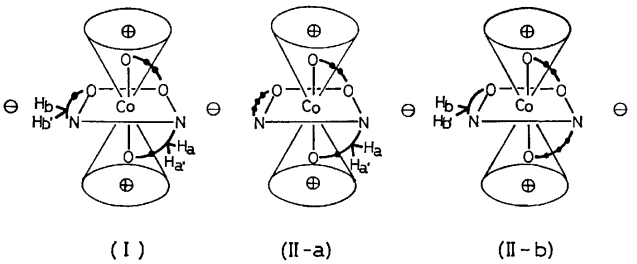

Fig. 5. The magnetic anisotropy induced on cobalt(III) chromophore.

+: Shift to up field, —: shift to down field.

The ^1H NMR data of isomer **6** gave a quartet signal due to the methylene-protons of glycine, at 3.38 ppm (Fig. 4). From the chemical shift and splitting pattern, it seems that these methylene-protons are in similar chemical environments to the higher field methylene-protons (H_a and H_a') of the C_1-*cis*(N) isomer of bis(glycinato)(oxalato)cobaltate(III) complex. The resonance line due to the methylene-protons of the glycinato chelate in isomer **7** (a singlet at 3.54 ppm) corresponds to that of the lower field methylene-protons (H_b and H_b') of C_1-*cis*(N)-$[Co(gly)_2(ox)]^-$. The correspondence leads to the conclusion that the structure of isomer **6** is *cis*(N)*trans*(O_β,N) and that of isomer **7** is *cis*(N)*trans*-(O_g,N) (Fig. 5, (II-a) and (II-b)).

The signals in the region 2—3 ppm should be assigned to the ethylene-protons of the β-alaninato chelate.

Electronic Absorption and CD Spectra. Electronic absorption and CD data of *trans*(N) complexes are given in Table 2. The absorption spectra of these complexes are very similar to each other. The intensity ratio of sub- and major-band of the first absorption band, (ε_{max}(sub)/ε_{max} (major)), for the *trans*(N)-$[Co(\beta\text{-ala})_2(ox)]^-$ is 0.58 and that for the *trans*(N)-$[Co(gly)_2(ox)]^-$ is

0.50. The ratio of the *trans*(N)-[Co(β-ala)(gly)(ox)]$^-$ is 0.55, greater than that of *trans*(N) bis(glycinato) and smaller than that of the *trans*(N) bis(β-alaninato) complex. The maximum of the second absorption band of the *trans*(N) (β-alaninato)(glycinato) complex was observed in a higher energy region than that of the bis(glycinato) complex, but in a lower energy region than that of the bis(β-alaninato) complex. For the second absorption bands of these three *trans*(N) complexes, the bis(β-alaninato) complex shows the lowest intensity (log ε_{max}) and the bis(glycinato) complex the highest intensity.

The CD curve of the $(+)_{546}$-*trans*(N) bis(glycinato) complex shows two negative bands in the first absorption band region and a positive band in the second absorption band region (Table 2). The CD curve of the $(+)_{546}$-*trans*(N) bis(β-alaninato) complex shows three negative bands in the first absorption band region, their intensities being significantly smaller compared with those of the bis(glycinato) complex.[13] However, the positive CD band of the bis(β-alaninato) complex observed in the second absorption band region is nearly equal to that of the bis(glycinato) complex. The CD curve of the $(+)_{546}$-*trans*(N)-[Co(β-ala)(gly)(ox)]$^-$ in the first absorption band region shows two negative bands which have somewhat smaller intensities than those of the $(+)_{546}$-*trans*(N) bis(glycinato) complex. The positive CD band of the mixed *trans*(N) complex in the second absorption band region is nearly equal in intensity to those of the other two *trans*(N) complexes. From the CD spectrum of the $(+)_{546}$-*trans*(N)-[Co(β-ala)$_2$(ox)]$^-$ in the first absorption band region, it is possible to assign its absolute configuration to Δ, as in the case of the $(+)_{546}$-*trans*(N) bis(glycinato) complex.[11]

For the four C_1-*cis*(N) complexes (**9**, **6**, **7**, and **4**) in Table 2, the first absorption maximum of the *cis*(N)*trans*-(O_β,N) (β-alaninato)(glycinato) complex **6** was observed in the highest energy region and that of the *cis*(N)*trans*-(O_g,N) (β-alaninato)(glycinato) complex **7** in the lowest energy region. However, the first absorption maximum of the *cis*(N)*trans*(O_β,O_g) (β-alaninato)(glycinato) complex **8** (pseudo C_2 symmetry) is located in a lower energy region than that of the C_2-*cis*(N) bis(glycinato) complex **10**, but in a higher energy region than that of the C_2-*cis*(N) bis(β-alaninato) complex **5**. The maxima of the first absorption band of the C_2-*cis*(N) complexes were observed in a lower energy region than those of the C_1-*cis*(N) complexes.

The *cis*(N)-[Co(α-am)$_2$(ox)]$^-$ type complexes containing glycine or L-serine show only one CD band in the first absorption band region. On the other hand, *cis*(N)-[Co(ida)$_2$]$^-$,[16] [Co(edta)]$^-$ [16,17] and *cis*(N)-[Co(L-alama)$_2$]$^-$ (L-alama: L-alanine-monoacetic acid)[18] have two CD bands of the opposite signs with comparable intensities. The *cis*(N)*trans*(O_β,N) (β-alaninato)(glycinato) complex **6** and the C_1-*cis*(N) bis(β-alaninato) complex **4** belong to the latter group, revealing two CD bands of the opposite signs and of nearly comparable intensities. The CD curves of the *cis*(N)*trans*(O_g,N) (β-alaninato)(glycinato) complex **7** and C_2-*cis*(N) bis(β-alaninato) complex **5** show different patterns from those of C_1-*cis*(N) bis(β-alaninato) and *cis*(N)*trans*(O_β,N) (β-alaninato)(glycinato) complexes in the first absorption band region. Namely, complex **5** shows three CD bands in the first absorption band region, while complex **7** shows two CD bands of opposite signs in the first absorption band region, but the CD intensity at 19800 cm^{-1} is significantly smaller than that of the opposite sign at 17150 cm^{-1}. The differences in the CD spectra would be caused by the difference in ligand field strength between O_g and O_β, and the difference in size of the chelate ring between the glycinato and β-alaninato chelates. However, the dominant factor is unknown.

The absolute configuration of the *cis*(N)-[Co(ida)$_2$]$^-$ isomer for which the CD bands in the first absorption band region show positive and negative signs listing from the lower energy side, was assigned to Λ by Van Saun and Douglas.[16] The Λ $(-)_{546}$-isomer of [Co(edta)]$^-$ shows a similar CD pattern in this region. From a comparison of CD patterns, it is concluded that the $(+)_{546}$-C_1- and $(+)_{546}$-C_2-*cis*(N) isomers of the bis(β-alaninato) complex and $(+)_{546}$-*cis*(N)*trans*(O_g,N) isomer of the (β-alaninato)(glycinato) complex take Δ configuration and the $(-)_{546}$-*cis*(N)*trans*(O_β,N) isomer of the (β-alaninato)(glycinato) complex takes Λ configuration.

The Formation and Structure of $Bi_{1.34}CrNbO_6$

Yasuyoshi Torii and Kanemitsu Hasegawa

Government Industrial Research Institute, Nagoya, Hirate-machi, Kita-ku, Nagoya 462

(Received February 18, 1977)

A new ternary oxide $Bi_{1.34}CrNbO_6$ was prepared and characterized. The unit cell is face-centered cubic with $a=10.455$ Å. The structure is assumed to be of the pyrochlore type based on the space group Fd3m and was refined by trial and error to a reliability factor R of 0.0564. This pyrochlore phase was confirmed to have vacancies at the A sites and also at the special oxygen sites, and may be considered to be a rare case in this respect. The Cr^{3+} and Nb_5^+ ions are bonded octahedrally to six oxygen atoms at 2.03 Å, while the Bi^{3+} ions are bonded to six oxygen atoms at 2.56 Å. The structure consists of bismuth tetrahedra, the centers of which are vacant. The highly polarizable Bi^{3+} ion plays an important role in the formation of the defect pyrochlore structure. Related pyrochlores were also prepared.

A number of mixed oxides with pyrochlore structure are known by the formula $A_2B_2O_7$,[1] and have provided a rich source of new materials exhibiting ferroelectricity[2] and promising electrooptic effects.[3] In recent years, many defect pyrochlores have been prepared based on the correlation between the perovskite and pyrochlore phases, and their structures and electrical properties have been investigated.[4-7] Most are oxygen deficient pyrochlores having the formula $A_2B_2O_{7-x}$ ($0<x\leqq 1$). Like $Pb_{1.5}Nb_2O_{6.5}$[2] and $TlSbWO_6$,[8] there are few pyrochlores which have vacancies at the A sites. During a study on the synthesis of Bi-containing mixed oxides, a new phase, $Bi_{1.34}CrNbO_6$, was found which exhibits an X-ray pattern of pyrochlore structure. As can be estimated from the chemical formula, this phase may be regarded as a rare defect pyrochlore which has vacancies at the A sites. In $TlSbWO_6$[8] and $Tl_{1-\alpha}(Ta_{1+\alpha}W_{1-\alpha})O_6$,[9] however, the A ions occupy special sites and, therefore, the latter is a nonstoichiometric pyrochlore. It is of interest to know how the structure of the defect pyrochlores can tolerate a balanced deficiency of both bismuth and oxygen ions. A suggestion can be given on the basis of systematic synthesis of defect pyrochlores. In the present study, the defect pyrochlore, $Bi_{1.34}CrNbO_6$, was prepared and are characterized. The position of the Bi^{3+} ions in the cubic unit cell was determined and is discussed, and the formula of this compound is established. Also, related pyrochlores, $Bi_{1.34}B'B''O_6$, where B′=Cr and Fe and B″=Nb, Ta, and Sb were prepared and their dielectric properties were measured.

Experimental

For sample preparations, starting materials were employed in the form of metal oxides. The reactants were all of reagent or better grade. Appropriate mixtures of metal oxides were fired at 950 °C for 2 h, ground and refined at 1050 °C for 3 h in air. An examination of the samples was carried out using the powder diffraction method employing a Philips diffractometer with Cu$K\alpha$ and occasionally Fe$K\alpha$ radiation. The lattice constants were determined from the reflection lines of (662) and (840). The X-ray intensity data were measured integrally for each peak. The theoretical intensity of a group of equivalent reflection lines was taken to be $I=KM(\mathrm{Lp})F^2$, where K is the scale factor, M the multiplicity, Lp the Lorentz-polarization factor, and F the structure factor.[10] For structural refinement, the observed intensity was compared with the sum of the calculated intensities which appeared at the same value of 2θ. The scattering factors for Bi^{3+}, Cr^{3+}, Nb^{5+}, and O^{2-} ions were taken from Moore.[11] The calculated structure factors were also corrected for anomalous dispersion using values given by Cromer.[12] The intensity computations were performed using a FACOM 270-30 computer with a Fortran program developed by this laboratory for the minimization of the reliability factor $R=\Sigma|I_{\mathrm{obsd}}-I_{\mathrm{calcd}}|/\Sigma I_{\mathrm{obsd}}$. Stereographic pictures of the pyrochlore structure were drawn using a computer program.[13] The dielectric constants were measured on a YHP universal bridge at 1 kHz. For the measurements, disks about 1 cm in diameter and 0.15 cm thick were coated with silver paint.

Results

Formation of $Bi_{1.34}CrNbO_6$ and Related Pyrochlores. The new phase was prepared by firing a powdered mixture of Bi_2O_3, Cr_2O_3, and Nb_2O_5 having a molar ratio of 4: 3: 3. The X-ray diffraction powder pattern was completely indexed on the basis of a face-centered cubic unit cell with the dimension $a=10.455$ Å, as shown in Table 1. This pattern exhibits the reflection lines characteristic of pyrochlore structure. The chemical formula of the new phase $Bi_{1.34}CrNbO_6$, however, does not differ from that of normal or oxygen deficient pyrochlore. When mixtures of metal oxides corresponding to the formulae Bi_2CrNbO_7 and $Bi_{1.5}CrNbO_{6.25}$ were fired separately, the formation of phases other than the cubic pyrochlore phase was observed. In the case of Bi-rich components, the reacted products were partly melted even when fired at 900 °C. In all cases, there was almost not change in the relative intensity ratio and in the positions of the reflection lines observed in the powder patterns. The best preparation of this new pyrochlore phase resulted from the mixture with a molar ratio of 4: 3: 3, and it was found that no nonstoichiometric pyrochlore phase appears to exist.

Thermal analysis was carried out in order to determine whether oxidation or reduction occurs in the sample during the formation process. In the TG and DTA curves, an increase in weight began at *ca.* 520 °C and then the broad peak of the exothermic reaction was observed at 700 °C at a heating rate of 10 °C/min. An X-ray diffraction analysis of the intermediate stage showed the formation of $(BiO)_2CrO_4$ and supported the hypothesis that the oxidation of Cr ion in the sample took place during the heating run in air. Upon heating above

8 8 0	0.924	0.6	0.6

760 °C, however, loss of oxygen occurred and the TG curve returned to its original level at *ca.* 950 °C. This level remained unchanged up to 1050 °C. After heating at this temperature for 2 h and then cooling, only formation of the new pyrochlore phase was found in the product. During a reheating run, the product showed no change in thermal analysis. Consequently, the Cr ions in this compound were assumed to be trivalent.

Table 2. Lattice and dielectric constants for some $Bi_{1.34}B'B''O_6$ pyrochlores

Compound	a (Å)	ε
$Bi_{1.34}CrNbO_6$	10.455	72
$Bi_{1.34}CrTaO_6$	10.449	35
$Bi_{1.34}CrSbO_6$	10.374	56
$Bi_{1.34}FeNbO_6$	10.506	116
$Bi_{1.34}FeTaO_6$	10.501	43
$Bi_{1.34}FeSbO_6$	10.421	39

The preparation of related compounds, all of which were of the pyrochlore type, was attempted. These lattice constants are shown in Table 2. The Cr^{3+}-containing pyrochlores are olive green in color, while the Fe^{3+}-containing compounds are dark organge, with a slight difference in hue. Attempts to prepare the V^{5+}-containing pyrochlores were unsuccessful even at high pressure (900 °C, 60 kb, 45 min). The lattice constant of $Bi_{1.34}CrNbO_6$ was slightly larger than that of $Bi_{1.34}CrTaO_6$, although both Nb^{5+} and Ta^{5+} ions are of the same size (0.64 Å) according to Shannon and Prewitt.[14] In this respect the Fe^{3+}-containing defect pyrochlores gave the same result as in the Cr^{3+}-containing ones. This is valid evidence for the existence of a defect pyrochlore type, since six pyrochlores could be prepared with starting compositions of $Bi_{1.34}B'B''O_6$.

Refinement of $Bi_{1.34}CrNbO_6$. The cell dimension and qualitative intensities of $Bi_{1.34}CrNbO_6$ strongly suggest that this compound has the pyrochlore structure belonging to the space group Fd3m.[15] Assuming $Bi_{1.34}CrNbO_6$ is of the pyrochlore type, one-third of the Bi^{3+} ions and one-seventh of the oxygen ions are missing in comparison with normal pyrochlore. Such a defect pyrochlore is rare. In $Pb_{1.5}Nb_2O_{6.5}$, the Pb^{2+} ions have been assumed to occupy the 16(d) sites.[2] In $TlSbWO_6$, the Tl^{1+} ions have been reported to occupy the 32(e) sites between the 8(b) and 16(d) sites.[8] Although the pyrochlore structure itself has been studied extensively, it is important in the establishment of the defect pyrochlore structure to determine the arrangement of atoms in the new phase, $Bi_{1.34}CrNbO_6$. Since there are only one or two positional parameters for the pyrochlore structure, the 23 reflection lines observed in the powder pattern are considered to be sufficient for structural analysis. Their intensities were calculated using the positions listed in Table 3. The site with $\bar{3}$m symmetry

Table 3. Atomic positions for $Bi_{1.34}CrNbO_6$

		Space group: Fd3m (No. 227)
		Lattice constant: 10.455 Å
		Cell content: $8Bi_{1.34}CrNbO_6$
	(0,0,0; 0,1/2,1/2; 1/2,0,1/2; 1/2,1/2,0)+	
Bi	16(d)	1/2,1/2,1/2; 1/2,1/4,1/4; 1/4,1/2,1/4; 1/4,1/4,1/2 occupancy probability: 67%
Cr(Nb)	16(c)	0,0,0; 0,1/4,1/4; 1/4,0,1/4; 1/4,1/4,0
O	48(f)	u,1/8,1/8; $\bar{u}$,7/8,7/8; 1/4−u,1/8,1/8; 3/4+u,7/8,7/8; 1/8,u,1/8; 7/8,$\bar{u}$,7/8; 1/8,1/4−u,1/8; 7/8,3/4+u,7/8; 1/8,1/8,u; 7/8,7/8,$\bar{u}$; 1/8,1/8,1/4−u; 7/8,7/8,3/4+u u=0.330
O	8(b)	3/8,3/8,3/8; 5/8,5/8,5/8 occupancy probability: 0%

was chosen as the origin. Firstly, the bismuth and oxygen vacancies were assumed to lie on one-third of the 16(d) sites and on the 8(b) sites, respectively, as shown in Fig. 1. Then, minimization of the reliability factor R to the final value of 0.0564 yielded the following results, u=0.330 and B=4.18 Å^2. The observed and calculated intensities for these parameters are listed on the right side of Table 1, and good agreement between both intensities is obtained. The density of the sample measured with a pycnometer was 6.01 g/cm^3, which corresponds to 8 formula weights of $Bi_{1.34}CrNbO_6$ per unit cell (theoretical density, 6.04 g/cm^3). When the random distribution of Bi^{3+} ions in the 16(d) and 8(b) sites or of oxygen ions in the 48(f) and 8(b) sites was assumed, the minimum values of R became considerably larger. This fact indicates erroneous assumptions. Next, when the Bi^{3+} ions were assumed to lie only on the

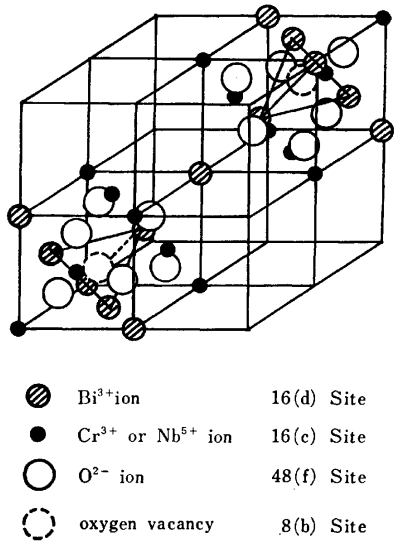

Fig. 1. Crystal structure of defect pyrochlore $Bi_{1.34}CrNbO_6$.

32(e) sites, instead of the 16(d) sites, the final R value was refined to be 0.0562 with $u_a=0.495$ (32(e) positional parameter) and $B=4.04$ Å^2. The slight decrease in the R value might be related with experimental errors in the intensity measurement. The u_a value obtained is close to 0.500, a value indicating the 16(d)-site occupancy of Bi^{3+} ions, differing from that ($u_a=0.403$) in $TlSbWO_6$.[8] From these results, it is not necessary to conclude that the Bi^{3+} ions lie on the 32(e) sites and that they deviate slightly from the 16(d) sites. The selected interatomic distances and angles in $Bi_{1.34}CrNbO_6$ were calculated on the first assumption, and are shown in Table 4. These values are in reasonable accord with the ionic sizes of Shannon and Prewitt.[14] The O–Cr(Nb)–O angles are a measure of the distortion of the oxygen octahedra, since all of these angles are 90° in the case of a regular octahedron.

Table 4. Selected interatomic distances and angles for $Bi_{1.34}CrNbO_6$

Distance	Å	Angle	Deg.
Bi–O	2.56	O–Bi–O	63.5
Cr(Nb)–O	2.03	O–Bi–O	116.5
O–O	2.70	O–Bi–O	180.0
O–O	3.03	O–Cr(Nb)–O	83.3
Bi–Bi	3.70	O–Cr(Nb)–O	96.7

In order to further examine this defect pyrochlore phase, the values of the reliability factor R for two series of proposed formulae, $Bi_{2-x}CrNbO_{7-3x/2}$ and $Bi_{2-x}Cr_{2-3x/2}Nb_{3x/2}O_6$, were calculated using the two parameters ($u=0.330$ and $B=4.18$ Å^2) determined previously. Figure 2 shows the relationship between R and x. In both curves, the R values are minima respectively when $x=2/3$, the x value of which corresponds to the chemical formula of $Bi_{1.34}CrNbO_6$. The R values rapidly increase with any deviation from this x value. This result provides conclusive proof that the defect pyrochlore phase has the true composition, $Bi_{1.34}CrNbO_6$.

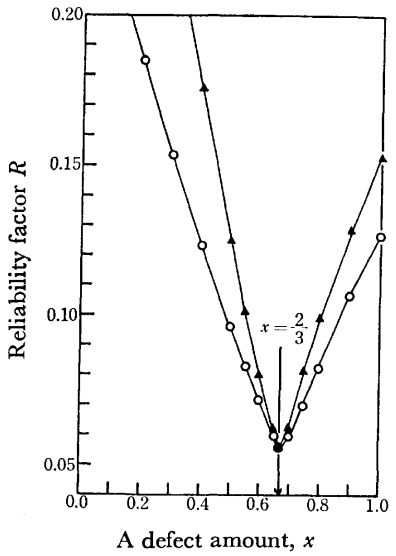

Fig. 2. Relation between R and x for two series of proposed formula.

Dielectric Properties. The six defect pyrochlores prepared had dielectric constants of *ca.* 30—110 at room temperature, as shown in Table 1, although no correction was made in regard to sample porosity. These values are relatively high in general, which fact renders them worth examining. The dielectric constants of Nb^{5+}-containing pyrochlores are considerably higher than those of Ta^{5+}- and Sb^{5+}-containing pyrochlores. Since these defect pyrochlores are of the cubic and centrosymmetric space group, the dielectric measurements were carried out in the temperature range from −150 to 20 °C. Figure 3 shows the temperature dependence of ε and tan δ for $Bi_{1.34}CrNbO_6$ and $Bi_{1.34}FeNbO_6$. No dielectric anomaly was observed, and ε and tan δ increased monotonically with increasing temperature. These defect pyrochlores are considered to be paraelectric in this temperature range. They have high electric resistivities which, although not

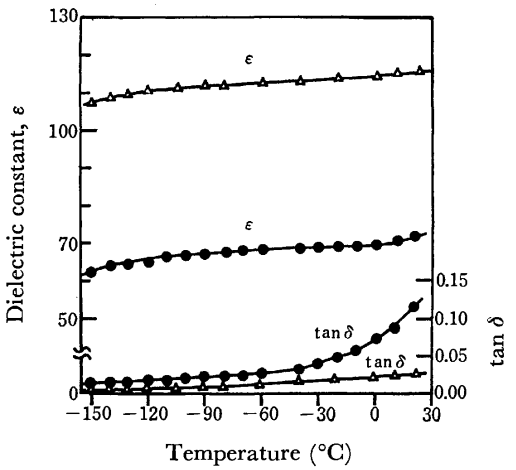

Fig. 3. Temperature dependence of ε and tan δ for two defect pyrochlores.
●: $Bi_{1.34}CrNbO_6$. △: $Bi_{1.34}FeNbO_6$.

measured directly, were high enough to balance a capacitance bridge. There should be a little change even when transition metal ions are present in the ambivalent oxidation state, since the electrical resistivity is expected to be sensitive to the state.

Discussion

The A cations in the pyrochlore structure are usually in eightfold coordination. In the case of $Bi_{1.34}CrNbO_6$, however, the Bi^{3+} ions have a sixfold coordination with an equivalent distance of 2.56 Å, since the 8(b) sites are not occupied by oxygen ions. The Cr^{3+} and Nb^{5+} ions are bonded octahedrally to six oxygen ions at a distance of 2.03 Å. The positional u parameter of 0.330 is within the range of 0.305 to 0.355 reported by Sleight[16] for twelve pyrochlores and is close to the values for rare-earth pyrochlores. The oxygen octahedra are slightly distorted because of the deviation from the 0.3125 value for a regular octahedron. The oxygen-oxygen distances in the octahedra are 2.70 and 3.03 Å. The octahedra form corners with other octahedra to form a three-dimensional framework, as shown in Fig. 4. The 8(b)-site vacancies are located at the

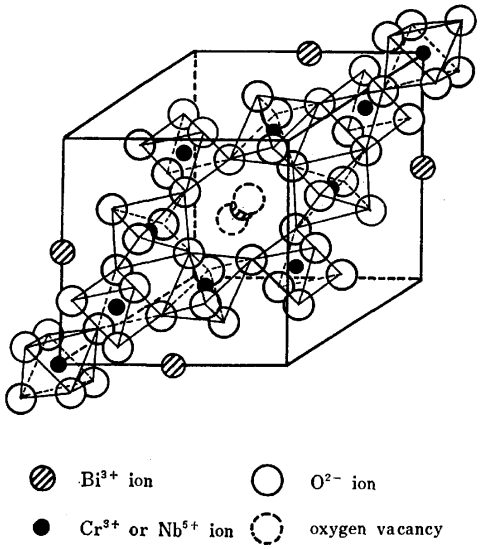

Fig. 4. Framework structure of defect pyrochlore $Bi_{1.34}CrNbO_6$.

centers of bismuth tetrahedra and the occupancy probability of Bi^{3+} ions is 67% at the tetrahedral corners. The Bi-Bi distance was 3.70 Å and the bismuth ions are in close proximity to each other, being unscreened. In normal pyrochlores, the 8(b) sites are filled by oxygen ions and, therefore, the defect pyrochlore structure should be unstable because of the repulsion between the Bi^{3+} ions, judging only from electrostatic considerations. No pyrochlore phases, however, were formed when the Bi^{3+} ion was replaced by a La^{3+} or Y^{3+} ion as the A-site ion in the $A_{1.34}CrNbO_6$ and A_2CrNbO_7 forms. Occupancy by a La^{3+} or Y^{3+} ion appears to be unfavorable for the formation of such a defect pyrochlore structure, while occupancy by a Bi^{3+} ion appears favorable. The ionic sizes of La^{3+}, Y^{3+}, and Bi^{3+} ions are 1.18, 1.015, and 1.11 Å respectively,[14] and these ions are of suitable size for the A-site ion in the pyrochlore structure. Consequently, the essential nature of A-site ions must be considered in the formation of defect pyrochlores. That is to say, the La^{3+} and Y^{3+} ions are of ionic character and the Bi^{3+} has a significant contribution of covalent character. Even though the Bi atom is completely ionized to the valence state of +3, the Bi^{3+} ion has outer $6s^2$ core electrons which easily polarize the neighiboring oxygen ions and exhibit directional bonding. The remarkable arrangement of unscreened Bi^{3+} ions in $Bi_{1.34}CrNbO_6$ has often been found for oxides containing an inert-pair ion, as in PbO, Bi_2O_3, and SnO.[17] The abnormal stereochemistry of these compounds is due to s-p hybridization. The trap-mediated metal-metal bond pointed out by Goodenough *et al.*[4] may also be responsible for the defect pyrochlore formation of $Bi_{1.34}CrNbO_6$. The 8(b)-vacancy sites act as traps for the outermost electrons of the Bi^{3+} ions, and the 6s and 6p orbitals spread out into the vacancy sites, where considerable electron density is concentrated. The electrostatic repulsion between the Bi^{3+} ions may be counteracted by the transfer of the outermost electrons to the vacancy sites, and the defect pyrochlore structure of $Bi_{1.34}CrNbO_6$ is stabilized by this Bi-Bi bonding. A 67% occupancy of Bi^{3+} ions at the 16(d) sites is naturally determined from the electroneutrality condition, considering that the Cr^{3+} and Nb^{5+} ions contribute to the framework of the defect pyrochlore structure. The value itself exhibits no significant meaning in this case. However, the case appears to be different for $TlSbWO_6$ where the occupancy probability of Tl^{1+} ions is only 50%. In the case of $TlSbWO_6$, the 32(e) positional parameter for the Tl^{1+} ion has been determined to be $u_a=0.403$.[8] The 32(e) site lies on a straight line between the 16(d) and 8(b) sites. As shown in Fig. 1, the 16(d) and 8(b) sites are the corners and center of the cationic tetrahedron, respectively. The 32(e) site corresponds to the 16(d) site at $u_a=0.500$, and to the 8(b) site at $u_a=0.375$. Consequently, the Tl-Tl distance becomes smaller with decreasing u_a. In $TlSbWO_6$, the 32(e)-site occupancy of Tl^{1+} ions, which deviates considerably from the 16(d) site, would enable the outermost electrons to overlap sufficiently at the vacancy sites despite the low occupancy probability. The circumstances under which the trap-mediated bond is formed may be severe because of the rather large Tl-Tl distance under the condition that the Tl^{1+} ions occupy half of the 16(d) sites. For that reason, the assumption that the Bi^{3+} ions occupy the 32(e) site with $u_a=0.495$ in $Bi_{1.34}CrNbO_6$ might be correct, although deviation from the 16(d) sites is slight. This slight deviation is probably due to the fact that the occupancy probability of A-site ions is higher in $Bi_{1.34}CrNbO_6$ than in $TlSbWO_6$. Thus, the Bi^{3+} ions not only occupy open spaces in the framework, but also play an important role in the formation of defect pyrochlore structures. $Bi_{1.34}CrNbO_6$ and related compounds are rare examples of a defect pyrochlore type which has vacancies at the A sites and also at special oxygen sites.

(Received February 21, 1977)

Two cobalt(III) complexes containing terdentate thioethers, bis[(2-aminoethylthio)acetato]cobalt(III)(1+), and bis[3-(2-aminoethylthio)propionato]cobalt(III)(1+) were prepared and separated into five and six geometrical isomers, respectively, by ion-exchange column chromatography. The isomers were identified on the basis of their electronic absorption and NMR spectra. The circular dichroism spectra of optically resolved isomers were measured and discussed in relation to the absolute configurations.

Some cobalt(III) complexes with multidentate thioether ligands have so far been reported.[2-15] It appears that the presence of thioether donor atoms induces an extreme specificity concerning the formation of geometrical isomers.[6-9] As an example, of the bis(terdentate) type cobalt(III) complexes with linear terdentate ligands having the donor atom sequence N–S–N[11,14] or O–S–O,[15] only one or two geometrical isomers of three possible ones have been isolated. Recently, a bis(L-methioninato)cobalt(III) complex[11] of the $[Co(N)_2(O)_2(S)_2]$ type has been prepared and its three geometrical isomers obtained. The complex is the first example for the isolation of all the possible isomers of a complex with multidentate thioethers.

In the present work, two linear terdentate ligands having the donor atom sequence N–S–O, (2-aminoethylthio)acetic acid (Haeta=$NH_2CH_2CH_2SCH_2CO_2H$) and 3-(2-aminoethylthio)propionic acid (Haetp=$NH_2CH_2CH_2SCH_2CH_2CO_2H$), were used, and the absorption and circular dichroism (CD) spectra of their cobalt(III) complexes studied. For the bis(terdentate-*N,S,O*) type cobalt(III) complexes, six geometrical isomers are possible. So far no report seems to have appeared with respect to the isolation of six geometrical isomers of such $[Co(A–B–C)_2]$ type complex, though two isomers of $[Co(aeta)_2]^+$ have recently been reported.[16]

Experimental

Preparation, Separation, and Optical Resolution of the Complexes. (1) Bis[(2-aminoethylthio)acetato]cobalt(III) Chloride, [Co(aeta)$_2$]Cl: To a hot solution (*ca.* 70 °C) of 9 g cobalt(II) chloride hexahydrate in 80 cm^3 of water was added a solution of 9.35 g of (2-aminoethylthio)acetic acid hemihydrochloride[1] and 1.51 g of sodium hydroxide dissolved in 80 cm^3 of water. Fifteen grams of PbO_2 was gradually added to the mixed solution on a water bath, whereupon the solution turned violet. The mixture was stirred at 70 °C for *ca.* 40 min. The reaction mixture was filtered in order to remove excess lead dioxide after being cooled to room temperature. A considerable amount of brownish violet precipitate appeared which was filtered off.

The filtrate was poured into an ion exchange column containing Dowex 50 W×8 resin (200—400 mesh, Na^+ form, 4.5×40 cm). After the column had been swept with water, the adsorbed band was eluted with a 0.15 M aqueous solution of NaCl at the rate of 1 cm^3 per min. Five colored bands, brownish violet (A-1), purple (A-2), red (A-3), another red (A-4), and reddish purple (A-5), were eluted in this order. The eluates of these bands were separately concentrated in a vacuum evaporator and then the deposit, NaCl, was filtered off. To each of the filtrates was added a large amount of ethanol. The complexes thus obtained were crystallized from a minimum quantity of water by adding ethanol and then acetone, and dried in a vacuum desiccator over $CaCl_2$. The isomers were obtained in comparable yields, except for A-2 which showed a somewhat higher yield. Found for A-1: C, 25.76; H, 4.44; N, 7.71%. Calcd for $[Co(aeta)_2]Cl=C_8H_{16}N_2S_2O_4ClCo$: C, 26.49; H, 4.45; N, 7.72%. Found for A-2: C, 26.28; H, 4.62; N, 7.82%. Calcd for $[Co(aeta)_2]Cl=C_8H_{16}N_2S_2O_4ClCo$: C, 26.49; H, 4.45; N, 7.72%. Found for A-3: C, 25.04; H, 4.83; N, 7.81%. Calcd for $[Co(aeta)_2]Cl\cdot H_2O=C_8H_{18}N_2S_2O_5ClCo$: C, 25.24; H, 4.77; N, 7.36%. Found for A-4: C, 24.46; H, 5.10; N, 7.56%. Calcd for $[Co(aeta)_2]Cl\cdot 1.5H_2O=C_8H_{19}N_2S_2O_{5.5}ClCo$: C, 24.65; H, 4.91; N, 7.15%. Found for A-5: C, 24.80; H, 4.85; N, 7.75%. Calcd for $[Co(aeta)_2]Cl\cdot H_2O=C_8H_{18}N_2S_2O_5ClCo$: C, 25.24; H, 4.77; N, 7.36%.

Of the five isomers, four except A-1 were optically resolved.

A-2, $(-)_{589}$-[Co(aeta)$_2$]Cl, (trans(O)): This isomer was resolved by using $(-)_{589}$-K[Co(edta)]·2H_2O as a resolving agent. The racemic chloride (0.36 g) and the resolving agent (0.21 g) were dissolved in 2 cm^3 of water at 40 °C. After being cooled to room temperature, the mixed solution was allowed to stand overnight in a refrigerator. A small amount of less soluble diastereomer was deposited as violet needles and recrystallized from a minimum quantity of water. The yield was 0.25 grams. Found: C, 27.91; H, 4.87; N, 7.33%. Calcd for $(-)_{589}$-$[Co(aeta)_2][Co(edta)]\cdot 5H_2O=C_{18}H_{38}N_4S_2O_{17}Co_2$: C, 28.28; H, 5.01; N, 7.33%.

Optically active chloride was obtained from the diastereomer by using an anion exchange resin (Dowex 1×8, Cl^- form). Found: C, 26.23; H, 4.49; N, 7.71%. Calcd for $(-)_{589}$-$[Co(aeta)_2]Cl=C_8H_{16}N_2S_2O_4ClCo$: C, 26.49; H, 4.45; N, 7.72%.

A-3, $(-)_{589}$-[Co(aeta)$_2$]Cl·H$_2$O, (trans(S)): Attempts to resolve this isomer by means of the resolving agents $(-)_{589}$-K[Co(edta)]·2H_2O, $(+)_{589}$-Na[Co(ox)$_2$(en)]·H_2O, $Na_2[Sb_2(d\text{-tart})_2]\cdot 2H_2O$, and $Ag_2(d\text{-}H_2tart)$; (d-$H_4tart=C_4O_6H_6$), were unsuccessful. However, spontaneous resolution[17] was observed for the crystals prepared as follows: 0.5 g of the racemic chloride monohydrate was dissolved in 5 cm^3 of water at 40 °C and the solution was kept standing in a refrigerator for several days for crystallization. Crystals arbitrarily chosen then showed optical activity. No hemihedral facets, however, were found for the crystals. Found: C, 24.93; H, 4.83; N, 7.45%. Calcd for $(-)_{589}$-[Co(aeta)$_2$]-

* Present address: Department of Chemistry, The University of Tsukuba, Ibaraki, 300-31.

$Cl \cdot H_2O = C_8H_{18}N_2S_2O_5ClCo$: C, 25.24; H, 4.77; N, 7.36%.

A-4, $(+)_{589}$-[Co(aeta)$_2$]$^+$, (cisciscis): The racemic chloride (0.39 g), dibenzoyl-*d*-tartaric acid (*d*-H_2tart-bz_2) (0.38 g), and sodium hydroxide (0.08 g) were dissolved in 10 cm^3 of water at 40 °C. The mixed solution was then evaporated to 2 cm^3 and cooled in a refrigerator overnight. The red diastereomer deposited was recrystallized from 2 cm^3 of hot water by adding acetone. Found: C, 36.47; H, 4.75; N, 4.92%. Calcd for $(+)_{589}$-[Co(aeta)$_2$]$_2$(*d*-tart-bz_2)$\cdot 5.5H_2O$ = $C_{34}H_{55}N_4S_4O_{21.5}Co_2$: C, 36.79; H, 4.99; N, 5.05%.

Optically active chloride was obtained from the diastereomer by using an anion exchange resin (Dowex 1×8, Cl^- form). The CD spectrum of this complex was measured with the eluate, and the concentration was calculated from the CD intensity referring to that of the diastereomer.

A-5, $(-)_{589}$-[Co(aeta)$_2$]Cl$\cdot 2.25H_2O$, (trans(N)): The racemic chloride (0.39 g) and the resolving agent $Na_2[Sb_2$(*d*-tart$)_2]\cdot 2H_2O$ (0.16 g) were dissolved in 3 cm^3 of water at 40 °C. The mixed solution was allowed to stand for a few days in a refrigerator to crystallize. The less soluble diastereomer (reddish purple) precipitated was filtered off and recrystallized from 2 cm^3 of hot water by adding ethanol. This was converted into the optically active chloride by using an anion exchange resin (Dowex 1×8, Cl^- form). Found: C, 23.46; H, 4.94; N, 6.90%. Calcd for $(-)_{589}$-[Co(aeta)$_2$]-$Cl \cdot 2.25H_2O = C_8H_{20.5}N_2S_2O_{6.25}ClCo$: C, 23.83; H, 5.12; N, 6.95%.

(2) Bis[3-(2-aminoethylthio)propionato]cobalt(III) Chloride, [Co(aetp)$_2$]Cl: This complex was prepared and separated according to the same method as that for [Co(aeta)$_2$]Cl with use of 3-(2-aminoethylthio)propionic acid[1] instead of (2-aminoethylthio)acetic acid.

Five colored bands, brownish violet (B-1), purple (B-2), another purple (B-3+B-4), reddish purple (B-5), and violet (B-6), were eluted in this order. The yields for B-1 and B-2 isomers were very low. It was confirmed by the absorption spectral behavior in the thioether charge transfer band region that the third eluate consists of two isomers B-3 and B-4, and that the B-1, B-2, and B-4 have a configuration in which the two sulfur atoms occupy *trans* positions. The eluates were separately concentrated in a vacuum evaporator and the deposit, NaCl, was filtered off. To each of the concentrated solution was added a large amount of ethanol. The desired complex was collected by filtration and recrystallized from a small amount of water by adding ethanol and acetone, and then dried in a vacuum desiccator over $CaCl_2$. However, complete separation of B-3 and B-4 isomers by means of an ion exchange resin (Dowex 50 W×8 or SP-Sephadex C-25) was unsuccessful. The pure products of these two isomers were obtained as follows. After removal of excess laed dioxide, the reaction mixture was evaporated to 50 cm^3 and cooled in an ice bath, and B-3 isomer was then crystallized as the bromide salt. On the other hand, the pure product of B-4 isomer could be fractionally crystallized from the mixed eluate of B-3 and B-4 isomers because of its low solubility. Found for B-1: C, 27.52; H, 5.70; N, 6.44%. Calcd for [Co(aetp)$_2$]$Cl \cdot 2.5H_2O = C_{10}H_{25}N_2S_2O_{6.5}ClCo$: C, 27.56; H, 5.78; N, 6.43%. Found for B-2: C, 26.76; H, 6.14; N, 5.90%. Calcd for [Co(aetp)$_2$]$Cl \cdot 4H_2O = C_{10}H_{28}N_2S_2O_8ClCo$: C, 25.95; H, 6.10; N, 6.05%. Found for B-3: C, 21.74; H, 5.06; N, 5.23%. Calcd for [Co(aetp)$_2$]$Br \cdot 3.5H_2O \cdot 1/2NaBr = C_{10}H_{27}N_2S_2O_{7.5}BrCo \cdot 1/2$-NaBr: C, 21.85; H, 4.95; N, 5.10%. Found for B-4: C, 27.96; H, 5.43; N, 6.58%. Calcd for [Co(aetp)$_2$]$Cl \cdot 2H_2O = C_{10}H_{21}N_2S_2O_6ClCo$: C, 28.14; H, 5.67; N, 6.56%. Found for B-5: C, 29.18; H, 5.50; N, 6.90%. Calcd for [Co(aetp)$_2$]-$Cl \cdot H_2O = C_{10}H_{22}N_2S_2O_5ClCo$: C, 29.38; H, 5.42; N, 6.85%. Found for B-6: C, 27.60; H, 5.73; N, 6.47%. Calcd for [Co(aetp)$_2$]$Cl \cdot 2.5H_2O = C_{10}H_{25}N_2S_2O_{6.5}ClCo$: C, 27.56; H, 5.78; N, 6.43%.

B-3, $(-)_{589}$-[Co(aetp)$_2$]Cl$\cdot 2H_2O$, (trans(O)): The racemic bromide (0.55 g) and the resolving agent $K_2[Sb_2$(*d*-tart$)_2]\cdot 3H_2O$ (0.32 g) were dissolved in 5 cm^3 of water at 50 °C. After cooling to room temperature, the mixed solution was allowed to stand for a week in a refrigerator. The less soluble diastereomer deposited was recrystallized from a small amount of water, and converted into the chloride salt by using an anion exchange resin (Dowex 1×8, Cl^- form). Found: C,23.47; H,4.68; N,5.40%. Calcd for $(-)_{589}$-[Co(aetp)$_2$]$Cl \cdot 2H_2O \cdot 1.2KCl = C_{10}H_{24}N_2S_2O_6ClCo \cdot 1.2KCl$: C,23.26; H,4.69; N,5.43%.

B-2, $(+)_{589}$-[Co(aetp)$_2$]$^+$, (mer-trans(S)); *B-4, $(+)_{589}$-[Co(aetp)$_2$]$^+$*, (trans(S)); *B-5, $(+)_{589}$-[Co(aetp)$_2$]$^+$*, (cisciscis); *and B-6, $(+)_{589}$-[Co(aetp)$_2$]$^+$*, (trans(N)): These four isomers were partially or completely resolved into their optical antipodes by chromatographic technique.

An aqueous solution containing 0.1 g of the complex was poured into a column of SP-Sephadex C-25 (Na^+ form, 3×120 cm). The adsorbed band was eluted with a 0.1 M aqueous solution of $K_2[Sb_2$(*d*-tart$)_2]\cdot 3H_2O$ at the rate of 0.3 cm^3/min. Under these conditions, 7—10 days were necessary for the complete elution of the complex, which produced a broad band. The eluate was separated into fractions of 5 cm^3 each. A few fractions eluted first, which showed CD spectra completely enantiomeric to those of the last fractions, were collected and after removal of the excess elution agents converted into the chloride salt by using an anion exchange resin (Dowex 1×8, Cl^- form). This eluate of the chloride salt was used to measure the CD spectrum, and its concentration was calculated from the optical density referring to that of the racemate.

In all of the four isomers, the first eluates showed positive optical rotations for the Na-D line. A complete band separation into the antipodes was only observed for B-4 isomer.

Measurements. The electronic absorption spectra were measured on a Shimadzu UV-200 spectrophotometer in aqueous solutions. The CD spectra were obtained with a Jasco MOE-1 spectropolarimeter, by use of a cell with 1 cm pathlength. A Jasco DIP-4 digital polarimeter was used to check the optical rotations. The ^1H NMR spectra were recorded in deuterium oxide on a Varian XL-100-15 spectrometer with DSS as the internal reference. All the measurements were carried out at room temperature.

Results and Discussion

Separation of Isomers. For the present [Co(terdentate-*N,S,O*)$_2$]$^+$ type complexes, six geometrical isomers are possible. They are denoted by *tr.tr.tr.*, *trans(S)*, *trans(O)*, *trans(N)*, *cisciscis*, and *mer-trans(S)*, respectively, as shown in Fig. 1.

In the [Co(aeta)$_2$]$^+$ complex, five geometrical isomers were obtained. A-1 and A-2 seem to correspond to the two isomers reported by Hori[16] from a comparison of absorption spectra. For the [Co(aetp)$_2$]$^+$ complex, six geometrical isomers were separated chromatographically, which is the first example for the isolation of all the possible isomers of the [Co(A–B–C)$_2$] type complex. A molecular model examination reveals that the aeta ligand, which forms two five-membered chelate rings by coordination, strongly prefers the facial coordina-

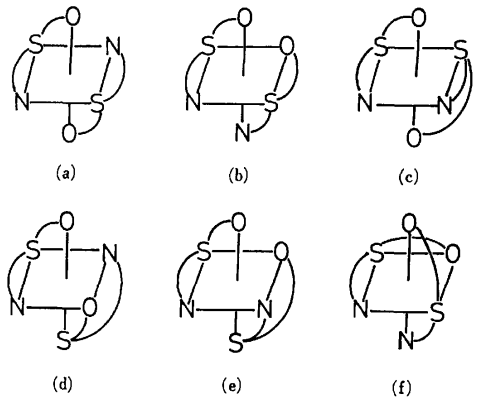

Fig. 1. Six possible geometrical isomers for the [Co(terdentate-*N,S,O*)$_2$]$^+$ type complex: (a) *tr.tr.tr.*, (b) *trans(S)*, (c) *trans(O)*, (d) *trans(N)*, (e) *cisciscis*, and (f) *mer-trans(S)*.

tion, whereas the aetp ligand which forms a five- and a six-membered chelate ring will take the meridionally coordinated form readily. It is therefore reasonable to expect that the *mer-trans(S)* isomer does not exist in the aeta complex. These circumstances seem to be common with the bis(terdentate) type cobalt(III) complexes containing linear *O,S,O*-[15] or *O,N,O*-terdentate[18-21] ligands.

An optical antipode exists for each five isomers of the six geometrical ones, except for *tr.tr.tr.* which has an inversion center. Accordingly, A-1 and B-1 isomers which could not be optically resolved are expected to have the *tr.tr.tr.* geometry.

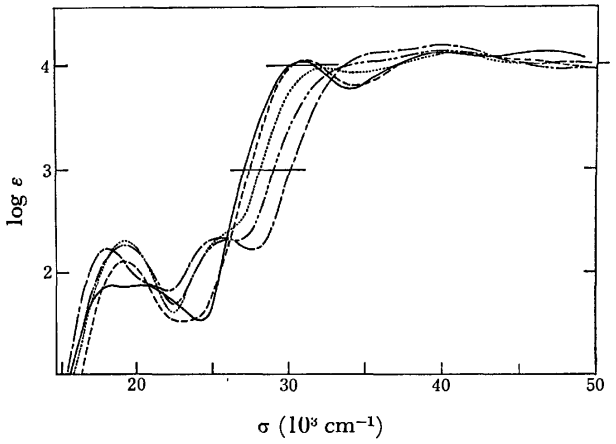

Fig. 2. Absorption spectra of the isomers of [Co(aeta)$_2$]-Cl: A-1 *tr.tr.tr.* (——), A-2 *trans(O)* (·—·—·), A-3 *trans(S)* (-----), A-4 *cisciscis* (—··—··—), and A-5 *trans(N)* (·····).

Absorption Spectra and Configuration Assignments. The absorption spectra of [Co(aeta)$_2$]$^+$ are shown in Fig. 2 and summarized in Table 1. In the near-ultraviolet region, the complexes show intense sulfur-to-metal charge transfer bands. The bands for A-1 and A-3 are located at lower energy side than those for the other three isomers. The charge transfer band of this type has been recognized to occur at a lower energy side for the cobalt(III) complexes with two ligating S atoms

Table 1. Absorption data of isomers of [Co(aeta)$_2$]Cl and [Co(aetp)$_2$]Cl

[Co(aeta)$_2$]Cl[a] Isomer	Configuration	σ_{max}[b] (log ε) First d-d band	Second d-d band	Charge transfer band region
A-1	*tr.tr.tr.*	18.4(1.87)		30.9(4.04)

in *trans* positions than for the corresponding *cis* complexes.[12,13,15] Additional support was recently given to this absorption spectral criterion by the X-ray crystal structure analysis of *trans(S)*-[Co(*S*-methyl-L-cysteinato)$_2$]ClO$_4$·H$_2$O.[22] Thus, A-1 and A-3 isomers can be assigned to the *trans(S)* or *tr.tr.tr.* configuration and others to the *trans(O)*, *trans(N)*, or *cisciscis* one.

In the first d-d absorption band region, the expected splittings can be calculated semiempirically;[23] the *tr.tr.tr.* and *trans(N)* isomers should have the component of lowest energy, since the sulfur atom in the present terdentate ligands is between the oxygen of the carboxyl group and the nitrogen of the amino group in the spectrochemical series.[1] The *tr.tr.tr.* and *trans(O)* isomers should have one component in close proximity to the transition of [Co(N)$_6$], and the splitting for *tr.tr.tr.* isomer should be greater than those for *trans(N)* and *trans(O)* forms. The *trans(S)* and *cisciscis* isomers should have two and three components, respectively, in about the same region.

Of the two isomers assigned to the *trans(S)* or *tr.tr.tr*, A-1 exhibits two splitting components with the same molar extinction coefficients in the first absorption band

region, while A-3 shows apparently a sharp band. This indicates that A-1 is *tr.tr.tr.* and A-3 *trans(S)*.

On the other hand, of the three isomers assigned to the *trans(O)*, *trans(N)*, or *cisciscis*, A-2 exhibits an explicit shoulder at the high energy side of the major peak in the first absorption band region, while both A-4 and A-5 show a sharp peak. In the [Co(L-methioninato)$_2$]-Br[12] complex, both *trans(N)* and *trans(O)* isomers showed a marked splitting in the first absorption band region, their splitting patterns differing from each other; the *trans(O)* isomer showed a broad band with a shoulder at high energy side of the major peak, the *trans(N)* one at low energy side. This confirms that A-2 isomer is *trans(O)*.

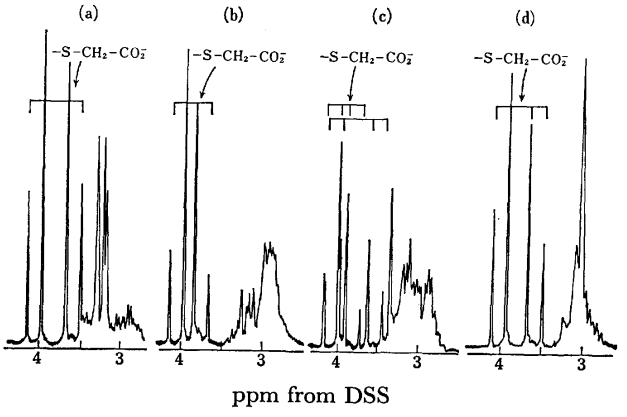

Fig. 3. The NMR spectra of the isomers of [Co(aeta)$_2$]-Cl in D_2O: (a) A-2 *trans(O)*, (b) A-3 *trans(S)*, (c) A-4 *cisciscis*, and (d) A-5 *trans(N)*.

The absorption spectra of A-4 and A-5 isomers are similar to each other, though there is a difference with respect to the position of thioether charge transfer band. ^{1}H NMR spectra of these isomers are shown in Fig. 3. A-2, A-3, and A-5 isomers exhibit a quartet due to methylene protons between carboxyl group and sulfur atom,[15] whereas A-4 shows two sets of quartet. The *trans(S)*, *trans(O)*, and *trans(N)* structures have C_2 symmetry, the *cisciscis* structure C_1. The latter isomer should show the most complicated pattern. Accordingly, A-4 can be assigned to *cisciscis*, and A-5 to *trans(N)*. Further support is given by the signals in the region of amine protons. The amine signals appear at 6.17 and 6.58 ppm from DSS for A-2, at 4.62 and 4.98 ppm for A-3, at 4.49, 4.90, and 6.36 ppm for A-4, and at 5.26 and 6.67 ppm for A-5. This is explained qualitatively in terms of the magnetic anisotropy associated with the C–O single bond.[24-27] In each of the present isomers there are two amine groups; two groups of *trans(S)* and *trans(N)* isomers and one group of *cisciscis* isomer are in the shield position from the C–O bond of the other ligand, whereas one group of *cisciscis* isomer and two groups of *trans(O)* isomer are deshielded by the C–O bond of the other ligand. It is possible to expect that *cisciscis* isomer with C_1 symmetry shows the most complicated signals over the wider region than the other three isomers with C_2 symmetry.

The absorption spectra of six isomers of [Co(aetp)$_2$]$^+$ are shown in Fig. 4 and summarized in Table 1. According to the same discussion as described above, B-1

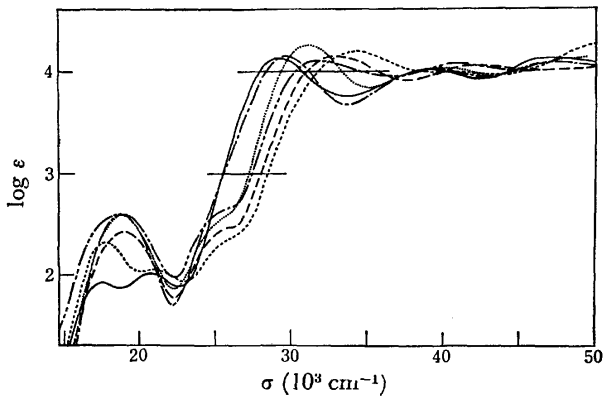

Fig. 4. Absorption spectra of the isomers of [Co(aetp)$_2$]-Cl: B-1 *tr.tr.tr.* (——), B-2 *mer-trans(S)* (·····), B-3 *trans(O)* (------), B-4 *trans(S)* (·-·-·), B-5 *cisciscis* (—·—·), and B-6 *trans(N)* (—···—); B-3 isomer is a bromide salt.

isomer can be assigned to *tr.tr.tr.* and B-3 to *trans(O)*. Of the remaining four isomers, B-5 and B-6 have the thioether charge transfer bands at the higher energy side than B-2 and B-4. Therefore, the former two and the latter two isomers can be assigned to the configurations with two ligating S atoms in *cis* and *trans* positions, respectively. In the first absorption band region, B-5 shows a sharp band, while B-6 exhibits a vague shoulder at the low energy side of the major peak. The spectral behavior corresponds to the expectation from semiempirical theory, and B-5 can be assigned to *cisciscis* and B-6 to *trans(N)*. The B-2 and B-4 isomers were assigned to *mer-trans(S)* and *fac-trans(S)* configurations, respectively, on the basis of the low yield of B-2 (see Experimental), and of absorption spectral behavior in which the low energy thioether charge transfer band of B-2 occurs at an exceptional position. These assignments have good correlation with the column chromatographic behavior. Namely, the complexes [Co(aeta)$_2$]$^+$ and [Co(aetp)$_2$]$^+$ have the same elution order of isomers except for B-2-*mer-trans(S)* isomer; the order is *tr.tr.tr.*, *trans(O)*, *trans(S)*, *cisciscis*, and *trans(N)* for both series.

Thus, the electronic absorption spectra of the corresponding isomers between [Co(aeta)$_2$]$^+$ and [Co(aetp)$_2$]$^+$ complexes are similar to each other but differ in detail. Firstly, the first d-d band intensities of the isomers of [Co(aetp)$_2$]$^+$ are two or three times larger than those of the corresponding isomers of [Co(aeta)$_2$]$^+$. Such kind of intensity difference has been observed between *trans(N)-RR*-[Co(L-promp)$_2$]$^-$ and *trans(N)-RR*-[Co(L-proma)$_2$]$^-$ complexes,[28] where L-promp and L-proma are L-prolinate-*N*-monopropionate and L-prolinate-*N*-monoacetate, respectively. Secondly, in the aetp complexes, the thioether charge transfer band is shifted to a lower energy side than that of the corresponding aeta isomer, and the shift direction is the same as that of the first d-d absorption band.

CD Spectra. The CD spectra are shown in Figs. 5—8 and Table 2. The complexes have two CD contributions, one from the configurational chirality due to the skew pair of chelate rings and the other from the chirality due to the sulfur donor atoms, though both contributions can not be separated. The observed CD

a) Wave numbers are given in 10^3 cm^{-1} unit. b) CD spectra were measured with eluates. c) A shoulder.

spectra differ significantly among the different geometrical isomers, but resemble the corresponding geometrical isomers of $[Co(aeta)_2]^+$ and $[Co(aetp)_2]^+$. Accordingly, it is convenient to discuss each pair of geometrical isomers individually.

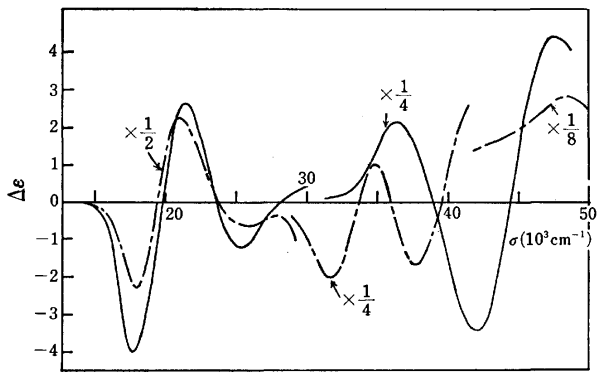

Fig. 5. CD spectra of *trans(O)* complexes: $(-)_{589}$-$[Co(aeta)_2]^+$ (——) and $(-)_{589}$-$[Co(aetp)_2]^+$ (·–·–·).

In the first absorption band region, both $(-)_{589}$-*trans(O)* aeta and $(-)_{589}$-*trans(O)* aetp complexes have two CD components, (−) and (+) from low energy side (Fig. 5), though three bands, (+), (−), and (+), have been observed for *trans(O)*-$[Co(L\text{-methioninato})_2]^+$ [12] and *trans(O)*-$[Co(S\text{-methyl-L-cysteinato})_2]^+$ [13] in the corresponding region. In the present *trans(O)* isomers with C_2 symmetry, there is a weaker field along the unique axis (O–Co–O) than along the other axes perpendicular to it. Thus it is predicted that the $^1A+{}^1B_b(C_2)$ level would be lower in energy than the $^1B_a(C_2)$ level. Consequently, the negative CD components at low energy are assigned to be $^1A+{}^1B_b(C_2)$, and the positive CD components at high energy $^1B_a(C_2)$. The absolute configurations of $(-)_{589}$-*trans(O)*-$[Co(aeta)_2]^+$ and $(-)_{589}$-*trans(O)*-$[Co(aetp)_2]^+$ are assigned to *ΔΔΛ*-(*RR*) and *ΔΔΛ*-(*SS*),[29] respectively, according to the CD sign of the $^1A+{}^1B_b(C_2)$ transition, where (*RR*) and (*SS*) represent the chiralities of the chiral sulfur atoms. The absolute configuration of $(-)_{589}$-*trans(O)*-$[Co(NH_2CH_2CH_2NHCH_2CO_2)_2]^+$,[30] which exhibits two CD

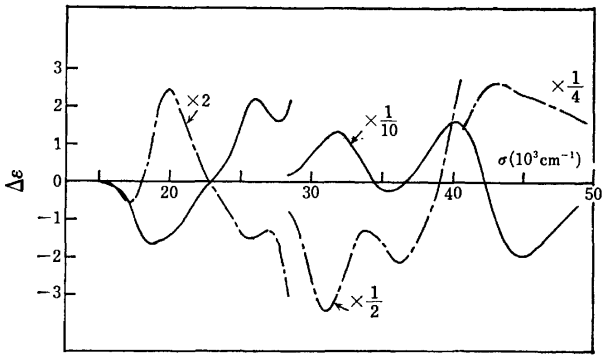

Fig. 6. CD spectra of *trans(N)* complexes: $(-)_{589}$-[Co(aeta)$_2$]$^+$ (——) and $(+)_{589}$-[Co(aetp)$_2$]$^+$ (·—·—·).

peaks of opposite sign, (−) and (+) from low energy side, in the first absorption band region, has been assigned to *ΔΔΛ*.

For the *trans(N)* isomers (Fig. 6), the aeta $(-)_{589}$-complex exhibits two negative CD bands at 18700 cm^{-1} ($\Delta\varepsilon=-1.63$) and *ca.* 20000 cm^{-1} ($\Delta\varepsilon=-1.48$), but the aetp $(+)_{589}$-complex shows two bands of opposite sign at 17200 cm^{-1} ($\Delta\varepsilon=-0.27$) and 19800 cm^{-1} ($\Delta\varepsilon=+1.25$). On the basis of a consideration similar to that mentioned above, the low energy band is assigned in each case to the $^1A\rightarrow{}^1B_a(C_2)$ transition and the high energy component to $^1A\rightarrow{}^1A+{}^1B_b(C_2)$. Worrell and Busch[7] studied some complexes containing a flexible quadridentate ligand, 1,8-diamino-3,6-dithiaoctane (dadt). Of these complexes, $(+)_{546}$-*sym-cis*-[Co(dadt)Cl$_2$]$^+$, $(+)_{546}$-*sym-cis*-[Co(dadt)ClH$_2$O]$^{2+}$ and $(+)_{546}$-*sym-cis*-[Co(dadt)(H$_2$O)$_2$]$^{3+}$, which have the two ligating NH_2 groups in *trans* positions and show a negative and a positive CD component from low energy side of the first absorption band region, were assigned to *Λ* absolute configurations, because in all three cases, the sign pattern is in agreement with that exhibited by the corresponding ethylenediamine and triethylenediamine complexes of *Λ* absolute configuration. The same argument is applied to the present system. The absolute configurations of $(-)_{589}$-*trans(N)*-[Co(aeta)$_2$]$^+$ and $(+)_{589}$-*trans(N)*-[Co(aetp)$_2$]$^+$ are assigned to *ΔΔΛ*-(*SS*) and *ΔΔΛ*-(*SS*) configurations, respectively, according to the sign of the $^1A+{}^1B_b(C_2)$ transition.

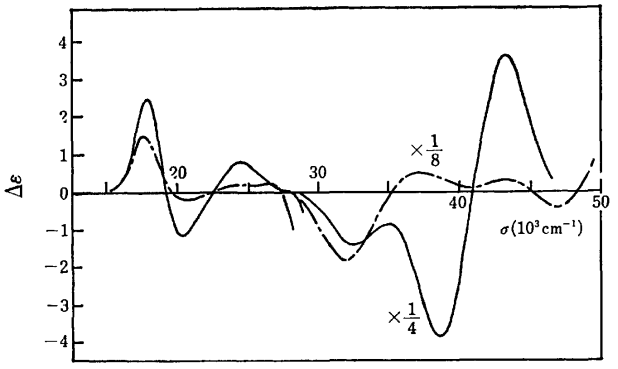

Fig. 7. CD spectra of *cisciscis* complexes: $(+)_{589}$-[Co(aeta)$_2$]$^+$ (——) and $(+)_{589}$-[Co(aetp)$_2$]$^+$ (·—·—·).

In the *cisciscis* isomers (Fig. 7), the parential arguments as above seem to have limited applicability because of the lowering of symmetry and the difficulty in the assignment of three components. However, the CD contribution of this geometrical isomer is mainly due to the configurational chirality, since the two chiral sulfur atoms form a meso combination ((*R*) and (*S*)). Therefore, the major CD component in the first absorption band region is related to the molecular framework; *cisciscis* isomers of both aeta and aetp $(+)_{589}$-complexes exhibit a strong positive and a negative band and can be assigned to *ΔΔΔ* configuration.

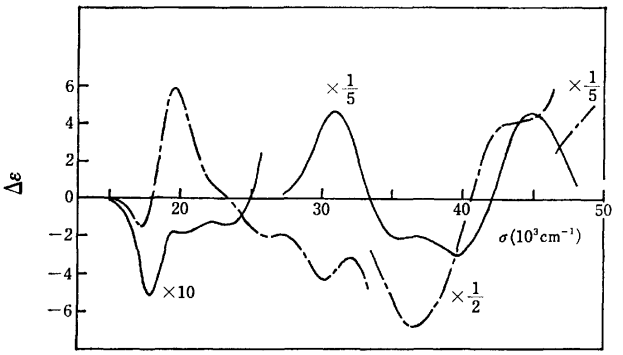

Fig. 8. CD spectra of *trans(S)* complexes: $(-)_{589}$-[Co(aeta)$_2$]$^+$ (——) and $(+)_{589}$-[Co(aetp)$_2$]$^+$ (·—·—·).

For the *trans(S)* isomers (Fig. 8), the aeta $(-)_{589}$-complex exhibits two weak CD components in the first absorption band region and a strong CD band in the thioether charge transfer band region, whereas the aetp $(+)_{589}$-complex shows a strong major CD band in the first absorption band region and a relatively weak band in the thioether charge transfer band region. These CD patterns cannot be related directly to their absolute configurations, because the *trans(S)* forms do not have CD contribution due to the skew pair of chelate rings according to the ring pairing method[31] but only the contribution due to the two chiral sulfur donor atoms.

In the low energy thioether charge transfer band region, medium or strong CD bands are generally observed for all isomers. The correlation of the charge transfer CD spectra of the *trans(N)* isomers between the aeta and aetp complexes is good as regards position and sign; the aeta *ΔΔΛ*-(*SS*)-complex has a (+) band, the aetp *ΔΔΛ*-(*SS*)-complex a (−) band.

One-dimensional System of Square-planar Bis(1,2-dicyanovinylene-1,2-dithiolato)metal Complexes. I. The Crystal Structure of $[(C_4H_9)_4N]_2[Ni(mnt)_2]$ and $[(C_2H_5)_4N][Ni(mnt)_2]$

Akiko KOBAYASHI and Yukiyoshi SASAKI

Department of Chemistry, Faculty of Science, The University of Tokyo, The Research Centre for Spectrochemistry, Hongo, Tokyo 113

(Received March 19, 1977)

X-Ray crystal structure analyses of $[(C_4H_9)_4N]_2[Ni(mnt)_2]$ (I) and $[(C_2H_5)_4N][Ni(mnt)_2]$ (II) {mnt: 1,2-dicyanovinylene-1,2-dithiolato $C_4N_2S_2^{2-}$} have been carried out from the viewpoint of one-dimensional system. Crystals of (I) belong to triclinic system: $a=12.360(6)$, $b=11.138(12)$, $c=9.833(9)$ Å, $\alpha=118.43(9)$, $\beta=92.05(6)$, $\gamma=91.91(6)°$, space group $P\bar{1}$ with $Z=1$. The compound (II) forms monoclinic crystals, $P2_1/a$: $a=20.018(18)$, $b=16.079(9)$, $c=7.118(6)$ Å, $\beta=110.43(6)°$, $Z=4$. Both structures, solved by the heavy-atom method, have been refined anisotropically by least-squares procedure to $R=0.049$ and 0.050 for (I) and (II), respectively. The bond distances of diamagnetic $Ni(mnt)_2^{2-}$ anion and paramagnetic $Ni(mnt)_2^{1-}$ anion are compared. A columnar structure was found in the structure of (II). The $Ni(mnt)_2^{1-}$ ions form a diadic unit, that is a repeating unit of two anions, within the columns. The electrical conductivity data are measured along the direction parallel to the $Ni(mnt)_2^{1-}$ stacks in the temperature range from room temperature to 373 K. This compound behaves as a semiconductor in this temperature range.

Recent studies of high conductive platinum complex of $K_2Pt(CN)_4Br_{0.3}\cdot xH_2O$ and TCNQ salts[1] have revealed their metallic behavior. Their magnetic, electrical and optical properties are also originated from one-dimensional interactions associated with a columnar crystallographic structure.[1] Like TCNQ, bis(1,2-dicyanovinylene-1,2-dithiolato)metal complexes are known in some cases to form compounds with high electrical conductivities.[2,3] Furthermore these dithiolene complexes form a series of stable compounds with the same central metal ion in different oxidation states *e.g.*, in the Ni, Pd, Pt, the 0, −1, −2 charged complexes are well known.[4]

We report here X-ray diffraction studies on single crystals of tetrabutylammonium salt of diamagnetic $Ni(mnt)_2^{2-}$ and tetraethylammonium salt of paramagnetic $Ni(mnt)_2^{1-}$. Electrical conductivity measurements were also performed on single crystals of $[(Et)_4N][Ni(mnt)_2]$ by the use of the four-probe methods. We are interested in the relationship between the crystal structures and electrical properties of one-dimensional system.

Experimental

Data Collections and Structure Analyses. The compounds $[(n\text{-}Bu)_4N]_2[Ni(mnt)_2]$ (I) and $[(Et)_4N][Ni(mnt)_2]$ (II) were prepared by the published method.[4] The tetrabutylammonium salt and tetraethylammonium salt were chosen because we could obtain suitable single crystals for experiments. The red crystals of (I) and black crystals of (II) were obtained from the original product through recrystallization by slow evaporation from acetone solution. For the purpose of the X-ray diffraction work, a specimen $0.25\times0.20\times0.37$ mm was used for (I) and $0.075\times0.125\times0.38$ mm for (II). The intensity data set were collected with monochromatized Mo$K\alpha$ radiation by the ω-2θ scan technique out to $2\theta=60°$. Reflections were scanned at a rate of 2 ° minute in 2θ. Background counts of 10 s were taken at each end of the scan range. Independent 3559 significant reflections for which $|F|\geqq3\sigma(F)$ were obtained for (I) and 2635 for (II), respectively. The data were corrected for Lorentz and polarization effects. No corrections were made for absorption.

The crystal data are as follows:

$[(n\text{-}Bu)_4N]_2[Ni(mnt)_2]$ (I)	$[(Et)_4N][Ni(mnt)_2]$ (II)
triclinic $P\bar{1}$	monoclinic $P2_1/a$
$a=12.360(6)$ Å	$a=20.018(18)$ Å
$b=11.138(12)$	$b=16.079(9)$

Since Wilson's statistics indicated the presence of a center of symmetry, the space group $P\bar{1}$ was assumed for (I). For solution and refinement of the structure usual heavy-atom methods were employed. The atomic parameters were refined by the block-diagonal least-squares method, using anisotropic temperature factors for all the nonhydrogen atoms and isotropic ones for hydrogen atoms. The effects of the anomalous dispersion of Ni and S atoms were included in the calculation. Final reliability factors are: (I), $R=0.049$, (II), $R=0.050$. The positional and thermal parameters of all atoms are presented in Tables 1 and 2.

The calculations were performed on a HITAC 8700/8800 computer at the Computer Center of the University of Tokyo using a local version of UNICS.[5] The atomic scattering factors and the values of $\Delta f'$ and $\Delta f''$ were taken from the International Tables for X-Ray Crystallography.[6] The weighting scheme used were: (I), $w=1$ for $|F_o|\geqq4.25$ (F_o: absolute scale), $w=0.0$ otherwise; (II), $w=1$ for $|F_o|\geqq15.15$, $w=0.2$ otherwise. The F_o-F_c tables are kept at the office of this Bulletin as Document No. 7726 and 7727.

Conductivity Measurements. $[(Et)_4N][Ni(mnt)_2]$ single crystals are black needles with long axis parallel to the crystallographic c axis, giving good optical reflections. Comparatively high electrical conductivity is expected for $[(Et)_4N][Ni(mnt)_2]$ single crystals because of its columnar structure:

TABLE 1. FRACTIONAL COORDINATES AND THERMAL PARAMETERS ($\times 10^4$) FOR $[(C_4H_9)_4N]_2[Ni(mnt)_2]$

Thermal parameters are for the expression $\exp\{-(h^2B_{11}+k^2B_{22}+l^2B_{33}+2hkB_{12}+2hlB_{13}+2klB_{23})\}$.

the details of the crystal structure will be mentioned later. Four-probe resistance measurements were made on single crystals (3—6 mm long and 0.45—0.5 mm in diameter) along the needle axis paralled to the $Ni(mnt)_2^{1-}$ stacks. The crystals were attached by four 0.025 mm gold wires on a Teflon sample holder. Electrical contact was made by wetting the gold wires with silver-paste paint. The resistivity data ($R=\sigma^{-1}$) are presented in Fig. 1a, where $\ln R/R_0$ is plotted as a function of T^{-1} in the limited range from room temperature to 373 K which shows straight-line behavior. Thus this compound is semiconductive. From this slope, one obtains the value of 0.35 eV for the activation energy. The room temperature resistivity parallel to $Ni(mnt)_2^{1-}$ stacks is $(3.5\pm1.2)\times10^5\ \Omega$ cm. Another type of $[(Et)_4N][Ni(mnt)_2]$ crystals (parallolepiped pillar) show different kinds of resistivity behavior in the temperature

TABLE 2. FRACTIONAL COORDINATES AND THERMAL PARAMETERS ($\times 10^4$) FOR $[(C_2H_5)_4N][Ni(mnt)_2]$

Thermal parameters are for the expression $\exp\{-(h^2B_{11}+k^2B_{22}+l^2B_{33}+2hkB_{12}+2hlB_{13}+2klB_{23})\}$.

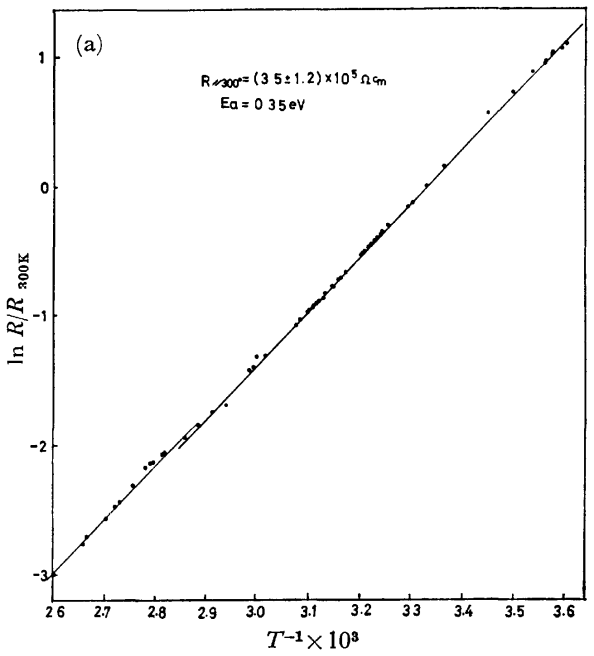
range of 323—363 K (Fig. 1b) and the resistivity of the room temperature is $R=(4.9\pm1.5)\times10^7\ \Omega$ cm. From the X-ray check both crystals are crystallographically identical but the latter data shows that the crystallization is bad. The accuracy of the absolute value of the conductivity is evidently limited by the crystalline imperfection.[7] It seems likely that the imperfections involved are microcracks or other large scale defects which limit the effective cross-sectional area of the samples.

Description of the Structure and Discussion

[(n-Bu)$_4$N]$_2$[Ni(mnt)$_2$]. Molecular geometry of the $Ni(mnt)_2^{2-}$ anion is shown in Fig. 2a. A projection of the structure as viewed along the c axis are presented in Fig. 3. This Ni^{2+} complex is isomorphous with Co^{2+} [8] and Cu^{2+} [9] complexes. The planar diamagnetic $Ni(mnt)_2^{2-}$ ion has a center of symmetry at the nickel atom and the two tetra-*n*-butylammonium ions are related to each other by a center of symmetry. The bond lengths and angles of the anion are listed in Table 3a. The nickel atoms are very well separated with the closest distance of approach in the shortest axial length of 9.84 Å. The anion is closely planar with the sulfur atoms in a square arrangement around the nickel atom and Ni, S(1), S(2), C(1), and C(2) make the five-membered ring. The distance of the various atoms from the least-squares plane are listed in Table 4a. The average Ni–S bond length is 2.175(1) Å, S–C 1.730(5), and C–C 1.410(7), respectively. The bond distance of



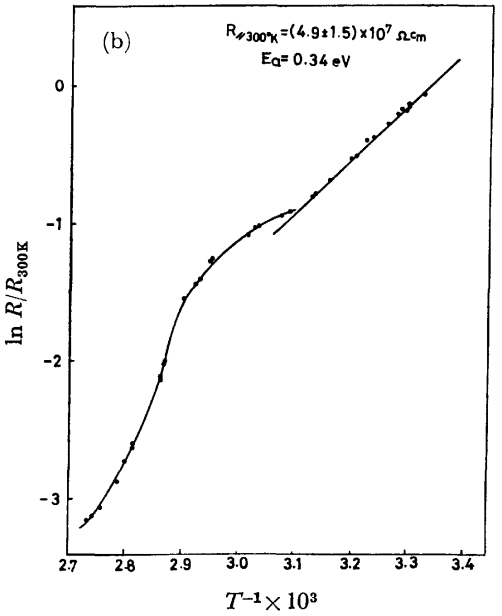


Fig. 1. Temperature dependence of electrical resistivity of $[(Et)_4N][Ni(mnt)_2]$, showing resistivity parallel to the anion stacks (crystallographic c axis).

C–C agrees well with those found in the conjugated C–C system like the benzene molecule. The S–Ni–S bond angle within the five-membered ring is found to be 92°. The bond lengths and angles of the cation is listed in Table 5a. Three of the butyl chains adopt the *trans* conformation, but one (C(9)—C(12)) adopts a *gauche* conformation. The dihedral angles for all the chains are listed in Table 6. The dihedral angle for the *gauche* chain is 72.4°.

$[(Et)_4N][Ni(mnt)_2]$. Molecular geometry of the anion is shown in Fig. 2b. A projection of the structure along the c axis is shown in Fig. 4. The anions are stacked in columns whose axes are parallel to c and

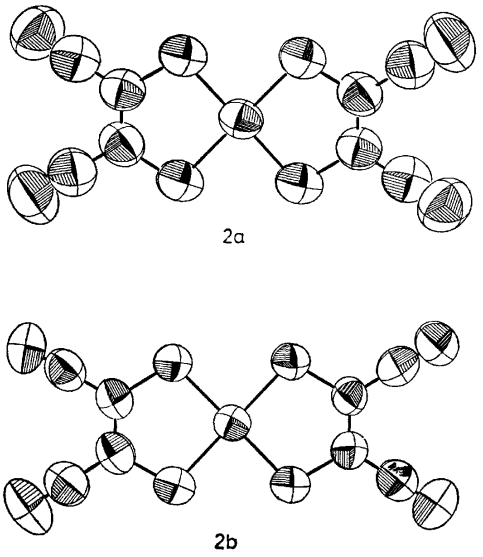

Fig. 2. Molecular geometry of the $Ni(mnt)_2^{2-}$ (2a) and $Ni(mnt)_2^{-1}$ (2b) anions. The 50% probability ellipsoids are shown.

Table 3b, and compared with those found for the $Ni(mnt)_2^{2-}$ anion in the $[(n\text{-}Bu)_4N]_2[Ni(mnt)_2]$. The paramagnetic anion is approximately planar, but deviations from planarity are considerably smaller than those in the $Ni(mnt)_2^{2-}$ ion. One of the cyanide group is bent a little out of the plane. The deviations of the atoms from the least-squares plane are listed in Table 4b. The average Ni–S bond length is 2.149 Å, S–C 1.725 Å, and C–C (in the five-membered ring) 1.369 Å. The S–Ni–S bond angle is 92.5°. Table 7 shows comparison of the bond lengths of $Ni(mnt)_2^{n-}$ ($n=1$, 2) in our structure analyses and those found in other $M(mnt)_2^{n-}$ structures. In $[(Et)_4N][Ni(mnt)_2]$ bond distances of the ligand agree well with our result of $[(n\text{-}Bu)_4N]_2[Ni(mnt)_2]$ and $[TMPD]_2[Ni(mnt)_2]$[11] by less than two standard deviations except Ni–S. Namely, Ni–S in (I)

is 2.175(1) Å and 2.149(2) Å in (II).

It is well known in organic compounds that bond lengths of molecules become longer or shorter in accordance with the change of the bond order or electronic state of molecules. When a molecular orbital which has the same sign on the neighboring two atoms is occupied with electrons, the bonding is strengthend and the bond length becomes shorter. If the sign is the reverse, the bonding is weakened. Similarly this discussion can be applied to complexes such as $Ni(mnt)_2^{n-}$ whose oxidation state could change with the molecular structure almost remaining unchanged.

The paramagnetic $Ni(mnt)_2^{1-}$ anion is thought to have the same electronic structure as that of the $Ni(mnt)_2^{2-}$ whose one electron is removed from the highest occupied level. The electronic structures of $Ni(mnt)_2^{n-}$ were studied by Gray and Schrauzer *et al.*[13,14] Gray's highest occupied orbital is $4a_g$ and Schrauzer's is $3b_{2g}$ (Fig. 5). These wave functions have the reverse sign on the Ni and S atoms, and the Ni–S bond length will be longer according to changing from $Ni(mnt)_2^{2-}$ to $Ni(mnt)_2^{1-}$. This agrees with the result of our crystal structure analyses. Similar relationship will be hold between $[(n\text{-}Bu)_4N]_2[Cu(mnt)_2]$ and $[(n\text{-}Bu)_4][Cu(mnt)_2]$ as to Cu–S bond distances (Table 7).

A characteristic feature of the crystal structure of $Ni(mnt)_2^{1-}$ complexes is the presence of columns of the $Ni(mnt)_2^{1-}$ anions weakly connected with each other. The mode of nearest neighbor overlapping within a $Ni(mnt)_2^{1-}$ column is shown in Fig. 6. The $Ni(mnt)_2^{1-}$ ions form a diadic unit within the columns. Similar columnar structure has been found in $[(n\text{-}Bu)_4N][Cu(mnt)_2]$, where columns are composed with tetradic units of $Cu(mnt)_2^{1-}$. The average interplanar

spacing of $Ni(mnt)_2^{1-}$ anion pairs in Fig. 6 is 3.5 Å and that of $Cu(mnt)_2^{1-}$ is 3.6 Å. In $Ni(mnt)_2^{1-}$ anion columns, overlapping of the Ni and S atoms is especially large, a similar columnar structure is also found in $[(n\text{-}Bu)_4N][Cu(mnt)_2]$.

The Study of Thermochemical Hydrogen Preparation. III.[1] An Oxygen-evolving Step through the Thermal Splitting of Sulfuric Acid

Masayuki DOKIYA, Tetsuya KAMEYAMA, Kenzo FUKUDA, and Yoshihide KOTERA*

National Chemical Laboratory for Industry, 2-19-19 Mita, Meguro-ku, Tokyo 153

(Received March 31, 1977)

The thermal decomposition of sulfuric acid is used as a step in the oxygen evolution in some thermochemical water-splitting cycles. The catalytic activity of metal oxides was studied in an attempt to find some suitable catalysts for sulfuric acid decomposition. The catalytic activity of SiO_2, Al_2O_3, ZnO, CuO, NiO, CoO, Fe_2O_3, MnO, Cr_2O_3, V_2O_5, TiO_2 was measured at high temperatures (800—870 °C) and at atmospheric pressure. Iron(III) oxide was found to have the highest activity as a catalyst. Low catalytic activity was observed for the oxides (Al_2O_3, ZnO, NiO, CoO, MnO) which change to their sulfates under the present reaction conditions. Since the reaction conditions were very severe (more than 800 °C and in the presence of steam), a rapid decrease in both the specific surface area and the catalytic activity was observed. In order to avoid these disadvantages and in order to prepare practically useful catalysts, iron(III) oxide was pelletized and sintered (1000 °C, 6 h). Upon this procedure, this catalyst showed an almost constant activity for 120 hours' reaction.

Among the many thermochemical water-splitting cycles[2-5] proposed thus far, the following cycle is thought to be one of the most promising ones. The most difficult problem of this cycle is, though, how to separate the hydroiodic acid from the sulfuric acid in Reaction 1:

$$I_2 + 2H_2O + SO_2 \longrightarrow H_2SO_4 + 2HI, \quad (1)$$

$$H_2SO_4 \longrightarrow H_2O + SO_2 + 1/2O_2, \quad (2)$$

$$2HI \longrightarrow H_2 + I_2. \quad (3)$$

Three solutions have been proposed for this problem by the present authors[1] and by others.[6-10]

The most simple solution is to omit Reaction 3 and to replace Reaction 1 by a Reaction 4 evolving hydrogen by electrolysis.[1,6-8,10] In this case, the electric power will be reduced to one-third of that needed in the electrolysis of water:

$$2H_2O + SO_2 \xrightarrow{\text{electrolysis}} H_2SO_4 + H_2. \quad (4)$$

Another solution was proposed by Russel *et al.*[9] They tried to separate hydroiodic acid from sulfuric acid by adding a large amount of iodine to the reaction mixture of Reaction 1, and then to separate it into two liquid phases.

The present authors showed the possibility of performing Reaction 1 as a cell reaction using a cation-exchange membrane, which serves as a diaphragm and a separator of hydroiodic acid and sulfuric acid at the same time.[1]

In every case, Reaction 2 serves as an oxygen-evolving reaction. The decomposition of sulfur trioxide seemed feasible when studied by Spewock *et al.*;[8] however, the composition of the catalyst has not been reported:

$$SO_3 \longrightarrow SO_2 + 1/2O_2. \quad (5)$$

Moreover, there exists a difference between Reactions 2 and 5; that is, steam is also present in Reaction 2 and not in Reaction 5. Thus, in the latter case, one more process step will be needed before Reaction 5 — the dehydration of sulfuric acid.

In this paper, the catalytic activities of various metal oxides have been studied for Reaction 2.

* Present address: Central Research Center, Showadenko Co., Ltd., 2-24-60 Tamagawa, Ohta-ku, Tokyo 146.

Experimental

The experimental system is shown in Fig. 1. To find out the most suitable chemical species for use as the catalyst for Reaction 2, the reaction vessel, C, was used. The same volume (2.8 cmϕ × 0.4 cm = 2.5 ml) of powder oxides of Si, Al, Zn, Cu, Ni, Co, Fe, Mn, Cr, V, and Ti were put in the reaction vessel, C. These oxides were all guaranteed reagents and were commercially available. The 60 wt% sulfuric acid was used as a reactant, as the concentration of sulfuric acid yielded in Reaction 1 could be expected to be 60 wt% on the basis of another experiment.[1] The sulfuric acid was introduced into the reaction vessel, C, which was kept at 820 ± 10 °C or 860 ± 10 °C, by the use of a microfeeder at the rate of 0.85 ± 0.04 ml/min. The reaction mixture, consisting of unreacted gaseous sulfuric acid, sulfur dioxide, and oxygen, was then cooled to room temperature at the cold trap, and the unreacted sulfuric acid was condensed out. The sulfur dioxide and oxygen gas mixture was washed with a sodium hydroxide solution, in which the sulfur dioxide was absorbed almost completely (less than 0.1 %); the amount of oxygen evolved per unit of time was measured by means of a conventional gas meter.

The decomposition of sulfuric acid with the sintered iron-(III) oxide catalyst was carried out by the use of the same

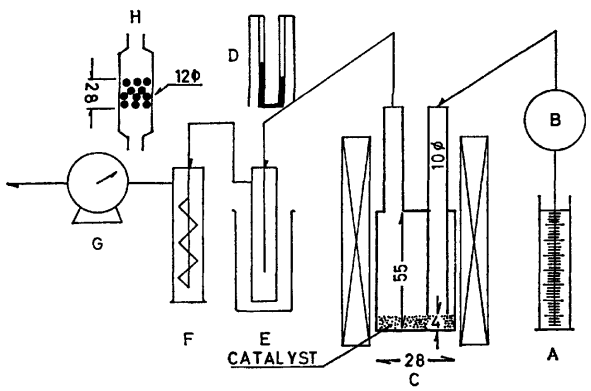

Fig. 1. Apparatus.
A: 60 wt%H_2SO_4, B: microfeeder, C: reaction vessel, D: manometer, E: cold trap, F: NaOH solution, G: gas meter, H: reaction vessel.

apparatus as in Fig. 1, except that the reaction vessel, C, was replaced by the vessel, H, as may be seen in the figure. The volume of the catalyst bed was 1.2 cmϕ×2.8 cm=3.2 ml. The iron(III) oxide catalyst was prepared as follows: iron(III) oxide powder was pressed at 5 tons/cm^2 into cylindrical pellets 4 cm in diameter and 1 cm in height. These pellets were sintered at 1000 °C for 6 h, and then crushed. Particles of 2—4 mm were used as the catalysts. The other procedure was almost the same as has been described above, except for the feeding rate of sulfuric acid.

Results and Discussion

Some typical results on the iron(III) oxide powder catalyst are shown in Fig. 2, where the amount of oxygen evolved per unit of time is plotted against the time. The rapid increase and decrease in the reaction rate observed at the initial stage at 820 °C was due to the time lag, during which the evolved sulfur dioxide and oxygen replaced the air in the experimental system. As may be seen in Fig. 2, the amount of oxygen evolved per unit of time gradually decreased with the reaction time at 860 °C. Such a tendency was observed with almost all kinds of chemical species the catalytic activity of which was examined.

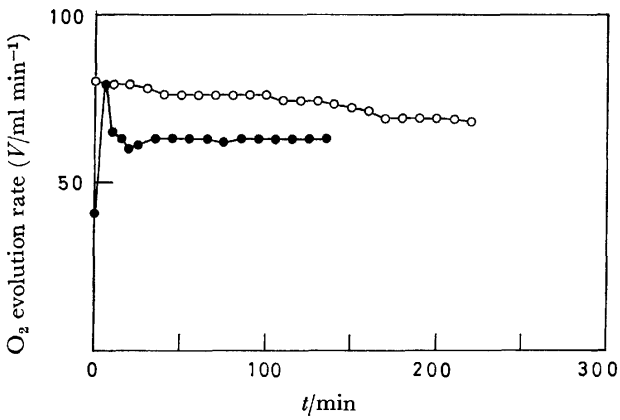

Fig. 2. The change of catalytic activity of Fe_2O_3 with time.
● 820 °C, ○ 865 °C.

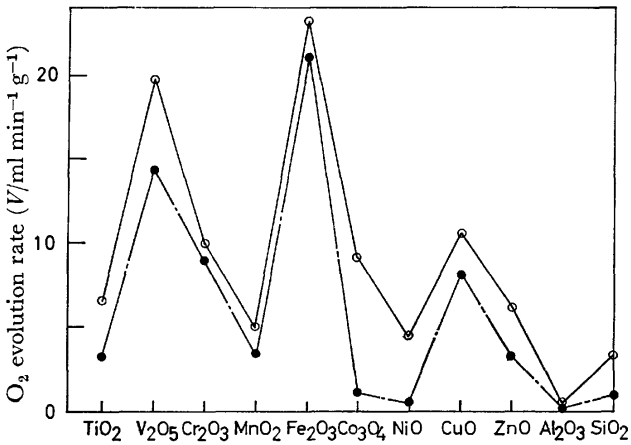

Fig. 3. The comparison of activity per unit weight of various oxides.
● 820±10 °C, ○ 860±10 °C.

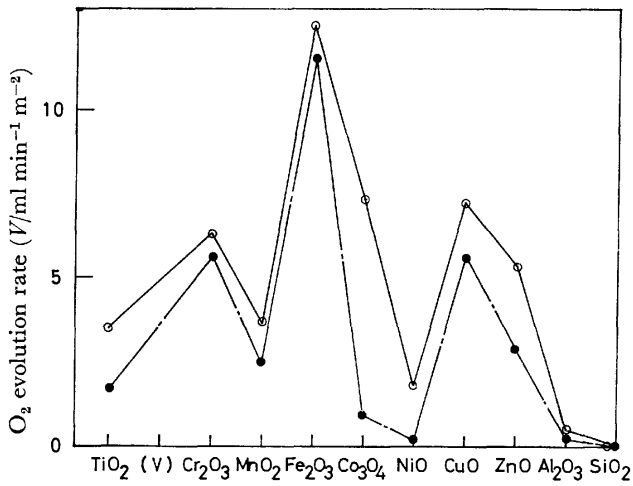

Fig. 4. The comparison of activity per specific surface area of various oxides.
● 820±10 °C, ○ 860±10 °C.

In Figs. 3 and 4, the amount of oxygen evolved per unit of time is plotted against the metal oxides used as catalysts. The ordinates of Figs. 3 and 4 are the amount of oxygen evolved per unit of time per unit of weight of the catalyst and the amount of oxygen evolved per unit of time per unit of the specific surface area, respectively. In Fig. 4, the value for vanadium(V) oxide is omitted because vanadium(V) oxide is a liquid at these reaction temperatures. Here, the amount of oxygen evolved per unit of time 4—5 h after the initiation of the reaction was chosen as the representative value of the amount of oxygen evolved per unit of time for each oxide. As may be seen from these results, iron(III) oxide has the highest activity among the oxides used.

Table 1. The crystal structure and specific surface area of catalysts

Catalyst		Surface area S/m^2 g^{-1}	
Original	Used	Original	Used
TiO_2	rutile≫ anatase	2.50	1.86
V_2O_5	V_2O_5	—	fused
Cr_2O_3	eskolaite	3.10	1.58
MnO_2	$MnSO_4$	31.8	1.43
Fe_2O_3	Fe_2O_3	9.21	1.85
Fe_3O_4	Fe_2O_3	—	—
SiO_2(am)	SiO_2(am)	655.0	95.5
Co_3O_4	Co_3O_4, CoO α-$CoSO_4$	0.88	1.24
CoO	Co_3O_4, CoO α-$CoSO_4$	—	—
NiO	NiO $NiSO_4$	0.42	2.48
CuO	CuO≫ $CuO(SO_4)$	1.84	1.48
ZnO	$ZnSO_4$ $Zn_5O_2(SO_4)_3$ $Zn_3O_2(SO_4)_2$	5.26	1.15
α-Al_2O_3	α-Al_2O_3 $Al_2(SO_4)_3$	6.20	1.41

As may be seen in Table 1, the speicfic surface area and the crystal structure of the catalysts used changed during the reaction. The specific surface area decreased except in the cases of cobalt(II) oxide and nickel(II) oxide. This fact and the gradual decrease in the amount of oxygen evolved per unit of time are noteworthy for the practical preparation of catalysts.

The oxides of Al, Zn, Ni, Co, and Mn, which were found as sulfates after the reaction (Table 1), showed low catalytic activity, as can be seen in Figs. 3 and 4. Among the active oxides (V, Cr, Cu, and Fe), iron(III) oxide was chosen as a candidate for catalyst for practical use, considering the cost of the catalyst and the environmental safety.

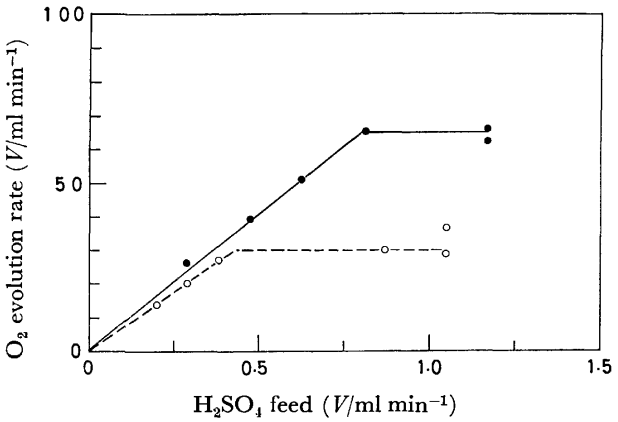

Fig. 5. The dependence of oxygen evolution rate upon the feeding rate of H_2SO_4.
○ 800 °C, ● 850 °C.

Five g of well-sintered particles of iron(III) oxide were used for each reaction, having been placed in the reaction vessel, H, shown in Fig. 1. In Fig. 5, the amount of oxygen evolved per unit of time *vs.* the feeding rate of the sulfuric acid is plotted. A linear dependence of the amount of oxygen evolved per unit of time on the feeding rate below 0.5 or 0.8 ml/min at 800 °C or 850 °C was observed. These results indicate that the space velocities based on the sulfur dioxide and oxygen gas produced are 560 ml/ml-catalyst-h (800 °C) and 1200 ml/ml-catalyst-h (850 °C). Their conversion were 69 and 79% respectively. On the basis of these results, the feeding rates of sulfuric acid at 1.1 ml/min (800 °C) and 1.3 ml/min (850 °C) were chosen as the feeding rates for the following experiments.

In Fig. 6, the results of the long-time examination of the stability of catalyst at 800 °C and 850 °C are shown. In each case, an increase of activity was observed around 25 hours' reaction. After that increase, the iron(III) oxide catalyst showed a constant activity up to 120 h. The specific surface area of the catalysts used were compared with those of the original ones; the results are summarized in Table 2. At 800 °C, an increase in the specific surface area was observed with the catalyst which was used for 28 hours' reaction (open square in Fig. 6); then the specific surface area of the catalyst remained substantially constant up to 120 h (solid square in Fig. 6). At 850 °C, the specific surface area still increased from 28 hours' reaction up to 120 h.

□,■ 800 °C, ○,● 850 °C.

Table 2. The specific surface area of ferric oxide catalysts

	Surface area S/m^2 (5 g)$^{-1}$		
	Original	Used 28 h	Used 120 h
850 °C	2.20	3.09	6.41
800 °C	2.20	2.80	2.74

No sulfate species were observed by means of X-ray diffractometry. However, it was observed that a few particles changed color from violet to red and that the crushing strength of the pellets was lowered in spite of the fact that their shape did not change at all.

From these results, the authors concluded that, from a practical stand point, the well-sintered iron(III) oxide catalyst has a high possibility of being utilized in the sulfuric acid thermal splitting reaction. The next problem may be whether this catalyst can be applied for a long term or not (for example, one year's operation), because of the necessary reaction conditions of a high temperature and the presence of steam. Silica or alumina would not be proper for a catalyst support, as they are not stable enough under the reaction conditions described above, as is shown in Table 1.

This work was done as part of the Sunshine Project of the Ministry of International Trade and Industry of Japan.

Conversion of Cobalt(II) and Nickel(II) Fixed on the Ion Exchange Resin into Their Trifluoroacetylacetonates and Gas Chromatography of the Chelates

Tooru TAMURA, Kunio OHZEKI, and Tomihito KAMBARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received April 18, 1977)

The conversion of cobalt(II) and nickel(II) ions collected on the ion exchange resin into the chelate compounds with trifluoroacetylacetone (Htfa) has been studied in various solvents. In the presence of pyridine, cobalt and nickel ions were quantitatively extracted from the resin into organic phase in the form of the base adducts $[Co(tfa)_2(py)_2]$ and $[Ni(tfa)_2(py)_2]$, respectively. The thermogravimetric and gas chromatographic behaviors of these compounds have been investigated. A gas chromatographic separation of $[Ni(tfa)_2]$ from $[Co(tfa)_2]$ was successfully performed.

The gas chromatography of metal chelates, particularly those with ligands of the β-diketone type, has been noted and reviewed.[1,2] The application of the gas chromatography to inorganic analysis has been limited by the problems involved in the quantitative conversion of metal ions in aqueous solution into the suitable metal chelates with adequate volatility and thermal stability for elution from gas chromatographic column.[3] The application of gas chromatography to divalent transition metal ions in the form of β-diketonates has proved particularly difficult, since the dihydrates of the bis chelates are hardly volatile.[4] Attempts have been made to separate cobalt(II) and nickel(II) ions as their 2-thenoyltrifluoroacetonates by gas chromatography,[5,6] and it was reported that the peak shapes of the chelates could be improved when the chelates were injected as the corresponding adducts with diethylamine.[6]

We have reported that iron(III),[7] copper(II),[8] nickel(II),[9] and cobalt(II)[10] ions fixed on the ion exchange resins were quantitatively extracted with acetylacetone or 2-thenoyltrifluoroacetone into organic medium by the aid of a small amount of pyridine or pyridine-water mixture.

It is worthwhile to examine the utility of the synergistic extraction of metal ions previously fixed on the ion exchange resin in the preparation of the chelate compounds suitable for gas chromatography. In this work, the synergistic extraction of cobalt(II) and nickel(II) with trifluoroacetylacetone in the presence of pyridine is studied and the gas chromatographic behavior of the resulting chelates is discussed.

Experimental

Apparatus. A Hitachi 508 atomic absorption spectrometer was used for the cobalt and nickel absorption measurements at 240.7 and 231.4 nm, respectively, in air-acetylene flame. The thermogravimetric data were obtained using a Shimadzu TG-20 thermogravimetric analyzer with *ca.* 5 mg of sample. The heating rate was programmed at 5 °C min^{-1} and helium was passed through the sample chamber at a flow rate of 30 cm^3 min^{-1}. A Hitachi 063 gas chromatograph equipped with a thermal conductivity detector was used.

Reagents. Trifluoroacetylacetone (1,1,1-trifluoropentane-2,4-dione, Wako Pure Chemicals Co.) was distilled and used. Pyridine and all other reagents used were of the guaranteed reagent grade.

Extraction of Metal Ions from the Resin with Htfa. The resin used was a sulfonate cation exchanger, Amberlyst 15, with a macroreticular structure. The Co(II)- and Ni(II)-form resins were prepared according to the method reported previously.[9,10] It was found that 3.43 meq of cobalt and 3.31 meq of nickel ions were adsorbed on 1.00 g of the airdried Co(II)- and Ni(II)-form resins, respectively. A 5-cm^3 portion of 0.1 mol l^{-1} Htfa in organic medium was poured onto the 25 mg of airdried Co(II)- or Ni(II)-form resin in an eggplant type flask and a small amount of pyridine was added. The mixture was shaken at a room temperature for 20 min for cobalt and 10 min for nickel. The resin was separated by filtration and washed with ethanol and then water. The cobalt or nickel ion remaining on the resin was eluted by 2 mol l^{-1} hydrochloric acid and determined by atomic absorption spectrometry.

Preparation of Chelates. A 100-cm^3 portion of 0.5 mol-l^{-1} Htfa in benzene was poured onto 4 g of the air-dried Co(II)- or Ni(II)-form resin in an eggplant type flask and 8 cm^3 of pyridine was added. The mixture was shaken for 1 h at a room temperature. After filtration, the filtrate was gently warmed and the solvent was removed with a stream of nitrogen gas. The residue was dissolved in benzene or ethanol and the adduct $[Co(tfa)_2(py)_2]$ or $[Ni(tfa)_2(py)_2]$ was recrystallized from the solution. The results of elemental analysis were: Found: C, 45.50; H, 3.86; N, 5.21; Co, 11.23%. Calcd for $[Co(tfa)_2(py)_2]$: C, 45.91; H, 3.47; N, 5.35; Co, 11.26%. Found: C, 45.62; H, 3.58; N, 5.58; Ni, 11.15%. Calcd for $[Ni(tfa)_2(py)_2]$: C, 45.92; H, 3.47; N, 5.36; Ni, 11.22%.

Results and Discussion

Extraction of Nickel(II) and Cobalt(II) from the Resin with Htfa. The removal of nickel and cobalt ions from the resin with Htfa into the organic solvent was successfully carried out in the presence of a small amount of pyridine, as shown in Figs. 1 and 2. Upon the addition of pyridine blue or dark orange color was immediately developed in the organic phase, indicating the formation of the base adduct, $[Ni(tfa)_2(py)_2]$ or $[Co(tfa)_2(py)_2]$. Nickel(II) ions on the resin were quantitatively extracted into Htfa-carbon tetrachloride and Htfa-benzene solution in the presence of pyridine in 1—6 and 1—4% (v/v), respectively. Cobalt(II) ions were also quantitatively extracted into Htfa-carbon tetrachloride, Htfa-benzene, and Htfa-cyclohexane solu-

tion in the presence of pyridine in 2—6, 2—4 and 10—14% (v/v), respectively.

Thermogravimetric Analysis. Thermogravimetric behavior of the chelates is shown in Fig. 3. A considerable volatility difference between the chelates was observed, while both chelates were not completely volatile. Some black residue was left in the sample pan after each run. The loose weight loss observed at the beginning of thermograms is attributed to the thermal dissociation of pyridine from the adduct. For comparison with the gas chromatographic behavior, the thermograms were obtained under the conditions in which the chelates were sublimated through a small amount of the column packing, *i.e.* 10% SE-30 or 5% Apiezon L on Chromosorb WAW was placed on the chelate in the sample pan. No remarkable differences were found with and without the column packing.

Thermal Dissociation of Pyridine from the Adducts. The thermal dissociation of pyridine from the adducts was investigated by gas chromatography as follows. A 25-cm glass column packed with 30% PEG 4000 on Celite 545 was used. The column temperature was held at 75 °C and injection port temperature was varied from 100 to 300 °C. An appropriate dead space was placed between the packing and injection port to avoid the thermal decomposition of the packing. The sample solution containing 33.8 mg of $[Co(tfa)_2(py)_2]$ or 42.1 mg of $[Ni(tfa)_2(py)_2]$ in 1.5 cm^3 of benzene was prepared and a 10-μl portion of ethylbenzene was added. Sample size injected was 2 μl for cobalt and 4 μl for nickel, respectively. The relationship between the injection port temperature and the amount of dissociated pyridine was examined with ethylbenzene as the internal standard. As shown in Fig. 4, the peak height ratio of

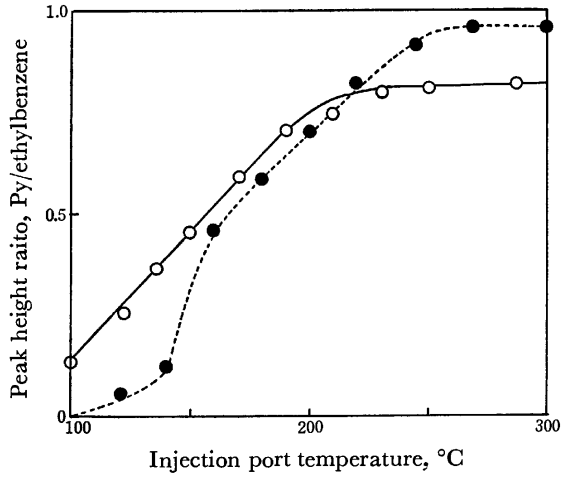

Fig. 4. Thermal dissociation of pyridine from the adduct.
○: $[Co(tfa)_2(py)_2]$, ●: $[Ni(tfa)_2(py)_2]$.

pyridine to ethylbenzene became constant above the injection port temperature around 230 and 270 °C for cobalt and nickel chelates, respectively. It is safely assumed that under the appropriate gas chromatographic conditions the liberation of pyridine takes place immediately after the sample injection, and hence, cobalt and nickel are eluted from the column in the form of $[Co(tfa)_2]$ and $[Ni(tfa)_2]$, respectively.

Choice of Column Packing. The following experiment was carried out to select the column packing suitable to elute the chelates. A J-shaped glass tube, the round part of which was packed with column packing, was affixed to injection port in the column oven.

The linear part of the tube stuck through a hole out of the wall of the oven, so that it was cooled to a room temperature resulting in the deposition of the metal complex at the inner wall of glass tube. The injection port temperature and column temperature were held at 210 and 230 °C, respectively. A benzene solution containing a known amount of the chelate was injected successively. Then the chelate condensed at the inner wall of the protruding section of tube was washed with methyl isobutyl ketone into a volumetric flask and the metal ion content was determined by atomic absorption spectrometry and compared with the injected amount. Among the several stationary liquids examined, the best result was obtained with silicone SE-30. With the use of 5% SE-30 on silanised Chromosorb W (80—100 mesh), 80, 84, and 86% of the injected amount of the cobalt chelate were found to be eluted from the glass tube, the packed length of which was 26, 10.5, and 4.5 cm, respectively. For nickel chelate 77% of the injected amount were found to be in the effluent from a 28 cm packed tube. On the other hand, no detectable amount of the chelate was found in the effluent from the tube packed with Apiezon L. This fact clearly indicates that the recovery does not depend on the packing length, but seriously depends on the packing material. No evidence of the thermal decomposition of the chelate at the injection port was found. It is supposed that the loss of the chelate is mainly due to the adsorption of chelate on the column packing adjacent to the injection port.[11]

Gas Chromatography. A glass column (25 cm long and 4 mm i.d.) packed with 10% SE-30 on Chromosorb WAW (60—80 mesh) was used. Gas chromatographic conditions were as follows. For $[Co(tfa)_2(py)_2]$, column temperature, 170 °C; injection port temperature, 210 °C; detector temperature, 200 °C. For $[Ni(tfa)_2(py)_2]$, column temperature, 230 °C; injection port temperature 260 °C; detector temperature, 240 °C. Detector current, 115 mA; helium flow rate, 25 cm^3 min^{-1}. The typical chromatograms are shown in Fig. 5. Sample quantities are 32 μg $[Co(tfa)_2(py)_2]$ and 113.4 μg $[Ni(tfa)_2(py)_2]$ in benzene. In the case of cobalt, a good separation of

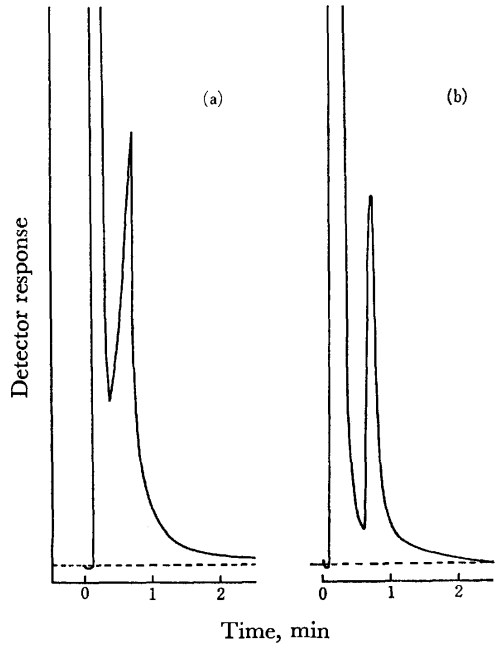

Fig. 5. Chromatograms of (a) $[Ni(tfa)_2]$ and (b) $[Co(tfa)_2]$. Column: 25 cm long × 4 mm i.d., borosilicate glass, filled with 10% SE-30 on 60—80 mesh Chromosorb WAW.

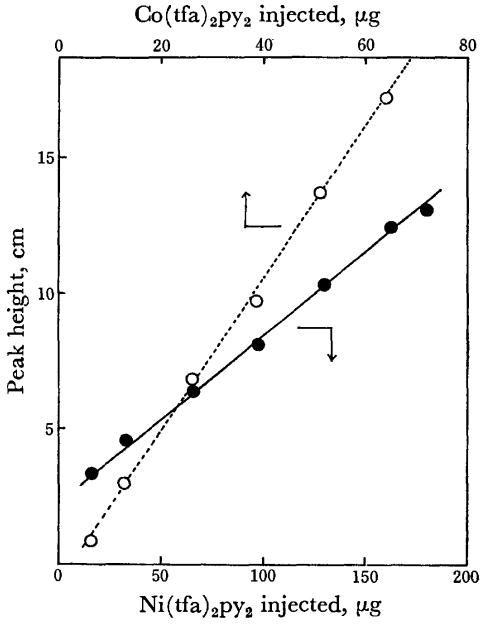

Fig. 6. Plot of the chelate peak height against the sample amount injected. ○: $[Co(tfa)_2(py)_2]$, ●: $[Ni(tfa)_2(py)_2]$.

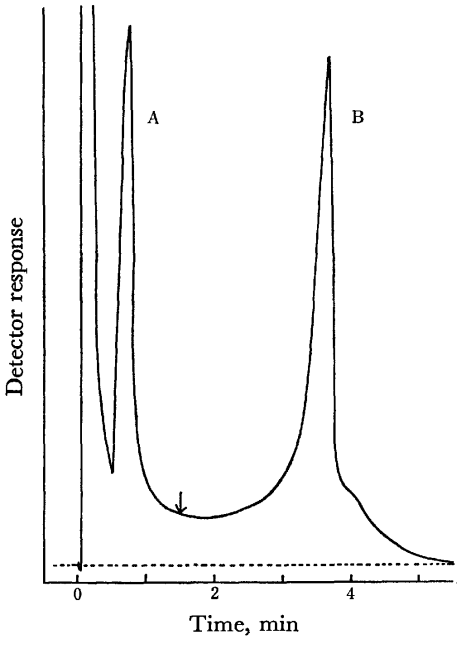

Fig. 7. Separation of Co(II) and Ni(II) trifluoroacetylacetonates by the programmed temperature method. Column: 25 cm long × 4 mm i.d., borosilicate glass, filled with 2% SE-30 on 80—100 mesh Chromosorb WHP. Temperature was programmed at the point indicated by an arrow from 165 to 230 °C at 20 °C min^{-1}. (A) $[Co(tfa)_2]$, (B) $[Ni(tfa)_2]$.

the chelate from the solvent was obtained. On the other hand, an isothermal separation of nickel chelate from the solvent was unsuccessful under the condition employed. The column temperature was too low for the chelate and too high for the solvent to give symmetrical peak shapes. The increase in the peak height with sample size was found to be linear as shown in Fig. 6.

Separation of Nickel(II) and Cobalt(II) Trifluoroacetylacetonates. The programmed temperature method was examined to separate these compounds. A 25-cm glass column packed with 2% SE-30 on Chromosorb WHP (80—100 mesh) was used. The temperatures of injection port and detector were held at 250 °C and 210 °C, respectively. The detector current was 125 mA and helium flow rate was 45 $cm^3\ min^{-1}$ at 165 °C. A mixture of 98.4 μg of $[Co(tfa)_2(py)_2]$ and 205.0 μg of $[Ni(tfa)_2(py)_2]$ in benzene was injected. The column temperature was held at 165 °C until the cobalt chelate was eluted, then programmed to 230 °C at 20 °C min^{-1}. A fair separation of cobalt and nickel trifluoroacetylacetonates was observed as shown in Fig. 7. A small shoulder was found for nickel chelate. An attempt was also made to separate these compounds in the extract from the resin. The column temperature was held at 110 °C until the solvent and the excess reagents were eluted, then programmed to 230 °C at 10 °C min^{-1}. A fairly good separation was attained, which indicates that the synergistic extraction of nickel(II) and cobalt(II) ions from the ion exchange resin onto which the metal ions are previously collected from the aqueous solution is effective in the preparation of metal chelates to be separated by gas chromatography.

Synthesis and Absorption Spectra of the $[Co(O-O)_2(py)_2]^-$-type Complexes

Yayoi IDA, Shuhei FUJINAMI, and Muraji SHIBATA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received April 22, 1977)

Five bis(dicarboxylato)bis(pyridine)-type complexes, *trans*-$[CoCO_3ox(py)_2]^-$, *trans*- and *cis*-$[Co(ox)_2(py)_2]^-$, and *trans*- and *cis*-$[Co(mal)_2(py)_2]^-$, have been isolated as crystals and characterized on the basis of the absorption spectra, the PMR spectra, *etc.* The *trans* isomers of the carbonatooxalato and bis(oxalato) complexes reveal spectra similar to that of the *trans*-$[Co(CO_3)_2(py)_2]^-$ complex synthesized previously; the splittings of the absorption bands are not observed in the I bands, but are observed in the II bands. On the other hand, the *trans* isomer of the bis(malonato) complex reveals no splittings in either the I band or the II band. The assignment of these absorption bands has been made from considerations based on the Angular Overlap Model.

In the studies previously carried out in our laboratory,[1-3] some dicarbonato complexes of the $[Co(CO_3)_2(a)_2]^{n-}$ type, where a represents unidentate ligands such as NH_3, NO_2^-, and CN^-, were synthesized by a method called the "tricarbonato method."[4] However, every complex isolated was of *cis* isomer. Under the circumstances, efforts were continued to find a *trans* isomer of this type of complex, and we finally succeeded in obtaining the isomer; the action of pyridine on an aqueous potassium bicarbonate solution of tricarbonatocobaltate(III) yielded not only the *cis* isomer, but also the *trans* one of the $[Co(CO_3)_2(py)_2]^-$ complex.[5] In addition to this success, it was found that the *trans* isomer revealed an unusual absorption spectrum; it showed a single maximum in the first absorption-band region (I band) and two maxima in the second absorption-band region (IIa and IIb bands).

Then, studies of the synthesis of the $[Co(O-O)_2(py)_2]^-$-type complexes were undertaken by using CO_3^{2-}, $C_2O_4^{2-}$, and $C_3H_2O_4^{2-}$ (malonate) ions as the bidentate O–O donor ligands. This paper will deal with the results of the studies; the synthesis gave a pair of *cis* and *trans* isomers for the $[CoCO_3ox(py)_2]^-$, $[Co(ox)_2(py)_2]^-$, and $[Co(mal)_2(py)_2]^-$ complexes. The *trans* isomers of the former two complexes revealed spectra similar to that of the *trans*-$[Co(CO_3)_2(py)_2]^-$ complex, while the *trans* isomer of the latter complex exhibited no splittings in either the first or the second absorption band.

Experimental

Synthesis. *1) Carbonatooxalatobis(pyridine)cobaltate(III).* *a) Potassium Salt of the* trans *Isomer,* trans-*K*$[CoCO_3ox(py)_2]\cdot 2.5H_2O$: To a green solution containing mainly the $[Co(CO_3)_2(ox)]^{3-}$ species, which had been prepared by the literature method[2] ($Co(NO_3)_2\cdot 6H_2O$, 15 g scale, 0.05 mol), we added pyridine (8 ml, 0.1 mol); the mixture was then stirred at 50 °C for 1.5 h. The resulting violet solution was kept in a refrigerator until red-violet crystals were deposited. The crystals were filtered and recrystallized from warm water (*ca.* 50 °C). The filtrate was preserved for the synthesis of the subsequent *cis* isomer. The yield was about 2.5 g. Found: C, 34.71; H, 3.66; N, 6.58%. Calcd for $K[CoCO_3(C_2O_4)(C_5H_5N)_2]\cdot 2.5H_2O$: C, 34.70; H, 3.36; N, 6.23%.

b) cis *Isomer,* cis-$[CoCO_3ox(py)_2]^-$: A portion of the filtrate (*ca.* 1/5 volume) was charged on a column of Dowex 1-X8 resin (100—200 mesh) in the Cl-form (4.0×25.0 cm). After washing with water, the column was treated with a 0.1 M NaCl aqueous solution; three bands were thus separated. The first-descending band was of *cis*-$[Co(CO_3)_2(py)_2]^-$, and the last band, *cis*-$[Co(ox)_2(py)_2]^-$, while the middle band was the desired one. This was collected in a fraction and concentrated to a small volume, but no crystals were obtained because of its great solubility.

2) Bis(oxalato)bis(pyridine)cobaltate(III). *a) Potassium Salt of the* trans *Isomer,* trans-*K*$[Co(ox)_2(py)_2]\cdot 3H_2O$: To an aqueous solution of $K_3[Co(ox)_3]\cdot 3H_2O$[6] (25 g, 0.05 mol in 60 ml H_2O), we added pyridine (8 ml, 0.1 mol) and activated charcoal (1 g); the mixture was then stirred at 60 °C for 2 h. The resulting solution was filtered once to remove the charcoal and any precipitated material, and then concentrated until pink crystals began to be deposited. After the whole had been cooled for a while, the crystals were collected by filtration and recrystallized from warm water (*ca.* 50 °C). The filtrate was preserved for the subsequent *cis* isomer. The yield was *ca.* 2 g. Found: C, 34.86; H, 3.55; N, 6.00%. Calcd for $K[Co(C_2O_4)_2(C_5H_5N)_2]\cdot 3H_2O$: C, 34.51; H, 3.31; N, 5.75%.

b) Lithium Salt of the cis *Isomer,* cis-*Li*$[Co(ox)_2(py)_2]\cdot H_2O$: The filtrate in *a*) was poured into a column of Dowex 50W-X8 resin (100—200 mesh) in the Li-form (5.0×10.0 cm) in order to obtain the lithium salt of the desired isomer. The effluent was collected and evaporated almost to dryness. The residue was then extracted with warm ethanol (*ca.* 50 °C), and the solution was kept in a refrigerator until violet crystals were deposited. The yield was about 1.5 g. Found: C, 40.23; H, 3.21; N, 6.75%. Calcd for $Li[Co(C_2O_4)_2(C_5H_5N)_2]\cdot H_2O$: C, 40.12; H, 2.89; N, 6.68%.

3) Bis(malonato)bis(pyridine)cobaltate(III). *a) Potassium Salt of the* trans *Isomer,* trans-*K*$[Co(mal)_2(py)_2]\cdot 2H_2O$: To a solution of potassium tris(malonato)cobaltate(III), which had been prepared by the literature method[7] ($Co(NO_3)_2\cdot 6H_2O$, 30 g scale, 0.1 mol), we added pyridine (16 ml, 0.2 mol); the mixture was then stirred at 50 °C for 40 min. After the insoluble material had been removed by filtration, the filtrate was concentrated to a small volume and then kept in a refrigerator until purple crystals separated out. The crystals were collected by filtration and recrystallized from warm water (*ca.* 50 °C). The filtrate was preserved for the subsequent *cis* isomer. The yield was about 2 g. Found: C, 38.73; H, 3.55; N, 5.68%. Calcd for $K[Co(C_3H_2O_4)_2(C_5H_5N)_2]\cdot 2H_2O$: C, 38.72; H, 3.66; N, 5.64%.

b) Bis(ethylenediamine)oxalatocobalt(III) Salt of the cis *Isomer,* $[Co(ox)(en)_2]\cdot$cis-$[Co(mal)_2(py)_2]\cdot 3H_2O$: The filtrate in *a*) was evaporated almost to dryness, after which the residue was extracted with methanol. The methanol solution was then dried, and the residue was again dissolved with a minimum amount of water. To this solution, we added an aqueous solution of bis(ethylenediamine)oxalato-

cobalt(III) acetate[8] (in excess). The whole was kept in a refrigerator until red-brown crystals were deposited. Recrystallization was performed from warm water (*ca.* 50 °C). The yield was about 3.5 g. Found: C, 35.73; H, 4.84; N, 11.03%. Calcd for $[Co(C_2O_4)(C_2H_5N_2)_2]\cdot[Co(C_3H_2O_4)_2(C_5H_5N)_2]\cdot 3H_2O$: C, 35.59; H, 4.88; N, 11.32%.

An attempt to resolve this complex was successful; the racemate (3.5 g, 0.005 mol) was ground in a mortar with water (5 ml), and then NaI (0.83 g, 0.005 mol) was added. The mixture was filtered to remove precipitates of $[Coox(en)_2]I$. To an aqueous solution of $(-)_{589}[Coox(en)_2]^+$ (0.003 mol in 7 ml H_2O), which had been prepared in the acetate form according to the literature method,[8] we added the above filtrate; the mixture was then cooled in an ice bath, and a small amount of ethanol was added. After the sides of the vessel had been scratched with a glass rod for some time, the whole was kept for an hour in an ice bath. The crystals thus deposited were recrystallized several times from water (*ca.* 40 °C). The less soluble diastereoisomer was found to be $(-)_{589}[Coox(en)_2]\cdot(+)_{589}[Co(mal)_2(py)_2]\cdot 3H_2O$.

4) Dicarbonatobis(pyridine)cobaltate(III), trans- *and* cis-*$K[Co(CO_3)_2(py)_2]\cdot 3H_2O$*: The syntheses of these isomers have been described in a previous paper.[5]

The synthesis was attempted using 3- or 4-methylpyridine in place of pyridine; the *trans* isomers could be isolated, but no *cis* isomers were isolated because of their great solubility in ethanol. In the case of 2-methylpyridine, no substitution reaction proceeded.

Measurements. For the measurement of the absorption spectra in solution, a Hitachi 323 recording spectrophotometer was used. The spectra of the *trans*- and *cis*-$[Co(CO_3)_2(py)_2]^-$ complexes were measured with aqueous solutions containing a small amount of $KHCO_3$ in order to prevent the decomposition of the complex species. For the $[Coox(en)_2]\cdot$*cis*-$[Co(mal)_2(py)_2]$ complex, the spectrum was measured with the effluent obtained by passing its aqueous solution through a column of Dowex 50W-X8 resin in the Na-form. The absorption spectrum of the *trans*-$[Coox(H_2O)_2(py)_2]^+$ species was measured with an acidified solution of the *trans*-$[CoCO_3ox(py)_2]^-$ complex with 10% $HClO_4$; the acid-hydrolyzed species was chromatographically pure, and its absorption spectrum was reformed into the original spectrum of the parent carbonato complex when $KHCO_3$ was added to the acidified solution. This fact was evidence for the complete retention of the configuration during the acid-hydrolysis. The crystal absorption spectra were measured with a microspectrophotometer constructed in our laboratory.[9]

The proton magnetic resonance (PMR) spectra were recorded on a JEOL JNM PS-100 NMR spectrometer at 25 °C, using TMSP as the internal reference. The infrared absorption (IR) spectra in the 700—4000 cm^{-1} region were measured by means of a KBr disc method using a JASCO IRA-2 grating infrared spectrophotometer. The far-infrared spectra were taken by the Nujol method using a JASCO IR-F far-infrared spectrophotometer.

The isomerization of the *trans*-$[Co(CO_3)_2(py)_2]^-$ species was monitored spectrophotometrically at 400 and 560 nm at 25 °C under the following conditions: $[Co^{III}\ complex]=(4.30-4.72)\times10^{-3}$ M, $[HCO_3^-]=0.25$ M, $[H^+]=3.98\times10^{-9}$ M and $[py]=6.18\times10^{-6}$ M. The ionic strength was made up to 1.0 M with KCl. The pH measurement was carried out with a Hitachi-Horiba M-7E pH-meter.

The calculations for curve analysis were carried out at Data Processing Center, Kanazawa University.

Results and Discussion

Characterization. In a previous work,[5] we characterized two isomers of the $[Co(CO_3)_2(py)_2]^-$ complex on the basis of the electronic absorption and the far-infrared spectra; the isomer which exhibits a distinct splitting in the second absorption band and a very simple pattern of the far-infrared spectrum was determined to be the *trans* isomer. Figure 1 shows the solution spectra for the isomers obtained at the earlier stage in each synthesis of the $[CoCO_3ox(py)_2]^-$ and $[Co(ox)_2(py)_2]^-$ complexes, the spectrum of the *trans*-$[Co(CO_3)_2(py)_2]^-$ being included for comparison. Both the isomers exhibit splittings of the second absorption bands (IIa and IIb), although the extents of the splittings are considerably reduced compared with that for *trans*-$[Co(CO_3)_2(py)_2]^-$. The absorption spectrum of the isomer obtained at the later stage in the synthesis of the $[Co(ox)_2(py)_2]^-$ complex and the spectrum of the *cis*-$[Co(CO_3)_2(py)_2]^-$ complex are compared in Fig. 2.

The spectra in the two figures are quite similar to each other. From a comparison of the spectra, the present isomers can be characterized.

The absorption spectra of the two isomers of the $[Co(mal)_2(py)_2]^-$ complex are shown in Fig. 3. The spectra are similar to each other except that there is a considerable difference in ε value between the isomers. However, as a successful resolution was effected with the isomer obtained at a later stage in the synthesis, the *cis* configuration is assigned to that isomer. Consequently, the remainder is regarded as the *trans* isomer. In this connection, the optical resolution was performed with one isomer of the $[Co(CO_3)_2(py)_2]^-$ complex and one of the $[Co(ox)_2(py)_2]^-$ complex. Our CD spectral studies of these *cis*-$[Co(O-O)_2(N)_2]^-$-type complexes[10] will be reported in a subsequent paper.

The PMR spectra of the present bis(pyridine) complexes are shown in Fig. 4. It is well known that, in free pyridine, the α-, γ-, and β-protons resonate at 8.50, 7.36, and 6.98 ppm (*vs.* TMSP) respectively. In the present complexes, these protons resonate at lower fields; for the *trans* isomers, at 8.9—8.7 ppm (α), 8.2—8.0 ppm (γ), and 8.0—7.6 ppm (β), while for the *cis* isomers, at 8.4—8.2 (α), 8.2—7.9 (γ), and 7.7—7.4 (β). A marked difference in chemical shift is observed between the α-protons of a *trans* isomer and those of the corresponding *cis* isomer. This phenomenon can be understood by the empirical rule of Watabe *et al.*[11] found from the studies of α-amino carboxylato complexes of cobalt(III): "The methine proton adjacent to the coordinated N atom resonates at a higher magnetic field when the O atom occupies the site *trans* to the N atom than when the N atom occupies the same site." The former case applies to the present *cis* isomer, which exhibits the resonance due to the α-protons at a higher magnetic field, the latter case, to the *trans* isomer.

Properties. The present compounds are all soluble in water, methanol, and ethanol. No *cis* isomer could be isolated as potassium or sodium salt because of their great solubilities in either an aqueous or an alcoholic medium. The use of the $[Coox(en)_2]^+$ ion as a counter ion was effective for the isolation of the *cis*-$[Co(mal)_2(py)_2]^-$ complex. The *cis*-$[Co(ox)_2(py)_2]^-$ complex was isolated as the lithium salt. The isolation of the *cis*-$[CoCO_3ox(py)_2]^-$ complex was unsuccessful in spite of various attempts. With respect to the corresponding *trans* isomers, all of the complexes were isolated as potassium salts.

Davies and Hung[12] investigated the kinetics of the reaction between the $[Co(CO_3)_3]^{3-}$ species and excess pyridine in an aqueous sodium hydrogencarbonate medium and reported that the reaction produced only the *cis*-$[Co(CO_3)_2(py)_2]^-$ species. Contrary to their statement, we found an isomerization of the *trans*-$[Co(CO_3)_2(py)_2]^-$ species; under the conditions mentioned in Experimental, *ca.* 40% of the initial amount of the *trans* species isomerized to the *cis* species after 12 h, and *ca.* 70% after 22 h, while the reaction was completed after 3 days.

The *trans*-$[CoCO_3ox(py)_2]^-$ species was acid-hydrolyzed in aqueous perchloric acid to give the *trans*-$[Coox(H_2O)_2(py)_2]^+$ species; the hydrolysis proceeded slowly. In a 10% perchloric acid medium, it took about an hour to complete the reaction. The absorption spectrum of the diaqua complex species thus produced is shown in Fig. 5.

The *trans*- and *cis*-$[Co(CO_3)_2(py)_2]^-$ species are also hydrolyzed in the same acid medium to give diaquacarbonato species. However, the species produced are not pure chromatographically because of the rather unstable nature of the parent dicarbonato species in an aqueous medium.

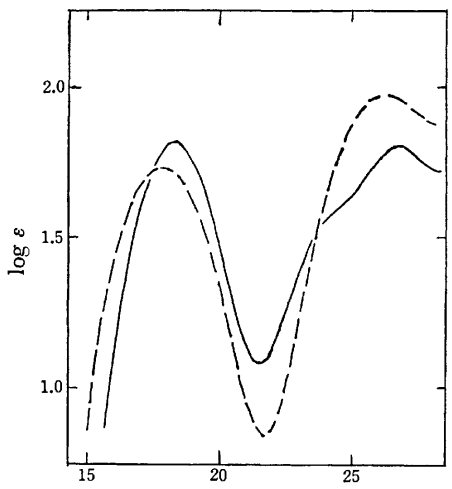

Fig. 5. Absorption spectra of;
—— *trans*-[Coox$(H_2O)_2(py)_2]^+$ and —— *trans*-[$CoCO_3$-ox$(py)_2]^-$.

When excess ammonia reacts on the $[Co(CO_3)_3]^{3-}$ complex, the reaction proceeds successively, yielding *cis*-$[Co(CO_3)_2(NH_3)_2]^-$ and then $[CoCO_3(NH_3)_4]^+$.[1] In contrast, the action of excess pyridine on the $[Co(CO_3)_3]^{3-}$ complex gives only the *trans*- and *cis*-$[Co(CO_3)_2(py)_2]^-$ complexes, no further reaction to give the tetrakis(pyridine) complex occurring. Springborg and Schäffer[13] reported that the action of excess pyridine on an aqueous potaasium bicarbonate solution of the $[Co(CO_3)_3]^{3-}$ complex, which had been prepared using $CoCl_2 \cdot 6H_2O$, at room temperature, yielded the $[CoClCO_3(py)_3]$ complex after 2—3 days. Further, the action of pyridine on this tris(pyridine) complex in the presence of bis(pyridine)mercury(II) perchlorate gave the tetrakis(pyridine) complex $[CoCO_3(py)_4]^+$. The acid decomposition of this carbonato complex to give carbon dioxide is unusually slow and results in the formation of the *trans*-$[Co(H_2O)_2(py)_4]^{3+}$ species.[13]

The coordination of the O–O donor ligands was ascertained from the IR spectral data according to the literature.[14,15] As to the IR spectra of pyridine complexes, Gill *et al.*[16] pointed out that coordinated pyridine is usually distinguished from the free base by the presence of a weak band between 1235 and 1250 cm^{-1}, by a shift of the strong 1578 cm^{-1} band to 1600 cm^{-1}, and by shifts of the 601 and 403 cm^{-1} bands to 625 and

420 cm^{-1} respectively. In our spectra, a similar trend was observed; a weak 1250 cm^{-1} band was observed in the spectrum of each of the dicarbonato and carbonato-oxalato complexes (in the spectra of the other complexes, this absorption region was hidden by other bands). The strong band at *ca.* 1580 cm^{-1} in the free base shifted to 1600—1610 cm^{-1}. The shifts in the *ca.* 600 and 400 cm^{-1} bands could not be identified, because other bands due to the coordinated O-O ligands occurred. There was little difference in the spectrum of the 700—4000 cm^{-1} region between any isomeric pair of the complexes. In the far-infrared region, however, a marked difference was observed between the *trans* and *cis* isomers of the $[Co(CO_3)_2(py)_2]^-$ complex,[5] while the spectra of the other isomeric complexes were weak and broad.

Absorption Spectra. In order to discuss this subject in some detail, we summarize the numerical data on the absorption spectra in Tables 1 and 2, also including the spectral data[17] on some related complexes. As to all the *trans* isomers except for the *trans*-bis(malonato) complex, the observed spectra were divided into three Gaussians (I, IIa, and IIb);[18] the calculations were repeated until the corrections became sufficiently small. The calculated data are included in Table 1 and are illustrated in Fig. 6.

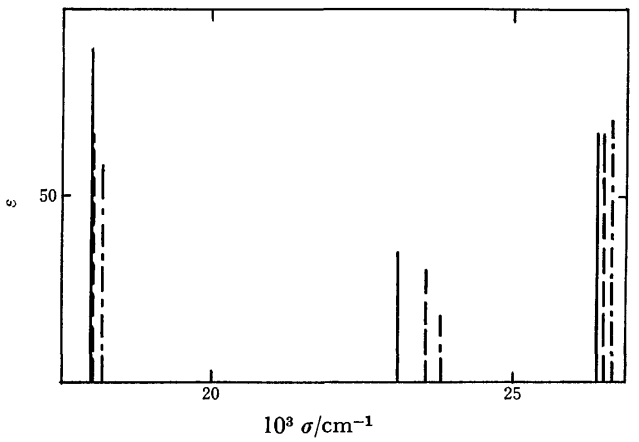

Fig. 6. Calculated positions and intensities for absorption maxima;
----- $[CoCO_3ox(py)_2]^-$, —·— $[Co(ox)_2(py)_2]^-$ and
—— $[Co(CO_3)_2(py)_2]^-$.

Most of the $[CoN_2O_4]^-$-type complexes thus far prepared contain the N-donor in the form of an amino acidate, iminodiacetate, or nitrilotriacetate ion, and their *trans*(*N*) isomers exhibit explicit splittings of their first absorption bands (Table 1).[17,19-21] The situation differs in the present complexes, which contain unidentate pyridine molecules; the *trans*-$[Co(CO_3)_2(py)_2]^-$, *trans*-$[CoCO_3ox(py)_2]^-$ and *trans*-$[Co(ox)_2(py)_2]^-$ complexes exhibit the first bands which can be expressed by only one Gaussian and the second bands which can be divided into two Gaussians, while the *trans*-$[Co(mal)_2(py)_2]^-$ complex shows no splittings in either the first or the second absorption band. As far as the *cis* isomers are concerned, their spectra are typical of the *cis*-$[CoN_2O_4]^-$-type (Table 2).

When the spectral data of the above-mentioned three *trans* isomers are compared with each other, the following tendencies can be found:

1) The maximum positions of the I bands are similar to each other. This was a rather unexpected fact in view of the ligand-field-strengths of the two ligands (the Δ values for octahedral $[Co(O-O)_3]^{3-}$ complexes are 17300 cm^{-1} (CO_3^{2-}) and 18000 cm^{-1} ($C_2O_4^{2-}$)).[22] The ε_{max} values decrease in the order of the dicarbonato, carbonatooxalato, and bis(oxalato) isomers.

2) The half-widths of the I bands are all narrow, but they tend to broaden progressively from the dicarbonato to the bis(oxalato) isomer.

3) The maximum positions of the IIa bands shift to shorter wavelengths in the order of the dicarbonato, carbonatooxalato, and bis(oxalato) isomers, and the ε_{max} values decrease in the same order. The half-widths also decrease in this order.

4) The IIb maxima are located at almost the same positions, and the ε_{max} values are nearly identical. The half-widths increase from the dicarbonato to the bis(oxalato) isomer.

Let us first discuss the assignment of the absorption bands for the three *trans* isomers besides the bis(malonato) isomer. It is well known that, under the D_{4h} symmetry, the $^1T_{1g}$ component in the O_h parentage splits into the $^1E_g{}^a$ and $^1A_{2g}$ components and the $^1T_{2g}$ into the $^1E_g{}^b$ and $^1B_{2g}$. From a comparison of our spectral data on the $^1T_{1g}$ region with those of the related *trans*(*N*)-$[CoN_2O_4]^-$-type complexes, it can be said that the observed I bands (18200—18400 cm^{-1}) are mainly due to the $^1A_{1g}\rightarrow{}^1E_g{}^a$ transition; the transitions to the $^1A_{2g}$ component are perhaps hidden by the feet of the I bands.

For the assignment of the IIa and IIb bands, the π contributions from the N and O donors must be considered. Schäffer *et al.*[23] have recently reported π-back bonding due to the N ligators with respect to the *trans*-$[Cr(py)_4AB]^{n+}$-type complexes. On the other hand, we previously reported that the positions of the IIa and IIb bands for the *trans*-$[Co(CO_3)_2(py)_2]^-$ complex calculated by means of Yamatera's prediction[24] roughly agreeded with the observed positions, although any π contribution was ignored in the calculation. We shall discuss this subject in more detail below.

According to the Angular Overlap Model,[25] the energies of the $(t_{2g})^6\rightarrow(t_{2g})^5(e_g)$ transition in a complex whose holohedrized symmetry is D_{4h} are expressed as follows:

$$\mathbf{E}(A_{2g}) = \langle x^2-y^2|\mathbf{A}|x^2-y^2\rangle - \langle xy|\mathbf{A}|xy\rangle - C \quad (1)$$

$$\mathbf{E}(B_{2g}) = \langle z^2|\mathbf{A}|z^2\rangle - \langle xy|\mathbf{A}|xy\rangle + 16B - C \quad (2)$$

$$\begin{vmatrix} E_g{}^a & \begin{matrix}3/4\langle z^2|\mathbf{A}|z^2\rangle \\ +1/4\langle x^2-y^2|\mathbf{A}|x^2-y^2\rangle \\ -\langle yz|\mathbf{A}|yz\rangle - C - \mathbf{E}\end{matrix} & \begin{matrix}\sqrt{3}/4\{\langle z^2|\mathbf{A}|z^2\rangle \\ -\langle x^2-y^2|\mathbf{A}|x^2-y^2\rangle\}\end{matrix} \\ E_g{}^b & \begin{matrix}\sqrt{3}/4\{\langle z^2|\mathbf{A}|z^2\rangle \\ -\langle x^2-y^2|\mathbf{A}|x^2-y^2\rangle\}\end{matrix} & \begin{matrix}1/4\langle z^2|\mathbf{A}|z^2\rangle \\ +3/4\langle x^2-y^2|\mathbf{A}|x^2-y^2\rangle \\ -\langle yz|\mathbf{A}|yz\rangle + 16B \\ -C-\mathbf{E}\end{matrix} \end{vmatrix} = 0 \quad (3)$$

where **A** represents a one-electron potential operator, and

where B and C denote Racah parameters. From these relations, the energies of the degenerate E_g states can be expressed by the parameters B and C, and the energies $\mathbf{E}(A_{2g})$ and $\mathbf{E}(B_{2g})$ and the energy difference between d_{yz} antibonding energy and d_{xy} antibonding energy, $\langle yz|\mathbf{A}|yz\rangle - \langle xy|\mathbf{A}|xy\rangle$ ($\equiv\Delta\mathbf{E}(\pi)$). Actually the $\mathbf{E}(B_{2g})$ value as well as the $\mathbf{E}(E_g{}^b)$ value can be estimated from the observed IIa maximum and the IIb maximum, and the $\mathbf{E}(A_{2g})$ value from the related complexes which exhibit remarkable splittings in their I band region. Thus, assuming C=4B,[26] the variation in the $\mathbf{E}(E_g{}^a)$ or the $\Delta\mathbf{E}(\pi)$ with varying B values is found.

Let us take the *trans*-$[Co(ox)_2(py)_2]^-$ complex as a representative example; we assume two cases, one of which is that the IIb band is assumed to be the $^1A_{1g}\rightarrow{}^1B_{2g}$ transition (Case a), and the other is that the IIb band is assumed to be the $^1A_{1g}\rightarrow{}^1E_g{}^b$ transition (Case b). For the $\mathbf{E}(A_{2g})$ value, various values are adopted in the 16000—17000 cm^{-1} region. The B parameter varies in the 400—520 cm^{-1} range. The results are illustrated in Figs. 7 and 8.

In Case a, the calculated $\mathbf{E}(E_g{}^a)$ values are almost independent of the varying $\mathbf{E}(A_{2g})$ values, and the estimated $\Delta\mathbf{E}(\pi)$ has positive values. On the other hand, in Case b the $\mathbf{E}(E_g{}^a)$ values are sensitive to the variation in the $\mathbf{E}(A_{2g})$, and the $\Delta\mathbf{E}(\pi)$ has negative values, which are evidence for a net π back-bonding from metal(III) to ligand. In this connection, for the other *trans* bis(pyridine) complexes similar situations were obtained.

The most suitable B value can be evaluated by fitting a calculated $\mathbf{E}(E_g{}^a)$ value to the observed I maximum; the value is estimated to be less than 400 cm^{-1} in Case a, while in Case b it is *ca.* 480 cm^{-1}. In view of the separation between the I maximum and the II maximum for the *cis*-$[Co(ox)_2(py)_2]^-$ complex, the value in Case a

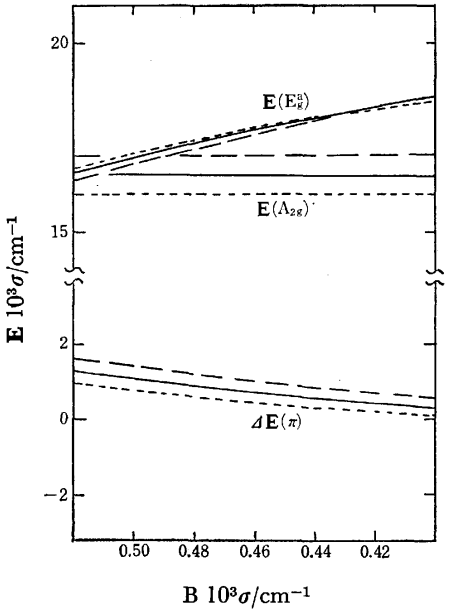

Fig. 7. The variation of $\mathbf{E}(E_g{}^a)$ or $\Delta\mathbf{E}(\pi)$ with B (Case a);
----$\mathbf{E}(A_{2g})=17000$, ——$\mathbf{E}(A_{2g})=16500$ and ·····$\mathbf{E}(A_{2g})=16000$ cm^{-1}.

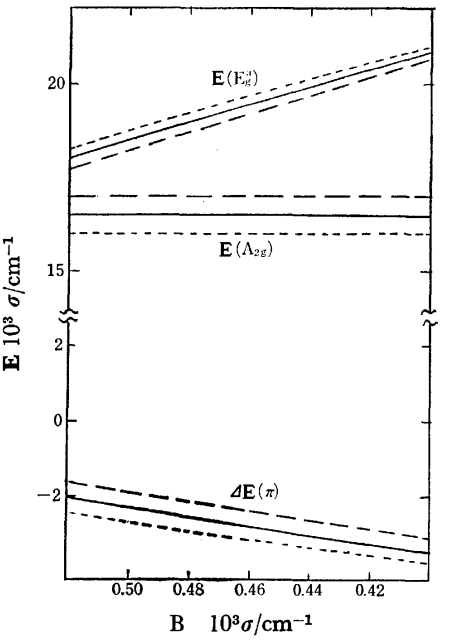

Fig. 8. The variation of $\mathbf{E}(E_g{}^a)$ or $\Delta\mathbf{E}(\pi)$ with B (Case b);
----$\mathbf{E}(A_{2g})=17000$, ——$\mathbf{E}(A_{2g})=16500$ and ·····$\mathbf{E}(A_{2g})=16000$ cm^{-1}.

($\approx$400 cm^{-1}) seems to lose its physical meaning.

Since the $^1A_{1g}\rightarrow{}^1A_{2g}$ and the $^1A_{1g}\rightarrow{}^1B_{2g}$ transitions correspond to the $xy\rightarrow x^2-y^2$ and the $xy\rightarrow z^2$ transitions respectively, the ratio of the transition oscillator strengths can be derived in a way similar to that used for the O_h transitions:[27]

$$\frac{f_{A_2}}{f_{B_2}}=\frac{3\times\mathbf{E}(A_2)}{\mathbf{E}(B_2)}\times\left(\frac{\mathbf{E}(B_2)-\mathbf{E}(CT)}{\mathbf{E}(A_2)-\mathbf{E}(CT)}\right)^2. \qquad (4)$$

Using this equation, the intensity of the $^1A_{1g}\rightarrow{}^1A_{2g}$ transition can be evaluated for the *trans*-$[Co(ox)_2(py)_2]^-$ complex; the $\mathbf{E}(A_{2g})$ value is estimated to be *ca.* 17000 cm^{-1} in view of the Ia maxima of the *trans*(*N*)-$[Co(ida)_2]^-$ and *trans*(*N*)-$[Coox(gly)_2]^-$ complexes (Table 1). The $\mathbf{E}(CT)$ value is assumed to be 41000 cm^{-1}, which corresponds to the CT maximum for the $[Co(ox)_3]^{3-}$ complex. Thus, the ε_{max} value due to the $^1A_{1g}\rightarrow{}^1A_{2g}$ transition is calculated to be *ca.* 42 in Case a and *ca.* 19 in Case b. If the fact that the observed I maximum has $\varepsilon_{max}=57.5$ is taken into consideration, then the ε_{max} in Case a seems to be too large. As to the *trans*-$[Co(CO_3)_2(py)_2]^-$ complex, it is difficult to adopt the same discussion about the intensity because the symmetry of this complex is actually lower than D_{4h}; in addition, the $\mathbf{E}(A_{2g})$ value is hard to estimate. On the basis of these considerations, we now assign the IIa band to the $^1A_{1g}\rightarrow{}^1B_{2g}$ transition and the IIb band to the $^1A_{1g}\rightarrow{}^1E_g{}^b$ transition.

In this connection, the same procedure was applied to the spectral data for the *trans*(*N*)-$[CoCO_3(mda)(NH_3)]^-$ (mda=*N*-methyliminodiacetate ion) complex[28] in order to find the variation in $\mathbf{E}(E_g{}^a)$ or $\Delta\mathbf{E}(\pi)$ with B. The results were quite similar; this fact suggests the minor contribution of the π bonding character due

to coordinated py molecules in the present bis(pyridine) complexes.

We adopt the more reasonable B value, 480 cm^{-1}. The $\langle xy|\mathbf{A}|xy\rangle$ value is assumed to be zero, because two p orbitals of any O donor in xy molecular plane are already used for σ hybridizations and so cannot be of any use in the π bondings. Using such a value, the π antibonding energy in the yz plane is evaluated to be:

$$\langle yz|\mathbf{A}|yz\rangle = -2200\,cm^{-1}. \quad (5)$$

This is expressed alternatively in terms of ligand-field parameters;

$$\Delta(O) + \Delta(N) = -4400\,cm^{-1}. \quad (6)$$

This value is more negative than the $\Delta(N)$ value (-3400——2000 cm^{-1}) for the *trans*-$[Cr(py)_4AB]^{n+}$-type complexes.[23] When the energies from the ligand to metal-charge-transfer transitions are compared between the $[Co(acac)_3]$ and $[Cr(acac)_3]$ complexes,[29] it is found that the metal orbitals in the cobalt(III) complex lie at rather lower levels than those in the chromium(III) complex, suggesting the existence of π-bonding contributions due to O-O donors in the present cobalt(III) complexes.

Let us next consider the spectrum of the *trans*-$[Co(mal)_2(py)_2]^-$ complex. No shoulder is observed in the I band, but the maximum shifts to a longer wavelength compared with those for the other *trans* isomers, and the half-width is enhanced. These facts suggest that the absorption due to the $^1A_{1g}\rightarrow{}^1A_{2g}$ transition gains a certain amount of intensity. The II band maximum also shifts to a considerably longer wavelength compared with the maxima of the IIb bands for the other isomers, and the half-width is also enhanced. These facts suggest that the absorptions due to the $^1A_{1g}\rightarrow{}^1B_{2g}$ and $^1A_{1g}\rightarrow{}^1E_g{}^b$ transitions occur in a closely-neighboring region with the comparable intensities. The same facts can be found more clearly in the spectrum of the *trans*-$[Coox(H_2O)_2(py)_2]^+$ complex (Fig. 5 and Table 1).

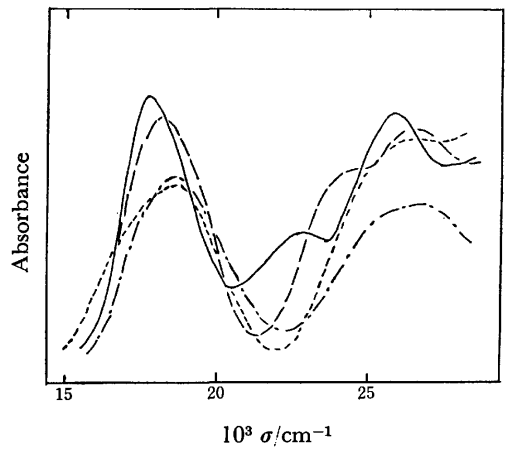

Fig. 9. Crystal spectra of *trans* isomers of;
—— $K[Co(CO_3)_2(py)_2]\cdot 3H_2O$,
---- $K[CoCO_3ox(py)_2]\cdot 2.5H_2O$,
-·-·- $K[Co(ox)_2(py)_2]\cdot 3H_2O$,
····· $K[Co(mal)_2(py)_2]\cdot 2H_2O$.

Figure 9 shows the nonpolarized crystal spectra of the *trans*-isomers; every spectrum resembles the corresponding solution spectrum in shape, but it is noteworthy that the spectrum of the *trans*-$[Co(mal)_2(py)_2]\cdot 2H_2O$ shows a shoulder on the longer-wavelength side (*ca.* 16400 cm^{-1}) of the main I band (18600 cm^{-1}). This may be due to the $^1A_{1g}\rightarrow{}^1A_{2g}$ transition, which disappears in the solution spectrum.

Association Constants of Optically Active $[Co(en)_3]^{3+}$ with (+)-Tartrate and Fumarate Ions Determined from the Kinetic Data of Hydrogen-Deuterium Exchange

Miho FUJITA* and Hideo YAMATERA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received April 25, 1977)

The hydrogen-deuterium exchange rates of *Λ*- and *Δ*-$[Co(en)_3]^{3+}$ were measured in D_2O solutions containing (+)-tartrate ions. From the kinetic data, the ion-association constants of the *Λ*- and *Δ*-isomers with (+)-tartrate ions were determined to be 40 and 32 (I=0.1) respectively. Similar measurements with fumarate resulted in the association constant of 16 (I=0.1).

In a previous paper,[1] we preliminarily reported the stereoselective hydrogen-deuterium exchange reaction of *Λ*- and *Δ*-$[Co(en)_3]^{3+}$ in D_2O solutions in the presence of (+)-tartrate ions.

The present paper will give a further analysis of the experimental results on the exchange reaction rates, from which the association constants of *Λ*- and *Δ*-$[Co(en)_3]^{3+}$ with the (+)-tartrate ion and with the fumarate ion will be derived.

Experimental

$[Co(en)_3]Br_3 \cdot H_2O$ was prepared by the usual method and resolved into the optical isomers by using silver (+)- and (−)-tartrate. The *Λ*- and *Δ*-$[Co(en)_3]Br_3 \cdot H_2O$ obtained showed $[\alpha]_D$ values of +125 ° and −124 ° respectively. (+)-Tartrate buffer solutions of a constant pH value (pH=5.00±0.03)** were prepared by dissolving the acid and its sodium salt at a given ratio in a E. Merck D_2O with an isotopic purity of 99.75%; the concentrations of sodium (+)-tartrate in these buffer solutions ranged from 0.006 to 0.15 M (=mol dm^{-3}). The fumarate buffer solutions (pH=5.33±0.03, 0.025—0.12 M) were similarly prepared.

After the complex had been dissolved in the buffer solutions at a constant concentration (0.03 M), the hydrogen-deuterium exchange rates were measured at 25.0 °C. The first-order rate constants were determined in the way described in a previous paper.[1]

Results and Discussion

Table 1 shows the first-order rate constants, k, of hydrogen-deuterium exchange reactions of *Λ*- and *Δ*-$[Co(en)_3]^{3+}$ in the presence of (+)-tartrate and of fumarate. The rate constants decreased with the increase in the (+)-tartrate concentration; the change in the rate constant was greater for *Λ*-$[Co(en)_3]^{3+}$ than for the *Δ*-isomer, showing a stereoselectivity between *Λ*- and *Δ*-$[Co(en)_3]^{3+}$ in the interaction with (+)-tartrate ions. Fumarate ions had a smaller effect without stereoselectivity. These data were analyzed in order to determine the association constants of *Λ*- and *Δ*-$[Co(en)_3]^{3+}$ with (+)-tartrate ions and with fumarate ions on the following assumptions:

Table 1. First-order rate costants of hydrogen-deuterium exchange reactions of *Λ*- and *Δ*-$[Co(en)_3]^{3+}$ in D_2O[a]

[(+)-tartrate]/M[b]	$10^4 k/s^{-1}$ *Λ*	$10^4 k/s^{-1}$ *Δ*	[fumarate]/M[c]	$10^3 k/s^{-1}$ *Λ*, *Δ*
0.00614	13.7	13.9	0.0240	3.05
0.0191	11.3	11.9	0.0248	3.00
0.0254	10.5	10.6	0.0359	2.53
0.0487	7.63	8.23	0.0467	2.38
0.0664	6.02	6.70	0.0700	2.02
0.0988	4.97	5.28	0.1079	1.73
0.1035	4.77	5.17	0.1228	1.51
0.1225	3.93	4.42		
0.1485	2.72	3.28		
0.2045	2.55	3.05		

a) The $[Co(en)_3]^{3+}$ concentration was 0.03 M in all cases. b) pH 5.00±0.03. c) pH 5.33±0.03.

i) There is the ion-association equilibrium:

$$RH^{3+} + B^{2-} \rightleftharpoons RHB^{+}$$

where RH^{3+} and B^{2-} represent the complex cation and the buffer anion respectively. The association constant, K, is given by:

$$K = \frac{[RHB^+]}{[RH^{3+}][B^{2-}]} \frac{f_1}{f_3 f_2} = \frac{x}{(c_A - x)(c_B - x)} \frac{f_1}{f_3 f_2}, \quad (1)$$

where c_A and c_B are the total concentrations of RH^{3+} and B^{2-} respectively, and x the concentration of the ion-pair, RHB^+, at equilibrium. The f_z (z=1, 2, and 3) notation represents the activity coefficient of the ions with the charge of z or $-z$.

ii) The hydrogen-deuterium exchange proceeds in the following steps:

$$RH^{3+} + OD^- \overset{K_{OD}}{\rightleftharpoons} RHOD^{2+}$$

$$K_{OD} = \frac{[RHOD^{2+}]}{[RH^{3+}][OD^-]} \frac{f_2}{f_3 f_1}, \quad (2)$$

$$RHOD^{2+} \overset{k'}{\longrightarrow} R^{2+} + HOD, \quad (3)$$

$$R^{2+} + D_2O \longrightarrow RD^{3+} + OD^-. \quad (4)$$

Step 3 with the rate constant, k', is rate-determining, and Step 4 is very fast. The activity coefficients were assumed to be identical for ions of the same $|z|$ value.

iii) The rate of the hydrogen-deuterium exchange of RHB^+ is very slow compared with that of RH^{3+}.

* Present address: Department of Chemistry, Nagoya City University, Mizuho, Nagoya 467.

** The pH values in this paper are the apparent ones of D_2O solutions measured with an ordinary pH meter. Two relations, pD=pH(apparent)+0.40[2] and $K_{W(D_2O)}=0.160\times K_{W(H_2O)}$,[3] were used for the determination of $[OD^-]f_{OD^-}$.

On these assumptions, the observed exchange rate, first-order in the concentration of the complex, c_A, is related to the rate of Step 3:

$$kc_A = k'[\mathrm{RHOD}^{2+}]. \quad (5)$$

Equations 2 and 5 give:

$$kc_A = k'K_{OD}[\mathrm{RH}^{3+}]\frac{f_3}{f_2}[\mathrm{OD}^-]f_1. \quad (6)$$

On the other hand, Eq. 1 is transformed to:

$$[\mathrm{RH}^{3+}] = c_A\{1+(c_B-x)\frac{f_3f_2}{f_1}K\}^{-1}. \quad (7)$$

Substituting Eq. 7 into Eq. 6, one obtains:

$$k(f_2/f_3) = k'K_{OD}[\mathrm{OD}^-]f_1\{1+(c_B-x)\frac{f_3f_2}{f_1}K\}^{-1}, \quad (8)$$

or

$$\log k(f_2/f_3) = \log k_{OD} + \log([\mathrm{OD}^-]f_1) - \log\{1+(c_B-x)\frac{f_3f_2}{f_1}K\}, \quad (9)$$

where k_{OD} is substituted for $k'K_{OD}$. Since the values of k_{OD} and $[\mathrm{OD}^-]f_1$ (activity of OD^- ions) are constant in the present experiments, a $-\log(1+X)$ *vs.* $\log X$ curve will fit the $\log k(f_2/f_3)$ *vs.* $\log\{(c_B-x)(f_3f_2/f_1)\}$ plots of the experimental results. The association constant and the k_{OD} value can be determined from the asymptotes of the curve.

The activity coefficient, f_z, was calculated by using the extended Debye-Hückel equation:

$$\log f_z = -\frac{Az^2\sqrt{I}}{1+Ba\sqrt{I}} + bI, \quad (10)$$

with the values of $a=6$ Å and $b=0.1$ z^2. The ionic strength (I) ranged from 0.18 to 0.64 for the sample solutions containing (+)-tartrate and from 0.12 to 0.43 for the fumarate solutions. All the kinetic data were corrected to $I=0.1$ by means of Eq. 10.

An approximate K value was obtained from the curve-fitting with the first approximation of $(c_B-x)(f_3f_2/f_1)=c_B(f_3f_2/f_1)$ and $I=6c_A+3c_B$, and was then used to calculate the value of x with Eq. 1. Then, f_1, f_2, and f_3 were recalculated with $I=6c_A+3c_B-6x$. The second curve-fitting for the $\log k(f_2/f_3)$ *vs.* $\log\{(c_B-x)(f_3f_2/f_1)\}$ plots gave a better K value. Further repetition of the procedure reproduced the K value within the limits of experimental error.

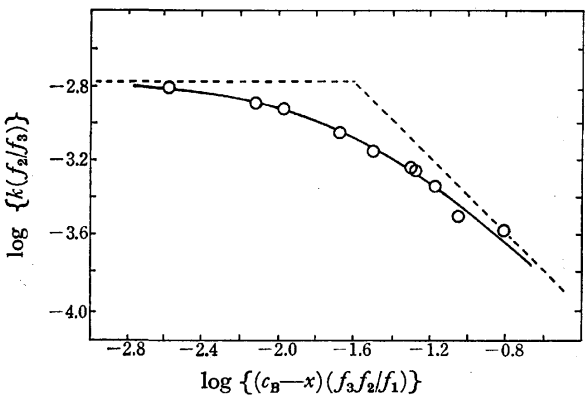

Fig. 1. The curve-fitting for the results on the Λ-[Co(en)$_3$]$^{3+}$-(+)-tartrate(2−) system. ○: Experimental values, ——: the normalized curve, ----: asymptotes for the curve.

Table 2. Values of the association constant, K, and of the rate constant, k_{OD}, at 25 °C

Ion-pair	K This work	K Ref. 4[a]	K Ref. 5[b]	$10^{-6}k_{OD}$/M^{-1} s^{-1} This work
Λ + (+)-tart(2−)	40	26±2	55.8±1.4	4.2
Δ + (+)-tart(2−)	32	21±2	50.4±1.8	4.1
Λ(Δ) + fumarate(2−)	16			4.5

a) Measured at $I=0.1$ (adjusted with $NaClO_4$). b) Corrected to $I=0.1$ using the equation: $\log f_z = -Az^2\sqrt{I}/(1+Ba\sqrt{I})$, with the value of $a=6$Å.

Figure 1 shows a typical example of the curve-fitting for Λ-[Co(en)$_3$]$^{3+}$ after repeated successive approximations as has been described above, while Table 2 summarizes the resulting K and k_{OD} values, together with the literature values. Our K values for the Λ- and Δ-[Co(en)$_3$]$^{3+}$-(+)-tartrate ion-pairs are intermediate between the two sets of literature values[4,5] obtained from spectrophotometric measurements. Yoneda *et al.*[5] have claimed that the smaller K values obtained by Ogino and Saito[4] may be ascribed to the neglect of the association of [Co(en)$_3$]$^{3+}$ with ClO_4^-; the latter authors added $NaClO_4$ to the sample solutions to adjust the ionic strength. In the present experiments, the sample solutions contained a constant amount of bromide ions derived from [Co(en)$_3$]$Br_3\cdot H_2O$. Therefore, our K values may be slightly too small because of the neglect of the association of [Co(en)$_3$]$^{3+}$ with Br^-.

The k_{OD} values given in Table 2 can be compared with the value of 2.4×10^6 M^{-1} s^{-1} obtained by Palmer and Basolo[6] in an acetate buffer solution, considering that different methods were used for the estimation of the OD^- concentrations. As is shown in Table 2, the K values are about twice as large for (+)-tartrate ions as for fumarate ions. This is consistent with the conclusion from our previous circular-dichroism studies that the (+)-tartrate ion would be favored in the formation of hydrogen bonds through N–H hydrogens of the complex ion.[7]

Complex Formation of Silver(I) Ion with Some Aliphatic Diamines

Hitoshi OHTAKI and Kenji CHO

Department of Electronic Chemistry, Tokyo Institute of Technology at Nagatsuta, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received June 7, 1977)

Complex formation of silver(I) ion with 1,3-propanediamine and 1,4-butanediamine has been studied potentiometrically at 25 °C in 3 mol dm^{-3} $LiClO_4$ aqueous solution. Some additional experiments have been carried out in the system of silver–1,2-ethanediamine of large diamine/Ag ratios, the system having been examined in a previous work at small diamine/Ag ratios. Over the pH range of 6—10.4, the emf data obtained in the silver–diamine solutions could be explained in terms of the formation of the following complexes (L denotes the free diamine molecule): In a solution of low pH (pH=6—8), the $AgHL^{2+}$ and $AgH_2L_2^{3+}$ complexes are formed. In an alkaline solution, the AgL^+, $Ag_2L_2^{2+}$, and AgL_2^+ complexes are formed, and the relative amounts of the complexes depend on the concentrations of the metal and ligand (L) and also the ratio of these concentrations. The Ag(OH)L complex becomes a main species at the highest pH examined. In some cases the formation of the $AgHL_2^{2+}$, $Ag_2HL_2^{3+}$, and Ag_2L^{2+} complexes is suggested from the graphical or computer analysis of the data, but the formation constants of the complexes are rather uncertain. Over the whole pH range examined, the $AgHL^{2+}$, $AgH_2L_2^{3+}$, AgL^+, and $Ag_2L_2^{2+}$ complexes are predominant in all the systems.

In a previous work we studied the complex formation of silver(I) ion with 1,2-ethanediamine and 1,2-propanediamine, and found various protonated and polynuclear complexes.[1] The equilibria between silver(I) and the diamines were more complicated than those described in the preceding papers.[2,3] In addition to the study on the effect of the methyl group attached to the methylene chain previously examined,[1] the effect of the length of the methylene chain on the reaction between silver(I) and diamines was explored in the present work.

Experimental

Reagents. 1,3-Propanediammonium perchlorate and 1,4-butanediammonium perchlorate were prepared from the corresponding diamines and perchloric acid. 1,3-Propanediamine and 1,4-butanediamine were purchased from Wako Pure Chemicals Co., Osaka and Aldrich Chemical Co., Inc., Milwaukee, USA, respectively. The method of preparation of the reagents was described in the previous paper.[1] Other chemicals were the same as those used previously.[1]

Apparatus. Beckman (Nos. 40495 and 40498) glass electrodes were used in combination with the Kawai-type of the half cell[4] for emf measurements. An Orion Digital pH Meter Model 801 was used.

Method of Measurements. During the potentiometic titrations the total concentration of perchlorate ions was kept constant at 3 M (M=mol dm^{-3}) by using lithium perchlorate. The concentrations of silver and diamines were changed over the range of 2—40 mM and 5—160 mM, respectively. The ratio of the concentration of the diamines to that of silver ion (C_L/C_{Ag}) was changed from 0.5—40.

Twelve titrations for silver–1,3-propanediamine and fifteen titrations for silver–1,4-butanediamine solutions were performed at 25.00±0.01 °C in a paraffin oil thermostat, which was placed in a room thermostated at 25±1 °C. Some additional titrations were carried out for silver–1,2-ethanediamine solutions under the same experimental conditions. The C_L/C_{Ag} ratio was 5 and 10 in this work, whereas the ratio had been 2—4 in the previous work.[1]

Details of the method of measurements were described elsewhere.[1]

Results

Titration curves of silver–1,3-propanediamine and –1,4-butanediamine solutions are shown in Figs. 1 and

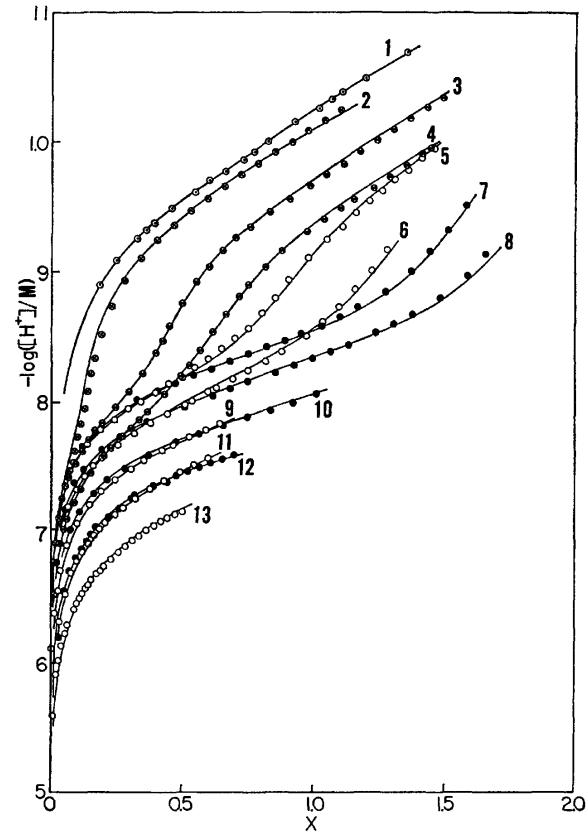

Fig. 1. Titration curves of 1,3-propanediamine and silver–1,3-propanediamine solutions. 2, respectively.

The pK Values of the Diammonium Perchlorates were obtained from the titration curves of the solutions without silver ion (curve 1 in Figs. 1 and 2). The pK values are tabulated in Table 1, together with the pK

Table 1. Acid dissociation constants of 1,2-ethanediamine, 1,3-propanediamine and 1,4-butanediamine (25 °C, 3 M $LiClO_4$).

	en	pn	bn
pK_1	7.93	9.71	10.39
pK_2	10.74	10.93	11.05
$\Delta pK=pK_2-pK_1$	2.81	1.22	0.66

values of 1,2-ethanediammonium perchlorate which were recalculated in the present work. Compared with the values reported by Ohtaki and Tanaka in a 0.1 M NaCl medium,[5] the pK values found in the 3 M $LiClO_4$ medium were larger, but $\Delta pK=pK_2-pK_1$ more rapidly converged to the statistical value of 0.6.

Estimation of the Composition and Formation Constants of Silver–Diamine Complexes. Along the line described in the previous paper,[1] we estimated the composition and the formation constants of the silver–diamine complexes first with the graphical method and then the mathematical treatment by using a high speed electronic computer in order to refine the constants. In the course of the computer calculations, some complexes were assumed in addition to the complexes graphically estimated in order to obtain a better fit of calculated titration curves with experimental ones.

At lower pH where most diamine molecules are present as H_2L^{2+} (L denotes the free base of diamine), the equilibrium between silver ion and a diamine may be written by Eq. 1.

$$pAg^+ + rH_2L^{2+} = Ag_pH_qL_r^{(p+q)+} + (2r-q)H^+. \quad (1)$$

The equilibrium constant is defined as follows:

$$\kappa_{pqr} = \frac{[Ag_pH_qL_r^{(p+q)+}][H^+]^{(2r-q)}}{[Ag^+]^p[H_2L^{2+}]^r} = \beta_{pqr}K_1^rK_2^r, \quad (2)$$

where β_{pqr} is the overall formation constant of the complex $Ag_pH_qL_r^{(p+q)+}$;

$$\beta_{pqr} = \frac{[Ag_pH_qL_r^{(p+q)+}]}{[Ag^+]^p[H^+]^q[L]^r}. \quad (3)$$

Here [ ] represents the concentration (M=mol dm^{-3}) of the species. From the material balance of the metal ion, Eq. 4 can be readily derived.

$$\frac{C_M-[Ag^+]}{[Ag^+]} = \phi - 1 = \sum_p\sum_q\sum_r p\kappa_{pqr}[Ag^+]^{p-1}[H^+]^{-(2r-q)}[H_2L^{2+}]^r. \quad (4)$$

If we assume as a first approximation that only one complex is formed in this pH range, the summations in Eq. 4 are dropped. If the assumption is acceptable, the plot of log $(\phi-1)$ against $-\log [H^+]$ should give straight lines with a slope of $(2r-q)$, the lines depending on the concentrations of the silver ion and diamine. However, the plots were independent of the concentration of the silver ion as is seen in Fig. 3. Therefore, it is obvious that the main species formed in the pH range shown in Fig. 3 is mononuclear with respect to silver. Since the slope of the line was approximately unity, $(2r-q)$ should be unity. Since it is readily found that the family of the straight lines is a function of log C_L (C_L is approximately equal to $[H_2L^{2+}]$ under the

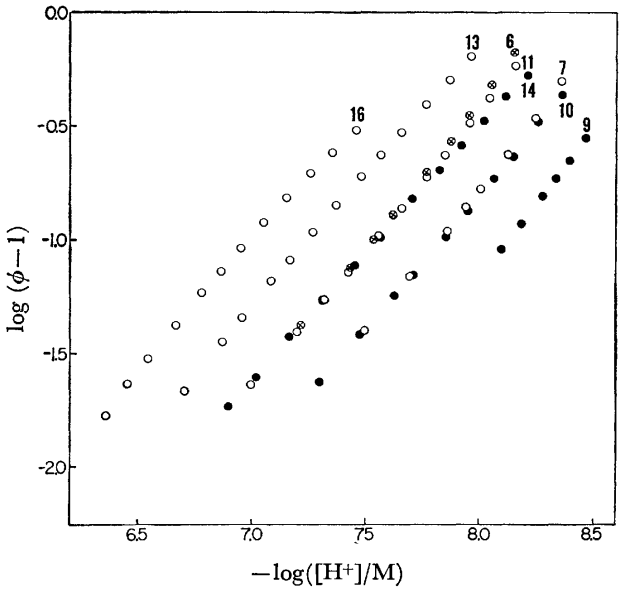

Fig. 3. Relationships between log $(\phi-1)$ and $-\log [H^+]$. Numbers in the figures correspond to those of Fig. 2.

present conditions), r should be unity, and thus $q=1$. Thus the composition of the species was determined to be $AgHL^{2+}$. Another species was found from the analysis of the second approximation of Eq. 4 by assuming two complexes, $AgHL^{2+}$ and $Ag_{p'}H_{q'}L_{r'}^{(p'+q')+}$, because the slope of the lines in Fig. 3 was slightly larger than unity. In order to avoid duplication of description, the treatment of the data is not described here and should be referred to the previous paper, Eqs. 14—17 of Ref. 1.[6] The second species $Ag_{p'}H_{q'}L_{r'}$ was $AgH_2L_2^{3+}$.

At higher pH the AgL^+ complex was found. In solution containing a large excess of a diamine compared with the silver ion, the $Ag_2L_2^{2+}$ and AgL_2^+ complexes were found in the same pH range.[7]

At the highest pH a hydrolyzed species Ag(OH)L formed.

The formation constants of the complexes, together with some other complexes which were not detected by the graphical treatment, were refined by the least squares method in which the error square sum $U=\sum(X-X_{calcd})^2$ was minimized by searching the best values of β_{pqr} for a set of the complexes $Ag_pH_qL_r^{(p+q)+}$. Here X denotes the ratio of the concentration of hydroxide ions added to the total concentration of a diamine in the solution, and X_{calcd} represents the calculated value of X and is given by Eq. 5.

$$X_{calcd}=\frac{2C_L+K_w/[H^+]-[H^+]-\sum_p\sum_q\sum_r q\beta_{pqr}[Ag^+]^p[H^+]^q[L]^r}{C_L}, \quad (5)$$

where K_w denotes the autoprotolysis constant of water in the 3 M $LiClO_4$ and is $10^{-13.867\pm0.009}$ M^2.[8]

The results are summarized in Table 2 in terms of $\log\beta_{pqr}$. For the silver–1,2-ethanediamine complexes, the formation constants of the complexes reported in the previous paper were recalculated by using all the data given in Ref. 1 and obtained in the present work. Some other complexes such as $AgHL_2^{2+}$, $Ag_2HL_2^{3+}$, and AgL_2^+ were found in the present calculation; these complexes have not been obtained in solutions of relatively small C_L/C_{Ag} ratios in the previous work.[1] On the other hand, the formation constant of the Ag_2L^{2+} complex was not detected with reasonable accuracy in the present calculation.

The $Ag_2HL_2^{3+}$ complex was not detected with reasonable certainty in both the systems of silver–1,3-propanediamine and –1,4-butanediamine. The formation constant of the AgL_2^+ complex was also not obtained in the former system by the least squares calculations. The value estimated by the graphical method is given in parentheses as reference in Table 2. For the silver–1,4-butanediamine solutions, the formation constant of the AgL^+ complex was uncertain as is shown in parentheses in Table 2. Some minor complexes added in the least squares caculation may sometimes refine the results, but the existence of the complexes is less certain and the formation constants obtained are rather unreliable. The $Ag_2HL_2^{3+}$ complex detected as a minor species in the present calculation is uncertain with this reason.

Table 2. Formation constants of the $Ag_pH_qL_r^{(p+q)+}$ complexes, $\log\beta_{pqr}$, in 3 M $LiClO_4$ at 25°C
$\beta_{pqr}=[Ag_pH_qL_r^{(p+q)+}]/[Ag^+]^p[H^+]^q[L]^r$ $M^{-(p+q+r-1)}$.

Complex	en	pn	bn	en[2]	pn[3]	bn[3]
HL	10.74	10.96	11.05	10.03	10.64	10.82

AgL_2	9.45	(9.8)[a]	8.6_2	7.7	—	—
Ag_2L	—	—	7.2_3	6.5	6.4	—

a) Values in parentheses are those estimated by curve-fitting in the concentration ranges where appreciable amounts of the relevant complexes are expected to be present, but these constants are not refined by the least-squares calculations with reasonable certainty.

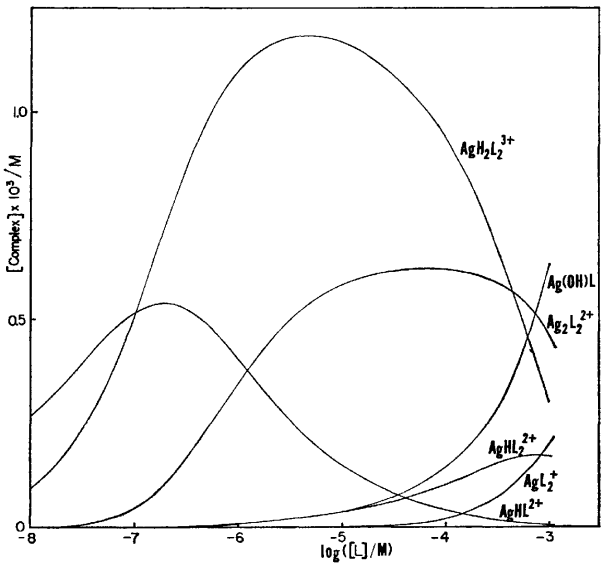

Fig. 4. Distribution of silver–1,4-butanediamine complexes.
$C_{Ag}=2.542$ mM, $C_L=20.00$ mM.

A typical set of the distribution curves of the complexes listed in Table 2 is shown for the 1,4-butanediamine system in Fig. 4. Similar sets of the distribution curves of the complexes were obtained for the 1,2-ethanediamine and 1,3-propanediamine systems. As is seen from the figure, $AgHL^{2+}$ is a major component of the complexes at the lowest pH's (pH=6—7). The $AgH_2L_2^{3+}$ complex is a main species over a wide range of pH examined. The $Ag_2L_2^{2+}$ complex and sometimes the AgL^+ complex become the main species. In the highest pH range the Ag(OH)L complex becomes one of the most important species in the solution.

Discussion

Stepwise formation constants of the $AgHL^{2+}$ and $AgH_2L_2^{3+}$ complexes are readily calculated from the values in Tables 1 and 2.

$$Ag^+ + HL^+ = AgHL^{2+}, \quad (6)$$

$$\log K(AgHL/HL) = 2.79(L=en),\ 3.39(pn),\ 3.63(bn),$$

and

$$AgHL^{2+} + HL^+ = AgH_2L_2^{3+}, \quad (7)$$

$$\log K(AqH_2L_2/HL) = 3.16(L=en),\ 3.65(pn),\ 4.10(bn),$$

where the constants $K(AgHL/HL)$ and $K(AgH_2L_2/HL)$ are defined as follows:

$$K(AgHL/HL) = \frac{[AgHL^{2+}]}{[Ag^+][HL^+]},$$

$$\text{and}\quad K(AgH_2L_2/HL) = \frac{[AgH_2L_2^{3+}]}{[AgHL^{2+}][HL^+]}, \quad (8)$$

and en, pn, and bn denote 1,2-ethanediamine, 1,3-propanediamine and 1,4-butanediamine, respectively.

The second formation constant $K(AgH_2L_2/HL)$ is larger than the first one $K(AgHL/HL)$ in all the cases, as has been pointed out in the previous paper.[1] The values of log $K(AgHL/HL)$ and log $K(AgH_2L_2/HL)$ approach the corresponding stepwise formation constants of the silver–ammine complexes, log $K_1=3.58$ and log $K_2=4.19$[9] with the length of the methylene chain. The values of the stepwise formation constants of the silver–1,4-butanediamine complexes are very close to those of the silver–ammine complexes. This fact suggests that the electrostatic repulsion between protons on the diamine molecules and the silver ion becomes negligible when they are separated by four methylene groups. The result that ΔpK of 1,4-butanediamine was close to the statistical value (0.6, see Table 1) supports this consideration. That the first stepwise formation constant is smaller than the second one is a known fact for a complex having a linear structure.

The stepwise formation constants of the AgL_n complex are given as follows:

$$Ag^+ + L = AgL^+, \quad (9)$$

$$\log K(AgL/L) = 5.2_6(L=en),\ 6.59(pn),\ (6.4)(bn),$$

and

$$AgL^+ + L = AgL_2^+, \quad (10)$$

$$\log K(AgL_2/L) = 4.1_9(L=en),\ (3.2)(pn),\ (2.2)(bn).$$

The values in parentheses are uncertain because the overall formation constants of these complexes were not determined with reasonable accuracy. However, we may still say that $K(AgL/L)$ is larger than $K(AgL_2/L)$, and the values of $K(AgL/L)$ for all the diamine complexes are smaller than β_2 of the diammine silver(I) complex. It is seen that $K(AgL/L)$ is much larger than K_1 of the monoammine silver complex and $K(AgHL/HL)$ of the $AgHL^{2+}$ complex. Therefore, we concluded that the diamine molecule combines with the silver ion as a bidentate ligand. The AgL_2^+ complex may have a tetrahedral configuration. The AgL^+ complex would have either a bent linear or a distorted tetrahedral structure with additional two water molecules attached to the vacant sites of the tetrahedron. As we will discuss later for the formation constant of the Ag(OH)L complex, the latter structure seems to be more possible than the former.

A large dimerization constant of the AgL^+ complex suggests a ring structure of the $Ag_2L_2^{2+}$ complex, as has been described by Schwarzenbach, *et al.*[2]

The formation constant of the $AgHL_2^{2+}$ complex from the AgL^+ and HL^+ complexes is given as follows:

$$AgL^+ + HL^+ = AgHL_2^{2+};$$

$$K(AgHL_2/HL) = \frac{[AgHL_2^{2+}]}{[AgL^+][HL^+]}, \quad (11)$$

$$\log K(AgHL_2/HL) = 2.8_6(L=en),\ 1.7_0(pn),\ (1.7)(bn).$$

Stabilization of the $AgHL_2^{2+}$ complex by combination of AgL^+ with HL^+ suggests that the $AgHL_2^{2+}$ complex has also a ring structure. The formation constant $K(AgHL_2/HL)$ smaller than $K(Ag_2L_2/AgL)$ may be attributed to the weaker H_2N–H^+–NH_2 bond than the H_2N–Ag^+–NH_2 bond in the ring structures.

The hydrolysis constant of the AgL^+ complex is given by Eq. 12.

$$AgL^+ + H_2O = Ag(OH)L + H^+;$$

$$K(Ag(OH)L/H_2O) = \frac{[Ag(OH)L][H^+]}{[AgL^+]}, \quad (12)$$

$$\log K(Ag(OH)L/H_2O) = -10.0_8(L=en),\ -10.1_6(pn),\ (-10.8)(bn).$$

These values are almost the same as the hydrolysis constant of the aqua silver(I) ion:

$$Ag^+ + H_2O = AgOH + H^+;$$

$$\log K(AgOH/H_2O) = -11.1\ (1\ M\ AgNO_3[10]). \quad (13)$$

The fact may show that no H_2N–Ag bond cleavage occurs by the hydrolysis of the AgL^+ complex. Therefore, the silver ion within the Ag(OH)L complex might be combined with at least three ligand atoms (two N and one O), and more probably the metal ion would be coordinated with two amino groups, one hydroxide ion and one water molecule.

The authors thank Dr. Takayoshi Kawai for his kind assistance.

Phthalimides. I. Base-catalyzed Lossen Rearrangement and Acid-catalyzed Beckmann Rearrangement with *N*-(Arylsulfonyloxy)phthalimides

A. F. M. Fahmy, N. F. Aly, A. Nada, and N. Y. Aly
Faculty of Science, Ain Shams University, Abbassia, Cairo, A.R.E.

(Received August 2, 1976)

N-(Arylsulfonyloxy)phthalimides undergo base-catalyzed Lossen rearrangement with amines, and amino acids to give *N,N'*-diaryl ureas and amine salts. They behave similarly with phenylhydrazine in alcohol to give a mixture of *N*-hydroxyphthalimide and phenylhydrazine salts. However, *N*-(arylsulfonyloxy)phthalimides undergo isomerization followed by Beckmann rearrangement to give a mixture of 4-aryl-1*H*-2,3-benzoxazin-1-ones and diarylsulfones.

N-(Hydroxy)phthalimides undergo Beckmann rearrangement but fail to undergo Lossen reangement.[1] We have reinvestigated the imide rearrangement starting with *N*-(arylsulfonyloxy)phthalimides (I) in order to see the effect of the introduction of *N*-arylsulfonyl group on the mode of rearrangement. It was found that Ia and b undergo base-catalyzed Lossen rearrangement and acid-catalyzed isomerization followed by Beckmann rearrangement.

Lossen Rearrangement of N-*(Arylsulfonyloxy)phthalimides. (A) Rearrangement in the Presence of Amines*: When *N*-(arylsulfonyloxy)phthalimides (Ia and b) are allowed to react with aromatic amines in refluxing benzene, they undergo aminolysis followed by base-catalyzed Lossen rearrangement to give the corresponding mixtures of *N*-[2-(arylcarbamoyl)phenyl]-*N'*-arylureas (IIa—d), and aromatic amine salts of aryl sulfonic acids (IIIa—h).

Structure (II) was confirmed by the following:

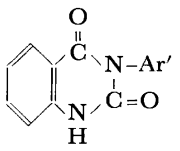
IR spectra: $\nu_{C=O}$ (anilide, 1710—1700 cm^{-1}), $\nu_{C=O}$[2] (*N,N'*-diarylureas, 1660—1640 cm^{-1}), and $\nu_{NH's}$ (3300—3200 and 3120—3100 cm^{-1}).

MS of IId: (molecular ion, m/e=399).

Pyrolysis of IIa—d to give the corresponding 3-aryl-1,2,3,4-tetrahydroquinazoline-2,4-diones (IVa—d).

Structure (IIIa—h) was confirmed by the following:

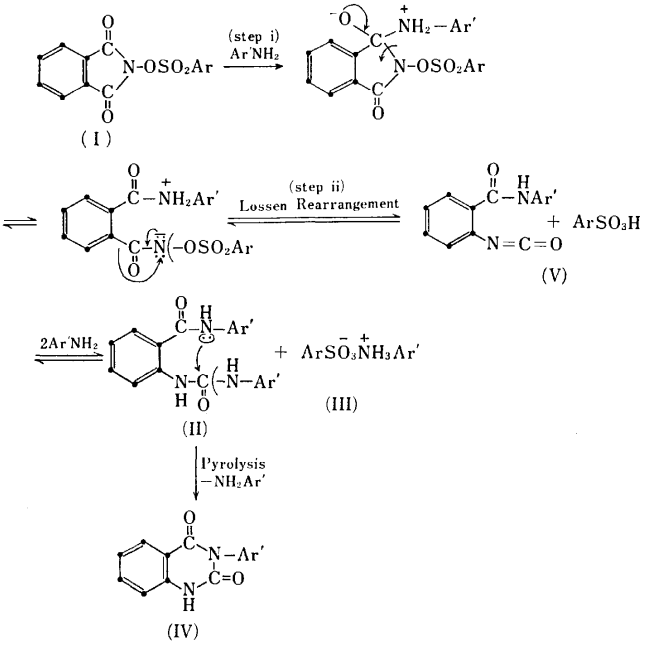
(i) IR spectra: $\nu^{+}_{NH_3}$ (3020—3000 cm^{-1}), $\overset{+}{N}H_3$ asymm. bending (1600—1575 cm^{-1}), $\overset{+}{N}H_3$[3] symm. bending (1500 cm^{-1}).



(IV)

a; Ar'=C_6H_5, b; Ar'=$C_6H_4CH_3(p)$,
c; Ar'=$C_6H_4OCH_3(p)$, d; Ar'=$C_6H_4Cl(p)$

(ii) Identity with authentic products.[4] The above reactions are summarized in the following scheme (Scheme 1).

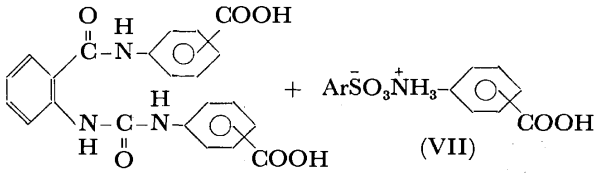


Scheme 1.

(B) Rearrangement in the Presence of Aminobenzoic Acids: *N*-(Arylsulfonyloxy)phthalimides (Ia and b) undergo base-catalyzed Lossen rearrangement with (*p*- and *m*-) aminobenzoic acids to give the corresponding mixtures of *N,N'*-diarylureas (VIa and b) and amino acid salts with sulfonic acids (VIIa—d).

Structure (VI) was confirmed by the following:

IR spectra: ν_{NH} (3320—3300 cm^{-1}), and $\nu_{C=O}$ (acid, 1720—1700 cm^{-1}).



(VI)
a; COOH(*p*-)
b; COOH(*m*-)

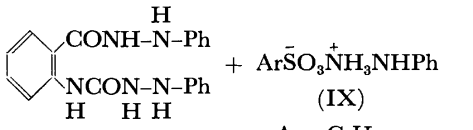
(VII)
a; Ar=C_6H_5, COOH(*p*-)
b; Ar=$C_6H_4CH_3$(*p*-), COOH(*p*-)
c; Ar=C_6H_5, COOH(*m*-)
d; Ar=$C_6H_4CH_3$(*p*-), COOH(*m*-)

Structure (VII) was confirmed by the following:

(i) IR spectra: $\nu^{+}_{NH_3}$ [3] (3000 cm^{-1}), and $\nu_{C=O}$ (acid, 1700—1680 cm^{-1}).[5]

(ii) Identity with products obtained by the reaction of arylsulfonic acids (V) with the corresponding amino acids.

(C) Rearrangement in the Presence of Phenylhydrazine: *N*-(Arylsulfonyloxy)phthalimides (Ia and b) undergo base-catalyzed Lossen rearrangement with phenylhydrazine in refluxing ethanol to give mixtures of VIII, and phenylhydrazine salts of sulfonic acids (IX).

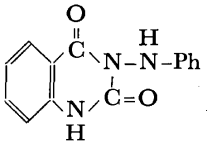


(VIII)

(IX)
a; Ar=C_6H_5
b; Ar=$C_6H_4CH_3$(*p*-)

Structure (VIII) was confirmed by the following:

IR spectra: $\nu_{NH's}$ at (3320—3280 cm^{-1}) and $\nu_{C=O's}$ at (1680—1660 cm^{-1}); pyrolysis to give 3-anilino-1,2,3,4-tetrahydroquinazoline-2,4-diones (X).



(X)

(II) Beckmann Rearrangement of N-(Arylsulfonyloxy)-phthalimides. *N*-(Arylsulfonyloxy)phthalimides undergo isomerization to 3-(arylsulfonyloxyimino)-phthalide followed by Beckmann rearrangement with anhydrous aluminium chloride as a Lewis acid.

N-(Arylsulfonyloxy)phthalimides (Ia and b) react with anhydrous aluminium chloride in 1,1,2,2-tetrachloroethane to give a mixture of phthalic acid and arylsulfonic acid (V).

It was also found that *N*-(arylsulfonyloxy)phthalimides (Ia and Ib) react with reactive aromatic substrates (benzene, toluene, anisole, and chlorobenzene) in the presence of anhydrous $AlCl_3$ to give the corresponding mixtures of 4-aryl-1*H*-2,3-benzoxazin-1-ones (XIa—d), and diarylsulfones (XIIa—g).

Structure (XI) was confiermd by the following:

(i) IR spectra: $\nu_{C=O}$ in six membered heterocyclic compounds, 1750—1740 cm^{-1}.

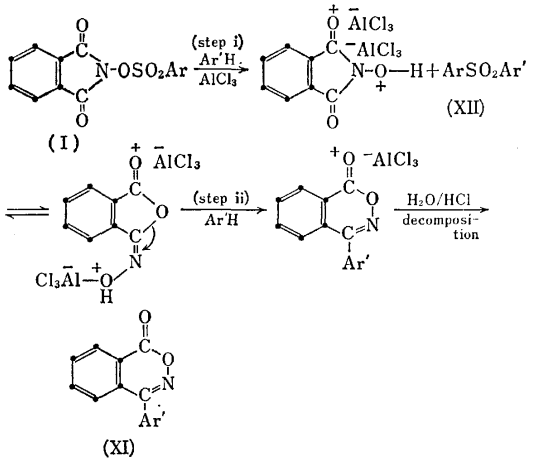
(ii) Identity with authentic products.[6-9]

Structure (XII) was confirmed by the following:

(i) IR spectra: ν_{SO_2} asymm. st. 1320—1310 cm^{-1}.

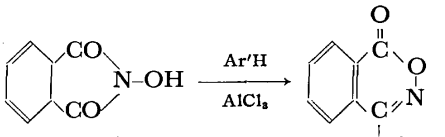
(ii) Identity with authentic products.[10-12]

The reaction is assumed to take place according to Scheme 2.



Scheme 2.

The above scheme was confirmed by the fact that *N*-hydroxyphthalimide (XIII) reacts with aromatic substrates in the presence of anhydrous $AlCl_3$ to give 4-aryl-1*H*-2,3-benzoxazin-1-ones.[1]



(XIII) (XI)

The results show that *N*-(arylsulfonyloxy)phthalimides undergo two types of molecular rearrangement. Lossen rearrangement occurs with amines, amino acids, and hydrazines; isomerization followed by Beckmann rearrangement occurs with Lewis acids such as anhydrous $AlCl_3$.

Experimental

Melting points were not corrected. IR spectra were carried out on an Unicam SP 1200 spectrophotometer by means of KBr Wafer technique.

(0.4 mol) in ethanol or benzene (20 ml) were heated under reflux for (6 h) and then cooled. The solid product was treated with ethanol and filtered off.

The residual solid was recrystallized from ethanol to give *N*-[2-(arylcarbamoyl)phenyl]-*N'*-arylureas (II) as white crystals. The mother liquor was concentrated by evaporation and trated with a few drops of benzene to give III as a solid product (Table 1).

It was proved to be an amine salt of arylsulfonic acids by mp and mixed mps with authentic samples prepared from the reaction of arylsulfonic acids (Va and b) with the corresponding amines.[3]

Pyrolysis of N-[*2-(Arylcarbamoyl)phenyl*]-N'-*arylureas*: *N*-[2-(Arylcarbamoyl)phenyl]-*N'*-arylureas (IIa—d) were heated above their mps on a sand bath for 2 h. The solid product was obtained in sublimed needles and collected in an air condenser. The product was proved to be 3-aryl-1,2,3,4-tetrahydroquinazoline-2,4-diones (IVa—d) by mp and mixture mp and IR spectra.[4]

I-B) Reaction of N-*(Arylsulfonyloxy)phthalimides with Aminobenzoic Acids.* A mixture of *N*-(arylsulfonyloxy)-phthalimide (I) (0.1 mol), aminobenzoic acid (0.3 mol) and a few drops of pyridine in benzene (10 ml) was heated under reflux for 4 h, then cooled. The solid product was treated with ethanol and filtered off. The residual solid was recrystallized from acetic acid to give *N,N'*-diarylureas (VIa and b) as white crystals (Table 2). The mother liquor was concentrated, and treated with a few drops of benzene to give-VII as a product (Table 2).

It was proved to be arylsulfonic acid salts of aminobenzoic acid by mp and mixture mp.

Reaction of Arylsulfonic Acids (V) with Aminobenzoic Acids: A mixture of arylsulfonic acids (V) (0.1 mol) and aminobenzoic acids (0.3 mol) and a few drops of pyridine in benzene was heated under reflux for 2 h, then cooled. The solid product obtained was filtered off, recrystallized from benzene and a few drops of ethanol were added to give white crystals. It was proved to be arylsulfonic acid salts of aminobenzoic acids by mp and mixture mp.

Reaction of N-*(Arylsulfonyloxy)phthalimides with Phenylhydrazine in Ethanol*: A mixture of *N*-(arylsulfonyloxy)phthalimides (I) (0.1 mol) and phenylhydrazine (0.3 mol) in ethanol was heated under reflux for (3 h), then cooled. The solid product was obtained, filtered off, recrystallized from ethanol to give VIII as white crystals, mp 193 °C. Found: C, 66.6; H, 5.0%. Calcd for $C_{20}H_{19}H_5O_2$: C, 66.48; H, 4.9%.

The mother liquor was concentrated by evaporation. A solid product was obtained. It was proved to be phenyl-

hydrazine salt of arylsulfonic acids (IX) by mp and mixed mps.[3]

Pyrolysis of VIII: VIII was heated above its mp on a sand bath for one hour, then cooled. A solid product obtained was filtered off, and recrystallized from ethanol to give a solid product. It was proved to be Xa—d by mp and mixed mp, and IR spectra. The mother liquor was concentrated by evaporation to give an oil.

It was proved to be phenylhydrazine by condensation with benzophenone to give benzophenone hydrazone.

IIA. Action of Anhydrous Aluminium Chloride in Dry 1,1,2,2-Tetrachloroethane on N-(Arylsulfonyloxy)pathalimides (I). Anhydrous aluminium chloride was added while stirring to a solution of *N*-(arylsulfonyloxy)phthalimides (I) in dry 1,1,2,2-tetrachloroethane. The reaction mixture was heated under reflux for 1/2 h, and the complex formed was decomposed with ice-cold dilute hydrochloric acid. The solvent was steam distilled. The solution was extracted with ether. The ethereal layer was separated, dried over anhydrous sodium sulfate, and the solvent was concentrated by evaporation.

The solid product obtained was filtered off, recrystallized from ethanol to give white crystals, mp 206 °C. It was proved to be phthalic acid by mp and mixed mp. The mother liquor was concentrated to dryness to give arylsulfonic acids.

IIB. Action of Anhydrous Aluminium Chloride in Aromatic Solvents on N-(Arylsulfonyloxy)phthalimides. Anhydrous aluminium chloride (0.6 mol) was added under stirring to a solution of *N*-(arylsulfonyloxy)phthalimide (I) (0.1 mol) in dry aromatic solvents. The reaction mixture was heated under reflux for 1 h, and the complex formed was decomposed with ice-cold dilute hydrochloric acid. The solvent was steam distilled. The residual solid was filtered off.

The crude product was dissolved in ethanol, concentrated, then cooled, and the solid obtained was filtered off and recrystallized from ethanol to give diarylsulfone (XII) as white crystals (*cf.* Table 3).

The mother liquor was concentrated then cooled to give solid product. It was proved to be 4-aryl-1*H*-2,3-benzoxazin-1-ones (XI), (*cf.* Table 3).

(Received December 13, 1976)

Polymers containing dicyclopentadiene units in their main chain were prepared by the polycondensation of dicyclopentadienedicarbonyl dichloride with bis(*p*-hydroxyphenyl) ether or 2,2-bis(*p*-hydroxyphenyl)propane. Thermal analysis showed that the dicyclopentadiene units dissociate reversibly. The results of thermal degradation in a nitrobenzene solution indicate that a reversible degradation occurs at 10% concentration of the polymer, and an irreversible one at concentration below 1%. The activation energy of the dissociation of dicyclopentadiene units in the main chain of the polymer was estimated to be 30 kcal/mol.

It is well-known that a molecule of dicyclopentadiene reversibly dissociates into two molecules of cyclopentadiene on heating. Thus, a polymer containing dicyclopentadiene ring in the main chain is expected to dissociate reversibly into polymers of lower molecular weight. Stille and Plummer attempted to synthesize polymer having such a structure by the Diels-Alder type polyaddition of bis(cyclopentadienyl)alkanes,[1] but obtained only polymers of low molecular weight. Thus the behavior of the thermally dissociative degradation of these polymers has not been clarified.

We obtained polymers of high molecular weight containing the dicyclopentadiene ring in the main chain by the polycondensation of dicyclopentadienedicarbonyl dichloride (DCPC) with bis(*p*-hydroxyphenyl) ether (HPE) or 2,2-bis(*p*-hydroxyphenyl)propane (HPP), and investigated their thermal behavior. This paper deals with thermally dissociative degradation of these polymers in solid state and in a nitrobenzene solution.

Experimental

Materials. HPP was recrystallized from toluene just before use, mp 160—161 °C. HPE was prepared[2] from bis(*p*-aminophenyl) ether as a starting material *via* the diazonium salt and then acetate; it was recrystallized from water, mp 167—168 °C; 15% yield (based on the starting material). DCPC was obtained by the chlorination of dicyclopectadienedicarboxylic acid with thionyl chloride,[3] and recrystallized from petroleum ether, mp 61.5—62.5 °C (lit, 62 °C[3]).

Model compound (diphenyl dicyclopentadienedicarboxylate). A solution of 2.21 g (8.9 mmol) DCPC in 10 ml dichloromethane was added to a mixture of 9.19 g (23.2 mmol) phenol, 3.23 ml (27.1 mmol) pyridine and 20 ml dichloromethane at 19—23 °C, followed by stirring at the same temperature. The reaction mixture was washed with a dilute aqueous solution of sodium carbonate and then with water. The oily layer was separated and dried with anhydrous calcium chloride, the solvent being removed. The viscous liquid so obtained was dissolved in methanol, poured into water to give a solid product, which was recrystallized from heptane to yield colorless crystals, mp 90.5—91.5 °C (lit, 92—94 °C[4]); 57.4% yield. Found: C, 77.38%; H, 5.32%. Calcd for $C_{24}H_{20}O_4$: C, 77.42%; H, 5.41%. The IR spectra showed absorptions for ester group at 1200 and 1735 cm^{-1} and for double bonds of dicyclopentadiene ring at 1600 and 1635 cm^{-1}.

Polycondensation. A typical procedure is as follows. A solution of 0.643 g (2.5 mmol) DCPC in 3.8 ml dichloromethane was added dropwise to a solution of 0.505 g(2.5 mmol) HPE and 0.8 ml (5.5 mmol) triethylamine in 7.5 ml dichloromethane under stirring at −3 °C. Stirring was continued for 45 min at −3——2 °C. The reaction mixture was poured into acetone containing 20% water to precipitate polymer. The polymer obtained was reprecipitated in benzene–methanol system and dried *in vacuo* to yield 80.8% of a white powdery polymer. The inherent viscosity(0.5% concn, *m*-cresol, 30 °C) was 0.67 dl/g. Found: C, 74.30%; H, 4.77%. Calcd for $C_{24}H_{18}O_5$: C, 74.60%; H, 4.70%. The IR spectra showed absorptions for the ester group at 1190 and 1700 cm^{-1} and for double bonds of the dicyclopentadiene ring at 1600 and 1630 cm^{-1}.

The polycondensation of DCPC with HPP gave high molecular weight polymers under the same reaction conditions as those described above except that reaction time was 10 minutes. The inherent viscosity (0.5% concn, *m*-cresol, 30 °C) was 0.84 dl/g. Found: C, 77.71%; H, 6.23%. Calcd for $C_{27}H_{24}O_4$: C, 78.62%; H, 5.86%. IR spectra showed not only the IR absorptions decribed for the polymer of DCPC with HPE, but also absorption for methyl group at 2960 and 1375 cm^{-1}.

Degradation and Measurement. DTA and TGA were carried out on a Rigaku Denki thermal analyzer (Cat. No 8085Dl) at a heating rate of 20 °C/min under a nitrogen stream.

Thermal degradation of a polymer solution was carried out in a sealed viscometer[5] for a dilute solution containing less than 1% of the polymer. A nitrobenzene solution of the polymer was added to the viscometer, degassed by a freeze-thaw procedure and sealed. The viscometer was heated at a specified temperature for a certain time, then rapidly cooled, viscosity being measured at 30 °C.

In the case of a solution of 10% concentration, a degassed polymer solution in a sealed glass tube was heated at a specified temperature for the desired time, and then diluted with nitrobenzene to 0.5%. The viscosity of the solution so obtained was measured at 30 °C with an Ubbelohde viscometer.

Results and Discussion

Preparation of Polymer. The polycondensation of DCPC with bisphenol was carried out in dichloromethane by low temperature solution polycondensation. The results are given in Table 1. The high molecular weight polymer of DCPC with HPE could be obtained at the reaction conditions of No. 5 in Table 1. With

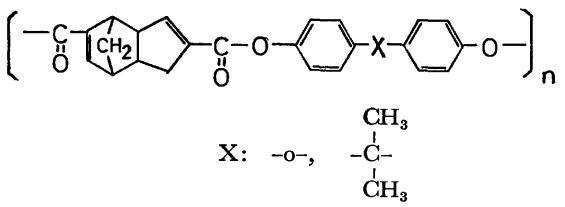
decrease in the concentrations of reactants, molecular weight of polymer decreased (Nos. 1 and 2). When the concentration of reactants was increased, a polymer insoluble in *m*-cresol was formed; it may be crosslinked (No. 6). An unnecessarily long reaction time also resulted in the formation of insoluble polymers. The polycondensation of DCPC with HPP proceeded in a similar way to that of DCPC with HPE with respect to the concentrations of reactants and the reaction time.

The resulting polymers were identified by elemental analysis and IR spectroscopy. Since the structure of DCPC was assigned by Peters[3,6] as endo-4,9-bis-(chloroformyl)tricyclo[5.2.1.$0^{2,6}$]deca-3,8-diene, the structures of the polymers obtained in this investigation are as follows.



Degradation in Solid State. TGA and DTA curves of the model compound show two endothermic peaks at 92 and 190—305 °C respectively (Fig. 1, Curve A). The one at lower temperature corresponds to the melting point of the model compound. The other accompanied by 93% weight loss is due to the dissociation of the model compound and the volatilization of dissociated compounds. TGA and DTA of the polymer of DCPC with HPE show two endothermic peaks at 190—250 and 300—420 °C (Curve B). The first peak of curve B seems to be caused by the dissociation of polymer chains, since the thermal dissociation of the model compound starts at almost the same temperature. This was confirmed by the following experiment. Thus the polymer heated to 237 °C (at this temperature, the first endothermic peak can be observed, but not the second one) was allowed to cool down to room temperature; on reheating of this polymer, an endothermic peak appeared at 223—260 °C. The endothermic peak on reheating may be responsible for some chemical change of polymer by heating. The second peak at 300—420 °C accompanied by *ca.* 70% weight loss is due to further degradation and volatilization of dissociated and degradated fragments. TGA and DTA of the polymers of DCPC with HPP gave endothermic peaks at 190—250 and 250—400 °C accompanied by *ca.* 75% weight loss. The temperature at which the dissociation of polymer chains begins was similar to that for the polymers of DCPC with HPE, but endothermic peaks were observed at slightly higher temperature (Fig. 1).

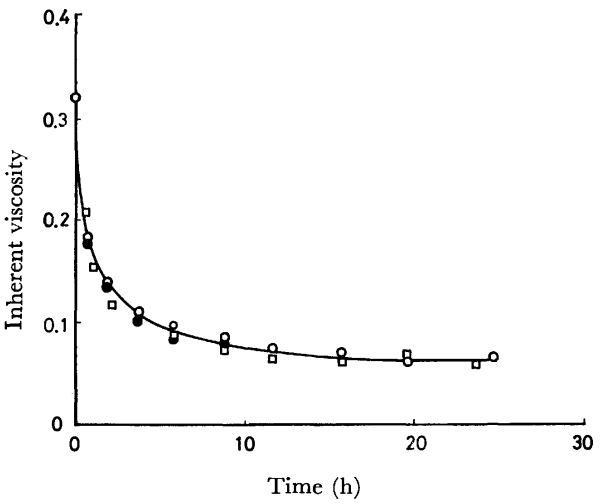

Fig. 3. Effect of polymer concentration on viscosity decrease of polymer at 80 °C: polymer concentration; ○, 1.0%; ●, 0.5%; □, 0.1%.

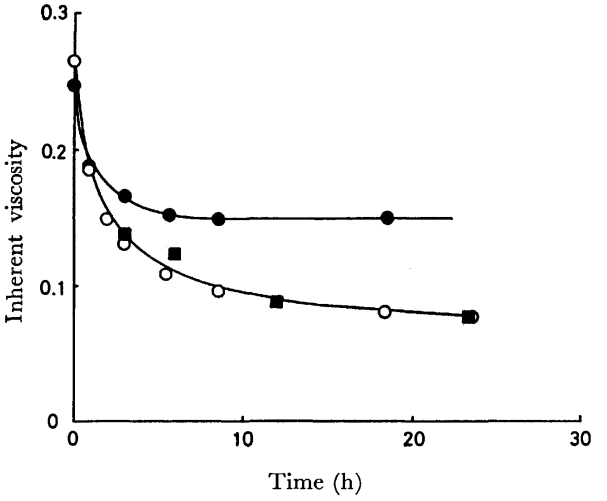

Fig. 4. Effects of polymer concentration and maleimide addition on viscosity decrease of polymer at 80 °C: ●, 10% polymer solution; ○, 1% polymer solution; ■, five times as much the molar quantity of *N*-phenylmaleimide as the dicyclophntadiene unit of the polymer was added to the 10% polymer solution. In the case of 10% polymer solutions viscosities were measured in 0.5%, and in the case of 1% no dilution was done.

processes of the polymers in a nitrobenzene solution were followed by viscometry. Figure 2 shows the viscosity change of a solution of the polymer of DCPC with HPE at a concentration of 0.5% at various temperatures. At 30 °C, no change in viscosity of the solution was observed for 30 h. This indicates that hardly any of the dicyclopentadiene ring in the main chains of the polymers dissociate at this temperature. With increasing temperature the viscosity decreased rapidly. At temperature higher than 80 °C, viscosity decreased a great deal at the initial stage of heating. When the polymers of DCPC with HPP were used, almost the same curves showing viscosity decrease as above were observed at 30 and 80 °C. Thus, further experiments were carried out on the polymers of DCPC with HPE only. For the polymer concentration from 0.1 to 1.0%, decrease in viscosity is not influenced by polymer concentration, (Fig. 3). This indicates that the polymer degrades irreversibly in a solution of concentration less than 1%. If the degradation of the polymer proceeds reversibly, the decay curve of the viscosity should be affected by the concentration of the polymer, since the forward reaction is of first-order with respect to the concentration of dicyclopentadiene unit and the reverse reaction is of second-order with respect to the concentration of cyclopentadienyl groups produced. Thermal degradation of the polymer in a solution of 10% concentration is shown in Fig. 4 together with that of the 1% polymer solution. In the case of the 10% polymer solution, the viscosity was measured for 0.5% polymer solution obtained by diluting the heat-treated 10% polymer solution with nitrobenzene. At 10% polymer concentration, viscosity fell to a constant value in a relatively short time, the value being higher than that of the 1% polymer solution. The 10% polymer solution heated for 18.5 h at 80 °C was allowed to stand for 48 h at room temperature, but no increase in viscosity of the polymer from the equilibrium value could be observed.

If the polymer is degraded in the presence of excess dienophile such as *N*-phenylmaleimide, cyclopentadienyl groups produced by the dissociation of dicyclopentadiene units in the polymers react exclusively with *N*-phenylmaleimide; thus a recombination reaction of two cyclopentadienyl groups present as end groups of the degraded polymers would be disturbed. As shown in Fig. 4, addition of the maleimide to the 10% polymer solution has predominant effect of the decrease of molecular weight of the polymers. The decay curve of the viscosity in the presence of the maleimide was similar to that observed for the 1% polymer solution in which irreversibly dissociative degradation took place. The addition of maleimide to the 1% polymer solution had no effect on the relationship between the viscosity of the polymers and heating time.

From the effect of polymer concentration and that of maleimide addition on viscosity decrease, it is concluded that in the 10% polymer solution the degradation of the polymers proceeds by a reversible process, the molecular weight of the polymer reaching an equilibrium value. In this case, however, no viscosity recovery could be observed by letting the solution to stand for 48 h at room temperature. This might be responsible for the very slow rate of the recombination reaction because of the low reaction temperature. In a dilute solution below 1%, recombination of cyclopentadienyl groups is disturded by dilution; consequently irreversible degradation was observed.

If the polymers degrade irreversibly under random scission of the main chain, a linear relationship can be expected to exist between the reciprocal of the degree of polymerization and heating time. The plots of $(1/[\eta])^{1/\alpha}$ against heating time should be linear, where α donates the exponential term of the Mark-Houwink equation and $[\eta]$ intrinsic viscosity. However, α has not yet been estimated for this polymer solution. By assuming that α equals 1/2, plots of $(1/\eta_{inh})^2$ against heating time were found to be linear at temperatures lower than 60 °C, using the data in Fig. 2, (Fig. 5). The Arrhenius plot of the slope of lines gave satisfactory linear relationship. The activation energy for the degradation of the polymer was calculated to be 30 kcal/mol. The activation energy corresponds to that for the dissociation of dicyclopentadiene units in the main chain of the polymer into cyclopentadienyl group, since the scission of the main chain seems to occur exclusively at the dicyclopentadiene units at a temperatures below 60 °C. The activation energy for the dissociation of dimethyl dicyclopentadienedicarboxylate was reported to be 30 kcal/mol in a tetraglyme solution.[7] It is interesting to note that the activation energy of the dissociation of dicyclopentadiene units in a polymer main chains agreed with that for a low molecular weight compound.

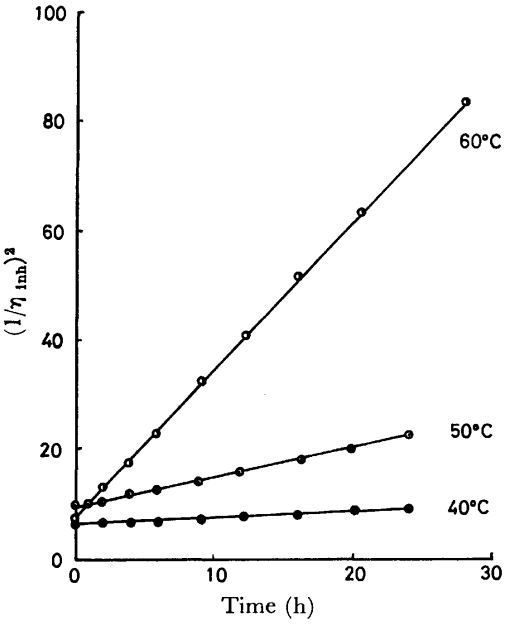

Fig. 5. Plots of $(1/\eta_{inh})^2$ against time.

Kinetic Study of the Reactions of Phenacyl Benzoates with Trialkyl Phosphites

Shizunobu HASHIMOTO, Isao FURUKAWA, and Takao TATSUMI

Department of Applied Chemistry, Faculty of Engineering, Doshisha University, Karasuma-imadegawa, Kamigyo-ku, Kyoto 602

(Received December 16, 1976)

The reactions of phenacyl benzoates, X-$C_6H_4COCH_2OCOC_6H_4$-Y (**1a—i**), with trialkyl phosphites (**2a—c**) giving dialkyl 1-arylvinyl phosphates (**3a—d**) in high yields were studied kinetically using the GLC technique. The overall reactions are second order, and exhibit a moderate solvent effect and catalysis upon the addition of certain organic acids. The activation energy, E_a=16.5 kcal/mol, and entropy, $\Delta S^{\neq}$=−38.5 e.u., were obtained from the reaction of **1a** with **2b**, and the ρ value obtained using σ for reactions of the two series of **1a** with **2b** was ρ_X=3.4 and ρ_Y=1.0, respectively. The reactivity of **2** in this reaction is markedly increased in the order, Me<Et<*i*-Pr. These and other data accumulated support a mechanism for this reaction involving a rate-determining addition of phosphorus atoms in **2** to the carbonyl carbon of the phenacyl group followed by rearrangement of the phosphorus moiety to the carbonyl oxygen of the phenacyl group.

Various studies have been published on the scope and mechanism of the Perkow reaction with α-halo ketones.[1-8] It is well known that the reactions of these ketones with trialkyl phosphites (**2**) lead to ketophosphonates (the Arbuzov reaction) and/or enol phosphates (**3**) (the Perkow reaction) (Scheme 1), and that the nature of the halogen atom in the α-halo ketones and the reaction temperature have a substantial effect on the course of the reaction.

It has been found that the reactions of phenacyl benzoates (**1**) with **2** form only **3** in high yields.[9] In this paper, kinetic studies on the reactions of two series of **1** with **2**, and to discuss the mechanism of the reactions.

Results

The reaction of **1** with **2**, which quantitatively yields enol phosphates (**3**), was studied kinetically in solution using the GLC technique (see Experimental). The reactions obey good second-order kinetics, and are first order with respect to both **1** and **2**, as shown by linear plots of log $(a-x)/(b-x)$ *vs.* time. The relative constancy of k_2 for the reaction of **1a** with **2b** for differing ratios of reactants is shown in Table 1. The rate law is expressed as

$$v = k_2[\text{triethyl phosphite}][\text{phenacyl benzoate}]. \quad (1)$$

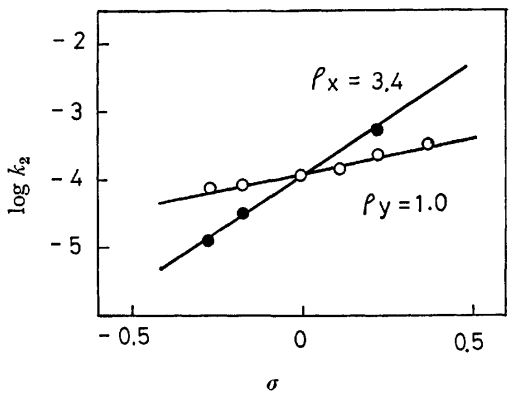

Fig. 1. Hammett plots of rates on the reaction of phenacyl benzoates (X-$C_6H_4COCH_2OCOC_6H_4$-Y) with triethyl phosphite in tetralin at 140 °C.

The rates of the reactions of phenacyl benzoates (**1a—i**) with **2b** at 140 °C are give in Table 2. The kinetic data gave a straight lines for Hammett plots with ρ_X=+3.4 and ρ_Y=+1.0 using the σ values shown in Fig. 1.

The rate constants ($M^{-1}\,s^{-1}$) of the reaction of **1a** with **2b** in tetralin at various temperatures were 3.10×10^{-5} at 110 °C, 4.64×10^{-5} at 120 °C, 1.16×10^{-4} at 140 °C, and 1.90×10^{-4} at 150 °C. The plots of log k_2 *vs.* $1/T$ produced a straight line, from which the energy, 16.5 kcal/mol, and the entropy of activation, −38.5 e.u., were obtained.

Table 3. Solvent effect on the rate of the reaction of **1a** with **2b** at 140° C[a)]

Solvent	Dielectric constant, ε	$10^4\,k_2$, $M^{-1}\,s^{-1}$

m-ClC_6H_4COOH	0.014	1.44

a) 0.4 M/l of **1a**, 0.4 M/l of **2b** in tetralin at 140 °C.

The solvent effect on the reaction of **1a** with **2b** at 140 °C is shown in Table 3. The rate constants increase with increasing solvent dielectric constant. When organic acids are added to the reaction mixture, the rate constants at 140 °C increase for the incipient step of the reaction (up to a conversion of about 30%) as shown in Table 4. The plots of k_2 *vs.* [propionic acid] show a straight line with a slope of $+1.40\times10^{-3}$ as expressed by

$$k_2 = 1.13\times10^{-4} + 1.40\times10^{-3}\,[\text{propionic acid}]. \quad (2)$$

The effect of the alkyl groups of **2** in the reactions with **1a** in tetralin was also studied, and the results are shown in Table 5. The reaction rates decrease in the order, *i*-Pr>Et>Me, corresponding to the nucleophilicity order of the phosphites.

Table 5. Effect of alkyl groups on the reaction of **2a**—**c** with **1a**[a)]

Compound	σ^*	$10^4\,k_2$, $M^{-1}\,s^{-1}$
2a	0	0.10 (110 °C)
2b	−0.10	0.26 (110 °C)

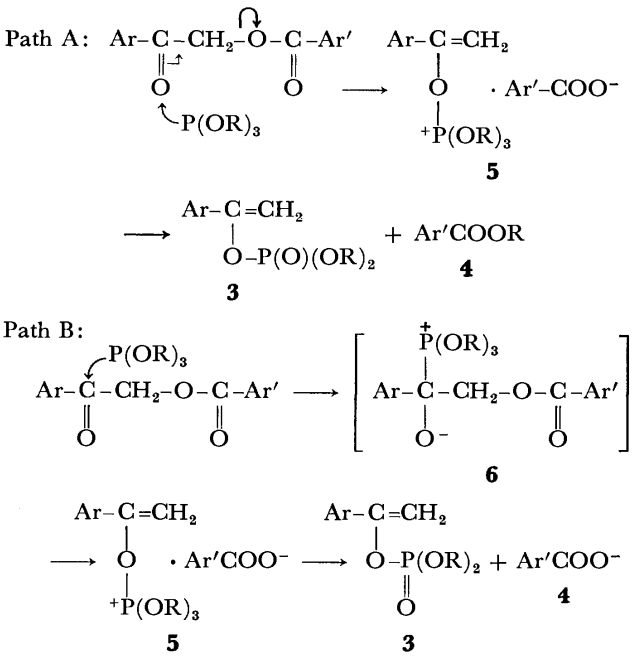
2c	−0.19	3.34 (140 °C)

a) 0.2 M/l of **1**, 0.8 M/l of **2** in tetralin.

Discussion

Although various mechanisms have been proposed for the Perkow reaction, the most likely for the reaction of **1** with **2** include pathway A: the addition of **2** to the carbonyl oxygen of the phenacyl group gives directly an enol phosphonium salt (**5**), and pathway B: the addition of phosphite to the carbonyl carbon of the phenacyl groups followed by rearrangement of the phosphorus moiety to oxygen giving **5** (Scheme 2).



Scheme 2.

Pathway A, formally an S_N2' type reaction, involves the loss of a benzoate anion in the rate-determining step. From the ρ value obtained and the solvent effect, the rate along this pathway, which was proposed by Miller,[10] Trippett,[11] and Ramirez *et al.*[12] may be considerable. However, this pathway appears to be unacceptable in our experiments from a consideration of the role of the acid catalysis. Therefore, pathway A is excluded.

On the other hand, pathway B, involving a rate-determining addition of phosphite to the carbonyl carbon of the phenacyl group followed by fast rearrangement and Arbuzov cleavage, is supported by the following facts.

A) The ρ values, $\rho_X=+3.4$ and $\rho_Y=1.0$, obtained from the reaction with X-$C_6H_4COCH_2OCOC_6H_4$-Y show that the reaction rate is determined by the nucleophilic addition of phosphite to the carbonyl carbon of the phenacyl group. The reaction of 2,4,6-trimethylphenacyl benzoate (**1j**) with **2b** with no solvent did not occur at 140 °C for 10 h because of steric hindrance due to the mesityl group.

B) When the solvent is changed from tetralin ($\varepsilon=2.77$) to acetophenone ($\varepsilon=17.39$), the rate increases by a factor of 2.7 (Table 3). The reaction *via* a charge-separated complex (**6**) should be facilitated by an increase in the polarity of the solvent.[13]

C) When organic acids are added to the mixture of **1a** and **2b**, the rate constant increases in the incipient step of the reaction as shown in Table 4. As the reaction proceeds, however, the accelerating effect gradually decreases. This phenomenon is due to the fact that a reaction of **2** with an acid occurs. In the presence of the acid, **1** may form weak hydrogen bonds

$$>C{=}O + HA \rightleftarrows >\overset{\delta+}{C}{=}O\cdots H\cdots\overset{\delta-}{A}$$

$$(RO)_3P + >\overset{\delta+}{C}{=}O\cdots H\cdots\overset{\delta-}{A} \rightleftarrows (RO)_3\overset{+}{P}-\underset{|}{C}-\overset{-}{O} + H{-}A$$

Scheme 3.

between the phenacyl group and the acid added, and the resulting bonds activate the carbonyl group for the nucleophilic attack by **2**. The reaction is believed to progress as shown in Scheme 3.

m-Chlorobenzoic acid is a more effective catalyst in this reaction (Table 4), because it is more acidic and, thus, more effective in forming a hydrogen bond with the carbonyl group. The acid catalysis and solvent effect, which have been observed for the reaction of α-halo ketones[4,5,8,13,14] and benzil[15] with trivalent phosphorus compounds, are similar to those obtained in this work. According to this mechanism, the second step, a rearrangement of the phosphorus moiety to oxygen, is not rate-determining in terms of the acid effect. The last step, Arbuzov cleavage of the alkyl group by the benzoate anion, which has been shown to be rapid and not rate-determining in the reaction of phosphite with ethyl iodide,[16] should not be accelerated in a polar solvent.

D) In view of the σ^* of Taft,[17] the nucleophilicity of the phosphites is considered to be in the order $(MeO)_3P<(EtO)_3P<(i\text{-}PrO)_3P$. The observed reactivity for the reaction of **1** with **2** is in agreement with the nucleophilicity of trialkyl phosphite.

E) For the reaction of aryl-substituted α-haloisobutyrophenones with **2b**, in which the rate-determining step is carbonyl addition, $E_a = 12.8$—13.3 kcal/mol and $\Delta S^{\neq} = -41$—-42 e.u.[4] These data are quite similar to those presented here. Also, the reaction of benzil with **2** has been postulated to proceed *via* a similar mechanism.[15] The large negative entropy of activation obtained should be consistent with a dipolar transition state **6**.[18,19]

F) This reaction leads exclusively to enol phosphate in very high yields.[9] Since the facility of the elimination of a leaving group in an S_N2 reaction is generally in the order $I>Br>Cl>OCOCH_3$,[20] the elimination of a benzoate anion should be more difficult than that of a halide anion. Consequently, it is believed that this reaction proceeds along pathway B shown in Scheme 2.

Experimental

Materials. Phenacyl benzoates (**1a**—**i**) were prepared from corresponding phenacyl bromides and sodium benzoates.[9] **1j** was prepared by the method described above. Mp 87.5—88.3 °C. NMR (CD_3Cl): δ 2.20 (s, 9H, $(CH_3)_3$), 5.02 (s, 2H, CH_2), 6.60—8.10 (m, 7H, aromatic-H). MS: *m/e* 283 (M^+). Trialkyl phosphites (**2a**—**c**) were prepared from a reaction of phosphorus trichloride with alcohols in the presence of a base and were distilled from metallic sodium.[21] All of the solvents used were purified by the usual method.[22]

Instruments. NMR spectra were recorded on a Hitachi Model R-24 (60 Mc) spectrometer using TMS as an internal standard. Mass spectra were recorded on a Hitachi Model RM-50GC gas chromatograph-mass spectrometer. GLC measurements were carried out on a Shimadzu Model GC-4BPT instrument equipped with a 0.5×2 m silicone SE-30 (5 wt%) on Chromosorb G (60—80 mesh) column at 200 °C, using H_2 as the carrier gas (90 ml/min). Melting points were determining on a Yanaco MP apparatus and uncorrected.

Kinetic Measurements. The reactions were carried out in a rubber-stoppered glass tube maintained at a given temperature using a stirred thermostatically-controlled bath. The reaction rates were estimated from the relative peak areas (corrected), which were determined by means of the internal standard method using the GLC technique. Pyrene was used as the internal standard. In a typical reaction, 2 mmol of **1**, 8 mmol of **2** and 0.3 g of pyrene were placed in a 10-ml volumetric flask. Then this solution was quickly increased to 10 ml with the addition of tetralin. This solution was transferred into a tube displaced with nitrogen, and was allowed to react at 140 °C. Aliquots were taken out by syringe at appropriate time intervals and their compositions were determined immediately by the GLC technique. No reaction of **1j** with **2b** occurred for 10 h at 140 °C, and both **1j** and **2b** were recovered.

The authors are indebted to Mr. S. Isogai for carrying out some of the kinetic determinations.

Syntheses of D-Arabinofuranosyl and 2'-Deoxy-D-ribofuranosyl 1,2,3-Triazolecarboxamides

Osamu MAKABE,* Hiroshi SUZUKI, and Sumio UMEZAWA**

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Kohoku-ku, Yokohama, Kanagawa 223

(Received February 14, 1977)

Several D-arabino- and 2'-deoxy-D-ribonucleosides of 1,2,3-triazolecarboxamides were synthesized by two methods, one involving acid-catalyzed fusion reactions of 1-*O*-acetyl derivatives (**3**, **5**) of the corresponding sugars and 1,2,3-triazole-4-carboxylate (**1**), and the other by glycosylation of the trimethylsilyl derivative (**2**) of **1** with glycosyl halides (**4**, **6**). Evidence for the *N*-glycosylation sites and anomeric configurations of the resulting nucleosides is presented.

Because of antiviral activity, some azole-carboxamides such as pyrazomycin[1,2] and virazole[3] have attracted attention. The synthesis of 1-(β-D-ribofuranosyl)-1,2,3-triazole-4-carboxamide, which is active *in vitro* against vaccinia viruses, has been reported.[4,5] Modifications of the glycosyl moiety of these nucleosides were of interest for the determination of structure-activity relationships. A report was given on the syntheses of D-arabinofuranosyl and 2'-deoxy-D-ribofuranosyl pyrazolecarboxamides.[6] The present paper deals with an extention of the work;[4] *i.e.* the synthesis of some 1,2,3-triazole nucleosides with modifications of the glycosyl moiety, including the arabinofuranosyl and 2-deoxyribofuranosyl derivatives of 1,2,3-triazole-4-carboxamide. Two methods have been employed to prepare these *N*-glycosyl-1,2,3-triazoles. One method (method A) is the acid-catalyzed fusion reaction of 1-*O*-acetyl derivatives of *O*-blocked sugars and ethyl 1,2,3-triazole-4-carboxylate (**1**), and the other (method B) is the glycosylation of the trimethylsilyl derivative (**2**) of ethyl 1,2,3-triazole-4-carboxylate with *O*-blocked glycosyl halides.

Results and Discussion

Since D-arabinosylation of purine and pyrimidine bases has often been successful in yielding antiviral and cytotoxic activities as exemplified[7] by 9-(β-D-arabinofuranosyl)adenine and 1-(β-D-arabinofuranosyl)cytosine, we performed the synthesis of 1-*N*-(β-D-arabinofuranosyl)-1,2,3-triazole-4-carboxamide (**13β**). Synthesis of the 1',2'-*cis* nucleoside was first performed by use of 1-*O*-acetyl-2,3,5-tri-*O*-benzyl-D-arabinofuranose[4] (**3**) in which the hydroxyl group at C-2 is blocked with benzyl group (a nonparticipating group). However, fusion of **3** with ethyl 1,2,3-triazole-4-carboxylate[8] in the presence of bis(*p*-nitrophenyl) hydrogenphosphate[9] gave a mixture of isomeric products (total yield 95.8%), *viz.*, ethyl 1-*N*-(2,3,5-tri-*O*-benzyl-β-D-arabinofuranosyl)-1,2,3-triazole-4-carboxylate (**7β**), its α-anomer (**7α**), ethyl 2-*N*-(2,3,5-tri-*O*-benzyl-β-D-arabinofuranosyl)-1,2,3-triazole-4-carboxylate (**8β**) and its α-anomer (**8α**) in a ratio of 1: 5: 7: 13.5, which were separated by chromatography. An improved yield of **7β** (16.7%) was obtained by application of the Lewis acid-catalyzed silyl Hilbert-Johonson reaction.[10] The trimethylsilyl derivative (**2**) of ethyl 1,2,3-triazole-4-carboxylate was treated with 2,3,5-tri-*O*-benzyl-D-arabinofuranosyl chloride[11] (**4**) in the presence of stannic chloride in 1,2-dichloroethane to give a mixture of **7β**, **7α**, **8β**, **8α**, and ethyl 1-*N*-(2,3,5-tri-*O*-benzyl-α-D-arabinofuranosyl)-1,2,3-triazole-5-carboxylate (**9α**) (total yield 83%) in a ratio of 1: 1.5: 1: 1.5: 1.2, which were readily separated by chromatography. The products (**7β**, **7α**, **8β**, **8α**, and **9α**) were converted into the corresponding carboxamides (**10β**, **10α**, **11β**, **11α**, and **12α**) by treatment with methanolic ammonia. The benzyl groups were readily removed by catalytic hydrogenolysis on palladium black to give 1-*N*-(β-D-arabinofuranosyl)-1,2,3-triazole-4-carboxamide (**13β**), its α-anomer (**13α**), 2-*N*-(β-D-arabinofuranosyl)-1,2,3-triazole-4-carboxamide (**14β**), its α-anomer (**14α**), and 1-*N*-(α-D-arabinofuranosyl)-1,2,3-triazole-5-carboxamide (**15α**), respectively.

The structures of these arabinonucleosides were assigned on the basis of their PMR (Table 1) and UV spectra (Table 2). The anomeric proton of **15α** (δ 6.81) appears at lower field than those of **13α** and **13β** (δ 6.16 and 6.40, respectively) and **14α** and **14β** (δ 6.00 and 6.29, respectively). The downfield shift of H-1' of nucleosides having a carbamoyl group adjacent to the site of glycosylation has been attributed to the anisotropic effect of the carbonyl group.[12,13] The signals for the H-5 of **13α** and **13β** (δ 8.86 and 8.70, respectively) appear at lower field than those of the isomeric **14α** and **14β** (δ 8.39 and 8.31, respectively), indicating[6,14] that **13α** and **13β** are 1-*N*-glycosides and **14α** and **14β** are

TABLE 1. PMR SPECTRAL DATA IN DMSO-d_6

Arabino-nucleosides	Anomeric proton	$J_{1',2'}$	H-5	2'-Deoxyribo-nucleosides	Anomeric proton	$J_{1',2'}$ $J_{1',2''}$	H-5
13α	δ 6.16	3.8 Hz	δ 8.86	**20α**	δ 6.43	2.5, 7.0 Hz	δ 8.72
13β	6.40	5.2	8.70	**20β**	6.40	6.0, 6.0	8.78
14α	6.00	5.3	8.39	**21α**	6.30	5.5, 6.5	8.20
14β	6.29	6.4	8.31	**21β**	6.31	5.0, 6.0	8.13
15α	6.81	4.6	8.35(H-4)				

2-*N*-glycosides. Comparison of **13β** and **14β** with their α-anomers (**13α** and **14α**, respectively) shows downfield shifts for the anomeric protons of the β-anomers as expected for 1',2'-*cis* nucleosides.[15] The coupling constants for the anomeric protons of **13α**, **13β**, **14α**, and **14β** also support their α- and β-configurations. The anomeric configuration of **15α** was deduced by its specific rotation.

TABLE 2. ULTRAVIOLET ABSORPTION DATA

Compound No.	Solvents λ_{max} nm and ε: pH 7 (H_2O) λ_{max}	ε	pH 1 (HCl) λ_{max}	ε	pH 13 (NaOH) λ_{max}	ε
13α	212	11200	211	10800	224	8600
13β	211	12000	211	12200	223	9800
14α	229	11900	230	12000	230	10500
14β	229	11600	229	12700	230	11500
15α	218	9700	217	10200	225	6150
20α	213	11100	212	11800	225	8000
20β	213	11900	213	12200	224	11000
21α	228	11400	227	10900	228	11500
21β	228	11600	228	12000	230	11300

The synthesis of 2'-deoxyribofuranosyl nucleosides was also performed by the two methods. The fusion reaction of 1-*O*-acetyl-2-deoxy-3,5-di-*O*-(*p*-nitrobenzoyl)-D-*erythro*-pentofuranose[6] (**5**) and **1** gave ethyl 1-*N*-[2-deoxy-3,5-di-*O*-(*p*-nitrobenzoyl)-β-D-*erythro*-pentofuranosyl]-1,2,3-triazole-4-carboxylate (**18β**), its α-anomer (**18α**), ethyl 2-*N*-[2-deoxy-3,5-di-*O*-(*p*-nitrobenzoyl)-β-D-*erythro*-pentofuranosyl]-1,2,3-triazole-4-carboxylate (**19β**) and its α-anomer (**19α**) in a ratio of 1.25: 1: 2.5: 1.75 (total yield 78.9%). Protection of hydroxy-groups with substituted benzoyl groups facilitates separation of the anomers usually formed in the synthesis of 2'-deoxyribonucleosides.[6,16] Glycosylation of the trimethylsilyl derivative (**2**) with 2-deoxy-3,5-di-*O*-(*p*-toluoyl)-D-*erythro*-pentofuranosyl chloride[17] in the presence of stannic chloride in 1,2-dichloroethane gave ethyl 1-*N*-[2-deoxy-3,5-di-*O*-(*p*-toluoyl)-β-D-*erythro*-pentofuranosyl]-1,2,3-triazole-4-carboxylate (**16β**), its α-anomer (**16α**), ethyl 2-*N*-[2-deoxy-3,5-di-*O*-(*p*-toluoyl)-β-D-*erythro*-pentofuranosyl]-1,2,3-triazole-4-carboxylate (**17β**), and its α-anomer (**17α**) in a ratio of 1.77: 2.4: 1: 1.1 (total yield 90.5%). Their treatment with methanolic ammonia afforded the corresponding carboxamides, **20β**, **20α**, **21β**, and **21α**, respectively. It should be noted that in the synthesis of the 2'-deoxyribonucleosides by method B, no formation of isomeric 5-carboxylate was detected as compared with a 14.7% yield of **9α** in the synthesis of arabinonucleosides. The H-5 protons of **20α** and **20β** appear at significantly lower field than those of **21α** and **21β**, indicating that the former are 1-*N*-glycosyl derivatives and the latter 2-*N*-glycosyl derivatives. Their UV spectra also show a characteristic difference[4] (Table 2). The anomeric proton of **20β** appears as a pseudotriplet with a peak width of 12 Hz which is in line with the β-configuration.[18,19] The anomeric proton of **20α** appears as a quartet whose *J*-values indicate the α-configuration. The anomeric configuration of **21α** and **21β** was deduced by their specific rotation, though their PMR spectra provided no definite assignments.

Of the nucleosides prepared, 1-*N*-(β-D-arabinofuranosyl)-1,2,3-triazole-4-carboxamide (**13β**) and 1-*N*-(2-deoxy-β-D-*erythro*-pentofuranosyl)-1,2,3-triazole-4-carboxamide (**20β**) were found to have antiviral and cytotoxic activities.[5]

Experimental

Melting points were determined on a micro hot stage and are uncorrected. Thin layer chromatography (TLC) was carried out with Wakogel B-5, silica gel column chromatography with Wakogel C-200. UV spectra were taken with a Hitachi Perkin-Elmer UV-VIS spectrometer 139 and PMR spectra with a Varian A-60D spectrometer with TMS as an internal standard.

Silylation of Ethyl 1,2,3-Triazole-4-carboxylate. To a solution of ethyl 1,2,3-triazole-4-carboxylate[8] (**1**, 5.0 g, 35.5 mmol) and chlorotrimethylsilane (7.45 g, 67.5 mmol) in dried 1,4-dioxane (48 ml) was added dropwise, with stirring, a solution of triethylamine (6.9 g) in dried 1,4-dioxane (3 ml). The reaction mixture was stirred for 12 h at room temperature. The precipitated triethylamine hydrochloride was filtered off and washed with two 5 ml portions of dried 1,4-dioxane. The filtrate and washings were combined and evaporated under reduced pressure. The resulting oil was distilled at 114 °C/1 mmHg, to give 6.86 g (91%) of a colorless oil (**2**).

Ethyl 1-N-(2,3,5-Tri-O-benzyl-β-D-arabinofuranosyl)-1,2,3-triazole-4-carboxylate (7β), Its α-Anomer (7α) and Ethyl 2-N-(2,3,5-Tri-O-benzyl-β-D-arabinofuranosyl)-1,2,3-triazole-4-carboxylate (8β), Its α-Anomer (8α) and Ethyl 1-N-(2,3,5-Tri-O-benzyl-α-D-arabinofuranosyl)-1,2,3-triazole-5-carboxylate (9α). *Method A*: A mixture of ethyl 1,2,3-triazole-4-carboxylate (**1**, 890 mg, 6.30 mmol) and 1-*O*-acetyl-2,3,5-tri-*O*-benzyl-D-arabinofuranose[4] (**3**, 2.19 g, 6.30 mmol) was heated at 143°C. To the melt was added bis(*p*-nitrophenyl) hydrogenphosphate (4 mg), and the mixture was heated at 143°C under reduced pressure for *ca.* 20 min until the evolution of acetic acid ceased. The resulting mixture was dissolved in a minimum amount of ethyl acetate and was placed on a column of silica gel (180 g, 2.8×70 cm, packed with 2:1 hexane–diisopropyl ether) and successively eluted with 2:1- (120 ml) and 1:1 hexane–diisopropyl ether. The effluent was fractionated into 12 ml-fractions.

Fractions 37—53 gave **8α**, colorless syrup, 1.38 g (40.2%). Fractions 54—63 gave a mixture of **8α** and **8β**, 820 mg (23.9 %), α:β=2:3 (from PMR). Fractions 64—69 gave **8β**, colorless syrup, 390 mg (11.4%). Fractions 81—91 gave **7α**, colorless syrup, 530 mg (15.4%). Fractions 92—98 gave a mixture of **7α** and **7β**, 90 mg (2.6%), α:β=1:1 (from PMR). Fractions 99—105 gave **7β**, colorless syrup, 80 mg (2.3%).

Method B: To a solution of 2,3,5-tri-*O*-benzyl-D-arabinofuranosyl chloride[11] (**4**, 2.00 g, 4.6 mmol) and silylated ethy-1,2,3-triazole-4-carboxylate (**2**, 1.00 g, 4.8 mmol) in 1,2-dichloroethane (50 ml) was added a solution of redistilled $SnCl_4$ (1.2 ml, 2.0 mmol) in 1,2-dichloroethane (3 ml) at 0 °C under stirring. The reaction mixture was stirred at room temperature for 12 h. After dilution with 1,2-dichloroethane (20 ml), the reaction mixture was washed with saturated aqueous $NaHCO_3$ solution. The organic layer separated by centrifugation was dried (Na_2SO_4), and evaporated under reduced pressure. The resulting mixture was dissolved in a minimum amount of ethyl acetate and chromatographed on a column of silica gel (140 g, 2.8×60 cm, packed with 1:1 hexane–diisopropyl ether) and eluted with the same solvent system. The effluent was fractionated into 11 ml-fractions.

Fractions 40—44 gave **8α**, colorless syrup, 396 mg (17.3%); $[\alpha]_D^{20}$ +58.4° (*c* 1.0, $CHCl_3$). PMR ($CDCl_3$): δ 8.25 (s, 1H, H-5), 7.40 (d, 15H, Ar), 6.39 (d, 1H, $J_{1',2'}$=3.7 Hz, H-1'), 5.05 (dq, 1H, H-2'), 4.70—4.30 (m, 10H, CH_2-ester, CH_2-Ar, H-3', H-4'), 3.75 (d, 2H, H-5',5''), 1.45 (t, 3H, CH_3-ester). Found: C, 68.14; H, 6.16; N, 7.53%. Calcd for $C_{31}H_{33}O_6N_3$: C, 68.49; H, 6.12; N, 7.73%.

Fractions 45—48 gave a mixture of **8α** and **8β**, 85 mg (3.7 %), α:β=1:1 (from PMR).

Fractions 49—52 gave **8β**, colorless crystal, 236 mg (10.3%); mp 101—102 °C. $[\alpha]_D^{20}$ −54.5° (*c* 1.0, $CHCl_3$). PMR ($CDCl_3$): δ 8.35 (s, 1H, H-5), 7.45 (d, 15H, Ar), 6.67 (d, 1H, $J_{1',2'}$= 4.8 Hz, H-1'), 4.50 (m, 11H, H-2', CH_2-Ar, CH_2-ester, H-3', H-4'), 3.75 (d, 2H, H-5',5''), 1.41 (t, 3H, CH_3-ester). Found: C, 68.63; H, 6.11; N, 7.86%. Calcd for $C_{31}H_{33}O_6N_3$: C, 68.49; H, 6.12; N, 7.73%.

Fractions 63—66 gave **9α**, colorless syrup, 358 mg (14.7%); $[\alpha]_D^{20}$ +55.0° (*c* 1.0, $CHCl_3$). PMR ($CDCl_3$): δ 8.12 (s, 1H, H-4), 7.30 (d, 15H, Ar), 6.85 (d, 1H, $J_{1',2'}$=3.3 Hz, H-1'), 5.20 (dq, 1H, H-2'), 4.70—4.20 (m, 10H, CH_2-Ar, CH_2-ester, H-3', H-4'), 3.69 (d, 2H, H-5',5''), 1.39 (t, 3H, CH_3-ester). Found: C, 68.58; H, 6.18; N, 7.51%. Calcd for $C_{31}H_{33}O_6N_3$: C, 68.49; H, 6.12; N, 7.73%.

Fractions 75—83 gave **7α**, colorless syrup, 465 mg (20.3%); $[\alpha]_D^{20}$ +61.0° (*c* 1.0, $CHCl_3$). PMR ($CDCl_3$): δ 8.44 (s, 1H, H-5), 7.45 (d, 15H, Ar), 6.42 (d, 1H, $J_{1',2'}$=1.5 Hz, H-1'), 4.75—4.20 (m, 11H, CH_2-Ar, CH_2-ester, H-2', H-3', H-4'), 3.73 (d, 2H, H-5',5''), 1.40 (t, 3H, CH_3-ester). Found: C, 68.26; H, 6.12; N, 7.55%. Calcd for $C_{31}H_{33}O_6N_3$: C, 68.49; H, 6.12; N, 7.73%.

Fractions 85—91 gave **7β**, colorless syrup, 380 mg (16.7%); $[\alpha]_D^{20}$ −30.2° (*c* 1.0, $CHCl_3$). PMR ($CDCl_3$): δ 8.65 (s, 1H, H-5), 7.45 (d, 15H, Ar), 6.65 (d, 1H, $J_{1',2'}$=4.0 Hz, H-1'), 4.70—4.10 (m, 11H, CH_2-Ar, CH_2-ester, H-2', H-3', H-4'), 3.75 (d, 2H, H-5',5''), 1.40 (t, 3H, CH_3-ester). Found: C, 68.69; H, 6.25; N, 7.63%. Calcd for $C_{31}H_{33}O_6N_3$: C, 68.49; H, 6.12; N, 7.73%.

1-N-(2,3,5-Tri-O-benzyl-α-D-arabinofuranosyl)-1,2,3-triazole-4-carboxamide (10α). A sample of **7α** (400 mg, 0.74 mmol) in absolute methanol (40 ml) saturated with ammonia at 0 °C was kept at room temperature for 12 h and evaporated under reduced pressure at 40 °C. The residual syrup was washed with hexane and the resulting gum was crystallized from ethyl acetate and diisopropyl ether to give **10α**, 315 mg (85%); mp 135—136 °C. $[\alpha]_D^{20}$ +67.2° (*c* 1.0, $CHCl_3$). PMR ($CDCl_3$): δ 8.48 (s, 1H, H-5), 7.40 (m, 15H, Ar), 6.40 (d, 1H, $J_{1',2'}$= 1.9 Hz, H-1'), 6.30 (br d, 2H, $CONH_2$), 4.65 (m, 8H, CH_2-Ar, H-2', H-3'), 4.30 (m, 1H, H-4'), 3.73 (d, 2H, H-5',5''). Found: C, 67.54; H, 5.81; N, 10.70%. Calcd for $C_{29}H_{30}O_5N_4$: C, 67.69; H, 5.88; N, 10.89%.

1-N-(2,3,5-Tri-O-benzyl-β-D-arabinofuranosyl)-1,2,3-triazole-4-carboxamide (10β). By a procedure similar to that for **10α**, **7β** (153 mg, 0.28 mmol) gave **10β**. Recrystallization from benzene–diisopropyl ether gave a pure sample, 110 mg (76%); mp 122—123 °C. $[\alpha]_D^{20}$ −47.5° (*c* 0.61, $CHCl_3$). PMR($CDCl_3$): δ 8.62 (s, 1H, H-5), 7.40 (m, 15H, Ar), 6.60 (d, 1H, $J_{1',2'}$= 4.3 Hz, H-1'), 5.85 (br d, 2H, $CONH_2$), 4.85—4.20 (m, 9H, CH_2-Ar, H-2', H-3', H-4'), 3.75 (d, 2H, H-5',5''). Found: C, 67.69; H, 5.97; N, 10.70%. Calcd for $C_{29}H_{30}O_5N_4$: C, 67.69; H, 5.88; N, 10.89%.

2-N-(2,3,5-Tri-O-benzyl-α-D-arabinofuranosyl)-1,2,3-triazole-4-carboxamide (11α). By a procedure similar to that for **10α**, **8α** (883 mg, 1.62 mmol) gave **11α**. Recrystallization from ethyl acetate and diisopropyl ether gave 701 mg (84%); mp 89.5°C. $[\alpha]_D^{20}$ +67.6° (*c* 1.4, $CHCl_3$). PMR ($CDCl_3$): δ 8.30 (s, 1H, H-5), 7.40 (m, 15H, Ar), 6.50 (br d, 2H, $CONH_2$), 6.30 (d, 1H, $J_{1',2'}$=3.5 Hz, H-1'), 5.00 (t, 1H, H-2'), 4.75—4.25 (m, 8H, CH_2-Ar, H-3', H-4'), 3.72 (d, 2H, H-5',5''). Found: C, 67.64; H, 6.05; N, 10.66%. Calcd for $C_{29}H_{30}O_5N_4$: C, 67.69; H, 5.88; N, 10.89%.

2-N-(2,3,5-Tri-O-benzyl-β-D-arabinofuranosyl)-1,2,3-triazole-4-carboxamide (11β). By a procedure similar to that for **10α**, **8β** (706 mg, 1.3 mmol) gave **11β**. Recrystallization from benzene–diisopropyl ether gave 535 mg (80%). mp 131—132 °C.

$[\alpha]_D^{20}$ −57.5° (*c* 1.2, $CHCl_3$). PMR ($CDCl_3$): δ 8.31 (s, 1H, H-5), 7.40 (m, 15H, Ar), 6.48 (d, 1H, $J_{1',2'}$=5.5 Hz, H-1'), 6.30 (br d, 2H, $CONH_2$), 4.80—4.20 (m, 9H, CH_2–Ar, H-2', H-3', H-4'), 3.90 (d, 2H, H-5',5''). Found: C, 67.82; H, 5.91; N, 10.82%. Calcd for $C_{29}H_{30}O_5N_4$: C, 67.69; H, 5.88; N, 10.89%.

1-N-(2,3,5-Tri-O-benzyl-α-D-arabinofuranosyl)-1,2,3-triazole-5-carboxamide (12α). By a procedure similar to that **10α**, **9α** (200 mg, 0.37 mmol) gave **12α**. Recrystallization from benzene-diisopropyl ether gave 153 mg (81%); mp 122—123 °C. $[\alpha]_D^{20}$ +65.5° (*c* 1.0, $CHCl_3$). PMR ($CDCl_3$): δ 8.00 (s, 1H, H-4), 7.30 (d, 15H, Ar), 6.92 (d, 1H, $J_{1',2'}$=3.1 Hz, H-1'), 6.60 (br s, 2H, $CONH_2$), 5.20 (dq, 1H, H-2'), 4.70—4.20 (m, 8H, CH_2–Ar, H-3', H-4'), 3.73 (d, 2H, H-5',5''). Found: C, 68.00; H, 6.10; N, 11.07%. Calcd for $C_{29}H_{30}O_5N_4$: C, 67.69; H, 5.88; N, 10.89%.

1-N-(α-D-Arabinofuranosyl)-1,2,3-triazole-4-carboxamide (13α). A sample of **10α** (300 mg, 0.583 mmol) in 6 ml methanol was hydrogenated over palladium black catalyst at 3.5 atm for 24h. After removal of the catalyst, the methanol layer was evaporated and the residue was crystalilzed from methanol and benzene to give **13α**, 101 mg (78%); mp 185—185.5 °C. $[\alpha]_D^{20}$ +89.1° (*c* 0.73, H_2O). PMR (DMSO-d_6): δ 8.86 (s, 1H, H-5), 7.80 (br d, 2H, $CONH_2$), 6.16 (d, 1H, $J_{1',2'}$=3.8 Hz, H-1'), 6.06 (d, 1H, OH), 5.67 (d, 1H, OH), 5.00 (t, 1H, OH), 4.60 (t, 1H, H-2'), 4.20 (m, 2H, H-3', H-4'), 3.69 (m, 2H, H-5,5''). Found: C, 39.37; H, 5.03; N, 23.22%. Calcd for $C_8H_{12}O_5N_4$: C, 39.34; H, 4.95; N, 22.94%.

1-N-(β-D-Arabinofuranosyl)-1,2,3-triazole-4-carboxamide (13β). A sample of **10β** (100 mg, 0.19 mmol) was hydrogenated and worked up in a similar manner to that described above. Recrystallization from methanol gave **13β**, 42 mg (84%); mp 163—164 °C. $[\alpha]_D^{20}$ −31.0° (*c* 1.0, H_2O). PMR (DMSO-d_6): δ 8.70 (s, 1H, H-5), 7.75 (br d, 2H, $CONH_2$), 6.40 (d, 1H, $J_{1',2'}$=5.2 Hz, H-1'), 5.70 (m, 2H, OH), 5.18 (d, 1H, OH), 4.40—3.90 (m, 3H, H-2', H-3', H-4'), 3.75 (m, 2H, H-5',5''). Found: C, 39.00; H, 4.88; N, 22.65%. Calcd for $C_8H_{12}O_5N_4$: C, 39.34; H, 4.95; N, 22.94%.

2-N-(α-D-Arabinofuranosyl)-1,2,3-triazole-4-carboxamide (14α). Similar hydrogenation of **11α** (515 mg, 1.0 mmol) followed by recrystallization from methanol gave **14α**, 181 mg (74%); mp 188—189 °C. $[\alpha]_D^{20}$ +89.0° (*c* 0.87, H_2O). PMR (DMSO-d_6): δ 8.39 (s, 1H, H-5), 7.89 (br d, 2H, $CONH_2$), 6.00 (d, 1H, $J_{1',2'}$=5.3 Hz, H-1'), 5.95 (d, 1H, OH), 5.61(d, 1H, OH), 4.90 (m, 2H, OH, H-2'), 4.15 (m, 2H, H-3', H-4'), 3.68 (m, 2H, H-5',5''). Found: C, 39.10; H, 4.94; N, 23.19%. Calcd for $C_8H_{12}O_5N_4$: C, 39.34; H, 4.95; N, 22.94%.

2-N-(β-D-Arabinofuranosyl)-1,2,3-triazole-4-carboxamide (14β). Similar hydrogenation of **11β** (118 mg, 0.23 mmol), followed by recrystallization from isopropyl alcohol, gave amorphos **14β**, 35.4 mg (63%); $[\alpha]_D^{20}$ −44.6° (*c* 0.42, H_2O). PMR (DMSO-d_6): δ 8.31 (s, 1H, H-5), 7.80 (br d, 2H, $CONH_2$), 6.29 (d, 1H, $J_{1',2'}$=6.4 Hz, H-1'), 5.60 (d, 1H, OH), 5.47 (d, 1H, OH), 4.78 (t, 1H, OH), 4.45 (m, 2H, H-2', H-3'), 3.80 (m, 3H, H-4', H-5',5''). Found: C, 39.35; H, 5.15; N, 22.65%. Calcd for $C_8H_{12}O_5N_4$: C, 39.34; H,4.95; N, 22.94%.

1-N-(α-D-Arabinofuranosyl)-1,2,3-triazole-5-carboxamide (15α). A sample of **12α** (80 mg, 0.16 mmol) in 5 ml methanol was hydrogenated over palladium black catalyst at 3.5 atm for 72 h. After removal of the catalyst, the methanol layer was evaporated and the residue was crystallized from methanol to give **15α**, 12 mg (31.6%); mp 189—190 °C. $[\alpha]_D^{20}$ +85.5° (*c* 0.5, H_2O). PMR (DMSO-d_6): δ 8.35 (s, 1H, H-4), 7.80 (br d, 2H, $CONH_2$), 6.81 (d, 1H, $J_{1',2'}$=4.6 Hz, H-1'), 6.00 (d, 1H, OH), 5.65 (d, 1H, OH), 4.80 (m, 2H, OH, H-2'), 4.18 (m, 2H, H-3', H-4'), 3.68 (d, 2H, H-5',5''). Found: C, 39.08; H, 4.97; N, 22.69%. Calcd for $C_8H_{12}O_5N_4$: C, 39.34; H, 4.95; N, 22.94%.

Ethyl 1-N-[2-Deoxy-3,5-di-O-(p-nitrobenzoyl)-β-D-erythro-pentofuranosyl]-1,2,3-triazole-4-carboxylate (16β), Its α-Anomer (16α) and Ethyl 2-N-[2-Deoxy-3,5-di-O-(p-nitrobenzoyl)-β-D-erythro-pentofuranosyl]-1,2,3-triazole-4-carboxylate (17β), Its α-Anomer (17α). Ethyl 1,2,3-triazole-4-carboxylate (**1**, 560 mg, 3.59 mmol) and 1-*O*-acetyl-3,5-di-*O*-(*p*-nitrobenzoyl)-D-2-deoxyribofuranose (**2**, 1.70 g, 3.59 mmol) were heated at 143 °C. To the melt was added bis(*p*-nitrophenyl) hydrogenphosphate (4 mg) and the mixture was heated at 143 °C under reduced pressure for *ca.* 20 min until the evolution of acetic acid cessed. The resulting gum was dissolved in ethyl acetate (5 ml). Silica gel (2.5 g) was added and the suspension was evaporated to dryness. The residue was placed on a column of silica gel (170 g, 3.2×70 cm, packed with benzene) and eluted with 10: 1 benzene–ethyl acetate. The effluent was fractionated into 9.2 ml-fractions.

Fractions 47—53 gave colorless crystals. Recrystallization from benzene gave **17β**, 430 mg (21.6%); mp 178.5—179 °C. $[\alpha]_D^{20}$ −37.5° (*c* 1.0, $CHCl_3$). PMR ($CDCl_3$): δ 8.43 (s, 8H, Ar), 8.25 (s, 1H, H-5), 6.79 (t, 1H, H-1'), 6.10 (m, 1H, H-3'), 4.75 (br s, 3H, H-4', H-5',5''), 4.53 (q, 2H, CH_2-ester), 3.60—2.75 (m, 2H, H-2',2''), 1.41 (t, 3H, CH_3-ester). Found: C, 51.89; H, 3.88; N, 12.82%. Calcd for $C_{24}H_{21}O_{11}N_5$: C, 51.90; H, 3.81; N, 12.82%.

Fractions 54—60 gave a mixture of **17β** and **17α**, 388 mg (19.6%).

Fractions 61—68 gave colorless crystals. Recrystallization from acetone gave **17α**, 212 mg (10.7%); mp 128—129°C. $[\alpha]_D^{20}$ +33.5° (*c* 1.0, $CHCl_3$). PMR ($CDCl_3$): δ 8.45 (d, 8H, Ar), 8.26 (s, 1H, H-5), 6.85 (t, 1H, H-1'), 5.90 (m, 1H, H-3'), 5.10 (m, 1H, H-4'), 4.83 (d, 2H, H-5',5''), 4.58 (q, 2H, CH_2-ester), 3.28 (t, 2H, H-2',2''), 1.47 (t, 3H, CH_3-ester). Found: C, 51.93; H, 3.90; N, 12.58%. Calcd for $C_{24}H_{21}O_{11}N_5$: C, 51.90; H, 3.81; N, 12.61%.

Fractions 76—96 gave a mixture of **16α** and **16β**, 566 mg. The crude gum of the mixture was crystallized from ethyl acetate giving **16β**, 256 mg (12%); mp 204.5—205.0 °C. $[\alpha]_D^{20}$ −33.0° (*c* 1.0, DMSO). PMR (DMSO-d_6): δ 9.18 (s, 1H, H-5), 8.50 (m, 8H, Ar), 6.87 (t, 1H, H-1'), 6.08 (m, 1H, H-3'), 4.80 (m, 3H, H-4', H-5',5''), 4.45 (q, 2H, CH_2-ester), 3.10 (m, 2H, H-2',2''), 1.35 (t, 3H, CH_3-ester). Found: C, 51.80; H, 3.97; N, 12.52%. Calcd for $C_{24}H_{21}O_{11}N_5$: C, 51.90; H, 3.81; N, 12.61%.

The mother liquor contains **16β** and **16α** (about 1: 4 from PMR). **16α** could not be isolated by recrystallization or chromatography with silica gel.

Ethyl 1-N-[2-Deoxy-3,5-di-O-(p-toluoyl)-β-D-erythro-pentofuranosyl]-1,2,3-triazole-4-carboxylate (18β), Its α-Anomer (18α) and Ethyl 2-N-[2-Deoxy-3,5-di-O-(p-toluoyl)-β-D-erythro-pentofuranosyl]-1,2,3-triazole-4-carboxylate (19β), Its α-Anomer (19α).
To a solution of 3,5-di-*O*-(*p*-toluoyl)-D-2-deoxyribofuranosyl chloride[17] (**6**, 3.99 g, 10.3 mmol) and silylated ethyl 1,2,3-triazole-4-carboxylate (**2**, 2.72 g, 12.7 mmol) in 1,2-dichloroethane (70 ml) was added a solution of redistilled $SnCl_4$ (1.73 ml, 14.1 mmol) in 1,2-dichloroethane (40 ml) at 0 °C under stirring. The reaction mixture was stirred at room temperature for 12 h. After dilution with 1,2-dichloroethane (60 ml), the reaction mixture was washed with saturated $NaHCO_3$ solution and the resulting emulsion was separated by centrifugation. The organic layer was dried (Na_2SO_4) and evaporated under reduced pressure. The resulting syrup was triturated with benzene and the insoluble product obtained by filtration was recrystallized from benzene to give **18β**, 1.13 g (22.3%); mp 157—158°C. $[\alpha]_D^{20}$ −64.5° (*c* 1.0, $CHCl_3$). PMR ($CDCl_3$): δ 8.32 (s, 1H, H-5), 7.90 (m, 4H, Ar), 7.30 (m, 4H, Ar), 6.58 (t, 1H, H-1'), 5.80 (m, 1H, H-3'), 4.70

(m, 3H, H-4′, H-5′,5″), 4.40 (q, 2H, CH_2-ester), 3.10 (m 2H, H-2′,2″), 2.40 (d, 6H, CH_3-Ar), 1.40 (t, 3H, CH_3-ester). Found: C, 63.03; H, 5.42; N, 8.70%. Calcd for $C_{26}H_{27}O_7N_3$: C, 63.27; H, 5.51; N, 8.52%. The filtrates were combined and evaporated. The resulting syrup was dissolved in ethyl acetate and was placed on a column of silica gel (150 g, 3.2 ×60 cm, packed with benzene) and eluted with 10: 1 benzene–ethyl acetate. The effluent was fractionated into 10 ml-fractions.

Fractions 52—57 gave colorless crystals. Recrystallization from ethanol gave **19β**, 761 mg (15.0%); mp 121—122 °C, $[\alpha]_D^{20}$ −33.0° (*c* 1.0, $CHCl_3$). PMR ($CDCl_3$): δ 8.15 (s, 1H, H-5), 8.00 (m, 4H, Ar), 7.28 (m, 4H, Ar), 6.65 (dt, 1H, H-1′), 5.98 (m, 1H, H-3′), 4.68 (m, 3H, H-4′, H-5′,5″), 4.37 (q, 2H. CH_2-ester), 3.6—2.4 (m, 2H, H-2′,2″), 2.43 (d, 6H, CH_3-Ar), 1.40 (t, 3H, CH_3-ester). Found: C, 63.40; H, 5.64; N, 8.51%. Calcd for $C_{26}H_{27}O_7N_3$: C, 63.27; H, 5.51; N, 8.52%.

Fractions 59—64 gave **19α**, colorless syrup, 780 mg (15.4%); $[\alpha]_D^{20}$ +35.0° (*c* 1.0, $CHCl_3$). PMR ($CDCl_3$): δ 8.12 (s, 1H, H-5), 7.90 (m, 4H, Ar), 7.25 (m, 4H, Ar), 6.58 (t, 1H, H-1′), 5.63 (m, 1H, H-3′), 4.94 (m, 1H, H-4′), 4.60 (d, 2H, H-5′,5″), 4.40 (q, 2H, CH_2-ester), 3.10 (m, 2H, H-2′,2″), 2.40 (d, 6H, CH_3-Ar), 1.37 (t, 3H, CH_3-ester). Found: C, 63.14; H, 5.59; N, 8.50%. Calcd for $C_{26}H_{27}O_7N_3$: C, 63.27; H, 5.51; N, 8.52%.

Fractions 77—88 gave **18α**, colorless syrup, 1.70 g (33.5%); $[\alpha]_D^{20}$ +72.0° (*c* 1.0, $CHCl_3$). PMR ($CDCl_3$): δ 8.35 (s, 1H, H-5), 7.80 (m, 4H, Ar), 7.20 (m, 4H, Ar), 6.55 (q, 1H, H-1′), 5.65 (m, 1H, H-3′), 4.80 (m, 1H, H-4′), 4.62 (d, 2H, H-5′5″), 4.40 (q, 2H, CH_2-ester), 3.08 (m, 2H, H-2′,2″), 2.38 (d, 6H, CH_3-Ar), 1.37 (t, 3H, CH_3-ester). Found: C, 63.00; H, 5.58; N, 8.61%. Calcd for $C_{26}H_{27}O_7N_3$: C, 63.27; H, 5.51; N, 8.52%.

Fractions 90—96 gave **18β**, colorless crystal, 218 mg (4.3%).

*1-N-(2-Deoxy-β-*D*-*erythro*-pentofuranosyl)-1,2,3-triazole-4-carboxamide (20β).* A sample of **18β** (600 mg, 1.45 mmol) in absolute methanol (60 ml) saturated with ammonia at 0 °C was kept at room temperature for 2 days and evaporated under reduced pressure below 40 °C. The residual syrup was dissolved in water (30 ml) and washed with ethyl acetate (10 ml ×3). The aqueous layer was evaporated to dryness. The crude syrup was crystallized from methanol and benzene to give **20β**, 264 mg (80%); 156—157 °C. $[\alpha]_D^{20}$ −32.2° (*c* 1.0, CH_3OH). PMR (DMSO-d_6): δ 8.78 (s, 1H, H-5), 7.60 (br d, 2H, $CONH_2$), 6.40 (t, 1H, H-1′), 5.30 (d, 1H, OH), 4.88 (t, 1H, OH), 4.45 (m, 1H, H-3′), 3.95 (m, 1H, H-4′), 3.55 (m, 2H, H-5′,5″), 2.90—1.90 (m, 2H, H-2′,2″). Found: C, 41.89; H, 5.16; N, 24.61%. Calcd for $C_8H_{12}O_4N_4$: C, 42.11; H, 5.30; N, 24.55%.

*1-N-(2-Deoxy-α-*D*-erythro-pentofuranosyl)-1,2,3-triazole-4-carboxamide (20α).* A sample of **18α** (1.00 g, 2.03 mmol) was subjected to ammonolysis and worked up in a similar manner to that described for **20β**. The crude syrup was crystallized from ethanol and benzene to give **20α**, 364 mg (78.5%); mp 161—162 °C. $[\alpha]_D^{20}$ +85.0° (*c* 1.0, CH_3OH). PMR (DMSO-d_6): δ 8.72 (s, 1H, H-5), 7.60 (br d, 2H, $CONH_2$), 6.43 (q, 1H, H-1′), 5.42 (d, 1H, OH), 4.80 (t, 1H, OH), 4.28 (m, 2H, H-3′, H-4′), 3.50 (m, 2H, H-5′,5″), 3.01—2.11 (m, 2H, H-2′, 2″). Found: C, 41.79; H, 5.22; N, 24.52%. Calcd for $C_8H_{12}O_4N_4$: C, 42.11; H, 5.30; N, 24.55%.

*2-N-(2-Deoxy-β-*D*-*eyythro*-pentofuranosyl)-1,2,3-triazole-4-carboxamide (21β).* Ammonolysis of **19β** (600 mg, 1.22 mmol) in a similar manner to that described above gave crude syrup which was crystallized from methanol and benzene to give **21β**, 233 mg, (84%); mp 139 °C. $[\alpha]_D^{20}$ −45.5° (*c* 1.0. CH_3OH). PMR (DMSO-d_6): δ 8.13 (s, 1H, H-5), 7.67 (br d, 2H, $CONH_2$), 6.31 (dt, 1H, H-1′), 5.30 (d, 1H, OH), 4.60 (m, 2H, OH, H-3′), 3.90 (m, 1H, H-4′), 3.40 (m, 2H, H-5′,5″), 3.05—2.10 (m, 2H, H-2′,2″). Found: C, 41.88; H, 5.20; H, 24.10%. Calcd for $C_8H_{12}O_4N_4$: C, 42.11; H, 5.30; N, 24.55 %.

*2-N-(2-Deoxy-α-*D*-erythro-pentofuranosyl)-1,2,3-triazole-4-carboxamide (21α).* Ammonolysis of **19α** (600 mg, 1.22 mmol) was subjected to and worked up in a similar manner to that described for the preparation of **20β**. The residual syrup was crystallized from ethanol and benzene to give **21α**, 210 mg (76 %); mp 125—126 °C. $[\alpha]_D^{20}$ +74.5° (*c* 1.0, CH_3OH). PMR (DMSO-d_6): δ 8.20 (s, 1H, H-5), 7.70 (br d, 2H, $CONH_2$), 6.30 (q, 1H, H-1′), 5.22 (d, 1H, OH), 4.75 (t, 1H, OH), 4.20 (m, 2H, H-3′ H-4′), 3.55 (m, 2H, H-5′, 5″), 2.90—2.20 (m, 2H, H-2′, 2″). Found; C, 41.88; H, 5.20; N, 24.80%. Calcd for $C_8H_{12}O_4N_4$: C, 42.11; H, 5.30; N, 24.55%.

The authors wish to thank Mr. Saburo Nakada, Department of Chemistry, Keio University, for the microanalysis. The research was supported in part by a grant for cancer research, Ministry of Education, Science and Culture.

(Received February 16, 1977)

The 1,3-dipolar cycloadditions of phenylglyoxylonitrile oxide, benzonitrile-*N*-phenylimine, or *N*-phenyl-*C*-*p*-nitrophenylnitrone to norbornadiene, 2,3-dicyanonorbornadiene, and 2,3-bis(methoxycarbonyl)norbornadiene give the *endo*-adducts, together with the *exo*-adducts. These findings show that the 1,3-dipolar cycloadditions to norbornadienes do not follow the "*exo* rule." It is suggested that the present 1,3-dipolar cycloadditions are kinetically controlled reactions. The *endo*-side of norbornadienes is found to be homoconjugated by their NMR spectra. The homoconjugation must be responsible for the observed phenomenon.

The "*exo* rule" has been deduced by Alder and Stein on the basis of the facts that phenyl azide (**7**) undergoes 1,3-dipolar cycloadditions to various bicyclic olefins with a moiety of a bicyclo[2.2.1]heptane skeleton to afford *only exo*-adducts.[2] In fact, the 1,3-dipolar cycloadditions to norbornenes which have thus far been examined follow the "*exo* rule" without exception.[3] Most norbornadienes also undergo cycloadditions by the "*exo* rule."[4] However, in the cycloadditions of **7** to norbornadiene (**1**) and of benzonitrile oxide to **1**, small amounts of the *endo*-adducts were found to be formed in addition to large amounts of the *exo*-adducts.[5,6] This fact stimulated us to elucidate whether or not the "*exo* rule" is applicable to 1,3-dipolar cycloadditions to norbornadienes; the formation of the *endo*-adduct is general. We carried out the 1,3-dipolar cycloadditions of phenylglyoxylonitrile oxide (**4**), benzonitrile-*N*-phenylimine (**5**), *C*,*N*-diphenylnitrone (**6a**), or *N*-phenyl-*C*-*p*-nitrophenylnitrone (**6b**) to **1**, 2,3-dicyanonorbornadiene (**2**), and 2,3-bis(methoxycarbonyl)norbornadiene (**3**). In these reactions, we found that the *endo*-adducts are formed in addition to the *exo*-adducts. On the basis of these results, we will discuss here the reason for the formation of the *endo*-adducts.

Results and Discussion

1,3-*Dipolar Cycloadditions.* The 1,3-dipolar cycloaddition of **4** to **1** was carried out as follows. To a stirred solution of α-chloro-α-hydroxyiminoacetophenone (**8**) with an excess of **1** in THF cooled in an ice bath, a solution of triethylamine in THF was added, drop by drop, over a period of one hour. The subsequent work-up of the reaction mixture gave a mixture of 5-benzoyl-3-oxa-4-azatricyclo[5.2.1.$0^{2,6exo}$]deca-4,8-diene (**9a**), 5-benzoyl-3-oxa-4-azatricyclo[5.2.1.$0^{2,6endo}$]deca-4,8-diene (**10a**), and bisadducts. Judging from the TLC, the bisadducts were composed of at least three isomers. Among the isomers, only 5,11-dibenzoyl-3,9-dioxa-4,10-diazatetracyclo[5.5.1.$0^{2,6exo}$0.^{8,12exo}]trideca-4,10-diene (**11**) has been isolated and characterized.

The cycloadditions of **4** to **2** and **4** to **3** were carried out by a method like that described above. In these reactions, the reagent, **4**, attacked the more electron-rich unsubstituted double bond of **2** and **3** to give 5-benzoyl-8,9-dicyano-3-oxa-4-azatricyclo[5.2.1.$0^{2,6exo}$]-deca-4,8-diene (**9b**) and 5-benzoyl-8,9-bis(methoxycarbonyl)-3-oxa-4-azatricyclo[5.2.1.$0^{2,6exo}$]deca-4,8-diene (**9c**) as the *exo*-adducts and 5-benzoyl-8,9-dicyano-3-oxa-4-azatricyclo[5.2.1.$0^{2,6endo}$]deca-4,8-diene (**10b**) and 5-benzoyl-8,9-bis(methoxycarbonyl)-3-oxa-4-azatricyclo[5.2.1.$0^{2,6endo}$]deca-4,8-diene (**10c**) as the *endo*-adducts. The bisadducts and the monoadducts produced by the attack of **4** on the more electron-poor double bond were not detected at all. These findings show that **4** acts as an electron-accepting 1,3-dipole toward **2** and **3**.

The nitrilimine, **5**, which was prepared from *N*-phenylbenzenecarbohydrazonoyl chloride (**12**) and triethylamine in benzene, reacted with an excess of **1** in benzene to afford a mixture of 3,5-diphenyl-3,4-diazatricyclo[5.2.1.$0^{2,6exo}$]deca-4,8-diene (**13**), 3,5-diphenyl-3,4-diazatricyclo[5.2.1.$0^{2,6endo}$]deca-4,8-diene (**14**),[7] and bisadducts.

The reaction of the nitrone **6a** with an excess of **1** in toluene gave two *exo*-monoadducts(4,5^{endo}-diphenyl-3-oxa-4-azatricyclo[5.2.1.$0^{2,6exo}$]dec-8-ene (**15a**) and 4,5^{exo}-diphenyl-3-oxa-4-azatricyclo[5.2.1.$0^{2,6exo}$]dec-8-ene (**16a**)[8]) and bisadducts. When a solution of the nitrone **6b** in benzene containing an excess of **1** was refluxed, however, an *endo*-adduct (4-phenyl-5^{exo}-*p*-nitrophenyl-3-oxa-4-azatricyclo[5.2.1.$0^{2,6endo}$]dec-8-ene (**17b**)) was obtained, together with two *exo*-monoadducts (4-phenyl-5^{endo}-*p*-nitrophenyl-3-oxa-4-azatricyclo[5.2.1.$0^{2,6exo}$]dec-8-ene (**15b**) and 4-phenyl-5^{exo}-

p-nitrophenyl-3-oxa-4-azatricyclo[5.2.1.$0^{2,6exo}$]dec-8-ene (**16b**)) and bisadducts.

The yields of the adducts and the product compositions are summarized in Table 1, together with the data of Findlay *et al.*[5] and Huisgen *et al.*[4c,d] As has been described above, the formation of the *endo*-adducts was observed in all reactions except for that of **6a** with **1**. This fact led us to conclude that the "*exo* rule" is not applicable to 1,3-dipolar cycloadditions to norbornadienes.

Analyses of NMR Spectra of Adducts. The *exo*- and *endo* assignments of each mono-adduct were based on the NMR data (Tables 2 and 3). The coupling contant between the bridgehead proton and the adjacent *endo*-proton of an *exo*-isomer was in the range from 0 to 1 Hz, while the coupling constant between the bridgehead proton and the adjacent *exo*-proton of an *endo*-isomer was in the range from 4 to 5 Hz. These coupling constants were consistent with the values cited in the literature.[9]

Table 3. Coupling constants in adducts[a,b]

Adducts	*exo* or *endo*	Coupling constants $J_{1,2}$	$J_{2,6}$	$J_{5,6}$	$J_{6,7}$
9a	*exo*	~0	9.0	—	~0
9b	*exo*	0—1	9.5	—	0—1
9c	*exo*	0—1	8.5	—	0—1

The *exo*-adduct **9c** exhibited the chemical shifts of methyl groups of two methoxycarbonyl groups at δ 3.78 and 3.81 ppm, while the *endo*-adduct **10c** at δ 3.33 and 3.78 ppm. The value of δ 3.33 ppm was assinged as being due to the methoxycarbonyl group attached to the C_8 position of **10c**. The molecular model of **10c**

Table 2. Chemical shifts of adducts[a,b]

Adducts	Protons H_1 and H_7	H_2	H_5	H_6	H_8 and H_9
9a	3.31	4.99	—	3.78	6.07 and 6.35
9b	3.78 and 3.92	5.20	—	4.06	—
9c	3.73	5.19	—	4.05	—
10a	3.40	5.37	—	4.09	6.05
10b	3.96	5.77	—	4.55	—
10c	3.71 and 3.82	5.57	—	4.40	—
13	3.25 and 3.46	4.39	—	3.77	6.15 and 6.34
14	3.46 and 3.60	4.79	—	4.12	5.89
15a	2.26 and 3.06	4.57	4.67	2.90	6.05 and 6.14
15b	2.20 and *ca.* 3	4.66	4.83	3.04	6.07 and 6.17

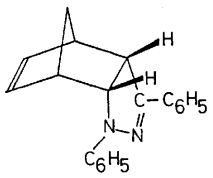
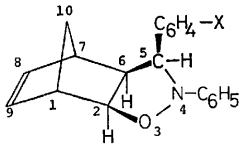
16b	2.89 and 3.00	4.53	3.95	2.58	6.06 and 6.22
17b	2.8—3.3	5.12	3.88	3.16	6.23 and 6.33

a) The spectra were recorded at 60 MHz. b) Expressed in δ ppm units, with TMS as the internal standard, in $CDCl_3$ solution.

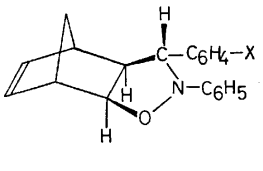


14

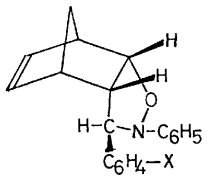


15a X=H
b X=*p*-NO_2

reveals that one of the two methoxycarbonyl groups lies in the shielding cone of the benzene ring of the benzoyl group attached on the C_5 position. The vinyl protons of **14** which are placed above the carbon-nitrogen double bond appeared in a field higher by 0.26—0.45 ppm than that of the corresponding vinyl protons of **13**. This upfield shift is probably due to the diamagnetic anisotoropy effect of the carbon-nitrogen double bond.[10] The chemical shifts of H_2 and H_5 of the *exo*-adduct **15a** were determined by means of the following observation. The former proton appeared as a doublet of triplets with a small coupling constant (J=*ca.* 1 Hz), while the latter proton appeared as a simple doublet. The small coupling was attributed to a "W-letter" coupling between $H_{10\text{-}anti}$ and $H_{2\text{-}endo}$ and to the coupling between H_1 and $H_{2\text{-}endo}$. The chemical shifts of H_2 and H_5 of the adducts **15b**, **16a**, and **16b** were also determined in the same way. The configurations of each isoxazoline moiety of **15a** and **16a**, both of which were *exo*-adducts, as shown in Table 3, were determined on the basis of the magnitude of the coupling constant between H_5 and H_6: the larger value (J=9.0 Hz) was assigned to the *cis*-coupling constant between H_5 and H_6 of **15a**, and the smaller value (J=7.0 Hz) to the *trans*-coupling constant between H_5 and H_6 of **16a**. Such an assignment has also been carried out for the two *exo*-adducts formed by the cycloaddition of the nitrone **6a** to norbornene.[4c] In the Δ^2-isoxazoline system, J_{cis} has been observed to be always larger than J_{trans}.[11] The assignments of the configurations of **15b** and **16b** were carried out in the same manner. The value (J= 6.5 Hz) of the coupling constant between H_5 and H_6 of the endo-adduct **17b** corresponds reasonably to the *trans*-coupling constant.

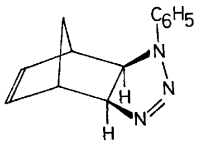


16a X=H
b X=*p*-NO_2

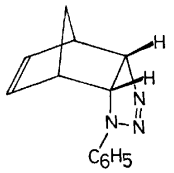


17a X=H
b X=*p*-NO_2

The presence of the symmetry along a C_2 axis of the bisadduct **11** was confirmed by a double-resonance technique: when the bridging methylene protons were irradiated with an additional radio frequency at their resonance position, the broad singlet was sharpened, but not divided into two singlets.

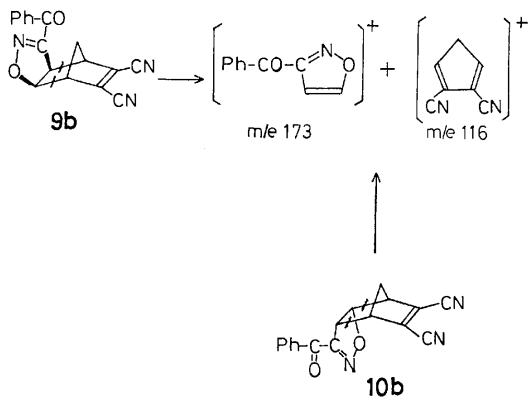


18



19

Thermal Stability of the exo-*Adducts (**9b** and **9c**) and the* endo-*Adducts (**10b** and **10c**).* When the *exo*-adduct, **9c**, and the *endo*-adducts, **10b** and **10c**, were each heated under reflux in THF for 2 h, they were recovered unchanged. The *exo*-adduct **9b**, when heated under the same conditions, gave a dirty mixture including **9b**, but not **10b**. The mass spectra of **9b** and **10b** showed the same fragmentation pattern (*m/e* 173, *m/e* 116, and no molecular ion peak; sample injection at 200 °C). This finding implies that the adducts **9b** and **10b** are liable to undergo the retro-Diels-Alder reaction by thermal decomposition to 2,3-dicyanocyclopentadiene and 3-benzoylisoxazole, rather than to the starting moieties, **2** and **4**. In addition, isoxazoles can not act as dipolarophiles.[3i]



Scheme 1.

From above findings, we suggest that the present 1,3-dipolar cycloadditions are kinetically controlled reactions.

An Explanation for the Formation of the endo-*Adducts.* 1,3-Dipoles cannot undergo cycloadditions from the *endo*-side of norbornene. This is probably because of the steric hindrance of the *endo*-5,6-hydrogens. On the other hand, in the case of norbornadiene, it is possible that, 1,3-dipoles attack the carbon-carbon double bond from the *endo*-side because of the absence of such steric hindrance. This is insufficient, however, to explain the formation of the *endo*-adducts. If the *endo*-side of norbornadiene suffers from no steric hindrance, the *endo*-adduct should be produced in a higher yield than the *exo*-adduct, or at least in an amount equal to that of the *exo*-adduct. As the results shown in Table 1 do not accord with this prediction, an alternative factor must be responsible for the observed phenomena.

We show in Fig. 1 that there is a good linear relationship between the δ values of the vinyl protons of five norbornadienes (**1**, **2**, **3**, **20**, and **21**) and the values of

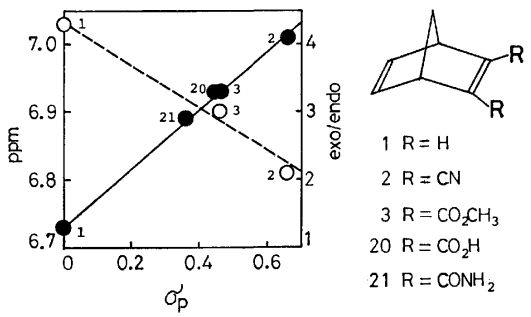


Fig. 1. Chemical shifts (TMS as an internal standard, in DMSO-d_6 solutions) of vinyl protons of 2,3-disubstituted norbornadienes *vs.* Hammett's σ_ps (—●—), and the exo/endo product ratios *vs.* Hammett's σ_ps (---○---)

Hammett's δ_ps[12] of the substituents. The phenomenon that the δ values of the vinyl protons are shifted to lower fields by the electron-withdrawing groups is likely to be attributable to homoconjugation on the *endo*-side of norbornadienes. The presence of homoconjugation between the two non-neighbouring carbon-carbon double bonds has also been found by investigating the photoelectron spectroscopy of norbornadiene.[13]

Inagaki *et al.* have proposed that the π-electron distribution of norbornene extends to the *exo*-side more than to the *endo*-side because of the interaction between the π-orbital and the methano-bridge orbital or the back-side of the anti C–H bond orbital at the C_7 position.[14] Such an interaction may also be present in norbornadiene. On the *endo*-side of norbornadiene, however, homoconjugation is present, as has been described above. This homoconjugation may result in extending the π-electron distribution toward the *endo*-side. Consequently, the difference in the π-electron distribution between the *exo*- and *endo*-sides of norbornadiene may be smaller than that of norbornene.

Thus, we may assume that the homocinjugation on the *endo*-side of norbornadiene brings about the formation of the *endo*-adducts in the cycloadditions of the electron-accepting 1,3-dipoles to norbornadienes.

Experimental

Materials. The precursors of 1,3-dipoles(**8**[15] and **12**[4d]), 1,3-dipoles(**6a**[16] and **6b**[16]), a norbornadiene **3**,[17] and norbornadiene-2,3-dicarboxylic acid(**20**)[17] were prepared by the method described in the literature. The **1** was purchased and distilled before use.

Preparation of **2**. Into a solution of ammonium chloride (24 g) in aq ammonia (240 cm³), **3** (47 g, 0.226 mol) was added, after which the mixture was stirred vigorously for 5 h at room temperature. The resulting white solid was separated by filtration, washed with ether, dried, and recrystallized from MeOH–EtOH to yield norbornadiene-2,3-dicarboxamide(**21**) mp 209—211 °C (dec) (lit,[18] 211—212 °C) in a quantitative yield. To a stirred suspension of **21**(5.0 g, 2.8 mmol) in DMF (28 g), cooled in an ice bath, a solution of thionyl chloride (10.0 g, 84 mmol) in DMF (10 g) was added, drop by drop, over a 30-min period. When the addition of the thionyl chloride solution was complete, the reaction mixture became a clear yellowish liquid. Then, the ice bath was removed and the solution was stirred for 2 days at room temperature. The resulting brown solution was poured into 150 g of ice–water, neutralized (aq Na_2CO_3), and extracted (ether 100 cm³ × 3). The resulting solution was dried($MgSO_4$) and evaporated to dryness to give a yellowish solid (3.77 g). It was chromatographed on alumina. Elution with benzene afforded colorless pure **2** (3.38 g, 85%): mp 44—46 °C (lit,[18] 44—45 °C).

Reaction of **4** *with* **1**. Into a stirred solution of **1** (2.00 g, 21.7 mmol) and **8** (1.84 g, 10.0 mmol) in dry THF (30 cm³) cooled in an ice bath, a solution of triethylamine (TEA)(1.30 g, 13 mmol) in dry THF (20 cm³) was added, drop by drop, over a 1-h period. After an additional 1 h of stirring at the same temperature, the resulting triethylammonium chloride was removed by filtration. It was chlomatographed on silica gel (200—300 mesh). Elution with benzene gave 1.81 g (76%) of a mixture of **9a** and **10a**. The NMR spectrum of the mixture showed that the exo/endo ratio was 81/19. Further elution with benzene afforded 0.316 g (17%) of a mixture of bisadducts ($C_{23}H_{18}O_4N_2$ by elemental analysis). The TLC of the mixture showed three spots (elution with benzene–ether (9:2)). It was recrystallized from EtOH–benzene to give 0.18 g of **11**: mp 181—182 °C; IR(KBr) 1650 (C=O) and 1565 cm^{-1}; NMR ($CDCl_3$) δ=1.55 (s, 2, CH_2), 3.15 (s, 2, H_1 and H_7), 3.83 (d, 2, J=8 Hz, H_6 and H_{12}), 4.76 (d, 2, J=8 Hz, H_2 and H_8), and 7.3—8.3 ppm (m, 10).

Found: C, 71.63; H, 4.82; N, 6.99%. Calcd for $C_{23}H_{18}O_4N_2$: C, 71.49; H, 4.70; N, 7.25%.

A mixture of **9a** and **10a** was column chromatographed on silica gel once again. Elution with benzene–hexane (6:1) gave **9a**. It was recrystallized from EtOH to afford colorless needles: mp 65—66 °C; IR(KBr) 1640 (C=O) and 1557 cm^{-1}.

Found: C, 75.20; H, 5.35; N, 5.77%. Calcd for $C_{15}H_{13}O_2N_1$: C, 75.30; H, 5.48; N, 5.85%.

Further elution with the same solvent gave **10a**. It was recrystallized from EtOH–H_2O to yield colorless needles: mp 53—54 °C; IR(KBr) 1655 (C=O) and 1560 cm^{-1}.

Found: C, 75.28; H, 5.35; N, 5.55%. Calcd for $C_{15}H_{13}O_2N_1$: C, 75.30; H, 5.48; N, 5.85%.

Reaction of **4** *with* **2**. Into a stirred solution of **2** (710 mg, 5.00 mmol) and **8** (460 mg, 2.50 mmol) in dry THF (40 cm³), cooled in an ice bath, a solution of TEA (330 mg, 3.26 mmol) in dry THF (10 cm³) was added, drop by drop, over a 1-h period. After an additional 1 h's stirring, the resulting triethylammonium chloride was removed by filtration. After the removal of the solvent, the residue was chromatographed on silica gel. Elution with benzene gave 351 mg of **2**. Further elution with benzene afforded **9b** (440 mg, 61%), which was subsequently recrystallized from EtOH to give colorless prisms: mp 140—141 °C; IR(KBr) 2220(C≡N), 1640(C=O), and 1570 cm^{-1}.

Found: C, 70.73; H, 3.67; N, 14.56%. Calcd for $C_{17}H_{11}O_2N_3$: C, 70.58; H, 3.83; N, 14.53%.

Elution with benzene–ethyl acetate (1:1) gave **10b** (208 mg, 29%). It was recrystallized from MeOH to afford colorless sticks: mp 127—127.5 °C; IR(KBr) 2225(C≡N) and 1660 cm^{-1} (C=O).

Found: C, 70.73; H, 3.64; N, 14.81%. Calcd for $C_{17}H_{11}O_2N_3$: C, 70.58; H, 3.83; N, 14.53%.

Reaction of **4** *with* **3**. To a stirred solution of **3** (1.04 g, 5.00 mmol) and **8** (0.92 g, 5.00 mmol) in dry THF (15 cm³), cooled in an ice bath, a solution of TEA (0.65 g, 6.50 mmol) in dry THF (10 cm³) was added, drop by drop, over a 1-h period. After an additional 1 h's stirring at the same temperature, the resulting ammonium chloride was removed by filtration. After the evaporation of the solvent, a yellowish oily residue was solidified by the addition of a few drops of

95% EtOH. The solid was separated by filtration and dried under a vacuum to give 1.69 g (95%) of a mixture of **9c** and **10c**. The NMR spectrum of the mixture showed that the exo/endo ratio was 75/25. The mixture was chromatographed on sillica gel. Elution with benzene–ether (20: 1) gave **9c**. It was recrystallized from 95% EtOH to give colorless sticks: mp 113—114 °C; IR(KBr) 1740 (ester C=O), 1715 (ester C=O), 1657 (C=O), 1635, and 1573 cm^{-1}.

Found: C, 64.14; H, 4.61; N, 3.76%. Calcd for $C_{19}H_{17}O_6N_1$: C, 64.22; H, 4.82; N, 3.94%.

Further elution with the same solvent afforded **10c**. It was recrystallized from 95% EtOH to give colorless sticks: mp 151—153 °C; IR(KBr) 1740(ester C=O), 1650(C=O), and 1620 cm^{-1}.

Found: C, 64.07; H, 4.65; N, 3.94%. Calcd for $C_{19}H_{17}O_6N_1$: C, 64.22; H, 4.82; N, 3.94%.

*Reaction of **5** with **1**.* A mixture of **1** (3.00 g, 32.6 mmol) and **12** (576 mg, 2.50 mmol) was dissolved in dry benzene 10 cm^3). Into the solution, TEA (1.3 cm^3) was added all at once, after which the solution was stirred for 24 h at room temperature. The resulting ammonium chloride was removed by filtration. The evaporation of the solvent left a yellow residue. It was chromatographed on alumina. Elution with benzene gave 680 mg (95%) of a mixture of **13** and **14**. The *exo/endo* ratio was 87/13 (from NMR). The developing solvent was changed to ethyl acetate to give 55 mg (4%) of a mixture of bisadduts (mp 281—305 °C (dec); $C_{33}H_{28}N_4$). A mixture of the monoadducts was chromatographed on alumina once again. Elution with hexane–benzene (3: 7) gave **13**. It was recrystallized from EtOH to give pale yellow needles: mp 134—135 °C (lit,[4d] 133—135 °C). Further elution with the same solvent afforded **14**. It was recrystallized from EtOH to give pale yellow needles: mp 110—111 °C; IR(KBr) 1595, 1550, and 1500 cm^{-1}.

Found: C, 83.65; H, 6.39; N, 9.86%. Calcd for $C_{20}H_{18}N_2$: C, 83.88; H, 6.34; N, 9.78%.

*Reaction of **6a** with **1**.* A mixture of **1** (1.84 g, 20.0 mmol) and **6a** (978 mg, 5.00 mmol) was dissolved in dry toluene (5 cm^3) and heated under reflux for 4 h. A large amount of the solvent was removed *in vacuo*. Then, the concnetrated solution was chromatographed on silica gel. Elution with toluene gave **15a** (595 mg, 41%). It was recrystallized from MeOH to afford colorless needles: mp 110—111 °C (lit,[4c] 111° C). Further elution with toluene afforded **16a** (467 mg, 32%). It was recrystallized from MeOH to give colorless needles: mp 76—77 °C; IR(KBr) 1595, 1490, and 1450 cm^{-1}.

Found: C, 83.26; H, 6.56; N, 4.71%. Calcd for $C_{20}H_{19}O_1N_1$: C, 83.01; H, 6.62; N, 4.84%.

The final elution with toluene gave a mixture of bisadducts in a 7% yield (88 mg): mp 218—233 °C (dec)(elemental analysis; $C_{33}H_{30}O_2N_2$).

*Reaction of **6b** with **1**.* A solution of **1** (1.84 g, 20.0 mmol) and **6b** (1.21 g, 5.00 mmol) in dry benzene (20 cm^3) was heated under reflux for 18 h. The solution was concentrated and chromatographed on silica gel. Elution with benzene gave the following products: **15b** (859 mg, 51%): mp 121—122 °C (pale yellow sticks from MeOH); IR(KBr) 1600, 1520 (NO_2), 1495, and 1350 cm^{-1} (NO_2).

Found: C, 72.06; H, 5.47; N, 8.31%. Calcd for $C_{20}H_{18}O_3N_2$: C, 71.84; H, 5.43; N, 8.38%. **16b** (353 mg, 22%): mp 153—154 °C (pale yellow sticks from MeOH); IR(KBr) 1595, 1510 (NO_2), 1490, and 1350 cm^{-1} (NO_2).

Found: C, 71.86; H, 5.44; N, 8.63%. Calcd for $C_{20}H_{18}O_3N_2$: C, 71.84; H, 5.43; N, 8.38%. **17b** (43 mg, 3%): mp 138—140 °C (pale yellow needles from MeOH); IR(KBr) 1595, 1510(NO_2), 1490, and 1355 cm^{-1} (NO_2).

Found: C, 71.81; H, 5.49; N, 8.15%. Calcd for $C_{20}H_{18}O_3N_2$: C, 71.84; H, 5.43; N, 8.38%. A mixture of bisadducts (83 mg; 7%): mp 231—246 °C (dec)($C_{33}H_{28}O_6N_4$).

*Examination of the Thermal Stability of **9b**, **9c**, **10b**, and **10c**.* A solution of **10b** (53 mg) in THF (3 cm^3) was heated under reflux for 2 h. The solvent was then evaporated to give a white solid composed of only one component (TLC). The NMR spectrum of the solid was identical with that of **10b**. **9c** and **10c** were treated in the same way. They were also recovered unchanged. When a solution of **9b** (53 mg) in THF (3 cm^3) was heated under the same conditions, a dirty mixture was obtained. It contained **9b**, but not **10b** (TLC, NMR).

The mass spectra of **9b** and **10b** showed the same pattern. MS (80 eV) *m/e* 173, 116, 105, 89, 77, 51, and 28.

*NMR Measurements of Norbornadienes (**1**, **2**, **3**, **20**, and **21**).* The NMR spectra of norbornadienes (**1**, **2**, **3**, **20**, and **21**) were recorded at 60 MHz, using TMS as the internal standard, in DMSO-d_6 solutions (10% solutions); δ values of vinyl protons: 6.73 (**1**), 7.01 (**2**), 6.93 (**3**), 6.93 (**20**), and 6.89 ppm (**21**).

The Glow-discharge Reactions of Pyrrole, Pyrrolidine, and Butylamine*

Shōichi KIKKAWA, Masakatsu NOMURA, and Noritaka HOSOKAWA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received February 25, 1977)

The glow-discharge reactions of pyrrole, pyrrolidine, and butylamine were carried out. Pyrrolidine produces a complex mixture of products, the most prevalent of which is  NCH(R)CN (R: H, CH_3, and C_2H_5), and butylamine yielded primarily $CH_3(CH_2)_3N{=}CHR$ (R: CH_3, C_2H_5, and C_3H_7) along with $CH_3(CH_2)_3NHCH_2CN$, whereas pyrrole afforded a mixture of acrylonitrile, crotononitrile, benzene, α-methylpyrrole and β-methylpyrrole, together with large amounts of HCN. The formation of characteristic products, α-(1-pyrrolidinyl) nitrile derivatives with pyrrolidine, and the yield of butylaminoacetonitrile with butylamine can be explained by considering the formation of a resonance-stabilized α-cyanoalkyl radical as the most probable intermediate which attacks a nitrogen atom of pyrrolidine and that of butylamine or which recombines with pyrrolidine-*N*-radical and butylamine-*N*-radical.

Extensive studies of the reaction of organic compounds in a radiofrequency discharge have been carried out.[1-3] There has, however, been little or no attempt to study the discharge reaction of a series of simple amine derivatives. In this paper, the individual reactions of pyrrole, pyrrolidine, and butylamine (three different types of C_4 amine) in a radiofrequency discharge will be reported. These compounds were chosen in an attempt to ascertain the behavior of these three amines under the influence of radiofrequency discharge and to observe the formation of the various products resulting therefrom.

Experimental

The radiofrequency generator was operated at a fixed frequency of 28 MHz, with an output of up to 150 W. The operating pressure in the system was 2.0 Torr through all the runs. The products were collected in a liquid nitrogen trap (−196 °C), as has previously been described.[4]

Analysis. Gas chromatography was employed for quantitative analysis. A Shimadzu GC-4BPTF instrument was used with the following columns: 4.5 m, Silicon SE-30 for the analysis of liquid products (oven temp: 30—270 °C, program rate: 10 °C/min), with H_2 as the carrier gas. The gaseous products were analyzed on a 3-m column packed with silica gel at 150 °C, using N_2 as the carrier gas.

Radiofrequency Decomposition of Pyrrole. Pyrrole vapor was passed through the glow discharge (see Table 1). The major portion of the gas fraction collected in the liquid nitrogen traps was a mixture of ethylene (44.1%), acetylene (31.2%), ethane (20.0%), propylene (0.8%), and propane (0.9%) (Table 1, Run No. 2). Noncondensable products were obtained from the exhaust gas of the vacuum pump connected to the nitrogen traps. Upon gas-chromatographic analysis, they were found to contain only hydrogen and methane (0.21 g; CH_4 22%, H_2 78% in Run No. 2). The fractional distillation of the liquid products collected from several runs and NMR measurements of the resulting fractions showed the presence of hydrogen cyanide (bp 28—29 °C), acetonitrile, propionitrile, acrylonitrile, crotononitrile,[3] benzene, α-methylpyrrole, and β-methylpyrrole. Their mass spectra also confirmed these assignments. The NMR data of these compounds are shown below. Acrylonitrile: NMR (δ ppm in CCl_4): 5.60 (1H, m, C<u>H</u>$_3$CN), 5.92 (1H, m, *trans* β-H), 6.10 (1H, m, *cis* β-H). Crotononitrile: NMR (δ ppm in CCl_4): 1.98 (3H, d.d, C<u>H</u>$_3$CH), 5.24 (1H, d.q, C<u>H</u>CN), 6.46 (1H, d.q, CH$_3$C<u>H</u>). Benzene: NMR (δ ppm in CCl_4): 7.24 (s, aromatic H). α-Methylpyrrole: NMR (δ ppm in CCl_4): 2.12 (3H, s, CH_3), 5.72 (1H, m, C_3–H), 5.94 (1H, m, C_4–H), 6.34 (1H, m, C_5–<u>H</u>). β-Methylpyrrole: NMR (δ ppm in CCl_4): 2.07 (3H, s, C<u>H</u>$_3$), 5.88 (1H, m, C_4–H), 6.28 (1H, m, C_2–H), 6.40 (1H, m, C_5–H).

Radiofrequency Decomposition of Pyrrolidine. For 20 min, a 7.7-g portion of pyrrolidine was passed through a radiofrequency glow discharge (Table 2, Run No. 5). The condensable gaseous products consisted of ethylene (62.4%), acetylene (18.9%), propylene (9.6%), ethane (7.6%), and propane (1.5 %), while the noncondensable products were hydrogen and methane. Gas-chromatographic analysis indicated the presence of twelve constituents in the liquid products. A fractional distillation of the reaction mixture isolated acetonitrile, propionitrile, and butyronitrile. Three major unknown compounds were separated by preparative gas chromatography (Shimadzu GC-2C, Silicon DC 550, 4.5 m, H_2). By referring to their NMR spectra, these three compounds were identified 1-pyrrolidinylacetonitrile, 2-(1-pyrrolidinyl)propionitrile, and 2-(1-pyrrolidinyl)butyronitrile respectively.

The analytical data of the identified products were as follows. Acetonitrile: NMR (δ ppm in CCl_4): 1.94 (s, C<u>H</u>$_3$-CN). IR: complete superimposable spectrum with an authentic sample. Propionitrile: NMR (δ ppm in CCl_4): 1.26 (3H, t, C<u>H</u>$_3$CH$_2$), 2.32 (2H, q, C<u>H</u>$_2$CN). Butyronitrile: NMR[δ ppm in $(CD_3)_2CO$]: 1.00 (3H, t, C<u>H</u>$_3$CH$_2$), 1.62 (2H, m, CH$_3$C<u>H</u>$_2$CH$_2$), 2.38 (2H, t, C<u>H</u>$_2$CN). Pyrrole: NMR (δ ppm in CCl_4): 6.02 (2H, m, β-H), 6.52 (2H, m, α-H). 1-Pyrrolidinylacetonitrile: NMR (δ ppm in $CDCl_3$): 1.86 (4H, m, C<u>H</u>$_2$C<u>H</u>$_2$), 2.68 (4H, m, C<u>H</u>$_2$NC<u>H</u>$_2$), 3.68 (2H, s, C<u>H</u>$_2$CN). IR (cm^{-1}): 2800 (=N–), 2230 (C≡N). MS (*m/e*): 110 (M^+). Found: C, 65.32; H, 9.00; N, 25.15%. Radiofrequency Decomposition of Butyronitrile. The glow-discharge reaction was carried out by means of a procedure similar to that described above. The condensable gaseous products in Run No. 9 were ethylene (44.2%), acetylene

* Organic Reaction Employing the Glow Discharge. VII. Part VI: S. Kikkawa, M. Nomura, and Y. Morita, *J. Syn. Org. Chem. Jpn.*, **34**, 36 (1976).

(7.2%), propylene (15.3%), butene (2.0%), ethane (18.6%), and propane (12.7%).

The compounds with the same retention times as acetonitrile were separated from the reaction mixtures and were identified as such. Butylaminoacetonitrile was separated by preparative gas chromatography and identified on the basis of its NMR spectrum. Two other major components were identified as *N*-ethylidenebutylamine and *N*-butylidenebutylamine[5] by comparing the retention times with authentic samples, and the mass spectra of the individual fraction (obtained by the use of Hitachi RMU-6MG type GC-MS), with authentic sample. Acetonitrile: NMR (δ ppm in $CDCl_3$) 2.01 (s, $C\underline{H}_3CN$). IR: complete superimposable spectrum with an authentic sample. Butylaminoacetonitrile: NMR (δ ppm in $CDCl_3$): 0.93 (3H, t, $C\underline{H}_3CH_2$), 1,30 (1H, s, $N\underline{H}$), 1.42 (4H, m, $CH_3C\underline{H}_2C\underline{H}_2CH_2$), 2.65 (2H, t, $C\underline{H}_2NH$), 3.48 (2H, s, $NHC\underline{H}_2CN$). Calcd for $C_6H_{12}N_2$: C, 64.24; H, 10.78; N, 24.98%. *N*-ethylidenebutylamine: MS (*m/e*): 99 (M^+), 84 $CH_3CH_2CH_2CH_2\overset{+}{N}{\equiv}CH$ (67.6), 57 $CH_3CH_2\overset{+}{N}{=}CH_2$ (54.0), 56 $CH_3CH{=}\overset{+}{N}{=}CH_2$ (100). *N*-Butylidenebutylamine: MS (*m/e*)[6]: 127 (M^+), 112  (12.5), 99 (15.3), 84 $CH_3CH_2CH_2CH{=}\overset{+}{N}{=}CH_2$ (100), 70  (27.8), 57  (75.0), 56 $CH_2{=}\overset{+}{N}HCH{=}CH_2$ (75.0). *N*-Propylidenebutylamine: MS (*m/e*): 113 (M^+), 98 (7.4), 84 $CH_3CH_2CH_2CH_2\overset{+}{N}{\equiv}CH$ (100), 71 (38.9), 70 (70.4), 57 (50.0), 56 (92.6).

Results and Discussion

The product distributions with the discharge reactions of pyrrole and pyrrolidine are shown in Tables 1 and 2 respectively, along with the reaction conditions. Under the influence of radiofrequency discharge, pyrrole produced HCN, CH_3CN, C_2H_5CN, $CH_2{=}CHCN$, *trans*-$CH_3CH{=}CHCN$, C_6H_6, α-$CH_3C_4H_4N$, and β-$CH_3C_4H_4N$ as the primary products, whereas pyrrolidine yielded the characteristic products of α-(1-pyrrolidinyl) nitrile,  NCH(R)CN (R=H, CH_3, and C_2H_5), in addition to other nitrile derivatives.

a) Duration of reaction: 20 min.

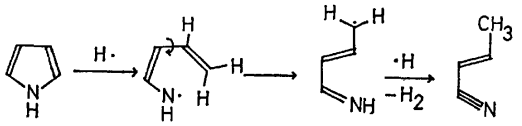
First, we will discuss the discharge reaction of pyrrole. In the experiment with a discharge current of 70 mA at 1.23 kV (Run No. 1), the primary products were HCN and crotononitrile. If this discharge reaction is assumed to proceed *via* the radical mechanism suggested in a previous paper,[7] the formation of crotononitrile may be explained by the following scheme, where the initial homolytic fission of C–N bond is accompanied by both the subsequent rotation of the C–C bond and the double-bond shift, leading to crotononitrile.

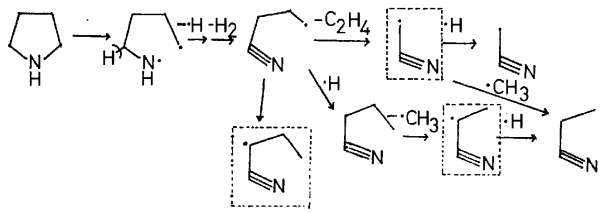
When the discharge current was changed from 70 to 90 mA, the crotononitrile yield decreased among the products while, the yields of HCN and acrylonitrile



Scheme 1.

increased. In view of these findings and its chemical structure, the formation of acrylonitrile is considered to proceed by means of the generation of crotononitrile. The fact that no detectable amounts of butyronitrile were found in the reaction mixture suggests that propionitrile was formed not by the hydrogenation of acrylonitrile, but by the recombination of $\cdot CH_2CN$ with the methyl radical. By analogy with the reactions of the atomic hydrogen produced by electric discharge with CH_3CN,[8] it seems likely that hydrogen atoms first attack one of the primary products, crotononitrile, to abstract the CN radical or methyl radical to produce HCN, CH≡CH, and the methyl radical, or CH_4, CH≡CH, and the CN radical, respectively. The formation of CH≡CH may partly compensate for the energy needed for the above bond cleavage. Accordingly, these cyano and methyl radicals which stem from crotononitrile produce C_2H_6 and CH_3CN *via* recombination. It is evident that the methyl radical formed in the discharge zone also attacks pyrrole to generate α- and β-methylpyrrole.

With the reaction of pyrrolidine, the radiofrequency discharge initiates a homolytic fission of the C–N bond, which is surely the weakest bond[9] in this molecule, accompanied by a subsequent dehydrogenation similar to that described above to deliver various saturated aliphatic nitriles, such as acetonitrile, propionitrile and butyronitrile, that is outlined in the following scheme.



Scheme 2.

Pyrrolidine produces, unlike pyrrole, the characteristic products of α-(1-pyrrolidinyl)nitrile derivatives, whose yields amount to 47.8%, on the basis of the converted pyrrolidine (Run No. 6). The product distribution indicates that, with anodic currents of 70, 80, and 90 mA (Run No. 4, 5, and 6), α-(1-pyrrolidinyl) nitriles are the main products, while small amounts of acetonitrile, propionitrile and butyronitrile are detected which are the alternative constituents of the α-(1-pyrrolidinyl) nitrile derivatives. These findings strongly suggest that pyrrolidine reacts with the resonance-stabilized α-cyanoalkyl radicals[10] to produce α-(1-pyrrolidinyl) nitrile. In this case it appears that α-cyanoalkyl radicals such as $\cdot CH_2CN$, $CH_3\dot{C}HCN$, and $CH_3CH_2\dot{C}HCN$ are not re-formed from the corresponding nitriles by the abstraction of a hydrogen atom, but are generated by the initial radical fission of the C–N bond of pyrrolidine, followed by dehydrogenation subsequent migration to a more stable radical, and the elimination of ethylene, ultimately forming an acetonitrile radical. Scheme 2 shows this, together with the production of saturated nitriles. In Scheme 2, the first-stage intermediate, $\cdot CH_2CH_2CH_2CN$, may rapidly abstract a hydrogen atom to yield butyronitrile, because it is an unstable primary radical. This route competes with another rearrangement leading to a more stable α-radical. Such an idea is supported by the fact that the amounts of butyronitrile were appreciable relative to the trace amounts of acetonitrile and propionitrile produced under rather mild conditions (Run No. 4 and Run No. 5).

Concerning the formation of α-(1-pyrrolidinyl) nitrile derivatives, two possible mechanisms may be considered; one is the recombination of the α-cyanoalkyl radical with the pyrrolidine-*N*-radical, and the other is the electrophilic attack of the α-cyanoalkyl radical towards the basic nitrogen atom of pyrrolidine, accompanied by the subsequent release of the H atom.

TABLE 3. EXPERIMENTAL CONDITIONS AND YIELDS OF THE LIQUID PRODUCTS FOR THE GLOW DISCHARGE REACTION OF BUTYLAMINE[a]

Reaction conditions	Run No 8	9	10

% Conversion	17.0	24.4	61.2

a) Duration of reaction: 10 min.

The product distribution and the reaction conditions with butylamine are shown in Table 3. The reaction mixture was found to contain acetonitrile, *N*-butylidenebutylamine, *N*-ethylidenebutylamine, and butylaminoacetonitrile, together with other unidentified products. In this case, the probable mechanism of butylaminoacetonitrile formation is considered to be the same as that for the formation of α-(1-pyrrolidinyl) nitrile derivatives in the discharge reaction of pyrrolidine; *e.g.*, α-acetonitrile radical resulting from ethylene-elimination and the dehydrogenation of butylamine either attacks a nitrogen atom of butylamine or combines with the butylamine-*N*-radical, forming butylaminoacetonitrile. *N*-Butylidenebutylamine is assumed to be formed by the recombination of intermediate radicals, $CH_3CH_2CH_2\dot{C}HNH_2$ and $CH_3CH_2CH_2CH_2\dot{N}H$, followed by the elimination of ammonia whose formation was confirmed in this experiment.

An inspection of Table 3 shows that the combined yield of $CH_3CH_2CH_2CH_2N{=}CHCH_3$ and $CH_3CH_2CH_2CH_2N{=}CHCH_2CH_2CH_3$ increases almost linearly with the anodic currents of discharge (70, 85, and 100 mA). As the release of the ethyl radical from the latter to

yield $CH_3CH_2CH_2CH_2N{=}CHCH_2\cdot$ seems to be an energetically preferred process, so the latter produced may be easily converted to $CH_3CH_2CH_2CH_2N{=}CHCH_3$ under these discharge conditions. Therefore, the formation of $CH_3CH_2CH_2CH_2N{=}CHCH_3$ may be supposed to be contingent upon the prior generation of CH_3CH_2-$CH_2CH_2N{=}CHCH_2CH_2CH_3$.

The Oxidative Solvolysis of Durohydroquinone Monobenzoates. A Study of the Mechanism

Makoto TAKAGI, Masato TAZAKI, and Tsutomu MATSUDA

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received February 25, 1977)

Durohydroquinone mono(*p*-substituted benzoate)s (**1a**—**1e**) were oxidized by DDQ in CH_3OH/CH_2Cl_2 at room temperature. The products were duroquinone dimethyl acetal **4** and *p*-substituted benzoic acids (**5a**—**5e**). None of the methyl esters **3** was formed. The details of the mechanism of a series of reactions, which start with the one-electron oxidation of **1**, is elucidated by the isolation and characterization of the intermediates as well as by a kinetic study in an acetonitrile solution. The relation between the mode of oxidation, whether it is a one-electron or two-electron process, and the activation of the acyl group was explicitly discussed in terms of the mechanism. Two-electron oxidation is suggested to offer a better chance for acyl activation. Some generalization of the mechanism is made for other oxidation-induced acyl, phosphoryl and sulfuryl activating systems.

The oxidation of hydroquinone monoesters is of considerable interest as models for biological energy conversion, wherein the free energy associated with redox reaction is conserved in such "energy-rich" bondings as phosphoric or carboxylic anhydrides. Research efforts have especially been focussed on the phosphate esters since some hydroquinone phosphates are believed to be involved in biological phosphorylation.[1-3] The oxidation of hydroquinone phosphates can generate a phosphorylating agent and the reaction mechanism, as well as the synthetic application, has been examined extensively.[4,5] The carboxylates behave similarly, and several implications of the mechanism involved have been made by Wieland and Aquila,[6] Bunton and Hellyer,[7] and Clark *et al.*[8] Thanassi and Cohen[9] have proposed a phosphate-free energy conservation cycle based on the ubihydroquinone monocarboxylate ester in mitochondria.

From the point of view of the mechanism, there have been controversial observations of this oxidation-assisted activation of phosphoryl and acyl groups, since both O–C(aryl) and O–P or O–C(acyl) bond fissions have been observed depending on the oxidation conditions.[4-12] The mode of oxidation, whether it is a one- or two-electron process, and the nature of the specific ionic species involved in the case of phosphate esters should be explicitly formulated in the delineation of the reaction mechanism which links oxidation to the phosphoryl and acyl transfer processes. There has been, however, little work along this line which traces back to the characterization of the reaction intermediates involved and studies the detailed behavior in the isolated state. As a substrate for a study of the mechanism involved the carboxylate has some advantages over the phosphate in that they do not dissociate under ordinary conditions and the physical-organic chemistry of the acyl group in general is much better founded than that of the phosphoryl group. In the present investigation, the mechanism of oxidation of durohydroquinone mono(*p*-substituted benzoate)s (**1**)[13a] by dichlorodicyano-*p*-benzoquinone ((DDQ) was studied by product analysis and by intermediate isolation and characterization, as well as by kinetic measurements. The one-electron oxidation process which does not lead to acyl activation[13b] has been elucidated, and the mechanism has been discussed in comparison with the two-electron oxidation process by bromine or NBS which was found to bring about acyl transfer.

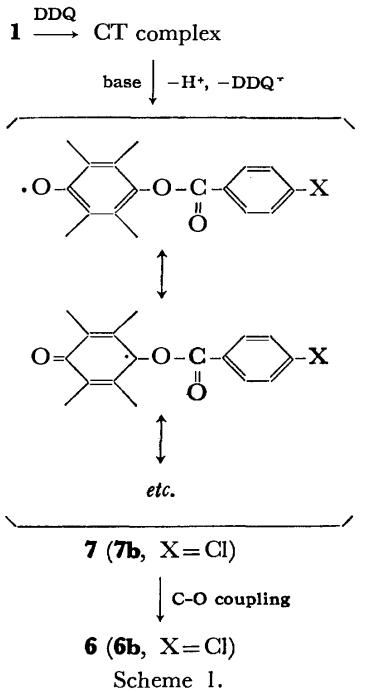
1b: X=Cl
1c: X=NO_2
1d: X=CH_3
1e: X=OCH_3

Results

Oxidation Products. Substrate **1** reacted with equimolar amounts of DDQ in CH_3OH/CH_2Cl_2 (50/50, v/v) at 30 °C, and the mixture was analyzed directly using GLC for duroquinone (**2**), methyl *p*-X-benzoate (**3**), duroquinone dimethyl acetal (**4**) and *p*-X-benzoic acid (**5**). The results are shown in Table 1. It is obvious that the nature of the products and their yields are the same, irrespective of the *p*-substituent on the benzoyl nucleus. About 90% of the durohydroquinone moiety was recovered as **4**, and 6 to 8%, as **2**. The combined yield accounts for more than 94% of the starting substrate. The benzoyl portions were almost quantitatively converted into the benzoic acids, and methyl benzoates were formed only in trace amounts. After work up, $DDQH_2$ and **5** were isolated in about 90% yield, and the combined yield of isolated **2** and **4** accounted for over 90% of the starting durohydroquinone ester. However, no methyl benzoate **3** was detected. Thus, the reaction can be formulated as

$$\mathbf{1} + DDQ + 2CH_3OH \xrightarrow[1\,h]{r.t.} \mathbf{4} + \mathbf{5} + DDQH_2. \quad (1)$$

Isolation of Reaction Intermediates. Dissolution of DDQ and **1b** in benzene produced a 1:2 (DDQ: **1b**) molecular complex as black-violet crystalline powder, having an IR spectrum very close to the superposition of those of **1b** and DDQ. Since the IR spectrum of the anion radical, $DDQ^{\cdot}$ (potassium salt[14]), was quite different, the structure of this molecular complex appears to involve the usual charge transfer (CT) interaction rather than an ionic or dative one with complete electron transfer. Similar CT complexes were isolated using other nonpolar solvents (1:1 or 1:2 stoichiometry). Recently, McNelis[15] reported a 1:1 CT complex between naphthalenediol monoacetate and DDQ.



Scheme 1.

When **1b** reacted with DDQ in benzene (CT complex formation) and was then treated with a 2 M NaOH solution, 4-(4-chlorobenzoyloxy)-4-[4-(4-chlorobenzoyloxy)-2,3,5,6-tetramethylphenoxy]-2,3,5,6-tetramethyl-2,5-cyclohexadienone **6b** was produced in a 90% yield as colorless crystals. The ^{1}H NMR spectrum is illustrated in Fig. 1. The assignment is based on a comparison with other structurally-related compounds synthesized in the present study, which are included together in the figure. The formation of **6** from the CT complex upon treatment with a base can be rationalized as follows. The base abstructed the phenolic proton from the CT complex.

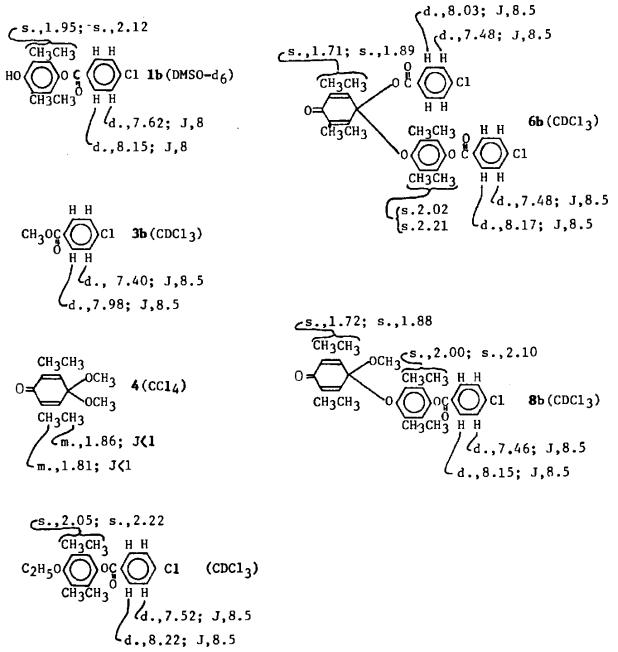


Fig. 1. ^{1}H NMR spectra of the oxidation products and related compounds. Chemical shifts are in ppm from TMS, and coupling constants in Hz.

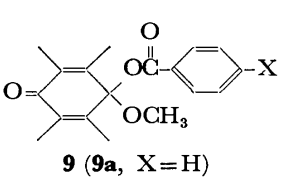
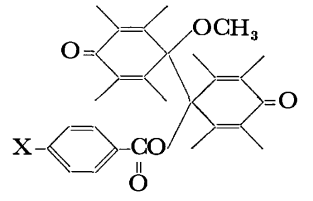
The CT interaction then proceeded to transfer an electron to form phenoxyl **7**, which in turn coupled bimolecularly at C- and O-terminals giving **6** (Scheme 1).

The reaction of **1** with DDQ in a medium containing alcohols as a major component proceeded rather rapidly (within 1 h) and gave **4**, **5** and $DDQH_2$ as final products (Reaction 1). However, when the reaction was quenched at a very early stage, the products were different. The oxidation of **1b** in $C_2H_5OH/CHCl_3$ (50/50, v/v) according to the similar procedure as described above for the reaction in benzene (1 min of reaction time before treatment with 2 M NaOH) produced **6b** in a 73% yield. In the alcoholic solvent, the CT complex is not a stable entity, but proceeds rapidly to further reactions. It is, therefore, uncertain whether **6b** was formed on contact with the added base (as is the case for the reaction in benzene) or was already being formed in the polar and hydroxylic reaction medium. The reaction mixture was quenched by aqueous ascorbate–sodium hydrogen carbonate. Then, the yield of **6b** was even higher (86%) in $C_2H_5OH/CHCl_3$, while in benzene no **6b** was obtained, and **1b** was recovered quantitatively. This indicates that the ascorbate anion reduced DDQ in the CT complex and completely suppressed the base promoted transformation of the CT complex to *p*-benzoyloxyphenoxyl (**7b**) and DDQ$^{\cdot-}$. These results strongly support the hypothesis that the reactions in Scheme 1 are under way in the initial phase of the reaction in the polar and hydroxylic mediums, such as CH_3OH/CH_2Cl_2 or $C_2H_5OH/CHCl_3$. On the other hand, the reaction does not proceed beyond the CT stage in the benzene solvent.

Scheme 1 describes the one-electron oxidation of **1** by DDQ. The oxidation was carried out with typical one-electron oxidizing agents for comparative purposes. The oxidation of **1b** with potassium hexacyanoferrate(III) in 2 M NaOH produced **6b** in a 70% yield. Oxidation with cerium(IV) ammonium nitrate in methanol turned out to be somewhat different, giving 4-[4-(4-chlorobenzoyloxy)-2,3,5,6-tetramethylphenoxy]-4-methoxy-2,3,5,6-tetramethyl-2,5-cyclohexadienone **8b** (yield 84%). Clark *et al.*[8] conducted a similar cerium(IV) oxidation experiment with **1a** and isolated a yellow solid for which the structure **9a** (X=H) was suggested. The ^{1}H NMR spectra of the preparation reported here (Fig. 1, **8b**) is not in accord with this type of structure. Another structure, **10b**, which is isomeric to **8b**, was excluded on the basis of a detailed comparison of the ^{1}H NMR chemical shifts of the related compounds in



9 (**9a**, X=H)



10 (**10b**, X=Cl)

Fig. 1. The product difference between hexacyanoferrate(III) oxidation and cerium(IV) oxidation can be rationalized by the lability of **6b** under acidic conditions.

TABLE 1. DDQ OXIDATION OF **1** IN CH_3OH/CH_2Cl_2[a)]

Substrate	Product, % yield			
	2	**3**	**4**	**5**
1a	6	<1	92	~100
1b	8	<1	92	~100
1c	6	<1	88	b)
1d	—	<1	88	~100
1e	6	<1	88	~100

a) $[\mathbf{1}]_0=[DDQ]_0=0.05$ M, CH_3OH/CH_2Cl_2 (50/50, v/v), 30 °C, 1 h. b) Not determined.

The reaction medium for cerium(IV) oxidation was rather strongly acidic, and it was shown in a control experiment that, under such circumstances, **6b** is readily converted into **8b**.

Chemical Transformations of Reaction Intermediates. The intermediates isolated in the foregoing section were found to be eventually transformed into the final products, **2**, **4**, and **5**, under the reaction conditions described in Table 1. In this context, the behavior of the isolated intermediates was studied with respect to the reactivity of the acetal linkages. Two types of reaction, *i.e.*, heterolytic and homolytic cleavages, were observed.

The acetal **6b** dissolved in $CHCl_3/CH_3OH$ (10/90, v/v) was maintained at 0 °C overnight. Work up of the mixture gave no recoverable **6b** but did give **8b** (in a 83% yield without purification) and *p*-chlorobenzoic acid, **5b**. No evidence was obtained for the formation of **1b**, which should be readily detectable from its characteristic IR absorption (ν_{OH}, 3415 cm^{-1}). This indicates that the acetal linkage C–OCOAr is much more labile than C–OAr′ under neutral to weakly acidic conditions (Reaction 2). Prolonged treatment of **6b** with methanol resulted in a complex mixture containing **2** and **4**, in addition to **5** and **8**. The reaction in ethanol proceeded similarly, but slowly in comparison with that in methanol:

$$\mathbf{6} + CH_3OH \begin{cases} \longrightarrow \mathbf{8} + \mathbf{5} \\ \longrightarrow\!\!\!\!\!\!\times\ \ \mathbf{9} + \mathbf{1} \end{cases} \qquad (2)$$

The time dependence of the ^1H NMR spectrum of a mixture of durohydroquinone monomethyl ether (**11**, 0.10 mmol) and DDQ (0.11 mmol) in $CD_3OD/CDCl_3$ (50/50, v/v, 400 μl) was inspected. The spectra in Fig. 2 indicate that, after 2 h, methyl trideuteriomethyl acetal of duroquinone, **12** (the compound **4** in which one of the CH_3O groups is replaced by CD_3O), was formed quantitatively. After 4 days, the CH_3O group in the acetal **12** was completely exchanged to CD_3O by further reaction with the solvent. A considerable amount of duroquinone was also formed by a reaction with the moisture in the solvent. The first phase of the reaction was very rapid, and the formation of **12** was, in fact, complete within 5 min according to the NMR measurement. The reaction of **11** and DDQ under alkaline conditions gave a quite different product. Thus, the solution of **11** and DDQ in benzene, after treatment with aqueous alkali, afforded 4-methoxy-4-(4-methoxy-2,3,5,6-tetramethylphenoxy)-2,3,5,6-tetramethyl-2,5-

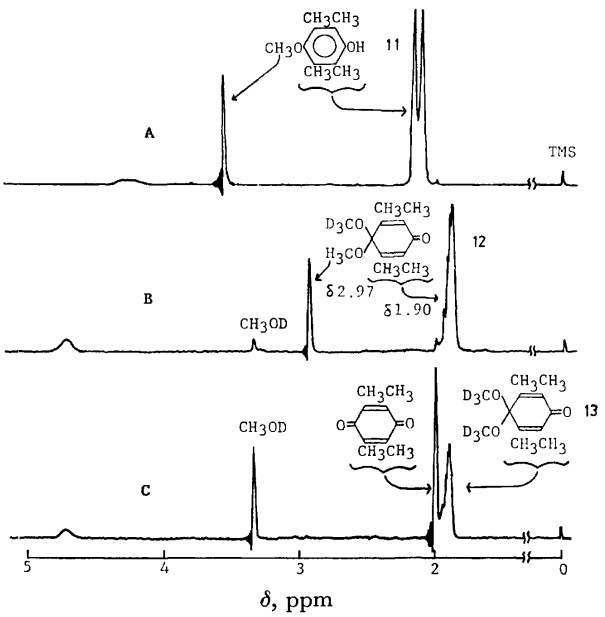


Fig. 2. DDQ oxidation of **11** (0.10 mmol) in $CD_3OD/CDCl_3$ (50/50, v/v, 400 μl) at room temperature. ^1H NMR spectra. A, **11** in $CDCl_3$; B, reaction mixture after 2 h; C, after 4 days.

cyclohexadienone **14** as colorless crystals (yield, 75%). The latter could also be prepared using an alkaline hexacyanoferrate(III) solution as the oxidizing agent.[16] Compound **14** was not only labile to acid forming **4** and **11** in acidified methanol (by the addition of $DDQH_2$) but also readily oxidizable (within 5 min) by DDQ in $CD_3OD/CDCl_3$ to give the acetal **12**. These facts indicate that **14** would be of only transient existence, even if it were formed in the DDQ oxidation of **11** in $CD_3OD/CDCl_3$. The ^1H NMR spectrum of **14** contained unusually broad resonance signals, which were barely assignable to the proposed structure. The ESR measurements made on the solution in benzene/toluene (Fig. 3)

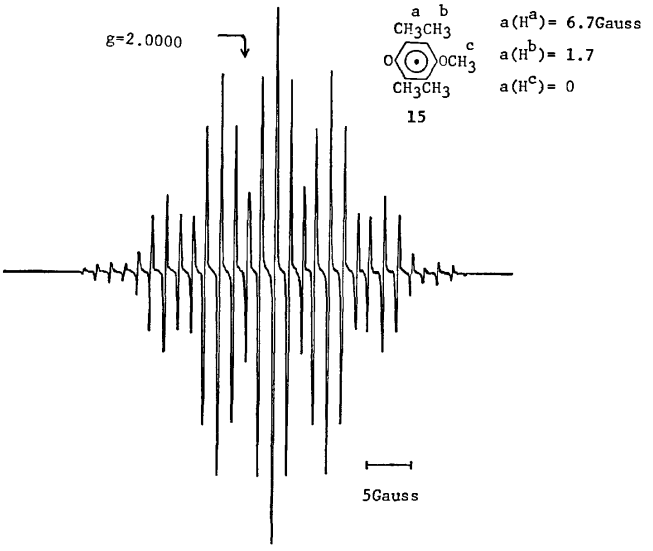

Fig. 3. The ESR spectrum of **14** in $C_6H_6/C_6H_5CH_3$ (40/60, v/v). $[\mathbf{14}]=0.67$M, room temperature. **14** ⇌ **2**·**15**.

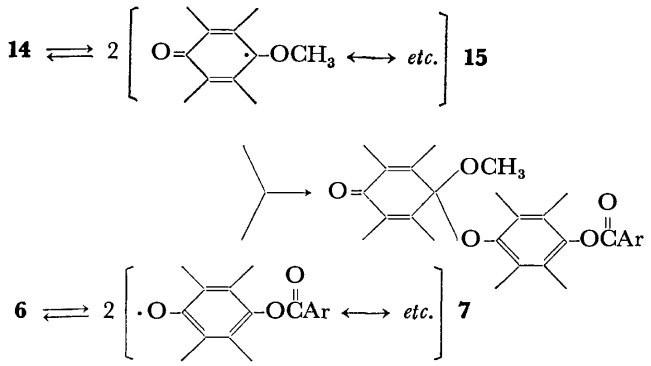
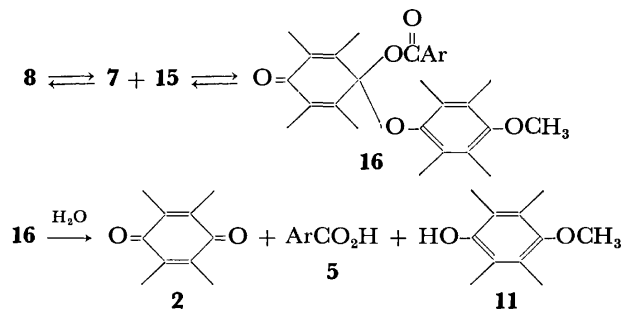
clearly indicate the presence of phenoxyl **15** in equilibrium with **14**. Similar behavior has been reported for a related compound.[17]

An equimolar mixture of **6b** and **14** was found to be converted into **8b** simply by dissolving the former in benzene followed by concentration under reduced pressure. This observation indicates that the radical dissociation of **6b** should be considered in addition to that of **14**. The reaction is illustrated in Scheme 2.



Scheme 2.

The intermediate **8** also appears to undergo facile homolytic cleavage of the acetal linkage, evidence for which has come from the attempted purification of **8b** by column chromatography on silica gel. On elution with benzene/ether, **8b** (1 mmol, contaminated with **5b**) decomposed to **1b** (0.55 mmol), **2** (0.89 mmol), **5b** (0.79 mmol) and **11** (0.26 mmol). Degradation accounts for the difficulty encountered in obtaining **8b**, and, in fact, it was this finding which prompted the examination of the DDQ oxidation of **11**. The reaction can be rationalized by the process illustrated in Scheme 3. A hydrolysis of acetal **8b** to **1b** and **2** should also be considered.



Scheme 3.

Kinetic Study in Dilute Solutions. In the preceeding sections, the chemical events after the completion of one-electron oxidation on the substrate were considered. Now, information is treated regarding the oxidation step using a kinetic method in dilute solutions. The oxidation for the kinetic study was carried out conveniently in CH_3CN or AcOH, and most of the kinetic runs presented herein involve the former as a solvent. When **1a** (0.5 mM) reacted with DDQ (0.5 mM) in dry CH_3CN at room temperature, the electronic spectra indicated the formation of $DDQ^{\cdot}$, in addition to $DDQH_2$ (Fig. 4). In accordance with the acid dissociation and

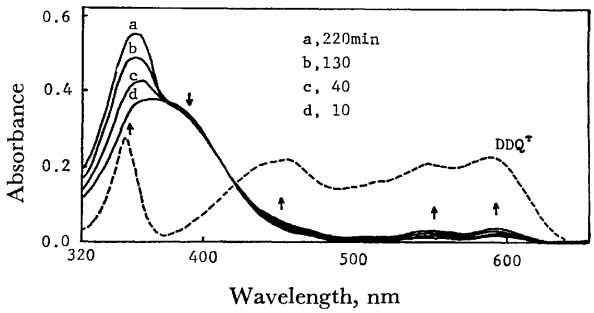


Fig. 4. The variation of electronic spectra accompanying the reaction of DDQ with **1a**. $[DDQ]_0=[\mathbf{1a}]_0=$ 0.5 mM, CH_3CN, 30 °C.

redox equilibrium between DDQ, $DDQH_2$, and $DDQ^{\cdot}$,[18] the relative $DDQ^{\cdot}$ and $DDQH_2$ concentra-

$$2DDQ^{\cdot} + 2H^+ \rightleftharpoons DDQ + DDQH_2, \quad (3)$$

tions formed during the oxidation reactions varied with the acidity of the medium. For example, upon the addition of excess trifluoroacetic acid, no $DDQ^{\cdot}$ was detected, and in the presence of equimolar 2,6-lutidine, $DDQ^{\cdot}$ was the sole product in the oxidation. The presence of basic material (*e.g.*, 2,6-lutidine, pyridine *N*-oxide or lithium acetate) not only affected the nature of the product (*i.e.*, increased the ratio of $DDQ^{\cdot}$/$DDQH_2$) but also drastically accelerated the oxidation rate. For instance, oxidation in the presence of equimolar 2,6-lutidine was instantaneous at room temperature, while the presence of several molar excess amounts of water, methanol, acetic acid or trifluoroacetic acid showed no measurable influence on the rate (*vide infra*). Base-assisted oxidation, which is in accord with Scheme 1, will be more fully treated in a separate communication.

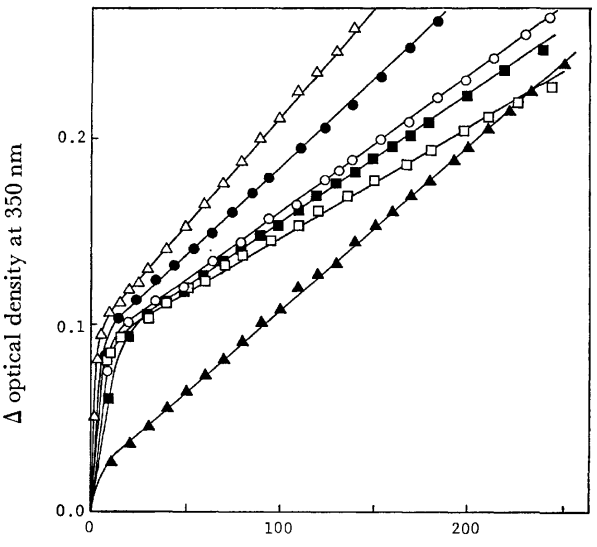

Fig. 5. The time dependence of the increase in absorption at 350 nm in CH_3CN at 30 °C. $[DDQ]_0=[\mathbf{1a}]_0$ =0.5 mM.
—■—, without additive; —○—, 0.06 M CH_3OH; —●—, 0.31 M CH_3OH; —△—, 0.61 M CH_3OH; —□—, 0.22 M AcOH; —▲—, 0.22 M CF_3COOH.

In Fig. 5, the increase in the absorbance at 350 nm, which corresponded to the formation of $DDQH_2$, was plotted against time for the oxidation of **1a** in CH_3CN. A small absorption due to $DDQ^{\cdot}$ was observed under these conditions, except for the case in which trifluoroacetic acid was present as an additive, but this constituted only a trivial correction to the amount of $DDQH_2$ formed on reduction by substrate **1a**. No sign of CT complex formation was observed in the spectra at the low concentration ranges of DDQ and **1a** utilized. Figure 5 exhibits the unusually fast production of $DDQH_2$ at the very early stages of the reaction (<2.5% conversion of DDQ), which was followed by a region (up to ≈8%) with a constant rate (pseudo-zero order kinetics). The first phase of the reaction was probably due to the presence of a small amount of basic impurity in the CH_3CN solvent, although it was carefully purified. The addition of trifluoroacetic acid eliminated most but not all of this irregular region. The relative reaction rates estimated from the slope of the second linear portion of the plots in Fig. 5 are 1.00 (without the additive), 0.83 (AcOH, 0.22 M), 1.23 (CF_3COOH, 0.22 M), 1.06 (CH_3OH, 0.06 M), 1.34 (CH_3OH, 0.31 M), and 1.69 (CH_3OH, 0.61 M). The small effect of the additives on the reaction rate even in the presence of a molar excess of **1a** of 1000 is more likely due to the change in the nature of the medium rather than to the specific effect of the additives. Thus, neither a nucleophilic process nor an acidic catalysis is involved in the rate-determining step of the formation of $DDQH_2$ (or $DDQ^{\cdot}$, refer to Reaction 3). The reaction products from **1** are probably similar to those mentioned in previous sections, but were not identified under the present reaction conditions. Where no nucleophilic additive was intentionally applied, a trace of water in the solvent might have assumed the role of a nucleophile.

Kinetics in acidified CH_3CN (0.16 M CF_3COOH) were studied. The initial concentration of DDQ was maintained constant at 0.5 mM and that of **1a** was varied between 0.25 and 3.99 mM. The pseudo-zero order rates, v_0, for the production of $DDQH_2$ in the early stages of the reaction (<7% conversion of DDQ) were obtained from the slopes of the plots similar to that shown in Fig. 5 and are plotted against the **1a** concentration in Fig. 6. The linear plot with a 1.0 slope indicates the first-order dependence of the rate on [**1a**]. The other series of experiments, in which DDQ (initial concentration, 0.1 mM) reacted with a large excess (4—7 mM) of **1a**, showed that the dependence on DDQ was also of the first order (pseuso-first order production of $DDQH_2$ with up to 90% conversion of DDQ), although the reactions for such low concentrations of DDQ were less reliable in this experiment. Kinetic studies with glacial acetic acid as the solvent also indicated a first-order dependence on both [DDQ] and [**1a**]. The calculated second-order rate constant k (M^{-1} min^{-1}), according to the expression $d[DDQH_2]/dt = k[\mathbf{1a}][DDQ]/2$, was 1.6 in CH_3CN (30 °C) and 2.0 in CH_3COOH (25 °C).

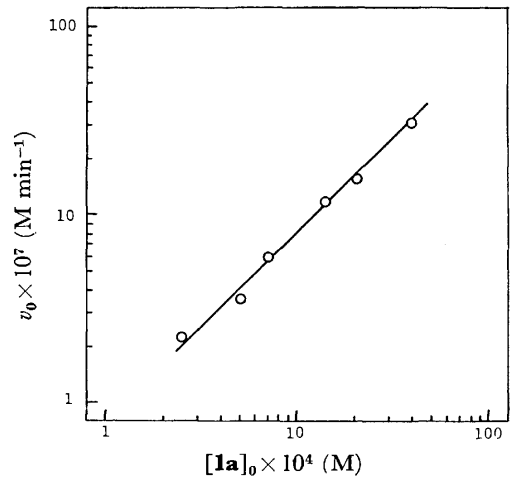

Fig. 6. The dependence of the initial rate of $DDQH_2$ formation on the substrate (**1a**) concentration. $[DDQ]_0$=0.5 mM, $[CF_3COOH]$=0.16 M, CH_3CN, 30 °C.

The effect of a *p*-substituent in the benzoyl group on the rate was investigated. The substrate (**1a**—**1e**, 0.5 mM) was oxidized by DDQ (0.5 mM) at 30 °C in acetonitrile containing 0.16 M trifluoroacetic acid. The previous initial rates were obtained, and the logarithm of the rate ratio was plotted against σ and σ$^+$ (Fig. 7).

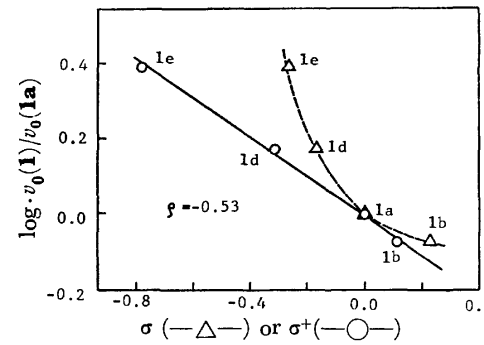

Fig. 7. Hammett's plot of the initial rate for the oxidation of **1a**—**1e** by DDQ. $[DDQ]_0=[\mathbf{1}]_0$=0.5 mM, $[CF_3COOH]$=0.16 M, CH_3CN, 30 °C.

The plot against σ$^+$ gave a straight line with a slope ρ=−0.53. This indicates that a positive charge develops on substrate **1** in the transition state of the rate-limiting step. This is in accord with the expectation that the transition state involves electron transfer or charge separation between **1** and DDQ. The small value of ρ reflects that the substituents are situated rather remote from the durohydroquinone nucleus which suffers oxidation.

Discussion

Reaction Products and Intermediates in DDQ Oxidation. The oxidation products in an alcoholic medium indicated that no activation of an acyl group or acyl transfer occurs (Reaction 1). Even the trace of **3** detected in direct GLC analysis could be an artifact due to the subsequent analytical operation. However, in their extensive study on the oxidation of hydroquinone monocarboxylates, Clark *et al.*[8] reported the activation of an acyl group in a system closely related to that

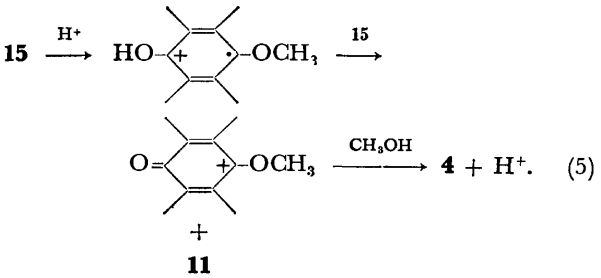
studied here. In their experiment, **1a**, **1c**, and **1e** reacted separately with DDQ in $C_2H_5OH/CHCl_3$ (50/50, v/v) at room temperature, and the formation of **2** and **3'** (ethyl esters) was observed in yields of 80—95 and 4—33%, respectively, by analyzing the reaction mixture directly using GLC. This reaction was re-examined and their results were reproduced (except for the production of **4**, which they did not mention) but only under subtly specific reaction conditions. Thus, when the GLC analysis was performed immediately after the dissolution of the reactants, the yield of **3'** was much higher than those reported. Analyses at various reaction times indicated a decreasing yield of **3'** with time. Analyses after the conventional work up indicated that no **3'** was formed throughout the reaction. Their results, therfore, do not appear to reflect the real progress of the reaction in the reaction vessel. Quite similar behavior was in fact observed also in the present system (reaction in $CH_3OH/CHCl_3$) and, under suitable conditions, a yield of **3** of more than 60% was realized by direct GLC analysis. These facts obviously indicate that the starting material, or more probably some reaction intermediates therefrom, reacted to give **3** at the high temperature in the injection part of the instrument. The behavior of reaction intermediate **6** was studied in this context. When a solution of **6b** in CH_3OH/CH_2Cl_2 or $C_2H_5OH/CHCl_3$ was injected onto a GLC column, no benzoate, neither **3b** nor **3b'**, was formed. Upon the addition of DDQ to the solution, the formation of 2—4% of the ester was indicated, which could be eliminated by treating the reaction mixture with aqueous sodium ascorbate before injection. Thus, the combination of **6** and DDQ partially simulate the reaction of **1** with DDQ to give benzoates. However, this is obviously not sufficient to explain the origin of the high yield (10—60%) of **3** at the initial stage of the oxidation reaction. It is most likely that the CT complex of **1** and DDQ is responsible for this reactivity:

$$\underset{\text{CT complex}}{\mathbf{1}\cdot DDQ_n} + CH_3OH \xrightarrow{\text{high temp}} \mathbf{2} + \mathbf{3} + DDQH_2 + (n-1)DDQ. \quad (4)$$

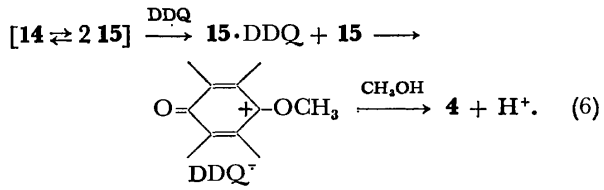
The strongly blackish coloration at the onset of the reaction and the isolation of the CT complex support this view.

Hageman *et al.*[15] have studied the oxidation of 2,3-dimethyl-1,4-naphthalenediol monoacetate by manganese dioxide and DDQ to give an oxidatively dimerized product and have suggested that the dimer is formed *via* an *o*-quinone methide intermediate. In the present system, no evidence for the presence of such an intermediate could be obtained, even after all attempts including the possible cyclo-addition of the intermediate with butyl vinyl ether. These same authors[15] have further assumed that the foregoing intermediate was preceeded by still other intermediates, the naphthoxyl and its dimer, which were in equilibrium. This supposition appears to be substantiated by the isolation of **6b** in the present study. Clark *et al.* have mentioned that the oxidation of hydroquinone monobenzoates with cerium(IV) ammonium nitrate produced an oxidatively dimerized compound with concurrent nitration.[8] The structure of this compound was not elucidated, but it could be similar to **6**.

Mechanism of Oxidative Solvolysis. It is reasonable to suppose that ordinary acid catalyzes the acetal exchange process for the degradation of **14** to **4** and **11** in methanol.[16] However, in consideration of the homolytic fission of **14**, it appears also possible to delineate the alternative radical mechanism, in which **15** is first protonated and the subsequent electron transfer results in the net heterolytic cleavage of the acetal bond of **14**:[19]



Another possibility would be the disproportionation of **15** involving a quinone methide intermediate.[17] In the presence of DDQ, still another modification can occur due to the Lewis acidity (or CT interaction) of DDQ. The protonated radical in Reaction 5 is then replaced by the CT complex, which subsequently decomposes into DDQ^- and the carbonium ion,[19] thus:

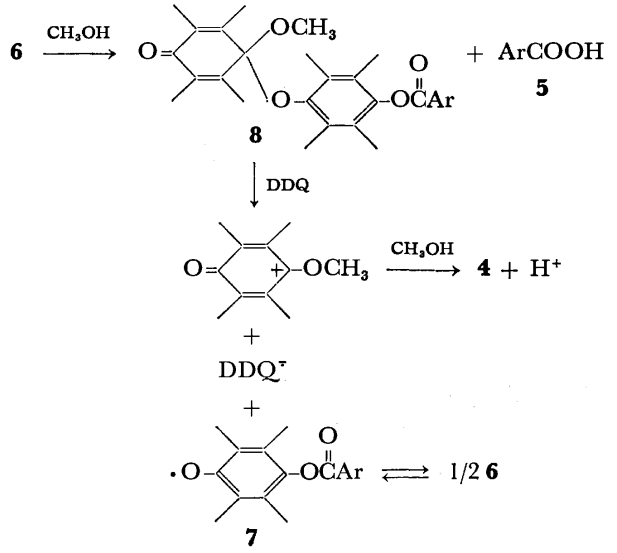


As has been noted, the oxidation of **11** and **14** by DDQ in $CD_3OD/CDCl_3$ is very rapid and is complete within 5 min at room temperature. The acid ($DDQH_2$) catalyzed degradation of **14** into **4** and **11** in the same solvent was also rapid and complete within 5 min under the conditions of the NMR spectral measurements (37 °C). Thus, under the present conditions, it was not possible to assign the major route of degradation of **14** from the alternative oxidation path (giving **4** and **15**, Reaction 6) and acid catalyzed paths (giving **4** and **11**, *e.g.*, *via* Reaction 5).

The homolytic scission of the acetal linkage of **8** poses a question similar to the case of **14** as regards the detailed mechanism of the acid catalyzed solvolytic reaction of **8** in methanol giving the dimethyl acetal **4** and **1** (a reaction similar to Reaction 5). The presence of DDQ here again introduces the possibility of an oxidation route, *i.e.*, the oxidative degradation of **8** to produce **4** and the *p*-aryloxyl radical **7** (which is in equilibrium with **6**) in a manner similar to that in Reaction 6. The data on hand show that both the acid catalyzed path and the oxidation path are again very rapid under the conditions for the NMR spectral measurements (complete within 5 min at 37 °C) and, therefore, it is difficult to determine which path is the major one under the reaction conditions given in Table 1. However, it is interesting to note that **6b** was very

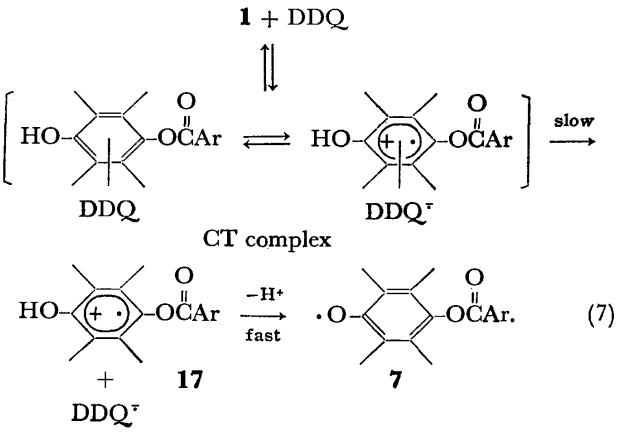
labile to acid, but not to DDQ. An equimolar mixture of DDQ and **6b** in $CD_3OD/CDCl_3$ showed no reaction after 5 min, although after 10 min, the NMR spectra implied the onset of the reaction, which was followed by a great increase in the rate. After 20 min, the reaction was complete and the products were **4** and **5b**. In the presence of $DDQH_2$ (an acid catalyst), **6b** was rapidly converted into **4**, **5b**, and **1b** (within 5 min). The insensitivity of **6b** to DDQ is deemed to reflect the reluctance of **1b** to undergo two-electron oxidation by DDQ.

The chemical events after the formation of **6** (Scheme 1) can now be delineated as in Scheme 4 (in which only the oxidation path is shown for the conversion of **8** into **4** and **7**), thus completing the overall reaction of Reaction 1.



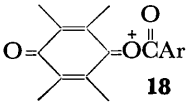
Scheme 4.

One-electron Oxidation of **1** *by DDQ.* The information obtained from this kinetic study can be summarized as follows. Under neutral to acidic conditions, the transition state of the oxidation step (i) contains one molecule each of DDQ and the substrate, (ii) does not involve the direct participation of a nucleophile such as water or methanol, (iii) does not involve acid catalysis, and (iv) carries a cationic character on the substrate. The following mechanism is consistent with these facts:

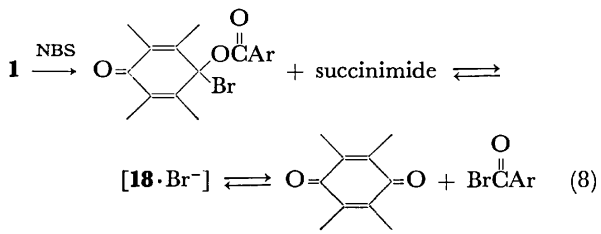


It is assumed that electron transfer within the CT complex is rapid and its dissociation into the solvated radical ion pair is rate determining. The degradation of the CT complex should be strongly facilitated in the presence of a base, since the phenoxyl **7** rather than its conjugate acid **17** can result from the interaction between the base and the CT complex. This view conforms to experimental observation. That the increase in the concentration of methanol in acetonitrile brought about rate enhancement suggests the solvation of the transition state by methanol molecules effectively acting as bases. For the oxidation of phenols by DDQ, both one-electron (as in Scheme 1 and Reaction 7) and two-electron (hydride abstraction mechanism) processes have been proposed,[17,20] and experimental distinction, in many cases, is difficult. The present kinetic evidence itself by no means excludes the alternative hydride abstraction mechanism. The preference for the one-electron oxidation with prior CT complex formation (Reaction 7) is in compliance with the results in the previous sections.

One- and Two-electron Oxidations and the Mechanism of Acyl Activation. Concerning the process of acyl activation *via* oxidation, it would be reasonable to suppose that, as a consequence of oxidation, the hydroquinone moiety of the ester should be converted into a group which exhibits an improved capacity to accommodate the negative charge. For the oxidation of **1** with DDQ, it was shown that **1** is first transformed into the phenoxyl **7** *via* a one electron process. The much stronger acidity of durosemiquinone (pK_a, 4.9—5.9[21]) than that of durohydroquinone (pK_a, 10.5, a guess from Ref. 22) renders the conjugate base of the former much more stable as a product anion. Therefore, from a comparison between the structures of **1** and **7**, we would expect the activated acyl group from **7**, rather than that from **1**. This type of activation should account for somewhat more than the difference in reactivities between phenyl (pK_a (C_6H_5OH) = 10.6) and *p*-nitrophenyl (pK_a (*p*-NO_2-C_6H_4OH) = 7.2) benzoates. The enhanced reactivity of the benzoyl group in **7**, however, could not be observed experimentally because of the involvement of other facile processes, which are initiated by the dimerization of **7** to **6** (Scheme 4). Since the dimerization of radicals is inevitable under ordinary reaction conditions, it is concluded that the acyl activation of hydroquinone monoester cannot generally be expected, when the oxidation is effected by the one-electron process. However, there is a prerequisite for this conclusion in that radical **7** dimerizes to **6** and the latter does not undergo further one-electron oxidation, which would lead in effect to the two-electron oxidation of the substrate, **1**. If the dimerization process is inhibited by certain factors, the expected activation should be observed. The unimolecular conditions (with respect to the substrate) imposed in enzymic reactions or possibly in reaction in a polymer matrix would qualify to be such factors. Concerning two-electron oxidation, there is no evidence up to now that either **6** or **7** is further one-electron oxidized by DDQ. Such a process would produce the very reactive hypothetical cation intermediate:



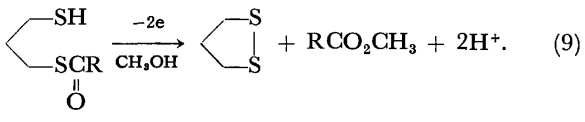
If **18** or a similar species which can conveniently be formulated as **18** on the basis of its reactivity is formed in the reaction mixture, a nucleophilic attack by methanol would be possible at two reactive sites, *i.e.*, at the acyl carbon and the carbonyl carbon of the quinone nucleus. The former gives methyl carboxylate, while the latter would lead eventually to dimethyl acetal (**4**) and carboxylic acid (**5**). Thus, the production of **18** is not necessarily equivalent to experimentally observable acyl activation. The literature indicates that the acyl activation (acyl transfer) has been verified successfully utilizing bromine, NBS, *etc.*, which are apparently two-electron oxidizing agents.[6,8,9] Some of these results were confirmed for the present substrate, **1**. A preliminary study on the mechanism suggests the intervention of **18** or a similar species. Thus, when **1b** reacted with equimolar NBS in benzene at room temperature, *p*-chlorobenzoyl bromide was obtained in a 10% yield, which was identified by IR spectroscopy and its derivation to the anilide. The reaction may be formulated as:



A similar process has been inferred previously.[8,10,23] The reaction with bromine gave similar results, but extensive bromination of the side chain of duroquinone occurred concurrently (acid catalysis by HBr).

It is reasonable to suppose that the actual structure of the intermediate in the two-electron oxidation process can vary according to the nature of the specific oxidizing agent. For NBS, the two electrons are abstracted directly from the hydroquinone nucleus through C–Br bonding (Reaction 8), while the formation of O–I[7,24] and O–Tl[8,25] bonding are assumed for oxidation with periodate and thallic salt, respectively. The efficiency of the nucleophilic attack on the acyl carbon in **18** is also dependent on these variations. A detailed study has yet to be made of this aspect. It is interesting to note in passing that the thermolysis of the CT complexes of **1** and DDQ produced methyl benzoates in a fairly high yield (up to 60%). The mechanism is by no means clear, but it is possible that the thermal decomposition of the CT complex resulted in a net two-electron oxidation and gave an intermediate of type **18**.

Generalization of the Mechanism. As is obvious from the foregoing discussion, two-electron oxidants have a greater probability of activating the acyl group than do one-electron oxidants. This proved also true of the oxidative acyl transfer observed in the reaction of 1,3-dithiol mono carboxylates:[26]



While iodine was the most effective oxidizing agent for the acyl activation, one-electron oxidizing agents lead to the linear disulfide (dimerization of the intermediate thiyl radical) without activating the acyl group. However, if we leave the carboxylate and proceed to the phosphates and sulfates, a different consideration has to be made. The essential difference between the acyl group displacement and that of the phosphoryl and sulfuryl groups resides in the fact that the acylium ion intermediate can never be formed under ordinary conditions, while the corresponding intermediates the metaphosphate anion[5,27] and sulfur trioxide,[28,29] respectively, are of a more realistic entity. There have been reports, although small in number, of one-electron oxidation processes resulting in the observable activation of the phosphoryl group (phosphoryl transfer).[4,11] This means that the radical intermediate corresponding to **7** evolves the metaphosphate anion, the semiquinone anion radical acting as an effective leaving group.[11,12] It is reasonable to assume in these cases that the dimerization of the radical intermediate was inhibited because of the unfavorable charge and steric effects. A similar process may also be possible for the sulfate.[28,30] On the other hand, much of the same above discussion applies to the two-electron oxidation of the phosphates and the sulfates except for allowance for the intervention of metaphosphate and sulfur trioxide intermediates, respectively.

Experimental

General. The melting points were determined on a hot-stage apparatus and are uncorrected. The infrared spectra were recorded in Nujol mulls on a Jasco IR-E instrument unless otherwise noted. The ultraviolet and visible spectra were measured on a Shimazu UV-200 spectrometer, and the NMR spectra were recorded with a Varian A-60 spectrometer for solutions in $CDCl_3$, CCl_4 or deuterated DMSO, using TMS as an internal standard. The ESR spectra were obtained on a Jasco ME-3X X-band spectrometer. The magnetic field was calibrated with Mn^{2+}: MgO. All solvents were purified by standard techniques. The acetonitrile for the kinetic study was retained over 3A Molecular Sieves after a final distillation from K_2CO_3. Kinetic measurements were made in a thermostatically-controlled cell, having an optical path of 10 mm and which was capped with silicone rubber and placed in the spectrometer. The solution was prepared in a nitrogen atmosphere and introduced by means of syringe. The reaction temperature was reproducible to within $\pm$0.2 °C.

Materials. DDQ (reagent grade, purchased from the Tokyo Kasei Kogyo Co.) was repeatedly recrystallized from benzene, and the CT complex therefrom was decomposed under reduced pressure to give pure DDQ. Durohydroquinone was synthesized according to the reported procedure.[31] The durohydroquinone mono *p*-X-benzoates, **1a**, **1c**, and **1e** were prepared according to the literature[8,32] and purified by repeated recrystallization from benzene and then methanol. **1a**: Yield (after purification), 20%; mp 227—228 °C (lit, 221—223°C[32]); IR 3420, 1710, 1292, 1250, and 1097 cm^{-1}; Found: C, 75.65; H, 6.72%. Calcd for $C_{17}H_{18}O_3$: C, 75.53; H, 6.71%. **1c**: Yield, 15%; mp 231.5—233.0 °C (lit, 231 °C[8]); IR 3440, 1720, 1536, 1350, 1290, 1245 and 1093 cm^{-1}; NMR (DMSO-d_6) δ 1.95 (6H, s), 2.15 (6H, s), 8.36 (4H, s); Found: C, 64.65; H, 5.51; N, 4.55%. Calcd for $C_{17}H_{17}NO_5$: C, 64.76; H, 5.43; N, 4.44%. **1e**: Yield, 16%; mp 239—241 °C (lit, 237 °C[8]); IR 3400, 1708, 1290, 1245, and 1100 cm^{-1};

NMR ($CDCl_3$) δ 2.06 (6H, s), 2.15 (6H, s), 3.89 (3H, s), 6.97 (2H, d, J=9 Hz), 8.18 (2H, d, J=9 Hz); Found: C, 71.96; H, 6.71%. Calcd for $C_{18}H_{20}O_4$: C, 71.98; H, 6.71%. The substrates **1b** and **1d** were prepared similarly. **1b**: Yield, 33%; mp 240—241 °C; IR 3415, 1715, 1290, 1245, and 1095 cm^{-1}; NMR, Table 1: Found: C, 67.07; H, 5.71%. Calcd for $C_{17}H_{17}ClO_3$: C, 67.00; H, 5.62%. **1d**: yield, 32%; mp 253.5—255.5 °C; IR 3410, 1712, 1290, 1245 and 1095 cm^{-1}; NMR (DMSO-d_6) δ 1.95 (6H, s), 2.15 (6H, s), 2.41 (3H, s), 7.36 (2H, d, J=8 Hz), 8.03 (2H, d, J=8 Hz); Found: C, 76.06; H, 7.16%. Calcd for $C_{18}H_{20}O_3$: C, 76.03; H, 7.09%. Durohydroquinone monomethyl ether (**11**) was synthesized according to the literature[23] and purified by repeated recrystallization from CCl_4/petroleum ether. Yield, 14%; mp 117—118 °C (lit, 115—116 °C[33]); IR 3330, 1242, 1076, and 1008 cm^{-1}; NMR ($CDCl_3$) δ 2.11 (6H, s), 2.16 (6H, s), 2.59 (3H, s), 4.2—4.5 (1H, broad). Durohydroquinone monoethyl ether was synthesized similarly (mp 122.5—124.5 °C; IR 3370, 1240, 1080, and 1030 cm^{-1}). 4-Ethoxy-2,3,5,6-tetramethylphenyl *p*-chlorobenzoate was prepared in a manner similar to that described for **1** by the reaction of *p*-chlorobenzoyl chloride with durohydroquinone monoethyl ether. Yield, 39%; mp 152—154 °C; IR 1738, 1269, 1235, and 1090 cm^{-1}; NMR, Table 1; Found: C, 68.25; H, 6.35%. Calcd for $C_{19}H_{21}ClO_3$: C, 68.57; H, 6.36%.

The Oxidation of ***1b*** *by DDQ in Methanol.* A mixture of 0.05 mmol of **1** and DDQ in 1 ml of CH_3OH/CH_2Cl_2(50/50, v/v) was stirred at 30°C for 1 h. The initially blackish mixture gradually faded to a brownish and then a reddish-orange color. After 40 min, no further reaction was visually observed, and the reaction mixture was analyzed directly on a GLC column for **2**,**3**,**4**, and **5**. Silicone SE 30 (10% on Celite) was utilized for the former three products (with dinitrodurene as the internal standard), and Polyester FA (10% on Celite) was used for the latter (with dinitrodurene or dimethyl phthalate as the standard). The yield of **2** was dependent on the analytical GLC conditions, and when Polyester FA was utilized, instead of Silicone SE 30, the yield increased to 32—34% at the expense of a decrease in the yield of **4**. This indicates hydrolytic decomposition of **4** during the GLC analysis and, thus, the values for **2** in Table 1 may be considered to be the upper limits of **2** present in the actual reaction mixture. The reddish-orange coloration of the final reaction mixture was caused by the displacement of the chloride atom on DDQ by CH_3OH, although this constituted only a minor side reaction since the reaction was carried out under neutral to acidic conditions.

The reaction was carried out on a preparative scale with 304 mg (1 mmol) of **1b** and 227 mg (1 mmol) of DDQ in 5 ml of CH_3OH at room temperature in a nitrogen atmosphere. After 24 h, the reaction mixture was concentrated under reduced pressure and extracted with 5 ml of CCl_4. The insoluble residue was found to be an approximately equimolar mixture of $DDQH_2$ and **5b** from an inspection of the IR spectrum, which accounted for ≈88% of the DDQ and **1b** utilized. The CCl_4 soluble portion was subjected to chromatography on silica gel to give 39 mg (24%) of **2** and 144 mg (69%) of **4**. The combined yield corresponded to 93% of the starting durohydroquinone ester. No methyl benzoate **3b** was detected. The yields of **2** and **4** were again dependent on the separation conditions, but the combined yield remained constant for duplicate runs. **4**: mp 48—54°C (lit, 56 °C[16]); IR 1678, 1638, 1075, and 1030 cm^{-1}; NMR (CCl_4) δ 1.81 (6H, m, J<1 Hz), 1.86 (6H, m, J<1 Hz), 2.88 (6 H, s). The corresponding diethyl acetal was synthesized according to the known procedure.[16] Mp 88—89.5 °C (lit, 68 °C[16]); IR 1686, 1650 and 1058 cm^{-1} NMR ($CDCl_3$) δ 1.19 (6H, t, J=7.0 Hz), 1.92 (12H, s), 3.05 (4H, q, J=7.0 Hz).

Reaction Intermediates. CT Complex: Upon the addition of DDQ (450 mg, 2 mmol) to a solution of **1b** (304 mg, 1 mmol) in benzene (50 ml), a black-violet crystalline powder (220 mg, dec 107 °C) was immediately separated out. The preparation as obtained gave reasonably good analysis for a 1:2 (DDQ: **1b**) molecular complex. Found: C, 61.35; H, 4.19; N, 3.41%. Calcd for $C_{42}H_{34}N_2Cl_4O_8$: C, 60.30; H, 4.10; N, 3.35%. The complex was unstable in the presence of moisture. **6b**: A mixture of **1b** (102 mg, 0.33 mmol) and DDQ (350 mg, 1.5 mmol) in benzene (20 ml) was stirred for 10 min, and the resultant suspension of the CT complex was treated with a cold 2M NaOH solution. The organic layer which immediately turned colorless was separated from the yellow aqueous solution after further addition of 30 ml of benzene. The organic layer was repeatedly washed with 2M NaOH until the latter became colorless. After the fiinal washing with water, the benzene solution was filtered through dry filter paper and evaporated under reduced pressure. The pale yellowish residue gave **6b** as colorless crystals (92 mg) after purification by reprecipitation from CCl_4/hexane. Yield, 90%; mp 145 °C (dec); UV λ_{max} (CH_3CN) 244 nm (ε 29000); IR (Jasco DS-403G, KBr pellet) 1732, 1720, 1676, 1639, 1594, 1269, 1228, 1088, 1070, 1012, 898, and 759 cm^{-1}; NMR, Table 1; Found: C, 67.32; H, 5.30%. Calcd for $C_{34}H_{32}Cl_2O_6$: C, 67.22; H, 5.31%. **8b**: The compound was isolated according to the procedure outlined in the text. After the addition of $NaHCO_3$, the reactions mixture ($CH_3OH/CHCl_3$) was concentrated under reduced pressure, and the residue was extracted twice with 20 ml of ether. After filtration through fine filter paper, the ether solution was evaporated to dryness, and the residue was purified by reprecipitation from CCl_4/petroleum ether giving colorless crystals of **8b**. Spectral data indicated the presence of *p*-chlorobenzoic acid as a minor contaminant, the complete elimination of which was not successful under the present conditions (also see text). Yield, 84%; mp 131 °C (dec); UV λ_{max} (CH_3CN) 240 nm (ε 36000); IR (Jasco DS-403G, KBr pellet) 1743, 1673, 1636, 1594, 1265, 1229, 1085, 1046, 1010, 948, and 759 cm^{-1}; Found: C, 68.63; H, 6.44%. Calcd for $C_{28}H_{31}ClO_5$: C, 69.63; H, 6.47%. **14**: To a solution of methyl ether **11** (180 mg, 1 mmol) in benzene (20 ml) was added DDQ (650 mg, 2.4 mmol), and the mixture was stirred for 10 min at room temperature. The resultant solution was washed with 2M NaOH until the washing became colorless. Workup of the organic layer in a manner similar to that reported[16] afforded **14** in a 75% yield. White crystals; mp 100—101 °C (lit, 101 °C[16]); IR 1678, 1643, 1247, 1085, 1045, 1010, and 945 cm^{-1}; NMR ($CDCl_3$) δ 1.5—2.3 (24 H, broad), 2.75—3.15 (3H, broad), 3.4—3.8 (3H, broad).

The authors are grateful to Dr. Yoshihisa Matsuda for ESR measurement.

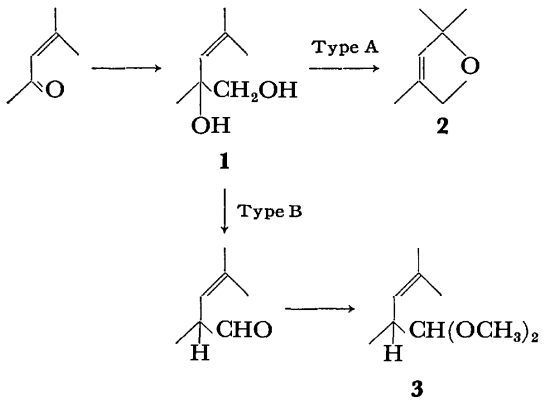
(Received February 25, 1977)

α,β-Unsaturated carbonyl compounds and esters, cyclopropyl ketones, β-diketones, Schiff's bases, and nitriles were irradiated in several alcohols in the presence of titanium(IV) chloride or uranyl chloride. In the titanium(IV) chloride-catalyzed reactions, the α-carbon atom of the primary alcohols underwent a bond formation, generally with the C=X (or C≡N) carbon atom of the substrates, while the bond formation occurred on a C=C carbon atom of the substrates in the uranyl chloride-catalyzed reactions. The reactions were examined under several conditions, and a possible scheme for the reactions was suggested.

We previously reported[2] that α,β-unsaturated ketones, when irradiated in alcohols in the presence of titanium(IV) chloride, underwent novel types of reaction with the formation of a C–C bond between the carbonyl carbon atom and the α-carbon atom of the alcohols. Pulegone and dypnone afforded dihydrofurans **2** (Type A), while mesityl oxide and 3-methyl-2-cyclohexenone afforded acetals **3** (Type B); these reactions are shown schematically in Scheme 1.



Scheme 1.

In the present study, we found that the reaction is applicable to other types of compounds and that uranyl chloride is also effective as a photocatalyst, but in a different mode from that observed with titanium(IV) chloride.

Results

Photoreactions in Methanol. α,β-Unsaturated carbonyl compounds and esters, cyclopropyl ketones, β-diketones, Schiff's bases, and nitriles were irradiated in methanol in the presence of titanium(IV) chloride or uranyl chloride. Several types of reactions were disclosed; the results are summarized in Tables 1 and 2. Evidently, in view of the observations obtained so far, the compounds containing a newly-formed C–C bond are products formed through the cooperation of light and the catalyst. The details concerning some blank experiments will be described in the Experimental part. The structure determinations of the products were done referring mostly to the spectroscopic data. Further support for the structures was also obtained from the following observations.

Photoreactions in the Presence of Titanium(IV) Chloride. α,β-Unsaturated Ketones: The irradiation of 1-acetylcyclopentene (**4**) gave glycol monomethyl ether **5**, acetal **6**, and methoxy ketone **7** (Run 1). The structure of **5** was supported by oxidizing it to an aldehyde **70**. Compound **5** corresponds to the diol **1**, which had been speculated as an intermediate for the formation of **2** or **3** (Scheme 1). Some reactions which terminated at the diol stage were also discovered in another systems (*vide infra*), and we classify these reactions as Type C. Several efforts to convert **5** into **6** were, however, unsuccessful.

Unlike the case of 3-methyl-2-cyclohexenone, which afforded an acetal *via* a Type B reaction,[2] 2-methyl-2-cyclohexenone (**8**) afforded a product in which two carbon units had been introduced (Run 2). The structure **9** was assigned to the product because it gave *o*-ethyltoluene upon treatment with hydrochloric acid through the elimination of water and methanol and a succeeding proton rearrangement. In order to eliminate the alternative structure **71**, which is also consistent with the observed spectroscopic data, we oxidized **9** with CrO_3–pyridine–HCl. Besides the main product **72** (the structure is not fully conclusive; see Experimental part), a small amount of a methoxy aldehyde **73** was isolated, which definitely supported the structure **9**. Further support for favoring **9** over **71** was obtained because the chemical shift of the *O*-methylene protons in **9** exhibited a greater down-field shift ($\Delta\delta\approx0.6$ ppm) than that of the *O*-methine proton ($\Delta\delta\approx0.1$ ppm) when derived into a phenylurethane derivative.

Reaction **8**→**9** can be shown schematically by the consecutive steps of: (1) the Type B reaction from **8** to form **74**: (2) the isomerization of **74** into an α,β-unsaturated aldehyde **75**, and (3) the Type C reaction from **75** to produce **9**. The photoreactions of α,β-unsaturated aldehydes will be described in the following section.

The absence of a methyl group in the 2-cyclohexenone system induced the reaction to proceed by way of a

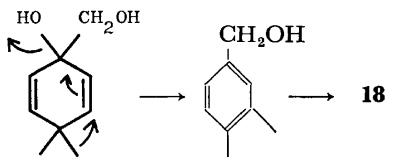
different course. The irradiation of **10** afforded a methoxy alcohol **11** as a titanium(IV) chloride-catalyzed photoproduct (Run 3). The oxidation of **11** with CrO_3–pyridine–HCl afforded an aldehyde **77**. The formation of **11** can be considered to involve the Type C reaction to produce a diol **76** followed by an S_N' reaction by the methoxyl group.

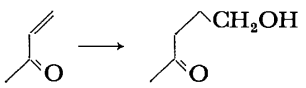
Since it is widely known that the photoreactions of cyclohexenone and cyclohexadienone systems proceed in a unique way to produce "lumi-products," we carried out the titanium(IV) chloride-catalyzed photoreactions with these substances. The products from **13** were methoxy alcohol **14**, acetal **15**, and a methoxy ketone **16** (Run 4). Evidently **14** and **15** are typical products *via* the titanium(IV) chloride-catalyzed photoreaction, and no products *via* "lumi products" were identified. The structure of **15** was confirmed by hydrolyzing it to an aldehyde **78**, and that of the alcohol **14**, by oxidizing it to an aldehyde **79**. The formation of **14** is another instance of a 2-cyclohexenone system carrying no methyl group.

The irradiation of **17** gave 3,4-dimethylbenzaldehyde (**18**) (Run 5). A possible sequence for the formation of this aromatic aldehyde is an initial hydroxymethylation (Type C), followed by aromatization, with a methyl migration and the succeeding oxidation of the benzyl alcohol to the aldehyde (Scheme 2). However, benzyl alcohol afforded benzyl methyl ether selectively without being oxidized to benzaldehyde under the same reaction conditions.



Scheme 2.

α,β-Unsaturated Aldehydes: With a view to comparing the reactivities of ketones and aldehydes, 2-butenal (crotonaldehyde, **19**) and 3,7-dimethyl-2,6-octadienal (citral, **22**) were irradiated under the same conditions. In contrast with the ketone system, **19** afforded a cyclic acetal **20** as the titanium(IV) chloride-catalyzed photoproduct (Run 6). The acetal was isolated as a mixture of *cis*- and *trans*-isomers, which could not be separated by GLC. The NMR spectrum was obtained as a sum of the two spectra, but on adding $Eu(DPM)_3$, each signal separated sufficiently well for the assignment to be made. We assumed that the methyl signal in the *cis*-isomer would exhibit a greater down-field shift when affected by the shift reagent as compared with that in the *trans*-isomer, and estimated the composition of *cis* to *trans* as 42: 58 from the intensities of the methyl signals of the two isomers.



Scheme 3.

It should be noted that the same reaction pattern was observed in the photoreaction under the catalytic action of tin(IV) chloride in place of titanium(IV) chloride. Generally, tin(IV) chloride did not reveal any catalytic activities in reaction to ketones. The formation of a by-product **21** was much less when tin(IV) chloride was used as the catalyst. The present reaction can be schematized as a 1,4-addition, in contrast with the 1,2-additions observed so far (Types A—C), and we would like to classify the reaction as Type D (Scheme 3). It was found that the 1,4-type reaction became the sole reaction pattern, even in a ketone system, when uranyl chloride was used as the catalyst (*vide infra*).

Type D is not necessarily an exclusive reaction type of unsaturated aldehydes. Citral (**22**), when allowed to react under the present reaction conditions, afforded a tetrahydrofuran **23**, along with **24** and **25** resulted from the titanium(IV) chloride-catalyzed dark reaction (Run 7). Evidently the reaction proceeded through the 1,2-type (Type C) to give **80**, followed by a cyclization involving a remote double bond.

α,β-Unsaturated Esters: It was found that the reaction of dimethyl maleate (**26**) was of the 1,4-type and afforded a hydroxymethyl derivative **27** and a lactone **28** (Run 8). Although the sensitized photoadditions of alcohols to α,β-unsaturated esters have been known to produce γ-butyrolactones,[3] the present reaction is considered to proceed through a different mechanism (see Discussion part). The hydroxymethyl derivative cyclized to the corresponding lactone upon heating at 150 °C and it can be assumed to be an intermediate to lactone. The same reaction occurred in the uranyl chloride-catalyzed photoreaction (*vide infra*).

Cyclopropyl Ketones: We observed that saturated alicyclic ketones (cyclohexanone and cycloheptanone) were intact under the present reaction conditions, and we were tempted to see if the cyclopropyl group would activate the carbonyl group to be involved in the present reaction. It was found that the two cyclopropyl ketones **29** and **32** mainly underwent Type B and Type C reactions to produce **30** (Run 9) and **33** (Run 10) respectively. The structure **30** was confirmed by comparing it with the sample prepared from the authentic aldehyde **31**. The structure of **33** was supported because the *O*-methylene protons exhibited an extensive down-field shift ($\Delta\delta\approx 0.6$ ppm) when the alcohol was derived into a phenylurethane derivative (*cf.* Run 2). Upon oxidation with CrO_3–pyridine–HCl, **33** gave an aldehyde **81**. When the work-up was performed after the irradiated solution had been refluxed, the acetal **34** became the sole product. This observation verifies the intermediacy of the diol **1** in the Type B reaction.

β-Diketones: 5,5-Dimethyl-1,3-cyclohexanedione (dimedone, **35**) afforded an acetal **36** and an enol ether **37**, upon the titanium(IV) chloride-catalyzed photoreaction (Run 11). Since the enol ether **37**, which is the exclusive product in the dark reaction of the present system, produced **36** under the same irradiation conditions, the reaction from **35** can be schemed as involving a primary dark step to produce **37**, followed by a Type B reaction to produce **36**. The acetal **36** gave an aldehyde **82** upon hydrolysis with hydrochloric acid.

Although 2-acetylcyclohexanone, under the present reaction conditions, afforded a complicated mixture of products, 2-acetylcyclopentanone (**38**) underwent a clear reaction (Run 12). The extraction of the reaction mixture and the evaporation of the solvent from the extract left an almost pure oil. The structure **39** is tentatively assigned as the product, although we could not eliminate the alternative structures such as **83** and **84**.

Unlike the cases of cyclic β-diketones mentioned above, open-chain β-diketones gave different types of products. Acetylacetone (**40**) afforded butenolide **41**, γ-keto ester **42**, and cyclic peroxide **43** (Run 13). The spectroscopic data of the butenolide **41** coincided with the reported data.[4] The structure of **42** was confirmed by comparing it with the authentic sample prepared from nitroethane and methyl methacrylate.[5] Evidently the oxidation state of the newly-introduced function is higher than those observed so far; we speculate a Cannizzaro-type oxidation of the intermediate aldehyde with the co-operation of the suitably located hydroxyl group and titanium to give the butenolide (*cf.* **86**), which partly undergoes methanolysis to afford a γ-keto ester **42**.

The formation of the cyclic peroxide **43** is without precedent, but it was found that its formation is not characteristic of the titanium(IV) chloride-catalyzed photoreaction. The peroxide was also obtained as the sole product by the hydrochloric acid-catalyzed photoreaction of **40**, although the rate in this case was much slower than the titanium(IV) chloride-catalyzed photoreaction.

The cyclic peroxide **43** was distillable under reduced pressure, but it decomposed cleanly into methyl acetate and methyl propionate at 150 °C (*cf.* **87**). When it was ignited, however, it was detonated violently. Its formation may be shown schematically as a proton-assisted addition of methanol to produce **88**, which was photooxidized to the product, titanium or oxygen in the air presumably serving as the oxidizing agent.

The reaction of 2,2,6,6-tetramethyl-3,5-heptanedione (dipivaloylmethane, **44**) was much more selective: the extraction of the irradiated solution with chloroform and the evaporation of the extract left a butenolide **45** as almost pure crystals in 65% yield (Run 14). The physical data of **45** and those of a reduction product **89** coincided with the reported values.[4]

In the same way, diketone **46** afforded a butenolide **47** under the same conditions (Run 15).

Schiff's Bases: In contrast with the diversity of the photoreactions reported with carbonyl compounds, only a few photoreactions of Schiff's bases have been known. However, it was found in the present study that the reactions of Schiff's bases also proceeded in a reaction pattern similar to that of carbonyl compounds when irradiated in the presence of titanium(IV) chloride.

The photoreaction of **48** afforded an oil which consisted of **49** as the main fraction, contaminated with a minor amount of **50**, as revealed by the NMR analysis (Run 16). No appreciable intensities of signals assignable to the other compounds were observed. Although **49** was stable in the presence of titanium(IV) chloride, it decomposed (probably polymerized) completely after 24 h at room temperature when isolated free from titanium(IV) chloride. From this mixture, a pure sample of **50** was isolated by column chromatography. The structure of **49** was confirmed by deriving it to the bis(*p*-nitrobenzoyl) derivative and the picrate. The formation of **49** is reasonable in view of the Type C reaction observed with carbonyl compounds. The oxazolidine **50** must be a secondary product from **49** and formaldehyde, which had been photolytically produced from methanol and titanium(IV) chloride. Actually, **49** was quantitatively transformed into **50** upon treat-

ment with formalin.

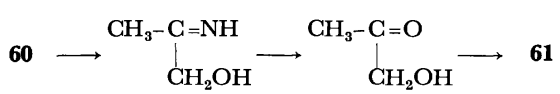
An example of the formation of oxazolidine upon the irradiation of Schiff's base in methanol has been reported by Cerutti and Schmid.[6] In the present case, however, it was confirmed that **49** and **50** were obtained only with the cooperation of light and titanium(IV) chloride. The same authors[7] reported the formation of imidazolidines **90** (*dl* and *meso*) from **48** through photoreductive dimerization, followed by the condensation of formaldehyde. These products were not identified under the present reaction conditions. The formation of the imidazolidines became the main reaction path upon irradiation in the presence of titanium(IV) chloride and sodium methoxide, which will be described in the next section.

A selective photoreaction was also observed in the case of **51** (Run 17). The extraction of the reaction mixture with chloroform and the evaporation of the extract left crystals of **52** in an almost pure state in a high yield. The treatment of **52** with formalin again afforded an oxazolidine **53**. Similarly, **54** afforded **55** and **56** under the same conditions (Run 18).

The photoreaction of ketimine also proceeded in the same way (Run 19). The NMR analysis of the crude reaction mixture from **57** revealed that the products are mainly **58**, accompanied by a small amount of **59**. The treatment of the crude mixture with formalin afforded **59**.

Nitriles: It has been established that the photochemical reaction of aromatic and aliphatic nitriles proceeds mostly on the carbon-carbon double bond (even in an aromatic system), to the exclusion of any products from the reaction at the cyano group. To the best of our knowledge, exceptions have been reported only by Cantrell[8] and recently by Yang,[9] who observed a 2+2 cycloaddition at the nitrile function upon the irradiation of aromatic nitriles with certain electron-rich olefins.

We have now observed that the cyano group was also induced to be involved in the photoreaction in the presence of titanium(IV) chloride. The irradiation of acetonitrile (**60**) gave a mixture of two stereoisomers (3:1) of **61** as the exclusive non-volatile product. Recrystallization furnished the major component as a pure sample which was identical with the crystals separated out from a 50% methanol solution of hydroxyacetone, but the stereochemistry was not elucidated. The reaction can be shown schematically as similar to a Type C reaction, followed by hydrolysis and dimerization (Scheme 4).



Scheme 4.

In contrast with the simple reaction observed with acetonitrile, the photoreaction of aromatic nitriles gave products exceeding expectations. The major product from benzonitrile (**62**) was a *C*- and *N*-methylated oxazolidine **59** (Run 21), which was identical with the product obtained from *N*-(α-methylbenzylidene)methylamine in Run 19. Similar reactions were observed with *p*- and *o*-tolunitrile, although no *N*-methylation was observed with the tolunitrile system (Runs 22 and 23). The by-product **63** was identified by comparison with an authentic sample. The by-product **64** was identical with the sample obtained in a small amount by the irradiation of acetophenone in methanol in the presence of titanium(IV) chloride.

No reasonable scheme for the *C*- and *N*-methylation can be proposed. For the titanium(IV) chloride-catalyzed photoreactions of ketones, we previously proposed a mechanism involving primary electron transfer from methanol to the carbonyl compound, followed by the proton transfer and cross-coupling of the resulting radicals.[2] In compliance with this scheme, we postulated in our previous communication[1b] a mechanism involving phenylazirine as a possible intermediate for the reaction. The scheme seemed to be attractive, but it has now been found to be unfavorable since phenylazirine did not afford the oxazolidine **59** under the present reaction conditions. Although the structure of the actual product, which was obtained as crystals, has not been determined, the NMR analysis indicated that neither *C*-methylation nor *N*-methylation took place on phenylazirine.

Photoreactions in the Presence of Uranyl Chloride. In contrast with the 1,2-type reactions (Types A—C) observed with most of the α,β-unsaturated carbonyl compounds (except in the cases of Runs 6 and 8), the photoreactions in the presence of uranyl chloride were of the 1,4-type (Type D, Scheme 3). The results are summarized in Table 2.

The primary products from **91** seem to be a mixture of stereoisomers of **108**, as revealed by NMR analysis, but these compounds decomposed cleanly into **92** upon vacuum distillation (Run 24).

The reaction of 2-butenal (**19**) proceeded in the same way (including stereochemistry) as the titanium(IV) chloride- and tin(IV) chloride-catalyzed reactions (Run 25, *cf.* Run 6). Similarly, mesityl oxide (**93**) furnished **94** as the main product, accompanied by a trace amount of **95** (Run 26). Small amount of **95** was also identified in the reactions in other alcohols (ethanol, 1- and 2-propanol, and water–2-methyl-2-propanol (1:1), *vide infra*); it is speculated that this product arose through the addition of the acetyl radical, which had been formed from **93** in a certain stage of the reaction, to another molecule of **93**. The addition of the acetyl radical to **93** to produce **95** has been reported.[10] The hydrolysis of **94** with hydrochloric acid gave a product which could be identified by NMR analysis as a tautomeric mixture of **109a** and **110a** (1:1).[11] The mixture, upon oxidation with CrO_3–pyridine–HCl, afforded a keto aldehyde **111** as the sole product.

The reaction of **96** produced **97** as the main product, accompanied by a small amount of a methanol adduct **99** (Run 27). A vacuum distillation of the mixture induced the elimination of methanol from **99**; the distillate consisted of **97** and the starting ketone **96**. The yields of products in the uranyl chloride-catalyzed reactions are sensitive to the reaction conditions (light intensities, duration of irradiation, quality of the catalyst, and pH of the solution; *vide infra*), and the

ring-opened product **98** was identified, along with the major product **97**, on some reactions of **96**.

The enone **13** also gave a ring-opened alcohol **101**, as well as a cyclic acetal **100** (Run 28). The reaction path through the "lumi-products" was not observed in the present case either (*cf.* Run 4). The primary alcohols **98** and **101** were oxidized to the aldehydes **112** and **113** respectively.

The same type of reaction as observed with titanium(IV) chloride-catalyzed reaction proceeded with the esters **26**, **102**, and **105** (Runs 29—31). The yields in Run 31 are low because of the extensive polymerization of the starting material. The oxidation of the γ-hydroxy ester **106** with CrO_3–pyridine–HCl gave an aldehydic ester **114**. As has been observed in Run 8, **103** and **106** cyclized to lactones **104** and **107** respectively upon heating. It should be noted that, while shorter-wavelength light (quartz-filtered light) was necessary to induce the reaction in the titanium(IV) chloride-catalyzed reaction, Pyrex-filtered light induced the reaction well with catalytic assistance by uranyl chloride.

Table 3. Concentration effect of $TiCl_4$ upon the product yields in the reaction of **96**

$TiCl_4$ Mol equiv to **96**	**96** (Recovd) (%)	**115** (%)	**116a** (%)	**117a** (%)	**99** (%)
0.1	12	30	trace	trace	25

Solutions of **96** (0.1 g, 0.91 mmol) and varying amounts of $TiCl_4$ in methanol (10 ml) were irradiated with Pyrex-filtered light for 7 h. The yields were determined by NMR analysis, using nitrobenzene as the internal reference.

Effects of the Reaction Conditions. Titanium(IV) Chloride-catalyzed Reactions: The effect of the catalyst concentration on the product yields was examined using 3-methyl-2-cyclohexenone (**96**) as the substrate. The yields of the products, as determined by NMR analysis, are summarized in Table 3. Although the maximum yield of the Type B products (**115**, **116a**, and **117a**) was obtained when about an equimolar amount of titanium(IV) chloride was used, it is evident that titanium(IV) chloride functions catalytically rather than stoichiometrically, because the amounts of the products exceed the amount of the catalyst at low concentrations of titanium(IV) chloride. Excess amounts of the catalyst complicated the reaction and afforded large amounts of by-products. At low concentration of titanium(IV) chloride, the polar addition of methanol to give **99** became efficient. Presumably the addition of methanol is catalyzed by the proton formed by the reaction of titanium(IV) chloride with methanol. It was confirmed that the proton-catalyzed photoaddition of methanol to **96** was remarkable at low concentrations of hydrochloric acid. Probably at higher proton concentrations, the thermal reverse reaction (elimination of methanol from **99**) would become efficient.

The reaction medium in the present reaction was acidic as a result of the formation of hydrochloric acid from titanium(IV) chloride and methanol. Since we observed, in our preliminary experiments,[2] that the acidic conditions are necessary to induce the present photoreaction, we carried out the titanium(IV) chloride-catalyzed photoreaction of **96** and **48** while adding varying amounts of sodium methoxide. Evidently the Type B reaction (**96**→**115**+**116a**+**117a**, Table 4) was

Table 4. Concentration effect of $NaOCH_3$ upon the product yields in the reaction of **96**

Solutions of **96** (0.1 g, 0.91 mmol), $TiCl_4$ (0.17 g, 0.91 mmol), and varying amounts of $NaOCH_3$ in methanol (10 ml) were irradiated and treated in the way described in the footnote in Table 3.

retarded remarkably when the amount of sodium methoxide exceeded two mole equivalents of that of titanium(IV) chloride. The effect of the sodium methoxide concentration was also observed in the case of the photoreaction **48**→**49**+**50** (Run 16), as is shown in Table 5. Notably, there was a change in the reaction pattern, and imidazolidines **90** (*dl* and *meso*) became the products at higher concentrations of sodium methoxide. Cerutti and Schmid reported the formation of **90** by the irradiation of **48** in methanol with a low-pressure mercury lamp under argon.[7] Although we could not duplicate their results, the spectroscopic data on our

Table 5. Concentration effect of $NaOCH_3$ upon the product yield in the reaction of **48**

3.0	50	0	0
4.0	19	7	6
5.0	5	15	13

Solutions of **48** (0.3 g, 2.5 mmol), $TiCl_4$ (0.17 g, 0.91 mmol), and varying amounts of $NaOCH_3$ in methanol (10 ml) were irradiated with quartz-filtered light for 3 h. An appropriate amount of 37% formalin was then added to the photolysate and the solution was worked-up in the way described in Run 16. The yields were determined by NMR analysis, using 1,1,2,2-tetrachloroethane as internal reference.

imidazolidines coincided with those previously reported.[12] *meso*-Imidazolidine **90** was prepared by the condensation of formaldehyde with an authentic ethylenediamine derivative **118** of mp 137 °C.[13] *dl*-Imidazolidine was also prepared from another isomer of **118**, which remained as an oil after the separation of the crystaline form of **118**.

We found that the imidazolidines were the sole products in the titanocene dichloride-catalyzed photoreaction of **48** in methanol. A decrease in the proton concentration or a change in the nature of the catalyst might be responsible for the effect of sodium methoxide, but no experimental evidence has been obtained.

Uranyl Ion-catalyzed Reactions: The uranyl chloride-catalyzed reaction is very sensitive to the pH of the solution. It was found from the experiment with **96** that the C–C bond-formation reaction proceeded most efficiently at pH 2—3. At pH 7, most of the starting material was recovered, while at pH 1, methanol addition to give **99** became the main reaction pattern.

The effect of the catalyst concentration on the product yields was examined using dimethyl maleate (**26**) as the substrate. In contrast with the case of the titanium(IV) chloride catalyst, the product yield (**27**+**28**) reached its maximum at a catalyst concentration of a one-tenth mole equivalent to that of the substrate, and thereafter held constant with increasing amounts of the catalyst. With increasing amounts of the catalyst, however, the cyclization to lactone (probably through the secondary thermal reaction) became appreciable.

Table 6. Effects of the counter ions in UO_2X_2 upon the product yields in the reaction (**26**→**27**+**28**)

Counter ions (X)	**26** (Recovd) (%)	**27**+**28** (%)
Cl	0	59
NO_3	52	24
OAc	79	8
SO_4	62	6

Solutions of **26** (0.15 g, 1.3 mmol) and uranyl compounds (0.13 mmol) in methanol (12 ml) was irradiated with Pyrex-filtered light for 6 h. The yields were determined by NMR analyses, using benzene as the internal reference. The yields of **28** did not exceed 3% of those of **27**.

It was found that the nature of the counter ions exerts a remarkable influence on the reaction of **26**, as is shown in Table 6. However, the trend should not be considered to be general, because uranyl sulfate was found to be as effective as uranyl chloride in the case of the reaction of mesityl oxide, although the acetate was poor in catalytic activity in both cases.

Reactions in the Other Solvents. Titanium(IV) Chloride-catalyzed Reaction of 3-Methyl-2-cyclohexenone (69): We have previously reported that the reaction of **96** in ethanol proceeded in the same way as in methanol to produce two methyl ketones **116b** (49%) and **117b** (12%).[2] The same type of reaction also occurred in other primary alcohols; the products were **116c** (34%) and **117c** (9%) in 1-propanol; **116d** (30%) and **117d** (8%) in 1-butanol; and **116e** (39%) in 2-methyl-1-propanol. Contrary to the primary alcohols, 2-propanol was found to be unreactive, the major part of the starting material being recovered unreacted, accompanied by a small amount of *m*-cymene (**119**), which is a product of a Type C reaction followed by dehydration and proton rearrangement. The reduced reactivity of 2-propanol was also indicated by the reaction of **96** in a mixed solvent of 2-propanol and methanol (1 : 1 by volume), which afforded a methanol-participated product **115** as the sole product. Most of the starting material was recovered by photoreactions in 2-butanol and 2-methyl-2-propanol.

Uranyl Chloride-catalyzed Reaction of Mesityl Oxide (93): The photoreaction of **93** in ethanol in the presence of uranyl chloride proceeded according to the same pattern as that in methanol and afforded a product which was identified by NMR analysis as a mixture of **109b** and **110b**. The subsequent oxidation of the product mixture by CrO_3–pyridine–HCl afforded **95** as the main product (13% from **93**), along with a small amount of a lactone **120**. The lactone must be a product of the oxidative demethylation from **110b**. In parallel with the observation described above, 2-propanol was also lacking the reactivity, and the products in this solvent were a diketone **95** and a cyclobutanol **121**. The diketone **95** became the major product by Pyrex-filtered light, while the ratio was reversed by quartz-filtered light. Both compounds were also the main products in a hydrochloric acid-catalyzed photoreaction in 2-propanol and in a titanium(IV) chloride-catalyzed photoreaction in water–2-methyl-2-propanol (1 : 1 by volume). The cyclobutanol **121** is known to be a photoproduct from 4-methylpent-4-en-2-one (isomesityl oxide),[14] and it can be presumed that the weak acidic conditions (pH 3) of the present reaction might catalyze the thermal isomerization of **93** into isomesityl oxide, from which the cyclobutanol is derived.

Uranyl Chloride-catalyzed Reactions of α,β-Unsaturated Esters: The reaction of dimethyl maleate (**26**) in ethanol proceeded in the same way as in methanol and furnished a mixture of *threo*-**122a**[15] (23%), *erythro*-**122a** (14%), *cis*-**123a** (13%), and *trans*-**123a** (6%), as revealed by NMR analysis. Heating induced cyclization, and a mixture of *cis*- and *trans*-**123a** was obtained. The assignments of the stereochemistry of the lactones were performed by referring to the reported data.[3b] The stereochemistry of the hydroxy esters **122a** was speculated from the relative amounts prior to and after the thermal cyclization to the lactones (*cf.* Experimental part).

In contrast with the reactions described above, 2-propanol was brought into the reaction with **26** with the catalytic assistance by uranyl chloride; we thus obtained **122b**, which was then further cyclized to a lactone **123b**.

Discussion

All the reactions described thus far can be shown schematically as involving a primary step of the formal addition of the hydroxymethyl radical to C=O, C=N,

and C≡N groups (1,2-type, in the titanium(IV) chloride-catalyzed reactions) or to an unsaturated carbon atom (1,4-type, in the uranyl chloride-catalyzed reactions). The photochemical 1,4-additions of alcohols[16] or ethers[17] to α,β-unsaturated carbonyl compounds by means of aromatic-ketone sensitization have been reported with various systems, and have been shown schematically involving radical species. It seemed conceivable that the present reaction might proceed through a radical initiation, particularly when uranyl chloride was used as the catalyst, since such a catalyst might produce chlorine radicals upon irradiation. This hypothesis was examined and rejected on the basis of the following observations.

No traces of products characteristic of the present metal-catalyzed photoreactions were identified from mesityl oxide upon (1) refluxing in methanol for 50 h while benzoyl peroxide was being added, (2) irradiating in methanol in the presence of benzophenone, or (3) the bubbling of chlorine into the methanol solution under irradiation with a tungsten lamp. The reaction with chlorine gave **124** and one more compound whose structure has not been elucidated. The fact that uranyl sulfate is as effective as uranyl chloride would also eliminate the possible intervention of the chlorine radicals.

Table 7. Solvent effects upon the product yields in the reaction (**125**→**126**+**127**)

Alcohols	UO_2Cl_2-catalyzed 1 h		UO_2Cl_2-catalyzed 6 h		Benzophenone-sensitized 6 h	
	126 (%)	**127** (%)	**126** (%)	**127** (%)	**126** (%)	**127** (%)
Methanol	45	0	65	0	0.6	0
Ethanol	19	0	39	0	0.6	0
2-Propanol	0	7	5	24	1.0	1.3

A solution of **125** (0.15 g, 1.5 mmol) and UO_2Cl_2 (0.044 g, 0.13 mmol) or benzophenone (0.029 g, 0.16 mmol) in alcohol (12 ml) was irradiated with Pyrex-filtered light.

Although the benzophenone-sensitized additions of alcohols to ethyl 2-butenoate (**125**) have been reported to be effected under irradiation for 50—72 h,[3a] no appreciable photoaddition was observed during the present irradiation time (1—6 h, see Table 7). The same authors investigated the photochemical addition of hydroxyalkyl groups to **125** with various alcohol systems, and found that the reactivities increased in the order of: methanol<ethanol<2-propanol, an order which is consistent with the proposed radical-chain mechanism. The same reactions with the catalytic assistance by uranyl chloride were now examined, and it was found that the order of the reactivities of these alcohols is completely reversed (Table 7). The decrease in the reactivities of the secondary alcohols, as observed in the cases described here and in the previous section, could be another evidence against the intervention of the free-radical species.

The uranyl ion-catalyzed photoisomerization of stilbene[18] and the photodimerization of dienone[19] have been reported. Energy transfer and a restricted orientation of dienone by coordination, respectively, have been presented as the mechanisms.

a) Runs 1—23. b) Runs 24—31. c) P: Pyrex, Q: quartz. d) $SnCl_4$.

The photoreaction of mesityl oxide in tetrahydrofuran in the presence of uranyl chloride resulted in the formation of a C–C bond, giving **128** as the main product (17%). The same product was obtained by the benzophenone-sensitized photoreaction, while the direct irradiation (without any additives) under the same conditions resulted in a recovery of the starting material, with a negligible formation of **128**. Evidently uranyl chloride functions as a sensitizer in the reaction in tetrahydrofuran, and the reaction proceeds through an intermediacy of the radical species, in marked contrast with the photoreactions in alcohols.

Some of the titanium(IV) chloride-catalyzed photoreactions were wave-length-dependent. Pyrex-filtered light could not induce the present reaction in the cases of 2-acetylcyclopentanone (**38**), dimethyl maleate (**26**), and acetonitrile (**60**). The acetylcyclopentanone **38** afforded **129**, while **26** and **60** were recovered intact under these conditions.

In considering possible mechanisms for the metal-

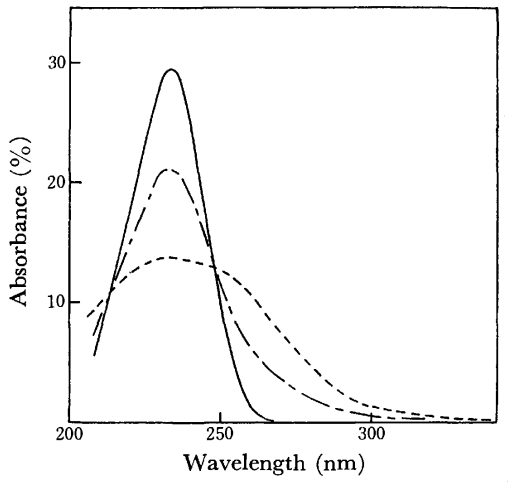

Fig. 1. Absorption spectra of **96** (——, 1.97×10^{-5} M, $\varepsilon=14900$), $TiCl_4$ (– – –, 1.96×10^{-5} M, $\varepsilon=6580$), and a mixture of an equal volume of both solutions (– – – –).

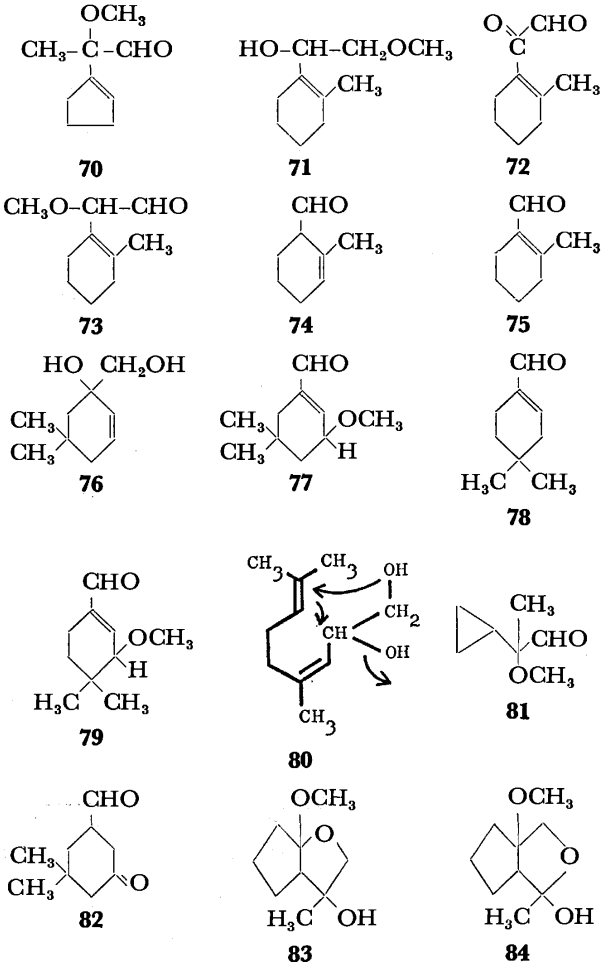
catalyzed photoreactions, it seems important to investigate the absorption characteristics. At low concentrations ($\approx2\times10^{-5}$ M), the mixing of 3-methyl-2-cyclohexenone (**96**) and titanium(IV) chloride did not result in any changes in the absorption curves in the 220—320 nm region; only a sum of the two absorption curves was obtained (Fig. 1). The same phenomena were observed with the uranyl chloride–dimethyl maleate (**26**) and uranyl chloride–mesityl oxide (**93**) systems. It was revealed from the experiments with more concentrated solutions (concentrations corresponding to the actual reactions, 10^{-2}—10^{-1} M), however, that a new absorption band appeared in the 350—480 nm region upon the mixing of the substrate and the metal compound in the **96**–$TiCl_4$, **93**–$TiCl_4$, and **93**–UO_2Cl_2 systems, while no development of the new band was observable in the **26**–UO_2Cl_2, **26**–$TiCl_4$, and **60**–$TiCl_4$ systems. The absorption coefficients (ε) calculated by assuming the formation of a 1 : 1 complex between the substrate and the metal compound were 5—7. We have not identified the character of this new band, and it remains unknown whether or not the light absorption corresponding to this band plays an indispensable role in inducing the present photoreactions. The action spectrum would be informative in this connection, but we have not carried out such an experiment.

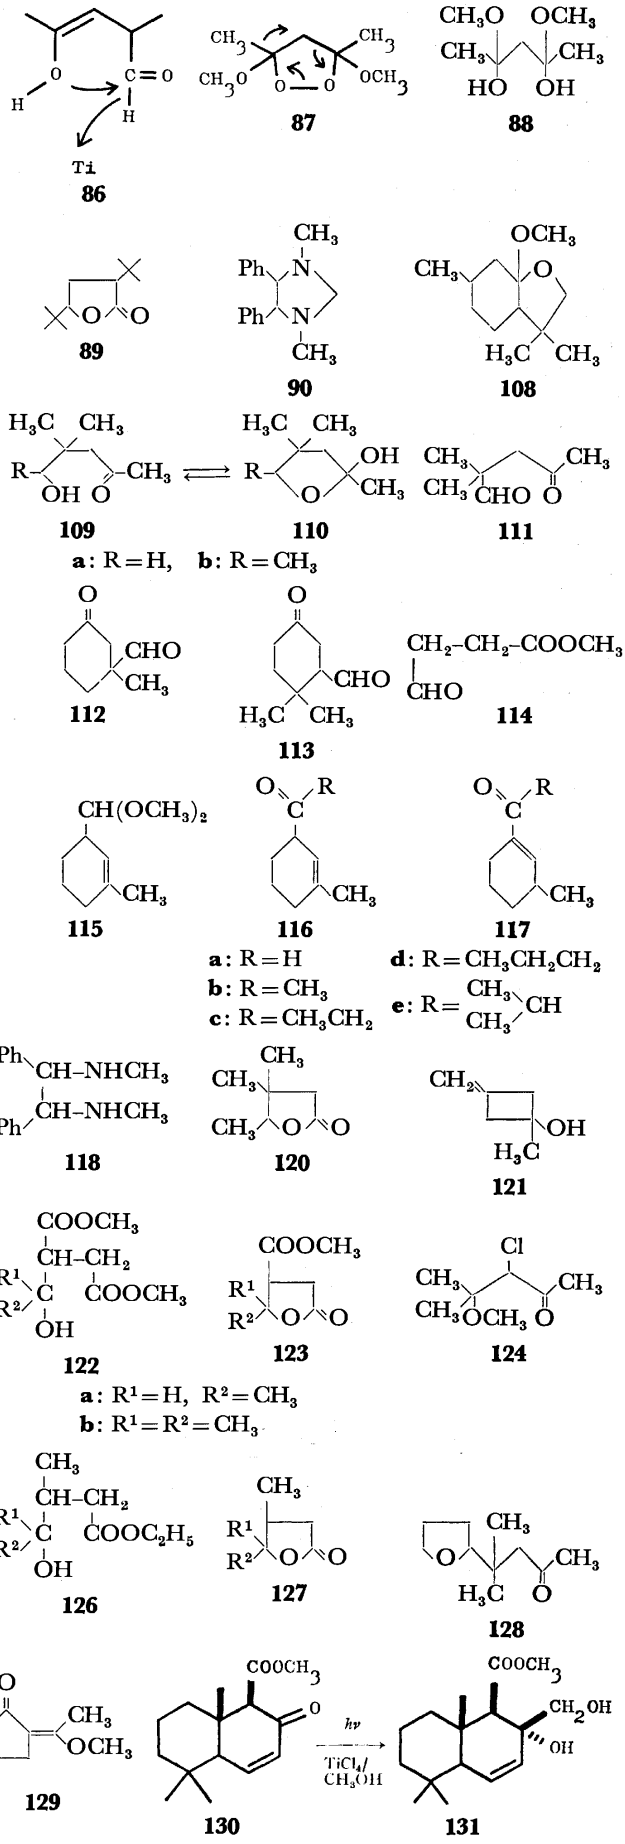
The intensity of the new band in the **96**–$TiCl_4$ system increased as a function of the time when kept in the dark. Actually, the color of the solution changed from light yellow (immediately after the mixing) to dark yellow, and became dark green after 24 h when kept in the dark. Despite the remarkable color change though, a work-up resulted in the recovery of only the starting ketone. No such color change in the dark was evident in other systems. Even in cases where no coloration was remarkable upon standing in the dark, most of the reactions are accompanied by a color change to some degree during irradiation. Obviously, it seems difficult to characterize the primary light-absorbing species.

The observations described so far provide convincing evidence that both the substrate and the catalyst are involved in the excited species, although a glance at Fig. 1 might lead one to conclude erroneously that the present photoreaction, particularly with Pyrex-filtered light, is induced by the excitation of the catalyst alone.

All these facts favor our previous proposal of a scheme comprising an initial electron transfer, followed by a proton transfer and succeeding cross coupling.[2] All these processes are considered to proceed consecutively within the coordination sphere of metal compounds, thus providing circumstances favorable for the cross coupling. We have no clear-cut interpretation of the different catalytic behavior between titanium(IV) chloride and uranyl chloride. The different mode of coordination could be responsible, but we have no experimental evidence for this argument at the present stage of our investigation.

Addendum. In their synthetic studies of sesquiterpenes, Isoe and his co-workers recently prepared **131** from **130** by means of the titanium(IV) chloride-catalyzed photoreaction, and established the configuration of the introduced hydroxymethyl group in **131** as exclusively *cis* to the methoxycarbonyl group.[56] Although further work should be done for the full interpretation of the stereoselectivity, an explanation of the selectivity can be obtained in terms of our present proposal that the whole reaction proceeds within the coordination sphere of titanium, which, in this case, might coordinate to oxygen atoms of both the ester and carbonyl groups in **130**.





Experimental

General Procedures. The instrumentation was the same as has been described previously.[20] All the irradiations were carried out under the conditions summarized in Table 8, with a high-pressure mercury vapor lamp (Ushio UM 452 (450W)) at the temperature of running water. After the irradiation, the solution was poured into water and shaken with chloroform or dichloromethane. The extract was dried (Na_2SO_4), and the solvent was removed *in vacuo*. The residual substance was treated as indicated in each entry.

Unless otherwise stated, all the spectroscopic data were determined on a sample collected on a preparative GLC, a carbon tetrachloride solution being used for the NMR and IR spectra determinations.

As for the blank experiments in the presence of hydrochloric acid, a solution in methanol and concd hydrochloric acid (10: 1 by volume) was used.

The yields shown in Tables 1 and 2 were determined on a crude reaction mixture by means of NMR and/or GLC analyses, using appropriate internal references. The isolated yields, when determined, are described in each entry.

Materials. *a) Uranyl Chloride*: Prepared (1) according to the previously reported method[21] or (2) by dissolving thoroughly washed $UO_2(OH)_2$, which had been precipitated from $UO_2(NO_3)_2$ by sodium hydroxide, in hydrochloric acid, evaporating the water, and drying the residue on solid sodium hydroxide under reduced pressure. *b)* **4**: Prepared from cyclopentene and acetyl chloride, using tin(IV) chloride as a condensing reagent, according to the reported procedure[22] with the following modifications. Dichloromethane was used as the solvent at the temperature of Dry Ice, and triethylamine in benzene was used in place of *N,N*-dimethylaniline. Bp 67—69 °C (19 mmHg). *c)* **8**: Prepared from 2-methylcyclohexanone according to the reported procedure,[23] using NBS and pyridine as the brominating and dehydrobrominating reagents respectively. Bp 72—73 °C (22 mmHg). *d)* **10**: Prepared from dimedone (**35**) according to the procedure reported for the preparation of cyclohexenone.[24] Bp 76°C (19 mmHg). *e)* **13**: Ref. 25. Bp 34—38°C (3 mmHg). *f)* **17**: Ref. 26. Bp 44 °C (4 mmHg). *g)* **22**: Commercial sample (*cis* 63% and *trans* 35%). *h)* **29**: Ref. 27. Bp 71—75 °C (20—22 mmHg). *i)* **32**: Ref. 28. Bp 106—110 °C. *j)* **38**: Prepared from 4-(1-cyclopentenyl)morpholine and acetic anhydride according to the procedure reported for the preparation of a six-membered ring homologue.[29] Bp 104—106 °C (12 mmHg). *k)* **44**: Ref. 30. Bp 86 °C (22 mmHg). *l)* **46**: Ref. 31. Bp 85—87 °C (45—50 mmHg). *m)* **48**: Ref. 32. Bp 67 °C (15 mmHg). *n)* **51**: Ref. 33. Bp 97—98 °C (3 mmHg). *o)* **54**: Prepared by stirring an aqueous solution (17.5 ml) of hexanal (5 g) and cyclohexylamine (7.5 g) at room temperature for 2 h. Bp 126—142 °C (30 mmHg). (Lit,[34] bp 115 °C (16 mmHg)). IR, 2960, 2925, 2855, 1665, 1550, 1470, 1450, and 1380 cm^{-1}. NMR, δ 0.6—3.1 (m, 22H) and 7.58 (t, J=8 Hz, 1H). *p)* **57**: Prepared according to the previously reported procedure[35] with the following modifications: methylamine (prepared from 30 g of the hydrochloride) was bubbled into a mixture of acetophenone (10 g) and Molecular Sieve 4A (4 g) in methanol (20 ml) at 60—70 °C. The solution was then decanted from the catalyst and fractionated. *q)* **96**: Ref. 36. Bp 65—66 °C (5 mmHg).

The other materials were commercially available and were subjected to the reaction without further purification.

Run 1. The chromatography of the crude oil on a silica gel column and subsequent purification on a preparative GLC afforded **5**, **6**, and **7** as products, although **6** was not

obtained in a highly pure state.

5: MS, *m/e* 125 (M−OMe, base peak), 95, 93, and 67. IR, 3440, 2950, 1370, and 1070 cm^{-1}. NMR, δ 1.30 (s, 3H), 1.6—2.1 (m), 2.1—2.5 (m), 3.10 (s, 3H), 3.28 and 3.52 (ABq, J=10 Hz, 2H), and 5.64 (bs, 1H).

6 (in an impure state): IR, no characteristic bands. NMR, δ 0.95 (d, J=8 Hz, 3H), 1.5—2.5 (m), 3.21 (s, 3H), 3.24 (s, 3H), 4.10 (d, J=8 Hz, 1H), and 5.35 (bs, 1H).

7: (Lit,[37] bp 131—132 °C (140 mmHg)). IR, 2960, 1720, 1360, and 1100 cm^{-1}. NMR, δ 1.4—2.0 (m), 2.15 (s, 3H), 2.83 (bs, 1H), 3.29 (s, 3H), and 3.82 (bs, 1H).

Irradiation in the absence of titanium (IV) chloride afforded a complicated mixture of products irrespective of the presence or absence of hydrochloric acid.

Oxidation of ***5***. A mixture of CrO_3–pyridine–HCl[38] (0.1 g) and **5** (0.066 g), which had been isolated by preparative TLC (silica gel), in dichloromethane (2 ml) was stirred for 1 h at room temperature. The decanted solution was then passed through a short column of Florisil, and the eluant was evaporated. The crude oil was purified by preparative GLC to give a pure sample of an aldehyde **70**. IR, 2960, 1750, and 1120 cm^{-1}. NMR, δ 1.31 (s, 3H), 1.5—2.5 (m), 3.23 (s, 3H), 5.75 (bs, 1H), and 9.38 (s, 1H).

Run 2. A crude oil (0.37 g) was obtained which was chromatographed on an alumina column to give a fraction (0.22 g) of **9**. MS, *m/e* 170 (M), 140, 139 (base peak), 107, 91, and 79. IR, 3420, 2920, and 1100 cm^{-1}. NMR, δ 1.6—2.3 (m), 1.70 (s, 3H), 3.20 (s, 3H), 3.28 (d of d, J=11 and 4 Hz, 1H), 3.49 (d of d, J=11 and 8 Hz, 1H), and 4.10 (d of d, J=8 and 4 Hz, 1H).

Irradiation in either the presence or absence of hydrochloric acid resulted in the recovery of the starting material.

Phenylurethane Derivative of ***9***. A mixture of **9** (0.19 g) and phenyl isocyanate (0.13 g) was heated at 60 °C for 5 min. Chromatography on a silica gel column (benzene–chloroform) gave crystals which were subsequently recrystallized from methanol–water. Mp 85 °C. IR, 2920, 1747, 1601, 1520, 1442, and 1205 cm^{-1}. NMR, δ 1.5—2.0 (m), 1.64 (s, 3H), 3.06 (s, 3H), 3.90 (d, J=8 Hz, 1H), 3.92 (d, J=4 Hz, 1H), and 4.18 (d of d, J=8 and 4 Hz, 1H).

Found: C, 70.53; H, 8.00; N, 4.69%. Calcd for $C_{17}H_{23}NO_3$: C, 70.56; H, 8.01; N, 4.84%.

Treatment of ***9*** *with Hydrochloric Acid.* A mixture of **9** (0.1 g), 3M-hydrochloric acid (15 ml), and ethanol (15 ml) was refluxed for 1.5 h. Subsequent extraction with chloroform gave *o*-ethyltoluene.

Oxidation of ***9***. The oxidation was carried out in the way described above. A small amount of **73** was obtained, along with the main product **72**. The structure of **72** is not conclusive because the fragmentation pattern of the mass spectrum was not consistent with the structure, although the NMR spectrum was satisfactory. The aldehyde **73** could not be completely freed from **72** by preparative GLC, so the spectrum was obtained by subtracting that of **72** from the spectrum of the mixture.

72: NMR, δ 1.5—1.8 (m, 4H), 2.0—2.3 (bs, 7H), and 9.98 (s, 1H).

73: NMR, δ 1.5—1.8 (m), 1.71 (s, 3H), 1.9—2.3 (m), 3.27 (s, 3H), 4.25 (bs, 1H), and 9.63 (bs, 1H).

Run 3. The oil remaining after the work-up was mainly **11**, accompanied by a small amount of **12**.

11: MS, *m/e* 139 (M−OMe, base peak), 107, 93, 91, 79, and 77. IR, 3400, 2950, and 1100 cm^{-1}. NMR, δ 0.90 (s, 3H), 1.02 (s, 3H), 1.5—1.9 (m, 4H), 3.30 (s, 3H), 3.6—3.9 (b, 1H), 3.90 (bs, 2H), and 5.70 (bs, 1H).

12; IR, 2950, 1708, and 1083 cm^{-1}. NMR, δ 0.88 (s, 3H), 1.10 (s, 3H), 1.15—2.3 (m, 6H), 3.30 (s, 3H), and 3.3—3.7 (m, 1H).

Direct irradiation in methanol resulted in the recovery of the starting material. Irradiation in the presence of hydrochloric acid or a dark reaction in the presence of titanium (IV) chloride gave the methanol adduct **12**.

Oxidation of ***11***. An oxidation and work-up in the way described above afforded an aldehyde **77**. MS, *m/e* 168 (M), 139 (base peak), 107, 91, and 79. IR, 2950, 2820, 2700, 1688, 1210, and 1102 cm^{-1}. NMR, δ 0.87 (s, 3H), 1.02 (s, 3H), 1.2—2.3 (m), 3.37 (s, 3H), 3.8—4.1 (b, 1H), and 9.48 (s, 1H).

Run 4. A crude oil was distilled at 4 mmHg into four fractions. Each fraction was found by GLC analyses to contain one or two of the products **14**—**16**. The isolated yields of the products were 12% for **14**, 3% for **15**, and 2% for **16**.

14: MS, *m/e* 170 (M), 139, and 114 (base peak). IR, 3420, 2920, 1209, and 1090 cm^{-1}. NMR, δ 0.85 (s, 3H), 0.95 (s, 3H), 1.0—2.0 (m), 3.22 (bs, 1H), 3.37 (s, 3H), 3.96 (bs, 2H), and 5.67 (bs, 1H).

15: MS, *m/e* 153 (M−OMe), 137, 121, 105, 93, 91, and 75 (base peak). IR, 2950, 1120, and 1055 cm^{-1}. NMR, δ 1.02 (s, 6H), 1.1—2.5 (m), 3.30 (s, 3H), 3.33 (s, 3H), 3.99 (d, J=9 Hz, 1H), and 5.47 (s, 2H).

Found: C, 71.46; H, 10.71%. Calcd for $C_{11}H_{20}O_2$: C, 71.69; H, 10.94%.

16: MS, *m/e* 156 (M), 141, 125, 100, 87, 75, and 70 (base peak). IR, 2920, 1720, and 1100 cm^{-1}. NMR, δ 1.02 (s, 3H), 1.10 (s, 3H), 1.2—1.6 (m, 1H), 1.6—1.9 (m, 1H), 2.1—2.6 (m, 4H), 3.03 (d of d, J=8 and 5 Hz, 1H), and 3.28 (s, 3H).

A dark reaction in the presence of titanium(IV) chloride gave **16** in 63% yield. Irradiation in either the presence or absence of hydrochloric acid gave a complicated mixture of products.

Oxidation of ***14***. The oxidation of **14** in the way described above afforded an aldehyde **79**. MS, *m/e* 168 (M), 112, and 83. IR, 2940, 2820, 2720, 1680, 1640, 1190, and 1095 cm^{-1}. NMR, δ 0.82 (s, 3H), 1.02 (s, 3H), 1.4—1.7 (m, 2H), 2.1—2.3 (m, 2H), 3.50 (s, 4H), 6.67 (bs, 1H), and 9.56 (s, 1H). The signal at δ 3.50 split into a three-proton singlet and a one-proton signal upon the addition of $Eu(FOD)_3$.

Hydrolysis of ***15***. The acetal **15** was treated with 3M-hydrochloric acid in methanol in the way described above to give an aldehyde **78**. MS, *m/e* 138 (M), 123, 109, and 95 (base peak). IR, 2960, 1680, and 1640 cm^{-1}. NMR, δ 1.00 (s, 6H), 1.4—1.6 (m, 2H), 2.0—2.5 (m, 4H), 6.73 (bs, 1H), and 9.57 (s, 1H).

Run 5. The work-up and preparative GLC afforded a pure sample of **18**. MS,[39] *m/e* 134 (M), 133 (base peak), 105, 91, 79, and 77. IR, 2930, 2840, 2720, 1690, 1610, and 1110 cm^{-1}. NMR, δ 2.36 (s, 6H), 7.21 and 7.53 (ABq, J=9 Hz, 2H), 7.57 (s, 1H), and 9.85 (s, 1H). These NMR data are not consistent with those of 2,4-[40] or 2,5-[41] dimethylbenzaldehyde.

No reaction occurred in the dark in the presence of titanium-(IV) chloride. Irradiation in methanol in either the presence or absence of hydrochloric acid gave a complicated mixture of products.

Run 6. The work-up afforded an oil which was an almost pure sample of **20**, accompanied by a small amount of **21**, as revealed by GLC and NMR analyses. The same products were obtained when titanium(IV) chloride was used as the catalyst, but, in this case, the amount of the by-product **21** was much greater.

20: MS, *m/e* 85 (M−OMe, base peak), 71, 56, and 41. IR, 3060, 1450, 1370, 1100, and 1030 cm^{-1}. NMR, [δ 0.98 (d,

J=8 Hz, for *trans*) and 1.02 (d, J=8 Hz, for *cis*)] 3H, 1.3—1.5 (m, 1H), 1.7—2.5 (m, 2H), [3.03 (s, for *trans*) and 3.06 (s, for *cis*)] 3H, 3.15 (t, J=8 Hz, 1H), [3.65 (t, J=8 Hz, for *cis*) and 3.75 (t, J=8 Hz, for *trans*)] 1H, and 4.60 (d, J=5 Hz, 1H). The signal assignments for the *cis*-and *trans*-isomers were performed by adding $Eu(DPM)_3$. From the intensities of the methyl signals, the ratio of the *cis*- to the *trans*-isomer was determined to be 42: 58.

Found: C, 61.59; H, 10.16%. Calcd for $C_6H_{12}O_2$: C, 62.04; H, 10.41%.

21: NMR, δ 1.05 (d, J=6 Hz, 3H), 1.45—1.55 (m, 2H), 3.10 (s, 9H), 3.1—3.2 (m), and 4.26 (d of d, J=4 and 3 Hz, 1H).

The irradiation of **19** in the presence of hydrochloric acid gave **21** as the exclusive product. The direct irradiation gave an oil which is considered from its NMR spectrum to be a mixture of *cis*- and *trans*-**19**, as well as their dimethyl acetals.

Run 7. The oil remaining after the work-up was distilled under reduced pressure to give a mixture of **23**—**25**. Each component was separated by preparative GLC.

23: MS, *m/e* 166 (M), 151, 136, 121, 108, and 93 (base peak). IR, 2950, 1460, 1380, 1170, and 1050 cm^{-1}. NMR, δ 1.0—2.0 (m), 1.14 (s, 6H), 1.68 (s, 3H), 3.33 (d of d, J=9 and 8 Hz, 1H), 3.90 (t, J=8 Hz, 1H), and 5.37 (bs, 1H).

24: The NMR data coincided with the reported data.[42]

25:[43] IR, 2960, 1620, 1360, 1250, 1160, and 1060 cm^{-1}. NMR, δ 1.49 (s, 6H), 2.40 (s, 3H), 3.07 (s, 3H), 7.04 and 7.18 (ABq, J=9 Hz, 4H).

The dark reaction in the presence of titanium(IV) chloride gave **24** and **25** in 31% and 10% yields respectively. Irradiation in either the presence or absence of hydrochloric acid gave a complicated mixture of products.

Run 8. The work-up afforded an oil which was identified by NMR analysis as a mixture of **27** and **28** (66: 34). Details concering the data will be described in Run 29. A dark reaction in the presence of titanium(IV) chloride resulted in the recovery of the starting material.

Run 9. The oil remaining after the work-up was an almost pure sample of **30**, accompanied by a small amount of **31**, as revealed by GLC analysis.

30: IR, 3080, 3000, 2920, 2840, 1470, 1360, and 1080 cm^{-1}. NMR, δ 0.0—0.9 (m, 11H), 3.35 (s, 6H), and 4.15 (d, J=5 Hz, 1H).

Found: C, 69.97; H, 10.32%. Calcd for $C_{10}H_{18}O_2$: C, 70.54; H, 10.66%.

The aldehyde **31** was identical with an authentic sample prepared according to the reported method.[44]

Irradiation in either the presence or absence of hydrochloric acid gave a complicated mixture of products.

Preparation of 30. A mixture of **31** (0.27 g), methyl orthoformate (0.5 g), and ammonium nitrate (0.025 g) in methanol (0.5 ml) was kept at room temperature for 8 h. A saturated solution of sodium carbonate was then added, and the solution was shaken with dichloromethane. The subsequent evaporation of the solvent from the extract left an oil which was identical with **30**.

Run 10. The oil remaining after the work-up was almost pure **33**, accompanied by a small amount of **34**, as revealed by NMR and GLC analyses.

33: MS, *m/e* 99 (M−OMe, base peak), 69, 67, and 41. IR, 3670, 3590, 3070, 1480, 1400, 1080, and 1050 cm^{-1}. NMR, δ 0.0—1.0 (m, 5H), 0.85 (s, 3H), 2.45 (bs, 1H, disappears by D_2O), 3.15 (s, 3H), and 3.20 and 3.30 (ABq, J= 11 Hz, 2H).

Found: C, 64.23: H, 11.33%. Calcd for $C_7H_{14}O_2$: C, 64.58; H, 10.84%.

34: MS, *m/e* 113 (M−OMe), 81, 75 (base peak), and 47 IR, 2960, 2920, 2820, 1450, 1380, and 1070 cm^{-1}. NMR, δ 0.0—0.7 (m, 5H), 0.7—1.1 (m, 4H), 3.12 (s, 6H), and 3.85 (d, J=7 Hz, 1H). The multiplet at δ 0.7—1.1 split into a three-proton doublet (J=8 Hz) and a one-proton distorted sextet (J=7—8 Hz) upon the addition of $Eu(DPM)_3$.

Found: C, 65.75; H, 11.30%. Calcd for $C_8H_{16}O_2$: C, 66.63; H, 11.18%.

When the photolysate was refluxed for 30 min and then worked-up in the same way as above, **34** was obtained as the sole product. The irradiation of **32** in methanol in either presence or absence of hydrochloric acid gave a complicated mixture of products.

Oxidation of 33. The oxidation of **33** in the way described above gave an aldehyde **81**. IR, 3030, 2970, 2830, 1740, and 1090 cm^{-1}. NMR, δ 0.2—1.0 (m, 5H), 1.10 (s, 3H), 3.23 (s, 3H), and 9.45 (s, 1H).

Phenylurethane Derivative of 33. The phenylurethane derivative of **33** was prepared in the way described in Run 2. Although the product seems to be pure, judging from its NMR spectrum, we could not effect the crystallization. NMR (in an impure state), δ 0.05—0.6 (m, 4H), 0.7—1.0 (m, 1H), 0.86 (s, 3H), 3.00 (s, 3H), 3.85 (s, 2H), 6.5—7.1 (m, 5H), and 7.18 (bs, 1H).

Run 11. The oil remaining after the work-up was a mixture of **36** and **37**, judging from the GLC and NMR analyses.

36: MS, *m/e* 169 (M−OMe), 153, 125, 97, and 74 (base peak). IR, 2950, 1700, 1120, and 1050 cm^{-1}. NMR, δ 0.95 (s, 3H), 1.15 (s, 3H), 1.3—2.5 (m, 7H), 3.35 (s, 6H), and 4.10 (d, J=6 Hz, 1H).

The enol ether **37** was identical with a sample prepared according to the reported method.[45]

When **36** was treated with 2,4-dinitrophenylhydrazine, the bis(2,4-dinitrophenylhydrazone) of the keto aldehyde **82** was obtained; it was subsequently recrystallized from dioxane-methanol. Mp 210—212 °C.

Found: C, 48.64; H, 4.13; N, 21.35%. Calcd for $C_{21}H_{22}N_8O_8$: C, 49.03; H, 4.31; N, 21.78%.

Hydrolysis of 36. A crude sample of **36** was refluxed in a mixture of methanol (10 ml) and conc. hydrochloric acid (4 ml) for 4 h. The solution was then diluted with water and extracted with chloroform. The subsequent evaporation of the solvent from the extract left an oil which was purified by preparative GLC to give **82**. MS, *m/e* 139 (M−Me), 126, 83, 69, 57, 55 (base peak), and 41. IR, 2930, 1710, and 1250 cm^{-1}. NMR, δ 0.92 (s, 3H), 1.12 (s, 3H), 1.3—2.8 (m, 7H), and 9.50 (d, J=0.5 Hz, 1H).

Irradiation of **37** *in the Presence of Titanium(IV) Chloride.* Irradiation was carried out under the same conditions as those used with **35**. An acetal **36** was obtained as the sole product.

Run 12. The oil remaining after the work-up was distilled under reduced pressure to give a pure sample of **39**. Bp 58—62 °C (15 mmHg), 0.1 g. MS, *m/e* 172 (M), 157, 155, 143, and 141 (base peak). IR, 3510, 2930, 1770 (weak), 1450, 1400, 1370, 1320, 1200, and 1020 cm^{-1}. NMR, δ 1.15 (s, 3H), 1.1—2.2 (m, 7H), 3.30 (s, 3H), and 3.73 and 3.82 (ABq, J=7 Hz, 2H).

Found: C, 62.67; H, 9.09%. Calcd for $C_9H_{16}O_3$: C, 62.76; H, 9.36%.

When **38** was irradiated in methanol without any additives, or when it was kept in methanol-hydrochloric acid in the dark, it gave an enol ether **129**. IR, 2950, 1740, 1720, 1435, 1360, and 1165 cm^{-1}. NMR, δ 1.45—1.65 (m), 2.05 (s, 3H), 2.1—2.5 (m), and 3.56 (s, 3H).

Run 13. The oil remaining after the work-up was distilled under reduced pressure. An oil, bp 39—45 °C (15

mmHg), was thus obtained which was found by GLC analysis to be a mixture of several compounds; three major fractions (**41**—**43**) were collected in pure states by preparative GLC (temperature, 70 °C).

41: MS, *m/e* 112 (M), 111, 97, and 69 (base peak). The IR and NMR spectra were identical with those previously reported.[4]

42: Identical with the authentic sample prepared according to the reported method.[5]

43: IR, 2940, 1450, 1370, 1320, 1180, and 1050 cm^{-1}. NMR, δ 1.45 (s, 6H), 2.60 (s, 2H), and 3.35 (s, 6H).

Found: C, 52.26; H, 9.00%. Calcd for $C_7H_{14}O_4$: C, 51.84; H, 8.70%.

Irradiation of **40** *in the Presence of Hydrochloric Acid.* A solution of **40** (0.1 g) and concd hydrochloric acid (0.4 ml) in methanol (10 ml) was irradiated in a Pyrex tube for 24 h. The subsequent evaporation of the extract left **43** in an almost pure state (GLC and NMR analyses). The temperature of the GLC should not exceed 70 °C.

Thermolysis of **43**. When a neat sample of **43** was kept at 150 °C for 2 h, an equimolar mixture of methyl acetate and methyl propionate was obtained, as established by GLC and NMR techniques.

Run 14. The crystals obtained after the work-up (0.26 g) were almost pure **45**. Recrystallization from carbon tetrachloride gave white needles; mp 91—92 °C (lit,[4] mp 92—94 °C). The IR and NMR data coincided with the reported values.[4] Hydrogenation over Pd/C gave **89**, which also indicated IR and NMR spectra identical with those previously reported.[4] Mp 73—75 °C (lit, mp 86—88 °C,[4] or 82—83 °C.[46])

Run 15. The oil remaining after the work-up was a mixture of **47** and one more product of an unknown structure. **47**: IR, 2980, 2925, 1760, 1440, 1090, and 1000 cm^{-1}. NMR, δ 1.36 (d, J=7 Hz, 3H), 1.75 (s, 3H), 1.95 (s, 3H), and 4.68 (q, J=7 Hz, 1H).

Run 16. The photolysate was diluted with water and made alkaline with a sodium hydroxide solution. The precipitates of titanium hydroxide were filtered off with the aid of Hyflo Super Cel, and the filtrate was shaken with dichloromethane. The subsequent evaporation of the solvent from the extract left an oil which was found by NMR analysis to be a mixture of **49** and **50** (4: 1). Distillation under reduced pressure gave **49** in an almost pure state. Bp 125—133 °C (6 mmHg), 0.75 g, 59%. (Lit,[47] bp 115—120 °C (4 mmHg)). NMR, δ 2.25 (s, 3H), 3.72 (bs, 2H), 4.72 (bs, 2H), and 7.2—7.7 (m, 5H).

When the crude material of **49** was treated with *p*-nitrobenzoyl chloride in benzene, crystals of bis (*p*-nitrobenzoyl) derivative were obtained. Recrystallization from chloroform-ethanol afforded a pure sample. Mp 167—168 °C.

Found: C, 60.94; H, 4.19; N, 8.99%. Calcd for $C_{23}H_{19}N_3O_7$: C, 61.47; H, 4.26; N, 9.35%.

The picrate of **49** was also obtained. Recrystallization from ethanol afforded a pure sample. Mp 188—191 °C.

Found: C, 46.74; H, 4.04; N, 14.46%. Calcd for $C_{15}H_{16}N_4O_8$: C, 47.37; H, 4.24; N, 14.73%.

Preparation of **50**. An appropriate amount of 37% formalin was added to the photolysate of **48**, and the solution was kept at room temperature for 7 days. The work-up described above afforded an oil which was almost pure **50**. IR, 2880, 2800, 1495, 1455, and 1070 cm^{-1}. NMR, δ 2.30 (s, 3H), 3.53 and 3.67 (d (J=8 Hz) of ABq, J=8 Hz, 2H), 4.08 (d, J=2 Hz, 1H), 4.25 (t, J=8 Hz, 1H), 4.78 (d, J=2 Hz, 1H), and 7.2—7.7 (m, 5H). The signals at δ 3.53 and 3.67 separated into two one-proton triplets (J=8 Hz) upon the addition of $Eu(DPM)_3$.

Run 17. The work-up described in Run 16 afforded crystals of **52**; 0.52 g, mp 87—95 °C. Recrystallization from carbon tetrachloride–hexane afforded a pure sample. Mp 107—109 °C. IR, 3400, 3120, 1445, 1055, and 1030 cm^{-1}. NMR, δ 0.9—1.4 (m, 5H), 1.4—1.8 (m, 4H), 1.8—2.1 (b, 1H), 2.2—2.5 (b, 1H), 2.40 (bs, 2H, disappears by D_2O), 3.48 [d (J=11 Hz) of AB (J=10 Hz), 1H], 3.70 [d (J=4 Hz) of AB (J=10 Hz), 1H], 3.96 (d of d, J=11 and 4 Hz, 1H), and 7.2—7.6 (m, 5H).

Found: C, 75.97; H, 9.57; N, 6.18%. Calcd for $C_{14}H_{21}NO$: C, 76.66; H, 9.65; N, 6.39%.

Preparation of **53**. A mixture of **52** (0.031 g) and 37% formalin (0.018 g) in methanol (0.5 ml) was stirred at 70 °C for 6 h. The work-up afforded a crude sample of **53**. NMR, δ 1.0—2.0 (m, 10H), 2.1—2.7 (bs, 1H), 3.5—3.7 (m, 1H), 4.0—4.3 (m, 2H), 4.5—4.75 (m, 2H), and 7.2—7.6 (m, 5H).

Run 18. The work-up described in Run 16 afforded a crude oil (0.34 g), which partly crystallized upon standing. The crystals were collected and recrystallized from carbon tetrachloride to give white needles of **55**. Mp 71—73 °C. IR (KBr), 3420, 3260, 2960, 2925, 2850, 1450, 1360, 1140, and 1120 cm^{-1}. NMR ($CDCl_3$), δ 0.77—2.1 (m, 2H), 2.07 (bs, 2H, disappears by D_2O), 2.35—2.88 (m, 2H), 3.20 [d (J=7 Hz) of AB (J=11 Hz), 1H], and 3.58 [d (J=4 Hz) of AB (J=11 Hz), 1H].

From the mother liquor separated from the crystals of **55**, a pure sample of **56** was obtained by preparative GLC. MS, *m/e* 225 (M), 194, 182, 154 (base peak), 72, and 55. IR, 2960, 2925, 2855, 1470, 1450, 1375, 1170, and 1028 cm^{-1}. NMR, δ 0.76—2.11 (m, 21H), 2.17—2.57 (m, 1H), 2.89—3.28 (m, 2H), 3.78 (t, J=7 Hz, 1H), and 4.15 and 4.42 (ABq, J=6 Hz, 2H).

Irradiation without any additive or a dark reaction in the presence of titanium(IV) chloride resulted in the recovery of the starting material. Irradiation in the presence of hydrochloric acid afforded a complicated mixture of products.

Run 19. The work-up described in Run 16 afforded a mixture of **58** and **59** (3: 2), as revealed by the NMR spectrum. When the mixture and 37% formalin (0.19 g) in methanol (0.5 ml) were kept at 70 °C for 2 h, and then at room temperature overnight, **59** was obtained; it was identical with the sample obtained in Run 21. The NMR spectrum of **58** was obtained by subtracting that of **59** from the mixture spectrum. δ 1.43 (s, 3H), 2.14 (s, 3H), 3.0—3.6 (b), 3.39 (s), and 7.2—7.6 (m).

Run 20. The work-up afforded white crystals (0.2 g). Recrystallization from methanol afforded white needles of **61**. Mp 122—127 °C. (Lit,[48] mp 125 °C). MS, *m/e* 144 (M—MeOH, base peak), 113, and 73. IR (KBr), 1370, 1285, 1196, 1175, 1065, and 1035 cm^{-1}. NMR, δ 1.15 (s, 6H), 3.20 (s, 6H), and 3.27 and 3.50 (ABq, J=11 Hz, 4H).

Found: C, 55.18; H, 9.59%. Calcd for $C_8H_{16}O_4$: C, 54.53; H, 9.15%.

It was speculated that the crude crystals contain a stereoisomer of **61** (one-third of **61**), since these crystals indicated NMR signals at δ 1.30 (s, 6H), 3.22 (s, 6H), and 3.27 and 3.50 (ABq, J=11 Hz, 4H, overlap with those of **61**), as well as those of **61**.

Compound **61** was identical with the crystals separated out from a 50% methanol solution of hydroxyacetone.

Run 21. The photolysate was made alkaline with a sodium hydroxide solution, and the solid was filtered off (Hyflo Super Cel). The filtrate was made acidic with hydrochloric acid and shaken with chloroform (Extract A). The aqueous solution was made alkaline with sodium hydroxide solution again, and shaken with chloroform (Extract B). Extract A, upon the evaporation of the solvent, gave a trace

amount of an oil from which two products, **63** and **64**, were obtained in pure states by preparative GLC. Compound **63** was identical with the authentic sample. **64**: IR (neat), 3450, 1610, 1505, 1455, 1030, 760, and 695 cm^{-1}. NMR, δ 1.35 (s, 3H), 2.4—2.9 (b, 2H), 3.26 and 3.45 (ABq, J= 11 Hz, 2H), and 6.8—7.1 (m, 5H).

Compound **64** was identical with the sample obtained in a small amount by the irradiation of acetophenone (0.12 ml) in methanol (12 ml) in the presence of titanium(IV) chloride (0.12 ml).

Extract B, upon the evaporation of the solvent, gave an oil which was subsequently distilled under reduced pressure to give 0.13 g of **59**. MS, *m/e* 177 (M), 162 (base peak), 146, 132, and 91. IR (neat), 2980, 2850, 2780, 1440, 1050, 758, and 690 cm^{-1}. NMR δ 1.35 (s, 3H), 2.05 (s, 3H), 3.52 and 3.65 (ABq, J=8 Hz, 2H), 4.07 and 4.27 (dist. ABq, J=2 Hz, 2H), and 6.7—7.2 (m, 5H).

Found: C, 73.82; H, 8.30; N, 7.75%. Calcd for $C_{11}H_{15}NO$: C, 74.54; H, 8.53; N, 7.90%.

Run 22. The photolysate was worked-up in the way described in Run 21. A trace amount of **67** was obtained from the extract from the acidic solution. The amount of the product corresponding to **64** was negligible. **67**: IR (neat), 3320, 2960, 1510, 1440, 1360, 1065, 1005, 890, and 810 cm^{-1}. NMR, δ 1.39 (d, J=7 Hz, 3H), 2.25 (s, 3H), 4.55 (q, J=7 Hz, 1H), and 6.78 and 6.90 (ABq, J=8 Hz, 4H).

The extract from the alkaline solution gave an oil which was subsequently distilled under reduced pressure to give 0.062 g of **66**. IR (neat), 3380, 2950, 2880, 1520, 1460, 1380, 1083, 1018, and 812 cm^{-1}. NMR, δ 1.35 (s, 3H), 2.21 (s, 3H), 3.43 and 3.52 (ABq, J=7 Hz, 2H), 4.03 and 4.23 (ABq, J=6 Hz, 2H), and 6.70 and 6.88 (ABq, J=8 Hz, 4H).

Found: C, 74.54; H, 8.82; N, 7.85%. Calcd for $C_{11}H_{15}NO$: C, 74.54; H, 8.53; N, 7.90%.

Run 23. The work-up was the same as that described in Run 21. The amounts of products corresponding to **63** and **64** were negligible. The extract from the alkaline solution gave an oil which was subsequently distilled under reduced pressure to give 0.088 g of **69**. MS, *m/e* 176 (M−1), 162, 147, 146 (base peak), 133, 132, 105, and 91. IR (neat), 2980, 2890, 1450, 1080, 1015, 900, and 758 cm^{-1}. NMR, δ 1.40 (s, 3H), 2.27 (s, 3H), 3.44 and 3.74 (ABq, J=7 Hz, 2H), 4.06 and 4.30 (ABq, J=6 Hz, 2H), 6.65—6.85 (m, 3H), and 7.17—7.35 (m, 1H).

Found: C, 74.62; H, 8.76; N, 7.71%. Calcd for $C_{11}H_{15}NO$: C, 74.54; H, 8.53; N, 7.90%.

Run 24. The oil remaining after the work-up indicated a complicated NMR spectrum suggestive of the structure **108** of a stereoisomeric mixture. Distillation induced the elimination of methanol from these isomers and gave **92** in an almost pure state; bp 72—78 °C (23 mmHg). IR, 2930, 1710 (weak), 1463, 1172, 1120, and 980 cm^{-1}. NMR, δ 0.97 (d, J=8 Hz, 3H), 1.00 (s, 6H), 1.5—2.1 (m, 7H), and 3.64 (s, 2H).

Found: C, 78.67; H, 11.23%. Calcd for $C_{11}H_{18}O$: C, 79.46; H, 10.92%.

Run 25. The oil remaining after the work-up was distilled to give **20** (bp 56—65 °C (25 mmHg)), which contained a small amount of chloroform. The IR and NMR spectra were identical with those obtained in Run 6.

Run 26. The oil remaining after the work-up was distilled to give **94** (bp 35—56 °C (3 mmHg)), which contained a small amount of chloroform. MS, *m/e* 113 (M−OMe, base peak), 112, and 97. IR, 2965, 2885, 1470, 1378, 1190, 1050, and 1028 cm^{-1}. NMR, δ 1.00 (s, 3H), 1.05 (s, 3H), 1.25 (s, 3H), 1.50 and 1.70 (ABq, J=13 Hz, 2H), 2.96 (s, 3H), and 3.23 and 3.30 (ABq, J=8 Hz, 2H).

From the crude oil prior to the distillation, a small amount of **95**[10] was isolated by preparative GLC. MS, *m/e* 142 (M), 100, 99, 85 (base peak), 82, and 43. IR, 2960, 1715, 1700, 1360, 1170, and 1130 cm^{-1}. NMR, δ 1.15 (s, 6H), 2.00 (s, 3H), 2.10 (s, 3H), and 2.60 (s, 2H).

When **94** was kept in a mixture of tetrahydrofuran–3M-hydrochloric acid (2: 1) at room temperature for 10 min, an oil was obtained which was identified from its NMR spectrum as a mixture of **109a** and **110a**. The oxidation of the oil with CrO_3–pyridine–HCl in the way described above afforded keto aldehyde **111**. MS, *m/e* 100 (M−CO), 85, and 43 (base peak). IR, 2960, 2800, 2650, 1725, and 1370 cm^{-1}. NMR, δ 1.10 (s, 6H), 2.10 (s, 3H), 2.65 (s, 2H), and 9.60 (s, 1H).

Run 27. The oil remaining after the work-up was a mixture of **97** and **99**, as revealed by NMR analysis. Distillation under reduced pressure induced the elimination of methanol from **99** and gave a mixture of the starting material and **97** (bp 68—94 °C (18 mmHg), 0.66 g). On some occasions, the product contained **98** (0—10% of **97**).

97: MS, *m/e* 156 (M), 141, 125, 113 (base peak), and 111. IR, 2990, 2900, 1457, 1195, 1105, 1030, and 1012 cm^{-1}. NMR δ 0.98 (s, 3H), 1.05—2.25 (m, 8H), 3.05 (s, 3H), and 3.30 and 3.40 (ABq, J=6 Hz, 2H).

98: MS, *m/e* 142 (M), 125, 112, 111 (base peak), and 99. IR, 3400, 1710, 1230, and 1050 cm^{-1}. NMR, δ 0.90 (s, 3H), 1.7—2.4 (m, 8H), and 3.25 (s, 2H).

99: IR, 2960, 2870, 1715, 1213, 1112, and 1065 cm^{-1}. NMR, δ 1.15 (s, 3H), 1.5—2.5 (m, 8H), and 3.00 (s, 3H).

Found: C, 66.79; H, 9.95%. Calcd for $C_8H_{14}O_2$: C, 67.57; H, 9.93%.

No reaction occurred in the dark in the presence of uranyl chloride. Irradiation in methanol in the presence of an ordinary amount of hydrochloric acid resulted in the recovery of the starting ketone, while in the presence of a small amount of hydrochloric acid (pH 2—3), a methanol adduct **99** was obtained exclusively.

Oxidation of 98. The oxidation of **98** in the way described above afforded an aldehyde **112**. MS, *m/e* 112 (M−CO), 111, 97, 83, 69, and 55 (base peak). IR, 2960, 2800, 2650, 1720, and 1220 cm^{-1}. NMR, δ 1.11 (s, 3H), 1.2—2.6 (m), and 9.34 (s, 1H).

Run 28. The work-up left an oil which was distilled under reduced pressure to give two fractions: Fraction 1 (bp 36—41 °C (1 mmHg), 0.17 g) contained 32% of **100**, while Fraction 2 (bp 62—68 °C (1 mmHg), 0.22 g) contained 51% of **101**, as revealed by GLC analyses.

100: MS, *m/e* 170 (M), 139, 125, 110, 100, and 99 (base peak). IR, 2960, 1310, 1190, and 1120 cm^{-1}. NMR, δ 0.97 (s, 3H), 1.02 (s, 3H), 1.1—2.0 (m), 3.24 (s, 3H), and 3.89 (m, 2H). The multiplet at δ 3.89 was transformed into a typical ABX type upon the addition of $Eu(DPM)_3$.

Found: C, 70.03; H, 10.50%. Calcd for $C_{10}H_{18}O_2$: C, 70.54; H, 10.66%.

101: MS, *m/e* 156 (M), 126, 125, 85, 83, 69, and 55 (base peak). IR, 3440, 2940, and 1710 cm^{-1}. NMR, δ 1.08 (s, 3H), 1.16 (s, 3H), 0.9—2.6 (m), and 3.3—3.9 (m, 2H).

Oxidation of 101. The oxidation of **101** in the way described above afforded an aldehyde **113**. MS, *m/e* 154 (M), 126, 111, 97, 83, 69, and 55 (base peak). IR, 2960 and 1730 cm^{-1}. NMR, δ 1.14 (s, 3H), 1.31 (s, 3H), 1.6—1.9 (m, 2H), 2.1—2.7 (m, 5H), and 9.98 (s, 1H).

Run 29. An oil (bp 108—110 °C (3.5 mmHg), 0.84 g) was obtained which was found by NMR analysis to be a mixture of **27** and **28** (93: 7). Further purification was not achieved, so the spectroscopic data of **27** were obtained by subtracting those of **28** from the spectra of the mixture. **27**: IR: 3440, 2920, 1740, and 1450 cm^{-1}. NMR, δ 2.57 and

2.64 (d of d, J=7 and 5 Hz, 2H), 2.8—3.0 (m, 1H), 3.30 (bs, 1H), 3.67 (bs, 3H+2H), and 3.70 (s, 3H).

When the mixture was kept at 200 °C for 1 h, **28**[49] was obtained in a 60% yield. Bp 96—97 °C (1.5 mmHg). IR, 1795, 1745, 1450, 1165, and 1015 cm^{-1}. NMR, δ 2.70 (d, J=10 Hz, 1H), 2.71 (d, J=7.5 Hz, 1H), 3.45 (dist. quintet, J=8 Hz, 1H), 3.78 (s, 3H), 4.40[d (J=7 Hz) of AB (J=10 Hz), 1H], and 4.51[d (J=9 Hz) of AB (J=10 Hz), 1H].

Found: C, 49.24; H, 5.63%. Calcd for $C_6H_8O_4$: C, 50.00; H, 5.60%.

Run 30. An oil (bp 63—67 °C (3 mmHg), 1.04 g) was obtained which was found by NMR analysis to be a mixture of **103** and **104** (84:16). Further purification was not achieved, and so the spectroscopic data of **103** were obtained by subtracting those of **104** from the spectra of the mixture. **103**: IR, 3490 and 1740 cm^{-1}. NMR, δ 0.90 (d, J=7 Hz, 3H), 1.85—2.56 (m), 3.35 (bs, 1H, disappears by D_2O), 3.36 (dist. quintet, J=6 Hz, 2H), and 3.57 (s, 3H).

When **103** was kept at 200 °C for 3 h, **104** was obtained. Bp 56—57 °C (3 mmHg) (lit,[50] bp 80—81 °C (10 mmHg)). IR, 2990, 1790, 1165, and 1025 cm^{-1}. NMR, δ 1.11 (d, J=7 Hz, 3H), 1.8—2.2 (m, 1H), 2.4—2.8 (m, 2H), 3.74 (d of d, J=9 and 7 Hz, 1H), and 4.29 (d of d, J=10.5 and 9 Hz, 1H).

Run 31. The oil remaining after the work-up was distilled under reduced pressure. Much of a colorless, viscous material remained undistilled. The distillate (bp 62—65 °C (2 mmHg), 0.28 g) was found by NMR analysis to be a mixture of **106** ans **107** (94:6). Further purification was not achieved, and so the spectroscopic data of **106** were obtained by subtracting those of **107** from the spectra of the mixture. **106** (lit,[51] bp 45—46 °C (0.2 mmHg)): IR, 3420 and 1745 cm^{-1}. NMR, δ 1.80 (quintet, J=7 Hz, 2H), 2.38 (t, J=7 Hz, 2H), 3.23 (bs, 1H), 3.58 (t, J=7 Hz, 2H), and 3.63 (s, 3H).

Found (with a sample of 94% purity): C, 50.69; H, 8.72%. Calcd for $C_5H_{10}O_3$: C, 50.83; H, 8.53%.

When **106** was kept at 200 °C for 3 h, **107** was obtained in a pure state; it was identical with γ-butyrolactone.

Oxidation of ***106***. The oxidation of **106** in the way described above afforded an aldehydic ester **114**. (Lit,[52] bp 79—80 °C (12 mmHg)). MS, m/e 88 (M−CO), 85, 59, and 57. IR, 2960, 2820, 2710, 1740, 1440, and 1175 cm^{-1}. NMR, δ 2.5—2.9 (A_2B_2m, 4H), 3.70 (s, 3H), and 9.95 (s, 1H).

*Irradiation of 3-Methyl-2-cyclohexenone (**96**) in Alcohols in the Presence of Titanium(IV) Chloride.* Solutions of **96** (0.1 g) and titanium(IV) chloride (0.17 g) in the following alcohols (10 ml) were irradiated in Pyrex tubes for 6 h. Subsequent work-ups afforded oils which were analyzed by GLC and NMR to determine the yields.

In 1-Propanol: The product was **116c**. MS, m/e 152 (M), 95 (base peak), 79, 77, and 67. IR, 2900, 1710, 1440, and 1110 cm^{-1}. NMR, δ 1.03 (t, J=8 Hz, 3H), 1.3—2.0 (b, 6H), 1.70 (bs, 3H), 2.41 (q, J=8 Hz, 2H), 2.94 (b, 1H), and 5.47 (bs, 1H).

In 1-Butanol: The products were **116d** and **117d**.

116d: MS, m/e 166 (M), 95 (base peak), 79, 77, 71, and 67. IR, 2920, 1710, and 1130 cm^{-1}. NMR, δ 0.91 (t, J=8 Hz, 3H), 1.0—2.2 (m), 1.68 (bs, 3H), 2.34 (t, J=8 Hz, 2H), 2.92 (b, 1H), and 5.48 (bs, 1H).

117d: IR, 2950, 2930, 1670, and 1200 cm^{-1}. NMR, δ 0.92 (t, J=8 Hz, 3H), 1.13 (d, J=8 Hz, 3H), 1.2—2.0 (m), 2.52 (t, J=8 Hz, 2H), and 6.51 (bs, 1H).

In 2-Methyl-1-propanol: The product was **116e**. MS, m/e 166 (M), 95 (base peak), 79, 77, 71, and 67. IR, 2960, 2930, and 1710 cm^{-1}. NMR, δ 1.06 (d, J=8 Hz, 6H), 1.5—2.0 (m), 1.70 (bs, 3H), 2.72 (heptet, J=8 Hz, 1H), 3.10 (b, 1H), and 5.45 (bs, 1H).

In 2-Propanol: The product was *m*-cymene. IR,[53] 2950, 2910, and 708 cm^{-1}. NMR, δ 1.21 (d, J=7 Hz, 6H), 2.18 (s, 3H), 2.85 (m, J=7 Hz, 1H), and 6.7—7.2 (m, 4H).

*Irradiation of Mesityl Oxide (**93**) in Alcohols in the Presence of Uranyl Chloride.* Solutions of **93** (0.1 g) and uranyl chloride (0.04 g) in the following alcohols (10 ml) were irradiated in Pyrex tubes for 6 h. Subsequent work-ups afforded the following products.

In Ethanol: The irradiation product, which was assumed, on the basis of NMR analysis, to be a mixture of **109b** and **110b** was directly oxidized with CrO_3–pyridine–HCl in the way described above. The products were **95** (13% from **93**) and **120** (trace). The spectroscopic data of **120** were identical with those previously reported.[54]

In 2-Propanol: The products were **95** and **121**. The compound **121** was identical with the one reported previously.[55]

*Irradiation of Dimethyl Maleate (**26**) in Alcohols in the Presence of Uranyl Chloride.* Solutions of **26** (1.0 g) and uranyl chloride (0.24 g) in the following alcohols were irradiated in Pyrex tubes for 1 h, and then treated as follows.

In Ethanol: The oil remaining after the work-up was distilled under reduced pressure to give an oil (bp 106—108 °C (4 mmHg), 0.79 g). Although this oil (Oil A) was assumed to be a mixture of stereoisomeric esters **122a** and lactones **123a** *(vide infra)*, it gave *cis*- and *trans*-lactones **123a** (54:46) (bp 99—102 °C (5 mmHg)) when kept at 200 °C for 2 h. The stereochemistry of the lactones was assigned on the basis of the NMR spectrum by comparing it with those previously reported.[3b] By subtracting the spectra of the lactones from the NMR spectrum of Oil A, we assigned the structure of the γ-hydroxy esters **122a** to the rest of the components. Although the amount of *cis*-lactone exceeds that of the *trans*-isomer in Oil A, amounts became almost equal after the thermal cyclization. We concluded from this result that the major component of the hydroxy esters in Oil A is probably the *threo*-isomer. From the distinctive methyl signals in the NMR spectrum of Oil A, we estimated the yields of the components as follows: *threo*-**122a** (23%), *erythro*-**122a** (14%), *trans*-**123a** (6%), and *cis*-**123a** (13%).

We assigned the NMR signals for **122a** as follows: [δ 1.15 (d, J=7 Hz) for *threo* and 1.18 (d, J=7 Hz) for *erythro*] 3H, 2.6—3.3 (m, 3H), 3.58 (b, 1H, disappears by D_2O), 3.75 (s, 3H), 3.79 (s, 3H), and 4.0—4.3 (m, 1H).

In 2-Propanol: The oil remaining after the work-up was identified by means of NMR analysis as a mixture of **122b**, **123b**, and the starting material (**26**) (76:11:13). Further purification was not achieved, and so the spectroscopic data of **122b** were obtained by subtracting those of **123b** and **26** from the spectra of the mixture. **122b**: IR, 3525, 1740, and 1175 cm^{-1}. NMR, δ 1.16 (s, 3H), 1.20 (s, 3H), 2.6—2.8 (bs, 3H), 3.18 (bs, 1H, disappears by D_2O), 3.63 (s, 3H), and 3.67 (s, 3H).

The distillation under reduced pressure induced the cyclization of **122b** into **123b**; the distillate (bp 108—110 °C (4 mmHg), 0.71 g) was a mixture of **122b**, **123b**, and **26** (9:74:17), as shown by NMR analysis. The spectroscopic data of the purified **123b** were identical with those previously reported.[3b,49]

*Irradiation of Mesityl Oxide (**93**) in Tetrahydrofuran in the Presence of Uranyl Chloride.* A solution of **93** (0.1 g) and uranyl chloride (0.03 g) in tetrahydrofuran (10 ml) was irradiated in a Pyrex tube for 4 h. A subsequent work-up afforded an oil which was almost pure **128**. MS, m/e 113 (M−CH_2COMe), 98, 86, 72 (base peak), and 71. IR (neat), 2950, 2860, 1700, 1355, and 1060 cm^{-1}. NMR, δ 0.89 (s, 3H), 0.98 (s, 3H), 1.4—2.0 (m, 4H), 2.05 (s, 3H), 2.18 and 2.40

(ABq, J=14 Hz, 2H), and 3.4—3.8 (m, 3H).

The authors are grateful to K. Ueda, T. Hamano, H. Kaneko, A. Kohda, K. Nagumo, K. Machida, and M. Morishita, who performed some parts of the experiments.

A Wittig-type Reaction of Phosphoranes with Carbon Monoxide Coordinated to Palladium. A Synthetic Route to Isocyanide Palladium Complexes

Jitsuo KIJI,* Akira MATSUMURA, Tomoyuki HAISHI, Satoshi OKAZAKI, and Junji FURUKAWA

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606

(Received March 9, 1977)

The reaction of carbon monoxide with triphenyl(phenylimino)phosphorane proceeded at room temperature in the coordination sphere of palladium to give a mixture of phenyl isocyanide and carbonyl complexes of palladium. Triphenyl(*t*-butylimino)phosphorane gave bis(*t*-butyl isocyanide)palladium chloride in a low yield. Benzophenone triphenylphosphazine and triphenyl(*p*-tolylsulfonylimino)phosphorane failed to react with carbon monoxide.

Although phosphoranes (ylides) and carbon monoxide are versatile reagents in organic synthesis, no reaction between them has been recorded. Coordinated carbon monoxide is susceptible to attack by many nucleophiles. For example, an attack by organolithium leads to the formation of aldehydes[1] or metal–carbene complexes.[2] Ylides possess a nucleophilic character and can be expected to react with coordinated carbon monoxide. In fact, Kaska and his co-workers[3] succeeded in applying the Wittig reaction to transition-metal carbonyl. Iminophosphoranes also react with iron carbonyl to form isocyanide-substituted iron carbonyls *via* a Wittig-type reaction.[4] These reactions seem to provide a method of preparing novel organotransition metal complexes.

While no Pd^{2+}-carbonyl with a definite stoichiometry has been characterized, carbonylation by carbon monoxide is generally accepted to occur in the coordination sphere of the Pd^{2+}-ion.[5] A preliminary work of the present study has been published.[6]

This paper will deal with the Pd^{2+}–assisted Wittig-type reaction of carbon monoxide with iminophosphoranes.

Results and Discussion

Triphenyl(phenylimino)phosphorane (I). Triphenyl(phenylimino)phosphorane (I) reacted with carbon monoxide under an atmospheric pressure in the presence of such palladium chloride complexes (hereafter abbreviated as "$PdCl_2$") as $PdCl_2$(COD) (COD=1,5-cyclooctadiene) or $[PdCl_2(styrene)]_2$. The product was revealed by the IR spectrum to be a mixture of

$$2C_6H_5N{=}P(C_6H_5)_3 + \text{"}PdCl_2\text{"} + CO \longrightarrow$$

I

$$-Pd-\overset{O^-}{\underset{\|}{C}}-\overset{P^+(C_6H_5)_3}{\underset{|}{N}}-C_6H_5 \xrightarrow{-OP(C_6H_5)_3}$$

$$[C_6H_5N{=}P(C_6H_5)_3]PdCl_2(CNC_6H_5) \xrightarrow[-C_6H_5NC]{CO}$$

II

$$[C_6H_5N{=}P(C_6H_5)_3]PdCl_2(CO) \qquad (1)$$

III

Pd²⁺–isocyanide (II) and –carbonyl (III) complexes. The formation of the isocyanide complex indicates an apparent Wittig-type reaction of the ylide (I) with carbon monoxide coordinated to the palladium. Triphenylphosphine oxide, which is the other typical product of the Wittig reaction, was isolated from the solution.

Complex II is soluble in chloroform and slightly soluble in toluene, while complex III is insoluble in common organic solvents. In dimethyl sulfoxide, III decomposed slowly. The separation of II from III could be achieved by extraction with a mixed solvent of toluene and acetone containing a small amount of chloroform. The analytical data of II and III are in accord with the formula of $PdCl_2$(ylide)L (II, L=C_6H_5NC; III, L=CO). The molecular weight (osmometry in $CHCl_3$) indicates that II is monomeric. The infrared and far infrared spectra of II show strong bands at 2200 and 340 cm^{-1} and a medium absorption at 324 cm^{-1}. Complex III has a strong infrared band at 1900 cm^{-1}. In benzene, III reacted slowly with 2 mol of triphenylphosphine, with the evolution of carbon monoxide, to give $PdCl_2[P(C_6H_5)_3]_2$.

It is noteworthy that $PdCl_2$(COD) itself is inactive to carbon monoxide in benzene.[7] All the systems of "$PdCl_2$" and ylide absorbed carbon monoxide slowly.

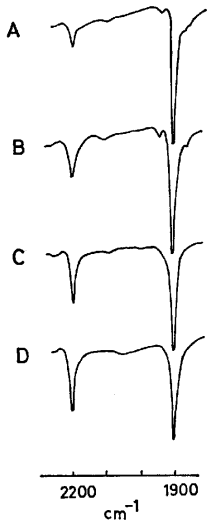

Fig. 1. Typical IR absorptions of ν_{CO} and ν_{CN} of the reaction products obtained from: (A) $PdCl_2$(COD), 27 h; (B) $PdCl_2(C_6H_5CN)_2$, 23 h; (C) $[PdCl_2(styrene)]_2$, 2.5 h. (D) A mixture (1 : 1) of II and III.

* To whom correspondence should be addressed. Present address: Department of Environmental Chemistry and Technology, Faculty of Engineering, Tottori University, Tottori 680.

The absorption continued for 25—30 h. The ratio of II to III depended upon the reaction time. In the early stages of the reaction a considerable amount of II was detected; it was slowly converted into III. Some typical spectra of the reaction products are shown in Fig. 1.

The reaction of II with carbon monoxide is noteworthy. In a toluene solution, II reacted with carbon monoxide to afford III. In the presence of I (I/II$<$1), however, the phenyl isocyanide coordinated to palladium reacted with I under an atmosphere of carbon monoxide to afford diphenylcarbodiimide in a moderate yield.[8] The formation of the carbodiimide was shown by the IR absorptions at 2137 and 2104 (sh) cm^{-1} and by isolating diphenylurea after hydrolyzing it with HCl–AcOH.

Triphenyl(t-butylimino)phosphorane (IV). The IV ylide was allowed to react with carbon monoxide under conditions similar to those described above. The product of the Wittig-type reaction in this case was off-white bis(*t*-butyl isocyanide)palladium chloride (V), which was identified with an authentic sample.[9] The infrared

$$2\,t\text{-}C_4H_9N{=}P(C_6H_5)_3 + 2CO + \text{“}PdCl_2\text{”} \longrightarrow$$
$$\text{IV}$$
$$PdCl_2(CNC_4H_9)_2 + 2OP(C_6H_5)_3 \quad (2)$$
$$\text{V}$$

spectrum coincides completely with that of the authentic sample in the 400—4000 cm^{-1} region. The characteristic bands due to ν_{CN} appear at 2240 and 2260 cm^{-1}. The yield after purification was low, because the separation from triphenylphosphine oxide was difficult (see Experimental). The formation of 2 mol of the isocyanide on palladium shows that basic IV reacts with carbon monoxide more smoothly within the coordination sphere of palladium. In this case, however, the reduction of "$PdCl_2$" with IV occurred competitively and a considerable amount of "$PdCl_2$" was reduced to metal.

Besides V, an insoluble carbonyl complex was also formed. However, it could not identified, because its purification was difficult as a result of poor solubility.

Benzophenone Triphenylphosphazine (VI). In the reaction of VI with carbon monoxide, brown "$PdCl_2$" gradually turned to an insoluble yellow solid. The solid was revealed to be a carbonyl–Pd^{2+} complex (VII).

$$(C_6H_5)_2C{=}N{-}N{=}P(C_6H_5)_3 + \text{“}PdCl_2\text{”} + CO$$
$$\text{IV}$$
$$\longrightarrow [(C_6H_5)_2C{=}N{-}N{=}P(C_6H_5)_3]PdCl_2(CO) \quad (3)$$
$$\text{VII}$$

The analytical data are in accord with VII. The yield was quantitative. The infrared spectrum shows a strong band at 1900 cm^{-1}. Neither isocyanide complex (or Wittig-type product derived from VI) nor triphenylphosphine oxide was detected in the reaction system. From these facts, it is concluded that VI fails to react with carbon monoxide at room temperature. Phosphazine VI, whose negative charge is delocalized, may be represented as follows:[10]

$$R_3P{=}N{-}N{=}C\!\!\prec \longleftrightarrow R_3\overset{+}{P}{-}\overset{-}{N}{-}N{=}C\!\!\prec \longleftrightarrow R_3\overset{+}{P}{-}N{=}N{-}\overset{-}{C}\!\!\prec$$

The lack of reactivity toward the coordinated carbon monoxide may be ascribed to this decreased nucleophilicity.

Other Phosphoranes. No reaction of triphenyl(*p*-tolylsulfonylimino)phosphorane (VIII) with carbon monoxide occurred. The lack of reactivity of VIII may be ascribed to its decreased nucleophilicity, caused by electron-withdrawing sulfonyl group.

$$CH_3\text{–}C_6H_4\text{–}SO_2N{=}P(C_6H_5)_3 \qquad (C_6H_5)_3P{=}C{=}P(C_6H_5)_3$$
$$\text{VIII} \qquad\qquad \text{IX}$$

Hexaphenylcarbodiphosphorane (IX) was allowed to react with carbon monoxide. The brown olefin–palladium complex gradually turned to an insoluble dark green solid which showed infrared bands at 2120 and 1900 cm^{-1}. The former frequency is tentatively assigned to the $\nu_{C\equiv C}$ vibration of $-\overset{|}{\underset{|}{Pd}}-C{\equiv}C-P(C_6H_5)_3$. Triphenylphosphine oxide was isolated from the solution. An analogous reaction has been observed between manganese carbonyl and IX. The absorption band of $Mn(CO)_4Br[C{\equiv}C{-}P(C_6H_5)_3]$ at 2105 cm^{-1} was assigned to the $\nu_{C\equiv C}$ band.[4] The product, which shows the IR band at 2120 cm^{-1}, was relatively stable in the dry state, but exceedingly unstable in solution. All attempts to isolate it in a pure form have been unsuccessful.

Experimental

Materials. The $C_6H_5N{=}P(C_6H_5)_3$[11], $t\text{-}C_4H_9N{=}P(C_6H_5)_3$[12], $(C_6H_5)_2C{=}N{-}N{=}P(C_6H_5)_3$[13], $p\text{-}CH_3C_6H_4SO_2N{=}P(C_6H_5)_3$[14], and $(C_6H_5)_3P{=}C{=}P(C_6H_5)_3$[15] compounds and the palladium complexes were prepared by the known methods. Toluene and benzene were purified by distillation in the presence of benzophenone sodium ketyl and were used under an argon atmosphere. Carbon monoxide (99.5% Matheson Co.) was used without further purification.

General Procedure for the Reactions with Carbon Monoxide. The conventional hydrogenation apparatus under an atmospheric pressure was used. In a round 50-ml flask, ylide, "$PdCl_2$," and toluene (solvent) were placed under an atmosphere of argon. The system was then placed under carbon monoxide by evacuating it by means of an aspirator and by filling it with carbon monoxide several times. Then the flask was shaken under an atmospheric pressure of carbon monoxide at room temperature. After shaking, the resulting solid was filtered off, washed, and dried. Some typical reactions are as follows.

Reaction of I. The ylide (I, 1 mmol) was allowed to react with carbon monoxide in the presence of $[PdCl_2(cyclooctene)]_2$ (0.25 mmol) for 22 h. The solid mass was then extracted with a mixed solvent of toluene, acetone, and chloroform (6:4:1). The subsequent evaporation of the solvent gave II in a 37% yield; mp 99 °C (dec.). Found: C, 58.26; H, 4.27; N, 4.44; P, 4.79%. Calcd for $C_{31}H_{25}N_2PPdCl_2$: C, 58.73; H, 3.95; N, 4.42; P, 4.89%. Complex III (21.6%) remained undissolved; mp 148 °C (dec.). Found: C, 54.20; H, 4.21; N, 2.55; P, 5.30%. Calcd for $C_{25}H_{20}NOPPdCl_2$: C, 53.72; H, 3.58; N, 2.51; P, 5.55%.

Reaction of III with $P(C_6H_5)_3$. III (0.2233 g) was suspended in 2 ml of benzene and was allowed to react with 0.2098 g of $P(C_6H_5)_3$ at a refuxing temperature for 4 h. Filtration gave $PdCl_2[P(C_6H_5)_3]_2$ in a 78% yield (Found: C,

61.65; H, 4.30; P, 8.82%).

Reaction of IV. The reaction of 0.143 g (0.5 mmol) of $PdCl_2(COD)$ with 1 mmol of IV in 10 ml of toluene under carbon monoxide gave gray-green solids after 70 h. After the filtration of the solids, the solution was evaporated to a small volume and ether was added to the concentrated solution. Triphenylphosphine oxide, which was soluble, was removed by this treatment. (In this procedure, a considerable amount of V remained in the solution.) The precipitate, which contained a small amount of the carbonyl compound, was extracted with benzene. The subsequent evaporation of benzene gave pure V; 3 mg (Found: N, 7.23%).

Reaction of VI. The reaction of the VI ylide (1 mmol) with carbon monoxide in the presence of "$PdCl_2$" (1 mmol) for 22 h gave VII in an 80% yield. Found: C, 57.84; H, 3.95; N, 4.46; P, 4.77%. Calcd for $C_{32}H_{25}N_2OPPdCl_2$: C, 58.06; H, 3.78; N, 4.23; P, 4.69.

Reaction of IX. The reaction of ylide IX (1.74 mmol) with "$PdCl_2$" (0.87 mmol) in 10 ml of toluene for 22 h gave 0.436 g of solids, which showed IR absorptions at 2120 and 1900 cm^{-1}.

Studies of Pyrazines. I. Pyrolyses of Substituted Pyrazines and Their Thermal Stabilities

Takeo KONAKAHARA and Yukio TAKAGI

Department of Applied Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received March 9, 1977)

The pyrolyses and thermal stabilities of 2,5-dialkylpyrazines (**1a—e**), 2,5-diethoxypyrazine (**2**), chloropyrazine (**3**), alkoxypyrazines (**4a—c**), alkylthiopyrazines (**5a, b**), and alkylaminopyrazines (**6a—d**) were studied by means of a mass spectrometer, by which the pyrolysates in the sample reservoir were analyzed. The temperature dependence of the molecular ions and/or fragment ions was also discussed. The thermal dehydrogenation from two α-methine groups makes the **1d** molecule thermally sensitive. The other 2,5-dibutylpyrazines were more stable than it, except for the *t*-butyl derivative, **1e**. Hydroxy- and aminopyrazine, **4a** and **6a**, were very stable. The alkoxypyrazines, **4b** and **4c**, and alkylthiopyrazines, **5**, underwent the thermal elimination of olefine to yield hydroxy- and mercaptopyrazine respectively. The latter disproportionated to form dipyrazinyl sulfide (**11**). At 280 °C, no analogous reactions of alkylaminopyrazines **6b—d** could be observed. The relative thermal stabilities of the compounds were as follows:

2, 4a, 6a, 4b>1c>1e>1b>6c, 5a>3>6b>1d>1a>6d, 5b>4c

The chemistry of pyrazine derivatives has been investigated in various kinds of fields.[1] Recently, several new synthetic methods of the pyrazine ring have been reported. Azirines undergo both acid-catalyzed and photochemical dimerization to give pyrazines.[2,3] Many kinds of pyrazines have been prepared from diaminomaleonitrile and its derivatives.[4,5] Both thermal and photochemical transformations of perfluoroalkyl pyridazines to perfluoroalkylpyrazines have been reported.[6,7] On the other hand, it is well known that the pyrazine ring is isomerized to other diazine rings under both photolytic and pyrolytic conditions.[1] Although many kinds of reactions of substituted pyrazines have been reported, it is difficult to find intramolecular γ-hydrogen abstruction reactions analogous to the Norrish Type II reaction of ketones except for a photoreaction of 2-alkylquinolines.[1,6b,8]

In this paper, we wish to report our findings on the thermal behavior of substituted pyrazines (**1—6**), which can be expected to undergo thermal elimination reactions analogous to those of acetates and of *S*-methyl xantates.[9-11] Indeed, pyrazines (**4c**, **5b**) eliminated propylene at a temperature (250 °C) lower than acetates.[9] Some of the others, (**1b—d**, **4b**, and **5a**), were confirmed to eliminate olefines at higher temperatures. The mercaptopyrazine (**10**) produced by thermal decomposition dispropotionates to give dipyrazinyl sulfide (**11**). The thermal stabilities of these compounds were also discussed.

Results and Discussion

Pyrolysis was carried out in an indirect-inlet system of a mass spectrometer under reduced pressure (see Experimental section). In order to minimize the mass-spectral fragmentations of the thermal decomposition products, the low-energy ionization technique was used. The substituted pyrazines, **1—6**, were heated in the vapor phase at 150—280 °C for a constant period (3—5 min), and then the pyrolysates were transferred into an ionization chamber without fractionation. The total ion current was approximately constant throughout the period. The temperature dependence on the molecular ion abundances (Σ_{26} values) are shown in Figs. 1, 3, 4, and 7, and the relative total ion current $I_r^+(t)$, in Table 1. $I_r^+(t)$ was calculated by means of the following Equation (1):

$$I^+(t) = \sum_{i=26}^{n} I_i^+(t)$$

$$I_r^+(t) = I^+(t)/I^+(150) \qquad (1)$$

where $I_r^+(t)$ is the relative abundance of a "*m/e i*" ion in a 16 eV spectrum at *t* °C and where *n* is the highest mass number in the spectrum. If all of the spectra are obtained under the same operating conditions except for the temperature of the sample reservoir, it is obvious that the changes in the spectra (for example, a change in the ion abundance, and the appearance of a new peak) are attributable to a change in the temperature. The operating conditions are shown in the Experimental section. For that reason, the temperature dependence of the molecular ion intensity and of the relative total ion current $I_r^+(t)$ give us information about the thermal reaction and stability of a compound.

Pyrolyses of 2,5-Dialkylpyrazines ***1***. Figure 1 shows the following facts: (i) the molecular ion abundances of the butyl and isobutyl derivatives, **1b** and **1c**,

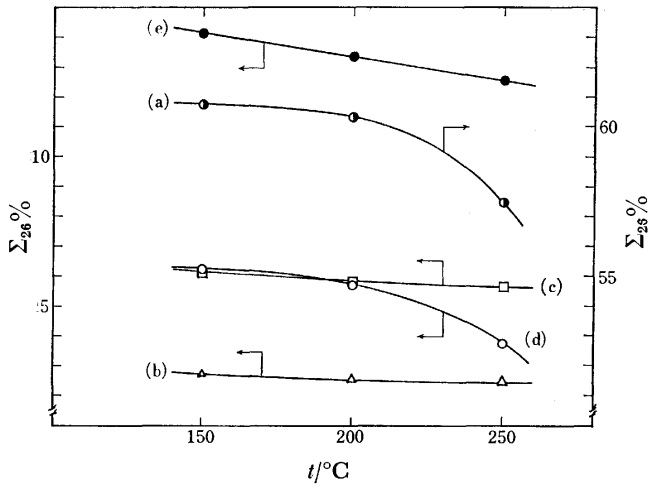

Fig. 1. Temperature dependence of M^+ of 2,5-dialkylpyrazines (**1**) at 16 eV: (a) 2,5-dimethylpyrazine(**1a**), (b) 2,5-dibutylpyrazine (**1b**), (c) 2,5-diisobutylpyrazine (**1c**), (d) 2,5-di-*s*-butylpyrazine (**1d**), (e) 2,5-di-*t*-butylpyrazine (**1e**).

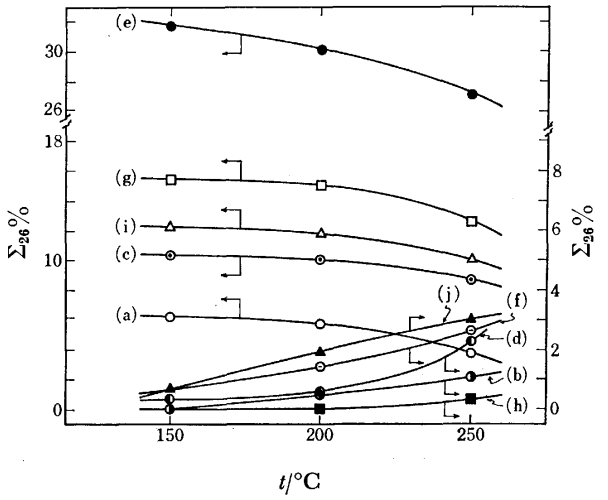

Fig. 2. Temperature dependence of fragment ion abundances of 2,5-di-*s*-butylpyrazine (**1d**): (a) M^+, *m/e* 192.1597 (error −2.8); (b) M−2, 190.1469 (0.0); (c) $M-CH_3$, 177.1391 (0.0); (d) $(M-CH_3)$ −2, 175.1232 (−0.2); (e) $M-C_2H_4$, 164.1306 (−0.6); (f) $(M-C_2H_4)$ −2, 162.1180 (2.4); (g) $(M-C_2H_4)-C_2H_5$, 135.0913 (−0.7); (h) $M-(C_2H_4+C_2H_5)$ −2, 133.0761 (−0.3), (i) $M-C_3H_6$, 150.1142 (−1.3); (j) $(M-C_3H_6)$ −2, 148.0987 mu (−1.2 mmu).

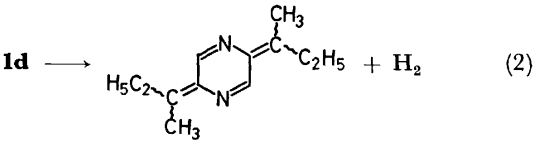
are almost independent of the temperature (150—250 °C), (ii) that of the *t*-butyl derivative (**1e**) decreases slowly with the rise in the temperature, and (iii) those of methyl and *s*-butyl derivatives (**1a**) and **1d**, show a strong temperature dependence at 200—250 °C. These results suggest the thermal unstability of **1a** and **1d**. In order to explain the unstability of **1d**, the temperature dependence of the fragment ions was examined (Fig. 2) and the elemental composition of each ion was determined by means of a high-resolution mass spectrometer. Although the intensity of the molecular ion ($C_{12}H_{20}N_2$, *m/e* 192.1597, error −2.8 mmu) decreases with the rise in the temperature, that of the dehydrogenated ion ($C_{12}H_{18}N_2$, *m/e* 190.1469, error 0.0 mmu) increases. The relative total ion current $I_r^+(t)$ also increases (see Table 1). This suggests that the thermal reaction, Eq. 2, occurs in the sample reservoir before the ionization by electron impact. No thermally induced elimination of ethylene from this compound was



(2)

7

observed at 250 °C (*cf.* Compounds (**4**) and **5**).[13c] In the case of **1a**, however, no increasing ion like (**7**) could be found in spite of the strong temperature dependence of its molecular ion abundance. Therfore, the decrease in the intensity of the molecular ion appears to result from a lack of stabilizing ability of the methyl group.

*Pyrolyses of Chloropyrazine (**3**), Hydroxypyrazine (**4a**), and Aminopyrazine (**6a**).* The temperature dependence of the molecular ions for these compounds is

shown in Fig. 3. Hydroxy- and aminopyrazine, **4a** and **6a**, are independent of the temperature. They are stabilized by the electron-donating substituents, while the electron-withdrawing chloro group makes its molecular ion thermally sensitive. This conclusion is also supported by the data in Tables 1 and 3.

*Pyrolyses of Alkoxypyrazines **4b**, **4c** and Alkylthiopyrazines **5a**, **5b**.* Except for **4b**, the pyrazines, **4c**, **5a**, and **5b**, are more thermally sensitive than the others. The molecular ion abundances of both **4c** and **5b** are especially strikingly decreased at 200—250 °C (Fig. 4). The details are shown in Figs. 5 and 6. In Fig. 5, a molecular ion (*m/e* 138) decreases with the rise in the temperature and almost disappears at 280 °C. On the other hand, the *m/e* 96 ion decreases at 150—250 °C and becomes constant at 250—280 °C. The abundance of the *m/e* 42 ion increases with the rise in the temperature and is constricted to a constant value. The behavior

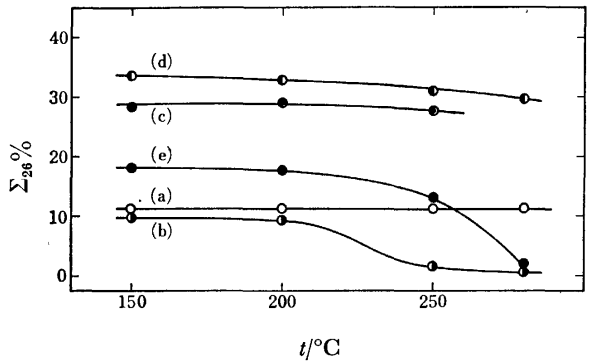

Fig. 4. Temperature dependence of M^+ of (a) ethoxypyrazine (**4b**), (b) isopropoxypyrazine (**4c**), (c) 2,5-diethoxypyrazine (**2**), (d) ethylthiopyrazine (**5a**), and (e) isopropylthiopyrazine (**5b**) at 16 eV.

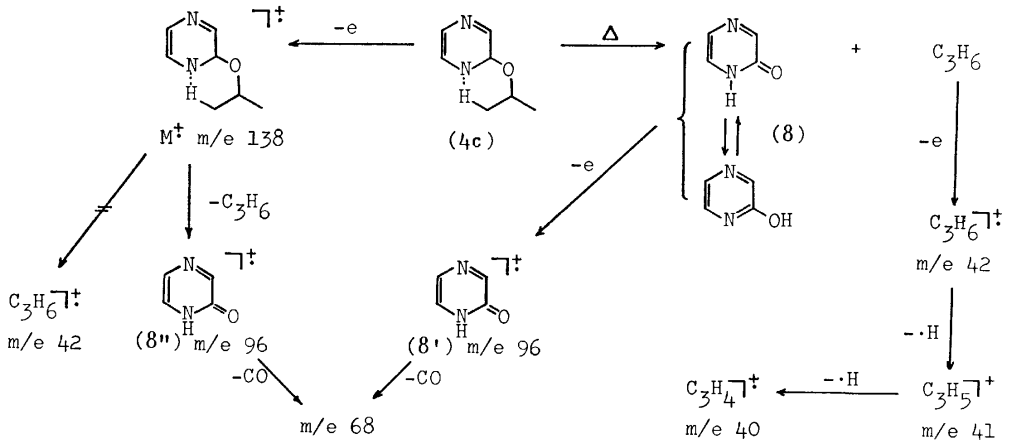

Scheme 1.

of the ions shown in Fig. 5 is explained by means of Scheme 1. In an electron-impact reaction, the abundances of the competing ion products generally reflect their relative ionization potentials (I_p). As the I_p of hydroxypyrazine is smaller than that of propylene, the formation of the ion (**8''**) (charge retention) is more favored than that of propylene ($CH_3CH{=}CH_2^+$/$C_4H_3N_2OH^+$=0.023 at 150 °C).[12] Moreover, hydroxypyrazine is independent of the temperature (Fig. 3). From these facts, it is obvious: (i) that isoproxypyrazine **4c** is thermally decomposed to give hydroxypyrazine **8** and propylene, and (ii) that curve (b) in Fig. 5 is composed of both **8'** and **8''** at 200—250 °C. That is, the low-temperature region is due to **8''** and the high-temperature region, to **8'**. In a kinetic study of the pyrolysis of alkoxypyrazines, it was found that ethoxypyrazine **4b** was decomposed in the same way as **4c**.[13a] Although a similar reaction of 2,5-diethoxypyrazine, **2**, which had two reaction sites, was not observed at these temperatures, it was expected to occur at more elevated temperatures.

A reaction analogous to that of **4c** was also observed in the pyrolysis of isopropylthiopyrazine, **5b**; it is illustrated in Fig. 6 and Scheme 2. Compared with **4c**, this compound showed more drastic changes in the abundances of the ion products, especially in a mass region higher than that of the molecular ion. At 200—250 °C, a new *m/e* 190 peak, the abundance of which was increased by the elevation of the temperature, appeared. It corresponds to the ionized dipyrazinyl sulfide, **11**, produced by the thermal disproportionation reaction of mercaptopyrazine, **10**. This disproportionation reaction was reported by Cheeseman in the pyrolysis of mercaptopyrazine at 220 °C.[14] Curve (b) in Fig. 6 suggests that, in the sample reservoir, most of the molecule of mercaptopyrazine, **10**, is disproportionated so easily that there is no molecule to give the ion radical (**9**) upon electron impact. Ethylthiopyrazine, **5a**, may also be expected to decompose similarly at temperatures higher than 280 °C.

*Pyrolyses of Alkylamino- and Dialkylaminopyrazines (**6b—d**).* As has previously been mentioned, amino-

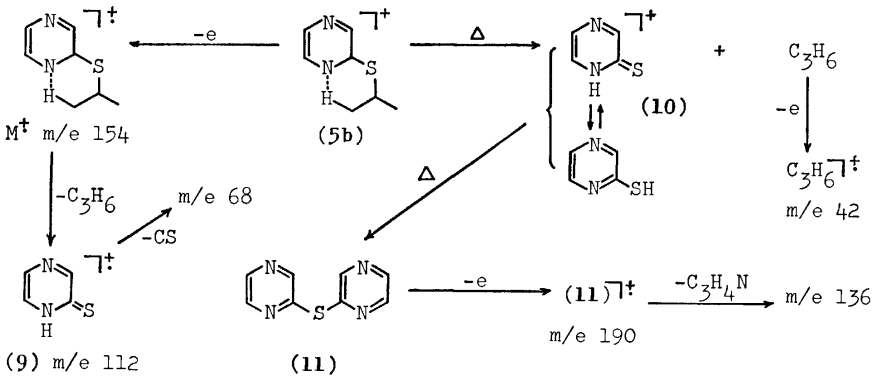

Scheme 2.

pyrazine, **6a**, is thermally stable. Its alkyl derivatives (**6b**—**d**), however, show interesting behavior. Monoalkylation on the amino group destabilizes the molecule more strikingly than dialkylation (see Figs. 3 and 7). This destabilization may be caused by dehydrogenation from the imino and/or alkyl group. The molecular ion abundance of isopropylaminopyrazine (**6d**) is more strongly suppressed at 280 °C than the others. Details of the thermal dehydrogenation from the **6b** and **6d** molecules are shown in Figs. 8 and 9 respectively. The isopropylamino derivative **6d** behaved much like **6b**. Reactions of **6b**, **6c**, and **6d** analogous to that of **4c** were observed at temperatures higher than 280 °C.[13b]

Thermal Stability of Compounds 1—6. Generally, changes in the thermal stability of a series of compounds have been determined by a comparison of half-lives,[15] the amount of evoluted volatile products,[16] the temperatures of the beginning of the evolution of volatile products,[17] and the thermogravimetric curves.[18] From the discussion above, the changes in the ion abundances have proved to be attributable to thermal decomposition reactions. If it is correlated to the reaction temperature, the thermal stability of the compound can be clarified. However, a complete treatment of this subject involves a detailed study of the kinetics of the thermal decomposition reactions, followed by electron-impact reactions, and is very complicated. Therefore, a qualitative treatment was employed in this work. A conversion, α, at a certain temperature is obtained from the following Eq. 3:

$$\alpha = \frac{M(T_0) - M(T)}{M(T_0)} \tag{3}$$

where $M(T)$ is a molecular ion abundance of the pyrazine derivative at T K (see Figs. 1, 3, 4, and 7). When T_0 was 423.15 K, a plot of ln α *vs.* $1/T$ gave a straight line with a negative slope, s. The s values are summarized in Table 3. The most unstable compound, **4c**, showed a small s value (−14.7 kK), and **1c**, more stable than **4c**, a large one (−1.4 kK) (Fig. 10). That is to say, the more unstable a compound is, the smaller the s value is, and *vice versa*. Accordingly, it can be adopted as one of the measures of the thermal stability for the compound. From the data in Table 3, the following order of the thermal stability of the pyrazines **1**—**6** is given:

$$\mathbf{2},\ \mathbf{4a},\ \mathbf{6a},\ \mathbf{4b} > \mathbf{1c} > \mathbf{1e} > \mathbf{1b} > \mathbf{6c},$$
$$\mathbf{5a} > \mathbf{3} > \mathbf{6b} > \mathbf{1d} > \mathbf{1a} > \mathbf{6d},\ \mathbf{5b} > \mathbf{4c} \tag{4}$$

As the molecular ion peaks of **2**, **4a**, **4b**, and **6a** were not affected by the temperature, they were classified into the group of the most stable compound. However,

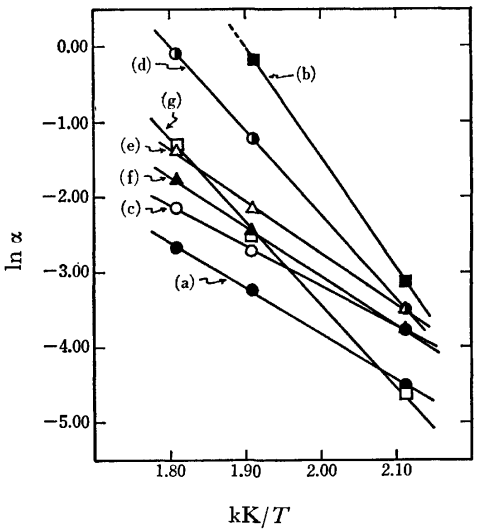

Fig. 10. A plot of ln α *vs.* $1/T$: (a) chloropyrazine (**3**), (b) isopropyrazine (**4c**), (c) ethylthiopyrazine (**5a**), (d) isopropylthiopyrazine (**5b**), (e) ethylaminopyrazine (**6b**), (f) diethylaminopyrazine (**6c**), (g) isopropylaminopyrazine (**6d**). The plot of ln α *vs.* $1/T$ for (**1a**)—(**1e**) was omitted in the Figure.

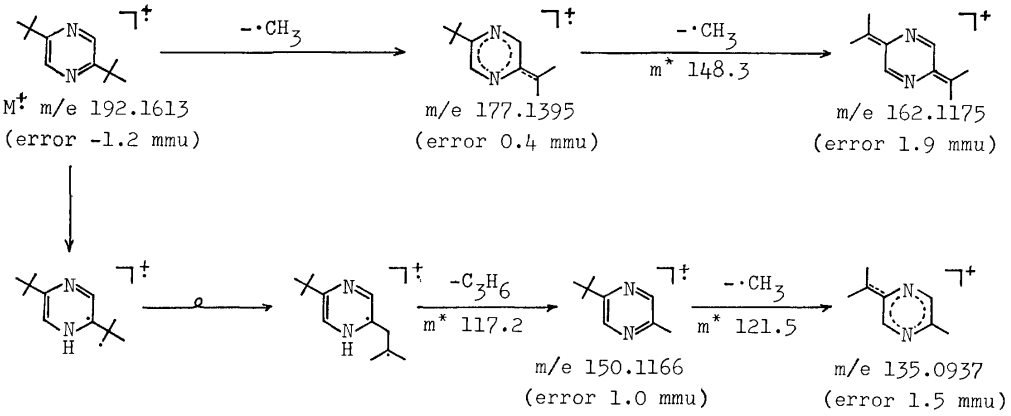
Table 3. Thermal stability of the pyrazines (1)—(6)

Compds	1a	1b	1c	1d	1e	2	3	4a	4b	4c	5a	5b	6a	6b	6c	6d
s/kK[a)]	−9.8	−3.9	−1.4	−8.0	—	−5.7	—	—	—	−14.7	−5.1	−11.2	—	−6.8	−5.0	−11.0

a) s: the slope obtained from $\ln \alpha$ *vs.* $1/T$.



Scheme 3.

4b was decomposed in the same way as **4c**. On the other hand, an attempt to compare the thermal stability of the pyrazines on the basis of the temperature dependence on the $I_r^+(t)$ values in Table 1 was also successful. Although neither $\ln I_r^+(t)$ nor $\ln(I_r^+(t)-1)$ yielded a linear relationship with $1/T$, the order of the thermal stability was obtained by a comparison of $\Delta I(t)$, which was calculated by means of the following Eq. 5.

$$\Delta I(t) = I_r^+(t) - 1 \quad (5)$$

The $\Delta I(250)$ values in Table 1 gave the following order:

$$\mathbf{2, 4a, 6a, 4b} > \mathbf{1c, 3, 1a, 1b, 5a,}$$
$$\mathbf{1e, 6c, 6d} > \mathbf{6b} > \mathbf{1d} > \mathbf{5b} > \mathbf{4c} \quad (6)$$

This is in agreement with the order of (4) except for the cases of **1a** and **6d**. The s value appears to be more suitable for a comparison of the thermal stability of the **1**—**6** pyrazines than $\Delta I(t)$. No theoretical interpretation of the linear relationship between $\ln \alpha$ and $1/T$ can be offered at the present time.

Mass-spectral Reaction. In the mass-spectral fragmentation of **6c**, the McLafferty rearrangement was scarcely observed; this is in contrast with the other cases (except for **1a**, **1e**, **3**, **4a**, and **6a**).[19] This appears to result from a steric effect of the diethylamino group. 2,5-Di-*t*-butylpyrazine, **1e**, produces the rearranged ion ($C_9H_{14}N_2$; *m/e* 150.116; error, 1.0 mmu), which is responsible for the base peak in low-energy spectra at various temperatures. At 70 eV, **1e** loses a methyl radical from one of the *t*-butyl groups to give a base peak.[20] The fragmentation pattern is shown in Scheme 3.

Experimental

All the melting points and boiling points are uncorrected. The melting points were measured with a Meiho micro-melting point apparatus or with a sealed capillary in silicon oil. The ultraviolet spectra were recorded on a Hitachi EPS-3T spectrophotometer. The infrared spectra were recorded on a Hitachi EPI-G2 type spectrometer. The NMR spectra were recorded with either a JNM 4H-100 or a Varian A-60 spectrometer for solutions in deuteriochloroform, carbon tetrachrolide, or deuterium oxide. The chemical shifts are reported in δ(internal tetramethylsilane). The unpublished UV and NMR data are summarized in Table 3. The analitycal GLC determinations were carried out with a Shimadzu GC-4APF apparatus using a 2 m by 4 mm glass column of 10% Silicon GE SE-30 liquid phase on Shimalite W support (60—80 mesh). Elemental analyses were performed at the Institute of Physical and Chemical Research.

Mass Spectra and Pyrolyses of the Compounds. Both normal and high-resolution mass spectra were recorded with a Hitachi RMU-7M double-focusing mass spectrometer at 70 eV. The pyrolyses of the compounds were performed in the indirect inlet system of this instrument. Both a liquid and a solid sample were vaporized at 100 °C under a highly reduced pressure and were transferred into a sample reservior heated previously, in which the gaseous sample was then heated at 150, 200, 250, and 280 °C at 10^{-4}—10^{-5} mmHg for a constant period (3—5 min). An equilibrium mixture of the pyrolysate was introduced into an ionizing chamber through a transfer line heated at the same temperature as the reservior. All of the inlet system was made of Pyrex glass, and a gold orifice (Q_o=0.3 ml/s, molecular leak) was used as the gas leak. The operating conditions in this experiment were fixed as follows: ionizing voltage, 16 eV; chamber temperature, 170 or 200 °C; target current, 10 or 13 μA; total emission current, 10, 12, or 13 μA.

Materials. 2,5-Dimethylpyrazine (**1a**),[21] 2,5-di-*s*-butylpyrazine (**1d**),[22] 2,5-di-*t*-butylpyrazine (**1e**),[20] 2,5-diethoxypyrazine (**2**),[23] and chloropyrazine (**3**)[24] were prepared by known methods.

Hydroxypyrazine (4a): The direct synthetic method devised by Karmas and Spoerri was employed.[24] Both the effect of the reaction temperature and of the addition velocity of alkali on the yield were examined.[25] In consequence, it was found that the following procedure gave the highest yield (the technique was substantially that of Karmas and Spoerri).[24] A solution of glycine amide hydrochloride (22.2 g, 0.2 mol) and water (40 ml) in methanol (400 ml) was stirred at −30——40 °C while a 40% glyoxal solution (34.8 g, 0.24 mol) was added rapidly. The mixture was then cooled at −50——60

°C, and 12.5 M sodium hydroxide (0.50 mol) was added, drop by drop, over a period of 55—60 min. After an additional stirring for 1 h at this temperature, the mixture was stirred at room temperature for 4 h. Then it was treated by the same way as before.[24] The lower the temperature, the higher the yield, unless the reaction mixture was solidified. It was solidified at a temperature lower than −60 °C. On the other hand, the maximum yield was obtained when alkali was added over a period of 55—60 min. Recrystallzation from ethanol using activated carbon was employed instead of purification with silver acetate. The purity of the product, determined by means of its UV spectrum, was 96% (corrected yield, 61%; mp 180 °C; lit,[24] 51%, 188—190 °C). This was used without further purification to prepare chloropyrazine **3**.

*2,5-Dibutylpyrazines (**1b**, **c**)*: The method of Newbold and Spring was applied.[22] The yields and physical properties are shown in Table 2.

*Alkoxypyrazines (**4b**, **c**)*: The following general procedure was used.[26] Chloropyrazine **3** (4 g, 0.035 mol) was added, drop by drop, into a stirred alcoholic solution of sodium alkoxide RONa (R=C_2H_5, *i*-C_3H_7) (from 1.6 g of sodium and 32 ml of the corresponding absolute alcohol), after which the mixture was heated under reflux for 1 h. After cooling, the mixture was poured into a saturated aq sodium chloride solution (200 ml) and then completely extracted with ether. The dried (Na_2SO_4) and evaporated extract was then distilled under reduced pressure (see Table 2).

*Alkylthiopyrazines (**5a**, **b**)*: The following general procedure was used. A solution of 0.045 mol of alkyl thiol RSH (R=C_2H_5, *i*-C_3H_7) and sodium hydroxide (1.9 g, 0.045 mol) in absolute ethanol (20 ml) was heated to boiling and then cooled. Chloropyrazine **3** (5.1 g, 0.045 mol) was subsequently added cautiously with stirring. The mixture was then refluxed for an additional 30 min. After cooling, the mixture was poured into a satulated aq sodium chloride solution (150 ml) and then extracted completely with ether. The dried (Na_2SO_4) and evaporated extract was distilled under reduced pressure (see Table 2).

*Aminopyrazine (**6a**)*: This was prepared by Erickson and Spoerri's method.[26] The crude product was purified by sublimation under reduced pressure (75—80 °C at 1.5 mmHg). Yield, 81%; mp 119 °C (lit,[26] 80%, 118—120 °C).

*Ethylaminopyrazine (**6b**) and Isopropylaminopyrazine (**6d**)*: These substances were prepared by an application of Cheeseman's method.[14] Chloropyrazine **3** (2 g, 0.017 mol), 70% aq ethylamine (or isopropylamine) (0.096 mol), and ethanol (10 ml) were used (see Table 2).

*Diethylaminopyrazine (**6c**)*: Diethylamine (7 g, 0.096 mol) and chloropyrazine **3** (2 g, 0.017 mol) in ethanol (15 ml) were heated in a sealed tube at 150 °C for 7 h. The cooled reaction mixture was then poured into 10 ml of *ca.* 8 M NaOH, extracted with chloroform, and washed with water. The dried (Na_2SO_4) and evaporated extract was then distilled under reduced pressure (see Table 2).

$RhCl(PPh_3)_3$-catalyzed Coupling of Diorganomercurials

Kentaro TAKAGI, Naomi HAYAMA, Tadashi OKAMOTO,* Yasumasa SAKAKIBARA,** and Shinzaburo OKA*

College of Liberal Arts and Science, Okayama University, Tsushima, Okayama 700

(Received March 11, 1977)

$RhCl(PPh_3)_3$ has been proved to be an effective catalyst for the reaction of various diorganomercurials to give such coupling products as conjugated diyne, conjugated diene, biaryl, and alkane in good yields under mild conditions. A probable mechanism including the oxidative addition of organomercurials to a rhodium complex and the subsequent reaction of two oxidative-addition adducts to yield the product was presented.

Organomercurials are attractive substrates for organic syntheses,[1] since pure substances, including configurationally pure ones,[2] are easily obtainable. In our previous study of the palladium(0)-catalyzed reaction of organomercurials with acyl halides, the coupling product of organomercurial (R–R) was obtained in a rather large quantity, accompanied by the desired ketone:[3]

$$R_2Hg + R'COBr \xrightarrow{Pd(PPh_3)_4} RCOR' + R\text{–}R \quad \text{(minor product)}$$

As for the decomposition of organomercurials, it is well known that it occurs only at elevated temperatures (generally above 300 °C). In the presence of some transition-metal compounds (Pt, Pd, Ag) the required temperature for the decomposition was lowered, but the conditions were still very drastic.[4] We examined the reaction in detail for the purpose of obtaining the coupling product under mild conditions and found that tris(triphenylphosphine)chlororhodium ($RhCl(PPh_3)_3$) is particularly effective for the reaction. While we have been continuing our study, several papers concerning the palladium-assisted coupling of organomercurials have appeared.[5] Here in this paper we will report the rhodium-catalyzed coupling of organomercurials, which is a more convenient system for the reaction.[6]

Results and Discussion

Reaction Conditions. The decomposition of diphenylmercury was examined with various catalysts and solvents; the results are compared in Table 1. The control experiment showed that a catalyst was essential for the reaction under the conditions examined. The decomposition of $Pd(PPh_3)_4$ occurred, and the reaction was incomplete (Run 1). $RuCl_2(PPh_3)_3$ showed little activity (Run 4). Contrary to palladium or ruthenium complex, $RhCl(PPh_3)_3$ was very effective as a catalyst and biphenyl was obtained quantitatively (Run 5 and Table 2). This implies that two phenyls in diphenylmercury are available for the reaction. Mercury metal was also separated quantitatively. Thus, the stoichiometry of rhodium-catalyzed coupling can be represented by the following equation:

$$(C_6H_5)_2Hg \xrightarrow{RhCl(PPh_3)_3} (C_6H_5)_2 + Hg$$

Table 1. Catalytic coupling of Ph_2Hg[a]

Run	Catalyst	Solvent	Time h	Biphenyl[b] %
1	$Pd(PPh_3)_4$	HMPA	4	13
2	$Pd(PPh_3)_4$	CH_3CN	8	31
3	$Pd(PPh_3)_4$	THF	8	16
4	$RuCl_2(PPh_3)_4$	HMPA	4	1
5	$RhCl(PPh_3)_3$	HMPA	4	100

12[d]	$RhCl(PPh_3)_3$	HMPA	4	10
13[e]	$RhCl(PPh_3)_3$	HMPA	1	8

a) Catalyst; 0.0065 mmol, Ph_2Hg; 0.25 mmol, solvent; 2 ml, temp.; 80 °C, under N_2. b) GLC analysis using an internal standard. c) PPh_3; 0.065 mmol. d) Under air. e) Galvinoxyl; 0.04 mmol.

Amoung the solvents examined, HMPA and acetonitrile gave better results. The reaction was pronouncedly retarded with galvinoxyl or oxygen. Inhibition by excess triphenylphosphine was also observed.

Syntheses of Conjugated Diynes, Conjugated Dienes, Biaryls, and Alkanes. Rhodium-catalyzed coupling was applied to the syntheses of various hydrocarbons. The results are listed in Table 2. In all cases, pure products were isolated with simple treatments. Thus, this catalytic reaction may be valuable for the syntheses of symmetrical conjugated diyne, symmetrical conjugated diene, and biaryl. The case of dibutylmercury was exceptional; the coupling product, octane, was never detected, as is shown in Run 25, although dibutylmercury undoubtedly reacted with the rhodium catalyst, even at room temperature. The red color of the catalyst

Table 2. $RhCl(PPh_3)_3$-catalyzed synthesis of diyne, diene, biaryl, and alkane

immediately changed into black when dibutylmercury was added. Presumably some side reaction, *e.g.* β-elimination of hydrorhodium in the organorhodium intermediate, would occur preferentially. Dibenzylmercury afforded 1,2-diphenylethane only on being heated to an elevated temperature.

Reaction Mechanism. The initial stage of the reaction is probably an oxidative addition of organomercurials to the rhodium catalyst:

$$R_2Hg + RhCl(PPh_3)_2 \longrightarrow \underset{\mathbf{1}}{(R)(RHg)RhCl(PPh_3)_2} \quad (1)$$

There are examples of the oxidative addition of organomercurials to such transition-metal complexes as Pd, Rh, Ir, and Pt.[7] The present result of the supression of the catalytic reaction by the addition of triphenylphosphine supports the idea.[8]

The coupling products are expected to be produced by the reaction of the oxidative-addition adduct(s). There is evidence that the reaction is not such a simple unimolecular demercuration as is shown in Eq. 2, which was suggested by Birch *et al.* for the reaction of Ref. 5a:[9]

$$R_2Hg + Rh \longrightarrow \underset{\mathbf{1}}{R\text{-}Rh\text{-}HgR} \xrightarrow{-Hg} R\text{-}Rh\text{-}R \longrightarrow R\text{-}R + Rh \quad (2)$$

A competitive reaction of an equimolar mixture of diphenylmercury and bis(*p*-tolyl)mercury afforded biphenyl, 4-methylbiphenyl, and 4,4′-dimethylbiphenyl (Table 3). The statistical ratio in diaryls indicates that the catalytic reaction does not follow Eq. 2; if it did, the molar ratio of Ph–Ph: Ph–Tol: Tol–Tol should be 1: 0: 1. Here, it should be noticed that the redistribution between diphenylmercury and bis(*p*-tolyl)mercury does not take place rapidly.[10]

Table 3. Competitive reaction of Ph_2Hg and $(p\text{-Tol})_2Hg$[a]

$$Ph_2Hg + (p\text{-Tol})_2Hg \xrightarrow{Rh} Ph\text{-}Ph + Ph\text{-}Tol\text{-}p + p\text{-}Tol\text{-}Tol\text{-}p$$

Conversion[b] %	Relative mol ratio		
	Ph–Ph	Ph–Tol-*p*	*p*-Tol–Tol-*p*
8	1.3	2.0	0.9
30	1.3	2.0	0.8
90	1.1	2.0	1.0

a) Ph_2Hg; 0.1 mmol, $(p\text{-Tol})_2Hg$: 0.1 mmol, $RhCl(PPh_3)_3$; 0.0065 mmol, HMPA; 2 ml, 80 °C, under N_2. b) Converison based on Ph_2Hg consumed.

At the present time, we propose the next reaction as the most plausible mechanism for the reductive elimination; in this reaction two molecules of **1** yield a coupling product:

$$2\underset{\mathbf{1}}{(R)(RHg)RhCl(PPh_3)_2} \longrightarrow R\text{-}R + 2RhCl(PPh_3)_2 + R_2Hg + Hg \quad (3)$$

Similar "complex" bimolecular reactions yielding organic coupling products are frequently found in organo-transition metal chemistry.[12]

Experimental

Materials. Commercial diphenylmercury and galvinoxyl were used without further purification. The $RhCl(PPh_3)_3$,[13] $RuCl_2(PPh_3)_3$,[14] $Pd(PPh_3)_4$,[15] and bis(2-phenylethynyl)mercury[16] were prepared by previously reported methods. The other organomercurial was prepared from a Grignard reagent and $HgCl_2$ according to a procedure in the literature[17] and was distilled or recrystallized from ethanol or benzene. The solvents were dried over a molecular sieve (3A).

Procedure. Preparation of Biphenyl: In a typical run (Run 5), a solution of diphenylmercury (89 mg, 0.25 mmol), $RhCl(PPh_3)_3$ (6 mg, 0.0065 mmol), and HMPA (2 ml) was stirred at 80 °C for 4 h under nitrogen. After the mercury metal had then been separated by decantation, aqueous sodium chloride (5 ml, 12.5%) was added to the resulting solution, and the organic materials, extracted with 4 ml of ether, were washed with 5 ml of 12.5% aqueous sodium chloride. Then the ether layer was treated with an ether solution of iodine to decompose the unreacted diphenylmercury. Subsequent analysis by GLC (Hitachi Perkin-Elmer F6D, 35% silicon DC 200 on Celite 545, 1 m, 170 °C, 0.5 kg cm^{-2} of N_2) revealed 38.6 mg (0.25 mmol) of biphenyl and a trace amount of iodobenzene. The separated mercury metal, after it had been washed several times with acetone and air-dried, weighed 48.2 mg (0.24 mmol).

Preparation of 1,4-Diphenyl-1,3-butadiyne: A mixture of bis(2-phenylethynyl)mercury (503.5 mg, 1.25 mmol), $RhCl(PPh_3)_3$ (6 mg, 0.0065 mmol), and HMPA (3 ml) was stirred at 50 °C for 1 h under nitrogen. Aqueous sodium chloride (10 ml, 12.5%) was then added to the mixture, and the organic materials were extracted with 10 ml of ether. The aqueous layer was extracted two times with 5-ml portions of ether. After the ether extract had been washed with two 5-ml portions of 12.5% aqueous sodium chloride, the ether was removed under reduced pressure. The purification of the residual solid by column chromatography on silica gel (2 g), using hexane as the eluant, gave 239 mg of 1,4-diphenyl-1,3-butadiyne (94.5%). Mp 86—86.5 °C (lit,[18] 87—88 °C) Found: C 95.13; H, 4.90%. Calcd for $C_{16}H_{10}$: C, 95.01; H, 4.99%.

Preparation of (E,E)-1,4-Diphenyl-1,3-butadiene: A mixture of bis((*E*)-2-phenylethenyl)mercury (101.7 mg, 0.25 mmol), $RhCl(PPh_3)_3$ (4.6 mg, 0.005 mmol), and HMPA (1 ml) was stirred at 70 °C for 1 h under nitrogen. Treatment similar to that described above gave 50.4 mg of (*E,E*)-1,4-diphenylbutadiene (99%). Mp 153.5—154 °C (lit,[19] 153—153.5 °C) Found: C, 93.16; H, 6.86%. Calcd for $C_{16}H_{14}$: C, 93.15; H, 6.85%.

Preparation of 4,4′-Dimethylbiphenyl: A mixture of bis(*p*-tolyl)mercury (574.8 mg, 1.50 mmol), $RhCl(PPh_3)_3$ (46.3 mg, 0.050 mmol), and HMPA (5 ml) was stirred at 80 °C for 4 h under nitrogen. Treatment similar to that above gave 234 mg of 4,4′-dimethylbiphenyl (86%). Mp 121.5 °C (lit,[20] 122 °C). Found: C, 91.97; H 7.86%. Calcd for $C_{14}H_{14}$: C, 92.24; H, 7.76%.

Preparation of 4,4′-Dichlorobiphenyl: A mixture of bis(*p*-chlorophenyl)mercury (635.4 mg, 1.50 mmol), $RhCl(PPh_3)_3$ (46.0 mg, 0.050 mmol), and HMPA (5 ml) was stirred at 80 °C for 5 h under nitrogen. Treatment similar to that above gave 304 mg of 4,4′-dichlorobiphenyl (91%). Mp 147—147.5 °C (lit,[21] 147—148 °C). Found: C, 64.55; H, 3.63%. Calcd for $C_{12}H_8Cl_2$: C, 64.60; H, 3.62%.

Imidazopteridines. I. Synthesis of Imidazo[1,2-*c*]pteridine and Its Alkyl Derivatives

Takashi SUGIMOTO, Keiko SHIBATA, and Sadao MATSUURA

Department of Chemistry, College of General Education, Nagoya University, Chikusa-ku, Nagoya 464

(Received March 25, 1977)

The synthesis of imidazo[1,2-*c*]pteridine and its alkyl derivatives is described. The reaction of 4-aminopteridine with chloroacetaldehyde gave the ring-opened 2-formamido-3-(2-imidazolyl)pyrazine and the isomeric 2-amino-3-(1-formyl-2-imidazolyl)pyrazine but no imidazopteridine. 4-Amino-2-methylpteridine and chloroacetaldehyde similarly gave 2-acetamino-3-(2-imidazolyl)pyrazine in high yield. Hydrolysis of these compounds gave 2-amino-3-(2-imidazolyl)pyrazine, which was used as the key intermediate for the synthesis of the title compounds. Thus it reacted with triethyl orthoformate and homologues to give respectively the parent imidazo-[1,2-*c*]pteridine and its 6-methyl and 6-ethyl homologues. Their 2,3-dimethyl derivatives were prepared likewise from 2-amino-3-(2-imidazolyl)-5,6-dimethylpyrazine, which in turn was prepared from 4-amino-6,7-dimethyl- or 4-amino-2,6,7-trimethylpteridine.

Interest in tricyclic imidazoazines with a bridgehead nitrogen atom has been enhanced by the isolation and structural elucidation of the fluorescent imidazo[1,2-*a*]-purines from baker's yeast ^{Phe}t-RNA[1] and *T. utilis* ^{Phe}t-RNA.[2] Also, imidazo[2,1-*i*]purines[3–8] and analogous systems[9,10] have been studied extensively; several phosphate derivatives of ribofuranosyl imidazo[2,1-*i*]-purine have been found to be active in several enzymatic systems.[4,5]

In continuing our research programs on tricyclic imidazoazines,[2,10,11] we became interested in the chemistry and possible biological activities of hitherto unknown imidazopteridines, since several hydrogenated derivatives of imidazo[1,2-*c*]quinazoline, the 1,4-deaza analogues of imidazo[1,2-*c*]pteridine, have interesting pharmacological activities on the central nervous system.[12,13] In this paper we describe the synthesis of the parent imidazo[1,2-*c*]pteridine (**6a**) and some of its alkyl derivatives (**6b**—**f**).

We first attempted to prepare the unsubstituted imidazo[1,2-*c*]pteridine (**6a**) by condensation of 4-aminopteridine (**1a**) with chloroacetaldehyde. The condensation in water gave several fluorescent compounds, but not the desired imidazopteridine (**6a**). From the mixture, three compounds (**A**, **B**, and **C**) were isolated; the remaining were too little to be isolated Compound **A** with the molecular formula $C_8H_7N_5O$ exhibited weak sky blue fluorescence. Acid hydrolysis of **A** in hot dilute hydrochloric acid afforded the intensely blue fluorescent 2-amino-3-(2-imidazolyl)pyrazine (**5a**). The ^{1}H NMR spectrum of **5a** in trifluoroacetic acid showed a singlet at δ 7.41 for both protons of the imidazole ring and a pair of doublets at δ 7.87 and 8.12 (J=3 Hz) for the protons of the pyrazine ring. The results suggest that compound **A** is a formyl derivative of **5a**, either 2-formamido-3-(2-imidazolyl)pyrazine (**2a**) or 2-amino-3-(1-formyl-2-imidazolyl)pyrazine (**3**). We assigned the structure **2a** to this compound, since its ^{1}HNMR spectrum showed a sharp singlet at δ 7.70 for the imidazole ring protons indicating that the two protons are chemically equivalent, a pair of doublets at δ 8.77 and 8.84 (J=3 Hz) for the pyrazine ring protons, and a singlet at δ 9.12 for the formyl group. The second product (**B**) was found to be the isomer of **A** from elemental analysis and gave **5a** on hydrolysis in dilute hydrochloric acid. The ^{1}H NMR spectrum of **B** showed two pairs of AB doublets at δ 7.27 and 7.42 (J=2 Hz) representing the imidazole ring protons and at δ 8.22 and 8.33 (J=3 Hz) representing the pyrazine ring protons, and a singlet at δ 9.54 for the formyl group. This indicates that the protons of the imidazole ring are no longer equivalent, and hence, compound **B** was assigned as 2-amino-3-(1-formyl-2-imidazolyl)pyrazine (**3**).

The third compound (**C**) was yellow, showing λ_{max} at a wavelength longer than **2a**: the neutral molecule absorbed at 371 nm and the cation at 380 nm (see Table 1). The mass spectrum of **C** exhibited the molecular ion(M) peak at *m/e* 221 and M+2 peak with an intensity about one third of the M peak, suggesting that **C** contains a chlorine atom. From these data and the fact that **C** yielded **5a** on heating in 1 M sodium hydroxide at 70 °C, we determined the compound **C** to be 2-(2-chloroethylideneamino)-3-(2-imidazolyl)pyrazine (**4**), a Schiff base formed by the condensation of **5a** with chloroacetaldehyde. This conclusion was supported by the ^{1}H NMR spectrum, in which the 2-chloroethylidene group appears as a set of a doublet at δ 4.00 (J=2 Hz) and a triplet at δ 6.70 (J=2 Hz), the imidazole ring protons as a sharp singlet at δ 7.55, and the pyrazine ring protons as a pair of doublets at δ 7.91 and 8.03 (J=3 Hz).

The relative yield of the three compounds depends a great deal on the acidity of the reaction solution. In general, when the reaction was carried out in a neutral solution at pH 6—7, **2a** was formed as the main product; in contrast, **4** became predominant in an acidic solution at pH 3—4. In either case, **3** was formed only in a small amount.

4-Amino-6,7-dimethylpteridine (**1c**) reacted similarly with chloroacetaldehyde, yielding 2-formamido-3-(2-imidazolyl)-5,6-dimethylpyrazine (**2c**) in a low yield.

It is obvious that these imidazolylpyrazines (**2a**, **3**, and **2c**) were produced by a ring-opening reaction of the initially formed **6a** or **6d** from 4-aminopteridine (**1a**) or the 6,7-dimethyl homologue (**1c**) with chloroacetaldehyde, respectively. This reaction took place most probably *via* a nucleophilic addition of water to the 6,5-double bond of **6a** or **6d**. We therefore expected that introduction of a blocking methyl group[14] at the

site of the nucleophilic addition would impede ring-opening, and accordingly investigated the reaction of of 4-amino-2-methylpteridine (**1b**) with chloroacetaldehyde in order to obtain 6-methylimidazo[1,2-*c*]-pteridine (**6b**). However, although the reaction was carried out under various conditions, no imidazopter-

b) Measured on a Varian HA-100 NMR spectrometer.

idine was obtained. Instead, only the ring-opened 2-acetamido-3-(2-imidazolyl)pyrazine (**2b**) was obtained in a high yield from **1b** and chloroacetaldehyde. The location of the acetyl group on the amino group, as in **2a**, was confirmed by the ^{1}H NMR spectrum which exhibits a sharp singlet at δ 7.50 for both protons of the imidazole ring (see Table 2).

4-Amino-2,6,7-trimethylpteridine (**1d**) and chloroacetaldehyde similarly gave 2-acetamido-3-(2-imidazolyl)-5,6-dimethylpyrazine (**2d**). Both **2b** and **2d** were converted in high yield into their 2-amino analogues (**5a** and **5b**), respectively, by boiling in dilute hydrochloric acid.

We then used the aminoimidazolylpyrazines (**5a** and **5b**) for the synthesis of imidazo[1,2-*c*]pteridine (**6a**) and its alkyl homologues and found that they are excellent precursors. Heating **5a** in a mixture of triethyl orthoformate and toluene under reflux gave the parent compound (**6a**) in a high yield. The compound was unstable in an aqueous solution, undergoing the ring-opening reaction. The change could be easily monitored by TLC on a Merck silica gel G plate developed by ethyl acetate.

Synthesis of 6-methylimidazo[1,2-*c*]pteridine (**6b**) from **5a** and triethyl orthoacetate required more severe conditions: **5a** was boiled in the ortho ester in the presence of trifluoroacetic acid as a catalyst. In the absence of the catalyst, **5a** was converted only to a small extent into **6b** after prolonged refluxing. Triethyl orthopropionate and **5a** similarly gave 6-ethylimidazo-[1,2-*c*]pteridine (**6c**). Likewise, their 2,3-dimethyl derivatives (**6d**, **6e**, and **6f**) were synthesized by the reaction of **5b** with an appropriate ortho ester. The structures of these imidazo[1,2-*c*]pteridines (**6a**—**f**) were confirmed by elemental analyses, pK_a values (Table 1), UV spectra (Table 1), and ^{1}HNMR spectra (Table 2).

Experimental

The elemental analyses were carried out at the Analytical Section, Faculty of Agriculture, Nagoya University, and at the Analytical Section, Meijo University, Nagoya. The pK_a values were determined by a spectroscopic method and the UV spectra on a JASCO UVIDEC-1 spectrophotometer. The ^{1}H NMR spectra were determined on a JEOL JNM-MH-60 or Varian HA-100 NMR spectrometer with TMS as an internal standard.

*2-Formamido-3-(2-imidazolyl)pyrazine (**2a**) and 2-Amino-3-(1-formyl-2-imidazolyl)pyrazine(**3**).* A solution of 4-aminopteridine[15] (0.50 g) and chloroacetaldehyde (50% aqueous solution, 5 g) in water (150 ml) was kept at 60 °C for 5 h; during this time the solution was maintained at pH 6—7 with sodium acetate. After being chilled in a refrigerator overnight, the solid (0.25 g) was collected by filtration. The solid was extracted with hot ethyl acetate to remove a little insoluble material and then chromatographed on five Merck silica gel 60 PLC plates (20×20 cm) using ethyl acetate as a solvent to give **2a** (150 mg) and **3** (15 mg). The main product (**2a**) melted at 214—215 °C (from ethyl acetate) (Found: C, 50.95; H, 3.57; N, 37.03%. Calcd for $C_8H_7N_5O$: C, 50.77; H, 3.74; N, 37.03%). The isomer (**3**) melted at 228—228.5 °C (from ethyl acetate) (Found: C, 50.62; H, 3.56; N, 36.99%).

*2-(2-Chloroethylideneamino)-3-(2-imidazolyl)pyrazine (**4**).* A solution of 4-aminopteridine (0.50 g) and chloroacetaldehyde (50%, 2 g) in water (150 ml) was kept at 60 °C for 24 h without the addition of alkali for neutralization; the pH of the solution reached *ca.* 3 at the end of the reaction. After neutralization with sodium acetate, the solution was concentrated to *ca.* 30 ml under reduced pressure and chilled to give a solid. Crystallization of the solid from methanol (about 50 ml) gave crude **2a**. The mother liquor was concentrated to *ca.* 10 ml and chilled to give yellow needles (0.18 g) of **4**, mp 173—173.5 °C (from ethyl acetate) (Found: C, 48.78; H, 3.71; N, 31.48%. Calcd for $C_9H_8ClN_5$: C, 48.76; H, 3.64; N, 31.61%).

*2-Formamido-3-(2-imidazolyl)-5,6-dimethylpyrazine (**2c**).* A solution 4-amino-6,7-dimethylpteridine[16] (0.40 g) and chloroacetaldehyde (50%, 20 g) in water (300 ml) was maintained at 60 °C for 10 h. The pH of the solution was adjusted at 6—7 with sodium acetate and then the solution was concentrated to *ca.* 50 ml under reduced pressure. A small amount of solid was removed by filtration and the filtrate was chilled in a refrigerator overnight to give a solid. The solid was purified by preparative layer chromatography (PLC) as above to give almost colorless needles (80 mg) of **2c**, mp 218.5—220 °C (from ethyl acetate) (Found: C, 55.29; H, 4.98; N, 32.22%. Calcd for $C_{10}H_{11}N_5O$: C, 55.29; H, 5.10; N, 32.24%).

*2-Acetamido-3-(2-imidazolyl)pyrazine (**2b**).* A solution of 4-amino-2-methylpteridine[17] (1.0 g) and chloroacetaldehyde (50%, 10 g) in water (200 ml) was heated at 60 °C for 5 h. The solution was neutralized with sodium acetate, concentrated to *ca.* 60 ml under reduced pressure, and chilled to give colorless needles (0.75 g) of **2b**, mp 227—228 °C (from methanol) (Found: C, 53.57; H, 4.48; N, 34.39%. Calcd for $C_9H_9N_5O$: C, 53.19; H, 4.47; N, 34.47%).

*2-Acetamido-3-(2-imidazolyl)-5,6-dimethylpyrazine (**2d**).* Replacement of 4-amino-2-methylpteridine by 4-amino-2,6,7-trimethylpteridine[18] (1.0 g) in the foregoing reaction gave colorless needles (0.76 g) of **2d**, mp 218—219 °C (from methanol) (Found: C, 57.33; H, 5.64; N, 30.08%. Calcd for $C_{11}H_{13}N_5O$: C, 57.12; H, 5.68; N, 30.29%).

2-Amino-3-(2-imidazolyl)pyrazine (5a). A solution of **2b** (200 mg) in 0.1 M hydrochloric acid (20 ml) was heated under reflux for 4 h. The solution was made alkaline with ammonia and chilled to give slightly yellow leaflets (160 mg) of **5a**. The analytical sample was prepared by sublimation at 140 °C/2 mmHg, mp 203—203.5 °C(Found: C, 52.25; H, 4.41; N, 43.64%. Calcd for $C_7H_7N_5$: C, 52.16; H, 4.39; N, 43.46%).

The same compound was obtained in a similar way from **2a** in 92% yield and from **3**. Heating of **4** in 1 M sodium hydroxide at 70 °C for 20 h and subsequent extraction with ether afforded **5a** in 80% yield.

2-Amino-3-(2-imidazolyl)-5,6-dimethylpyrazine (5b). A solution of **2d** (200 mg) in 1 M hydrochloric acid (40 ml) was heated at 80 °C for 4 h. The solution was evaporated to dryness under reduced pressure at *ca.* 40 °C. The residue, dissolved in water (10 ml) and made alkaline with ammonia, gave slightly yellow leaflets (130 mg) of **5b**, mp 226—226.5 °C (sublimed at 140 °C/2 mmHg)(Found: C, 57.23; H, 6.01; N, 37.04%. Calcd for $C_9H_{11}N_5$: C, 57.11; H, 5.87; N, 37.01%).

The same compound was obtained in 93% yield by boiling **2C** (90 mg) in 0.1 M hydrochloric acid (5 ml) under reflux for 4 h, followed by neutralization with ammonia and chilling in a refrigerator.

Imidazo[1,2-c]pteridine (6a). 2-Amino-3-(2-imidazolyl)-pyrazine (80 mg) was dissolved in triethyl orthoformate (60 ml) by gentle heating. After addition of toluene (30 ml), the solution was heated under reflux for 24 h. The solution was evaporated to dryness under reduced pressure and the residue triturated with a small amount of ethyl acetate and filtered. Sublimation of the solid at 180 °C/2 mmHg gave a colorless solid (60 mg), analytically pure **6a**, mp 303—304 °C (dec) (Found: C, 56.25; H, 2.90; N, 40.93%. Calcd for $C_8H_5N_5$: C, 56.13; H. 2.95; N, 40.92%).

6-Methylimidazo[1,2-c]pteridine (6b). To a solution of **5a** (65 mg) in triethyl orthoacetate (20 ml) was added trifluoroacetic acid (30 μl). The solution was heated under reflux for 2.5 h. After cooling, the solution was diluted with acetone (60 ml), treated with Dowex 1X2 anion exchange resin(OH form) for neutralization, and then evaporated to dryness under reduced pressure. The residue was triturated with cold ethanol (2 ml) and filtered to give colorless needles (45 mg) of **6b**, mp 278—279 °C (dec)(sublimed at 180 °C/2 mmHg)(Found: C, 58.42; H, 3.87; N, 37.72%. Calcd for $C_9H_7N_5$: C, 58.36; H, 3.82; N, 37.82%).

6-Ethylimidazo[1,2-c]pteridine (6c). Aminoimidazolyl-pyrazine(**5a**)(160 mg), trifluoroacetic acid (160 μl), and triethyl orthopropionate (30 ml) were heated under reflux for 7 h. After dilution with acetone (100 ml) and neutralization with Dowex 1X2 resin as above, the solution was evaporated to dryness under reduced pressure. The residue was crystallized from ethyl acetate to give colorless prisms (155 mg) of **6c**, mp 184—184.5 °C (sublimed at 155 °C/2 mmHg)(Found: C, 60.58; H, 4.52; N, 35.16%. Calcd for $C_{10}H_9N_5$: C, 60.28; H, 4.52; N, 35.16%).

2,3-Dimethylimidazo[1,2-c]pteridine (6d). A solution of **5b** (100 mg) in triethyl orthoformate (10 ml) and toluene (30 ml) was heated under reflux for 9 h. Evaporation to dryness under reduced pressure and subsequent crystallization from toluene gave colorless needles (99 mg) of **6d**, mp 304—305 °C (dec)(sublimed at 200 °C/2 mmHg)(Found: C, 59.90; H, 4.56; N, 35.38%. Calcd for $C_{10}H_9N_5$: C, 60.28; H, 4.52; N, 35.16%).

2,3,6-Trimethylimidazo[1,2-c]pteridine (6e). A solution of **5b** (65 mg) in a mixture of triethyl orthoacetate (30 ml) and trifluoroacetic acid (50 μl) was heated under reflux for 6 h. Dilution with acetone (50 ml), neutralization with Dowex 1X2 resin, and evaporation to dryness under reduced pressure gave a solid. The solid was crystallized from ethanol to give colorless needles (47 mg) of **6e**, mp 308—309 °C (dec)(sublimed at 195 °C/2 mmHg)(Found: C, 62.01; H, 5.28; N, 32.61%. Calcd for $C_{11}H_{11}N_5$: C, 61.94; H, 5.21; N, 32.84%).

6-Ethyl-2,3-dimethylimidazo[1,2-c]pteridine (6f). A solution of **5b** (320 mg) and trifluoroacetic acid (300 μl) in triethyl orthopropionate (30 ml) was heated under reflux for 5 h. The solution was chilled to give slightly brown prisms (280 mg) which were collected by filtration and washed with ether. The prisms were then dissolved in cold ethanol and treated with Dowex 1X2 anion exchange resin (OH form) till the solution became neutral. After removal of the resin by filtration, the filtrate was evaporated to dryness under reduced pressure and the residue was triturated with a little ether. The solid was collected by filtration and sublimed at 160 °C/2 mmHg to give colorless needles (250 mg) of **6f**, mp 235—235.5 °C(Found: C, 63.50; H, 5.84; N, 30.96%. Calcd for $C_{12}H_{13}N_5$: C, 63.41; H, 5.78; N, 30.82%).

We thank Miss N. Itoh for measuring the pK_a values and UV spectra, Dr. D. Uemura for measuring the 100 MHz ^{1}HNMR spectra, and Prof. T. Sakaki for his interest in this work. We are also grateful to Dr. D. J. Brown, Australian National University, for his disucssion.

Preparation and the Properties of π-Allylic Palladium(II) Complexes of Amino Acid

Yoshihiro NAKAGAWARA, Kiyoshi KIKUKAWA, Makoto TAKAGI, and Tsutomu MATSUDA

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received March 29, 1977)

The preparation of π-allylic and related organopalladium(II) complexes with amino acid anions as bidentate ligands is described. The complexes were characterized by means of ^{1}H NMR.

In a previous communication[1] we reported a variable-temperature ^{1}H NMR spectral survey of π-allylic palladium complexes of α-amino acid without giving details of the preparation of the complexes. Some complexes were later found to show an interesting catalytic activity in oligomerizing butadiene preferentially to tetramers.[2] We report herewith on the preparation and characterization of the metal complexes concerned.

Results and Discussion

The principle in preparing the complexes was to displace the di-μ-chloro bridge of dimeric organopalladium complexes by bidentate and chelating amino acid anions. The latter was used as silver salts. After publication of our communication, Benedetti *et al.*[3] reported the preparation of similar amino acid complexes, in which potassium salts of amino acids were utilized. The alkali metal salts can not always be prepared. However, the corresponding silver salts are readily available. Thus the use of the latter salts is preferable for the present study. The π-allylic palladium complexes prepared are given in Table 1 along with the ^{1}H NMR chemical shifts of allylic protons. The aryl- or alkylpalladium(II) amino acid complexes of similar type could also be

a) When signals were broad or no definite assignment could be made, the region where the signals appeared is indicated. Coupling constants between the central and terminal protons were 6.5—7.5 Hz and 11—12.5 Hz for *syn* and *anti* positions, respectively. Geminal couplings of the terminal protons were $\lesssim$1 Hz. b) Amino acids are of natural (L-) configuration. Bz-Ala, *N*-benzoylalaninate; Cbz-Gly, *N*-benzyloxycarbonylglycinate; Bzl-Ala, *N*-benzylalaninate; 6-MP, 6-methylpicolinate; BTA, (benzylthio)acetate. c) M, CD_3OD; C, $CDCl_3$. d) The methyl group is in *anti* position.

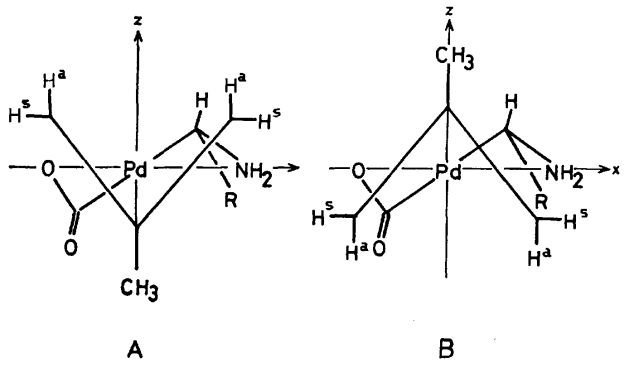

Fig. 1. Schematic view of [π-(2-methylallyl)]Pd(II) complex of α-amino acid.

prepared, including those derived from *N,N*-dimethylbenzylamine-,[4] *N*-benzylideneaniline-[5] or methoxydicyclopentadiene[6]-palladium(II) chloride (see Experimental).

Figure 1 shows a schematic picture of π-(2-methylallyl)palladium complex of amino acid as viewed down Cartesian y axis. Because of the "ligand atom effect" and "chirality effect,"[1] the four front octants in which allylic protons H^s and H^a are placed should differ from each other in their magnetic environment. If the relative configuration of the allylic ligand and the amino acid ligand is fixed as in pictures A and B, then four *anti* proton signals as well as the same number of *syn* proton signals should be observed. The low temperature ^1H NMR at 90 MHz was studied for π-(2-methylallyl)-palladium glycinate (**8**), alaninate (**9**) and prolinate (**11**) complexes at temperatures between 0 and −90 °C. No further change in spectral pattern was observed by lowering the temperature below −40 °C in line with the previous study at 60 MHz. However, the signals were sharpened, and additional small splittings (1—3 Hz) were disclosed. A schematic representation of the experimentally observed spectra is given in Fig. 2 for selected signals. Splittings of *syn* or *anti* proton signal(s) into four signals or less for **9** and **11** are in line with the expectation that the relative configuration of the two ligands on the metal is fixed at low temperature, and all or at least three out of the four front octants differ from each other in their magnetic environment. Examination of intensities of the signals reveals that the relative population of configuration A and B are equal. This is reasonable since no direct steric or dipolar interaction can be expected between the coordinated allylic ligand and the amino acid ligand. Glycinate complex **8** gave the splitting of *syn* and *anti* proton signals (which are singlets at room temperature) into doublets, but the absence of chirality in the glycine molecule allowed no further splitting. The freezing of the chelate ring conformation of the glycine ligand might have occurred at low temperature (−90 °C), but the effect was not sufficient to bring about measurable splittings of the signals.

The dynamic process as revealed by the temperature-dependent ^1H NMR signals was most satisfactorily rationalized either by π-allyl rotation[1] or base assisted N,O-ligand atom exchange of amino acid ligand.[1,7] No

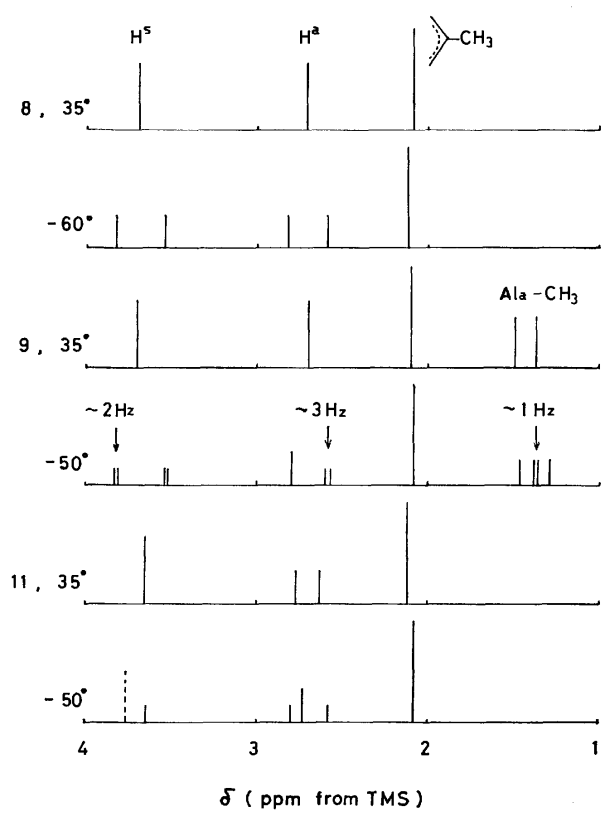

Fig. 2. A schematic representation of selected proton signals observed for π-allylic complexes. Low temperature spectra (−50, −60 °C) were obtained at 90 MHz, and those at 35 °C were at 60 MHz.

effect of the complex concentration[7] on the spectral shape was observed, indicating that the process is unimolecular with respect to the complex. Preference of the π-allyl rotation as a plausible mechanism is suggested. However, the possibility that the solvent molecule (methanol-d_4) acts effectively as base and that the process is the N,O-ligand atom exchange can not be excluded. As to the ^1H NMR behavior of other π-allyl- or π-(2-methylallyl)palladium complexes (Table 1), most of them seem to be grouped into one of the three typical types (Fig. 2). Complex **13** shows a complicated temperature-dependent behavior, rejecting simplified spectral interpretation.

Experimental

General. The ^1H NMR spectra were obtained with a Varian A-60 spectrometer at 60 MHz and a Hitachi R-22 spectrometer at 90 MHz. Natural (L-) amino acids and their derivatives were used. π-Allylic palladium(II) chloride complexes were prepared according to the reported procedures[8] and used as obtained or after purification by column chromatography.

Silver Salts of Amino Acid. The general procedure for the preparation of the salts is as follows. Silver nitrate (1 mmol) dissolved in water or aqueous methanol was added under stirring to an equimolar mixture (1 mmol each) of lithium hydroxide monohydrate and an amino acid in a similar solvent. Silver salt precipitated as withe powder. The solvent was chosen considering the solubility of the starting material and the product. For silver salt easily

hydrolyzable in water (typically, those of proline, *N*-phenylglycine and tryptophan), 80—90% methanol was used. For the stable salts (*e.g.*, those of glycine and β-phenylalanine), water was used. In each case the use of minimum amount of the solvent was preferred. Yields were 60% to quantitative.

π-Allylic Palladium(II) Complexes of Amino Acid. The complexes were prepared according to the following general procedure. π-Allylic palladium(II) chloride (1 mmol) was stirred with the suspension of excess silver salt of amino acid (3 mmol) in methanol or chloroform (20—40 ml) in the dark until the yellow coloration due to the starting complex disappeared (5—20 min). Filtration and concentration of the reaction mixture followed by gradual addition of ether produced the amino acid complex as pale yellowish crystalline powder. Yields were 60% to quantitative. The product was in most cases analytically pure, but in some cases reprecipitation was needed for further purification after treatment with decolorizing charcoal. The stable complexes could be purified by recrystallization. Numerous complexes other than those given in Table 1 were also prepared according to the procedure outlined above. The complexes of Phe were the most stable, while those containing Pro were air-sensitive, the manipulation of the solution being preferably carried out under dry nitrogen. The proline complexes could not be stored more than a week. The elemental analyses of the complexes were statisfactory except for a few cases. No analyses were made for **12** and **17**. The IR and NMR spectra are in line with the composition and structure of the complexes. Details for the selected complexes are given in the following. **4.** π-Allylpalladium(II) chloride[8] was reacted with silver salt of Phe in methanol. The complex was recrystallized from water or water containing a small amount of ethanol, yield 73—95%, dec 160—175 °C, $\nu_{C=O}$ 1600 cm^{-1}. NMR for Phe (δ, ppm from TMS; D_2O): 2.2—2.6 (t, J=5.0 Hz, >CH–), 3.31 (d, J=5.0 Hz, –CH_2–), 7.75 (s, –C_6H_5). Found: C, 46.24; H, 4.76; N, 4.52%. Calcd for $C_{12}H_{15}NO_2Pd$: C, 46.25; H, 4.85; N, 4.49%. **9.** π-(2-Methylallyl)palladium(II chloride[8] was reacted with silver alaninate in chloroform, yield 80—87%, dec 138—150 °C, MW (vapour pressure osmometer) 236 (Calcd: 249.6), $\nu_{C=O}$ 1603 cm^{-1}. NMR for Ala (CD_3OD): 3.54 (q, J=7.0 Hz, >CH–), 1.41 (d, J=7.0 Hz, –CH_3). Found: C, 33.04; H, 5.21; N, 5.54%. Calcd for $C_7H_{13}NO_2Pd$: C, 33.69; H, 5.25; N, 5.61%. **11.** π-(2-Methylallyl)palladium(II) chloride[8] was reacted with silver prolinate in chloroform, yield 60—90%, dec 110—138 °C, MW 294 (Calcd: 275.6), $\nu_{C=O}$ 1608 cm^{-1}. NMR for Pro (CD_3OD): 1.7—2.2(m, C–CH_2CH_2–C), 3.1—3.4 (m, N–CH_2–C), 3.7—3.9 (m, >CH–). Found: C, 39.00; H, 5.41; N, 5.01%. Calcd for $C_9H_{15}NO_2$-Pd: C, 39.22; H, 5.49; N, 5.08%. **15.** The silver salt of BTA was obtained as white precipitate from aqueous reaction mixture. The reaction with π-(2-methylallyl)palladium(II) chloride[8] was carried out in chloroform, yield 76%, dec 110—125 °C, $\nu_{C=O}$ 1634 cm^{-1}. NMR for BTA ($CDCl_3$): 3.47 (s, benzyl-CH_2–), 4.08 (s, –$COCH_2S$–), 7.38 (s, –C_6H_5). Found: C, 45.69; H, 4.70%. Calcd for $C_{13}H_{16}O_2PdS$: C, 45.56; H, 4.71%. π-(1-Ethoxycarbonylallyl)palladium(II) glycinate. π-(1-Ethoxycarbonylallyl)palladium(II) chloride[8] was reacted with silver glycinate in methanol, yield 80—97%, dec 150—160 °C, $\nu_{C=O}$ 1600, 1620 cm^{-1}. Found: C, 32.73; H, 4.33; N, 4.95%. Calcd for $C_8H_{13}NO_2Pd$: C, 32.73; H, 4.33; N, 4.77%. The complex is stable at room temperature. Other complexes. *o*-(Dimethylaminomethyl)-phenylpalladium(II) alaninate. The organopalladium chloride[4] was reacted with silver alaninate in chloroform in the usual way, white crystalline powder, yield 97%, $\nu_{C=O}$ 1625 cm^{-1}. NMR (CD_3OD): 6.8—7.0 (m, Ar–H), 3.88 (s, benzyl CH_2), 3.57 (q, J=7.0 Hz, –CH–), 2.79 (s, N–CH_3), 1.49 (d, J=7.0 Hz, C–CH_3). Found: C, 42.82; H, 5.58; N, 8.47%. Calcd for $C_{12}H_{18}N_2O_2Pd$: C, 42.85; H, 5.52; N, 8.52%. 3a,4,7,7a-Tetrahydro-*exo*-6-methoxy-*endo*-4,7-methanoindene-*endo*-5σ,2π-palladium(II) alaninate. The organopalladium(II) chloride[6] was reacted with silver alaninate in methanol. Manipulation under nitrogen produced white powder, yield 88%, $\nu_{C=O}$ 1632, ν_{C-O} 1090 cm^{-1}. NMR for Ala (CD_3OD): 3.3—3.6 (q, >CH–), 1.58 (d, J=7.5 Hz, –CH_3). The signals for the π-enyl moiety were similar to those of the chloride complex.[6]

The authors' acknowledgements are due to Prof. Y. Tsuno and Dr. M. Mishima, Faculty of Science, Kyushu University, for the measurement of low temperature ^{1}H NMR spectra.

Reactions of Thiocarboxylic Acids with Oximes and Nitrones. A New Synthesis of Thiones

Kazuhiko KIMURA, Hiroaki NIWA, and Shinichi MOTOKI

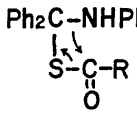
Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received March 29, 1977)

The reactions of ketone derivatives containing carbon-nitrogen double bond such as oximes (**3**), *N*-alkyloximes (nitrones, **11**), oxime *O*-alkyl ethers, phenylhydrazones and semicarbazones with thiocarboxylic acids were studied for the purpose of preparing thioketones. Both **3** and **11** reacted with thiocarboxylic acids to give thioketones in good yields. The reaction did not proceed in the cases of other ketone derivatives, the starting materials being recovered. The reaction of benzophenone oxime with thiobenzoic acid gave thiobenzophenone, dibenzoyl disulfide and ammonium benzoate, while that of benzophenone-*N*-methylnitrone with thioacetic acid gave thiobenzophenone and *N*-acetyl-*N*-methylhydroxylamine. The mechanisms of these reactions are presented.

Various procedures for the preparation of thiones including the thionation of ketones by hydrogen sulfide or phosphorus pentasulfide have been worked out.[1,2] Conversion of ketodichlorides[3] or ketimines[4] (Scheme 1) into thiones by the action of thiocarboxylic acids have been used for preparing diaryl or heterocyclic thiones. We were interested in these simple synthetic methods using thiocarboxylic acids and have examined the reaction of more readily available derivatives of ketones such as oximes, nitrones, hydrazones, and semicarbazones with thiobenzoic (**1**) or thioacetic acid (**2**).

$$Ph_2C{=}NPh + RCOSH \longrightarrow$$



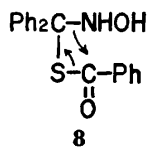
$$\longrightarrow Ph_2C{=}S + RCONHPh \quad (1)$$

Results and Discussion

When benzophenone oxime (**3a**) was mixed with an equimolar amount of **1** in benzene at room temperature, thiobenzophenone (**4a**) was obtained in low yield after being left to stand for 3 days. However, ammonium benzoate (**5**) and dibenzoyl disulfide (**6**) were formed as by-products instead of benzohydroxamic acid (**7**) which was expected to be formed according to the following scheme. Since **7** does not react with **1**, **3a**

$$Ph_2C{=}NOH + PhCOSH \longrightarrow$$

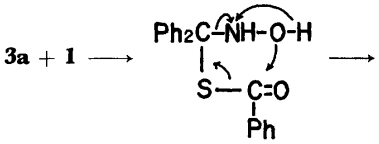
3a **1**



$$\longrightarrow Ph_2C{=}S + PhCONHOH \quad (2)$$

4a **7**

8



$$Ph_2C{=}S + H_2NOCPh \quad (3)$$

4a **9**

or **4a** to form **5** or **6** under the same reaction conditions, another pathway involving intramolecular nucleophilic attack of oxygen to carbonyl carbon followed by proton transfer in the intermediate (**8**) to form **4a** and *O*-benzoylhydroxylamine (**9**) has been considered. *O*-Acylhydroxylamines react readily with various nucleophiles at nitrogen atom to form carboxylate ion.[5,6]

$$RCO_2NH_2 + :Nu \longrightarrow RCO_2^- + NH_2Nu \quad (4)$$

It seems probable that a portion of **1** in the reaction mixture would react as nucleophile with **9** to afford **5** and **6** as follows. If these steps take part in the reaction

$$\mathbf{9} + \mathbf{1} \longrightarrow PhCO_2H + (PhCOSNH_2)$$
$$(PhCOSNH_2) + \mathbf{1} \longrightarrow \mathbf{6} + NH_3$$
$$PhCO_2H + NH_3 \longrightarrow \underset{\mathbf{5}}{PhCO_2NH_4} \quad (5)$$

and proceed relatively rapid, overall reaction would be as follows. Support for this proposal is supplied by the

$$Ph_2C{=}NOH + 3PhCOSH \longrightarrow$$

3a **1**

$$Ph_2C{=}S + PhCO_2NH_4 + PhCOSSCOPh \quad (6)$$

4a **5** **6**

fact that **9** prepared from *p*-nitrophenyl benzoate and hydroxylamine reacts with 2 mol of **1** at room temperature to give **5** and **6** and that the yield of **4a** increases to *ca.* 80% by using over 3 mol of **1** (Table 1). The other ketoximes reacted similarly to give the corresponding thiones in relatively good yields. The results are given in Table 2.

Table 1. Relation of molar ratio (thiobenzoic acid (**1**)/oximes) and yield of thiobenzopehnone (**4a**)

Molar ratio	1	2	3
Yield of **4a** (%)	30	50	78

The reactions of ketoximes with thioacetic acid (**2**) proceeded rapidly to give thioketones and acetamide along with a small amount of diacetyl disulfide. No ammonium acetate was obtained.

No reaction took place with **1** and benzophenone oxime *O*-methyl ether (**10**), which structurally cannot cause proton transfer in the intermediate.

Nitrones were found to react with thiocarboxylic acids much more readily than oximes. When benzo-

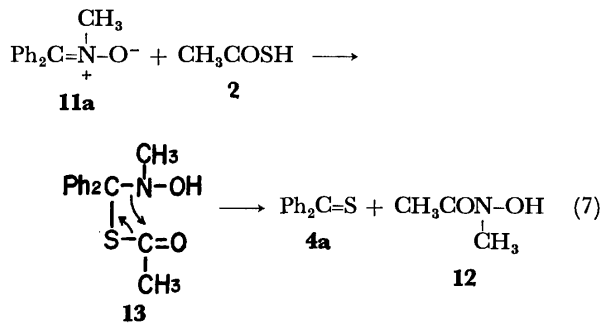
phenone-*N*-methylnitrone (**11a**) was allowed to react with **2**, **4a** and *N*-acetyl-*N*-methylhydroxylamine (**12**) were obtained.* The latter was identified by elementary analyses and comparison of its IR spectra with those of an authentic sample. Thus, the reaction is considered to proceed by intramolecular nucleophilic attack of nitrogen on carbonyl carbon in the intermediate (**13**)



* The reactions of **11** with **1** proceeded similarly, but gave unsatisfactory results in the yield and purity of **4**.

as in the case of Scheme 1. The other thiones were obtained similarly (Table 3).

The cause of such differences in the mechanisms of the reaction of oximes and nitrones has not been clarified.

Phenylhydrazones and semicarbazones did not react with thiocarboxylic acids even in refluxing benzene, the starting materials being recovered. In these compounds, the following resonance effects may markedly lower the reactivity of imino carbon toward uncleophilic addition of thiocarboxylic acids, retarding the reaction.

Experimental

All melting and boiling points were uncorrected. The IR spectra were measured on a Hitachi EPI-21G spectrometer. The mass spectra were obtained on a Hitachi RMU-7M mass spectrometer operating at an ionization energy of 70 eV. Silica gel column chromatography was performed with Wakogel C-200 (Wako Pure Chem.).

Materials. Commercial benzophenone and acetophenone were used without further purification. The other ketones were prepared by the Friedel-Crafts reaction of the corresponding acid chlorides. Oximes were prepared by the usual methods. **3f** was prepared from the corresponding ketone and hydroxylamine hydrochloride in pyridine.[7] *N*-Methylnitrones were prepared by the reaction of the corresponding oximes with dimethyl sulfate[8] or methyl iodide.[9] Acetophenone-*N*-methylnitrone was prepared from acetophenone diethyl acetal and *N*-methylhydroxylamine hydrochloride.[10] *O*-Benzoylhydroxylamine was synthesized from *p*-nitrophenyl benzoate and hydroxylamine hydrochloride in the presences of sodium hydroxide.[11] *N*-Acetyl-*N*-methylhydroxylamine was prepared according to the method given by Exner.[10] Thioacetic and thiobenzoic acid were

prepared according to general methods.[12,13]

Preparation of Thiobenzophenone (4a). Reaction of Benzophenone Oxime (3a) With Thiobenzoic Acid (1): A solution of **1** (12.4 g, 0.09 mol) in bry benzene (30 ml) was added to a solution of **3a** (6 g, 0.03 mol) in dry benzene (140 ml) at room temperature under nitrogen atmosphere. The solution gradually turned blue, white precipitates separating. The reaction mixture was allowed to stand in the dark for 4 days. Filtration of the precipitate gave ammonium benzoate (2.7 g, mp 189—191 °C (from EtOH), lit, mp 190 °C). The blue filtrate was evaporated under reduced pressure. The residue was chromatographed on a silica gel column (80 g) by elution with petroleum ether to afford **4a** (4.7 g, 78%, bp 120—125 °C/1 mmHg, mp 47—50 °C (from petroleum ether (bp 60—80 °C); lit,[14] mp 53—54 °C). Further elution with benzene gave dibenzoyl disulfide (3 g, mp 128 °C (from EtOH); lit,[15] mp 130 °C).

Reaction of 3a with Thioacetic Acid (2): A solution of **2** (6.8 g, 0.09 mol) in dry benzene (15 ml) was added to a solution of **3a** (6 g, 0.03 mol) in dry benzene (140 ml) at room temperature under nitrogen atmosphere and the mixture was allowed to stand in the dark for 4 days. The blue solution obtained was evaporated under reduced pressure. The residue was chromatographed on a silica gel column (80 g) by elution with petroleum ether to afford **4a** (4.8 g, 80%). Further elution with benzene–ethanol (1: 1) gave acetamide (1 g, mp 80—81 °C; lit, mp 81—82 °C) and diacetyl disulfide (0.2 g, bp 72—74 °C/2 mmHg, lit[16] bp 60—61 °C/1 mmHg). Acetamide was identified by its IR spectra and by admixture with an authentic sample. **4b—h** were obtained by a similar procedure. The thiones obtained were identified by their physical constants (**4c**,[3] **4d**,[17] **4e**,[18] **4f**,[19] **4g**,[20] **4h**[18]) and conversion into 2,4-dinitrophenylhydrazone.

Reaction of O-Benzoylhydroxylamine (9) with Thiobenzoic Acid (1). A solution of **9** (2.2 g, 0.016 mol) in dry benzene (15 ml) was added to a solution of **1** (4.4 g, 0.032 mol) in dry benzene (50 ml) with stirring at room temperature under nitrogen atmosphere and allowed to stand for 3 days. The white precipitate separated was removed by filtration to give ammonium benzoate (1.4 g, mp 190—193 °C). The filtrate was evaporated under reduced pressure and the residue was recrystallized from ethanol to give dibenzoly disulfide (2.6 g, mp 127—128 °C).

Reaction of Benzophenone-N-methylnitrone (11a) with Thioacetic Acid (2). A solution of **2** (7.1 g, 0.092 mol) in dry benzene (15 ml) was added to a solution of **11a** (19.5 g, 0.092 mol) in dry benzene (100 ml) at room temperature under nitrogen atmosphere. The reaction mixture which rapidly turned blue was allowed to stand in the dark for 2 days. After removal of the solvent, fractional distillation under reduced pressure gave **4a** (15 g, 76%, bp 120—125 °C/1 mmHg, mp 48—50 °C) and *N*-acetyl-*N*-methylhydroxylamine (5 g, bp 93—95 °C/3 mmHg; lit,[10] bp 80 °C/2 mmHg); IR(liquid): 3150, 2850, and 1630 cm^{-1}; MS *m/e* 73 (M^+—O), 58, and 43. **4b**, **4c**, **4e**, and **4g** were obtained by a similar procedure.

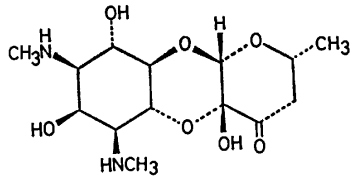
Synthesis of Tetrahydrospectinomycin

Tetsuo SUAMI,* Shigeru NISHIYAMA, Hikaru ISHIKAWA,
Hiroshi OKADA, and Takeshi KINOSHITA
Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama 223
(Received April 5, 1977)

Condensation of 1,3-bis-*N*-(benzyloxycarbonyl)actinamine (**2**) with 2-*O*-chloroacetyl-4,6-dideoxy-3-*O*-*p*-nitrobenzoyl-α-D-xylohexopyranosyl chloride (**8**), followed by deacylation and catalytic hydrogenation afforded 5-*O*-(4,6-dideoxy-β-D-xylohexopyranosyl)actinamine (**11**). Compound **11** was found to be identical with one of the four tetrahydrospectinomycins. ^{1}H and ^{13}C NMR spectra were determined and analyzed.

Spectinomycin is an unique aminocyclitol antibiotic produced by the fermentation of *Streptomyces spectabilis*,[1,2] and is widely used in clinical treatment. Its structure was established by Wiley *et al.*,[3] the configuration being assigned by X-ray diffraction study,[4] as shown in Scheme 1.



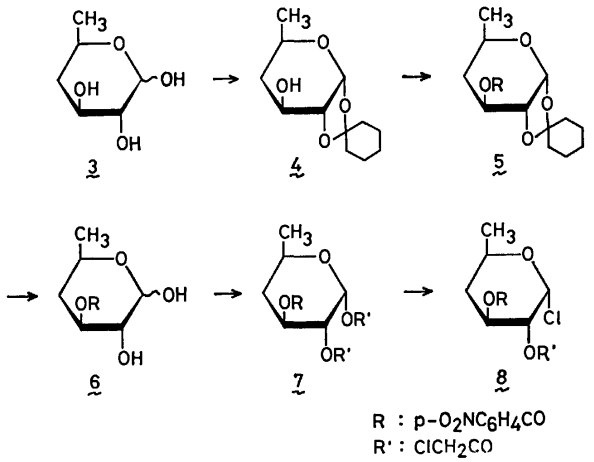
Spectinomycin

Scheme 1.

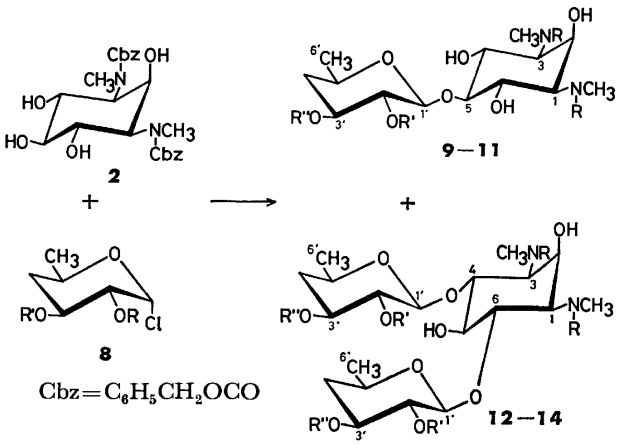
Reduction of spectinomycin with sodium borohydride or hydrogen in the presence of a catalyst gave two epimeric dihydrospectinomycins,[3] further reduction of the dihydrospectinomycins yielding four tetrahydrospectinomycins.[5]

We have directed our studies toward a total synthesis of spectinomycin, and wish to report the synthesis of tetrahydrospectinomycin by the following reaction route (Schemes 2 and 3).

Actinamine dihydrochloride (**1**) was prepared by the hydrolysis of hexa-*N*,*O*-acetylactinamine[6] in 6 M hydrochloric acid. Treatment of **1** with benzyl chloroformate gave 1,3-bis-*N*-(benzyloxycarbonyl)actinamine (**2**).



Scheme 2.



8 R=$ClCH_2CO$, R′=*p*-$O_2NC_6H_4CO$
9 R=Cbz, R′=$ClCH_2CO$, R″=*p*-$O_2NC_6H_4CO$
10 R=Cbz, R′=R″=H
11 R=R′=R″=H
12 R=Cbz, R′=$ClCH_2CO$, R″=*p*-$O_2NC_6H_4CO$
13 R=Cbz, R′=R″=H
14 R=R′=R″=H

Scheme 3.

2-*O*-Chloroacetyl-4,6-dideoxy-3-*O*-*p*-nitrobenzoyl-α-D-xylohexopyranosyl chloride (**8**) was prepared from 4,6-dideoxy-D-xylohexopyranose[7] (**3**) in five steps. A chloroacetyl group was used as protecting group on the hydroxyl group of C-2 because of relative ease of removal under milder conditions as compared with the *p*-nitrobenzoyl group.[8] This was demonstrated by the preparation of methyl 4,6-dideoxy-3-*O*-*p*-nitrobenzoyl-β-D-xylohexopyranoside (**17**) from methyl 2-*O*-chloroacetyl-4,6-dideoxy-3-*O*-*p*-nitrobenzoyl-β-D-xylohexopyranoside (**16**) in an aqueous pyridine solution.

Condensation of **2** with **8** in dry benzene in the presence of mercury(II) cyanide and "Drierite" gave a mixture of three products (R_f 0.28, 0.34, and 0.38) which were detectable on TLC. The mixture was fractionated on a silica gel column with benzene–ethanol as an eluant. Fractions showing a single spot at R_f 0.28 on TLC were combined and evaporated to give the desired compound: 1,3-bis-*N*-(benzyloxycarbonyl)-5-*O*-(2-*O*-chloroacetyl-4,6-dideoxy-3-*O*-*p*-nitrobenzoyl-β-D-xylohexopyranosyl)actinamine (**9**) as crystals in 7.8% yield.

Besides compound **9**, 1,3-bis-*N*-(benzyloxycarbonyl)-4,6-bis-*O*-(2-*O*-chloroacetyl-4,6-dideoxy-3-*O*-*p*-nitrobenzoyl-β-D-xylohexopyranosyl)actinamine (**12**) was obtain-

* To whom correspondence should be addressed.

ed from the fractions (R_f 0.38) in 13% yield. From the fractions (R_f 0.34), an isomer of **9** (**15**) was obtained in 1.7% yield, the structure of which has not been clarified.

By removing the protecting group, **9** gave 5-*O*-(4,6-dideoxy-β-D-xylohexopyranosyl)actinamine (**11**) which was found to be identical with one of the four tetrahydrospectinomycins described by Knight and Hoeksema.[5]

By removing the protecting group, **12** gave 4,6-bis-*O*-(4,6-dideoxy-β-D-xylohexopyranosyl)actinamine (**14**). The β-anomeric configuration of the two glycosidic linkages in **14** were established by ^{1}H NMR spectroscopic study, and their positions attached to the actinamine were confirmed by carbon-13 NMR spectrum in connection with that of **11**.

The normal proton-decoupled natural-abundance carbon-13 Fourier transform spectra of **11** and **14** were determined. The resonances were separated into those originating from an actinamine moiety and those from 4,6-dideoxy-β-D-xylohexopyranosyl group.

When the spectra were determined at pD<1, the resonances arising from the actinamine moiety shifted more or less from those determined in a free base by the effect of protonation on an amino group.[9]

The spectrum of **11** revealed the presence of 14 carbon atoms. The resonance at 33.3 ppm (2 carbons) was attributed to the two *N*-methyl carbons shifted to 31.6 ppm at pD<1, the resonance at 62.9 ppm (2 carbons) being ascribed to C-1 and C-3 which shifted to 62.0 and 61.7 ppm respectively, at pD<1. The resonance at 63.7 ppm is due to C-2, since a large upfield shift (3.6 ppm) was observed at pD<1. These assignments were established in connection with those of spectinomycin.[10] The resonance at 88.0 ppm was assigned to C-5, since methylation of a hydroxyl group causes a large downfield shift of the carbon bearing this hydroxyl group,[11] the result being extended to the glycosidation of a hydroxyl group.[12] C-5 of hyosamine in hygromycin B_2 revealed its resonance at 86.4 ppm[13] and that of 2-deoxystreptamine in ribostamycin at 85.0 ppm.[14] The two resonances at 71.3 and 72.0 ppm were ascribed to the remaining C-4 and C-6, respectively, owing to a large upfield shift at pD<1.

The other 6 resonances were attributed to 6 carbon atoms of the 4,6-dideoxy-β-D-xylohexopyranosyl group. The resonances at 20.6 and 40.6 ppm were clearly due to C-6′ and C-4′, respectively. The resonances at 104.5 and 76.2 ppm were ascribed to C-1′ and C-2′, respectively, since those of methyl β-D-glucopyranoside resonate at 104.2 and 74.1 ppm.[15] The resonance at 69.7 ppm was ascribed to C-5′, since the corresponding carbon atom of spectinomycin revealed its resonance at 69.2 ppm.[10] Thus, the remaining resonance at 71.1 ppm is attributable to C-3′. The assignment was rationalized by the fact that C-4′ of nebramine shows its resonance with a large upfield shift (5.2 ppm) as compared to C-4′ of neamine.[16]

The assignments of the resonances are given in Table 1.

The resonances of the spectrum of **14** were assigned in connection with those of **11**. In the spectrum of **14**, resonances originating from 4,6-dideoxy-β-D-xylohexopyranosyl groups were readily recognized by the formation of pairs of signals at the same position observed in the spectrum of **11**. The two glycosyloxy groups were linked to C-4 and C-6 of the actinamine, since two resonances at 82.7 and 84.8 ppm were ascribed to the carbon atoms where the glycosyloxy groups attached[12] and the resonances of C-4 and C-6 (71.3 and 72.0 ppm) in the spectrum of **11** were not observed in the spectrum of **14**, C-5 showing its resonance at 75.5 ppm instead.

a) In parts per million downfield from tetramethylsilane.
b), c), d) The signals may be reversed.

Experimental

General Methods. Melting points were determined in capillary tubes and are uncorrected. Solutions were evaporated under reduced pressure below 40 °C. Opitcal rotations were recorded on a Japan Spectroscopic DIP-SL polarimeter. IR spectra were measured on a Hitachi 225 spectrophotometer in KBr disks. ^{1}H NMR spectra were recorded on a Varian A-60D spectrometer at 60 MHz or a Varian XL-100 spectrometer at 100 MHz in deuteriochloroform or deuterium oxide with tetramethylsilane or sodium 4,4-dimethyl-4-silapentane-1-sulfonate as an internal standard. The peak positions are given in δ-values. ^{13}C NMR spectra were recorded for solutions in deuterium oxide with an internal dioxane reference, the chemical shifts being reported in ppm downfield from tetramethylsilane (δ_C for dioxane= −67.4). The spectra were obtained on a Varian XL-100 transform with Varian VFT-100 computer. TLC was performed on Wakogel B-10 (Wako Pure Chemical Co. Ltd.) plates, silica gel (Wakogel C-300) being employed for column chromatography. Elemental analyses were performed by Mr. Saburo Nakada.

Actinamine Dihydrochloride (1). A 5.63 g portion of hexa-*N*,*O*-acetylactinamine[6] was heated in 6M hydrochloric acid (40 ml) for 6 h under reflux. The solution was evaporated to dryness and the residue was recrystallized from aqueous

acetone giving 3.38 g (99%) of **1**, mp above 250 °C.

Found: C, 34.24; H, 7.08; N, 9.93; Cl, 25.49%. Calcd for $C_8H_{18}N_2O_4 \cdot 2HCl$: C, 34.42; H, 7.22; N, 10.03; Cl, 25.40%.

*1,3-Bis-*N*-(benzyloxycarbonyl)actinamine (2).* A 3.57 g portion of **1** was suspended in 60% aqueous acetone (550 ml) containing sodium carbonate (13.8 g). 30% Benzyl chloroformate in toluene (43.5 g) was added to the suspension under ice cooling with agitation. After being left to stand overnight at room temperature, the reaction mixture was evaporated to dryness and the residue was extracted with warm acetone. The acetone extracts were evaporated and the residue was triturated with ether. The crude product was recrystallized from ethanol–ether to give 5.11 g (84%) of **2**, mp 161—163.5 °C. An analytically pure sample was obtained by further recrystallizartion fom water, mp 164—165 °C.

Found: C, 61.01; H, 6.30; N, 5.98%. Calcd for $C_{24}H_{30}N_2O_8$: C, 60.75; H, 6.37; N, 5.90%.

*4,6-Dideoxy-*D*-xylohexopyranose (3).* The compound was prepared by the method of Jones and his co-workers.[7]

*1,2-*O*-Cyclohexylidene-4,6-dideoxy-α-*D*-xylohexopyranose (4).* Compound **3** (2.10 g) was suspended in cyclohexanone (74 ml) containing *p*-toluenesulfonic acid (60 mg) and "Drierite" (2.0 g). After being stirred overnight at room temperature, the reaction mixture was added with sodium hydrogencarbonate (5.5 g). The mixture was filtered and the filtrate was evaporated. The residue was purified by silica gel column chromatography with 1:3 (v/v) 2-butanone-toluene as an eluant. Fractions showing a single spot at R_f 0.42 on TLC in the same solvent were combined and evaporated to give 2.45 g (76%) of **4** as a syrup, $[\alpha]_D^{22}$ +35.3 ° (*c* 5.8, chloroform). ^{1}H NMR ($CDCl_3$): δ 1.23 (d, 3, J=6.5 Hz, C$\underline{H}_3$), 2.74 (broad s, 1, OH), 5.56 (d, 1, J=4.5 Hz, H-1).

Found: C, 62.84; H, 8.65%. Calcd for $C_{12}H_{20}O_4$: C, 63.13; H, 8.83%.

*1,2-*O*-Cyclohexylidene-4,6-dideoxy-3-*O*-p-nitrobenzoyl-α-*D*-xylohexopyranose (5).* To a suspension of *p*-nitrobenzoyl chloride (4.96 g) in pyridine (90 ml) was added a solution of **4** (2.33 g) in pyridine (5 ml) under ice cooling with agitation. After being stirred overnight at room temperature, the reaction mixture was poured into ice cold water (700 ml) and extracted with chloroform (50 ml×3). The combined chloroform layers were washed with sodium hydrogencarbonate solution and water. After being dried over anhydrous sodium sulfate, the solution was evaporated to give 3.13 g of a syrup. The product was recrystallized twice from ether–pentane to give 2.49 g (65%) of **5**, mp 94—97 °C; $[\alpha]_D^{24}$ +72 ° (c 1.1, chloroform). ^{1}H NMR ($CDCl_3$): δ 1.29 (d, 3, J=6.5 Hz, C$\underline{H}_3$), 5.68 (d, 1, $J_{1,2}$=2.5 Hz, H-1).

Found: C, 60.35; H, 6.06; N, 3.51%. Calcd for $C_{19}H_{23}NO_7$: C, 60.47; H, 6.14; N, 3.71%.

*4,6-Dideoxy-3-*O*-p-nitrobenzoyl-*D*-xylohexopyranose (6).* Compound **5** (1.51 g) was heated in 80% aqueous acetic acid (30 ml) for 1 h under reflux. The solution was evaporated and the residue was dissolved in ethanol. Petroleum ether was added to the ethanolic solution to give 1.01 g (85%) of **6** as amorphous powder, $[\alpha]_D^{22}$ +148.8 °→+142.1 ° (*c* 1.45, pyridine).

Found: C, 52.29; H, 5.27; N, 4.49%. Calcd for $C_{13}H_{15}NO_7$: C, 52.53; H, 5.27; N, 4.71%.

*1,2-Bis-*O*-chloroacetyl-4,6-dideoxy-3-*O*-p-nitrobenzoyl-α-*D*-xylohexopyranose (7).* Compound **6** (456 mg) was dissolved in a mixture of dioxane (5 ml) and pyridine (0.4 ml). To the solution was added chloroacetyl chloride (0.4 ml) under ice cooling with agitation. After 1 h, the reaction mixture was poured into ice cold water (30 ml) and extracted with chloroform (30 ml×3). The combined chloroform layer was washed with sodium hydrogensulfate solution, sodium hydrogencarbonate solution and water. After being dried over anhydrous sodium sulfate, the solution was evaporated to give 778 mg of a crude product. Recrystallization from ethanol gave 382 mg (55%) of **7**, mp 136—138 °C; $[\alpha]_D^{23}$ +128 ° (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$): δ 1.14 (d, 3, J=6.0 Hz, C$\underline{H}_3$), 3.95 (s, 2, C$\underline{H}_2$Cl), 4.15 (s, 2, C$\underline{H}_2$Cl), 6.43 (d, 1, $J_{1,2}$=3.0 Hz, H-1).

Found: C, 45.53; H, 3.84; N, 3.06; Cl, 15.44%. Calcd for $C_{17}H_{17}NO_9Cl_2$: C, 45.35; H, 3.81; N, 3.11; Cl, 15.75%.

*2-*O*-Chloroacetyl-4,6-dideoxy-3-*O*-p-nitrobenzoyl-α-*D*-xylohexopyranosyl Chloride (8).* Hydrogen chloride was bubbled into a solution of **7** (610 mg) in dry ether (150 ml) until saturated and the solution was left to settle overnight in a refrigerator. The solution was evaporated and the residue was dissolved in chloroform (30 ml). The chloroform solution was washed with sodium hydrogencarbonate solution and water. After being dried over anhydrous sodium sulfate, the solution was evaporated. The residue was recrystallized from chloroform–ether to give 364 mg (69%) of **8**, mp 147—149 °C; $[\alpha]_D^{15}$ +216 ° (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$): δ 1.26 (d, 3, J=6.5 Hz, C$\underline{H}_3$), 3.98 (s, 2, C$\underline{H}_2$Cl), 6.34 (d, 1, $J_{1,2}$=4.0 Hz, H-1).

Found: C, 45.82; H, 3.81; N, 3.46; Cl, 18.11%. Calcd for $C_{15}H_{15}NO_7Cl_2$: C, 45.94; H, 3.86; N, 3.57; Cl, 18.08%.

Condensation of 2 and 8. A mixture of **2** (3.08 g, 6.5 mmol) and **8** (4.82 g, 12.3 mmol) in dry benzene (60 ml) containing mercury(II) cyanide (3.5 g) and "Drierite" (3.1 g) was heated for 41 h under reflux. The mixture was filtered and the filtrate was evaporated. The residue was fractionated on a silica gel column with 20:1 (v/v) benzene–ethanol as an eluant.

Fractions showing a single spot at R_f 0.28 on TLC in the same solvent system were combined and evaporated. The residue was recrystallized from chloroform–ethanol to give 421 mg (7.8%) of 1,3-bis-*N*-(benzyloxycarbonyl)-5-*O*-(2-*O*-chloroacetyl-4,6-dideoxy-3-*O*-*p*-nitrobenzoyl-β-D-xylohexopyranosyl)actinamine (**9**) as crystals, mp 143—144 °C; $[\alpha]_D^{20}$ +45.4 ° (*c* 1.0, chloroform). ^{1}H NMR ($CDCl_3$): δ 1.35 (d, 3, J=6.0 Hz, C$\underline{H}_3$), 3.06 (s, 3, NC$\underline{H}_3$), 3.10 (s, 3, NC$\underline{H}_3$), 4.03 (s, 2, C$\underline{H}_2$Cl).

Found: C, 56.15; H, 5.26; N, 5.05; Cl, 4.39%. Calcd for $C_{39}H_{44}N_3O_{15}Cl$: C, 56.42; H, 5.34; N, 5.06; Cl, 4.27%.

Fractions showing a single spot at R_f 0.34 on TLC were combined and evaporated. The residue was recrystallized from chloroform–ethanol giving 92 mg (1.7%) of 1,3-bis-*N*-(benzyloxycarbonyl)-*O*-(2-*O*-chloroacetyl-4,6-dideoxy-3-*O*-*p*-nitrobenzoyl-D-xylohexopyranosyl)actinamine (**15**), mp 172—173.5 °C; $[\alpha]_D^{22}$ +87.5 ° (*c* 1.0, chloroform). ^{1}H NMR ($CDCl_3$): δ 1.24 (d, 3, J=6.0 Hz, C$\underline{H}_3$), 3.09 (s, 3, NC$\underline{H}_3$), 3.11 (s, 3, NC$\underline{H}_3$), 4.04 (s, 2, C$\underline{H}_2$Cl).

Found: C, 56.37; H, 5.32; N, 5.01; Cl, 4.39%. Calcd for $C_{39}H_{44}N_3O_{15}Cl$: C, 56.42; H, 5.34; N, 5.06; Cl, 4.27%.

Fractions showing a single spot at R_f 0.38 on TLC were combined and evaporated. The residue was recrystallized from chloroform–ether giving 989 mg (13%) of 1,3-bis-*N*-(benzyloxycarbonyl)-4,6-bis-*O*-(2-*O*-chloroacetyl-4,6-dideoxy-3-*O*-*p*-nitrobenzoyl-β-D-xylohexopyranosyl)actinamine (**12**), mp 152—153 °C; $[\alpha]_D^{22}$ +14.0 ° (*c* 1.0, chloroform). ^{1}H NMR ($CDCl_3$): δ 1.21 (d, 3, J=6.5 Hz, C$\underline{H}_3$), 1.40 (d, 3, J=6.5 Hz, C$\underline{H}_3$), 3.05 (s, 6, 2×NC$\underline{H}_3$), 4.02 (s, 4, 2×C$\underline{H}_2$Cl).

Found: C, 54.51; H, 4.93; N, 4.55; Cl, 6.28%. Calcd for $C_{54}H_{58}N_4O_{22}Cl_2$: C, 54.69; H, 4.93; N, 4.72; Cl, 5.98%.

*1,3-Bis-*N*-(benzyloxycarbonyl)-5-*O*-(4,6-dideoxy-β-*D*-xylohexo-*

pyranosyl)actinamine (10). Compound **9** (290 mg) was deacylated in saturated methanolic ammonia (20 ml) overnight at ambient temperature with gentle agitation. The solution was evaporated and the residue was recrystallized from methanol giving 206 mg (98%) of **10**, mp 244—246 °C; $[\alpha]_D^{18}$ −1.1 ° (*c* 1.0, pyridine).

Found: C, 59.37; H, 6.53; N, 4.83%. Calcd for $C_{30}H_{40}N_2O_{11}$: C, 59.59; H, 6.67; N, 4.63%.

5-O-(4,6-Dideoxy-β-D-xylohexopyranosyl)actinamine (11). A solution of **10** (115 mg) in 50% aqueous methanol (20 ml) was hydrogenated in the presence of palladium black (20 mg) overnight in a Parr apparatus in hydrogen atmosphere (3.4 kg/cm²). The filtrate was evaporated after the catalyst had been filtered off. The residue was purified by Amberlite CG-50 (H^+) resin column chromatography with 0.05 M ammonia as an eluant. The product was recrystallized from ethanol to give 59 mg (92%) of **11** as needles, mp 222—225 °C; $[\alpha]_D^{21}$ −21.8 ° (*c* 1.0, water). ^{1}H NMR (D_2O): δ 1.28 (d, 3, *J*=6.5 Hz, $C\underline{H}_3$), 2.41 (s, 6, 2×$NC\underline{H}_3$), 4.58 (d, 1, *J*=7.5 Hz, H-1). IR and ^{1}H NMR spectra of **11** were superimosable on those of an authentic sample of tetrahydrospectinomycin prepared by the method of Knight and Hoeksema.[5] [Lit,[5] mp 227—231 °C; $[\alpha]_D$−22 ° (*c* 1.0, water)].

Found: C, 49.79; H, 8.19; N, 8.35%. Calcd for $C_{14}H_{28}N_2O_7$: C, 49.99; H, 8.39; N, 8.33%.

1,3-Bis-N-(benzyloxucarbonyl)-4,6-bis-O-(4,6-dideoxy-β-D-xylohexopyranosyl)actinamine (13). Compound **12** (0.4 g) was deacylated by a procedure analogous to that described for **10**. The product was purified by column chromatography with 15:1 (v/v) benzene–ethanol. Fractions showing a single spot at R_f 0.58 on TLC in 5:1 (v/v) benzene–ethanol were combined and evaporated. The residue was dissolved in benzene. Hexane was added to the solution giving 190 mg (75%) of **13** as amorphous powder, mp 111—128 °C; $[\alpha]_D^{22}$ −25.0 ° (*c* 1.0, pyridine).

Found: C, 57.52; H, 6.68; N, 3.62%. Calcd for $C_{36}H_{50}N_2O_{14}\cdot H_2O$: C, 57.44; H, 6.96; N, 3.72%.

4,6-Bis-O-(4,6-dideoxy-β-D-xylohexopyranosyl)actinamine (14). Hydrogenolysis of **13** (124 mg) was carried out by a procedure analogous to that described for **11**. The product was recrystallized from ethanol to give 63 mg (82%) of **14**, mp 243—247 °C; $[\alpha]_D^{22}$ −26.0 ° (*c* 1.0, water). ^{1}H NMR (D_2O): δ 1.28 (d, 6, *J*=6.0 Hz, 2×$C\underline{H}_3$), 2.44 (s, 6, 2×$NC\underline{H}_3$), 4.50 (d, 1, *J*=7.5 Hz, anomeric proton), 4.62 (d, 1, *J*=7.5 Hz, anomeric proton).

Found: C, 51.61; H, 8.02; N, 6.01%. Calcd for $C_{20}H_{38}N_2O_{10}$: C, 51.49; H, 8.21; N, 6.00%.

Methyl 2-O-Chloroacetyl-4,6-dideoxy-3-O-p-nitrobenzoyl-β-D-xylohexopyranoside (16). A solution of **8** (340 mg) in dichloromethane (1.5 ml) was added to methanol (5 ml) containing mercury(II) cyanide (340 mg). The mixture was stirred at ambient temperature for 2 h and filtered. The filtrate was evaporated, and the residue was dissolved in chloroform. The chloroform solution was filtered and the filtrate was evaporated. The residue was recrystallized from ethanol to give 238 mg (71%) of **16**, mp 122—123 °C; $[\alpha]_D^{16}$ + 58 ° (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$): δ 1.34 (d, 3, *J*=6.0 Hz, $C\underline{H}_3$), 3.50 (s, 3, $OC\underline{H}_3$), 3.98 (s, 2, $C\underline{H}_2Cl$), 4.44 (d, 1, *J*=8.0 Hz, H-1).

Found: C, 49.36; H, 4.70; N, 3.69; Cl, 8.97%. Calcd for $C_{16}H_{18}NO_8Cl$: C, 49.56; H, 4.68; N, 3.61; Cl, 9.14%.

Methyl 4,6-dideoxy-3-O-p-nitrobenzoyl-β-D-xylohexopyranoside (17). Water (4 ml) was added to a solution of **16** (158 mg) in pyridine (7 ml), and the pH of the mixture was adjusted to 7 by addition of 6M hydrochloric acid. The mixture was settled at ambient temperature for 5 h. The mixture was diluted with chloroform, and the solution was washed successively with sodium hydrogensulfate solution, sodium hydrogencarbonate solution and water. After being dried over anhydrous sodium sulfate, the solution was evaporated. The residue was recrystallized from ethanol–petroleum ether to give 103 mg (81%) of **17**, mp 133—134 °C; $[\alpha]_D^{22}$ +30° (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$): δ 1.32 (d, 3, *J*=6.0 Hz, $C\underline{H}_3$), 2.66 (broad s, 1, OH), 3.57 (s, 3, $OC\underline{H}_3$), 4.26 (d, 1, *J*=8.0 Hz, H-1).

Found: C, 54.19; H, 5.50; N, 4.56%. Calcd for $C_{14}H_{17}NO_7$: C, 54.02; H, 5.51; N, 4.50%.

This work was supported in part by a grant-in-aid from the Ministry of Education.

Dehydroannulenes. VII. Synthesis of 3,7,10,14-Tetrasubstituted 1,8-Bisdehydro[14]annulenes

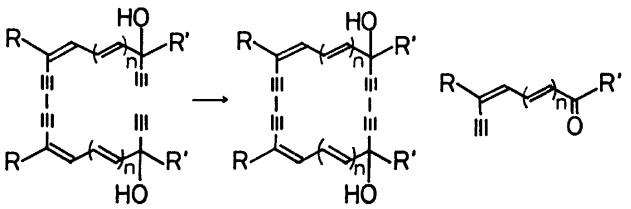
Kunisuke FUKUI, Tateo NOMOTO, Shin'ichi NAKATSUJI, Shuzo AKIYAMA, and Masazumi NAKAGAWA*

Department of Chemistry, Faculty of Science, Osaka University Toyonaka, Osaka 560

(Receired April 18, 1977)

It was found that dienyne ketones such as 2,2-dimethyl-7-*t*-butyl-4,6-nonadien-8-yn-3-one, 2,2-dimethyl-7-phenyl-4,6-nonadien-8-yn-3-one and 1,5-diphenyl-2,4-heptadien-6-yn-1-one give the corresponding tetrasubstituted 14-membered cyclic glycols on treatment with a suspension of potassium hydroxide in liquid ammonia. Reactions of the cyclic glycols with tin(II) chloride in organic solvent saturated with hydrogen chloride afforded strongly diatropic tetrasubstituted bisdehydro[14]annulenes.

Oxidative coupling of polyentetrayne glycols (**1** or **2**) with copper(II) acetate in pyridine–methanol–ether in high dilution[1] yielded the corresponding 18-membered (**3**) or 22-membered cyclic glycols (**4**), precursors of tetrakisdehydro[18]-[2] and [22] annulenes,[3] in unexpectedly high yields. This seems to be a reflection of the favorable configuration of the acyclic glycols (**1** and **2**) on intramolecular oxidative coupling, suggesting the possibility of cyclic dimerization of polyenyne ketones (**5**) to give cyclic polyendiyne glycols under suitable conditions. The cyclic glycols may be transformed into bisdehydro[4n+2]annulenes by the reductive dehydroxylation reaction adopted in the conversion of the cyclic tetrayne glycols (**3** and **4**) into tetrakisdehydro[18]- and [22]annulenes.[2,3]



1: n=1 **2**: n=2 **3**: n=1 **4**: n=2 **5**

In this paper we wish to report on the cyclic dimerization of dieyne ketones (**6**) to 14-memberd cyclic glycols (**7**) and their transformation into 3,7,10,14-tetrasubstituted 1,8-bisdehydro[14]annulenes (**8**).[4] The parent compound 1,8-bisdehydro[14]annulene (**8d**) was obtained by Sondheimer and his co-workers by prototropic rearrangement accompanied by an unexpected dehydrogenation by atmospheric oxygen in the course of synthesis of monodehydro[14]annulene.[5] The present studies have opened an efficient route to the synthesis of 1,8-bisdehydro[14]annulenes.

Synthesis. Ethynylation of carbonyl compounds with acetylene or monosubstituted acetylenes in organic solvent in the presence of alkali hydroxide, carbonate or alcoholate is well-known (Favorskii method).[6] Formation of a trace of the cyclic glycol (**7c**) could be recognized on treatment of the diphenyldienyne ketone (**6c**) with potassium hydroxide in tetrahydrofuran or pyridine. No indication of the formation of **7c** could be obtained with alkali amide in liquid ammonia, sodium hydroxide in tetrahydrofuran or pyridine, potassium hydroxide in *N,N*-dimethylformamide or in ether, or sodium hydroxide and calcium carbide in tetrahydrofuran. It was found that slow addition of a solution of **6** in tetrahydrofuran to a stirred suspension of finely powdered potassium hydroxide in liquid ammonia caused the cyclic dimerization of **6** to give a diastereomeric mixture of the desired cyclic glycol (**7**) in a high yield. In the case di-*t*-butyl ethynyl ketone (**6a**), an amorphous solid with an unidentified structure was obtained in addition to the desired cyclic glycol (**7a**).

TABLE 2. 60 MHz ^{1}H NMR PARAMETERS OF BISDEHYDRO[14]ANNULENES (**8**) (τ-VALUES)

	8a	**8b**	**8c**	**8d**
Outer protons	H^a, H^e 0.58 d J=13.5	H^a 0.12 d J=13.5 H^e 0.47 d J=13.5	H^a, H^e 0.06 d J=13.5	H^a, H^e 0.45 dd J=13.3, 8 R,R′ 1.57 d J=13.3
o-Protons of phenyl		1.2—1.5 m	1.1—1.5 m	
m,p-Protons of phenyl		2.2—2.8 m	2.1—2.6 m	
Protons of *t*-butyl	8.10 s	8.02 s		
Inner protons	14.39 t J=13.5	13.42 t J=13.5	12.56 t J=13.5	15.54 t J=13.3
Solvent	THF-d_8	THF-d_8	THF-d_8	$CDCl_3$

reaction mixtures were worked up in the usual way to give the tetrasubstituted 1,8-bisdehydro[14]annulenes (**8a—c**). The yields and melting points of cyclic glycols (**7a—c**) and annulenes (**8a—c**) together with the color of crystals of the annulenes are given in Table 1.

Properties. The tetrasubstituted 1,8-bisdehydro-[14]annulenes (**8a—c**) were found to be quite stable, no decomposition being observed in the air at room temperature under diffused daylight for a long time. The ^{1}H NMR spectra of **8a—c** indicate that they sustain fairly strong diamagnetic ring current as evidenced by low-field and high-field signals of the outer and inner protons, respectively. The ^{1}H NMR parameters are summarized in Table 2 together with those of the parent compound (**8d**).[5] As a representative example, the ^{1}H spectrum of the tetra-*t*-butyl derivative (**8a**) is shown in Fig. 1. The di-*t*-butyl-diphenyl derivative (**8b**) exhibits two outer proton signals as doublets at τ 0.12 and 0.47. The lower field signal (τ 0.12) could be assigned H^a which undergoes the deshielding effect of the ring current both of the annulene ring and the phenyl groups. The multiplets observed at τ 1.1—1.5 and 2.2—2.8 in the spectra of **8a** and **8c** could be assigned to *o*- and *m,p*-protons of the phenyl groups, since the protons of the phenyl groups are disposed in the deshielding region of diamagnetic ring current of the annulene ring, and lower field shift of the *o*-protons can

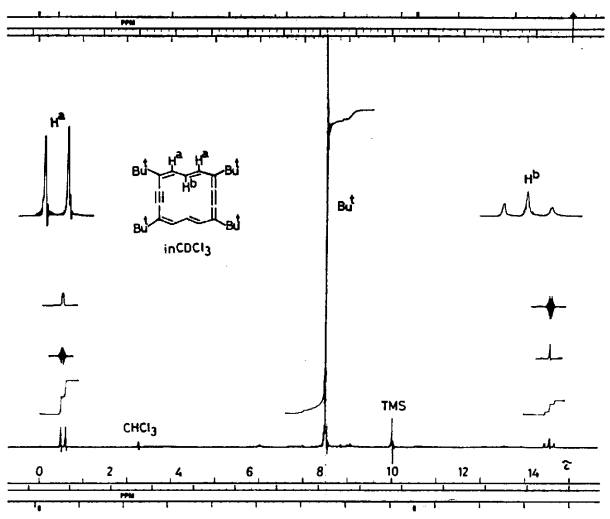

Fig. 1. 100 MHz ^{1}H NMR spectrum of tetra-*t*-butyl-bisdehydro[14]annulene (**8a**) in $CDCl_3$.

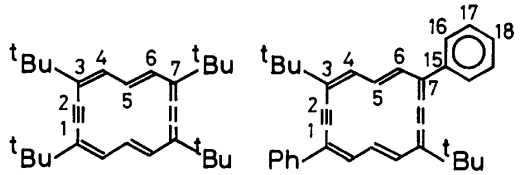

8a **8b**

TABLE 3. ^{13}C NMR PARAMETERS OF **8a** AND **8b** IN $CDCl_3$ (ppm FROM TMS)

8a		**8b**	
t-Bu	32.2(CH_3), 37.8(C)	*t*-Bu	32.3(CH_3), 37.8(C)
C^1,C^2	116.7	C^1,C^2	114.7, 115.7
C^3	131.3	C^3,C^7,C^{15}	119.8, 113.7, 139.9
C^4	130.4	C^4,C^6	130.3, 130.7
C^5	129.0	C^5	132.3
		C^{16},C^{17}	128.0, 128.7
		C^{18}	127.3

be attributed to their proximate position to the 14-membered ring. The most remarkable feature of ^{1}H NMR spectra is the marked low-field shift of signals of inner protons in the tetrasubstituted derivatives (**8a—c**) as compared with that of the parent compound (**8d**). A slight low-field shift of the outer protons of phenyl substituted derivatives (**8b, c**) was also observed.

Carbon-13 NMR spectral parameters of **8a** and **8b** are given in Table 3. The spectrum of **8c** could not be obtained owing to the poor solubility in NMR solvents. Assignment was made on the basis of chemical shift, off resonance technique and the magnitude of NOE. However, the signals of tertiary carbon atoms (C^3, C^7 and C^{15}) and *o,m*-carbons of phenyl groups (C^{16} and C^{17}) could not be discriminated. The sp-hybridized carbon atoms in symmetrical **8a** exhibits only one signal at an intermediate region of acetylene[7,8] and cumulene[8] carbon atoms, suggesting strongly the identity of acetylenic and cumulenic linkages incorporated in aromatic [4*n*+2]π-electron system.[2g,h] On the other hand, two signals were observed in the corresponding region in the spectrum of **8b**. This seems to be ascribable to the difference in electron density between C^1 and C^2 caused by the different inductive effect of *t*-butyl and phenyl groups.

TABLE 4. ELECTRONIC SPECTRA OF **8a—c** IN THF
λ_{max} IN nm (ε)[a)]

8a	228.5(6670), 301 sh(28100), 329(272000), 432 sh (11900), 452(24600) 500 sh(150), 525(100), 548 (210), 567 sh(240), 590(920)

8c	224 sh(13400), 246(26000), 268(23200), 274.5 (24700), 282.5(24400), 326(18100), 343(30900), 372 sh(68100), 388(289000), 521(26300), 549(53200), 600 sh(830), 658(2520)

a) The absorption curves were given in a preliminary report.[4)]

The electronic spectra of the tetrasubstituted 1,8-bisdehydro[14]annulenes (**8a—c**) consist of three main absorption bands characteristic of aromatic [4*n*+2]-annulenes. The numerical data are given in Table 4.

Increase in the number of phenyl substitution causes a progressive bathochromic shift of the main three absorption bands and appreciable intensification of the medium and the longest wavelength bands indicating electronic perturbation of phenyl groups on the annulene ring. The same trend has been observed in the electronic spectra of tetrakisdehydro[18]-[2e)] and [22]annulenes.[3)]

Tetra-*t*-butyl- (**8a**) and di-*t*-butyl-diphenyl derivatives (**8b**) formed 1:1 CT complexes with 2,4,7-trinitrofluorenone. On the other hand, the tetraphenyl analogue (**8c**) gave CT complex with 2 moles of the nitro compound.

Experimental

All melting points are uncorrected. The IR spectra were measured with a Hitachi EPI-2 or EPI-3G spectrophotometer, the weak, medium and strong absorptions being indicated by w, m and s, respectively. The electronic spectra obtained on a Hitachi EP-3T spectrophotometer were recorded in nm. The ε-values are given in parentheses, the shoulder being denoted by sh. The mass spetra were measured with a Hitachi RM-50 spectrometer (ionization potential 70 eV). The ^{1}H NMR spectra were obtained on a Varian T-60 or a Varian XL-100 spectrometer, and are recorded in τ-values with respect to TMS as an internal standard. The coupling constants (J) are given in Hz. The ^{13}C NMR spectra were measured with an XL-100 spectrometer operated at 25.2 MHz using pulse FT technique with a deuterium internal lock, and given in ppm from TMS as an internal standard. Silica gel (Merck, Kiesel Gel 60) or alumina (Merck, Act. II—III) was used for column chromatography, unless otherwise stated.

1,4,8,11-Tetra-t-butyl-4,6,11,13-cyclotetradecatetraen-2,9-diyn-1,8-diol (7a). A solution of 2,2-dimethyl-7-*t*-butyl-4,6-nonadine-8-yn-3-one (**6a**, 0.21 g, 0.96 mmol)[2d,e)] in THF (50 ml) was added over a period of 8 h to a stirred suspension of finely powdered potassium hydroxide (1.5 g, 27 mmol) in liquid ammonia (200 ml) at −40—−50 °C. After the mixture had been stirred for 5—6 h at −30—−40 °C, powdered ammonium chloride (3.0 g, 56 mmol) was added at −40 °C, and the ammonia was allowed to evaporate. Water was added to the residue and the mixture was extracted with ether. The ethereal solution, after being washed with water and dried (sodium sulfate), was evaporated under reduced pressure. The residue was chromatographed on silica gel (Wako, 15 g). Elution with hexane–benzene gave colorless crystals, mp 202—205 °C (dec), 65 mg, 31%. The IR, NMR and mass spectral data indicate that the colorless srystals are oligomeric, presumably trimeric, cyclic alcohol. However, no further studies on the structure have been performed. Further elution with benzene and benzene–ether (9:1) yielded a diastereomer of **7a**, colorless crystals, mp 230.9—232.4 °C (dec), 39 mg, 19%; Mass (*m/e*) 436 (M^+). Elution with a solvent of increased polarity (benzene–ether) gave another diastereomer of **7c**, colorless crystals, mp 220.0—222.2 °C (dec), 105 mg, 50%; IR(KBr-disk) 3600, 3455 m (OH), 1633 w (C=C), 975 s (*trans* -CH=CH-) cm^{-1}; NMR ($CDCl_3$) 2.34 (dd, 2, J=10.5, 16.0, H^b), 3.67 (d, 2, J=10.5, H^c), 4.06 (d, 2, J=16.0, H^a), 8.45 (s, 2, OH, disappeared on addition of D_2O), 8.85 (s, 18, *t*-butyl adjacent to OH), 8.94 (s, 18, *t*-butyl).

Found: C, 82.75; H, 10.40%; M^+ 436. Calcd for $C_{30}H_{44}O_2$: C, 82.51; H, 10.16%; M 436.

3,7,10,14-Tetra-t-butyl-1,8-bisdehydro[14]annulene (8a). A diastereomeric mixture of **7a** (59 mg, 0.14 mmol) in ether (50 ml) was mixed at −60 °C with the same solvent saturated with hydrogen chloride (10 ml) and finely powdered tin(II) chloride dihydrate (200 mg). After being stirred for 15 min, the resulting deep red solution was worked up in the usual way. Red crystals (57 mg) obtained on evaporating the solvent were dissolved in hexane and chromatographed on alumina (20 g) to give pure **8a**, red crystals, mp 298.0—299.0 °C (dec), 36 mg, 64%; IR(KBr-disk) 963 (*trans* -CH=CH-) 2000 (-C≡C-↔=C=C=) cm^{-1}; NMR($CDCl_3$) 0.65 (d, J=13.5, outer-H), 14.50 (t, J=13.5, inner-H), 8.10 (s, *t*-butyl).

Found: C, 89.49; H, 10.53%; M^+ 402. Calcd for $C_{30}H_{42}$: C, 89.42; H, 10.63%; M 402.

The reaction product obtained on treatment of **6a** with potassium hydroxide in liquid ammonia could be converted without purification under similar reaction conditions into **8a** (67%).

CT Complex of 8a with 2,4,7-Trinitrofluorenone. Brown crystals of CT complex of **8a** with 2,4,7-trinitrofluorenone were obtained on admixing a solution of the nitro compound (9 mg, 0.029 mmol) in ethanol (4 ml) with a hot solution of **8a** (9 mg, 0.022 mmol) in cyclohexane (3 ml).

Found: C, 72.19; H, 6.65; N, 5.91%. Calcd for $C_{30}H_{42}\cdot C_{13}H_5N_3O_5$: C, 71.94; H, 6.60; N, 5.85%.

1,8-Di-t-butyl-4,11-diphenyl-4,6,11,13-cyclotetradecatetraen-2,9-diyn-1,8-diol (7b). 2,2-Dimethyl-7-phenyl-4,6-nonadien-8-yn-3-one (**6b**) was prepared by a slight modification of the reported method[2g,h)] (mp 77.5—76.0 °C, 52% based on 3-phenyl-2-penten-4-ynal). A solution of **6b** (0.500 g, 2.22 mmol) in THF (60 ml) was added over a period of 7 h to a stirred suspension of potassium hydroxide (2.0 g) in liquid ammonia (1000 ml) at the boiling point of the solvent. After the mixture had been stirred overnight at the same temperature, finely powdered ammonium chloride (6 g) was added to the reaction mixture at −65 °C, and then the ammonia was allowed to evaporate. Ethereal extract (500 ml) of the residue was evaporated to yield crystalline material. An examination with TLC indicated predominant formatiom of one of the diastereomers. The material was washed successively with hexane–benzene (9:1) and hexane. Colorless fine crystals (0.480 g, 96%), thus obtained, were recrystallized twice from benzene to give pure **7b**, colorless crystals, mp 241—243 °C (dec); IR(KBr-disk) 970 s (*trans* -CH=CH-), 2220 w (-C≡C-), 3440 w, 3560 m (OH) cm^{-1}; NMR (acetone-d_6) 1.96—2.23 (m, 6, H^b and *o*-H of phenyl), 2.49—2.76 (m, 8, H^a and *m*, *p*-H of phenyl), 3.65 (d, 2, J=15, H^c),

5.23 (s, 2, OH, disapppeared on addition of D_2O), 8.85 (s, 18, *t*-butyl).

Found: C, 85.60; H, 7.58%. Calcd for $C_{34}H_{36}O_2$: C, 85.67; H, 7.61%.

7,14-Di-t-butyl-3,11-diphenyl-1,8-bisdehydro[14]annulene (8b). To a stirred solution of **7b** (0.110 g, 0.23 mmol) in ether (100 ml) kept at −60 °C was added a solution of tin(II) chloride dihydrate (0.40 g) in the same solvent saturated with hydrogen chloride (20 ml). The cooling bath was removed and the reaction mixture was stirred for 20 min. The mixture was worked up in the usual way. Ethereal extract of the product was evaporated under reduced pressure and the crystalline residue was washed thoroughly with hexane to give fairly pure **8b**, reddish brown fine crystals, 85 mg, 83%, which were recrystallized from benzene–ethanol to give an analytical specimen of **8b**, brown violet crystals, mp 284.0—284.5 °C (dec); IR(KBr-disk) 962 (*trans* –CH=CH–), 2020 (–C≡C–↔=C=C=); NMR($CDCl_3$, 60 MHz) 0.12 (d, 2, J=13.5, H^a), 0.53 (d, 2, J=13.5, H^c), 1.2—1.6 (m, 4, *o*-H of phenyl), 2.2—2.7 (m, 6, *m,p*-H of phenyl), 8.07 (s, 18 *t*-butyl), 13.58 (t, 2, J=13.5, H^b); (THF-d_8, 100 MHz) 0.16 (d, 2, J=13, H^a), 0.49 (d, 2, J=13, H^c), 1.39 (m, 4, *o*-H of phenyl), 2.3—2.7 (m, 6, *m,p*-H of phenyl), 8.05 (s, 18, *t*-butyl), 13.45 (*t*, 2, J=13, H^b).

Found: C, 91.96; H, 7.70%. Calcd for $C_{34}H_{34}$: C, 92.26; H, 7.74%.

CT Complex of 8b with 2,4,7-Trinitrofluorenone. A hot solution of 2,4,7-trinitrofluorenone (15.0 mg) in ethanol (6 ml) was mixed with a hot solution of **8b** (15.0 mg) in benzene (2 ml). On cooling the mixture the CT complex was obtained as violet brown crystals.

Found: C, 74.27; H, 5.16; N, 5.57%. Calcd for $C_{34}H_{34}\cdot C_{13}H_5N_3O_7$: C, 74.49; H, 5.19; N,5.54%.

1,8,4,11-Tetraphenyl-4,6,11,13-cyclotetradecatetraen-2,9-diyn-1,8-diol (7c). A solution of 1,5-diphenyl-2,4-heptadien-6-yn-1-one (**6c**, 396 mg, 1.53 mmol)[2c,d,e] in THF (25 ml) was added over a period of 17 h to a suspension of potassium hydroxide (1.6 g, 29 mmol) in liquid ammonia (600 ml) at −55——65 °C. After the mixture had been stirred at −55 °C for 4 h, ammonium chloride (4 g) was added to the reaction mixture, and the ammonia was allowed to evaporate. The residue was digested with ether by decantation. The insoluble material was dissolved in water, and the aqueous solution was extracted with ether. The combined organic layer was worked up in the usual way. Crystalline solid obtained on evaporating the solvent was dissolved in THF and passed through a short column of silica gel (10 g). The filtrate was concentrated under reduced pressure to give pale brown crystals, which were washed with hexane-benzene to give slightly impure **7c** (369 mg, 93%). The material was recrystallized from THF to give colorless crystals, and was found to contain half mole of THF as a solvent of crystallization, mp 236—237 °C (dec); IR(KBr-disk) 974 s (*trans* –CH=CH–), 2210 w (–C≡C–), 3550 w, 3340 broad (OH) cm^{-1}; NMR(THF) 2.23—2.92 (m, 24, H^a, H^b, and phenyl), 3.69 (d, 2, J=15.0, H^c).

Found: C, 85.47; H, 5.72%. Calcd for $C_{38}H_{28}O_2$–1/2 C_4H_8O: C, 85.68; H, 5.75%.

3,7,10,14-Tetraphenyl-1,8-bisdehydro[14]annulene (8c). Finely powdered tin(II) chloride dihydrate (600 mg) was added under nitrogen atmosphere to a solution of **7c** (45.0 mg, 0.087 mmol) in dimethoxyethane (40 ml) at −60 °C. To the stirred mixture was added ether saturated with hydrogen chloride (4 ml) at −50——55 °C. After the mixture had been stirred for 10 min at −55——60°C, the resulting deep purple solution was poured into water and extracted with ethyl acetate. The extract was worked up in the usual way. Deep purple crystals obtained on evaporating the solvent under reduced pressure were washed with hexane–ether (1: 1) to give pure **8c**, deep purple crystals, mp >300 °C (dec.), 35 mg, 83%; IR(KBr-disk) 945 s (*trans* –CH=CH–) cm^{-1}.

Found: C, 94.57; H, 5.43%. Calcd for $C_{38}H_{26}$: C, 94.26; H, 5.45%.

CT Complex of 8c with 2,4,7-Trinitrofluorenone. The bisdehydro[14]annulene (**8c**, 10.0 mg, 0.032 mmol) was dissolved in hot toluene (20 ml), and the solution was mixed with a solution of 2,4,7-trinitrofluorenone (10.0 mg, 0.032 mmol) in ethanol (5 ml) and toluene (5 ml). After addition of ethanol (10 ml), the mixture was kept in a refrigerator to give 1: 2 CT complex as violet crystals.

Found: C, 68.87; H, 3.23; N, 7.59%. Calcd for $C_{38}H_{26}\cdot 2C_{13}H_5N_3O_7$: C, 69.06; H, 3.26; N, 7.55%.

The Synthesis of Peptides by Means of Proteolytic Enzymes

Yoshikazu Isowa, Muneki Ohmori, Tetsuya Ichikawa, Hideaki Kurita, Masanari Sato, and Kaoru Mori

Sagami Chemical Research Center, Nishi-Ohnuma Sagamihara, Kanagawa 229

(Received April 15, 1977)

Nagarse, papain, pepsin and thermolysin were found to catalyze the peptide bond formation between two amino acids or peptides, one protected with a suitable group at the amino group and the other at the carboxyl group. Experiments with various combinations of amino acids and dipeptides show specificity in the catalytic action in varying degree which depending on the nature of the enzyme. Since the condensation takes place efficiently under mild conditions, this method opens up a useful way for the synthesis of peptides.

During the last three decades several important general methods and a large number of coupling reagents for peptide bond formation have been developed.[1] Almost all the coupling methods involve the possibility of side reactions and racemization. Racemization may always be expected to some extent when the carboxyl group of an N-protected amino acid or peptide is activated. Careful control of coupling conditions may be used to minimize or eliminate these side reactions and racemization in chemical synthesis.

On the other hand, proteolytic enzyme is expected to provide a potential method for the peptide synthesis without racemization, if hydrolytic action is supressed.

However, no successful result seems to have been reported except for that of Bergmann and Fraenkel-Conrat which involves the condensation of acylamino acid and amino acid anilide in the presence of papain.[2] Fruton[3] referred to their method as an interesting approach to the synthesis of peptide but one involving difficulties which prevent it from being a general synthetic method.

With the expectation that the above difficulties can be overcome by means of the protecting groups of the substrates, we have examined the possibility of using proteolytic enzymes for practical preparation of peptides since a few years ago. The study has produced a considerable amount of useful findings, and in this paper we give some typical examples from the results obtained so far.

Examination was made of the catalytic action of four representative enzymes[4-7] each from seryl-, thiol-, acid-, and metallo-proteinase groups on the following peptide forming reactions between two amino acids or dipeptides suitably protected at the amino group (carboxyl component) or at the carboxyl group (amine component):

1. Z-X-OH + H-Phe-Val-OBu^t ⟶ Z-X-Phe-Val-OBu^t
2. Z-Phe-X-OH + H-Phe-Val-OBu^t ⟶ Z-Phe-X-Phe-Val-OBu^t
3. Z-X-Y-OH + H-Phe-ODPM ⟶ Z-X-Y-Phe-ODPM
4. Z-X-OH + H-Val-ODPM ⟶ Z-X-Val-ODPM
5. Z-X-OH + H-Phe-Phe-OBu^t ⟶ Z-X-Phe-Phe-OBu^t

In these formulas, X and Y stand for arbitrary amino acid residues with Z, benzyloxycarbonyl; Bu^t, *t*-butyl; and DPM, diphenylmethyl as protecting groups.

Materials and Methods

Enzymes: Papain (2.1×10^2 units/mg, Midori Juji Co.), Nagarse (5×10^2 units/mg, Nagase Co.), Thermolysin (8.08×10^3 units/mg, Daiwa Kasei Co.) and porcine pepsin (1.9×10^3 units/mg, Sigma Chemical Co., U.S.A.) were used without further purification.

Substrates: All the amino acids used had the L-configuration.

Phenylalanine Diphenylmethyl Ester p-*Toluenesulfonate and Valine Diphenylmethyl Ester* p-*Toluenesulfonate*: These were prepared in the same manner as described for the corresponding benzyl ester.[8]

Phenylalanine Diphenylmethyl Ester p-*Toluenesulfonate.* The yield was 83%, mp 217—220 °C (from methanol–ether).

Found: C, 68.88; H, 5.76; N, 2.71%. Calcd for $C_{29}H_{29}NO_5S$: C, 69.16; H, 5.80; N, 2.78%.

Valine Diphenylmethyl Ester p-*Toluenesulfonate.* The yield was 65%, mp 173 °C (from methanol–ether).

Found: C, 65.41; H, 6.51; N, 2.96%. Caldc for $C_{25}H_{29}NO_5S$: C, 65.91; H, 6.42; N, 3.07%.

The following dipeptide derivatives were prepared by the procedure given in literature: H-Phe-Val-OBu^t,[9] H-Phe-Phe-OBu^t,[10] Z-Phe-Gly-OH,[11] Z-Phe-Ser-OH,[12] Z-Phe-Arg-(NO_2)-OH,[13] Z-Leu-Phe-OH,[14] Z-Phe-Tyr-OH.[15]

Z-Phe-Val-OEt. To 48.5 g (0.267 mol) of H-Val-OEt in 180 ml of DMF at −10 °C was added 30 ml (0.270 mol) of *N*-methylmorpholine, 80 g (0.267 mol) of Z-Phe-OH, 36.5 g (0.27 mol) of 1-hydroxy-benztriazole and 56.7 g (0.276 mol) of dicyclohexylcarbodiimide in 180 ml of of DMF. After 20 h, the reaction mixture was worked up by the usual procedure. The product was recrystallized from ethanol–water: yield 107.5 g (94%); mp 103—105 °C; $[\alpha]_D$ −18.4° (*c* 1, ethanol).

Found: C, 67.45; H, 7.09; N, 6.61%. Calcd for $C_{24}H_{30}N_2O_5$: C, 67.58; H, 7.09; N, 6.57%.

Z-Phe-Val-OH. A solution of 60 g (0.141 mol) of Z-Phe-Val-OEt in 350 ml of ethanol was saponified with 180 ml of 1 M aqueous sodium hydroxide for 12 h. The solution was acidified with 2M hydrochloric acid and filtered. The sample was recrystallized from ethanol–water for analysis: yield 52.4 g (93%); $[\alpha]_D$ −7.1° (*c* 1, ethanol).

Found: C, 66.11; H, 6.60; N, 7.05%. Calcd for $C_{22}H_{26}N_2O_5$: C, 66.31; H, 6.58; N, 7.03%.

General procedures of the synthesis with enzymes are as follows.

Peptide Synthesis by Papain: 20 ml of a McIlvaine buffer solution having pH 6.6 was added to 1.0 mmol each of a carboxyl component and an amine component. 150 mg

of papain and 0.1 ml of 2-mercaptoethanol were then added to the mixture. After incubation at 38° for 24 h, the resulting precipitate was filtered off and washed in succession with water, 7% aqueous ammonia, 0.5 M hydrochloric acid and water. The product was dissolved in 50 ml of hot methanol and the solution was treated with active carbon. The solution was concentrated *in vacuo* and the residue was recrystallized from an appropriate solvent to give a pure crystalline product.

Peptide Synthesis by Nagarse: 20 ml of a McIlvaine buffer solution having pH of 7.2 was added to 1.0 mmol each of a carboxyl component and an amine component. 150 mg of nagarse was then added to the mixture. After incubation at 38 °C for 24 h, the product was isolated by the same procedure as described above.

Peptide Synthesis by Pepsin: 20 ml of an acetate buffer solution having pH of 4.5 was added to 1.0 mmol each of a carboxyl component and an amine component. 100 mg of pepsin was then added to the mixture and the mixture incubated at 38 °C for 24 h. The product was isolated by the same procedure as described above.

Peptide Synthesis by Thermolysin: 20 ml of a veronal buffer solution having pH of 7.5 was added to 1.0 mmol each of a carboxyl component and an amine component. 20 mg of thermolysin was then added to the mixture. After incubation at 38 °C for 24 h, the product was isolated by the same procedure as described above.

Results and Discussion

The effect of papain and thermolysin on the reaction of benzyloxycarbonyl amino acids with phenylalanyl-valine *t*-butyl ester is given in Table 1.

Table 1. Effect of enzymes on th ereaction
Z-X-OH+H-Phe-Val-OBu^t→Z-X-Phe-Val-OBu^t

Compound(-X-)	Enzyme Yield (%)	
	Papain	Thermolysin
Gly	43	85
Val	—	47
Tyr	15	63
Ser	31	76
Arg(N_{O_2})	49	58

While papain and thermolysin displayed a similar synthetic activity toward these substrates, nagarse and pepsin were ineffective in reaction 1. Thermolysin appears to be more potent than papain in the tripeptide formation.

The effect of papain, thermolysin and nagarse on the reaction of Z-Phe-X-OH with phenylalanyl-valine *t*-butyl ester is given in Table 2.

Table 2. Effect of enzymes on the reaction
Z-Phe-X-OH^t+H-Phe-Val-OBu^t→Z-Phe-X-Phe-Val-OBu^t

Compound(-X-)	Yield (%)		
	Papain	Thermolysin	Nagarse

Val	12	50	22
Tyr	—	72	35
Ser	84	65	—
Arg(NO_2)	91	52	21

Papain, thermolysin and nagarse exhibit a synthetic activity, while pepsin was ineffective in these tetrapeptide formations.

A comparison of the results obtained in reactions 1 and 2 shows that acyl dipeptides (Z-Phe-X-OH) are more prone to give condensation products than acyl amino acids (Z-X-OH) as carboxyl component.

The effect of papain and pepsin on the reaction of benzyloxycarbonyl dipeptide acids (Z-X-Y-OH) with phenylalanine diphenylmethyl ester is given in Table 3.

Table 3. Effect of enzymes on the reaction
Z-X-Y-OH+H-Phe-ODPM→Z-X-Y-Phe-ODPM

Compound (-X-Y-)	Yield (%)	
	Papain	Pepsin
Leu-Phe	98	84.7
Phe-Tyr	94	63
Val-Tyr	100	0

Both enzymes show the same synthetic activity in the case of Z-Leu-Phe-OH or Z-Phe-Tyr-OH with phenylalanine diphenylmethyl ester. It is of interest that there is a striking difference between these enzymes in the case of Z-Val-Tyr-OH as carboxyl component. However, nagarse and thermolysin were ineffective in these reactions.

The effect of papain on the reaction of benzyloxycarbonyl amino acids with valine diphenylmethyl ester is given in Table 4.

Papain exhibits wide peptide formation activity for various amino acids as a carboxyl component.

The effects of papain and thermolysin in the reaction of benzyloxycarbonyl amino acids with phenylalanyl-phenylalanine *t*-butyl ester are compared in Table 5.

These two enzymes show similar activities, the specificity as regards the nature of reacting amino acids being low.

It appears that the low specificity in the peptide bond formation is generally associated with the low specificity in the hydrolysis of protein, such as papain[5] and thermolysin.[7]

The results shown that the utilization of proteolytic enzymes as a catalyst in the formation of a peptide linkage is advantageous for practical synthesis of oligopeptides because of ready condensation under mild conditions.

The authors wish to express their deep gratitude to Drs. Y. Morino and O. Shimamura for their constant encouragement throughout the work. Thanks are due to Mrs. K. Kogure for her skilful assistances throughout the experiments.

The Enzymatic Synthesis of Protected Valine-5 Angiotensin II Amide-1

Yoshikazu Isowa, Muneki Ohmori, Masanari Sato, and Kaoru Mori

Sagami Chemical Research Center, Nishi-Ohnuma Sagamihara, Kanagawa 229

(Received April 15, 1977)

An example of the use of proteolytic enzymes to facilitate the peptide synthesis by fragment condensation is provided for the preparation of protected valine-5 angiotensin II amide-1 using *t*-butoxycarbonylpeptides as a carboxyl component and a peptide ethyl ester as an amine component. The proteolytic enzymes used are papain, nagarse (subtilisin BPN') and microbial metalloenzyme isolated from *St. caespitosus*. Papain-catalyzed condensation reaction afforded the corresponding oligopeptide in the ester form, whereas nagarse and microbial metalloenzyme-catalyzed condensation reactions afforded the products in the carboxyl free form. Assignment of the product was made on the basis of a comparison of physical properties with those of the peptide prepared by the solution method.

Previous work in this series has shown that typical proteolytic enzymes, *e.g.*, papain, thermolysin, nagarse (subtilisin BPN') and pepsin, may be capable of catalyzing peptide bond formation between acylamino acids or acyldipeptides and amino acid or dipeptide esters.[1] The first instance of such a reaction was the amide bond formation between an acylamino acid and amino acid anilide in the presence of papain reported by Bergmann and Fraenkel-Conrat,[2] who also examined the effect of the peptide bond formation by chymotrypsin using an amino acid anilide as an amine component.[3,4] These observations indicate that the proteolytic enzymes catalyze the formation of small peptides such as di, tri, and tetrapeptides. However, since the enzymes essentially catalyze the hydrolysis of peptides, it is of interest to examine them with respect to their ability to catalyze the formation of oligopeptides without undesirable reactions.

This investigation was undertaken to provide a fundamental information on the enzymatic synthesis of oligopeptides using papain,[5] nagarse (subtilisin BPN')[6] and microbial metalloenzyme[7] as catalysts. For this purpose, the preparation of protected valine-5 angiotensin II amide-1 *via* the enzymatic fragment condensation was studied. This peptide hormon consists of eight amino acid residues having a L-configuration. Its constructional formula is as follows.

H–Asn^1–Arg^2–Val^3–Tyr^4–Val^5–His^6–Pro^7–Phe^8–OH

The octapeptide was first synthesized by Schwyzer and co-workers.[8] Several angiotensin peptides have since been prepared by means of solution or solid phase method.

It was demonstrated that the angiotensin undergoes cleavage at a tyrosyl residue on the carboxyl side by the action of chymotrypsin or chymotrypsin-like endopeptidases.[9,10] The peptide bond chosen for the fragment condensation was therefore Tyr^4–Val^5 linkage in this synthetic procedure. The scheme for the preparation of N-terminal dipeptide and tetrapeptide used for carboxyl component is given in Fig. 1 and that of C-terminal tetrapeptide for amino component in Fig. 2.

In order to facilitate isolation the side-chain functional groups of Arg, Tyr, and His were protected by nitro or benzyl group.[11] As an amino protecting group for Arg(NO_2), His(BZL), and Pro, 2,4,6-trimethylbenzyloxycarbonyl (TMZ) group, which was readily

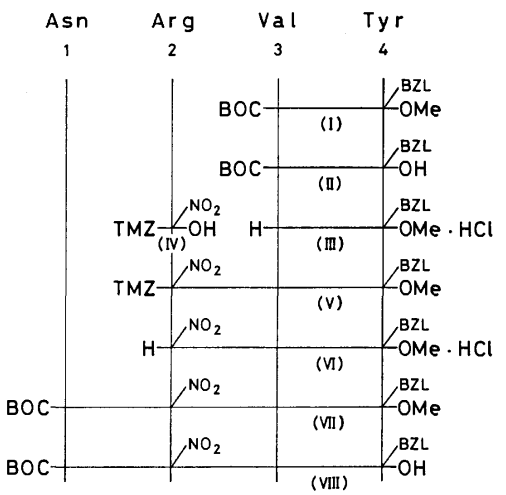

Fig. 1. Preparation of peptide substrates, II and VIII, as carboxyl component; prefix L for amino acids is omitted; BOC, *t*-butoxycarbonyl; TMZ, 2,4,6-trimethylbenzyloxycarbonyl; BZL, benzyl; Me, methyl.

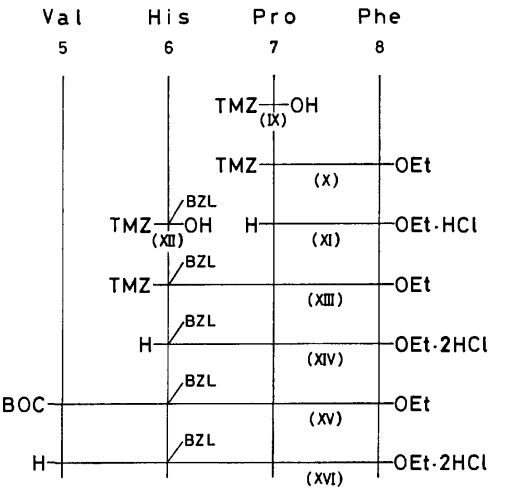

Fig. 2. Preparation of peptide substrate, XVI, as amine component; Et, ethyl.

introduced by the reaction with 2,4,6-trimethylbenzyl 2,4,5-trichlorophenyl carbonate by a modification of the *t*-butoxycarbonylation[12] and smoothly removed by acidolysis, was employed because of the fine crystallization of their peptide derivatives. In a comparison of

VI and XI with samples obtained from the corresponding BOC-derivatives, no detectable amount of optical inpurity was observed.

The reaction sequence for the preparation of the valine-5 angiotensin 3—8 fragment and the protected valine-5 angiotensin II amide-1 as authentic samples is shown in Fig. 3.

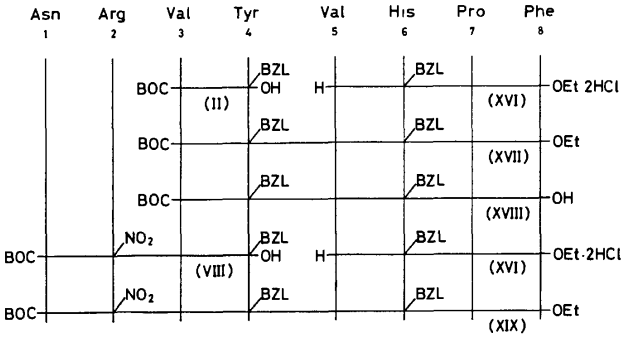

Fig. 3. Preparation of authentic samples, XVII, XVIII, and XIX, by solution method.

In all cases, the coupling reactions were carried out by means of HOBt/DCCI method,[13] the tertiary base being *N*-methylmorpholine, and the solvent *N*,*N*-dimethylformamide. The resulting products were isolated in the usual way. When necessary, the *t*-butoxycarbonyl or 2,4,6-trimethylbenzyloxycarbonyl group was removed by treatment with hydrogen chloride in ethyl acetate. Saponification of the peptide esters was carried out in methanol or *N*,*N*-dimethylformamide solution in the presence of sodium hydroxide at room temperature.

The enzymatic condensation reactions were carried out by incubating the substrates in buffer solutions of the pH comparable to those of the hydrolytic reactions, either in the absence or presence of methanol; the McIlvaine buffer of pH 5.5, 7.5 and Veronal buffer of pH 7.0 were employed for the papain, nagarse and microbial metalloenzyme-catalyzed reactions, respectively. When hydrochloride was used as an amine component, the required quantity of 1 M sodium hydroxide was added. Details of the composition of the reaction mixture and of the reaction conditions are given in Experimental.

All the products obtained in these reactions were identified by direct comparison of their melting point, optical rotation and R_f value of thin layer chromatography with those of samples prepared by the solution method (Fig. 3).

Results and Discussion

1) Syntheses of the Protected Valine-5 Angiotensin II 3-8 Fragment by Papain, Nagarse and Microbial Metalloenzyme-catalyzed Reaction. The possibility of the ploteolytic enzymes to catalyze the formation of oligopeptides was examined in the condensation of BOC–Val–Tyr(BZL)–OH (II) with H–Val–His(BZL)–Pro–Phe–OEt·2HCl (XVI). The results are summarized in Fig. 4.

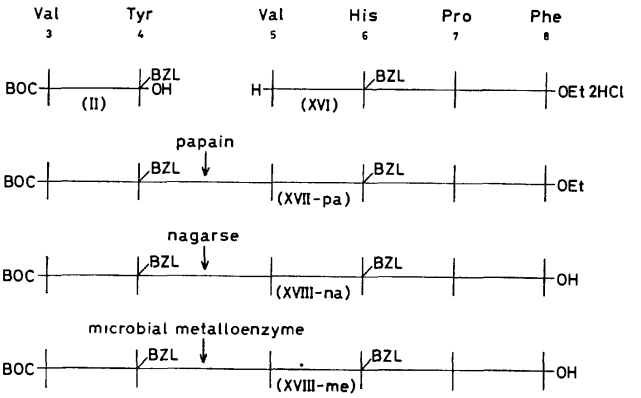

Fig. 4. Enzymatic condensation of BOC–Val–Tyr(BZL)–OH (II) with H–Val–His(BZL)–Pro–Phe–OEt·2HCl (XVI); suffix -pa, -na, and -me indicate the products obtained respectively by papain, nagarse, and microbial metalloenzyme-catalyzed reaction.

The papain-catalyzed reaction in McIlvaine buffer of pH 5.5 containing methanol (1/1, v/v) afforded the corresponding hexapeptide ethyl ester (XVII-pa) as the major product. The presence of all the amino acid residues constituting the hexapeptide and of the ethyl ester were determined by its NMR spectrum (see Experimental). Further structural elucidation was achieved by a comparison of physical properties with those of the peptide ester prepared by the HOBt/DCCI method (Table 1).

Table 1. Comparison of physical properties of XVII-pa with those of XVII prepared by solution method

		Type of condensation	
		Papain-catalyzed condensation (XVII-pa)	HOBt/DCCI (XVII)
Mp(°C)		167—173	164—173
$[\alpha]_D$ (c 1.0)	DMF	−36.0°	−35.3°
	MeOH	−58.5°	−59.2°
R_f (TLC)	system I	0.79	0.79
	system II	0.74	0.75

The observation that the protected hexapeptide ethyl ester (XVII-pa) is mainly obtained by the enzymatic reaction seems to be incompatible with the fact that papain possesses an esterase activity.[5,14] This is of considerable importance from a practical point of view.

The nagarse-catalyzed condensation reaction in McIlvaine buffer of pH 7.5 gave the corresponding hexapeptide in the carboxyl free form (XVIII-na). The melting point, optical rotation and R_f values of thin layer chromatography agree with those of XVIII obtained from the synthetic XVII by saponification (Table 2).

The result is in line with the fact that the serine proteinases catalyze the hydrolysis of ethyl or methyl ester linkage to a great extent.[15,16]

The microbial metalloenzyme-catalyzed reaction in Veronal buffer of pH 7.0 afforded the corresponding

Table 2. Comparison of physical properties of XVIII-na with those of XVIII prepared by saponification of the synthetic XVII

		Type of condensation	
		Nagarse-catalyzed condensation (XVIII-na)	Solution method (XVIII)
MP (°C)[a]		165—169	172—179
$[\alpha]_D$ (c 1.0)	DMF	−27.4°	−28.7°
R_f (TLC)	system I	0.41	0.41
	system II	0.64	0.63

a) Discrepancy in the melting points may be due to the water of crystallization; XVIII-na, $2H_2O$; synthetic XVIII, H_2O.

hexapeptide acid (XVIII-me). In spite of the fact that the microbial metalloenzymes are inactive against the ester substrates,[17,18] no measurable amount of the hexapeptide ester was detected in the condensation product. This might be attributed to an impurity in the microbial metalloenzyme employed.[7]

The investigations into the peptide bond forming ability of the proteolytic enzymes show that the protected hexapeptides can be enzymatically prepared by the fragment condensation of II with XVI without loss of amino acid residues. However, except in the case of the papain-catalyzed reaction, the hexapeptide was obtained in a carboxyl free form even when the condensation reactions were carried out in the presence of methanol.

2) Synthesis of the Protected Valine-5 Angiotensin II Amide-1 by the Papain-catalyzed Reaction. Since the papain-catalyzed reaction afforded the product in the form of the ethyl ester as described in the synthesis of hexapeptide, preparation of the protected valine-5 angiotensin II amide-1 was attempted with use of papain. The product obtained by the papain-catalyzed condensation of fragment 1—4 (VIII) with 5—8 (XVI) in a mixture of McIlvaine buffer of pH 5.5 and methanol (1/1, v/v) was the corresponding octapeptide ester (XIX-pa) containing two of the water of crystallization. Its structure was determined by means of elemental and NMR analysis.

BOC–Asn–Arg(NO_2)–Val–Tyr(BZL)–OH (VIII) + H–Val–His(BZL)–Pro–Phe–OEt (XVI)

↓ papain, in buffer/methanol=1/1 (v/v)

BOC–Asn–Arg(NO_2)–Val–Tyr(BZL)–Val–His(BZL)–Pro–Phe–OEt

Protected valine-5 angiotensin II amide-1 (XIX-pa)

The significant physical properties of XIX-pa were the same as those of XIX prepared by the solution method (Table 3). A small amount of the octapeptide acid was concomitantly obtained when the reaction was carried out in the absence of methanol. It seems to be reasonable to assume that the papain-catalyzed esterolysis is repressed by the addition of methanol to the reaction mixture.

This finding indicates that papain also catalyzes the octapeptide formation *via* fragment condensation without loss of amino acid residues. Furthermore, it is of interest to note that by the addition of methanol to the reaction mixture, the papain-catalyzed reaction affords the product in the form of ethyl ester.

Table 3. Comparison of physical properties of XIX-pa with those of XIX prepared by solution method

		Type of condensation	
		Papain-catalyzed condensation (XIX-pa)	HOBt/DCCI (XIX)
MP (°C)		186—195	189—195
$[\alpha]_D$ (c 1.0)	DMF	−27.3°	−26.5°
	MeOH	−48.3°	−48.4°
R_f (TLC)	system I	0.62	0.63
	system II	0.56	0.55

It is apparent that the proteolytic enzymes, papain, nagarse and microbial metalloenzyme, are capable of synthesizing oligopeptide by fragment condensation. The oligopeptide formation can be attributed to the insolubility of the products, which influences the equilibrium in favor of the peptide bond formation.

In view of the low solubility of the protected oligopeptides, the application of this enzymatic procedure, enzymatic procedure, along with a combination of the solution method, promises a new possibility of facile preparation of the peptide.

Experimental

The melting points were determined on a Yanagimoto micro melting point apparatus and are uncorrected. The optical rotations were measured with a Yanagimoto automatic polarimeter OR-50 type. The NMR spectra were recorded on a Varian HA-100 High Resolution NMR spectrometer, using tetramethylsilane as an internal or external standard. The thin layer chromatography was carried out on precorted plates of silica gel G (E. Merck). The developing solvents commonly used were 2-butanol–3% ammonia water (8: 3, v/v) (system I) and 1-butanol–acetic acid–water (4: 1: 5, v/v) (system II).

Enzymes. All the proteolytic enzymes used in this investigation were commercial preparations; papain (Midori Juji Co., E-2 1200 U/g); nagarse (Nagase Sangyo Co., 50×10^4 PUN/g); microbial metalloenzyme *(St. caespitosus)* (Kyowa Hakko Kogyo Co.). The proteolytic activities of the papain, nagarse and microbial metalloenzyme, assayed by the casein digestion method of Tsuru, Yamamoto, and Fukumoto[19] with the exception that the papain was preincubated with cysteine, were 2.20×10^5, 1.15×10^6 and 2.64×10^5 PU/g, respectively. The microbial metalloenzyme seems to be contaminated with alkaline proteinases, since the proteolytic activity is inhibited by not only EDTA but also diisopropyl fluorophosphate.[7]

BOC–Val–Tyr(BZL)–OMe (I). A mixture of BOC–Val–OH (10.9 g, 50 mmol) and H–Tyr(BZL)–OMe·HCl (16.1 g, 50 mmol) in 120 ml of *N,N*-dimethylformamide was cooled at −5 °C with stirring. To the chilled solution were added *N*-methylmorpholine (5.1 g, 50 mmol) and 1-hydroxybenzotriazole (6.8 g, 50 mmol), followed by a solution of dicyclohexylcarbodiimide (10.7 g, 52 mmol) in 50 ml of *N,N*-dimethylformamide. Stirring was continued at the same temperature

for 1 h and then at room temperature for 8 h. After removal of the urea by filtration the filtrate was evaporated to dryness *in vacuo* and the residue was treated with water. The solid product was collected by filtration and washed with 5% sodium hydrogencarbonate, water, 1 M hydrochloric acid and water. Recrystallization twice from methanol–water yielded 20.3 g (83.7%) of I; mp 114—116 °C; $[\alpha]_D$ −13.0° (*c* 1.0, methanol).

Found: C, 67.17; H, 7.31; N, 5.79%. Calcd for $C_{27}H_{36}N_2O_6$: C, 66.92; H, 7.49; N, 5.78%.

BOC–Val–Tyr(BZL)–OH (II). A solution of I (14.5 g, 30 mmol) in methanol was treated with 1 M sodium hydroxide (33 ml) at room temperature for 2 h. After removal of methanol *in vacuo*, the aqueous solution was acidified with 2 M hydrochloric acid under ice-cooling. The precipitate was collected by filtration and washed with water, and then recrystallized from methanol–water; 11.6 g (82.2%); mp 142—145 °C; $[\alpha]_D$ +0.2° (*c* 1.0, methanol). A sample was further recrystallized from a small volume of methanol for analysis; mp 143—145 °C.

Found: C, 66.51; H, 7.01; N, 6.07%. Calcd for $C_{26}H_{34}N_2O_6$: C, 66.36; H, 7.28 N, 5.95%.

H–Val–Tyr(BZL)–OMe·HCl (III). Eighty milliliter of 5 M hydrogen chloride in ethyl acetate was added to a suspension of I (9.69 g, 20 mmol) in 40 ml of ethyl acetate. The substance dissolved immediately to form a clear solution. After being left to stand for 2 h at room temperature, the solution was evaporated to dryness *in vacuo*. The residue was crystallized by addition of ether; 8.10 g (96.2%); mp 175—179 °C; $[\alpha]_D$ +29.2° (*c* 1.0, methanol).

Found: C, 62.94; H, 6.82; N, 6.45%. Calcd for $C_{22}H_{29}N_2O_4Cl$: C, 62.77; H, 6.94; N, 6.66%.

2,4,6-Trimethylbenzyl 2,4,5-Trichlorophenyl Carbonate. 2,4,6-Trimethylbenzyl alcohol (26.2 g, 174 mmol) was allowed to react with 2,4,5-trichlorophenyl chloroformate (45.2 g, 174 mmol) in 200 ml of dichloromethane in the presence of quinoline (23.2 g, 180 mmol), by the same procedure as that for the preparation of *t*-butyl 2,4,5-trichlorophenyl carbonate.[12] Recrystallization from ligroine yielded colorless needles of the carbonate; 43.0 g (66.1%); mp 113—115 °C.

Found: C, 54.41; H, 4.18; Cl, 28.73%. Calcd for $C_{17}H_{15}O_3Cl_3$: C, 54.64; H, 4.05; Cl, 28.47%.

TMZ–Arg(NO$_2$)–OH (IV). Twenty-eight milliliter of 40% benzyltrimethylammonium hydrxide was added to a suspension of H–Arg(NO$_2$)–OH (10.6 g, 48.5 mmol) in 100 ml of methanol and the resulting mixture was stirred at 55—60 °C until solution was complete (2 h). The solvent was removed *in vacuo* and replaced by a mixture of 200 ml of dioxane and 50 ml of water. To the solution obtained was added 2,4,6-trimethylbenzyl 2,4,5-trichlorophenyl carbonate (18.7 g, 50.0 mmol) and the solution was stirred for 6 h at 55 °C. After removal of the solvent *in vacuo*, the residue was taken up in 250 ml of water and the aqueous solution was washed three times with 100 ml of ether. IV was precipitated by bringing the pH of the solution to 4—5 with citric acid. The crude material was collected, washed with water, and recrystallized from ethanol–ether; 17.2 g (89.7%); mp 176—178 °C; $[\alpha]_D$ +20.7° (*c* 1.0, methanol) and +0.8° (*c* 1.0, tetrahydrofuran).

Found: C, 51.52; H, 6.36; N, 17.48%. Calcd for $C_{17}H_{25}N_5O_6$: C, 51.63; H, 6.37; N, 17.71%.

TMZ–Arg(NO$_2$)–Val–Tyr(BZL)–OMe (V). Condensation of III (4.21 g, 10 mmol) with IV (3.95 g, 10 mmol) was carried out as described for I. Recrystallization of the product twice from methanol–water yielded V as a colorless powder; 5.97 g (78.4%); mp 191—192 °C; $[\alpha]_D$ +3.0° (*c* 1.0, *N,N*-dimethylformamide).

Found: C, 61.33; H, 6.67; N, 12.80%. Calcd for $C_{39}H_{51}N_7O_9$: C, 61.48; H, 6.75; N, 12.87%.

H–Arg(NO$_2$)–Val–Tyr(BZL)·OMe·HCl (VI). Deprotection of V (5.20 g, 6.83 mmol) with 5 M hydrogen chloride in ethyl acetate was carried out in the way as in the preparation of III. The solid product obtained on evaporation was recrystallized from methanol–ether; 4.16 g (98.0%); mp 220—223 °C; $[\alpha]_D$ +25.7° (*c* 1.0, methanol); thin layer chromatography, R_f 0.59 (system I).

Found: C, 53.95; H, 6.43; N, 15.82%. Calcd for $C_{28}H_{40}N_7O_7Cl$: C, 54.05; H, 6.48; N, 15.76%.

This compound was found to be identical with that obtained from the corresponding BOC-derivative (amorphous powder) by comparison of the melting point, optical rotation and R_f value of thin layer chromatography: VI obtained from BOC-derivative; mp 219—223 °C, no depression on admixture with above product; $[\alpha]_D$ +25.4° (*c* 1.0, methanol): thin layer chromatography of a mixed sample, R_f 0.60 (system I).

BOC–Asn–Arg(NO$_2$)–Val–Tyr(BZL)–OMe (VII). To a chilled (−5 °C) solution of BOC–Asn–OH (5.8 g, 25 mmol) and VI (15.6 g, 25 mmol) in 120 ml of *N,N*-dimethylformamide were added *N*-methylmorpholine (2.5 g, 25 mmol) and 1-hydroxybenzotriazole (3.4 g, 25 mmol), followed by dicyclohexylcarbodiimide (5.4 g, 26 mmol) in 20 ml of *N,N*-dimethylformamide. The mixture was stirred at −5 °C for 2 h and then at room temperature for 10 h. The mixture, after removal of urea, was evaporated to dryness *in vacuo* and the residue was treated with 80 ml of water. The resulting solid product was collected by filtration and washed with 5% sodium hydrogencarbonate, water, 1 M hydrochloric acid and water. Recrystallization from *N,N*-dimethylformamide—water gave 16.9 g (85.5%) of VII, mp 198—201 °C. For analysis, a small amount of the product was further recrystallized from *N,N*-dimethylformamide–methanol–water; mp 201—203 °C; $[\alpha]_D$ −5.2° (*c* 1.0, *N,N*-dimethylformamide).

Found: C, 55.80; H, 6.41; N, 15.59%. Calcd for $C_{37}H_{53}N_9O_{11}$: C, 55.56; H, 6.68; N, 15.76%.

BOC–Asn–Arg(NO$_2$)–Val–Tyr(BZL)–OH (VIII). To a stirred solution of VII (1.0 g, 1.25 mmol) in 20 ml of *N,N*-dimethylformamide was added dropwise 0.1 M sodium hydroxide until the pH became 11. The solution was maintained at this pH by gradual addition of sodium hydroxide over a period of 1 h (the total amount of sodium hydroxide required was 30 ml). After stirring for 2 h at room temperature, 4 ml of 1 M hydrochloric acid was added with stirring over 15 min under ice-cooling. The mixture was concentrated *in vacuo* nearly to dryness and the residue was triturated with water. The resulting solid product was collected by filtration, washed thoroughly with water, and recrystallized from ethanol–water; 0.87 g (88.6%); mp 167—170 °C; $[\alpha]_D$ −5.0° (*c* 0.5, methanol); thin layer chromatography, R_f 0.57 (system I) and 0.69 (system II).

Found: C, 54.82; H, 6.49; N, 16.04%. Calcd for $C_{36}H_{51}N_9O_{11}$: C, 55.02; H, 6.54; N, 16.04%.

TMZ–Pro–OH (IX). The 2,4,6-trimethylbenzyloxycarbonylation of H–Pro–OH (11.5 g, 100 mmol) with 2,4,6-trimethylbenzyl 2,4,5-trichlorophenyl carbonate (39.2 g, 105 mmol) was carried out as described for IV. The oily material which separated on acidification of the aqueous solution was extracted with 400 ml of ethyl acetate, the ethyl acetate solution being washed with water and dried over sodium sulfate. Removal of solvent gave 28.6 g (98.2%) of IX as a colorless viscous oil; $[\alpha]_D$ −31.4° (*c* 2.03, methanol). The homogeneity of this product was established by thin layer chromatography, R_f 0.47 (system I) and 0.79 (system II). The oily product was further characterized by the preparation of the corresponding dicyclohexylamine salt; mp 165—168 °C; $[\alpha]_D$ −20.0° (*c* 1.0, methanol).

Found: C, 71.32; H, 9.54; N, 5.82%. Calcd for $C_{25}H_{44}N_2O_4$: C, 71.15; H, 9.38; N, 5.93%.

TMZ-Pro-Phe-OEt (X). Condensation of IX (23.6 g, 81 mmol) with H-Phe-OEt·HCl (18.6 g, 81 mmol) in the presence of *N*-methylmorpholine (8.2 g, 81 mmol), 1-hydroxybenzotriazole (10.9 g, 81 mmol) and dicyclohexylcarbodiimide (17.1 g, 83 mmol) was carred out as described for I. The product was recrystallized twice from ethyl acetate–hexane; 34.5 g (85.9%); mp 97—99 °C; $[\alpha]_D$ −46.0° (*c* 1.0, ethanol).

Found: C, 69.56; H, 7.13; N, 5.95%. Calcd for $C_{27}H_{34}N_2O_5$: C, 69.50; H, 7.35; N, 6.01%.

H-Pro-Phe-OEt·HCl (XI). X (10.0 g, 21 mmol) was treated with 5 M hydrogen chloride in ethyl acetate by the same procedure as for III. The product obtained on evaporation of the reaction mixture was recrystallized from ethanol–ether; 6.51 g (94.9%); mp 151—153 °C; $[\alpha]_D$ −35.0° (*c* 1.0, ethanol).

Found: C, 58.77; H, 7.10; N, 8.62%. Calcd for $C_{16}H_{23}N_2O_3Cl$: C, 58.80; H, 7.09; N, 8.57%.

This compound was found to be identical with that obtained from BOC-Pro-Phe-OEt (oily material) by comparison of melting point, optical rotation and thin layer chromatography: XI obtained from BOC-derivative; mp 151—153 °C, no depression on admixture with a sample prepared above; $[\alpha]_D$ −35.1° (*c* 1.0, ethanol); thin layer chromatography of a mixed sample gave a single spot, R_f 0.68 (system I).

TMZ-His(BZL)-OH (XII). H-His(BZL)-OH (12.3 g, 50 mmol) was allowed to react with 2,4,6-trimethylbenzyl 2,4,5-trichlorophenyl carbonate (19.4 g, 52 mmol) as in the preparation of IV. The product was recrystallized from methanol–water; 17.8 g (84.5%); mp 181—183 °C; $[\alpha]_D$ +34.2° (*c* 1.0, methanol) and +12.0° (*c* 1.0, *N,N*-dimethylformamide).

Found: C, 68.49; H, 6.40; N, 9.98%. Calcd for $C_{24}H_{27}N_3O_4$: C, 68.39; H, 6.46; N, 9.97%.

TMZ-His(BZL)-Pro-Phe-OEt (XIII). A solution of XII (13.1 g, 31.0 mmol) and XI (10.0 g, 30.6 mmol) in 80 ml of *N,N*-dimethylformamide was cooled at −5 °C with stirring. To this solution were added *N*-methylmorpholine (3.10 g, 30.6 mmol) and 1-hydroxybenzotriazole (4.13 g, 30.6 mmol), followed by a solution of dicyclohexylcarbodiimide (6.40 g, 31.0 mmol) in 30 ml of *N,N*-dimethylformamide. Stirring was continued for 2 h at this temperature and 8 h at room temperature. After the urea was filtered off, the filtrate was evaporated *in vacuo* and the residue was taken up in 300 ml of ethyl acetate. The ethyl acetate solution was washed with 7% aqueous ammonia and water, dried over sodium sulfate, and then evaporated to dryness *in vacuo*. The resulting semi-solid product was purified by dissolution in 200 ml of hot ethyl acetate, treated with charcoal, and concentration to a small volume followed by the addition of 100 ml of petroleum ether to yield XIII as an amorphous powder; 20.8 g (97.8%); $[\alpha]_D$ −37.2° (*c* 1.0, methanol). The homogeneity was confirmed by thin layer chromatography; R_f 0.84 (system I) and 0.72 (system II).

Found: C, 68.81; H, 6.68; N, 10.08%. Calcd for $C_{40}H_{47}N_5O_6$: C, 69.24; H, 6.83; N, 10.09%.

All attempts to crystallize the product were unsuccessful. It was thus used for the reaction without further purification.

H-His(BZL)-Pro-Phe-OEt·2HCl (XIV). Fifty milliter of 5 M hydrogen chloride in ethyl acetate was added to a solution of XIII (8.20 g, 11.8 mmol) in 25 ml of ethyl acetate. After being left to stand for 2 h at room temperature, the solution was evaporated *in vacuo* to afford a solid product which was collected by filtration with the aid of ether and washed thoroughly with ether. Recrystallization from ethanol gave colorless needles of XIV; 6.62 g (95.1%); mp 215—218 °C; $[\alpha]_D$ −6.3° (*c* 1.0, methanol).

Found: C, 58.88; H, 6.36; N, 11.89%. Calcd for $C_{29}H_{37}N_5O_4Cl_2$: C, 59.08; H, 6.33; N, 11.88%.

BOC-Val-His(BZL)-Pro-Phe-OEt·2H₂O (XV). BOC-Val-OH (3.74 g, 17.2 mmol) was coupled with XIV (9.98 g, 16.9 mmol) in the presence of *N*-methylmorpholine (3.42 g, 33.8 mmol), 1-hydroxybenzotriazole (2.28 g, 16.9 mmol) and dicyclohexylcarbodiimide (3.51 g, 17.0 mmol) by the same procedure as for XIII. Removal of urea by filtration followed by concentration of the filtrate *in vacuo* gave an oily residue, which was taken up in 200 ml of ethyl acetate. The ethyl acetate solution, after being washed with 7% aqueous ammonia, was dried over sodium sulfate and evaporated to dryness *in vacuo*. Trituration of the residue with a mixture of ether and petroleum ether afforded a solid material. Recrystallization from ethanol–ether gave XV as an amorphous powder with two molecules of the water of crystallization; 11.2 g (88.0%); mp 111—116 °C; $[\alpha]_D$ −36.0° (*c* 1.0, methanol); thin layer chromatography, R_f 0.82 (system I) and 0.70 (system II).

Found: C, 61.97; H, 7.25; N, 11.24%. Calcd for $C_{39}H_{52}N_6O_7\cdot 2H_2O$: C, 62.21; H, 7.49; N, 11.16%.

H-Val-His(BZL)-Pro-Phe-OEt·2HCl (XVI). A suspension of XV (9.03 g, 12.0 mmol) in 40 ml of ethyl acetate was treated with 96 ml of 5 M hydrogen chloride in ethyl acetate. After being left to stand for 2 h at room temperature the solution was evaporated *in vacuo* and the residue was taken up in 150 ml of water. The aqueous layer was washed three times with 50 ml of ethyl acetate, followed by treatment with charcoal. Removal of the solvent by azeotropic distillation *in vacuo* gave an oily material. This was solidified by triturating with ethanol–ether and recrystallized from the same solvent; 7.40 g (89.4%); mp 158—162 °C; $[\alpha]_D$ −15.9° (*c* 1.0, methanol) and −10.4° (*c* 1.0, ethanol).

Found: C, 58.96; H, 6.98; N, 12.33%. Calcd for $C_{34}H_{46}N_6O_5Cl_2$: C, 59.21; H, 6.72; N, 12.19%.

BOC-Val-Tyr(BZL)-Val-His(BZL)-Pro-Phe-OEt·1/2 H₂O (XVII) as an Authentic Sample. To a cooled solution (−5 °C) of II (2.35 g, 5.00 mmol) and XVI (3.45 g, 5.00 mmol) in 50 ml of *N,N*-dimethylformamide were added *N*-methylmorpholine (1.01 g, 10.0 mmol) and 1-hydroxybenzotriazole (0.68 g, 5.00 mmol) with stirring, followed by a solution of dicyclohexylcarbodiimide (1.05 g, 5.10 mmol) in 5 ml of *N,N*-dimethylformamide. The mixture was stirred for 2 h at −5 °C and for 36 h at room temperature. Removal of urea by filtration followed by concentration of the filtrate *in vacuo* gave a solid material, which was collected by suction with water, washed with 7% aqueous ammonia and water, and then dissolved in 20 ml of a mixture of *N,N*-dimethylformamide and water (5: 1, v/v). A small amount of insoluble substance was removed by filtration, the filtrate being passed through a column of Sephadex LH-20. The effluent was evaporated to dryness *in vacuo*, and the product was suspended in water, collected by filtration, and dried. Recrystallization twice from methanol–water gave XVII as a colorless powder; 3.89 g (71.5%); mp 164—173 °C; $[\alpha]_D$ −59.2° (*c* 1.0, methanol) and −35.3° (*c* 1.0, *N,N*-dimethylformamide). The homogeneity of this product was confirmed by thin layer chromatography, R_f 0.79 (system I) and 0.75 (system II). Prior to analysis, the compound was dried over phosphorus pentaoxide at 70 °C and 2 mmHg.

Found: C, 66.77; H, 7.09; N, 10.32%. Calcd for $C_{60}H_{76}N_8O_{10}\cdot 1/2\ H_2O$: C, 66.82; H, 7.19; N, 10.39%.

BOC-Val-Tyr(BZL)-Val-His(BZL)-Pro-Phe-OH·H₂O (XVIII) as an Authentic Sample. To a stirred solution of XVII (2.17 g, 2.0 mmol) in 40 ml of ethanol was added 48 ml of 0.1 M sodium hydroxide dropwise at room temperature

over a period of 1 h. After being stirred for 2 h the reaction mixture was neutralized with Dry Ice according to the method of Schwyzer, *et al.*,[20] and evaporated to a small volume *in vacuo*. The residue obtained was taken up in 40 ml of water and the solution was acidified with citric acid to yield a solid product. Recrystallization from ethanol gave XVIII as colorless needles with one molecule of the water of crystallization; 1.29 g (62.3%); mp 172—179 °C; $[\alpha]_D$ −28.7° (*c* 1.0, *N,N*-dimethylformamide); thin layer chromatography, R_f 0.41 (system I) and 0.63 (system II).

Found: C, 65.86; H, 6.92; N, 10.69%. Calcd for $C_{58}H_{72}N_8O_{10}\cdot H_2O$: C, 65.76; H, 7.04; N, 10.58%.

BOC–Asn–Arg(NO_2)–Val–Tyr(BZL)–Val–His(BZL)–Pro–Phe–OEt·2H_2O(XIX) as an Authentic Sample. *N*-Methylmorpholine (2.02 g, 20 mmol) and 1-hydroxybenzotriazole (1.35 g, 10 mmol) were added with stirring to a cooled (−5 °C) solution of VIII (7.86 g, 10 mmol) and XVI (6.70 g, 10 mmol) in 80 ml of *N,N*-dimethylformamide. To this was added in one portion a solution of dicyclohexylcarbodiimide (2.27 g, 11 mmol) in 10 ml of *N,N*-dimethylformamide. After being stirred for 48 h at room temperature, the reaction mixture was worked up by the same procedure for XVII. Recrystallization from ethanol–water gave XIX as a colorless powder with two molecules of the water of crystallization; 10.6 g (74.3%); mp 189—195 °C; $[\alpha]_D$ −48.4° (*c* 1.0, methanol) and −26.5° (*c* 1.0, *N,N*-dimethylformamide). Only one spot was obtained in thin layer chromatography, R_f 0.63 (system I) and 0.55 (system II).

Found: C, 59.07; H, 6.72; N, 14.75%. Calcd for $C_{70}H_{93}N_{15}O_{15}\cdot 2H_2O$: C, 59.17; H, 6.88; N, 14.79%.

Enzymatic Syntheses of the Protected Valine-5 Angiotensin II 3—8 Fragment. *i) Papain-catalyzed Condensation of II with XVI (XVII-pa)*: Papain (150 mg) and 0.1 ml of 2-mercaptoethanol were added to a solution of II (471 mg, 1.0 mmol) and XVI (690 mg, 1.0 mmol) in a mixture of 15 ml of McIlvaine buffer (pH 5.5) and 15 ml of methanol containing 2 ml of 1 M sodium hydroxide. After being incubated at 38 °C for 2 h, the product precipitated was collected by filtration, washed with 7% aqueous ammonia, 2% citric acid and water, and then dried. Recrystallization from methanol–water gave the hexapeptide ester (XVII-pa) as colorless crystals with a half molecule of the water of crystallization; 615 mg (57.0%); mp 167—173 °C, no depression on admixture with XVII prepared by the solution method; $[\alpha]_D$ −36.0° (*c* 1.0, *N,N*-dimethylformamide) and −58.5° (*c* 1.0, methanol). Only one spot was obtained in thin layer chromatography, R_f 0.79 (system I) and 0.74 (system II).

Found: C, 66.72; H, 7.16; N, 10.55%. Calcd for $C_{60}H_{76}N_8O_{10}\cdot 1/2\ H_2O$: C, 66.82; H, 7.19; N, 10.39%.

The NMR spectrum in DMSO-d_6 showed the following signals in ppm: 0.74 (12H; $-CH_3$ of Val), 1.05 (3H: $-CH_3$ of OEt), 1.36 (9H; $-CH_3$ of BOC), 1.75 (4H; β,γ–CH_2– of Pro), 1.91 (2H; β–CH– of Val), 2.78—3.28 (8H; δ–CH_2– of Pro and β–CH_2– of Phe, His and Tyr), 3.92 (2H; $-CH_2-$ of OEt), 4.98—5.05 (4H; $-CH_2-$ of BZL in His and Tyr), 6.79 and 7.02 (4H; $-C_6H_4-$ of Tyr), and 7.18—7.34 (15H; $-C_6H_5$ of Phe and BZL in His and Tyr).

ii) Nagarse-catalyzed Condensation of II with XVI (XVIII-na): Nagarse (40 mg) was added to a suspension of II (282 mg, 0.60 mmol) and XVI (414 mg, 0.60 mmol) in 8.0 ml of McIlvaine buffer of pH 7.5 containing 1.2 ml of 1 M sodium hydroxide. After being incubated at 38 °C for 6 h, the product precipitated was collected by filtration, washed with 2% citric acid and water, and then dried. The product was purified by solution in 40 ml of hot ethanol, treatment with charcoal, and concentration into a small volume, followed by the addition of ethyl acetate which gave the hexapeptide acid (XVIII-na) as a colorless powder with two molecules of the water of crystallization; 476 mg (73.7%); mp 165—169 °C; $[\alpha]_D$ −27.4° (*c* 1.0, *N,N*-dimethylformamide); thin layer chromatography, R_f 0.41 (system I) and 0.64 (system II).

Found: C, 64.87; H, 6.90; N, 10.52%. Calcd for $C_{58}H_{72}N_8O_{10}\cdot 2H_2O$: C, 64.66; H, 7.11; N, 10.40%.

The NMR spectrum of XVIII-na in DMSO-d_6 showed the following signals in ppm: 0.75 (12H; $-CH_3$ of Val), 1.36 (9H; $-CH_3$ of BOC), 1.69 (4H; β,γ–CH_2– of Pro), 1.92 (2H; β–CH– of Val), 2.80—3.11 (8H; δ–CH_2– of Pro and β–CH_2– of Phe, His and Tyr), 4.97 and 5.07 (4H; $-CH_2-$ of BZL in His and Tyr), 6.79 and 7.01 (4H; $-C_6H_4-$ of Tyr), and 7.18—7.33 (15H; $-C_6H_5$ of Phe and BZL in His and Tyr). No signals of ethyl ester were observed in this spectrum.

iii) Microbial Metalloenzyme-catalyzed Condensation of II with XVI (XVIII-me): Microbial metalloenzyme (50 mg) was added to a suspension of II (235 mg, 0.50 mmol) and XVI (345 mg, 0.50 mmol) in 8.0 ml of Veronal buffer of pH 7.0 containing 1.0 ml of 1 M sodium hydroxide. After being incubated at 38 °C for 6 h, the reaction mixture was worked up in the same way as for XVIII-na. XVIII-me was obtained as a colorless powder with two molecules of the water of crystallization; 222 mg (41.2%); mp 164—169 °C, no depression on admixture with XVIII-na; $[\alpha]_D$ −27.9° (*c* 0.5, *N,N*-dimethylformamide); thin layer chromatography, R_f 0.42 (system I) and 0.65 (system II).

Found: C, 64.89; H, 7.01; N, 10.32%. Calcd for $C_{58}H_{72}N_8O_{10}\cdot 2H_2O$: C, 64.66; H, 7.11; N, 10.40%.

The NMR spectral data of XVIII-me were consistent with those of XVIII-na.

Enzymatic Synthesis of the Protected Valine-5 Angiotensin II Amide-1. Papain-catalyzed Condensation of VIII with XVI (XIX-pa): Papain (100 mg) and 0.07 ml of 2-mercaptoethanol were added to a solution of VIII (472 mg, 0.60 mmol) and XVI (414 mg, 0.60 mmol) in a mixture of 10 ml of McIlvaine buffer (pH 5.5) and 10 ml of methanol containing 1.2 ml of 1 M sodium hydroxide. After being incubated at 38 °C for 2 h, the product precipitated was collected by filtration, washed 7% with aqueous ammonia, 2% citric acid and water. Recrystallization carried out by evaporating an ethanol solution of the product gave a colorless powder of the octapeptide ester (XIX-pa) with two molecules of the water of crystallization; 685 mg (78.1%); mp 186—195 °C, no depression on admixture with XIX prepared by solution method; $[\alpha]_D$ −27.3° (*c* 1.0, *N,N*-dimethylformamide) and −48.3° (*c* 1.0, methanol). Only one spot was obtained in thin layer chromatography, R_f 0.62 (system I) and 0.56 (system II).

Found: C, 59.11; H, 6.62; N. 14.92%. Calcd for $C_{70}H_{93}N_{15}O_{15}\cdot 2H_2O$: C, 59.17; H, 6.88; N, 14.79%.

The NMR spectrum of XIX-pa in DMSO-d_6 showed following signals in ppm: 0.75 (12H; $-CH_3$ of Val), 1.08 (3H; $-CH_3$ of OEt), 1.36 (9H; $-CH_3$ of BOC), 1.50—1.80 (8H; β,γ–CH_2– of Pro and Arg), 3.45 (2H; δ–CH_2– of Arg), 3.92 (2H; $-CH_2-$ of OEt), 4.98—5.21 (4H; $-CH_2-$ of BZL in His and Tyr), 6.80 and 7.12 (4H, $-C_6H_4-$ of Tyr), and 7.20—7.32 (15H; $-C_6H_5$ of Phe, and BZL in His and Tyr).

Efficient Methods for Oxidation of Alcohols

Koichi NARASAKA, Anri MORIKAWA, Kazuhiko SAIGO,* and Teruaki MUKAIYAMA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received April 18, 1977)

Treatment of alkoxymagnesium bromides, prepared *in situ* from alcohols and Grignard reagent, with *N*-chlorosuccinimide, *m*-chloroperbenzoic acid, or (diacetoxyiodo)benzene in the presence of *t*-butoxymagnesium bromide afforded the corresponding carbonyl compounds in good yields. A wide variety of alcohols, after being converted into their bromomagnesium salts by treatment with propylmagnesium bromide, were also selectively oxidized with 1,1′-(azodicarbonyl)dipiperidine to afford the corresponding ketones or aldehydes in excellent yields.

In the preceding communications, convenient methods were reported for the oxidation of alcohols to the corresponding ketones or aldehydes by the treatment of trialkyltin methoxide[1] or bis(tributyltin) oxide,[2] and by that of alkoxymagnesium bromides with *N*-chlorosuccinimide in the presence of lithium *t*-butoxide.[3]

These reactions were successfully applied to the oxidation of alcohols such as secondary alcohols, allylic alcohols, and benzylic alcohols, but not aliphatic and olefinic primary alcohols. Improvement of the methods was undertaken in order to establish an effective method for the oxidation of a wide variety of alcohols, especially aliphatic and olefinic primary alcohols.

In the previous methods, effective acid captors such as lithium *t*-butoxide, trialkyltin methoxide and bis(tributyltin) oxide were employed in order to scavenge hydrogen halides generated during the course of the reactions. It was found that the yields of the products depend a great deal on the kinds of acid captor. The effects of the other acid captors were reexamined in detail. The yields of the carbonyl compounds increased remarkably when *t*-butoxymagnesium bromide was used as an acid captor instead of lithium *t*-butoxide in the reaction of alkoxymagnesium bromide with *N*-chlorosuccinimide, the carbonyl compounds being obtained in the best yields when the molar ratio of alkoxymagnesium bromide, *t*-butoxymagnesium bromide, and *N*-chlorosuccinimide was 1 : 1.2 : 1.2. When several aliphatic primary alcohols, after being converted into the bromomagnesium salts by propylmagnesium bromide, were treated with a 1.2 molar amount of *N*-chlorosuccinimide in the presence of a 1.2 molar amount of *t*-butoxymagnesium bromide in tetrahydrofuran for 30 min at room temperature, the corresponding aldehyde were produced in good yields (Table 1). In the case of the oxidation of olefinic primary alcohol such as 7-phenyl-4-hepten-1-ol, the desired 7-phenyl-4-heptenal was obtained in low yield (34%), some by-products being produced.

In order to find suitable oxidizing reagents for the oxidation of olefinic primary alcohols, several oxidizing reagents were examined. It was found that when *m*-chloroperbenzoic acid or (diacetoxyiodo)benzene is used for the oxidation of the bromomagnesium salt of 7-phenyl-4-hepten-1-ol in the presence of *t*-butoxymagnesium bromide, 7-phenyl-4-heptenal is obtained in fairly good yields. The bromomagnesium salt of 7-phenyl-4-hepten-1-ol, prepared from the alcohol and propylmagnesium bromide, was treated with a 1.2 molar amount of (diacetoxyiodo)benzene or *m*-chloroperbenzoic acid in the presence of a 1.2 molar amount of *t*-butoxymagnesium bromide in tetrahydrofuran for 30 min at room temperature. The desired 7-phenyl-4-heptenal was isolated in 76 and 74% yields, respectively. In a similar way, several kinds of alcohols such as aliphatic primary alcohol, secondary alcohol, benzylic alcohol, and allylic alcohol were oxidized to the corresponding carbonyl compounds in good yields by use of these reagents (Table 2). The yields of the oxidation

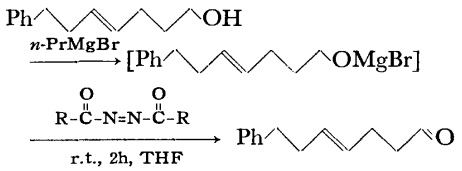
product of the olefinic primary alcohol, 7-phenyl-4-hepten-1-ol, were not so good in comparison with those of the other kinds of alcohols, small amounts of by-products being obtained.

Further examination of suitable oxidizing reagents for the oxidation of olefinic primary alcohol was carried out. Concerning the oxidation of alcohols, an efficient method for ketone synthesis was reported.[4] That is, *s*-alkoxymagnesium bromides were prepared by the reaction of aldehydes with Grignard reagents followed by treatment with diethyl azodicarboxylate or 1,1′-(azodicarbonyl)dipiperidine, resulting in the formation of the corresponding ketones in good yields. Generally these azo compounds are inactive to olefinic linkage, and the use of azo compounds is expected to suppress the side reactions with respect to olefinic linkage of the alcohol. The oxidation of 7-phenyl-4-hepten-1-ol was attempted first by employing diethyl azodicarboxylate as an oxidant. However, the desired oxidation could not be observed and only an ester-exchanging reaction took place to give ethyl 7-phenyl-4-heptenyl azodicarboxylate and bis(7-phenyl-4-heptenyl)azodicarboxylate. To avoid this side reaction, dibenzoyldiimide was used as an oxidizing reagent instead of diethyl azodicarboxylate. The desired 7-phenyl-4-heptenal was obtained in only 20% yield, a by-product, 7-phenyl-4-heptenyl benzoate, being isolated in 38% yield accompanied by the cleavage of carbon-nitrogen bond of dibenzoyldiimide.

On the other hand, when 7-phenyl-4-hepten-1-ol was allowed to react with a 1.2 molar amount of propylmagnesium bromide in tetrahydrofuran and then treated with a 1.2 molar amount of 1,1′-(azodicarbonyl)-dipiperidine at room temperature for 2 h, the desired 7-phenyl-4-heptenal was obtained in 89% yield along with 1,1′-(hydrazodicarbonyl)dipiperidine in 93% yield, 7% of 7-phenyl-4-hepten-1-ol being recovered after the separation by column chromatography (silica gel) (Table 3).

Table 3. Oxidation of 7-phenyl-4-hepten-1-ol with several azo compounds

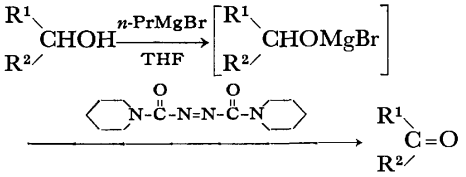


R	Isolated yield (%)
-OEt	0
-OPh	20
-N⟨⟩	89

Similarly, the oxidation of various kinds of alcohols with 1,1′-(azodicarbonyl)dipiperidine afforded the corresponding ketones and aldehydes in excellent yields (89—99%). The results are summarized in Table 4.

An alternative method was adopted for the oxidation of alcohols having the carbonyl group for prevention of the addition reaction of the Grignard reagent to the carbonyl group. When *t*-butoxymagnesium bromide was employed in place of the Grignard reagent for the conversion of testosterone into the bromomagnesium salt, the oxidation of testosterone proceeded successfully, 4-androsten-3,17-dione being obtained in 96% yield (Eq. 1).

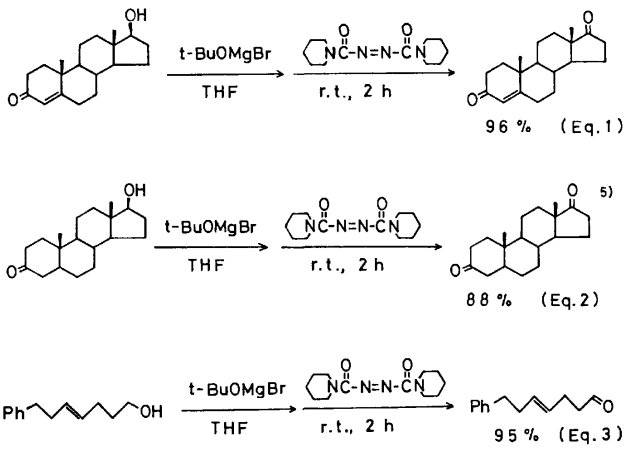
Table 4. Oxidation of various alcohols with 1,1′-(azodicarbonyl)dipiperidine



Alcohol	Time	Yield (%)[a]
7-Phenyl-4-hepten-1-ol	2 h	89
Cinnamyl alcohol	2 h	92
Geraniol	2 h	96
Benzhydrol	2 h	99
2-Phenyl-1-butanol	2 h	90
2-Octanol	over night	91[b]
3β-Cholestanol	over night	93
Citronellol	2 h	89

a) Isolated yield. b) Yield determined by GLC.

Similarly, stanolone and 7-phenyl-4-hepten-1-ol were oxidized to give the corresponding carbonyl compounds in excellent yields (Eqs. 2, 3).



Azo compounds such as diethyl azodicarboxylate[6] and 4-phenyl-1,2,4-triazoline-3,5-dione[7] react with free alcohols to afford the corresponding carbonyl compounds, but the yields are not so good. A long reaction time and elevated temperature are required for the oxidation with diethyl azodicarboxylate. 4-Phenyl-1,2,4-triazoline-3,5-dione is very unstable. Contrary to these results, the oxidation of alcohols proceeded under mild conditions (room temperature) by use of alkoxymagnesium bromide in place of free alcohol, the corresponding carbonyl compounds being obtained in excellent yields. Use of 1,1′-(azodicarbonyl)dipiperidine instead of *N*-chlorosuccinimide, *m*-chloroperbenzoic acid and (diacetoxyiodo)benzene makes it possible to oxidize various kinds of alcohols selectively to the corresponding

carbonyl compounds without addition of acid captors such as lithium *t*-butoxide and *t*-butoxymagnesium bromide.

In general, reagents such as CrO_3–pyridine complex,[8] CrO_3–acetone,[9] dimethyl sulfoxide–dicyclohexylcarbodiimide,[10] dimethyl sulfide–*N*-chlorosuccinimide or chlorine[11] are widely employed for the oxidation of alcohols to the corresponding ketones or aldehydes. However, some of them are very toxic [Cr(VI)], causing side reactions such as further oxidation of produced aldehydes and the formation of alkyl chlorides and sulfides. We have confirmed that a wide variety of alcohols are oxidized selectively to the corresponding ketones or aldehydes in excellent yields by the present procedure utilizing alkoxymagnesium bromides and 1,1′-(azodicarbonyl)dipiperidine.

Experimental

Materials. Commercial *N*-chlorosuccinimide was recrystallized quickly from hot water before use. The purity was determined by iodometry (purity>98%). *m*-Chloroperbenzoic acid was prepared by the reaction of *m*-chlorobenzoyl chloride with aqueous hydrogen peroxide and purified by washing with a phosphate buffer of pH 7.5 according to the procedure given in literature.[12] The purity was determined by iodometry (purity>97.5%). (Diacetoxyiodo)benzene was synthesized by the reaction of iodobenzene with peracetic acid,[13] the purity being determined in a smilar way (purity >97%). 1,1′-(Azodicarbonyl)dipiperidine was prepared by the reaction of diethyl azodicarboxylate with piperidine,[14] and purified by recrystallization from a mixture of benzene and hexane (mp 134—135 °C). 7-Phenyl-4-heptene-1-ol was synthesized from dihydrofuran and 2-phenylethylmagnesium bromide according to the procedure of Brandron *et al.*[15] and purified by distillation (bp 119—120 °C/1.0 mmHg).

General Procedure of Oxidation of Alkoxymagnesium Bromide with N-Chlorosuccinimide. To a solution of propylmagnesium bromide in dry THF (3 ml) prepared from magnesium (58 mg, 2.4 mmol) and propyl bromide (320 mg, 2.6 mmol) was added dropwise a solution of alcohol (1.0 mmol) and *t*-butyl alcohol (89 mg, 1.2 mmol) in THF (4 ml) at room temperature under argon atmosphere. After the reaction mixture had been stirred for 10 min, *N*-chlorosuccinimide (160 mg, 1.2 mmol) was added all at once at room temperature. The reaction mixture was stirred for 30 min, quenched by the addition of brine and solid $Na_2S_2O_3 \cdot 5H_2O$, and extracted with diethyl ether. The ether layer was washed with saturated aqueous $NaHCO_3$ and brine, and dried over anhydrous Na_2SO_4. The yeild of the corresponding aldehyde was determined by vapor phase chromatography or isolation using preparative thin layer chromatography (silica gel).

General Procedure of Oxidation of Alcohols with m-Chloroperbenzoic Acid. A solution of propylmagnesium bromide (1.2 mmol) in THF (3 ml) was prepared in a similar way and treated with a THF (4 ml) solution of an alcohol (1 mmol) and *t*-butyl alcohol (89 mg, 1.2 mmol) at room temperature under argon atmosphere, and stirred for 10–15 min at room temperature. This solution was then treated with crystalline *m*-chlorobenzoic acid (1.2—1.8 mmol) at room temperature, stirred for 30 min at room temperature, and quenched by the addition of brine and solid $Na_2S_2O_3 \cdot 5H_2O$. Benzene was added to the mixture and the resulting precipitate was filtered off. The organic layer was washed with saturated aqueous $NaHCO_3$ and brine, and dried over anhydrous Na_2SO_4. After removal of the solvent, the corresponding carbonyl compound was isolated by preparative thin layer chromatography (silica gel).

General Procedure of Oxidation of Alcohols with (Diacetoxyiodo)-benzene. A solution of alkoxymagnesium bromide (1 mmol) and *t*-butoxymagnesium bromide (1.2 mmol) in THF (7 ml) was prepared in a similar way, treated with crystalline (diacetoxyiodo)benzene (1.2—1.5 mmol) at room temperature. After being stirred for 30 min at room temperature, the mixture was quenched by addition of brine and solid $Na_2S_2O_3 \cdot 5H_2O$, and extracted with ethyl acetate. The organic layer was washed with saturated aqueous $NaHCO_3$ and brine, and dried over anhydrous Na_2SO_4. After removal of the solvent, the yield was determined by isolation using preparative thin layer chromatography (silica gel) or column chromatography (silica gel).

Oxidation of 7-Phenyl-4-hepten-1-ol with (Diacetoxyiodo)benzene. A THF (3 ml) solution of propylmagnesium bromide was prepared from magnesium (58 mg, 2.4 mmol) and propyl bromide (320 mg, 2.6 mmol), then treated with a THF (4 ml) solution of 7-phenyl-4-hepten-1-ol (186 mg, 0.98 mmol) and *t*-butyl alcohol (89 mg, 1.2 mmol) at room temperature under argon atmosphere. The reaction mixture was stirred for 10 min at room temperature, a THF (10 ml) solution of (diacetoxyiodo)benzene (429 mg, 1.33 mmol) being added dropwise within the period of 20 min. The mixture was stirred for additional 30 min. After the usual work-up, 7-phenyl-4-heptenal (140 mg, 76%) was isolated by column chromatography (silica gel).

NMR (CCl_4) δ 2.12—2.80 (m, 8H), 5.32—5.55 (m, 2H), 7.15 (s, 5H), 9.70 (s, 1H); IR 1725 cm^{-1}.

2,4-dinitrophenylhydrazone, mp 96.0—96.2 °C. Found: C, 61.94; H, 5.38; N, 15.02%. Calcd for $C_{19}H_{20}N_4O_4$: C, 61.94; H, 5.47; N, 15.21%.

Oxidation of 7-Phenyl-4-hepten-1-ol with 1,1′-(Azodicarbonyl)-dipiperidine Utilizing Propylmagnesium Bromide. To a THF (3 ml) solution of propylmagnesium bromide (160 mg, 1.3 mmol) was added dropwise a THF (2 ml) solution of 7-phenyl-4-hepten-1-ol (190 mg, 1.0 mmol) at room temperature under argon atmosphere. A THF (4 ml) solution of 1,1′-(azodicarbonyl)dipiperidine (320 mg, 1.2 mmol) was then added dropwise to the mixture. The mixture was stirred for 2 h at room temperature, quenched by addition of brine, and extracted with ethyl acetate. The organic layer was washed with saturated aqueous $NaHCO_3$ and brine, and dried over anhydrous Na_2SO_4. After removal of the solvent, the residue was separated by column chromatography (silica gel). Elution with benzene, methylene chloride, and methanol afforded the desired 7-phenyl-4-heptenal (167 mg, 89%), 7-phenyl-4-hepten-1-ol (13 mg, 7%) and 1,1′-(hydrazodicarbonyl)dipiperidine (234 mg, 92%), respectively.

General Procedure of Oxidation of Alcohols with 1,1′-(Azodicarbonyl)dipiperidine Utilizing Propylmagnesium Bromide. To a solution of propylmagnesium bromide in THF (3 ml) prepared from magnesium (29 mg, 1.2 mmol) and propyl bromide(160 mg, 1.3 mmol) was added dropwise a THF (2 ml) solution of an alcohol (1 mmol) at room temperature under argon atmosphere. A THF (4 ml) solution of 1,1′-(azodicarbonyl)-dipiperidine was then added dropwise at room temperature. The mixture was stirred for 2 h—overnight, quenched by addition of brine, and extracted with ether. After filtration of the precipitate, the organic layer was washed with saturated aqueous $NaHCO_3$ and brine, and dried over anhydrous Na_2SO_4. The yield of the corresponding ketone or aldehyde was determined by isolation using column chromatography (silica gel) or by vapor phase chromatography analysis.

Oxidation of Testosterone with 1,1′-(Azodicarbonyl)dipiperidine

Utilizing t-Butoxymagnesium Bromide. To a THF (3 ml) solution of propylmagnesium bromide prepared from magnesium (29 mg, 1.2 mmol) and propyl bromide (160 mg, 1.3 mmol) was added drowise a THF (2 ml) solution of *t*-butyl alcohol (89 mg, 1.2 mmol). A THF (2 ml) solution of testosterone (388 mg, 1.0 mmol) was then added, and the mixture was treated with a THF (4 ml) solution 1,1'-(azodicarbonyl)-dipiperidine (302 mg, 1.2 mmol). After the usual work-up, the desired 4-androsten-3,17-dione (374 mg, 96%) was isolated by preparative thin layer chromatography (silica gel).

NMR($CDCl_3$) δ 0.93 (s, 3H), 1.23 (s, 3H), 5.72 (s, 1H); IR 1660, 1740 cm^{-1}, mp 170—171 °C (lit, 169—170 °C[10]) Found: C, 79.42; H, 9.30%. Calcd for $C_{19}H_{26}O_2$: C, 79.68; H, 9.15%.

The Addition Reaction of Acyl Radicals to 9,10-Phenanthrenequinone in the Presence of the Corresponding Aldehydes. A Support for the In-Cage Mechanism of the Photochemical Reaction of 9,10-Phenanthrenequinone with Aldehydes

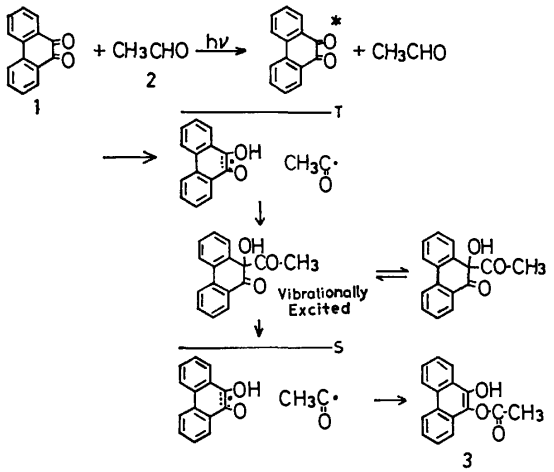
Kazuhiro MARUYAMA, Hiroshi SAKURAI, and Tetsuo OTSUKI
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606
(Received April 18, 1977)

Regarding the photochemical reaction of 9,10-phenanthrenequinone, **1**, with acetaldehyde, **2**, two reaction mechanisms have been proposed: the in-cage mechanism (Eq. 1) and the radical chain mechanism involving an acyl radical as the chain carrier (Eq. 2). For the establishment of the true reaction mechanism, the thermal addition reaction of an acyl radical to 9,10-phenanthrenequinone was investigated. The products in the thermal reaction were the dimeric isomers of the aryloxyl radical, **6**, *i.e.*, **4** and **5**, which were quite different from the product of the photochemical reaction of 9,10-phenanthrenequinone with acetaldehyde, *i.e.*, 9-acetoxy-10-hydroxyphenanthrene, **3**. These results, as well as the estimation of the quantum efficiency for the photochemical reaction, exclude the radical chain mechanism (Eq. 2) and strongly support the in-cage mechanism (Eq. 1) for the photochemical reaction of 9,10-phenanthrenequinone with aldehyde.

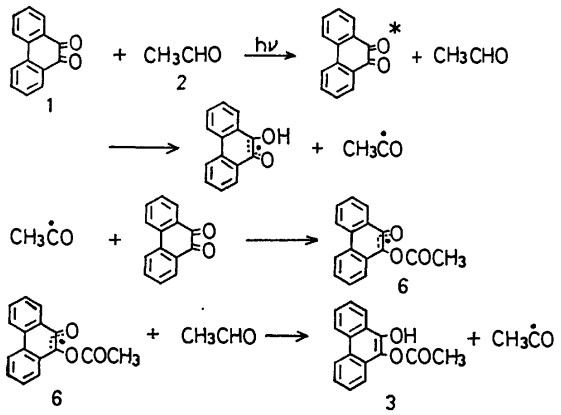
The photochemical reactions of quinone have been of great practical significance, providing a method of synthesizing complex organic molecules.[1] The mechanistic elucidation of these reactions are essential to ensure further success in preparative organic photochemistry.

The irradiation of a benzene solution of 9,10-phenanthrenequinone, **1**, and acetaldehyde, **2**, for example, gives 9-acetoxy-10-hydroxyphenanthrene, **3**, in a quantitative yield. The other aldehydes, aliphatic and aromatic, behave similarly to give the corresponding 9-acyloxy-10-hydroxyphenanthrenes in good yields. Recently for the above reaction the present authors proposed the intervening contribution of a radical pair, *i.e.*, the in-cage mechanism, mainly on the basis of an investigation using the ^{1}H-CIDNP technique (Eq. 1).[2] In contrast, Moore and Waters suggested about twenty years ago a radical-chain mechanism involving the acetyl radical as a chain carrier (Eq. 2)[3]

In the present investigation the acetyl radical generated from the hydrogen abstraction of acetaldehyde by the *t*-butoxyl radical was allowed to react with 9,10-phenanthrenequinone, **1**, and the products were compared with those of the photochemical reaction of 9,10-phenanthrenequinone, **1**, with acetaldehyde, **2**.



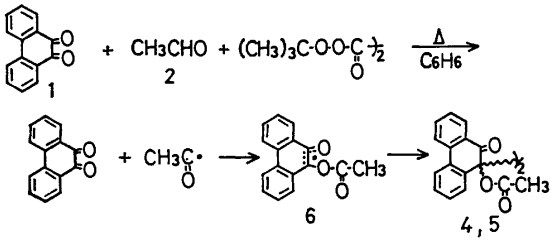
(Eq. 1)



(Eq. 2)

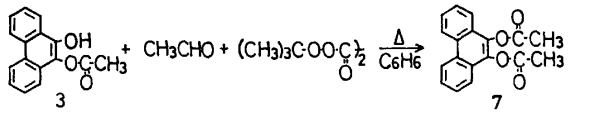
Results and Discussion

Product Analysis. The acetyl radical was generated by the thermal decomposition (70 °C) of di-*t*-butyl diperoxyoxalate[4] dissolved in benzene in the presence of an excess amount of acetaldehyde, **2**. When the acetyl radical was allowed to react with 9,10-phenanthrenequinone, **1**, the yellow color due to **1** disappeared. After the evaporation of the solvent, column chromatography on silica gel gave two white crystals in nearly equal amounts (total yield: 90%). Their molecular weights, as determined by the vapor-pressure method, indicated that both of them are dimers of the aryloxy radical, **6**. The aryloxy radical, **6**, is to be yielded by the addition of an acetyl radical to 9,10-phenan-



(Eq. 3)

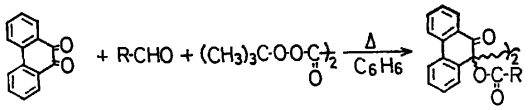
threnequinone. On the basis of their mass analysis and spectral data, the two products were concluded to be configurational isomers with each other and were identified as **4** ("*dl*-form") and **5** ("*meso*-form") respectively[5] (see Eq. 3). The other products were quite small in their amounts, but different from 9-acetoxy-10-hydroxyphenanthrene, **3**, which was the sole product in the photolysis of a solution of **1** and **2**.[2] Further, the possible formation of **4** and **5** *via* **3** was examined by treating **3** with di-*t*-butyl diperoxyoxalate in the presence of acetaldehyde, but no **4** or **5** was found. The exclusive product in this reaction was 9,10-diacetoxyphenanthrene, **7** (Eq. 4). Thus, we can exclude the intermediacy of **3** in the formation of **4** and **5**. As will be described in the following section, the time-dependent parallelism of the amount of **4** relative to **5** also supports



(Eq. 4)

the above consideration. In the reaction with other acyl radicals 9,10-phenanthrenequinone gives dimeric mixtures analogous to that of **4** and **5**. The total yields of the isomeric dimers are summerized in Table 1.

TABLE 1. THE THERMAL REACTION OF 9,10-PHENANTHRENEQUINONE WITH THE ACYL RADICAL



R	Yields of dimers (%)
CH_3–	90
C_3H_7–	83
p-CH_3–C_6H_4–	88
p-CH_3O–C_6H_4–	66

The Yield of **4** *Relative to that of* **5** versus *the Reaction Time.* With the progress of the reaction the amount of **4** relative to **5** was followed; the amounts of **4** and **5** increased monotonously with the time. As was concluded from Fig. 1, the relative yield, **4**/**5**, was invariably constant throughout the reaction. Thus, both **4** and **5** must be primary products in the reaction; hence, **3** cannot be a precursor of **4** and **5**.

Concluding Remarks. Without doubt the acetyl radical adds to 9,10-phenanthrenequinone, **1**, to form the **6** radical in the primary step of the reaction. Subsequently, the **6** radical could undergo dimerization, resulting in the formation of **4** and **5** in nearly comparable amounts. Thus, the *free* acetyl radical adds to **1** even in the presence of a large excess of acetaldehyde, as summarized in Eq. 3.

Contrary to the present reaction, the photochemical reaction of 9,10-phenanthrenequinone, **1**, with acetaldehyde gives **3** in a quantitative yield without **4** or **5**. Therefore, in the photochemical reaction of 9,10-phenanthrenequinone with acetaldehyde the intervention of the *free* acetyl radical, and thus the intermediacy of the aryloxyl radical, **6**, can be excluded completely. That is, the photochemical reaction of 9,10-phenanthrenequinone with acetaldehyde may proceed *via* the in-cage radical pair, *i.e.*, the in-cage mechanism, resulting in the quantitative formation of **3** (Eq. 1). The exclusion of the radical-chain mechanism (Eq. 2) was further supported by the disappearance of 9,10-phenanthrenequinone in the presence of a 10-fold molar quantity of acetaldehyde. Its quantum efficiency was about 0.21.

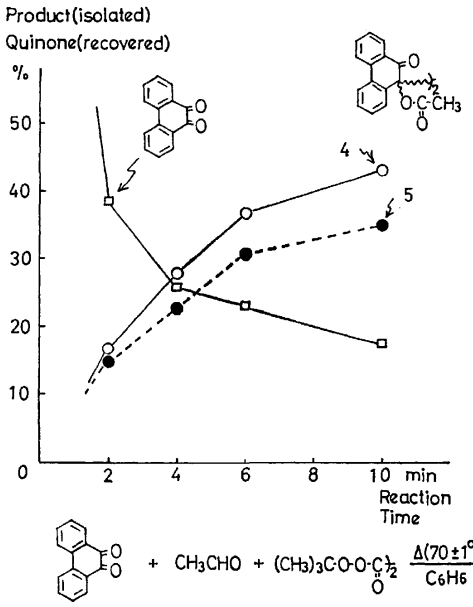


Fig. 1. The effect of the reaction time.

Experimental

Materials. The 9,10-phenanthrenequinone was prepared by the oxidation of phenanthrene with potassium dichromate; mp 202—204 °C. The di-*t*-butyl diperoxyoxalate was prepared according to the method in the literature.[4] All the aldehydes examined here were commercially available and were submitted to the thermal reactions after purification by distillation.

General Procedures. 9,10-Phenanthrenequinone (7.2 mmol) and aldehyde (26.8 mmol) were dissolved in dry benzene (30 ml), while the temperature of the solution was kept at 70 °C. To the solution di-*t*-butyl diperoxyoxalate (10.2 mmol) was added in portions. After an appropriate reaction time, the reaction was quenched by cooling and the reaction mixture was purified by chromatography on silica gel.

Identification of Products. *9,9'-Diacetoxy-9,9',10,10'-tetrahydro[9,9'-biphenanthrene]-10,10'-dione*: yield, 90%. dl-*9,9'-Diacetoxy-9,9',10,10'-tetrahydro[9.9'-biphenanthrene]-10,10'-dione (4)*: white crystals; mp 200.2—201.2 °C. *9,9'-Bis(*p*-toluoyloxy)-9,9',10,10'-tetrahydro[9,9'-biphenanthrene]-10,10'-dione*: yield, 88%; white crystals, mp 195 °C (dec) as a mixture of nearly equal amounts of two isomers. Mass; *m/e*=327 (monomer$^+$). IR (KBr); 1740, 1690 cm^{-1}. ^{1}H-NMR ($CDCl_3$); δ: 2.35 (s,CH_3(*dl*-form)), 2.42 (s, CH_3 (*meso*-form)), 6.42 (d, J=8 Hz, aromatic-H (*dl*-form)), 6.8—8.2 ppm (m). UV max (CH_2Cl_2); 338, 248 nm.

*9,9'-Bis(*p*-arisoyloxy)-9,9',10,10'-tetrahydro[9,9'-biphenanthrene]-10,10'-dione*: yield, 66%; white crystals; mp 151—161 °C as a mixture of nearly equal amounts of isomers. Mass; *m/e*=343 (monomer$^+$). IR (KBr); 1720, 1690 cm^{-1}. ^{1}H-NMR ($CDCl_3$); δ: 2.34 (s, OCH_3(*dl*-form)), 2.40 (s, OCH_3-(*meso*-form)), 6.64 (s, J=8 Hz, aromatic-H(*dl*-form)), 6.8—8.1 (m, aromatic-H(*dl*-form)), 7.0—8.0 ppm (m, aromatic-H (*meso*-form)). UV max (CH_2Cl_2); 337, 255 nm.

9,10-Diacetoxyphenanthrene (**7**): white crystals; mp 196.0—197.5 °C. Mass; *m/e*=294 (M^+). IR (KBr); 1780 cm^{-1}. ^{1}H-NMR($CDCl_3$); δ: 2.52 (6H,s), 7.7—8.0 (6H,m), 8.6—8.8 ppm (2H,m). UV max (CH_2Cl_2); 295, 285, 275, 255, 245 nm. 9,10-Diacetoxyphenanthrene was also yielded by the reductive acetylation (Zn–Acetic anhydride) of 9,10-phenanthrenequinone.

The Estimation of the Quantum Efficiency. The light sourse was a high-pressure Hg arc lamp (300W); by the use of a filter (Toshiba KL-50), the irradiation was carried out by selected light (wavelength: 498±8 nm) at 15.0±0.5 °C. The quanta of light absorbed by the reaction mixture was calibrated using an aqueous solution of potassium tris(oxalo)ferrate(III) as a chemical actinometer.[7] The reaction mixture submitted to the measurement was a benzene solution of 1.92×10^{-3} M of 9,10-phenanthrenequinone and 2.3×10^{-2} M of acetaldehyde. The quantum efficiency, followed by the disappearance of 9,10-phenanthrenequinone, was estimated to be 0.21.

Copper-initiated Decomposition of *N,N*-Dichloromethanesulfonamide

Noboru TORIMOTO, Tadao SHINGAKI,* and Toshikazu NAGAI*

Science Education Institute of Osaka Prefecture, Karita-cho, Sumiyoshi-ku, Osaka 558
**College of General Education, Osaka University, Toyonaka, Osaka 560*

(Received April 25, 1977)

The reactions of *N,N*-dichloromethanesulfonamide (I) with substrates such as hydrocarbons and ethers gave the *N*-substituted methanesulfonamide (II) and methanesulfonamide (III) in the presence of copper. The reaction with 2-methylbutane gave the product only with a tertiary C–H bond, though the singlet nitrene which was generated from methanesulfonyl azide reacted with the primary, secondary, and tertiary C–H bonds in the ratio of 1: 4.2: 9.6. The reactions with the tertiary C–H bonds of *cis*- and *trans*-1,4-dimethylcyclohexanes proceeded non-stereospecifically, in contrast to those of the nitrene with them. The addition of a radical inhibitor, hydroquinone, reduced the yield of II, while it increased the yield of III. The reaction with alcohols led to a quantitative yield of III, accompanied by the corresponding aldehydes. These results suggest that the reaction proceeds not by a nitrene mechanism, but by a metal-radical mechanism.

The existence of a nitrene intermediate has been shown in several reactions which afford the same products or product mixtures *via* two or more independent routes. Phenylnitrene, for example, seems to be the intermediate in the pyrolysis[1] and photolysis[2] of phenyl azide, in the deoxygenation of nitrosobenzene[3] and nitrobenzene,[4] and in the photolyses of oxaziridines,[5] for the intermediate always leads to the same product, 2-dialkylamino-3*H*-azepine, in the presence of a dialkylamine. The species generated by the photolysis[6] and the thermolysis[7] of ethyl azidoformate and by the α-elimination of *N*-(*p*-nitrophenylsulfonyloxy)urethane[8] nearly the same regioselectivities toward the C–H bonds of 2-methylbutane. These demonstrations have been explained by the intervention of ethoxycarbonylnitrene in each instance.

Breslow and Sloan[9] reported that the reaction of dichloramine-T with zinc dust in cyclohexane gave *N*-cyclohexyl-*p*-toluenesulfonamide, and suggested that a free sulfonylnitrene was formed as an intermediate, since the insertion into C–H bonds is a distinctive nitrene reaction:

$$p\text{-}CH_3C_6H_4SO_2NCl_2 + Zn \longrightarrow p\text{-}CH_3C_6H_4SO_2N(Cl)(ZnCl)$$
$$\longrightarrow p\text{-}CH_3C_6H_4SO_2\ddot{N}: + ZnCl_2$$
(sulfonylnitrene)

On the other hand, the thermolysis of *N,N*-dichloromethanesulfonamide in benzene afforded methanesulfonamide in an 82% yield, with gas-chlomatographically detectable biphenyl, but neither *N*-mesylaniline nor azepine derivatives.[10] This finding, by Abramovitch, shows that the formation of nitrene in the reaction might be ruled out. Prior to his paper, we ourselves reported that the reaction of *N,N*-dichloromethanesulfonamide (I) with hydrocarbons and ethers in the presence of copper proceeded by means of a radical mechanism involving no sulfonylnitrene.[11]

We are investigating decomposition mechanisms of chloramide. As a part of this work, the reactions of I with the substrate hydrocarbons, ethers, and alcohols have been studied in further detail. The results will be discussed here in comparizon with those of the direct and the sensitized photolyses of methanesulfonyl azide.

Results and Discussion

Reactions of I in the Presence of Copper. Copper powder was suspended in a substrate (IV), and *N,N*-dichloromethanesulfonylamide (I) was added to the stirred suspension in small portions in a stream of nitrogen. The yields of the products are listed in Table 1.

TABLE 1. REACTION OF I WITH ETHERS AND HYDROCARBONS

(R′: hydrocarbon rest or ether rest)

The products, II and III, correspond formally to those from insertion into the C–H bonds, and from the abstraction of the hydrogen atoms, by methylsulfonylnitrene respectively. In the reactions with cyclic ethers, the α-substituted derivatives were isolated in good yields. The preferential formation of the α-substituted derivatives in IVb and IVc parallel those in the direct and sensitized photolyses of ethyl azidoformate in cyclic[13] and acyclic[12] ethers. The reaction of I with propylene oxide gave large quantities of a colorless, viscous substance whose IR spectrum showed a strong O–H stretching absorption. The products with the ring or the methyl C–H bonds were not isolated. The reactions in IVe and IVf gave, besides III, products with only the tertiary C–H bonds. This finding for the reaction with IVf is different from that of the direct photolysis of methanesulfonyl azide (V) in IVf; the singlet sulfonylnitrene generated by the direct photolysis reacted with the primary, secondary, and tertiary C–H bonds of IVf in the ratio of 1: 4.2: 9.6.[14] The difference in the regioselectivities toward the C–H bonds between the present reaction and the photolysis of V means that the singlet sulfonylnitrene is probably not involved in the former.

Attempting the reaction of I with aromatic substrates, the decomposition in *p*-xylene gave the reaction product (IIi) with only the side-chain C–H bond, although the reaction in benzene gave that with the aromatic nucleus, besides III. On the contrary, the thermolysis of V in toluene gave no *N*-benzylmethanesulfonamide corresponding to IIi, but methanesulfonyltoluidide isomers and III in 76.8 and 22.7% yields respectively.[15] Such aromatic nucleus derivatives are formed *via* an aziridine intermediate or a transition state with the sulfonylnitrene.[15,16] The formation of IIi in the present reaction also supports the idea that the reaction proceeds by means of a mechanism involving no singlet nitrene.

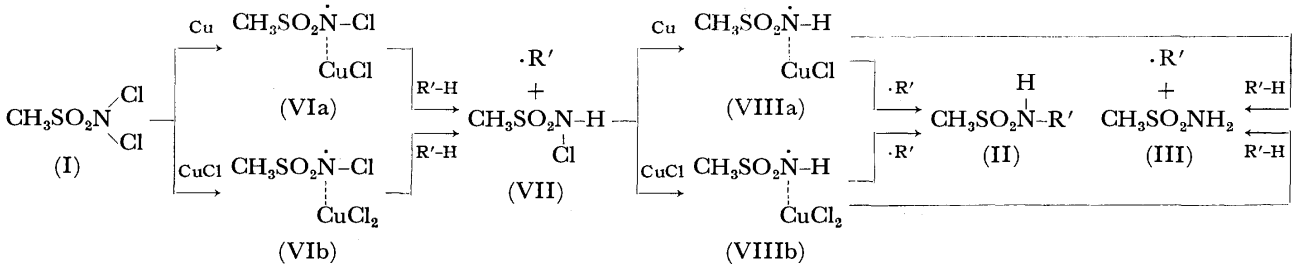
Next, the reactions of I were carried out in *cis*- and *trans*-1,4-dimethylcyclohexanes (*cis*-IV and *trans*-IV) in order to obtain information about the stereospecificity. The results are listed in Table 2, where they are compared with those of the direct[11] and the sensitized[17] photolyses of V. The reaction of I with either *cis*-IV or *trans*-IV gave a mixture of *cis*-II and *trans*-II (stereoisomers). On the other hand, in the photolyses of V, only one product isomer (*cis*-II or *trans*-II) was isolated in each reaction; the reaction was virtually completely stereospecific. The insertion of the sulfonylnitrene into the C–H bonds of hydrocarbons is a concerted reaction involving the singlet nitrene. Breslow *et al.* also recently reported that the insertion of methylsulfonylnitrene, generated by the thermolyses of V, into the tertiary C–H bonds of *cis*- and *trans*-1,2-dimethylcyclohexanes proceeded stereospecifically.[18] The stereospecific formation of *cis*-II or *trans*-II shows that the radical, $CH_3SO_2\dot{N}H$, produced by the hydrogen abstraction of the triplet nitrene is not able to recombine with a hydrocarbon radical. Therefore, the non-stereospecific formation of *cis*-II or *trans*-II in the reactions of I means that neither the singlet nor the triplet nitrene takes part in the formation of II. The non-stereospecific formation of *cis*-II or *trans*-II in the sensitized photolyses of V can be explained by the triplet azide mechanism.[17]

The reactions of I with ethyl alcohol and butyl alcohol did not give the product with the O–H bonds, but the hydrogen abstraction product, III, in yields of 97.2 and 97.8% respectively, accompanied by the corresponding aldehydes. The formation of the aldehydes in the alcohols suggests that the reaction of I involves a radical process. Therefore, the reaction of I was repeated in the presence of hydroquinone as a potential inhibitor. When *cis*-IV was employed, the addition of the hydroquinone reduced the yield of the mixture of *cis*-II and *trans*-II from 23% to below 0.3%, while it increased the yield of III from 60 to 77%. When

TABLE 3. REACTION OF I IN THE PRESENCE OF COPPER (I) CHLORIDE

Substrate (IV)	Product (%)[a]				
	II				III
IVb	IIb	57.6			43
trans-IV[b]	*trans*-II	9.7	*cis*-II	7.3	60
cis-IV[b]	*trans*-II	8.6	*cis*-II	6.1	64

a) Calculated on the basis of the I used. b) A mixture of IV and 1,2-dichloroethane in a molar ratio of 0.7: 0.3 was used.



Scheme 1.

IVb was employed, IIb was not detected, while the yield of III increased from 45.6 to 98.4%. These facts show that the reaction of I with the substrates in the presence of copper powder involves a radical mechanism.

Reactions of I in the Presence of Copper(I) Chloride. The reactions of I with the substrates were carried out in the presence of copper(I) chloride instead of copper. The yields of the products are listed in Table 3. The same products as those formed in the presence of copper were obtained. In the reaction with *cis*-IV and *trans*-IV, the products, II, were obtained only when 1,2-dichloroethane was used as a diluent, and the reactions were non-stereospecific.

Reaction Mechanism. A tentative reaction mechanism, which perhaps involves a metal-radical complex, may be outlined as in Scheme 1.

The reactions of I with the substrates do not proceed in the absence of copper or copper(I) chloride under our conditions. The decomposition of I must be initiated by copper or copper(I) chloride. The elimination of one chlorine atom gives a metal-radical complex (VI), followed by the formation of *N*-chloromethanesulfonamide (VII). The sulfonamide radical (VIII) which is formed from VII with copper or copper(I) chloride recombines with the substrate radical (·R'), giving II. On the other hand, VIII abstracts a hydrogen atom from the substrate to give III. It is well known that the metal-radical complex, generated from organic halides and transition metal compounds, behaves somewhat differently from those of radicals generated from such initiators as organic peroxides.[19] As has been mentioned above, the $CH_3SO_2\dot{N}H$ radical generated from V in hydrocarbons, was not able to recombine with a hydrocarbon radical. However, the radical generated by the present reaction would be stabilized by forming the metal-radical complex, as is shown in the Scheme. Consequently, the recombination of the radical with a hydrocarbon radical may be possible.

Photolyses of V in the Presence of Copper(I) Chloride. The presence of a metal compound in the photolysis of V would lead us to expect the recombination of $CH_3SO_2\dot{N}H$ with a hydrocarbon radical. Thus, the direct photolysis of V was carried out in *cis*-IV in the presence of copper(I) chloride. Unexpectedly, the reaction gave only one tertiary isomer, *cis*-II; the reaction was completely stereospecific. The sensitized photolyses of V were carried out in *cis*-IV and *trans*-IV in the presence of copper(I) chloride. As the photolyses proceeded, the solution had a color varying from an initial light yellow to dark green at the end. However, there was no significant difference in the product yields between the absence of copper(I) chloride (shown in Table 2) and its presence (shown in Table 4).

Table 4. Sensitized photolyses of V in the presence of copper(I) chloride

Hydrocarbon (IV)	Product (%)[a]		
	trans-II	*cis*-II	III
trans-IV	5.9	2.4	22
cis-IV	12.7	4.3	27

a) Calculated on the basis of of the I used.

The copper compound did not exhibit any effect on the reaction involving the azide, though it was evident that the copper compound played an important role in the present chloramide system; the absence of copper compound did not result in the formation of the *N*-substituted methanesulfonamide.[10]

Experimental

The IR spectra were recorded on a Hitachi EP-S photometer and a Nippon Bunko (JASCO) Model A-3 photometer, while the NMR spectra were taken on Hitachi R-20 and Hitachi R-24 instruments, using tetramethylsilane as the internal standard. The gas chromatography (VPC) was conducted on Shimadzu GC-2C and Nippon Denshi (JEOL) JGC 20K units by means of the following columns: A, 20% Ucon Oil 5 HB 2000 on Celite (60—80 mesh); B, 10% Polyethylene Glycol Succinate on Neopak 1A (60—80 mesh). The products were separated by VPC, and the structures of the products were determined by means of elemental analyses and by measurements of the IR and NMR spectra. The structures of some of the products were determined by comparing their IR and NMR spectra with those of authentic samples. The quantitative analyses of the products by VPC and testing for the stability of each product during VPC analysis have been described in a previous paper.[20]

Materials. The *N,N*-dichloromethanesulfonamide (I) was prepared by the method of Newcombe.[21] The methanesulfonyl azide (V) was prepared by the method of Reagan and Nickon.[22] The propylene oxide, tetrahydrofuran, tetrahydropyran, 1,4-dioxane, 2,3-dimethylbutane, 2-methylbutane, cyclohexane, benzene, *p*-xylene, ethyl alcohol, butyl alcohol, and 1,2-dichloroethane were used after the commercial reagents had been purified according to the published directions.[23] Analytical-grade reagents of copper(I) chloride, copper, hydroquinone, and acetophenone were used without further purification. The preparation of *cis*- and *trans*-1,4-dimethylcyclohexanes (*cis*-IV and *trans*-IV) has already been described.[17]

Authentic Samples. The preparation of *N*-cyclohexylmethanesulfonamide (IIg), *N*-(*cis*-1,4-dimethylcyclohexyl)methanesulfonamide (*cis*-II), and *N*-(*trans*-1,4-dimethylcyclohexyl)-methanesulfonamide(*trans*-II) has been described previously.[17] *N*-Phenylsulfonamide (IIh) was prepared from aniline and methanesulfonyl chloride in a way similar to that used in the preparation of *N*-cyclohexylurethane;[24] mp 98 °C, IR (Nujol, cm^{-1}): 3270 (NH), 1330, and 1155 (SO_2). NMR ($CDCl_3$, τ): 2.70 (C_6H_5, 5H, s), 2.72 (NH, 1H, bs), and 7.00 (SCH_3, 3H, s).

Reactions of I with Ethers, Hydrocarbons, and Alcohols in the Presence of Copper. Copper powder (4.8 g, 0.075 mol) was suspended in a substrate (0.6 mol of ethers, hydrocarbons, or alcohols), and *N,N*-dichloromethanesulfonamide (I, 4.1 g, 0.025 mol) was added to the stirred suspension in small portions in a stream of nitrogen. The reactions with ethers and alcohols were carried out at 5—7 °C, except for that with dioxane, which was done at 12 °C. After I had been added, the stirring was continued for about another 5 h. Then the suspension was filtered, and the filtrate was concentrated under reduced pressure. In the reactions with hydrocarbons, the residue was analyzed by VPC on Column A and B. On the other hand, the residual material resulted from the filtration of the suspension was extracted with three 50-ml portions of 1M-hydrochloric acid and the hydrochloric acid was evaporated under reduced pressure. The abstraction product (III) contained in the residue was dissolved in ethyl alcohol and analyzed by means of VPC on Column A. In the cases of the ethers and alcohols, the residue was extracted with three 50-ml portions of hot benzene. The colorless crystals (II), obtained by evaporating the benzene, were dried *in vacuo* and weighed. The NMR spectrum of each of the crystals showed it to contain no contaminant. The crystals were then recrystalized from benzene, and the melting points were measured. On the other hand, III was also obtained from the insoluble material in the hot benzene. Methanesulfonamide (III), formed from every experiment, had IR and NMR spectra and a VPC retention time identical with those of the authentic sample.

In Tetrahydrofuran (IVb), Tetrahydropyran (IVc), and 1,4-Dioxane (IVd): *N*-(2-Tetrahydrofuryl)methanesulfonamide (IIb, 1.90 g), *N*-(2-tetrahydropyranyl)methanesulfonamide (IIc, 2.32 g), and *N*-(1,4-dioxan-2-yl)methanesulfonamide (IId, 2.08 g) were isolated respectively. IIb: Mp 75 °C, IR (Nujol, cm^{-1}): 3240 (NH), 1325, and 1170 (SO_2). NMR ($CDCl_3$, τ): 4.44 (NH, 1H, bs), 4.48—4.90 (ring-CH, 1H, m), 5.60—6.34 (ring δ-CH_2, 2H, m), 6.93 (SCH_3, 3H, s), and 7.33—8.52 (ring β- and γ-CH_2, 4H, m). Found: C, 36.10; H, 6.59; N, 8.30%. Calcd for $C_5H_{11}O_3NS$: C, 36.36; H, 6.71; N, 8.48%. IIc: Mp 102 °C, IR (Nujol, cm^{-1}): 3300 (NH), 1330, and 1155 (SO_2). NMR ($CDCl_3$, τ): 3.90 (NH, 1H, bd), 4.82—5.58 (ring-CH, 1H, m), 5.66—6.68 (ring ε-CH_2, 2H, m), 6.85 (SCH_3, 3H, s), and 7.78—8.74 (ring β-, γ- and δ-CH_2, 6H, m). Found: C, 39.81; H, 7.05; N, 7.75%. Calcd for $C_6H_{13}O_3NS$: C, 40.22; H, 7.31; N, 7.82%. IId: Mp 109 °C, IR (nujol, cm^{-1}): 3265 (NH), 1335, and 1155 (SO_2). NMR ($CDCl_3$, τ): 4.05 (NH, 1H, bd), 4.76—5.22 (ring-CH, 1H, m), 5.68—6.78 (ring-CH_2, 6H, m), and 6.90 (SCH_3, 3H, s). Found: C, 32.95; H, 6.01; N, 7.62%. Calcd for $C_5H_{11}O_4NS$: C, 33.14; H, 6.12; N, 7.73%.

In 2,3-Dimethylbutane (IVe), 2-Methylbutane (IVf), and Cyclohexane (IVg): *N*-(1,1,2-Trimethylpropyl)methanesulfonamide (IIe, 0.31 g), *N*-(1,1-dimethylpropyl)methanesulfonamide(IIf, 0.29 g), and *N*-cyclohexylmethanesulfonamide (IIg, 0.24 g) were isolated respectively. The IR and NMR spectra of IIe, IIf, and IIg have been described previously.[17]

In Benzene (IVh) and p-*Xylene (IVi):* *N*-Phenylmethanesulfonamide (IIh, 0.24 g) and *N*-(*p*-tolylmethyl)methanesulfonamide (IIi, 0.45 g) were isolated. The IR and the NMR spectra of IIh were identical with those of the authentic sample. IIi: IR (neat, cm^{-1}): 3260 (NH), 1330, and 1160 (SO_2). NMR ($CDCl_3$, τ): 2.83 (C_6H_4, 4H, s), 5.00 (NH, 1H, bs), 5.75 (CH_2, 2H, d), 7.19 (SCH_3, 3H, s), and 7.66 (CH_3, 3H, s). Found: C, 53.81; H, 6.43; N, 6.92%. Calcd for $C_9H_{13}O_2NS$: C, 54.26; H, 6.58; N, 7.03%.

In trans-*IV*: *N*-(*trans*-1,4-Dimethylcyclohexyl)methanesulfonamide (*trans*-II, 0.63 g) and *N*-(*cis*-1,4-dimethylcyclohexyl)-methanesulfonamide (*cis*-II, 0.56 g) were isolated. The IR and the NMR spectra of *trans*-II and *cis*-II have been described previously.[17]

In cis-*IV*: *trans*-II (0.62 g) and *cis*-II (0.53 g) were isolated.

In Ethyl Alcohol and Butyl Alcohol: For each of the reactions with alcohols, the excess substrate and the volatile product, aldehyde, were trapped in a flask immersed in a dry ice-methanol bath reduced pressure. The trapped solution was added to a 2,4-dinitrophenylhydrazine solution, and the aldehyde was converted to the hydrazone. For ethyl alcohol and butyl alcohol, acetaldehyde and butyraldehyde were isolated as the hydrazones in yields of 2.30 g (41.1%) and 0.42 g (6.7%) respectively.

Reaction of I with IVb and cis-*IV in the Presence of Copper and Hydroquinone.* Hydroquinone (2.8 g, 0.025 mol) was added to the system of I-substrate-copper mentioned above. The reaction with IVb was carried out at 5—7 °C, while that with *cis*-IV was carried out at 70 °C. The reaction mixture was treated with the procedures described for the reaction in the absence of hydroquinone. In the reaction with *cis*-IV, trace amounts (0.01 g) of a mixture of *trans*-II and *cis*-II were isolated. In the reaction with IVb, only the abstraction product (III) was isolated.

Reaction of I with Ether and Hydrocarbons in the Presence of Copper(I) Chloride. Copper(I) chloride (7.1 g, 0.075 mol) was suspended in ether (0.5 mol) or a mixture of hydrocarbon (0.35 mol) and 1,2-dichloroethane (0.15 mol). I (4.1 g, 0.025 mol) in small portions was then added to the stirred suspension in a stream of nitrogen. The reaction with IVb was carried out at 5—7 °C, while those with *trans*-IV and *cis*-IV were carried out at 70 °C. After I had been added, the reaction mixture was treated with the procedures described for the reaction in the presence of copper.

In IVb: IIb (2.37 g) was isolated.

In trans-*IV*: *trans*-II (0.50 g) and *cis*-II (0.37 g) were isolated.

In cis-IV: *trans*-II (0.44 g) and *cis*-II (0.31 g) were isolated.

Sensitized Photolyses of Methanesulfonyl Azide (V) in Hydrocarbons in the Presence of Copper(I) Chloride. A powder of copper (I) chloride (1.9 g, 0.019 mol) was suspended in a mixture of V (1.5 g, 0.0124 mol), hydrocarbon (0.15 mol), 1,2-dichloroethane (0.3 mol), and acetophenone (0.15 mol). The mixture was then irradiated, with stirring at 25 °C, by a high-pressure mercury lamp under an atmosphere of nitrogen. A 1.5M-$CuSO_4$ aqueous solution was circulated as a filter. The filter completely inhibited the direct excitation of V. The irradiation was continued until the evolution of nitrogen was no longer observed. After the copper compound had been filtered out, the excess substrate was removed by distillation at 50—80 °C under 20—30 mmHg. The residue was analyzed by VPC on Columns A and B.

In trans-*IV*: *trans*-II (0.15 g) and *cis*-II (0.06 g) were isolated.

In cis-*IV*: *trans*-II (0.32 g) and *cis*-II (0.11 g) were isolated.

Direct Photolysis of V in cis-*IV in the Presence of Copper(I) Chloride.* A powder of copper(I) chloride (1.9 g, 0.019 mol) was

suspended in a mixture of V (1.5 g, 0.0124 mol), *cis*-IV (0.15 mol), and 1,2-dichloroethane (0.3 mol). The suspension was irradiated, with stirring and cooling at 0 °C, by a low-pressure mercury lamp (mainly 2537 Å) under an atmosphere of nitrogen until the evolution of nitrogen was no longer observed. Then, the reaction mixture was treated with the procedures described for the sensitized photolyses. *cis*-II (0.12 g, 4%) was isolated.

The authors are particulary indebted to Dr. Hisao Arakawa and Dr. Akira Matsumoto of the Science Education Institute of Osaka Prefecture for help in the preparation of this paper and for many useful suggestions.

The Thallium(I) Salt-catalyzed Formation of Isothiocyanates from Isocyanides and Disulfides

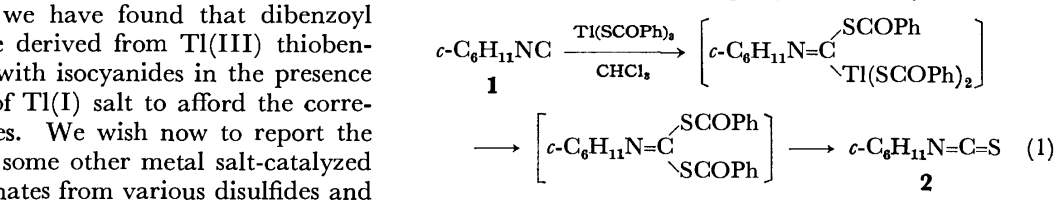
Sakuya TANAKA, Sakae UEMURA, and Masaya OKANO*
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received May 11, 1977)

The reactions of various isocyanides with diacyl disulfides or tetraethylthiuram disulfide occur smoothly in the presence of thallium(I) acetate and thiocarboxylates in various organic solvents to give the corresponding isothiocyanates in good yields. Lead(II) acetate has an activity almost identical with that of thallium(I), while cadmium(II) and silver(I) acetates and copper(I) oxide show a slightly lower activity than the above thallium and lead salts. An ionic scheme involving a complex formation between the metal salt and one S atom of the disulfide, followed by a nucleophilic attack of isocyanide on the adjacent S atom, is proposed for this reaction. It is revealed that the reaction of isocyanide with one equivalent of thallium(III) thiobenzoate in refluxing chloroform similarly affords a good yield of the isothiocyanate through the above mechanism after the decomposition of the thallium(III) salt to thallium(I) thiobenzoate and dibenzoyl disulfide, rather than through a pathway involving thiothallation (α-addition).

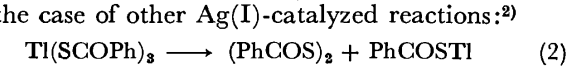
Several reactions involving the oxymetallation of isocyanides (α-addition) with Hg(II), Tl(III), or Pb(IV) salts have recently been reported.[1] While examining the reaction of isocyanides with similar metal salts containing a S atom, we have found that dibenzoyl disulfide, which can be derived from Tl(III) thiobenzoate, reacts smoothly with isocyanides in the presence of a catalytic amount of Tl(I) salt to afford the corresponding isothiocyanates. We wish now to report the results of the Tl(I)- or some other metal salt-catalyzed formation of isothiocyanates from various disulfides and isocyanides, and to discuss its reaction mechanism. It should be noted here that similar metal salt-promoted reactions of disulfide have been known[2] in the cases of amine and methanesulfinate ion using Ag(I) salt.

Results and Discussion

Reaction of Cyclohexyl Isocyanide (1) with Metal Thiocarboxylates (Table 1). By analogy with the oxidation of isocyanides with Hg(II), Tl(III), or Pb(IV) acetate giving isocyanates,[1c] isothiocyanate formation can be expected to proceed by means of the reaction of isocyanides with these salts of thiocarboxylic acids. When **1** was treated with Tl(III) thiobenzoate in chloroform under reflux, cyclohexyl isothiocyanate (**2**) was obtained in a good yield, whereas none of it was formed by the reaction with Hg(II) thioacetate. If the product is formed through the thiometallation of **1** (Scheme 1), it should also be obtained by the use of Hg(II) thiocarboxylate, since it is generally known that oxymercuration occurs more rapidly than oxythallation.[3]



Furthermore, although the reaction with Tl(I) or Pb(II) thiobenzoate did not give **2**, that with Tl(I) thioacetate did afford it.[4] The formation of **2** with the Tl salt of a lower oxidation state can not also be explained by this scheme. Therefore, such a mechanism does not seem to be operative for the isothiocyanate formation. The possibility of the participation of elemental sulfur, which might be formed from the Tl salts in some way or other,[5] can nearly be excluded also, because separate experiments revealed that only a small amount of **2** was formed from **1** and solid sulfur in either the presence or absence of Tl(I) acetate under similar reaction conditions. The most likely route is the nucleophilic attack of **1** upon dibenzoyl or diacetyl disulfide, which can be formed by the thermal decomposition of the corresponding Tl(III)[4a] or Tl(I) thiocarboxylate (Schemes 2 and 3), since similar S–S bond scissions in alkyl, aryl, and acyl disulfides by various O-, S-, N-, P-, As-, and C-nucleophiles have been reported.[2,6,7] In fact, when **1** was treated with dibenzoyl disulfide in the presence of Tl(I) thiobenzoate, **2** was obtained in a good yield. On the other hand, the yield of **2** was quite low without the addition of the Tl(I) salt, suggesting that the electrophilic assistance of Tl(I) salt may be involved, as in the case of other Ag(I)-catalyzed reactions:[2]



Reaction of Isocyanides with Various Disulfides in the Presence of Tl(I) Salts (Table 2). Since the Tl(I)-assisted interaction between **1** and dibenzoyl disulfide was proved, the scope and limitations of this reaction were examined by using various kinds of disulfides,

isocyanides, Tl(I) salts, and solvents (Scheme 4). The following points are evident from the table: (i) Dibenzoyl, diacetyl, and tetraethylthiuram disulfides give good yields of isothiocyanates, while dialkyl and diaryl disulfides scarcely react at all. (ii) Tl(I) acetate is the most effective salt among the salts examined, and a catalytic amount of it is enough for the reaction. (iii) The reaction is applicable to both aliphatic and aromatic isocyanides. (iv) The yield of isothiocyanate does not vary significantly when the solvents are changed. (v) The reaction seems to proceed through an ionic pathway, since many radical scavengers exert no effect on the reaction.

Reaction of **1** *with Dibenzoyl Disulfide in the Presence of Various Kinds of Metal Salts (Table 3).* The catalytic effects of several metal salts other than Tl(I) were examined in the reaction of **1** with dibenzoyl disulfide under reflux for 3 h in chloroform. As can be seen from the table, the salts of soft metal ions (soft acid) are generally effective ($Tl^+ \geqslant Pb^{2+} > Cd^{2+} \geqslant Ag^+ \geqslant Cu^+ \geqslant Hg^+$) in the preparation of **2**, while those of hard ones are not at all effective. From the HSAB principle,[8] it can be deduced that the interaction of soft metal ions with either of the two S atoms of the disulfide (soft base) plays an important role in this reaction. Though considerable differences in catalytic activity between two salts of Cu(I) or Fe(II) (depending on the anion component) were observed, it appears to be difficult to offer a reasonable explanation.

Reaction Scheme. In order to clarify the reaction scheme, the following experiments were carried out in the presence of Tl(I) acetate as a catalyst. First, the

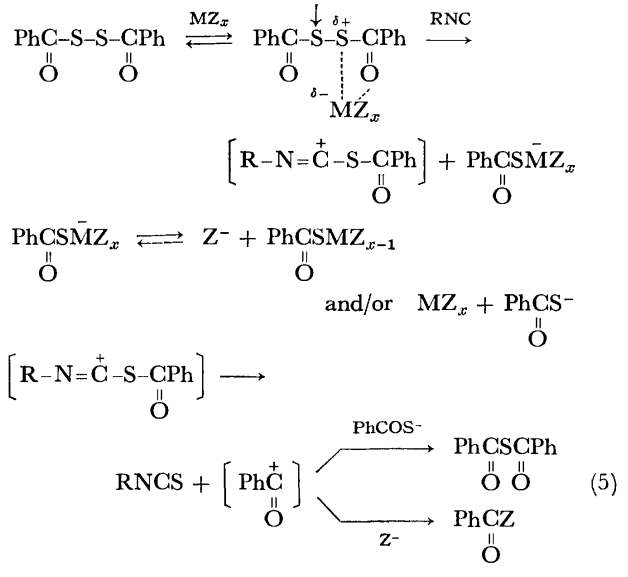
a) **1** (1 mmol), TlOAc (1 mmol), and $CHCl_3$ (10 ml) were used; at reflux. b) By GLC.

competitive reaction between **1** and phenyl isocyanide with dibenzoyl disulfide (1 mmol of each reactant) in chloroform at reflux for 3 h afforded **2** (60%) and phenyl isothiocyanate (40%), the unreacted **1** and phenyl isocyanide amounting to 19% and 38% respectively. Second, the yields of **2** in the reaction of **1** with representative 4,4'-disubstituted dibenzoyl disulfides were compared with that with a non-substituted one (Table 4). As a result, it was revealed that the reaction rate decreases in the following order: *p*-NO_2>H>*p*-MeO. Both results can be explained by assuming that a nucleophilic attack of isocyanide on one S atom of disulfide is an important step in this reaction.

By summarizing all the data described above, we propose Scheme 5 as a reaction scheme. The reaction may involve the initial complex formation between soft metal salt and one S atom of disulfide and the subsequent nucleophilic attack of isocyanide on the adjacent S atom. The latter step would be rate-determining. The removal of the benzoyl cation from the transient imidoyl cation affords isothiocyanate. The last step, namely, the combination of the benzoyl cation with the anion, was explained by the presence of PhCOSPh and PhCOOAc as products of the reactions using TlSPh and TlOAc respectively:



There may be another route involving the attack of the isocyanide-metal salt complex on disulfide, since isocyanides are known to form complexes with various metal salts.[9] It is obvious, however, that the nucleophilic reactivity of isocyanide decreases with complexation,[10] and so such a pathway would be less probable. It was observed in a separate experiment that, when the cyclohexyl isocyanide–CuCl complex prepared separately[9] was treated with dibenzoyl disulfide, **2** (21%) and free **1** (79%) were obtained under reflux for 3 h in chloroform. The result is comparable to that of the reaction catalyzed by CuCl; this suggests that no significant participation of the isocyanide-metal complex is present.

Experimental

The IR and NMR spectra were recorded with a Hitachi EPI-S2 and a Varian EM-360 apparatus respectively. The GLC analyses were carried out on a Shimadzu 4BMPF apparatus, using EGSS-X(30%)-Chromosorb-W(1 m)column (N_2 as the carrier gas).

Materials. Most of the isocyanides (RNC: R=*c*-C_6H_{11}, *n*-Bu, *t*-Bu, Ph) were prepared by the dehydration of *N*-substituted formamides with $POCl_3$,[11] while 4-ethoxybutyl isocyanide[R=$EtO(CH_2)_4$] was prepared by the reaction of the corresponding bromide with AgCN at 75—80 °C for 24 h; bp 89—94 °C/30 mmHg. The cyclohexyl, butyl, *t*-butyl, and 4-ethoxybutyl isothiocyanates (prepared previously in our laboratory[12]) and commercial phenyl isothiocyanate were used as authentic samples for GLC analyses. Some disulfides (R'SSR': R'=MeCO,[4a] PhCO,[4a] Ph,[4a] $PhCH_2$,[4a] *p*-MeO-, and *p*-$NO_2C_6H_4CO$[13]) were prepared by the oxidation of the corresponding thiols or thiocarboxylic acids, while those of R'=*n*-Bu and Et_2NCS were commercial products. Metal salts such as $Tl(SCOPh)_3$,[4a] TlSCOPh,[4a] TlSCOMe,[4a] TlSPh,[4a] and $Pb(SCOPh)_2$[4b] were prepared by the respective reported methods. The $Hg(SCOMe)_2$[mp 140 °C (d)] was prepared by the reaction of yellow HgO with thioacetic acid in chloroform at 5—10 °C for 1 h and then recrystallized from chloroform. The radical scavengers and other metal salts were commercial products and were used without further purification. The organic solvents were purified by distillation before use.

Reaction of 1 with Tl(SCOPh)$_3$. To a stirred suspension of $Tl(SCOPh)_3$(0.62 g, 1 mmol) in chloroform(8 ml) we added **1** (0.11 g, 1 mmol) in chloroform(2 ml) at 55 °C; the resulting mixture was stirred for 3 h under reflux. After being cooled, the solid was filtered off and the filtrate was washed with water, dried over Na_2SO_4, and analyzed by GLC, using iodobenzene as the internal standard. Analysis revealed the presence of 0.66 mmol(66% yield; based on Tl salt) of **2** and 0.28 mmol of unreacted **1**.

From the reaction using **1** (20 mmol), $Tl(SCOPh)_3$ (10 mmol), and chloform(20 ml), **2** was isolated by distillation (1.20 g; bp 72 °C/7 mmHg, $\nu_{N=C=S}$ 2120 cm^{-1}); it was identical with an authentic sample in GLC, NMR, and IR. In addition, 2.4 g of benzoic acid was isolated by the column chromatography of the residue after distillation (Wakogel C-100; diethyl ether as the eluent). No $(PhCO)_2S$ or PhCOSH was obtained by this procedure. These substances may be hydrolyzed to benzoic acid by these treatment.

Reaction of 1 with Dibenzoyl Disulfide in the Presence of TlOAc. To a stirred suspension of TlOAc (0.263 g, 1 mmol) in chloroform (5 ml) we added slowly a mixture of **1** (0.109 g, 1 mmol) and dibenzoyl disulfide (0.274 g, 1 mmol) in chloro-

form (5 ml) at room temperature, after which the resulting mixture was stirred for 3 h under reflux. After being cooled, the solid was filtered off and the filtrate was washed with water and dried over Na_2SO_4. Its GLC analysis reveled the presence of 0.96 mmol (96% yield; based on Tl salt) of **2**. The presence of PhCOOAc was confirmed by the IR of the residue after the evaporation of the solvent from the filtrate.

Competitive Reaction between 1 and Phenyl Isocyanide. A mixture of **1** (0.109 g, 1 mmol), phenyl isocyanide (0.103 g, 1 mmol), and dibenzoyl disulfide (0.274 g, 1 mmol) was stirred for 3 h under reflux in the presence of TlOAc (0.263 g, 1 mmol) in chloroform (10 ml). After treatment as described above, the GLC analysis of the filtrate revealed the presence of 0.60 mmol of **2** (60%), 0.40 mmol of phenyl isothiocyanate (40%), **1** (0.19 mmol, 19%), and phenyl isocyanide (0.38 mmol, 38%).

Reaction of 1 with Dibenzoyl Disulfide in the Presence of TlSPh. A mixture of **1** (1.09 g, 10 mmol), dibenzoyl disulfide (2.74 g, 10 mmol), and TlSPh (3.13 g, 10 mmol) in chloroform (10 ml) was stirred for 3 h under reflux and then treated as above. The GLC analysis of the filtrate revealed the presence of **2** (4.26 mmol, 43%), **1** (5.60 mmol, 56%), diphenyl disulfide (3.84 mmol, 38%), and PhCOSPh (2.37 mmol, 24%). The last two compounds were separated by column chromatography (Wakogel C-100; benzene–ethyl acetate as the eluent), the retention time of GLC, the melting point, and IR spectrum being found identical with those of an authentic sample for each compound.

Reaction of Cyclohexyl Isocyanide-Copper(I) Chloride Complex with Dibenzoyl Disulfide. To a chloroform (10 ml, freed from ethanol) solution of the **1**–CuCl complex[9] (0.208 g, 1 mmol) we added dibenzoyl disulfide (0.274 g, 1 mmol) at room temperature, and the resulting mixture was stirred for 3 h under reflux. After being cooled, the precipitated solid was filtered off. The GLC analysis of the filtrate revealed the presence of 0.21 mmol of **2** (21% yield; based on the complex) and 0.79 mmol of **1** (79%).

(Received March 25, 1977)

The ^{13}C NMR spectra of 4-chromanone, 4*H*-1-benzothiopyran-4-one, 4*H*-1-benzothiopyran-4-one 1,1-dioxide, and their methyl and phenyl substituted homologs were examined. The salient effect depending on the kinds of the hetero atoms or the group at the 1-position has been observed on the chemical shifts, especially for C-2, C-3, C-8, C-4a, and C-8a.

^{13}C NMR spectroscopy has been used extensively to elucidate the structures of complex molecules. Although ^{13}C NMR studies of several flavones were performed in connection with the structural elucidation of naturally occuring flavonoid compounds,[1] its applications to this field have so far been limited.[2] We wish to report here a study of the ^{13}C NMR spectra of 4-chromanone (**2**), 4*H*-1-benzothiopyran-4-one (**7**), 4*H*-1-benzothiopyran-4-one 1,1-dioxide (**12**), and their methyl and phenyl substituted homologs, undertaken with the object of providing background data for use in future structural studies of the heterocyclic compounds.

Natural-abundance 25.15 MHz ^{13}C FT-NMR spectra in $CDCl_3$ were obtained using the ^1H noise-decoupling technique. The signals were assigned by comparing the signal shifts due to differences in structures between closely related compounds and by the use of the ^1H off-resonance decoupling technique. A shift reagent, $Yb(dpm)_3$ was used to aid the assignments of the resonances to specific carbon atoms.[3] The chemical shifts, δ, thus obtained are listed in Table 1, in which the carbon numbering relates, for purposes of comparison, to the equivalent carbon in the flavanone series (Fig. 1).

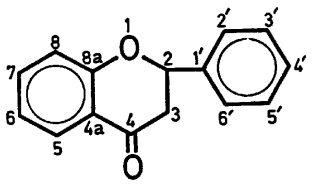

Fig. 1.

Results and Discussion

The resonance of the carbonyl carbon of 1-tetralone (**1**) occurs at δ 197.90. Upon the replacement of the 1-methylene group (the numbering system follows that of **2**) with a hetero atom, the carbonyl carbon signals moved upfield; that of **12** appears at the highest field among the simplest members of each series of compounds, **1**, **2**, **7**, and **12**. Analogous trends were observed in the ^{13}C NMR spectra of cyclohexanone and 1-hetera-4-cyclohexanones.[4] The substituent parameters of a sulfur and an oxygen atom, and a sulfonyl group in simple 1-hetera-4-cyclohexanones are negative (upfield shift) for a γ-carbon. The chemical shifts of C-2 and C-3 of **1**, **2**, **7**, and **12** also exhibited trends similar to those observed in the series of 1-hetera-4-cyclohexanones. The chemical shifts of C-2 are described in the order of the electron-withdrawing abilities of the atoms or the group at the 1-position. The C-3 resonances of **2** and **7** occur at a field lower, while that of **12** appear at one higher than that of **1**. The effect of the sulfonyl group in the C-3 chemical shift indicated a negative value, the reverse of those of the oxygen and the sulfur atom. This may be due to the steric γ-gauche interaction of C-3 with one of the oxygen atoms of the sulfonyl group, which takes an axial-like orientation.[4] The carbonyl chemical shifts of the 2-substituted compounds are similar to those of the corresponding parent compounds. On the other hand, the carbonyl signal of 3-methyl-4-chromanone (**4**) moved downfield by about 3 ppm.

On the addition of $Yb(dpm)_3$ to the solution examined, the carbonyl signal was moved downfield. The magnitude of the lanthanoid-induced shifts (LIS) of **12** and 1-thioflavanone 1,1-dioxide (**15**) were much smaller than those of **2**, flavanone (**5**), **7**, and 1-thioflavanone (**10**). Ytterbium ions may coordinate to the oxygen atoms of the sulfonyl group as well as to the carbonyl oxygen atom.

The signal of the methyl group at the 3-position resonates at an apparently high field (δ 10.55). This indicates that the through-bond interaction of the oxygen atom at the γ-position participates significantly, because the arrangement of the oxygen atom and the methyl carbon is anti-periplanar.[5] However, when a sulfur atom is introduced at the 1-position, the methyl signal appears at δ 13.8; the electronic γ-effect of a sulfur atom, the third-row hetero atom, is negligible.[5] The methyl resonance of 2-methyl-4*H*-1-benzothiopyran-4-one 1,1-dioxide (**13**) occurs at a field slightly higher than that of 2-methyl-4*H*-1-benzothiopyran-4-one (**8**) because of the steric γ-gauche interaction of the oxygen atoms of the sulfonyl group.

The resonances of substituted aromatic carbons are easily distinguished from those of other aromatic carbons by the off-resonance decoupling technique. Since the substituent parameters of the carbonyl group on both α- and β-carbons are positive, the former smaller than the latter, the signals at δ 144.39 and 132.56 of **1** can be ascribed to C-4a and C-8a respectively. The

a) $Yb(dpm)_3$-induced shift (downfield shift), see experimental section. b) The values in parentheses may be interchanged.

magnitude of the LIS values also supports these signal assignments; the LIS value for the C-4a signal is larger than that for C-8a. Taking into account the substituent parameters of a methyl and an acetyl group on a benzene ring, the resonance of C-7, which is placed at the position *para* to the acetyl group, appears at a field lower than that of C-6, which is in the *meta* position in the chromanone system. The chemical shifts of all the aromatic carbons except C-4a and C-8a are supposed to be in the order of: C-7>C-5>C-6>C-8. The resonances of these carbons demonstrate that the more remote from the carbonyl carbon, the smaller were the LIS usually observed in this system.

For **7**, the resonances of C-4a and C-8a were easily distinguished from those of other aromatic carbons as in the case of the chromanone system. The ^{13}C NMR spectrum of thiophenol indicates that the mesomeric effect of the sulfur atom is smaller on the aromatic ring than that of the oxygen atom: substituted-C, δ 130.80; *o*- or *m*-C, δ 129.28 or 128.92; *p*-C, δ 125.40.[6]

Unlike the case of phenol, the resonance of the *para*-related carbon appeared at a field higher than that of the *ortho*-related carbons. The C-4a signal moved downfield by about 10 ppm, and that for C-8a, upfield by about 20 ppm, compared to those of the corresponding carbons of chromanone. This may be a result of the smaller mesomeric effect of the sulfur atom than that of the oxygen atom. Other aromatic carbon signals are tentatively assigned in taking of the effect of the sulfur atom on the aromatic carbons which appeared in the ^{13}C NMR spectrum of thiophenol. These assignments are supported by their LIS values, much as in the case of the chromanone system.

Since the sulfur atom of the sulfonyl group has no lone-pair electrons, and since this group polarizes as $O\diagdown\!\!\!\!\diagup O^-$ (S), this group may act as an electron-attracting group, such as a nitro group. Since the ^{13}C chemical shifts of nitrobenzene are in this order: substituted> *para*->*meta*->*ortho*-related carbons, the resonances at 123—124 and 128—129 are assigned to C-8 and C-5 respectively. The LIS values for these carbons observed in **12** and **15** support these signal assignments. The LIS values suggest that the signals at δ 133.19 and δ 134.90 for **15** correspond to C-6 and C-7 respectively, because carbons which are more remote from the carbonyl group experience smaller shift reagent effects in this system.

Since the resonances of substituted carbons of monoalkylbenzenes are known to occur around δ 140—150, the resonances around δ 140 must correspond to C-1′ in the flavanone system. The resonance of C-1′ of **15** occurs at a field higher than those of other phenyl-substituted compounds. This may be due to the steric γ-gauche interaction with the oxygen atoms of the sulfonyl group, such as the methyl carbon of **13**. When we compare the chemical shifts of alkylbenzenes, the signals of C-2′ and C-6′ or C-3′ and C-5′ may be expected to appear at the same position of the magnetic field, the former carbon atoms appearing at a field slightly higher than those of the latter two.

Experimental

NMR Spectra. The ^{13}C FT-NMR spectra were obtained at 25.15 MHz with a JEOL JNM-MH-100 instrument equipped with a JNM-MFT-100 Fourier transform accessory; the instrument was controlled with a JEC-6 spectrum computer. Samples were observed in 5-mm spinning tubes at 20 $\pm$5% solution in $CDCl_3$ at 28 °C. The solvent provided the internal lock signal. The measurement conditions were as follows: pulse width, 27.5 μs (*ca.* 45°); repetition time, 4 s; spectral width, 6250 Hz; data point, 8192; acquisition time, 0.65 s. All the chemical shifts are expressed in δ (ppm downfield from internal Me_4Si). Each observed chemical shift is estimated to be accurate to δ $\pm$0.06. The LIS values were obtained as follows: each compound (1 mmol) was dissolved in $CDCl_3$ (0.2 ml), and then Yb(dpm)$_3$ (0.15 mmol) was added to the solution, $\Delta Yb = \delta_{Yb} - \delta$.

Materials. The compounds employed in this study have all been previously prepared except **14**: **1**,[7] (bp 82 °C/0.3 mmHg); **2**,[8] (mp 38 °C); **3**,[9] (mp 32 °C); **4**,[10] (bp 125—128 °C/11 mmHg); **5**,[11] (mp 76 °C); **6**,[12] (mp 76—77 °C); **7**,[13] (mp 29—30 °C); **8**,[14] (bp 146—147 °C/9 mmHg); **9**,[14] (bp 188—190 °C/12 mmHg); **10**,[15] (mp 55—56 °C); **11**,[16] (bp 170—176 °C/0.5 mmHg); **12**,[17] (mp 131—132 °C); **13**,[18] (mp 138—139 °C); **15**,[18] (mp 133—134 °C); **16**,[16] (mp 151—152 °C). Compound **14** was prepared as follows: 3-methyl-4*H*-1-benzothiopyran-4-one (1 g) in AcOH (10 ml) was treated with H_2O_2 (30%, 2 ml), and then the solution was allowed to stand for 2 days. The product was precipitated by the addition of water. Crystallization from ethanol afforded **14** as colorless prisms; mp 143—145 °C.

The Studies of the Activated Compound. III.[1] A Synthesis of Muscalure: (*Z*)-9-Tricosene

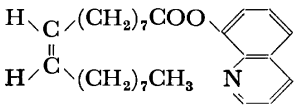
Kyo ABE, Tomio YAMASAKI, Nobuo NAKAMURA, and Takeo SAKAN

Department of Chemistry, Faculty of Science, Osaka City University, Sugimotocho, Sumiyoshi-ku, Osaka 558

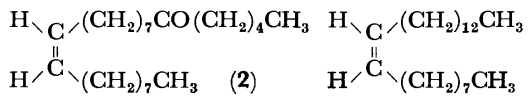
(Received May 16, 1977)

Synopsis. A synthesis of muscalure, (*Z*)-9-tricosene, was carried out as an application of metal-induced acylation.

Muscalure, (*Z*)-9-tricosene (**3**), is a sex-attractant pheromone for the female house fly (*Musca domestica L.*). Its synthesis has been accomplished by two groups.[2,3] We ourselves also previously carried out the synthesis of the muscalure as an application of metal-induced acylation.[4,5]



(**1**)



(**2**) (**3**)

The activated starting material, 8-oleoyloxyquinoline (**1**), was prepared from oleoyl chloride and 8-quinolinol in a good yield by the Schotten-Baumann method. A solution of 8-oleoyloxyquinoline (**1**) in dichloromethane was treated with an ethereal solution of pentylmagnesium bromide at −90 °C to give (*Z*)-14-tricosen-6-one (**2**) as the sole product in a 75% yield. The enone (**2**) was reduced by means of Hung-Minlon's procedure to afford muscalure, (*Z*)-9-tricosene (**3**), in an 84% yield. It was found to be identical to an authentic sample by a study of its IR and NMR.[2] An advantage of this route to muscalure (**3**) is in the preparation of the enone (**2**).

Experimental

Synthesis of 8-Oleoyloxyquinoline (1). To a stirred suspension of 8-quinolinol (2.390 g; 0.02 mol) and powdered sodium hydroxide (0.96 g; 0.02 mol) in tetrahydrofuran (20 ml), we added, drop by drop, a solution of oleoyl chloride (6.020 g; 0.02 mol) in tetrahydrofuran (20 ml) at 0 °C over a period of 15 min under an argon atmosphere. The reaction mixture was then kept at 0 °C for 1 h, allowed to stand at room temperature overnight, poured into ice-cooled water, and extracted with ether (30 ml×3). The extracted organic layer was washed with a 1% aqueous solution of sodium hydroxide (20 ml×2) and saturated brine (10 ml), and dried over sodium sulfate. The removal of the solvent from the organic layer gave a crude product (**1**) (7.20 g; 88% yield), which could be used for the next step without any purification. IR (neat): 1770, 1140, 1120 cm^{-1}. NMR (CCl_4): δ 0.83 (3H, t, J=5 Hz), 1.00—1.60 (broad peak centered at 1.26, 22H), 1.60—2.00 (broad peak centered at 1.94, 4H), 2.26 (2H, t, J=7 Hz), 5.18 (2H, m), 7.00—7.60 (4H, m), 7.90 (1H, dd, J=4, 2 Hz).

Synthesis of (Z)-14-Tricosen-6-one (2). An ethereal solution of pentylmagnesium bromide, generated from magnesium turnings (0.178 g; 7.33 mg atom) and pentyl bromide (1.24 g; 7.33 mmol), and a catalytic amount of iodine in dried ether, was added at −90 °C to a solution of 8-oleoyloxyquinoline (**1**) (2.00 g; 4.9 mmol) in dichloromethane (8 ml) under an argon atmosphere. The reaction mixture was then allowed to warm up to room temperature and left to stand overnight. The yellow precipitate in the reaction mixture was then filtered off and the filtrate was washed with a 1 M aqueous hydrochloric acid solution and with saturated brine, and dried over sodium sulfate. By evaporating the solvent, 1.23 g of the residue was obtained. It was purified by preparative TLC (SiO_2, developed with $CHCl_3$) to give the pure enone (**2**). IR (neat): 3015, 2925, 2850, 1715, 1460, 1380, 725 cm^{-1}. NMR (CCl_4): δ 0.88 (6H, t, J=5 Hz), 0.96—1.60 (28H, broad peak), 1.92 (4H, m), 2.23 (4H, t, J=7 Hz), 5.16 (2H, m). Found: C, 81.71; H, 12.83%. Calcd for $C_{23}H_{44}O$: C, 82.07; H, 13.18%. MS *m/e* 336 (M^+).

Synthesis of (Z)-9-Tricosene (3). A mixture of (*Z*)-14-tricosen-6-one (**2**) (127 mg; 1.14 mmol), 80% hydrazine hydrate (71 mg; 1.14 mmol), and potassium hydroxide (76 mg; 1.14 mmol) in 0.8 ml of diethylene glycol was heated at 140 °C for 1.5 h and then at 190 °C for an addition 4 h. After cooling to room temperature, the reaction mixture was diluted with ice water, neutralized with a 6 M hydrochloric acid solution, and then extracted with pentane (10 ml) several times. The extracted organic layer was washed with saturated brine and dried over sodium sulfate. The removal of the solvent from the organic layer gave a crude product. It was purified by means of column chromatography (SiO_2, eluted with hexane) to give (*Z*)-9-tricosene (**3**) (112 mg; 84% yield). Its IR and NMR spectra were both identical with the spectra of an authentic sample. IR (neat): 3015, 2930, 2855, 1460, 725 cm^{-1}. Found: C, 85.60; H, 13.88%. Calcd for $C_{23}H_{46}$: C, 85.63; H, 14.37%. NMR (CCl_4): δ 0.60—1.60 (40H, m), 1.90 (4H, m), 5.16 (2H, t, J=4 Hz). MS *m/e* 322 (M^+).

The authors wish to thank Dr. Gordon W. Gribble and Dr. Robert L. Cargill for sending charts of the IR and NMR spectra of muscalure.

Micelle Formation of Purified Dinonylnaphthalenesulfonates in Benzene

Kiyoshi INOUE, Yoshiharu NOSE, and Harumichi WATANABE

Central Technical Research Laboratory, Nippon Oil Co., Ltd., Chidori-cho, Naka-ku, Yokohama 231

(Received January 27, 1977)

Synopsis. The removal of trace amounts of unsulfonated dinonylnaphthalene contained in sulfonates by rubber membrane dialysis in pentane increased the apparent aggregation number of the micelles of dinonylnaphthalenesulfonate measured using vapor-pressure osmometry. The interaction between the cation and sulfonate ion was a factor affecting the aggregation, in addition to the steric factor of the hydrocarbon group and the solute-solvent interaction.

The micelle formation of metal salts of dinonylnaphthalenesulfonic acid (DNNS) in nonpolar solvents has been extensively studied using many methods, such as fluorescence depolarization,[1,2] viscometry,[3] ultracentrifuge separation,[4] and vapor-pressure osmometry.[5] It has been considered that the micelle formation of DNNS in nonpolar solvents is mainly due to the strong interaction between polar groups.[6] Furthermore, considerations of the steric or geometric factor and the solute-solvent interaction are also important. Kaufman and Singleterry[2] have studied the effect of cations on the micelle formation and the apparent molar volume of DNNS anions in benzene. However, the effect of the cation on the aggregation number for DNNS salts, which is a direct measure of the strength of the interaction between polar groups, has not been determined. In the present paper, the effect of the cation on the aggregation number for DNNS salts is reported and the importance of purification of the DNNS salts for vapor-pressure osmometry are also discussed.

Experimental

Alkali and alkaline-earth metal salts of DNNS were synthesized as described previously.[7] Metal salts of DNNS were further purified by rubber-membrane dialysis[8] for 72 h in pentane. This purification period was found to be sufficient to gain the limiting value of the aggregation number. The final product was freed from the solvent by evacuation at 70 °C for 24 h. The benzene used as the solvent for the vapor-pressure osmometric measurements was passed through activated alumina in order to remove water and polar contaminants. The water content in the benzene was determined using the Fischer titration method and was found to be less than 0.01%. The vapor-pressure osmometric measurements were carried out with a Mechrolab Model 301A vapor-pressure osmometer at 38 °C.

Results and Discussion

The relation of the apparent aggregation number for DNNS sodium salt (NaDNNS) and its concentration in benzene are shown in Fig. 1. The apparent aggregation number for NaDNNS was increased by the removal of the trace amount of unsulfonated dinonylnaphthalene contained in the NaDNNS using rubber-membrane dialysis in pentane. Although vapor-pressure osmometry is the most advantageous and accurate technique for investigating the aggregation of a surfactant in a nonpolar and volatile solvent, the result is strongly affected by the presence of trace amounts of low molecular-weight impurities. In addition to the effect mentioned above, the residual impurity in a surfactant which is similar to the surfactant in shape and structure should affect the state of aggregation by solubilization or the formation of co-micelle. To avoid this problem, purification by rubber-membrane dialysis is available for determining the micelle formation of high molecular-weight detergents, such as oil-soluble sulfonates.

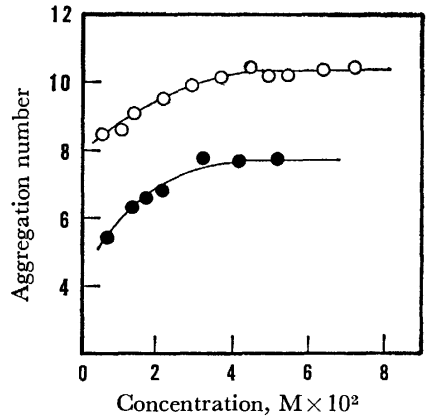

Fig. 1. Effect of purification of sodium dinonylnaphthalenesulfonate by rubber membrane dialysis on the aggregation number in benzene at 38 °C.
(—●— Before dialysis, —○— after dialysis).

Little and Singleterry[5] have studied the micelle formation of DNNS salts in various nonpolar solvents using vapor-pressure osmometry and have reported that the micelle aggregation number in benzene is 7 for Li and Na salts, and 6 for Cs salt. From the consideration that the aggregation of an ionic surfactant in a nonpolar solvent is mainly due to the interaction between the gegenion and the surfactant ion in the micellar cores, it is difficult to understand that the cations have little effect on the micelle aggregation number. Therefore, the present authors reexamined the micelle formation of DNNS salts, which were purified using vapor-pressure osmometry. The effect of the cation radius on the aggregation numbers of metal salts of DNNS in benzene is shown in Fig. 2. The aggregation number plotted in Fig. 2 shows the saturated value in the curve of the concentration-aggregation number as in Fig. 1. A strong correlation is found between the saturated aggregation number and the reciprocal of e^2/r_i for each cation studied, where e and r_i are the charge and radius of the cation, respectively. Kitahara and Kon-no[9] have reported the same effect of halogen ions on the aggregation number of didodecyldimethyl ammonium

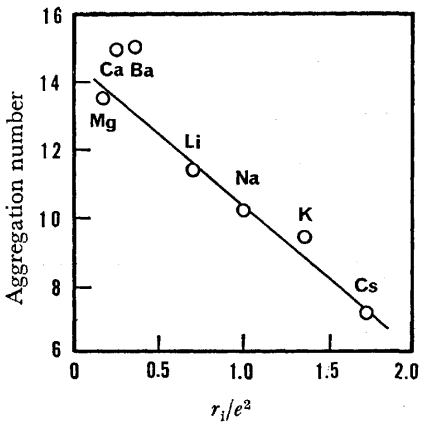

Fig. 2. Effect of cations of dinonylnaphthalenesulfonates on the aggregation number (acid residue/micelle) in benzene at 38 °C.

halides in benzene. Born[10] has suggested that e^2/r_i is proportional to the energy of hydration of gaseous spherical ions and that this value might be considered to be a measure of Lewis acidity. It is clearly seen in Fig. 2 that the driving force for the aggregation of micelles of DNNS salts in nonpolar solvents is the strong acid-base interaction between the polar groups in micellar cores. Kaufman and Singleterry[2] have also reported that such strong acid-base interactions cause a decrease in the apparent molar volume of anions of DNNS salts and an increase in the packing density from solution density measurements. A deviation from the linear relation in Fig. 2 is found in the case of alkaline-earth metal salts of DNNS. The deviation of the bivalent DNNS salts is ascribed to the increased polarity of their ionic head and the different contribution of the hydrocarbon group in the packing of the micelle from that of the monovalent DNNS salts.

Consequently, the micelle formation of DNNS salts in nonpolar solvents is mainly due to the strong interaction between polar groups in micellar cores, in addition to the steric factor and the solute-solvent interaction which have been discussed by Heilweil,[11] and Little and Singleterry,[5] respectively.

OH^- as a Possible Cause of the Electron-donor Property of the ZrO_2-TiO_2 System

Kunio ESUMI, Hiroaki SHIMADA, and Kenjiro MEGURO

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received March 15, 1977)

Synopsis. The electron-donor property of the zirconia-titania system was investigated by means of the adsorption of TCNQ. The TCNQ anion radicals were formed as a result of electron transfer to adsorbed TCNQ from the zirconia-titania surface. The radical concentration on the zirconia-titania system decreased with a increase in the titania content, reached a minimum point at a titania content of 38%, and then increased with the further increase in the titania content. This behavior can explained by the relative amount of OH^- sites, which must be proportional to both, or either one, the relative contents of the pure zirconia phase or the pure titania phase existing on the surface of the zirconia-titania system.

The formation of anion-radical ions on electron-donor sites of some simple metal oxide surfaces has been reported, these electron-donor sites have been also associated with the surface hydroxide ions and the surface oxide ions.[1-5] On the other hand, Flockhart *et al.*[1] studied the electron-donor property of two-component metal oxide systems, they found that silica-aluminas had negligible electron-donating power at low alumina contents, but silica-aluminas of high alumina contents possessed strong electron-donor properties. Hosaka *et al.*[6] studied the electron-donor property of silica-alumina, silica-titania, and alumina-titania systems in the base of the results of the adsorption of 7,7,8,8-tetracyanoquinodimethane (TCNQ), they found that the difference in electron-donor properties among metal oxide systems can be characterized by the change in the concentration of TCNQ anion radicals formed.

These studies are of metal oxides in the Group IV elements. This group, starting with silica, is of interest with respect to changes in size of the metal, coordination, and bonding type. In the present work, the electron-donor property of the zirconia-titania system, estimated by means of the TCNQ adsorption, will be reported.

The preparation of zirconia-titania samples was carried out as follows: Zirconium tetrachloride and titanium one mixtures, in different molar ratios, were dissolved in distilled water, and then, to these solutions, diluted aqueous ammonia was added under vigorous stirring. The precipitates formed were washed with distilled water until free from Cl^- ions. The products were then dried for 48 h at 120 °C. The dried products were calcined in air for 2 h at 500 °C in an electric furnace, followed by cooling *in vacuo*.

The composition of zirconia and titania in each product was determined by means of X-ray fluorometry. The compositions were, respectively, 0, 13, 38, 80, and 100 in the weight-percentage ratio: $TiO_2/(TiO_2+ZrO_2)$. The abbreviations used here are as follows: Z, zirconia; T, titania; Z4T, ZT, and ZT4, zirconia-titania containing 13, 38, and 80% titania.

The surface areas of the zirconia-titania system, as determined by nitrogen adsorption, were as follows: Z, 88; Z4T, 224; ZT, 282; ZT4, 140; T, 69 m^2/g.

The TCNQ was supplied by Dainippon Ink Chemical, Ltd. It was recrystallized from acetonitrile for purification. The acetonitrile used as the solvent was of a reagent grade.

The apparatus and procedure used in this study have been previously described.[7]

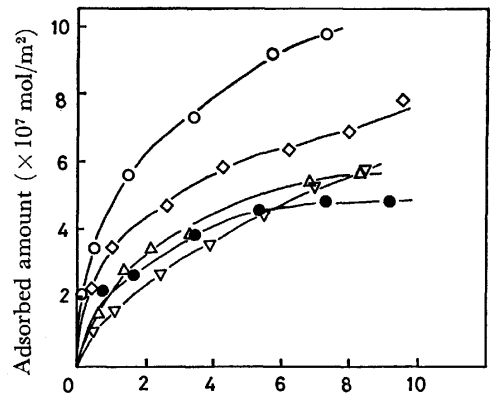

Fig. 1. Adsorption isotherms of TCNQ on zirconia-titania system (at 25 °C): zirconia, △; Z4T, ○; ZT, ▽; ZT4, ◇; titania, ●.

Figure 1 shows the adsorption isotherms of TCNQ from the acetonitrile solution at 25 °C on the zirconia-titania surfaces. All the isotherms follow Langmuir plots.

The radical concentration formed on the surfaces of

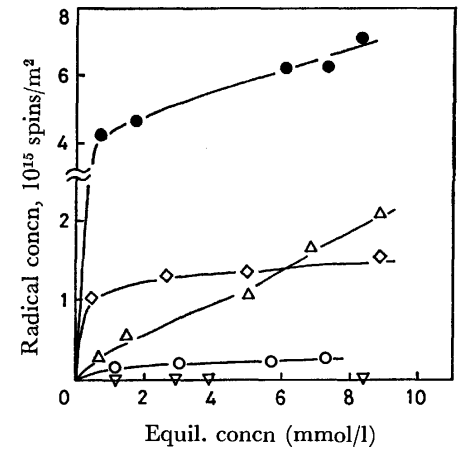

Fig. 2. Radical concentration on zirconia-titania system *vs.* equilibrium concentration of TCNQ: zirconia, △; Z4T, ○; ZT, ▽; ZT4, ◇; titania, ●.

zirconia-titania, plotted against the equilibrium concentration of TCNQ, is shown in Fig. 2.

When TCNQ was adsorbed from a solution in acetonitrile on the surfaces of zirconia-titania, the surfaces of zirconia-titania showed a remarkable coloration, such as violet. The colored samples gave an unresolved ESR spectra with a *g*-value of 2.003, that of TCNQ anion radicals.[6,7] These TCNQ anion radicals were formed as a result of electron transfer from the electron-donor sites of the zirconia-titania surface to adsorbed TCNQ. In the ZT sample, however, the ESR absorption was scarcely observed at all. The unresolved ESR spectra can be explained by the decrease in the freedom of the TCNQ anion radicals adsorbed and by the hyperfine structure becoming obscure of the spectra.

The half-values of the saturated amounts of TCNQ adsorbed, as estimated from the Langmuir plots, are given in the second column of Table I. As can be seen, the half-values are almost the same in all the samples except the Z4T. This indicates that the half-values which consist of neutral TCNQ and TCNQ anion radicals are little affected by the change in the composition of the zirconia-titania system.

For the evaluation of the change in the radical concentration on the surface of zirconia-titania with the composition, the amount of the radical concentration corresponding to the half-values of adsorbed TCNQ in saturation is employed, as is shown in the third column of Table 1. The zirconia-titania (Z4T, ZT, and ZT4) had a much lower radical concentration than titania only. The same tendency has been reported by Hosaka *et al.*[6] in the silica-alumina, silica-titania, and alumina-titania systems. The radical concentration decreased gradually between zirconia and Z4T, but decreased remarkably between Z4T and ZT. On the other hand, in the crystal features of the zirconia-titania system, the pure zirconia phase was present until Z4T, but it became amorphous, as is shown in the fourth column of Table 1. From these results, it may be supposed that the amount of the pure zirconia phase present on the surface of the zirconia-titania system plays an important role in determining the radical concentration. However, the increase in the radical concentration from ZT to ZT4 can be related to the pure titania phase present slightly on the surface of ZT4. It is noteworthy that a weak anatase pattern of ZT4 suggests the presence, in the conglomerate, of a pure titania phase. The steep increase in the radical concentration from ZT4 to the titania corresponds to the increase in the amount of the pure titania phase on the surface.

Table 1. Data of TCNQ adsorption

Sample	Half-values of saturated amounts ($\times 10^7$ mol/m^2)	Radical concn to corresponding half-values of saturated amounts 10^{14} spins/m^2	Phase
Zirconia	3.6	6.8	M*+T(w)
Z4T	5.8	1.7	T(w)
ZT	3.9	negligible	A
ZT4	3.9	11.9	An(w)
Titania	2.8	48.0	An

* M=monoclinic, T=tetragonal, A=amorphous, An=anatase, (w)=weak.

The electron-donor sites of two-component metal oxides are not well known. However, the electron-donor sites of titania, one of the parent oxides in the zirconia-titania system, have been associated with surface hydroxide ions and Ti^{3+} ions.[2,8] Infrared spectroscopy of zirconia has shown that the surface of zirconia contains hydroxide ions.[9] Indeed, Fomin *et al.*[10] have reported that electron transfer from the hydroxide ion can occur in certain solvent systems, provided a suitable acceptor molecule is present. The electron-transfer adsorption of TCNQ on the zirconia-titania system may result from surface hydroxide ions and Ti^{3+} ions. The other product of the electron-transfer adsorption is mainly the OH radical, although only the TCNQ anion radicals are observed in the ESR spectra. The change in the radical concentration of the zirconia-titania system, shown in Table 1, depends on the amount of the pure zirconia phase or the pure titania phase present on the surface of the zirconia-titania system. From the above considerations, it can be expected that the electron-donor sites are surface hydroxide ions(Zr–OH^-) in zirconia-titania of a higher zirconia content, and surface hydroxide ions(Ti–OH^-) and Ti^{3+}ions in the case of zirconia-titania of a higher titania content.

Measuremets of the Thermal Transpiration Effects of NO at 90 K and of CO, N_2, O_2, CH_4, and He at 77 K

Shozo FURUYAMA

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700

(Received March 18, 1977)

Synopsis. The thermal transpiration effect of the title gases was measured by a relative method by using a diaphragm-type pressure transducer. The data fit the Takaishi-Sensui equation $[P_1/P_2=(AX^2+BX+C\sqrt{X}+\sqrt{T_1/T_2})/AX^2+BX+C\sqrt{X}+1)]$ quite well in the region of X $(=P_2d_2)$ higher than 0.03 mmHg mm. The values for A, B, and C are 25.5, 9.3, and 0.6 for NO at 90 K, 28.5, 10.5, and 0.6 for CO and N_2, 24.0, 9.2, and 0.8 for O_2, 44.0, 11.4, and 1.2 for CH_4, and 2.96, 0.6, and 1.6 for He at 77 k respectively. The values for the temperature-independent constants, A^*, B^*, and C^* deduced from the values for A, B, and C above, were in agreement with the literature values and/or the estimated values.

In studies of the physical adsorption of nitric oxide and carbon monoxide gases,[1] we measured the thermal transpiration effect[2] of NO and CO. Since no data for the thermal transpiration effect of NO and CO are available in the literature, it may be worthwhile to report our data in detail. To check the reliability of our measuring system, other common gases, N_2, O_2, He, and CH_4, were also studied, and the results were compared with existing data.

Experimental

The nominal purities of N_2, He, O_2, CO, NO, and CH_4 were 99.999, 99.99, 99.9, 99.9, 99.9, and 99.9% respectively. NO was further purified by a method described elsewhere.[1]

The thermal transpiration value, P_1/P_2, was obtained as a function of log P_2d_2 by the relative method. The apparatus used is shown schematically in Fig. 1, where the meanings of P_1, P_2, d_2, *etc.* are illustrated. The pressure difference, P_2-P_3, was measured by means of a Datametrics Barocell Pressure sensor-Electronic Manometer. Then, P_3 was determined by evacuating the chamber, B_2, of the pressure sensor to 10^{-5} Torr. P_2 was calculated from the $P_2=P_3+(P_2-P_3)$ relation. Finally, P_1 was determined from P_3 by the usual method.[3,4] The temperature on the lower side was held at 90 K for NO, and at 77 K for the other gases. The temperature on the higher side was always held at 300 ± 1 K. The pressure region extended down to 2×10^{-2} Torr.

The pressure indication of the electronic manometer was calibrated by the gas-expansion method. The accuracy was within 0.2% at pressures above 1 Torr, within 1.2% between 1 and 0.1 Torr, and within 3% between 0.1 and 0.02 Torr.

Results and Discussion

The P_1/P_2 and P_3/P_2 values of NO measured at 90.5 K are plotted against log P_2d_2 in Fig. 2. The curves for CO and other gases were obtained at 77.5 K, but are not shown in the present paper.

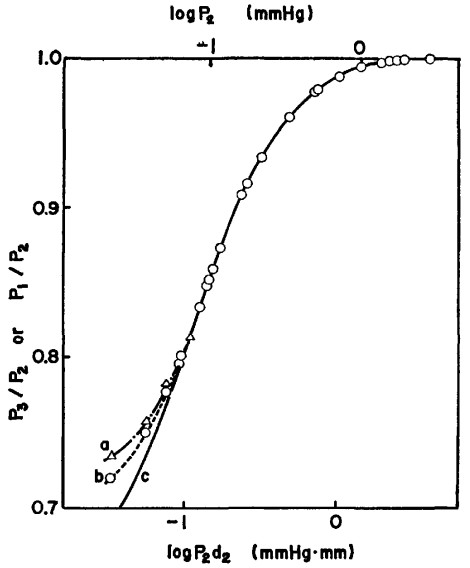

Fig. 2. Plots of thermal transpiration values of NO at 90.5 K.
a: Observed P_3/P_2 *vs.* log P_2d_2,
b: observed P_1/P_2 *vs.* log P_2d_2,
c: calculated P_1/P_2 *vs.* log P_2d_2.

Takaishi and Sensui have proposed the following empirical equation for the thermal transpiration effect:[5]

$$\frac{P_1}{P_2}=\frac{AX^2+BX+C\sqrt{X}+\sqrt{T_1/T_2}}{AX^2+BX+C\sqrt{X}+1} \qquad T_1<T_2, \qquad (1)$$

where A, B, and C are constants and where X is P_2d_2. By substituting the experimental data into the equation, the best-fitting values for A, B, and C have been obtained as summarized in Table 1. The degree of their fitness can be seen from Fig. 2.

Table 1. Values[a] for the constants, A, B, and C, contained in the Takaishi-Sensui equation 1, the viscosity coefficient,[b] and the collision diameter[c]

	A (mmHg mm)$^{-2}$	B (mmHg mm)$^{-1}$	C (mmHg mm)$^{-1/2}$	$10^6\eta$ (poise)	D (Å)
NO	25.5	9.3	0.6	179	3.67
CO	28.5	10.5	0.6	166	3.75
N_2	28.5	10.5	0.6	166	3.75
O_2	24.0	9.2	0.8	192	3.60
CH_4	44.0	11.4	1.2	102	4.26
He	2.96	0.6	1.6	186	2.23

a) Values at 90.5 K for NO and those at 77.5 K for other gases. b) Values at 0 °C. "Kagaku Binran," Chemical Society of Japan, p. 470. c) Values calculated from η (see text).

Takaishi and Sensui have demonstrated that the constants, A, B, and C can be written as:

$$A^* = A \times \bar{T}^2, \quad (2)$$

$$B^* = B \times \bar{T}, \quad (3)$$

$$C^* = C\sqrt{\bar{T}}, \quad (4)$$

where $\bar{T}$ is $(T_1+T_2)/2$ and where A^*, B^*, and C^* are the temperature-independent constants. The determined values for A^*, B^*, and C^* are summarized in Table 2 and compared with the literature values. Since no literature values for NO and CO are available, another way of comparison must be made. The A^*, B^*, and C^* constants of NO and CO are estimated from the following Takaishi-Sensui equations:[5,6]

$$\log A^* = 0.507D + 4.146, \quad (5)$$

$$\log B^* = 0.607D + 0.663, \quad (6)$$

$$C^* = (110/D) - 14. \quad (7)$$

Here, D represents the collision diameter of the gases and is calculated from the viscosity coefficient, η, by the aid of $\eta=5\sqrt{\pi mkT}/16\pi D^2$ relation. By using the values of D summarized in Table 1, the values for A^*, B^*, and C^* are calculated. The results are summarized in Table 2. The agreement between the observed values for the constants and the literature and/or estimated values is reasonably good for all of the gases measured.

Table 2. Constants, A^*, B^*, C^*, contained in Eqs. 2—7

Relations between the Thermodynamic Properties of Alkali Halides at the Melting Point

Hitoshi KANNO

Department of Chemistry, Meisei University, Hino, Tokyo 191

(Received March 26, 1977)

Synopsis. Two new empirical formulas are presented for alkali halides at the melting point. There is a set of linear relations between the initial slope of melting curve (dT_m/dP) and the solid volume (V_s) for the sequences LiX, NaX, KX, and RbX (X=F, Cl, Br, and I).

Alkali halides are the most typical ionic salt for which theoretical and analytical studies have been made in order to clarify the melting of ionic compounds.[1-3] However, the phenomenon of melting still remains unclarified. It is expected that the relations between various thermodynamic properties associated with fusion might help us understand the mechanism of melting of ionic crystals.

In a previous paper,[4] the following empirical formula was given for the entropy change on fusion (ΔS_m) for the sequences of LiX, NaX, KX, and RbX (X=F, Cl, Br, and I).

$$\Delta S_m = \alpha^{1/3}\left(\frac{A}{r}+B\right) \quad (1)$$

where α and r are the electronic polarizability and interionic distance of the salt, respectively; A and B are constants.

A similar relation holds for the relative volume change on fusion:

$$\frac{\Delta V_m}{V_s} = \alpha^{1/3}\left(\frac{C}{r}+D\right), \quad (2)$$

where ΔV_m and V_s are the volume change on melting and the volume of the solid salt at the melting point, respectively; C and D are constants for the salts with the same cation (LiX, NaX, KX, and RbX, X=halogen ion). Although a small deviation from the straight line is seen for a few salts, good linear correlation for the halides of the same cation (Fig. 1) indicates that electronic polarizability, a measure of the deformation of electron cloud in ion, is a very important factor for characterizing melting of these salts in contrast to the argument of Pauling[5] that apparent irregular variation of thermodynamic properties (melting point, boiling point) of alkali halides is ascribed to the radius-ratio effect. Obviously, regular or irregular variation of a certain property depends on the choice of a set of parameters and coordinates.

Irregular variation of cesium halides (CsCl, CsBr, and CsI) is presumably due to the difference in crystal structure between CsCl (face-centered cubic structure at the melting point) and CsBr and CsI (both simple cubic structure at their melting points). The percentage volume expansion of CsCl on melting (10.0%) is considerably smaller than that of the bromide and iodide (26.8 and 28.5%, respectively).[6,7] However, an extrapolation of the molar volume of the low temperature form of CsCl up to the melting point would give a volume expansion on fusion of 28.3%. Conversely, if the volume expansion (17.6%) associated with the transition in CsCl from simple cubic to face-centered cubic structure is applied to the bromide and iodide, hypothetical cesium bromide and iodide would result in a volume expansion on melting of 9.2 and 10.3%, similar to the value of 10.0% for the chloride. This fact was pointed out by Johnson *et al.*[6] who reasoned that large volume expansion of CsBr and CsI is attributed to the reduction in coordination number from eight to about five on melting, whereas the melting from NaCl structure involves only small change in coordination number (from six to about five). It was proposed and verified by X-ray diffraction study[6,8] that the structure of liquid cesium bromide and iodide is very similar to that of the chloride. It is noteworthy that relations (1) and (2) include lithium halides because it has often been pointed out that lithium salts do not obey the corresponding-state law of other alkali halides.[9,10]

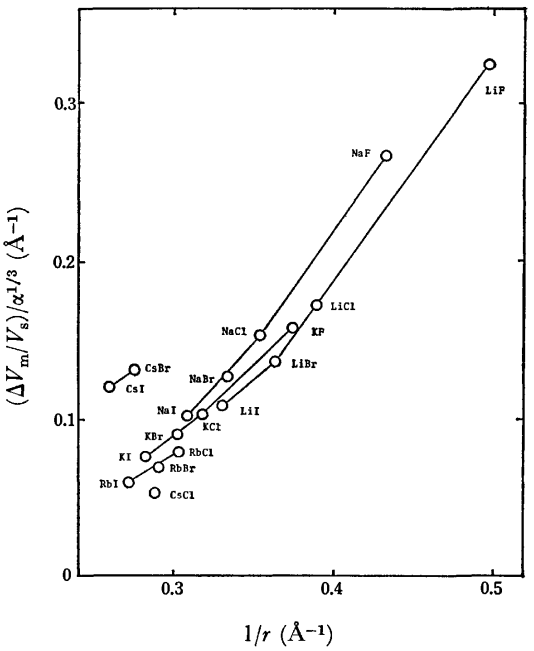

Fig. 1. Relative volume expansion of alkali halide at the melting point. Sources of data: ΔV_m and V_s; H. Spindler and F. Sauerwald, *Z. Anorg. Allg. Chem.*, **335**, 267 (1965), electronic polarizability; J. R. Tessman, A. H. Kahn, and W. Schockley, *Phys. Rev.*, **92**, 890 (1953), Interionic distance; L. Pauling, "The Nature of the Chemical Bond," third ed, Cornell Univ. Press, Ithaca, N. Y. (1960), p. 527.

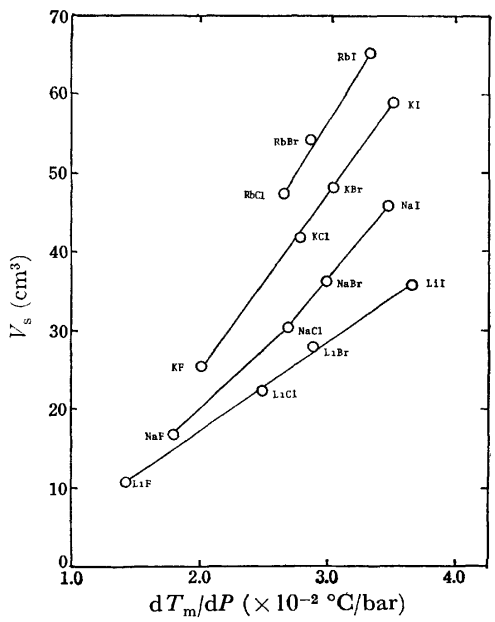

Fig. 2. Linear relation of (d T_m/d P) with solid volume at the melting point ($\bar{V}_s$) for the sequences LiX, NaX, KX, and RbX. Sourece of data: ΔS_m values are calculated from ΔH_m and T_m data compiled by L. Brewer and E. Brackett, *Chem. Rev.*, **61**, 425 (1961).

From relations (1) and (2), we get

$$\left(\frac{dT_m}{dP}\right)_{p=1atm} = \frac{\Delta V_m}{\Delta S_m} = \frac{V_s\left(\frac{C}{r}+D\right)}{\left(\frac{A}{r}+B\right)} = \frac{V_s(C+Dr)}{(A+Br)}$$

$$\simeq EV_s \qquad (3)$$

where E is a constant for the sequence (LiX, NaX, KX, or RbX). Formula (3) suggests that the initial slope of melting curve $(dT_m/dP)_{p=1atm}$ is proportional, as a first approximation, to the volume of the solid salt at the melting point (V_s). As is shown in Fig. 2, there is a good linear relation between the initial slope of the melting curve and the volume of the salt for a sequence of alkali halides of the same cation. It is expected from this relation that at certain high pressures the salt having larger volume should have higher melting point than those of smaller volume if the relation (3) holds up to high pressures. In fact the normal order of melting points of sodium halides is reversed above *ca.* 60 kbars with NaF having the lowest and NaI the highest melting point,[11] and a similar behavior is found for the potassium and rubidium halides at lower pressures.[12,13]

The initial slope of the melting curve $(dT_m/dP)_{p=p_0}$ is expressed as $T_0/a\,c$ by differentiation of the well-known Simon equation, $P-P_0=a\{(T/T_0)^c-1\}$, where T_0 and P_0 are the triple-point temperature and pressure, respectively; a and c are constants. From the corresponding law developed by Reiss *et al.*,[9] the melting point of alkali halide is inversely proportional to ionic distance, *i.e.*, $T_0 \propto 1/r$. Combining this relation and formula (3), we see that $a\,c$ is inversely proportinal to r^4, in accord with the conclusion given by Owens[10] in his analysis of melting curves of alkali halides.

Finally it should be pointed out that the calorimetric heats of fusion of NaI, KI, RbI, and CsI redetermined by Bousquet *et al.*[14] are considerably higher than those of Dworkin and Bredig.[15] However, a comparison of the observed values of the initial slopes of the melting curves of alkali halides[16] with those calculated by means of the Clapeyron-Clausius equation indicates that the data of Dworkin and Bredig are more accurate.

The ESR and ENDOR Spectra of the [2.2](2,7)Pyrenophane Anion Radical

Kazuhiko Ishizu, Yoshinori Sugimoto, Teruo Umemoto,* Yoshiteru Sakata,* and Soichi Misumi*

Department of Chemistry, Faculty of Science, Ehime University, Matsuyama, Ehime 790

**The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka 565*

(Received April 4, 1977)

Synopsis. The ESR and ENDOR spectra of the [2.2](2,7)-pyrenophane anion, which was prepared by reduction with alkali metal in ethereal solvents, were observed. From a comparison of the spin densities for the anion with those for the pyrene anion, the delocalization of the unpaired electron between the stacked aromatic rings was demonstrated.

Since ESR was successfully used in studies of the intramolecular electron exchange in the [2.2]paracyclophane anion by Weissman,[1] the transannular interaction between the aromatic nuclei has been reported for several cyclophanes, such as [2.2](1,4)naphthalenophane[2] and [2.2](9,10)anthracenophane,[3] where the cyclophane derivative has been regarded as an artificial dimer of the alkyl-substituted aromatics, and the proton hyperfine splitting showed nearly half the value of that for the corresponding monomer anion. In the present note, we wish to report our ESR and ENDOR studies of the [2.2](2,7)pyrenophane anion. Studies of [2.2]-(2,7)pyrenophane have been interesting since, because the pyrenophane MO occupied by the unpaired electron has a node at the bridging positions (2,7) of the pyrene ring, the delocalization of the unpaired electron due to σ-π exchange or the hyperconjugative interaction between the methylene and aromatic groups can be ignored. Therefore, one may expect to elucidate the pure transannular effect on the spin density regardless of either the hyperconjugative or the inductive effect of the bridged ethylene groups in the present case.

Experimental

The synthesis of materials has been described elsewhere.[4] The anion radical was prepared by reduction with sodium in 1,2-dimethoxyethane (DME) and tetrahydrofuran (THF). The ENDOR spectra were recorded with a JEOL-type EX-EDX-1 spectrometer under the operating conditions similar to those described previously.[5]

Results and Discussion

Figure 1 shows the ESR spectrum of the pyrenophane anion, which was prepared by reduction with sodium in DME. The ESR spectrum is composed of 25 hyperfine lines equally spaced, with a line width of 150 mG. The ESR hyperfine structure can be adequately analyzed in terms of the splittings (2.18 G) due to the 8 equivalent protons; the structure is split further into 9 lines attributable to the other equivalent protons with a splitting constant of nearly half. No important changes were detected in the ESR hyperfine structure obtained with THF, and the extra splittings of the alkali metal cation have never been observed anywhere.

The ENDOR spectra of pyrene and pyrenophane anions are shown in Fig. 2. The pyrene anion gives the three ENDOR signals (15.33, 16.88, and 20.71 MHz) above the free proton frequency (13.89 MHz). The splittings were assigned with reference to the previous ESR studies;[6] $a_2^H=a_7^H=1.02$, $a_4^H=a_5^H=a_9^H=a_{10}^H=2.13$, and $a_1^H=a_3^H=a_6^H=a_8^H=4.87$ G. On the other hand, the ENDOR signals of the pyrenophane anion were recorded at 15.40 and 17.05 MHz above the free proton frequency. No ENDOR absorption

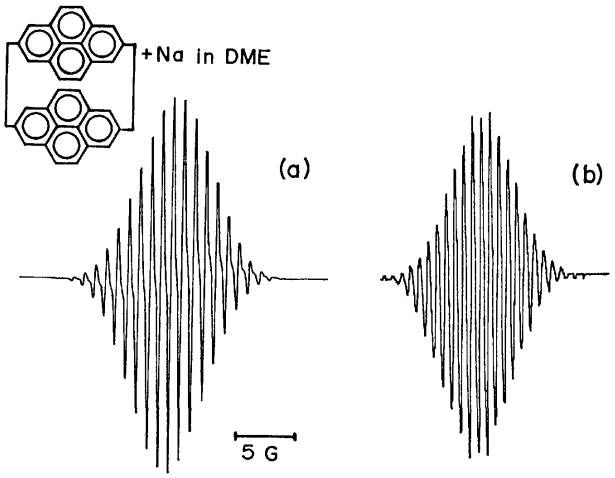

Fig. 1. (a) ESR spectrum of [2.2](2,7)pyrenophane anion recorded at room temperature. (b) A computer simulation of the ESR spectrum.

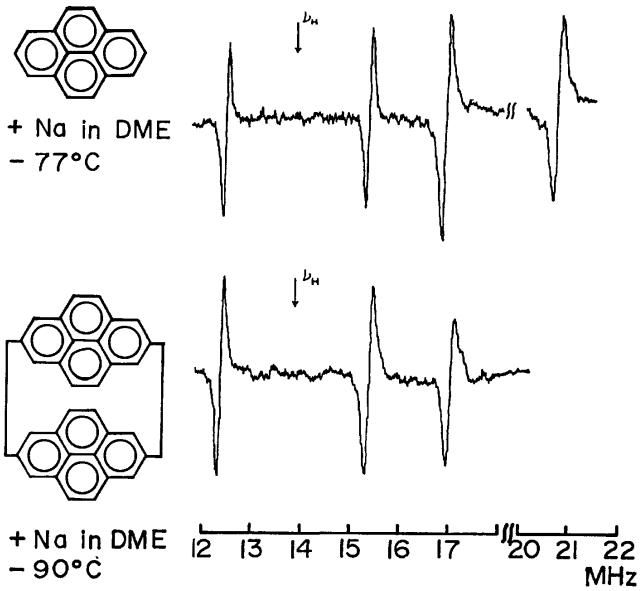

Fig. 2. Higher frequency halves of ENDOR spectra of pyrene and [2.2](2,7)pyrenophane anions. ν_H: free proton frequency.

attributable to the bridging methylene groups can be detected. The splittings of each pyrene group were determined to be 1.08 G for a_4^H, a_5^H, a_9^H, and a_{10}^H and 2.25 G for a_1^H, a_3^H, a_6^H, and a_8^H. Based on the present assumption, computer calculations of the ESR line intensities showed an excellent agreement with the observed spectrum, as is shown in Fig. 1.

The splittings of the pyrene and pyrenophane anions thus determined are summarized in Table 1.

In the previous ESR works on the cyclophane anions, it was pointed out that the spin-density distrubution showed a large dependence on the degree of the transspatial exchange of the unpaired electron in the cyclophane. In [2.2]paracyclophane, however, the doubly degenerated antibonding orbital of the benzene anion causes much difficulty.[7] The importance of the inductive effect of the methylene groups was recently proposed, and the unpaired electron is believed to occupy the orbital which can be expressed by a linear combination of the antisymmetric orbital relative to a plane passing through the two opposite centers and perpendicular to the benzene ring.[8] For [2.2](9,10)anthracenophane, the largest spin densities were assigned to the bridging positions, 9 and 10. Therefore, the possibility of the hyperconjugative interaction of the methylene, which also causes a perturbation on the spin densities, in particular, for the positions with small spin densities, can not safely be ruled out.

Table 1. Proton hyperfine splittings of pyrene and the [2.2](2,7)pyrenophane anion (absolute value in G)

Position	2, 7	4, 5, 9, 10	1, 3, 6, 8
Pyrene	1.02	2.13	4.87
Pyrenophane	$<$150 mG	1.08	2.25

As may be seen in Table 1, the observed ring-proton splittings of the pyrenophane anion are very close to the half-values of those of the pyrene anion radicals, and the methylene proton splitting is very small. This means that the unpaired orbital of the pyrenophane is antisymmetric with respect to the plane passing through the bridging position and perpendicular to the aromatic plane, indicating a negative spin density at the bridging position.

A perturbation of the spin densities due to the hyperconjugative interaction of the methylene group can thus be ignored. A tentative calculation of the methylene proton was performed under the assumptions that the spin densities at the bridging positions, ρ^π, are not affected much by the methylene substitution and that the magnitude of the spin density is reduced to the half-value from that of the pyrene anion.[9] If the methylene protons are tightly fixed in the positions taking the dihedral angle to be $\theta=60°$, the methylene proton splitting can be estimated to be 0.220 G, based on McConnell and Heller's equation, $a^R=B\rho^\pi \cos^2\theta$, $|B|=50$ G.[10] The calculated value is indeed small, and it would be diminished to the order of the ESR linewidth in the real molecule.

On the Low Dimensionality in Organo-magnetic Material: 9-(α-Fluorenylidene-*p*-chlorobenzyl)-9-fluorenyl

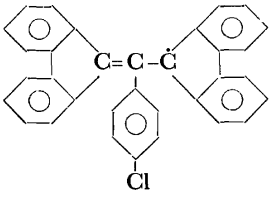
Jun YAMAUCHI and Yasuo DEGUCHI

College of Liberal Arts and Sciences, Kyoto University, Kyoto 606

(Received April 16, 1977)

Synopsis. The low-dimensional character in the organic free radical, *p*-Cl-BDPA, is discussed. The temperature dependence of the *g*-values can provide a method of discrimination between the short- and long-range-ordering effects, and the organic free radical can be regarded as a one-dimensional organo-magnetic material at first approximation, but its interchain interaction is appreciable, amounting to the order of $|J'/J|=0.2$; thus, $|J'|/k=0.88$ K.

Recently the magnetic interactions between unpaired electron spins in crystalline organic free radicals have been of great interest. Especially in the case of neutral organic free radicals, much information has been accumulated so far, and it is generally accepted that there are two regions characteristic of the magnetic interaction between unpaired electron spins in organic free radicals, that is, the short- and long-range-ordered regions.[1] One of the present authors (J.Y.) has discussed in detail the linear antiferromagnetic interaction and the possibility of long-range ordering in organic free radicals.[2] Thus, organic free radicals have been classified as among low-dimensional magnetic materials, that is, low-dimensional organo-magnetic material. An organic free radical, 9-(α-fluorenylidene-*p*-chlorobenzyl)-9-fluorenyl (hereafter abbreviated as *p*-Cl-BDPA),



is a typical example, exhibiting magnetic low dimensionality in the short-range-ordered region and experiencing a magnetic phase transition to a long-range-ordered state.[2]

In order to clarify the magnetic interactions in organic free radicals and to obtain more information about low dimensionality and the magnetic structure, various kinds of experiments have been carried out on *p*-Cl-BDPA.[3-8] In the course of these investigations an important question has been arisen— to what extent does the organic free radical, *p*-Cl-BDPA, have a magnetic low dimensional character. This may be one question to which it is not possible to give a definite answer. In this paper, however, attention will be paid mainly to the low dimensionality of the organic free radical, *p*-Cl-BDPA.

It was shown in our previous papers that the low-dimensional character can be found in susceptibility,[2] magnetic heat capacity,[3] ESR linewidth,[2] and NMR intensity[4] as a function of the temperature and that *p*-Cl-BDPA has a nearly one-dimensional magnetic interaction with an exchange interaction parameter of $J/k=-4.4$ K, where k is Boltzmann's constant. In the

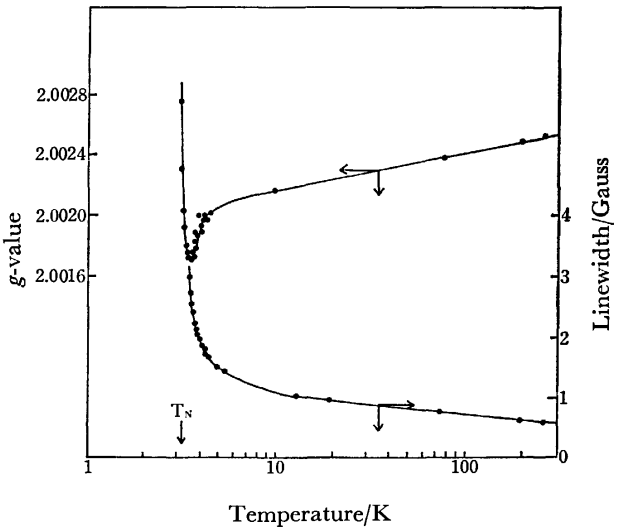


Fig. 1. Temperature dependences of *g*-value and linewidth of *p*-Cl-BDPA. It should be noted that the linewidth is different from that published previously.[2]

microscopic information concerning the ESR linewidth or the NMR intensity, however, the low-dimensional effect could not be discriminated from the long-range-ordering effect.

The experimental results on the ESR *g*-values of polycrystalline *p*-Cl-BDPA as a function of the temperature are shown in Fig. 1, which indicates a *g*-value deviation from a room-temperature *g*-value as the temperature is lowered and its divergence after reaching a minimum at 3.6 K when the temperature approaches the magnetic-phase-transition temperature, 3.25 K. This deviation may be attributed to the magnetic short-range-ordering effect, and the divergence may be due to the magnetic long-range-ordering effect.

Nagata *et al.* classically estimated the simple relations between the anisotropies of the *g*-value and the susceptibility by introducing a small magnetic dipolar interaction and a single ion D-term, both of a uniaxial symmetry referred to the directions of the linear chain interaction.[9] The relationships were as follows:

$$\Delta g_{//}/g = (\chi_{//}-\chi_{\perp})/\chi_{//}, \quad (1)$$

$$\Delta g_{\perp}/g = (\chi_{\perp}-\chi_{//})/2\chi_{\perp}. \quad (2)$$

When we assume the following relation for a powder sample:

$$\Delta g_{iso} = (\Delta g_{//}+2\Delta g_{\perp})/3, \quad (3)$$

equations 1 and 2 give this expression:

$$\Delta g_{iso}/g = -(\chi_{//}-\chi_{\perp})^2/3\chi_{//}\chi_{\perp}. \quad (4)$$

Equation 4 indicates that the *g*-value observed on the powder sample decreases with a decrease in the tem-

perature. The g-value deviation of p-Cl-BDPA is comprehensible from the theory and, therefore, implies a one-dimensional short-range ordering of unpaired electron spins in a linear chain. In the long-range-ordered region, ESR shows an antiferromagnetic resonance pattern, and the resonance shifts to the down-magnetic-field become much larger.[6] This leads to a large g-value anisotropy and to a divergence of the g-value in the short-range-ordered region near the long-range-ordering temperature. This may be the reason why the divergence of g-values can be observed in the case of p-Cl-BDPA.

It is generally accepted that one-dimensional magnetic interactions characterize ESR absorptions at room temperature; that is, the line shape is different from the usual Lorenzian or Gaussian line shapes, and the linewidth angular variation is different from that of the three- or two-dimensional magnetic interaction.[10] These facts are explained at present on the basis of a one-dimensional spin diffusion model. Although the line shape of p-Cl-BDPA was observed, we could not obtain any characteristic behavior such as is mentioned above, but it exhibits a Lorenzian line shape exactly. This fact indicates that p-Cl-BDPA is not a purely one-dimensional magnetic material and implies the presence of fairly large interactions between the magnetic linear chains. As for the angular variations in the linewidth, we can not draw any decisive conclusion because of the lack of the single crystal measurements.

The interchain interaction can not be estimated directly from the experimental results, but the relationship between the intrachain interaction, J, the interchain interaction, J', and the phase transition temperature can be anticipated. Oguchi deduced this relationship in the case of a two-dimensional interchain interaction using the Green function method,[11] which gives the interchain interaction, J', of p-Cl-BDPA. In Table 1 the results obtained are listed, together with those of other organic free radicals for comparison. It can be seen there that $|J'/J|=0.2$ leads to $|J'|/k=0.88$ K and that the interchain interaction is fairly large and not negligible compared with that of the TANOL radical,[12] amounting to the same order of magnitude as in the BDPA-Bz radical.[2,13]

Table 1. Intrachain- and interchain-exchange interaction parameters of several organic free radicals

	J/k	T_N[c]	J/kT_N	$\|J'/J\|$	$\|J'\|/k$
p-Cl-BDPA	−4.4 K	3.25 K	−1.4	0.2	0.88 K
BDPA-Bz[a]	−4.4 K	1.695 K	−2.6	0.04	0.18 K
TANOL[b]	−5.0 K	0.49 K	−10.2	0.004	0.02 K

a) 1,3-Bisdiphenylene-2-phenyl-allyl and benzene complex. b) 2,2,6,6-tetramethyl-4-piperidinol-1-oxyl. c) Antiferromagnetic phase transition temperature.

In conclusion, the temperature dependence of the g-values of the organic free radical, p-Cl-BDPA,can provide a method of discrimination between the short- and long-range-ordering effects, and p-Cl-BDPA can be regarded as a one-dimensional organo-magnetic material at first approximation, but its interchain interaction is appreciable, amounting to the order of $|J'/J|=0.2$; thus, $|J'|/k=0.88$ K.

Formation and Characterization of Lead Monoxide Prepared by the Alkoxy-Method

Osamu YAMAGUCHI, Minoru YAMADERA, and Kiyoshi SHIMIZU

Department of Applied Chemistry, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602

(Received March 7, 1977)

Synopsis. Lead alkoxide was hydrolyzed at various temperatures from 28 to 85 °C. The products consisted of only massicot or litharge, or a mixture of the two for modifications of PbO, depending on the reaction temperature and pH of the suspension.

PbO has two polymorphic modifications, litharge (tetragonal) and massicot (orthorhombic). Although litharge transforms into massicot at about 500 °C,[1] the reverse transformation does not occur. On the other hand, massicot transforms readily into litharge by grinding[2-4] or wet ball-milling.[5,6] Commercial PbO, prepared by oxidation of the molten Pb, is usually a mixture of the two modifications.[6] The present paper is concerned with the conditions for the formation of the two modifications and the characterization for the alkoxy-derived PbO.

Experimental

An alcoholic solution containing 6.5 wt% lead alkoxide was prepared by the reaction of anhydrous lead acetate with sodium isopropoxide in the presence of an excess amount of isopropyl alcohol:

$$Na + C_3H_7OH \longrightarrow Na(OC_3H_7) + 1/2H_2, \quad (1)$$

$$Pb(CH_3COO)_2 + 2Na(OC_3H_7) \xrightarrow[C_3H_7OH]{83^\circ C,\ 12\,h} Pb(OC_3H_7)_2 + 2CH_3COONa\downarrow. \quad (2)$$

The purities of anhydrous lead acetate and sodium metal used in the reaction were 99.5 and 99.9%, respectively. Isopropyl alcohol was purified by fractional distillation of the guaranteed reagent. The hydrolysis was carried out as follows. A five-necked flask was equipped with a reflux condenser, a dropping funnel, a stirring rod, a thermometer and a thermo-controller. A definite quantity of water in the range from 100 to 1000 ml was introduced into the flask, and then heated to the desired temperature. A solution of 100 ml of the alkoxide in the dropping funnel was added dropwise to the stirred water in the fiask. After completion of the addition, the suspensions were further stirred for 15 min. The products were separated from the suspensions by filtration, washed repeatedly with water, and dried at 60 °C under reduced pressure. The products were examined by means of X-ray diffraction using Ni filtered Cu$K\alpha$ radiation.

Results and Discussion

All products obtained at various temperatures in 400 ml of water were identified as PbO only as massicot or a mixture of massicot and litharge. The yield was about 67%. Table 1 shows the composition of the two modifications for each PbO powder. The composition was determined by measuring the relative intensities, I_M and I_L, of the strongest peaks in the massicot and litharge spectra. For the alkoxy-derived PbO, as described subsequently, these peaks correspond to $d(002)=2.95$ Å for massicot and $d(002)=2.51$ Å for litharge. The product consisting of only massicot was obtained at 28 °C. A small amount of litharge in addition massicot was formed at 40 °C and the litharge content of the products increased with an increase in temperature up to 85 °C, but no product consisting of only litharge was formed. On the other hand, the products consisted of only litharge when the alkoxide solution was added to water all at once at temperatures ranging from 70 to 85 °C. Judging from the yield described above, it can be assumed that the unreacted sodium alkoxide was involved in the lead alkoxide (see Reaction 2). In view of the fact that sodium alkoxide changes into sodium hydroxide upon hydrolysis, the difference between the results at 70 to 85 °C may be ascribed to a change in

Table 1. Composition of the two modifications for PbO obtained by hydrolyzing lead alkoxide

the pH of the suspensions during the course of hydrolysis. Accordingly, the 100 ml alkoxide solution was added dropwise to various quantities of water at 85 °C. As shown in Fig. 1, an approximately linear relationship exists between the composition of the two modifications in the products and the pH of the suspensions. When the pH value of the suspensions was below about 11.4, the massicot content of the products were greater than the litharge content. A further increase in the pH resulted in the formation of litharge. From the results, it was found that the compositon of the two modifications for PbO prepared by the alkoxy-method is due to the pH of the suspension, as well as the hydrolysis temperature.

Electron micrographs of the PbO powders are shown in Fig. 2. Massicot with an orthorhombic crystal structure consists of rhombic plate-like particles. On the other hand, litharge with a tetragonal crystal structure is composed of tetragonal plate-like particles. The morphology is shown more clearly in Fig. 3, in which well-defined rhombic and tetragonal plates are easily discernible.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 50 (10), 2807—2808 (1977)

The Preparation of Mixed Carbonato Complexes of Cobalt(III) with 2-Pyridinecarboxylic Acid

Yayoi IDA, Masaharu SAKAI, Shigeru SAKAI, and Muraji SHIBATA
Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920
(Received March 25, 1977)

Synopsis. By the successive replacement of CO_3^{2-} ions in the $[Co(CO_3)_3]^{3-}$ complex with 2-pyridinecarboxylic acid (Hpicol), the $[Co(CO_3)_2(picol)]^{2-}$ complex and two geometrical isomers of the $[CoCO_3(picol)_2]^-$ complex have been prepared. By the reaction of the *cis*-$[Co(CO_3)_2(NH_3)_2]^-$ complex and picol, three geometrical isomers of the $[CoCO_3(picol)(NH_3)_2]$ have been prepared.

The most remarkable feature of the preparative method for cobalt(III) complexes starting from a potassium hydrogencarbonate aqueous solution of the tricarbonatocobaltate(III) is the successive replacement of the CO_3^{2-} ions with another ligand, and the first substitution step in the reaction with such a ligand as ammonia, ethylenediamine, pyridine, nitrite ion, or cyanide ion resulted in a dicarbonato complex.[1] However, the action of an α-amino acid (glycine, alanine or valine) on the $[Co(CO_3)_3]^{3-}$ complex resulted not in the dicarbonato complex, but in the carbonatobis (amino acidato) complex.[1] Thus, we adopted 2-pyridinecarboxylic acid (picolinic acid, abbreviated as Hpicol) in order to investigate successive substitution. In addition, the reaction of *cis*-$[Co(CO_3)_2(NH_3)_2]^-$ with 2-pyridinecarboxylic acid to give $[CoCO_3(picol)(NH_3)_2]$ was investigated.

Experimental

2-Pyridinecarboxylic acid was prepared from 2-methylpyridine in the form of hydrochloride by a familiar method.[2]

To a freshly prepared solution of tricarbonatocobaltate(III) ($Co(NO_3)_2 \cdot 6H_2O$, 29.1 g, 0.1 mol), we added a solution of Hpicol (0.1 mol); the mixture was stirred at *ca.* 50 °C for 40 min, whereupon the solution turned blue-green. The resulting solution was allowed to cool in an ice bath. Ethanol was added, to the cold solution for the successive removal of the coexisting salts. Finally, an ethanol–ether (1: 1) mixture was added to the solution, and the whole was kept in a refrigerator until blue-green crystals separated out. Recrystallization was performed by dissolving the crude product in a minimum amount of water, followed by the addition of an ethanol–ether (1: 1) mixture when cold. Yield, *ca.* 15 g. Found: C, 24.77; H, 1.44; N, 3.90%. Calcd for $K_2[Co(CO_3)_2(C_6H_4NO_2)] \cdot 1/2H_2O$: C, 24.75; H, 1.30; N, 3.61%.

A solution of Hpicol (0.05 mol) was added to a freshly prepared solution of $[Co(CO_3)_3]^{3-}$ (0.025 mol); when the mixture was then stirred at 60 °C for 4 h, it turned violet. The resulting solution was concentrated to a small volume with a rotary evaporator at *ca.* 35 °C. To the concentrated solution we added an ethanol–ether mixture (1: 1), and the whole was kept in a refrigerator overnight. The crude product thus obtained was filtered and recrystallized in the way described above. On the other hand, the filtrate was charged on a column containing Dowex 1 X-8 in the Cl-form (9×15 cm). By elution with a 0.3 M KCl aqueous solution, a broad band consisting of univalent anionic species was descended; it was collected in a fraction. This was again chromatographed using a column (5×30 cm) and 0.3 M KCl; three violet bands were then separated. They were collected in fractions labeled A-1—A-3. The absorption spectra of these fractions indicated that the crystals obtained prior to the chromatographic separation were identical with the species in the A-2 fraction. Each fraction was evaporated almost to dryness, the residue being extracted with ethanol. After a small amount of water had been added to the extracted solution, the whole was kept in a refrigerator until crystals separated out. This was successful with the fractions A-2 and A-3, crystallization from the A-1 fraction being unsuccessful because of the poor yield and easy isomerization of the species. Yields, *ca.* 3 g for the A-2 fraction plus the crystallized crop and *ca.* 0.5 g for the A-3 fraction. Found for the A-2 complex: C, 35.82; H, 3.02; N, 6.60%. Calcd for $K[CoCO_3(C_6H_4NO_2)_2] \cdot 2H_2O$: C, 35.62; H, 2.76; N, 6.39%. Found for the A-3 complex: C, 36.44; H, 2.57; N, 6.17%. Calcd for $K[CoCO_3(C_6H_4NO_2)_2] \cdot 3/2H_2O$: C, 36.37; H, 2.58; N, 6.53%.

Three isomers of the diamminecarbonatopicolinatocobalt(III) complex were obtained analogously to those of the $[CoCO_3(gly)(NH_3)_2]$ complex.[3] To a solution of $K[Co(CO_3)_2(NH_3)_2] \cdot H_2O$[1] (10 g, 0.037 mol in *ca.* 20 ml H_2O) we added a solution of the Hpicol ligand (0.05 mol); the mixture was then stirred at room temperature for 3 h. During the reaction, a considerable amount of red-violet crystals separated out as the first crop. The crystals were collected by filtration, and the filtrate was concentrated to a small volume. Ethanol was added to the concentrate, and then the whole was cooled in an ice bath, the second crop of the crystals being thus obtained. The combined first and second crops of crystals were recrystallized from a large quantity of hot water (50 °C).

On the other hand, the filtrate from the second crop of crystals was chromatographed on a column containing 100—200 mesh Dowex 50W-X 8 resin in the Na-form (4.5×25 cm). By washing the column with water, the band of unreacted $[Co(CO_3)_2(NH_3)_2]^-$ was descended first, followed by the three bands of the desired isomers. Since the first-descended band was very poor in yield and was found to be identical with the crystals separated during the reaction, this portion of the eluate was discarded. The second and third bands were collected in fractions. Each fraction was concentrated to a small volume. After the addition of ethanol, the concentrate was kept in a refrigerator overnight. Red needle-like crystals separated out from the fraction of the second band, while pink plates were obtained from the fraction of the third band. Yields, *ca.* 1 g (red-violet crystals), *ca.* 0.5 g (red crystals), and *ca.* 0.5 g (pink crystals). Found for the red-violet crystals: C, 30.53; H, 4.03; N, 14.86%. Calcd for $[CoCO_3(C_6H_4NO_2)(NH_3)_2]$: C, 30.56; H, 3.66 N, 15.07%. Found for the red crystals: C, 27.00; H, 4.87; N, 13.18%. Calcd for $[CoCO_3(C_6H_4NO_2)(NH_3)_2] \cdot 2H_2O$: C, 27.02; H, 4.54; N, 13.51%. Found for the pink crystals: C, 28.79; H, 4.42; N, 14.43%. Calcd for $[CoCO_3(C_6H_4NO_2)(NH_3)_2] \cdot$

H_2O: C, 28.68; H, 4.13; N, 14.34%.

The absorption spectra were measured with a Hitachi Model 323 spectrophotometer. The proton magnetic resonance (PMR) spectra were recorded on a JEOL JNM-PS-100 NMR spectrometer at *ca.* 25 °C, using D_2O as the solvent. The values of the chemical shifts were referred to internal sodium d_4-trimethylsilylpropionate (TMSP).

Results and Discussion

The absorption spectra in solution for the present three kinds of complexes are shown in Figs. 1 and 2. The numerical data are summarized in Table 1, the data[4] on related complexes being included for comparison. When the spectral data of the $[Co(CO_3)_2(picol)]^{2-}$ complex are compared with those of the $[Co(ox)_2(gly)]^{2-}$ complex. a bathochromic shift is observed in the spectrum of the dicarbonato complex. This shift can reasonably be explained by the facts that the CO_3^{2-} is ranked in a position of the spectrochemical series lower than the $C_2O_4^{2-}$ ion, and that the picol lies close to the gly ligand in the series.[5]

The absorption spectra of the two isomers of the $[CoCO_3(picol)_2]^-$ complex are quite similar to each other (Fig. 1); hence, the geometrical configurations have not been determined from the spectral data. Although another isomer had not been isolated as crystals from the eluate, the spectrum of the eluate exhibited the first band at 18200 cm^{-1} which is rather broader than those for the isolated two isomers and the second band at 25200 cm^{-1}. Concerning the $[Coox(gly)_2]^-$ complex, Matsuoka *et al.*[4] reported that one somer, whose structure is determined to be *trans*(*N*)i from the splitting of the first absorption band, corresponds to the first-eluated band in chromatographic separation, and that other two isomers, determined to be C_1-*cis*(*N*) and C_2-*cis*(*N*) on the basis of the PMR spectra, correspond to the second band and the third band respectively. The two isomers isolated in the present work exhibit the proton signals due to the pyridine rings of picol in the region of δ 7.4—9.2 ppm. The patterns were so complicated that the assignments of the peaks have not been performed, but the spectrum of the isomer from the second eluate exhibited a more complex pattern than that from the third eluate. Considering these differences in the absorption spectrum, in the elution order, and in the PMR spectrum, the three isomers are assumed to adopt *trans*(*N*), C_1-*cis*(*N*), and C_2-*cis*(*N*) configurations respectively, according to the order of elution.

Table 1. Absorption spectral data ($\bar{\nu}$ in 10^3 cm^{-1})

Complex	I Band		II Band	
	$\bar{\nu}_{max}$	log ε	$\bar{\nu}_{max}$	log ε
$[Co(CO_3)_2(picol)]^{2-}$	17.0	2.16	24.1	2.28
$[Co(ox)_2(gly)]^{2-}$ [4]	17.9	2.20	25.0	2.26
$[CoCO_3(picol)_2]^-$				
trans(*N*) (1)[a]	18.2	—	25.2	—
C_1-*cis*(*N*) (2)	18.2	2.19	25.3	2.27
C_2-*cis*(*N*) (3)	18.4	2.06	25.2	2.30
$[Coox(gly)_2]^-$ [4]				
trans(*N*) (1)	16.7 18.9	1.70 2.00	25.8	2.23
C_1-*cis*(*N*) (2)	18.3	2.15	25.8	2.24
C_2-*cis*(*N*) (3)	17.8	2.08	25.9	2.20
$[CoCO_3(picol)(NH_3)_2]$				
mer-cis(NH_3) (1)	18.3	2.02	26.8	2.26
mer-trans(NH_3) (2)	19.2	2.04	25.0(sh) 28.4(sh)	
fac (3)	18.9	2.07	26.9	2.23
$[CoCO_3(gly)(NH_3)_2]$ [3]				
mer-cis(NH_3) (1)	18.1	2.03	26.5	2.25
mer-trans(NH_3) (2)	18.7	2.07	24.9(sh) 27.3	1.85
fac (3)	18.7	2.02	26.7	2.13

a) Numbers in parentheses indicate the elution order.

The characterization of the three isomers of the $[CoCO_3(picol)(NH_3)_2]$ complex can be made in the same way as that used for the isomers of the $[CoCO_3(gly)(NH_3)_2]$ complex;[3] the isomer, exhibiting splitting of the second absorption band is identified as that of *mer-trans*(NH_3); the isomer exhibiting the first absorption band with the largest half-width, as that of the *mer-cis*-(NH_3) isomer, and the remainder, which was obtained from the last eluate, as the *fac* one.

Electrochemical Fluorination of Ethanethiol

Hajime BABA, Kazuo KODAIRA, Shunji NAGASE, and Takashi ABE

Government Industrial Research Institute, Nagoya, Hirate-machi, Kita-ku, Nagoya 462

(Received May 9, 1977)

Synopsis. The electrochemical fluorination of ethanethiol has been carried out. A number of new fluoroalkyl sulfur compounds have been isolated and characterized.

With bivalent sulfur compounds, the electrochemical fluorination of alkyl sulfides has frequently been carried out,[1] but little work has been reported on the electrochemical fluorination of thiols.[2] The present paper will describe the results of a study of the electrochemical fluorination of ethanethiol, a study initiated in order to examine the possible use of this method for the preparation of partially-fluorinated alkyl sulfur compounds.

The results turned out to be very complex, yielding almost all possibly producible fluoroethyl derivatives of sulfur hexafluoride, most of them new. However, their yields were quite small (<13%). The extensive cleavage of the carbon-sulfur bond of the thiol was observed giving fluorocarbons and sulfur hexafluoride. There were also formed dialkyl sulfur tetrafluoride compounds, that may be yielded as a consequence of the fragmentation of the thiol and the combination of the fragments, showing the complexity of the nature of the electrochemical fluorination of sulfur compounds.[1c,f] The low yields of the fluorinated products may be ascribed partly to the instability of the thiols in hydrogen fluoride[3] and also to the formation of tar-like materials during fluorination.

TABLE 1. FLUOROALKYL SULFUR COMPOUNDS

Compound	Bp[a] (°C)	n_D^{20}	Elemental analysis[b] C (%)	H (%)	F (%)
$CHF_2CF_2SF_5$	31.6	<1.28	10.63 (10.53)	0.70 (0.44)	74.6 (75.0)
$CF_3CH_2SF_5$	39.5	<1.28	11.55 (11.43)	0.95 (0.96)	72.4 (72.4)
CHF_2CHFSF_5	48.0	1.2866	11.57 (11.43)	1.16 (0.96)	72.9 (72.4)
$CHF_2CH_2SF_5$	56.0	1.2967	12.25 (12.50)	1.75 (1.58)	69.0 (69.2)
$C_2H_5SF_5$	59.6	1.3114	15.56 (15.38)	3.67 (3.23)	60.5 (60.9)
$CH_2FCHFSF_5$	62.2	1.3048	12.72 (12.50)	1.77 (1.58)	69.1 (69.2)
cis-$(C_2F_5)_2SF_4$	71.7	1.2832	13.81 (13.88)		76.4 (76.9)
$CF_3CHFSF_4C_2F_5$	81.4	1.2870	14.63 (14.64)	0.50 (0.31)	74.7 (75.3)
$CF_3CH_2SF_4C_2F_5$	88.6	1.2941	15.26 (15.49)	0.85 (0.65)	73.0 (73.5)
$C_2F_5SF_4C_2F_4SF_5$	132.0	1.3057	10.77 (10.58)		75.2 (75.3)

a) Recorded, uncorrected, at atmospheric pressure.
b) The calculated values are given in parentheses.

The physcial constants and elemental analyses of the new sulfur-containing compounds are listed in Table 1. From the kinds of the products, such as $CF_3CH_2SF_5$, $CHF_2CH_2SF_5$, and $C_2H_5SF_5$, it may be said that, during the fluorination, the sulfur atom in the thiols is oxidized to the sexivalent state, mainly in the initial stage of the fluorination, before the fluorination of the alkyl group is complete, as has been shown in the fluorination of alkyl sulfides.[1b,c,f]

The ^{19}F NMR spectroscopy was particularly useful in the structure determination of these kinds of compounds.[4,5] For example, fluoroethylsulfur pentafluorides could be confirmed by indicating the presence of two differently shielded types of fluorine nucleus bonded to the sulfur in the correct intensity ratio of 1:4 in the regions expected. The axial fluorine nuclei are more shielded than the equatorial fluorine nuclei. The ^{19}F and ^1H NMR data are shown in Table 2. Except for the case of bis(pentafluoroethyl)sulfur tetrafluoride, the *trans* configuration of the dialkyl groups of disubstituted derivatives of sulfur hexafluoride was confirmed: all of the $-SF_4-$ fluorine atoms are equivalent, showing a single multiplet expected for only the *trans*-isomer.

The bis(pentafluoroethyl)sulfur tetrafluoride obtained was found to be a mixture of *cis* ($A_2B_2X_4Y_6$ system)- and *trans* ($A_4X_4Y_6$ system)-isomers in an approximate ratio of 1:6, which could be resolved by gas chromatography. For the *trans*-isomer, the $-SF_4-$ signals are a multiplet centered at −26.7 ppm (in CCl_4, with respect to internal CCl_3F). In the case of the *cis*-isomer, in the sulfur-fluorine regions, two triplets of multiplets of an equal intensity, centered at −21.8 and −61.4 ppm, are exhibited. The coupling interaction between SF_{ax} and SF_{eq} is 89.5 Hz. This is the first example of the formation and identification of the *cis*-isomer of bis(perfluoroalkyl)sulfur tetrafluoride in the electrochemical fluorination. Only the *trans*-isomers have been yielded *via* the electrochemical fluorination of the sulfides.[1b-d,4,5]

Experimental

The electrolytic fluorination apparatus and operating procedures were similar to those described previously.[6] The mass spectra were recorded on a Hitachi RMU-7 instrument at 70 eV, the ^{19}F NMR spectra, on a Hitachi R-20B instrument at 56.4 MHz, and the ^1H NMR spectra, on a Hitachi R-22 instrument at 90 MHz.

A representative run and the results obtained will be described below. The sample (25.5 g, 0.410 mol) was dissolved in anhydrous hydrogen fluoride (400 ml) in the cell and fluorinated under the following conditions: sodium fluoride, 20.0 g; anodic current density, 3.5 A/dm^2 (the effective surface areas of the anodes and the cathodes were both 7.7 dm^2); cell voltage, 5.5—6.5 V; cell temperature, 17—18 °C; electricity supplied, 312 A h (690 min); helium, 100 ml/min. (Though this flouorination could be carried out without using a conductivity additive, the use of sodium fluoride increased the yields of partially-fluorinated ethylsulfur pentafluorides). The products (75.5 g) obtained were rectified into four fractions by means of a low-temperature rectification column, and each fraction was then subjected to gas-chromatographic analysis using the following stainless-steel column, 2 m×3 mm, silica gel; 4 m×3 mm, Daifl oil 3 (20%) on Chromosorb P-AW, 4 m×3 mm, Silicone DC QF-1 (15%) on Chromosorb P-AW.

The following compounds were obtained (the compositions were calculated on the basis of the chromatographic peak

Synthesis and Properties of 2,8-Dioxabicyclo[3.2.1]octane Derivatives

Hajime IRIKAWA, Tsukasa ISHIKURA, and Yasuaki OKUMURA

Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka 422

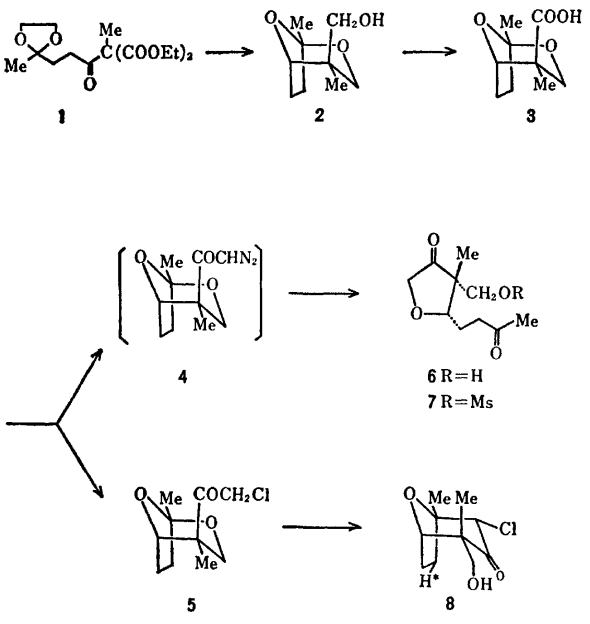
(Received December 13, 1976)

Synopsis. In order to study the isomerization of daphniphylline into isodaphniphylline, 1,4-dimethyl-2,8-dioxabicyclo[3.2.1]octane-4-carboxylic acid (**3**), a degrada tion product of daphniphylline, was synthesized from the keto diester and transformed into the 3-oxacyclopentanones (**6**, **7**).

A *Daphniphyllum* alkaloid, daphniphylline, undergoes isomerization in hydrochloric acid into isodaphniphylline, by which the 2,8-dioxabicyclo[3.2.1]octane structure is transformed into the 3-oxacyclopentanone skeleton.[1] This paper deals with a model reaction of the isomerization, and the synthesis of 1,4-dimethyl-2,8-dioxabicyclo[3.2.1]octane-4-carboxylic acid (**3**), a degradation product of daphniphylline.

Condensation of diethyl methylmalonate with 4,4-ethylenedioxypentanoyl chloride gave the keto diester (**1**), which afforded acetal alcohol (**2**) on reduction with lithium aluminium hydride followed by treatment with hydrochloric acid. Oxidation of **2** with potassium permanganate gave acetal acid (**3**), whose IR and NMR spectra were identical with those of the authentic sample.[1] Thus, *exo* orientation of the hydroxymethyl group in **2** is clear.

For conversion into the 3-oxacyclopentanone skeleton, the sodium salt of **3** was converted into the diazo ketone (**4**) accompanied by the chloro ketone (**5**) with oxalyl dichloride followed by treatment with diazomethane in ether. Treatment of **4** with methanolic hydrochloric acid gave 3-oxacyclopentanone (**6**), which afforded mesylate (**7**). The IR (3670, 3490, 1762, and 1713 cm^{-1}) and NMR (δ 2.19 ppm, 3H, s) spectra of **6** are in line with the assigned structure. The formation of **6**, which bears the substituents shown in the formula, is explained by a nucleophilic attack on the α-keto methylenediazonium group by the 8-oxygen atom in **4** in close proximity.



Scheme

An attempt to convert **5** into **6** by treatment with 30% methanolic hydrogen chloride failed, giving isomeric ketone (**8**) instead. The doublet proton signal at 4.55 ppm (–CHCl–) of **8** is due to the long-range coupling with H*, indicating *endo* configuration of the chlorine atom. The isomerization might proceed through an intermediate, which has an enol group bearing the chlorine atom *trans* to the carbon chain.

By analogy with the conversion of **4** into **6**, the isomerization of daphniphylline seems to involve an intramolecular substitution of the protonated acetoxyl group or protonated hydroxyl group (upon hydrolysis) by the bridge-oxygen in close proximity.

Experimental

All melting points and boiling points are uncorrected. The NMR spectra were obtained on a JNM-C-60H in $CDCl_3$ solution, with TMS as an internal standard.

The Keto Diester ***1.*** To a mixture of 17.4 g of diethyl methylmalonate, 4.8 g of 50% NaH and 100 ml of ether was added a solution of 4,4-ethylenedioxypentanoyl chloride in 50 ml of ether, prepared from 18.2 g of sodium 4,4-ethylenedioxypentanoate[2] and 18.5 g of oxalyl dichoride. After being stirred at room temperature for 6 h, the reaction mixture was refluxed for 1 h, and worked up in the usual way to give 16.8 g (53.2% from the sodium salt) of **1** as a colorless oil: bp 148—151 °C/1.2 mmHg; IR(neat) 1755 and 1726 cm^{-1}; NMR δ 1.30 (3H, s), 1.30 (6H, t, J=7 Hz), 1.63 (3H, s), 1.96 (2H, m), 2.74 (2H, m), 3.89 (4H, s) and 4.24 ppm (4H, q, J=7 Hz). Found: C, 57.06; H, 7.74%. Calcd for $C_{15}H_{24}O_7$: C, 56.95; H, 7.65%.

The Acetal Alcohol ***2.*** A mixture of 22.1 g of **1**, 7.6 g of $LiAlH_4$ and 250 ml of ether was refluxed for 6 h, and then treated with 150 ml of 6 M HCl at room temperature overnight. The work-up in the usual way gave 5.1 g (42%) of **2** as a colorless oil: bp 109—110 °C/3.2 mmHg; IR (CCl_4) 3640 and 3480 cm^{-1}; NMR δ 0.74 (3H, s), 1.46 (3H, s), 1.98 (4H, m), 3.22 (1H, s, disappeared on addition of D_2O), 3.40 (1H, d, J=12 Hz), 3.65 (1H, d, J=12 Hz), 3.78 (2H, AB-q, J=11 Hz) and 4.18 ppm (1H, m). Found: C, 63.03; H, 9.43%. Calcd for $C_9H_{16}O_3$: C, 62.76; H, 9.36%.

The Acetal Acid ***3.*** A mixture of 3.1 g of **2**, 0.5 g of NaOH, 6.1 g of $KMnO_4$ and 85 ml of water was stirred at 0 °C for 24 h. Work-up in the usual way gave 1.8 g (55%) of **3** as colorless plates, mp 144—145 °C ($CHCl_3$), whose IR ($CHCl_3$) and NMR spectra were identical with those of the authentic sample. The melting point higher than that of the authentic sample (mp 122—123 °C) indicates that the synthetic **3** is in a form of racemic compound.

Transformation of ***3*** *into Chloro Ketone* ***5*** *and Cyclopentanone* ***6.*** To a mixture of 611 mg of the sodium salt of **3**, 3 drops of

pyridine and 5 ml of benzene was added a solution of 2 ml of oxalyl dichloride in 5 ml of benzene. After being left to stand at room temperature for 3 h, the reaction mixture was concentrated *in vacuo*. Treatment of the residue with ethereal diazomethane (from 5 g of *N*-nitrosomethylurea) at room temperature for 2 days, and then with methanolic hydrochloric acid* (2 ml of 1 M HCl in 3 ml of MeOH) at room temperature for 10 min gave an oily product, which was chromatographed on 5 g of silica gel. Elution with $CHCl_3$ afforded 120 mg (19%) of **5** as colorless needles: mp 76—77 °C (in a sealed tube, diisopropyl ether); IR (Nujol) 1730 cm^{-1}; NMR δ 0.92 (3H, s), 1.47 (3H, s), 2.02 (4H, m), 3.60 (1H, d, J=12 Hz), 4.23 (1H, q, J=12 and 2 Hz), 4.6 (1H, m), and 4.64 ppm (2H, s); MS (70 eV), *m/e*, 218 (M^+), 183 and 141. Found: C, 55.23; H, 7.24%. Calcd for $C_{10}H_{15}O_3Cl$: C, 54.93; H, 6.91%. Elution with 5% MeOH–$CHCl_3$ gave 163 mg (28%) of **6** as a colorless oil; IR ($CHCl_3$) 3670, 3490, 1762, and 1713 cm^{-1}; NMR δ 1.07 (3H, s), 2.00 (2H, m), 2.19 (3H, s), 2.59 (1H, s, disappeared on addition of D_2O), 2.73 (2H, m), 3.69 (2H, s), 3.84 (1H, m), 3.88 (1H, d, J=17 Hz) and 4.12 ppm (1H, d, J=17 Hz); MS (70 eV), *m/e*, 170 (M^+−30), 152, 113, and 112.

The Mesylate 7. Treatment of 127 mg of **6** with 0.3 ml of methanesulfonyl chloride in 1 ml of pyridine at room temperature for 3 h gave 54 mg (31%) of **7** as colorless plates: mp 90—91 °C (EtOH); IR (Nujol) 1759, 1710, 1348, and 1176 cm^{-1}; NMR δ 1.21 (3H, s), 2.01 (2H, m), 2.21 (3H, s), 2.73 (2H, m), 3.03 (3H, s), 3.88 (1H, q, J=9 and 5 Hz), 3.95 (1H, d, J=17 Hz), 4.15 (1H, d, J=17 Hz), and 4.23 ppm (2H, s); MS (70 eV), *m/e*, 278 (M^+), 221 and 191. Found: C, 47.30; H, 6.55%. Calcd for $C_{11}H_{18}O_6S$: C, 47.47; H, 6.52%.

Isomerization of the Chloro Ketone 5. A solution of 51 mg of **5** in 5 ml of 30% methanolic hydrogen chloride was refluxed for 3 h. Evaporation *in vacuo* and subsequent crystallization from benzene–hexane gave 31 mg (61%) of **8** as colorless needles: mp 86—88 °C (in a sealed tube); IR (CCl_4) 3610, 3580 and 1720 cm^{-1}; NMR δ 1.42 (3H, s), 1.60 (3H, s), 1.7—2.2 (5H, m), 3.65 (2H, AB-q, J=12 Hz), 4.20 (1H, q, J=5 and 2 Hz) and 4.55 ppm (1H, d, J=2 Hz); MS (70 eV), *m/e*, 218 (M^+), 183 and 165. Found: C, 54.77; H, 7.01%. Calcd for $C_{10}H_{15}O_3Cl$: C, 54.93; H, 6.91%.

* **5** was also obtained on treatment with AcOH instead of methanolic hydrochloric acid.

Carbon-13 NMR Spectra of Methyl-1,3-dioxolanes

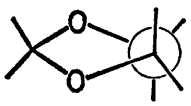
Yasuhisa SENDA, Jun-ichi ISHIYAMA, and Shin IMAIZUMI

Department of Applied Science, Faculty of Engineering, Tohoku University, Aoba, Sendai 980

(Received February 21, 1977)

Synopsis. The ^{13}C NMR spectra of thirteen methyl substituted 1,3-dioxolanes were measured. The carbon chemical shifts of the methyl groups imply that the 1,3-transannular nonbonded interaction of the methyl groups is negligible, except in the cases of 2,2,4-trimethyl- and 2,2,4,5-tetramethyl-1,3-dioxolanes.

Various attempts have been made to determine the configurations of dimethyl-1,3-dioxolanes by means of the physical constants, such as the boiling point[1] or the reflactive index.[2] Kametani and Sumi have determined the steric configurations of some di- and trimethyl-1,3-dioxolanes by means of the ^1H NMR spectra.[3] In this investigation the ^{13}C NMR spectra of methyl-substituted 1,3-dioxolanes were measured in order to probe the influence of stereochemistry on the carbon chemical shifts of these compounds.



Conformation of 1,3-dioxolane.

The carbon resonance for one of the methyl groups of *cis*-2,4-dimethyl-1,3-dioxolane (*cis*-**5**) that which appeared at δ 20.2 is assigned to the 2-methyl carbon, and at δ 18.9, to the 4-methyl one, on the basis of the chemical shifts of 2-methyl- (**2**) and 4-methyl-1,3-dioxolanes (**3**). The chemical shifts for the methyl groups of *trans*-**5** are similar to those of *cis*-**5**. The 1,3-transannular nonbonded interaction between 2- and 4-methyl groups of *cis*-**5** is practically negligible because of the high flexibility of the five-membered ring system.[4] A similar observation was made in the ^{13}C NMR spectra of stereoisomeric 1,3-dimethylcyclopentanes.[4] The carbon resonances for the methyl groups of *cis*-4,5-dimethyl-1,3-dioxolane (*cis*-**6**) moved upfield by 2.2 ppm compared to that of *trans*-**6**. Such upfield shifts may be due to the dihedral angle of the two vicinal methyl groups of *cis*-**6** being smaller than that of *trans*-**6**.[5] In the case of 2,4,5-trimethyl-1,3-dioxolanes (**7**) the carbon resonances for the methyl groups appeared in two separate regions of the magnetic fields, at δ 20.7—21.3 and 14.3—17.4. Comparing the carbon chemical shifts for the methyl groups of **2**, **5**, and **6**, the signals in the former region are found to be of the 2-methyl, while those in the latter are of the 4- and 5-methyl carbons. Since the carbon chemical shifts for the 2-methyl groups of *trans*-2,2,4,5-tetramethyl-1,3-dioxolane (*trans*-**9**) are δ 27.4, the signal of 2,2,4-trimethyl-1,3-dioxolane (**8**) at δ 27.2 is assigned to the methyl group *cis*, and that at δ 25.9, to the one *trans*, to the 4-methyl group. Much as in the case of **8**, the methyl carbon resonance of the *cis*-**9** at δ 28.7 is ascribed to the one *cis* to the methyl group at the 4- and 5-positions. The chemical shifts for one of the 2-methyl groups of **8** and *cis*-**9** are the same as those for the methyl groups of 2,2-dimethyl-1,3-dioxolane (**4**), while the chemical shifts for the alternative methyl groups *cis* to the 4-methyl one moved downfield by 1.5—3.0 ppm. This indicates the presence of a 1,3-transannular nonbonded interaction between 2-, and 4- and/or 5-methyl groups in the compounds which have two methyl groups at the 2-position. Although the two 2-methyl groups of *trans*-**9** are indistinguishable

TABLE 1. ^{13}C CHEMAICAL SHIFTS OF METHYL-1,3-DIOXOLANES

1,3-Dioxolane	2-Me	4-Me	5-Me	C-2	C-4	C-5
Parent (**1**)				95.1	64.7	64.7
2-Methyl- (**2**)	19.8			101.7	65.0	65.0
4-Methyl- (**3**)		18.1		95.0	72.3	71.0
2,2-Dimethyl- (**4**)	25.7			108.5	64.5	64.5
cis-2,4-Dimethyl- (*cis*-**5**)	20.2	18.9		101.6	73.0	71.0
trans-2,4-Dimethyl- (*trans*-**5**)	20.2	18.5		100.7	71.8	72.0
cis-4,5-Dimethyl- (*cis*-**6**)		14.7	14.7	93.6	74.1	74.1
trans-4,5-Dimethyl- (*trans*-**6**)		16.9	16.9	94.0	78.8	78.8
r-2,*c*-4,*c*-5-Trimethyl- (*r*-2, *c*-4, *c*-5-**7**)	20.9	15.6	15.6	100.3	74.8	74.8
r-2,*c*-4,*t*-5-Trimethyl- (*r*-2, *c*-4, *t*-5-**7**)	20.7	17.4	17.2	100.2	80.0	78.2
r-2,*t*-4,*t*-5-Trimethyl- (*r*-2, *t*-4, *t*-5-**7**)	21.3	14.3	14.3	99.6	74.3	74.3
2,2,4-Trimethyl- (**8**)	27.2(*c*)[a] 25.9(*t*)[b]	18.6		108.7	72.0	70.9
cis-2,2,4,5-Tetramethyl- (*cis*-**9**)	28.7(*c*) 25.8(*t*)	15.6	15.6	107.2	74.0	74.0
trans-2,2,4,5-Tetramethyl- (*trans*-**9**)	27.4	16.9	16.9	107.4	78.3	78.3

a) *cis* to the 4-methyl group. b) *trans* to the 4-methyl group.

in ^{13}C NMR, the carbon resonance at δ 27.4 implies the presence of the 1,3-transannular nonbonded interaction.

Experimental

NMR Spectra. The ^{13}C FT-NMR spectra were obtained at 25.15 MHz with a JEOL JNM-MH-100 instrument equipped with a JNM-MFT-100 Fourier transform accessory. Samples were observed in 5-mm spinning tubes with 25±5% solutions in $CDCl_3$ at 24 °C. All the chemical shifts are expressed in δ (ppm downfield from the internal TMS). Each observed chemical shift is estimated to be accurate to $\delta \pm 0.1$.

1,3-Dioxolanes. The compounds employed in this study were prepared by the methods of Dauben *et al.*[6] and Carmack and Kelley:[7] **1**, bp 74—76 °C; **2**, bp 81—83 °C, **3**, bp 82—85 °C; **4**, bp 92—93 °C; **5**, bp 91 °C, separated by preparative GLC; **6**, bp 74—85 °C, separated by preparative GLC; **7**, bp 80—90 °C, separated by preparative GLC; **8**, bp 95—98 °C; **9**, bp 67—69 °C, separated by preparative GLC. All the compounds were checked by analytical GLC and by means of the IR and ^1H NMR spectra.

The Radical Addition of Toluene to Fluorocyclobutenes

Hiroshi KIMOTO, Hiroshige MURAMATSU, and Kan INUKAI

Government Industrial Research Institute, Nagoya, Hirate-machi, Kita-ku, Nagoya 462

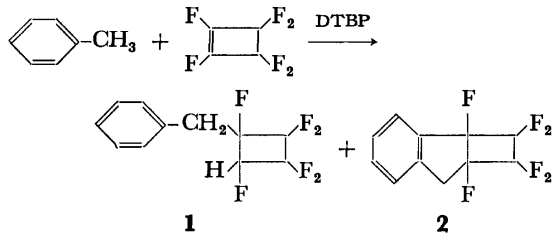
(Received March 4, 1977)

Synopsis. Fluorine-containing cyclobutane derivatives, 1-benzyl-1,2,2,3,3,4,-hexafluorocyclobutane (**1**) and 1,5,6,6,7,7-hexafluorobenzo[2,3]bicyclo[3.2.0]hept-2-ene (**2**), were synthesized in one step by the radical reaction of toluene and hexafluorocyclobutene. On the other hand, a similar reaction of toluene and 1,2-dichlorotetrafluorocyclobutene gave no adduct, but a substituted product, 1-benzyl-2-chlorotetrafluorocyclobutene (**4**).

In earlier papers, the radical addition reactions of such compounds as alcohols, ethers, and aldehydes to hexafluorocyclobutene (HFCB) and 1,2-dichlorotetrafluorocyclobutene (CFCB) have been reported to give the corresponding 1:1 adducts or their dehydrochlorinated products.[1] However, no investigation is known into the addition of aromatic compounds to these fluorocyclobutenes. In the present work, we carried out a di-*t*-butyl peroxide-induced reaction of toluene to HFCB and CFCB as a part of our synthetic studies of the free-radical addition of aromatic compounds to fluoro olefins.[2,3]

Two different reaction conditions, Methods A and B, were employed. In Method A, excess toluene to fluorocyclic olefins and small amounts of DTBP were used, whereas in Method B, equimolar amounts of toluene and cyclic fluoro olefins were reacted in the presence of large amounts of DTBP in an inert solvent. The conditions employed in Method A had been found suitable for the synthesis of 1:1 adducts, and those in Method B, for the preparation of cycloadducts.[2]

Addition Reaction of Toluene to Hexafluorocyclobutene.



1 **2**

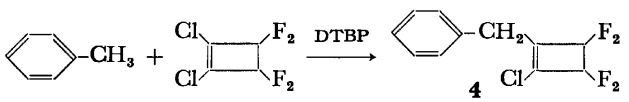
The reaction of toluene and HFCB by Method A afforded 1-benzyl-1,2,2,3,3,4-hexafluorocyclobutane (**1**) as a 1:1 adduct in a 25.6% yield, together with 1,5,6,6,7,7-hexafluorobenzo[2,3]bicyclo[3.2.0]hept-2-ene (**2**) as a cycloadduct in 1.7% yield. The GLC of **1** indicated the presence of two stereoisomers in the ratio of 86:14. The mass and IR spectra of these isomers give an almost identical pattern, and the NMR spectra show complex splitting due to H–F and F–F coupling. The assignment of their configurations is made on the basis of the internal chemical shift values between two non-equivalent fluorine atoms of CF_2 groups. The signals of the fluorine atoms of the CF_2 groups of the predominant isomer appear in the AB quartet (43.1 ppm, 55.3 ppm, $J_{F-F}^{gem}=226$ Hz) and are nearly equivalent as a broad singlet (50.5 ppm). Those of the other isomer appear in two AB quartets (39.4 ppm, 55.6 ppm, $J_{F-F}^{gem}=226$ Hz and 47.4 ppm, 53.4 ppm, $J_{F-F}^{gem}=226$ Hz). The fluorine chemical shifts in the cyclobutane series can be predicted by considering the electric-field effect of the neighboring substituents.[4] Since, in the *cis*-isomer, the electric-field effect of the substituents is additive on the same geminal fluorine nucleus, whereas in the *trans*-isomer this effect is partially compensated for, the *cis*-isomer should show a greater non-equivalence of the fluorine atoms of CF_2 groups than does the *trans*-isomer. Therefore, the predominant isomer is estimated to have the *trans*-configuration, in which a hydrogen and a benzyl group are on opposite sides of the plane of the four-membered ring. As will be mentioned later, the configuration of the *trans*-isomer is supported by the NMR spectrum of its oxidized product.

In order to increase the yield of the cycloadduct (**2**), the reaction was carried out by Method B. However, **2** was obtained in only a 4.9% yield, together with **1** (3.9% yield) and large amounts of a high-boiling residue. As compared with Method A, the yield of **1** in Method B decreased markedly, whereas that of **2** increased, though only slightly. The low yield of **2** may be due to the instability of the strained structure with the fused four-, five-, and six-membered ring.

1-Benzyl-2-methylhexafluorocyclobutane (**3**) was obtained as a by-product in a 2.7% yield. The mechanism for the formation of **3** may be explained in terms of the coupling of the benzyl radical and the 2-methyl-1,2,3,3,4,4-hexafluorocyclobutyl radical generated by the addition of a methyl radical to HFCB.

Although a similar reaction of cumene and HFCB was attempted, most of the HFCB was recovered and neither 1:1 adduct nor cycloadduct was obtained, presumably because of the steric hindrance of methyl groups

Addition Reaction of Toluene to 1,2-Dichlorotetrafluorocyclobutene. The reaction of toluene and CFCB gave benzyl chloride and 1-benzyl-2-chlorotetrafluorocyclobutene (**4**). The corresponding 1:1 adduct was not obtained. In Method A, the conversion of CFCB was low (14.5%) and the yield based on the amounts of CFCB consumed was 48.4%. In Method B, 28.4% of the CFCB was consumed and **4** was obtained in a 12.1% yield.

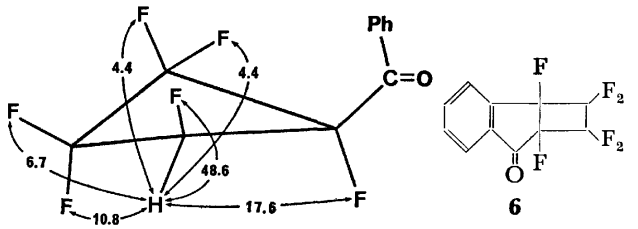


4

Thus, the substitution of a vinylic chlorine by a benzyl group occurred in the reaction of CFCB. The product, **4**, is probably formed by the chlorine elimination from an intermediate radical generated by the addition of a benzyl radical to CFCB. The different behavior between HFCB and CFCB in the radical

reaction with toluene seems to be due mainly to the difference in the carbon-halogen bond dissociation energy. Similar chlorine-substituted products have been reported to be obtained by the radical reaction of alkylbenzenes and chloro olefins.[5]

Oxidation of the Adducts. The methylene groups of **1** and **2** were oxidized to carbonyl groups. The oxidation of **1** by chromium trioxide afforded 1-benzoyl-1,2,2,3,3,4-hexafluorocyclobutane (**5**) in a 72.9% yield. The NMR spectrum of **5** is more simple than that of **1**. The *trans* configuration is also supported by a comparison of the chemical shifts and coupling constants of **5** with those of the 1:1 adduct which was obtained from the photochemical stereospecific *trans*-addition of trichlorosilane and HFCB.[6] A similar oxidation of **2** also gave 1,5,6,6,7,7-hexafluorobenzo[2,3]bicyclo[3.2.0]hept-2-en-4-one (**6**). An attempt to oxidize **4** was unsuccessful and gave only small amounts of benzoic acid. The oxidation of the double bond took place in the case of **4**.



5

6

Experimental

Addition Reaction of Toluene and Hexafluorocyclobutene. *Method A*: A mixture of toluene (115 g, 1.25 mol), HFCB (53 g, 0.327 mol), and DTBP (7.5 g, 0.051 mol) was heated at 130—140 °C for 24 h. After the recovery of unchanged HFCB (11.4 g; conversion, 78.5%), the liquid product was distilled *in vacuo*. A crude 1:1 adduct (16.8 g) and a high-boiling residue (6.2 g) were obtained. Three components, two stereoisomers of the 1:1 adduct and a cycloadduct, were detected by GLC in the ratio of 80.5:13.0:6.5. They were separated by preparative GLC.

Trans-1-Benzyl-1,2,2,3,3,4-hexafluorocyclobutane (13.5 g, 20.6% yield): mp 30.8 °C; bp 188 °C; NMR (50% CCl_4 solution) δ 7.14 (5H, s), 3.13 (2H, d-m, 25.2 Hz), 4.92 (1H, d-m, 48.6 Hz), 92.3 (1F, m), 135.8 (1F, d), 43.1 and 55.3 (2F, AB, 226 Hz), 50.5 (2F, broad s); Found: C, 52.01; H, 3.22%. Calcd for $C_{11}H_8F_6$: C, 51.98; H, 3.17%, *cis*-1-benzyl-1,2,2,3,3,4-hexafluorocyclobutane (2.2 g, 3.3% yield): bp 200 °C; n_D^{20} 1.4363; d_4^{20} 1.385; NMR (20% CCl_4 solution) δ 7.1—7.4 (5H, m), 3.11 (2H, d-m, 25.2 Hz), 4.75 (1H, d-m, 50.8 Hz), 110.0 (1F, t-m), 138.8 (1F, d-m), 39.4 and 55.6 (2F, AB, 226 Hz), 47.4 and 53.4 (2F, AB, 226 Hz); Found: C, 52.08; H, 3.07%. Calcd for $C_{11}H_8F_6$: C, 51.98; H, 3.17% and 1,5,6,6,7,7-hexafluorobenzo[2,3]-bicyclo[3.2.0]hept-2-ene (1.1 g, 1.7% yield): bp 199 °C; n_D^{20} 1.4442; d_4^{20} 1.438; NMR (50% CCl_4 solution) δ 7.1—7.5 (4H, m), 3.2—3.7 (2H, AB), 112.3 (1F, m), 97.0 (1F, m), 47.1 and 53.6 (2F, AB, 218 Hz), 40.6 and 52.1 (2F, AB, 226 Hz); Found: C, 52.39; H, 2.68%. Calcd for $C_{11}H_6F_6$: C, 52.40; H, 2.40%.

Method B: A solution of toluene (46.1 g, 0.500 mol), HFCB (80.0 g, 0.494 mol) and DTBP (75 g, 0.513 mol) in 1,1,2-trichlorotrifluoroethane (187 g, 1.00 mol) was heated at temperatures gradually rising from 130 °C to 160 °C for about 6 h. The product was separated by vacuum distillation and preparative GLC to give **1** (4.9 g, 3.9% yield), **2** (6.1 g, 4.9% yield), and 1-benzyl-2-methylhexafluorocyclobutane[7] (3.6 g, 2.7% yield; bp 198—202 °C; n_D^{20} 1.4325; d_4^{20} 1.322; Found: C, 53.83; H, 3.99%. Calcd for $C_{12}H_{10}F_6$: C, 53.74; H, 3.76%), together with a high-boiling residue (57 g).

Addition Reaction of Toluene and 1,2-Dichlorotetrafluorocyclobutene. *Method A*: By a procedure similar to that described above, the reaction of toluene (115 g, 1.25 mol), CFCB (60.8 g, 0.312 mol), and DTBP (7.5 g, 0.051 mol) gave benzyl chloride (3.6 g), 1-benzyl-2-chlorotetrafluorocyclobutene (5.5 g, 48.4%; bp 209 °C; n_D^{20} 1.4687; d_4^{20} 1.321; IR $\nu_{C=C}$ 1655 cm^{-1}; NMR (50% CCl_4 solution) δ 7.0—7.2 (5H, m), 3.49 (2H, t-m, 2.6 Hz), 36.6 and 37.9 (4F, AA'BB'); Found: C, 52.76; H, 3.25%. Calcd for $C_{11}H_7ClF_4$: C, 52.72; H, 2.82%), and a high-boiling residue (2.3 g).

Method B: By a procedure similar to that described above, the reaction of toluene (46.1 g, 0.500 mol), CFCB (97.5 g, 0.500 mol), and DTBP (75 g, 0.513 mol) in 1,1,2-trichlorotrifluoroethane (187 g, 1.00 mol) gave benzyl chloride (12.7 g), **4** (4.3 g, 12.1% yield), and a high-boiling residue (23.4 g).

Oxidation of the Adducts. 1-Benzoyl-1,2,2,3,3,4-hexafluorocyclobutane (5): To a solution of chromium trioxide (3.0 g, 0.030 mol) in water (5 ml), a solution of **1** (2.6 g, 0.010 mol) in glacial acetic acid (15 ml) was added. The mixture was then refluxed for 16 hr and poured into an ice-cooled aqueous sodium hydrogen sulfite solution. Dichloromethane (100 ml) was then added, and the organic layer separated was washed and dried over magnesium sulfate. The solvent was allowed to evaporate to give an oily residue (2.6 g), which contained **5**, together with small amounts of unchanged **1**. Further purification was done by preparative GLC to give pure **5** (2.0 g, 72.9% yield): bp 215 °C; n_D^{20} 1.4530; d_4^{20} 1.467; IR $\nu_{C=O}$ 1705 cm^{-1}; NMR (50% CCl_4 solution) δ 7.2—7.9 (5H, m), 5.44 (1H, d-m, 48.6 Hz), 85.9 (1F, m), 132.2 (1F, d), 38.1 and 57.5 (2F, AB, 226 Hz), 46.9 (2F, broad s); Found: C, 49.19; H, 2.24%. Calcd for $C_{11}H_6OF_6$: C, 49.27; H, 2.26%.

1,5,6,6,7,7-Hexafluorobenzo[2,3]bicyclo[3.2.0]hept-2-en-4-one (6): By a similar procedure, the oxidation of a mixture (1.3 g) of **1** (40%) and **2** (60%) by chromium trioxide (2.0 g) gave a mixture (1.2 g) of **5** and **6**. They were separated by preparative GLC to give **6**: n_D^{20} 1.4629; IR $\nu_{C=O}$ 1754 cm^{-1}; NMR (5% CCl_4 solution) δ 7.6—8.0 (4H, m), 105.8 (1F, t-d-d), 123.3 (1F, d-d-d-d), 35.5 and 51.3 (2F, AB, 209 Hz), 40.2 and 49.1 (2F, AB, 226 Hz); Found: C, 49.58; H, 1.63%. Calcd for $C_{11}H_4OF_6$: C, 49.64; H, 1.51%.

The Synthesis of 3-Substituted Tropilidenes by the Dehydration of 1-Substituted 2,6-Cycloheptadienols. A New Unambiguous Route

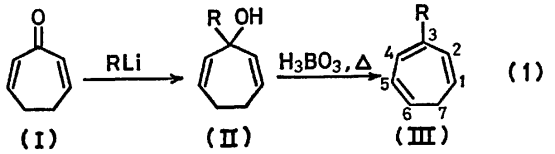
Ken'ichi TAKEUCHI, Takashi MAEDA, and Kunio OKAMOTO

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received March 8, 1977)

Synopsis. 3-Alkyl-, 3-aryl-, and 3-deuteriotropilidenes are prepared in 21—29% yields by the dehydration of the corresponding 1-substituted 2,6-cycloheptadienols with boric acid. The present method provides an unambiguous route to the title compounds.

Several methods have been proposed for the synthesis of 1-, 2-, or 3-substituted tropilidenes. The relatively simple ones include: (a) the reaction of substituted tropylium ions with metal hydrides,[1] (b) the thermal[2] or photochemical[3] isomerization of 7-substituted tropilidenes, and (c) the ring-expansion of aromatic compounds with carbene.[4] However, such methods generally afford a mixture of isomeric substituted tropilidenes which are separated from each other only with considerable difficulty because of the similarity of the boiling points. Previously we reported an unambiguous route to 3-alkyl-2,4-dimethyltropilidenes which involves the addition of alkyllithiums to 2,7-dimethyl-2,6-cycloheptadienone and the subsequent dehydration of 1-alkyl-2,7-dimethyl-2,6-cycloheptadienols in the presence of boric acid.[5] In the present work the method has been applied to 2,6-cycloheptadienone (I), utilizing lithium aluminum deuteride or various alkyl- and phenyllithiums, in the hope of exploring a selective route to 3-substituted tropilidenes (III) (Eq. 1).



The alcohols (II) were obtained in approximately quantitative yields except for the cases of R=*i*-Pr or *t*-Bu.[6] The dehydration of the crude alcohols with boric acid,[7] followed by a single distillation, afforded 3-substituted tropilidenes (III) in a greater than 96% purity. The results of the synthesis are shown in Table 1. Although the yields of III are generally low (21—29%) because of the formation of polymers during dehydration, the excellent purity of the tropilidenes permits the use of the method applicable to the unambiguous synthesis of III. It should be noted that the present method provides a unique route to highly pure tropilidene-3-*d*, which has never been accessible by any other methods.

For comparison, the dehydration of 1-methyl-2,6-cycloheptadienol with boric anhydride, oxalic acid, or potassium bisulfate was examined. It was found that boric anhydride works much like boric acid, whereas oxalic acid and potassium bisulfate give 3-methyltropilidene in a purity of 89% in each case, the impurities being difficult to separate by repeated distillations.

Table 1. Results of the synthesis of 3-substituted tropilidenes

Lithium compound	3-Substituent	Yield[a] %	Purity %	Boiling point °C (Torr)
$LiAlH_4$	H	24	—	115—116
$LiAlD_4$	D	29	100[b]	115—116
MeLi	Me	25	96[c,d]	45— 48 (21)
i-PrLi	*i*-Pr	21	97[c,d]	99—100 (50)
c-PrLi	*c*-Pr	24	97[c,d]	58— 62 (70)
PhLi	Ph	29	99[c,d]	137—139 (3)

a) Overall isolated yield. b) Determined by NMR. c) Determined by GLC. d) Preparative GLC is required for further purification.

The extension of the present method to the selective synthesis of 1-substituted tropilidenes was attempted starting with 3,5-cycloheptadienone, but such an application was found not to be straightforward, since 3,5-cycloheptadienone, when treated with methyllithium, afforded the corresponding alcohol in a low yield (31%) and the rest of the starting ketone was recovered unchanged. Presumably the enolization of 3,5-cycloheptadienone is preferable to the addition reaction in the presence of methyllithium.

The present method has been successfully applied to the preparation of mixtures of isomeric disubstituted tropilidenes as the precursors of 1,2-disubstituted tropylium ions; the work will be reported elsewhere, together with the results of the one-electron reduction of substituted tropylium ions with chromium (II).[8]

Experimental

Materials. 2,6- and 3,5-Cycloheptadienones were prepared by the procedure of Garbisch.[9]

1-Substituted 2,6-Cycloheptadienols (II). 2,6-Cycloheptadienone was treated with a 30% excess amount of the appropriate lithium compound in anhydrous ether at 0—20 °C, except that the reaction with *t*-butyllithium was conducted at −72 °C. For isopropyllithium, pentane was used in place of ether as the solvent.[10] The NMR spectra of the crude product showed that all the lithium compounds, except for isopropyl- and *t*-butyllithium, gave the expected alcohols (II) in approximately quantitative yields. Isopropyllithium afforded a mixture composed of the expected alcohol and unidentified ketones, which were presumably formed by the 1,4-addition reaction. A detailed characterization of the products has not been carried out. *t*-Butyllithium failed to give 1-*t*-butyl-2,6-cycloheptadienol, as demonstrated by the IR spectrum of the crude product; instead, it afforded a mixture of unidentified ketones and ether-insoluble polymers.

Table 2. NMR spectra of 3-substituted tropilidenes

3-Substituent R	δ, ppm CCl_4, 60 MHz)							Coupling constant, Hz
	H-1	H-2	H-4	H-5	H-6	H-7	R	
D	5.25	6.12	6.48	6.05	5.25	2.20	—	$J_{1,2}=J_{5,6}=9.0$ $J_{1,7}=J_{6,7}=6.4$ $J_{4,5}=3.0$
Me	≈5.20	5.92	6.28	5.97	≈5.20	2.17	2.03 s	$J_{1,2}=J_{5,6}=9.2$ $J_{1,7}=J_{6,7}=6.2$ $J_{4,5}=6.0$
i-Pr	≈5.23	6.02	6.32	6.00	≈5.23	2.15	1.10 d 2.50 m	$J_{1,2}=J_{5,6}=9.2$ $J_{1,7}=J_{6,7}=6.6$ $J_{4,5}=6.0$
c-Pr	≈5.15	5.75	6.21	5.89	≈5.15	2.12	0.63 m 1.57 m	$J_{1,2}=J_{5,6}=9.0$ $J_{1,7}=J_{6,7}=6.0$ $J_{4,5}=6.0$
Ph	≈5.37	6.28	6.80	6.17	≈5.37	2.25	7.25 m	$J_{1,2}=J_{5,6}=8.6$ $J_{1,7}=J_{6,7}=7.0$ $J_{4,5}=6.0$

In each case the crude product was used in the dehydration step without further purification.

Dehydration of 1-Substituted 2,6-Cycloheptadienols. Crude 1-substituted 2,6-cycloheptadienol prepared from 20 mmol of 2,6-cycloheptadienone was mixed with pulverized boric acid (20 mmol) in a short test tube provided with a glass tube connected to a receiver, and the mixture was heated in an oil bath at 150 °C for five min. The pressure of the system was gradually reduced until the products distilled out and thereafter kept constant. The temperature of the oil bath was then gradually raised to 200 °C. The distillate was extracted with ether, dried, and subjected to distillation. The structure of the 3-substituted tropilidenes was determined by means of NMR; the data are shown in Table 2.

The Effects of Solvents on the Electronic Absorption Spectrum of Sodium 4-Nitrophenoxide in the Presence of 15-Crown-5 Ether

Shinichi UEJI and Masayuki KITADANI

Institute of Chemistry, College of General Education, Kobe University, Tsurukabuto, Nada, Kobe 657

(Received April 14, 1977)

Synopsis. The electronic absorption spectrum of sodium 4-nitrophenoxide was determined in 21 solvents of varying polarities by the aid of the ability of 15-crown-5 ether to solubilize the salt in nonpolar solvents. These spectra showed a marked difference between hydroxylic solvents and nonhydroxylic solvents. A possible interpretation for this difference is presented.

In the course of our study of the relationships between solvent polarity parameters and solvent-induced spectral shifts in spectroscopic investigations, we previously observed interesting solvent effects on the IR frequency shifts[1] and on the NMR chemical shifts.[2] In this report the effects of solvents on the electronic absorption spectrum of sodium 4-nitrophenoxide will be discussed on the basis of the correlation between the solvent shifts and Dimroth's solvent polarity parameter, E_t (hereafter abbreviated as D's E_t), values.[3]

Results and Discussion

The Table summarizes the solvent-induced spectral shifts for sodium 4-nitrophenoxide relative to 4-nitroanisole in a range of solvents. In certain nonpolar solvents, in order to obtain a solubility of the salt sufficient for the measurement of the λ_{max} value, a large excess of the sodium chelatent, 15-crown-5 ether, was used. Since it is desirable that solvent shifts be compared under the same conditions, all the spectra were measured in the presence of a large excess of the crown ether. The crown ether's effects on the spectra are also given in the Table.

It is found that the enhanced red shifts ($-\Delta\nu_{max}$ values in the Table) are correlated well by the D's E_t values (see Figure). As can be seen in the Figure, however, the correlation is separated into two set of straight lines,

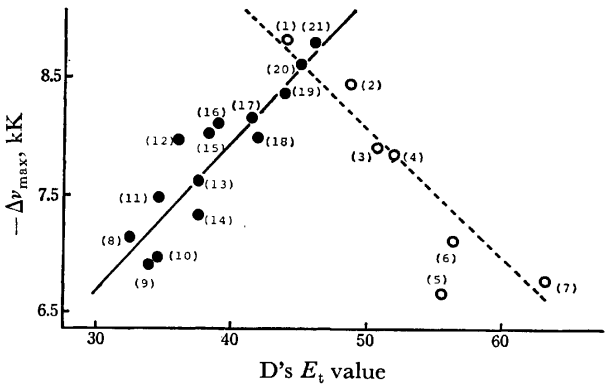

Figure. Correlation between $-\Delta\nu_{max}$ value and D's E_t value.
(○): Hydroxylic solvents, (●): nonhydroxylic solvents.

TABLE ELECTRONIC SPECTRAL SHIFTS FOR SODIUM 4-NITROPHENOXIDE (I) RELATIVE TO 4-NITROANISOLE (II) IN THE PRESENCE OF 15-CROWN-5 ETHER IN A RANGE OF SOLVENTS[a]

a) The apporopriate compound (II) was used as a reference standard, because the solvation effects on 4-nitrophenyl portion are assumed to be similar in both compounds; reproducibility <1 nm. b) The λ_{max} value is attributed to a $\pi\rightarrow\pi^*$ transition with the character of an intramolecular charge transfer from the oxygen anion to the hydrocarbon portion. The values in parentheses represent the magnitude of the crown ether effect on the λ_{max} value; positive numbers indicate red shifts. c) Enhanced red shifts for Compound (I) as compared with Compound (II);
$-\Delta\nu_{max}$, kK $= [1/\lambda\,(\mathrm{I}) - 1/\lambda\,(\mathrm{II})] \times 10^4$
d) Not sufficiently soluble in the absence of 15-crown-5 ether.

one for hydroxylic solvents and the other for nonhydroxylic solvents. Furthermore, it should be noted that the slopes of the two straight lines show opposite signs.

In the hydroxylic solvents, the phenoxide anion is presumably present as a cation-free anion rather than as sufficiently tight ion aggregates, because the anion is supposed to be strongly solvated by hydrogen bonding. Indeed, the addition of crown ether produces essentially no effect on the λ_{max} value (see Table). Therefore, it seems reasonable to assume that the hydroxylic solvent-

induced shifts are mainly due to the direct H-bonding solvation of the phenoxide anion. A stronger H-bonding solvation should produce a larger blue shift, because the oxygen of phenoxide is more negative in the ground state than in the excited state. In fact, the decreasing order of the $-\Delta\nu_{max}$ values is consistent with the α-scale of solvent H-bond donor acidities (HBD)[4] reported by Taft and Kamlet, except for the case of methanol. Furthermore, the parallelism between the $-\Delta\nu_{max}$ value and the D's E_t value (see Figure) suggests the operation of similar H-bonding solvation mechanisms, because the D's E_t value is based on the electronic transition of the pyridinium betain with the phenoxide anion site.

On the other hand, the nonhydroxylic solvents are presumed to be poor anion solvators, so that direct solvations of the phenoxide anion can be neglected. The nonhydroxylic solvent shifts can be interpreted by assuming an interaction between the sodium cation bound by the crown ether and the phenoxide anion. It is known[5] that the D's E_t value is correlated with such measures of the ionizing power of solvents as Winstein's Y value[6] and Kosower's Z value.[7] Therefore, the increasing D's E_t value may be expected to cause a larger charge separation between the sodium cation bound by the crown ether and the phenoxide anion, and this charge separation should produce red shifts.[8] Indeed, the observed red shifts are found to be proportional to the D's E_t value (see Figure). Furthermore, the absence of any effect of crown ether in the dipolar aprotic solvents suggests that the salt is a relatively free ion.

Consequently, the $-\Delta\nu_{max}$ value –D's E_t value correlation revealed a difference in the solvation mechanism of sodium 4-nitrophenoxide between the hydroxylic solvents and the nonhydroxylic solvents.[9]

Experimental

The electronic spectra were obtained using a Hitachi 124 automatic recording spectrophotometer. A quartz cell 1.0 cm in length was employed, and the concentration of the sample was of the order of 10^{-4} M.

Sodium 4-nitrophenoxide was prepared by a known method and dried *in vacuo* at 110 °C overnight. The solvents were freshly distilled before use, and the spectro-grade solvents were used without further purification, except for chloroform, which was chromatographed on alumina. The 15-crown-5-ether was a commercial sample (Aldrich Chemical Company, Inc.).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 50 (10), 2821—2822 (1977)

Studies of Lignoids in *Lauraceae*. III.[1] A New Lignan from the Heart Wood of *Cinnamomum Camphora* Sieb.

Daisuke TAKAOKA, Minoru IMOOKA, and Mitsuru HIROI

Department of Chemistry, Faculty of Science, Ehime University, Bunkyo-cho, Matsuyama 790

(Received April 16, 1977)

Synopsis. From the heart wood of *Cinnamomum Camphora* Sieb., a new lignan, (−)-*trans*-2-(3,4-dimethoxybenzyl)-3-(3,4,5-trimethoxybenzyl)butyrolactone [I] and 3-hydroxy-5,7-dimethoxy-3′,4′-methylenedioxyflavan [IV], were isolated, and their structures were determined.

In a previous report,[2] we described the isolation and structural determination of several lignans from the leaves of four kinds of *Cinnamomum Camphora*, the camphor tree.[3] We will report here a new lignan, (−)-*trans*-2-(3,4-dimethoxybenzyl)-3-(3,4,5-trimethoxybenzyl)-butyrolactone [I] and 3-hydroxy-5,7-dimethoxy-3′,4′-methylenedioxyflavan [IV], isolated from the heart wood of the "sesquiterpene tree,"[3] a kind of camphor tree which contains nerolidol as a major component of the leaf oil, along with dimethylmatairesinol [II] and kusunokinin [III].[2]

Results

(−)-trans-*2-(3,4-Dimethoxybenzyl)-3-(3,4,5-trimethoxybenzyl)butyrolactone [I].* This compound is a γ-lactone (ν_{max}^{KBr} 1760 cm^{-1}). The NMR spectrum of aliphatic protons indicates that this compound has a *trans*-substituted γ-lactone ring, as in the case of dimethylmatairesinol;[2] δ (ppm) 2.55 (4H, m), 2.90 (2H, m), and 3.8—4.25 (2H, m). Five methoxyl groups are also detectable.

In the region of aromatic protons, the signal at δ 6.18 ppm (2H, s) indicates two protons of a symmetric trimethoxybenzyl group, *i.e.*, either the 3,4,5-trimethoxybenzyl or the 2,4,6-trimethoxybenzyl group. Of them, the latter can be excluded because the chemical shifts of benzyl C**H**$_2$ are almost identical with those of dimethylmatairesinol; *i.e.*, benzyl CH$_2$ is not flanked by two methoxyl groups.

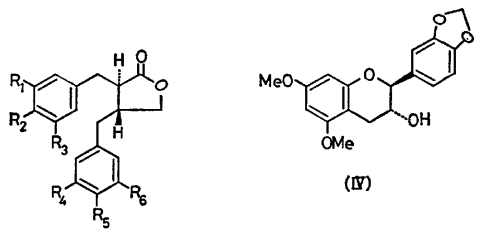
The signals at δ 6.61 (1H, d, J=8 Hz), 6.68 (1H, br s), and 6.75 ppm (1H, d, J=8 Hz) show three protons of a dimethoxybenzyl group which has two protons located at positions ortho to each other-, *i.e.*, the 3,4-, 2,4- or 2,5-dimethoxybenzyl group. It may be supposed that the 3,4-dimethoxybenzyl group is the most probable from the fact that the signals of the three protons appear in a narrow range and that the two coupled protons are not so equivalent. This supposition is confirmed by the co-occurence of this compound with dimethylmatairesinol [II] and kusunokinin [III].

From these results, this compound is determined to be either *trans*-2-(3,4-dimethoxybenzyl)-3-(3,4,5-trimethoxybenzyl)butyrolactone [I] or *trans*-2-(3,4,5-trimethoxybenzyl)-3-(3,4-dimethoxybenzyl)butyrolactone [Ia].

The MS spectrum shows an ion of *m/e* 208. The fragmentation (Scheme 1) is considered to proceed in the same manner as in the case of kusunokinin,[2] and the formation of this ion can be explained on the basis of [I, but not on that of Ia.]

The CD curve of this compound shows a negative Cotton effect at 235 and 270 nm, as in the case of thujaplicatin methyl ether and related compounds.[4] Therefore, the absolute configuration may be concluded to be 2R, 3R.

(−)-trans-*3-Hydroxy-5,7-dimethoxy-3′,4′-methylenedioxyflavan (IV).* The IR spectrum shows an OH group (3300 cm^{-1}). The NMR spectrum shows a methylenedioxy group, two methoxy groups, and five aromatic protons. The B ring is a 1,3,4-trisubstituted one, because its protons appear as a singlet at δ 7.14 ppm, and there are two doublets (J=8 Hz), at δ 6.91 and 7.06 ppm, all benig finely splitted. The A ring is a 1,2,3,5-tetrasubstituted one, because two protons appear as two doublets (J=3 Hz) at δ 6.19 and 6.27 ppm, as in the case of tetramethylcatechin.[5] H-2 and H-3 are supposed to be located *trans* to each other, because H-2 appears as a doublet (J=2 Hz) at δ 4.99 ppm (equatorial-equatorial coupling). This supposition is confirmed by the very small signal of M$^+$−18 in the



(IV)

(I) R_1, R_2, R_4, R_5, R_6 : OMe , R_3:H

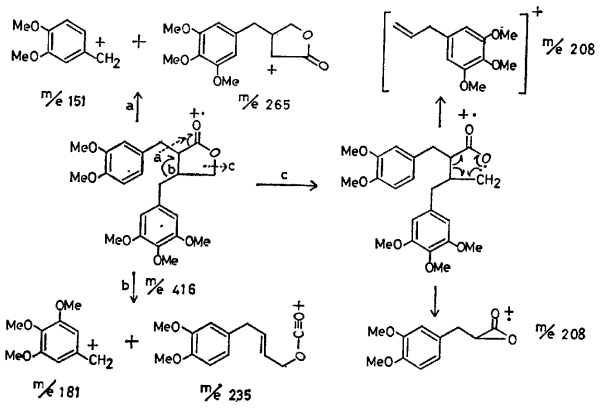

Scheme 1.

MS spectrum (resistant to dehydration[6]). Therefore, this compound is identified as *trans*-3-hydroxy-5,7-dimethoxy-3′,4′-methylenedioxyflavan [IV].

Experimental

Instruments. The CD curve, and the IR, NMR, UV, and MS spectra were obtained by using ORD UV-5 (JASCO), IR-400 (Shimadzu), JNM-4H-100 (JEOL), ESP-3T (Hitachi), and JMS-OlSG-2 (JEOL) apparatuses respectively. $[\alpha]_D$ was measured by the use of a Yanako OR-50 (Yanagimoto) apparatus, and elemental analyses were carried out with a CHN Corder MT-2 (Yanagimoto).

Isolation. Shaves of the heart wood (10 kg) of the tree (10 years old) were extracted with hexane; the hexane solution was then concentrated in *vacuo* and steam-distilled to remove any volatile components. The residue (70 g) was dissolved in hexane and chromatographed on a silica gel column (solvent: hexane: ethyl acetate=100: 0—0: 100) into 22 fractions.

The 19 th fraction (3.7 g) was rechromatographed on a silica gel column (solvent: benzene: ethyl acetate=75: 25) into 18 fractions. From the second fraction, [III] was isolated by TLC.

The 20 th fraction of the first chromatography (4.8 g) was rechromatographed on a silica gel column (solvent: benzene: ethyl acetate=100: 0—0: 100) into 8 fractions. A crystalline material (mp 106—107 °C) was obtained from the second fraction by TLC; this substance shows one spot on TLC with benzene–ethyl acetate (60: 40), but with hexane–chloroform–methanol (6: 3: 1) it shows two spots, which were separated by TLC. The less polar compounds was identified by means of its spectral data as [II].

The more polar compound [I]: a minor component, mp 120—121.5 °C, λ_{max}^{EtOH} 229 nm ($\varepsilon=1.4\times10^4$), 280 nm ($\varepsilon=3.2\times10^3$), $[\alpha]_D$ −17.8° ($c=0.51$ in $CHCl_3$). Found: C, 66.4%; H, 6.2%. Calcd for $C_{23}H_{28}O_7$: C, 66.3%; H, 6.7%. IR cm^{-1} (KBr): 1760, 1590, 1510. NMR (δ ppm in $CDCl_3$): 2.55 (4H, m), 2.90 (2H, m), 3.28 (s), 3.32 (s) (15H), 3.8—4.25 (2H, m), 6.18 (2H, s), 6.61 (1H, d, J=8Hz), 6.68 (1H, br s), 6.75 (1H, d, J=8 Hz). MS: *m/e* 416 (M^+), 386 (M^+-30), 265, 235, 209, 208, 181, 151 (base peak).

The 17 th fraction of the first chromatography (3.0 g) was rechromatographed into 8 fractions in the same manner as in the case of the 19 th fraction. From the 3 rd fraction, a crystalline substance [IV] was isolated by TLC: a minor component, mp 164—165 °C, $[\alpha]_D$ −39.3° ($c=0.84$ in $CHCl_3$), λ_{max}^{EtOH} 286 nm ($\varepsilon=3.4\times10^3$). Found: C, 65.8%; H, 5.2%. Calcd for $C_{18}H_{18}O_6$: C, 65.5%, H, 5.5%. IR cm^{-1} (KBr) 3300, 1610, 1490. NMR (δ in $CDCl_3$): 1.82 (1H, d, J=6 Hz, **OH**), 2.95 (2H, m, H_2-4), 3.83 (6H, s, 2×CH_3O), 4.28 (1H, m, H-3), 4.99 (1H, d, J=2 Hz, H-2), 6.03 (2H, s, OCH_2O), 6.19 (1H, d, J=3 Hz, H-8 or H-6), 6.27 (1H, d, J=3 Hz, H-6 or H-8), 6.91 (1H, d, J=8 Hz, H-5′ or H-6′), 7.05 (1H, d, J=8 Hz, H-6′ or H-5′), and 7.14 ppm (1H, s, H-2′).

Preparation of Mannich Bases from 6-Methoxy-2*H*-pyran-3(6*H*)-one and Its Epoxide

Sigeru TORII, Hideo TANAKA, and Hisasi TAKAO

Department of Industrial Chemistry, School of Engineering, Okayama University, Okayama 700

(Received March 10, 1977)

Synopsis. 4-Morpholinomethyl-2*H*-pyran-3(6*H*)-ones **3** and **8** were prepared directly from 6-methoxy-2*H*-pyran-3(6*H*)-one (**1**) and its epoxide **4** by treatment with morpholine and aqueous 37% formalin in methanol in 70—88% yield. The mechanisms of the reaction have been discussed on the basis of the intermediates 5,6-dimethoxytetrahydropyran-3-one (**2**), 2,6-dimethoxy-5-hydroxytetrahydropyran-3-one (**5**), 2,6-dimethoxy-2*H*-pyran-3(6*H*)-one (**6**), and 2,5,6-trimethoxytetrahydropyran-3-one (**7**).

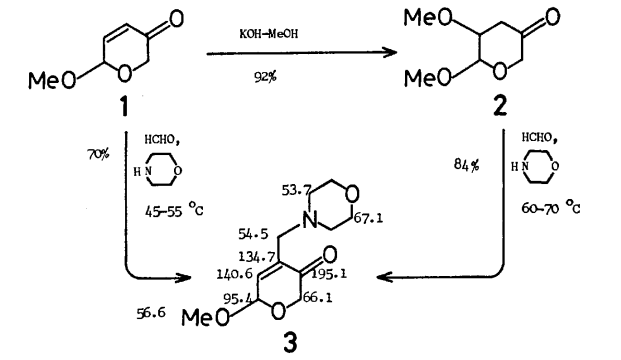
Potential biological activities of Mannich bases along with their very reactive properties have aroused great interest.[1] In connection with our interest in the chemistry of 2*H*-pyran-3(6*H*)-ones[2] we report here our studies on 6-methoxy-2*H*-pyran-3(6*H*)-one (**1**) and its epoxide **4**, functionalized with morpholinomethyl group as a Mannich base.

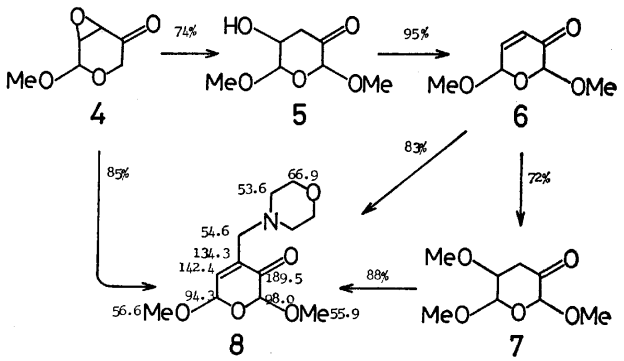
Various studies have been made on Mannich synthesis, but investigations of the reaction at the α position of α,β-unsaturated carbonyl compounds are very limited.[3] No report seems to have appeared on the reaction with α,β-epoxy carbonyl compounds.

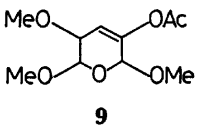
The Mannich products **3** and **8** were synthesized directly from the reactive intermediates **1** and **4**.[2] The 4-morpholinomethyl derivatives **3** and **8** could be prepared in several steps *via* 5-methoxytetrahydropyran-3-ones **2** and **7**. The latter case in particular reveals the fact that introduction of methoxyl function as well as the morpholinomethyl group could be achieved at C-2 and C-4 positions of **4**, respectively.

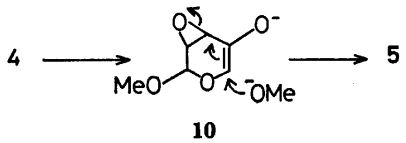
*Conversion of **1** and **2** into **3**.* Stirring **1** in methanol with potassium hydroxide below 5 °C gave **2** in 92% yield.[4] Both **1** and **2** could be converted into the Mannich adduct **3** in 70—84% yields by treatment with morpholine and aqueous formalin in methanol at 45—70 °C for 4—6 h. Under the reaction conditions proton abstraction from C-4 position of **2** followed by nucleophilic attack to formaldehyde would give the Mannich adduct **3**. A possible mechanism for the direct conversion of **1** into **3** can be also rationalized by considering the formation of the intermediate **2**.

*Conversion of **4**, **6**, and **7** into **8**.* Treatment of **4** in methanol with potassium hydroxide at 15—20 °C for 3 h gave **5** in 74% yield together with a small amount of **7**. Addition of the excess base increased the formation of **7**. The treatment of **5** with a mixture of acetic anhydride and pyridine at room temperature for 6 h gave the enone **6**, whereas a similar treatment of **7** afforded the acetate **9** in 97% yield. The transformation of **4**, **6**, and **7** into **8** in 83—88% yields was carried out by heating with morpholine and aqueous 37% formalin in methanol at 40—65 °C for 3—4 h. A plausible mechanism for the formation of the Mannich adduct **8** directly from **4** can be formulated as follows.









In the presence of morpholine as a base, methoxide ion would be able to react with **10** at C-2 position to give **5**. Subsequent dehydration in the medium would afford **6** smoothly. The assignments of carbon 13 NMR spectra of **3** and **8** are shown on the structural formula.

Experimental

Boiling points are uncorrected. IR spectra were determined with a JASCO IRA-I infrared recording spectrophotometer fitted with a grating. PMR spectra were determined at 60 MHz with a Hitachi R-24 spectrometer. The chemical

shift values are expressed in δ values (ppm) relative to a Me_4Si internal standard. CMR spectra were taken at 25.05 MHz in the Fourier mode with a JEOL FX-100 spectrometer. Samples were dissolved in $CDCl_3$ containing Me_4Si as an internal standard. The mass spectra were obtained with a JEOL Model JMS-OIBM-2, ionizing voltage 75 eV.

5,6-Dimethoxytetrahydropyran-3-one (2). To a mixture of KOH (20 mg) in MeOH (4 ml) was added dropwise a solution of **1**[2] (200 mg, 1.56 mmol) in MeOH (1 ml) at 0—5 °C. The mixture was stirred below 5 °C for 10 min and quenched with 5% aqueous tartaric acid. The mixture was poured into ice water, extracted with AcOEt, washed with brine, and dried ($MgSO_4$). Removal of the solvent gave **2** (239 mg, 92%): bp 61—64 °C/2 Torr; IR (neat) 1732 cm^{-1} (C=O); PMR ($CDCl_3$) δ 2.70 (m, 2, CH_2), 3.39 (s, 3, CH_3O), 3.50 (s, 3, CH_3O), 3.67 (m, 1, CHO), 4.00 (s, 2, CH_2O), 4.77 (d, 1, J=2 Hz, OCHO).

6-Methoxy-4-morpholinomethyl-2H-pyran-3(6H)-one (3). To a solution of **2** (116 mg, 0.72 mmol) and morpholine (73 mg, 0.86 mmol) in MeOH (2 ml) was added dropwise aqueous 37% formalin (67 mg, 0.83 mmol) at room temp. The mixture was stirred at 60—70 °C for 4 h. After removal of the solvent, the residue was chromatographed (SiO_2, benzene–AcOEt/3: 1) to give **3** (137 mg, 84%) as a pale yellow oil: bp 91—96 °C/0.005 Torr; IR (neat) 1688 cm^{-1} (C=O); PMR ($CDCl_3$) δ 2.44 (m, 4, CH_2N), 3.15 (t, 2, J=1 Hz, CH_2N), 3.51 (s, 3, CH_3O), 3.69 (m, 4, CH_2O), 4.10 (d, 1, J=16 Hz, CH_2O), 4.40 (d, 1, J=16 Hz, CH_2O), 5.15 (d, 1, J=4 Hz, CHO), 6.86 (m, 1, HC=C). Found: C, 57.91; H, 7.53%. Calcd for $C_{11}H_{17}NO_4$: C, 58.14; H, 7.54%.

Morpholinomethyl Derivative 3 from 1. To a solution of **1** (136 mg, 1.06 mmol) in MeOH (3 ml) was added dropwise morpholine (130 mg, 1.50 mmol) and aqueous 37% formalin (119 mg, 1.50 mmol). The mixture was stirred at 45—55 °C for 6 h and concentrated. The residue was chromatographed (SiO_2, benzene–AcOEt/3: 1) to give **2** (167 mg, 70%) as a pale yellow viscous oil, whose IR and PMR spectral data were identical with those given above.

2,6-Dimethoxy-5-hydroxytetrahydropyran-3-one (5). To a solution of **4** (287 mg, 1.99 mmol) in MeOH (3 ml) was added dropwise a 0.2 M KOH–MeOH solution (2 ml) at 5—10 °C. The mixture was stirred for 3 h at 15—20 °C and then neutralized with aqueous 5% tartaric acid. After removal of the solvent, the residue was taken up in AcOEt, washed with brine, and dried (Na_2SO_4). Removal of the solvent gave **5** (258 mg, 74%) as a yellow oil, after being chromatographed (SiO_2, benzene–AcOEt/3: 1): IR (neat) 3420 (OH), 1742 cm^{-1} (C=O); PMR ($CDCl_3$) δ 2.73 (d, 1, J=7 Hz, CH_2), 2.75 (d, 1, J=6 Hz, CH_2), 3.14 (broad, 1, OH), 3.53 (s, 3, CH_3O), 3.56 (s, 3, CH_3O), 3.90 (m, 1, CHO), 4.65 (s, 1, CHO), 4.83 (d, 1, J=6 Hz, OCHO). Found: C, 47.73; H, 6.85%. Calcd for $C_7H_{12}O_5$: C, 47.73; H, 6.87%.

2,6-Dimethoxy-2H-pyran-3(6H)-one (6). A mixture of **5**(122 mg, 0.69 mmol), pyridine (0.5 ml) and Ac_2O (0.5 ml) was stirred at room temp for 6 h. The mixture was poured into 2 M HCl. The organic phase was extracted with AcOEt, washed with aqueous $NaHCO_3$, and dried (Na_2SO_4). Removal of the solvent gave **6** (104 mg, 95%) as a pale yellow oil: bp 61—64 °C/1 Torr; IR (neat) 1708 (C=O), 1632 cm^{-1} (C=C); PMR ($CDCl_3$) δ 3.46 (s, 3, CH_3O), 3.52 (s, 3, CH_3O), 4.76 (s, 1, CHO), 5.35 (m, 1, CHO), 6.04 (dd, 1, J=2 Hz, J=11 Hz, HC=C), 6.78 (dd, 1, J=2 Hz, J=11Hz, HC=C); MS *m/e* (rel intensity, %) 158 (M^+, 22), 144 (12), 127 (31), 116 (100), 98 (57), 55 (15), 43 (58). Found: C, 53.31; H, 6.13%. Calcd for $C_7H_{10}O_4$: C, 53.16; H, 6.37%.

2,5,6-Trimethoxytetrahydropyran-3-one (7). To a solution of **6** (218 mg, 1.38 mmol) in MeOH (3 ml) was added dropwise a MeOH–KOH solution (0.2 M, 2 ml) at 0—5 °C. After being stirred at 0—5 °C for 30 min, the mixture was neutralized with aqueous 5% tartaric acid. The mixture was poured into brine and extracted with AcOEt. The extracts were washed with brine, dried (Na_2SO_4), and concentrated, giving **7** (188 mg, 72%) as a pale yellow oil: bp 64—67 °C/1 Torr; IR (neat) 1742 cm^{-1} (C=O); PMR ($CDCl_3$) δ 2.73 (d, 1, J=9 Hz, CH_2), 2.75 (d, 1, J=5 Hz, CH_2), 3.42, 3.53, 3.58 (s, 9, CH_3O), 3.60 (m, 1, CHO), 4.71 (s, 1, CHC=O), 4.88 (d, 1, J=5 Hz, CHO). Found: C, 50.36; H, 7.64%. Calcd for $C_8H_{14}O_5$: C, 50.52; H, 7.42%.

2,6-Dimethoxy-4-morpholinomethyl-2H-pyran-3(6H)-one (8) from 7. A mixture of **7** (116 mg, 0.61 mmol), aqueous 37% formalin (67 mg, 0.82 mmol), and morpholine (75 mg, 0.89 mmol) in MeOH (2 ml) was stirred at 55—65 °C for 4 h. After removal of the solvent, the residue was chromatographed (SiO_2, benzene–AcOEt/3: 1) to give **8** (137 mg, 88%) as a pale yellow oil: bp 81—84 °C/0.04 Torr; IR (neat) 1700 cm^{-1} (C=O); PMR ($CDCl_3$) δ 2.42 (m, 4, CH_2N), 3.14 (t, 2, J=2 Hz, CH_2N), 3.52, 3.54 (s, 6, CH_3O), 3.65 (m, 4, CH_2O), 4.92 (s, 1, CHC=O), 5.47 (m, 1, CHO), 6.84 (m, 1, HC=C); MS *m/e* (rel intensity, %) 257 (M^+, 53), 225 (76), 196 (70), 121 (27), 100 (100), 83 (31), 56 (27), Found: C, 55.99; H, 7.37%. Calcd for $C_{12}H_{19}NO_5$: C, 56.02; H, 7.44%.

Morpholinomethyl Derivative 8 from 6. A mixture of **6** (158 mg, 1.00 mmol), aqueous 37% formalin (97 mg, 1.16 mmol) and morpholine (104 mg, 1.20 mmol), in MeOH (3 ml) was heated for 4 h at 45—55 °C. After work-up in a similar way to that described above, **8** (213 mg, 83%) was obtained.

Morpholinomethyl Derivative 8 from 4. To a solution of **4** (590 mg, 4.09 mmol) and morpholine (460 mg, 5.48 mmol) in MeOH (5 ml) was added dropwise aqueous 37% formalin (443 mg, 5.47 mmol) at room temp and the mixture was heated at 55—65 °C for 4 h. After work-up in a similar way to that above, **8** (892 mg, 85%) was obtained.

3-Acetyl-2,5,6-trimethoxy-5,6-dihydro-2H-pyran (9). A solution of **7** (101 mg, 0.53 mmol) in a mixed solution of pyridine (0.5 ml) and Ac_2O (0.5 ml) was stirred at room temp for 12 h. After work-up in a similar way to that above, **9** (120 mg, 97%) was obtained as a colorless oil: bp 93—97 °C/1 Torr; IR (neat 1764 cm^{-1} (AcO); PMR ($CDCl_3$) δ 2.17 (s, 3, CH_3CO), 3.45, 3.50, 3.57 (s, 9, CH_3O), 3.88 (m, 1, CHO), 4.77 (d, 1, J=6 Hz, HC=C), 5.09 (s, 1, HCC=O), 5.68 (d, 1, J=3 Hz, CHO). Found: C, 51.70; H, 6.86%. Calcd for $C_{10}H_{16}O_6$: C, 51.72; H, 6.94%.

Cyclopropanes from Allylic Halides. I. Synthesis of Dimethyl 3-(2-Methyl-1-propenyl)-2,2-dimethylcyclopropane-1,1-dicarboxylate and Pyrocin as Precursors of Chrysanthemic Acid

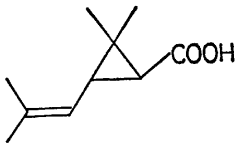
Sigeru TORII, Hideo TANAKA, and Yosio NAGAI

Department of Industrial Chemistry, School of Engineering, Okayama University, Okayama 700

(Received May 9, 1977)

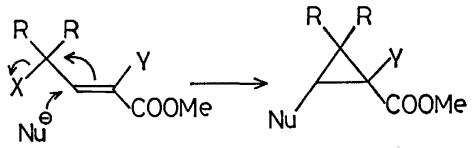
Synopsis. Dimethyl 3-(2-methyl-1-propenyl)-2,2-dimethyl-cyclopropane-1,1-dicarboxylate and pyrocin as precursors of chrysanthemic acid were synthesized by the reaction of (2-halo-2-methylpropylidene)malonate with 2-methyl-1-propenylmagnesium bromide.

Chrysanthemic acid (**1**), an important moiety of pyrethrins and a naturally occurring pesticide, has been a subject of interest as regards its synthesis.[1] In contrast to the nucleophilic substitution reaction of allylic halides taking place at the α- or γ-position, nucleophilic attack with cyanide at the β-carbon of allylic halides **2**



1

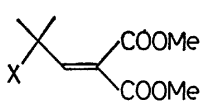
bearing alkoxycarbonyl groups in the γ-position followed by cyclization, giving cyclopropanecarboxylates **3**, was observed.[2] The diverse nature of allylic halides prompted us to examine the reaction of dimethyl (2-halo-2-methylpropylidene)malonate (**4**) with various nucleophiles.



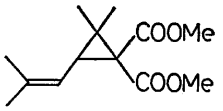
2 **3**

The present paper describes the results obtained in the reaction of **4** with 2-methyl-1-propenylmagnesium bromide[3] as a nucleophile as well as the synthesis of pyrocin (**7b**)[4] using the same starting materials.

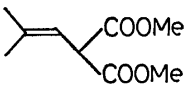
(2-Halo-2-methylpropylidene)malonate (**4**) was treated with 2-methyl-1-propenylmagnesium bromide in tetrahydrofuran under the conditions given in Table 1. Chloride **4a** was allowed to react with 2-methyl-1-propenylmagnesium bromide at 24 °C for 45 h to give the desired **5** in 46% yield as well as 11% of **6** and the recovered **4a** (30%) (run 1), whereas the reaction at 45 °C for 18 h resulted in a mixture of 55% of **5**, 19% of **6**, and 14% of **7a** (run 2). When the same reaction was carried out in the presence of catalytic amounts of copper(I) chloride,[5] most of **4a** was consumed within 45 min, giving 51% of **5** and 37% of **6** along with minor product **7a** (4%) (run 3). The presence of a good leaving group in the allylic halide **4** is not sufficient for the reaction, since the same reaction with **4b** (runs 4 and 5) carried out at 24 °C afforded the dehalogenated product **6** principally[6] and **5** showed only 25—32% yields as compared to 46—55% for **5** from **4a**.



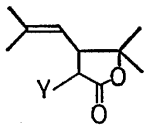
4a, X=Cl
b, X=Br



5

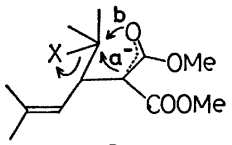


6



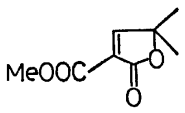
7a, Y=COOMe
b Y=H

The ambident ion **8** is believed to be formed by an unusual nucleophilic reaction of 2-methyl-1-propenide ion on the β-position of **4**. The formation of the cyclopropane ring of **5** can be rationalized by S_N2 type nucleophilic attack of the carbanion of **8** to the γ-position (Path a), while the formation of the parent compound **7a** could be attributed to nucleophilic attack by the enolate ion at the γ-position (Path b).



8

When **4b** was heated to 170 °C for 2 h under nitrogen, the 2-butenolide **9** was obtained in 76% yield. Subsequently, Michael addition of **9** with 2-methyl-1-propenylmagnesium bromide gave **7a** in 85% yield.[7] Demeth oxycarbonylation of **7a** in wet dimethyl sulfoxide-sodium chloride at 170 °C afforded pyrocin (**7b**) smoothly.



9

Experimental

All boiling points and melting points were uncorrected, the boiling points indicated being air-bath temperatures. Ir spectra were recorded on a Japan Spectroscopic Co., Ltd., IRA-I infrared recording spectrophotometer with a grating.

Table 1. Reaction of **4a** and **4b** with 2-methyl-1-propenylmagnesium bromide

a) Isolated Yields. b) Copper(I) chloride (10 mg) was added.

NMR spectra were recorded at 60 MHz on a Hitachi R-24 spectrometer with an internal standard of tetramethylsilan. Elemental analyses were carried out in this laboratory.

Dimethyl (2-Chloro-2-methylpropylidene)malonate (4a). A mixture of dimethyl (2-methylpropylidene)malonate[8] (3.0 g, 16.1 mmol), *t*-butyl hypochlorite[9] (2.0 g, 18.4 mmol), and azobisisobutyronitile (AIBN) (30 mg) in CCl_4 (3 ml) was heated under reflux for 2 h. After removal of the volatile substance, CCl_4 (3 ml), *t*-butyl hypochlorite (2.0 g, 18.4 mmol) and AIBN (30 mg) were added to the residue. The resulting mixture was refluxed for 2 h. The operation was repeated 5 times and the resulting **oil** was distilled to give **4a** (1.78 g, 50%): bp 75—77 °C/3 Torr; IR (neat) 1740 (C=O), 1651 cm^{-1}, (C=C); NMR ($CDCl_3$) δ 1.76 (s, 6, CH_3CCl), 3.77 (s, 6 CH_3), 6.93 (s, 1, HC=C). Found: C, 49.17; H, 6.01%. Calcd for $C_9H_{13}O_4$: C, 48.99; H, 5.94%.

Dimethyl (2-Bromo-2-methylpropylidene)malonate (4b). **4b** was prepared by bromination of dimethyl (2-methylpropylidene)malonate with *N*-bromosuccinimide, bp 92—95 °C/18 Torr, according to the reported procedure.[10]

Dimethyl 2,2-Dimethyl-3-(2-methyl-1-propenyl)cyclopropane-1,1-dicarboxylate (5). The reaction conditions and results are given in Table 1. A typical experimental procedure (run 2) is as follows: To aTHF solution (3 ml) of **4a** (1.0 g, 4.5 mmol) was added dropwise a THF solution (7 ml) of 2-methyl-1-propenylmagnesium bromide,[3] prepared from 2-methyl-1-propenyl bromide (1.22 g, 9.0 mmol) and magnesium (0.22 g, 9.0 mmol) at room temperature. After being stirred for 30 min at this temperature and for 18 h at 45 °C, the mixture was quenched with aqueous 10% NH_4Cl, extracted with ether, washed with brine and dried (Na_2SO_4). Removal of the solvent followed by column chromatography (SiO_2, THF–hexane, 1/20) gave **5** (597 mg, 55%), **6** (160 mg, 19%), and **7a** (143 mg, 14%).

Compound 5: Bp 81—84 °C/10 Torr; IR (neat) 1730 cm^{-1} (C=O); NMR ($CDCl_3$) δ 1.23 (s, 3, CH_3), 1.27 (s, 3, CH_3), 1.74 (br s, 6, CH_3C=C), 2.44 (d, 1, J=8 Hz, CH), 3.68 (s, 3, CH_3O), 3.72 (s, 3, CH_3O), 5.02 (diffused d, 1, J=8 Hz, HC=C). Found: C, 64.99; H, 8.59%. Calcd for $C_{13}H_{20}O_4$: C, 64.98; H, 8.39%.

Compound 6: Bp 73—76 °C/8 Torr: IR (neat) 1735 cm^{-1} (C=O); NMR ($CDCl_3$) δ 1.67 (diffused s, 3, CH_3C=C), 1.77 (diffused s, 3, CH_3C=C), 3.71 (s, 6, CH_3O), 4.24 (d, 1, J= 9 Hz, CHCO), 5.43 (diffused d, 1, J=9 Hz, HC=C). Found C, 58.29; H, 7.47%. Calcd for $C_9H_{14}O_4$: C, 58.05; H, 7.58%.

Compound 7a: Mp 81—81.5 °C (hexane–ether, 10/1); IR (Nujol) 1770 (lactone C=O), 1734 (C=O), 1675 cm^{-1} (C=C); NMR ($CDCl_3$) δ 1.27 (s, 3, CH_3), 1.44 (s, 3, CH_3), 1.73 (m, 6, CH_3C=C), 3.48 (d, 1, J=10 Hz, CHC=O), 3.56 (dd, 1, J=5 and 10 Hz, CHC=C), 3.76 (s, 3, CH_3O), 4.98 (diffused d, 1, J=5 Hz, HC=C). Found: C, 63.82; H, 8.05%. Calcd for $C_{12}H_{18}O_4$: C, 63.70; H, 8.02%.

4,4-Dimethyl-2-methoxycarbonyl-2-butenolide (9). The diester **4b** (940 mg, 3.55 mmol) was heated in a Claisen flask to 170 °C for 2 h under N_2 and then distilled to give **9** (456 mg, 76%): bp 90—95 °C/5 Torr; mp 72—73 °C (hexane); IR (Nujol) 1758 (lactone C=O), 1721 (C=O), 1640 cm^{-1} (C=C); NMR ($CDCl_3$) δ 1.54 (s, 6, CH_3), 3.87 (s, 3, CH_3O), 8.08 (s, 1, HC=C). Found: C, 56.43; H, 5.79%. Calcd for $C_8H_{10}O_4$: C, 56,47; H, 5.92%.

4,4-Dimethyl-3-(2-methyl-1-propenyl)-2-(methoxycarbonyl)butanolide (7a). To a THF solution (3 ml) of **9** (100 mg, 0.95 mmol) was added dropwise a THF solution (2 ml) of 2-methyl-1-propenylmagnesium bromide, prepared from 2-methyl-1-propenyl bromide (135 mg, 1.0 mmol) and magnesium (24 mg, 1.0 mmol) at room temperature. After being stirred for 16 h at this temperature, the mixture was quenched with aqueous 10% NH_4Cl, extracted with ether, washed with brine and dried (Na_2SO_4). Removal of the solvents followed by chromatography (SiO_2, hexane–ether, 20/1) gave **7a** (113 mg, 85%): mp 81—81.5 °C (hexane–ether, 10/1). The IR and NMR spectra were identical with those described above.

Pyrocin (7b). A solution of **7a** (40 mg, 0.18 mmol) in DMSO (1.24 ml) containing NaCl (5 mg) and a few drops of water was heated in a sealed tube at 170 °C for 1 h. The mixture was diluted with water and extracted with ether. The extract was washed with brine, dried (Na_2SO_4), and concentrated *in vacuo*. A short-path distillation of the residue gave **7b** (21 mg, 71%): bp 80—85 °C/3 Torr (lit,[4] bp 130—137 °C/17 Torr). The IR and NMR spectra were identical with those reported.[4]

Aryl Alkanehydrazonates and Their Thio Analogs. Synthesis of Some 2-Alkyl Derivatives of 4*H*-1,3,4-Benzoxadiazines and 4*H*-1,3,4-Benzothiadiazines

Ahmad Sami SHAWALI[1] and Hamdi Mahmoud HASSANEEN*,[2]

(Received November 24, 1976)

Synopsis. Synthesis of some *p*-nitrophenyl alkanethiohydrazonates, $RC(SC_6H_4NO_2\text{-}p)=NNHC_6H_3BrNO_2(2,4^-)$, and *p*-nitrophenyl alkanehydrazonates, $RC(OC_6H_4NO_2\text{-}p)=NNHC_6H_3BrNO_2(2,4^-)$ is described. Upon treatment with triethylamine in ethanol at reflux the thiohydrazonates give directly 2-alkyl-4-(*p*-nitrophenyl)-7-nitro-4*H*-1,3,4-benzothiadiazines, whereas the hydrazonates yield the hydrazides, $RCONHN(C_6H_4NO_2\text{-}p)C_6H_3BrNO_2(2,4^-)$. The latter hydrazides can be cyclized, under stronger basic conditions, into 2-alkyl-4-(*p*-nitrophenyl)-7-nitro-4*H*-1,3,4-benzoxadiazines by displacement of the 2-bromine atom.

We have been exploring the synthesis and thermal rearrangement of several hydrazonate esters of type I (Z=aryl, C_2H_5OOC, C_6H_5NHCO, and X=O or S).[3-6] We wish now to describe the synthesis of some alkanethiohydrazonates (II, R=alkyl and X=S) and the use of such esters in the synthesis of 2-alkyl derivatives of 4*H*-1,3,4-benzoxadiazines (III, X=O) and the thiadiazine analogs (III, X=S) respectively.

Scheme 1.

The required *S*-*p*-nitrophenyl alkanethiohydrazonates, IIa to IIc, were obtained by treating the corresponding alkanehydrazonoyl bromides with *p*-nitrobenzenethiol in ethanol in the presence of triethylamine at room temperature. The other alkanehydrazonates, IId and IIe, were similarly prepared using *p*-nitrophenol in place of *p*-nitrobenzenethiol. The structures of these esters were confirmed by their elemental analysis and the spectral data. For example, esters IId and IIe exhibited in infrared spectra bands at 1250 and 1065 cm^{-1} assignable to an aryl ether linkage. Their electronic absorption pattern in ethanol was of typical hydrazones.

Treatment of thiohydrazonate IIa with triethylamine in ethanol at reflux gave the corresponding thiadiazine, IIIa. The other thiohydrazonates, IIb and IIc, similarly gave the thiadiazines, IIIb and IIIc, respectively. The structures of the latter products were evidenced by their elemental analysis and spectra (see Experimental). To account for this, it is assumed that the reaction proceeds through the formation of the anionic species of the rearranged thiohydrazide (IV, X=S), which undergoes cyclization to thiadiazine (III, X=S) as it is formed (Scheme 1). This is analogous to the reaction of arenehydrazonoyl bromides with thioacetate ion[7] and the recently reported rearrangement of aryl thiohydrazonates.[8]

In contrast to thiohydrazonates IIa to IIc, hydrazonates IId and IIe rearranged to the corresponding hydrazides (IV, X=O) in refluxing ethanol-triethylamine generally within 100 min. The structures of the latter hydrazides,

$$R\text{-}CX\text{-}NHN(C_6H_4NO_2\text{-}p)C_6H_3BrNO_2(2,4^-)$$
IV

were evidenced by the appearance of bands at 1680 cm^{-1}

a) λ_{max}^{EtOH} (log ε) 363 (4.383); 320 (4.156) b, nm; $\bar{\nu}$ (KBr) 3297 (NH); 1344 (C–S–C) cm^{-1}; $\delta(CDCl_3)$ 2.14 (s, 3H, CH_3), 7.0—8.40 (m, 8H, ArH and hydrazone NH) ppm. b) λ_{max}^{EtOH} (log ε) 363 (4.321), 325 sh (4.156), 260 sh (4.010) nm; $\bar{\nu}$(KBr) 3375 (NH), 1336, 1038 (aryl ether linkage) cm^{-1}; $\delta(CDCl_3)$ 1.28 (d, 6H, J=7 Hz, $(CH_3)_2CH$), 2.75 (septet, 1H, J=7 Hz, $(CH_3)_2CH$), 7.0—8.6 (m, 8H, ArH and hydrazone NH) ppm.

(CO) and the absence of the Ar–O–C bands in their infrared spectra. This base catalyzed rearrangement of II to IV (X=O) appears to follow nucleophilic substitution mechanism (Scheme 1) rather than the free radical sequence proposed for the thermally induced rearrangement of aryl arenecarbohydrazonates to *N*-aroyl-*N'*,*N'*-diarylhydrazines.[9] The *p*-nitro substituent in the *O*-aryl moiety probably increases the stability of the five-membered cyclic transition state. In this respect the present O→N aryl migration can be seen as a Smiles-type rearrangement;[10] in agreement with the views of Elliott *et al.*[11] who indicated that aryl arenecarbohydrazonates substituted such that the *O*-aryl ring is sufficiently electron deficient, undergo a facile base-catalyzed Smiles rearrangement to give the corresponding hydrazides.

The cyclization of IV (X=O) into III (X=O) was effected only by boiling with an equivalent amount of sodium hydroxide in *N*,*N*-dimethylformamide–triethylamine mixture for 10 h. The structure of the benzoxadiazines prepared followed their elemental analysis and was confirmed by the absence of NH and CO absorption bands in their infrared spectra. The mechanism favoured for this cyclization seems to be analogous to that proposed for the cyclization of IV—III (X=S); *i.e.*, the anionic species derived from the hydrazide is thought to attack the 2-position of the 2-bromo-4-nitrophenyl group to form the heterocyclic ring by nucleophilic displacement of bromine.

Experimental

All melting points are uncorrected. Microanalyses were performed by Alfred Berhardt, Mikroanalytische Laboratorium, West Germany. The IR and UV spectra were recorded with Pye-Unicam SP 1000 and SP 8000 spectrophotometers respectively. PMR spectra were recorded on a Varian T60A spectrometer using tetramethylsilane as an internal reference.

Alkanehydrazonoyl bromides were prepared by literature method;[12] their physical constants (mp.s) corresponded with data reported.[12]

p-Nitrophenyl *N*-(2-bromo-4-nitrophenyl)alkanehydrazonates (IId—e) and their thio analogs (II—ac). General Procedure. A mixture of hydrazonoyl bromide (0.01 mol), *p*-nitrophenol (or *p*-nitrobenzenethiol) (0.01 mol) and triethylamine (0.02 mol) in ethanol (50 ml) was stirred at room temperature for 1 h. The product that precipitated was collected, washed with water and purified by crystallization from ethanol. The results are summarized in Table 1.

N-Isobutyryl-N'-(2-bromo-4-nitrophenyl)-N'-(p-nitrophenyl)-hydrazine (IVd). The hydrazonate IId in 1: 1 (v/v) ethanol–triethylamine mixture was refluxed for 1 h. The reaction mixture was then concentrated, diluted with water and the solid formed was collected. Crystallization from methanol gave the hydrazide IVd, mp 168 °C. Found: C, 45.41; H, 3.50: N, 13.20%. Calcd for $C_{16}H_{15}N_4O_5Br$: C, 45.40; H, 3.57; N, 13.24%. $\bar{\nu}$(KBr) 1680 (CO); 3250 (NH) cm^{-1}; λ_{max}^{EtOH} (log ε) 363 (4.274); 325 (3.997) sh; 260 (3.912) sh; δ ($CDCl_3$) 1.22 (d, 6H, J=7 Hz, $(CH_3)_2CH$) 2.58 (septet, 1H, J=7 Hz, Me_2CH); 7.0—8.6 (m, 8H, ArH and hydrazide NH) ppm.

2-Isopropyl-4-(p-nitrophenyl)-7-nitro-4H-1,3,4-benzoxadiazine, IIId. Equivalent amounts of the hydrazide IVd and sodium hydroxide were dissolved in a mixture of *N*,*N*-dimethylformamide and triethylamine and refluxed for 10 h. The solution was then cooled, poured into excess of 5% acetic acid. The solid that precipitated was collected and washed with water. Crystallization from methanol gave IIId in 50% yield, mp 165 °C. Found: C, 55.98; H, 4.20; N, 16.20%. Calcd for $C_{16}H_{14}N_4O_5$: C, 56.14; H, 4.12; N, 16.36%. $\bar{\nu}$(KBr) 1350, 1040 (cyclic ether).

2-Alkyl-4-(p-nitrophenyl)-7-nitro-4H-1,3,4-benzothiadiazines, IIIa—c. The appropriate thiohydrazonate (0.5 g) was refluxed in a 1: 1 (v/v) mixture of ethanol and triethylamine (40 ml) for 4 h. The solution was then concentrated and the solid that separated on cooling was collected. Crystallization from dioxane gave the following benzothiadiazines.

Compound IIIa, mp 240 °C. Found: C, 50.90; H, 3.13; N, 16.59%. Calcd for $C_{14}H_{10}N_4O_4S$: C, 50.90; H, 3.05; N, 16.96%. λ_{max}^{EtOH} (log ε) 410 (4.163); 295 sh (3.833) nm; $\delta(CDCl_3)$ 2.40 (s, 3H, 2-CH_3); 7.0—8.4 (m, 7H, ArH) ppm.

Compound IIIb, mp 180 °C. Found: C, 51.95; H, 4.10; N, 16.23%. Calcd for $C_{15}H_{12}N_4O_4S$: C, 52.32; H, 3.51; N, 16.27%.

Compound IIIc, mp 160 °C. Found: C, 53.41; H, 3.78; N, 15.41%. Calcd for $C_{16}H_{14}N_4O_4S$: C, 53.62; H, 3.93; N, 15.63%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 50 (10), 2829—2830 (1977)

Graft Polymerization on Pulverized Solid Surface. I. Grafting Polystyrene on a Clay Surface Treated with Silane Coupling Agents

Takuo NAKATSUKA, Hitoshi KAWASAKI, and Katsuhiko ITADANI

Industrial Technical Center of Okayama Prefecture, Ifuku-cho, Okayama 700

(Received January 13, 1977)

Synopsis. Styrene was graft-polymerized on kaolin clay treated with silane coupling agents *e.g.* (γ-methacryloyloxypropyl)trimethoxysilane. Although the silane-styrene copolymer was soluble in benzene, the polystyrene-grafted clay swelled in the same medium. A clay-crosslinked, three-dimensional structure is suggested and conditions for gelation are also discussed.

In order to elucidate the interfacial interactions between organic matrices and inorganic fillers in composite materials, studies of the graft polymerization of organic monomers onto inorganic pulverized solid surfaces are of importance.

Many papers appear in the literature dealing with topochemical graft polymerization. But only a single paper has been published on the clay-crosslinked structure of graft polymerization products. Dekking[1] has prepared the adduct of bentonite and 2,2′-azobis-isobutyramidine hydrochloride, which initiated the polymerization of vinyl monomers and gave gel-like compositions.

Although silane coupling agents are often used in many composite materials, neither graft polymerization on kaolin clay treated with silane agents nor the characteristic structure of the products has been reported. In the present paper, the crosslinking role of the clay in the polystyrene-silanized clay composition is described.

Experimental

Materials. X-Ray analysis showed that Kaolinite was the principal mineral in the kaolin clay used. (Found: SiO_2, 44.84; Al_2O_3, 39.59; Fe_2O_3, 0.36; TiO_2, 1.12; CaO, 0.14; MgO, 0.06; Na_2O, 0.07; K_2O, 0.20; Ig. loss, 13.99%. Calcd for kaolin; SiO_2, 46.54; Al_2O_3, 39.49; H_2O, 13.96%). The percentage of water adsorbed on the clay under atmospheric conditions was determined to be 0.56% by the Fischer method and, after the desorption treatment procedure described it was found to be 0.02%. The specific surface area was found to be 6.89 m^2/g by the BET method.

(γ-Methacryloyloxypropyl)trimethoxysilane (**1**) was obtained commercially and used without further purification. Benzene was purified in the usual way and styrene was freshly distilled prior to use. Other organic solvents were of reagent grade. The 2,2′-azobisisobutyronitrile (AIBN) used was also of reagent grade.

Procedure. In a 200-ml two-necked round-bottomed flask equipped with a magnetic stirring bar, a condenser and a three way stopcock was placed 2.0 g of clay. The flask was heated to 70 °C under *ca.* 1 mmHg (1 mmHg≈133 Pa) for 1 h, and then allowed to cool down to room temperature at which time nitrogen was introduced into the vessel. After 5.0 ml of benzene and 0.2 ml of **1** were added to the clay, the mixture was stirred at room temperature for 30 min. Moreover, 5.0 ml of styrene and 40 mg of AIBN were added to the mixture, which was heated at 80 °C with stirring in a nitrogen atmosphere for 2 to 4 h. The reaction mixture was poured into hexane and the precipitate was filtered, dried *in vacuo*, and weighed. Non-graft polymer was extracted from the precipitate with benzene for 12 h. Then, in order to determine the graft polystyrene, the residual solid was submitted to pyrolysis gas chromatography whose decomposing temperature was *ca.* 570 °C.

Results and Discussion

As shown by Solomon and Rosser,[2] and Kawasaki *et al.*,[3] kaolin clay can initiate the polymerization of styrene (conv. 93%) by desorption of water from the clay surface, although no graft polymer is observed on the clay surface. The polymerization is inhibited by the addition of either pyridine or **1**. This is probably due to poisoning of the acidic sites on the clay surface.

Table 1. Styrene graft polymerization on clay

Experiment	I[a]	II	III
Clay (g)	2.0	2.0	2.0
Benzene (ml)	5.0	5.0	5.0
1 (ml)	0.2	0.2	0.2
Styrene (ml)	2.0	2.0	2.0
AIBN (mg)	40	41	40
React. temp (°C)	80	80	80
React. time (h)	2	2	4
St. conv. (%)	35	71	79
Free poly-st/free poly-st and graft poly-st wt ratio	0.85	0.94	0.88
Graft efficiency	0.046	0.041	0.084

a) 0.2 ml of pyridine was added.

The data for styrene graft polymerization are given in Table 1. The graft efficiency is indicated by the weight ratio of the graft polystyrene to the polymer-clay composition. These values varied from 0.041 to 0.084. It is noteworthy that the polystyrene-clay products swelled and formed gels in benzene as do vulcanized rubbers. The conditions for gelation were further explored as explained below.

The amount of **1** adsorbed on the clay was determined. Two kinds of procedures were employed for the treatment of **1** on the clay. (A) One procedure was to add **1** in a solution of methanol–water (9: 1) to the air-dried clay. After evaporation, benzene was added to dissolve the non-adsorbed **1**, which was determined by ir spectroscopy (1716 cm^{-1}; ester band of **1**). The amount of **1** adsorbed was calculated from these data. (B) In the other method, the addition of **1** in a benzene solution

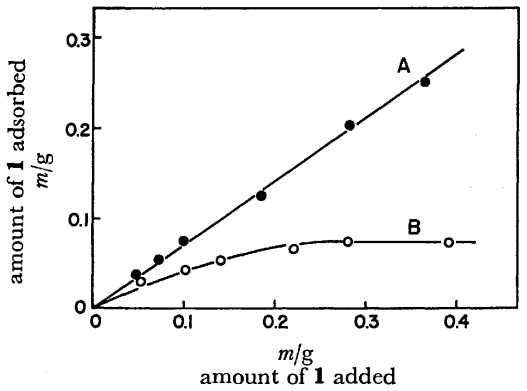

Fig. 1. Amounts of **1** adsorbed on the clay (2.0 g). A) ●: As methanol–water solution (5 ml). B) ○: As benzene solution (5 ml). IR ester band of **1** (1716 cm^{-1}) was used for determination.

was employed. The adsorbed **1** was determined by a similar method. These results are summarized in Fig. 1.

Figure 1 shows that the adsorption of **1** was effective in the presence of enough water to hydrolyze the methoxy moiety of **1** and that the adsorption of **1** increased proportionally to the amount of **1** added in method A. However, in the case of method B, the amount of **1** adsorbed is shown to have a plateau at *ca.* 0.07 g. The specific surface area of the clay is 6.89 m^2/g and the minimum specific surface area of **1** is 314 m^2/g.[4] From these observations, it is considered that **1** forms a multimolecular layer on the clay surface, although it was added as an anhydrous benzene solution.

Subsequently, polymerization was carried out in the presence of the clay which had been treated with various amount of **1** by method A. The results are listed in Table 2. The reproducibility of the graft efficiency and of the amount of *p*-xylene absorbed was rather poor probably due to heterogenity.

As seen in Table 2, when nearly the same amount of **1** was added to the clay, bulk polymerization was found to be preferable to the solution polymerization for the gel compositions. It was also found that gelation of the products brought a considerable increase in the graft efficiency. From the results in Fig. 1, it may be said that the amount of **1** on the clay surface is one of the gelation conditions.

Table 2. Effects of the amount of **1** on the gelation, crosslink density, and graft efficiency of the products

1 (ml)	State of products[a]	Absorbed *p*-xylene[b]	Graft efficiency
0.4	g	0.40	0.247
0.3	g	1.17	0.086
0.2	p	1.10	0.041
0.1	n	—	0.002
0.05	n	—	0.002
0.2[c]	g	0.65	0.250
0.1[c]	g	1.03	0.251
0.05[c]	p	2.98	0.236

a) g: gel, p: partially gel, n: non-gel. b) The amount of *p*-xylene absorbed (g-*p*-xylene/g-composition) was determined by glpc.[5] c) Bulk polymerization was carried out in a manner similar to that for solution one, except for benzene.

The crosslink density of the composition was estimated from the amount of the solvent, such as *p*-xylene, absorbed. Table 2 also shows that the density increases for an increase in the amount of **1** added to the clay.[6]

Then, the polystyrene-clay compositions were compared with the styrene-**1** copolymer (**2**) of the same feed composition. The ir spectra of the two polymers were essentially identical in the 3100—1400 cm^{-1} region. However, the decomposition patterns for differential thermal analysis of the two in air are evidently different (250—450 °C). Therefore, a difference in structure of the organic polymer is suggested. Further work on these results is now in progress.

In contrast to the solubility of copolymer **2** in benzene, the polymer-clay composition swelled by the same solvent. These facts are consistent with the clay-bridged, three-dimensional structure illustrated in Fig. 2.

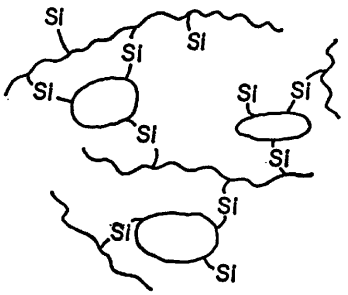

Fig. 2. Model of the polystyrene-clay composition. ⬭: Clay, ～～: styrene-**1** copolymer.

It was hoped to obtain more information about the crosslinking role of the clay. However, attempts to prepare the polymer-clay gel composition by the reaction of copolymer **2** with the clay were not successful. This appears to be due to the decreased accessibility of the silanols or alkoxysilane groups in the copolymer to the clay surface.

On the Behavior of Paramagnetic Species Formed in the Pure V_2O_5 Crystal under SO_2-Oxidation

Yoshiya KERA and Keiji KUWATA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received March 10, 1977)

Two types of ESR spectra were found in the highly purified V_2O_5 crystal under conditions of SO_2 oxidation. The shapes and the intensities of the spectra were investigated in detail in the temperature range from 470 to 656 °C under various mixing ratios of SO_2 to O_2. Below *ca.* 600 °C a sharp and asymmetric spectrum existed stably, while above that temperature it was replaced by a spectrum with an hfs of 29 lines, the intensities of which always were very weak. The low-temperature-type spectrum was reasonably assigned to the $VOSO_4$ phase, and the high-temperature-type, to an oxygen defect surrounded equivalently by four vanadium ions in the V_2O_5 phase. The interchange between the two spectra near 600 °C occurred reversibly and was related favorably to the following process in the surface layer of the V_2O_5 crystal: $2VOSO_4=V_2O_5+SO_3+SO_2$. The change in the working states of a pure V_2O_5 crystal according to the conditions of SO_2 oxidation was discussed.

There have been numerous reports[1–10] on the mechanism of SO_2 oxidation over vanadium oxide catalysts, which are used in the states of a fused mixture of V_2O_5 with alkali sulfates and of a mixture supported on silica and alumina gels. Many authors[5–10] have determined the changes in the mechanisms of SO_2 oxidation over the catalysts at around 450 °C; they have been discussed mainly from the point of view of reaction kinetics. Mastikhin *et al.*[11] have observed the ESR spectra of $V_2O_5 \cdot 3.5\,K_2S_2O_7$ supported on alumina gel during SO_2 oxidation and have suggested that the changes in the kinetics are related to some changes in the working states of the catalyst. However, no full solution to this problem has yet been given for multicomponent catalysts because of the complicated changes in the ESR spectra according to the reaction conditions.

In the highly purified V_2O_5 crystal, however, simple spectra were found under the conditions of SO_2 oxidation. The shapes and the intensities of the spectra showed clear changes depending upon the SO_2/O_2 ratio and the reaction temperature. The purpose of this paper is mainly to give proper assignments to the paramagnetic species and to discuss in detail the behavior of the species on the surface of the pure V_2O_5 crystal depending on the conditions of SO_2 oxidation.

Experimental

Materials. The V_2O_5 powder, which has been obtained by the decomposition of NH_4VO_3 (Special grade, Wako Pure Chem. Ind. Co.) was further chemically purified according to the methods of McCarley *et al.*[12] and Haemers.[13] The V_2O_5 single crystals were prepared by a zone-melting method with a Pt-boat. The crystals were cut into a proper size for contact with the reaction gases and for the ESR measurements. The $VOSO_4 \cdot 3H_2O$ (Special grade, Mitsuwa Chem. Ind. Co.) was used without further purification for the observation of the changes in the ESR spectra by dehydration and sintering.

Procedures. The V_2O_5 single crystal was placed in a quartz tube with an inner diameter of 0.3 cm and a length of 3 cm, which was connected by a gradual joint to a glass tube 0.6 cm in inner diameter. After pretreatment at 500 °C under evacuation for 1 h, it was cooled to room temperature. A given amount of a gaseous mixture of SO_2 and O_2 was introduced into the sample tube, and then the tube was sealed off. The reaction was carried out by heating the sample tube in an electric furnace for a long time. It was quenched by immersing it quickly in cold water before the ESR measurement. The procedure was repeated at various temperatures between 470 and 656 °C, the temperature fluctuation being kept within ±1 °C. The reaction conditions are summarized in Table 1.

TABLE 1. EXPERIMENTAL CONDITIONS OF SO_2 OXIDATION ON V_2O_5 CRYSTAL

Sample	SO_2 Torr[a]	O_2(air) Torr	SO_2/O_2 ratio	V_2O_5 mg	Volume cm^3
S_s-1	370	40(200)	9	29	4
S_s-2	375	34(170)	11	45	25
S_s-3	480	6(31)	80	32	25
S_s-4	556	0	∞	18	5

a) 1 Torr = 1.334×10^2 Pa.

The dehydration of $VOSO_4 \cdot 3H_2O$ and its sintering were done in the same ESR sample tube described above.

ESR Measurements. The ESR spectra were recorded at room temperature and at 77 K with an X-band spectrometer. The modulation frequency of the magnetic field was 455 kHz. The frequency of the microwave was determined to be 9326 MHz by the use of a wave meter. The calibration of the static magnetic field was done with DPPH and the Mn(II) ion doped in MgO as standards.

Determination of Spin Concentration. The spin concentration was determined with a single mode cavity (T_{011}) by the use of $CuSO_4 \cdot 5H_2O$ (single crystal) and DPPH (benzene soln) as the primary and the secondary standards of the spin concentrations respectively. A capillary tube which contained

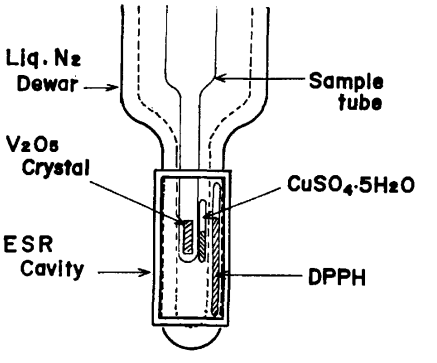

Fig. 1. Arrangement of V_2O_5 crystal and DPPH and $CuSO_4 \cdot 5H_2O$ standards in ESR cavity.

DPPH was always fixed on the outer wall of the quartz Dewar. On the other hand, a capillary tube which contained the $CuSO_4 \cdot 5H_2O$ was placed on the outer wall of the sample tube and was immersed together with it in the Dewar. The arrangement of the sample and the standards in the cavity are shown schematically in Fig. 1. The $CuSO_4 \cdot 5H_2O$ crystal was placed in the capillary tube so as to make the $g_{//}$ and $g_{\perp}$ axes nearly parallel to H_0 during the rotations of the sample tube around the axes. The spin concentrations were mainly obtained by a comparison of the integrated intensities of the standards with those of the samples. In the case of low spin concentrations, the amplitude of the first derivative curve of DPPH was used as a secondary standard.

Results

ESR Spectra in a Single Crystal of Highly Purified V_2O_5 under the Conditions of SO_2 Oxidation. No ESR signal was observed in the single crystal prepared from the cautiously purified V_2O_5 powder in air by the zone-melting method, although the signals ascribed to both vanadium ions (IV) with hfs of 15 lines and to the Fe ion as an impurity were usually found in the spectrum of the unpurified crystal. When the purified V_2O_5 single crystal was placed in contact with a gaseous mixture of SO_2 and O_2, an ESR spectrum with hfs of 15 lines and an hf-splitting constant, $A_{//}$, of 8.8 mT appeared initially. The spectrum is probably the same as has been found in pure and doped V_2O_5 by many authors,[14-16] as has been mentioned below. On prolonged contact the spectrum was replaced by an asymmetric spectrum, and the intensity of new spectrum increased with the time. When the temperatures were raised above *ca.* 600 °C, the asymmetric spectrum abruptly disappeared and a new spectrum with hfs whose splitting constant, $A_{//}$, is about 4.3 mT appeared. The former will hereafter be called the low-temperature-type spectrum, and the latter, the high-temperature-type spectrum.

In Run S_S-4, in which the crystal was treated at 617 °C with SO_2 alone, the spectrum with an hfs of 15 lines appeared initially, but soon disappeared. By this time the brilliance of the surface and the transparency disappeared completely, and the surface was covered with black and velveteen polycrystallines. Except for Run S_S-4, the surface brilliance of the cleaved plane (010) did not vary clearly upon the repetition of the heating and cooling, although the color and the transparency of the crystal did change.

Low-temperature-type Spectrum. The growth of the sharp asymmetric spectrum on Sample S_S-2 during the contacts at 470 °C is illustrated in Fig. 2. The line shapes of the asymmetric spectra at $H_0//b$ and $H_0 \perp b$ in Fig. 2 seem to show a typical randomly oriented paramagnetic species with an axially symmetric g-tensor. In the intermediate direction between $H_0//b$ and $H_0 \perp b$, however, an additional sharp line appeared in the asymmetric spectrum. The sharp line moved from the static magnetic field (position) corresponding to $g_{//}=1.924$ to that corresponding to $g_{\perp}=1.970$, according to the change in the direction of the static magnetic field from $H_0//b$ to $H_0 \perp b$ in the ac-plane. In a previous paper,[17] the angular dependencies of the spectrum

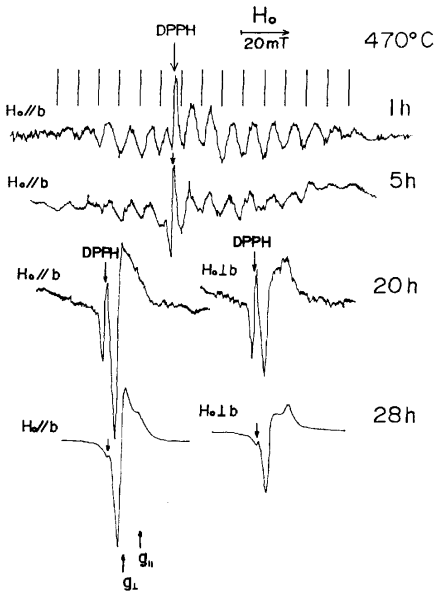

Fig. 2. Changes in ESR spectrum of a highly purified V_2O_5 single crystal during contact with a reaction mixture of SO_2 and O_2 at 470 °C.—Appearance and disappearance of ESR spectrum with hfs of 15-lines and then appearence of a sharp asymmetric spectrum (the so-called low temperature type spectrum).

TABLE 2. CHANGES IN SPECTRUM AND ITS SPIN CONCENTRATION IN SAMPLE S_S-1 WITH THE TEMPERATURE

Temp °C	Time h	Low-temperature type Spin concn $\times 10^{17}$/29 mg	High-temperature type
505	134	8.2	—
639	43	4.7	—
656	17	0.7	hfs 29 lines
656	39	—	hfs 29 lines (4×10^{15})
599	166	3.8	—
549	163	6.8	—
532	70	6.6	—

were examined in detail and it was concluded that the asymmetric sharp spectrum was as a composite: one component was ascribed to the spectrum caused by an axially symmetric g-tensor ($g_{//}=1.924$ and $g_{\perp}=1.970$) taking a relatively random orientation to the crystalline lattice of the V_2O_5 and the other, to that taking a definite orientation, *i.e.*, the $g_{//}$//b-axis of the V_2O_5 crystal.

The changes in the spin concentrations according to the reaction conditions are given for Samples S_S-1, S_S-2, and S_S-3 in Tables 2, 3, and 4 respectively. All the data were also graphically shown together in Fig. 3. In the case of Sample S_S-2, the time responses for the appearance and disappearance of the low-temperature-type spectrum are given in Fig. 4. It may be seen from the figures that the appearance and disappearance occur abruptly within the temperature range between 586 and 595 °C.

High-temperature-type Spectrum. At higher temperatures the low-temperature-type spectrum was re-

placed by a new spectrum with hfs of more than twenty lines, whose hf-splitting constant was a half of that of the previous spectrum ($A_{//}$=4.3 mT). Such a change in the spectrum of Sample S_s-1 is illustrated in Fig. 5.

ESR Spectrum of Pure Vanadium Sulfate Powder. In mixtures of V_2O_5 and alkali sulfates under the reaction conditions of SO_2 oxidation, quite similar spectra with low-temperature-type spectra have been reported and ascribed to some states of vanadium sulfates.[11] The ESR spectrum of pure vanadium sulfate was also examined. The ESR spectrum of $VOSO_4 \cdot 3H_2O$ and the spectra obtained after heating $VOSO_4 \cdot 3H_2O$ in air at 490 °C for 24 h and then at 600 °C for 1 h are shown in Fig. 6. The higher the temperature, and the longer the treatment, the sharper and the more asymmetric the line shape. The *g*-values of the spectra are summarized in Table 5. In the limiting case we could obtain the spectrum with a *g*-value similar to that of the low-temperature-type spectrum. Upon heating at 620 °C the sharp asymmetric spectrum disappeared completely.

Discussion

High-temperature-type Spectrum in V_2O_5 Crystal under the Conditions of SO_2 Oxidation. There have been many reports on the ESR spectra of doped and undoped V_2O_5 single crystals. For instance, the spectrum with an hfs of 15 lines was found in Fe-, V-, and Cu-doped crystals,[14,15] and that with an hfs of 29 lines in Li- and Na-doped crystals.[20] In undoped V_2O_5 single crystals, spectra with hfs of 15 and 29 lines[16,18] were also reported; the spectra were ascribed to some kinds of oxygen vacancies in the crystalline lattices. No clear differences in the spectra with an hfs of 15 lines can be found between the doped and undoped crystals so long as only the ESR parameters are compared.

These results indicate that the hf-coupling constants

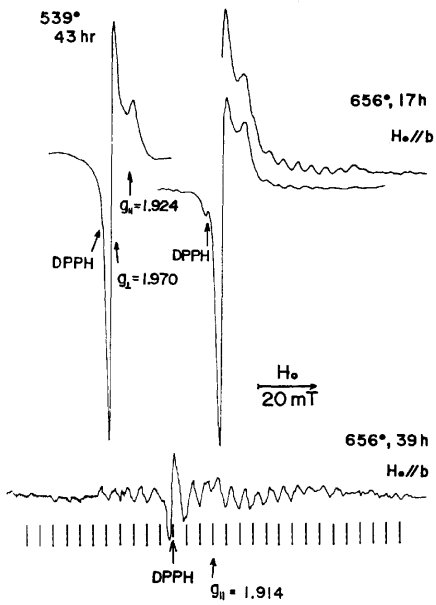

Fig. 5. Low temperature type spectrum at 539 °C, and disappearance of the spectrum and appearance of a new spectrum with hfs of more than 20 lines by the contact at 656 °C (the so-called high temperature type spectrum).

are related inversely to the number of ^{51}V nuclei, interacting equivalently with an unpaired electron, and thus to the number of the hf-lines, as has previously been suggested by Ioffe and Patrina.[14] According to such a rule, the spectrum with an hfs of 15 lines ($A_{//}$= 8.8 mT) in Fig. 2 can be ascribed to an oxygen vacancy of the Gillis type.[16] The high-temperature-type spectrum with the hf-splitting of 4.3 mT at H_0//b in Fig. 5 could also be identified with the spectrum with an hfs of 29 lines,[18] although not all the hf-lines appear and the relative intensities of the hf-lines do not accord with a polynomial distribution. The lack of the full number of hf-lines and the correct intensity distribution might be caused by the relatively low concentration and the small fluctuation in the orientations of the paramagnetic species in the surface layer. Such a low concentration could be understood by thermochemical considerations, as will be mentioned below, and such a fluctuation in the orientations could be expected for the sample quenched from a real working state of SO_2-oxidation.

The positions of the hf-lines, however, were explained well by the following procedure and ESR parameters. Including the magnetic hyperfine interaction to the second order, the resonance field is given approximately by Eq. 1:[21]

$$H(m_I) = H_0 - Km_I/g\beta - (4H_0)^{-1}\cdot(g\beta)^{-2}\cdot A_{\perp}^2\cdot(A_{//}^2+K^2)K^{-2}\cdot \{I(I+1)-m_I^2\} - (2H_0)^{-1}\cdot(g\beta)^{-2}\cdot (A_{//}^2-A_{\perp}^2)K^{-2}\cdot g_{\perp}^2\cdot g_{//}^2\cdot g^{-4}\cdot z^2(1-z^2)m_I^2, \quad (1)$$

where

$$H_0 = h\nu/g\beta,\ g^2 = g_{\perp}^2 + (g_{//}^2-g_{\perp}^2)z^2$$

and

$$K^2g^2 = A_{//}^2g_{//}^2z^2 + A_{\perp}^2g_{\perp}^2(1-z^2).$$

In the limiting case of $z=\cos\delta=1$,

$$H(m_I) = H_{//} - (A_{//}m_I/g_{//}\beta) - (2H_{//})^{-1}\cdot(g_{//}\cdot\beta)^{-2}\cdot A_{\perp}^2\cdot\{I(I+1)-m_I^2\}, \quad (2)$$

can be derived. The positions of the hf-lines (at any m_I, $m=m_{I1}+m_{I2}$ and $m_{I1}+m_{I2}+m_{I3}+m_{I4}$ respectively),

S_8-2	5.6	27	0.05	30	0.0017
S_8-3	0.5	41	0.01	21	0.0005

which were calculated by means of Eq. 2 using the parameters of $g_{//}=1.924$; $A_{//}=8.4$, $A_{\perp}=3.3$ mT and $g_{//}=1.917$; $A_{//}=4.3$ mT, are given above and below the spectra in Figs. 2 and 5 respectively. In the latter case the third term of Eq. 2 is neglected. The parameters are listed in Table 6 for the sake of comparison.

From the discussions both the g-values and the hf-coupling constants, it is clear that the ESR spectra, like what those which have previously been observed in doped and undoped V_2O_5 by many authors,[14-18] can also exist in the highly purified V_2O_5 under the conditions of SO_2 oxidation. The spectra with hfs values of 15 lines and more than 20 lines can, then, be conclusively ascribed to the $V^{4+}\cdots V^{5+}$ and $\begin{matrix} V^{4+}\cdots V^{5+} \\ \vdots \quad\quad \vdots \\ V^{5+}\cdots V^{5+} \end{matrix}$ sites, produced by the elimination of lattice oxygens without the interpositions of other metal impurities.

Low-temperature-type Spectrum of the V_2O_5 Crystal under the Conditions of SO_2 Oxidation. The thermal analysis of $V_2O_5\cdot nH_2O$ has been carried out in several atmospheres by many authors.[22-25] From those results, above *ca.* 140 °C $VOSO_4\cdot 3H_2O$ is known to start to change in air to $VOSO_4\cdot H_2O$ and above *ca.* 200 °C to anhydrated $VOSO_4$; this will be followed by further decomposition, $VOSO_4\rightarrow V_2O_5$, on heating above *ca.* 550 °C. On the basis of our present knowledge, the changes in the spectrum from a symmetric and broad type to an asymmetric and sharp one in Fig. 6 seems to correspond to the progress in the dehydration and sintering: $VOSO_4\cdot 3H_2O\rightarrow VOSO_4$. It is known from the suggestion by Ballhausen *et al.*[26] and Ladwig[24] that, in $VOSO_4\cdot 3H_2O$, some of the water molecules remain in the ligand sites and are replaced by SO_4^{2-} ions as the dehydration progresses. Thus, the crystalline-field splittings of the oxovanadium(IV) ion, and thus the g-values, should differ between $VOSO_4\cdot 3H_2O$ and anhydrated $VOSO_4$, as will be discussed below.

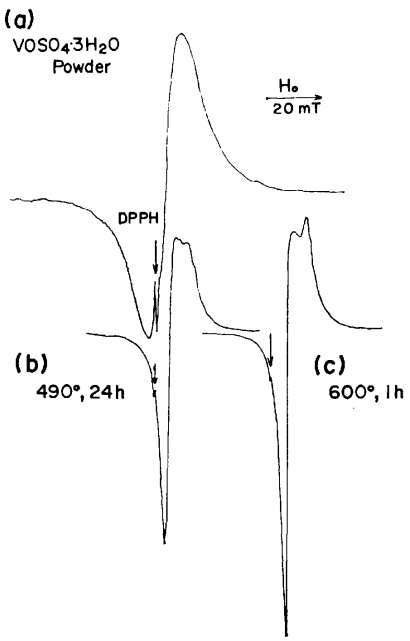

Fig. 6. Changes in ESR spectrum of $VOSO_4\cdot 3H_2O$ powder with heat treatments, see Table 5.

The rather symmetric line shape of the spectrum of $VOSO_4\cdot 3H_2O$ might be caused by a similar extent of increase in the linewidth with the anisotropy of the g-tensor of the spectrum of anhydrated $VOSO_4$ in Fig. 6. Such an increase in the linewidth must be due mainly to some effects of the ligand water on the relaxation time.[27] The reason can not be explained fully now, although the fact that the structure,[24,28] linked tightly by SO_4^{2-} tetrahedrons, is realized by the elimination of the ligand water seems to give a hint.

The g-values of powdered $VOSO_4\cdot 5H_2O$[29] and $VOSO_4\cdot 2H_2O$[30] have been reported to be $\langle g\rangle=1.99$ and 1.96 respectively. The tendency for $\langle g\rangle$ to decrease as the dehydration progresses corresponds closely to the results in Table 5. It is shown in the table, that finally, the g-value became close to the value of the low-temperature-type spectrum. Such a decrease in the g-value could be caused by the increase in the covalency of the vanadyl complex due to the replacement of the water molecules in the ligand sites by the SO_4^{2-} ions.[27] By these comparisons, it seems possible to assign the low-temperature-type spectrum under the conditions of SO_2 oxidation to the $VOSO_4$ phase, formed on the V_2O_5 crystalline lattice.

The amounts of SO_3 formed and SO_2 remaining in the equilibrium at 580 °C were roughly estimated from the initial amounts of SO_2 and O_2 and the equilibrium constant of the reaction, $SO_2+{}^1/_2O_2=SO_3$. The values are given in Table 7, while the total number of vanadium atoms in the V_2O_5 crystal and the spin concentrations for the low-temperature-type spectrum at 580 °C are given in Fig. 3. By comparing the data, especially between Samples S_8-2 and S_8-3, it can be surmised that n_{spin} decreases with a decrease in n_{SO_3} and inversely with an increase in n_{SO_2}. Thus, the spectrum can be ascribed to the $VOSO_4$ phase; in contrast to this, the possibility of a different assignment to some kinds of reduced vanadium oxides can clearly be ruled out.

Formation of the $VOSO_4$ Intermediate and the Reaction Mechanism of SO_2 Oxidation on the V_2O_5 Crystal. It is known that the $(n_{spin}/n_{vanad.})$ ratio is 1/2000—1/330, as is shown in Table 7. This indicates that the

paramagnetic species, ascribed to $VOSO_4$, is formed only in the surface layer of the crystal, even if the reaction is much prolonged. The curves for the increase in intensity of the low-temperature-type spectrum with the time at 470 and 586 °C in Fig. 4 show clearly the existence of a very fast process at the initial stage and a relatively slow process after that. The initial process can be attributed to the growth of the $VOSO_4$ phase on the surface, especially on the (010) plane, and the second process, to the diffusion of the $VOSO_4$ phase into the bulk.

The abrupt increase and decrease in the intensity of the low-temperature-type spectrum near 600 °C seems to occur reversibly in Figs. 3 and 4. The temperature range where the spectrum suddenly disappears may be consistent with the temperature at which the $VOSO_4$ phase in a V_2O_5–SO_2–SO_3–$VOSO_4$ system is decomposed thermally, although the range should change according to the reaction conditions of the SO_2 oxidation on V_2O_5.[31] The disappearance of the spectrum can, therefore, be related to the process of Eq. 3:

$$2VOSO_4 \rightarrow V_2O_5 + SO_3 + SO_2. \quad (3)$$

At low temperatures the SO_2 oxidation reaction on pure V_2O_5 crystal can be expected to proceed through the $VOSO_4$ intermediate as in the following scheme, Eq. 4:

$$2SO_2 + \frac{1}{2}O_2 + V_2O_5 \rightarrow 2VOSO_4 \rightarrow V_2O_5 + SO_3 + SO_2. \quad (4)$$

On the other hand, at high temperatures it would proceed by the participation of the oxygen defect, surrounded equivalently by four vanadium ions on the V_2O_5 surface, as is suggested by the appearance of the spectrum with an hfs of 29 lines.

The findings that the formation and decomposition of the $VOSO_4$ phase in the V_2O_5 crystal occur reversibly and that the surface brilliance of the (010) plane is kept seem to show the possibility of some regular arrangement of the $VOSO_4$ phase on the surface of the V_2O_5 crystal, as was suggested in a previous paper.[17]

The Adsorption Mechanism of Methanol on Alkali Halides[1)]

Masatoshi CHIKAZAWA and Takafumi KANAZAWA

Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158

(Received April 14, 1977)

The amounts of methanol adsorbed on (100) planes of the crystals of six alkali halides (LiCl, NaCl, NaBr, KCl, KBr, and KI) and the isosteric heats of their adsorption were measured. For the chloride samples, the order of magnitude of the adsorption heats at a coverage of $\theta=0.5$ was found to be LiCl>NaCl>KCl, while the order for the bromide samples was NaBr>KBr. The monolayer capacities estimated from the adsorption isotherms for KCl and NaBr were in accord with the values calculated by assuming that one methanol molecule is adsorbed on one surface anion of the crystal. In the cases of the NaCl and LiCl salts, whose lattice spacings are smaller than that of NaBr, the methanol molecule was adsorbed on the surface anion with a ratio below 1 : 1. On the other hand, for the KBr and KI samples, whose lattice spacings are larger than that of KCl, alcohol was adsorbed on the surface anion in a ratio above 1 : 1. These phenomena are reasonably interpreted in terms of a relationship between the cross-sectional area of a methanol molecule and the lattice spacing of the salt concerned. An adsorptive mechanism deduced from the isosteric heat curves was compatible with the above explanation.

In the adsorption of polar molecules on the surfaces of alkali halide particles, interaction forces between the surface anions of the salt and the adsorbates will be large. Especially, when the adsorbates form hydrogen bonds with the surface anions, the role of the anions is presumed to be very significant.[2-5)]

A methanol molecule (MeOH) has one OH group expected to form a hydrogen bond with the surface anion. Therefore, in the present paper, MeOH is used as an adsorbate for several alkali halides, and the adsorption characteristics of the samples and the role of the surface anion in MeOH adsorption are discussed.

Experimental

Materials. Samples of five alkali halides (NaCl, NaBr, KCl, KBr, and KI) were purified by two recrystallizations of special-grade reagents using distilled water. A solution of an alkali sample (*ca.* 100 ml, 20—30 wt%) was added to about a five-fold volume of ethanol cooled to −80——90 °C with stirring. The precipitate was filtered, washed four times with absolute ethanol, and then dried under a reduced pressure of 10^{-3} mmHg. Lithium chloride was prepared by the pulverization of a special-grade reagent in a ball-mill for 10 min. The LiCl and NaBr samples, which are able to form the hydrates, were heat-treated at 350 and 450 °C respectively for 2—3 days under a reduced pressure of 10^{-6} mmHg, while the other samples were evacuated with an oil diffusion pump ($<10^{-6}$ mmHg) for 1—2 days at room temperature prior to the adsorption measurements. These samples were found by microscopy to be very small cube crystals (1—8 μm).

The methanol was purified by distillation from a reagent for the UV spectrum measurements, and then used.

Surface Area Measurement. The specific surface areas of the samples were determined by the nitrogen adsorption method at 77 K, assuming the cross-sectional area of a nitrogen molecule to be 16.2 Å^2.

Methanol Adsorption Isotherm. The adsorption isotherms of MeOH on the alkali halides at 10, 20, 30, and 40 °C were determined volumetrically by using the adsorption apparatus reported previously by the present authors.[6)]

Results and Discussion

Adsorption Isotherms. The adsorption isotherms of MeOH on alkali halides are given in Fig. 1. In

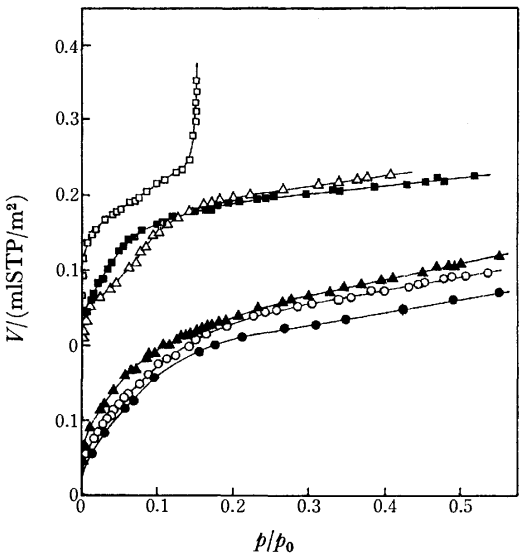

Fig. 1. Adsorption isotherms of MeOH on alkali halides at 20 °C.
—□—: LiCl, —■—: NaCl, —△—: KCl, —▲—: NaBr, —○—: KBr, —●—: KI.

the case of LiCl, it is characteristic that the amount of MeOH adsorbed increased rapidly at pressures above $p/p_0=0.14$ and that, simultaneously, the dissolution of LiCl into the adsorbed MeOH films occurred. The relative vapor pressure of a MeOH solution saturated with LiCl is about $p/p_0=0.15$ at 20 °C. The volume adsorbed at $p/p_0=0.15$ was estimated from the adsorption isotherm to be 0.28 ml STP/m^2. This volume agreed with the amount required to cover the surface of the LiCl particle with a 1.36 molecular layer of MeOH, assuming that the cross-sectional area of a MeOH molecule is 18 Å^2 [7)] (calculated from the density of liquid MeOH at 20 °C). The considerable solubility of LiCl into such a small amount of adsorbed MeOH will be explained on the basis of a strong interaction between the Li ion and the MeOH molecule. This interpretation is supported by the fact that the solubilities[8)] of lithium halides in methanol are higher than those of sodium halides in spite of the considerably larger lattice energies[9)] of the former.

TABLE 1. MONOLAYER CAPACITIES OF MeOH ADSORBED ON ALKALI HALIDES

Sample	V_{BET}(ml STP/m²)	V_B(ml STP/m²)	V_{cal}(ml STP/m²)	V_B/V_{cal}
LiCl	0.23	0.17—0.18	0.282	0.62
NaCl	0.23	0.18—0.19	0.234	0.79
NaBr	0.205	0.24—0.25	0.209	1.17
KCl	0.19	0.18—0.20	0.188	1.01
KBr	0.23	0.24—0.25	0.171	1.40
KI	0.21	0.22—0.23	0.149	1.50

A: Side view ◯: MeOH, ○: Cl^-, ○: Na^+.

B: Ground plane ◯: MeOH, ○: Cl^-, ○: Na^+.

The monolayer capacities, V_{BET} and V_B, were determined by two methods, the BET and the point B methods respectively. The values thus obtained are summarized in Table 1. As for the salt with a lattice spacing smaller than that of KCl or NaBr, V_B was less than V_{BET}. On the other hand, for the sample whose lattice spacing is larger than that of KCl or NaBr, V_B was greater than V_{BET}. These phenomena may be due to differences in the adsorption mechanisms at a coverage of $\theta=1$. This will also be discussed in the section on the mechanism of adsorption. The disagreement between V_B and V_{BET} values in each sample was within 20%.

Mechanism of Adsorption. The two assumptions introduced here to simplify the mechanism of MeOH adsorption on alkali halides are as follows: (I) all the surfaces of alkali halides particles consist of (100) planes, and (II) one MeOH molecule is adsorbed on one surface anion by an interaction such as a hydrogen bond. The former assumption for the surface structure of the salts will be reasonable in view of two experimental proofs, an electron microscopic observation of alkali halides surfaces made by Yao[2] and the fact found by Young[10] that approximately 80% of the surfaces of pulverized KCl is composed of (100) planes. The amounts of MeOH (V_{cal}) necessary for covering the unit surface area (1 m²) were calculated for all the samples (*cf.*, Table 1). The adsorptive situation of MeOH on the surface, *i.e.*, the (100) plane of NaCl, is illustrated in Fig. 2, in which the OH axis in the molecule is perpendicular to the surface of the crystal. The van der Waals radii of the hydrogen atom, the oxygen atom, and the CH_3 group are assumed to be 1.2, 1.4, and 2.0 Å respectively.[11] In the case of NaCl, some overlaps of neighboring adsorbed MeOH molecules occur, as is shown with the shaded area in Fig. 2-B. Considering this schematic structure of MeOH adsorption, a certain degree of steric hindrance is expected to arise among the adsorbed molecules at the monolayer completion. If an OH axis of MeOH is slightly oblique to the normal surface, such steric hindrance can be avoided in the adsorption. However, since the V_B/V_{cal} value for NaCl was smaller than 1, the steric hindrance is considered to remain to some extent. On the contrary, the V_B/V_{cal} values obtained for KCl and NaBr were approximately equal to 1. Therefore, the lattice spacings of the both salts will be regarded as convenient spacings for MeOH adsorption.

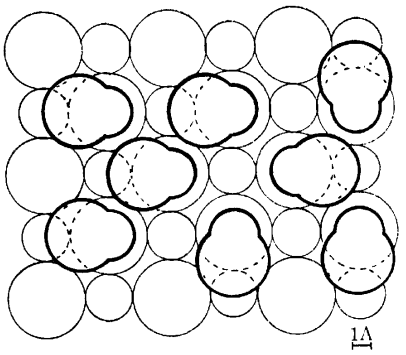

Fig. 3. Schematic diagram of MeOH adsorption on (100) plane of KBr.

○: Br^-, ○: K^+, ◯: MeOH.

In the case of the salt whose lattice spacing is smaller than that of NaCl, the steric hindrance will unavoidably be induced in the adsorbed MeOH, and the number of MeOH molecules adsorbed becomes less than that of anions on the surface. On the other hand, for KBr, whose spacing is larger than that of KCl, MeOH

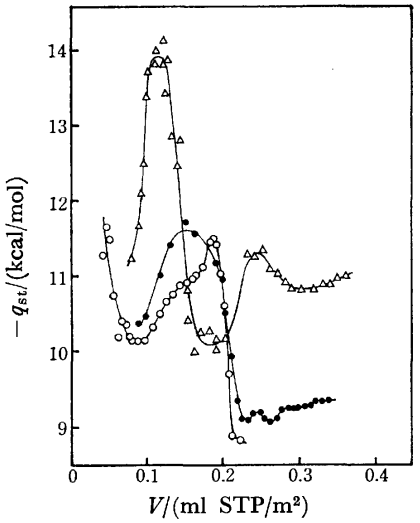

Fig. 4. Isosteric heats of adsorption of MeOH on alkali chlorides.
—△—: LiCl, —●—: NaCl, —○—: KCl.

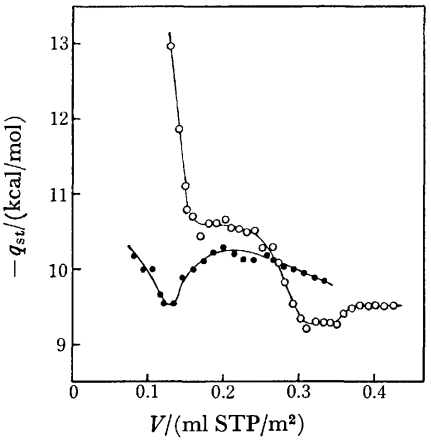

Fig. 5. Isosteric heats of adsorption of MeOH on alkali bromides.
—○—: NaBr, —●—KBr.

is adsorbed first on the surface anion in the ratio of 1 : 1. At this time, however, a vacant space is produced among the adsorbed molecules, as is shown in Fig. 3. In further adsorption, MeOH is packed more closely to diminish the vacant space. Therefore, the monolayer capacity is larger than the value to be expected from the adsorptive structure of one MeOH for one surface anion. When such a vacant space becomes larger, the amount of MeOH necessary for covering the space rises. Hence, the value of V_B/V_{cal} increases with an increase in the lattice spacing of the salt. The change in the V_B/V_{cal} values with the alteration of the samples will be explained in terms of the difference in their lattice spacings. Moreover, this explanation is supported by the discussion in the next section.

Heat of Adsorption. In Figs. 4 and 5, the isosteric heats ($-q_{st}$) of MeOH on the alkali halides are plotted against the amounts adsorbed. In the case of the chloride samples, the order of magnitude of the adsorption heats at $\theta=0.5$ ($V=0.11$ ml STP/m²) was found to be LiCl>NaCl>KCl. For the bromide

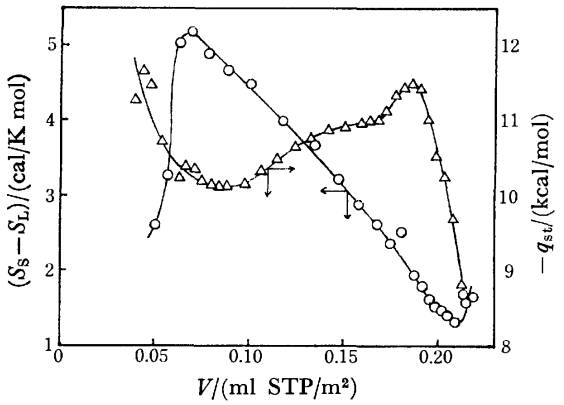

Fig. 6. Molar integral entropy of MeOH adsorbed on KCl.
S_S: Molar integral entropy of adsorbed MeOH.
S_L: Molar integral entropy of liquid MeOH at 20 °C.

samples, the order was NaBr>KBr. The heat of MeOH adsorption rose with an increase in the ionic radius ratio, r_{anion}/r_{cation}, of the crystal. These results are consistent with the adsorptive structure described above that MeOH molecules are adsorbed on the surface anion by the hydrogen bond.

The heats of adsorption for LiCl, NaCl, and KCl were noticed to have maximum values at a coverage below $\theta=1$ (<0.2 ml STP/m²). This phenomenon is considered to be caused by a lateral interaction induced among the adsorbed molecules. The heats of adsorption for NaCl and KCl had smaller values than the liquefaction heat of MeOH at the adsorbed amounts of above $V=0.225$ and 0.21 ml STP/m² respectively. When a MeOH molecule is adsorbed on the surface of the (100) plane, as is shown in Fig. 2, the polar OH group in MeOH is located under the CH_3. Therefore, an interaction between MeOH and the polar groups in the formerly adsorbed molecules is expected to be depressed on the further adsorption of MeOH, *i.e.*, a two-layer adsorption, and the isosteric heat of adsorption will be small at this time. This interpretation is compatible with the molar integral entropy change in MeOH adsorbed on KCl, as is shown in Fig. 6. These entropy values were calculated from adsorption isotherms omitted in this report. At low coverages, $V<0.07$ ml STP/m², the entropy of adsorbed MeOH became small with a decrease in the amounts adsorbed. This entropy change suggests that the MeOH molecule is tightly adsorbed on the surface of KCl in the early stage of the adsorption.

In the case of KBr, MeOH is considered to be adsorbed first on the surface anion, as is illustrated in Fig. 3. The lateral interaction induced among the adsorbed MeOH molecules will be very weak, owing to the long lattice spacing of KBr. It will be stated, in view of such an adsorption mechanism, that the heat of adsorption decreases with the amount adsorbed until the adsorbed molecules come in contact with each other. In the vicinity of the monolayer completion, the adsorbed molecules come in touch with each other, and the lateral interaction increases to cause a peak in the isosteric heat of adsorption at $V=0.21$ ml STP/m². This value is approximately equal to the monolayer

capacity estimated from the cross-sectional area of 18 Å^2 for a MeOH molecule. A peak caused by the lateral interaction was also observed in the curve of the adsorption heat of LiCl in the high-pressure region.

A Study of the Behavior of Surface Oxygen of V_2O_5 Catalysts by the Use of the ^{18}O-Tracer

Yoshiya KERA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received April 15, 1977)

By the use of highly concentrated ^{18}O-carbon dioxide, both the rate of the isotopic exchange of CO_2 and the surface oxygen of a powderd V_2O_5 catalyst and that of the isotopic equilibration of CO_2 on the surface were determined simultaneously in the temperature range from 330 to 450 °C. The rate of the isotopic exchange on the thin-plate crystallines, in which the (010) plane of V_2O_5 crystal was mainly exposed, was also determined. The equilibration rate was 30—40 times faster than the exchange rate. The exchange process on the thin-plate crystallines was found to be extremely rapid, although such a phenomenon has never been found on the powdered catalyst. Based on these results, the relationship of the reaction steps of the isotopic exchange and the isotopic equilibration with those on the triangular scheme of CO-oxidation, previously proposed, was discussed in detail. A small cycle of alternate reduction-oxidation on the top of the surface, especially on the (010) plane, was conclusively confirmed.

The bonding energy of the surface oxygen of metal oxides and its energy distribution have been determined by many authors[1-12] as important parameters for catalytic activities. Information on the dynamical aspects of oxygen species on the surface of metal oxides has also been obtained successfully by the applications of ^{18}O-tracer techniques.[13-16]

In our previous paper[17] the behavior of the surface oxygens of powdered V_2O_5 during the course of CO-oxidation were examined by the use of ^{18}O-tracer techniques, and a mechanism, that is, a "triangular" reaction scheme, was proposed. The very high activity of the surface V=O group, asserted by Tarama *et al.*,[18] was confirmed practically by the simultaneous applications of the IR and ^{18}O-tracer techniques.[19] Evidence of the alternate reduction-oxidation of the oxygen of the V=O group has also been given by the measurements of the reflectance spectra of IR by Fahrenfort *et al.*[20] However, the relationship between the exchangeable oxygen and the most reactive oxygen in CO-oxidation has not been established well enough, as has been pointed out by Sachtler[20] and Emmett.[21]

In this work, first the rates of two processes, the isotopic exchange between CO_2 and the surface oxygen of powdered V_2O_5, Eq. 1, and the isotopic equilibration of oxygen in CO_2 on the surface, Eq. 2, were simultaneously determined and compared with each other:

$$C^{18}O_2 + {}^{16}O(s) = C^{18}O^{16}O + {}^{18}O(s), \quad (1)$$

$$C^{18}O_2 + C^{16}O_2 = 2C^{18}O^{16}O. \quad (2)$$

Secondly, the rate of the exchange process on the powdered V_2O_5 was compared with that on the thin-plate crystallines, in which the (010) plane of V_2O_5 crystal was mainly exposed. On the basis of the results, the relationship of the reaction steps of the isotopic exchange and the isotopic equilibration with those of CO-oxidation was successfully discussed and the triangular scheme, previously proposed, was confirmed further.

Experimental

Materials. A commercial V_2O_5 (special grade, Mitsuwa Chem. Ind. Co.) was used as the powdered catalyst without further treatment. Thin-plate crystallines of V_2O_5, with the (010) plane mainly exposed, were obtained by the pulverization of a single crystal and by sieving with an 80-mesh sieve. Crystal I (smaller size—above 80-mesh) and Crystal II (larger size—below 80-mesh) were used as the catalysts of the thin-plate crystallines. The BET surface area of powdered V_2O_5 and Crystal I were determined to be 2.5 and 0.55 m^2/g respectively.

Gaseous CO_2 containing ^{18}O was prepared by the oxidation of carbon with heavy gaseous oxygen (^{18}O), which had been highly concentrated by the thermal diffusion method.[22] After purification by the usual procedures, no impurities were detected mass-spectrometrically.

Procedure and Experimental Conditions. Reaction systems and procedures similar to those of previous papers[17,19] were adopted. The reaction conditions are summarized in Table 1. The reaction temperatures were controlled within ±1 °C, and the accuracies in the determination of the ^{18}O-concentration were ±0.02—0.05 atom%.

Results

1) Simultaneous Determinations of the Rates of the Isotopic Exchange and the Isotopic Equilibration. Simultaneous determinations of the rates of both the isotopic exchange, Eq. 1, and isotopic equilibration, Eq. 2, over powdered V_2O_5 were attempted. In a preliminary experiment, the determination of the rate of the isotopic equilibration was quite difficult, for the isotopic compositions in carbon dioxide ($C^{16}O_2$, $C^{18}O_2$, and $C^{16}O^{18}O$) were greatly disturbed by the exchange process, which occurred simultaneously. In this experiment, therefore, small amounts of V_2O_5 (0.03 g) were used, and the changes in the isotopic compositions were measured only at the initial stage in order to avoid the trouble as much as possible. The results under the conditions shown in Table 1 are given in Table 2. In the Table, x, γ, and K denote ^{18}O atom% in CO_2, $C^{16}O^{18}O$ molecular percent in CO_2, and the value of $\{C^{16}O^{18}O\}^2/\{C^{16}O_2\}\{C^{18}O_2\}$ at a certain reaction time respectively. The increases in γ and K indicate the progress of the equilibration reaction and the decrease in x the progress in the exchange reaction. When the changes in x become large, the values of γ and K will be affected directly and the rate of the equilibration can not be determined accurately. The changes in x and γ with the time are illustrated again by Fig. 1. It can clearly be seen at 450 °C that γ is practically disturbed by

relatively large changes in x.

2) Comparison of the Rates of the Isotopic Exchange on the Powdered V_2O_5 with That on the Thin-plate Crystallines. In order to make clear the effects of the particle size and shapes of V_2O_5 on the catalytic activities and to ascertain the differences in the activities among the crystalline planes, the rate of the isotopic exchange was measured over three types of V_2O_5 samples, shown in Table 1, and compared. The changes in the ^{18}O-concentration-(atom%) in CO_2 with the time are given in Fig. 2. The equilibration reaction took place too fast to determine the rate — the equilibration has already arrived at the first point in the figure. From Fig. 2 it is clear at 410 °C that the rate on the powdered V_2O_5 is faster than that on the Crystal I, while that on the Crystal I faster than that on the Crystal II. These differences must be caused by the differences in the surface areas. In the figure it can also be seen in the initial stage that the rates on the Crystal II are less even at 490 °C

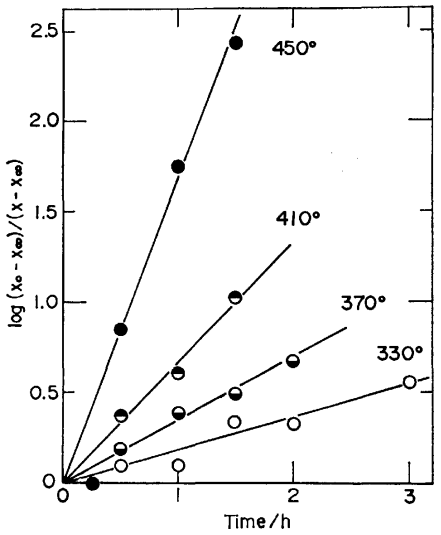

Fig. 3. Kinetical treatment of the data on the isotopic exchange in Table 2 with Eq. 4.

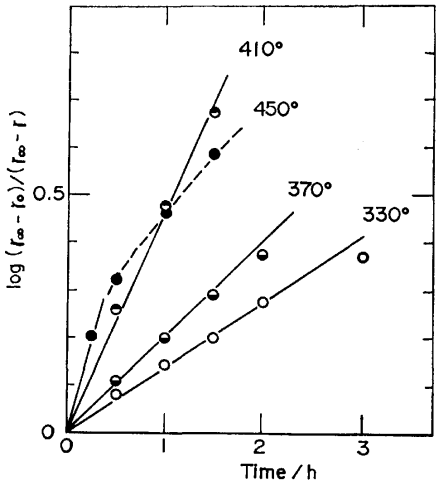

Fig. 4. Kinetical treatment of the data on the isotopic equilibration in Table 2 with Eq. 6.

than those on the Crystal I at 410 °C. The slope of the curve of the ^{18}O-concentration *vs.* the time was kept constant; however, after 30 h on the former sample, it became considerably larger than that on the latter. This feature may correspond to the indication[14,16] that oxygen diffusion in the inner bulk of V_2O_5 crystal is extremely stimulated above 500 °C.

Discussion

Comparison of the Rate of the Isotopic Exchange with That of the Isotopic Equilibration on the Powdered V_2O_5.

The rate of the isotopic exchange can be generally described by Eq. 3 if the oxygen atoms in the oxide (O_1) are alike in exchangeability and if the kinetical isotope effects are neglected:

$$-(dx/dt) = k_{ex}(x-x_\infty). \quad (3)$$

The integrated form is given by Eq. 4:[13-16]

$$\ln\{(x_0-x_\infty)/(x-x_\infty)\} = k_{ex}\cdot t, \quad (4)$$

where x is the ^{18}O-concentration in carbon dioxide at any time, x_0 and x_∞ denote the initial and the final values respectively, and k_{ex} is an apparent rate constant. The total reaction rate, R_{ex}, is obtained by multiplying k_{ex} by the total number of oxygen atoms in carbon dioxide, n_g. x_∞ in Eq. 4 can be estimated using Eq. 5:

$$x_\infty = \{n_g/(n_g+n_{ex})\}x_0. \quad (5)$$

Since the amount of exchangeable oxygen in V_2O_5, n_{ex}, is not known in the present experiment, it is assumed preliminarily that n_{ex} is equal to the total number of oxygen atoms in V_2O_5, n_t. x_∞ was estimated as about 3 atom% by using the values of $n_g=1\times10^{20}$ and $n_t=5\times10^{20}$ atoms. Plots of $\log\{(x_0-x_\infty)/(x-x_\infty)\}$ *vs.* the time are shown in Fig. 3.

The rate of the isotopic equilibration, Eq. 2, can be described by Eq. 6 if there is no disturbance of the isotopic composition in carbon dioxide by the exchange reaction:

$$(d\gamma/dt) = k_{eq}(\gamma_\infty-\gamma). \quad (6)$$

The integrated form is given by Eq. 7:[13-16]

$$\ln\{(\gamma_0-\gamma_\infty)/(\gamma-\gamma_\infty)\}=k_{eq}\cdot t, \quad (7)$$

where γ is the concentration of $C^{16}O^{18}O$ in carbon dioxide, γ_0 and γ_∞ denote the initial and the final values respectively, and k_{eq} is an apparent rate constant. The total reaction rate, R_{eq}, is obtained by multiplying k_{eq} by the total number of CO_2 molecules.

γ_∞ in Eq. 6 can be estimated as follows: when the initial contents of $C^{16}O_2$, $C^{18}O_2$, and $C^{16}O^{18}O$ are denoted by α_0, β_0, and γ_0, the values at equilibrium can be described as (α_0-u), (β_0-u), and (γ_0+2u) respectively, using an unknown value, u. The value of K is approximately equal to 4 in the present temperature range. Therefore, Eq. 8 holds:

$$K = (\gamma_0+2u)^2/(\alpha_0-u)(\beta_0-u) = 4, \quad (8)$$

and thus u can be represented by Eq. 9:

$$u = (4\alpha_0\beta_0-\gamma_0^2)/4. \quad (9)$$

Therefore, γ_∞ is described by Eq. 10:

$$\gamma_\infty = \gamma_0 + 2u = \gamma_0 + (4\alpha_0\beta_0-\gamma_0^2)/2. \quad (10)$$

Plots of $\log\{(\gamma_0-\gamma_\infty)/(\gamma-\gamma_\infty)\}$ *vs.* the time are shown in Fig. 4.

k_{ex} and k_{eq} can be directly estimated from the slopes of the curves in Figs. 3 and 4 respectively, although the errors are rather large. In Fig. 4 the higher the temperature and the longer the reaction time, the larger the deviation from the straight lines. This indicates that the disturbance of the isotopic compositions by the exchange reaction can not be neglected as the temperature increases and as the time becomes longer. At 450 °C especially, disturbance appeared more clearly as time passes; thus, k_{eq} was estimated by considering only the first point in the curve. k_{ex}, k_{eq}, R_{ex}, and R_{eq} are summarized in Table 3. From the comparison of R_{ex} with R_{eq}, the equilibration rate is known to be about 20—40 times faster than the exchange rate. Arrhenius plots of k_{ex} and k_{eq} are given in Fig. 5. The apparent pre-exponential factors and activation energies were evaluated as follows:

$$k_{0,eq} = 1.3\times10^{-2}(cm^{-2}\,s^{-1}), \quad E_{eq} = 14(kcal/mol),$$
$$k_{0,ex} = 5\times10^{-4}(cm^{-2}\,s^{-1}), \quad E_{ex} = 15(kcal/mol),$$

TABLE 3. THE ISOTOPIC EXCHANGE RATE AND THE ISOTOPE EQUILIBRATION RATE

Temperature °C	k_{ex} 10^{-9} cm^{-2} s^{-1}	Exchange rate 10^{11} atoms cm^{-2} s^{-1}	k_{eq} 10^{-7} cm^{-2} s^{-1}	Equilibration rate 10^{13} molecules cm^{-2} s^{-1}
450	14.4	15.8	7.0	3.8
410	5.6	6.1	4.0	2.2

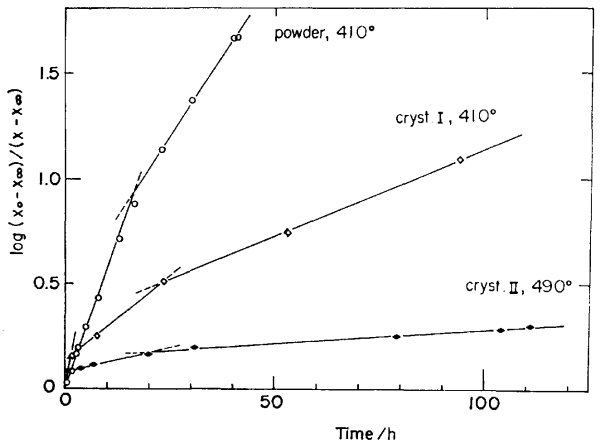

Fig. 6. Comparison of kinetics of the isotopic exchange on the powdered V_2O_5 with that on the thin plate crystallines.

Comparison of the Exchange Rate on the Powdered V_2O_5 with That on the Thin-plate Crystallines. On the application of Eq. 4 to the data of the exchange reaction on the powdered V_2O_5, if an appropriate value is assumed for x_∞, plots of $\log\{(x_0-x_\infty)/(x-x_\infty)\}$ *vs.* the time show two clear straight lines with a break point, as has been mentioned in a previous paper.[17] The appearance of the break suggests that the reactivity or mobility of oxygen in the surface layer of the powdered V_2O_5 can be differentiated from that in the inner bulk during the exchange reaction.

The data on the powdered V_2O_5 (410 °C), the Crystal I (410 °C) and the Crystal II (490 °C), given in Fig. 2, were treated with Eq. 4 assuming appropriate values of x_∞. The results are given in Fig. 6. In the cases of the thin-plate crystallines, an extremely rapid process appeared before the two processes found in the powdered run. The extremely rapid process must have appeared because of relatively high exposure of the (010) plane. This would also give experimental proof that the (010) plane has a considerably higher activity than the other planes. In the case of the powdered V_2O_5, only the process on the (010) plane seems not to be differentiated from that on the other planes; this is because of following reasons: a rapid process would occur not only on the (010) plane, but also on many kinds of surface grain boundaries, and all planes might be exposed with a nearly equal possibility on powdered V_2O_5.

It was found previously by the simultaneous applications of IR and ^{18}O-tracer techniques that the oxygen in the V=O group, projected from the (010) plane, was first exchanged, followed by the oxygen in the V–O–V layer.[19] With reference to these results, of the three straight lines in Fig. 6, the first line corresponds to the exchange of the oxygen in the V=O group, projected perpendicularly to the (010) plane; the second, to that of oxygen in the surface layer (that is, the oxygen near the surface of the other planes or the V–O–V layer), and the third, to the exchange between the surface layer and the inner bulk. Kakioka *et al.*[23] have examined in detail the rate of the isotopic exchange of oxygen in CO_2 with that in powdered V_2O_5 and Mo-doped V_2O_5. They have also demonstrated the existence of two processes — the exchange between the gaseous phase and the surface layer and the diffusion in the inner bulk. The rate and the activation energy of the present second process, R_{ex}, are nearly equal to the rate and the activation energy of the exchange process respectively, as obtained by Kakioka *et al.*

From the intersections of vertical axis with the extrapolated second and third straight lines in Fig. 6, the idealized amounts of exchangeable oxygen atoms corresponding to the top of the surface, n_{S_1}, and the surface layer, n_{S_2}, respectively, could be estimated. Besides, the amounts of the exchangeable oxygen corresponding to the inner bulk, n_b, can be easily estimated as the difference between the total exchangeable oxygen, n_{ex} and $n_{S_1}+n_{S_2}$. The amounts of exchangeable oxygen obtained by those procedures are summarized in Table 4. The overall rates at the initial stage, $R_{0,ex}$, were preliminarily estimated as the decrease in the ^{18}O-concentration for the initial hour. The results are added to Table 4 for the sake of comparison. n_{S_1} is 4—5 times less than n_g in Table 4. The initial rates, $R_{0,ex}$, may not indicate the real values because, in this situation, the exchange between the gaseous phase and the top of the surface possibly arrives at equilibrium within

TABLE 4. AMOUNTS OF EXCHANGEABLE OXYGENS OF V_2O_5 CRYSTAL AND THE INITIAL EXCHANGE RATE

Sample (Temp/°C)	n_g 10^{20} atoms	n_{s_1} 10^{20} atoms	n_{s_2} 10^{20} atoms	n_b 10^{20} atoms	n_t 10^{20} atoms	$R_{0,ex}$ atoms cm^{-2} s^{-1}
Powder (410)	1.03	1.36		7.4	49.4	3.8×10^{11}
Crystal I (410)	1.92	0.37	0.57	2.2	49.4	3.3×10^{12}
Crystal II (490)	1.58	0.30	0.31	35.1	49.4	(1.1×10^{13}) a)

a) The surface area was assumed to be 0.2 m^2/g in this run.

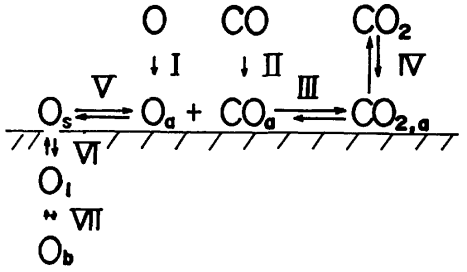

Fig. 7. Relations of reaction paths among the isotopic exchange, the isotopic equilibration, and CO-oxidation. The first, the second, and the third processes of the isotopic exchange are controlled by step V, VI, and VII, respectively and the isotopic equilibration by step V and CO-oxidation by step I and II.
$\{r(+\mathrm{I})=r(+\mathrm{II})=r(+\mathrm{III})-r(-\mathrm{III})$
$=r(+\mathrm{IV})-r(-\mathrm{IV})=r(\pm\mathrm{VI}),\ r(\pm\mathrm{V})\approx30r(\pm\mathrm{VI})\}$

1 h. Practically, larger values could be expected. The exchange rate on the thin-plate crystallines is known, from Table 4, to be more than 10 times faster than that on the powdered V_2O_5. This seems to mean that the exchange rate on the top of the surface of the (010) plane is comparable to the equilibration rate. This could be confirmed, however, only under the experimental condition of $n_g \ll n_{s_1}$.

Relationship of the Reaction Steps on the Isotopic Exchange and the Isotopic Equilibration with Those on the Triangular Scheme of CO-oxidation. The previous reaction scheme[17] of CO-oxidation was further generalized, as is shown in Fig. 7, by adding some steps of oxygen transfer in V_2O_5 crystallines on the basis of the above discussion. In the isotopic exchange on the powdered V_2O_5 Step V could not be observed, only Step VI. In the simultaneous determination of the exchange and the equilibration rates, R_{eq}, which should be related to the rate of Step V, was about 20—40 times faster than R_{ex}, correspondng to the rate of Step VI. On the other hand, on the thin-plate crystallines the rate of Step V was more than 10 times faster than that of Step VI; moreover, R_{ex} on the top of the surface of the (010) plane was suggested to be comparable to the R_{eq}, observed on the powdered V_2O_5. At the steady state of the exchange reaction, therefore, the length of the arrow of Step VI is 20—40 times shorter than the length of the forward and backward arrows in Steps III, IV, and V.

On the powdered V_2O_5, the overall rate of CO-oxidation, R_{oxid}, was nearly equal to R_{ex}, as was shown in a previous paper.[17] It was suggested, furthermore, that the R_{oxid} was controlled by the length of the arrow of Step I or of Step II in Fig. 7. At the steady state the length should be equal to the differences between the forward and backward arrows of Steps III and IV. At the steady state of CO-oxidation, therefore, the length of the arrow of Step VI would be nearly equal to the difference between the forward and the backward arrows in Steps III and IV. With respect to the absolute length of the arrows, Steps III and IV are both also about 20—40 times longer than Step VI. On the basis of the reaction scheme it can easily be understood that the catalytic oxidation proceeds according to a small cycle of alternate reduction-oxidation on the top of the surface, especially on the (010) plane.

In the present experiment the extremely high activity of oxygen on the (010) plane was shown only under the atmosphere of CO_2. The surface composition of vanadium and oxygen seems to be nearly stoichiometric in the working states. An acceleration of the exchange rate has been previously found on the addition of CO.[17] In this case the surface of V_2O_5 is probably kept in reduced states. Therefore, the question of whether or not the small cycle of reduction-oxidation can hold on the strongly reduced surface of V_2O_5 remains for future study.

Recently Boreskov *et al.*[24] and Kazanskii *et al.*[25] examined in detail the reaction of CO-oxidation over vanadium oxide, supported or not supported, and gave valuable suggestions as to the reaction mechanism. However, it is difficult to compare the mechanisms presented by Boreskov, Kazanskii, and the present authors, because the reaction conditions and surface states of the catalysts seem to be very different. In a forthcomming paper the effects on the rate of CO-oxidation will be investigated in detail in connection with the particle sizes and shapes, the degrees of oxidation and reduction of the surface, and the purities of the V_2O_5 catalyst.

Semiconducting Properties of $(Ln_I, Ln_{II})CuO_4$ and of $(Ln, A)_2CuO_4$ (Ln=rare earth, A=alkaline earth)

Tadao KENJO and Seishi YAJIMA

Oarai Branch, Research Institute for Iron, Steel and Other Metals, Tohoku University, Oarai-machi, Ibaraki 311-13

(Received December 13, 1976)

The ternary oxides, $(La,Pr)_2CuO_4$, $(Gd,Tb)_2CuO_4$, $(La,Tb)_2CuO_4$, $(La,Ca)_2CuO_4$ and $(La,Ba)_2CuO_4$, were prepared and their semiconducting properties were investigated. When the mean ionic radius of Ln^{3+} ($\bar{r}$) is increased, the $(La,Pr)_2CuO_4$ compounds transform from semiconductors to metals at a critical $\bar{r}$ value of 1.05 Å. The metal-semiconductor transition which accompanies the shrinkage of the a axis, is explained as being due to the π-bond formation of the Cu–O bond. Compounds in the composition range from $La_{1.3}Tb_{0.7}CuO_4$ to $La_{1.4}Tb_{0.6}CuO_4$ are peculiar to the $(La,Tb)_2CuO_4$ compounds. The crystal structure is the same as that of Ln_2CuO_4, but it is different from Ln_2CuO_4 as regards the c/a ratio and resistivity. The doping of 20 mol% CaO or 10 mol% BaO into La_2CuO_4 lowers the resistivity to tenth of that of La_2CuO_4.

In the CuO-Ln_2O_3 system (Ln=rare earth), there are three different types of compounds, the metallic La_2CuO_4 compound, the semiconductive Ln_2CuO_4 compounds (Ln=Pr—Gd) and the insulating $Ln_2Cu_2O_5$ compounds (Ln=Tb—Lu).[1-3] The resistivities of the Ln_2CuO_4 compounds decrease with increasing ionic radius of the Ln^{3+} ions continuously for Ln=Gd—Pr, but a semiconductor-metal transition takes place between Ln=Pr and La; the La_2CuO_4 compound is metallic.[3] The lattice parameters of these compounds vary with the size of the Ln^{3+} ions in accordance with the electrical behavior. The lattice parameters, both of the *a* and *c* axes, increase with increasing ionic radius of the Ln^{3+} ion continuously for Ln=Gd—Pr, but between Ln=Pr and La they change discontinuously; the *a* parameter for the La_2CuO_4 compound is smaller than that for the Pr_2CuO_4 compound although the La^{3+} ion is larger than the Pr^{3+} ion.[3] The ternary $(La,Pr)_2CuO_4$ compounds are expected to reveal how critically the resistivities and lattice parameters change with variations in the ionic radius between those of the Pr^{3+} and La^{3+} ions, because the ionic radii of the Ln^{3+} ions can be continuously varied by changing the La/Pr ratio.

The ternary $(La,Tb)_2CuO_4$ compounds would continuously cover ionic radii of the Ln^{3+} ion ranging from that of the La^{3+} ion to that of the Tb^{3+} ion, if the La^{3+} ion can freely be replaced by a Tb^{3+} ion. These ternary compounds would reveal how the resistivity and the lattice parameters of Ln_2CuO_4 compounds vary with the $\bar{r}$ value ($\bar{r}$=mean ionic radius of rare earth ions) over the above range and will also reveal whether or not the ternary compounds containig two kinds of rare earth ions, the ionic radii of which are very different from each other, are the same as the binary compounds as regards the variation of structure and resistivity with the $\bar{r}$ value.

The resistivities of the Ln_2CuO_4 compounds decrease with increasing ionic radius of the Ln^{3+} ions.[3] If this trend could be extended to the region of the ionic radius beyond the La^{3+} ion, Ln_2CuO_4 compounds containing larger trivalent ions than La^{3+} ions would show a lower resistivity than that for La_2CuO_4. Such large trivalent ions are very difficult to obtain, but the less electronegative metals, such as alkaline earth metals, can be expected to give the same effect on the resistivity because this trend appears to be related to the electronegativity of atoms in the Ln^{3+} sites. Since the Gd^{3+} ions in the Gd_2CuO_4 compound are partially replaced by alkaline earth ions,[4] the La^{3+} ions in La_2CuO_4 can be expected to be replaced by some alkaline earth ions. CaO and BaO were added to the La_2CuO_4 compound to see if the resistivity decreased.

The composition of the Ln_2O_3–CuO compounds changes discontinuously between Ln=Gd and Tb; Gd_2CuO_4 and $Tb_2Cu_2O_5$ are known,[1,2] but $Gd_2Cu_2O_5$ and Tb_2CuO_4 are unknown. It is of interest to determine whether $Ln_2Cu_2O_5$ and Ln_2CuO_4 compounds coexist in a region of the ionic radius of the Ln^{3+} ion or the Ln_2CuO_4 compound changes into the $Ln_2Cu_2O_5$ compound at a certain critical Gd/Tb atomic ratio. Furthermore, these compounds also have different electrical properties. Gd_2CuO_4 is a semiconductor, while $Tb_2Cu_2O_5$ is an insulator. Since the mean ionic radius of the Ln^{3+} ion can be varied continuously by using ternay $(Gd,Tb)_2CuO_4$ compounds, these discontinuous compositional and electrical changes between Ln=Gd and Tb will be investigated in more detail.

Experimental

Reagents and Materials. Stock solutions of $Ln(NO_3)_3$, $Ba(NO_3)_2$, and $Ca(NO_3)_2$ were obtained by dissolving Ln_2O_3 (Nihon Yttrium Co., 99.9% pure), $BaCO_3$ and $CaCO_3$ (Wako Pure Chemical Co., Ltd., GR grade) into nitric acid (Wako Pure Chemical Co., Ltd., GR grade). A stock solution of $Cu(NO_3)_2$ was obtained by dissolving $Cu(NO_3)_2 \cdot 3H_2O$ (Kanto Chemical Co., GR grade) into distilled water. The solutions were standardized by the EDTA chelatometric titration method.

Procedure. Samples were prepared using the same method as that described in a previous paper.[3] Aliquot portions of the solutions of $Ln(NO_3)_3$, $Cu(NO_3)_2$ (and an alkaline earth nitrate, when necessary) were mixed. A sodium hydroxide solution (1M) (and sodium carbonate solution (1M) for the addition of an alkaline earth nitrate) was added and the mixture was stirred. After the mixture had stood overnight, filtering and washing were repeated until no sodium ions were detected in the filtrate using the flame test. The mixtures of precipitates thus obtained were preheated to 750 °C in air. The dry powder of the oxide mixture thus obtained was milled, pressed into 15 mm diameter pellets and heated to 1000 °C for 15 h in air. The resistivity was measured using the 4-probe method in the same manner as described

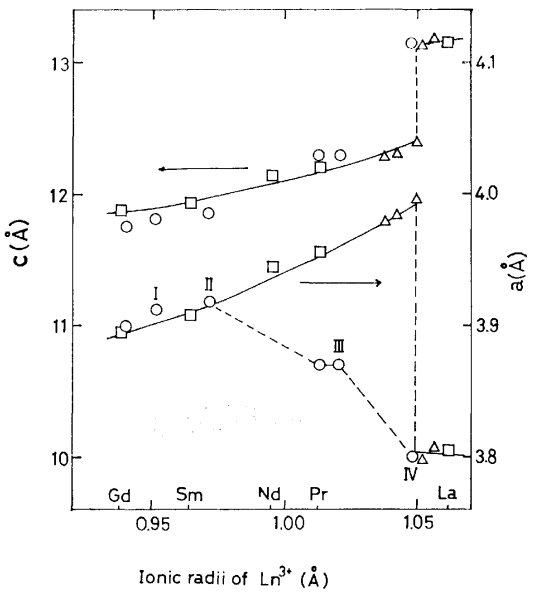

Fig. 1. Variation of lattice parameters of Ln_2CuO_4 with ionic radii or mean ionic radii of rare earth ions. □: Ln_2CuO_4, ○: $(La,Tb)_2CuO_4$, △: $(La,Pr)_2CuO_4$.

in a previous report.[3] An X-ray diffractometer was used for the measurement of lattice parameters and for the solid solubility determination in the ternary system.

Results and Discussion

Figure 1 gives the variation of the lattice parameters of binary Ln_2CuO_4 and ternary $(Ln_I,Ln_{II})_2CuO_4$ compounds with the ionic radius, or the mean ionic radius of the Ln^{3+} ion ($\bar{r}$). Both the a and c axes expand for an increase in the ionic radius of the Ln^{3+} ions for Ln=Gd—Pr. For Ln=La, the c axis expands more than the value estimated by extrapolating the data for Ln=Gd—Pr, and the a axis shortens (□). La_2CuO_4 is electrically metallic, while Pr_2CuO_4 is semiconductive.[3] This marked difference between Ln=La and Pr can be explained as a change in the nature of the Cu–O bond on the a axis ($(Cu–O)_a$) as described below.

The Cu^{2+} ions in the Ln_2CuO_4 lattice are octahedrally surrounded by six O^{2-} ions.[5] According to ligand field theory,[6] in the ground state with the Cu^{2+} ion coordinated octahedrally, the $3d_{z^2}$, $3d_{x^2-y^2}$, 4s and 4p orbitals of the Cu^{2+} ion are used for the σ-bonds. The $3d_{xy}$, $3d_{yz}$, and $3d_{zx}$ orbitals (t_{2g}) can form π-bonds with the coordinating O^{2-} ions, but for Ln=Gd—Pr, they are essentially nonbonding. The upper edge of the valence band originates from the antibonding σ-orbitals (e_g^*). The conduction band is formed of the π-orbitals of higher energy levels, probably the 4d orbitals of the Cu^{2+} ions. For Ln=Gd—Pr the relatively long bond-length of the $(Cu–O)_a$ bond prevents any great overlapping in the π-bond so that the conduction band is located at a higher energy level than the e_g^* orbitals, or the valence band. Therefore, the Ln_2CuO_4 compounds are semiconductive for Ln=Gd—Pr. When the effective change of the O^{2-} ions on the c axis is enhanced, the energy levels of the t_{2g} orbitals are elevated due to the electrostatic repulsive force. Since the less electronegative Ln atom or the atom with the smaller atomic number pushes more electrons toward the O^{2-} ions surrounding the Ln^{3+} ions, the effective charge of the O^{2-} ions increases with decreasing atomic number of the Ln atom so that the energy levels of the t_{2g} orbitals are elevated. For Ln=La, the t_{2g} energy level is maximum so that the La_2CuO_4 lattice becomes unstable. To stabilize it, the $(Cu–O)_c$ bond expands; this weakens the electrostatic repulsive force [$(Cu–O)_c$ is the Cu–O bond on the c axis]. This is the reason why the c axis of La_2CuO_4 expands more than expected from the size of the La^{3+} ion. The lengthening of the $(Cu–O)_c$ bond weakens it, that is, lowers its σ-bond energy but this energy lowering is compensated for by the π-bond formation in the $(Cu–O)_a$ bond composed of the $3d_{xz}$ and $3d_{yz}$ orbitals. This is the reason for the shortening of the a axis in La_2CuO_4. The shortening of the $(Cu–O)_a$ bond also enhances the electron overlap in the conduction band, lowering the energy level of the conduction band to that of the e_g^* band. Thus, the upper edge of the e_g^* band overlaps the lower edge of the conduction band and metallic conduction results. This is the reason why La_2CuO_4 is metallic.

The lattice parameters for the ternary $(La,Tb)_2CuO_4$ compounds are given in Fig. 1 (open circles). In the region of $\bar{r}$ from 0.94 to 0.97 Å, these increase with increasing $\bar{r}$ as do the lattice parameters of binary compounds. This phase is called phase 1. However, when the $\bar{r}$ value increases beyond 0.97 Å, another phase appears as a separated phase and the relative amount of the phase increases with increasing amount of the La^{3+} ions. The X-ray diffraction data reveal that this phase is a single phase in the composition range from $La_{1.3}Tb_{0.7}CuO_4$ to $La_{1.4}Tb_{0.6}CuO_4$ and that the X-ray diffraction patterns can be indexed as Ln_2CuO_4 structures. Since this phase exists as a phase separated from phase 1 and its c/a ratio is different from that of all binary Ln_2CuO_4 compounds, it should be considered to be a new phase which is peculiar to the $(La,Tb)_2CuO_4$ system. This phase is called phase 2.

When the $\bar{r}$ value increases beyond $\bar{r}$=1.015 Å, the La_2CuO_4 phase appears and coexists with phase 2. This fact indicates that phase 2 is different from both phase 1 and the La_2CuO_4 phase. Beyond $\bar{r}$=1.05 Å the La_2CuO_4 phase occurs as a single phase.

The semiconducting properties of this system correspond well to the structural behavior described above. Figure 2 gives the log ρ *vs.* $1000/T$ plots for the $(La,Tb)_2CuO_4$ compounds (ρ=resistivity). The roman numerals refer to the sample numbers given in Fig. 1. The ρ values at a given temperature for phase 1 decrease with increasing $\bar{r}$ value, but with slopes that are essentially the same (I and II). The plots for phase 2 (III) give a less steep slope than those for phase 1, indicating that the activation energy for the phase 2 sample is lower than that of phase 1.

The lowering of the activation energy in phase 2 can be explained as being due to π-bond formation in the $(Cu–O)_a$ bond. As described in the previous sec-

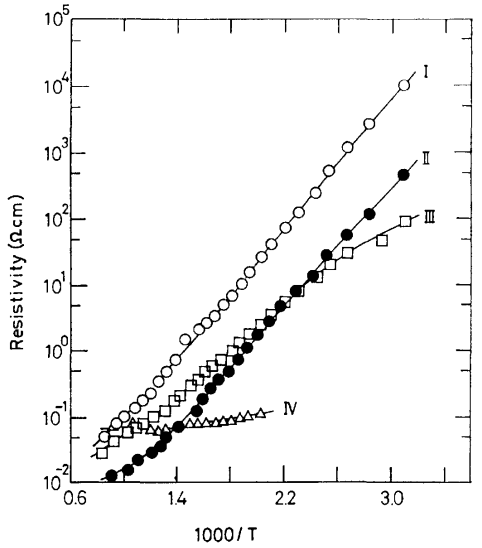

Fig. 2. Temperature dependence of resistivities of (La, Tb)$_2$CuO$_4$ compounds.
○(I): $La_{0.28}Tb_{1.72}CuO_4$, ●(II): $La_{0.6}Tb_{1.4}CuO_4$, □(III): $La_{1.4}Tb_{0.6}CuO_4$, △(IV): $La_{1.8}Tb_{0.2}CuO_4$.

tion, the shortening of the $(Cu–O)_a$ bond can be attributed to the π-bond formation of the t_{2g} orbitals of the Cu^{2+} ions and the degree of π-electron overlap increases with decreasing $(Cu–O)_a$ bond length. The $(Cu–O)_a$ bond length in phase 2 is between that of phase 1 and of La_2CuO_4 so that the $(Cu–O)_a$ bond in phase 2 can be expected to include π-bond characteristic although the electron overlap is not as great as for La_2CuO_4. The π-bond formation lowers the energy of the conduction band, resulting in a lower activation energy.

The fact that the composition range of phase 2 is very narrow and that the La/Tb ratio is two approximately suggests that the phase 2 compound is $La_4Tb_2Cu_3O_{12}$, although no super lattice lines due to ordering of the La^{3+} and Tb^{3+} ions were observed.

The triangles in Fig. 1 show the variation of the lattice parameters for the $(La,Pr)_2CuO_4$ compounds with $\bar{r}$. These lattice parameters change very critically at $\bar{r}=1.05$ Å. No stable specimens of compounds having $\bar{r}\simeq 1.05$ Å could be obtained; the pellets spontaneously reduced to powder when removed from the furnace and cooled to room temperature. Therefore, it was not determined whether or not the critical change in lattice parameters is accompanied by a semiconductor-metal transition, although shortening of the a axis and the very great lengthening of the c axis strongly suggests the same semiconductor-metal transition as that between La_2CuO_4 and Pr_2CuO_4.

As described previously, the La atom, which has the lowest electronegativity of the Ln atoms, causes the π-bond formation of the $(Cu–O)_a$ bond to which the metallic conductivity of La_2CuO_4 is ascribable. One can expect that for metals less electronegative than La, the effective charge of the O^{2-} ions on the c axis are enhanced to a value greater than that for La_2CuO_4 so that the $(Cu–O)_c$ bond is longer and the $(Cu–O)_a$ bond is shorter than in the case of the La atom. Since

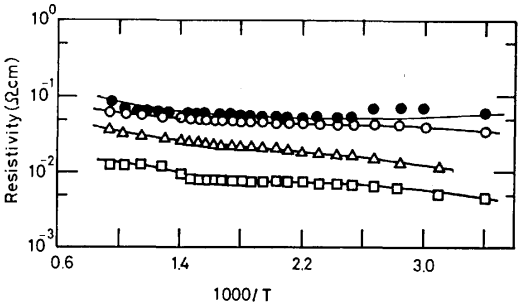

Fig. 3. Temperature dependence of resistivities of CaO-doped La_2CuO_4 compounds.
●: La_2CuO_4, ○: 2.5 mol% CaO-doped, △: 5 mol% CaO-doped, □: 20 mol% CaO-doped.

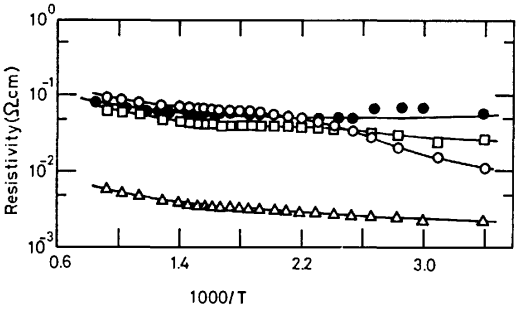

Fig. 4. Temperature dependence of resistivities of BaO-doped La_2CuO_4 compounds.
●: La_2CuO_4, ○: 2.5 mol% BaO-doped, □: 5 mol% BaO-doped, △: 10 mol% BaO-doped.

the shortening of the $(Cu–O)_a$ bond enhances the degree of π-electron overlap and this results in an enhancement of the conducting electron mobility, the replacement of the La^{3+} sites with less electronegative atoms will enhance the conductivity of La_2CuO_4. Calcium and barium are less electronegative than La and it is known that they can replace parts of the Gd^{3+} ions in Gd_2CuO_4.[4] Therefore, Ca^{2+} and Ba^{2+} ions can be expected to replace La^{3+} ions and to enhance the conductivity of La_2CuO_4. Figures 3 and 4 show the log ρ *vs.* $1000/T$ plots for CaO-doped and BaO-doped La_2CuO_4 compounds, respectively. These are seen to be metallic, with the resistivities of the former decreasing with increasing CaO content and, at 20 mol% doping, the ρ value decreases to one-tenth of that of undoped La_2CuO_4. Similarly, the BaO dopant lowers the resistivity; at 10 mol% doping the ρ value becomes one-tenth of that for undoped La_2CuO_4.

Table 1 gives the lattice parameters of undoped and 20 mol% CaO-doped and 10 mol% BaO-doped La_2CuO_4 compounds. Although the Ba^{2+} ion is larger than the La^{3+} ion, the a axis or the $(Cu–O)_a$ bond shortens due to the BaO-doping. This is evidence for

Table 1. Lattice parameters for undoped and CaO- and BaO-doped La_2CuO_4

	a(Å)	c(Å)	c/a
La_2CuO_4	3.808	13.200	3.466
$La_{1.6}Ca_{0.4}CuO_4$	3.790	13.189	3.480
$La_{1.8}Ba_{0.2}CuO_4$	3.796	13.274	3.497

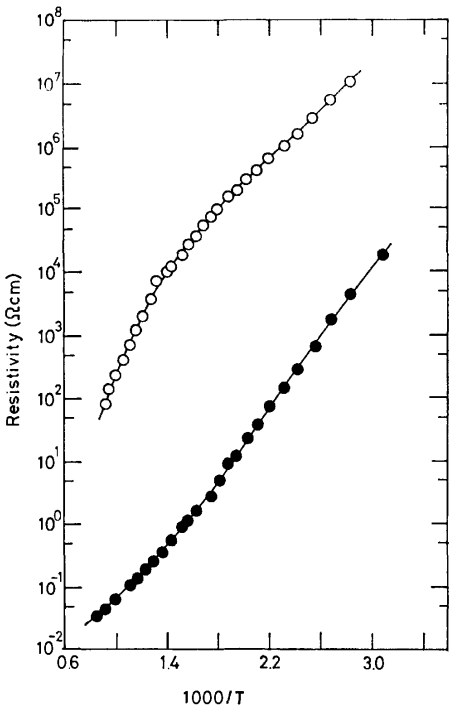

Fig. 5. Temperature dependence of resistivities of $Gd_{0.96}Tb_{1.04}Cu_2O_5$ (○) and $Gd_{0.84}Tb_{1.16}CuO_4$ (●).

an enhancement in the degree of π-electron overlap, which was expected. The CaO dopant shortens the a axis but enhances the c/a ratio. This suggests that the shortening of the a axis due to the CaO dopant is not only due to the smaller size of the Ca^{2+} ion, but is due partly to an enhancement of the π-electron overlap. Thus, the lowering of the resistivity due to doping with alkaline-earth oxides can be attributed to an increase in the degree of π-electron overlap in the conduction band.

The positive-charge deficiency in the La^{3+} site due to doping with divalent alkaline-earth ions may be balanced partly by the oxygen vacancies and partly by the formation of Cu^{3+} ions, as for alkaline-earth doped Gd_2CuO_4. This contributes to a decrease in the number of electron carriers, but the decrease in conductivity due to this effect is negligibly small in comparison with the increase in conductivity due to π-electron overlapping, since La_2CuO_4 is metallic.

The composition of the CuO–Ln_2O_3 system changes discontinuously between Gd and Tb; $CuO/Ln_2O_3=1$ for Ln=La—Gd and $CuO/Ln_2O_3=2$ for Ln=Tb—Lu. Since the $\bar{r}$ value can be varied continuously by varying the Gd/Tb ratio, the ternary system, Gd_2O_3–Tb_2O_3–CuO, will reveal how the CuO/Ln_2O_3 ratio depends upon the $\bar{r}$ value between Gd and Tb. Powder X-ray diffraction data reveal that the limit composition for a compound with $CuO/Ln_2O_3=1$ is $Gd_{0.84}Tb_{1.16}CuO_4$ and that for $CuO/Ln_2O_3=2$ is $Tb_{1.04}Gd_{0.96}Cu_2O_5$. This indicates that overlap occurs in both types of compounds for Gd/Tb ratios ranging from 0.72 to 1.08, that is, there is no critical ionic radius of the Ln^{3+} ions at which the Ln_2CuO_4 type compound transforms into the $Ln_2Cu_2O_5$ type compound.

$Tb_2Cu_2O_5$ is an insulator and Gd_2CuO_4 is a semiconductor.[1,2] It is not known whether this difference in the resistivities is ascribable to the difference in the crystal structures or to the difference in the ionic radii of the Gd^{3+} and Tb^{3+} ions. Figure 5 indicates that the resistivity of the $Tb_{1.04}Gd_{0.96}Cu_2O_5$ compound is still greater than that of the $Gd_{0.84}Tb_{1.16}CuO_4$ compound by three orders of magnitude, although the $\bar{r}$ value of the former is greater than that of the latter. Therefore, the difference in the resistivities of Gd_2CuO_4 and $Tb_2Cu_2O_5$ is not due to the difference in size of the Ln^{3+} ion but due to the difference in the crystal structures.

The Determination of the Critical Volume for the Free Motion of Solute Entities in an Aqueous Solution[1)]

Shizuo FUJIWARA, Kozo NAGASHIMA,* Hiroshi MORITA,** and Yasushi KANAOKA
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113
(Received December 27, 1976)

A certain volume of a solution, (20—30 Å)^3 per unit of solute entity, designated the "molecular space," is assigned as the necessary volume for the free motion of the solute. By the use of ESR, the actual size of the molecular space has been determined for the cupric ion and 2,2,5,5-tetramethyl-3-carbamoylpyrollidin-1-oxyl. It is pointed out that the concentrations of the important solutions in nature, such as sea water or human serum, may correspond to the moleuclar space of ions.

Solute entities in solution, such as ions or molecules, undergo diffusional and rotational motions in the solvent media. Those motions depend on the conditions of the solution, such as the concentration, the volume, the temperature, or the chemical propterties of the system, and the behavior of the solutes can be investigated by analogy with gaseous systems, where non-elastic and the elastic collisions characterize ideal and real gases. The free motion of the solute entity colud be defined as the motion in which the solute fulfils any one or a combination of the following conditions; 1) the motion is isotropic, 2) the solute does not exist as an ion-pair, 3) the solute is completely hydrated, or 4) the correlation time τ of the rotational motion obeys Debye's formula, $\tau_c=4\pi\eta a^3/3kT$, where η is the viscosity of the solution; a, the ionic radius; k, the Boltzman constant, and T, the absolute temperature. Whether or not the solute entity is in the state of free motion can be seen by its NMR or ESR spectral features. This paper will report that a certain volume of a solution is required for the maintenance of the free motion of the solute entity. The minimum volume of a solution which allows the solute entity free motion is defined as V_c. The results of the investigation which has been carried out for the measurement of V_c will be presented.

In the investigation, the magnitude of V_c was evaluated first by the examination of the concentration dependence of the linewidths of the ESR spectra of aqueous cupric ions. In this experiment, the conditions of 1, 2, and 3 cited above were taken as measures of the free motion of ions. (Experiment 1).

We planned then to measure V_c more directly by the control of the space of the solution available to the solute entity. Two systems were adopted for this purpose, one silica gel (Experiment 2) and the other, cross-linked poly(vinylalcohol), PVA, gel (Experiment 3). One of the most notable findings of these experiments is that the magnitude of V_c is several times larger than the actual size of the solute entity. The relevance of this finding will be discussed with respect to the recent results of the measurement of the viscosity or the relaxation times of magnetic resonance. The significance of V_c in nature will also be discussed in the text.

Experimental

Experiment 1: Concentration dependence of the ESR linewidth of cupric ions in aqueous solutions. The ESR linewidth of cupric ions in aqueous solutions, ΔH, has been measured as the function of the concentration of ions. As the details of the experimental conditions have already been published elsewhere,[2)] they will not be repeated in this article for except Fig. 1. Figure 1 has been reproduced for convenience, and it has been augmented with some additional data and a recalibration of the scale of the linewidth.

It is evident in Fig. 1 that ΔH is not dependent on the concentration nor on the anion species in the range lower than about 0.1 M. This result has been interpreted in terms of the fact that the cupric ions are wholly hydrated in the concentration range lower than 0.1 M, whereas, in the higher concentration range, ion pairs are formed, resulting in the reduction and the anion dependence of ΔH. Hence, the conditions of the free motion, 1, 2, and 3, which have been raised in the introduction, are fulfilled, and 0.1 M can be taken as the limiting concentration which allows the free motion of ions.

This value of the critical concentration refers to a certain volume of solution (a cube of 20Å) per ion ($=1000\ \text{ml}/2\times 0.1\times 6.02\times 10^{23}$).

Experiment 2: ESR pattern of aqueous solutions of Cu^{2+} adsorbed in silica gel. In order to evaluate V_c more directly, another experiment was undertaken*** with the use of aqueous solutions of cupric sulfate spread over the surface of silica gel.

Two types of experiment were performed: A) with the silica gel dipped in aqueous solutions of different concentra-

*** This section is a part of the B. Sc. thesis submitted by H. Morita to the University of Tokyo, 1970.

Table 1. Contents of water and cupric sulfate absorbed in silica gel

Sample	Mother solution	H_2O g/g SiO_2	Cu^{2+} mM/g SiO_2
i	0.25 M	1.1	0.26
ii	0.5 M	1.1	0.56
iii	1.0 M	1.1	1.1

The values of water and cupric ions refer to those contained in the silica gel just after it is taken out of the mother solution and after it has been drained.

tions of cupric sulfates, and B) with thin-layered silica gel plates over which the cupric sulfate was developed. In both cases, the ESR of the cupric ions and the contents of ions and water in silica gel were measured.

Conditions of Experiment 2-A:

Silica gel: Wako Gel,

ESR: J 3BS Spectrometer, made by Japan Electron Optics Laboratory Co. X band, 100 kHz modulation.

Procedure. The silica gel was put in equilibrium with three aqueous solutions (i, ii, and iii) with concentrations of 0.25, 0.5, and 1.0 M respectively. No solution with a concentration lower than *ca.* 0.2 M was adopted in the present experiment because of the limitations of the ESR measurements. After filtration, the excess solution was gently removed as drainage. The contents of water and cupric ions in the samples as well as the ESR were measured at the same time at this stage. As a wet sample lowers the Q value of the ESR spectrometer, the sample size must be kept small. This condition brings another difficulty-that the number of cupric ions which are brought into the ESR cavity is reduced. Efforts were made to find out the optimal conditions. Another difficulty lay in the treatment of silica gel. The silica gel which had became wet with the solution showed a tendency to squeeze the solution out of the gel when it was treated for the transference into the capillary sample tube of ESR measurements. Efforts were made to transfer the wet silica gel into the capillary without any distortion. The results of the analysis are shown in Table 1.

Results of 2-A: In Table 1 it may be seen that the water content is the same for all three samples, 1 ml/gSiO_2. This value may be taken as the volume of solution which can "naturally" be held in silica gel. As the results of the analysis of the copper content also show that 1.1 ml of each mother solution is held in the silica gel, *ca.* a 1-ml solution over gSiO_2 would be a good value of water, with reference to the value of V_c. With the values of the surface of the silica gel from 4 to 6, m^2/gSiO_2†, a water layer 20±5 Å thick (=1 ml/4—6 m^2) is taken as the space which allows the solute ions "almost" free motion. The motion in the latter case is called "almost free" because the ions with the concentration of the experiment are assumed to be ion-paired to some extent. There was a slight worry that the samples might hold excess solution as a result of an incomplete removal of the drainage. Accordingly, Experiment 2-B was carried out, where the samples were assumed to be prepared in more homogeneous condition.

Experiment 2-B: Thin-layered silica gel plates were prepared on glass plates according to the usual technique of thin-layer chromatography. The thickness of the silica gel layers was assumed to be a few hundred microns. The silica gel used is the one same used in Experiment 2-A.

Two solutions of cupric sulfate with concentrations of 0.20 and 0.46 M were developed in the layers. After the development, each layer of silica gel was cut into 9 portions, equal in length, from the bottom to the top of the plate. The contents of water, cupric, and sulfate ions were measured as well as the ESR spectra for all samples. Table 2 presents the results of the measurement with respect to the bottom portion of the plates.

† Determined by the nitrogen gas adsorption.

Table 2. Water content in silica gel just after the development of the solution of cupric sulfate

Sample	Mother solution	H_2O Content just after development
iv	0.20 M	1.2 g/g SiO_2
v	0.46 M	1.0 g/g SiO_2

Results of 2-B. In Table 2 it may be seen that the two samples of thin-layered silica gel, iv and v, also hold about 1 ml (actually 1.2 and 1.0 ml) of the solution. Because the patterns of the ESR spectra are of a single line with a fairly good symmetry, it is certain that the cupric ions are in a state of almost "free' motion. Summarizing the results of A and B, the ions in the samples of both cases are in almost "free' motion in the water layer (20±5 Å thick) which is spread over the surface of the silica gel.

Experiment 3††: *Use of the network of γ-irradiated PVA.* For the purpose of the measurement of V_c, the cross-linked network of polyvinyl alcohol, PVA, which was produced by the γ-ray irradiation was utilized. By the γ-ray irradiation of the aqueous solution of PVA, the latter molecules are cross-linked and form a three-dimensional network. The average distance between the end terminals of the PVA molecules, $\langle l \rangle$, can be controlled by the control of the concentration of PVA, C, and the total dose of the γ-rays, R. The value of $\langle l \rangle$ actually refers to the size of the hole in the network which can hold ions in the solution. Thus, the cross-linked PVA gel is used as a convenient medium for the control of the motion of the solutional ions. Some examples of the application have already been reported.[3]

The value of $\langle l \rangle$ may be calculated according to the following equation:[4]

$$\langle l \rangle = 2.5 \times [(5.1 \times 10^8 + 1.37 \times 10^8 C)/R]^{1/2}, \quad (1)$$

where C refers to the value in g PVA per 100 ml of H_2O and R is in rads. In practice, the degree of the polymerization of PVA is about 2000, and C is 5 g PVA/100 g H_2O. The source of the γ rays is the University of Tokyo, the γ-ray source of Co-60 with 3000 Curies, and R is 2×10^6 rads. First in this experiment, a), the symmetry of the ESR spectra was examined by a comparison of the half-maximum linewidths of the two parts of the derivative curve. That is, after recording the derivative of the single line of the ESR absorption spectrum, the half-maximum linewidths, Δh_1 and Δh_2, were measured with respect to both the higher-field and lower-field parts (*cf.* Fig. 2), respectively. It was confirmed that the cupric ions in the gel of $\langle l \rangle$ almost equal to, or smaller than, 25 Å gave Δh_2 values for the lower field side derivative about 5% larger than the Δh_1 values for the higher-field side. However, the ions showed almost symmetric lines in the gel of $\langle l \rangle$ larger than 25 Å. That is, the V_c for Cu^{2+} ions was counted as about 25 Å.

In the b) experiment, the relative heights of the three hyperfine lines of the ESR signal of the radical were compared. The correlation time, τ_c, was then calculated by the use of the observed results and the following equation,[5] where the

†† This section forms a part of the B. Sc. thesis of Yasushi Kanaoka, University of Tokyo, 1975.

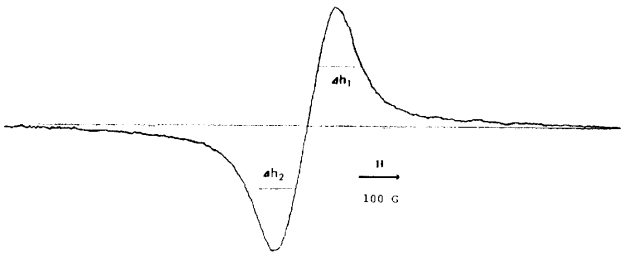

Fig. 2. Derivative of the ESR spectrum of Cu^{2+} 0.01 M solution in PVA gel of $\langle l \rangle = 20$ Å, where $\Delta h_1 > \Delta h_2$ by 5%. When $\langle l \rangle \geqq 25$Å, $\Delta h_1 = \Delta h_2$.

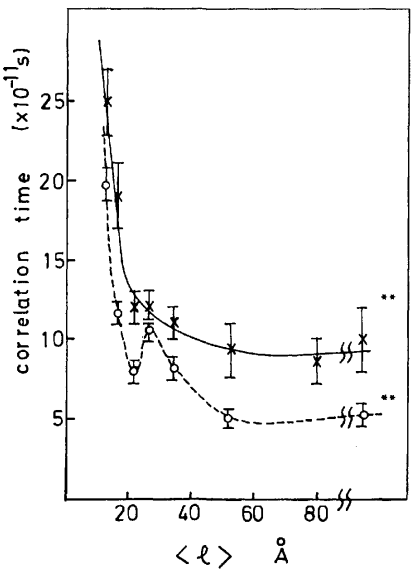

Fig. 3. Correlation time, τ_c, for the motion of 2,2,5,5-tetramethyl-3-carbamoylpyrrolidin-1-oxyl, TMCA, as the function of the molecular space in PVA gel.

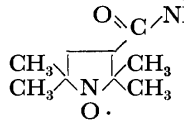

—×—: 0.01 M in PVA gel, —○—: 0.001 M in PVA gel, **: τ_c in bulk solution.

values of the hyperfine constants of A_{xx}, and A_{zz} were obtained from the literature:[6]

$$\tau = \left[\left(\frac{h(0)}{h(1)}\right)^{1/2} + \left(\frac{h(0)}{h(-1)}\right)^{1/2} - 2\right] \times \frac{3\pi\Delta\nu(0)}{2C_2}, \quad (2)$$

where $C_2 = 2\pi/9[A_{zz} - A_{xx}]^2$ and where h refers to the derivative height of each hyperfine line. The results of the measurement are shown in Fig. 3, where a marked increase of τ_c is seen in the gels of $\langle l \rangle$ lower than about 20 Å.

Discussion

According to the results of all the experiments shown above, it is evident that a certain volume of a solution, $(20 \pm 5)^3$ Å per unit solute entity, is required for the free motion of the solute entity of a simple structure, like Cu^{2+} or a low-molecular-weight compound. A problem of current interest is the fact that V_c is several times larger than the real size of the solute entity. This fact may have some connection with the discussion related with the microviscosity, which assumes the presence of a structural sphere surrounding the solute entity.[7] It may also be related to the discussion which has recently been made in the field of magnetic relaxation.[8] It should be stressed that V_c has been measured directly in the present investigation, unlike as in former investigations of microviscosity or magnetic relaxation. Further investigation will be necessary for a real understanding of the structure of V_c. Another point to be noted in this article is the possible significance of V_c in nature. As one considers the situation of the solute entity, where it is held in the concentration range of V_c, the whole system of the solution is assumed to be stabilized by the buffer action of the solute entity. That is, in the solution where the solute entity just holds the space of V_c, each individual solute entity behaves as free from the others and also as free from the external system. Nevertheless, it should easily respond to the action of the external system, for the concentration is not far from the condition which produces the mutual interaction of the solutes or the reaction with the external system. In connection with this statement, reference may be made to the fact that the concentrations of the salt in the important solutions in nature fall in the range of the concentration of V_c. For example, the concentration of the human serum is about 0.1 M, that of the silk worm egg is 0.1 M,[9] and that of the sea water is about 0.5 M. In addition to this, we may refer to the work of Ehrenberg.[10] He assumed the case of an adult human with a body of weight of 70 kg, 50 kg of water and 20 kg other materials, mainly organic. He evaluated the total interface of the macromolecules (and membranes) to be of the order of 10—100 km^2 (10^7—10^8 m^2). If one spreads, according to this formula, the 50 kg of water in an uniform layer over this area, the thickness of the layer becomes 5—50 Å. He assumes that there would be, on the average, less than 20 water molecules between the most distant point in the water and the surface.

Valuable discussions with Professors K. Higasi and A. Ehrenberg are heartily acknowledged.

Studies of the Aqueous Solutions of Guanidinium Salts. VI. Complexes of Guanidinium Halides and Symmetrical Tetraalkylammonium Halides

Koichiro MIYAJIMA, Hiromitsu YOSHIDA, and Masayuki NAKAGAKI

Faculty of Pharmaceutical Sciences, Kyoto University, Yoshidashimoadachi-cho, Sakyo-ku, Kyoto 606

(Received March 22, 1977)

Guanidinium halides (bromide and chloride) form crystalline complexes with symmetrical tetraalkylammonium bromides (tetraethyl-, tetrapropyl-, and tetrabutylammonium bromides and tetrabutylammonium chloride) in aqueous solutions at room temperature. These complexes were analyzed and found to be either binary complexes of two kinds of salts or ternary complexes with water as a third component. Each complex showed complicated peaks in the DSC measurements, which indicated the phase transition in the solid state. The solubility of each salt in ternary systems was measured, and phase diagrams were constructed for some of the ternary systems. A mutual salting- in effect was observed in all the ternary systems, and this effect was discussed in terms of complex formation and the structual change of water.

The guanidinium ion has a strong resemblance to urea in its shape, size, and functional group except for a charge which is distributed around the periphery of the disc-shaped ion. Even in aqueous solutions, the guanidinium ion and urea have a similar effect toward hydrophobic solutes when they are mixed with hydrocarbon gas[1] and symmetrical tetraalkylammonium salts.[2,3] These properties of urea and guanidinium salts are regarded as the main factor in the denaturation of protein in their aqueous solutions.[4] In 1966 Saito *et al.*[5] reported the complex formation of urea with various tetraalkylammonium salts in aqueous solutions. Therefore, it seems worthwhile to investigate the interaction between a hydrophobic solute and a guanidinium salt in an aqueous solution, especially at a high concentration.

From these points of view, we studied the mutual solubility of a guanidinium halide and a symmetrical tetraalkylammonium halide in aqueous solutions and isolated crystalline complexes containing each salt from aqueous ternary solutions. In this paper, we wish to report the preparation and characterization of various crystalline complexes formed by guanidinium halides and tetraalkylammonium halides in aqueous solutions. In addition, the solubilities of these salts were measured in ternary solutions, the total concentrations and the mole ratio being changed. From these data, phase diagrams were constructed for some of the ternary systems.

Experimental

Materials. Symmetrical tetraalkylammonium halides were obtained from the Nakarai Chemical Co., and were purified by recrystalization from appropriate solvents described elsewhere.[6] The guanidinium halides used were the same as those of the previous paper.[7] Reagent-grade urea obtained from Wako Chemical Co., Ltd., was used without further purification after being dried *in vacuo*.

Preperation of Complex. A guanidinium halide and a tetraalkylammonium halide were mixed at an appropriate mole ratio, after which a desired quantity of water was added to dissolve the solid. The solution was then subjected to natural evaporation in an open beaker at room tempetature. The crystals thus formed were collected by filtration, cut to small pieces, and pressed between filter papers to remove the mother liquid. These crystals were powdered and dried for several hours at a relative humidity of 30—50% at room temperature and used for the direct analysis of complexes.

Method of Analysis. For each of the crystalline complexes, wet residues, and saturated solutions, the halide ion was determined by Mohr's method, and the tetraalkylammonium ion, by colorimetry. The latter method is based on the fact that the tetraalkylammonium ion and Metyl Orange form a complex which is slightly soluble in water and soluble in organic solvents, such as chloroform and 1,2-dichloroethane. Therefore, the contents of the tetraalkylammonium ions were determined by measuring the optical densities of extracted solutions of the tetraalkylammonium–Methyl Orange complex at 425 nm. This method was useful in the presence of guanidinium salts. The difference between the contents of the halide and tetraalkylammonium ions correspond to the content of the guanidinium ion. The water content was also deternined from these values and the total weight of the sample.

The phase diagrams were obtained by Schreinmakers' "wet residue" method.[8] In this method, the solid components were dissolved in water at various concentrations, and solutions were agitated in a thermostat until equilibrium was reached. Then the liquid phase and the wet residue were separated, and both were weighed and determined. The compositions obtained by the above procedure are plotted on a triangular diagram in Fig. 1. Let the points a, b, and c represent the compositions of the saturated solutions, and the points a′, b′, and c′, the compositions of the corresponding wet residues. Then, the tie-line a-a′, b-b′, and c-c′, must pass, on the extention past a′, b′, and c′, through the composition of the solid complex P.

Results

Crystalline Complexes and Phase Diagrams. Tetrabutylammonium Bromide [(n-*Bu*)$_4$*NBr*]*–Guanidinium Bromide* [*GuBr*]*–Water.* By applying Scheinmakers' wet residue method, the triangular diagram shown in Fig. 1 was obtained for the (n-Bu)$_4$NBr–GuBr–H_2O system. In this diagram, A and B are the solubilities of (n-Bu)$_4$-NBr and GuBr respectively in water at 25 °C. Curve ACDB shows the compositions of saturated solutions containing both (n-Bu)$_4$NBr and GuBr. As is shown in the plots, Scheinmakers' wet residue method indicated the presence of the P complex, which contains equimolar amounts of (n-Bu)$_4$NBr, GuBr, and H_2O in a crystal. This conclusion was confirmed by the direct analysis of the crystal obtained from mixed solutions containing both salts in different mole ratios. The crystal form

and the melting point of the complex are shown in Table 1. The crystal of the P complex is stable in an atmosphere at room temperature, but when it was allowed to stand for several hours *in vacuo* at room temperature, it melted by losing water. The amount of water lost corresponded almost exactly to the amount obtained by the direct analysis of the crystal. Tetrabutylammonium bromide forms a clathlate hydrate, $(n\text{-Bu})_4NBr \cdot 32.8H_2O$ at low temperature.[9] Therefore, the same experiment as was done at room temperature was carried out again at 3 °C, no clathlate hydrate was found to form when enough guanidinium bromide was dissolved in the solution. In the $(n\text{-Bu})_4NBr\text{–}GuCl\text{–}H_2O$ or $(n\text{-Bu})_4NCl\text{–}GuBr\text{–}H_2O$ system, a similar crystalline complex was isolated from the mixed solutions, but the half mole of the bromide ion was replaced by the chloride ion in the crystal.

Tetrapropylammonium Bromide $[(n\text{-}Pr)_4NBr]\text{–}GuBr\text{–}H_2O$. As is shown in Fig. 2, the wet residue method indicated the presence of two kinds of complexes, P′ and Q′. These complexes did not contain water, and the mole ratio of $(n\text{-Pr})_4NBr$ and GuBr was 2 to 1 and 3 to 5 for the P′ and Q′ complexes respectively. The crystal forms and melting points are shown in Table 1.

Tetraetylammonium Bromide $[(Et)_4NBr]\text{–}GuBr\text{–}H_2O$. Tetraetylammonium bromide also formed two kinds of complexes with GuBr in aqueous solutions. As is shown in Fig. 3, the P″ complex contained equimolar amounts of the two salts, and no water, while the Q″ complex contained $(Et)_4NBr$, GuBr, and H_2O in the mole ratio of 1 : 2 : 1. The crystal forms and melting points are shown in Table 1.

We did not study ternary systems containing the salts with only a chloride or iodide ion as a common anion, but we may predict with a high possibility of success the formation of crystalline complexes in these systems, judging from the formation of a crystalline complex in the $(n\text{-Bu})_4NBr\text{–}GuCl\text{–}H_2O$ system.

Thermochemical Properties of the Complexes. For the elucidation of the thermochemical properties of these complexes, DSC was employed. Some typical DSC charts and heats of fusion are shown in Fig. 4. and Table 2 respectively. The heats of fusion were determined by comparing the peak area with that of urea. As may be seen in Fig. 4, these DSC charts may be classified into three typical groups. A peak with a shoulder is observed for Type A, a doublet peak for Type C, and two isolated peaks for Type B. No complex shows

Table 2. Some thermochemical properties of the crystalline complexes

Complex	Type of chart	Transition temp by DSC (°C)	Heat of transition (kcal/mol of complex)
$[(n\text{-Bu})_4NBr][GuBr][H_2O]$	A	59.6 (shoulder) 63.7 (peak)	2.68
$[(n\text{-Pr})_4NBr]_2[GuBr]$	B	135.4 (peak) 155.2 (peak)	1.43 1.59

a single peak. These phenomena seem to suggest the presence of polymorphism in each complex. As may be seen in Table 2, the melting points, as determined by the usual method, correspond to the temperature of the second peaks in Fig. 4. Therefore, the shoulders of the first peaks in Fig. 4 may arise from the phase change in the solid states. The structure of these complexes are now being studied by means of X-ray diffraction analysis.

Solubility Measurement. As is shown in Fig. 1, 2, and 3, the solubility of each salt in a ternary solution increased as compared with that in pure water. The effect of tetraalkylammonium bromide on the solubility of GuBr is shown in Fig. 5. Each tetraalkylammonium bromide has a salting-in effect toward GuBr in aqueous solutions, $(n\text{-Bu})_4$NBr having the strongest effect among them. As is shown in Fig. 6, GuBr also has a salting-in effect toward tetraalkylammonium bromide and is most effective toward $(n\text{-Bu})_4$NBr. These phenomena constitute the so-called "mutual salting-in" effect. These salting-in effects of GuBr toward tetraalkylammonium bromides are greater than those of urea.[5] This fact is consistent with the effectiveness of GuBr and urea for protein denaturation in aqueous solutions.

Discussion

Guanidinium halides form complexes with symmetrical tetraalkylammonium halides in aqueous solutions just as urea does, though the compositions of complexes are not the same. However, the fact that urea, thiourea,[5] and guanidinium halides form complexes with symmetrical tetraalkylammonium halides suggests that the shape, the size, and the functional group play important roles in the reaction of the complex formation, although there is a quite significant difference (electrolyte and nonelectrolyte) between urea and guanidinium halides.

$(n\text{-Bu})_4$NBr does not form a clathlate hydrate, but does form complexes with guanidinium halides in the presence of enough guanidinium halide, even at low temperatures. This fact indicates the presence of a stronger interaction between guanidinium bromide and $(n\text{-Bu})_4$NBr than between water and $(n\text{-Bu})_4$NBr. As for the structures of crystalline complexes, we must await a detailed X-ray analysis. However, the following things may be deduced. $(n\text{-Bu})_4$NBr forms the clathlate hydrate in which the tetrabutylammonium ion is surrounded by a cage formed by water molecules and bromide ions.[9] In contrast with the clathlate hydrate, the amount of guanidinium bromide and water in the crystalline complex seems to be too small to form a cage. On the other hand, the difference of ionic size between the guanidinium ion and the tetrabutylammonium ion is too much to form a mixed crystal as in the case of alkali halide. Therefore, the crystal structures of these tetraalkylammonium halide-guanidinium halide complexes may be different from those of either a clathlate hydrate or a mixed crystal.

We can postulate two kinds of mechanisms for the mutual salting-in effect in the ternary systems. One is the salting-in due to the formation of a water-soluble complex in the ternary solutions (Mechanism A). If the water-soluble complex is a 1-to-1 complex of GuBr and tetraalkylammonium bromide, and if the specific hydration of the complex is not taken into account, the solubility ratio (S/S_0) must be proportional to the concentration of the solubilizing salt (m) and the slope must correspond to $KS/(1+KS_0)$, where K is the formation constant of the water-soluble complex. As has been stated in the experimental section, tetrabutylammonium bromide and tetraethylammonium bromide form a crystalline complex in which guanidinium bromide and tetraalkylammonium bromide are in a mole ratio of 1-to-1. However, as may be seen in Figs. 5 and 6, a linear relation between (S/S_0) and m was not obtained in either case. This fact suggests that even if the water-soluble complexes were formed in an mixed aqueous solution, the compositions of water-soluble complexes would be different from those of crystalline complexes.

The other mechanism is the salting-in due to the interaction between the guanidinium ion and the tetraalkylammonium ion through the alteration of the water structure (Mechanism B). The guanidinium ion is a structure breaker, while the tetraalkylammonium ions are hydrophobic structure makers. Since an aqueous solutions of tetraalkylammonium bromide is more structured than pure water, the guanidinium ion breaks the water structure in the aqueous solution of tetraalkylammonium bromide more clearly than that in pure water. This effect decreases the activity coefficient of guanidinium bromide. On the other hand, when tetraalkylammonium bromide is added to an aqueous solution of guanidinium bromide, which is less structured than pure water, the ability of the tetraalkylammonium ion to form a water structure will decrease as compared with that in pure water. Thus, the effect of the addition of guanidinium bromide on the structure of water is similar to that of the elevation of the temperature. This effect decreases the activity coefficient of tetraalkylammonium bromide.

We can say that Mechanism A is based on the contribution of the enthalpy change, while Mechanism B is based on that of the entropy change. The thermodynamic way of determining which of these two mechanisms is really working is to measure the free energy and the heat change on mixing these two salts in an aqueous solution. When the free energy change on mixing tetrabutylammonium bromide and guanidinium bromide in an aqueous solution was investigated, large negative free energy changes were obtained.[3] Therefore, a promising avenue to the elucidation of the mutual salting-in effect may be to measure the heat of mixing tetraalkylammonium and guanidinium bromides in aqueous solutions.

^{31}P Magnetic Relaxation in Polynucleotides*

Kazuyuki AKASAKA, Atsuko YAMADA, and Hiroyuki HATANO
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606
(Received April 11, 1977)

Phosphorus-31 nuclear spin-lattice relaxation times and nuclear Overhauser enhancement upon nonselective proton saturation were measured on polyriboadenylic acid, polyribocytidylic acid, and polyribouridylic acid. A method is described to separate dipolar contribution from the contribution of chemical shift anisotropy for the phosphorus relaxation by the combined use of T_1 and NOE data. Chemical shift anisotropies ($\delta_{//}-\delta_{\perp}$) of phosphorus in these polynucleotides in solution are estimated to be in the range 120—165 ppm. The molecular motion of the phosphorus moiety becomes faster in the order, poly(A)<poly(C)<poly(U), the thermal activation processes being characterized by single activation energies, *i.e.*, 5.1, 5.3—6.0, and 7.2—8.1 kcal/mol for poly(U), poly(C), and poly(A), respectively.

Phosphorus nucleus plays a key role in the main chain structure of nucleic acids. Its relatively large nuclear moment with its 100% natural abundance makes the ^{31}P nucleus a good sample for nuclear magnetic resonance studies. Numerous reports are available on ^{31}P magnetic resonance of nucleic acid systems, but most of them are based on the analysis of chemical shift[1] and spin-spin coupling constant.[2] Studies of nucleic acids by ^{31}P relaxation measurements have only recently begun, and their relaxation mechanisms and use for the study of nucleic acid structures and dynamics have not been investigated in detail.

Akasaka studied dynamic structure of polyriboadenylic acid using ^{31}P relaxation assuming solely dipolar mechanism for relaxation.[3] Recently Hayashi *et al.* applied ^{31}P relaxation to studies of structures of yeast transfer RNA^{phe} based on more rigorous analysis of ^{31}P relaxation including the contribution from chemical shift anisotropy.[4] In the present paper, a detailed account is given on the method of analysis of ^{31}P relaxation as well as the results of its application to single-stranded polyribonucleotides.

Experimental

Materials. Homopolyribonucleotides (poly(A), poly(C), and poly(U)) (M_r>100,000) from Sigma Chemical Company were used. They were dialyzed extensively in 0.1 M NaCl, mainly to remove paramagnetic metal ions. Samples for ^{31}P NMR measurements were prepared in concentrations of 60—90 mM (in monomer unit) in 99.75% D_2O containing a small amount of EDTA ([EDTA]/[P]=1/20). All the samples were throughly degassed on a vacuum line before NMR measurements.

ApU (from Sigma) was treated with chelex and then prepared for NMR measurements as in the case of polynucleotides.

Methods. Measurements of ^{31}P spin-lattice relaxation times (T_1) were performed on a JEOL PFT-100 Fourier transform NMR spectrometer operating at 40.48 MHz under proton noise irradiation, by utilizing 180°-t-90° (inversion recovery) pulse sequences.

Nuclear Overhauser enhancement of ^{31}P resonance upon proton irradiation was obtained as relative integrated intensity of ^{31}P resonance between conditions with the proton noise-decoupler on and off by using sodium pyrophosphate as an internal standard. The proton decoupling power was kept less than 10 watts to avoid temperature rise in the samples.

* Presented at XVth NMR Symposium of Japan, Tokyo, October 1976.

Analysis of ^{31}P Relaxation

Three major mechanisms are considered to be important in determining ^{31}P longitudinal relaxation in nucleic acids:
(1) dipolar interaction with neighbouring protons, (2) chemical shift anisotropy, and (3) interaction with paramagnetic ions. These interactions are coupled with molecular motions to cause phosphorus relaxation in solution, and must be separated in order to utilize ^{31}P relaxation for a quantitative study of nucleic acid structures and dynamics.

First, the contribution from paramagnetic impurities and dissolved oxygen can be removed almost throughly (see Experimental). The absence of paramagnetic effects can be verified by observation of large nuclear Overhauser enhancements.

Separation of the dipolar contribution from the chemical shift anisotropy contribution is more intricate, requiring inspection into the nature of the relaxation mechanisms. One way frequently used on phospholipid systems[5] is to measure line widths at more than one observing frequency. This is based on the fact that, while the magnitude of the dipolar interaction is independent of the observing frequency ω, that of the chemical shift anisotropy depends on ω^2.[6] However, often in ^{31}P line width, contribution from the component that is linearly dependent ω can not be neglected, leading to errors in the evaluation of chemical shift contribution. Moreover, the availability of ^{31}P NMR spectrometers for a few to several different frequencies can not be usually expected.

In the present work, we have taken an alternative approach for separating two mechanisms, utilizing nuclear Overhauser enhancement of ^{31}P signals upon saturation of proton signals. The utility of the method lies in the fact that the nuclear Overhauser effect occurs only in the case of dipolar relaxation with protons, but not in the case of chemical shift anisotropy relaxation.

Following three basic assumptions are made. (1) The molecular motion of the phosphorus moiety can be approximated as isotropic and is therefore characterized by a single correlation time τ_c. (2) The same correlation time τ_c can be used in common for both the dipolar relaxation and the chemical shift anisotropy relaxation. (3) The geometrical as well as the electronic structure of the phosphorus moiety is invariant in the measured

temperature range so that the distances between the phosphorus atom and the neighbouring protons (*e.g.*, $H_{3'}$, $H_{5'}$, and $H_{5''}$) as well as the anisotropy in the phosphorus chemical shift can be treated as temperature independent quantities.

Assumptions (1) and (2) are expected from simple approaches in NMR theory[6], and can be allowed as a first step. On the other hand, (3) might not be justified easily in a relatively flexible polymer such as a single-stranded polynucleotide. However, as an example, in the case of ApA and UpU phosphorus-proton coupling constants, $^3J_{PH_{5'}}$, $^4J_{PH_{4'}}$, and $^3J_{PH_{3'}}$, show only small variations (less than 10%) in going from 20 °C to 80 °C,[7] indicating relative invariance of rotamer populations about the $C_{3'}$—$O_{3'}$ and $C_{5'}$—$O_{5'}$ bonds with temperature. Unfortunately, no such data are available for polynucleotides, but the variations in rotamer populations might be expected to be even smaller in polynucleotides. In view of this, assumption (3) is considered to be reasonable.

Based on assumptions (1) and (2), the time dependence of the longitudinal magnetization $\langle I_Z\rangle_P$ of phosphorus, in the absence of relaxation contribution from paramagnetic impurities, should obey the equation[8]

$$\frac{d\langle I_Z\rangle_P}{dt}=(\sum_i\rho_{PH_i}+\rho_P)(I_{0P}-\langle I_Z\rangle_P)+\sum_i\sigma_{PH_i}(I_{0H_i}-\langle I_Z\rangle_{H_i}), \tag{1}$$

where I_{0P} and I_{0H_i} denote the magnetization of phosphorus and the i-th proton, respectively, at thermal equilibrium with the lattice, and $\langle I_Z\rangle_P$ and $\langle I_Z\rangle_{H_i}$ the magnetization of phosphorus and i-th proton, respectively, at time t after application of a 180° pulse.

ρ_{PH_i} and σ_{PH_i} are relaxation terms due to dipolar interaction between the phosphorus nucleus and the i-th proton, and expressed by

$$\rho_{PH_i}=\frac{\gamma_P^2\gamma_H^2\hbar^2}{r_i^6}\left\{\frac{1}{10}\frac{1}{1+(\omega_P-\omega_H)^2\tau_c^2}+\frac{6}{10}\frac{1}{1+(\omega_P+\omega_H)^2\tau_c^2}+\frac{3}{10}\frac{1}{1+\omega_P^2\tau_c^2}\right\}\tau_c, \tag{2}$$

$$\sigma_{PH_i}=\frac{\gamma_P^2\gamma_H^2\hbar^2}{r_i^6}\left\{-\frac{1}{10}\frac{1}{1+(\omega_P-\omega_H)^2\tau_c^2}+\frac{6}{10}\frac{1}{1+(\omega_P+\omega_H)^2\tau_c^2}\right\}\tau_c, \tag{3}$$

where r_i represents the distance between the phosphorus atom and the i-th proton, ω_P and ω_H are the Larmor angular frequencies for phosphorus and proton, respectively. ρ_P is the relaxation term due to chemical shift anisotropy and given by[6]

$$\rho_P=\frac{2}{15}(\delta_{//}-\delta_\perp)^2\omega_P^2\frac{\tau_c}{1+\omega_P^2\tau_c^2}, \tag{4}$$

where axial symmetry is assumed for the chemical shift tensor.

Under saturation of all the proton resonances due to proton-noise irradiation, $\langle I_Z\rangle_{H_i}=0$ for all i and Eq. 1 can be solved, giving

$$\langle I_Z\rangle_P=I_{0P}\left(1+\frac{\sum_i\sigma_{PH_i}}{\sum_i\rho_{PH_i}+\rho_P}\cdot\frac{\gamma_H}{\gamma_P}\right)(1-2e^{-t/T_1}), \tag{5}$$

with

$$\frac{1}{T_1}=\left(\frac{1}{T_1}\right)_{dipole}+\left(\frac{1}{T_1}\right)_{c.s.a.}=\sum_i\rho_{PH_i}+\rho_P$$
$$=A\left\{\frac{1}{10}\frac{1}{1+(\omega_P-\omega_H)^2\tau_c^2}+\frac{6}{10}\frac{1}{1+(\omega_P+\omega_H)^2\tau_c^2}+\frac{3}{10}\frac{1}{1+\omega_P^2\tau_c^2}\right\}\tau_c+B\cdot\frac{\tau_c}{1+\omega_P^2\tau_c^2}, \tag{6}$$

where

$$A=\sum_i\frac{\gamma_P^2\gamma_H^2\hbar^2}{r_i^6}, \tag{7}$$

$$B=\frac{2}{15}\omega_P^2(\delta_{//}-\delta_\perp)^2. \tag{8}$$

The fractional increase (η) of phosphorus magnetization upon saturation of proton signals, *i.e.*, the nuclear Overhauser enhancement, is given by

$$\eta=\frac{\sum_i\sigma_{PH_i}}{\sum_i\rho_{PH_i}+\rho_P}\cdot\frac{\gamma_H}{\gamma_P}=\frac{2.47\sum_i\sigma_{PH_i}}{\sum_i\rho_{PH_i}+\rho_P} \tag{9}$$

Under conditions of extreme narrowing ($(\omega_P+\omega_H)^2\tau_c^2\ll1$), Eqs. 6 and 9 become

$$\frac{1}{T_1}=(A+B)\tau_c, \tag{10}$$

$$\eta=1.235\left(\frac{A}{A+B}\right). \tag{11}$$

If we may assume that the average molecular conformation of the ribose-phosphate moiety does not change significantly with temperature (assumption (3)), we may regard A and B as parameters independent of temperature.

$1/T_1$ expressed by Eq. 6 goes through a maximum (or T_1 goes through a minimum) at a certain value of τ_c ($\tau_c\simeq\omega_P^{-1}$), the particular value of which depending on the observing frequency ω_P and the relative values of A and B. On the other hand, the nuclear Overhauser enhancement η, which is nearly zero or very small for $\tau_c>\omega_P^{-1}$ (see Eq. 9), increases monotonically with the decrease of τ_c to a final value given by Eq. 11. Such behavior of T_1 and η is illustrated in Fig. 1, as a function of τ_c for three representative cases, $B=0$, $A/B=1$, and $A=0$.

Information Obtainable from ^{31}P Relaxation and Nuclear Overhauser Enhancement

In practice, if we know the relative values of A and B from measurements obtained under extreme narrowing conditions (Eq. 11), we can determine the τ_c value at the minimum point of T_1 by using Eq. 6. Knowing both the τ_c value and the T_1 value at the minimum point of T_1, we can also determine from Eq. 6 the absolute values of A and B, which in turn, give information as to the effective phosphorus-proton distance, defined by

$$\bar{r}_{P-H}=(\sum_i 1/r_i^6)^{-1/6}, \tag{12}$$

and the magnitude of the effective ^{31}P chemical shift anisotropy ($\delta_{//}-\delta_\perp$) in solution.

Since A and B values are fixed as temperature invariant quantities, the only unknown variable in the right-hand side of Eq. 6 is τ_c. From a measured

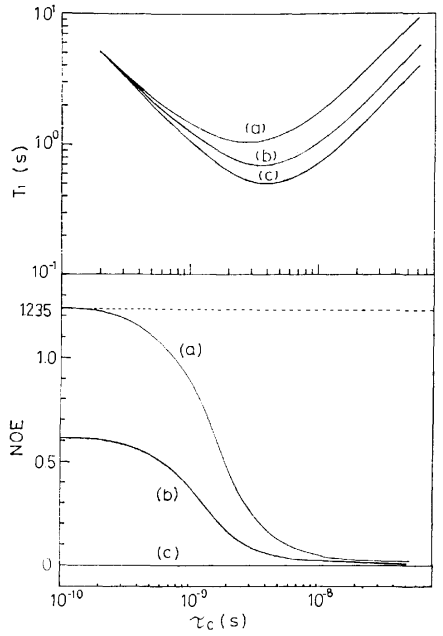

Fig. 1. Theoretical dependence of ^{31}P spin-lattice relaxation time (T_1) and the nuclear Overhauser enhancement (η) upon nonselective proton saturation on the rotational correlation time τ_c for three representative cases of relaxation mechanism:
(a) dipolar 100% ($B=0$ in Eq. 6), (b) dipolar 50%, chemical shift anisotropy 50% ($A/B=1$), (c) chemical shift anisotropy 100% ($A=0$). Isotropic molecular rotation is assumed and the resonance frequency of ^{31}P nucleus at 40.5 MHz is presumed.

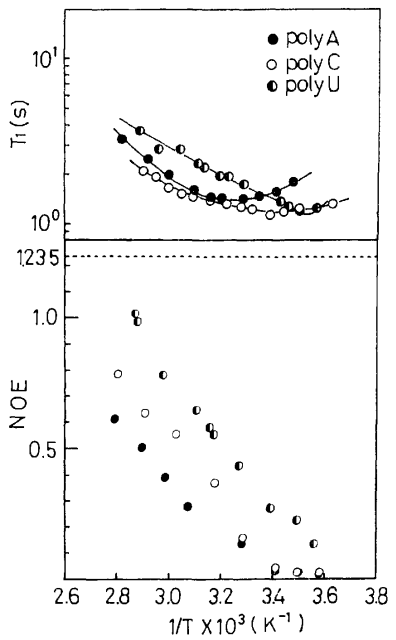

Fig. 2. Temperature dependence of ^{31}P spin-lattice relaxation times and ^{31}P nuclear Overhauser enhancement (η) upon nonselective proton saturation of poly U, poly C, and poly A in neutral D_2O solutions (pH= 6.0+0.1, $[Na^+]=0.1$ M). Concentration of polynucleotides are 92 mM for poly U, 73 mM for poly C, and 60 mM for poly A (monomer unit).

value of T_1 at any desired temperature, we can determine τ_c, a quantity that characterizes the molecular motion around the phosphorus moiety.

Application to Polynucleotides

Figure 2 shows the temperature dependence of spin-lattice relaxation time (T_1) for phosphorus in three polyribonucleotides, poly(U), poly(C), and poly(A), in single-stranded forms in neutral D_2O solutions. Data for poly(A), taken from a previous work[3], are subjected to a more rigorous treatment here. Poly(G) behaves in a distinctly different manner from other polynucleotides, showing neither T_1 minimum nor nuclear Overhauser enhancement ($\omega_p^2\tau_c^2 \gg 1$) because of its unique multi-stranded structure. We notice the following from Fig. 2,
(1) Each polynucleotide shows a minimum value of T_1 in the temperature range of measurement so that the method of analysis described above can be applied.
(2) The temperature at which $T_{1\,\mathrm{min}}$ occurs increases in the order, poly(U)<poly(C)<poly(A), showing that the rate of molecular rotation around the phosphorus atom decreases in this order.

The lower part of Fig. 2 shows the corresponding nuclear Overhauser enhancement (η) for these polynucleotides. We see that:
(3) Nuclear Overhauser enhancement at the highest observed temperature ($\eta=0.6$—1.0) is greater than 50% of that ($\eta=1.235$) expected for the case of 100% dipolar relaxation under extreme narrowing conditions ($B=0$ in Eq. 11), although except for poly(U), the systems may not be under extreme narrowing conditions even at the highest observed temperatures.
(4) At any temperature, the nuclear Overhauser enhancement decreases in the order, poly(U)>poly(C)>poly(A), in line with the rate of molecular motion estimated above from the T_1 data.

Observation (3) shows that $A/(A+B)>0.5$ holds for the three polynucleotides, and the dipolar mechanism is a dominant source of ^{31}P longitudinal relaxation at 40.48 MHz. To ensure measurement of nuclear Overhauser effect under extreme narrowing conditions, a model compound of lower molecular weight ApU was investigated, which indicated $\eta=1.0$.

By using the maximum values of nuclear Overhauser enhancement in the measured temperature range, and the T_1 and τ_c values at $T_{1\,\mathrm{min}}$, the values or the ranges for A and B are determined in each polynucleotide, and the corresponding values or the ranges for $\bar{r}_{P-H}$ and $(\delta_{//}-\delta_{\perp})$ are estimated, according to the method of analysis described. The values are summarized in Table 1. The corresponding quantities for yeast transfer RNA^{Phe}, previously obtained from a similar analysis[4] are given for comparison.

The relatively small variation of $\bar{r}_{P-H}$ values among different polynucleotides seems to indicate that conformational variation is small among the backbone structures of these polynucleotides. The values of chemical shift anisotropy $(\delta_{//}-\delta_{\perp})$ were obtained in the range 120—160 ppm. Differences in $(\delta_{//}-\delta_{\perp})$ values between different polynucleotides can not be discussed in view of the limited accuracy of the present method

TABLE 1. SUMMARY OF ^{31}P RELAXATION DATA AND MOLECULAR PARAMETERS DEDUCED THEREFROM IN HOMOPOLYRIBONUCLEOTIDES AND RELATED SUBSTANCES

Nucleotide	$(T_1)_{min}$ (s)	NOE	Dipolar contribution (%)	$\bar{r}^{a)}_{P-H}$ (Å)	$\delta_{//}-\delta_{\perp}$ (ppm)	E_a (kcal/mol)
poly(U)	1.18	2.0 (72 °C)	$\simeq$ 80	2.33	128	5.1
poly(C)	1.15	1.8 (83 °C)	$>$ 65	2.1—2.4	$<$165	5.3—6.0
poly(A)	1.41	1.6 (83 °C)	$>$ 50	2.2—2.6	$<$158	7.2—8.1
(helix)	1.55			2.49	130	
$tRNA^{phe}_{yeast}$		1.9 (80 °C)	$\simeq$ 73			
(random)	1.80			2.25	120	6.0 (45—80 °C)
ApU[c)]		2.0 (79 °C)	80			

a) Effective P-H distance; $1/\bar{r}^6_{P-H}=\sum_i(1/r_i^6)$. b) Data taken from Ref. 4. c) Measured at 20 mM.

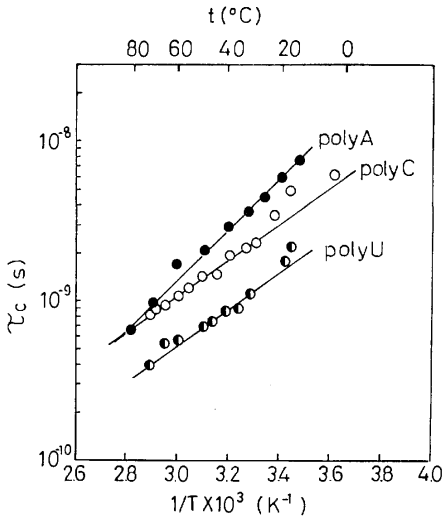

Fig. 3. Temperature dependence of rotational correlation times (τ_c) of poly U, poly C, and poly A as deduced from T_1 and NOE data of Fig. 2.

although the isotropic value of the chemical shift definitely varies.[9] Extreme narrowing conditions are insufficiently fulfilled for poly(A) and poly(C). On the other hand, ApU which is certainly under extreme narrowing conditions in all the temperature ranges measured shows $\eta\simeq 1.0$ or 80% dipolar contribution. By taking account of these facts, we expect that if measurements were done under extreme narrowing conditions for poly(A) and poly(C), the value of η would become as large as that of ApU. Then a probable value of $(\delta_{//}-\delta_{\perp})$ in single stranded polynucleotides in an aqueous solution can be placed in the lower side of the range, *i.e.*, 120—130 ppm.

Furthermore, the τ_c value is obtained as a function of temperature for each polynucleotides (Fig. 3).

It is to be noted that τ_c follows approximately the following equation:

$$\tau_c^{-1}=\tau_0^{-1}\exp(-E_a/RT) \qquad (13)$$

where E_a is the activation energy. The fact that these single-stranded polynucleotides approximately follow a single activation process indicates that their thermal melting is non-cooperative, *i.e.*, the motional activation occurs in a non-cooperative fashion. This makes a sharp contrast with the result for tRNA, which shows a few distinctive steps of activation process.[4]

The τ_c values observed are in the order of 10^{-9} s and can be considered to represent not the whole motion of the molecule ($M_r>100{,}000$) but the local torsional motions around the sugar phosphate backbone. Consequently, the E_a values are considered to represent primarily the torsional barriers around the sugar-phosphate back bone. The observation that the E_a value increases in the order poly(U)$<$poly(C)$<$poly(A) seems to reflect the fact that the incressing tendency of base-stacking gives additional barriers for the molecular motion of the sugar-phosphate moiety.

Conclusion

Important conclusions obtained by inspection of Table 1 and Figs. 2 and 3 may be summarized as follows.

1) The relaxation mechanisms are dipolar dominant (more than 50% in the extreme narrowing region) at this observing frequency (40.48 MHz).

2) Conformations involving the phosphorus atom and the neighbouring protons do not seem to vary significantly between different polynucleotides, as judged from $\bar{r}_{P-H}$ values.

3) Phosphorus chemical shift anisotropy, $(\delta_{//}-\delta_{\perp})$, of single-stranded polynucleotides in solution is in the range 120—165 ppm. It would probably range around 120—130 ppm if measurements could all be made under extreme narrowing conditions.

4) Molecular motions around the phosphate group of single-stranded homopolyribonucleotides become faster in the order, poly(A)$<$poly(C)$<$poly(U). The thermal activation is characterized by single activation energies, 5.1, 5.3—6.0, and 7.2—8.1 kcal/mol for poly(U), poly(C), and poly(A), respectively. These results seem to imply that the base-stacking plays an important role in restricting flexibility of the main chain structure of single-stranded polynucleotides.

We thank Dr. Hayashi for the measurement of the nuclear Overhauser effect in ApU.

Structural Studies of Asymmetric Hydrogenation. III. The Crystal Structure of (*R*)-1-(Methoxycarbonyl)ethyl(*R*)(+)-α-methylbenzylaminebis(dimethylglyoximato)cobalt(III)

Yuji OHASHI and Yoshio SASADA

Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received April 12, 1977)

The structure of (*R*)-1-(methoxycarbonyl)ethyl(*R*)(+)-α-methylbenzylaminebis(dimethylglyoximato)cobalt-(III) has been determined by X-ray analysis. The crystal is monoclinic, the space group $P2_1$, $Z=2$ with $a=7.899(5)$, $b=16.397(2)$, $c=9.054(7)$ Å, and $\beta=90.98(7)°$. The structure was deduced by the heavy atom method and refined by the block-diagonal least-squares method to a final R value of 0.048 for 2146 observed reflections. The bis(dimethylglyoximato)cobalt moiety is twisted around its long axis, owing to the steric repulsion from the (*R*)-1-(methoxycarbonyl)ethyl group and the optically active amine. It is proposed that this twist is one of the factors inducing the asymmetry in the hydrogenation catalyzed by the complex of bis(dimethylglyoximato)cobalt and the active amine. At the step of Co–C bond cleavage the reaction proceeds mainly through inversion of the configuration.

The complexes of bis(dimethylglyoximato)cobalt (abbreviated to $Co(dmg)_2$ or cobaloxime) and optically active amine catalyze asymmetric hydrogenation of olefins.[1-6] The hydrogenation proceeds as follows:

$$\begin{array}{l} \qquad\qquad\qquad\quad H_2C{=}CXY \\ \qquad\qquad\qquad\quad \vdots \\ H_2C{=}CXY + \underset{\underset{B^*}{|}}{Co(dmg)_2} \longrightarrow \underset{\underset{B^*}{|}}{Co(dmg)_2} \longrightarrow \quad \tfrac{1}{2}H_2 \\ \\ H_3CC^*XY \\ \quad | \\ \quad \underset{\underset{B^*}{|}}{Co(dmg)_2} \longrightarrow \quad \tfrac{1}{2}H_2 \qquad H_3CC^*HXY + \underset{\underset{B^*}{|}}{Co(dmg)_2}\ , \end{array}$$

where B* is the optically active amine. In order to clarify the mechanism of inducing asymmetry, several crystal structures of related complexes have been determined by X-ray analysis. In Part II of this series on the crystal structure of methyl(*R*)(+)-α-methylbenzylaminebis(dimethylglyoximato)cobalt(III) benzene solvate[7] (abbreviated to methyl complex), it has been shown that the $Co(dmg)_2$ moiety of the catalyzer is deformed by the steric repulsion from the optically active amine coordinated to the cobalt atom so that its symmetry changes from D_{2h} to C_{2h}. We proposed that this deformation is one of the factors inducing asymmetry in the reaction step of π-bond formation. The present study has been undertaken to disclose the mechanism of Co–C(σ) bond formation and its cleavage.

Experimental

Dark red crystals of the title complex were obtained from aqueous methanol solution. The unit cell dimensions were determined from zero layer Weissenberg photographs using Co$K\alpha$ radiation about b and c axes. Spacings of 40 high angle reflections ($\theta \geqq 60°$), calibrated with superposed silicon powder lines, were subjected to the least-squares treatment. The crystal data are summarized in Table 1.

With the use of a crystal of dimensions $0.2\times0.4\times0.3$ mm, the intensities for $3° \leqq 2\theta \leqq 60°$ were collected on a Hilger-Watts linear diffractometer with Mo$K\alpha$ radiation. The balanced Y/Zr filter pair was used. Out of 3055 accessible reflections, 2149 for which $I \geqq 3\sigma(I)$ were regarded as observed. The usual Lorentz and polarization, but no absorption, corrections were made.

Fourier map phased with these seven atoms.

The structure was refined by the block-diagonal least-squares method. After several cycles of refinement, the three strongest reflections were excluded because they seemed to be affected by secondary extinction. All the hydrogen atoms were found on the difference map. The final refinement was made including these hydrogen atoms with isotropic temperature factors. The weighting scheme, $w=(34.44/|F_o|)^2$ if $|F_o|>34.44$, $w=1.0$ if $34.44\geqq|F_o|\geqq8.61$, $w=0.3$ if $|F_o|<8.61$, was employed. The final R value became 0.048 for 2146 observed reflections. At the final stage, no peaks higher than 0.30 e Å^{-3}, except for the peaks of 0.45 e Å^{-3} around the cobalt atom, were found on the difference map. Atomic scattering factors were taken from the International Tables for X-Ray Crystallography.[8]

The absolute configuration was determined from Weissenberg photographs using Cu$K\alpha$ radiation. The observed and calculated structure factors of 13 Bijvoet pairs are compared in Table 2.

Final atomic parameters and their standard deviations are given for non-hydrogen atoms and hydrogen atoms in Tables 3 and 4, respectively. A list of the observed and calculated structure factors is kept in the office of the Chemical Society of Japan (Document No. 7719). The computation was done on a HITAC 8800 computer at the University of Tokyo and a HITAC 8700 computer at this Institute.

Description of the Structure

Co(dmg)$_2$ Moiety. The equations of the mean planes of four nitrogen atoms and two dmg's, (I), (II), and (III), are given in Table 5, together with the deviations of atoms from the planes. Figure 1 shows the structure of the complex projected on plane (I) and the short contacts between the non-bonded atoms in the complex. The molecular coordinates, x and y, are taken in plane (I), where x is the projection of the line passing through the mid-points of N(1)···N(2) and N(3)···N(4) on the plane, y being perpendicular to x passing through the cobalt atom. Two arrows indicate

the vectors normal to the planes of (II) and (III).

The Co(dmg)$_2$ moiety is significantly bent downward to avoid the short contact with the 1-(methoxycarbonyl)-ethyl group (abbreviated to mce group). The Co(dmg)$_2$ moiety in the methyl complex,[7] which contains the methyl group instead of the mce group and the same amine, is slightly bent in the opposite direction. The cobalt atom in the present complex is significantly displaced upward from the mean plane whereas that in the methyl complex is shifted downward (0.04 Å). Moreover, each dmg is inclined to the y direction. Contacts with the axial ligands, especially between C(18) and N(1) and between H(N51) and N(2), tilt the plane of (II), whereas contacts between C(9), C(11), and N(4), and between N(3), C(3), and O(6) tilt the plane of (III) in the opposite sense. A similar twist of Co(dmg)$_2$ is found in the crystal of 4-pyridyltributylphosphinecobaloxime.[9]

Bond distances and angles are shown in Fig. 2 and Table 6, respectively. In Table 7 the bond lengths in the Co(dmg)$_2$ moiety are compared with those in the methyl complex and the average distances suggested by Bigotto *et al.*[10] In regard to the bond lengths of N–C and C–CH$_3$ and three angles around the endo-cyclic carbon atom, the symmetry of C_{2h} holds good for the present complex.

However, four distances of Co–N are nearly the same and close to the value of Bigotto *et al.*[10] Two bonds of N(3)–O(3) and N(4)–O(4) are longer than N(1)–O(1) and N(2)–O(2). Two hydrogen atoms, H(O1) and H(O2), are bonded to O(4) and O(3), respectively.

Equivalence of four Co–N bonds might be caused

by the steric repulsions between C(18) and N(1) and between C(19) and N(4). The highly negative O(5) and O(6) atoms would draw the positive H(O1) and H(O2) atoms toward O(4) and O(3), respectively, by electroattractive force. Thus in the step of σ-bond formation, not only the twist of $Co(dmg)_2$ but also slight changes of bond distance occur as a result of electrostatic force and the short contacts between the mce group and $Co(dmg)_2$.

1-(Methoxycarbonyl)ethyl Group. The Co–C(17) distance of 2.067 Å is significantly greater than the usual Co–C(sp^3) length. Various Co–C(sp^3) lengths so far determined in the cobaloxime complexes are summarized in Table 8. As the number of the bulky substituents bonded to the ligating carbon atom increases, the Co–C distance is lengthened. This can be interpreted by the steric repulsion between the substituents and the $Co(dmg)_2$ moiety. The C(17)–C(19) distance of 1.466 Å is significantly smaller than the corresponding one in propionic acid (1.50 Å) and slightly smaller than that in *O*-methyl-(Co–C)carboxymethylpyridinecobaloxime (1.48 Å).[11] Since C(17)–C(18) is shorter than the usual C(sp^3)–C(sp^3) single bond, this suggests that the hybridization of C(17) is modified by coordination. The other distances are in good agreement with the corresponding ones of *O*-methyl-(Co–C)carboxymethylpyridinecobaloxime. The angle of Co–C(17)–C(18), 115.7°, is greater than the tetrahedral angle, probably due to the steric repulsion from $Co(dmg)_2$. Three angles around the C(19) atom, 125.5, 121.5, and 113.1°, are close to those of propionic acid, 125, 122,

and 112°, respectively. Four atoms of C(17), C(19), O(5), and O(6) are coplanar within the limit of 0.001 Å, its plane making an angle of 27.5° with the plane (I) of $Co(dmg)_2$.

α-Methylbenzylamine Ligand. In Table 9, the characteristic dimensions of amine ligand (abbreviated to mba) are compared with those in the methyl complex. The $Co(dmg)_2$ plane is bent toward the amine so that the steric repulsion from the amine should be stronger than that of the methyl complex. To release this, rotation around Co–N(5) and N(5)–C(9) and bending of the phenyl group occur. Co–N(5) rotates from the stable conformation, in which the dihedral angle of N(4)–Co–N(5)–C(9) is 13°.[7] The conformation around N(5)–C(9) is shown in Fig. 3. The N(5)–C(9) bond rotates by about 15° from the conformation of

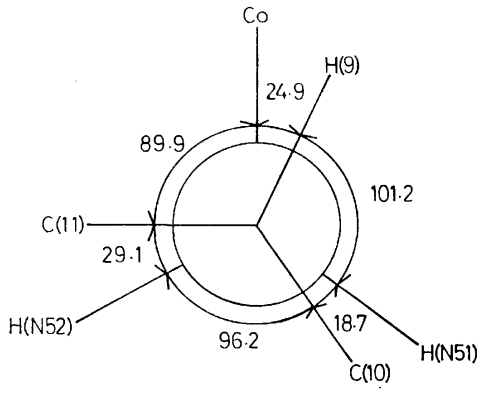

Fig. 3. Newman projection of mba along C(9)–N(5) with the angles (ϕ/°) between the projected bonds.

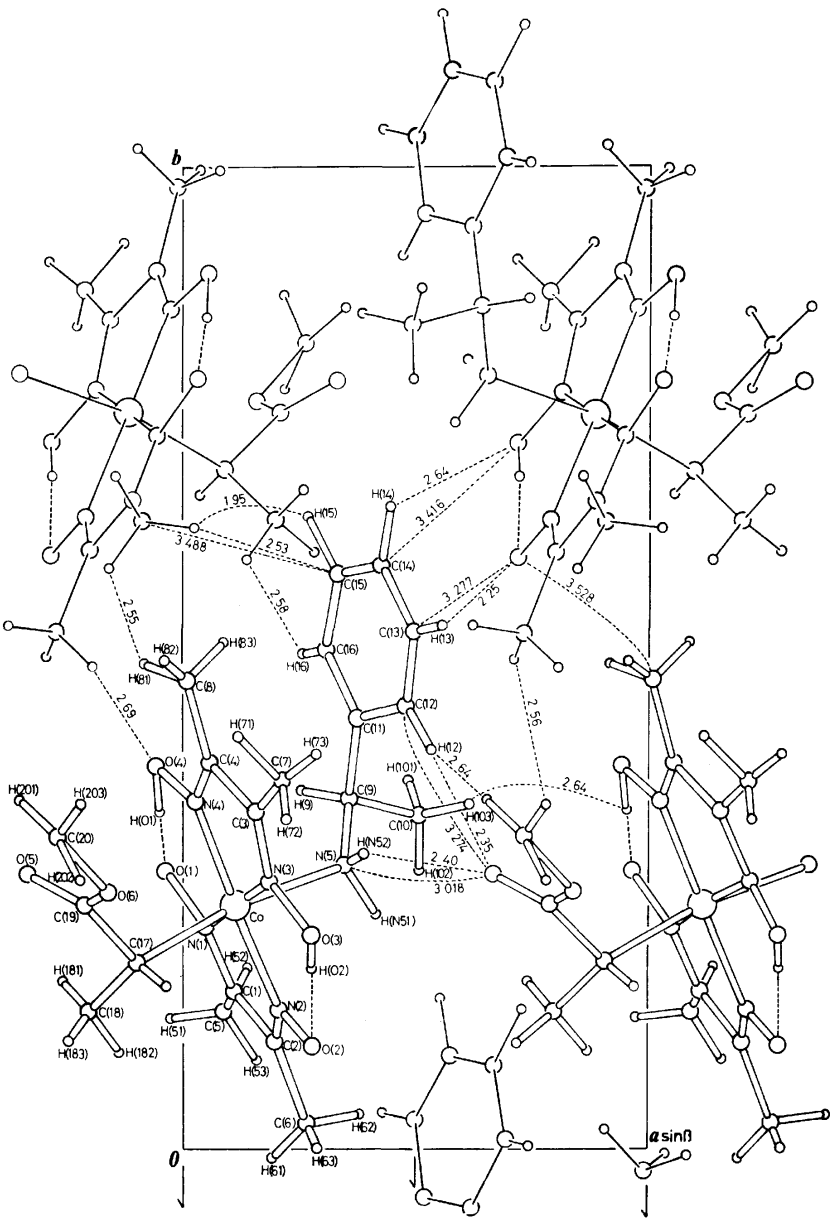

Fig. 4. Projection of the crystal structure along the c axis and short contacts between complexes. Along the c axis the contacts, 3.379 Å for O(3)···C′(5) and 3.580 Å for O(1)···C′(20) are observed.

the methyl complex to the unstable eclipsed form. On the other hand, the Co–N(5) distance is smaller than that in the methyl complex, probably by the effect of the *trans* ligand. The N(5)–C(9) and C(9)–C(11) lengths are in good agreement with the usual distances, 1.472±0.005 and 1.505±0.005 Å, respectively.[12]

Crystal Structure. The crystal structure viewed along the c axis is shown in Fig. 4, the short contacts also being given. There is a fairly short distance, 3.018 Å, between N(5) and O′(5) in the neighbouring complex along the a axis. Although this may be a hydrogen bond of N–H···O in view of N···O distance,[13] O′(5)···H(N52) is not so short and the angle of N(5)–H(N52)···O′(5) is 136°. Therefore, the interaction of N–H···O, if any, should be very weak.[14] Others are normal van der Waals contacts.

Discussion

The $Co(dmg)_2$ moiety is twisted as a 'propeller' by the steric repulsion with the mce group and mba ligand. The N(1) and N(4) atoms are shifted downward and upward, respectively, from the plane, to avoid the short contacts with the methyl of mce group and the asymmetric mba ligand. The carbonyl group with smaller van der Waals radius is located over N(4). If the absolute configuration of the mce group is *S*, as indicated by broken lines in Fig. 5, the methyl of mce group comes close to N(2), which is above the mean plane, giving rise to the strong steric repulsion. It is plausible that the σ-complex containing the *S*-mce group is less stable energetically than that having *R*-mce group, if the asymmetric amine has *R* configuration. We propose that this is one of the factors inducing asymmetry in the step of σ-bond formation of this hydrogenation reaction. This hypothesis, however, is based on the assumption that the *S*-mce group does not change seriously.

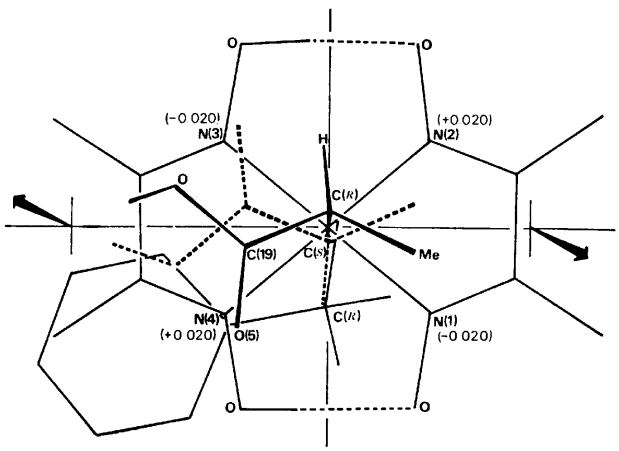

Fig. 5. A presumed conformation of σ-complex containing *S*-mce group (broken lines). The deviations of four nitrogen atoms from the mean plane are in parentheses.

As regards the mechanism of Co–C bond cleavage, the absolute configuration of the mce group was determined to be *R* by an anomalous dispersion method. The reaction product of (+)-methyl propionate-2-*d*, which was obtained by deuterogenation of this complex, was determined to have *S* configuration from the specific rotation.[6] It is, therefore, concluded that the Co–C bond cleavage proceeds mainly through inversion of configuration at the carbon atom.

The authors are grateful to Dr. Yoshiaki Ohgo for supply of the specimens and for valuable discussions.

The Vibrational Spectra and Rotational Isomerism of Methylvinylsilane and Allylsilane[1)]

Keiichi OHNO, Keijiro TAGA, and Hiromu MURATA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received April 21, 1977)

The infrared and Raman spectra have been measured for methylvinylsilane, CH_2=$CHSiH_2(-D_2)CH_3$, and allylsilane, CH_2=$CHCH_2SiH_3(-D_3)$. The fundamental vibrations have been assigned, and the normal coordinate treatment for possible molecular forms has been carried out. For methylvinylsilane, the *cis* and *skew* forms coexist in the gaseous and liquid states, while only the former persists in the solid state. In the liquid state the *cis* form is more stable by 0.66±0.05 kcal/mol than the *skew* form. For allylsilane, the form near the *skew* form predominantly exists in the gaseous, liquid, and solid states.

The ultraviolet absorption maximum of allyltrimethylsilane appears at a wavelength longer than that of trimethylvinylsilane.[2)] Previously, the bathochromic effect of the allyl derivative has been commonly cited as evidence of (p-d)π bonding between the double bond and the silicon.[3)] Recently, however, this effect has been interpreted in terms of σ-π hyperconjugation[4,5)] between the double bond and the Si–C σ bond, whose magnitude may vary with the dihedral angle about the axis between the carbon atoms in the α- and β-positions in allylsilane.

In the present paper, we will, therefore, deal with the molecular vibrations of methylvinylsilane and allylsilane in relation to the rotational isomerism in order to obtain information on the stereospecific effect.

Experimental

The samples of methylvinylsilane, CH_2=$CHSiH_2(-D_2)$-CH_3, and allylsilane, CH_2=$CHCH_2SiH_3(-D_3)$, were prepared by the reduction of commercial products of dichloro(methyl)vinylsilane (K & K Co., U.S.A.) and allyltrichlorosilane (Aldrich Chem. Co., U.S.A.) with lithium aluminium hydride or deuteride in dibutyl ether[6)] and were purified by low-temperature bulb-to-bulb distillation in a vacuum. Their purities were checked by means of their nuclear magnetic resonance spectra; CH_2=$CHSiH_2CH_3$ NMR(CCl_4): δ 0.21 (t, 3H, J=4 Hz, Si**C**$\mathbf{H_3}$), 3.94 (dq. 2H, J=1 and 4 Hz, Si**H**$_2$), 5.5—6.5 (m, 3H, **C**$\mathbf{H_2}$=**C**$\mathbf{H}$), CH_2=$CHSiD_2CH_3$ NMR (CCl_4): δ 0.21 (s, 3H, Si**C**$\mathbf{H_3}$), 5.5—6.5 (m, 3H, **C**$\mathbf{H_2}$=**C**$\mathbf{H}$), CH_2=$CHCH_2SiH_3$ NMR(CCl_4): δ 1.69 (sex, 2H, J=4 Hz, **C**$\mathbf{H_2}$Si), 3.53 (t, 3H, J=4 Hz, Si**H**$_3$), 4.8—6.2 (m, 3H, **C**$\mathbf{H_2}$=**C**$\mathbf{H}$), CH_2=$CHCH_2SiD_3$ NMR(CCl_4): δ 1.69 (d, 2H, J=8 Hz, **C**$\mathbf{H_2}$Si), 4.8—6.2 (m, 3H, **C**$\mathbf{H_2}$=**C**$\mathbf{H}$).

The infrared and Raman spectra were recorded on a Perkin-Elmer instrument (Model 621) and a JEOL Raman Spectrometer (Model JRS-400D) with an argon-ion laser respectively. The infrared spectra in the gaseous state were measured using a 10-cm gas cell fitted with CsI windows. The infrared spectra in the liquid state at low temperatures were measured at about 150 K by condensing the gaseous samples on a CsI window cooled with liquid nitrogen. For the Raman spectra in the solid state, the sample in the ampoule was held on a copper block cooled with liquid nitrogen; the solid was obtained by the use of a long period of cooling.

Results

Normal Coordinate Treatment. The normal vibrations were calculated in order to determine the molecular forms and the assignments of the observed spectra to rotational isomers. The valence angles of the CH_2=CH group and the bond lengths used were transferred from those of vinylsilane,[7)] dimethylsilane,[8)] and 1-butene.[9)] The other valence angles were assumed to be tetrahedral, and the dihedral angles were 0° for the *cis* form and 120° for the *skew* form. The modified Urey-Bradley force field was used in the calculation. The force constants of the CH_2=CH group and those of the skeletal torsion were taken so as to predict well the observed frequencies of vinylsilane, CH_2=$CHSiH_3$

relative intensities of the infrared bands and the Raman lines and the comparison with the spectra of analogous molecules[10,11,15)] are consistent with the results of the calculation, except for the assignments of the SiH_2 twisting and Me–Si stretching modes for methylvinylsilane-d_0 and those of the CH_2 wagging and twisting modes for allylsilane-d_0 and -d_3.

Rotational Isomerism. Figures 1 and 2 show the Raman spectra of methylvinylsilane-d_0 and allylsilane-d_0 in the region below 1700 cm^{-1}; the upper and lower spectra are for the liquid state at room temperature and for the solid state at about 100 K respectively. For 1-butene[9)] and methylvinylsilane,[13)] the stable conformations have been confirmed by means of the microwave spectra to be *cis* and *skew* about the C–C or C–Si axes adjacent to the double bond. For methylvinyl-

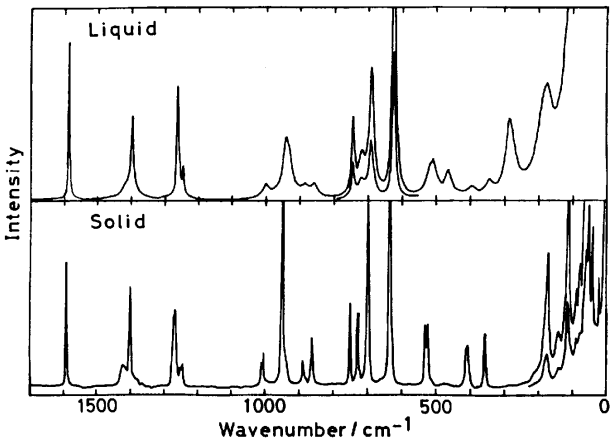

Fig. 1. Raman spectra of methylvinylsilane-d_0.

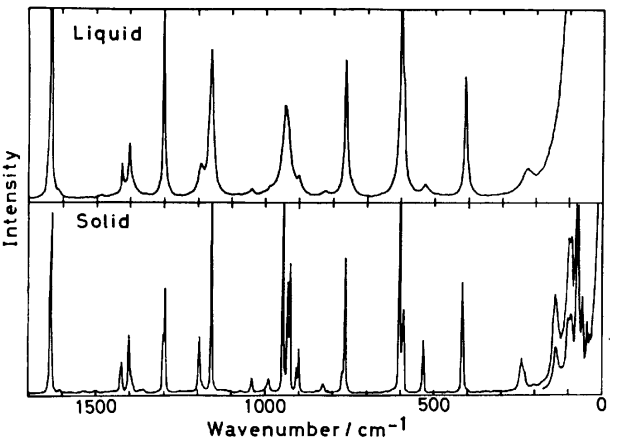

Fig. 2. Raman spectra of allylsilane-d_0.

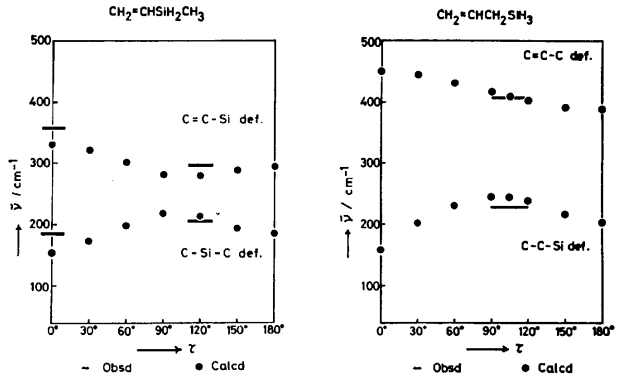

Fig. 3. Dependence of skeletal deformation frequencies on dihedral angle for methylvinylsilane-d_0 and allylsilane-d_0.

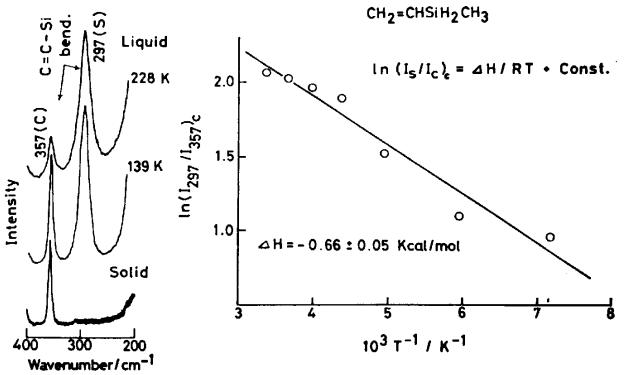

Fig. 4. Raman spectra of methylvinylsilane-d_0 in the 200—400 cm^{-1} region and a plot of $\ln(I_{297}/I_{357})_c$ *vs.* $1/T$.

silane, several Raman lines observed in the liquid state vanish in the solid state, but for allylsilane all the Raman lines observed in the liquid state remain in the solid state. On the other hand, all the vibrational frequencies observed in the solid state for methylvinylsilane and allylsilane are assigned to the fundamental vibrations of one isomer, as Tables 2—5 show. In the 150—450 cm^{-1} region for both the molecules, two skeletal deformation and one torsional vibrations are expected for one isomer; the CH_3 and SiH_3 torsional vibrations may, in general, be very weak in the Raman scattering. For methylvinylsilane-d_0, four Raman lines —at 357, 297, 205, and 185 cm^{-1}—are observed in the liquid state, and two of them remain in the solid state, indicating that two isomers coexist in the liquid state and that one of them persists in the solid state. For allylsilane-d_0, two Raman lines—at 408 and 227 cm^{-1}—are observed in both the liquid and solid states, indicating the existence of only one isomer in both the liquid and solid states. The same results are obtained from methylvinylsilane-d_2 and allylsilane-d_3.

In order to determine the molecular forms, the normal coordinate treatment was carried out for seven possible molecular forms of methylvinylsilane-d_0 and allylsilane-d_0. Figure 3 shows the observed and calculated frequencies of the skeletal deformations. The calculations indicate that, for methylvinylsilane-d_0, *cis* and *skew* forms coexist in the liquid state, while only the *cis* form persists in the solid state, and that for allylsilane-d_0 only the molecular form near the *skew* form exists in both the liquid and solid states.

Enthalpy Difference of the Isomers in Methylvinylsilane. The relative intensities of the Raman lines at 297 and 357 cm^{-1} assigned to the C=C–Si deformation vibrations for the *skew* and *cis* forms of methylvinylsilane-d_0 respectively were measured in the liquid state at temperatures ranging from 297 to 139 K. In the solid state the band at 297 cm^{-1} disappears, but that at 357 cm^{-1} persists. Figure 4 shows some typical examples at 228 and 139 K among seven different temperatures and a plot of $\ln(I_s/I_c)[(1-e^{-h\nu_s/kT})/(1-e^{-h\nu_c/kT})]$ against $1/T$. From the slope of the straight line, the value of the enthalpy difference, $\Delta H(H_{skew}-H_{cis})=0.66\pm0.05$ kcal/mol, is obtained.

Discussion

For allylsilane, the form near the *skew* form is determined on the basis of the normal coordinate treatment to exist predominantly in the liquid and solid states. This result is also supported by the infrared spectra in the gaseous state; no *c*-type bands for the *cis* form were observed, and all the bands were assigned to the fundamental vibrations of only one isomer. On the other hand, for methylvinylsilane, the *cis* and *skew* forms are confirmed to coexist in the gaseous and liquid states; the *cis* form is more stable than the *skew* form by 0.66

±0.05 kcal/mol in the liquid state. For 1-butene, the *skew* form has been reported to be more stable than the *cis* form by only 150±150 cal/mol (from the analysis of microwave spectra[9]) and by −100±50 cal/mol (from the NMR spectra[14]). For allyl halides (X= Cl, Br, I), the *cis* and *skew* forms have been confirmed to coexist in the liquid state, although a larger steric repulsion between the CH_2=CH group and halogen is to be expected.[15]

Recently, Weidner and Schweig have demonstrated, from the photoelectron spectra and CNDO/2 calculations, the importance of σ-π hyperconjugation in trimethylvinylsilane and allyltrimethylsilane.[5] CNDO/2 model calculations have indicated that allyltrimethylsilane has a conformation near the *skew* form as a result of the σ-π hyperconjugation between the Si–C σ bond and the double bond. Thus, the present result on allylsilane is consistent with the conformation of allyltrimethylsilane. Therefore, the form near the *skew* of allylsilane may have a dihedral angle between the 120° of the ordinary *skew* form and the 90° of the maximal σ-π interaction. Actually, Hayashi *et al.* have, from the microwave spectra, reported an estimated dihedral angle of 103°40′ for allylsilane.[16]

The authors wish to express their thanks to Dr. Hiroatsu Matsuura for his valuable discussion.

The Interaction of Acridine Orange with Poly(*S*-carboxymethyl-L-cysteine)

Toyoko IMAE and Shoichi IKEDA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received April 25, 1977)

The interaction of Acridine Orange with poly(*S*-carboxymethyl-L-cysteine) has been investigated by observing the solubility behavior, absorption spectra, and circular dichroism of the mixture. When the dye is added to aqueous solution of the polymer, the mixture is homogeneous at higher pH, but precipitation takes place at lower pH; the threshold pH ranges from 3.5 to 6, depending on the mixing ratio. For [P]/[D] 1 or less, the mixture is again homogeneous at very low pH between 4 and 2, when no salt is added. Various type of circular dichroism are induced for the homogeneous solutions, which are characteristic of the bound dye species on the polymer and the structure of dye-polymer complex. The binding of dye with the polymer is mainly caused by electrostatic effect, and the solubility of the mixture is interpreted by considering the ionization of polymer and the binding of dye to the polymer.

The visible absorption spectra of Acridine Orange in water are characterized by two absorption bands at 492 and 470 nm, which are ascribed to the monomer and dimer, respectively, of the dye.[1] The relative abundance of the two forms of the dye depends on its concentration. A structure of antiparallel stacked type has been proposed and accepted[2,3] for the dimeric dye molecule. In highly concentrated dye solutions, higher aggregates of dye are formed, the absorption band shifting down to around 450 nm.

When Acridine Orange is mixed with poly(*S*-carboxymethyl-L-cysteine), its absorption spectra change remarkably from those of free dye in the position and intensity of visible band.[4,5] The peak position indicates the state of aggregation of dye molecules in solution, while the hypochromism suggests the binding of dye to the polymer.

It has also been found that the circular dichroism (CD) is induced on Acridine Orange at its absorption bands in the presence of poly(*S*-carboxymethyl-L-cysteine).[4,5] The induced CD spectra observed at various [P]/[D] (mole of polymer residue/mole of added dye) mixing ratios and pH can be classified into fundamental types or their combinations. The fundamental types are characterized with reference to the bound species of dye molecules on the polymer and the conformation of the polypeptide chain. The latter is deduced from the CD spectra associated with the electronic transitions of peptide groups.

The CD spectrum of Type I was induced on aggregates of dimeric dyes bound to the polymer in the β-conformation.[4,6] Type II CD spectrum was induced on a dissymmetric array of dimeric dyes bound to the randomly coiled polymer at low ionization.[5,7] The CD of Type III was characteristic of low [P]/[D] ratios and was induced on another kind of array of dimeric dyes bound to the randomly coiled polymer at high ionization. Other types of CD, Types II′ and III′, originate from bound monomeric dyes and are considered to be counterparts of Types II and III, respectively.

The experiments so far reported[4,5] were performed on solutions of weakly acidic or higher pH, since the dye–polymer mixture precipitated at lower pH. It was found that the mixture was again homogeneous at very low pH region and for low [P]/[D]. The present work concerns with the interaction of Acridine Orange with poly(*S*-carboxymethyl-L-cysteine), as revealed in the solubility behavior and circular dichroism.

Experimental

Poly(*S*-carboxymethyl-L-cysteine) (code E602) was the same sample as that previously used.[8] Low-molecular-weight poly(*S*-carboxymethyl-L-cysteine) (code E515) was also used for comparison.[8] Acridine Orange was purified from commercial zinc salt and obtained as a hydrochloride salt.[1,4]

The stock solution of dye was added to aqueous solution of polymer. The pH was then adjusted by HCl or NaOH, followed by dilution to the desired dye concentration. For the preparation of solutions at a desired ionic strength, NaCl was added to the stock solution of polymer. The mixed solutions were kept overnight before measurements.

The pH was measured with a Hitachi-Horiba F5-X pH Meter. Absorption spectra were recorded with a 5 mm quartz cell on a Hitachi 323 Recording Spectrophotometer. The CD measurements were performed by using a 10 mm cell on a Jasco J-20 Circular Dichrometer, which was calibrated by use of aqueous solution of *d*-10-camphor sulfonic acid.[9] Measurements were carried out at room temperature.

The molar extinction coefficient, ε_D, and the molar ellipticity, $[\theta_D]$, are expressed on the basis of the total molar concentration of added dye.

Results

Solubility and Phase Separation of Dye–Polymer Mixture. Figure 1 shows the pH region for various [P]/[D] values, indicating where the mixed solution of Acridine Orange and poly(*S*-carboxymethyl-L-cysteine) is homogeneous and where precipitation takes place. A red precipitate is formed when the polymer concentration is high, and a fine gel separates when the polymer concentration is low.

The pH region where the mixture is soluble changes with the [P]/[D] ratio; as [P]/[D] decreases, the pH of phase separation becomes higher. The mixture is soluble above pH 5.8, when [P]/[D] is 0.9. At [P]/[D] lower than 0.9, the pH of phase separation is lowered. When solutions of different concentrations are compared at a given [P]/[D], it is found that the more concentrated mixture precipitates at slightly higher pH.

When [P]/[D] is 1 or less, homogeneous solutions appear at pH between 4 and 2. The upper and lower pH of homogeneous solutions change parallel to the pH

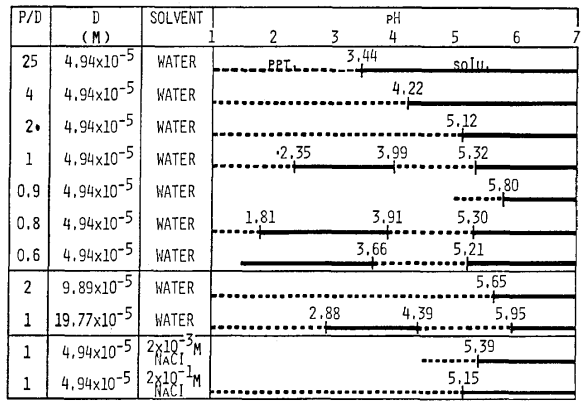

Fig. 1. Solubility of Acridine Orange–poly(*S*-carboxymethyl-L-cysteine) mixture in water and in aqueous NaCl solutions. ——, Solutions; ----, precipitation.

of phase separation around pH 5.5. In the solution of the lowest [P]/[D], 0.6, precipitation does not take place even at pH 1.80. Redissolution occurs for [P]/[D] 1, even when the dye concentration and consequently the polymer concentration are increased by four times. Addition of 0.2 M NaCl prevents the mixture of [P]/[D] 1 from becoming homogeneous in the pH region 4—2, and yields extremely fine gels in this region.

Dye–Polymer Mixture at Higher pH Region. In a higher pH region where no phase separation occurs, the dye molecules on the complex for high [P]/[D] generally form dimers or higher aggregates, while those for low [P]/[D] exist as monomers. The blue shift of the main visible absorption band down to 450 nm occurs for solutions of [P]/[D] higher than 1, suggesting the formation of highly aggregated dye. In the solutions of [P]/[D] 1 and 0.9, the dye molecule is in different states, depending on the pH. For [P]/[D] 0.8 and 0.6, the absorption band of monomeric dye is always dominant. The observed molar extinction coefficient of the main absorption band of dye in the visible region shows hypochromism, which implies extensive binding of dye to the polymer.

The induced CD spectra drastically vary with pH and [P]/[D]. Table 1 gives the wavelength of CD bands belonging to different types of CD. For [P]/[D] higher than 4, the CD of Type I is induced at acidic pH.[4] A strong positive band is located at 466 nm, and a weak negative one at 433 nm. The CD of Type II, which is observed for solutions of [P]/[D] 2 or 1 at pH 6.8 or 5.8, consists of paired bands with a strong negative band at 472 nm and a weak positive band at 415 nm, and of an additional broad positive band around 560 nm. The CD is also induced even at the neutral or alkaline pH when [P]/[D] is lower than 4. It is characterized by three bands, having opposite signs to those of Type II. This type of CD has been called Type III. The other type of CD, Type III′, occurs for solutions of [P]/[D] 0.9—0.6 at acidic pH. A positive band is manifest at 545 nm, and a negative one at 421 nm. Some of the spectral characteristics of the dye–polymer mixtures have already been reported.[5] The pH and [P]/[D] values for the induction of CD of various types are given in Table 2.

Table 1. Wavelength, sign, and magnitude of CD of various types[a]

a) Wavelength is given in nm. Magnitude is classified into strong (s), medium (m), weak (w), and shoulder (sh).

Dye–Polymer Mixture at Very Low pH Region. The mixtures of [P]/[D] 1 or less are homogeneous at pH 4—2, when no salt is added. However, thier absorption spectra appreciably change from those of the solutions mentioned above. As illustrated in Figs. 2 and 3, the absorption spectra for [P]/[D] 1, 0.8, and 0.6 have two peaks at 492 and 470 nm, and their extinction coefficients differ slightly from those for the free dye at the same concentration.[1,4] This suggests that only a few dye molecules are bound to the polymer.

In this region, the CD behavior is even more complicated. As shown in Fig. 2, the CD for [P]/[D] 1 belongs to Type II at the most acidic pH. Upon raising pH, the three CD bands in the visible region change their signs, while the ultraviolet bands keep them unchanged. However, the solutions of [P]/[D] 0.8 and 0.6 exhibit the CD of Type III′, which has a strong positive band at 541 nm, as seen in Fig. 3. Although the apparent CD is weak in this region, the actual molar ellipticity might be stronger than that shown, if correction is made for the amount of bound dye.

The absorption band of Acridine Orange at 470 nm becomes stronger when the dye concentration increases.[1] Its molar extinction coefficients are slightly influenced by the presence of the polymer for [P]/[D] 1 in very low pH region, which indicates very low binding of dye to the polymer. The CD spectra belong to Type II.

Dye–Low-molecular-weight Polymer Mixture. The low-molecular-weight polymer (E515) has a disordered conformation for all the pH in both absence[8] and presence[5] of Acridine Orange, and it interacts with the dye in a different way from the high-molecular-weight polymer. The induced CD spectra observed in the presence of the dye differ from each other, although the absorption spectra in the visible region are quite similar.

Absorption spectra indicate aggregation of dye in the solution of [P]/[D] 2 and more, as seen in Table 2. In the mixture of [P]/[D] 1, the species of dye changes at both sides of pH 5.4, while for [P]/[D] 0.8 the monomeric dye is dominantly present at all the pH examined. The hypochromism suggests the extensive binding of

Table 2. The pH region for the induction of CD of various types

dye to the polymer.

The CD is induced only at pH lower than about 6 for all the [P]/[D] values. The CD of the complexes formed at [P]/[D] higher than 1 belongs to Type II. The observed CD spectrum for [P]/[D] 0.8 consists of a positive band at 427 nm and a negative one at 533 nm, and it has been called Type II′, as shown in Table 1.

The low-molecular-weight polymer (E515) yields precipitates at pH 3.51, 4.98, 4.80, and 4.36 for [P]/[D] 25, 2, 1, and 0.8, respectively. At very low pH, 2.0—3.7, the mixture of [P]/[D] 0.8 is soluble again and exhibits the CD of Type II′ combined with Type II, as shown in Fig. 4. Since the absorption spectra in this region are very similar to those of free dye, indicating very few bound dye on the polymer, the observed CD has to be corrected for the amount of bound dye.

Discussion

Free Acridine Orange in water is dominantly in monomeric form at a concentration of 5×10^{-5} M, while it aggregates at high ionic strengths.[1,4] In the dye–polymer mixtures of low [P]/[D], monomeric form of dye is dominant over all the pH region. On the other hand, for higher [P]/[D], dimeric or higher aggregates of dye are formed on the polymer, since ionized carboxyl groups of the polymer and counter ions behave as the ionic atmosphere surrounding the dye molecules, making the dye molecules stack together.

The binding of dye to the polymer occurs primarily electrostatically, and a nitrogen atom of the cationic dye would be close to an ionized carboxyl group of the polymer, irrespective of whether the dye is monomeric or dimeric. In the absence of dye, the pH for the phase separation of polymer solution is lowered with decrease in concentration. For high [P]/[D], where the binding of dye is relatively low, the solubility of the polymer would not be influenced by such a binding. Thus the complex precipitates at low pH where the polymer is only slightly ionized. However, for [P]/[D] as low as 2, the phase separation occurs at pH as high as 5. When the divalent cationic dimer of Acridine Orange[1,2,10] binds to an ionized carboxyl group of the polymer, the charge on the carboxyl group turns from negative to positive. Thus the phase separation observed around pH 5 can be interpreted as the isoelectric precipitation of ampholytic complex. For [P]/[D] lower than 2, the dye is mainly in monomeric form at low pH. When the monomeric dyes are bound to the polymer, the complex becomes electrically neutral at a certain pH and precipitates.

When greater amounts of cationic dyes are added to the polymer, or when [P]/[D] is lowered further, the pH of phase separation should be higher. However, the pH decreases for [P]/[D] less than 0.9. This could be caused by the decrease in concentration of the polymer. In the same way, more concentrated mixture for [P]/[D] 1 precipitates at slightly higher pH (Fig. 1), reflecting the solubility of the polymer itself.[8]

For the complexes of [P]/[D] 1 or less formed at low pH 4—2, the amount of bound dye is very small, since ionization of carboxyl groups is low and the cationic dye does not bind to uncharged carboxyl groups. However, the net charge of the complex would be positive and the complex becomes soluble. In this complex the polymer chain would be a random coil owing to the electric repulsion between attached positive charges. Thus it is unlikely that the observed CD is of Type I as observed for the β-conformation. The observed CD was either of Type II or Type III′. At very low pH around 2.5, the ionization of the polymer is too low to be soluble in solution.

The same discussion on the solubility behavior of the dye–polymer mixture would apply to that of the dye–low-molecular-weight polymer mixtures, and also to the dye–poly(L-glutamic acid) mixtures.[11]

Electronic States of the Crystals of TCNE Complexes with Hexamethylbenzene, Acenaphthene, and Dibenzofuran

Masashi TANAKA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received May 2, 1977)

The polarized reflection spectra were measured on crystals of tetracyanoethylene and its charge-transfer complexes, and the absolute intensity of the absorption parallel to the crystalline axes has been obtained by the Kramers-Kronig transformation. The charge-transfer degree and the stabilization energy in the ground state were estimated for each complex by analyzing the charge-transfer bands in the crystalline state. In the TCNE–hexamethylbenzene(HMB), acenaphthene, and dibenzofuran complexes, the charge-transfer degrees are 9.05, 12.3, and 4.95% respectively in the ground state.

Tetracyanoethylene, TCNE, is a strong electron acceptor. The formation of charge-transfer complexes with a variety of aromatics in dichloromethane solutions has been studied by Merrifield and Phillips.[1] These complexes are characterized by an intense electronic absorption in the visible or near-ultraviolet region that can be attributed to neither component of the complex alone, but to a new molecular species, the complex itself. Mulliken[2] has developed a theory of the intermolecular charge-transfer (CT) interaction which has been applied successfully to the interpretation of the absorption bands characteristic of molecular complexes. Aihara, Tsuda, and Inokuchi[3] examined the gas-phase spectra of these CT complexes and discussed how an increase in solvent polarity results in a shift of the CT band to a higher-energy region.

The infrared spectra of the complexes showed new bands which appeared on the complex formation,[4,5,16] and the resonance-enhanced Raman band was concluded to be due to the direct participation of the lowest CT state of the complex in the intermediate states of Raman scattering.[6–9]

Some of the molecular complexes of tetracyanoethylene can be obtained as crystalline solids, which often exhibit characteristic absorption bands analogous to the CT bands of the molecular complexes in solution. Kuroda *et al.*[10,11] revealed the presence of marked dichroism in these characteristic bands; the absorption is stronger as the light is polarized parallel to the alternate stack of donor and acceptor molecules, in agreement with the theoretical prediction for a CT transition. Furthermore, the CT interaction between donor and acceptor molecules has been applied to the interpretation of the mechanism of the electrical condition in these crystals of TCNE complexes.[12]

However, no study has been reported hitherto on the correlation of the electronic states of these complexes with the absolute absorption intensity of the CT band. In the present paper, the author shows the crystal absorption spectra obtained by the K-K transformation of the reflection spectra of TCNE complexes with HMB, acenaphthene, and dibenzofuran and gives information about the electronic states of the complexes.

Experimental

The single crystals of TCNE complexes with HMB, acenaphthene, and dibenzofuran were grown by sublimation in bottles. These crystals have the crystal habits shown in

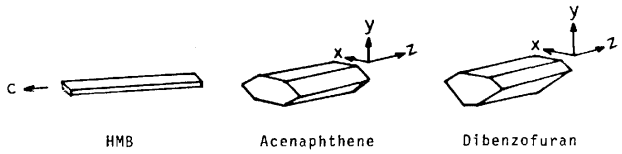

Fig. 1. The crystal habits of TCNE–HMB, acenaphthene, and dibenzofuran.

Fig. 1.

The reflection spectra at the normal incidence have been measured over the range of 10000—40000 cm^{-1} with a reflection spectrophotometer made in our laboratory, while the absorption spectra have been obtained by the Kramers-Kronig transformation. The oscillator strength along the α axis of the crystal may be evaluated by using the following equation:

$$f^{\alpha} = 4.32\times10^{-9}\int n_{\alpha}(\sigma)\varepsilon_{\alpha}(\sigma)\mathrm{d}\sigma,$$

where the integration is calculated over the whole band, σ is the wave number, and n_{α} and ε_{α} are the α components of the refractive index and the molar extinction coefficient. The oscillator strenghts for the three orthogonal axes in the crystal should be compared with that in solution:

$$f^{x} + f^{y} + f^{z} = 3f^{\mathrm{solution}}.$$

Theoretical

The basic theory of the CT complex was given by Mulliken[2]; and the energy diagrams are shown in Fig. 2.

In the AD type, the ground state is partly ionic and

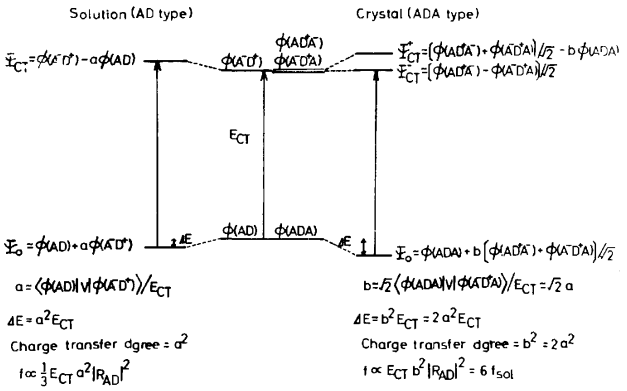

Fig. 2. The energy diagrams of the charge-transfer complexes.

may be described by a wavefunction

$$\Psi_0 \simeq \phi(\mathrm{AD}) + \sum_i a_i\phi_i(\mathrm{A^-D^+}) ,$$

where $\phi(\mathrm{AD})$ represents a non-bonding, and $\phi_i(\mathrm{A^-D^+})$ the i-th CT wavefunction involving the transfer of an electron from D to A. Then, the charge-transfer degree and the stabilization energy are given as $\sum_i a_i^2$ and $\Delta E=\sum_i a_i^2 E_{\mathrm{CT}}{}^i$. For the i-th charge-transfer excited state, we can write the wavefunction, $\Psi_{\mathrm{CT}}{}^i$ given by

$$\Psi_{\mathrm{CT}}{}^i \simeq \phi_i(\mathrm{A^-D^+}) - a_i\phi(\mathrm{AD}).$$

This is responsible for the characteristic color of the complex and the oscillator strengths in the solution and crystal are given as follows:

$$f_i(\mathrm{AD})^{\mathrm{solution}} = 1.085\times10^{11}E_{\mathrm{CT}}{}^i a_i^2|R_{\mathrm{AD}}|^2 ,$$

$$f_i(\mathrm{AD})^{\mathrm{crystal}} = 3f_i(\mathrm{AD})^{\mathrm{solution}} ,$$

where R_{AD} is the vector between the acceptor and donor molecules in the unit of cm and $E_{\mathrm{CT}}{}^i$ the excitation energy in $\mathrm{cm^{-1}}$.

In the ADA type, the ground state can also be described by a wavefunction

$$\Psi_0 \simeq \phi(\mathrm{ADA}) + \sum_i b_i\{\phi_i(\mathrm{AD^+A^-}) + \phi_i(\mathrm{A^-D^+A})\}/\sqrt{2} ,$$

where $\phi(\mathrm{ADA})$ represents a non-bonding, and $\phi_i(\mathrm{AD^+A^-})$ and $\phi_i(\mathrm{A^-D^+A})$ the i-th CT wavefunctions. Then, the charge-transfer degree and the stabilization energy in the ground state are given as $\sum_i b_i^2$ and $\Delta E=\sum_i b_i^2 \cdot E_{\mathrm{CT}}{}^i$. Therefore, it should be noted that they are twice as much as those in the AD type. The wavefunction, $\Psi_{\mathrm{CT}}{}^i(-)$, for the optically allowed i-th excited state is given by

$$\Psi_{\mathrm{CT}}{}^i(-) \simeq \{\phi_i(\mathrm{AD^+A^-}) - \phi_i(\mathrm{A^-D^+A})\}/\sqrt{2} ,$$

and the oscillator strengths in the solution and crystal are as follows:

$$f_i(\mathrm{ADA})^{\mathrm{solution}} = 1.085\times10^{11}E_{\mathrm{CT}}{}^i b_i^2|R_{\mathrm{AD}}|^2,$$

$$f_i(\mathrm{ADA})^{\mathrm{crystal}} = 3f_i(\mathrm{ADA})^{\mathrm{solution}}.$$

Accordingly, by a comparison between the experimental and theoretical oscillator strengths, we can obtain the magnitude values of a_i^2 or b_i^2 and get information about the electronic states of the CT complexes. Furthermore, TCNE complexes form configurations of the AD type in the solution and of the ADA type in the crystal. This means that the oscillator strength in the crystal is six times that in the solution:

$$f_i(\mathrm{ADA})^{\mathrm{crystal}} = 6f_i(\mathrm{AD})^{\mathrm{solution}}.$$

Results

TCNE. TCNE forms monoclinic crystals of the $P2_1/n$ space group, and there are two centrosymmetric molecules in the unit cell. The polarized absorption spectra can be obtained from the reflection spectra, as is shown in Fig. 3. The long-axis transition band of the molecule has a structure; its origin is located at 36300 $\mathrm{cm^{-1}}$, and other vibronic levels appear at 37600, 38800, and 39800 $\mathrm{cm^{-1}}$.

TCNE–HMB Complex. The TCNE–HMB complex forms triclinic crystals,[13] as is shown in Fig. 1. TCNE and HMB molecules are stacked alternately in columns parallel to the c axis. Both molecular planes are perpendicular to the c axis, and the interplanar separation, R_{AD}, is 3.35 Å. The reflection spectra are observed for the polarizations parallel and perpendicular to the c axis, and the absorption spectra are obtained by the K-K transformation of the reflection spectra, as is shown in Fig. 4.

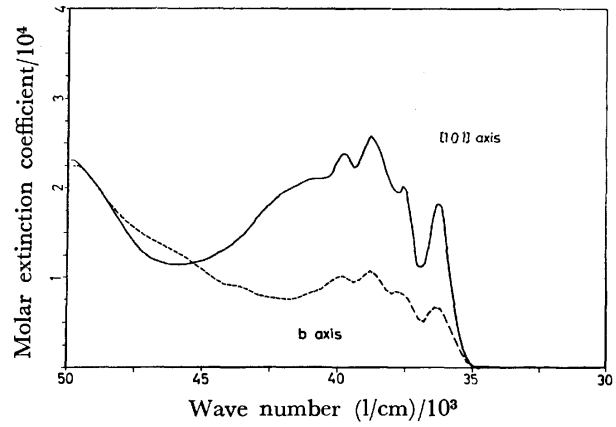

Fig. 3. The absorption spectra of TCNE crystal obtained from the K-K transformation of the reflection spectra.

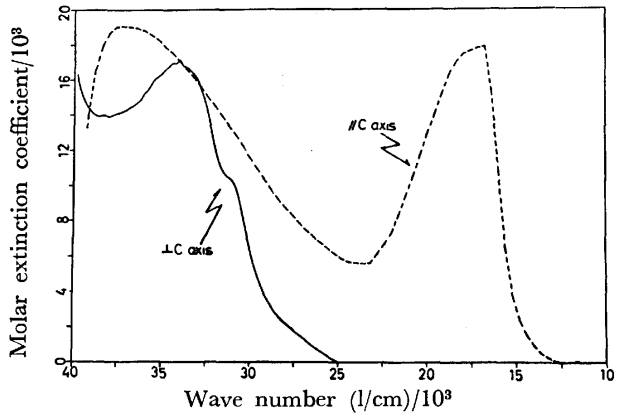

Fig. 4. The absorption spectra of the crystal of TCNE–HMB complex obtained from the K-K transformation of the reflection spectra.

The 17000 $\mathrm{cm^{-1}}$ band is exclusively polarized along the c axis, which can be assigned to a CT band. The oscillator strength of this band is 0.563, and the charge-transfer degree is 9.05%. The stabilization energy in the ground state is given as 4.40 kcal, as is shown in Table 1. The spectrum polarized perpendicular to the c axis consists of the locally excited band of the TCNE molecule, and the broad band in the region of 30000—37000 $\mathrm{cm^{-1}}$ corresponds to the 36000 $\mathrm{cm^{-1}}$ band of the TCNE crystal.

TCNE–Acenaphthene Complex. The crystal of this complex (ρ_{obsd}=*ca.* 1.3 $\mathrm{g/cm^3}$) is a brownish black prism, and its crystal structure is not known. The reflection spectra are observed for the light polarized along the three orthogonal axes (x, y, and z), and the absorption spectra are obtained by the K-K transformation of the reflection spectra, as is shown in Fig. 5.

The z-axis spectrum has three bands— at 14800, 23200, 30000 $\mathrm{cm^{-1}}$— which can be assigned to the CT band. The oscillator strengths of these bands are 0.388,

Table 1. The observed transition energy (E_{CT} in 10^3 cm^{-1}) and oscillator strength (f) and the calculated charge-transfer degree (b^2 in %) and stabilization energy (ΔE in kcal) in the ground state of TCNE complexes

TCNE complex	f	E_{CT}	b^2	ΔE
HMB	0.563	17.0	9.05	4.40
Acenaphthene	0.388	14.8	7.17	3.03
	0.238	23.2	2.80	1.86
	0.250	30.0	2.28	1.96
(Total)			12.3	6.85
Dibenzofuran	0.269	21.4	3.44	2.11
	0.160	29.0	1.51	1.25
(Total)			4.95	3.36

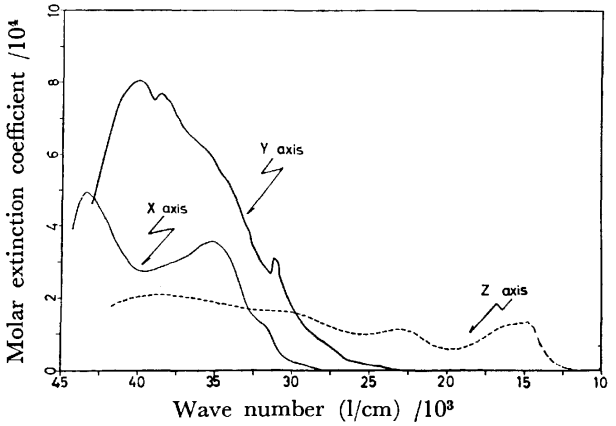

Fig. 5. The absorption spectra of the crystal of TCNE-acenaphthene complex obtained from the K-K transformation of the reflection spectra.

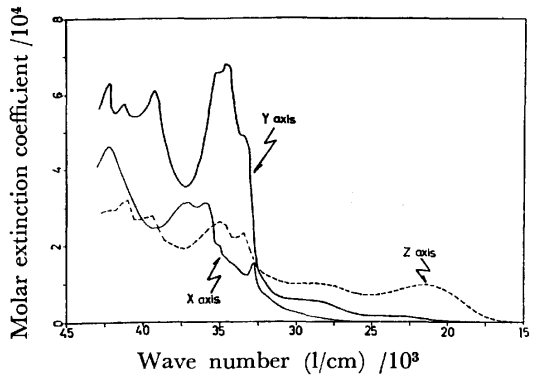

Fig. 6. The absorption spectra of the crystal of TCNE-dibenzofuran complex obtained from the K-K transformation of the reflection spectra.

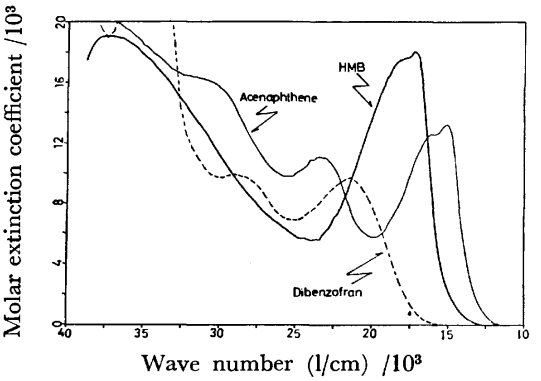

Fig. 7. The absorption spectra characteristic of crystals of TCNE complexes with HMB, acenaphthene, and dibenzofuran.

0.238, and 0.250 respectively. Each band contributes to the charge-transfer degree in the ground state, and the total degree becomes 12.3% by using R_{AD}=3.35 Å, as is shown in Table 1. The stabilization energy is also given as 6.85 kcal. The y-axis spectrum may consist of the α and β bands corresponding to the 30900 and 41800 cm^{-1} bands of the acenaphthene crystal,[14] while the x-axis spectrum consists of the p and β' bands corresponding to two bands at 31400 and 45000 cm^{-1} of the acenaphthene crystal and one band at 36000 cm^{-1} of the TCNE crystal.

TCNE–Dibenzofuran Complex. The crystal of this complex (ρ_{obsd}=*ca.* 1.3 g/cm^3) is a brownish black prism; its crystal structure is not known. The reflection spectra are observed for the light polarized along the three orthogonal axes (x, y, and z), while the absorption spectra are obtained by the K-K transformation of the reflection spectra, as is shown in Fig. 6.

The CT bands located at 21400 and 29000 cm^{-1} are observed in the z and y axes spectra. The total oscillator strengths of these two bands are 0.269 and 0.160, and the total charge-transfer degree in the ground state is estimated to be 4.95% by using R_{AD}=3.35 Å. The stabilization energy is also calculated to be 3.36 kcal, as is shown in Table 1. The y-axis spectrum may consist of the α*, p, and β' bands corresponding to the 33300, 39100, and 46000 cm^{-1} bands of dibenzofuran[15] in addition to two CT bands. The x-axis spectrum may consist of the α and β bands corresponding to two bands at 32600 and 42500 cm^{-1} of the dibenzofuran crystal and one band at 36000 cm^{-1} of the TCNE crystal.

Discussion

The absorption bands characteristic of crystals of TCNE complexes are again depicted in Fig. 7. The first CT band of the TCNE complexes with HMB and acenaphthene splits into doublets, the separation of which are 1500—1200 cm^{-1}. In the crystal of the TCNE–HMB complex,[13] the TCNE residues are disordered in two perpendicular orientations about the normal plane, with relative occupancies of 3 : 1. Therefore, two independent energy bands can be formed in the crystal as a result of the disorder and observed as a doublet.

Another characteristic of the absorption spectra of the TCNE complexes is the appearance of the second and third CT bands. This phenomenon can be observed with complexes of acenaphthene and dibenzofuran. These bands may be assigned to the CT transition from the highest, second highest, and third highest occupied orbitals of the donor to the lowest vacant orbital of TCNE.

The molar extinction coefficient, ε, and the half-

width of the TCNE–HMB complex are 4390[1,9] and 5200[8] cm^{-1} in the CH_2Cl_2 solution, and the oscillator strength is calculated to be $f^{solution}=0.09$; the value of $6f^{solution}=0.54$ is comparable to that of $f^{crystal}=0.563$ which is shown in Table 1.

PMR Studies of the Phase Transition in *N,N,N′,N′*-Tetramethyl-*p*-phenylenediamine (Wurster's Blue) Perchlorate

Motomichi INOUE, Hiroyoshi KURAMOTO, and Daiyu NAKAMURA
Department of Chemistry, Nagoya University, Chikusa, Nagoya 464

(Received May 27, 1977)

The powder PMR spectra of $[TMPD]^+(ClO_4)^-$ were recorded in the temperature range 110—300 K. The spectra observed above 140 K consist of two widely separated simple absorption curves of intensity ratio approximately equal to 3 : 1. Spin densities on the carbon and nitrogen atoms of the cation radical were evaluated from the observed field shift ascribable to the Fermi contact interaction. The spin density distribution of the radical ion changes at the transition temperature of 189 K.

The phase transition of *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine (TMPD) perchlorate attracts particular attention, because the crystals display phase transition at *ca.* 189 K accompanied by a novel magnetic behavior.[1,2] X-Ray crystal analysis carried out at 300 and 110 K has revealed that cation radicals, in the high-temperature phase, are stacked equidistantly to form a one-dimensional array, whereas radical ions are dimerized to construct alternating chains in the low-temperature phase.[3] The magnetic interaction between radical ions is closely related to the stacking of cations and also to the distribution of an unpaired electron within radicals.[4,5] The latter can be determined by observing the contact shift of PMR. Kawamori and Suzuki[6] have reported that the PMR absorption curve of TMPD-perchlorate powders consists of two component curves, and that the separation between the centers of the curves varies with temperature in proportion to the magnetic susceptibility of the compound. However, the authors failed to determine the absolute values of the PMR shifts. In the present investigation, we have precisely recorded the PMR spectrum of the radical salt at various temperatures between 110 and 300 K, and have determined the spin density distribution of the TMPD cations in crystals.

Experimental

TMPD perchlorate was prepared by the method of Michaelis and Granick.[7] Crystalline powders obtained were dried *in vacuo* for *ca.* 4 h to eliminate solvent molecules completely.

The PMR spectra were recorded by means of a JEOL JNM-MW-40 NMR spectrometer operating at 40 MHz with a field-modulation amplitude of 0.5 G.* Isohexane (isomeric mixture) was employed as an external standard. The temperature of the specimen was determined with a copper-constantan thermometer inserted directly in the specimen before and after recording each PMR spectrum. The temperature was automatically controlled within ±1° by the following method. Cold vapor evaporated from liquid nitrogen was conducted to the specimen through a transfer tube, in which a heater was mounted. The evaporation of liquid nitrogen was kept at a constant rate, and the temperature of flowing gas was controlled by use of the heater connected to a conventional PID temperature controller. The homogeneity of temperature in the specimen was difficult to keep within ±1°, because of a large volume of the specimen amounting to *ca.* 4 cm^3. The accuracy of the temperature was estimated to be within ±2° over the temperature range investigated.

* The unit corresponds to 10^{-4} T in the SI unit system.

Results

Figure 1 shows some typical derivative curves of PMR absorptions observed at various temperatures. Above *ca.* 140 K, each curve observed can be resolved into two component curves of intensity ratio equal to 3 : 1. The stronger component shifts to a low field, whereas the weaker one does to a high field. From the intensity ratio, the former can be assigned to *N*-methyl protons and the latter to the protons of benzene rings. The amount of the shifts from the external standard is plotted against the temperature for each component as shown in Fig. 2. The temperature dependence of the PMR shifts closely resembles that of the magnetic susceptibility. This is consistent with the results reported by Kawamori and Suzuki.[6]

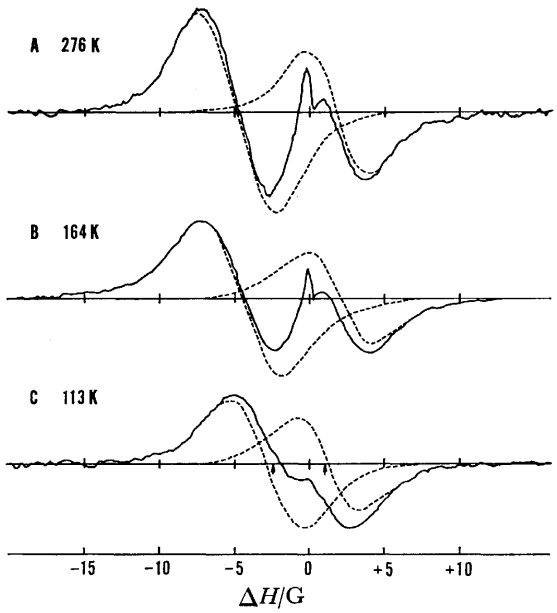

Fig. 1. PMR absorption derivative curves of $[TMPD](ClO_4)$ at various temperatures. Each curve can be resolved into two simple derivative curves (broken curves). Sharp components at $\Delta H=0$ in the spectra A and B are due to isohexane employed as an external standard. The spectrum C dispalys the curve recorded without the external standard to show the inherent curve clearly. The arrows in the spectrum C show the resonance fields estimated by use of the coupling constants of the low-temperature phase.

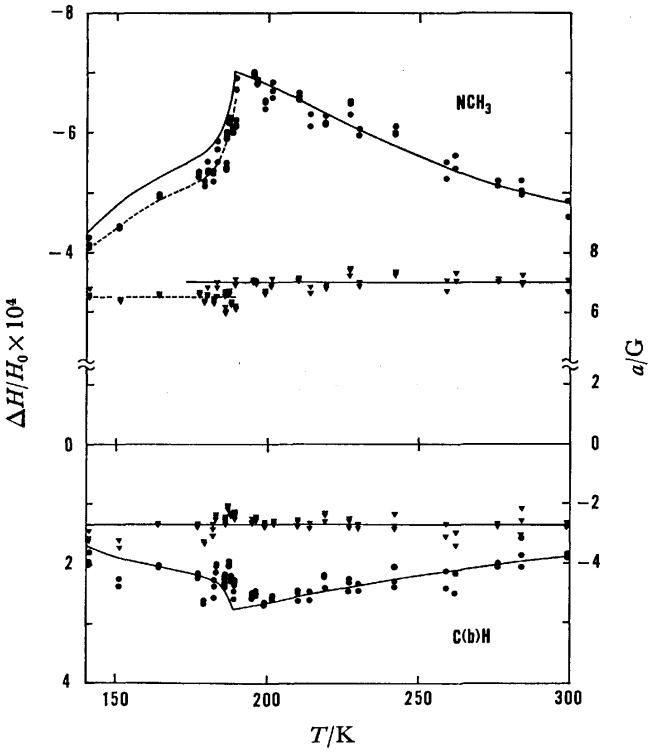

Fig. 2. Observed PMR shifts (●) and the coupling constants (▼) of *N*-methyl protons and ring protons. The straight lines show the respective averaged values of the coupling constants. The solid curves display the shifts evaluated with the coupling constants of the high-temperature phase. The a_{NCH_3} value averaged below T_c gives the broken curve reproducing well the shifts of *N*-methyl protons observed below T_c.

Each curve observed below 140 K can be decomposed into two simple derivative curves, the intensity ratio of which, however, varies with temperature. For example, the spectrum C in Fig. 1 observed at 113 K is made up of two components of intensity ratio nearly equal to 2 : 1. In this paper, the discussion is based solely on the data observed above 140 K.

Discussion

The PMR shift $\Delta H/H$ is attributable to the Fermi contact shift, which is proportional to magnetic susceptibility χ:[8]

$$\frac{\Delta H}{H_0} = -\frac{a_i}{g_N\mu_N}\cdot\frac{\chi}{cN}, \tag{1}$$

where, apart from the usual notations, a_i is the contact coupling constant in Gauss and c is the radical concentration determined from the Curie constant. Thus, the coupling constants, a_{NCH_3} for *N*-methyl protons and $a_{C(6)H}$ for ring protons, can be evaluated from the corresponding PMR shifts and the magnetic susceptibility which has been reported by Duffy, Jr.[1] and Okumura[2] in the temperature range 77—300 K. The temperature, at which the PMR shift shows a sharp decrease, agrees with the transition temperature T_c determined by Okumura rather than by Duffy, Jr. Therefore, the coupling constants were evaluated on the basis of Okumura's data (T_c=189 K and c=0.86$_7$). Each coupling constant is practically constant above T_c as shown in Fig. 2. The averaged values of the constants are listed in Table 1 along with estimated standard deviations. The shifts observed above T_c are well reproduced by the solid curves calculated using Eq. 1.

The coupling constant $a_{C(i)H}$ is proportional to spin density $\rho_{C(i)}$ localized on a carbon atom bonded to the proton:[8]

$$a_{C(i)H} = Q_{CH}\rho_{C(i)}, \tag{2}$$

where Q_{CH} is a proportionality constant. When the rotation of *N*-methyl groups is hindered in >N–CH_3 systems, the contact coupling constant depends on the torsional amplitude ϕ as well as the equilibrium angle θ_j between an N–C–H(j) plane and the axis of the nitrogen p-orbital involving the unpaired electron:[9]

$$a_{NCH_3}(j) = B\langle\cos^2\theta_j\rangle_\phi\rho_N, \tag{3}$$

where j stands for the jth proton of an *N*-methyl group and B is a proportionality constant. For freely rotating methyl groups, all the protons are equivalent so that the coupling constant is simply proportional to the spin density ρ_N of nitrogen:

$$a_{NCH_3} = Q_{NCH_3}\rho_N. \tag{4}$$

The *N*-methyl groups of TMPD cations can be assumed to undergo a free rotation about the threefold axis in the high-temperature phase, because of the following facts: (1) the component curve attributable to *N*-methyl protons has a peak-to-peak width nearly equal to that of the curve due to the ring protons, and shows no appreciable structure, and (2) the absolute values of the coupling constants agree well with the corresponding values determined by an ESR experiment[10] carried out on the radical ions in solution (Table 1), in which *N*-methyl groups perform a free rotation. The proportionality constants have been estimated as Q_{CH}=−28 G and Q_{NCH_3}=25 G.[11] By using these values, the spin density can be evaluated as given in Table 1. All the carbon atoms in the benzene ring carry positive spin densities. The spin density distribution has been calculated on the basis of various MO models.[11,12] The distribution determined by McLachlan[11] yields the best fit to the present result.

Below the transition temperature, the observed shifts of *N*-methyl protons deviate systematically from the solid curve in Fig. 2 calculated with the value of a_{NCH_3} evaluated above T_c, while the broken curve shows the temperature dependence of the shift calculated with a_{NCH_3}=6.52 G, reproducing well the data observed below T_c. The a_{NCH_3} value of the low-temperature phase differs clearly from that of the high-temperature phase. Although the magnetic data reported by Duffy differ slightly from Okumura's data, the coupling constants evaluated on the basis of Duffy's data agree with the corresponding values based on Okumura's data over the whole temperature range except near T_c (180—190 K). Therefore, it can be concluded that the "a_{NCH_3} gap" accompanying the phase transition is inherent in the radical salt. Two interpretations are conceivable for the marked a_{NCH_3} gap: (a) the spin density on nitrogen atoms changes appreciably at the transition

Table 1. Contact coupling constant a_i and spin density ρ_i of a TMPD cation[a)]

	a_{NCH_3}/G	$a_{C(b)H}$/G	ρ_N	$\rho_{C(b)}$	$\rho_{C(a)}$[b)]
$T>189$ K	7.01±0.20	−2.71±0.22	0.28_0	0.09_7	0.02_6
$T<189$ K	6.52±0.21	−2.69±0.35	0.26_1	0.09_6	0.04_7
ESR[c)]	6.76	(−)1.97	0.27_0	0.07_0	0.09_0

a)  b) $\rho_{C(a)}=\{1-(2\rho_N+4\rho_{C(b)})\}/2$. c) Ref. 10.

temperature, and (b) a hindered rotation of *N*-methyl groups below T_c yields an apparent Q_{NCH_3} value different from that for freely rotating *N*-methyl protons. Equation 3 indicates that, in case (b), three protons within an *N*-methyl group display PMR shifts different from one another, and, hence, the component curve attributable to *N*-methyl protons is expected to display an incipient indication of structure. Contrary to expectation, the component curve obtained below T_c exhibits no appreciable change in shape and line width as compared with that above T_c, suggesting that the *N*-methyl groups practically perform a free rotation even below the temperature. The aforementioned value of Q_{NCH_3} gives a smaller spin density ρ_N in the low-temperature phase than that in the high-temperature phase. This indicates that a fraction of an unpaired electron, in the former phase, is delocalized from nitrogen onto the aromatic ring to a greater extent. X-Ray crystal analysis[3)] has shown that the C–N bond length 1.346 Å at 110 K is evidently shorter than the length of 1.359 Å at 300 K, suggesting a larger double-bond character in the C–N bonds below T_c. This gives support to the present conclusion. The $a_{C(b)H}$ values averaged above and below T_c agree with each other, although the constant is difficult to determine accurately owing to the small absolute value. Hence, it can be presumed that $\rho_{C(b)}$ remains almost unchaged with decreasing temperature through T_c, despite the discernible change of $\rho_{C(a)}$. In fact, X-ray crystal analysis has shown that the C(*a*)–C(*b*) bond distance increases by 0.005 Å at 110 K whereas the C(*b*)–C(*b*) distance remains unchanged, suggesting that there is no significant alteration in the charge distribution on C(*b*) atoms above and below T_c.

The present investigation presents a unique example showing that the phase transition is accompanied by spin-distribution change in a molecule as well as change of molecular arrangement.

The Crystal and Molecular Structures of *trans*-Bis(trimethylphosphine)-[1,2-bis(methoxycarbonyl)vinyl](phenylethynyl)palladium(II)

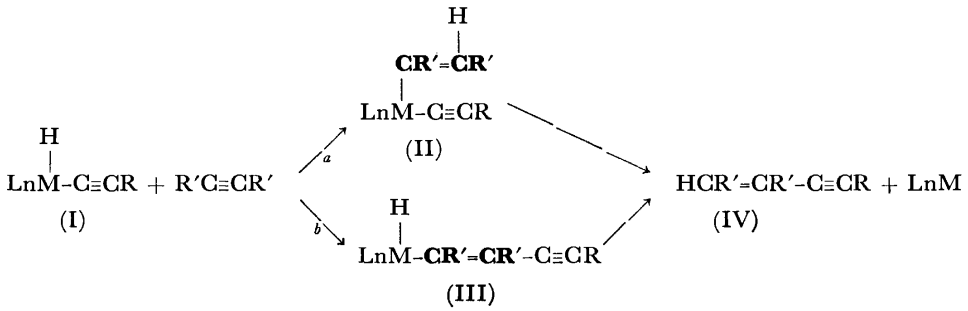
Takao YASUDA, Yasushi KAI, Noritake YASUOKA, and Nobutami KASAI*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received June 11, 1977)

The X-ray molecular structure of the addition product of *trans*-$HPd(PEt_3)_2(C{\equiv}CPh)$ with dimethyl acetylenedicarboxylate has been determined to be [*trans*-{$(MeO_2C)HC{=}C(CO_2Me)$}$Pd(PEt_3)_2(C{\equiv}CPh)$]. The crystal belongs to the monoclinic system, space group $P2_1/c$, with eight formula units in a cell with dimensions of a= 17.844(3), b=9.476(3), c=36.061(4) Å, β=98.18(1)°. Two independent molecules have similar structures except for the conformation of the phenylethynyl groups and one of the triethylphosphine groups. The 1,2-bis(methoxycarbonyl)vinyl and phenylethynyl groups are σ-bonded to the palladium atom. No significant difference is observed between the Pd-C(sp)[2.04(2) and 2.03(2) Å] and Pd-C(sp^2)[2.05(2) and 2.06(2) Å] bond lengths. The environment of the palladium atom is approximately square-planar: Pd-P=2.321(5), 2.312(5), and 2.305(5), 2.311(5) Å.

It has been reported that a hydridoalkynylmetal complex (I), which is formed by the oxidative addition of a terminal acetylene group to the metal, can be considered to be an intermediate in the oligomerization of terminal acetylenes catalyzed by low-valent transition-metal complexes,[1] and that the hydrido or alkynyl groups of such an intermediate may add to acetylenes to form an alkynylalkenyl (II) or a hydridoalkenyl (III) complex,[2] which can subsequently undergo reductive elimination to the dimer and reform the starting low-valent complex (Scheme).



Spectroscopic studies of the reaction products of dimethyl acetylenedicarboxylate with hydridoalkynyl complexes of palladium(II) and platinum(II) suggest that the addition may produce alkenylalkynyl derivatives[3] (Path *a* in the scheme). In order to establish the molecular structure and clarify the reaction mechanism, an X-ray structure analysis of the addition product of *trans*-$HPd(PEt_3)_2(C{\equiv}CPh)$ with dimethyl acetylenedicarboxylate has now been carried out.

Experimental

Yellow needle crystals of the addition product mentioned above were supplied by Professor N. Hagihara and his coworkers. The unit-cell parameters were determined by the least-squares fit, using 35 2θ values of high-angle reflections.

Crystal Data: [*trans*-{$(MeO_2C)HC{=}C(CO_2Me)$}$Pd(PEt_3)_2$-$(C{\equiv}CPh)$], $C_{26}H_{42}O_4P_2Pd$, F. W. 591.0, monoclinic, $P2_1/c$, a=17.844(3), b=9.476(3), c=36.061(4) Å, β=98.18(1)°, U=6036(2) Å^3, λ(Mo$K\alpha$)=0.71069 Å, D_m=1.29 g·cm^{-3}, Z=8, D_c=1.29 g·cm^{-3}, μ(Mo$K\alpha$)=7.59 cm^{-1}.

The intensity data were collected on a Rigaku automated, four-circle diffractometer using the θ-2θ scan technique. The graphite-monochromatized Mo$K\alpha$ radiation was used. The crystal used had dimensions of *ca.* 0.3×0.3×0.2 mm. The integrated intensity was determined by scanning over a peak at a rate of 4° min^{-1} and by subtracting the background obtained by averaging the two values measured for 5 s at both ends of a scan. The scan width in 2θ was $(1.6+0.70\theta_c)°$, where θ_c is the calculated Bragg angle for Mo$K\alpha_1$. A total of 4920 reflections was measured ($\sin\theta/\lambda \leqq 0.46$), of which 954 were less than $\sigma(F)$ and were classed "unobserved". Five standard reflections measured after every 60 reflections showed no significant change in intensity throughout the data collection. The Lorentz and polarization corrections were made in the usual way.

Structure Solution and Refinement

Two independent molecules are contained in an asymmetric unit. The palladium atoms were located from the Patterson map. The non-hydrogen atoms were then located from the subsequent Fourier synthesis. The structure was refined anisotropically by the block-diagonal least-squares procedure, using the HBLS V program.[4] The function minimized was $\Sigma w(\Delta F)^2$, where w was taken as unity. The final refinement reduced the R to 0.075 for 3966 non-zero reflections($\sin\theta/\lambda \leqq 0.46$). Hydrogen atoms were not included in the refinement. The atomic scattering factors were taken from the International Tables for X-Ray Crystallography, Vol. IV.[5] The positional and thermal parameters are given in Table 1.**

* To whom the correspondence should be addressed.

** The table of observed and calculated structure factors is kept as Document No. 7720 at the Chimical Society of Japan.

TABLE 1. ATOMIC PARAMETERS ALONG WITH THEIR ESTIMATED STANDARD DEVIATIONS IN PARENTHESES

Positional parameters in fraction of cell edges and thermal parameters in the form of $\exp[-\{B(11)h^2+B(22)k^2+B(33)l^2+B(12)hk+B(13)hl+B(23)kl\}]$.

Results and Discussion

Figure 1 shows a stereoscopic view of the two independent molecules in an asymmetric unit. The two molecules (A and B) have similar structures except for the conformation of the phenylethynyl groups and one of the triethylphosphine groups. Selected bond lengths and bond angles are given in Fig. 2.

The main feature of the structure is that the 1,2-bis(methoxycarbonyl)vinyl and phenylethynyl groups are σ-bonded to the palladium atom, and that they are

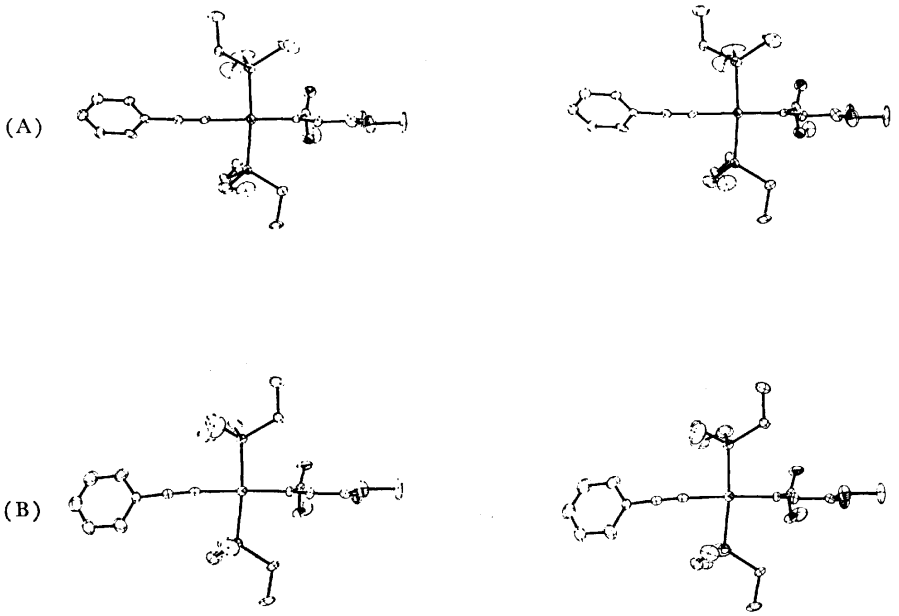

Fig. 1. Stereoscopic drawing of two independent molecules of [*trans*-{$(MeO_2C)HC{=}C(CO_2Me)$}$Pd(PEt_3)_2(C{\equiv}CPh)$].

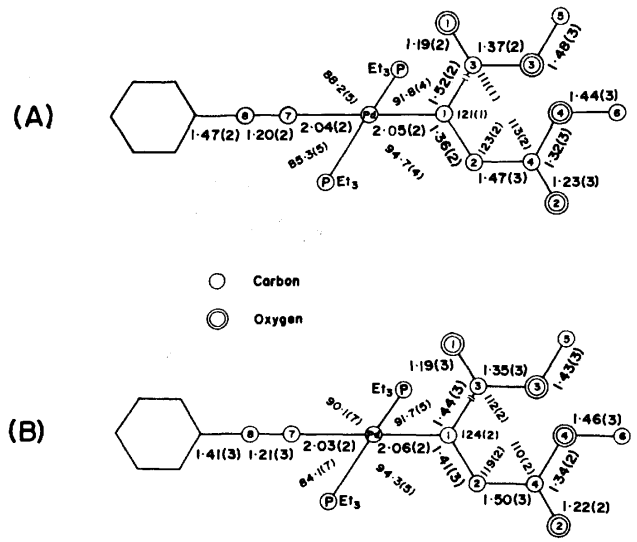

Fig. 2. Selected bond lengths and bond angles. E.s.d.'s in parentheses.

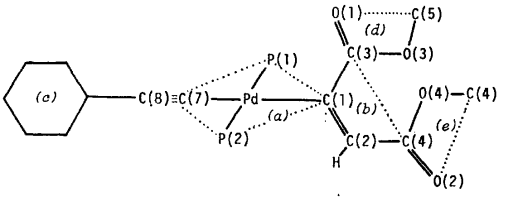
both in the *trans* position. This indicates that, of the two possible reaction paths in the scheme, the terminal acetylene reacted with the hydridoalkynylmetal complex to give the alkenylalkynyl derivative (Path *a* in the scheme). A third feature is that two methoxycarbonyl groups are mutually *cis*, the insertion of dimethyl acetylenedicarboxylate into the palladium atom being found to be a *cis*-insertion. This may be caused by the electronic repulsion between the methoxycarbonyl group and the palladium atom.

The environment of the palladium atom is approximately square-planar: the Pd, P(1), P(2), C(1), and C(7) atoms lie on a plane within 0.13 Å. The two Pd–P lengths are equal [2.321(5), 2.312(5) and 2.305(5), 2.311(5) Å], and no significant difference is found between the Pd–C(sp) [2.04(2) and 2.03(2) Å] and Pd–C(sp^2) lengths [2.05(2) and 2.06(2) Å].

TABLE 2. DIHEDRAL ANGLES



Molecule	Dihedral angles [°] between				
	(*a*) & (*b*)	(*a*) & (*c*)	(*a*) & C(7)≡C(8)	(*b*) & (*d*)	(*b*) & (*e*)
A	82.6	51.2	1.8	89.0	2.7
B	83.2	24.3	9.9	95.5	13.3

The alkenyl group, or, more exactly, the vinyl plane ((*b*) in Table 2), is roughly perpendicular to the co-ordination plane (*a*). The bulkiness of the alkenyl group probably causes the P(1)–Pd–C(1) and P(2)–Pd–C(1) bond angles to be larger than 90°. One of the methoxycarbonyl groups (*d*) is approximately perpendicular to, whereas the other one (*e*) is nearly parallel to, the vinyl plane (*b*). It seems that the C(4)=O(2) double bond lengths [1.23(3) and 1.22(2) Å] are slightly longer than the C(3)=O(1) lengths [1.19(2) and 1.19(3) Å], though this is not really significant; it can be explained by the conjugation of the C(4)=O(2) bond with the vinylic π-system.

The phenylethynyl groups in two molecules have rather different conformations: the C(7)–C(8) bonds make different angles of 1.8 and 9.9° with the co-ordination plane. The dihedral angles between the phenyl ring and the co-ordination plane also have different values [51.2 and 24.3°]. This is probably the result of the difference in the conformations of the triethylphosphine groups (Fig. 1). The bond lengths

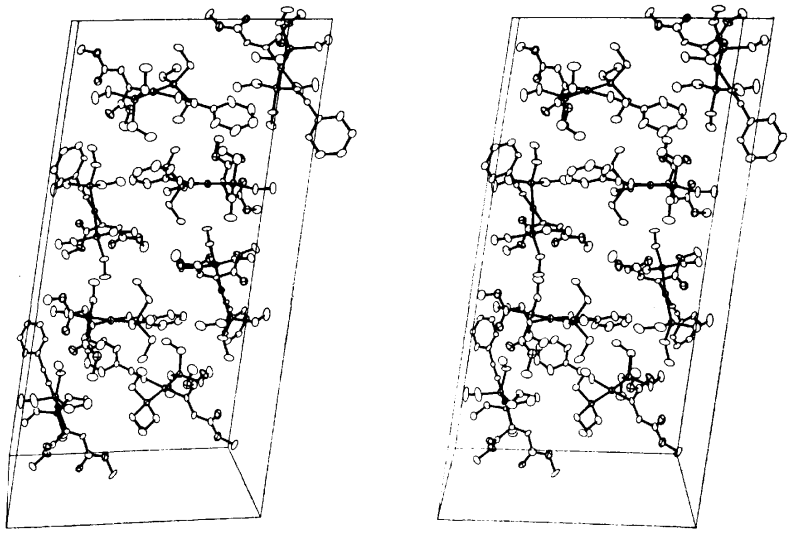


Fig. 3. Stereoscopic view of the crystal structure projected along the b axis. Non-hydrogen atoms are represented by thermal ellipsoid at 50% probability level.

(av. 1.40 and 1.40 Å) and bond angles (av. 120 and 120°) in the phenyl groups are normal.

As has been mentioned before, the triethylphosphine groups, including the P(1) atom have different conformations in two independent molecules: the PEt_3 group in Molecule B is rotated about 120° from that in A (Fig. 1). The exceptionally large thermal parameters of C(23) and C(33) atoms in A and the unusually short C(23A)–C(33A) bond length [1.28(5) Å] suggest disorder in these atoms. The other C–C bond lengths in ethyl groups have normal values (av. 1.55 Å).

The crystal structure is shown in Fig. 3. No close intermolecular atomic contacts less than the usual van der Waals distances can be observed.

All the computations in the present study were carried out on a NEAC 2200-700 computer at Osaka University. Figures 1 and 3 were drawn on a NUMERICON 7000 system at Osaka University, with a local version of ORTEP.[6]

The authors wish to express their deep thanks to Professor Nobue Hagihara, Professor Kenkichi Sonogashira, and their co-workers of Osaka University for their kindness in supplying crystals and for their many helpful discussions.

Solution Properties of Phycocyanin. IV. Studies of the Self-association Equilibrium of Phycocyanin in a pH 6.8 Solution*

Naomichi Iso, Haruo Mizuno, Takahide Saito, Noriko Nitta, and Katsuaki Yoshizaki**

Department of Food Science and Technology, Tokyo University of Fisheries, Konan, Minato-ku, Tokyo 108

(Received May 7, 1977)

The self-association of phycocyanin in a buffer of pH 6.8 with an ionic strength of 0.1 has been studied by sedimentation equilibrium measurements in the temperature range from 5.2 to 25 °C. The self-association of this system increases with a decrease in the temperature. A quantitative evaluation of the experimental data for this system indicates that the type of the association reaction is not a simple mechanism such as a monomer⇌*n*-mer, but the discrete monomer⇌trimer⇌tetramer mechanism is probable. Several thermodynamic quantities, such as the Gibbs free energy change, $\Delta G°$, the enthalpy change, $\Delta H°$, and the entropy change, $\Delta S°$, accompanying the self-association reaction were computed on the basis of the equilibrium constants. From the results, it is considered that the association process is similar to the ordinary crystallization, and that the formation of a tetramer proceeds at a higher concentration than that in which the trimerization reaction is completed.

Phycocyanin isolated from red or blue-green algae undergoes reversible self-associating reactions according to changes in the environment such as the pH, the ionic strength, the temperature, and the protein concentration of the solution.

In the course of our study of the solution properties of phycocyanin,[1-3] it was supposed, from an analysis of the sedimentation velocity data and of the sedimentation equilibrium data, that the self-association equilibrium was predominantly a monomer⇌hexamer at pH 5.4 and also probably a monomer⇌trimer at pH 6.8, both at the temperature of 25 °C. In the higher-concentration region at pH 6.8, however, the formation of the various aggregates higher than a trimer was probable, judging from the osmotic pressure measurements.

The purpose of the work reported here was to investigate the self-association reacting equilibrium of phycocyanin at pH 6.8 in more detail. That is, the equilibrium constants of the self-association of phycocyanin under various conditions of temperature were determined by sedimentation equilibrium measurements. The characteristic functions, such as the Gibbs free energy change, $\Delta G°$, the enthalpy change, $\Delta H°$, and the entropy change, $\Delta S°$, accompanying the self-association were evaluated on the basis of the equilibrium constants obtained.

Experimental

Materials. The crystalline phycocyanin used in this study was obtained from red alga *Porphyra tenera* by repeated precipitations with ammonium sulfate. The details of the purification of the protein were presented in an earlier paper.[1] The ionic strength was limited to 0.1 in the phosphate buffer in this work.

Sedimentation Equilibruim Measurements. The sedimentation equilibrium measurements were carried out using a magnetically suspended equilibrium-type ultracentrifuge and a Hitachi Model UCA-1 ultracentrifuge, with an interference optical system. All the measurements were made in about a 2-mm liquid column at a given speed for approximately 24 h so as to ensure that an equilibrium was established. The rotor speeds were set at approximately 8000—9000 rpm, and the measurements were done in the temperature range from 5.2 to 25.0 °C.

The apparent weight-average molecular weight at a position, r, in the solution column, $M_w^{app}(r)$, was calculated from the following equation:

$$M_w^{app}(r) = \frac{2RT}{(1-\bar{v}\rho)\omega^2}\frac{\mathrm{d}\ln c}{\mathrm{d}(r^2)}, \quad (1)$$

where $\bar{v}$ is the partial specific volume of the solute; ρ, the density of the solvent; ω, the angular velocity of the rotor; R, the gas constant, and T, the absolute temperature. The concentration, c, was calculated from the concentration difference, Δc, by the use of the formula

$$\Delta c = \Delta N\lambda/(\mathrm{d}n/\mathrm{d}c)L,$$

where ΔN is the number of fringes: λ, the wavelength of light (546 nm); $\mathrm{d}n/\mathrm{d}c$, the refractive-index increment, and L, the thickness of the cell (12 mm).

The Solvent Density and the Partial Specific Volume. The solvent density, ρ, at 16.5—25.0 °C was determined by means of a pycnometer approximately 10 ml in volume. The values of 1.0027 g/ml, 1.0039 g/ml, and 1.0046 g/ml were obtained at 25.0, 20.0, and 16.5 °C respectively. The values of 1.0052 g/ml at 11.5 °C and of 1.0056 g/ml at 5.2 °C were obtained by the linear extrapolation of the values at 16.5—25.0 °C.

Bull and Breese[4] have pointed out that the variation in the partial specific volume of the protein, $\bar{v}$, with the temperature is only *ca.* 0.08% at 5—25 °C. Accordingly, the literature value[5] of 0.744 ml/g was used for the partial specific volume of phycocyanin in all the measurements in this work.

The Refractive-index Increment. The refractive-index increment, $\mathrm{d}n/\mathrm{d}c$, was calculated from the schlieren pattern of a protein solution of a known concentration at 25.0 °C; this pattern has been obtained by using a synthetic-boundary cell. The value of 0.180 ml/g was obtained, and this value was used for the analysis of the experimental data in this work.

Results and Discussion

Figure 1 shows the concentration dependence of the apparent weight-average molecular weight of phycocyanin at pH 6.8, with the open and closed marks being indicative of the experiments performed at 5.2 and 25.0

* Presented at the 25th Annual Meeting of the Society of Polymer Science, Japan, Tokyo, May 30, 1976.

** Department of Chemistry, Tokyo Kyoiku University, Otsuka, Bunkyo-ku, Tokyo 112.

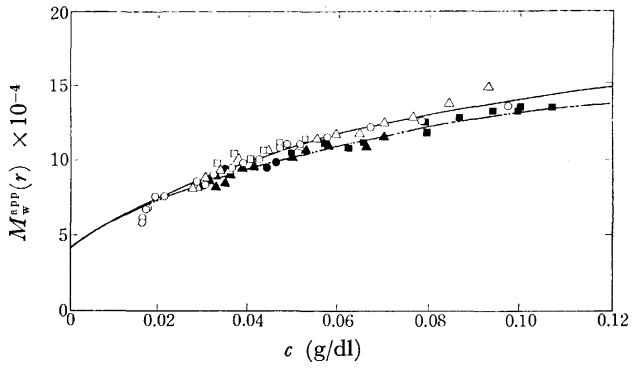

Fig. 1. Plots of $M_w^{app}(r)$ *versus* c for phycocyanin in a buffer of pH 6.8 and ionic strength 0.1 at 5.2 °C (upper curve) and at 25.0 °C (lower curve). The closed mark and the open mark correspond to the values at 25.0 °C and those at 5.2 °C, respectively. The various mark represent the values obtained with solutions of different initial concentration (g/dl): ○, 0.0048; △, 0.0054; □, 0.0031; ●, 0.0053; ▲, 0.0043; ■, 0.0084.

°C respectively. Similar results were obtained from the measurements performed at 20.0, 16.5, and 11.5 °C; these results stood between those at 25.0 °C and those at 5.2 °C in Fig. 1, in the order of the temperature. Consequently, it is clear that the association proceeds with a decrease in the temperature.

In our preceding paper,[3] the molecular weight of the monomer, M_1, of phycocyanin was assumed to be 42000 on the basis of the results of the osmotic pressure measurements. The value of 42000 is, then, used as the molecular weight of the monomer in the following analysis.

Tang and Adams[6] have proposed an analytical method applicable to any monomer⇌n-mer association system; by using it we can determine both the value of n and the equilibrium constant, K_n. According to their theory, the weight fraction of a monomer, f_1, is given as follows:

$$f_1 = \frac{U+2-(2/n)-\{[U+2-(2/n)]^2-8(Un-1)/n\}^{1/2}}{4(n-1)/n}, \tag{2}$$

where

$$U = 2(M_1/M_n^{app}(r)) - (M_1/M_w^{app}(r)) = \frac{2}{c}\int_0^{c_1}\left(\frac{c}{c_1}\right)dc_1 - \left(\frac{c}{c_1}\right)\frac{dc_1}{dc}, \tag{3}$$

$M_n^{app}(r)$ is the apparent number-average molecular weight at a position, r, which can be calculated from the value of $M_w^{app}(r)$ as measured by using the following equation:[7]

$$\frac{M_1}{M_n^{app}(r)} = \frac{1}{c}\int_0^c \frac{M_1}{M_w^{app}(r)}dc, \tag{4}$$

where c indicates the concentrations of all the species and where c_1 is the monomer concentration ($c_1=cf_1$). With the value of f_1, the following equation is derived:

$$(1-f_1)/f_1 = K_n(cf_1)^{n-1}. \tag{5}$$

If the arbitrarily chosen value of n is suitable, a plot of $(1-f_1)$ *versus* $c^{n-1}f_1^n$ will give a straight line which passes through the point of orgin.

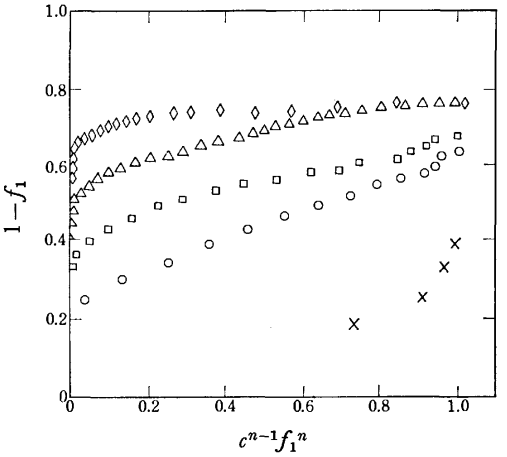

Fig. 2. Plots of $(1-f_1)$ *versus* $c^{n-1}f_1^n$, which are based on Eq. 5, for phycocyanin in a buffer of pH 6.8 and ionic strength 0.1 at 25.0 °C. ×, $n=2$; ○, $n=3$; □, $n=4$; △, $n=6$; ◇, $n=12$.

Their theory was applied to the self-association of phycocyanin in a buffer of pH 6.8 with ionic strength 0.1 at 5.2—25.0 °C. Figure 2 shows the plot of $(1-f_1)$ *versus* $c^{n-1}f_1^n$ at 25.0 °C, in which the n-values are chosen from 2 to 12. As is shown in Fig. 2, the plots were not straight lines passing through the point of origin; similar results were obtained at other temperatures. From these results, it may be concluded that the type of the association of phycocyanin in a buffer of pH 6.8 with an ionic strength 0.1 is not so simple as a monomer⇌n-mer.

In previous works[1,2] it was shown that the type of the association of phycocyanin at pH 6.8 was a monomer ⇌trimer at relatively low concentrations and that various higher aggregates were formed at higher concentrations. Therefore, we assume in this work that the type of the association of phycocyanin at this pH is a monomer⇌trimer⇌tetramer or a monomer⇌trimer⇌hexamer. Adams *et al.*[7,8] have analyzed the multi-component system and have proposed a procedure for evaluating an equilibrium constant for a monomer⇌dimer⇌trimer and a monomer⇌dimer⇌tetramer associations. Extending their treatment to a monomer ⇌trimer⇌tetramer, the following equation may be developed:

$$12M_1/M_w^{app}(r) = 7 + 6f_a e^{-BM_1c} + 6BM_1c - 1/[(M_1/M_w^{app}(r) - BM_1c], \tag{6}$$

where B is the non-ideal parameter. Moreover, the quantity f_a is the apparent weight fraction of the monomer and is obtained from the values of $M_w^{app}(r)$ and c according to the following equation:

$$\ln f_a = \int_0^c \left(\frac{M_1}{M_w^{app}(r)} - 1\right)\frac{dc}{c}. \tag{7}$$

In this work, it is assumed that all of the systems considered here are pseudo-ideal solutions, since the thermodynamic pseudo-ideality of the phycocyanin solution was confirmed by the experimental results from the osmotic pressure measurements.[2]

When the non-ideal parameter, B, is zero, the following equation may be derived for a monomer⇌trimer

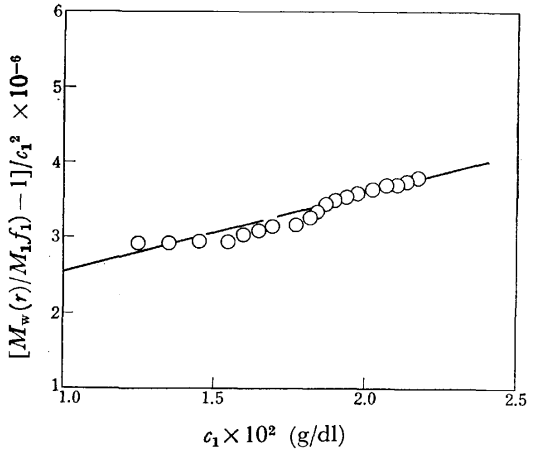

Fig. 3. Plot of $[(M_w(r)/M_1f_1)-1]/c_1^2$ *versus* c_1, which is based on Eq. 8, for phycocyanin in a buffer of pH 6.8 and ionic strength 0.1 at 25.0 °C.

⇌tetramer equilibrium:

$$[(M_w(r)/M_1f_1)-1]/c_1^2 = 3K_3 + 4K_4c_1, \quad (8)$$

where K_3 and K_4, which are calculated on the basis of the weight concentration (g/dl), are the equilibrium constants of a monomer⇌trimer equilibrium and a monomer⇌tetramer equilibrium respectively. According to Eq. 8, the plot of the value of the left-hand side of Eq. 8 *versus* c_1 will be linear. An example of such a plot is shown in Fig. 3, which is obtained from the data of the measurement at 25.0 °C. The plots at all the other temperatures were linear, like that at 25.0 °C, although they were excluded from Fig. 3 for the sake of simplicity. That is, all the plots of $[(M_w(r)/M_1f_1)-1]/c_1^2$ *versus* c_1 were linear. This means that the type of the association of phycocyanin in a buffer of pH 6.8 with an ionic strength 0.1 is probably a monomer⇌trimer⇌tetramer in the temperature range from 5.2 to 25.0 °C.

In the case of a linear plot such as that at 25.0 °C in Fig. 3, the values of K_3 and K_4 may be obtained from the intercept and the slope of the plot respectively. The values thus obtained are summarized in Table 1. These K_3- and K_4- values suggest that the lower aggregate, the trimer, decreases, while the higher aggregate, the tetramer, increases, with a decrease in the temperature. In order to ascertain the obtained values of K_3 and K_4, the values of $M_w(r)$ at some concentrations were calculated by using the K_3- and K_4-values and were compared with the values obtained experimentally. The calculated values were in good agreement with the experimental ones. Table 2 shows an example of the comparison.

A similar analytical procedure was applied to the experimental data assuming a monomer⇌trimer⇌hexamer system. The equilibrium constants of hexamerization, K_6, obtained decreased with a decrease in the temperature. The association proceeds with a decrease in the temperature, as is shown in Fig. 1. On the assumption that the higher aggregate may increase relatively with the process of association, the value of K_6 should increase with a decrease in the temperature. Thus, the associating mechanism of a monomer⇌trimer⇌hexamer system was not considered in this report.

Table 1. The equilibrium constants of the monomer ⇋ trimer and monomer ⇌ tetramer of phycocyanin at pH 6.8 and an ionic strength 0.1

0.12	13.0	12.4

Figures 4 and 5 show the plots of $\ln k_3$ *versus* $1/T$ and $\ln k_4$ *versus* $1/T$ respectively, where k_3 and k_4 are the molar equilibrium constants. The values of enthalpy change, $\Delta H°$, accompanying the trimerization and the tetramerization were calculated to be 6.4 kcal/mol and −3.8 kcal/mol respectively from the slope in each plot. Table 3 lists the enthaply changes, $\Delta H°$, the Gibbs free energy changes, $\Delta G°$, and the entropy changes, $\Delta S°$, for both reactions.

From the negative value of $\Delta G°$ and the positive value of $\Delta S°$, it is clear that the aggregation process is spontaneous under the experimental conditions in this study. The Gibbs free energy changes in Table 3 correspond to −4——5 kcal/mol per monomer unit. The values are comparable to the values reported for many other proteins.[9] Oosawa and Asakura[10] have suggested that the aggregation process of protein is similar to a crystallization mechanism. Figure 6 shows the relation between the concentration of the aggregate and the total concentration of the solution, which is estimated by using the values of K_3 and K_4 here obtained. The behavior shown in Fig. 6 may be considered to be similar to crystalization. The estimation using the values of K_3 and K_4 shows that the c_4 becomes equal to c_3 when $c=ca.$ 0.78 g/dl. In Fig. 6, the concentration range is limited to that used in the sedimentation equilibrium measurements. After that concentration the tetramer forms quickly.

Table 3. The characteristic thermodynamic functions accompanying the self-association reaction of phycocyanin

The units of ΔH° and ΔG° are (kcal/mol), and that of ΔS°, (cal/mol K)

	k (l/mol)$^{2 \text{ or } 3}$	ΔH°	ΔG°	ΔS°
monomer-trimer	$(2.0—4.0)\times10^{10}$	6.4	−13.1—−14.4	69—70
monomer-tetramer	$(4.5—9.3)\times10^{15}$	−3.8	−20.1—−21.3	59—60

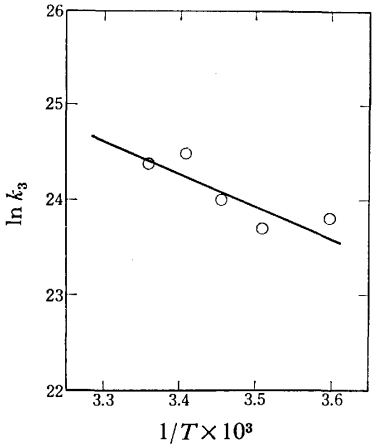

Fig. 4. Plot of $\ln k_3$ *versus* $1/T$.

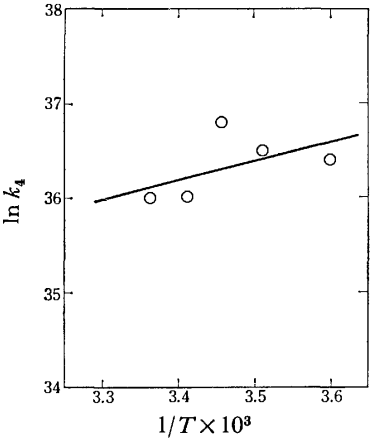

Fig. 5. Polt of $\ln k_4$ *versus* $1/T$.

Although a large part of the aggregate is a trimer in concentrations under 0.1 g/dl at this pH and ionic strength, small amounts of a higher aggregate, which is assigned to a tetramer in this work, also exist in this system. That is the reason why we could not determine the molecular shape of phycocyanin at the pH and ionic strength of a previous work.[2] The number-average molecular weight, M_n of 1.7×10^5 was obtained in the concentration range from 0.5 to 1.5 g/dl from the osmotic pressure measurements.[2] The M_n is calculated to be 1.4×10^5 in the same concentration range by using the values of K_3 and K_4 here obtained. The calculated value of 1.4×10^5 is comparable to the experimental value of 1.7×10^5. Considering the facts

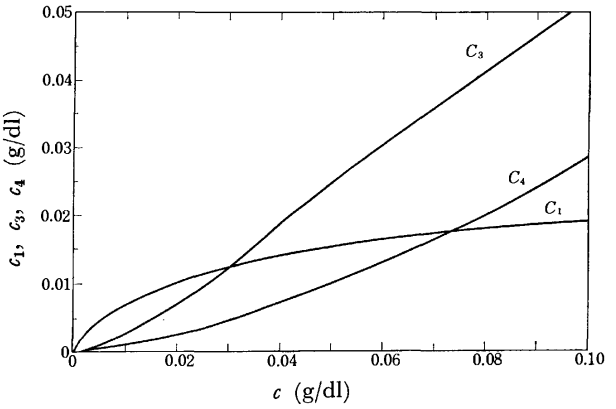

Fig. 6. The relation between the concentration of aggregate (c_3 and c_4) and the concentration of solution, which is estimated by using the values of K_3 and K_4 obtained.

that the phycocyanin molecule is most stable in solution at pH 5.4, and that the predominant species is assumed to be hexamer under this pH condition,[3] the associating system in this work may be intermediate from a monomeric state to a stable polymeric state, the hexamer. This is clear from the thermodynamic analysis of the association reaction of phycocyanin at pH 5.4.

Violet Emission Spectra of CN($B^2\Sigma$) Produced in the Photodissociation of HCN and DCN

Setsuko TATEMATSU and Kozo KUCHITSU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received June 17, 1977)

Emission spectra of the CN violet band system ($B^2\Sigma$-$X^2\Sigma$, $\Delta v=0$) produced in the photodissociation of HCN and DCN by Lyman-α radiation (121.6 nm) were observed with resolution of about 0.2 nm and with sample pressures of 0.01—1.5 Torr. The spectral features of the two were similar, but the main peaks ($v'=0$—4) from DCN appeared more sharply than the corresponding peaks from HCN. The relative vibrational populations and the effective rotational temperatures were estimated by a band-envelope analysis. No indication of vibrational population inversion was observed. The CN($B^2\Sigma$) radical produced from DCN is likely to have slightly higher vibrational (0.31 ± 0.08 eV measured from the zero-point energy) and rotational energies (0.15 ± 0.02 eV) than that from HCN (0.23 ± 0.08 and 0.11 ± 0.02 eV, respectively).

There has recently been a spate of theoretical and experimental investigations on the photofragmentation of simple polyatomic molecules. Many of them provide valuable information on the partitioning of internal and kinetic energies of fragments.[1,2] Diatomic radicals produced from linear molecules, particularly the CN($B^2\Sigma$) radicals from various cyanides, have been studied most extensively.[3] For instance, the CN($B^2\Sigma$) radicals from cyanogen halides were analyzed in detail by Mele and Okabe[4] and were recently reinvestigated by Ashfold and Simons[5,6] with much higher resolution.

One of the problems of current interest is the isotope effect on the production of CN($B^2\Sigma$) from HCN/DCN by vacuum ultraviolet radiation. In a number of recent theoretical studies,[7-10] model repulsive potentials for the C–H/C–D bond were estimated by fitting the vibrational distributions of CN($B^2\Sigma$) from HCN observed by Mele and Okabe,[4] and isotope effects on the photofragmentation probability and the vibtational distributions for the krypton and xenon resonance lines were predicted. The predictions made by Band and Freed[7] and by Atabek *et al.*[9,10] differed drastically from each other, but they equally emphasized the importance of an experimental measurement of this isotope effect for the elucidation of the mechanism and dynamics of photodissociation. It should be ideal for this purpose if the CN violet and red emission bands from HCN and DCN by radiations of several different wavelengths were to be measured with high resolution and high accuracy.

The present study is our effort in this direction but only to the limit of our current experimental facilities.[11] Relative vibrational distributions of the CN($B^2\Sigma$) produced from HCN and DCN with various sample pressures by Lyman-α radiation (121.6 nm) have been estimated by analyzing the violet emission spectra measured with medium resolution. The rotational distributions have been estimated by band-envelope simulation.

Experimental

The apparatus and experimental details have been reported previously.[11] The Lyman-α radiation was obtained by 2.45 GHz microwave discharge of a 1 : 3 mixture of hydrogen and helium. Fluorescence in the visible region from the sample cell was detected by a Nikon P-250 grating monochromator (1200 Gr/mm) blazed at 500 nm. The CN violet $\Delta v=0$ bands around 388 nm were observed with slit widths of 40—60 μm. The slit width of 50 μm corresponds to an energy resolution of about 0.2 nm. The signal from a photomultiplier (HTV R585) was measured by a photon counting system.

The sample of HCN was prepared by the reaction[12] of sodium cyanide with sulfuric acid at 60—80 °C. DCN was prepared in a similar way, D_2SO_4 and D_2O being used in place of H_2SO_4 and H_2O. The samples were purified by vacuum distillation. An infrared spectrum of HCN showed no trace of impurity. The isotopic purity of DCN was estimated from the Balmer emission intensities of H and D atoms produced by impact of 200 eV electrons.[13] The upper limit of hydrogen impurity was estimated from the observed intensity ratio to be about 10%.

Analysis

Spectral Features. The $\Delta v=0$ sequences of the CN violet band ($B^2\Sigma$-$X^2\Sigma$) produced from HCN and DCN were observed at pressures ranging from 0.01 to 1.5 Torr. The spectra observed around 388 nm were assigned according to the table prepared by Pearse and Gaydon.[14] The $\Delta v=-1$ sequence was also observed around 420 nm, but it was much weaker than the $\Delta v=$

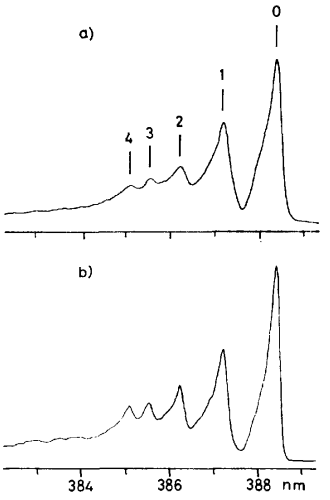

Fig. 1. Emission spectra of the CN violet ($B^2\Sigma$-$X^2\Sigma$) $\Delta v=0$ band from a) HCN, 0.04 Torr and b) DCN, 0.02 Torr with a slit width of 50 μm. The numbers indicate positions of the P-branch heads of the $v'=$ 0—4 bands.

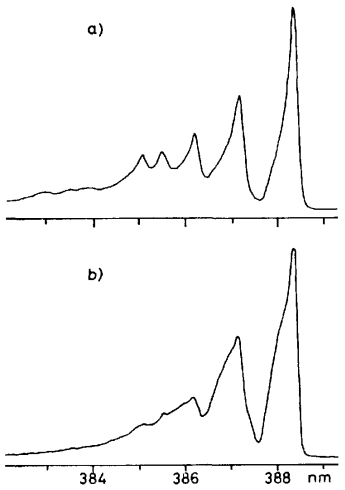

Fig. 2. Typical pressure dependence of the CN($B^2\Sigma$-$X^2\Sigma$) $\Delta v=0$ band from DCN at a) 0.01 Torr and b) 0.62 Torr. The effective rotational temperatures were estimated from best-fit analysis to be a) 1700±200 K and b) 1000±200 K.

0 sequence. Though the isotope effect on the emission yield was not measured quantitatively, there appeared to be no drastic isotope difference at this wavelength. Typical emission spectra measured under similar experimental conditions and at the lowest practicable sample pressures are shown in Fig. 1. The peak intensities of the bands decreased monotonically from $v'=0$ to 4, and no anomalous population distributions were observed. The bands from DCN had sharper peaks than those from HCN. The rotationally perturbed lines[5,6,15] were not observed significantly, but the spectral resolution was insufficient to prove or disprove their presence.

For both species the spectral features were essentially independent of the sample pressure below about 0.4 Torr, but they started to change when the pressure was further increased, as shown in Fig. 2: At a higher pressure the peaks were broadened and those with $v'=2$—4 became obscured. This trend has not been observed clearly for other cyanides studied concurrently[11,16] (BrCN, ICN, and $(CN)_2$).

Band-Envelope Analysis. The vibrational populations, $P_{v'}$, and the effective rotational temperatures, $T_r(v')$, of the CN($B^2\Sigma$) states immediately after production from HCN and DCN, *i.e.*, essentially free from subsequent collisional relaxations, were estimated by a band-envelope analysis.[11,17,19] Since the bands with $v'=5$—10 were buried within those of the lower vibrational levels, only crude estimates of $P_{v'}$ for $v'\geqq 5$ could be obtained. In addition, since the rotational lines were not resolved, the effective rotational temperatures for all the vibrational states were assumed to be equal. The parameters, $P_{v'}$ and T_r, were adjusted by trial and error to obtain the best fit of the calculated band envelope to the observed spectrum. A typical comparison of the observed and calculated band envelopes is shown in Fig. 3. The effective rotational temperatures were thus estimated to be 1300±200 and 1700±200 K for HCN and DCN, respectively. The relative vibrational populations, $P_{v'}/P_0$, in the low-pressure limit are listed in Table 1.

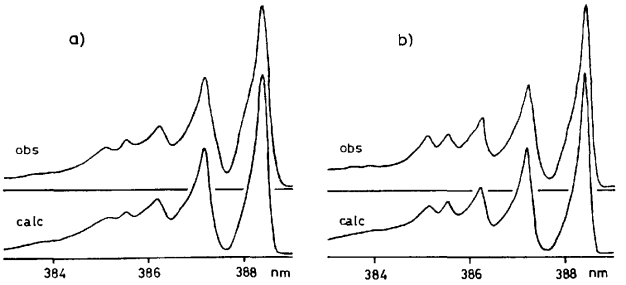

Fig. 3. Comparisons of the observed and best-fit calculated band envelopes of the CN($B^2\Sigma$-$X^2\Sigma$) $\Delta v=0$ from (a) HCN and (b) DCN.

Table 1. Relative vibrational populations ($P_{v'}/P_0$) for CN($B^2\Sigma$) produced in the photodissociation of HCN and DCN

v'	HCN[a]	DCN[a]	HCN[b]
0	1.00	1.00	1.00
1	0.54(5)	0.56(5)	0.40
2	0.20(5)	0.28(5)	0.09
3	0.10(4)	0.17(4)	0.012
4	0.06(3)	0.09(3)	0.006
5	0.04	0.07	—
6	0.02	0.04	—
7	<0.01	0.01	—

a) The present study, by Lyman-α radiation (121.6 nm). Uncertainties represent estimated limits of error in the last significant digits. The relative populations for $v'\geqq 5$ are only crude estimates. b) Crude estimates made by Mele and Okabe (Ref. 4) for the CN($B^2\Sigma$) produced by krypton resonance lines (116.5 and 123.6 nm).

Discussion

Distributions of Internal Energy. By use of the relative populations estimated in Table 1 and the known vibrational energy levels,[20] the average vibrational energies (above the zero-point energy) of the CN($B^2\Sigma$) produced from HCN and DCN are calculated to be 0.23±0.08 and 0.31±0.08 eV, respectively. The average rotational energies, given by kT_r, are estimated to be 0.11±0.02 and 0.15±0.02 eV for HCN and DCN, respectively. The estimated uncertainties include those due to the overlapping of the observable bands, the approximations made in the analysis, and the various sources of experimental error.

The available excess energy in the production of CN($B^2\Sigma$) from HCN corresponds to the difference between the photon energy (10.2 eV) and the sum of the C–H bond dissociation energy (5.2[21] or 5.5[22] eV) and the electronic energy of CN($B^2\Sigma$) from the ground vibrational state of CN($X^2\Sigma$) (3.1 eV).[23] Thus, the fractions of the available energy used for vibrational and rotational excitations are about 15 and 8%, respectively. These estimates agree with those reported by Mele and Okabe[4] for the CN($B^2\Sigma$) produced from HCN by the Kr (and Xe) resonance lines, about 13

and 7%.

Notwithstanding the appreciable uncertainties estimated above, the present study indicates slight isotope effects on the vibrational and rotational excitations of CN($B^2\Sigma$) produced from HCN and DCN.[24] A further more accurate measurement is necessary for a critical comparison of experimental and theoretical distributions of vibrational and rotational energies. In this connection, it is noteworthy that significant isotope effects on the vibrational and rotational distributions of CN($B^2\Sigma$) produced from HCN and DCN have been found in our recent study of electron-impact dissociation (*ca.* 200 eV) with much higher resolution.[25]

Pressure Effect. The observed changes in the spectrum when the sample pressure is higher than 0.4 Torr— the decrease in the peak intensities corresponding to $v'=2$—4 and the apparent decrease in the effective rotational temperatures— may be ascribed to collisional relaxations. If one assumes that the rotational relaxation takes place effectively at about 0.5 Torr, where the mean time between the formation of the CN($B^2\Sigma$) radicals and their collisions with the parent molecules is comparable with their natural radiative lifetime (presumably about 60 ns[26-28]), then it is possible to estimate roughly the effective cross section for the rotational relaxation of CN($B^2\Sigma$). Since the mean velocity of CN($B^2\Sigma$) is estimated to be about 6×10^4 cm/s, the cross section for rotational relaxation is probably of the order of 150 Å^2.

The research has been supported by Science and Technology Grants of Toray Science Foundation.

The Two-Photon Excitation Spectrum of Phenanthrene Crystal

Hiroshi OTOKOZAWA, Shigehiro INOMATA, Naohiko MIKAMI, and Mitsuo ITO
Department of Chemistry, Faculty of Science, Tohoku University, Aramaki, Aoba, Sendai 980
(Received July 14, 1977)

The two-photon excitation spectrum of phenanthrene crystal was measured and compared with the corresponding usual one-photon absorption spectrum. It was found that the two-photon spectrum consists of a one-photon like system and a system characteristic of a two-photon process. The vibronic couplings in phenanthrene were discussed on the basis of the observed results.

The two photon excitation spectra of benzene and naphthalene have recently been studied by many workers.[1-9] The most characteristic feature of the two-photon absorption of these molecules from the ground state to the lowest excited electronic state $^1B_{2u}(L_b)$ is the appearance of strong vibronic bands involving a b_{2u} vibration whose frequency in the excited state is about 1500 cm^{-1}. This is regarded as evidence of vibronic coupling involving the ground state.[10]

For both phenanthrene and naphthalene, the lowest excited electronic state is ^1L_b. For phenanthrene, it is $^1A_1(L_b)$, for which both one-photon and two-photon transitions from the ground state are allowed under the molecular symmetry C_{2v}. (See Fig. 1.) This is in contrast to naphthalene, where the transition to the $^1B_{2u}(L_b)$ state is one-photon allowed but two-photon forbidden. The purpose of the present work is to see how different the one-photon and two-photon spectra are for phenanthrene, where the electronic transition is simultaneously allowed by both one-photon and two-photon selection rules.

Phenanthrene was purified by zone refining. The single crystal was grown by the Bridgman method, and the ab cleavage plane was normal to incident light. The two-photon excitation spectra were measured at 4.2 K by irradiating with a dye laser over the tunable wavelength region between 580 and 700 nm and detecting the resulting fluorescence. These two-photon energies cover the entire spectral region of the lowest excited electronic state of phenanthrene (300 to 350 nm). The method of the spectral measurements is the same as that reported in our previous paper.[9] The accuracy of the observed frequencies is ±2 cm^{-1} for sharp bands. It was found that a trace of anthracene remaining in the phenanthrene crystal as an imputiry serves as an efficient fluorescence sensitizer. Polarization measurements were attempted. However, no significant difference was found between the main bands of the spectra with light polarized parallel to either the a or the b axis of the crystal. The two-photon excitation spectrum was observed also for the mixed crystal of biphenyl at 4.2 K. It was found that the spectrum of the mixed crystal is essentially the same as that of the pure crystal.

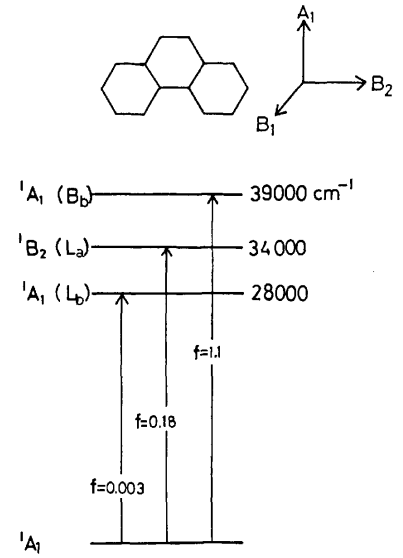

Fig. 1. Low lying electronic states of phenanthrene.

Figure 2 shows the two-photon excitation spectrum of the phenanthrene crystal, together with the corresponding usual absorption spectrum reproduced from a paper by Craig and Gordon.[11] Table 1 lists the observed frequencies of the main bands. It is seen from Fig. 2 that the 0,0 band appears strongly in the two-photon spectrum. This indicates that the electronic transition $^1A_1(L_b)$—$^1A_1$ is two-photon allowed as expected. Details of the Davydov splitting of the 0,0 band are somewhat different for the one-photon and the two-photon cases. In both spectra the lower frequency Davydov component is very sharp and has the same frequency. On the other hand the higher frequency component is very broad in the two-photon spectrum but is sharp in the one-photon spectrum. The maximum of the higher frequency component is

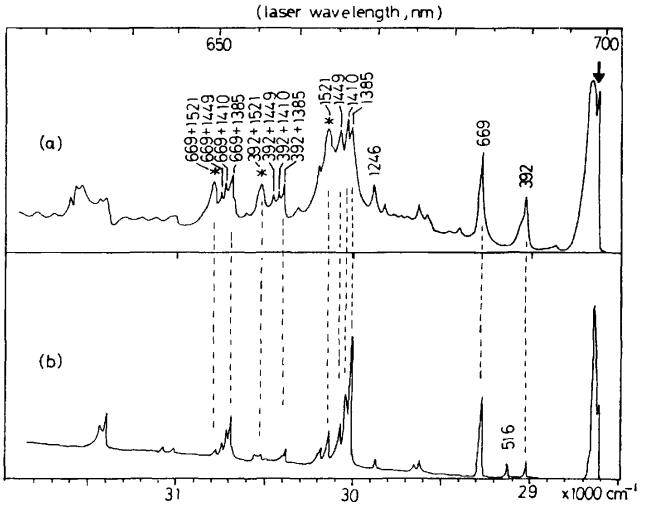

Fig. 2. (a) Two-photon excitation spectrum of phenanthrene crystal at 4.2 K. (b) One-photon absorption spectrum of phenanthrene crystal at 4.2 K taken from Ref. 11. The arrow indicates the position of the average frequency of the Davydov components of the one-photon 0,0 band (28627 cm^{-1}).

also shifted by 7 cm^{-1} toward higher frequency from the corresponding one-photon peak. The breadth and frequency shift of the higher frequency band suggest a considerable contribution by a low frequency lattice phonon to the intensity of the 0,0 band of the two-photon spectrum. Coupling with the phonon is also suggested for other broad vibronic bands.

In our vibrational analysis of the two-photon excitation spectrum, the average frequency of the Davydov components of the one-photon 0,0 band (28627 cm^{-1})[11] was taken as the origin from which frequency differences of the main vibronic bands were measured. It is seen from Fig. 2 and Table 1 that the observed frequency differences of the main bands agree very well with those of the one-photon spectrum within experimental error. There is a one-to-one correspondence between the one-photon and two-photon spectra for all the main vibronic bands, showing again the simultaneous one-photon and two-photon allowed transition.* However, the relative intensities of the vibronic bands are somewhat different in the two spectra. The two-photon vibronic bands can be classified into two groups, **A** and **B**, on the basis of their relative intensities in comparison with the intensities of the corresponding one-photon bands. The bands belonging to groups **A** are those for which the intensities relative to that of the 0,0 band are similar to those of the one-photon spectrum. The main bands in this group are 392, 669, 1385, 1410, 1449 cm^{-1} and their combinations. With a few exceptions they are generally very sharp. Group **B** consists of the vibronic bands involving 1521 cm^{-1} shown by asterisk in Fig. 2. These bands are weak in the one-photon spectrum, but fairly strong in the two-photon spectrum. They are also characterized by their broadness.

According to the ordinary absorption studies of the pure and mixed crystals of phenanthrene by Craig and Gordon[11] and by Hochstrasser and Small,[12] all the main bands in the **A** system involve totally symmetric vibrations in the excited state. The most interesting feature of the **A** system is the origin of the 669 cm^{-1} band. Craig and Gordon,[11] Hochstrasser and Small,[12] and Craig and Small[13] concluded that the 669 cm^{-1} band in the one-photon spectrum borrows part of its intensity from higher excited electronic states by vibronic coupling. Since 669 cm^{-1} is a totally symmetric vibration, this is an interesting example of vibronic coupling through a totally symmetric vibration. If this interpretation is correct, we expect some difference in the intensity of the 669 cm^{-1} band relative to that of the 0,0 band between the one-photon and two-photon spectra, because vibronic coupling schemes reflected in the two spectra are generally different. On the other hand, if the 0,1 band is not a vibrationally induced one, the relative intensity should be equal both for the one-photon and the two-photon spectra.

It is difficult to compare quantitatively the intensity

* The one-photon band, 0,0+516 cm^{-1} is missing in the two-photon spectrum. This will be discussed later.

ratio of the 0,0 band and the 0,0+669 cm^{-1} band in the two spectra because of rather large errors in the intensity estimation. However, qualitatively the observed ratios are not greatly different. At least the intensity relation between the 0,0 band and the 0,0+669 cm^{-1} band is similar in the two spectra. The intensity of the 669 cm^{-1} band relative to the 1385 cm^{-1} band, which has a non-vibronic origin according to Craig and Small[13], is also similar. These facts seem to support a non-vibronic origin for the 669 cm^{-1} band, contrary to the conclusion of Craig *et al.* However our qualitative intensity data are not good enough to derive a definite conclusion at the present time. We merely point out here that comparison between the relative intensities of one-photon and two-photon spectra may provide an additional clue for the origin of vibronic bands.

We shall consider next the **B** system, which consists of the vibronic bands involving the totally symmetric excited-state frequency of 1521 cm^{-1}. The **B** system is fairly strong in the two-photon spectrum and weak in the one-photon one. As mentioned before, the strong appearance of vibronic bands whose excited-state frequency is about 1500 cm^{-1} is a common characteristic of the ^1L_b—^1A two-photon absorption spectra of benzene and naphthalene.[1-9] Therefore, the **B** system of phenanthrene may be assumed to arise from the same cause as that of benzene and naphthalene. The effective vibrations of benzene and naphthalene are bond alternating C–C stretching modes. In benzene they are $\nu_{14}(b_{2u})$ (1566 cm^{-1} in the $^1B_{2u}(L_b)$ state and 1309 cm^{-1} in the ground state) and in naphthalene $\nu_{21}(b_{2u})$ (1535 cm^{-1} in $^1B_{2u}(L_b)$ state and 1361 cm^{-1} in the ground state). Mikami and Ito[10] concluded that these vibronic bands are due to vibronic coupling between the ground state and the lowest excited $^1B_{2u}(L_b)$ state through these vibrations. The excited-state vibration at 1521 cm^{-1} of phenanthrene probably corresponds to ν_{14} of benzene and ν_{21} of naphthalene, although it is a totally symmetric vibration in phenanthrene because of reduction of the molecular symmetry. Assuming that the vibronic coupling involving the ground state is similar to the cases of benzene and naphthalene, the corresponding ground state frequency should be smaller than 1521 cm^{-1}. It is expected to be between 1300 and 1400 cm^{-1} by analogy to benzene and naphthalene. There are several totally symmetric vibrations in this frequency region.[14] Unfortunately, it is difficult to pick a specific one because of the lack of knowledge about the detailed vibrational modes.

Finally, it may be worthwhile to mention that the moderately intense one-photon vibronic band 0,0+516 cm^{-1}, reported by Craig and Gordon[11] is entirely missing in our two-photon spectrum (see Fig. 2). In the one-photon spectrum it has about the same intensity as that of the nearby band 0,0+392 cm^{-1}. The latter appears with a considerably intensity in the two-photon spectrum, but the former is absent. This suggests that the 0,0+516 cm^{-1} band has a vibrationally induced origin which occurs selectively in the one-photon spectrum. The excited-state vibration of 516 cm^{-1} was assigned by Craig and Gordon[11] and by Hochstrasser and Small[12] to a totally symmetric vibration. The frequency is close to the excited-state $\nu_6(e_{2g})$ mode of benzene at 520 cm^{-1} [15] (606 cm^{-1} in the ground state) and to the excited-state $\nu_{33}(b_{3g})$ of 438 cm^{-1} of naphthalene[16] (506 cm^{-1} in the ground state). These vibrations are well known to be the most effective perturbing vibrations in mixing the ^1L_b states and ^1B states of benzene and naphthalene. Therefore, it is highly probable that the totally symmetric 516 cm^{-1} vibration of phenanthrene is the perturbing vibration coupling the lowest excited $^1A_1(L_b)$ state and the third lowest $^1A_1(B_b)$ state of this molecule.

We are appreciative to Drs. K. Kaya, Y. Udagawa, and F. A. Miller for the useful comments and discussions.

Magnetic Cross-over in Hexa-coordinate Iron(II) Complexes of Several Schiff Bases

Yonezo MAEDA, Shunji SHITE, Yoshimasa TAKASHIMA, and Yuzo NISHIDA

Department of Chemistry, Faculty of Science 33, Kyushu University, Hakozaki, Higashiku, Fukuoka 812

(Received October 26, 1976)

Iron(II) complexes with the Schiff bases of 6-methyl-2-pyridinecarbaldehyde and 2-quinolinecarbaldehyde, and with α,α′-diimine were prepared. The Mössbauer spectra and magnetic susceptibilities of the complexes, $Fe(cbi)_2(NCS)_2\cdot\frac{2}{3}CHCl_3$, $Fe(tbi)_2(NCS)_2\cdot CHCl_3$, $Fe(mpmea)_2(ClO_4)_2$, and $Fe(mepma)_3(ClO_4)_2$, were studied in the range of 80—298 K. It was found that these complexes show a $^5T_2$-$^1A_1$ spin transition in the solid state.

A number of iron(II) complexes have been shown to exhibit a $^5T_2$-$^1A_1$ spin equilibrium.[1-3] In this paper we wish to describe new iron complexes exhibiting such a spin equilibrium. The ligand abbreviations used in this work are as follows.

Abbreviation	*Ligand*
pbi	*N,N′*-diphenyl-2,3-butanediimine
tbi	*N,N′*-di-*p*-tolyl-2,3-butanediimine
cbi	*N,N′*-bis(*p*-chlorophenyl)-2,3-butanediimine
mbi	*N,N′*-bis(*p*-methoxyphenyl)-2,3-butanediimine
mepma	*N*-(6-methyl-2-pyridylmethylene)-methylamine
pmea	*N*-(2-pyridylmethylene)-2-(2-pyridyl)ethylamine
pema	*N*-[1-(2-pyridyl)ethylidene]-(2-pyridyl)methylamine
peea	*N*-[1-(2-pyridyl)ethylidene]-2-(2-pyridyl)ethylamine
mpmma	*N*-(6-methyl-2-pyridylmethylene)-2-pyridylmethylamine
mpmea	*N*-(6-methyl-2-pyridylmethylene)-2-(2-pyridyl)ethylamine
qmma	*N*-(2-quinolylmethylene)-2-pyridylmethylamine
qmea	*N*-(2-quinolylmethylene)-2-(2-pyridyl)ethylamine

Experimental

The preparation of the 2-quinolinecarbaldehyde was accomplished by the reduction of ω,ω-dibromoquinaldine with silver nitrate.[4] 6-methyl-2-pyridinecarbaldehyde, 2-pyridylmethylamine, and 2-(2-pyridyl)ethylamine were purchased from the Aldrich Co., Ltd. The ligands, α,α′-diimines, were isolated before the preparation of the complexes. The other Schiff bases were used without isolating them as solids. The complexes were prepared by mixing iron(II) salts and the Schiff bases in oxygen-free ethanol. The crude products were recrystallized from chloroform or ethanol. All the complexes except $Fe(qmma)_2(ClO_4)_2$ and $Fe(qmea)_2(ClO_4)_2$ were generally stable for oxidation.

The analytical data of the complexes prepared are listed in Table 1. The microanalyses were carried out at the Elemental Analysis Center of Kyushu University. The Mössbauer, electronic reflectance, and infrared spectra, and the conductivities in organic solvents were obtained as has been described elsewhere.[3] The effective magnetic moments, μ_{eff}, were obtained from the $\mu_{eff}=2.83\sqrt{\chi_m^T}$ relation, where χ_m is the molar susceptibility after applying diamagnetic corrections for both the ligands and anions.

Results and Discussion

Characterization of the Samples. The molar conductivities of the complexes listed in Table 2 indicate that the thiocyanates are non-electrolytic in acetone or chloroform, while the perchlorates behave as unibivalent electrolytes. The infrared spectra of the perchlorates show absorptions around 1090 cm^{-1}, which indicate that the perchlorate ion is ionic in these complexes.

Magnetic Susceptibilities. Figure 1 shows the variation in μ_{eff} with the temperature for the complexes which have cross-over points. Although we observed the Mössbauer absorptions of only low-spin states in

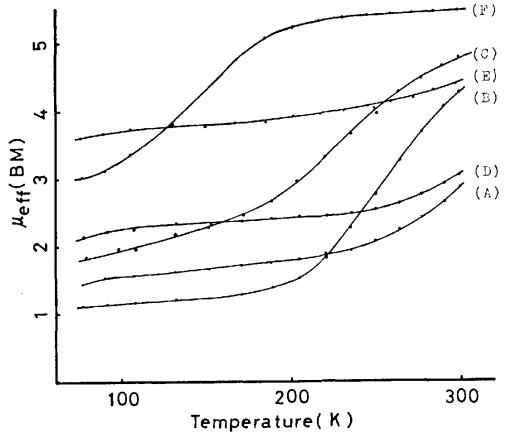

Fig. 1. Variation of the magnetic monemt μ_{eff} with temperature for (A) $Fe(pbi)_2(NCS)_2 \cdot \frac{1}{2}CHCl_3$, (B) $Fe(tbi)_2(NCS)_2 \cdot CHCl_3$, (C) $Fe(cbi)_2(NCS)_2 \cdot \frac{2}{3}CHCl_3$, (D) $Fe(mbi)_2(NCS)_2$, (E) $Fe(mpmea)_2(ClO_4)_2$, and (F) $Fe(mepma)_3(ClO_4)_2$.

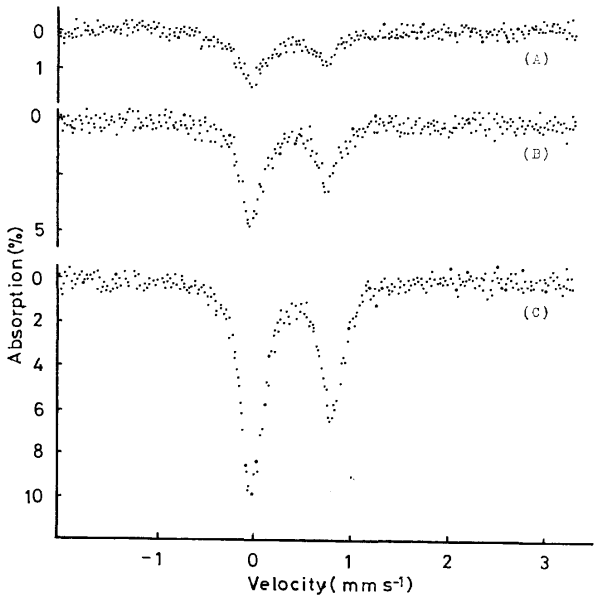

Fig. 2. Mössbauer spectra of $Fe(pbi)_2(NCS)_2 \cdot \frac{1}{2}CHCl_3$ at (A) 296 K, (B) 196 K, and (C) 80 K.

$Fe(pbi)_2(NCS)_2 \cdot \frac{1}{2}CHCl_3$ and $Fe(mbi)_2(NCS)_2$ at 296 K, the magnetic moments of the complexes probably increase at high temperatures, in view of the tendency of the curves. The magnetic data at 295 K show that $Fe(pmea)_2(ClO_4)_2$, $Fe(pema)_2(ClO_4)_2$, $Fe(peea)_2(ClO_4)_2$, $Fe(mpmma)_2(ClO_4)_2 \cdot H_2O$, and $Fe(qmma)_2(ClO_4)_2$ adopt a low-spin configuration (Table 2). A small residual paramagnetism is commonly observed in low-spin iron complexes with imine chelates. A large residual paramagnetism has been observed in the polymorph II of $Fe(phen)_2(NCS)_2$.[5] The origin of the rather high paramagnetism of $Fe(cbi)_2(NCS)_2 \cdot \frac{2}{3}CHCl_3$, $Fe(mbi)_2(NCS)_2$, $Fe(pbi)_2(NCS)_2 \cdot \frac{1}{2}CHCl_3$, and $Fe(mpmma)_2(ClO_4)_2 \cdot H_2O$ at low temperatures is not clear.

$Fe(mpmma)_2(ClO_4)_2 \cdot H_2O$ (five- and five-membered ring) adopts a low-spin configuration, and $Fe(mpmea)_2(ClO_4)_2$ (five- and six-membered ring) is a cross-over complex. $Fe(qmma)_2(ClO_4)_2$ (five- and five-membered ring) and $Fe(qmea)_2(ClO_4)_2$ (five- and six-membered ring) adopt low- and high-spin configurations respectively. These facts show that, in the complexes studied here, the ligands fields of the ligands forming five- and five-membered rings are stronger than those of the ligands forming five- and six-membered rings. The change in the spin multiplicity of iron upon the substitution of the methyl group at the 6-position of the pyridine ring is best attributed to the steric effect of methyl.

Mössbauer Spectra. Table 3 shows the Mössbauer parameters of the complexes. The isomer shifts, δ_{Fe}, were measured relative to the center of the spectrum

TABLE 3. MÖSSBAUER PARAMETERS FOR SEVERAL IRON COMPLEXES (mm/s)

Complexes	At 296 K		At 196 K		At 80 K		Spin state
	δ_{Fe}	ΔE	δ_{Fe}	ΔE	δ_{Fe}	ΔE

$Fe(qmea)_2(ClO_4)_2$	0.94	2.59			1.00	2.96	$S=2$

a) Was not observable.

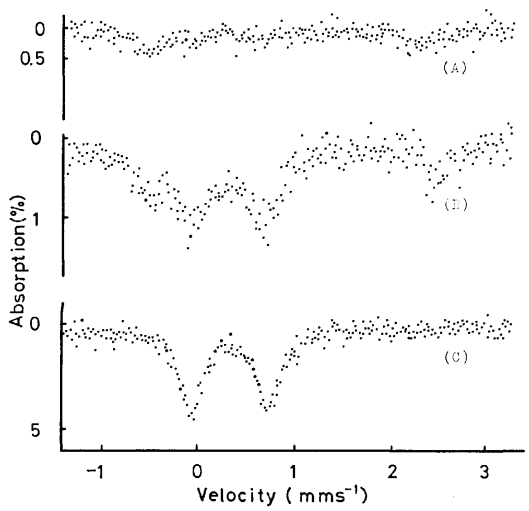

Fig. 3. Mössbauer spectra of $Fe(tbi)_2(NCS)_2\cdot CHCl_3$ at (A) 296 K, (B) 196 K, and (C) 80 K.

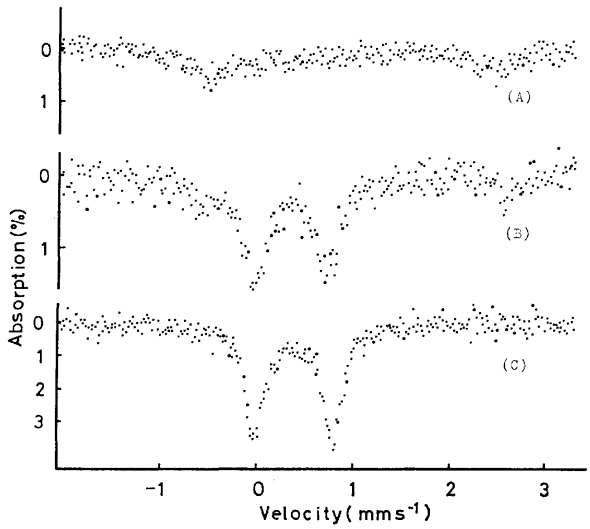

Fig. 4. Mössbauer spectra of $Fe(cbi)_2(NCS)_2\cdot\frac{2}{3}CHCl_3$ at (A) 296 K, (B) 196 K, and (C) 80 K.

of iron foil. The Mössbauer spectrum of $Fe(pbi)_2(NCS)_2\cdot\frac{1}{2}CHCl_3$ shows an asymmetric doublet, the center of which is situated in the range of low-spin iron(II) complexes at 296 and 80 K. The Mössbauer spectrum of $Fe(mbi)_2(NCS)_2$ at 296 K is virtually identical with that of $Fe(pbi)_2(NCS)_2\cdot\frac{1}{2}CHCl_3$, both giving only a low-spin state, though the former spectrum is not shown here. No spectrum of a high-spin state has been observed because of the small recoilless fraction or small populations of the high-spin isomer at 296 K, as can be seen in Fig. 2.

$Fe(tbi)_2(NCS)_2\cdot CHCl_3$ and $Fe(cbi)_2(NCS)_2\cdot\frac{2}{3}CHCl_3$ clearly show the Mössbauer absorptions of the $^1A_1$ and $^5T_2$ states at 196 K, as is shown in Figs. 3 and 4.

The Mössbauer spectra of $Fe(mpmea)_2(ClO_4)_2$ and $Fe(mepma)_3(ClO_4)_2$ in Figs. 5 and 6 show absorptions consisting of two species at 80 K, *i.e.*, high-spin and low-spin states. The component of the low-spin configuration increases as the temperature descends.

Assuming that the Debye-Waller factors, $f(^5T_2)$ and $f(^1A_1)$, are equal, we are able to calculate the proportions of the high-spin isomer, $S(^5T_2)$, from the Mössbauer spectral area and the magnetic data respectively. The magnetic moment values for $S=2$ and $S=0$ states were taken to be 5.30 and 0.80 BM for $Fe(mpmea)_2(ClO_4)_2$, and 5.46 and 0.80 BM for $Fe(mepma)_3(ClO_4)_2$, respectively. The results are shown below:

$Fe(mpmea)_2(ClO_4)_2$;	Temp(K)	196	80	14
(from Mössbauer data)	$S(^5T_2)(\%)$	50	45	50
(from magnetic data)	$S(^5T_2)(\%)$	53	45	—

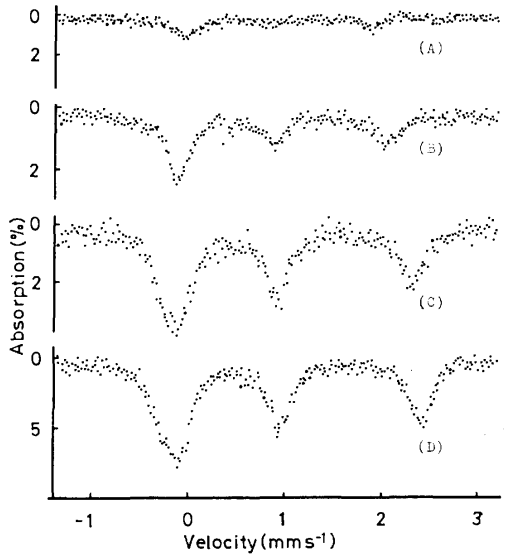

Fig. 5. Mössbauer spectra of $Fe(mpmea)_2(ClO_4)_2$ at (A) 296 K, (B) 196 K, (C) 80 K, and (D) 14 K.

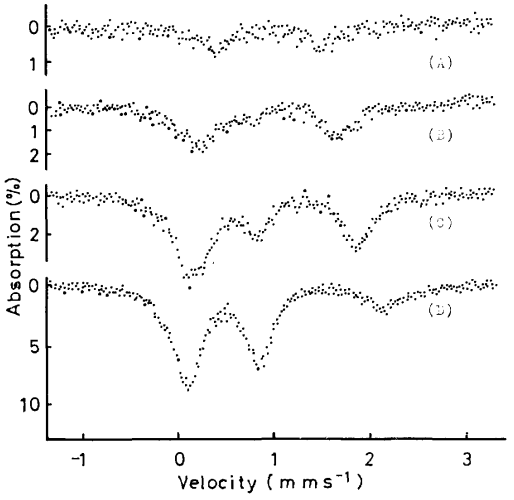

Fig. 6. Mössbauer spectra of $Fe(mepma)_3(ClO_4)_2$ at (A) 296 K, (B) 196 K, (C) 147 K, and (D) 80 K.

$Fe(mepma)_3(ClO_4)_2$;	Temp(K)	196	147	80
(from Mössbauer data)	$S(^5T_2)$(%)	68	63	33
(from magnetic data)	$S(^5T_2)$(%)	91	59	30

The difference between the populations of the high-spin isomer calculated from the Mössbauer spectral area and from the magnetic moment may show that the Debye-Waller factor $f(^5T_2)$ is less than $f(^1A_1)$.

For an axial field resulting from a trigonal ligand symmetry, the quadrupole splitting results primarily from an electron either in $t_{2g}{}^0(d_z{}^2)$ or in $t_{2g}{}^{\pm}$, where the $t_{2g}{}^{\pm}$ are:

$$t_{2g}{}^{+} = \frac{1}{3}(\sqrt{2}\,|d_{x^2-y^2}> - |d_{zx}>),$$

$$t_{2g}{}^{-} = \frac{1}{3}(\sqrt{2}\,|d_{xy}> + |d_{yz}>).$$

For the determination of the orbital ground state it is necessary to know the sign of the electric-field gradient tensor(V_{zz}). In $Fe(mephen)_3(ClO_4)_2$[6] and $Fe(2\text{-Cl-phen})_3(ClO_4)_2$,[7] negative quadrupole splittings have been observed. The lowest orbital of $Fe(mepma)_3(ClO_4)_2$, therefore, may be $d_z{}^2$. In this state, the field splitting of t_{2g} orbitals increases when the temperature is lowered (*i.e.*, from about 165 cm^{-1} at 296 K to 210 cm^{-1} at 80 K) in Ingall's approximation (assuming $\lambda = -80$ cm^{-1}).[8] This result corresponds to an increasing compression of the coordination octahedron over the $^5T_2$-$^1A_1$ transition region as the temperature descends.

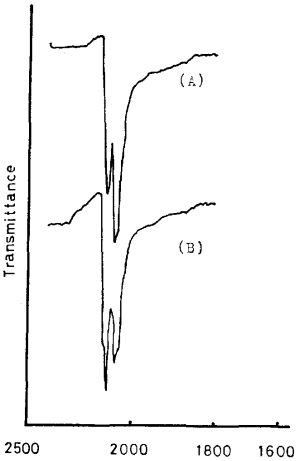

Fig. 7. The C=N stretching vibration region of the infrared spectra of $Fe(pbi)_2(NCS)_2 \cdot \frac{1}{2}CHCl_3$ at (A) 340 K and (B) 298 K.

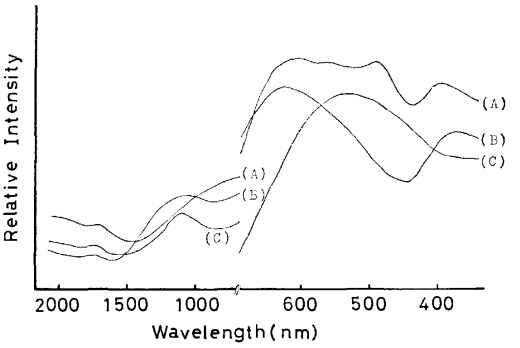

Fig. 8. Electronic reflectance spectra for (A) $Fe(mpmea)_2(ClO_4)_2$, (B) $Fe(cbi)_2(NCS)_2 \cdot \frac{2}{3}CHCl_3$, and (C) $Fe(mepma)_3(ClO_4)_2$.

Infrared Spectra. The data in Table 2 show that, in the $^5T_2$ state, the thiocyanate ion is *N*-bonded.[9] It has been reported that the C–N stretching modes in the $^1A_1$ state are observed in the range of 2100—2128 cm^{-1}.[10] Figure 7 shows the infrared spectra of $Fe(pbi)_2(NCS)_2 \cdot \frac{1}{2}CHCl_3$ in the range of 1800—2400 cm^{-1} at about 298 and 340 K. The spectrum at 340 K may be considered to be predominantly populated in the $^5T_2$ ground state, and the spectrum at 298 K, in the $^1A_1$ ground state.

The splitting of the C–N stretching band has been assigned to a *cis*-configuration of the compound.[10] If $Fe(tbi)_2(NCS)_2 \cdot CHCl_3$ (having an unsplitted C–N stretching band) had a *trans*-configuration, its quadrupole splitting in the low-spin state would be twice as large as that of the other complexes.[11] It seems to be ambiguous, therefore, for the splitting of the ν_{C-N} band

to be used to distinguish between *cis*- and *trans*-configurations.

Electronic Spectra. Figure 8 shows the electronic reflectance spectra of several complexes. The positions of the absorption maxima are listed in Table 2. The d-d spectra for α,α-diimine complexes show a shoulder band at about 10500 cm^{-1}. If we take $\Delta(^5T_2)=10D_q=10500\ cm^{-1}$, $\Delta(^5T_2)$ should be almost equal to the spin-pairing energy $\pi=\frac{5}{2}B+4C=18.5B$ (assuming the usual relation, $C=4B$, between the electron-repulsion parameters). Thus, taking $\Delta(^5T_2)=\pi$, one obtains $B(^5T_2)=568\ cm^{-1}$. Since B is 1058 cm^{-1} for free Fe^{2+}, the nephelauxetic ratio is $\beta=B(\text{complex})/B(\text{free ion})=0.54$. Since the value of D_q for $Fe(H_2O)_6^{2+}$ is estimated to be 1040 cm^{-1},[12] and since the critical D_q has been reported to be in the range of 1160—1340 cm^{-1}, or 1250±80 cm^{-1},[13] the D_q for iron-diimine complexes is considered to be significantly small. There are two plausible reasons for the small D_q of the iron-diimine complexes. First, the peak of 10500 cm^{-1} is one component of the doublet, while the other, on the high-energy side, is masked by the stronger charge-transfer band because site symmetry for the metal is distorted from O_h. Second, the Racah parameters for the free metal ion may be reduced drastically by ligand coordination because of the concomitant reduction of interelectronic repulsions.

Gel Chromatography of β-Diketones and Their Metal Complexes. III. The Chromatographic Behavior of Metal(II, III) Chelates with Acetylacetone in Systems of a Poly(vinyl acetate) Gel and Various Eluting Solvents[1]

Nobuo SUZUKI and Koichi SAITOH

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

(Received February 3, 1977)

Chelate compounds of acetylacetone (2,4-pentanedione) with metal ions (Al(III), Cr(III), Fe(III), Co(III), and Be(II)) were passed through a chromatograph in columns packed with a cross-linked poly(vinyl acetate) gel (Merckogel OR-2000). Various organic solvents (chloroform, benzene, toluene, 1,4-dioxane, ethyl acetate, butyl acetate, acetone, ethyl methyl ketone, and methanol) were used as the eluents. The distribution coefficient, K_{av}, for each chelate in a given column system was measured to within 0.7% of the relative standard deviation. The K_{av} values of a chelate were dependent on the solvent used. With most of the solvents, the K_{av} values of the metal(III)-chelates were close together and smaller than the K_{av} value of the Be(II)-chelate. The effective molar volume, V_{eff}, of the chelates thus determined, using calibration charts prepared on the basis of elution data for normal alkanes, depended strongly on the solvent used. With all the solvents except chloroform, the V_{eff} values of each chelate were smaller than the literature value of the molar volume for that chelate.

The uniqueness of gel chromatography can be found in its separation mechanism which is usually referred to as the molecular sieve effect resulting from the difference in the molecular dimensions of the solute species. This method is actively used in the fields of polymer and biological chemistry, not only as a method of separation, but also as a means of determining the molecular weight and size of solute molecules. Gel chromatography of neutral metal complexes has not yet been actively studied. Only a few papers have dealt with this subject.[2]

The program of the present study was initiated in an attempt to utilize the unique capabilities of gel chromatography in studying metal complexes in organic solvent media.[3] Acetylacetone (Hacac) and its metal chelates have been exclusively selected as model compounds and Merckogel OR-2000, a cross-linked poly(vinyl acetate) gel, has so far been used as the column-packing material. In the work dealing with metal(II, III) chelates with acac and normal alkanes in the column system, including tetrahydrofuran as an eluent, it was observed that these two sets of compounds are differ in their relationships between the distribution coefficient and the molar volume.[4] In an effort to elucidate this fact, the elution behavior of normal alkanes[5] and the degree of gel swelling[6] were investigated from a viewpoint of solvent effects.

In the present work, the distribution coefficients of some metal(II, III) chelates with acac were measured in various solvent systems, and determinations of the effective molar volume of these chelates were attempted.

Experimental

Metal Chelates. Tris(acetylacetonato)aluminum(III), -chromium(III), -iron(III), and -cobalt(III) (hereafter abbreviated to $[Al(acac)_3]$, $[Cr(acac)_3]$, $[Fe(acac)_3]$, and $[Co(acac)_3]$, respectively) were prepared and purified according to methods in the literature.[7-9] The results of elemental analysis are as follows. $[Al(acac)_3]$. Found: C, 55.19; H, 6.54%. Calcd: C, 55.56; H, 6.54%. $[Cr(acac)_3]$. Found: C, 51.87; H, 6.29%. Calcd: C, 51.56; H, 6.07%. $[Fe(acac)_3]$. Found: C, 51.02; H, 5.98%. Calcd: C, 51.00; H, 6.00%. $[Co(acac)_3]$. Found: C, 50.42; H, 5.99%. Calcd: C, 50.56; H, 5.95%. Bis(acetylacetonato)-beryllium(II) (hereafter abbreviated to $[Be(acac)_2]$) (Dojin Labs.) was further recrystallized from benzene and petroleum ether. Found: C, 57.99; H, 6.83%. Calcd: C, 57.77; H, 6.94%.

Solvents. Benzene, toluene, 1,4-dioxane, ethyl acetate, butyl acetate, acetone, ethyl methyl ketone and methanol were carefully distilled. Since the purified material was unstable, reagent-grade chloroform (Wako Chemicals) was used without further purification.

Columns and Apparatus. Most of the parts coming into contact with the liquids were made of PTFE or Pyrex, rather than metal, in order to avoid undesirable effects. The chromatographic column was a 100 cm long Pyrex tube with a 5-mm inside diameter packed with Merckogel OR-2000 (E. Merck) swollen by the solvent to be used. A Model FLC-350 syringe-type pump (JASCO) and a Model 1107L refractometric detector (L. D. C.) were used. The detection signal was fed into a JEC-5 computer (JEOL) for on-line data processing.

Procedure. A sample solution was prepared by dissolving 15 mg of a metal chelate and 5 mg of a mono-dispersed polystyrene standard (M_w=200 000, Pressure Chemical Co.) in 5 cm^3 of the solvent used as the eluent. With methanol, methylated blue dextran which had been prepared by methylation of Blue Dextran 2000 (Pharmacia)[5] was used in place of polystyrene. A 0.05-cm^3 portion of the sample solution was fed into the column with the aid of a loop injector, and elution was carried out at a solvent flow-rate of 0.20 cm^3 min^{-1} and at a column temperature of 25.0±0.02 °C. The UV and visible absorption spectra of the eluates were recorded in order to confirm the species eluted. Each experiment on a sample in a given column system was carried out at least three times.

Results and Discussion

Shape of Elution Curves. The chelates except for $[Fe(acac)_3]$ gave elution curves without excessive skewness in all solvent systems studied, with the values of the skew ratio[10] ranging from 0.9 to 1.0. $[Al(acac)_3]$ gave an exceptionally skewed elution curve with methanol. On the other hand, $[Fe(acac)_3]$ gave somewhat tailing elution curves in all solvent systems used.

Table 1. K_{av} values of metal chelates with acac in systems of Merckogel OR-2000 and various eluting solvents at 25.0 °C

No.	Eluting solvent	K_{av}[a]				
		$Al(acac)_3$	$Cr(acac)_3$	$Fe(acac)_3$	$Co(acac)_3$	$Be(acac)_2$

7	Acetone	0.858	0.908	0.931	0.946	0.964
8	Ethyl methyl kotone	0.895	0.942	0.945	0.981	0.980
9	Butyl acetate	1.23	1.34	1.36	1.24	1.41

a) Values converted from the K_{av} values.

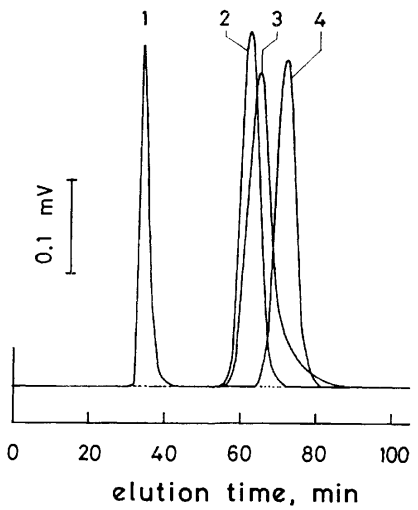

Fig. 1. Elution curves of (1) polystyrene (M_w= 200 000), (2) $[Cr(acac)_3]$, (3) $[Fe(acac)_3]$, and (4) $[Be(acac)_2]$.
Merckogel OR-2000 column, 100 cm×5 mm I. D., 25.0±0.02 °C; eluting solvent, 1,4-dioxane, 0.2 $cm^3 \cdot min^{-1}$; R. I. Detector, sens. 16 for (1), (2), and (4), sens, 8 for (3).

With methanol, both $[Al(acac)_3]$ and $[Fe(acac)_3]$ gave such skewed elution curves that no elution data with high reproducibility could be obtained for these two chelates. Typical elution curves obtained are shown in Fig. 1.

Distribution Coefficient. The elution volume, V_e, of a substance passed through a chromatograph in a given column system is expressed by

$$V_e = V_o + K_{av}V_x, \quad (1)$$

where V_o, V_x, and K_{av} are the column void volume, the volume of the gel phase, and the distribution coefficient, respectively.[11] In the present work, the K_{av} value of each chelate was calculated according to the relation,

$$K_{av} = (V_e - V_o)/(V_t - V_o), \quad (2)$$

where V_t is the total volume of the column ($V_t = V_o + V_x$). The V_t values of all columns used in this work were exactly 19.63 cm^3. The V_o value of the column was determined from a measurement of the V_e value of either a polystyrene standard or methylated blue dextran which are regarded as substances to be completely excluded from the Merckogel OR-2000 gel network. The dead volume related to that part of the tubing was corrected for in the calculation of the K_{av}

Table 3. Separation factor, α, for the $[Be(acac)_2]$-$[Cr(acac)_3]$ pair on Merckogel OR-2000 columns at 25.0 °C

No.	Eluting solvent	α
1	Chloroform	1.24
2	Benzene	1.58
3	Toluene	1.63
4	1,4-Dioxane	1.31
5	Tetrahydrofuran	1.20
6	Ethyl acetate	1.15
7	Acetone	1.06
8	Ethyl methyl ketone	1.04
9	Butyl acetate	1.05
10	Methanol	1.51

value.

The K_{av} values of the metal chelates were obtained with high reproducibility, the relative standard deviation in each instance being not more than 0.7%. However, precise data for $[Al(acac)_3]$ and $[Fe(acac)_3]$ could not be obtained in the systems with methanol. The results are given in Table 1 together with previous data on the system with tetrahydrofuran.

The gel chromatographic behavior of a solute substance is characterized also by the elution parameter K_d, derived from the relation,

$$V_e = V_o + K_d V_i, \quad (3)$$

where V_i is the volume of the internal solvent in the swollen gel beads. When V_x is assumed to be equal to the sum of V_i and the volume of the gel matrix, V_g, K_d can be obtained from K_{av} according to the following relation,

$$K_d = (V_x/V_i)K_{av} = [Q/(Q-1)]K_{av}, \quad (4)$$

where Q is the degree of gel swelling defined as the reciprocal of the volume fraction of the gel matrix in the swollen gel. The K_d values of metal chelates thus calculated from the available K_{av} and Q values[6] are given in Table 2.

It is obvious that both the K_{av} and K_d values of the chelates are strongly dependent on the solvent used. The solvents are arranged in Tables 1 and 2 in order of increasing K_{av} and K_d values for $[Al(acac)_3]$.

The K_{av} values of metal(III) chelates in a solvent are close together. This fact implies that separation of these chelates is not easy if a solvent is used as the eluent. The K_{av} value of $[Be(acac)_2]$ is larger than that of a metal(III) chelate in any solvent. The separation factor, α, defined as the ratio of the K_{av} values, for the $[Be(acac)_2]$-$[Cr(acac)_3]$ pair is given in Table 3. The α value for this solute pair depends on the solvent used, which reveals the importance of the choice of the solvent as the eluent for gel chromatographic separation.

Effective Molar Volume. For large molecules such as polymers, the molecular weight is frequently used as a size parameter for a compound in gel chromatography, whereas for small molecules having molecular weights less than 1000, the molar volume, V_m, is an effective size parameter.[12] The molar volume experimentally determined by means of gel chromatography

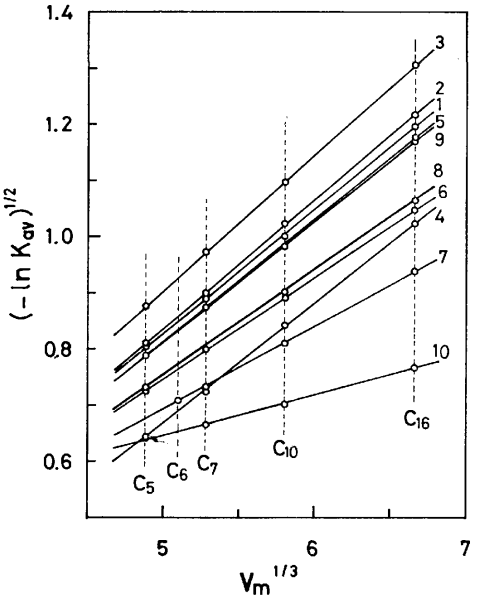

Fig. 2. Relationship between K_{av} and V_m for normal alkanes in the systems of Merckogel OR-2000 and various eluting solvents.
C_5, C_6, C_7, C_{10}, and C_{16} denote pentane, hexane, heptane, decane, and hexadecane, respectively. Numerals 1—10 denote solvents as in Table 1.

is termed the effective molar volume, V_{eff}, as distinct from V_m.[13,14] The V_{eff} values of the metal chelates were obtained in this work using the calibration charts based on the elution data for normal alkanes.

Laurent and Killander[11] have proposed the following equation,

$$K_{av} = \exp[-\pi L(r_r + r_s)^2], \quad (5)$$

where r_s is the radius of the solute molecule, and L and r_r are constant for a given combination of gel matrix and solvent. Assuming r_s to be proportional to the cube root of V_m, we can write

$$(-\ln K_{av})^{1/2} = k_1 + k_2 V_m^{1/3}, \quad (6)$$

where k_1 and k_2 are constants in a column system. The $(-\ln K_{av})^{1/2}$ *versus* $V_m^{1/3}$ plots in Fig. 2 are based on the K_{av} values for normal alkanes on Merckogel OR-2000[5] and the V_m values calculated from the molecular weight and density data for the respective compounds.[15] When these plots are used for calibration, the V_{eff} values of the chelates were obtained by comparing their K_{av} values with the plots. The results are given in Table 4. It is obvious that the V_{eff} values for each chelate is strongly dependent on the solvent used. The V_{eff} values of $[Cr(acac)_3]$, for example, range from 27 to 317 $cm^3\ mol^{-1}$.

Irving and Smith have shown that the partial molar volume of $[Cr(acac)_3]$ is nearly constant in different organic solvents[16] and Irving have reported V_m values of the chelates as follows: $[Al(acac)_3]$, 271; $[Cr(acac)_3]$, 267; $[Fe(acac)_3]$, 269; $[Co(acac)_3]$, 261 $cm^3 \cdot mol^{-1}$.[17] When the semi-empirical relation expressed by

$$V_{m,M(acac)_n} = 0.9\, n V_{m,Hacac}, \quad (7)$$

is used, the V_m value of $[Be(acac)_2]$ is estimated to be

Table 4. The V_{eff} values of metal chelates with acac determined using the calibration charts based on the gel chromatographic data for normal alkanes

No.	Eluting solvent	V_{eff}/cm^3 mol^{-1}				
		$Al(acac)_3$	$Cr(acac)_3$	$Fe(acac)_3$	$Co(acac)_3$	$Be(acac)_2$
1	Chloroform	315	317	245	317	266
2	Benzene	211	202	150	210	108
3	Toluene	150	143	126	144	56
4	1,4-Dioxane	234	230	217	232	155

6	Ethyl acetate	128	106	102	99	65
7	Acetone	143	120	110	104	94
8	Ethyl methyl ketone	111	97	96	86	88
9	Butyl acetate	48	27	23	47	13
10	Methanol	—	95	—	216	—

184 cm^3 mol^{-1}, where $V_{m,Hacac}$ and $V_{m,M(acac)_n}$ are the molar volumes of Hacac (=102 cm^3 mol^{-1}) and of its metal chelate containing an integral number n of $(acac)^-$ anions, respectively.[18] Comparing the V_m value of a chelate with the V_{eff} values shown in Table 4, it is obvious that the latter values are different from the former value. The V_{eff} values of the chelates, except for $[Fe(acac)_3]$ in chloroform, are marked larger than the V_m values of the respective chelates. Considering that many metal chelates with acac form solvated species in chloroform,[19,20] the larger V_{eff} values observed in this solvent may refer to solvations. Despite the fact that the V_m values of the 4 metal(III) chelates studied are close together, the V_{eff} values of $[Fe(acac)_3]$ are smaller than those of other metal(III) chelates in many solvents. Recalling that $[Fe(acac)_3]$ gave elution curves with a tailing and larger K_{av} values relative to other metal(III) chelates, and considering that Fe(III)-chelate is known to be a labile complex, it is deduced that some partial dissociation of the chelate occured in the chromatographic process. It is reasonable to consider that the relatively smaller V_{eff} values for $[Fe(acac)_3]$ result from such anomalous chromatographic behavior.

The fact that the K_{av} value for $[Be(acac)_2]$ in a given solvent is larger than the K_{av} values of the metal(III) chelates indicates that one of the factors governing the chromatographic behavior of those compounds is the molecular sieve effect. Considering that V_{eff} values of the chelates are different from the expected values (V_m values) and also that the K_d values, in some instances, are larger than unity, it is reasonable to assume that gel chromatography of the chelates is based not only on the molecular sieve effect but also on some other effects caused by interactions among the solute, solvent and gel matrix.

The selection of an appropriate eluting solvent is quite important for the purpose of estimating the molar volume of a solute species. According to the available data, the V_{eff} value of a metal chelate with acac obtained using 1,4-dioxane as an eluent appears to be close to the V_m value.

The solvent dependence of the gel chromatographic behavior is an attractive problem to be further elucidated. The details of the solvent effects and the so-called secondary effect in gel chromatography will be treated in a subsequent paper.

A Method for the Analysis of Halogenated Organic Compounds in Tap Water by Means of Mass Fragmentography of GC-MS

Toshihiro FUJII

Division of Chemistry and Physics, National Institute for Environmental Studies, Yatabe, Tsukuba, Ibaraki 300-21

(Received February 17, 1977)

A simple, sensitive and practical method for the halogenated organic compound analysis of tap water is reported. A pentane extraction procedure using a ten fold increase in concentration by volume (without further concentration) followed by mass fragmentography of GC-MS was used. As little as 0.05 ppb concentration of each compound was detectable. Five simple halogenated organic compounds, including CCl_4 and $CHBr_3$ whose concentrations are relatively small, were determined for tap water in Japan.

Recent years have seen an increasing concern[1,2] for levels of trace organic contaminants in water ultimately used for human consumption. In some cases less than 1 μg/l (1ppb) of the minimum detectable limit is required for specific compounds. This concentration is significant and all methods should approach this sensitivity requirement. Until now, procedures used for obtaining the required sensitivity have involved some sort of extraction procedure. Solvent extraction,[3-5] followed by further concentration for extreme trace concentration samples, has been commonly used. Although this method meets the sensitivity requirement, it suffers from serious interferences due to accumulation of solvent impurities as well as the informative substances.

However, solvent extraction without further concentration can be successfully applied to even extreme trace concentrations, when very high sensitive and specific detection is possible. Mass fragmentography[6] of GC-MS is a useful technique to meet the high sensitive and specific detection requirement, which provides specific information at a sensitive level that often surpasses that of the electron capture detector. I wish to report here a method for the analysis of halogenated organic compounds in tap water, utilizing mass fragmentography of GC-MS. A pentane extraction procedure without further concentration followed by mass fragmentography of GC-MS does not seem to have been reported.

Experimental

Apparatus. Gas chromatographic separation and mass spectrometric analysis were performed on a Finnigan 3300F gas chromatograph-quadrupole mass spectrometer equipped with multiple ion detector (Finnigan, PROMIM), by which mass fragmentography can be carried out. A selected mass can be quickly set with the aid of a digital mass marker display. The GC-MS interface utilizes an all glass jet-type enrichment device. A 3 m × 2 mm (i.d.) glass column packed with 5% SE-30 on 60/80 mesh Chromosorb W. AW. DMCS. (Johns-Manville) was used. Other conditions were: flow rate of helium carrier gas 30 ml/min, temperature of gas chromatograph injection port 200 °C, temperature of interface and transfer line 200 °C, pressure in the mass spectrometer 6×10^{-6} Torr, electron energy 70 eV, emission current 0.45 mA, electron multiplier 1450 volts.

Standard Solutions. A series of $CHCl_3$ standard concentrations in the range 0.5—400 ppb were made by successive dilution into special grade pentane (Wako pure chemicals) starting with pure $CHCl_3$ (Dojin chemicals). Calibration standards were made from pure reagents for each organohalide, $CHCl_2Br$, $CHClBr_2$, $CHBr_3$, and CCl_4 (Tokyo Kasei chemicals). Water used for recovery works was prepared by double distillation of ground water.

Procedure. Pretreatment of water samples was performed as follows, using pentane extraction procedure as a concentration technique. 10 ml of pentane was floated on 100 ml of water samples in a tightly closed container and agitated rigorously for 10 min. 10 μl injection of the extract was then made with a 10-μl Hamilton syringe (701-RN). At the start of each run the column was maintained at 40 °C for 7 min and programmed from 40 to 70 °C at 4 °C/min. The mass spectrometer was set to unit resolution (10% valley between adjacent nominal masses). The mass spectrometer was then set to monitor a specific mass of the examined compounds. The resulting ion currents were recorded on a strip chart recorder.

Positive identification of the compounds is supported not only by known retention times of the standards but also by the selectivity afforded by specific ion detection. The ions chosen to be monitored[7] include the chlorine and (or) bromine of each compound. Comparison of the expected ratio of isotope clusters with the observed ratio gives the permissible limit for analyzing unknown substances and determining whether they are free of coeluting impurities. Quantitative information was obtained using peak areas.

Results and Discussion

Detection Limit. Detection response (peak area) was linear over the range of standard solutions for each organohalide. The range was chosen to cover the concentrations likely to be found in various tap water samples. The detection limit of each compound (concentration of substance producing a peak five times higher than noise level) was found to be 0.5 ppb. Thus, water samples of 0.05 ppb concentration compound were determined by the extraction procedure using a ten fold increase in concentration by volume (10 ml of pentane per 100ml of water).

Recovery. Recovery was tested with amounts of the examined compounds similar to those which would be present in samples. A testing solution for recovery was prepared by mixing standard solutions of the compounds in treated and pretested water. The extraction was carried out as mentioned above. Recovery of each compound is given in Table 1. It is seen that efficient recovery was obtained for all tested substances, although a decrease in precision was observed at low concentration levels.

Table 1. Recovery of the halogenated organic compounds spiked into water

Compounds	Concentration added to water (μg/l)	Average[a] recovery (%)
$CHCl_3$	20	96±4
$CHCl_2Br$	1	94±8
$CHClBr_2$	1	93±7
$CHBr_3$	0.1	95±15
CCl_4	0.1	109±18

a) Average of five recovery works.

Table 2. Halogenated organic compounds in tap water

Compounds	Retention time (min)	Mass monitored (*m/e*)
$CHCl_3$	3.9	83,[a] 85
$CHCl_2Br$	7.2	83, 85, 127,[a] 129
$CHClBr_2$	10.8	127,[a] 129
$CHBr_3$	14.5	171, 173,[a] 175
CCl_4	4.9	117, 119[a]

a) Specific ions chosen for quantitative information of each compound.

Table 3. Halogenated organic compound concentrations (ppb) in tap water sample (July 8, 1976)

Location	$CHCl_3$	$CHCl_2Br$	$CHClBr_2$	$CHBr_3$	CCl_4
Hanamuro[a]	22.5	0.6	0.24	undetectable	0.1
Kanamachi[b]	17.5	2.6	1.7	0.06	0.08
Hamura[c]	18.8	1.0	0.53	undetectable	0.05

a) Tsukuba Research Center. b) West Tokyo. c) East Tokyo.

Solvent. The pentane used as the diluent of the standard solutions and the solvent of the extraction was found to contain no detectable $CHCl_2Br$, $CHClBr_2$ and $CHBr_3$ with the exception of $CHCl_3$ and CCl_4. The presence of $CHCl_3$ (0.06 ppb to be estimated with exploration) and CCl_4 (0.05 ppb) as a trace contaminant in pentane limited the accuracy. However, there is no trouble with $CHCl_3$ since its amount is negligibly small to affect the signal. There is a much wider choice of solvents, such as the higher alkanes. However, these solvents obscure the volatile extraction components. It is more difficult to obtain them in sufficient purity. Pentane was found to be the most suitable solvent.

Tap Water Analysis. Many halogenated organic compounds have been found in tap water in the U. S.,[1,2,5,8-10] considerable interest in their determination being aroused. Analyses were made in an attempt to survey the amounts of five halogenated organic compounds in tap water in Japan. Table 2 summarizes their retention times and masses monitored. These compounds were major components of the halogenated organic compounds discovered in the U.S. water supplies. Figure 1 shows typical mass fragmentograms (*m/e* 83, 119, 127, 173), results of the analysis of tap water

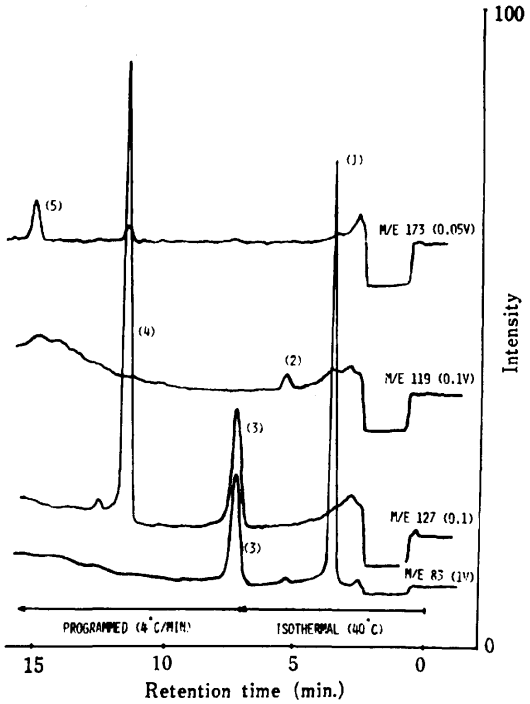

Fig. 1. Typical analysis of halogenated organic compounds in the tap water by mass fragmentography. A 10 μl injection.
Peaks are: (1) $CHCl_3$, (2) CCl_4, (3) $CHCl_2Br$, (4) $CHClBr_2$, (5) $CHBr_3$.

taken at Kanamachi in Tokyo. The results of measurements are given in Table 3. The $CHCl_2Br$ and $CHClBr_2$ concentrations were remarkably invariant. The related compound $CHBr_3$ was found in very low concentrations (0.06 ppb). The CCl_4 levels were very low. Individual samples of CCl_4 produced the same or a slightly higher peak than that of the trace contaminants in pentane. Quantitative values of CCl_4 were obtained by subtracting the amount of CCl_4 trace contaminants in pentane.

The Mutual Separation of ^{227}Ac, ^{227}Th, ^{223}Ra, and ^{223}Fr by the Solvent Extraction Technique Using Bis(2-ethylhexyl)phosphoric Acid as an Extractant

Toshiaki MITSUGASHIRA, Hajimu YAMANA, and Shin SUZUKI

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Katahira 2-chome, Sendai 980

(Received March 11, 1977)

The separation and purification of ^{227}Ac, ^{227}Th, ^{223}Ra, and ^{223}Fr were studied by the solvent extraction method using HDEHP (bis(2-ethylhexyl)phosphoric acid) as an extractant. The mutual separation of Ac, Th, and Ra was achieved, and new milking processes for ^{223}Fr and ^{228}Ac are presented.

The cyclic relation between ^{227}Ac, ^{227}Th, ^{223}Fr, and ^{223}Ra in natural actinium decay series is shown in Fig. 1. These nuclides are important as radioactive tracers, and interesting from the viewpoint of investigation of natural radioactive substances. Measurement of the radioactivity of ^{227}Ac is especially difficult, since its γ-activity and α-activity are very weak and the energy of β-rays are too low for quantitative detection. Many authors have reported on the application of radiation of its daughter nuclides to the detection and determination of ^{227}Ac. The separation of these nuclides is very important for the chemistry of natural radioactive substances.

The separation of Ac and Ra has been attempted by the cation exchange[1] and solvent extraction methods utilizing the TTA-TBP synergistic effect,[2] but these methods have certain drawbacks.

The cation exchange method,[1] because of its rather prolonged elution time, is not suitable for the separation of short-lived tracers such as ^{228}Ac ($t_{1/2}$=6.13 h)[3] and ^{223}Fr ($t_{1/2}$=21 min)[3] from each other. In the solvent extraction method using TTA as an extractant, it is necessary for the aqueous solution to have acidity of 4—5 pH, in spite of the remarkable tendency of Ac and Th toward hydrolysis in such a low acidic solution. The separation coefficient of Ac and Ra is expected to increase with the decrease in acidity of the aqueous solution, and there is a possibility of the hydrolysis of Ac also increasing in such a low acidic solution. Once the hydrolysis of Ac occurs, the separation coefficient should decrease because of the decrease in the proportion of the native ion Ac^{3+} in aqueous solution. It would be better to extract Ac from the solution whose acidity is as high as possible. Since HDEHP can extract some multivalent metal elements selectively from a highly acidic solution,[4] it is expected that Ac, Ra, and Th can be effectively separated from each other by HDEHP extraction. We have studied the application of HDEHP as an extractant to the separation of ^{227}Ac, ^{227}Th, ^{223}Ra, and ^{223}Fr.

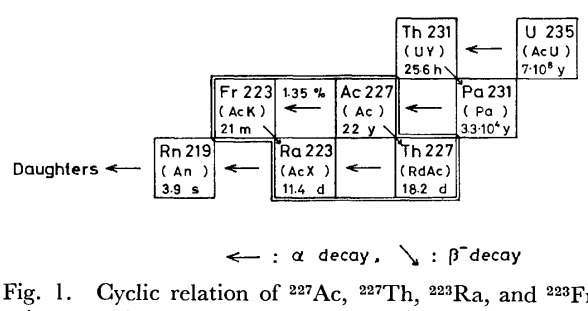

Fig. 1. Cyclic relation of ^{227}Ac, ^{227}Th, ^{223}Ra, and ^{223}Fr in natural actinium decay series.

It is well known that Th is quantitatively extracted by 1 M HDEHP–benzene solution from 0.2—0.5 M HCl solution. However, the extraction behavior of Ac, Ra, and Fr in the HDEHP extraction system is not known as yet. From the difference in the charge of the native ions Ac^{3+}, Ra^{2+}, and Fr^{+}, we can expect that Ac can most easily be extracted. Thus, the extraction conditions of Ac in the HDEHP extraction system were investigated first. It was found that Th is much more extractable than Ac and the separation of Ac and Th is easy. Thus the main problem was to separate Ac and Ra or Fr, and we tried to find the exact conditions for the separation of Ac and Ra. Fr goes to the Ra-fraction in our separation method, and there remains the problem of separating ^{223}Ra and ^{223}Fr. However, the difference in their half-lives is too large, and makes our procedures feasible. It is rather worthwhile to establish a new milking method of ^{223}Fr by which we can easily get ^{223}Fr grown from ^{227}Ac.

Experimental

Reagents. All the chemicals used were of analytical grade. HDEHP was purified by the procedures reported previously.[5]

Radioisotopes and Their Detection. *Ac*: ^{228}Ac was used as a tracer of Ac, whose γ-activity is very easy to detect,[3] and was prepared by the cation exchange chromatography method from ^{228}Ra isolated from ^{232}Th. When a sample of ^{228}Ac contains any amount of ^{228}Ra that is a parent nuclide of ^{228}Ac, the γ-activity of the sample does not vanish because of the radio-equilibrium between ^{228}Ac and ^{228}Ra. Thus, the purity of the sample of ^{228}Ac could be confirmed by checking the decay out of the γ-activity of the sample in each experiment.

Ra and Th: ^{223}Ra and ^{227}Th isolated from ^{227}Ac in their radio-equilibrium by cation exchange chromatography were used as the tracers. These two nuclides were determined by measuring their γ-spectra by Ge(Li) detector and calculating the peak area of their characteristic γ-ray peaks.

pH Buffer Solution. Considering the fact that the distribution ratios of multivalent metal ions in HDEHP extraction system are expected to be a sensitive function of the acidity of the solution, the pH value of the aqueous phase must be fixed in order to keep the reproducibility of the extraction. Thus, we used "Clark-Lubbs pH buffer solution"[6] which consists of KCl and HCl in the range of pH$\leq$ 2.2, and KH phthalate and HCl in the range of pH$\geq$2.2, where the concentration of both salts in each solution is 0.05 M. Solutions, the pH values of which were 1.0—3.6 were prepared using this buffer solution in this work. Since there might be difference in their behavior between KCl-system and KH phthalate-system, two kinds of solutions made from two different salts were prepared in the range of 2.1$\leq$pH$\leq$

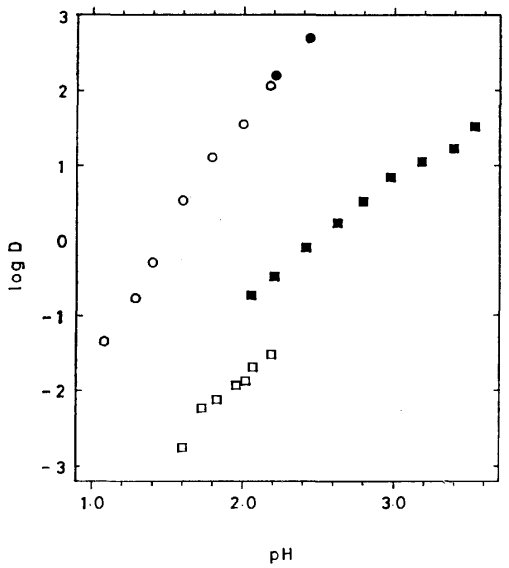

Fig. 2. Relations between D_{Ac}, D_{Ra} and the acidity of the aqueous phase.
○● : D_{Ac} when KCl (○) and KH phthalate (●) buffer solution was used. □■ : D_{Ra} when KCl (□) and KH phthalate (■) buffer solution was used.

2.2, and the data were compared with each other.

Apparatus. The apparatus used are as follows. *Separatory Funnel Shaker*: IWAKI KM type (200—400 rpm), *Ge(Li) Detector*: ORTEC model number 8101-1820 (the effective volume is about 60 ml), *Multichannel Pulse Height Analyser*: TOSHIBA USC-1 4096 ch (controlled by a mini-computer TOSBAC-40 A), *NaI Scintillation Counter*: HITACHI well type $1^3/_4'' \times 2''$, *Digital pH Meter*: ORION 801-A type.

Procedures. The back extraction behavior of Ac was investigated according to the following procedures. The pH value of the ^{228}Ac solution was adjusted to 3.0 and ^{228}Ac was extracted with a 1M HDEHP-benzene solution. Then a 5 ml portion of the organic phase containing ^{228}Ac was poured to the another separatory funnel and shaken for 20 min with 5 ml of buffer solution.

The forward extraction of ^{223}Ra was investigated with the shaking time of 20 min.

In both cases of Ac and Ra, the pH value of the aqueous phase was checked after extraction with a digital pH meter. A 2 ml portion of each phase was taken into a polyethylene test tube and their γ-rays were measured. The calculation of the peak area of the characteristic γ-rays of ^{223}Ra and ^{227}Th were carried out with a mini-computer system[7] connected to the multichannel pulse height analyzer.

For the final experiment to check the separation method, a mixed solution of ^{227}Ac, ^{227}Th, and ^{223}Ra in radio-equilibrium was used. A radio-equilibrium mixture of ^{227}Ac and ^{223}Fr was used for the check of the milking of ^{223}Fr.

The distribution ratio of each element is defined by

$$D_M = C_{M.org}/C_{M.aq}$$

where M denotes metal element, $C_{M.org}$ the concentration of M in the organic phase and $C_{M.aq}$ that in the aqueous phase. The separation coefficient is defined by

$$\alpha_{Ac,Ra} = D_{Ac}/D_{Ra}.$$

Results and Discussion

Dependence of D_{Ac} and D_{Ra} on the pH in 1 M HDEHP–Benzene Extraction System. Figure 2 shows the relation between the logarithm of D_{Ac} or D_{Ra} and the pH value of the aqueous phase. They show linearity with different slopes. The slope for Ac is *ca.* 3.0 and that for Ra, 1.9. In the data of D_{Ra}, there is a large difference between the two kinds of buffer solutions containing KCl and KH phthalate. Two explanations are possible. One is the difference of the stability of the complex ion of Ra with Cl^- or $C_6H_4(COO)_2^{2-}$; the other is the synergistic effect caused by the coordination of the neutral phthalic acid molecules to the extracted compound of Ra. However, we could not decide which explanation is feasible, while it is clear that D_{Ra} shows a larger value when KH phthalate is used than when KCl is used. Considering that there is no difference between the two kinds of buffer solution in the data of D_{Ac}, it is obvious that the separation coefficient of Ac and Ra ($\alpha_{Ac,Ra}$) becomes larger when KCl is used and the KCl-buffer solution is more suitable for the separation of Ac and Ra. The calculated values of $\alpha_{Ac,Ra}$ using the above-mentioned data, are given in Table 1. These values were calculated from the two straight lines drawn by the method of linear least square fitting. There is the tendency that $\log(\alpha_{Ac,Ra})$ increases in proportion to the pH value. The maximum of $\alpha_{Ac,Ra}$ is 4.1×10^3 at pH=2.2 where over 99.4% of Ac is extracted into the orgaic phase and over 99.9% of Ra remains in aqueous phase. Thus, the separation of Ac from Ra can be made by adjusting the pH of the aqueous solution to 2.2 and then shaking it with 1 M HDEHP–benzene solution, as described in the following. Th which is more extractable than Ac can be

separated from Ra and goes to the Ac-fraction.

The Mutual Separation of Ac, Ra, and Th. From the above result, and the fact that Th is quantitatively extracted by 1 M HDEHP–benzene solution from 0.1—0.5 M HCl solution, we propose the following separation method for Ac, Th, and Ra system (Fig. 3).

The acidity of the mixed solution of Ac, Th, and Ra is adjusted to pH=2.2 and the solution is shaken with 1 M HDEHP–benzene solution. Ac and Th are quantitatively extracted to the organic phase while Ra remains in the aqueous phase. Pure Ra solution can be easily prepared by washing the aqueous phase with the same organic solution. The organic phase is washed by the solution of pH 2.2 and shaken with 0.5 M HCl solution. Ac is back-extracted to the aqueous phase while Th remains in the aqueous phase.

Ra is recovered as HCl solution whose pH is equal to 2.2, Ac, as 0.5 M HCl solution, and Th, as 1 M HDEHP–benzene solution. The yield of each element is over 99%.

Figure 4 shows the γ-spectrum of each fraction after the separation of ^{227}Ac, ^{227}Th, and ^{223}Ra which were in radio-equilibrium. Comparing the spectrum of each fraction with that of the original mixed solution, we see that these elements are isolated and purified. No characteristic γ-peaks could be found in the ^{227}Ac-fraction. However, when a sample of ^{227}Ac having a much higher specific activity is used, the growth of the γ-peaks of ^{223}Fr will be detected in a period of about 40 min after purification of ^{227}Ac.

Milking Method for ^{223}Fr Using HDEHP–Solvent Extraction. We can easily carry out the milking of ^{223}Fr from ^{227}Ac by utilizing the principle of the above-mentioned separation method. The procedure is shown in Fig. 5. After recovering ^{227}Ac as 0.5 M HCl solution (Fig. 3), the pH is adjusted again to 2.2 and shaken with 1 M HDEHP–benzene solution to prepare the organic solution of ^{227}Ac to be used as a milking source. Extraction of ^{227}Ac is carried out twice because ^{223}Fr has γ-rays very similar to those of ^{227}Th and it is better to completely eliminate the contamination of ^{227}Th. By shaking the milking source with the solution of pH 2.2 once, ^{223}Fr and a small amount of ^{223}Ra that have grown in the organic phase is back-extracted to the aqueous phase. In a period of 2.5—3.0 h after the first back-extraction, ^{223}Fr whose half-life is 21 min grows and attains radio-equilibrium with ^{227}Ac in the organic phase. Thus, after standing for 2.5—3.0 h, ^{223}Fr should be back-extracted to the aqueous phase by shaking with the same buffer solution. ^{223}Ra also grows in this period. However, because the half-life of ^{223}Ra is 11.4 days and too long compared with that of ^{223}Fr, the growth of ^{223}Ra in this period does not need to be considered, unless the amount of ^{227}Th in the organic phase is not too large. ^{223}Fr is easily isolated from ^{227}Ac by carrying out the same extraction twice. Figure 6 shows the γ-spectrum of ^{223}Fr purified by this milking method. In the second measurement,

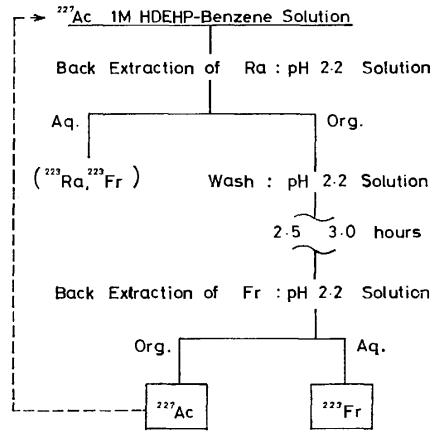

Fig. 5. Milking procedures for ^{223}Fr.

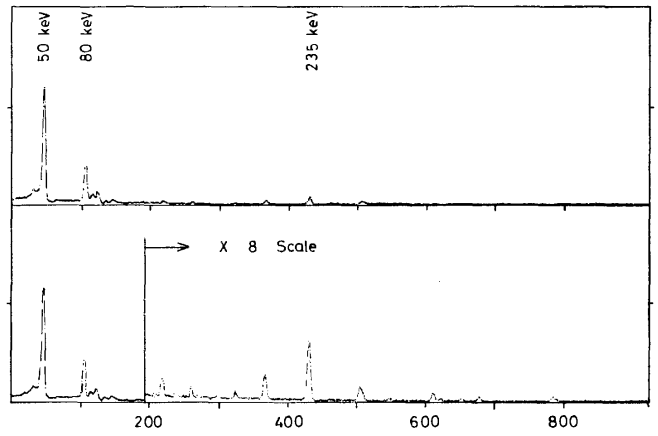

Fig. 6. γ-Spectrum of ^{223}Fr obtained by the proposed milking method.

almost all of the γ-peaks disappeared and a slight growth of the characteristic γ-peaks of ^{223}Ra and the Kx-rays of Rn were observed.

Possibility of the Determination of ^{227}Ac Utilizing the γ-Activity Measurement of ^{223}Fr. It is impossible to detect and determine ^{227}Ac by its γ-activity since it has no characteristic γ-rays that have intensity sufficient for measurement. Thus, the only way to detect and determine ^{227}Ac by the γ-ray measurement is to measure the γ-activity of its daughter nuclides (^{223}Ra, ^{223}Fr, and ^{227}Th). However, for ^{223}Ra and ^{227}Th, because of their long half-lives of 11.4 and 18.2 days respectively, we must wait more than 3 months for the attainment of radio-equilibrium for the determination of ^{227}Ac. For ^{223}Fr, since its γ-rays are similar to those of ^{227}Th, correct measurement of its γ-activity is difficult. However, the proposed separation method can eliminate the contamination of ^{227}Th which prevents accurate measurement of ^{223}Fr, and we can expect a new method to determine ^{227}Ac by measuring the γ-activity of ^{223}Fr in radio-equilibrium with ^{227}Ac. As shown in Fig. 6, the peak of 50 keV of ^{223}Fr has sufficient intensity to be measured and ^{227}Ac can be easily determined by correct measurement of this peak. It is also possible to determine the absolute amount of ^{227}Ac by this γ-ray, if we know the absolute abundance ratio of this γ-transition and its relation with the absolute disintegration rate of ^{227}Ac. The proposed method for the determination of ^{227}Ac is very attractive. However, we must be careful no to allow even a slight contamination of ^{227}Th in ^{223}Fr fraction, since ^{227}Th also has intense γ-ray of 50 keV. Elimination of ^{227}Th is completely done by the separation method, and check of contamination of ^{227}Th could be easily made by checking the relative ratio of the intensity of each γ-peak.

Separation of ^{228}Ac and ^{228}Ra in Natural Thorium Decay Series. The separation method using HDEHP extraction can be applied to the ^{232}Th-^{228}Ra-^{228}Ac chain in the natural thorium decay series. ^{228}Ac is the most useful radioactive tracer of Ac, and is convenient for obtaining ^{228}Ac from ^{228}Ra by applying the simple milking method. The separation of ^{228}Ra and ^{228}Ac can be easily made by HDEHP extraction, and a new milking method for ^{228}Ac utilizing HDEHP extraction was proposed as shown in Fig. 7.

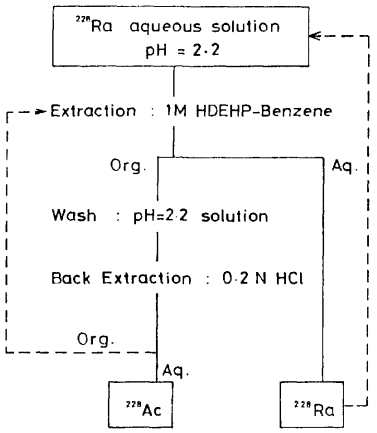

Fig. 7. Milking procedures for ^{228}Ac from ^{228}Ra.

Linear-sweep Voltammetry and the Simultaneous Determination of Purine Bases and Their Nucleosides in the Glassy Carbon Electrode

Toshio YAO, Tamotsu WASA, and Soichiro MUSHA
Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Mozuumemachi, Sakai 591
(Received March 12, 1977)

Adenine, adenosine, guanine, and guanosine were voltammetrically oxidized in a glassy carbon electrode in aqueous solutions, but at different potentials. In general, the nucleosides were oxidized at more positive potentials than their bases. The bases and their nucleosides were strongly adsorbed on the surface of the glassy carbon electrode at the pH values around neutrality, so that the concentration *vs.* anodic peak current curves were not linear. The adsorption on the electrode was very dependent on the pH, and at pH values below 4 good linear relationships were observed between the anodic peak current and the concentration. The differences between the peak potentials of each of the purine bases and their nucleosides were most pronounced at pH 2—4. Consequently, it was possible to determine simultaneously both in mixtures of the purine bases and their nucleosides by using Britton-Robinson buffer as a supporting electrolyte in the pH range of 2—4. The proposed method is simple and rapid, since no prior treatment or separation procedure is required.

The electrochemical reduction and oxidation of biologically-important compounds have been investigated with much interest. The electrochemical reduction of purine bases, which are important components of nucleic acids, has been investigated in both aqueous[1-3] and nonaqueous solutions.[4] It is known that adenine is reduced and guanine is not at a dropping mercury electrode(DME). Adenosine appears to be reduced by the same mechanism, but, as the half-wave potentials are very close, the polarographic analysis of mixtures of adenine and adenosine is not possible. Also, the ultraviolet absorption spectra of these bases are very similar, so it is very difficult to work out a simple method for the analysis of such mixtures. A paper chromatographic method[5] for the quantitative determination of purine bases and their nucleosides involves extracting the paper chromatogram after separation and determining the amount of each species by UV spectrophotometry. Apart from being time-consuming, this method can be applied only to samples containing relatively high concentrations of the bases and their nucleosides.

A few studies[6-8] on the electrochemical oxidation of the purine bases were done at the pyrolytic graphite electrode(PGE) in aqueous solutions. Dryhurst[9] determined adenine in the presence of fairly large amounts of adenosine by taking advantage of the competitive adsorption of the two compounds on the PGE. However, this method cannot be applied to the simultaneous determination of adenine and adenosine in mixtures of the two compounds, because large amounts of adenosine must be added to test solutions.

In the present work, the oxidation behavior of purine bases and their nucleosides was investigated by linear-sweep voltammetry using a stationary, planar glassy carbon electrode (GCE). Also, in order to develop a satisfactory analytical method it was found necessary to investigate in some detail the adsorption of the purine bases on the GCE. This paper will describe a method whereby adenine, adenosine, guanine, and guanosine in mixtures of these bases can be determined simultaneously by utilizing the voltammetric oxidation peak of each of these bases at the GCE.

Experimental

Chemicals. The adenine, adenosine, guanine, and guanosine were all obtained from the Wako Pure Chemical Co. and were recrystallized two times from distilled water before drying *in vacuo* at 60 °C. The Britton-Robinson buffer used throughout this work was prepared from reagent-grade chemicals.

Apparatus. The polarograms and anodic voltammograms were recorded using a Yanagimoto P-8 type Polarograph at a scan rate of 3.3 mV/s. The three-electrode voltammetric cell maintained at (25±0.1)°C was used for all the experiments. An aqueous saturated calomel electrode(SCE) was used as the reference electrode, and a platinum wire served as the counter electrode.

The DME used had the following characteristics: mercury flow rate, $m=2.28$ mg/s and drop time, $t=3.35$ s at an open circuit with a mercury head of 70 cm in 1 M $HClO_4$.

The working electrode for anodic voltammetry was constructed from a 3-mm glassy carbon rod (Grade GC-20, Tokai Electrode Co.). The rod was cut into a length of 10 mm and was sealed in one end of a glass tube 3 mm in diameter with epoxy cement. The end of the glass tube-carbon rod assembly was polished with 400-grade emery paper until it was quite smooth. Then, by polishing with 1500-grade emery paper and a paste of sedimented calcium carbonate, the surface of the electrode was brought to a mirror finish.

Voltammetric Procedure. In order to obtain reproducible results, a standard pretreatment procedure was applied before recording each voltammogram. The GCE was polished for 60 s with 1500-grade emery paper and then for 30 s with a paste of sedimented calcium carbonate. The surface of the electrode was then washed for about 10 s with a fine spray of water. Any water remaining on the electrode surface and the shaft of the electrode was removed by touching the surface very gently with a piece of soft absorbent paper. Test solutions were not deaerated. The voltage scan was commenced after quiescency for 20 s at the starting potential (always 0.0 V *vs.* SCE). At least three replicate voltammograms were recorded for each test solution. A voltammogram of the background solution was recorded in the same way, while the peak current was obtained by arithmetrically subtracting the observed background current at the peak potential from that of the test solution.

Results and Discussion

Effect of pH. The half-wave potentials for the polarographic reduction of adenine and adenosine at the DME shifted linearly towards negative potentials with the increase in the pH. The wave-heights for both compounds were relatively constant at pH values below 5, but began to decrease sharply with a further increase in the pH. Adenine and adenosine also had practically identical $E_{1/2}$ values at all the pH values where the polarographic waves were observed, *e.g.*, at the pH 4.0 $E_{1/2}=-1.31$ V for adenine and -1.32 V for adenosine, so that the polarographic analysis of mixtures of the two compounds was not possible. Also, since the polarographic waves of both guanine and guanosine occurred close to the background-discharge potential, it was difficult to measure the limiting current accurately.

Each of the purine bases and their nucleosides gave a well-defined oxidation peak at a stationary GCE. The effect of the pH on the voltammetric peaks was investigated by recording the voltammograms of 0.05 mM purine bases and their nucleosides in Britton-Robinson buffer solutions. Adenine and adenosine both gave the single voltammetric oxidation peaks over the pH range of 2—12. The half-peak potentials($E_{p/2}$) of the voltammetric oxidation peaks of adenine and adenosine shifted linearly towards negative potentials with the increase in the pH; $E_{p/2}$(V *vs.* SCE)$=1.45-0.064$ pH for adenine and $E_{p/2}$(V *vs.* SCE)$=1.49-0.032$ pH for adenosine (Fig. 1). Both guanine and guanosine also gave single voltammetric oxidation peaks at the GCE. The half-peak potential shifted linearly towards negative potentials with the increase in the pH according to the following equations: $E_{p/2}$(V *vs.* SCE)$=1.13-0.059$ pH for guanine and $E_{p/2}$(V *vs.* SCE)$=1.25-0.046$ pH for guanosine. The analytical significance of these experimental results lies in the facts that the voltammetric oxidation peak-potential for each of the purine bases and their nucleosides is quite different in the pH range of 2—4, and that the oxidation potential for each of the purine bases is more negative than that for each of their nucleosides at all the pH values studied.

a) Peak current (μA).

The peak current of the voltammetric oxidation peaks of purine bases and their nucleosides increased gradually with the decrease in the pH, as is shown in Fig. 1. This experiment was undertaken at a very low concentration (0.05 mM) of the purine bases. When the depolarizer concentration was fairly high (1.0 mM), the pH values were found to have a pronounced effect on the peak current of the purine bases and their nucleosides. This result is shown in Table 1. The peak current increased sharply with the decrease in the pH and remained almost constant at pH values below 4. The same result was obtained in other buffers (acetate buffers and chloride buffers) and acid solutions (1 M HCl, H_2SO_4, $HClO_4$, and H_3PO_4) as supporting electrolytes; in electrolytes containing chloride ions the oxidation peaks of both adenine and adenosine were masked by the oxidation of the chloride ion in the background electrolytes. Also, in the acid solutions the oxidation peak of adenosine occurred close to the background discharge potential, so that the accurate measurement of the peak current was impossible.

Effect of the Scan Rate. In order to study the adsorption of the purine bases and their nucleosides on the stationary GCE, the effect of the voltage scan rate on the peak current of these compounds was examined.

The electrochemical oxidation of the purine bases and their nucleosides was irreversible, as was shown by cyclic voltammetric experiments in which no cathodic peak corresponding to the reduction of the oxidation product was observed at any scan rate.

For a linear diffusion-controlled irreversible peak, the peak current function, $i_p/ACV^{1/2}$, shoud be a constant,[10] and a plot of this function *vs.* $V^{1/2}$ should be a straight line parallel to the $V^{1/2}$ axis, where A is the area of the electrode surface; C, the bulk concentration of depolarizer; and V, the scan rate. At pH values below 4, the peak current functions of both adenine and adenosine were almost independent of the scan rate. At pH values above 4, however, the peak current functions increased markedly with the increase in the scan rate. This behavior is typical of an electrode process where the

reactant is adsorbed on the electrode.[11] In the cases of both guanine and guanosine, also, similar effects of the pH and the scan rate on the peak current function were observed.

Effect of the Concentration. In the Britton-Robinson buffer with pH values above 4, each of the purine bases studied showed a non-linear relationship between the peak current and the concentration, as is shown in Fig. 2. Such curves clearly indicate that the adsorption of the depolarizer takes place on the surface of the GCE. Also, the peak potential of the voltammetric oxidation peak for each of the purine bases and their nucleosides was dependent on the concentration and slightly shifted to more positive values with an increase in the concentration. Over the concentration range of 0.05—0.5 mM this shift was about 30—50 mV for all the purine bases.

In equimolar solutions (pH 7.0) of adenine and guanine, guanine showed a non-linear relationship between the peak current and the concentration similar to that shown in Fig. 2, but the peak current of adenine decreased in concentrations more than 0.25 mM in spite of the increase in the adenine concentration. However, in the Britton-Robinson buffer at pH 3 these purine bases showed a linear relationship between the peak current and the concentration, as is shown in Fig. 3.

These effects of the concentration and the pH and the scan rate on the peak current imply that the adsorption of the depolarizer on the GCE is very dependent on the pH, but in the electrolytes at pH values below 4 the voltammetric oxidation is a diffusion-controlled process.

The Simultaneous Determination of the Purine Bases and Their Nucleosides. The anodic voltammograms for the mixtures of adenine, adenosine, guanine, and guanosine were recorded in Britton-Robinson buffer solutions of various pH values (Fig. 4). At pH values below 4 four successive well-defined oxidation peaks were observed, but a further increase in the pH made the voltammetric peaks sensitive to the adsorption of

depolarizer on the GCE. Also, the differences between the peak potentials of each of the purine bases and their nucleosides were most pronounced at pH 2—4. Accordingly, for the quantitative determination of the purine bases and their nucleosides a Britton-Robinson buffer in the pH range of 2—4 is suitable.

In order to test the quantitative method developed here, the voltammograms for some mixtures of four purine bases were recorded in the Britton-Robinson buffer of pH 3.0 at a stationary GCE. The concentration of each of the purine bases was determined by the calibration-curves method from the respective heights of the resulting voltammetric oxidation peaks. Some typical analytical results are shown in Table 2. Clearly this method is readily capable of determining simultaneously each component in mixtures of the purine bases and their nucleosides.

The principal advantage of the proposed method is the rapidity of analysis. The speed of analysis is aided by the fact that no prior treatment or separation procedure is needed. Furthermore, as dissolved oxygen does not interfere with the anodic voltammetry, no deaeration is required. One disadvantage is that the electrode must be pretreated before every voltammogram in order to ensure reproducibility. In addition, the method is of only moderate sensitivity, and traces (sub ppm) of the purine bases cannot be detected. It would be possible to improve the sensitivity by utilizing a pulse voltammetric method.

Reaction of Ru(II)-EDTA in Sodium Formate–Formic Acid Solutions*

Kunio SHIMIZU

Department of Chemistry, Faculty of Science and Technology, Sophia University, Chiyoda-ku, Tokyo 102

(Received May 2, 1977)

When $[Ru^{III}(Hedta)(H_2O)]$ was reduced at mercury electrode in sodium formate–formic acid solutions, the reduced species gradually became polarographically inactive. The final product of the deactivation reaction was isolated and identified as $Na_2[Ru^{II}(edta)(CO)]$. The kinetics follows the second-order rate equation, $-dc_1/dt=k_{obsd}\,c_1\,c_2$, where $c_1=[[Ru^{II}(Hedta)(H_2O)]^-]+[[Ru^{II}(edta)(H_2O)]^{2-}]$ and $c_2=[HCOO^-]+[HCOOH]$. The k_{obsd} value was found to be expressed by $k\,[H^+]/(K_A+[H^+])(K_R+[H^+])$, where $K_A(=3.28\times10^{-4}$ mol dm$^{-3})$ and $K_R(=6.92\times10^{-4}$ mol dm$^{-3})$ are the acid-dissociation constants of formic acid and $[Ru^{II}(Hedta)(H_2O)]^-$, respectively, with $k=1.01\times10^{-5}$ s^{-1} at 25 °C (ionic strength=0.5 mol dm^{-3}). Several possible mechanisms for the reaction were discussed. Probably the reaction proceeds through the formation of an intermediate involving one formate anion followed by dehydration and rearrangement.

Formation of carbonyls through decarbonylation of organic compounds by metal complexes has attracted considerable interest in recent years and a number of such reactions have been reported.[1–8] Halpern and Kemp studied the decarbonylation of formic acid by ruthenium(II) chloride in strongly acid solutions (about 3 mol dm^{-3} HCl) and obtained $(NH_4)[Ru^{II}(CO)Cl_4(H_2O)]$.[3] They also examined the kinetics of the decarbonylation and claimed that the reaction is of the second-order with respect to the ruthenium(II) species and *formic acid*. However, their results may be equally well explained by postulating formate anion as a reactant.

It has been pointed out[9] that electrolytically generated $[Ru^{II}(Hedta)(H_2O)]^-$ or $[Ru^{II}(edta)(H_2O)]^{2-}$ ** undergoes a deactivation process in formate–formic acid buffer solutions.

In the present work the final reaction product of this process has been identified as a carbonyl–edta-complex of ruthenium(II), the kinetics of its formation being examined in detail.

Experimental

Materials. Aqua(hydrogenethylenediaminetetraacetato)ruthenium(III) tetrahydrate, $[Ru(Hedta)(H_2O)]\cdot4H_2O$, was prepared according to the procedure of Mukaida *et al.*[10] with some modifications. An intensely blue ruthenium(II) cluster complex[11] was prepared by evaporating a mixture of 200 cm^3 of ethanol and 150 cm^3 of 3 mol dm^{-3} HCl solution containing 1.05 g of ruthenium(III) on a water bath. It was dissolved in a small portion of water, and a solution of 2.4 g of disodium ethylenediaminetetraacetate was added. The mixture, after being acidified by the addition of 1 cm^3 of concentrated hydrochloric acid, was evaporated nearly to dryness. The residue was dissolved in a small amount of water and evaporated again. The procedure was repeated several times until an orange solution was obtained on dissolving the residue. The pH of solution was then adjusted to *ca.* 2 with a sodium hydroxide solution. Ethanol was solwly added to the solution with stirring until a yellow precipitate appeared, and the mixture was left to stand overnight in a refrigerator. The yellow precipitate was filtered, washed several times with ethanol, and then dried *in vacuo* at 40 °C (yield, 2.4 g). Found: Ru, 20.57; C, 24.61; N, 5.60; H, 4.48%. Calcd for $[Ru(Hedta)(H_2O)]\cdot4H_2O$: Ru, 21.04; C, 25.00; N, 5.83; H, 4.28%. The IR spectrum of the product agreed with that reported by Mukaida *et al.* Its purity as determined by alkalimetric titration was 99.3%.

Deionized water distilled in an all-glass apparatus was used for the electrochemical experiments. The oxygen dissolved in the electrolytic solutions was removed by bubbling nitrogen gas which had been passed through acid vanadium(II) sulfate solution and then distilled water. The other chemicals used were of guaranteed reagent grade.

Measurements. All the electrochemical measurements were carried out at (25.0±0.1) °C under nitrogen atmosphere. All the potentials were measured against a saturated calomel electrode (SCE).

The electrolysis for the preparation of the final reaction product was performed with a Yanagimoto Controlled Potential Electrolyzer CE-3. The geometry of the electrolytic cell is illustrated in Fig. 1.

Controlled potential coulometry was carried out as described earlier[9] except that the integration of the electrolytic current was carried out on a digital counter (Takedariken, Universal Counter TR-5104) by converting the current signal into pulses with a voltage-frequency converter (Aiko VF 500).[12]

* Partly presented at the 22nd Annual Meeting on Ploarography and Electroanalytical Chemistry, October, 1976 in Nagano.

** The following abbreviations will be used: Ru(II)-Hedta$^-$ for $[Ru^{II}(Hedta)(H_2O)]^-$, Ru(III)-Hedta for $[Ru^{III}(Hedta)(H_2O)]$, Ru(II)-edta^{2-} for $[Ru^{II}(edta)(H_2O)]^{2-}$, and Ru(III)-edta$^-$ for $[Ru^{III}(edta)(H_2O)]^-$.

All the polarograms were recorded with a potentiostat-type dc-ac polarograph constructed in this laboratory. The drop time of the DME was controlled by an electronic drop-dislodger.[13,14] The device incorporated a relay which cuts off the polarographic current signal to the recorder at the moment of drop dislodging in order to suppress the noise accompanying the drop fall and to enhance the S/N ratio.[15] The polarographic current signal was sampled at 3.50 s after dislodgement. The flow rate of mercury from the DME was 1.78 mg s^{-1} under a mercury head of 50 cm. All the polarographic currents were corrected for the residual currents.

Infrared spectra were recorded with a Hitachi EPI-G2 IR spectrophotometer by the potassium bromide disk technique. Visible spectra were measured with a Hitachi 124 spectrophotometer. Conductivity was measured in distilled water with a TOA Electronics Conduct Meter CM-6A. Magnetic properties were measured by the Gouy method.

All the pH_c† values of the solutions were determined with a Radiometer pH meter 25E equipped with a glass electrode Type G202B and an SCE Type K401, whose meter readings were calibrated against standard hydrochloric acid solutions adjusted to 0.5 mol dm^{-3} of ionic strength by the addition of NaCl.

Analysis. Elemental analysis of C, H, and N was carried out by means of a Yanagimoto MT2 CHN Corder.

Spectrophotometric determination of ruthenium in the complexes was carried out according to the ruthenate method.[16] A weighed sample (*ca.* 10 mg) was decomposed in a nickel crucible by heating, and then fused with 0.1 g of potassium hydroxide and 0.3 g of potassium nitrate. The melt was dissolved in 50 cm^3 of a solution containing 10 g of potassium hydroxide, the solution volume then being adjusted to 100 cm^3 with water. The absorbance of the solution was measured at 465 nm.

The content of sodium ions in the final reaction product was determined by the cation-exchange method. A weighed sample (*ca.* 0.1 g) dissolved in 10 cm^3 of water was passed through a column of an H-form cation exchanger (Dowex 50-X8, 100—200 mesh), the column was washed with water and the combined eluate was titrated with a standard sodium hydroxide solution.

The content of water of crystallization was estimated by thermal gravimetric analysis with a Rigakudenki TG-DTA M8075.

Procedure. Isolation of the Final Reaction Product: A 20 cm^3 portion of sodium formate–formic acid (0.5 mol dm^{-3} each) containing 1.0 g of Ru(III)-Hedta was placed in the electrolytic cell and deoxygenated. Electrolysis was carried out at −0.5 V with stirring until more than 99% of the Ru(III)-Hedta was reduced. After the cell solution had been left to stand for 2 h under a nitrogen atmosphere, it was transferred into a flask and concentrated to one-fourth the initial volume under a reduced pressure at 40 °C. Ethanol was slowly added to the resulting solution until fine, pale yellow crystals precipitated; the mixture was allowed to stand in a refrigerator overnight. The precipitate, after being filtered, was recrystallized from methanol. The product was washed several times with ethanol and then dried *in vacuo* at 40 °C.

Measurement of Acid-dissociation Constants: The acid-dissociation constants of formic acid and Ru(III)-Hedta in 0.5 mol dm^{-3} NaCl solution were determined from the respective pH-titration curves.[17] The constnat of Ru(II)-Hedta$^-$ was calculated from the pH_c dependence of the reversible half-wave potential of the Ru(III)-Hedta reduction step in acid buffer solutions (sodium chloride–hydrochloric acid–0.001% Triton X-100 for $pH_c<2$, sodium formate–formic acid for $2<pH_c<4$, sodium acetate–acetic acid for $pH_c>4$; ionic strength = 0.5 mol dm^{-3} (NaCl)). The method was essentially the same as that described earlier;[9] but in the present case the data for $pH_c = 1.8$—5.5 were used so as to secure a higher precision for K_R. The values are given in Table 1.

TABLE 1. ACID-DISSOCIATION CONSTANTS
(Ionic strength = 0.5 mol dm^{-3}, 25 °C), $K = [H^+][X]/[HX]$.

Symbol	X	K/mol dm^{-3}
K_A	$HCOO^-$	3.28×10^{-4}
K_O	$[Ru^{III}(edta)(H_2O)]^-$	2.22×10^{-3}
K_R	$[Ru^{II}(edta)(H_2O)]^{2-}$	6.92×10^{-4}

Kinetic Measurements: For the kinetic measurements, sodium formate was used as the supporting electrolyte and the ionic strength of the solution was adjusted to 0.5 mol dm^{-3} by the addition of sodium *p*-toluenesulfonate. A 12 cm^3 portion of the supporting electrolyte solution was placed in the cell and deoxygenated. The solution was pre-electrolyzed at −0.5 V unitl a constant electrolytic current (usually about 3 μA) was reached. A known amount of Ru(III)-Hedta (*ca.* 20 μmol) was dissolved in the pre-electrolyzed solution, and the polarogram was recorded. When *ca.* 80% of Ru(III)-Hedta was reduced at −0.5 V to the bivalent state, a known amount of concentrated formic acid was injected into the solution from a microsyringe. After bubbling the nitrogen for 2—3 min, the decreasing anodic diffusion current at 0 V was recorded (chart speed, 2.5×10^{-2} cm s^{-1}) until it reached one-tenth the initial current.

Results and Discussion

Final Reaction Product. Elemental analyses of the final reaction product gave Ru, 19.48; C, 26.09; N, 5.59; H, 3.30%. The thermal gravimetric analysis showed that the water content in the product is 6.5%. These results indicate that the product contains 11 carbon, 2 nitrogen and 16—17 hydrogen atoms, and 2 molecules of water per ruthenium atom. The presence of protonated carboxyl groups and coordinated water is excluded by the fact that the final reaction product had no dissociable hydrogen. The cation-exchange experiment showed the complex ion in the product to be an anion, the number of sodium ions per ruthenium atom being 1.92.

The IR spectrum of the product is similar to that of the Ru(III)-Hedta. Two points, the presence of a very strong absorption at 1940 cm^{-1} and the absence of the >C=O stretching band which would be expected for a protonated carboxyl group (1730 cm^{-1} for Ru(III)-Hedta), were noted. The former strongly suggests the existence of a carbonyl group coordinated to ruthenium (II).[2,3,18] The latter indicates that each of the four carboxyl groups is either ionized or coordinated; in this event the >C=O absorption band should appear at 1590—1650 cm^{-1}.[19] In fact, a band was observed at 1630 cm^{-1}.

The oxidation state of the ruthenium in the final reaction product is considered to be II (t_{2g}^6) since the substance is diamagnetic. This view is supported by the fact that the product in acetate–acetic acid buffer solutions shows no polarographic step in the potential

† pH_c represents $-\log([H^+]/\text{mol dm}^{-3})$.

range +0.2——1.2 V. The effect of the coordinating carbonyl in ruthenium(II) complexes has been discussed in terms of the strong back-bonding with the metal orbitals of d_π-symmetry.[20] Coordination of carbonyl to ruthenium(II) renders the complex much less oxidizable. The frequency of the CO band also leads to the same conclusion: if the oxidation state of ruthenium were higher than II, the frequency would be higher because of the increase in positive charge on the central atom; for example, the ν(CO) is 1950 cm^{-1} in $(NH_4)_2[Ru^{II}Cl_4(CO)(H_2O)]$ and 2059 cm^{-1} in $(NH_4)_2[Ru^{III}Cl_5(CO)]$.[2] We infer $Na_2[Ru^{II}(edta)(CO)]\cdot 2H_2O$ as the formula of the final reaction product. The elemental composition calculated on the basis of the formula is in line with the experimental values: Ru, 20.24; C, 26.46; N, 5.61; H, 3.23%.

The molar conductivity of the product at 8.01×10^{-4} mol dm^{-3} in aqueous solution was 250 S mol^{-1} cm^2 at 25 °C, which is reasonable for a 1 : 2 type electrolyte.

The absorption peak in the visible region was at 428 nm at which the molar absorption coefficent was 9.06×10^4 mol^{-1} cm^2.

Results of Kinetic Studies. When Ru(III)-Hedta was partially electrolyzed in solutions containing sodium formate and sodium *p*-toluenesulfonate at a potential on the diffusion-current plateau of its reduction step, a single oxidation-reduction polarographic step appeared at about −0.25 V. The anodic limiting current, I_a, was proved to be diffusion-controlled, being proportional to the quantity of electricity consumed for the reduction, *i.e.*, to the total concentration of the Ru(II) species (in such weakly alkaline solutions, $[Ru^{II}(edta)(OH)]^{3-}$ is also present together with Ru(II)-$edta^{2-}$). No change in the polarogram was observed at least for a few hours at 25 °C.

When formic acid was present, however, the anodic current decreased with time as shown in Fig. 2, while the cathodic current remained constant. In the presence of excess formic acid–formate ion (at least 50-fold the concentration of Ru(II) species), the rate of decrease of the anodic diffusion current always obeyed the pseudo-first-order rate expression (Eq. 1) until the reaction had proceeded at least 80% to completion (Fig. 3):

$$-\ln\frac{I_a(t)}{I_a(0)} = k'_{obsd}\,t, \qquad (1)$$

where $I_a(t)$ and $I_a(0)$ are the anodic diffusion current at time t and $t=0$, respectively. The values of k'_{obsd} determined from the slopes of the first-order rate plots were substantially independent of the concentrations of initially present ruthenium(II) and coexisting ruthenium(III) species.

At a given hydrogen ion concentration, k'_{obsd} was proportional to the sum of the concentrations of formate ion and formic acid (Fig. 4). Hence Eq. 1 becomes

$$-\ln\frac{I_a(t)}{I_a(0)} = k_{obsd}\,c_2\,t, \qquad (2)$$

where $c_2=[HCOO^-]+[HCOOH]$ and k_{obsd} is the second-order rate constant. As seen from Fig. 5, k_{obsd} is a function of the hydrogen ion concentration, increasing almost linearly up to a maximum at $[H^+]=5\times10^{-4}$ mol dm^{-3}, after which it decreased slowly. The kinetic data are summarized in Table 2.

Interpretation of Kinetic Results. Under the experimental conditions there may be four reactant species participating in the deactivation reaction: Ru(II)-$Hedta^-$, Ru(II)-$edta^{2-}$, $HCOO^-$, and HCOOH. Here, $[Ru^{II}(edta)(OH)]^{3-}$ is ignored because the acid-dissociation constant for

$$[Ru^{II}(edta)(H_2O)]^{2-} \rightleftharpoons [Ru^{II}(edta)(OH)]^{3-} + H^+$$

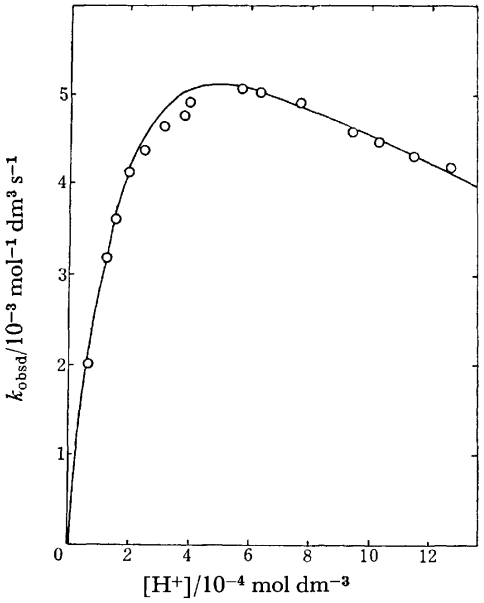

Fig. 5. Dependence of k_{obsd} on hydrogen ion concentration (ionic strength=0.5 mol dm^{-3}, 25 °C). The curve is calculated from Eq. 8 with $k=1.01\times10^{-5}$ s^{-1}.

should be appreciably smaller than that of the corresponding Ru(III)-edta$^-$ (pK=7.63)[9] so that its concentration is negligible in formic acid–formate buffer solutions.

There are several mechanisms involving these four reactants that can explain the experimental data. Most probably, the reaction will proceed through some intermediate(s) which contains formate ion or formic acid:

$$\text{Reactants} \xrightarrow{\text{(I)}} \text{Intermediate(s)} \xrightarrow{\text{(II)}} \text{Product}$$

Either step (I) or step (II) may be rate-determining.
Case I: step (I) rate-determining.

c_2=[HCOO$^-$]+[HCOOH]

Mechanism Ia

$$\text{Ru(II)-Hedta}^- + \text{HCOOH} \xrightarrow{k_1} \text{intermediate}, \quad \text{(R1)}$$

$$\text{Ru(II)-Hedta}^- + \text{HCOO}^- \xrightarrow{k_2} \text{intermediate}, \quad \text{(R2)}$$

$$\text{Ru(II)-edta}^{2-} + \text{HCOOH} \xrightarrow{k_3} \text{intermediate}, \quad \text{(R3)}$$

$$\text{Ru(II)-edta}^{2-} + \text{HCOO}^- \xrightarrow{k_4} \text{intermediate}, \quad \text{(R4)}$$

where k_1, k_2, k_3, and k_4 are the corresponding second-order rate constants. If these reactions proceed in parallel, the rate of decrease of the total concentration of the Ru(II) species (c_1=[Ru(II)-Hedta$^-$]+[Ru(II)-edta^{2-}]), is given by

$$-\frac{dc_1}{dt} = k_1[\text{Ru(II)-Hedta}^-][\text{HCOOH}] + k_2[\text{Ru(II)-Hedta}^-][\text{HCOO}^-] + k_3[\text{Ru(II)-edta}^{2-}][\text{HCOOH}] + k_4[\text{Ru(II)-edta}^{2-}][\text{HCOO}^-]. \quad (3)$$

Since the proton transfer reactions between Ru(II)-Hedta$^-$ and Ru(II)-edta^{2-} and between HCOOH and HCOO$^-$ must be very fast and remain in a quasi-equilibrium state so that (R2) and (R3) are kinetically indistinguishable, the above expression is reduced to

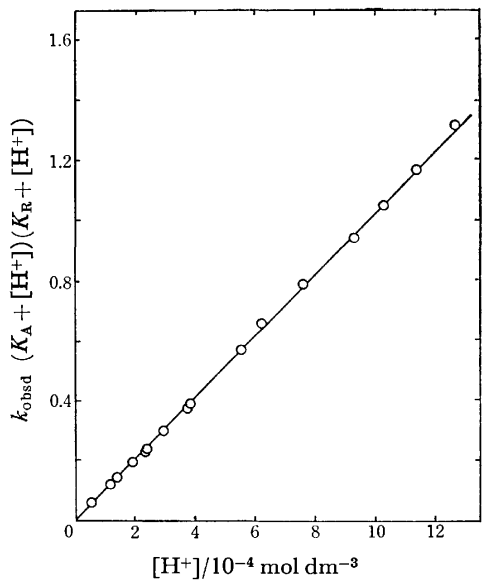

Fig. 6. Plot of k_{obsd} $(K_A+[H^+])(K_R+[H^+])$ against hydrogen ion concentration (ionic strength=0.5 mol dm^{-3}, 25 °C).

$$-\frac{dc_1}{dt}=\frac{k_1[H^+]^2+(k_2K_A+k_3K_R)[H^+]+k_4K_AK_R}{(K_A+[H^+])(K_R+[H^+])}c_1c_2. \quad (4)$$

Equation 4 is integrated with $c_1=c_2(0)$ at $t=0$ and c_2=constant. Since I_a is proportional to c_1, by comparing the resulting expression with Eq. 2, we obtain

$$k_{obsd}=\frac{k_1[H^+]^2+(k_2K_A+k_3K_R)[H^+]+k_4K_AK_R}{(K_A+[H^+])(K_R+[H^+])}. \quad (5)$$

Thus the plot of $k_{obsd}(K_A+[H^+])(K_R+[H^+])$ against hydrogen ion concentration generally should be a parabola.

The plot gives a straight line with zero intercept (Fig. 6). Hence, k_1 and k_4 must be negligibly small with respect to k_2 and/or k_3, since $[H^+]$, $K_A[H^+]$, $K_R\cdot[H^+]$, and K_AK_R are of the same order of magnitude under the experimental conditions.

Mechanism 1b

The termoleclar rate determining step,

$$Ru(II)\text{-}edta^{2-}+HCOO^-+H^+ \xrightarrow{k_5} \text{intermediate}, \quad (R5)$$

is also possible but seems unlikely on statistical grounds.

Case II: step (II) is rate determining. In this case step (I) is in quasi-equilibrium state.

Mechanism 2a

$$Ru(II)\text{-}Hedta^-+HCOOH \underset{k_6}{\overset{K_6}{\rightleftharpoons}} \text{intermediate(6)} \xrightarrow{} \text{product}, \quad (R6)$$

$$Ru(II)\text{-}Hedta^-+HCOO^- \underset{k_7}{\overset{K_7}{\rightleftharpoons}} \text{intermediate(7)} \xrightarrow{} \text{product}, \quad (R7)$$

$$Ru(II)\text{-}edta^{2-}+HCOOH \underset{k_8}{\overset{K_8}{\rightleftharpoons}} \text{intermediate(8)} \xrightarrow{} \text{product}, \quad (R8)$$

$$Ru(II)\text{-}edta^{2-}+HCOO^- \underset{k_9}{\overset{K_9}{\rightleftharpoons}} \text{intermediate(9)} \xrightarrow{} \text{product}, \quad (R9)$$

where K_6, K_7, K_8, and K_9 are the equilibrium constants for respective reactions, and k_6, k_7, k_8, and k_9 are the first-order rate constants for the respective intermediate. Here, intermediates(6)—(9) are not necessarily different.

If the intermediates are also oxidized at the potential where I_a is measured and their diffusion coefficients are the same or nearly the same as that of Ru(II) species, $-dI_a(t)/dt$ is proportional to

$$-d([Ru(II)\text{-}Hedta^-]+[Ru(II)\text{-}edta^{2-}]+\sum_{i=6}[\text{intermediate}(i)])/dt.$$

If these reactions proceed in parallel, a simple calculation similar to that in the preceeding section leads to

$$k_{obsd}=\frac{k_6K_6[H^+]^2+(k_7K_7K_A+k_8K_8K_R)[H^+]+k_9K_9K_AK_R}{(K_A+[H^+])(K_R+[H^+])}. \quad (6)$$

For the same reason as in the case of Mechanism 1a, the reaction paths (R6) and (R9) are neglected.

If the intermediates are electro-inactive at the potential concerned and hence I_a is proportional to Ru(II) species only, the resulting expression becomes consistent with the experimental results only when the concentrations of the intermediates are very small. In such a case k_{obsd} is obtained by Eq. 6.

Mechanism 2b

$$Ru(II)\text{-}edta^{2-}+HCOO^- \underset{k_{10}}{\overset{K_{10}}{\rightleftharpoons}} \text{intermediate} \xrightarrow{} \text{product} \quad (R10)$$

If the intermediate is electro-active, we get

$$k_{obsd}=\frac{k_{10}K_{10}K_AK_R[H^+]}{(K_A+[H^+])(K_R+[H^+])}, \quad (7)$$

which is compatible with the experimental results.

On the other hand, if the intermediates is electro-inactive, the resulting expression is reduced to Eq. 7 only when the intermediate concentration is very small.

The probable mechanisms 1a, 1b, 2a, and 2b are kinetically indistinguishable and their discrimination requires further information.

At present, the rate constant is expressed by

$$k_{obsd}=\frac{k[H^+]}{(K_A+[H^+])(K_R+[H^+])}, \quad (8)$$

where k is a constant equal to 1.01×10^{-5} s^{-1} at 25 °C (ionic strength=0.5 mol dm^{-3}).

Conclusion

Cleare and Griffith[8] in their study of the formation of halogeno-carbonyl complexes of the platinum metals identified formato-intermediates from the formic acid-hexahalogenorhodate(2—) reactions by IR spectroscopy. Although no such intermediate was identified in the case of ruthenium, they noted "indications that the reactions proceed *via* formato- and formato-halogeno-carbonyl intermediates (the use of hydrochloric acid in the reactions appears to inhibit the formation of formato complexes)."

Most probably, the present reaction also will proceed through such formato-intermediates. The reaction path that involves Ru(II)-Hedta$^-$ and HCOOH (R1

or R6) is not compatible with the experimental results. Since HCOOH does not react with Ru(II)-Hedta$^-$, it will not react with Ru(II)-edta^{2-} because it is improbable that HCOOH, being an uncharged species, behaves in an essentially different way depending on the charge of the bulky reaction partner: (R3) and (R8) are excluded. A reaction path involving no hydrogen ion such as (R4) and (R9) has been excluded on the basis of the kinetic data.

The formato-intermediate requires one proton to undergo the subsequent dehydration process to [Ru^{II}-(edta)(CO)]$^{2-}$. The proton is involved in the rate determining step as indicated by the kinetic data. In (R2) or (R7) the proton is supplied from Ru(II)-Hedta$^-$, the concentration of which is much larger than the free hydrogen ion concentration in the solution.

The above discussion and the kinetic analysis lead to three probable mechanisms:

Mechanism 1a

$$\text{Ru(II)-Hedta}^- + \text{HCOO}^- \xrightarrow[\text{slow}]{k_2} \text{Ru(II)-Hedta-HCOO}^{2+}$$

$$\text{Ru(II)-Hedta-HCOO}^{2-} \xrightarrow[\text{fast}]{} \text{Ru}^{II}\text{(edta)(CO)}^{2-} + \text{H}_2\text{O}$$

Mechanism 2a

$$\text{Ru(II)-Hedta}^- + \text{HCOO}^- \overset{K_7}{\rightleftharpoons} \text{Ru(II)-Hedta-HCOO}^{2-}$$

$$\text{Ru(II)-Hedta-HCOO}^{2-} \xrightarrow[\text{slow}]{k_7} \text{Ru}^{II}\text{(edta)(CO)}^{2-} + \text{H}_2\text{O}$$

Mechanism 2b

$$\text{Ru(II)-edta}^{2-} + \text{HCOO}^- \overset{K_{10}}{\rightleftharpoons} \text{Ru(II)-edta-HCOO}^{3-}$$

$$\text{Ru(II)-edta-HCOO}^{3-} + \text{H}^+ \xrightarrow[\text{slow}]{k_{10}} \text{Ru}^{II}\text{(edta)(CO)}^{2-} + \text{H}_2\text{O}$$

The second steps of these mechanisms involve dehydration and rearrangement of the formato ligand. Direct evidence for the formato-intermediate is yet to be sought, but information on the kinetics of acetylacetonato-ruthenium(II)–formate reactions[21] suggests that it may be formed through substitution of the aqua ligand by formate ion. At present, the experimental data available are insufficient to establish the most probable mechanism. The numerical values for the rate constants as interpreted according to the three mechanisms are given in Table 3.

Equation 8 implies that the rate is maximum when $[H^+]=(K_AK_R)^{1/2}$, in this case, 4.76×10^{-4} mol dm^{-3}. It should be noted that a mild acidic condition is favorable for preparing carbonyl complexes when the reaction mechanism is similar to the present one.

The author would like to express grateful appreciation to Prof. Gen P. Satô, Sophia University, for his continuous guidance and encouragenent. Thanks are also due to Profs. Kunio Nakano and Tatsujiro Ishimori, St. Paul's (Rikkyo) University, for their valuable suggestions; to Mr. Kenji Hirose and Mr. Misao Hayashi for their assistance in the preliminary experiments; and to Sr. Jean Michalce for correcting the manuscript.

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education in 1973.

TABLE 3. RATE CONSTANT FOR PROBABLE MECHANISMS

Mechanism	k	Experimental value
1a	k_2k_R	$k_2=3.08\times10^{-2}$ mol^{-1} dm^3 s^{-1}
2a	k_7K_7	$k_7K_7=3.08\times10^{-2}$ mol^{-1} dm^3 s^{-1}
2b	$k_{10}K_{10}K_AK_R$	$k_{10}K_{10}=44.5$ mol^{-2} dm^6 s^{-1}

Hydrolytic Behavior of Oxovanadium(IV) Ions

Akitoshi KOMURA, Mutsuo HAYASHI, and Hiroto IMANAGA

Faculty of Technology, Kanazawa University, Kanazawa 920

(Received March 18, 1977)

The hydrolysis of VO^{2+} was investigated in 0.1 M $LiClO_4$ by potentiometric, conductometric and turbidimetric measurements. The following values of the equilibrium constants were obtained: $\beta_{11}=[VOOH^+][H^+]/[VO^{2+}]=9.0\times10^{-6}$ M (M=mol dm^{-3}); $\beta_{22}=[(VO)_2(OH)_2{}^{2+}][H^+]^2/[VO^{2+}]^2=1.9\times10^{-7}$ M. The solubility product of $VO(OH)_2$ given by $K_{sp1}=[VO^{2+}][OH^-]^2$ was found to be 6.6×10^{-23} M^3 from the pH values at which precipitation occurs. Only one species with a stoichiometric ratio VO/OH=2.5 is present in basic solutions in the pH range 9—12. The solubility product of $VO(OH)_2$ given by $K_{sp2}=[H^+][(VO)_2(OH)_5{}^-]$ is $\log K_{sp2}=-11.1$. A less soluble salt $Na(VO)_2(OH)_5$ or $NaHV_2O_5$ was isolated from strongly basic solutions. Measurements of Na^+ concentration at which the solid phase first appears give $\log K_{sp3}=-3.74$ as its solubility product, $K_{sp3}=[Na^+][(VO)_2(OH)_5{}^-]$.

The species with metal-oxygen multiple bonds are of particular interest in connection with their reactivities and structures.[1,2] The oxovanadium(IV) ion seems to be the most stable diatomic ion known, forming a wide variety of stable complexes and persisting in VO^{2+} entity.[3] The susceptibility of the VO^{2+} ion to hydrolysis, however, may greatly complicate the coordinative behavior of vanadium(IV) in aqueous solution. Investigations[4-6] on the hydrolysis of VO^{2+} in acidic solutions have provided strong evidence for the existence of a simple monohydroxo species accompanied by the formation of a dinuclear species. On the other hand, only a few quantitative studies have been made on the nature of vanadium(IV) in neutral or basic solutions. Titration curves obtained by Britton and Welford[7] showed the presence of the $V_4O_9{}^{2-}$ species in basic solutions. The polarographic data by Lingane and Meites[8] were interpreted in terms of the formation of two ions $V_2O_5{}^{2-}$ and $V_4O_9{}^{2-}$. A recent ESR study[9] showed that the vanadium(IV) species in basic solutions was monomeric $VO(OH)_3{}^-$. Various vanadate(IV) compounds, often called either vanadites or hypovanadates, were isolated from strongly basic solutions of vanadium(IV).[10,11] The present authors have examined the hydrolysis of VO^{2+} over a wide range of pH, using potentiometric, conductometric and turbidimetric techniques, in order to identify the hydrolysis species of vanadium(IV) and clarify their formation equilibria.

Experimental

Materials. Chemicals of guaranteed quality were used without further purification. Stock solutions of oxovanadium perchlorate in dilute perchloric acid (*ca.* 0.1 M) were prepared by dissolving vanadium(IV) hydroxide in a perchloric acid solution, and standardized by permanganate titration. The free acid in the oxovanadium perchlorate solution was determined by passing an aliquot portion of the stock solution through a cation-exchange resin, and titrating the effluent with a standard base. Lithium perchlorate was prepared from perchloric acid and lithium carbonate, and recrystallized twice from water. A standard carbonate-free sodium hydroxide solution was prepared by the usual procedure from a saturated NaOH solution, and stored in a polyethylene bottle under a CO_2-free atmosphere. Perchloric acid solutions were prepared by dilution of concentrated perchloric acid (Wako Super Special Grade).

Apparatus and Procedures. Potentiometric titration was carried out by means of a Horiba F-7SS pH meter with a Horiba glass electrode and an asbestos fiber-junction calomel electrode in a gas-tight cell under a stream of purified nitrogen. All the pH measurements were made in $LiClO_4$ solutions at a constant ionic strength (I=0.1 M) and at 25±0.05 °C. The electrode system was calibrated in terms of free hydrogen ion concentration, h, with standard $HClO_4$ and NaOH solutions. The liquid junction potential of the cell was independent of h within the limit of experimental error (0.5 mV) in the range $h\leq0.001$ M. The value of h in the vanadium solutions was determined by comparing the cell potential of the solutions with that of a standard solution of 0.001 M $HClO_4$ in 0.1 M $LiClO_4$. In order to remove the oxygen dissolved, nitrogen was bubbled through sample solutions for 1 h before titration. Small increments of a standardized NaOH or $HClO_4$ solution were added to the titration cell with a microburet and the pH was read every 2—3 min after each addition of the titrant. The decrease in concentration of ions due to dilution in the course of titration was below 2% of initial concentration over the pH range studied. The concentrations of ions were corrected for the dilution effect on the basis of the added amount of titrant.

Conductometric titration was carried out under purified nitrogen at 25±0.01 °C with the use of a Yokogawa conductance bridge (1000 Hz) and a conductometric cell with platinized platinum black electrodes. Precipitation boundaries were determined by measuring the concentration of H^+ or Na^+ at which a solid phase first appeared in vanadium(IV) solutions. The experimental procedure was similar to that for the potentiometric titration, except that titrants were added very slowly to the cell. The turbidity of the vanadium solutions was observed either visually under irradiation with a beam of light or by means of a Hitachi 124 spectrophotometer. The formation of a solid phase was detected as a sudden development of turbidity. Electronic spectra of solutions were recorded on a Hitachi 124 spectrophotometer with the use of matched 10 mm quartz cells fitted with ground-glass stoppers. All solutions for spectral measurements were prepared under anaerobic conditions. In basic solutions, extreme care was required to prevent oxidation of vanadium(IV).

Results and Discussion

Hydrolysis in Acidic Solution. The average number of hydroxide ions bound per vanadium, $\bar{n}$, is calculated at any point of titration from the following relationship:

$$\bar{n}=\frac{h-C_H}{C_m}, \quad (1)$$

where C_H and C_m are the total analytical concentrations of H^+ and vanadium(IV). The hydrolysis of VO^{2+}

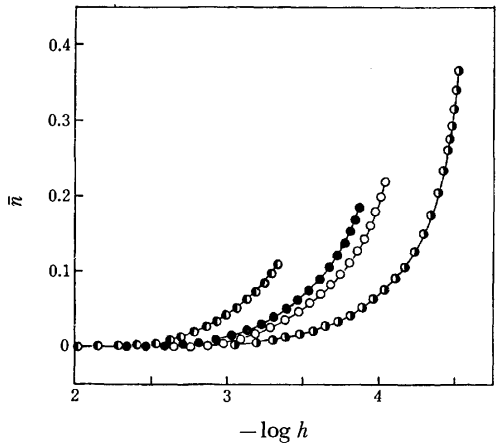

Fig. 1. Average number, $\bar{n}$, of hydroxide ions bound per vanadium as a function of log h.
The total concentrations of vanadium: ◐, 5×10^{-2} M; ●, 10^{-2} M; ○, 5×10^{-3} M; ◑, 10^{-3} M.

can be expressed by

$$pVO^{2+} + qH_2O \rightleftharpoons (VO)_p(OH)_q^{2p-q} + qH^+, \quad (2)$$

where p and q are positive integral numbers. Equilibrium constants β_{pq} and $\bar{n}$ are defined as follows:

$$\beta_{pq} = [(VO)_p(OH)_q^{2p-q}][VO^{2+}]^{-p}h^q, \quad (3)$$

$$\bar{n} = \frac{\Sigma q[(VO)_p(OH)_q^{2p-q}]}{C_m}. \quad (4)$$

The total concentration of vanadium is given by

$$C_m = [VO^{2+}] + \Sigma p[(VO]_p(OH)_q^{2p-q}]. \quad (5)$$

Precipitation of vanadium hydroxide at a low value of $\bar{n}$ restricts the region of measurements accessible to the study of solution equilibrium. As shown in Fig. 1, $\bar{n}$ *vs.* log h curves in the region without precipitation are parallel to each other over the range C_m=0.001—0.05 M. The treatment for the general 'core-links' complexes[12] was applied. Analysis of the data in the range C_m=0.001—0.05 M strongly indicates the species with p=2 and q=2 to be the predominant hydrolysis product of VO^{2+}, in agreement with Rossotti and Rossotti.[4] A value of β_{22} of 1.9×10^{-7} M was obtained on the assumption that only the $(VO)_2(OH)_2^{2+}$ species was formed. The assumption could not, however, explain satisfactorily the experimental data for C_m below 0.001 M. The possible presence of hydrolysis species other than $(VO)_2(OH)_2^{2+}$ was tested by a curve-fitting procedure. The potentiometric data over a wide range of C_m could best be interpreted in terms of the additional formation of the mononuclear $VOOH^+$ species at lower C_m values. The β values evaluated by the procedure were β_{11}=$(9\pm1)\times10^{-6}$ M and β_{22}=$(1.9\pm0.5)\times10^{-7}$ M. If the species $(VO)_2(OH)_2^{2+}$ and $VOOH^+$ are the only two complexes formed, the following relation can also be derived from Eqs. 3, 4, and 5.

$$h\bar{n}(1-\bar{n})^{-1} = \beta_{11} + 2\beta_{22}C_m h^{-1}(1-\bar{n}). \quad (6)$$

A plot of $h\bar{n}(1-\bar{n})^{-1}$ *vs.* $C_m h^{-1}(1-\bar{n})$ should give a straight line with a slope equal to $2\beta_{22}$ and an intercept equal to β_{11} (Fig. 2). The straight line gives the same values of β as those obtained above. The β_{22} value we obtained is in good agreement with that of $10^{-6.88}$ M in 3 M $NaClO_4$ reported by Rossotti and Rossotti,[4] whereas our β_{11} value is 8—9 times as large as that[4] in 3 M $NaClO_4$. A noticeable difference is also observed between the β_{11} values in literature.[4,13-15]

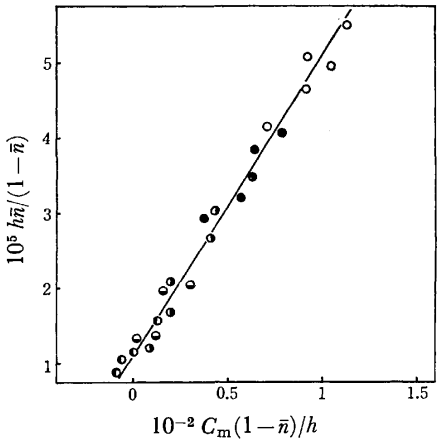

Fig. 2. A plot of $h\bar{n}/(1-\bar{n})$ as a function of $C_m(1-\bar{n})/h$.
The total concentrations of vanadium: ○, 5×10^{-2} M; ●, 10^{-2} M; ◑, 10^{-3} M; ◒, 5×10^{-4} M; ◐, 10^{-4} M.

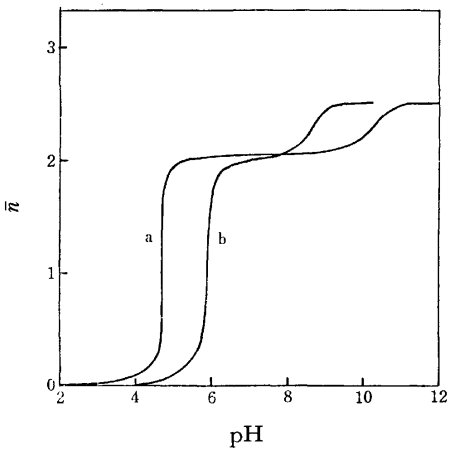

Fig. 3. The $\bar{n}$ *vs.* pH curves over a wide range of $\bar{n}$.
The total concentrations of vanadium: a, 10^{-3} M; b, 5×10^{-5} M.

Figure 3 shows $\bar{n}$ *vs.* pH curves over a wide range of $\bar{n}$. The curves exhibit a plateau at $\bar{n}$=2 corresponding to the precipitation of vanadium(IV) hydroxide. The IR spectrum of the hydroxide isolated (found: V, 50.2%) has a strong band at *ca.* 970 cm^{-1} assigned to the V=O stretching vibration. According to Selbin[3], a very strong band at 985 ± 50 cm^{-1} indicates the presence of the V=O bond. Thus the vanadium hydroxide appears to have the formula $VO(OH)_2$ or $VO_2\cdot H_2O$ (calcd: V, 50.5%). The solubility product, K_{sp_1}, of $VO(OH)_2$ given by Eq. 8 was determined as follows:

$$VO^{2+} + 2OH^- \rightleftharpoons VO(OH)_2(s) \quad (7)$$

$$K_{sp_1} = [VO^{2+}][OH^-]^2 \quad (8)$$

In the pH range where no precipitation of $VO(OH)_2$ occurs, the concentration of unhydrolyzed oxovanadium(IV) ions is given by

$$[VO^{2+}] = (1-\bar{n})C_m. \quad (9)$$

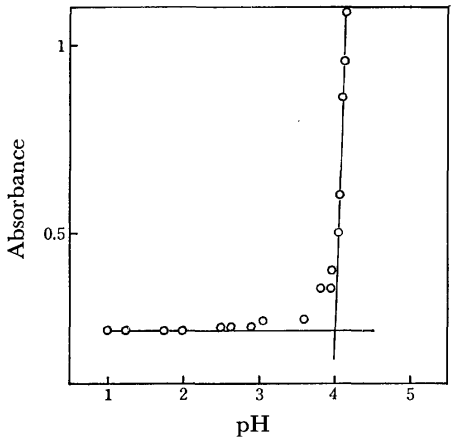

Fig. 4. The absorbance of vanadium(IV) solution as a function of pH.
The concentration of vanadium is 10^{-3} M. Wavelength, 240 nm.

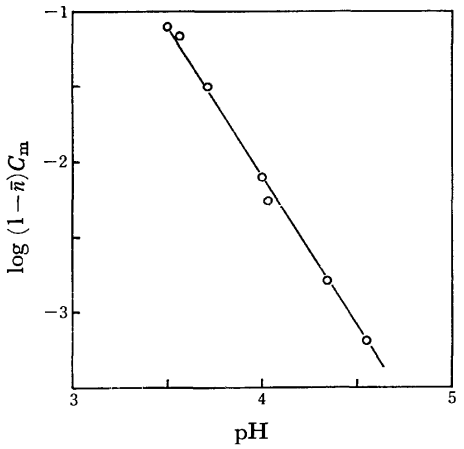

Fig. 5. The relation between the total concentration of vanadium and the pH at which vanadium hydroxide first appeared in acidic solutions.

Equation 9 can be derived from Eqs. 4 and 5, since only the $VOOH^+$ and $(VO)_2(OH)_2^{2+}$ species are the hydrolysis products of VO^{2+}. If Eq. 9 holds at the pH at which precipitation first takes place, the following relation can be derived from Eqs. 8 and 9:

$$\log K_{spl} = \log (1-\bar{n})C_m + 2\log K_w + 2pH, \quad (10)$$

where K_w is the ionic product of water. The pH at which precipitation first takes place was determined by measuring the absorbance of vanadium(IV) solutions at a given C_m as a function of pH. Figure 4 shows the plot at $C_m=0.001$ M. Extrapolation of the linear portion in the plot gave the critical pH at which solid phase first appeared at the given C_m. Figure 5 shows a plot of the critical pH *vs.* $\log (1-\bar{n})C_m$, giving a straight line with a slope −2 which corresponds to the value given by Eq. 10. If we use $\log K_w=-13.78$ in 0.1 M $NaClO_4$,[16] the K_{spl} value of 6.6×10^{-23} M^3 is obtained from the intercept.

Species of Vanadium(IV) in Basic Solution. The $VO(OH)_2$ precipitate dissolves in alkali to give a golden brown solution indicative of the formation of a new species. The electronic spectra of vanadium(IV) in basic solutions are given in Table 1, together with those of VO^{2+} for comparison. The spectrum of the vanadium species in basic solutions differs from that of VO^{2+} in the appearance of the third d-d band which is hidden under the strong charge-transfer band at 240 nm in the spectrum of VO^{2+}. The same spectrum of vanadium(IV) in a basic solution has also been obtained by Iannuzzi and Rieger.[9] They indicated that the Raman spectrum of vanadium(IV) in 1 M NaOH has a strong band at 987 cm^{-1} indicating the presence of the V=O group in the vanadium species. Basic solutions of vanadium(IV) may contain any species of the general formula $(VO)_p(OH)_q^{2p-q}$. The vanadium species in a basic solution were formulated in the following way. A solution of NaOH in 0.1 M $LiClO_4$ was titrated with a vanadium-containing solution of $HClO_4$ and a vanadium-free solution of $HClO_4$, respectively. The values of $\bar{n}$ are then given by

Table 1. Electronic spectra (λ_{max}/nm) of vanadium(IV)[a]

0.1 M $HClO_4$	0.5 M NaOH
764 (17.4)	790 (14)
620sh (7.50)	525 (15)
240 (242)	418 (25)

a) Molar absorption coefficients (M^{-1} cm^{-1}) are given in parentheses.

$$\bar{n} = \frac{C_{OH}-C_{OH}'}{C_m}, \quad (11)$$

where C_{OH} and C_{OH}' are the total analytical concentrations of OH^- added to reach the same pH in the presence and in the absence, respectively, of vanadium. Addition of VO^{2+} to NaOH solutions gave the soluble species in the basic pH region followed by precipitation of a vanadium compound in the region of nearly neutral pH. Table 2 gives the $\bar{n}$ values obtained in the pH region where no precipitation occurs. The potentiometric data indicate that $\bar{n}$ is 2.5 over the range of C_m and pH studied. A constant value of $\bar{n}=2.5$ suggests that only one species with a stoichiometric ratio $q/p=2.5$ is present in basic solutions in the pH range 9—12. The formation of this species is also seen as the second plateau of the potentiometric titration curves (Fig. 3), for which low C_m values were used in order to cause rapid redissolution of the oxovanadium hydroxide precipitated. Further evidence of the above stoichiometry was obtained by means of conductometric titration, in which an acid solution of $VO(ClO_4)_2$ was added incrementally to a NaOH solution. The titration was carried out at low C_m value so as to effect no precipitation up to neutral pH. From the electroneutrality condition on the titration system, we have

$$C_b + [H^+] = C_a + [OH^-] + \Sigma q[(VO)_p(OH)_q^{2p-q}], \quad (12)$$

where C_a and C_b are the analytical concentrations of $HClO_4$ and NaOH, respectively, in the system. At $[H^+]=[OH^-]$, $\bar{n}$ is given as follows from Eqs. 4 and 12:

$$\bar{n} = \frac{C_b-C_a}{C_m}. \quad (13)$$

The point of minimum conductivity in titration curves

Table 2. The $\bar{n}$ values evaluated potentiometrically in basic solutions of vanadium(IV)

pH	a) (10^4 C/M)				pH	b) (10^3 C/M)			
	C_{OH}'	C_{OH}	C_m	$\bar{n}$		C_{OH}'	C_{OH}	C_m	$\bar{n}$
11.8	25.9	36.0	3.98	2.54	12.0	5.80	8.81	1.23	2.45
11.4	16.4	33.2	6.70	2.51	11.6	3.08	8.02	2.01	2.46

8.60	3.45	29.4	10.6	2.45	9.00	0.69	7.32	2.68	2.47

a) A solution of 0.004 M NaOH in 0.1 M $LiClO_4$ was titrated with a solution 0.1 M in $VO(ClO_4)_2$ and 0.1 M in $HClO_4$, and a 0.1 M $HClO_4$ solution, respectively. b) A solution of 0.01 M NaOH in 0.1 M $LiClO_4$ was titrated with a solution 0.2 M in $VO(ClO_4)_2$ and 0.2 M in $HClO_4$, and a 0.2 M $HClO_4$ solution, respectively.

Table 3. The $\bar{n}$ values of basic vanadium species determined by conductometric titrations[a)]

C_b	C_a	C_m	$\bar{n}$
7.84	3.08	1.87	2.55
7.56	1.35	2.48	2.50
3.87	0.650	1.28	2.52
1.94	0.316	0.639	2.54

a) Each C (10^{-3} M) is the concentration at $[H^+]=[OH^-]$.

was taken as that corresponding to the relation $[H^+]=[OH^-]$. The conductometric data (Table 3) indicate that the $\bar{n}$ values obtained are practically 2.5, regardless of C_m. This is in line with the potentiometric measurements. At low C_m, the occurrence of precipitation in the neutral pH region, if any, probably leads to no significant error in the estimation of $\bar{n}$. Attempts were made to determine ionic charge (z) of the vanadium species in basic solutions by use of an anion-exchange resin. However, the results are not decisive, although the ion-exchange behavior of the species suggests that $|z|$ is not greater than 2. The experiments were accompanied with a great difficulty due to the fact that the species is highly sensitive to oxygen. If the smallest integers giving the above stoichiometric ratio are taken as the values of p and q, the dinuclear, probably monohydroxo-bridged ion $(VO)_2(OH)_5^-$ or $HV_2O_5^-$ should be presented as the vanadium species in basic solutions. In the range of pH below 12, no evidence was found for the monomeric $VO(OH)_3^-$ species proposed by Iannuzzi and Rieger[9] corresponding to the stoichiometric ratio $q/p=3$. They obtained an indication of the $VO(OH)_3^-$ ion from experiments in more basic solutions, in which potentiometric measurements seemed impracticable.

A dark brown precipitate of vanadium is obtained on addition of acid to its basic solution, and a gray precipitate on neutralization of its acidic solution. Britton and Welford[7] state that oxovanadium hydroxide, on first precipitation, is grayish-white, turning dark brown as precipitation proceeds. The color change results from the formation of a sparingly soluble sodium vanadite. Stoichiometry of the formation of the dark brown precipitate might be expressed as follows;

$$(VO)_2(OH)_5^- + mH^+ + yM^+ \rightleftharpoons M_y(VO)_2(OH)_{2n}(s) + mH_2O, \quad (14)$$

where M^+ is a +1 charged ion, $n=(5-m)/2$, and $y=1-m$. The solubility product, K_{sp2}, of the solid is defined by

$$K_{sp2} = [(VO)_2(OH)_5^-][H^+]^m[M^+]^y. \quad (15)$$

If the concentration of $(VO)_2(OH)_5^-$ is still equal to $C_m/2$ at the pH where precipitation first occurs, the following relation is obtained:

$$\log K_{sp2} = \log C_m/2 - m\mathrm{pH} + y \log [M^+]. \quad (16)$$

The pH at which the solid phase first appears was determined at a given ionic strength (0.1 M). Figure 6 represents a plot of the critical pH *vs.* $\log C_m/2$ giving a straight line. The slope $m=1$ of the line indicates that $n=2$ and $y=0$. Thus the dark brown precipitate also has the formula $VO(OH)_2$. The dark brown color of the precipitate might be due to co-precipitation of the $(VO)_2(OH)_5^-$ ion, as presumed from its formation reaction,

$$(VO)_2(OH)_5^- + H^+ \rightleftharpoons 2VO(OH)_2(s) + H_2O. \quad (17)$$

The solubility product of $VO(OH)_2$ in basic solutions is found to be $\log K_{sp2}=-11.1$ from the intercept of the line in Fig. 6. From the values of K_{sp1} and K_{sp2}, we can estimate the equilibrium constant, β_{25}^b, for the reaction,

$$2VO^{2+} + 5OH^- \rightleftharpoons (VO)_2(OH)_5^-, \quad (18)$$

$$\beta_{25}^b = \frac{[(VO)_2(OH)_5^-]}{[VO^{2+}]^2[OH^-]^5} = \frac{K_{sp2}}{K_w K_{sp1}^2} = 1.8\times10^{47}\ M^{-6}. \quad (19)$$

Vanadium(IV) is less soluble even in strongly basic solutions, as noticed by Iannuzzi and Rieger.[9] Various vanadates(IV) compounds have been isolated from basic solutions of vanadium, *e.g.*, $M_2^{IV}V_4O_9\cdot xH_2O$,[10,11] $M_2^{IV}V_2O_5\cdot xH_2O$[10] and $K_2V_3O_7\cdot 2H_2O$.[9] When a large excess of Na^+ is added to a basic solution containing $(VO)_2(OH)_5^-$ ion, a solid is precipitated owing to the common ion effect. The formula of the compound was determined on the basis of stoichiometry of its precipitation. Figure 7 shows the concentration of Na^+ at which the solid phase first appears at given C_m and basicity. A plot of $\log[Na^+]$ *vs.* $\log C_m/2$ gives a straight line with

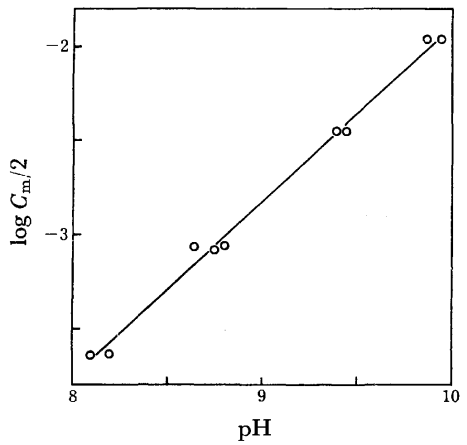

Fig. 6. The relation between the total concentration of vanadium and the pH at which the vanadium hydroxide first appeared in basic solutions.

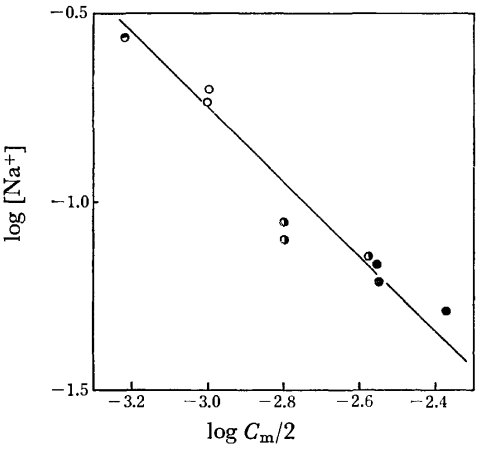

Fig. 7. The concentrations of sodium ion at which less soluble vanadium salt first appeared in NaOH solutions. The concentrations of NaOH: ◓, 0.01 M; ○, 0.015 M; ●, 0.03 M, ◑, 0.05 M.

a slope of −1. Thus the value of y in Eq. 16 is 1, and the values of m and n in reaction 14 are 0 and 2.5, respectively. The results of the measurements indicate that the less soluble compound may have the stoichiometric formula $Na(VO)_2(OH)_5$ or $NaHV_2O_5$ apart from the hydration water. The formula corresponds to sodium vanadate(IV) $Na_2V_4O_9 \cdot xH_2O$ which has occasionally appeared in literature.[7,10,11] The intercept of the straight line gives $\log K_{sp3} = -3.74$ as the solubility product of the compounds defined by Eq. 21.

$$Na^+ + (VO)_2(OH)_5^- \rightleftharpoons Na(VO)_2(OH)_5\ (s), \quad (20)$$

$$K_{sp3} = [Na^+][(VO)_2(OH)_5^-]. \quad (21)$$

Under the experimental conditions, the present work gave no indication of such salts as $M_2^IV_2O_5$ and $K_2V_3O_7$ formulated by Crow[10] and by Iannuzzi and Rieger,[9] respectively.

Processes in the Reaction of Y_2O_3 with WO_3

Kiyoshi KURIBAYASHI and Toshiyuki SATA

Research Laboratory of Engineering Materials, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received April 2, 1977)

The processes of the solid state reaction of Y_2O_3 with WO_3 were studied for samples mixed in the molar ratios of $Y_2O_3 : WO_3 = 1 : 3$, $1 : 1$, $7 : 4$, $5 : 2$, and $3 : 1$. It was found that all the reactions except $Y_2O_3 : WO_3 = 5 : 2$ from the powders of both Y_2O_3 and WO_3 in air proceeded according to the following order step reactions: $Y_2O_3 \cdot 3WO_3 \rightarrow Y_2O_3 \cdot WO_3 \rightarrow 7Y_2O_3 \cdot 4WO_3 \rightarrow 5Y_2O_3 \cdot 2WO_3$ and $5Y_2O_3 \cdot 2WO_3 \rightarrow 3Y_2O_3 \cdot WO_3$, with temperatures rising from 600 to 1300 °C and with an unknown compound, X, always first formed below 700 °C. In a reaction couple in contact with both Y_2O_3 and WO_3 pellets, WO_3 components preferentially diffused to the Y_2O_3 side to form $Y_2O_3 \cdot 3WO_3$ (orthorhombic form) on the boundary between them at 1000 °C.

The compounds formed in the reaction of the sesquioxides of the rare earth elements (R_2O_3) with WO_3 are attracting the attention of research workers because of the possibility of using them as engineering materials: refractory materials, dielectrics, laser materials, and luminescents materials. They are also interesting from a crystallographical point of view and from the point of view of reaction kinetics.

H. J. Borchardt[1] studied a phase relation in the Y_2O_3–WO_3 system and reported that there were six compounds: $Y_2O_3 \cdot 3WO_3$, $Y_2O_3 \cdot WO_3$, $3Y_2O_3 \cdot 2WO_3$ (metastable phase), $15Y_2O_3 \cdot 8WO_3$, $9Y_2O_3 \cdot 4WO_3$, and $3Y_2O_3 \cdot WO_3$. Recently, G. H. McCarthy *et al.*[2] reported that five compounds existed in the system: $Y_2O_3 \cdot 3WO_3$ (YW_3), $Y_2O_3 \cdot WO_3$(YW), $7Y_2O_3 \cdot 4WO_3$-(Y_7W_4), $5Y_2O_3 \cdot 2WO_3$(Y_5W_2), and $3Y_2O_3 \cdot WO_3$(Y_3W). However, the Y_2O_3-rich region of the system has not yet been made clear.

In the present study, the processes of the solid state reaction between Y_2O_3 and WO_3 were studied. Also, we tried to determine what the diffusion component was through an interface where the two oxides came in contact using an electron-probe microanalyzer (EPMA).

Experimental

Both dried Y_2O_3(Rare-Metallic Co., 99.99%) and WO_3 (Mitsuwa Chemical Co., 99.9%), calcined at 800 °C for 3h, were weighed in the appropriate oxide ratio and were mixed thoroughly in an agate mortar. These oxide mixtures were then pressed into pellets at 800 kg cm^{-2}. The pellets were then heated in air on an alumina boat for 48 h at temperatures from 600 °C up to 1300 °C in a mullite tube in a silicon carbide furnace. The temperature was controlled within ±10 °C. After heating, the products were identified by the X-ray powder diffraction methods.

Y_2O_3 was pressed into a pellet at 3200 kg cm^{-2} and sintered in air at 1400 °C for 48 h; the apparent porosity of the pellet was 19%. The surface of the pellet was polished with diamond paste. A 0.2 mmϕ platinum wire was fixed as a marker on the Y_2O_3 pellet and was then pressed into a larger pellet, with WO_3 powder covering the pellet, at 3200 kg cm^{-2}. It was heated on an alumina boat in air for 72 h at 1000 °C. After cooling, the pellet was cut off perpendicular to the interface between the Y_2O_3 and WO_3 layers, as is shown in Fig. 1a. The cut surface was polished and measured by means of an EPMA.

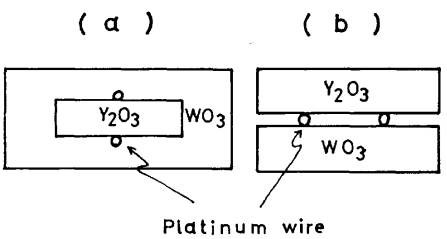

Fig. 1. Schematic diagrams of specimen to study diffusion components.

Each portion of Y_2O_3 or WO_3 was pressed into a pellet at 3200 kg cm^{-2}. The Y_2O_3 pellet was sintered at 1400 °C, while the WO_3 was sintered at 1000 °C for 48 h. After cooling, both the pellets were placed with a 0.2 mmϕ platinum wire sandwiched between, in order to give a clearance of 0.2 mm between them, as is shown in Fig. 1b. The above sandwich-type specimen, wrapped up by a platinum plate, was covered with WO_3 powder in order to confirm the occurrence of a reaction of solid-state Y_2O_3 with WO_3 vapor and was heated on an alumina boat in air at 1000 °C for 72 h.

Results

The relative amounts of phases present in the products after Y_2O_3–WO_3 reactions for 48 h in air at each temperature are shown in Fig. 2a—e. The relative amounts were obtained from the intensities of the peaks on the X-ray diffraction pattern from each compound. It was found that all the reactions except $Y_2O_3 : WO_3 = 5 : 2$ from both Y_2O_3 and WO_3 in air proceeded according to the following order: $YW_3 \rightarrow YW \rightarrow Y_7W_4 \rightarrow Y_5W_2$ and $Y_5W_2 \rightarrow Y_3W$, with temperatures increasing from 600 °C up to 1300 °C, though for the reaction of $5Y_2O_3 + 2WO_3$, Y_3W was formed by the reaction of Y_2O_3 with a part of the Y_7W_4 and the reaction of $6(Y_3W) + Y_7W_4 \rightarrow 5(Y_5W_2)$ yielded the Y_5W_2 compound. The unknown compound, X, was first formed for all the reactions; its X-ray diffraction diagram, shown in Table 1, has not been indexed. Oxide mixtures weighed in the molar ratios of $Y_2O_3 : WO_3 = 1 : 2$, $1 : 3$, or $1 : 4$ were heated in air at temperatures from 600 °C up to 800 °C for 5 days in order that Compound X could be studied in detail. The pellets were reground twice during the heating schedule and then pelletized again in order to insure homogeneity. The products are shown in Table 2. It was impossible to obtain Compound X alone for each composition because of the incomplete reactions. The same results were obtained from 10 days' heating.

A microscopical photograph of the EPMA specimen

(a) Y_2O_3–$3WO_3$, (b) Y_2O_3–WO_3, (c) $7Y_2O_3$–$4WO_3$, (d) $5Y_2O_3$–$2WO_3$, (e) $3Y_2O_3$–WO_3. Y_2O_3, (662), (○); X, 2θ=18.8, (⊙); YW_3, 2θ=20.3, (●); α-YW, 2θ=33.6, (△); β-YW, (112), (△); Y_7W_4, (003), (▲); Y_5W_2, (113), (◇); Y_3W, (003), (◆).

(Fig. 1a) and the results of the EPMA measuremnts are shown in Fig. 3. The WO_3 layer was detached from the reaction layer because of a difference in thermal expansion between WO_3 and the reaction product. A reaction layer 120μm thick was produced as a single layer in the Y_2O_3 layer. The diffusion of Y_2O_3 component to WO_3 side was negligible. The reaction layer was found to be YW_3(orthorhombic form) using the X-ray powder diffraction methods and the EPMA.

On the other hand, no reaction layer was found by the X-ray powder diffraction methods or microscopic observation of the specimen shown in Fig. 1b and heated for 72h at 1000 °C.

Discussion

The Sample Mixed in the Ratio of Y_2O_3 : WO_3=1 : 3. Compound X began to form at about 600 °C, and YW_3 (orthorhombic from) was produced above 800 °C. It

was impossible to obtain Compound X alone because of the slow reaction rate at low temperatures, as is shown in Table 2; *i.e.*, oxide mixtures with this bulk composition, when subjected to the usual heat treatment at 600 or 700 °C, yielded products which consisted of Compound X and unreacted Y_2O_3 and WO_3. The phase changes for $R_2O_3 \cdot 3WO_3$ (R=Dy and Ho) were reported by V. E. Plyuschev and V. M. Amosov[3] and those for R=La—Dy, by K. Nassau *et al.*[4] M. Yoshimura *et al.*[5-7] synthesized $2R_2O_3 \cdot 9WO_3$ (R=La,

Ce, Pr, and Nd) and pointed out that rare earths which are heavier than Sm would be too small to form this type of compound. Considering the above reports and the present results, Compound X can be assumed to be a high-temperature form of YW_3 or a compound near to YW_3. This compound may exist as a metastable phase between 600 and 700 °C.

The Sample Mixed in the Ratio of Y_2O_3 : WO_3=1 : 1. Compound X began to form at about 600 °C, and the Y_3W_2 (metastable phase) reported by H. J. Borchardt[1] was yielded about 700 °C. Recently, M. Yoshimura *et al.*[8] reported that this metastable phase was a high-temperature form(β-phase) of YW plus Y_2O_3. A low-temperature form(α-phase) of YW was produced above 900 °C through the process of Compound X→β-YW→α-YW. YW_3 (orthorhombic form) was not observed in this process.

The Sample Mixed in the Ratio of Y_2O_3 : WO_3=7 : 4. The compound of Y_7W_4 was produced above 960 °C through the process of Compound X→β-YW→Y_7W_4. YW_3 and α-YW(low-temperature form) were not formed, as is the case of the sample mixed in the ratio of Y_2O_3 : WO_3=1 : 1. Similar results were obtained for the formation of Y_5W_2 and Y_3W.

The Sample Mixed in the Ratio of Y_2O_3 : WO_3=5 : 2. After passing through the process of Compound X→β-YW→Y_7W_4, the reaction of Y_2O_3 with a part of Y_7W_4 yielded Y_3W. The Y_5W_2 compound was produced by the reaction of Y_7W_4 with Y_3W at temperatures higher than 1300 °C.

G. J. McCarthy *et al.*[2] reported that $5R_2O_3 \cdot 2WO_3$ was found only for the rare earths, R=Gd—Ho and Y. The reaction products from mixtures with their bulk compositions, after usual heat treatment at 1400 °C, consisted of $3R_2O_3 \cdot WO_3$, plus $7R_2O_3 \cdot 4WO_3$ for other rare earths. $5R_2O_3 \cdot 2WO_3$ may be also yielded by heating at temperatures higher than 1400 °C for the other rare earths, because the reactions proceeding at 1400 °C for them correspond to that of the mixture of $5Y_2O_3$ and $2WO_3$ heated at 1200 °C.

The Sample Mixed in the Ratio of Y_2O_3 : WO_3=3 : 1. After passing through the process of Compound X→β-YW→Y_7W_4, the compound of Y_3W(low-temperature form) was produced by a reaction of Y_2O_3 with Y_7W_4 and Y_5W_2 above 1200 °C. The high-temperature form of Y_3W was not yielded before the production of the low-temperature form from this oxide mixture. It is different from the other samples because the reaction temperature is sufficiently high to enhance the mobilities of the reactant ions, and transition temperature of Y_3W is about 1800 °C too high compared to this reaction temperature.

Reaction of Pellets of Y_2O_3 and WO_3. Considering that the vapor pressure of WO_3 was as low as 10^{-5} Torr[9] at 1000 °C and that the reaction layer did not form in the specimen shown in Fig. 1b, it can be said that the solid state reaction of pellets of both Y_2O_3 and WO_3 occurred in the specimen shown in Fig. 1a. Flor Giorgio *et al.*[10] reported that the $WO_3+SrCO_3 \rightarrow SrWO_4+CO_2$ solid state reaction was controlled by the counterdiffusion of cations involving W^{6+} and Sr^{2+}. E. V. Tkachenko *et al.*[11] reported that the elements of the tungsten sublattice in $CuWO_4$ and Cr_3WO_6 had a higher mobility than that of the copper sublattice. It is possible to consider the diffusion of W^{6+}, so W^{6+} and O^{2-} may be preferentially diffused to the Y_2O_3 side in the reaction of the pellets of both Y_2O_3 and WO_3. The reaction process of Y_2O_3 with WO_3 is similar to that of boron with tungsten metal reported earlier by one of the present authors;[12] the reaction from both BN and W proceeded thus: $WB_4 \rightarrow WB_2 \rightarrow WB$ and $WB \rightarrow W_3B$ with an increase in the temperature because the diffusibility of B is higher than that of W. Such a reaction is due to the significant difference in mobilities between the reactant ions. The diffusion species, W^{6+}, or any W–O complex ions must be confirmed by a more detailed examination of the reaction kinetics.

Conclusion

(1) All the reactions of the powders of both Y_2O_3 and WO_3 in air proceeded according step-by-step in the following order: $YW_3 \rightarrow YW \rightarrow Y_7W_4 \rightarrow Y_5W_2$ and $Y_5W_2 \rightarrow Y_3W$ with the elevation of the temperature from 600 °C up to 1300 °C, and an unknown compound, X, was always first formed below 700 °C.

(2) In a reaction couple bringing Y_2O_3 and WO_3 pellets in contact with each other, WO_3 components preferentially diffused to the Y_2O_3 side to form YW_3 (orthorhombic form) on the boundary between them at 1000 °C.

The authors wish to thank Dr. Masahiro Yoshimura of this laboratory for his helpful advice and discussions.

Ion-Pair Effect on the Rate of the Base Hydrolysis of the Pentaamminechlorocobalt(III) Complex

Masayasu IIDA* and Hideo YAMATERA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received May 16, 1977)

The rate of the base hydrolysis of pentaamminechlorocobalt(III) ions was measured in the presence of multivalent anions at a constant ionic strength. The results were analyzed in view of the S_N1 C.B. mechanism considering the formation of ion-pairs. The ion-pairing has the effect of suppressing the acid dissociation of the complex or the formation of its conjugate base, which acts as the intermediate of the reaction. This effect out-weighs the adverse effect of the probable acceleration of the rate-determining step of the base hydrolysis. The association constants obtained for $[CoCl(NH_3)_5]^{2+}\cdot SO_4^{2-}$ and $[CoCl(NH_3)_5]^{2+}\cdot P_3O_9^{3-}$ were 40±5, and 82±5, respectively (I=0.1, 25 °C).

The effect of multivalent anions on the rates of the acid and base hydrolyses of pentaamminechlorocobalt-(III) ions has been studied by Monk *et al.*, who found that ion-pairing accelerated the acid hydrolysis[1] and retarded the base hydrolysis.[2,3] If the latter is assumed to be a simple bimolecular reaction, the retardation can be explained on electrostatic grounds by the reduced positive charge of the ion-pair. However, among several possible mechanisms[4] thus far proposed for this base hydrolysis, the most widely accepted is the S_N1 C.B. mechanism, with which Monk *et al.*[3] failed to explain the retardation effect.

In this paper, the effect of multivalent anions on the rate of the base hydrolysis of pentaamminechlorocobalt-(III) cations at a constant ionic strength is analyzed in view of the S_N1 C.B. mechanism and is explained by considering the formation of the ion-pairs of the ammine and the amido complexes with the multivalent anions.

Experimental

Materials. *Pentaamminechlorocobalt(III) Perchlorate*: The chloride of the complex, prepared by the method of Hynes *et al.*,[5] was dissolved in hot water and was then converted to the perchlorate by treating it with concentrated perchloric acid and by then cooling the solution in ice. The complex was identified spectrophotometrically.

Sodium Perchlorate: Sodium perchlorate was prepared from a saturated sodium hydroxide solution and perchloric acid. Heavy metal impurities in the sodium perchlorate were precipitated as hydroxides at pH 9, and the removal of heavy metals was confirmed by means of PAN(= 1-(2-pyridylazo)-2-naphthol).

Sodium Acetate: Anhydrous sodium acetate, a guaranteed reagent of Wako Pure Chemical Co, was used after dried at 110 °C.

Sodium Sulfate: Anhydrous sodium sulfate, a guaranteed reagent of Wako Pure Chemical Co, was recrystallized from water at 80 °C and dried at 100 °C.

Sodium Trimetaphosphate:[6] Disodium hydrogenphosphate was heated at about 800 °C for 200 h, after which the product was cooled very slowly. Then the sodium trimetaphosphate thus produced was extracted with a small amount of water and recrystallized by the addition of alcohol and cooling in a refrigerator. The purity of the twice-recrystallized salt was confirmed by paper chromatography.

Kinetic Runs. The rate was measured spectrophotometrically by following the change in the absorbance of solutions containing the complex (2.0×10^{-4} M (= mol dm^{-3})), an ammonia (2×10^{-3} M)-ammonium perchlorate (2×10^{-4} M) buffer, added salts (in appropriate concentrations), and sodium perchlorate, the last being added so as to adjust the ionic strength to 0.1. The reaction mixture, contained in a 1-cm quartz cell, was placed in the cell compartment of a Carl-Zeiss spectrophotometer, PMQ II, maintained at 25± 0.05 °C by circulating water from a thermostat.

pH Measurement. After the reaction had reached completion, the pH value of the sample solution was measured with a Beckman Research pH meter standardized with a buffer solution of Na_2CO_3–$NaHCO_3$ (pH 10.02 at 25 °C). As the internal solution of the reference electrode, a saturated NaCl solution was used so as to avoid the precipitation of $KClO_4$. The change in the liquid junction potential due to the displacement of the added salts was assumed to be negligible.

Results and Discussion

The experimental conditions and the rate constant observed for each run are shown in Fig. 1 and Tables 1—5. The rates were determined by plotting $\ln(D_\infty - D_t)$ against the time t, where D_∞ and D_t are the absorbances at an infinite time and at the time t respectively. The pseudo-first-order rate constant, k_{obsd} was thus

obtained as the slope of this plot. Therefore, the rate of the reaction measured in the buffer solution is:

$$\text{Rate} = k_{obsd}[CoCl(NH_3)_5^{2+}]_0, \quad (1)$$

where $[CoCl(NH_3)_5^{2+}]_0$ is the total concentration of the complex.

On the other hand, according to the S_N1 C.B. mechanism, the following reaction scheme has been proposed:

$$[CoCl(NH_3)_5]^{2+} + OH^- \underset{\text{fast}}{\overset{K}{\rightleftharpoons}} [CoCl(NH_2)(NH_3)_4]^+ + H_2O, \quad (2)$$

$$[CoCl(NH_2)(NH_3)_4]^+ \underset{\text{slow}}{\overset{k}{\longrightarrow}} [Co(NH_2)(NH_3)_4]^{2+} + Cl^-, \quad (3)$$

$$[Co(NH_2)(NH_3)_4]^{2+} + H_2O \underset{\text{fast}}{\longrightarrow} [Co(OH)(NH_3)_5]^{2+}, \quad (4)$$

where K is the equilibrium constant and k is the rate constant of the rate-determining step (3). Unless otherwise stated, the equilibrium constants appearing in this paper are the concentration equilibrium constants under the present experimental conditions (I= 0.1, 25 °C).[7] In such a case, the rate equation for the hydrolysis would be:

$$\begin{aligned}\text{Rate} &= k[CoCl(NH_2)(NH_3)_4^+] \\ &= kK[CoCl(NH_3)_5^{2+}][OH^-] \\ &= k\frac{K_a}{K_w}[CoCl(NH_3)_5^{2+}][OH^-], \end{aligned} \quad (5)$$

where K_a represents the acid dissociation constant of the ammine complex, and K_w, the ionic product of water.

Considering $[CoCl(NH_3)_5^{2+}] \gg [CoCl(NH_2)(NH_3)_4^+]$ under the present experimental conditions, a comparison of Eqs. 1 and 5 would give:

$$k_{obsd} = k\frac{K_a}{K_w}[OH^-]. \quad (6)$$

The concentration of hydroxide ions can be related to the measured pH by:

$$\log[OH^-] = \text{pH} - 14 - \log y_{OH}.$$

Under the condition of a constant ionic strength, y_{OH} is almost kept constant, and the observed differences in the pH among the different solutions can be attributed to the effects of the added salts on the $NH_3+H_2O \rightleftharpoons NH_4^+ + OH^-$ equilibrium. To allow for the pH change, the second-order rate constant, k_{II}, defined by Eq. 7 will be used in the following discussion.

$$k_{II} = k_{obsd}/y_{OH}[OH^-]. \quad (7)$$

Figure 1 shows that k_{II} changed with the change in the amount of salt added at the constant ionic strength of 0.1. Thus, the simple reaction scheme (Eqs. 2, 3, and 4) is not adequate in the presence of multivalent anions. However, the scheme given below is considered to relate the observed change in the reaction rate to the ion-pairing between the complex cations and the added anions:

$$\begin{array}{ccc} [CoCl(NH_3)_5]^{2+} & \overset{K_{22}}{\rightleftharpoons} & [CoCl(NH_3)_5]^{2+}\cdot X^{n-} \\ \Big\downarrow{\scriptstyle K_a} & & \Big\downarrow{\scriptstyle K_a^{IP}} \\ [CoCl(NH_2)(NH_3)_4]^{+} & \overset{K_{12}}{\rightleftharpoons} & [CoCl(NH_2)(NH_3)_4]^{+}\cdot X^{n-} \\ \searrow{\scriptstyle k^\circ} & & \swarrow{\scriptstyle k^{IP}} \\ & [Co(NH_2)(NH_3)_4]^{2+} & \\ & \Big\downarrow{\scriptstyle \text{fast}} & \\ & [Co(OH)(NH_3)_5]^{2+} & \end{array} \quad (8)$$

where X^{n-} represents the added multivalent anions, K_{22} and K_{12} are the ion association constants; K_a and K_a^{IP}, the acid dissociation constants, and k° and k^{IP}, the rate constants of the rate-determining steps. In this reaction scheme, the rate expression is:

$$\begin{aligned} \text{Rate} &= k^\circ[CoCl(NH_2)(NH_3)_4^+] \\ &\quad + k^{IP}[CoCl(NH_2)(NH_3)_4^+\cdot X^{n-}] \\ &= \frac{k^\circ K_a}{K_w}[CoCl(NH_3)_5^{2+}][OH^-] \\ &\quad + \frac{k^{IP}K_a^{IP}}{K_w}[CoCl(NH_3)_5^{2+}\cdot X^{n-}][OH^-] \end{aligned} \quad (9)$$

For a weakly basic solution where $[CoCl(NH_3)_5^{2+}] \gg [CoCl(NH_2)(NH_3)_4^+]$, Eq. 9 becomes:

$$\text{Rate} = \frac{(k^\circ K_a + k^{IP}K_a^{IP}K_{22}[X^{n-}])[OH^-]}{K_w(1+K_{22}[X^{n-}])}[CoCl(NH_3)_5^{2+}]_0$$

Relating this equation to Eq. 1, one obtains:

$$k_{obsd} = \frac{(k^\circ K_a + k^{IP}K_a^{IP}K_{22}[X^{n-}])[OH^-]}{K_w(1+K_{22}[X^{n-}])}$$

Then Eq. 7 leads to:

$$k_{II} = \frac{k^\circ K_a + k^{IP}K_a^{IP}K_{22}[X^{n-}]}{K_w y_{OH}(1+K_{22}[X^{n-}])} \quad (10)$$

Substituting k_{II}° for $(k^\circ K_a)/(K_w y_{OH})$ in Eq. 10 and using the relation:

$$K_a^{IP}/K_a = K_{12}/K_{22} \quad (11)$$

one obtains:

$$k_{II} = k_{II}^\circ \frac{1+(k^{IP}/k^\circ)K_{12}[X^{n-}]}{1+K_{22}[X^{n-}]} \quad (12)$$

This equation will be used below for the explanation of the change in k_{II} shown in Fig. 1.

Monk *et al.*[2] observed little change in the rate when sodium perchlorate was replaced by potassium chloride. On the other hand, our experiments have shown that acetate ions have the effect of decreasing the reaction rate (Table 1). Thus, the substitution of acetate for perchlorate resulted in a slight decrease in k_{obsd} in spite of the increased pH of the solution; therefore, the second-order rate constant, k_{II}, showed an unmistakable decrease. Since electrostatic theories[8] of ion association predict only a slight difference between perchlorate and acetate ions in the tendency to form ion-pairs, the observed reaction rates seem to suggest some interaction such as hydrogen-bonding operating between the acetate and the complex ion.

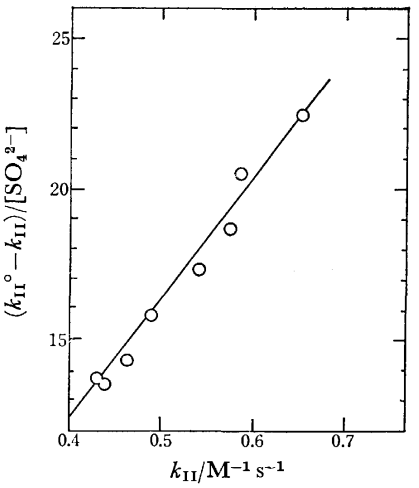

Fig. 2. Determination of the formation constant of the $[CoCl(NH_3)_5]^{2+}\cdot SO_4^{2-}$, ion-pair. (slope$=K_{22}$)

The substitution of sodium sulfate for sodium perchlorate caused a remarkable decrease in k_{obsd} (Table 2). For a quantitative treatment of the effect of the ion-pair formation between the bivalent complex cations and sulfate ions, the net concentration of free sulfate ions must be known. The decrease in the concentration of free sulfate ions due to the formation of hydrogensulfate ions and of the ion-pairs with the complex cations was estimated to be negligible at very low concentrations of hydrogen ions ($\approx 10^{-10}$ M) and the complex cations (2×10^{-4} M). On the other hand, the formation of the $Na^+\cdot SO_4^{-2}$ ion-pairs cannot be neglected.[9] The third column of Table 3 gives the concentrations of free sulfate ions, which were calculated by using the value of 2.0 (at $I=0.1$) for the formation constant of the $Na^+\cdot SO_4^{2-}$ ion-pairs. The last column of the table shows how the ionic strength decreases as a result of the ion-pair formation. According to the Brønsted-Bjerrum equation,[10] this decrease in the ionic strength will cause a decrease in the reaction rate of only 3% at most, a magnitude of the same order as the experimental error. This Brønsted-Bjerrum neutral-salt effect was, therefore, disregarded. For the analysis of the experimental results, Eq. 12 was transformed to:

$$(k_{II}^\circ - k_{II})/[X^{n-}] = K_{22}k_{II} - (k^{IP}/k^\circ)K_{12}k_{II}^\circ. \quad (13)$$

By taking X^{n-} as free sulfate ions, $(k_{II}^\circ - k_{II})/[X^{n-}]$ was plotted against k_{II}. As Fig. 2 shows, a linear relationship was observed, and the slope gives the K_{22} value of 40±5. Then, in order to avoid mathematical difficulty at $[X^{n-}]=0$, Eq. 13 was transformed to:

$$k_{II}(1+K_{22}[X^{n-}]) = k_{II}^\circ + (k^{IP}/k^\circ)K_{12}[X^{n-}]k_{II}^\circ.$$

With the K_{22} value determined above, the left-hand side of this equation was plotted against $[X^{n-}]$ $(=[SO_4^{2-}])$. This plot gave the values of k_{II}° and $(k^{IP}/k^\circ)K_{12}k_{II}^\circ$, from which $(k^{IP}/k^\circ)K_{12}$ was found to be 6±1.

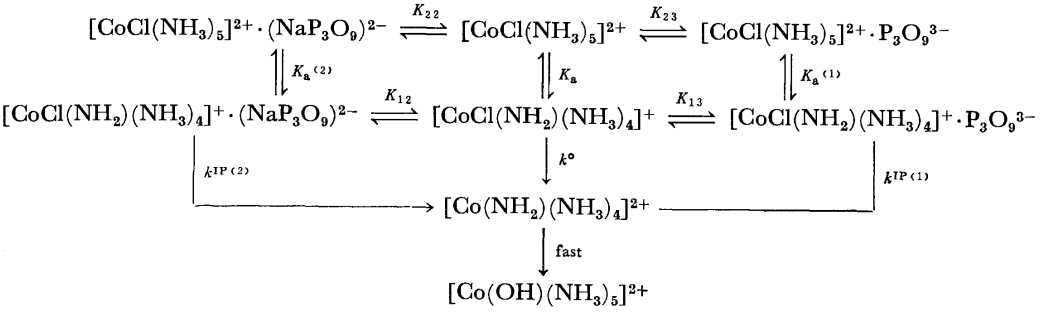
	2.60	Ref. 8 (Fuoss Eq.)

a) The notation a represents the closest distance of the approach of ions.

In Table 6, the K_{22} value here obtained is compared with other experimental and theoretical values. Our K_{22} value is in good agreement with those obtained by Monk *et al.* in a solubility study[11] and in a kinetic study of acid hydrolysis,[1] but it is about three times greater than the theoretical values. This difference can be attributed to the fact that the complex ion is not spherical but has an electric dipole moment in addition to the electric charge.

The value of K_{12} for the 1—2 ion-pair can be estimated with the Yokoyama-Yamatera equation[12] to be 4.7 ($I=0$), which is in reasonable agreement with the experimental K_{12} values for alkali metal sulfates, 5—10 ($I=0$).[13] Then, with K_{12} ($I=0.1$)$=2$, one obtains $k^{IP}/k^{\circ}=3\pm0.5$. This value can be compared with the corresponding value of 2.35 experimentally obtained by Monk *et al.* for the acid hydrolysis,[1] if allowance is made for the probable overestimate in the present k^{IP}/k° value. This overestimate is due to the neglect of the polarity of the complex ion, leading to an underestimated K_{12} value.

In a system with added sodium trimetaphosphate, the reaction scheme is more complicated. The decrease in free trimetaphosphate ions by the formation of hydrogentrimetaphosphate ions ($pK_{a1}=2.05$)[14] as well as by the ion-pair formation with the complex cations can be ignored, as in the case of sulfate. The formation of ion-pairs between sodium and trimetaphosphate ions, $Na^+ + P_3O_9^{3-} \rightleftharpoons Na^+\cdot P_3O_9^{3-}$, was studied by Gardner *et al.*,[15] who found the ion-association constant to be 25.1 at an infinite dilution. Then, the ion-association constant at $I=0.1$ would be 5.7. This value was used in the calculation of the net concentrations of the ions derived from the added sodium trimetaphosphate (Table 5). Although the decrease in the ionic strength is larger in this case than in the case of the sulfate ions, its effect on the reaction rate was estimated to be still of a magnitude within the limits of experimental error. Ignoring the formation of the ion-pairs with univalent anions, as in the case of the sulfate ions, the reaction scheme is:



(14)

where the definitions of the parameters are similar to those in the case of Eq. 8. In this scheme, the rate expression is:

$$k_{II} = k_{II}^{\circ}\frac{1+(k^{IP(1)}/k^{\circ})K_{13}[P_3O_9^{3-}]+(k^{IP(2)}/k^{\circ})K_{12}[Na^+\cdot P_3O_9^{3-}]}{1+K_{23}[P_3O_9^{3-}]+K_{22}[Na^+\cdot P_3O_9^{3-}]}. \quad (15)$$

As a first approximation, ignoring the formation of the $Na^+\cdot P_3O_9^{3-}$ ion-pairs, one can simplify Eq. 15 to obtain:

$$k_{II} = k_{II}^{\circ}\frac{1+(k^{IP(1)}/k^{\circ})K_{13}[P_3O_9^{3-}]_0}{1+K_{23}[P_3O_9^{3-}]_0}, \quad (16)$$

where $[P_3O_9^{3-}]_0$ is the total concentration of sodium trimetaphosphate. With Eq. 16, the experimental results were analyzed in a manner similar to that used in the case of sulfate; the values $K_{23}=75\pm5$ and $(k^{IP(1)}/k^{\circ})K_{13}=9\pm2$ were thus obtained. Since Eq. 15 involves too many parameters, all the parameters except for K_{23} and K_{22} were estimated by theory or by analogy. The K_{13} and K_{12} values were calculated by means of the Yokoyama-Yamatera theory of ion-association,[8] which gave $K_{13}=5.1$ and $K_{12}=1.5$ under the present experimental condition (or 22.3 and 4.0 respectively at $I=0$), assuming the closest distance of approach of ions to be 7 Å (=0.7 nm). The values for $k^{IP(1)}/k^{\circ}$ and $k^{IP(2)}/k^{\circ}$ were estimated at 2.5[16] and 2.0[1] respectively from the values for analogous acid hydrolyses. Using these parameter values and starting with the $K_{23}=75$ obtained with Eq. 16, successive approximations with Eq. 15 resulted in the final values, $K_{23}=82\pm5$ and $K_{22}=40\pm10$. Since no experimental results on the same system are found in the literature,

the constants are compared with those for the systems of similar charge types, such as bivalent metal ions–trimetaphosphate ions and pentaamminechlorocobalt-(III) ions–sulfate ions. The comparison in Table 6 shows that the values obtained are of reasonable magnitude.

It has been shown above that the experimental results can be explained on the basis of the scheme shown in Eqs. 8 and 14 giving ion-association constants of an acceptable magnitude. The discussion also shows that the retardation of the base hydrolysis of pentaamminechlorocobalt(III) ions by multivalent anions can be attributed mainly to the multivalent anions preferring the ammine complex rather than the amido complex (the reaction intermediate) in the ion association or, in other words (using Eq. 11), to the suppression of the acid dissociation of the ammine complex by the ion-pairing. The probable acceleration effect at the rate-determining step, represented by the k^{IP}/k° term is relatively small, so that the net effect of ion-pairing is the retardation of the rate of hydrolysis.

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Formation and Properties of Strontium Uranates

Hiroaki TAGAWA, Takeo FUJINO, and Jun TATENO

Division of Chemistry, Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki 319-11

(Received May 28, 1977)

The formation and nonstoichiometry of strontium uranates, especially those with the Sr/U atom ratio around unity, were examined by means of thermogravimetry and X-ray diffraction. The reaction of $SrCO_3$ with U_3O_8 in air, where Sr/U=1, produced the stoichiometric β-$SrUO_4$, which had an orthorhombic structure. The reactions in vacuum and in hydrogen yielded the products of the composition $SrUO_{3.563}$ and $SrUO_{3.175}$, respectively. On the other hand, the reduction of β-$SrUO_4$ in vacuum and in hydrogen gave $SrUO_{3.48}$ and $SrUO_{3.65}$, respectively. Stoichiometric $SrUO_3$ was prepared by the reaction of SrO with UO_2. The reduction product of β-$SrUO_4$, $SrUO_{4-x}$, was oxidized in air below 500 °C to α-$SrUO_4$ which was rhombohedral. During the phase transition to β-$SrUO_4$, α-$SrUO_4$ exhibited anomalous behavior; that is, α-$SrUO_4$ was first reduced and then reoxidized to nearly the initial composition with the formation of β-$SrUO_4$. Of the uranates with $Sr/U \neq 1$, the formations of SrU_4O_{13}, SrU_2O_7, and Sr_2UO_5 were examined; the single phase SrU_2O_7 was not obtained. Thermograms for their reduction, followed by the oxidation of the resultants, suggest the existence of the compounds SrU_4O_{11} and $SrU_2O_{6.0-6.6}$. No uranates containing only U(IV) were obtained by hydrogen reduction of the uranates containing U(VI) formed in air at high temperatures.

It is widely known that so-called uranates[1] are formed by the reaction of uranium oxides with alkali or alkaline earth oxides, carbonates, nitrates, chlorides, *etc.* There have been many reports concerning the preparation, properties, and crystal structures of these uranates. However, the literature data on their composition and crystal structure often seem to be incomplete or conflicting. Interest in these uranates, which are possibly produced in the reactions of the matrix oxide with the alkali and alkaline earth metals as fission products in nuclear fuel, has given the stimulus to investigate systematically the compound systems.

Strontium uranates can be, according to Keller,[2] classified into the following three groups of compounds: $SrUO_3$,[3,4] Sr_2UO_4(?),[3] and Sr_3UO_5[5,6] in the system SrO–UO_2 containing uranium in tetravalent state; SrU_2O_6[5,7,8] in the system SrO–U_2O_5 containing U(V); and SrU_4O_{13},[6,9] SrU_2O_7(?),[5,6,10] $Sr_2U_3O_{11}$,[6] (α and β) $SrUO_4$,[6,9,11-17] Sr_2UO_5,[4,6,9,16-19] and Sr_3UO_6[3,6,15,20-22] in the system SrO–UO_3 containing U(VI). However, the physical and chemical properties as well as the phase relations of these strontium uranates have not been well investigated. In the present paper, we examine the formation, reactivity, and nonstoichiometry of the uranates; our interst was centered on the compounds with the Sr/U atom ratio around unity as determined by means of thermogravimetry.

Experimental

Materials. Strontium carbonate, $SrCO_3$, uranium dioxide, UO_2, and triuranium octoxide, U_3O_8, were used as starting materials. $SrCO_3$ was prepared by adding strontium nitrate aqueous solution into ammonium carbonate ammoniacal solution, similar to the procedure for producing the precipitated calcium carbonate.[23] U_3O_8 was prepared by heating ammonium diuranate in air at 900 °C for one day. UO_2 was obtained by reducing U_3O_8 at 1000 °C in a stream of hydrogen for 10 h.

Almost all reactions were performed with samples in the form of pressed pellets. The compounds of $SrCO_3$ and UO_2 or U_3O_8 were thoroughly mixed in an agate mortar and compacted at 3 ton/cm^2 into cylindrical pellets of 10 mm in diameter and of about 2 mm in thickness. The weight of each pellet was usually about 800 mg.

Apparatus and Procedures. The experimental apparatus for thermogravimetry was similar to that described in an earlier paper, where the equilibrium nitrogen pressure was measured in the UN–U_2N_3 system.[24] It consists of a Cahn RH-type automatic electrobalance, a Kanthal resistance furnace, a pressure measurement system, and vacuum pumps. The balance was adjusted so as to have a maximum weight change of 500 mg, and a sensitivity of 0.01 mg. A fused quartz crucible, 20 mm in height and 18 mm in outer diameter, was suspended from the balance, and then a quartz tube of 26 mm in inner diameter was connected to the vessel containing the balance. After being connected, the system was evacuated to 1×10^{-5} mmHg or below.

The temperature of the specimen was measured by means of a Pt/Pt+13%Rh thermocouple placed close to the crucible inside the reaction tube. Most of the experiments were made at the heating rate of 2 °C/min unless otherwise specified.

X-Ray Analysis. The samples were finely ground and loaded into capillaries, and then vacuum-sealed. The X-ray powder photographs were obtained with a Nerelco 114.6 mm camera using the nickel-filtered Cu$K\alpha$ radiation.

Results and Discussion

Reaction of $SrCO_3$ with U_3O_8 ($Sr/U=1$). Strontium monouranate, $SrUO_4$, is known to be dimorphic: one is rhombohedral[11] and the other is orthorhombic.[13,20] They are conventionally named α- and β-$SrUO_4$ respectively. The reaction of $SrCO_3$ with U_3O_8 in air, where the Sr/U atom ratio is unity, yielded yellow colored β-$SrUO_4$. The equiatomic mixture was heated in air from room temperature to 1100 °C, and then it was kept at 1100 °C for 3 h. A typical thermogravimetric curve is shown in Fig. 1, together with the results obtained in other atmospheres, and also with the decomposition curve of $SrCO_3$. The weight loss of $SrCO_3$ due to decomposition should be 29.1%, but in this figure it was normalized to the $SrCO_3+1/3U_3O_8$ mixture for the sake of convenience, where the value was to be 10.27%. This was attained at 1100 °C. As seen in the figure, the reaction of $SrCO_3$ with U_3O_8 in air began at 470 °C and then it proceeded stepwise. When the thermogravimetric curve of the reaction is compared with the decomposition curve of $SrCO_3$, it may be deduced that the first step is the reaction

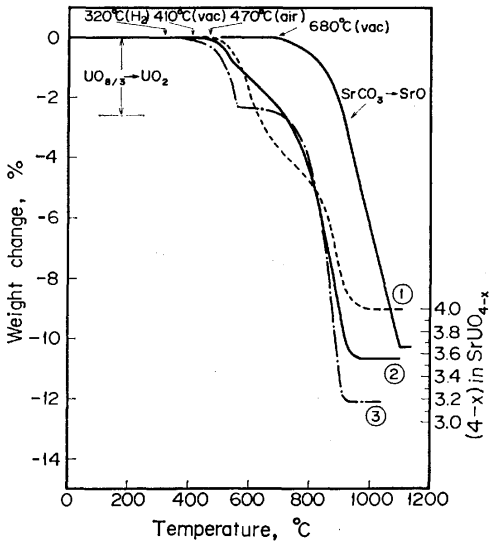

Fig. 1. Thermograms for the reaction of $SrCO_3$ with U_3O_8 in various atmospheres: ① in air; ② in vacuum; ③ in hydrogen; heating rate, 2 °C/min.

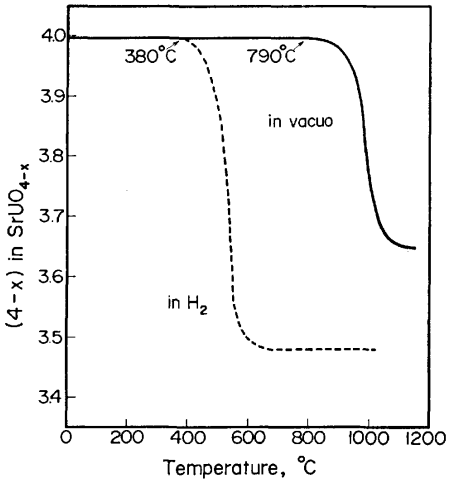

Fig. 2. Thermograms for reduction of β-$SrUO_4$ in vacuum and in hydrogen atmosphere: heating rate, 2 °C/min.

of $SrCO_3$ with U_3O_8, and that the second is the reaction of the decomposition product of $SrCO_3$ with U_3O_8. The X-ray pattern of the product was identical with that of the β-$SrUO_4$, which is orthorhombic and isomorphous with $BaUO_4$ with space group Pbcm, $z=4$.[13,17] The composition of the product was $SrUO_{3.997}$. Therefore, the overall weight change consists of weight loss due to the thermal decomposition of $SrCO_3$ plus weight gain due to oxidation in forming the uranate. The average valency of uranium in the compound is seen to increase from +5.33 to +5.99 during the reaction.

In vacuum, the reaction occurred at 410 °C and finished at about 950 °C. The composition of the product was $SrUO_{3.563}$ under the condition that the sample was heated to 1100 °C and then kept at that temperature for 1 h. Because the formal valency of uranium in this compound is +5.13, the U_3O_8 is regarded as losing a part of the combined oxygen. In a strict sense, the oxygen content varies as functions of oxygen pressure, temperature, and holding time; the number of oxygen atoms per formula can be changed in the range between 3.55 and 3.65 at 1100—900 °C in vacuum. According to X-ray analysis, the crystal was rhombohedral with space group $R\bar{3}m$, $z=1$, which is isomorphous with $CaUO_4$.[11] Although the structure of oxygen deficient $SrUO_{4-x}$ is basically the same as that of the α-$SrUO_4$, it has vacant O(II) sites due to nonstoichiometry.[25] The product was dark green.

In a hydrogen atmosphere, the reaction of $SrCO_3$ with U_3O_8 started at 320 °C. The reaction obviously proceeded stepwise, as seen in Fig. 1. The first is the reduction of U_3O_8 to UO_2 in the reaction mixture, because the same curve is obtained when U_3O_8 is reduced to UO_2 in hydrogen. The second step proceeds at temperatures above 700 °C, and probably corresponds to the reaction of $SrCO_3$ with UO_2. The overall composition of the product heated to 1000 °C was $SrUO_{3.175}$. The product was dark gray. No stoichiometric $SrUO_3$ was obtained by the reaction under the following conditions: maximum temperature, 1000 °C; holding time at 1000 °C, 1 h; atmosphere, hydrogen; and heating rate, 2 °C/min. The bulk composition of the products obtained under the conditions was $SrUO_{3.18-3.20}$.

The products, obtained by the reactions in vacuum or in hydrogen, gradually took up oxygen into the crystal even at room temperature when exposed to air, and the color changed from dark green or dark gray to red over 3 months. According to X-ray analysis, the red product was rhombohedral with nearly the same lattice parameters as those of the stoichiometric α-$SrUO_4$.[26]

Reaction of $SrCO_3$ with UO_2 ($Sr/U=1$). Behavior of the reaction in a vacuum was similar to that of the second step of the reaction of $SrCO_3$ with U_3O_8 in a hydrogen atmosphere. The reaction began at about 580 °C and finished at 950 °C. The composition of the product heated to 1100 °C was $SrUO_{3.21}$; the stoichiometric $SrUO_3$ was not obtained.

Reduction of β-$SrUO_4$. Thermograms of β-$SrUO_4$ heated in vacuum and in a hydrogen atmosphere are in Fig. 2. When the reaction was performed in a vacuum of 10^{-6} mmHg, the dissociation began at 790 °C and continued at a slow rate even at 1100 °C. The composition of the product kept at 1100 °C for 3 h was $SrUO_{3.65}$; its oxygen amount was slightly larger than that obtained by the reaction of $SrCO_3$ and U_3O_8 in vacuum, *i.e.* $SrUO_{3.56}$. As already mentioned, the oxygen content of the product is not only a function of temperature and of oxygen pressure, but tends to decrease with time at temperatures as high as 1100 °C. If the sample is heated for a longer time, the oxygen content must be smaller than that in $SrUO_{3.65}$. The equilibrium oxygen pressure over $SrUO_{4-x}$ at the given temperatures has not been measured.

The reduction in hydrogen began at 380 °C and finished at about 650 °C. The composition of the product heated to 1000 °C and kept at that temperature for 1 h was $SrUO_{3.48}$. Its oxygen content was much larger than that obtained by the reaction of $SrCO_3$ with U_3O_8 in hydrogen, *i.e.* $SrUO_{3.18}$. It was very dif-

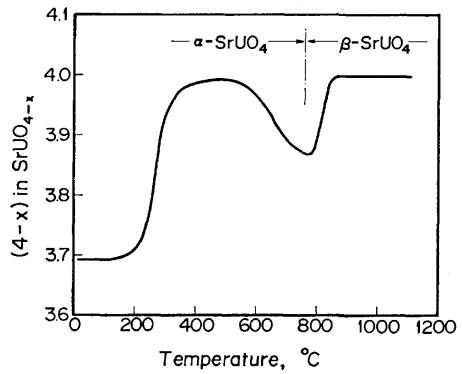

Fig. 3. Thermogram for oxidation of α-$SrUO_{4-x}$ in air: sample weight, 0.86476 g; heating rate, 2 °C/min.

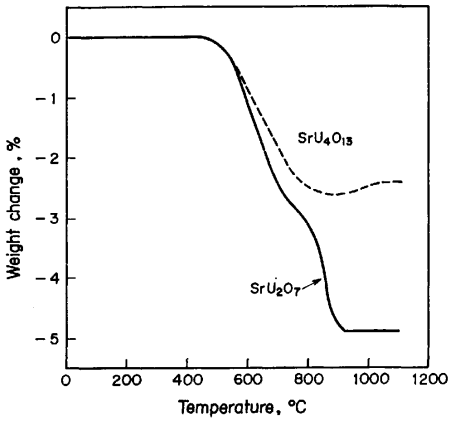

Fig. 4. Thermograms for formation of SrU_4O_{13} and SrU_2O_7 by the reaction of $SrCO_3$ with U_3O_8 in air at a heating rate of 2 °C/min.

ficult to get a lower oxygen content than that for $SrUO_{3.48}$, even if β-$SrUO_4$ was heated in a hydrogen atmosphere at 1000 °C for more than 3 h.

Preparation of $SrUO_3$. As already mentioned, the attempts to prepare $SrUO_3$ in a hydrogen atmosphere at temperatures below 1000 °C by the reaction of $SrCO_3$ with U_3O_8 and by the reduction of $SrUO_4$ were unsuccessful. Thus, as a next step, an equimolar mixture of SrO and UO_2 was heated in a vacuum at 1100 °C for 3 h. The product had the composition $SrUO_{3.04}$ and was yellowish-brown. When the compound was heated in air at a rate of 2 °C/min, it ignited at about 60 °C and changed into yellow β-$SrUO_4$, passing through a red-heated state for a short time of about 10 min.

In another experiment, an equimolar mixture of SrO and UO_2 was heated in a vacuum at 1650 °C for 5 h by using a tantalum-resistor high temperature vacuum furnace. For comparison, in one further experiment β-$SrUO_4$ was reduced in a hydrogen stream at 1500 °C for 3 h by using a high frequency-induced furnace. Both the products had the composition $SrUO_3$ and their X-ray diffraction lines were in the same pattern. However, these patterns were not consistent with the reported data, which have been assigned to the orthorhombic perovskite structure.[2] The structure analysis of $SrUO_{3.00}$ by X-ray and neutron diffraction will be reported elsewhere.

Oxidation of α-$SrUO_{4-x}$. The nonstoichiometric $SrUO_{4-x}$, which was prepared by the reaction of $SrCO_3$ with U_3O_8 or by the reduction of $SrUO_4$ in a vacuum or in hydrogen, had the rhombohedral structure. Here this uranate is designated as α-$SrUO_{4-x}$. Although the compound is oxidized at a very slow rate in air even at room temperature, the oxidation is accelerated by heating. Figure 3 shows a thermogram for the oxidation of α-$SrUO_{4-x}$ in air, where the initial composition of the sample is $SrUO_{3.688}$. As seen in Fig. 3, the α-$SrUO_{3.688}$ began to be oxidized at about 150 °C, and attained to its maximum oxygen content, $SrUO_{3.991}$, around 500 °C. This oxidation process is not reversible. Above 500 °C the compound with the composition $SrUO_{3.991}$ began to lose its oxygen. The weight loss continued till 770 °C, at which the minimum oxygen content, $SrUO_{3.867}$, was observed. The compound was still in the α phase region, and if it was cooled from 770 °C, the oxygen content again increased on the same line with that of the heating process up to the maximum point at 500 °C, and the oxygen content remained unchanged on further cooling of the temperature. On the other hand, if the sample was heated above the temperature giving the minimum oxygen content, the α phase transformed into the β phase, along with oxidation. The transition was finished at 870 °C. The product was a mixture of α-$SrUO_4$ and β-$SrUO_4$ at temperatures between 770 and 870 °C. The oxidation process in this region was not reversible.

The temperature and the composition at the minimum point varied with oxygen pressure and heating rate. When α-$SrUO_{4-x}$ was heated in oxygen at different pressures, the composition and the transition temperature were as follows: $SrUO_{3.867}$ at 770 °C in air (160 mmHg O_2), $SrUO_{3.839}$ at 790 °C in 50 mmHg O_2, and $SrUO_{3.805}$ at 800 °C in 10 mmHg O_2.[26] When the heating rate of the sample was varied from 2 to 5 °C/min, the composition at the minimum point in air was changed from $SrUO_{3.867}$ at 770 °C to $SrUO_{3.838}$ at 800 °C.

The weight loss of α-$SrUO_4$ at temperatures from 500 to 770 °C in air is due to oxygen nonstoichiometry, because the weight loss is enhanced with temperature and also with decreasing oxygen pressure. Therefore, the minimum point of oxygen content in Fig. 3 seems to have resulted from the competitive reactions between the weight loss due to the reduction of the α-$SrUO_4$ and the weight gain due to the formation of the β-$SrUO_4$.

Formation of Strontium Uranates with $Sr/U<1$. Strontium uranates SrU_4O_{13} and SrU_2O_7 were prepared by the reactions between $SrCO_3$ and U_3O_8 in air. Figure 4 shows thermograms for the formation of these compounds. The shape of the curves for the formation of SrU_4O_{13} is different from that for SrU_2O_7. In the case of SrU_4O_{13}, the minimum oxygen content appeared at about 900 °C. The shape of the curve and the initiation temperature of the reaction for SrU_2O_7 were similar to those obtained by the reaction of the equiatomic mixture of $SrCO_3$ and U_3O_8. The reactions proceeded stepwise. The compositions of the products were $SrU_4O_{12.741}$ for Sr : U=1 : 4 and $SrU_2O_{6.933}$ for Sr : U=1 : 2. They were not in the stoichiometric compositions.

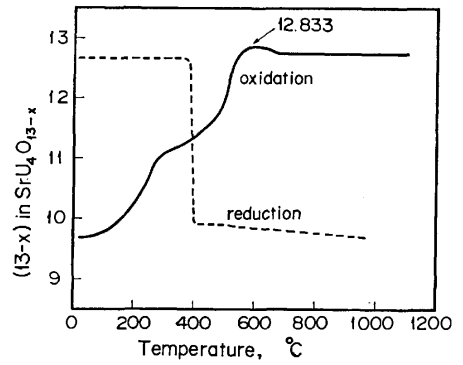

Fig. 5. Thermograms for reduction of SrU_4O_{13} in hydrogen and for oxidation of the resultant uranate in air at a heating rate of 2 °C/min.

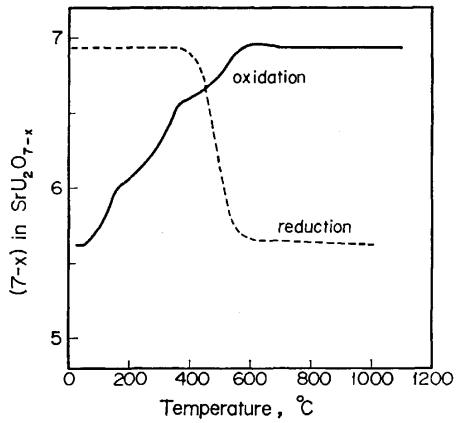

Fig. 6. Thermograms for reduction of SrU_2O_7 in hydrogen and for oxidation of the resultant uranate in air at a heating rate of 2 °C/min.

The SrU_4O_{13} obtained here was reduced in a hydrogen atmosphere by heating from room temperature to 1000 °C. The result is shown in Fig. 5. As seen in the figure, the composition was changed from $SrU_4O_{12.741}$ to $SrU_4O_{9.668}$ by reduction. The latter was found to be a mixture of UO_2 and α-$SrUO_{4-x}$. When the resultant product was oxidized in air to 1100 °C, the thermogram showed a bend near the composition SrU_4O_{11}. The existence of the compound SrU_4O_{11} has not been reported so far, and we did not examine further whether there was a compound or not at this composition. The compound SrU_4O_{13} has been prepared by using the reaction of $Sr(NO_3)_2$ with U_3O_8.[6] Cordfunke and Loopstra[6] have pointed out that it shows nonstoichiometry; $SrU_4O_{12.8}$. Our results were in good agreement with theirs.

Figure 6 shows thermograms of the reduction of the compound with Sr : U=1 : 2, followed by the oxidation of the product obtained in the reduction process. The compound obtained in air showed a nearly stoichiometric bulk composition $SrU_2O_{6.933}$, but it was seen not to be a single phase compound from the X-ray pattern, as Cordfunke and Loopstra[6] stated. When heated in a hydrogen atmosphere, it was reduced to $SrU_2O_{5.572}$. Next, the resultant product was oxidized by heating in air. As shown in the thermogram in Fig. 6, the curve bends near the compositions of $SrU_2O_{6.0}$ and $SrU_2O_{6.6}$.

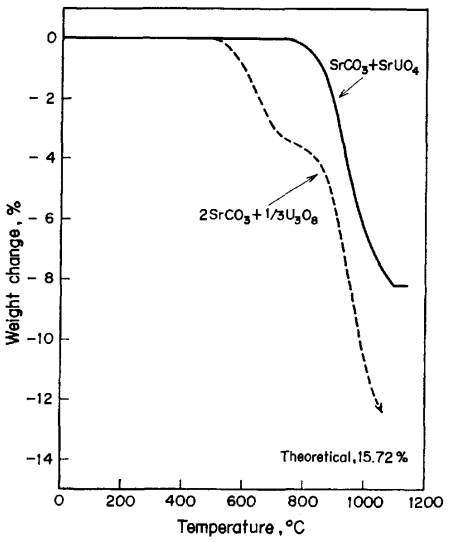

Fig. 7. Thermograms for formation of Sr_2UO_5 by the reaction of $SrCO_3$ with U_3O_8 and by the reaction of $SrCO_3$ with $SrUO_4$ in air at a heating rate of 2 °C/min.

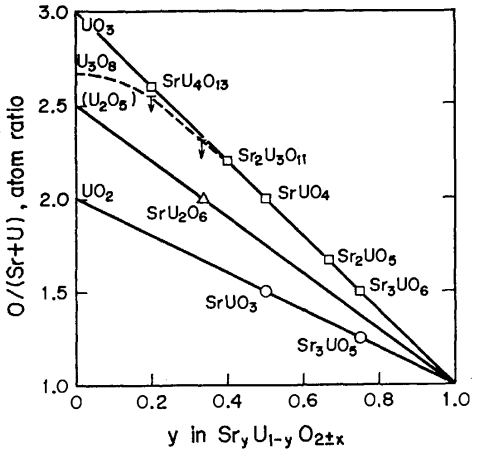

Fig. 8. Summary for compounds in the system Sr–U–O.

According to Hoekstra and Katz,[5] there exists a nonstoichiometric compound $SrU_2O_{6\pm x}$ with CaF_2-type f.c.c. structure. The anomalies in our curve may be interpreted to correlate with the lower and the upper limits of this nonstoichiometric $SrU_2O_{6\pm x}$.

Formation of Sr_2UO_5. For preparing the compound Sr_2UO_5, the reaction of $SrCO_3$ with U_3O_8 was first examined. A thermogram for this reaction is shown in Fig. 7. The shape of the curve was similar to that observed in the formation reaction of the other uranates mentioned above, for example $SrUO_4$. The theoretical weight loss of this reaction was 15.72%, but the reaction did not finish when the sample was heated to 1060 °C and kept at that temperature for 3 h. Next, the reaction of $SrCO_3$ with $SrUO_4$ was studied as a way to obtain Sr_2UO_5. Its thermogram is also shown in Fig. 7. The reaction started at about 750 °C and finished at 1100 °C. The product was the stoichiometric Sr_2UO_5, which was pale yellow. To prepare Sr_3UO_6, a mixture of $SrCO_3$ with $SrUO_4$ was heated under the same conditions as in the formation of Sr_2UO_5, but the

reaction did not terminate. It seems that the chemical reactivity in the formation reaction of the uranates tends to be lowered as the content of strontium increases.

Reduction of Sr_2UO_5 by hydrogen at 1000 °C did not yield Sr_2UO_4, but the product with the composition of $Sr_2UO_{4.618}$. When heated in air, the reduction product was again oxidized in a manner similar to the case where the α-$SrUO_{4-x}$ was oxidized in air. From the curve, it could not be distinguished whether the reduction product is a new compound or a mixture containing α-$SrUO_{4-x}$.

Summary for Strontium Uranates. All of the strontium uranates are shown in Fig. 8. In the system SrO–UO_3, five uranates are known. The valence state of uranium in the uranates formed in air is nearly or exactly +6. This value is higher than +5.33 of uranium in U_3O_8, which is the most stable compound in the uranium–oxygen system in air. However, the compound SrU_4O_{13} is not stoichiometric, the valence state of uranium being +5.87. The dashed line in Fig. 8 shows the bulk composition when a mixture of $SrCO_3$ and U_3O_8 is heated in air. In the system SrO–U_2O_5, there is only one compound SrU_2O_6 which shows a rather wide range of oxygen nonstoichiometry. Although it was reported that the uranate has the homogeneity range between 5.95 and 6.4 in the number of oxygen atoms per formula,[5] there is another report in which the SrU_2O_6 is described to be a mixture of CaF_2-type f.c.c. uranate, $Sr_yU_{1-y}O_{2\pm x}$, and a solid solution containing β-$SrUO_4$.[10] Our results show that the nonstoichiometry range is 6.0 to 6.6 in air. In the system SrO–UO_2, two uranates are known. When reduced in hydrogen at 1000 °C, U_3O_8 is readily converted into the stoichiometric UO_2. However, strontium uranates containing U(VI) are not reduced to the uranates containing U(IV) under the same condition; *i.e.* $SrU_4O_{9.69}$ for SrU_4O_{13}, $SrU_2O_{5.57}$ for SrU_2O_7, and $SrUO_{3.48}$ for $SrUO_4$. In addition to this, when exposed to air at room temperature, these uranates, which are prepared by vacuum or hydrogen reduction, are gradually oxidized by accommodating oxygen into the crystal, whereas UO_2 is scarcely oxidized. The uranates containing U(IV) can be produced only by the reactions of SrO with UO_2.

The Liquid-Phase Oxidation of Aldehydes with Metal Tetra(*p*-tolyl)porphyrins

Yasukazu OHKATSU and Tetsuo OSA

Department of Synthetic Chemistry, Faculty of Engineering, University of Tokyo, Bunkyo-ku, Tokyo 113

(Received October 1, 1975)

The effects of the kind of metal of metal porphyrins and the substituent of the phenyl group of porphynato plane were discussed, using them as catalysts in the autoxidation of aldehydes. The effect of the solvent and the additive on the above-mentioned catalytic activity of the porphyrins was put into order by means of their $pK_a(BH^+)$ and $pK_a(H^+)$ values; the increased $pK_a(BH^+)$, namely, the electron-donating power of solvents, seemed to lead to their strong coordination, followed by the initiation of the coordination of oxygen. On the other hand, the oxygen which had been activated on the porphyrins was estimated to react with or be stabilized by a solvent with a low $pK_a(H^+)$; it could not initiate the autoxidation with ease.

The interaction of molecular oxygen with hemoproteins is important in respiratory and metabolic processes. Many investigators have studied this interaction using a metal porphyrin as a model of such hemoproteins as hemoglobin and myoglobin. It has been one of their most important aims to ioslate a so-called dioxygen complex, such as the "picket fence porphyrin" obtained by Collman *et al.*[1] On the other hand, there have been reported[2,3] a number of studies of Fe(II) dioxygen complexes in terms of the effect of the environmental conditions of dioxygen complexes on their stability or instability—the concept of axial bases and hydrophobic circumstances.

Welscher and Anderson[4] reported the *trans* effect of axial bases on the dissociation of Fe(TPP)(base)(O_2), namely, the reversible liberation of the oxygen of the dioxygen complex, to be in the order of pyridine> piperidine≫ 1-methylimidazole, and concluded that π-donating ability of an axial base was responsible for the instability of the dioxygen complex. Bringer, Chang, and Traylor[5] showed the effect of the basicity of the media on the oxygenation of porphyrin.

The above-mentioned papers, however, offer no detailed information about whether axial bases help the stabilization of the oxygen of the dioxygen complex, or whether they act as activating agents of such an oxygen molecule for a substrate approaching from the outside. We have tried to make it clear, in the autoxidation of organic compounds, how oxygen molecule behaves on complexes such as metal polyphthalocyanines and cobalt tetra(*p*-tolyl)porphyrin in its interaction with cumene,[6] and aldehydes[7–10] as proton donors. In these studies, it has been found that the interactions among all chemical species including an oxygen molecule, a substrate to be oxidized, and a solvent are of importance.[10] However, there remain a few points to be clarified, because Taft's equation, which is considered in these experiments to show, only incompletely, the direct correlation with the electron-donating and electron-accepting natures of chemical species, has been used in the measurements.

In this paper, the interactions among all of chemical species are more distinctly discussed using the acidity and basicity of the chemical species in place of the σ^* and ρ^* values of Taft's equation. It is also discussed how the concentrations of chemical species are important in addition to their electron-donating and electron-accepting properties.

Experimental

Materials. Metal tetra(*p*-substituted phenyl)porphyrins used for this study were metal tetra-(*p*-methoxyphenyl)-, -(*p*-tolyl)-, -phenyl-, and -(*p*-chlorophenyl)-porphyrins, which were prepared according to the procedure described in an earlier paper.[11] As metals, nickel, copper, manganese, and cobalt were introduced.[12]

Aldehydes, such as acetaldehyde and benzaldehyde, were purified under nitrogen by the conventional methods just before use in order to avoid the formation of the corresponding peracids.

Solvents, such as ethyl acetate and ethyl isobutyrate, and additives as a part of the solvents, such as pyridine, *N,N*-dimethylformamide, water, acetone, ethanol, trichloroethanol, nitroethane, succinic acid, benzoic acid, trichloroacetic acid, benzamide, urea, quinoline, benzylamine, piperidine, and acridine, were purified by standard methods.

Procedure. The oxidation of aldehydes with a porphyrin complex catalyst and the titration of peracids and hydrogen peroxide were carried out as has been described in a previous paper.[10]

Results and Discussion

General Aspect of Oxidation. The liquid-phase oxidation of aldehyde with a porphyrin complex catalyst proceeds according to the autoxidation mechanism represented by the rate equation,

$$-d[O_2]/dt = k[RCHO]^{3/2}[porphyrin]^{1/2}[O_2]^{1/2}, \quad (I)$$

as has been described before.[10] The rate of initiation can be written as

$$R_i = k'[RCHO][porphyrin][O_2]. \quad (II)$$

According to the ESR study by many investigators[13,14] and by us,[15] porphyrins can activate molecular oxygen as superoxide ions, which abstract hydrogen atom from a substrate to be oxidized, initiating autoxidation as follows:[16,17]

$$Co(II)TPP + O_2 \rightleftharpoons Co(III)TPP\cdots O_2^-, \quad (1)$$

$$Co(III)TPP\cdots O_2^- + RCHO \rightarrow Co(III)TPP\cdots O_2H^- + R\dot{C}O. \quad (2)*$$

The nature of the central metal of a porphyrin

* Step (2) may be followed by

$$Co(III)TPP\cdots O_2H^- \rightarrow Co(II)TPP + {}^{\cdot}O_2H, \quad (3)$$

$$RCHO + {}^{\cdot}O_2H \rightarrow R\dot{C}O + H_2O_2. \quad (4)$$

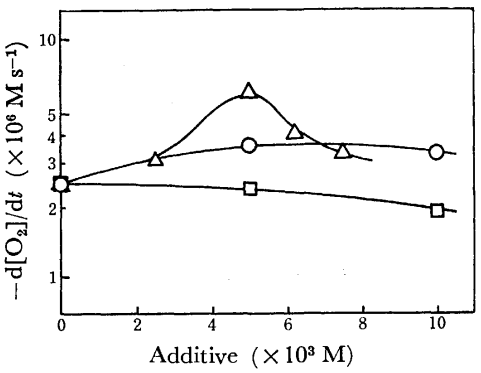

Fig. 2. Effective of some additives on oxidation rate. Reaction conditions: Co tetra(*p*-tolyl)porphyrin, 5.0×10^{-3} M; acetaldehyde, 0.5 M; solvent, ethyl acetate; temperature, 10 °C; (O_2), 1 atm.
△: Pyridine, ○: *N*,*N*-dimethylformamide, □: water.

affected its activity little, compared with the case of metal polyphthalocyanine (Table 1), but the substituents of the phenyl group in the porphynato plane had a considerable effect (Table 2); the effects of substituents on the rate of oxidation were in the order of $CH_3 \gg CH_3O > H > Cl$. This order, though it cannot be easily explained by only the electron-donating and electron-attracting properties of the substituent, coincides with that of the influence of chemical substituents on the catalytic activity for oxidative dehydrogenation, as studied for tetra(*p*-substituted phenyl)porphyrins by Manassen (see Column 3 in Table 2).[18]

A metal porphyrin had little activity to decompose a peracetic acid as one of oxidation products and produced the peracid quantitatively, as is in the case of a metal polyphthalocyanine (Fig. 1). Hydrogen peroxide was also considerably stable in the presence of the porphyrin at 10 °C. This result suggests that the formation of free radicals by the redox decomposition of peracid with a metal porphyrin, if any, is less important as an initiation reaction in this oxidation.

The addition of a small amount of pyridine, *N*,*N*-dimethylformamide, or water to a main solvent such as ethyl acetate used in the reaction system affected the activity of the catalyst, as is observed in the case of a metal polyphthalocyanine (Fig. 2). Water did not affect, or was apt to decrease the oxidation rate upon addition, whereas pyridine or *N*,*N*-dimethylformamide gave the maximum rate when the catalytic amount was added. A small addition of such an electron-donating additive is likely to increase the catalytic activity, which depends on the characteristic donating power of the additive. The effect of additives was of the order of pyridine > *N*,*N*-dimethylformamide > water.

The increase in the catalytic activity of a metal porphyrin can be well explained by the coordination of an additive to the metal, resulting in the activation of oxygen molecule at the trans-position, as has been reported with respect to a metal polyphthalocyanine.[6] The decrease upon the addition of more than a catalytic amount of the additive, on the contrary, may be ascribed to the occupation of both axial positions by the additive. The effect of the additive on the decrease mentioned

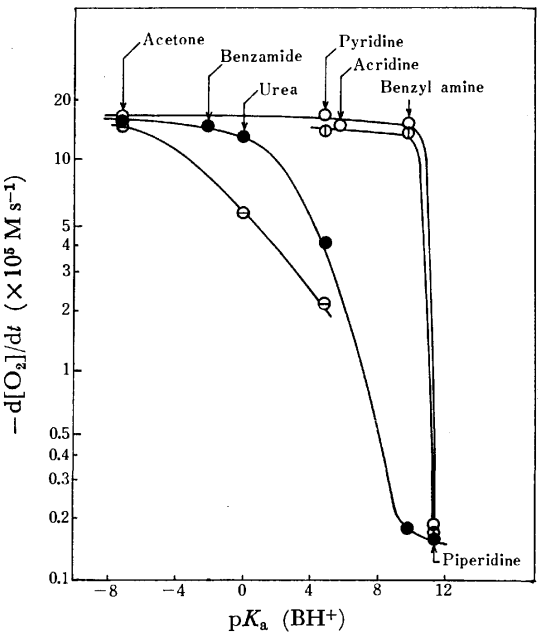

Fig. 3. Effect of pK_a(BH$^+$) of basic additive on oxidation rate. Reaction conditions: Co tetra(*p*-tolyl)porphyrin, 2.5×10^{-3} M; benzaldehyde, 0.4 M; solvent, ethyl isobutyrate; temp, 10 °C; (O_2), 1 atm; additive ○: 2.5×10^{-3} M, ⊕: 6.0×10^{-3} M, ●: 2.5×10^{-2} M, ⊖: 4.0×10^{-2} M.

Reaction conditions: Cobalt tetra(*p*-tolyl)-porphyrin, 2.5×10^{-3} M; benzaldehyde, 0.4 M; solvent ethyl isobutyrate; temperature, 10 °C; (O_2), 1 atm; additive, ●: acetone (pK_a(BH$^+$)$=-7.2$), ○: quinoline (4.83), △: pyridine (5.21), ▲: acridine (5.50), □: benzylamine (9.33), ■: piperidine (11.12).

above will be discussed in the next paragraph.

Effect of Additives. *Effect of Bases*: An additive with an elctron-donating or electron-accepting ability was added to the oxidation system consisting of cobalt tetra(*p*-tolyl)porphyrin as a catalyst, benzaldehyde, and oxygen, with ethyl isobutyrate as the main solvent. Figure 3 shows the relation of the pK_a(BH$^+$) of an additive as a conjugated acid to the oxidation rate under same concentrations of acetaldehyde and a catalyst, and oxygen pressure. The additive with a higher pK_a(BH$^+$) value—that is, a stronger electron-donating ability, suppressed the oxidation by preventing the oxygen from coordinating, depending on the amount present. Based on the mole of the catalyst, the catalytic and 2.4 times as much of the additive gave the point of the abrupt suppression of the rate near pK_a(BH$^+$)$=10$; 10 times, near pK_a(BH$^+$)$=-2$, and 160 times, pK_a(BH$^+$)$=-8$. In addition, it is very surprising that a small change in the pK_a(BH$^+$) values near 10 brought about a sudden decrease in the oxidation rate, even in the presence of a catalytic amount of the additive.

The effect of the additive concentration on the rate is illustrated in Fig. 4. The pK_a(BH$^+$) of the oxygen molecule is not known. However, it is considered to be under about 5, because the pK_a(BH$^+$) of the superoxide ion has been reported as 4.8.[19] Acetone with a pK_a(BH$^+$) of -7.2 did not affect the rate even if it was present in an amount 100 times that of the moles of the catalyst. The additive of a relatively high pK_a(BH$^+$), such as quinoline (4.83), pyridine (5.21), or acridine (5.50), reduced the rate gradually when the concentration went over a certain amount. However, an additive such as benzylamine of pK_a(BH$^+$)$=$ 9.33 lowered the oxidation rate abruptly, and piperidine (11.12) inhibited the oxidation almost completely even if there was only a little more than the catalytic amount. In other words, as the pK_a(BH$^+$) of the additive became higher, the degree of competitive coordination between an additive and the molecular oxygen increased. In the case of piperidine, almost all substances added seem to occupy the coordination sites of the catalyst because of its high pK_a(BH$^+$) value.

The competitive reaction can be successfully explained by the above-mentioned results and discussion. However, a minor effect, namely, the steric effect of an additive, may be observed. On quinoline, pyridine, and acridine, the respective pK_a's are 4.81, 5.21, and 5.50. These additives, accordingly, would lead to the lowering of the oxidation rate in the order of: quinoline $>$ pyridine $>$ acridine when present in inhibitive amounts. However, the experimental order was reversed in quinoline and pyridine. This may be due to the difference in steric bulkiness on gaining access to the central metal of catalyst: quinoline$>$pyridine.

Effect of Acids. For the start of oxidation, it is essential for the substrate to be oxidized to approach and react with the activated oxygen. The ease of approach will be discussed using the electron-attracting, namely, the proton-giving, property of the chemical species in the reaction system, such as an aldehyde, a solvent, and an additive. Such a point of view with respect to aldehydes has been previously reported.[12] The role of the last additive is shown in Fig. 5. The figure shows that a decrease in the oxidation rate was observed below pK_a(H$^+$) of 4 on the addition of a proton-donating substrate corresponding to the amount of a catalyst, below pK_a(H$^+$)$=6$ on the addition of 10 times the amount, and below pK_a(H$^+$)$=10$ on the addition of 100 times the amount. It is also well known in the field of electrochemistry that the superoxide ion, which is fairly stable under an alkaline condition,

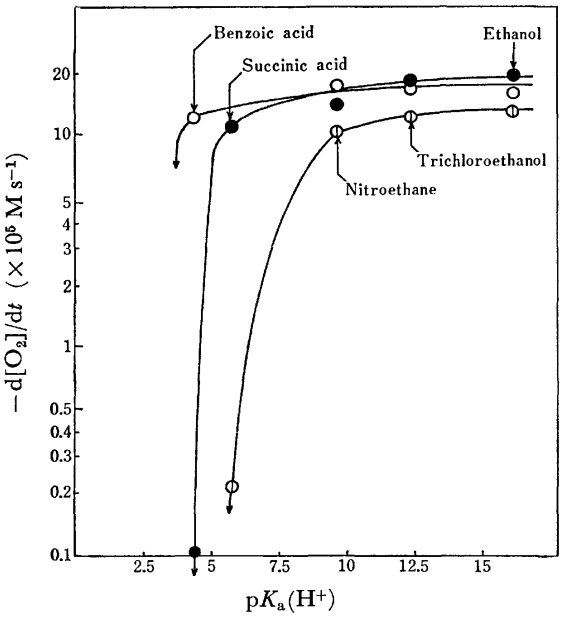

Fig. 5. Effect of $pK_a(H^+)$ of protic additive on oxidation rate. Reaction conditions: Co tetra(*p*-tolyl)-porphyrin, 2.5×10^{-3} M; benzaldehyde, 0.4 M; solvent, ethyl isobutyrate; temp, 10 °C; (O_2), 1 atm; additive, ○ 2.5×10^{-3} M, ● 2.5×10^{-2} M, ⓘ 2.5×10^{-1} M. Arrow (↓) means no absorption of oxygen in trichloroacetic acid ($pK_a(H^+)=0.65$).

reacts easily with a proton-giving substrate thus:

$$O_2 + e + H^+ \rightarrow HO_2^{\cdot}, \quad (5)$$

$$HO_2^{\cdot} + e + H^+ \rightarrow H_2O_2. \quad (6)^{20)}$$

These facts imply that the oxygen activated on porphyrin is deactivated by a protic substrate. If its acidity is stronger than that of benzaldehyde, it obstructs the hydrogen abstraction of benzaldehyde and converts the activated oxygen into the other form which interacts with the aldehyde only with difficulty.

This may be explained by plotting the oxidation rate against the amount of an additive added (Fig. 6). In the presence of ethanol ($pK_a(H^+)=15.9$) or trichloroethanol ($pK_a(H^+)=12.24$), the oxidation rate begins to be suppressed only after the addition of approximately the same amount of the additive as benzaldehyde. This means that the solvent with a $pK_a(H^+)$ over about 12 has no power to compete with benzaldehyde in approaching to the activated oxygen because of its lower electrophilic property: the $pK_a(H^+)$ of aldehyde is from about 10 to about 13.5; that of formaldehyde, 13.29, and that of chloralaldehyde, 10.93. On the other hand, benzoic acid ($pK_a(H^+)=4.20$) inhibited the oxidation considerably even if only 2.5×10^{-2} M was present, corresponding to 10 times the catalytic amount. Trichloroacetic acid ($pK_a(H^+)=0.65$) prevented the oxidation almost completely in the presence of the catalytic amount.

These experimental facts coincide well with the curve of oxygen absorption (Fig. 1). The oxidation of acetaldehyde and benzaldehyde produces acetic and benzoic acids respectively as follows:

$$RCOOOH + RCHO \rightarrow 2RCOOH. \quad (7)$$

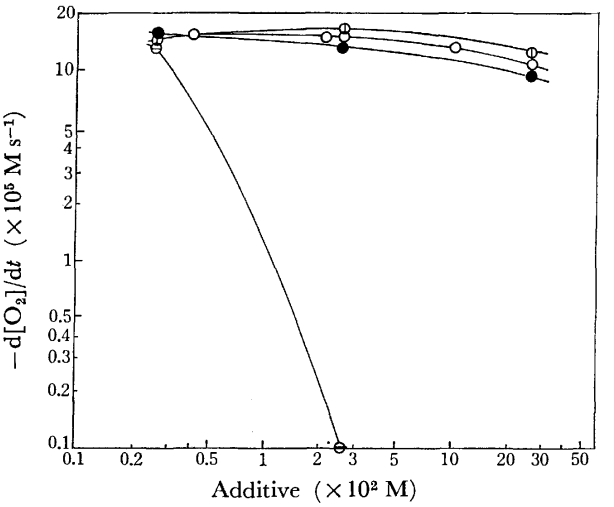

Fig. 6. Effect of the amount of protic additive on oxidation rate. Reaction conditions: Cobalt tetra(*p*-tolyl)-porphyrin, 2.5×10^{-3} M; benzaldehyde, 0.4 M; solvent ethyl isobutyrate; temperature, 10 °C; (O_2), 1 atm; additive, ⓘ: ethanol, ○: trichroloethane, ●: nitroethane, ○: benzoic acid.

These acids may deactivate the activated oxygen; the $pK_a(H^+)$ values of these acids are 4.76 and 4.20 respectively.**

Conclusion

As an additive included in a solvent has some parallel interaction with a porphyrin and its active intermediate, its pK_a plays an important role in the initiation reaction in terms of change of the rate. The concentration of the solvent relative to other chemical species is also important. These results and this dicussion can considerably clarify the questionable aspects proposed by other investigators.

F. A. Walkner, for example, studied the thermodynamics of the reaction of molecular oxygen with a cobalt porphyrin.[21] The thermodynamics data of the reaction,

$$CoP\cdot B + O_2 \rightleftarrows CoP\cdot B\cdot O_2, \quad (8)$$

in which B represents an axial base, probably corresponding to the activation of the oxygen molecule, were measured at −65 °C for bases such as pyridine, 4-picoline, 3,4-lutidine, 4-methylimidazole, and piperidine. He could not find any direct relationship between the pK_a of the coujugated acids of amines and the equilibrium constants of Scheme 8 or the ΔH of the formation of the Co–O bond. In this paper, moreover, there remain a few questions with respect to the following points: (A) The stabilization of coordinated oxygen by the base $CoP\cdot O_2\cdot B$ was not taken into account in the kinetical treatment of formation of oxygen complexes. This action of the amine cannot always be neglected, though; Pauling[22] and others[23,24] suggest that a more distinct imidazole from

** The sudden decrease in the oxidation rate after a certain amount of oxygen has been absorbed (Fig. 1) may be attributed to the formation of such an acid.

the histidine residue (E-7) projecting into the oxygen-binding pocket in the oxygen-carrying protein may somehow stabilize the coordinated dioxygen by hydrogen bonding. (B) The sample used in his experiments contained cobalt tetra(*p*-tolyl)porphyrin in a concentration of $(8-9)\times10^{-4}$ M and the above-mentioned amine in a concentration of $1\times10^{-2}-1\times10^{-1}$ M. In other words, the ratio of the amine to porphyrin was from about ten to one hundred. This ratio is considered to be in the range of concentration ratios in which some bases can stop the oxidation completely (see Fig. 4) and the formation of dioxygen complex may be suppressed, and in which only 0.8% of the cobalt would be in the form of the oxygen adduct under an atmosphere in the presence of 4-dimethylaminopyridine or *N*-methylimidazole as an axial base. The ratio seems to be too high for us to dicuss the formation of the oxygen complex kinetically. In autoxidation under such a ratio, a difference in the slopes of the straight parts of the graphs in relation with pK_a was observed, namely, the equilibrium constants, as shown in Figs. 4 and 6, and the straight parts sometimes crossed each other. A discussion based on the special ratio may, therefore, misunderstand the actual phenomena. The results reported by Stynes and Ibers[25] for the similar cobalt protoporphyrin IX dimethyl ester·B system, including pyridine, 4-butylpyridine, *N*-methylimidazole, and several others as axial bases, showed a direct relationship between the $pK_a(BH^+)$ of the base and the formation of the Co–O bond. The ratio of 2—3 which they used will be suitable for a discussion of the interaction of porphyrin with the oxygen molecule. (C) Though the steric hindrance of bases is probably small, it should also be considered.

We wish to express many thanks to Professor Teiji Tsuruta for giving us fruitful advice and discussion through this work.

The Kinetics and Mechanism of the Radical Addition of Hydrogensulfite Ions to 1-Dodecene in a Micellar Solution of Sodium 1-Dodecanesulfonate

Teijiro MIYATA, Akihisa SAKUMOTO, and Masamitsu WASHINO

Japan Atomic Energy Research Institute, Takasaki, Gunma 370-12

(Received September 16, 1976)

The addition reaction induced by Co-60 gamma-rays proceeded without any detectable induction period under homogeneous conditions in the presence of sodium 1-dodecanesulfonate. The consumption rate of 1-dodecene was equal to that of sodium hydrogensulfite and proportional to the square roots of the hydrogensulfite-ion and 1-dodecene concentrations. The *g*-value of 1-dodecene consumption was 860 at the concentrations of 0.260 mol/l of sodium hydrogensulfite, 0.0966 mol/l of 1-dodecene, and 0.11 mol/l of sodium 1-dodecanesulfonate at the dose rate of 2.70×10^{15} eV/g·s and the dose of 1.62×10^{18} eV/g. The apparent rate constant was 2.6×10^{-4} s^{-1} under these reaction conditions. The reaction of $CH_3(CH_2)_9\dot{C}HCH_2SO_3^-$ with the sulfite radical ion was proposed as the termination step of the reaction.

It is well known that the addition of hydrogensulfite ions to olefins initiated by oxidizing agents,[1-4] by ultraviolet light[5] or gamma irradiation[6] proceeds by a radical process, but the reaction is still not sufficiently understood. Investigations in this area have recently been stimulated by the interest in converting 1-alkenes with 8 to 18 carbon atoms into 1-alkanesulfonates, but to date no kinetic study has been made, probably because of the low solubilities of these olefins in water.

1-Alkanesulfonates with 8 to 18 carbon atoms have good surfactant properties.[7] Surfactants have been utilized extensively for the enhancement and the inhibition of industrially and biologically important radical processes.[8] Emulsion polymerization[9] is perhaps the prime example of this application of surfactants. Similarly, micellar amphiphiles affect the rate of the oxidation of dispersed or emulsified hydrocarbons,[10] aldehydes,[11] and unsaturated esters.[12] In the present study, some preliminary experiments showed that the addition reaction started at a significant rate and without any detectable induction period in the presence of sodium 1-dodecanesulfonate, though hardly no reaction occurred in its absence.

The present study was undertaken in order to throw some light on the kinetics and mechanism of the radiation-induced addition of hydrogensulfite ions to 1-dodecene in micellar solutions of sodium 1-dodecanesulfonate. In this study an aqueous *t*-butyl alcohol solution, which has been reported to be the most appropriate solvent for the similar photo-reaction,[5] was used as the solvent, and the reaction was carried out under homogeneous conditions.

Experimental

Materials. The sodium hydrogensulfite was of a guaranteed grade and was used without further purification. The 1-dodecene (97.8%) was distilled under a reduced pressure of nitrogen. The water and *t*-butyl alcohol were distilled. The sodium 1-dodecanesulfonate was prepared from sodium hydrogensulfite and 1-dodecene as follows. Sodium hydrogensulfite (0.25 mol/l), 1-dodecene (0.25 mol/l), water (200 ml), and *t*-butyl alcohol (200 ml) were added to a flask (1000 ml) fitted with a stirrer. The rapidly stirred mixture was irradiated with Co-60 gamma-rays (3.47×10^{15} eV/g·s) for about 2 h at room temperature and then neutralized with dilute hydrochloric acid. After the neutralization, the mixture was irradiated again for 1 h to complete the reaction. The irradiated mixture was then dried under reduced pressure overnight to give a white powder as the product. Neither sodium hydrogensulfite nor 1-dodecene was observed in the product.

Procedure and Irradiation. A reaction mixture was prepared by dissolving sodium hydrogensulfite, 1-dodecene, and sodium 1-dodecanesulfonate (0.11 mol/l) in a *t*-butyl alcohol–water (50 vol%) mixture. In order to keep the starting reaction mixture a single liquid phase, it is necessary that the initial concentrations of sodium hydrogensulfite and 1-dodecene be in the ranges of 0.04—0.30 mol/l and 0.03—0.20 mol/l respectively. The reaction mixture was placed in a glass tube (50 ml) and irradiated with Co-60 gamma-rays at room temperature after the tube had been deaerated under reduced pressure. The dose rate was determined by means of a Fricke dosimeter, taking $G(Fe^{3+})=15.6$. No correction was introduced (<1%) for the electronic density difference between the dosimetric solutions and those studied. The pH of the reaction mixture was measured before and after irradiation using a Tōa Denpa HM-5A pH meter; no significant differences in the pH values (about 4.1) were found.

Analytical Procedure. The determination of unreacted 1-dodecene was made on a gas chromatograph (Yanagimoto model G-80) equipped with a flame-ionization detector and a 1.5 m stainless steel column packed with 60—80 mesh Celite 545 and coated with 30% Silicone DC 550, where aqueous samples were directly injected into the gas chromatograph without pretreatment.

Unreacted sodium hydrogensulfite was determined by titration: after the oxidations of sulfite and hydrogensulfite ions into the sulfate ion with hydrogen peroxide, the sulfate ion was titrated with barium perchlorate using 4,5-dihydroxy-3,6-[(2-sulfo-4-methylphenyl)azo]-2,7-naphthalenedisulfonic acid, Na_2 salt (*m,m'*-dimethyl sulfonazo III[13]) as the indicator.

The product was identified as sodium 1-dodecanesulfonate by a comparison of its infrared spectrum [721, 798 (νC–S), 1063 (νS–O), 1175, 2855, 2924 cm^{-1} (νC–H)] with the spectra of the alkanesulfonates in the literature.[14] The spectrum was obtained by the use of an infrared spectrophotometer, Hitachi EPI-S_2, using a potassium bromide disk method.

Results and Discussion

Hydrogensulfite-ion Concentration. The hydrogensulfite-ion concentration in an aqueous solution is given by[15]

$$[HSO_3^-] = \left\{1+\left(\frac{[a_{H^+}]}{K_1}\right)\left(\frac{f_{HSO_3^-}}{f_{H_2SO_3}}\right)+\left(\frac{K_2}{[a_{H^+}]}\right)\left(\frac{f_{HSO_3^-}}{f_{SO_3^{2-}}}\right)\right\}^{-1}\cdot[NaHSO_3], \quad (1)$$

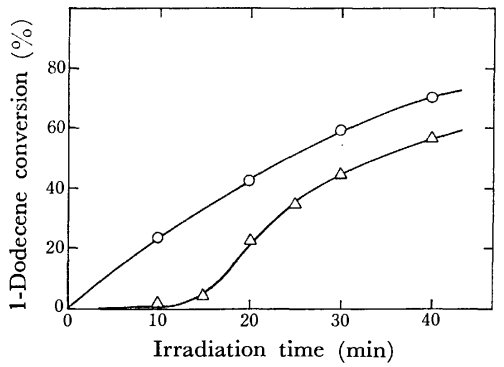

Fig. 1. The conversion of 1-dodecene as a function of irradiation time.
○—$NaHSO_3$: 0.260 mol/l, 1-dodecene: 0.0966 mol/l, $1\text{-}C_{12}H_{25}SO_3Na$: 0.11 mol/l, dose rate: 2.70×10^{15} eV/g·s. △—$NaHSO_3$: 0.46 mol/l, 1-dodecene: 0.47 mol/l, dose rate: 1.11×10^{16} eV/g·s.

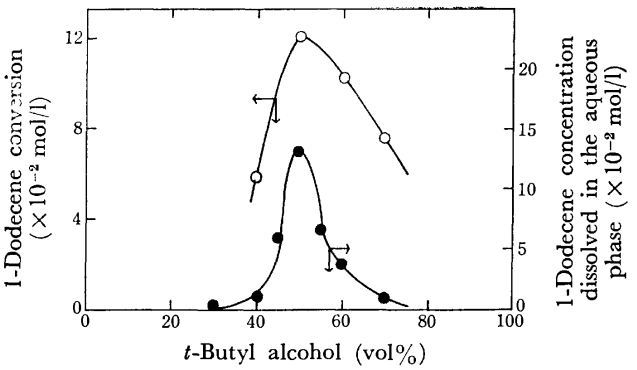

Fig. 2. The conversion of 1-dodecene and the concentration of 1-dodecene dissolved in the aqueous phase as a function of the content of *t*-butyl alcohol.
○—$NaHSO_3$: 0.458 mol/l, 1-dodecene: 0.214 mol/l, dose: 1.42×10^{17} eV/g at the dose rate of 2.37×10^{15} eV/g·s. ●—$NaHSO_3$: 0.229 mol/l, 1-dodecene: 0.225 mol/l, $1\text{-}C_{12}H_{25}SO_3Na$: 0.055 mol/l.

where K_1 and K_2 are the dissociation constants of H_2SO_3 and HSO_3^- respectively; $f_{H_2SO_3}$, $f_{HSO_3^-}$, and $f_{SO_3^{2-}}$, the activity coefficients of H_2SO_3, HSO_3^-, and SO_3^{2-} respectively; $[a_{H^+}]$, the activity of the hydrogen ion, and $[NaHSO_3]$, the concentration of the sodium hydrogensulfite initially dissolved in the solution.

The pH values of sodium hydrogensulfite solutions in water and in a *t*-butyl alcohol–water (50 vol%) mixture were roughly independent of the sodium hydrogensulfite concentration. The pH value observed in the *t*-butyl alcohol–water mixture was only about 0.2 pH-units higher[16] than that (about 3.9) in water. Therefore, the pa_{H^+}, $-\log[a_{H^+}]$, value in the mixture was roughly estimated to be equal to the pH value in water, by analogy with the pa_{H^+}-determination of succinate buffer solutions in alcohol–water mixtures.[17] Accordingly, $[a_{H^+}]$ in Eq. 1 is 1.3×10^{-4} mol/l. Since K_1 and K_2 are 1.54×10^{-2} and 1.02×10^{-7} [18] respectively at 18 °C, and since the activity coefficient ratios of $f_{HSO_3^-}/f_{H_2SO_3}$ and $f_{HSO_3^-}/f_{SO_3^{2-}}$ do not differ greatly from unity,[15,19] the substitution of these values into Eq. 1 gives,

$$[HSO_3^-] \approx [NaHSO_3].$$

Reaction in Micellar Solution. Alkanesulfonates with a straight-chain alkyl group of from 8 to 18 carbon atoms are usually capable of forming micelles and solubilizing olefins in aqueous solutions above their critical micelle concentrations.[20] The critical micelle concentration of sodium 1-dodecanesulfonate in an aqueous solution is 9.8×10^{-3} mol/l at 31 °C[21], and the addition of alcohols except methyl alcohol to the solution causes a decrease in the critical micelle concentration.[22–25] In the present work, 0.11 mol/l of sodium 1-dodecanesulfonate was added to the reaction solution so that the reaction might be carried out under homogeneous conditions. It follows, then, that the micelles must be formed in this solution. Accordingly, it may be noted that the solution, though it is seemingly a single liquid phase under the homogeneous conditions, comprises both a micellar phase and a bulk phase in the presence of the surfactant. In such a solution, it is necessary to consider that the rate of the addition reaction is subject to the influence of the solubilization of 1-dodecene by the micelles, since this olefin is hardly soluble in water.

Figure 1 shows two typical plots of the 1-dodecene conversion against the absorbed dose. The reaction began without any detectable induction period in the presence of the surfactant, while hardly no reaction occurred for up to 10 min in its absence. In this case, at the beginning of the reaction, the reaction solution was apparently homogeneous in the former case, while it comprised both an organic (olefin) phase and an aqueous (hydrogensulfite ion) phase in the latter case. The 1-dodecene concentration in the aqueous phase was only 0.014 mol/l, less than that in the former solution by a factor of about 10. Figure 2 shows the plots of the 1-dodecene conversion and of the 1-dodecene concentration in the aqueous phase as functions of the vol% of *t*-butyl alcohol under such heterogeneous conditions that this solution comprises both the organic and aqueous phases in the presence of 0.055 mol/l of sodium 1-dodecanesulfonate. The 1-dodecene concentration in the aqueous phase decreased with the decrease in the *t*-butyl alcohol content below 50 vol% of *t*-butyl alcohol. It follows, then, that the 1-dodecene concentration in the organic phase must increase with the decrease in the *t*-butyl alcohol content below 50 vol% of *t*-butyl alcohol. In addition, the organic-phase portion of the solution increased with the decrease in the *t*-butyl alcohol content. If the reaction takes place predominantly in the organic phase, the 1-dodecene conversion will increase with the decrease in the *t*-butyl alcohol content below 50 vol% of *t*-butyl alcohol. On the contrary, if the reaction takes place predominantly in the aqueous phase, the rate of 1-dodecene consumption will depend on the 1-dodecene concentration in the aqueous phase. As is evident from Fig. 2, the 1-dodecene conversion did not increase with the decrease in the *t*-butyl alcohol content below 50 vol% of *t*-butyl alcohol; rather a nearly close correlation was found between the 1-dodecene conversion and the 1-dodecene concentration in the aqueous phase. From the facts described above, it appears more likely that

TABLE 1. CONVERSIONS OF 1-DODECENE UNDER VARIOUS REACTION CONDITIONS

the reaction takes place predominantly in the aqueous phase in the presence of the surfactant.

1-Dodecene was hardly soluble in the aqueous phase in the absence of the surfactant. As can be seen in Fig. 2, however, the 1-dodecene concentration in the aqueous phase was 0.255 mol/l at 50 vol% of *t*-butyl alcohol in the presence of 0.055 mol/l of sodium 1-dodecanesulfonate. Since this surfactant can solubilize 1-dodecene in aqueous solutions above its critical micelle concentration, most of this olefin dissolved in the aqueous phase can be considered to be solubilized by the surfactant. Table 1 shows the 1-dodecene conversion at various surfactant concentrations under the homogeneous conditions. This conversion was independent of the surfactant concentration in the range studied. It can, therefore, be considered that most of the olefin is solubilized by the surfactant under the homogeneous conditions, because the distribution of the olefin between the micellar and the bulk phases, which is responsible for the alteration of the reaction rate, will vary with the surfactant concentration if the olefin is present in these two phases. From this result and from the experimental findings described above, it can be concluded that solubilized 1-dodecene predominantly takes part in the addition reaction in the presence of the surfactant.

Reaction Mechanism. The addition of the hydrogensulfite ion to 1-dodecene is known to proceed by a radical chain process involving the chain-carrying steps given by[1]

$$\dot{S}O_3^- + CH_3(CH_2)_9CH{=}CH_2 \rightarrow CH_3(CH_2)_9\dot{C}HCH_2SO_3^-, \quad (2)$$

$$CH_3(CH_2)_9\dot{C}HCH_2SO_3^- + HSO_3^- \rightarrow CH_3(CH_2)_9CH_2CH_2SO_3^- + \dot{S}O_3^-. \quad (3)$$

In general, the action of ionization radiation upon dilute solutions results in the degradation of the solvent.[26]

The degradation of water by radiation is expressed as[27]

$$H_2O \rightsquigarrow \cdot OH, \cdot H, e_{aq}^-, H_2, H_2O_2$$

and the radiolysis of *t*-butyl alcohol gives such species as $\cdot H$, $\dot{C}H_2(CH_3)_2COH$, and $e_{sol.}^-$.[28] Of these species, $\cdot H$, $\cdot OH$, and e_{aq}^- or e_{sol}^- react with the hydrogensulfite ion to give the sulfite radical ion.[29,30]

Figure 3 shows the plots of the 1-dodecene conversion as a function of the irradiation time at various dose rates and at various concentrations of the hydrogensulfite ion and of 1-dodecene. The reaction began without any detectable induction period under these reaction conditions. Table 2 shows that a 1 : 1 product is formed independently of the dose and the dose rate. Most of the product obtained was identified as sodium 1-dodecansulfonate.

The termination of the addition reaction may result mostly from processes such as the dimerization of the chain-carrying radicals given in Eqs. 2 and 3 or a coupling reaction of these radicals. If the dimerization of the sulfite radical ion takes place as the termination, the rate of 1-dodecene disappearance should be proportional to the 1-dodecene concentration, by analogy with kinetic analysis in general.[31] Similarly, if the dimerization of the alkanesulfonate radical takes place, the rate should be proportional to the hydrogensulfite ion concentration. On the other hand, if the alkanesulfonate radical couples with the sulfite radical ion to terminate the addition reaction, the rate should be proportional to the square roots of both the 1-dodecene

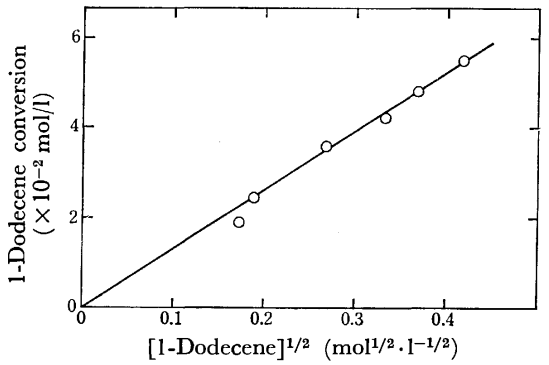

Fig. 4. The conversion of 1-dodecene as a function of the square root of the initial concentration of 1-dodecene.
$NaHSO_3$: 0.260 mol/l, 1-$C_{12}H_{25}SO_3Na$: 0.11 mol/l, dose: 2.43×10^{18} eV/g at the dose rate of 2.70×10^{15} eV/g·s.

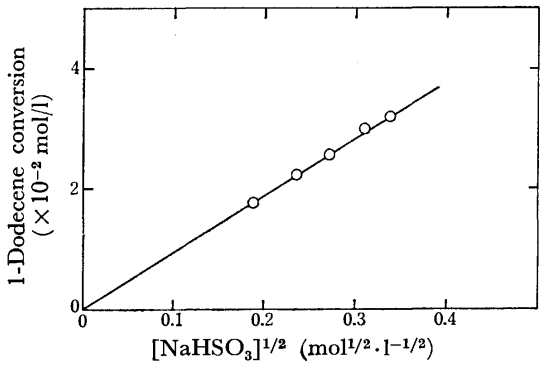

Fig. 5. The conversion of 1-dodecene as a function of the square root of the initial concentration of sodium hydrogensulfite.
1-Dodecene: 0.0902 mol/l, 1-$C_{12}H_{25}SO_3Na$: 0.11 mol/l, dose: 4.05×10^{18} eV/g at the dose rate of 2.70×10^{15} eV/g·s.

and hydrogensulfite ion concentrations. The conversion was independent of the surfactant concentration in the range studied, as can be seen in Table 1. Figures 4 and 5 show the plot of the 1-dodecene conversion against the square root of the initial 1-dodecene concentration, and that against the square root of the initial hydrogensulfite ion concentration, respectively. These results indicate that the rate of 1-dodecene disappearance is proportional to the square roots of both the 1-dodecene and hydrogensulfite ion concentrations. Consequently, the termination can be deduced to be the coupling reaction of the alkanesulfonate radical with the sulfite radical ion to give dodecanedisulfonate. In fact, substantial amounts of dodecanedisulfonate were identified in a similar radical-addition initiated by nitrate salts.[1)]

On the basis of the above experimental findings and the chain-carrying steps cited above, the basic reaction mechanism of the addition reaction may be deduced to be as follows:

$$\text{Solvent} \sim\!\!\sim\!\!\sim\!\!\rightarrow \text{A}, \tag{4}$$

$$\text{A} + HSO_3^- \longrightarrow \text{AH} + \dot{S}O_3^-, \tag{5}$$

$$\dot{S}O_3^- + CH_3(CH_2)_9CH{=}CH_2 \longrightarrow CH_3(CH_2)_9\dot{C}HCH_2SO_3^-, \tag{6}$$

$$CH_3(CH_2)_9\dot{C}HCH_2SO_3^- + HSO_3^- \longrightarrow CH_3(CH_2)_9CH_2CH_2SO_3^- + \dot{S}O_3^-, \tag{7}$$

$$CH_3(CH_2)_9\dot{C}HCH_2SO_3^- + \dot{S}O_3^- \longrightarrow CH_3(CH_2)_9CH(SO_3^-)CH_2SO_3^-, \tag{8}$$

where A represents the above-mentioned radiolytic species which participate in the initiation of the addition reaction.

Rate Equation. According to Eqs. 4 to 8, and assuming the usual steady-state approximation for each radical we obtain the over-all rate equation of the 1-dodecene consumption in the micellar solution as follows:

$$-\frac{d[RCH{=}CH_2]}{dt} = \frac{g_oI_o}{4}\left\{1+\left(1+\frac{8k_6k_7}{g_oI_ok_8}[RCH{=}CH_2][HSO_3^-]\right)^{1/2}\right\}, \tag{9}$$

where g_o is the number of A per absorbed dose of one eV; I_o, the dose rate (eV/g·s); k_6, k_7, and k_8, the rate constants of Eqs. 6, 7, and 8 in the micellar solution respectively, and $[RCH{=}CH_2]$, the 1-dodecene concentration.

From Fig. 1, the g-value (the number of molecules reacted per 100 eV of radiation energy absorbed) of 1-dodecene consumption was calculated to be 860 at the absorbed dose of 1.62×10^{18} eV/g (in irradiation time of 10 min) and at the concentrations of 0.0966 mol/l of 1-dodecene, 0.260 mol/l of sodium hydrogensulfite, and 0.11 mol/l of sodium 1-dodecanesulfonate. This g-value is very large compared to the primary yields of the active species produced from the radiolysis of water and organic compounds,[32,33)] so it may be assumed that, in Eq. 9, $8k_6k_7[RCH{=}CH_2][HSO_3^-]/g_oI_ok_8 \gg 1$. Consequently, Eq. 9 can be simplified to

$$-\frac{d[RCH{=}CH_2]}{dt} = k[RCH{=}CH_2]^{1/2}[HSO_3^-]^{1/2}, \tag{10}$$

where,

$$k = \left(\frac{g_oI_ok_6k_7}{2k_8}\right)^{1/2}. \tag{11}$$

The expression of Eq. 10 agrees well with the experimental findings shown in Figs. 4 and 5.

Since the conversion of 1-dodecene was equal to that of sodium hydrogensulfite, Eq. 10 becomes

$$\frac{dx}{dt} = k(a-x)^{1/2}(b-x)^{1/2}, \tag{12}$$

where x is a variable representing the decrease in the concentrations of the reactants in the given time and where a and b are the initial concentrations of 1-dodecene and the hydrogensulfite ion respectively. On integrating Eq. 12 with the boundary condition, $x=0$ at $t=0$, the apparent rate constant of the 1-dodecene consumption can be derived as

$$k = \frac{2}{t}\ln\left\{\frac{(a-x)^{1/2}-(b-x)^{1/2}}{a^{1/2}-b^{1/2}}\right\}. \tag{13}$$

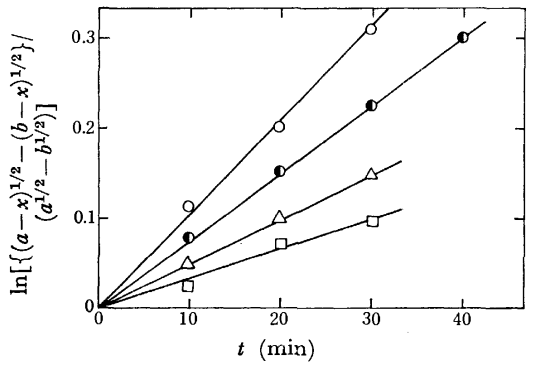

Fig. 6. Plots of $\ln[\{(a-x)^{1/2}-(b-x)^{1/2}\}/(a^{1/2}-b^{1/2})]$ against t.
○, ◐, △, □: See Fig. 4.

Apparent Rate Constant. According to Eq. 13, a plot of $\ln[\{(a-x)^{1/2}-(b-x)^{1/2}\}/(a^{1/2}-b^{1/2})]$ against the time, t, should be a straight line, passing through the point of origin, with a slope equal to $k/2$. As is shown in Fig. 6, a good straight line was obtained for each dose rate by using the same data as those given in Fig. 3. The apparent rate constants can be calculated from the slopes of these straight lines; they are summarized in Table 3, together with those calculated from the values given in Table 1.

Dose-rate Dependence of the Apparent Rate Constant. According to Eq. 11, a plot of the logarithm of k against the logarithm of I_0 should be a straight line with a slope of 0.5. The plot of the experimental data gave a straight line with a slope of 0.73, as is shown in Fig. 7. This value is somewhat different from 0.5. This difference may be attributable to the termination steps other than Eq. 8, a part of which is presumably the reactions of the alkanesulfonate radical with radicals from the irradiated solvent.

Surfactant Effects. Although the coupling reaction of the alkanesulfonate radical with the sulfite radical ion was proposed as the termination of the addition reaction, it is possible to postulate another coupling reaction, the dimerization of the alkanesulfonate radical, by analogy with radical reactions in general. According to the accepted model[34] for ionic micelles, the hydrophobic part of the aggregated surfactants forms the core of the micelles, which is liquid-paraffin-like in character, while the polar-head groups are located at the micelle-water interface in contact with, and hydrated by, a number of water molecules. The unpaired electron of the alkanesulfonate radical is assumed, on this basis, to be located at the micelle-water interface. On the contrary, the charged species, such as the sulfite, hydrogensulfite or sulfite radical ions, are generally in the bulk phase.[20] However, water molecules very probably penetrate beyond the polar-head groups at the micellar exterior.[35] Accordingly, it is assumed that solutes in the bulk phase may interact with the alkanesulfonate radical solubilized in the micelle, without penetrating into the nonpolar micellar core. Since there are a great number of micelles in the reaction solution, two or more alkanesulfonate radicals are scarcely ever produced in the micelle at the same time. Therefore, the rate of the dimerization of this radical may be very slow because there is electrostatic repulsion between the micelles. Consequently, the coupling reaction of the alkanesulfonate radical with the sulfite radical ion may be more predominant than the dimerization of the alkanesulfonate radical as the termination of the addition reaction.

The authors wish to thank Dr. Akira Mitsui for his valuable discussions.

The Synthesis of α-Aminonitriles Starting from the Corresponding Amino Acids. I. Use of *o*-Nitrophenylsulfenyl as an N-Protecting Group[1)]

Katsuhiro KAWASHIRO, Hideyuki YOSHIDA, and Shiro MORIMOTO

Department of Chemical Engineering, Faculty of Engineering, Tokushima University, Minamijosanjima, Tokushima 770

(Received October 25, 1976)

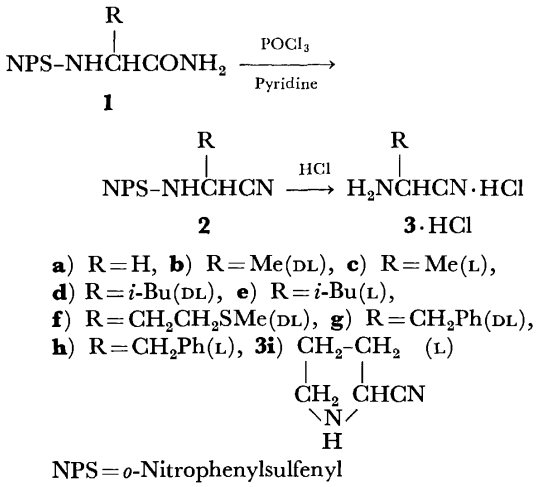
N-*o*-Nitrophenylsulfenylamino acid amides of glycine, alanine (DL and L), leucine (DL and L), methionine (DL), phenylalanine (DL and L), and proline (L) were dehydrated in $POCl_3$–pyridine. The N-protected α-aminonitriles obtained were treated with anhydrous HCl affording the corresponding α-aminonitrile hydrochlorides. The optical purity of the L-α-aminonitriles was well retained.

α-Aminonitriles can be synthesized by reactions of ammonium cyanide with carbonyl compounds, which is known as Zelinsky-Stadnikoff synthesis[2)] and which always yields racemic products. It may be more convenient to prepare α-aminonitriles from the corresponding amino acids on a laboratory scale. The purpose of this study is to obtain some racemic and enantiomerically pure α-aminonitriles from the corresponding amino acids, and also to establish a procedure applicable to the enantiomeric analysis of α-aminonitriles.

Several investigators[3–7)] have reported the preparation of N-protected α-aminonitriles by dehydrating the corresponding amino acid amides. They employed benzyloxycarbonyl, phthaloyl, or acetyl as an N-protecting group. These N-protecting groups have not been removed. Recently, Ojima *et al.*[8)] have reported the asymmetric synthesis of some α-aminonitriles *via* cyanosilylation of the Schiff bases.

Alanyl-α-aminopropiononitriles have been obtained as hydrochlorides by the dehydration of the corresponding *N*-*o*-nitrophenylsulfenyl(NPS)-dipeptide amides, followed by treatment with anhydrous HCl.[9)] The present paper is concerned with the preparation of α-aminonitriles, which includes the dehydration of NPS-amino acid amides and the subsequent removal of the N-protecting groups.

As model compounds, NPS derivatives[10)] of α-aminonitriles (aminoacetonitrile and DL-α-aminoglutaronitrile) were prepared. Their NPS groups were easily removed by treatment with anhydrous HCl, and ion-exchange chromatography of each α-aminonitrile obtained gave a single peak. On the basis of this work, the nine α-aminonitrile hydrochlorides were synthesized as shown in Scheme 1.



Scheme 1.

The methyl esters of NPS-glycine and alanine (DL and L) were easily converted into the corresponding amides (**1a—c**) by ammonolysis at room temperature for several days in methanol saturated with NH_3. The other NPS-amino acid amides (**1d—i**) were not obtained by ammonolysis of the corresponding NPS-amino acid methyl esters but were prepared by the reaction of the amino acid amides with *o*-nitrobenzensulfenyl chloride. The NPS-amino acid amides (**1a—i**) were dehydrated in cold $POCl_3$–pyridine according to the method of Liberek *et al.*[4)] to afford the corresponding nitriles (**2a—i**), among which the N-protected nitrile derivatives of glycine, alanine (DL and L), and DL-leucine (**2a—d**) were obtained as crystalline products and those of the other amino acids (**2e—i**) as oily products. When the NPS-α-aminonitriles (**2a—i**) dissolved in ethyl acetate or diethyl ether were treated with anhydrous HCl, the α-aminonitrile hydrochlorides (**3a—i**·HCl) shown in Table 1, were obtained. The yields of the products based on the corresponding NPS-amino acid amides (**1a—i**) were poor (10—40%). The IR spectra of the products had absorption bands at 2250—2260 cm^{-1} corresponding to the C≡N stretching vibration.

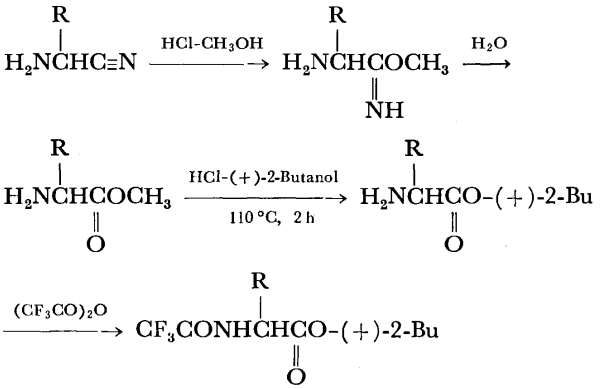
3b, **3c**	3.7 (4.6)	c)	0.55 (0.49)
3d, **3e**	4.0 (3.7)	d)	0.86 (0.69)
3f	2.5 (4.4)	d)	0.70 (0.63)
3g, **3h**	5.2 (6.9)[e]	d)	0.80 (0.63)
3i	1.8 (2.4)	d)	0.43 (0.53)

a) Values in parentheses are those of the corresponding amino acid amides. b) Carried out with Toyo filter paper No. 50 using a *n*-BuOH–AcOH–H_2O (4 : 1 : 2 v/v) solvent system. c) 0.25ϕ × 50 cm column. Thirty min after the elution began, the eluent was changed from a pH 3.25 buffer to a pH 5.28 buffer. d) 0.25ϕ × 15 cm column, eluent: pH 5.28 buffer. e) Eluent: pH 5.28 buffer-*t*-BuOH (8 : 2 v/v).

The results of ion-exchange chromatography of the α-aminonitriles (**3a—i**) are summarized in Table 2. Only the small peaks of NH_3 were observed in the chromatograms, in addition to the α-aminonitriles. These α-aminonitriles were eluted more rapidly than the corresponding amides with the exception of the α-aminoisocapronitriles (**3d** and **e**), which were not separated from leucine amide when a 0.25ϕ × 15 cm column and a pH 5.28 buffer were used. The chromatograms presented in Fig. 1 show that the chromatographic method is available for quantitative analysis of the α-aminonitriles. Aminoacetonitrile (**3a**) and DL-α-aminopropiononitrile (**3b**) were identified by comparing their retention times on the chromatograms with those of authentic samples. The results of paper chromatography of the α-aminonitriles (**3a—i**) are also summarized in Table 2. In this case, **3d** and **3e** were separated from the corresponding amides.

Configuration retention for the L-α-aminonitriles (**3c**, **e**, **h**, and **i**) was confirmed using a gas chromatographic method.[11] These compounds were transformed into the corresponding *N*-trifluoroacetyl(TFA)-amino acid (+)-2-butyl esters as shown in Scheme 2.



Scheme 2.

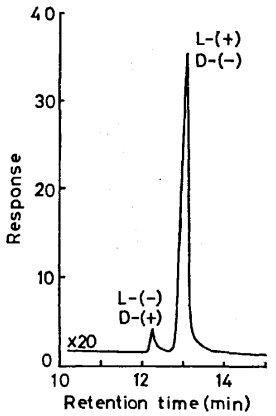


Fig. 2. Gas chromatogram of *N*-TFA-analine (+)-2-butyl ester derived from **3c**.

TABLE 3. A COMPARISON OF THE GAS CHROMATOGRAMS OF *N*-TFA-AMINO ACID (+)-2-BUTYL ESTERS DERIVED FROM BOTH L-AMINO ACIDS AND L-α-AMINONITRILES

Derivative	Retention time (min)		Fraction of peak height[c]	
	I[a]	II[b]	Derivative of L-amino acid	Derivative of L-α-aminonitrile
Ala	12.2	13.0	0.93	0.93 (**3c**)
Leu	21.8	22.8	0.93	0.93 (**3e**)
Phe	64.0	64.8	0.92	0.94 (**3h**)
Pro	44.4	45.2	0.94	0.93 (**3i**)

a) D-(+), L-(−) Diastereomer, b) L-(+), D-(−) Diasteromer. c) Peak height of II/sum of peak heights of I and II.

Each of the *N*-TFA-amino acid (+)-2-butyl esters was analyzed by gas chromatography on a capillary column coated with LB 550X. The *N*-TFA-L-amino acid (+)-2-butyl esters derived from L-amino acids (alanine, leucine, phenylalanine, and proline) were also analyzed. The chromatogram of the sample derived from **3c** is presented in Fig. 2. The sample from L-alanine also gave a similar chromatogram, which shows that the (+)-2-butanol[12] used in this work contains a small amount of the (−)-isomer. The gas chromatographic data are summarized in Table 3, which shows that the fraction of observed peak heights of the sample for each L-α-aminonitrile is approximately equal to that of the sample for the corresponding standard L-amino acid. These results indicate that the enantiomeric purity of the L-α-aminonitriles (**3c**, **e**, **h**, and **i**) is well retained and also that the procedure described in Scheme 2 is available for the enantiomeric analysis of α-aminonitriles.

The poor yields of **2a**—**d** may be due to the unfavorable elimination of the NPS group during the dehydration of the corresponding amides (**1a**—**d**) in $POCl_3$–pyridine. Although the overall yields of **3a**—**i** are also poor, the method described in Scheme 1 may be useful for preparing racemic and enantiomeric α-aminonitriles of as high a purity as possible.

Experimental

All the melting points were determined with a Yanagimoto micro-melting point apparatus and are uncorrected. IR spectra were taken with a Hitachi EPI-G2 spectrometer. The optical rotations were measured with a Yanaco OR-50 polarimeter. Ion-exchange chromatography was carried out with a Sibata amino acid analyzer, AA-600, under the following conditions: column size, $0.25\phi \times 50$ cm or $0.25\phi \times 15$ cm (Aminex A-4); eluent, citrate buffer of pH 3.25 (0.2 M Na) and pH 5.28 (0.35 M Na); flow rate, 6 ml/h; jacket temperature, 30 °C. Gas chromatography was carried out with a Hitachi gas chromatograph 063 provided with a flame ionization detector; column, 0.01ϕ in $\times$ 150 ft stainless steel capillary column coated with LB 550X (Perkin Elmer); temperature 100—170 °C, 1 °C/min; carrier gas He, 6 ml/min. Amino acid methyl ester hydrochlorides were prepared by the thionyl chloride method.[13] *o*-Nitrobenzenesulfenyl chloride was prepared from bis(*o*-nitrophenyl) disulfide and chlorine.[14] Amino acid amides were prepared according to the method of Yang and Rising.[15]

NPS-α-aminonitriles. The neutral sulfate of the α-aminonitrile (aminoacetonitrile or DL-α-aminoglutaronitrile) (0.04 mol) was dissolved in a mixture of 2 M aq NaOH (20 ml) and dioxane (25 ml). Into the solution, *o*-nitrobenzenesulfenyl chloride (0.04 mol) was added in small portions as 2 M aq NaOH (24 ml) were added dropwise, with vigorous stirring during a period of 20 min. The reaction mixture was filtered and diluted with water (400 ml). A yellow product precipitated out, which was recrystallized from ethyl acetate–petroleum ether.

NPS-aminoacetonitrile: Yield, 80%; mp 112—114 °C. Found: C, 46.12; H, 3.50; N, 20.09%. Calcd for $C_8H_7N_3O_2S$: C, 45.93; H, 3.37; N, 20.08%.

NPS-DL-α-aminoglutaronitrile: Yield, 73%; mp 100—102 °C. Found: C, 50.50; H, 3.70; N, 21.21%. Calcd for $C_{11}H_{10}N_4O_2S$: C, 50.37; H, 3.84; N, 21.36%.

Removal of the NPS from the Model NPS-α-aminonitriles. When 5 ml of diethyl ether including anhydrous HCl (3 M) was added to the solution of the NPS-α-aminonitrile (aminoacetonitrile or DL-α-aminoglutaronitrile) (5 mmol) in a minimum amount of ethyl acetate, the α-aminonitrile hydrochloride precipitated out. The precipitates collected were washed with diethyl ether and dried in a vacuum without further purification. The recovery yields of aminoacetonitrile and DL-α-aminoglutaronitrile were 58 and 69%, respectively. The results of ion-exchange chromatography of the products showed that the samples included no impurities such as the corresponding amino acids or amino acid amides.

NPS-amino Acid Methyl Esters. These compounds were prepared according to the method of Zervas *et al.*[10]

NPS-DL-alanine Methyl Ester: Yield, 60% mp 79—81 °C. Found: C, 46.94; H, 4.65; N, 10.76%. Calcd for $C_{10}H_{12}N_2O_4S$: C, 46.87; H, 4.72; N, 10.93%.

Ammonolysis of NPS-amino Acid Methyl Esters. The NPS-amino acid methyl esters of glycine, DL-alanine, and L-alanine were dissolved in small amounts of ethanol and then large excess amounts of methanol saturated with NH_3 were added. The solutions were allowed to stand at room temperature for 2—3 d. The crystals precipitated were collected and recrystallized from hot ethanol. The experimental results for the NPS-amino acid amides (**1a**—**c**) are shown in Table 4.

*NPS-amino Acid Amides (**1d**—**i**).* These compounds were prepared by reactions of the amino acid amides with *o*-nitrobenzenesulfenyl chloride in chloroform in the presence of triethylamine and recrystallized from hot ethanol. In the case of **1d**, the reaction was carried out in chloroform–ethanol (1 : 1 v/v). The experimental results for the NPS-amino acid amides (**1d**—**i**) are shown in Table 4.

*NPS-α-aminonitriles (**2a**—**i**).* An NPS-amino acid amide dissolved in a minimum amount of pyridine or pyridine–dimethylformamide (2 : 1 v/v) was cooled on an ice salt bath below −5 °C and a slight excess of $POCl_3$ was added dropwise to the solution. After the mixture had been allowed to stand at room temperature for 30 min, ice was added to it in order to decompose the excess $POCl_3$ and then the solution was treated with ethyl acetate to extract the product. The extract was washed successively with water, dilute aq HCl, and water, and then dried over anhydrous Na_2SO_4. After evaporation of the ethyl acetate from the extract, the product was separated out as a solid (**2a**—**d**) or an oil (**2e**—**i**) by the addition of petroleum ether. Recrystallization was performed from ethyl acetate–petroleum ether. The crystalline products (**2a**—**d**) obtained are shown in Table 5.

*α-Aminonitrile Hydrochlorides (**3a**—**i**·HCl).* Into a solution of an NPS-α-aminonitrile in a minimum amount of ethyl acetate or diethyl ether were added two equivalents of anhydrous HCl in diethyl ether to afford the α-aminonitrile

Table 4. NPS-amino acid amides

hydrochloride. After a large amount of diethyl ether had been added to it, the precipitated crystals were collected and recrystallized from ethanol–diethyl ether.

Derivation of L-α-*Aminonitriles for Gas Chromatographic Analysis.* About 10 mg of each L-α-aminonitrile hydrochloride were dissolved in 9 M HCl in methanol (10 ml) and then water (0.05 ml) was added to the solution. After 2 d, the solution was evaporated to dryness to remove the excess methanol and the residue (amino acid methyl ester hydrochloride) was heated to 100—110 °C for 2 h in (+)-2-butanol (1 ml) saturated with anhydrous HCl. After transesterification, the solution was evaporated to dryness in a vacuum to remove the excess (+)-2-butanol. Trifluoroacetic anhydride (1 ml) was added to the residue and then a clear solution was obtained. Methylene dichloride (5 ml) was added to the solution and it was allowed to stand overnight at room temperature. After trifluoroacetylation, the solution was evaporated to dryness carefully and the residue was taken up in nitromethane for direct injection into the gas chromatographic column.

Preparation of N-*TFA*-DL- *and* L-*amino Acid (+)-2-Butyl Esters.* About 10 mg of the amino acid were suspended in (+)-2-butanol (1 ml) saturated with anhydrous HCl. The suspension was heated to 100—110 °C for 3 h and then a clear solution was obtained. After esterification, the solution was evaporated to dryness in a vacuum and trifluoroacetylation was carried out in a manner similar to that described above.

Proton Magnetic Resonance Studies of *cis-trans* Equilibria of Some *N*-(2,5-Dichlorophenyl)-3-aminocrotonamides

Michio KONDO

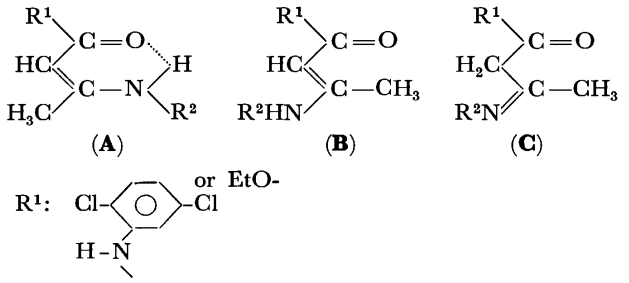
Central Research Laboratories, Sankyo Co., Ltd., Hiromachi 1-2-58, Shinagawa-ku, Tokyo 140

(Received November 16, 1976)

The ^{1}H NMR spectra of 3-(alkylamino)crotonamides indicate that these substances exist in solution as a mixture of the geometric isomers, *cis* and *trans*, in which the chelated *cis* form is predominant. Unsubstituted 3-aminocrotonamide appears to exist in the *cis* form only, and *N*,*N*-disubstituted derivatives in the *trans* form. In the case of 3-(alkylamino)crotonamide it is found that the *cis-trans* equilibrium is solvent dependent and that the apparent rate of interconversion between the isomers is very slow in chloroform-*d*, fast in dimethyl-d_6 sulfoxide, and intermediate in acetone-d_6 and methanol-d_4. It seems that the *cis-trans* equilibrium is almost independent of both temperature and concentration, and that the replacement of the olefinic H by D proceeds through enamine⇌imine tautomerization.

^{1}H NMR spectroscopy has proved to be a powerful method for studying structural problems such as tautomeric equilibrium and proton-deuteron exchange. The previous paper reported the ^{1}H NMR spectroscopic study of *N*-(2,5-dichlorophenyl)acetoacetamide (**7**), in which the *enol* form was found to be a minor component in any solvent used.[1] The ^{1}H NMR spectral study of the title compounds, easily prepared from **7** and appropriate amines, will give further information about their conformations.

From the ^{1}H NMR spectral studies of 3-aminocrotonic esters it has been found that *N*-monosubstituted derivatives exist as mixtures of two geometric isomers, *cis* (**A**) and *trans* (**B**).[2,3] In the case of the title compounds there is another problem, the *cis-trans* isomerism about the amide bond, but its conformation can be confined to *trans* on the basis of the diagnostic acylation-deshielding shifts of the ring proton-6.[4] Hereafter the terms *cis* and *trans* will refer to the conformation about the olefinic bond, C_2–C_3, unless otherwise noted.



Another point of interest is that the shift direction of the olefinic proton signals of the title compounds was opposite to that for ethyl 3-(alkylamino)crotonate when the solvent was changed from $CDCl_3$ to DMSO.

Experimental

Materials. To 2,5-dichloroacetoacetanilide (1/20 mol) suspended in ethanol (50 ml) was added an appropriate amine in slight excess. The reaction mixture was gently warmed to give a pale yellow solution and then concentrated to near dryness at room temperature. Repeated crystallizations of the precipitates from ethanol or aqueous ethanol gave the pure compounds, as proved by the satisfactory results of elemental analyses. This indicates that the condensation reaction occurred at either the acetyl-carbonyl or the amide-carbonyl group. However, the latter position may be ruled out from the constancy of the chemical shifts of the ring protons of these six compounds. Therefore, it is concluded that the reaction products are 3-aminocrotonamides (**A** and **B**) or their imino-tautomer (**C**). The structure **C** can be ruled out on the basis of the absence of signals assignable to methylene protons.

(2,5)$Cl_2C_6H_3NHCOCH$=$C(CH_3)X$

	1	**2**	**3**

mp(°C)	130.5	72.5	85.0
	4	**5**	**6**
X	$N(CH_3)_2$	$N(CH_2CH_2)_2O$	$N(CH_3)CH_2C_6H_5$
mp(°C)	141(dec)	195.5	157

The ^{1}H NMR spectra were recorded on a Varian T-60A spectrometer. Sample concentrations were 20 mg/ml unless otherwise noted. The concentration dependence of the chemical shifts of **2** was examined in DMSO and found to be negligible. The temperature dependence of the spectra of **2** was tested in DMSO at higher temperatures, using a Varian A-60D spectrometer.

Results and Discussion

Signal Assignment. A single set of signals was observed for $CDCl_3$ solution of **2** and **3**, whereas two sets of signals were observed for DMSO solutions of **2** and **3**; one set of the two corresponded well to the signals observed for the $CDCl_3$ solution. The amino proton signals of **2** and **3** in $CDCl_3$ are located at δ 9.17 and 9.21 respectively, suggesting a molecular conformation containing an intramolecular hydrogen bond between the amino proton and the amide carbonyl, *i.e.*, the *cis* conformation (**A**). The other set of signals of the DMSO solutions of **2** and **3** can be attributed to the *trans* conformation. The chemical shifts thus assigned to the *cis*- and *trans*-C–CH_3, N–CH_3, and =CH protons of **2** in DMSO, for example, are in fair agreement with those reported for the corresponding protons of ethyl 3-(methylamino)crotonate (**8**) in DMSO.[3]

Each of the ^{1}H NMR spectra of **1**, **4**, **5**, and **6** consists of only a single set of signals in both $CDCl_3$ and DMSO solutions. The chemical shifts of various kinds of protons of **1**, except for the amino protons, are close to those of **2** in the *cis* form, leading to the conclusion that the molecular conformation of **1** in the solutions is *cis*. A similar comparison of the chemical shifts of

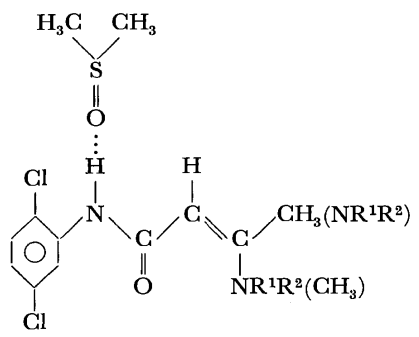
various kinds of protons of **4**, **5**, and **6**, with those of **2** leads to the conclusion that these three amides have *trans* conformation in the solutions.

The chemical shifts thus determined are collected in Table 1.

DMSO-induced Shifts. The changes ($\delta_{DMSO}-\delta_{CDCl_3}$) in the chemical shifts of various protons are summarized in Table 2.

The chemical shifts of the ring protons show characteristic changes upon changing solvents from $CDCl_3$ to DMSO: proton 3 and 4 show downfield shifts of about 0.1—0.2 ppm and proton 6 an upfield shift of about 0.33 ppm. Similar observations were reported for a number of acetanilides having an electronegative ortho substituent capable of forming an intramolecular hydrogen bond with the amide proton.[4]

The same solvent change caused slight upfield shifts of the C–CH_3 and N–CH_3 signals (<0.1 ppm), but remarkable downfield shifts of the olefinic proton (0.22—0.56 ppm) and the amide proton signals (1.20—1.40 ppm). This DMSO-induced downfield shift of the olefinic proton signal may be explained in terms of the deshielding effect[5] of a DMSO molecule intermolecularly hydrogen bonded with the amide proton (**D**), because DMSO is known as a powerful solvent for disrupting the intermolecular association among amide molecules through forming intermolecular hydrogen bonds with the amide proton.[6] This kind of deshielding effect is not expected for *N*,*N*-dimethylamide or the ethyl ester of 3-aminocrotonic acid, because each of them can be supposed to have no specific interactions with DMSO molecules. In fact, the olefinic proton signals for these compounds remained at almost the same field for the solvent change described above.[3,7]



(**D**)

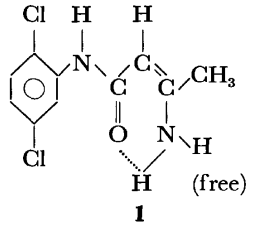
The fact that the *cis* form was observed for **1**, **2**, and **3** only is indicative of the important role of the intramolecular hydrogen bond between the amino proton and the carbonyl oxygen in stabilizing the *cis* form.

As for the amino protons of **1**, the DMSO-induced deshielding shift is 0.90 ppm. The deshielding shift for the amino proton not involved in the intramolecular hydrogen bond could be calculated as 1.92 ppm (see next section). This value is a little larger than the deshielding shift of about 1.3 ppm for the amide proton, probably reflecting stronger interactions with DMSO molecules.

Intramolecular Hydrogen Bonds. The amino protons of **2** and **3** in the *cis* form resonate at very low fields (δ 9.17 and 9.21, respectively) even in $CDCl_3$. The concentration dependence of these resonances was found to be negligible. This means that the *cis*-amino proton is involved in the intramolecular hydrogen bond with the carbonyl oxygen. With the change of solvents from $CDCl_3$ to DMSO, this amino-signal showed only a trivial upfield shift which may be a reflection of the persistence of the intramolecular hydrogen bond with almost the same strength even in DMSO. The UV absorption spectrum of **2** in DMSO is very similar to that in cyclohexane; this supports the above argument about the intramolecular hydrogen bond.

The amino protons of **1** resonate at δ 6.60 in $CDCl_3$ and at δ 7.50 in DMSO. These values are smaller by as much as about 2.59 and 1.56 ppm than those for the *cis*-amino protons of **2** and **3** in $CDCl_3$ and those in DMSO, respectively, mainly because of time averaging through a rapid internal exchange on the NMR time scale between the two amino protons (one is involved and the other is not involved in the intramolecular hydrogen bond) and partly because of the difference between NH_2 and NHR (R=CH_3 or C_2H_5).

It is reasonable to assume that the inductive effect due to the alkyl group is common and has the same magnitude for both the *cis* and *trans* amino protons. In this approximation, the hydrogen bonded and free amino protons of **1** in DMSO are expected to resonate at $\delta_{h.b.}=9.06-\Delta I$ and $\delta_{free}=6.57-\Delta I$, where ΔI stands for the inductive effect. From these two values and the observed chemical shift (δ 7.50), the inductive effect is evaluated as $\Delta I=0.32$ ppm. Since the inductive effect can be assumed to be solvent independent, the hydrogen bonded amino proton of **1** dissolved in



1

$CDCl_3$ is expected to resonate at δ 8.87. Therefore, the free amino proton of **1** in $CDCl_3$ would resonate at δ 4.33. The free amino proton of ethyl 3-(methylamino)crotonate in $CDCl_3$ was reported to resonate at δ 5.18 at −30 °C.[8] This difference could be ascribed to the difference in intermolecular interactions under different temperatures as well as the difference between the ester and the amide. The DMSO-induced shift for the free amino proton would be calculated as 1.92 ppm.

The splitting of about 5 Hz in the N–CH_3 signal of **2** and the N–CH_2 signal of **3** suggests that the intramolecular hydrogen bond is not the RH_2C=N···HO–C type but the RH_2CNH···O=C type. Dudek *et al.* discussed a similar problem for some ^{15}N enriched anilides.[9]

Population Equilibrium between the two Isomers and the H/D Exchange of the Olefinic Proton. In this section the isomeric equilibrium of **2** will be discussed in some detail. The equilibrium is solvent dependent; the percentage of the *trans* isomer is negligible in $CDCl_3$ even after two days, 7% in acetone, 22% in methanol-d_4, and 32% in DMSO at the sample concentration of 100 mg/ml at room temperature, respectively.

In a $CDCl_3$ solution of **2**, the ^{1}H NMR spectrum consists of only the *cis*-signal; the *trans*-signals were not observed even after two days. In the case of a methanol-d_4 solution of **2**, on the other hand, the ^{1}H NMR spectrum recorded just after dissolution consists of almost only the *cis*-signals and then the *trans*-signals for the C–CH_3 and the N–CH_3 grew gradually on repeated recording at the expense of the *cis*-signals until the *cis-trans* equilibrium was attained after about 30 min. These observations can be explained by assuming the *cis* conformation of **2** in the crystalline state.

During the *cis-trans* equilibration in the methanol solution of **2** described above, the *cis*-signal for the olefinic proton disappeared.

In acetone solution of **2** the *cis-trans* equilibrium is established in one and a half hours. An addition of D_2O of about 10% v/v to this acetone solution induced the disappearance of the olefinic proton signal without any change in the intensity ratio of *trans*/*cis*. Each of the doublet signals due to the N–CH_3 protons for both the *cis* and *trans* forms collapsed more rapidly because of the remarkable reduction in the spin-spin coupling constant by the deuteration of the amino proton. However, the C–CH_3 signals did not show any change in either their signal positions or their relative intensities.

Almost the same behavior was observed for a DMSO solution of **2**, with the addition of D_2O (5% v/v). The H/D replacement at the olefinic site attained equilibrium in about 40 min (Fig. 1).

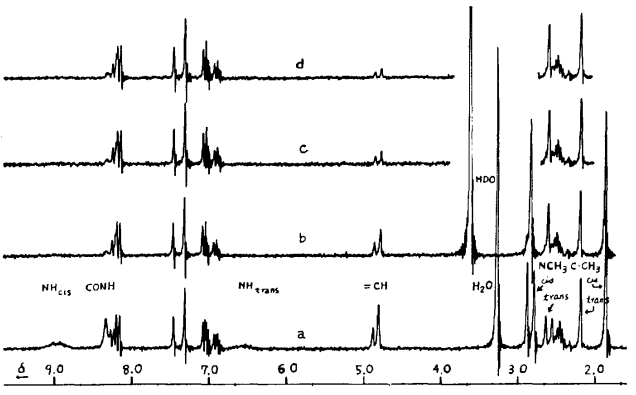


Fig. 1. The time dependent ^{1}H NMR spectrum of *N*-(2,5-dichlorophenyl)-3-(methylamino)crotonamide (**2**) in DMSO-D_2O (20 : 1) (*ca.* 80 mg/ml!): a) no D_2O; b) just after the addition of D_2O; c) after 25 min; d) after 43 min.

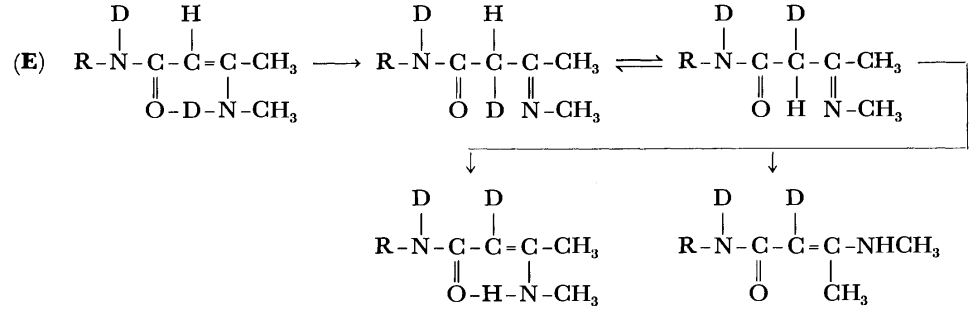
From these observations, the H/D replacement at the olefinic site seems to proceed through a transient state which is also involved in the *cis*⇌*trans* isomerization process.

In order to clarify whether or not the *cis*-amino proton plays an important role in the H/D exchange, the ^{1}H NMR spectrum of **6** in DMSO–D_2O was recorded. The addition of D_2O of about 5% v/v to a DMSO solution of **6** induced a very slow reduction in the intensity of the olefinic proton signal and the amide one, without any changes in the other signals. The plot of the log-value of the ratio, I/I_0, of the intensity of the olefinic proton signal to the initial intensity *vs.* time yielded a straight line. This suggests that a unimolecular mechanism is operative in the H/D exchange at the olefinic site. The exchange rate is much slower for **6** than for **2**, suggesting that the olefinic proton exchange in **2** may occur mainly through enamine⇌imine tautomerization (*E*), but there must be some other mechanism concurrently contributing to the H/D exchange.



The deuteration of the vinyl proton of some enamino ketones was detected by means of the ^{1}H NMR spectroscopy; the imine tautomer has been proposed as an intermediate in the *cis-trans* isomerization.[10] The replacement of the olefinic proton by a deuteron was found to be rapid (<10 min) for *N*,*N*-dimethyl-3-(methylamino)crotonamide, but much slower for methyl 3-(1-pyrrolidinyl)crotonate, upon addition of D_2O to the DMSO solutions. These results are consistent with the above argument about the exchange mechanism.

The concentration dependence of the *cis-trans* equilibrium was tested for DMSO solutions of **2** and found to be negligible over the concentration range from 10 to 140 mg/ml, reflecting the relative importance of the intramolecular mechanism for the isomerization.

The temperature variation of the ^{1}H NMR spectrum of **2** in DMSO was found to be negligible for all protons except for the amide proton and the *trans* amino proton; their signals shifted upfield with raising the temperature, probably because of reduced intermolecular interactions both between the solute-solute and the solute-solvent molecules. The population ratio of the *trans* to the *cis* isomer seemed to be constant within the experimental accuracy over the temperature range from room temperature to about 90 °C. This fact may be ascribed to an occasional cancellation between two counteracting factors: (i) increased thermal motions at the elevated temperatures would break the intramolecular hydrogen bond and shift the equilibrium to the *trans* preference, and (ii) weaker intermolecular interactions at elevated temperatures would destabilize the *trans* form.

Stereochemical Studies of the Electrolytic Reactions of Organic Compounds. IV.* Electrolytic Reduction of Optically-active 1-Pyridylalkanols to the Corresponding Substituted-alkyl Pyridines

Tsutomu NONAKA, Tetsuro OTA,** and Toshio FUCHIGAMI

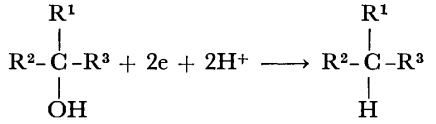
Department of Electronic Chemistry, The Graduate School, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received January 12, 1977)

The mechanism of electrolytic reduction of 1-pyridylalkanol to the corresponding substituted-alkyl pyridine was examined by electrolyzing several optically-active 1-pyridylalkanols in an aqueous sulfuric acid solution in the vicinity of a mercury cathode. The alkyl pyridine from 1-(2-pyridyl)alkanol showed optical rotation, while that from 1-(4-pyridyl)alkanol was almost racemized.

Alcoholic hydroxyl groups are generally difficult to reduce electrolytically.[1-3] In a previous work,[4] it was found that 1-(2-pyridyl)- and (4-pyridyl)alkanols are electrolytically reduced to the corresponding substituted-alkyl pyridines in high yields and current efficiencies with a mercury cathode in an aqueous sulfuric acid solution. Also a tentative mechanism for the reductive elimination of the hydroxyl group of 1-pyridylalkanols was proposed on the basis of their adsorption on a cathode surface and the steric hindrance effect of their substituents. Namely, the two electrons required for the reduction were supposed to be introduced from the cathode to a carbon atom adjacent to the hydroxyl group following the route of the conjugated π-electron system of a pyridine nucleus.

In order to discuss the stereochemical aspects of the reaction mechanism, the starting 1-pyridylalkanol and the alkyl pyridine formed must be chiral. In this work, the three kinds of optically-active 1-pyridylalkanols (**1**, **2**, and **3**) studied are electrolytically reduced to the corresponding substituted-alkyl pyridines.



1 : R^1=4-Pyridyl, R^2=Methyl, R^3=Ethyl
2 : R^1=4-Pyridyl, R^2=Methyl, R^3=Phenyl
3 : R^1=2-Pyridyl, R^2=Ethyl, R^3=Phenyl

Results and Discussion

Although a number of racemic 1-pyridylalkanols were synthesized, only 2-(4-pyridyl)-2-butanol (**1**), 1-(4-pyridyl)-1-phenylethanol (**2**), and 1-(2-pyridyl)-1-phenyl-1-propanol (**3**) could be optically resolved by fractional recrystallization of their salts with optically-active acids, such as (+)-camphor-10-sulfonic acid or (+)-tartaric acid.

Electrolysis was carried out at a constant cathodic potential, for which the initial cathodic current density was 6 A/dm^2 and no hydrogen evolution was observed. The electrolytic results are summarized in Table 1.

Optically-active 1-(4-pyridyl)alkanols (**1** and **2**) were reduced to the corresponding alkylpyridines, which were almost racemized, in high yields. On the other hand, the reduction of optically-active 1-(2-pyridyl)alkanol (**3**) afforded the optically-active alkylpyridine in a low yield, and two by-products were detected by gas chromatograph. The amount of these by-products increased steadily with increasing electric charge passed, while the amount of alkylpyridine reached a maximum of 3 to 4×10^5 C/mol of electric charge passed.[5] This fact indicates that the alkylpyridine formed was further reduced to the by-products. Although the by-products could not be isolated, their molecular weights were both determined to be 201 using a gas chromatograph-mass spectrometer. Therefore, they may be two isomers of 2-(1-phenylpropyl)tetrahydropyridine, though the position of the double bond was undetermined. Polymeric substances insoluble in ether were also formed upon the reduction of **3**.

No optical yield of the alkylpyridines could be estimated because the attempt to determine the optical purities of both the starting 1-pyridylalkanols and the alkylpyridines formed using an optically-active NMR shift reagent, such as europium tris[3-(trifluoromethylhydroxymethylene)-*d*-camphorate,[6] was unsuccessful.

The absolute steric configurations of the 1-pyridylalkanols and the alkylpyridines are unknown. Therefore, the change in relative configuration in the course of the reduction was investigated on the basis of an empirical rule, the so-called Freudenberg displacement rule.[7] The rule states that, when two similarly constituted dissymmetric compounds are chemically changed in the same way and the change produces a considerable shift in optical rotation in the same direction, then the two compounds probably have the same configuration. In order to apply the rule to determining the relative configuration of the 1-pyridylalkanols and the corresponding alkylpyridines, their derivatives were prepared by the same way. As shown in Table 2, for 1-substituted pyridinium halides from **3** and the corresponding alkylpyridine, the shifts were in the same direction. This fact suggests that the configurations of **3** and the alkylpyridine are the same, *i.g.*, in the reduction of **3** to the alkylpyridine, retention of the configuration is predominant over inversion. On the other hand, the free base and N-oxide of either **3** or the alkylpyridine may not fall in the category of the displacement rule, since the intramolecular hydrogen bonding in these compounds should give a rather different contribution

Scheme.

to their optical activities. Such an exception to the displacement rule is acceptable.[7]

In the cases of **1** and **2**, the optical rotations of not only the original alkylpyridines, but also their derivatives, were so small that the displacement rule could not be applied.[8] Such small optical rotations may indicate that racemization occurs almost exclusively in the reduction of **1** and **2**.

Although the reductive elimination of the hydroxyl group of a 1-pyridylalkanol is formally similar to that of the halo group of an alkyl halide, it is doubtful that these eliminations proceed *via* similar mechanisms. If the reduction of a 1-pyridylalkanol proceeds *via* a mechanism similar to that for the reduction of an optically-active alkyl halide,[9] the formation of configurationally inverted alkylpyridine is expected, since an intermediate radical formed by the first one-electron transfer appears to be sufficiently planar in its steric form to result in an inverted carbanion as a result of the second electron transfer. The planarity of a pyridylmethyl radical is thought to be due to the interaction between an unpaired electron and the π-electrons of a pyridine nucleus.

The electrolytic results, however, indicate that the reduction involves configurational retention and racemization in the cases of 1-(2-pyridyl)- and (4-pyridyl)-

alkanols, respectively. A mechanism involving the pyridylmethyl radical as an important intermediate should also be inadequate to explain such a difference between the electrolytic results of 1-(2-pyridyl)- and (4-pyridyl)alkanols.

According to the mechanism proposed in a previous paper[4] two electrons are supplied to a pyridine nucleus *via* a pyridinium nitrogen atom adsorbed on the cathode surface and then migrate to an asymmetric carbon atom through the π-electron system of the pyridine nucleus. As is shown in the scheme, a protonated 1-(2-pyridyl)-alkanol molecule (I) promotes adsorption at a pyridinium nitrogen, on which a positive charge would be localized to some degree, and at a hydroxonium oxygen. The orientation perpendicular to the cathode surface of the adsorbed pyridine nucleus may contribute to relaxing the steric hindrance between the cathode and I. Two electrons are transferred to the pyridine nucleus from the cathode. Excess electrons in the resulting intermediate (Ia), which should be substantially regarded as an unstable dihydropyridine such as Ib, are sequentially introduced into the bonding σ orbital of the C–O bond lengthened by the attachment of a positive hydroxonium group, and then water is eleminated from the asymmetric carbon. Consequently, a carbanion (Ic), the configuration of which is retained, is formed by the restoration of the completely conjugated system of the pyridine nucleus. The sequence of processes from I to Ic may be regarded as a multi-centered reaction involving two adsorption sites on the cathode.

On the other hand, a protonated 1-(4-pyridyl)-alkanol molecule (II) should promote adsorption only at its pyridinium nitrogen, which has an electron density lower than that of the hydroxonium oxygen, because of the rigidity of the molecule. In the course of the formation of the carbanion from IIb, an electron should be introduced not only into the bonding σ orbital of the C–O bond but also into the antibonding σ^* orbital. The latter process may be accelerated by a proton approaching to the asymmetric carbon from the opposite side of the hydroxonium group. Racemization in the reduction of 1-(4-pyridyl)alkanols should be rationalized as being due to the almost even competition between the above two processes, one of which results in configurational inversion and the other of which results in retention. In the above discussion, it is tacitly assumed that the configurations of the carbanions (Ic and IIc) are stable enough not to be racemized before undergoing protonation. Such an assumption should be acceptable, especially in a strongly acidic medium, since it is known that no recemization occurs in the reduction of optically-active alkyl halides to the corresponding alkanes in neutral media,[9,11,12] which involves a carbanion as an intermediate.[10]

In conclusion, the mechanism proposed in a previous paper[4] is consistent with the stereochemical data obtained in this work.

Experimental

Materials. *Optically-active 2-(4-Pyridyl)-2-butanol (**1**)*: Racemic **1** was prepared from 4-cyanopyridine using the method of Nakajima.[13] Yield 12%, mp 103—104 °C (lit,[13] 113—114 °C), and *m/e* 151 (M^+). Found: C, 71.46; H, 9.01; N, 8.94%. Calcd for $C_9H_{13}NO$: C, 71.49; H, 8.64; N, 9.25%. After 30 g (0.2 mol) of racemic **1** and 46 g (0.2 mol) of (+)-camphor-10-sulfonic acid ($[\alpha]_D^{20}$ +22.1° in water) were dissolved in 90 ml of absolute ethanol at 60 °C, the mixture was slowly cooled to room temperature. The resulting crystals were repeatedly recrystallized (three times) from ethanol. Optically-active **1** was finally obtained: Yield 6.4 g with $[\alpha]_D^{20}$ −1.7° (in ethanol).

*Optically-active 1-(4-Pyridyl)-1-phenylethanol (**2**)*: Racemic **2** was synthesized from 4-pyridyl pheny ketone and methylmagnesium iodide in benzene. Yield 80 g, mp 146—148 °C (lit,[14] 148—150 °C), and *m/e* 199 (M^+). Found: C, 77.76; H, 6.48; N, 6.82%. Calcd for $C_{13}H_{13}NO$: C, 78.46; H, 6.58; N, 7.03%. The compound, **2**, was optically resolved using the method of Thakar and Pathak.[11] $[\alpha]_D^{20}$ +2.4° (in methanol) (lit,[14] $[\alpha]_D^{31}$ +1.567°).

*Optically-active 1-(2-Pyridyl)-1-phenyl-1-propanol (**3**)*: The synthesis and optical resolution of **3** were carried out by the method of Davies.[15] Mp 84—85 °C (lit,[15] 80—81 °C) and *m/e* 213 (M^+). Found: C, 78.61; H, 7.33; N, 6.42%. Calcd for $C_{14}H_{15}NO$: C, 78.84; H, 7.09; N, 6.57%. $[\alpha]_D^{20}$ +80.0° (in chloroform) (lit,[12] $[\alpha]_D^{23}$ +65.9°).

Electrolytic Procedure. Electrolysis was carried out using a method similar to that used in previous work.[4] The products were analyzed by a gas chromatograph (OV-1 column at 150 °C) and were isolated by fractional distillation.

Alkylpyridines. *4-(2-Butyl)pyridine*: Bp 36—37 °C/1.5 Torr (lit,[13] 93—97 °C/15 Torr) and *m/e* 135 (M^+). Picrate: Mp 145—146 °C. Found: C, 49.37; H, 4.42; N, 15.07%. Calcd for $C_{15}H_{16}N_4O_7$: C, 49.45; H, 4.43; N, 15.38%.

4-(α-Methylbenzyl)pyridine: Bp 96—98 °C/1 Torr and *m/e* 183 (M^+). Picrate: Mp 153—154 °C. Found: C, 55.32; H, 3.93; N, 13.29%. Calcd for $C_{19}H_{16}N_4O_7$: C, 55.34; H, 3.91; N, 13.59%.

2-(1-Phenylpropyl)pyridine: Bp 89—90 °C/1 Torr (lit,[16] 104—106 °C/0.01 Torr) and *m/e* 197 (M^+). Picrate: Mp 144—145 °C. Found: C, 56.53; H, 4.38; N, 12.78%. Calcd for $C_{20}H_{18}N_4O_7$: C, 56.34; H, 4.26; N, 13.14%.

N-Substituted Derivatives of 1-Pyridylalkanols and Alkylpyridines. *4-(1-Hydroxy-1-phenylethyl)-1-phenacylpyridinium Bromide*: Compound **1** was heated at 70 °C in an excess amount of phenacyl bromide for 2.5 h. Yield 45% and mp 220—222 °C. Found: C, 63.16; H, 5.15; N, 3.22%. Calcd for $C_{21}H_{20}NO_2Br$: C, 63.33; H, 5.06; N, 3.52%.

4-(α-Methylbenzyl)-1-phenacylpyridinium Bromide: This compound was prepared by a method similar to that described above. Yield 70% and mp 228—229 °C. Found: C, 65.86; H, 5.36; N, 3.43%. Calcd for $C_{21}H_{20}NOBr$: C, 65.98; H, 5.27; N, 3.66%.

2-(1-Hydroxy-1-phenylpropyl)-1-methylpyridinium Iodide: Compound **3** was heated with an excess amount of methyl iodide at 50—60 °C for 3 days in a sealed tube. Yield 40% and mp 119—120 °C. Found: C, 50.57; H, 5.40; N, 3.56%. Calcd for $C_{15}H_{18}NOI$: C, 50.72; H, 5.11; N, 3.94%.

2-(1-Phenylpropyl)-1-methylpyridinium Iodide: 4-(1-Phenylpropyl)pyridine was reflexed in an excess amount of methyl iodide for 5 h and the separated oil was solidified by treatment with diethyl ketone. The titled compound was obtained in a form including three molecules of diethyl ketone as a solvent of crystallization. Yield 36%, mp 100 °C, and $\nu_{C=O}$ 1690 cm^{-1} Found: C, 60.41; H, 7.75; N, 1.97%. Calcd for $C_{15}H_{18}NI \cdot 3C_5H_{10}O$: C, 60.30; H, 8.09; N, 2.34%.

2-(1-Hydroxy-1-phenylpropyl)-1-benzylpyridinium Bromide: An equimolar mixture of **3** and acetic acid was heated at 90 °C in an excess amount of benzyl bromide for 12 h. Yield 70% and mp 97—100 °C. Found: C, 65.70; H, 5.58; N, 3.50%.

Calcd for $C_{21}H_{22}NOBr$: C, 65.63; H, 5.77; N, 3.64%.

2-(1-Phenylpropyl)-1-benzylpyridinium Bromide: 2-(1-Phenylpropyl)pyridine was heated in an excess amount of benzyl bromide at 90 °C for 4 h. Yield 60% and mp 121—123 °C. Found: C, 68.30; H, 6.18; N, 3.61%. Calcd for $C_{21}H_{22}NBr$: C, 68.48; H, 6.21; N, 3.80%.

2-(1-Hydroxy-1-phenylpropyl)pyridine 1-Oxide: Two grams of **3** and 4 ml of 30% hydrogen peroxide were heated in 10 ml of acetic acid at 80 °C for 24 h. Yield 74%, mp 119—120 °C, and *m/e* 229 (M^+). Found: C, 73.02; H, 6.59; N, 5.83%. Calcd for $C_{14}H_{15}NO_2$: C, 73.34; H, 6.59; N, 6.11%.

2-(1-Phenylpropyl)pyridine 1-Oxide: This compound was prepared by a method similar to that described above. Yield 78%, mp 99—101 °C, and *m/e* 213 (M^+). Found: C, 78.48; H, 7.17; N, 6.37%. Calcd for $C_{14}H_{15}NO$: C, 78.84; H, 7.17; N, 6.59%.

This work was supported by a grant from the Kawakami Memorial Foundation, to which the authors wish to express their deep appreciation.

The Reaction of *N*-(Phenylsulfonyl)benzohydrazonoyl Chloride with *N*-Substituted Benzamidines, with Benzimidates, and with 2-Aminopyridines*

Suketaka Ito, Yumo Tanaka, Akikazu Kakehi, and Hirotaka Miyazawa

Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano 380

(Received December 9, 1976)

4-Alkyl or aryl-3,5-diphenyl-4*H*-1,2,4-triazoles, 3-phenyl-1,2,4-triazolo[4,3-*a*]pyridine, and -pyrimidine are obtained by the title reactions. The reaction may proceed *via* the nucleophilic attack of amidine or imidate on the imidoyl carbon of hydrazonoyl chloride and the subsequent intramolecular cyclization of the intermediate formed in the initial step, with the removal of the amino or alkoxyl and phenylsulfonyl groups.

N-(Phenylsulfonyl)benzohydrazonoyl chloride(**1**) does not function as a 1,3-dipole source for the cyclo-addition reaction because of the strong electron-withdrawing nature of the phenylsulfonyl group.[1] However, since the arylsulfonyl group can be eliminated as an arenesulfinate anion or -sulfonyl cation, and since the imidoyl carbon and amino nitrogen of **1** possess electrophilic and nucleophilic[2] characters respectively, **1** may serve for synthesizing heterocycles.

In the previous paper,[3] we reported the synthesis of 2,5-diaryltetrazoles by the reaction of **1** with arylhydrazine, in which the elimination of the benzenesulfinate ion was observed.

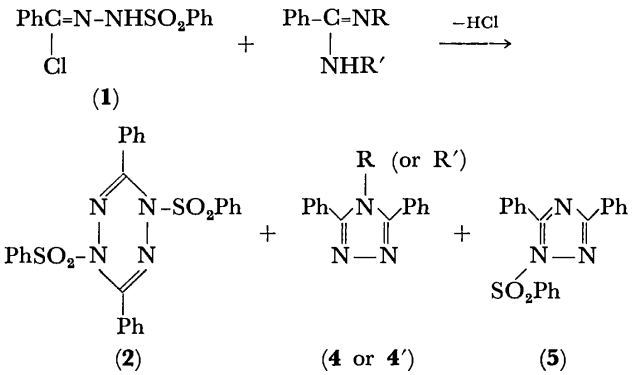
The present paper will deal with the formation of 1,2,4-triazoles from **1** and *N*-substituted benzamidines, benzimidates, or 2-aminopyridines. In this reaction, the phenylsulfonyl group may be removed cationically.

Fusco and Musante[4] reported the preparation of 1-substituted 1*H*-1,2,4-triazoles using *N*-phenylbenzohydrazonoyl chloride and unsubstituted benzamidines. Similarly, Huisgen *et al.*[5] obtained 1,2,4-triazole by the reaction of ethyl acetimidate with *N*-phenylbenzohydrazonoyl chloride in the presence of triethylamine. In these methods, however, *N*-substituted benzamidines or imidates cannot be used, and the resulting triazole bears the *N*-substituent of the starting hydrazonoyl chloride, virtually the phenyl group only, as its 1-substituent.

In contrast, the present method, using various amidines and imidates, gives 4-aryl or alkyl substituted 4*H*-1,2,4-triazoles as well as 1-phenylsulfonyl-1*H*-1,2,4-triazole.

Results and Discussion

Reaction with Benzamidines. The reaction of **1** with benzamidines was carried out in a 1 : 2 mole ratio in THF at room temperature, giving 4-substituted 3,5-diphenyl-4*H*-1,2,4-triazole (**4** or **4'**), and/or 1-phenylsulfonyl-3,5-diphenyl-1*H*-1,2,4-triazole(**5**), and 1,4-dihydro-3,6-diphenyl-1,4-bis(phenylsulfonyl)-1,2,4,5-tetrazine(**2**), together with a trace amount of 3,6-diphenyl-1,2,4,5-tetrazine.[6] The results are summarized in Scheme 1 and Table 1.



Scheme 1.

Benzenesulfonamides and *N*-phenylsulfonylated amidine were also obtained. Interestingly, the formation of benzenesulfonyl chloride was observed in the reaction with *N*,*N*-disubstituted benzamidines.[7]

As is shown in Table 1, *N*-arylbenzamidines gave **4** predominantly, and the reaction with benzamidine and its *N*-alkylated derivatives resulted in an increase in the yield of **2**. Aliphatic amidines such as *N*-ethylacetamidine, a stronger base than benzamidines, gave **2** primarily, and a small amount of *N*-(phenylsulfonyl)-*N*-[*N*-(phenylsulfonyl)benzohydrazonoyl]benzohydrazonoyl chloride(**2'**)[8] was isolated in this case.

Since the phenylsulfonyl group is a strong electron-withdrawing group, the amino hydrogen of **1** may be acidic and may be abstracted easily by amidine, a base, and the resulting *N*-(phenylsulfonyl)benzohydrazonoyl chloride anion(**1'**) may be also stable. Considering the isolation of **2'** in the reaction with *N*-ethylacetamidine, the following mechanism involving the nucleophilic attack of **1'** on **1** may be possible for the formation of **2** (Scheme 2).[9] The increased formation of **2** observed in the reaction with benzamidine and its *N*-alkylated derivatives may be attributed to their basicity being stronger than that of *N*-arylbenzamidines.

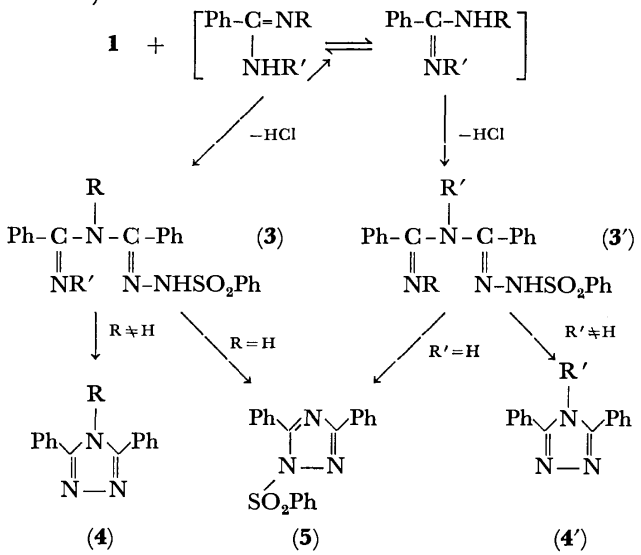
Ehrhart, *Ber.*, **55**, 1559 (1922); "Beilsteins Handbuch der Organischen Chemie," E2, Bd. XXVI (1954), p. 49. i) Lit, mp 163.5—164.5 °C: L. A. Lee, R. Evans, and J. W. Wheeler, *J. Org. Chem.*, **37**, 343 (1972). j) Lit, mp 242—243 °C: L. A. Lee and J. W. Wheeler, *ibid.*, **37**, 348 (1972).

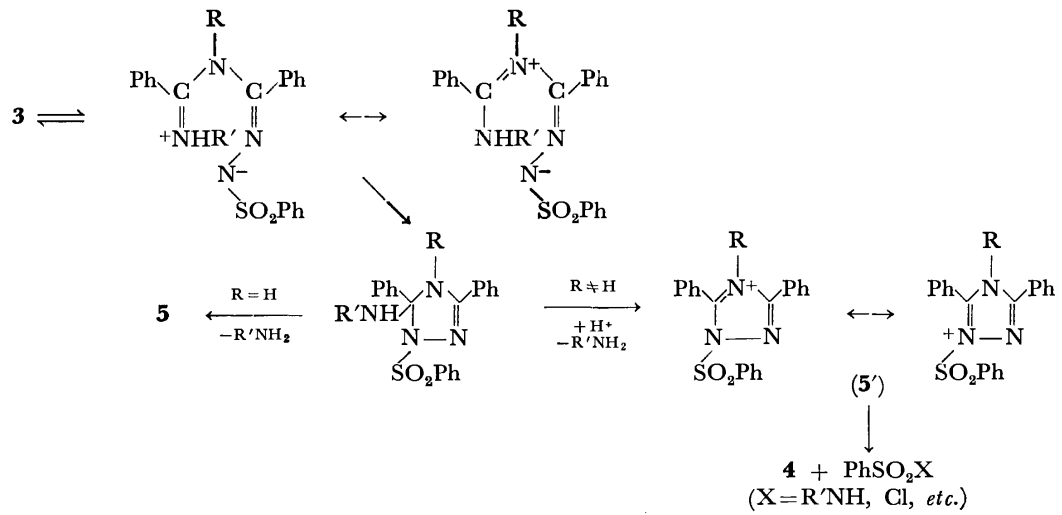
The attempted reactions of **1** with a number of dipolarophiles in the presence of a base *via* the 1,3-dipolar cyclo-addition were unsuccessful, but resulted in the formation of **2** in all cases. The reactivity of **1** different from that of *N*-phenylbenzohydrazonoyl chloride is probably due to the fact that the negative-charge delocalizability of the phenylsulfonyl group is superior to that of the phenyl group: the charge on the amino nitrogen of **1′** is delocalized by the phenylsulfonyl group, so **1′** does not release the chloride anion to form a 1,3-dipole.

Thus, the 1,3-dipolar cyclo-addition mechanism may not be applicable to the reaction of **1** with amidines, and a step-by-step mechanism involving the nucleophilic attack of amidine on **1**, followed by the intramolecular cyclization of the resultant *N*-hydrazonoylbenzamidine (**3** or **3′**)[10] *via* the nucleophilic attack of amino group on the imino carbonyl carbon of the original amidine moiety, can be postulated as more probable (Schemes 3 and 4):



Scheme 3.

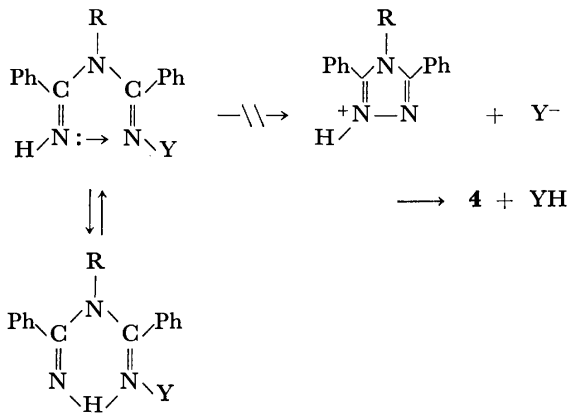
Amidines are a tautomeric compound, so that the nucleophilic attack of amidine on the imidoyl carbon of **1** may take place in two ways. Since the nucleophilicity of imino nitrogen of amidine is stronger than that of amino nitrogen, the predominant formation of **4** in the reaction with *N*-arylbenzamidines indicates that the amidines exist preferentially as arylimino tautomers. This preference is probably a result of the



Scheme 4.

conjugation between the aryl and imino groups.[11] On the other hand, *N*-alkylbenzamidines gave **5** as the major product: presumably, this result is due to the steric hindrance of the *N*-alkyl group.

Since the arylsulfonamido group is also workable as a leaving group, as may be seen in the diazo-transfer reaction with tosyl azide,[12] an alternative process involving the direct replacement of the sulfonamido group, given in Scheme 5, is conceivable for the cyclization of **3** or **3'**; in such a case, R'=H in **3** or R=H in **3'**.



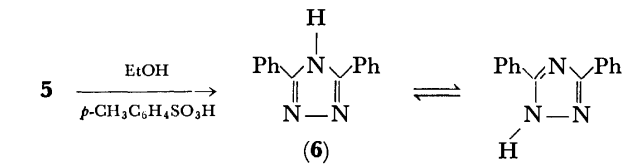
(**3**, R'=H) : Y=$PhSO_2NH$
(**7**) : Y=$PhSO_2$

Scheme 5.

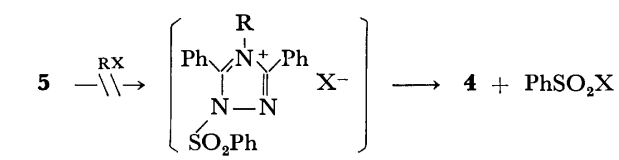
In this route, benzenesulfonamide should be the only product carrying a phenylsulfonyl group. Actually, however, *N*-phenylsulfonylated amidine and amine were mainly obtained, and benzenesulfonamide was a minor product. Consequently, this reaction route is improbable.[13]

Stirring the reaction mixture obtained in the first step of the reaction of **1** with amidine with potassium carbonate after the removal of the precipitates led to the formation of 3,5-diphenyl-4*H*-1,2,4-triazole(**6**) in part, which must have been derived from 1-phenylsulfonyl-3,5-diphenyl-1*H*-1,2,4-triazole(**5**). The combined yield of the two products were almost invariable.

The transformation of **5** to **6** proceeded excellently when the ethanolic solution of **5** was refluxed in the presence of a catalytic amount of *p*-toluensulfonic acid.



Attempts to derive **5** to **4** by alkylation with alkyl halide were, however, unsuccessful.

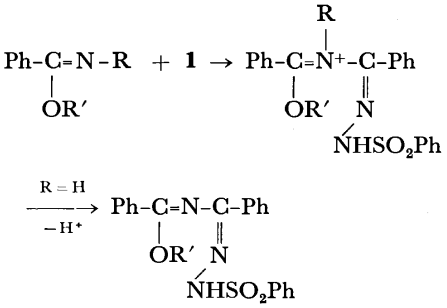


N-Benzylidenebenzamidine gave **5** upon the removal of the benzylideneamine moiety, and the elimination of benzenesulfinic acid from the primary intermediate could not be observed in the presence of alkali.

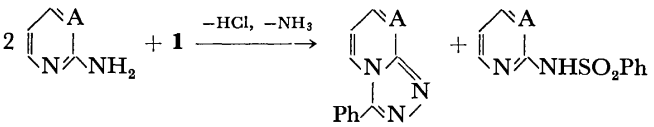
Table 2. 3,5-diphenyl-1,2,4-triazoles from benzimidates(Ph-C(=NR)-OR')

Benzimidate R	Benzimidate R'	Triazole (Yield, %)	
H	Et	**5**	(95)
Ph	Et	**4**(R=Ph)	(25)
Me	Me	**4**(R=Me)	(33)

Reaction with Benzimidates. The reaction of **1** with benzimidates took place analogously with the removal of the alkoxyl group to give triazoles (Table 2). With a slight modification of Schemes **3** and **4** by replacing R'NH by R'O, the reaction route can be represented. In the case of *N*-substituted benzimidates, the reaction proceeded slowly and gave **2** as the main product; this may be due to the uneasy formation of an intermediate because of the lack of a hydrogen atom to be removed as a proton in the imidates.



Reaction with 2-Aminopyridine and -Pyrimidine. 2-Aminopyridine(**8a**) and -pyrimidine(**8b**), cyclic amidines known to exist as amino tautomers, reacted with **1** in a manner similar to that above to give 3-phenyl-1,2,4-triazolo[4,3-*a*]pyridine and -pyrimidine(**9**) respectively in fairly good yields (Table 3).



(**8a**: A=CH, **8b**: A=N) (**9**)

The main phenylsulfonylated products were 2-(phenylsulfonylamino)pyridine and -pyrimidine. These results indicate that the initial hydrazonoylation took place at the ring nitrogen, and that the 2-amino group was removed. No product *via* the alternative process could be isolated.

Since several methods for preparing 4-substituted 3,5-diaryl-4*H*-1,2,4-triazoles are available,[14] the present method is not always useful from the synthetic point of view. On the other hand, for preparing 1,2,4-triazolopyridines, known to be useful anti-convulsants and tranquilizers, the reaction of 2-hydrazinopyridine with carboxylic acid[15] may be the only available method. Thus, because of the ready availability of starting materials, the simplicity of procedure, and the comparatively higher yield of products, this reaction might be useful in obtaining this type of compound.

Calcd for $C_{11}H_8N_4$: C, 67.33; H, 4.11; N, 28.56%. d) Overlapped with C-3 phenyl-proton.

Experimental

The melting points were determined with a Yanagimoto micromelting point apparatus, Model MP-S3, and are uncorrected. The microanalysis was performed on a Perkin-Elmer elemental analyzer, Model 240. The IR and NMR spectra were recorded with a JASCO DS-301 spectrometer and a JEOL C60-HL spectrometer respectively.

The *N*-(phenylsulfonyl)benzohydrazonoyl chloride(**1**) was prepared by the previously reported method,[3] while the benzamidines were obtained from ethyl benzimidate hydrochloride or *N*-substituted benzimidoyl chlorides according to methods described in the literature. The products were identified by means of their analytical and spectral data and by comparison with authentic specimens prepared by other synthetic methods.

*Reaction of **1** with Amidines.* *General Procedure*: A solution of amidine(0.01 mol) in THF(15 ml) was added, drop by drop, to a solution of **1**(0.005 mol) in THF(15 ml) at room temperature. Within a few minutes, precipitates began to separate. The reaction mixture was stirred for 2 h and then allowed to stand overnight. The separated precipitates were filtered and washed with THF. The filtrate combined with the washings was concentrated and then chromatographed on a silica gel(20 g) column, using benzene as the eluent, to give dihydrotetrazine, benzenesulfonamides, *N*-phenylsulfonylamidine, and 1,2,4-triazole. Benzenesulfonyl chloride, when formed, was obtained as the first eluate. Most of the 4-substituted 3,5-diphenyl-4*H*-1,2,4-triazole was obtained in a fairly pure state by washing the precipitates above separated with water, followed by cold ethanol. The results are summarized in Tables 1 and 3.

*Reaction of **1** with Benzimidates.* The reaction was conducted in a manner similar to that used with amidines. The results are summarized in Table 2.

6) Amine and amidine hydrochloride separated as precipitates in the reaction.

7) This fact might support the possible and potential intermediacy of **5′**(Scheme 4), which may be a strong phenylsulfonylating agent.

8) Compound **2′**: mp 160—162 °C(dec), IR(KBr, cm^{-1}), 3190(ν_{NH}), 1370; 1350; 1170(ν_{SO_2}). Found: C, 56.79; H, 3.79; N, 10.12%. Calcd for $C_{26}H_{21}N_4S_2O_4Cl$: C, 56.47; H, 3.83; N, 10.13%.

9) Wawzonek and Kellen obtained 1,4-dihydro-3,6-diphenyl-1,4-bis(*p*-tolylsulfonyl)-1,2,4,5-tetrazine by treating *N*-(*p*-tolylsulfonyl)benzohydrazonoyl chloride with triethylamine, and suggested the same reaction route for this dehydrochlorodimerization(S. Wawzonek and J. N. Kellen, *J. Org. Chem.*, **38**, 3627 (1973)).

10) The overall reaction generally proceeded easily at room temperature, and the primary product or intermediate, **3** or **3′**, could not be isolated. However, **1** is able to function as a hydrazonoylating agent: for example, the formation of **2′** should be ascribed to the hydrazonoylation of **1′** with **1**, and the reaction of **1** with arylhydrazines[3] proceeds *via* the *N*-hydrazonoylation of hydrazine with **1**. Therefore, the postulation of **3** or **3′** is reasonable.

12) M. Regitz, *Angew. Chem.*, **79**, 786 (1967).

13) In order to obtain some mechanistic information, the ring closure of N^1-phenyl-N^1-benzimidoyl-N^2-(phenylsulfonyl)-benzamidine(**7**, prepared from *N*-(phenylsulfonyl)benzimidoyl chloride and *N*-phenylbenzamidine, mp 222—225 °C) to **4** was examined. However, even under reflux in xylene in the presence of alkali, no remarkable change was observed, and most of the **7** was recovered. The concerted 1,5-*cis* elimination of benzenesulfinic acid should not be possible because of the anti-aromaticity of the transition state; in the intramolecular S_N2-type route(Scheme 5), the separation of an unlike charge is required for the activation process; the most stable configuration of **7** may be the U-shaped form with hydrogen-bonding. These seem to be the reasons for the unreactivity of **7**.

The Photochemical Reaction of 1,2-Naphthoquinones with Aldehydes. III.[1] The Reactions with Aromatic Aldehydes and α,β-Unsaturated Aliphatic Aldehydes

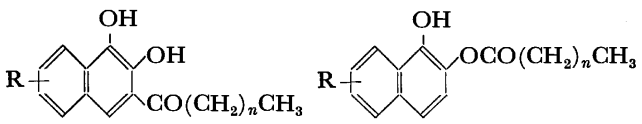
Akio TAKUWA

Department of Chemistry, Faculty of Literature and Science, Shimane University, Nishikawatsu-cho, Matsue 690

(Received December 24, 1976)

Photochemical reactions of 1,2-naphthoquinone and the substituted derivatives with a variety of aldehydes in the liquid phase have been investigated. The reaction with saturated aliphatic aldehydes gives a mixture of 3-acyl-1,2-naphthalenediol and 1,2-naphthalenediol monoacyl esters. On the other hand, the irradiation of the benzene solution of a 1,2-naphthoquinone derivative and an aromatic aldehyde gives, in general, 1,2-naphthalenediol monoaroyl esters, together with small amounts of other products. Unlike saturated aliphatic aldehydes, α,β-unsaturated aldehydes; *i.e.*, propenal, 2-butenal, *trans*-2-hexenal, 1-cyclopentenecarbaldehyde, and 1-cyclohexenecarbaldehyde, behave similary to the aromatic aldehydes in the photochemical reaction, giving only 1,2-naphthalenediol monoesters. However, 10-undecenal, 3-phenylpropanal, cyclopentanecarbaldehyde, cyclohexanecarbaldehyde, and 3-cyclohexenecarbaldehyde give mixtures of 3-acyl-1,2-naphthalenediols and 1,2-naphthalenediol monoacyl esters similar to those from saturated aliphatic aldehydes. The origin of these significant differences is discussed.

Light-induced reactions between quinone and aldehyde have been extensively studied by several workers,[2] but there have been few studies of those of 1,2-naphthoquinone derivatives, probably because of their instability.[3] Awad and Hafez, for example, failed to isolate photo-adducts by the photolysis of 1,2-naphthoquinone in the presence of acetaldehyde.[4] The successful isolation of photo-adducts in the photochemical reactions of 1,2-naphthoquinone with saturated aliphatic aldehydes was first reported by the present author.[1] Thus, 3-acyl-1,2-naphthalenediols, **1**, (C-attacking product) and 1,2-naphthalenediol monoacyl esters, **2**, (O-attacking product) were isolated as the reaction products.



1 (C-attacking product) **2** (O-attacking product)

R=H, 4-CN, 6-Br, 6-CH_3; n=0—8

On the contrary, a preliminary investigation of the photochemical reactions of aromatic or α,β-unsaturated aliphatic aldehydes with 1,2-naphthoquinones revealed that the reaction products consisted exclusively of 1,2-naphthalenediol monoesters. On the other hand, *p*-quinones, in general, give C-attacking products as their major products in photochemical reactions with aliphatic or aromatic aldehydes.[2] In this paper, a detailed investigation of the reaction products, as well as of the effect of the structure of aldehydes and the substituent effect of 1,2-naphthoquinones on the product distributions, will be described.

Results and Discussion

The quinones examined in this work are 1,2-naphthoquinone and its 3-chloro-, 3-bromo-, 4-cyano-, 4-methyl-, 4-methoxy-, 6-bromo-, 6-chloro-, and 6-methyl derivatives. Benzaldehyde, and its *p*-nitro-, *m*-nitro-, *p*-methyl-, *p*-methoxy-, 2,4-dimethoxy-, 3,4,5-trimethoxy-, 2,4,6-trimethyl-, and 2,4,6-triisopropyl derivatives are examined as typical aromatic aldehydes. As representative α,β-unsaturated aliphatic aldehydes, propenal, 2-butenal, *trans*-2-hexenal, 1-cyclopentenecarbaldehyde, 1-cyclohexenecarbaldehyde, and cinnamaldehyde are used in this work. In addition, 10-undecenal, 3-phenylpropanal, cyclopentanecarbaldehyde, cyclohexanecarbaldehyde, 3-cyclohexenecarbaldehyde, and 3-chlorobutanal are also examined.

A benzene solution of a 1,2-naphthoquinone derivative and an aldehyde was irradiated by means of a 300-W high-pressure Hg arc lamp for a suitable time. The reaction mixture was then concentrated and chromatographed on silica gel. The products are summarized in Tables 1, 2, and 3.

In the reaction of 1,2-naphthoquinone with benzaldehyde, only 1,2-naphthalenediol monobenzoate, **3a**, is obtained. The other aromatic aldehydes used here behave much like benzaldehyde, giving the corresponding 1,2-naphthalenediol monoaroyl esters (O-attacking products), together with no ring-substituted derivatives (C-attacking products). Other substituted 1,2-naphthoquinone derivatives give O-attacking products exclusively in photochemical reactions with aromatic aldehydes (see Table 1).

These results are surprising because, in the photochemical reactions of 1,2-naphthoquinones with saturated aliphatic aldehydes, acetaldehyde, for example, gives 3-acetyl-1,2-naphthalenediols in a yield comparable to that of 1,2-naphthalenediol monoacetates. In addition, it is well known that *p*-benzoquinones and 1,4-naphthoquinones, in general, give C-attacking products predominantly, along with minor O-attacking products, in photochemical reactions with both aliphatic and aromatic aldehydes.[2]

In the photochemical reactions of 1,2-naphthoquinones with aromatic aldehydes, the larger steric requirement of the phenyl than of the alkyl group might be the cause of the absence of the C-attacking product. Cyclopentanecarbaldehyde and cyclohexanecarbaldehyde, however, give both C-attacking products and O-
