Photoionization of Chlorpromazine Hydrochloride in Binary Mixed Solvent Systems

Teiki IWAOKA and Michio KONDO

Central Research Laboratories, Sankyo Co., Ltd., Hiromachi 1-2-58, Shinagawa-ku, Tokyo 140

(Received November 1, 1975)

Flash photolytic photoionization of chlorpromazine hydrochloride has been investigated in several binary solvent systems, one component being always water. With changing solvent composition, the ionization yield in aerated state shows a convex curve. Opposite roles of oxygen toward photoionization have been found in aqueous and organic solutions: *i.e.* the deaeration causes an efficient ionization in organic solvents, but practically no ionization in water. A change in the reaction mechanism has been suggested in the mixed solvent with water content of about 85 %. It has been found that the photoionization proceeds monomolecularly *via* an excited state, the lifetime of which is far shorter than that of the lowest excited (π-π^*) triplet state.

The interest in the photoionization of chlorpromazine arises from its importance in photodynamic action and photoallergic side effects.[1] It is possible that both hydrophobic and hydrophillic interactions of biological systems influence the photochemical reaction of a substrate (drug) bound into biopolymers or biomembranes. It is considered to be important, for a comparison of a photobiological reaction *in vivo* with a model reaction *in vitro*, that solvent effects of water and organic solvents on the photochemical processes are clarified. We previously investigated the photooxidation of chlorpromazine and established that the formation of the cation radical from photoionization is the initial process in the oxidative formation of the chlorpromazine sulfoxide as a photoproduct.[2] However, the elucidation of the interaction of oxygen with the excited state remained to be investigated. The significant solvent effect found in that photooxidation prompted us to study in detail the photoionization process in binary mixed solvents.

It is the purpose of this paper to show that the characteristic dependence of the photoionization upon the solvent composition is due to the change in the ionization mechanism.

Experimental

Materials. Commercial chlorpromazine hydrochloride was purified by recrystallization from diethyl ether. 2-Chlorophenothiazine (Aldrich Chemical Co.) was chromatographed on a column of silica gel (Kiesel Gel 60, Merck and Co., Inc.), with benzene as the eluent, and was recrystallized twice from this solvent. *N*-Methyl-2-chlorophenothiazine was prepared by adding slowly methyl iodide to a 2-chlorophenothiazine anion, previously prepared from sodium hydride and 2-chlorophenothiazine in dimethyl sulfoxide in a stream of nitrogen. The spectral-grade solvents—dioxane, acetonitrile, and glycerol of Merck and Co., Inc., and G. R.-grade ethanol (Iwai kagaku Co., Ltd.)—were used without further purification. The water was distilled twice in a Pyrex vessel.

Apparatus and Procedure. Flash photolytic experiments were carried out with an Ushio UFP 105 photolysis apparatus, using a combination of UV-D25 and UV-29 or UV-2 only (Toshiba color filters). The intensity of the exciting light was varied by the use of neutral filters or by the interchange of the electric capacitor. Absorption and emission measurements were made with a Hitachi 356 two-wavelength spectrophotometer and a Hitachi MPF-2 spectrofluorimeter. The absolute intensities of the flash light were determined by a ferric oxalate actinometer.

Results

Photoionization in an Aerated Mixture of Water and Organic Solvent. The first absorption band of chlorpromazine (CPZ) has its λ_{max} at 305—310 nm (*e.g.* in ethanol, 308 nm). Flash excitation was confined to this band by the use of coupled glass filters. As has been reported previously,[2] the flash excitation of CPZ in aerated water gave a cation radical (CPZ^+) as a result of electron ejection, the molecular oxygen probably an electron acceptor. The formation of CPZ^+ was negligibly small in air-saturated ethanol. However, it is found in this ionization process that a mixture of water and ethanol (1: 1) exceeds the aqueous solution in efficiency by a factor of more than five. Figure 1 shows the ionization yield (CPZ^+ yield) for several solvent pairs: ethanol–water, dioxane–water, acetonitrile–water, and glycerol–water. The spectrum of CPZ^+ is not influenced in its shape or peak position by the solvents used.

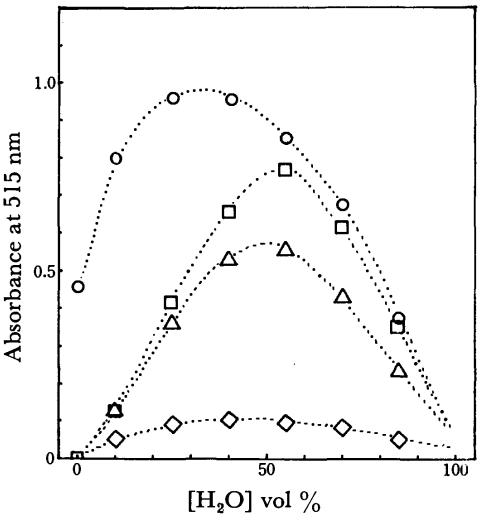

Fig. 1. CPZ^+ yields (absorbance at 515 nm) in the aerated mixed solvents. [CPZ]$=2.0\times10^{-4}$ M. □: Ethanol–water. ○: Glycerol–water. △: Dioxane–water. ◇: Acetonitrile–water.

Transients in the Deaerated State. The transient spectra obtained in the deaerated ethanol upon flash excitation are shown in Fig. 2. The transient absorption at 465 nm can safely be assigned to the (π-π^*) triplet

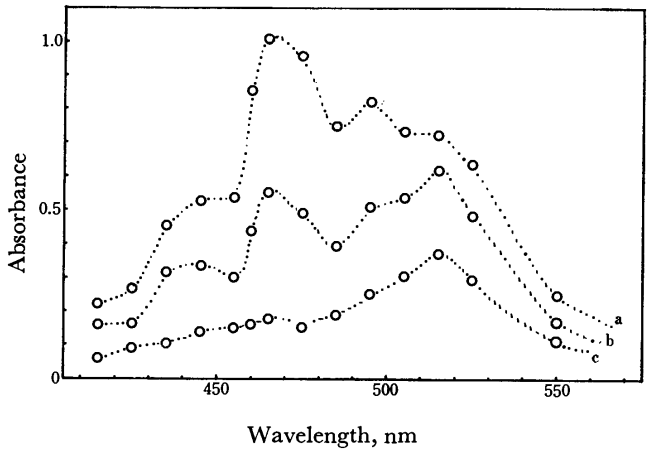

Fig. 2. Transient absorption spectra obtained by the flash photolysis of the degassed ethanol solution of CPZ. [CPZ]=2.0×10^{-4} M. a: 0 μs (immediately after flash), b: 25 μs, c: 175 μs.

state (^{3}CPZ),[2] while that at 515 nm is in fair agreement with the spectrum of CPZ$^+$. These two transients decay at different rates, and at 175 μs after the flash the absorption is practically all due to CPZ$^+$. When the technique of argon gas bubbling was applied instead of degassing *in vacuo*, no appreciable change was observed in the transient species. The lifetime of ^{3}CPZ in this case is, however, short (k_d(Ar): 5.8×10^4 s^{-1}, k_d (degassed): 2.6×10^4 s^{-1}), perhaps because of a quenching by residual oxygen in the solution.

The flash photolysis of CPZ in dioxane, glycerol, and acetonitrile gave ^{3}CPZ and CPZ$^+$ similarly, but in an aqueous solution no transients were observed.

Dependence of the Photoionization Yield on the Solvent Composition. The absorption increase of CPZ$^+$ at 515 nm is coincident with the time profile of a flash, as is the case for the (π-π^*) triplet state and the maximum value of the absorbance is used for the comparison of the relative ionization yields. The dependences of the yield

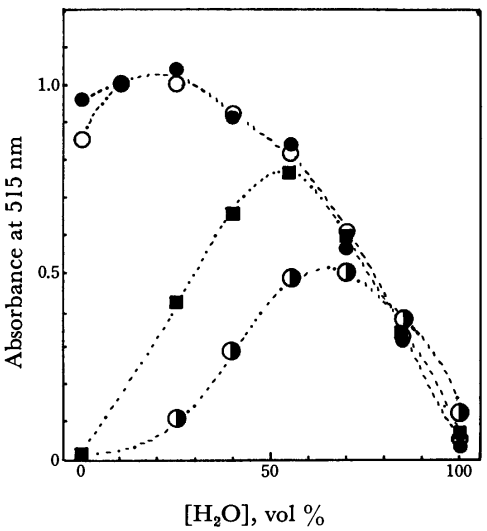

Fig. 3. CPZ$^+$ yields(absorbance at 515 nm) in the degassed (●), argon bubbled (○), air saturated (■), and oxygen bubbled (◑) mixed solvents of ethanol and water. [CPZ]=2.0×10^{-4} M.

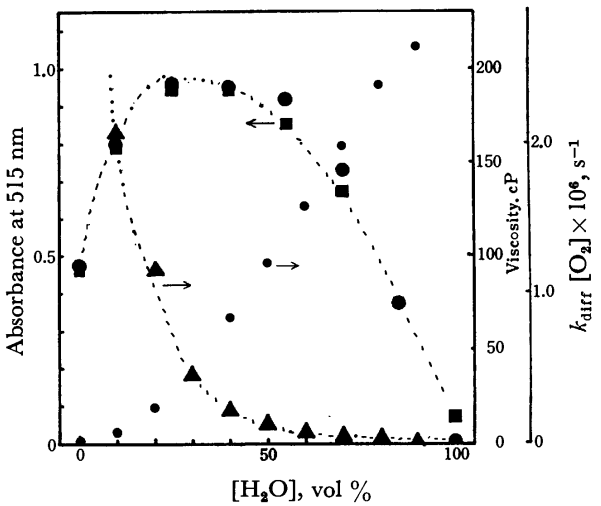

Fig. 5. CPZ$^+$ yields(absorbance at 514 nm) in glycerol–water. ●: Argon bubbled. ■: Air saturated. Viscosities (▲) and quenching rate by oxygen, k_{diff} [O_2] (●) are also shown.

of photoionization upon the solvent composition of the above solvent pairs are shown in Figs. 3—5, which illustrate a characteristic effect of the oxygen concentration on the ionization. The decay rates of the resultant CPZ$^+$ are summarized in Tables 1—2, which confirm that the decay feature of CPZ$^+$ is determined by the solvent composition, not by the oxygen concentration. The effects of the light intensity of the exciting flash were examined in anhydrous ethanol, ethanol, and ethanol–water (1 : 1) *in vacuo*. The yields of CPZ$^+$ and that of ^{3}CPZ were directly proportional to the flashing light intensity.

Reaction of ^{3}CPZ with Water. The triplet-triplet absorption in organic solvents *in vacuo* decreased drastically upon the addition of water and was not observed at a concentration of 10% v/v in water. A linear relation-

ship of Φ $(^3CPZ)^{-1}$ against [H_2O] was obtained. The yields and lifetimes of CPZ^+, however, do not show such a sharp decrease upon the addition of water.

Quantum Yields of Fluorescence, Phosphorescence and Photoionization. A rough estimation of the quantum yields of the fluorescence (Φ_f), phosphorescence (Φ_p), and photoionization (Φ_i) of CPZ was carried out (Table 3). The quantum yield of photoionization was estimated in aerated glycerol using the reported value of the molecular extinction coefficient of CPZ^+.[3] The procedure is as follows. The exciting light absorbed by CPZ is given by:

$$I_{abs} = \int I_{ex}(\lambda) I_f(\lambda)\,(1-e^{-\alpha(\lambda)cd})\,10^3\,d\lambda \qquad (1)$$

where $I_{ex}(\lambda)$, $I_f(\lambda)$, $\alpha(\lambda)$, c, and d are the light intensity of an exciting flash, the transmittance of the filter system, the absorption coefficient, the molar concentration of CPZ, and the optical path length respectively. The quantum yield (Φ_i) is estimated by:

$$\Phi_i = A_{CPZ^+}/(I_{abs}\,\varepsilon d) \qquad (2)$$

The quantum yields of fluorescence and phosphorescence were determined by comparing the emission from CPZ with that of quinine sulfate[4] and that of triphenylene in EPA[5] respectively. It is obvious from Table 3 that the value of $(\Phi_f+\Phi_p+\Phi_i)$ does not exceed one.

Discussion

A comparison of the results in the presence of oxygen with the deaerated ones (Figs. 3 and 4) shows that oxygen inhibits the ionization at concentration smaller than 60% v/v of water. The differences in the yields of CPZ^+ between the air-saturated and oxygen-bubbled solutions imply that the intermediate state responsible for the ionization is of a very short lifetime. An estimation of the lifetime of such an intermediate state is possible from the ratio of the ionization yield ($\Phi_i(O_2)/\Phi_i$(air)), assuming a diffusional quenching by oxygen. Several tens of nanoseconds were obtained for dioxane–water, and *ca.* 200 nanoseconds for the ethanol–water system. Thus, the increase in the ionization efficiency with the increase in the water content in the aerated state (Fig. 1) may be

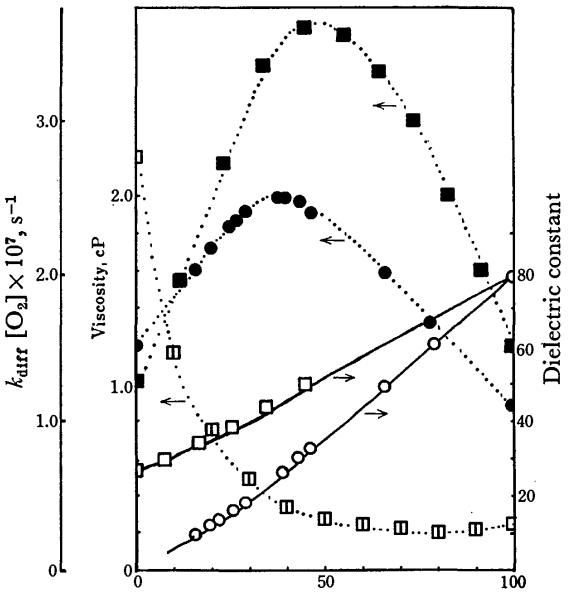

Fig. 6. Dependences of dielectric constant, viscosity and diffusional quenching rate by oxygen (k_{diff} [O_2]) on the composition of the mixed solvents.[8] Dielectric constant, □; ethanol–water, ○; dioxane–water. Viscosity, ■; ethanol–water, ●; dioxane–water. Quenching rate, ▥; ethanol–water.

attributed to the decrease in the quenching rate caused by the changes in the viscosity and oxygen concentration shown in Fig. 6.[6] It is quite reasonable that the difference in the ionization yield between air-saturated and argon-bubbled glycerol is quite small, since any diffusional quenching of the intermediate state with oxygen should be entirely suppressed. It may be said further that the efficiency of the photoionization in question is independent of the polarities and the hydrogen bonding abilities of the solvent employed.

An oxygen-catalyzed photoionization of a low yield prevails in the aqueous and nearly aqueous solutions. Either an electron transfer from the excited singlet state of CPZ to oxygen or a dissociation from the excited state of a charge-transfer complex ($CPZ^{\delta+}O_2^{\delta-}$) into CPZ^+ and O_2^- is possible for such an ionization.[7] The complexation of CPZ with oxygen in water on the basis of polarographic studies has been reported by Martin *et al.*[8] Autophotoionization from the excited state of such a change-transfer complex as $(CPZ^{\delta+}O_2^{\delta-})^*$ can be expected to occur in polar solvents, and it is natural that this photoionization process becomes dominant with an increase in the water content.

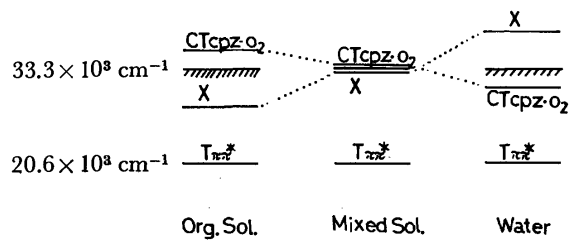

Fig. 7. Assumed changes with solvent in the disposition of energy levels of CPZ. $T_{\pi-\pi^*}$: Lowest (π-π^*) triplet state. X: Intermediate state responsible for the ionization. CT_{CPZ-O_2}: Excited state of charge transfer complex of CPZ with oxygen. Blue edge of the exciting light (///) is also shown.

The ionization in the deaerated state poses a problem regarding the solvent effect on the ionization; that is, why does the ionization efficiency shows a steep drop at a H_2O concentration of more than 50—60% v/v. A possible explanation is that the intermediate species for the photoionization is labilized and becomes short in its lifetime upon the addition of water. The energy level diagram shown in Fig. 7 is likely to elucidate our experimental results. When the employed solvent is alcohol, the transient state (X) serves as a reactive one within the available photon energy, and oxygen acts as an inhibitor of the ionization. The excited state of a charge-transfer complex ($CPZ^{\delta+}O_2^{\delta-}$) is expected to be located far above the excitation energy. In an aqueous solution, however, X possibly disposes at a higher energy, and practically no ionization is observed in the absence of oxygen. The low solubility of 2-chlorophenothiazine in water (10^{-7} M, practically insoluble) predicts that the solvation of the aromatic moiety by an organic solvent dominates over an equimolar ratio in the mixed solvent employed. Thus, it may be considered that ionization retains its high yield until a water content of about 60%.

The fluorescence of CPZ shows a large Stokes shift in both organic and aqueous solutions; this suggests an increase in the coplanarity of the two benzene rings in the fluorescent state. Both 2-chlorophenothiazine and *N*-methyl-2-chlorophenothiazine show the same locations as those of CPZ and a similar degree of Stokes shift in their fluorescence spectra. This excludes the possibility that the emission of CPZ originates from its intramolecular exciplex state. The biphotonic pathway for the ionization is definitely excluded by the findings of the proportionalities of the CPZ^+ yield with the flash intensities. Oxygen does not affected the fluorescence intensity.

The oxidation potentials of phenothiazine derivatives have been estimated from electrochemical anodic oxidation: phenothiazine (PTH, 306 mV *vs.* NCE), 2-chlorophenothiazine (354 mV), and CPZ (473 mV). These values were discussed by Malieu and Pullman[9] in terms of the "H (*R*)-intra" and "H (*R*)-extra" configurations of PTH. The degree of conjugation of the benzene rings was proposed to be dependent upon these configurations. Fulton and Lyons[10] gave the ionization potentials of several phenothiazine tranquilizers from their charge-transfer bands, 6.96 eV for PTH and 7.38 eV for CPZ. The formation of the cation radical observed in the deaerated solutions, however, shows that the photoionization occurs at about 4.1 eV, corresponding to the blue edge in an exciting flash light. Preliminary experiments on the photoionization of *N*-methylphenothiazine and *N*-methyl-2-chlorophenothiazine reveal that the photoionization proceeds more efficiently by chlorine substitution on the phenothiazine ring at 2 position. Hence, it seems that the ease of oxidation in the excited state is not necessarily parallel to that in the ground state, and that a conformation of the excited state different from that of the ground state may be a factor responsible for that.

The photoionization of *N*-methyl-2-chlorophenothiazine was examined with respect to the solvent depend-

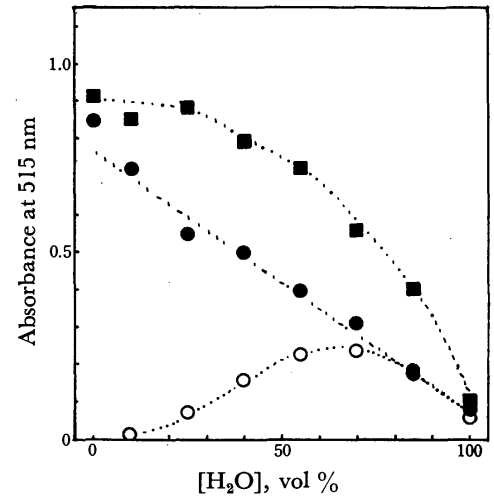

Fig. 8. Ionization yields in dioxane–50% v/v aqueous acetic acid. Comparison of CPZ with *N*-methyl-2-chlorophenothiazine. *N*-Methyl-2-chlorophenothiazine, ●; argon bubbled, ○; air saturated. CPZ, ■; argon bubbled.

ence of ionization in a dioxane–50% v/v aqueous acetic acid solution (Fig. 8). The transients observed and their dynamic behaviors were the same as those of CPZ. Even though the electronic system of this compound was the same as that of CPZ, the ionization shows a linear relationship between the CPZ^{+} yield and the solvent composition. It is probable that the side-chain amine causes some modification of the ionization yield, as a result of the proximity of tetravalent nitrogen[11] to the aromatic ring. The most suitable orientation for the ionization of the side-chain amine to the aromatic ring could be realized over a range of mixed solvents appropriately composed.

A further investigation of the reaction of CPZ with water was warranted, since no transients were found from ^{3}CPZ and since an internal quenching of ^{3}CPZ by the side-chain amine is possible. A similar quenching of the acetone triplet by alkylamine has been reported.[12] Neither the addition of 3-chloro-*N*,*N*-dimethylpropylamine at 6.7×10^{-1} M nor that of triethylamine (10^{-1} M) to an ethanol solution of CPZ caused any quenching of ^{3}CPZ. The absorption spectra after the prolonged UV irradiation of CPZ in a deaerated aqueous solution indicated only the decomposition of CPZ. These results made it probable that the (π-π^{*}) triplet of CPZ reacts with water in some degradative mode.

Our tentative scheme for the photoionization of CPZ explains well the characteristic solvent dependence and quenching effect by oxygen, however, the lifetimes obtained suggest that the intermediate state in question is not the excited state, but some transient species of a very short lifetime. Either a half-ionized state or a geminate ion pair may be possible for such a transient. Further investigations from this point of view are now in progress.

Excited States of *N*-Salicylidenealkylamines Chelating to Zinc(II)

Takeshi OHNO, Shunji KATO, Akira TAKEUCHI, and Shoichiro YAMADA
Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560
(Received February 7, 1976)

For several different forms of *N*-salicylidenealkylamines (Schiff bases), the absorption and emission spectra, and the yields, lifetimes, and polarizations of the emissions were measured. The neutral Schiff bases exist in two forms, the enolimine and the ketoamine, in an alcoholic solution. All anions of the Schiff bases emit a moderate fluorescence at room temperature and a strong fluorescence and a very weak phosphorescence at 77K. Chelating to Zn^{2+} and Be^{2+}, they strongly emit a fluorescence and phosphorescence similar to those of the free anions. In the bis-bidentate complexes, the phosphorescence increases and the fluorescence decreases compared to those of the mono-bidentate complexes—this change in the emission yields may be due to the increase in the intersystem crossing rate, enhanced by an interaction between the ligands perpendicular to each other.

It is well known that many aromatic chelating reagents, such as 8-quinolinol,[1] *N*-salicylideneanilines,[2] β-diketones,[3] and azo dyes with a hydroxyl group at their ortho position,[4] fluoresce strongly on coordinating to a light metal ion and that the first three of the above compounds phosphorescence at a lower temperature on coordinating to a heavy metal ion. We (Ohno and Kato) recently proved that the excited states of the bidentate ligands (β-diketones, 1,10-phenanthroline, and 2,2′-bipyridine) were influenced by the following coordination effects; (1) the metal-ligand bond(s) prevent(s) the excited state from undergoing internal conversion,[5] (2) the metal-ligand bond(s) using a non-bonding orbital raise(s) the levels of $^1(n\text{-}\pi^*)$ and $^3(n\text{-}\pi^*)$, followed by a change in the rates of the radiative and nonradiative processes,[6] and (3) a weak ligand-ligand interaction produces a larger spin-orbit interaction[5] and a delocalization of the excited state through the ligands, resulting in a decrease in the nonradiative transition rate.[5,6] However, no strong molecular exciton interaction in the bis- and tris-bidentate complexes was observed in the absorption spectra, even at 4.2 K,[7] contrary to the expectations based on the circular dichroic spectra.[8]

In order to confirm such coordination effects, the emissions of several *N*-salicylidenealkylamine complexes were examined.

Experimental

Material. Bis(*N*-salicylideneisopropylaminato)zinc(II)[9] ($Zn(Sal\text{-}propyl)_2$), bis(*N*-salicylidenemethylaminato)-zinc(II) ($Zn(Sal\text{-}methyl)_2$), bis(*N*-salicylidenecyclohexylaminato)zinc(II) ($Zn(Sal\text{-}ch)_2$), and (*N,N′*-disalicylidene-1,2-propanediaminato)zinc(II)[10] (Zn(Sal-pn)) were prepared from $Zn(CH_3COO)_2\cdot 2H_2O$ and salicylaldehyde and the appropriate amines.

Free Ligands. *N*-salicylidenecyclohexylamine (H-sal-ch), *N,N′*-disalicylideneethylenediamine (H_2-sal-en), and *N*-(3-methoxysalicyliden)methylamine (H-methoxy-sal-methyl) were prepared from the appropriate amines and salicylaldehyde or 3-methoxysalicylaldehyde, and were purified by means of recrystallization or distillation. $Zn(CH_3COO)_2\cdot 2H_2O$ was recrystallized from acetic acid, and $Be_4O(CH_3COO)_6$, from ethanol and then from chloroform.

Measurements. The absorption and emission spectra, the quantum yields, the lifetimes, and the polarizations of the emissions were measured in the ways described in the preceding papers.[5,6]

Procedures. The free ligands were dissolved in a mixture of methanol and ethanol (1:4 by volume) or methylcyclohexane, while the neutral complexes were dissolved (10^{-5}—10^{-4} M) in the mixed solvent in which the complexes did not practically dissociate. The solutions of the mono-bidentate complexes were prepared by dissolving the bis-bidentate complexes and an excess of $Zn(CH_3COO)_2\cdot 2H_2O$ or $Be_4O(CH_3COO)_6$. The Zn(Sal-ch)$^+$ solution was prepared from H-sal-ch and an excess of $Zn(CH_3COO)_2\cdot 2H_2O$.

Results and Discussion

Free Ligands. The near UV absorption spectra of H-sal-ch, H_2-sal-en, and H-methoxy-sal-methyl in the mixed solvent of methanol and ethanol consist of two bands, as is shown in Fig. 1; one has the band peak at

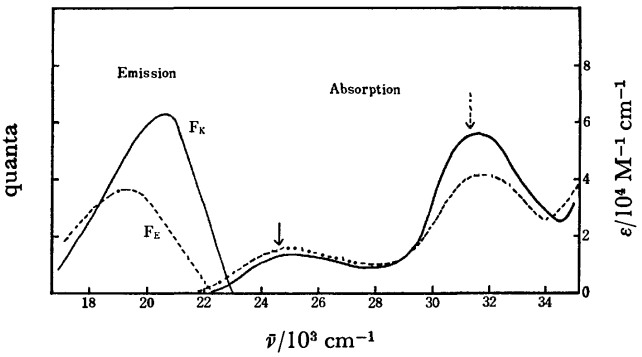

Fig. 1. Absorption and emission spectra of H-sal-ch in a mixture of methanol and ethanol (1:4 by volume). ——: The absorption spectrum at room temperature, ——: the absorption spectrum at 77 K, F_K: the fluorescence spectrum at 77 K on excitation with 24.5×10^3 cm^{-1} light (↓), and F_E: the fluorescence spectrum at 77 K on excitation with 31.5×10^3 cm^{-1} light (↓).

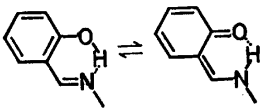
25×10^3 cm^{-1} (K-band), and the other, at 31.5×10^3 cm^{-1} (E-band). At 77 K, the intensity of the K-band increases and that of the E-band decreases. In methylcyclohexane, the E-band is intensified at room temperature and the K-band is so weakened that it can barely be detected at 77 K (see Fig. 1). The observed changes in the band intensity with the solvents and the temperatures suggest the presence of an equilibrium between the ketoamine and the enolimine:



According to Hoffman *et al.*,[11] who have proposed a similar equilibrium for salicylideneisopropylamine in some solvents by measurements of IR and UV spectra, the K-band is attributable to the ketoamine, and the E-band, to the enolimine.

A weak and structureless fluorescence is observed when the ketoamine of H-sal-ch is excited at 77 K in both alcohol and methylcyclohexane. As the temperature is raised, the fluorescence fades and escapes from detection at room temperature ($\Phi_F < 10^{-4}$). The enolimine at 77 K emits much weaker fluorescence (F_E) with a very large Stokes shift (12000 cm^{-1}), which has a spectrum a little different from the fluorescence (F_K) of the ketoamine, as Fig. 1 shows. A similar situation may be seen in H_2-sal-en and H-methoxy-sal-methyl (see Table 1). It is probable that the fluorescence on the excitation of the enolimine may come from the kind of ketoamine, with some difference in the rotation of the C–N bond and/or the solvation from the directly excited ketoamine. In the cases of some (*N*-nitrosalicylidene)-anilines[12] and *N*-(2-hydroxynaphthylidene)aniline,[13] which exist in an equilibrium with their ketoamines in the ground state, Becker and Richey considered the weak fluorescences with maxima different from those of the ketoamines to come from the kind of ketoamine with the anilino group and the salicylidene or the naphthylidene group in different planes.

a) Room temperature. b) Shoulder.

When sodium ethoxide is added as a base to an H-sal-ch ethanol solution, a new absorption band ($\bar{\nu}_{max}$: 28400 cm^{-1}) appears and both the K-band and the E-band disappear, as Fig. 2 shows. In the case of H_2-sal-en, the band peak is at 27900 cm^{-1}. This new band is undoubtedly attributable to the anion. As is shown in Fig. 2, the anion emits a new fluorescence with $\bar{\nu}_{max}$:

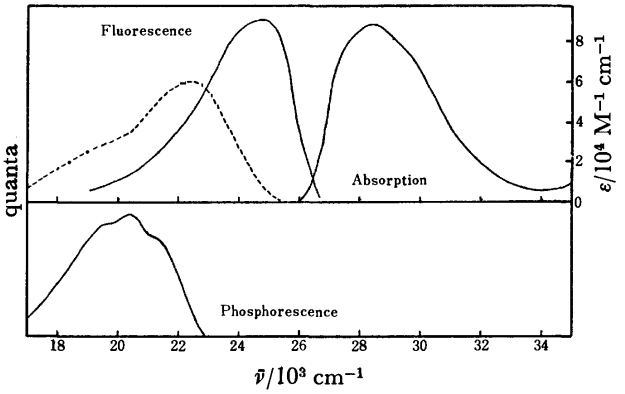

Fig. 2. Absorption and emission spectra of Sal-ch in ethanol containing sodium ethoxide at 77 K and room temperature.
——: The absorption, fluorescence, and phosphorescence (the lower section) spectra of 77 K, and ——: the fluorescence spectrum at room temperature.

24700 cm^{-1} at 77 K and 22400 cm^{-1} at room temperature. The large red shift (2300 cm^{-1}) with a rise in the temperature is probably due to the reorientation of the solvent molecules around the excited molecule with a larger dipole moment. The absence of the intramolecular H-bonding allows large yields of the fluorescence: $\approx 10^{-1}$ at 77 K and $\approx 10^{-2}$ at room temperature. Moreover, a weak phosphorescence with $\bar{\nu}_{0-0}$ at 21500 cm^{-1} was observed by using the sector method (see Fig. 2). A similar situation is seen in the basic nonaqueous solution of H_2-sal-en.

In a 0.01 N NaOH methanol solution containing 20% water, both the absorption and fluorescence spectra of H-sal-ch and H_2-sal-en are different from those of the corresponding anions in the ethanol including sodiumc ethoxide; the $\bar{\nu}_{max}$ of the absorption band is 26000 cm^{-1}, and that of the fluorescence is 19200 cm^{-1} at room temperature and 22500 cm^{-1} at 77 K for both H-sal-ch and H_2-sal-en. This behavior is the same as that of salicylaldehyde in the same solvent; therefore, it can be concluded that the species exhibiting these absorption and emission spectra is the salicylaldehyde anion. It is thus probable that the spectra of H_2-sal-en and H-sal-methyl in the methanolic KOH which were reported by Water *et al.*[14] are the absorption spectra of the salicylaldehyde anion.

Coordinating Forms of Sal-ch, Sal-propyl, and Sal-pn. When $Zn(CH_3COO)_2 \cdot 2H_2O$ is added to an alcoholic solution of H-sal-ch, both the absorption and fluorescence spectra are changed into forms very similar to those of the anion (see Figs. 2 and 3). Moreover, the same spectrum is obtained for a Zn(Sal-ch)$_2$ (3×10^{-5} M) solution with an excess (10^{-3} M) of $Zn(CH_3COO)_2 \cdot 2H_2O$. It may easily be concluded that the new band is due to the formation of Zn(Sal-ch)$^+$. It is noticeable that the coordinating Sal-ch has a broad asymmetric absorption band with a long tail on the higher-frequency side; this band may be supposed to consist of two different transitions.

On the excitation of Zn(Sal-ch),$^+$ a strong fluorescence is observed at room temperature and at 77 K. As Fig. 3 shows, the band peak of the fluorescence is red-

The upper section consists of the absorption and emission spectra at 77 K. ——: $Zn(Sal\text{-}ch)_2$, ——: Zn(Sal-ch)$^+$ ($[Zn(Sal\text{-}ch)_2]$: 3×10^{-5} M and $Zn(CH_3COO)_2$: 10^{-3} M).
The lower section consists of the fluorescence of Zn(Sal-ch)$^+$ at room temperature and the excitation polarization spectra of the fluorescence at 77 K.

shifted from 24400 to 22400 cm^{-1} by a rise in the temperature, as in the case of the anion. In addition to the fluorescence, there is observed a strong phosphorescence with a $\bar{\nu}_{0-0}$ value of 21800 cm^{-1}, which is near to the weak phosphorescence of the anion. In the case of Sal-pn, the absorption, fluorescence, and phosphorescence spectra of the coordinating Sal-pn are similar to those of Sal-en, as Table 1 shows. Further, all coordinating Schiff bases, even at room temperature, retain the high fluorescence yields obtained at 77 K.

The high fluorescence yields of the coordinating Schiff bases may have two causes. One is that the electronic state of the ligand is not similar to those of the ketoamine and the enolimine, but to that of the anion. The other is the rigid chelation to the zinc ion, suppressing the internal conversion, which usually depresses the fluorescence yields of the anions at room temperature. The high phosphorescence yields may thus be caused not by a spin-orbit interaction due to the zinc ion, but by the formation of the rigid chelation, because the complex of the lighter metal ion—Be^{2+} has a yield similar to those of the Zn-complexes.

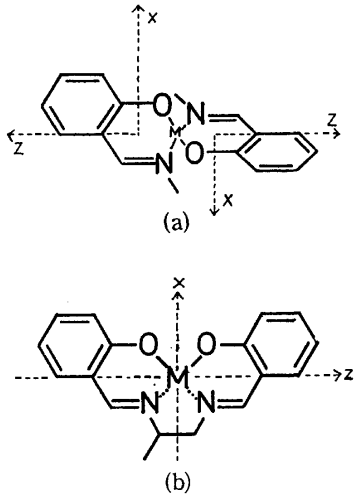

Fig. 4. Intramolecular axes of the complexes of salicylidenealkylamine (a) and Sal-pn (b).

Ligand-Ligand Interaction. In the cases of Be(Sal-methyl)$_2$, Zn(Sal-ch)$_2$, and Zn(Sal-propyl)$_2$, the inter-ligand interaction is considered not to be large because they have four coordinating atoms (2 N and 2 O) at the appexes of the tetrahedron, as has been shown by means of X-ray analysis in the case of Zn(Sal-propyl)$_2$[15] (see Fig. 4-a). They have an asymmetric absorption band similar to those of the monobidentate complexes, as Fig. 3 shows. The asymmetric band is resolved into two bands by measuring the excitation polarization spectrum of the fluorescence of Zn(Sal-ch)$_2$.*

Table 2. The quantum yields and the rate constants from the triplet states at 77 K

Compounds	Φ_F	Φ_P	Φ_P/Φ_F	Φ_T	k_r+k_{nr}	k_r	k_{nr}

Be(Sal-methyl)$^+$	—	—	2.0	—	—	—	—
$Be(Sal\text{-}methyl)_2$	—	—	3.8	—	—	—	—

Ligand-ligand interaction in the bis-bidentate complexes is reflected in the yields and lifetimes of the emissions. Their phosphorescence yields with shorter lifetimes become larger by 0.06—0.14, as is shown in Table 2, compared with the yields of the corresponding monobidentate complexes. Assuming that the rate of internal conversion from the excited singlet state is much smaller than those of the fluorescence and the intersystem crossing processes, the sum of the triplet yield (Φ_T) and the fluorescence yield (Φ_F) becomes unity and the phosphorescence yield (Φ_P) is expressed as $\Phi_P = \Phi_T \cdot k_r/(k_r+k_{nr}) = (1-\Phi_F)\, k_r/(k_r+k_{nr})$, where k_r is the rate

* The constant fluorescence polarization of the monobidentate complex suggests that the emitting dipole lies between the two absorption dipoles. This idea is partly supported by the large separation between the maxima of the absorption and the fluorescence spectra, in addition to the structureless band shapes. While the intensity of the transition along the z-axis is multiplied by a factor of 2 on bis-coordination, the intensity of the transition along the x-axis is multiplied by a factor of $\sqrt{2}$. Therefore, the transition without the z-component has a larger angle against the transition with x- and z-components in the bis-bidentate complex than in the mono-bidentate complex. If the higher absorption transition has no z-component and if the emitting has both components, x and z, the value of the fluorescence polarization is smaller on excitation to the higher excited state.

constant of the radiative process and where k_{nr} is the rate constant of the nonradiative process from the triplet state. Then, the values of k_r and k_{nr} are calculated using the phosphorescence lifetime, $(k_r+k_{nr})^{-1}$. These values and Φ_T are shown in Table 2.

The increases in Φ_T and k_r are mainly caused by the increment in the spin-orbit coupling. Such an increase in the intersystem crossing rate ($k_{S\to T}$) due to intramolecular interaction has also been observed for some β-diketonato complexes,[5] diphenylmethane, and triphenylmethane.[16] The values of k_r and k_{nr} of Zn(Sal-ch)$_2$ and Zn(Sal-propyl)$_2$ are three times as large as those of Zn(Sal-ch)$^+$ and Zn(Sal-propyl)$^+$ respectively, as Table 2 shows; therefore, the increase in the k_{nr} may come from the larger spin-orbit coupling. This is in contrast with the cases of the tris-β-diketonato complexes and triphenylmethane, where the $k_{S\to T}$ values are larger and the k_{nr} values are smaller than those of the mono-β-diketonato complexes and toluene respectively. Even if the triplet delocalization through the two ligands of a Schiff base affects the k_{nr}, the effect will be canceled out by the chelation being less rigid than that in the mono-bidentate complex, which emits phosphorescence several hundreds times as strongly as does the free anion.

As for planar Zn(Sal-pn)[17] (see Fig. 4-b), the absorption band in the near UV region has a shoulder on the lower-frequency side, as Fig. 5 shows. The shoulder

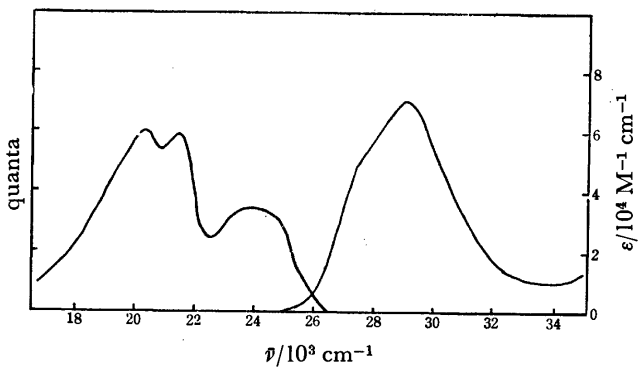

Fig. 5. Absorption and emission spectra of Zn(Sal-pn) in a mixture of methanol and ethanol at 77 K.

indicates the existence of another transition, which was suggested by Bosnich[10] on the basis of a Gaussian analysis of the asymmetric absorption band observed at room temperature. Since the fluorescence polarization is constant from $26\times10^3\,cm^{-1}$ to $31\times10^3\,cm^{-1}$ and is similar to that of Zn(Sal-ch)$^+$, the existance of two transitions does not indicate a large exciton splitting. Probably, a weak interaction between the salicylideneamine groups makes observable a second band which is hidden in the mono-bidentate complex.

Kinetic Studies in the Selective Formation of Thymol from *m*-Cresol and Propylene in the Liquid Phase over "$FeSO_4$-Al_2O_3" Catalysts

Tohr YAMANAKA and Fumio NAKATA

Central Research Laboratory of Takasago Perfumery Co., Ltd., Kamata, Ohta-ku, Tokyo 144

(Received February 12, 1976)

The kinetics in a liquid-phase isopropylation of *m*-cresol (I) with 9—25 kg/cm² of propylene (VI) was studied at 240—280 °C over catalysts prepared from $FeSO_4$ and γ-Al_2O_3. The rates of the formation of thymol (II) and 4-isopropyl-5-methylphenol (III) and the subsequent isopropylations of II and III were fitted to an irreversible, firstorder rate equation with respect to each starting material. All of the rate constants were roughly proportional to the 1.5th power of the surface acidity of $1 \leq H_0 \leq 3$ of catalysts and the 2.2nd power of the pressure of VI. The apparent activation energies were 22 kcal/mol for Steps I→II, II→2,4-diisopropyl-5-methylphenol (V), and III→V and 6.5 kcal/mol for Steps I→III and II→2,6-diisopropyl-5-methylphenol (IV).

For several years,[1] we have been studying the development of solid catalysts for the isopropylation of *m*-cresol (I) with propylene (VI) in the liquid phase, trying to prepare thymol (II), which is an important starting material for menthol. γ-Al_2O_3[2,3] and some metal sulfates[1,3] impregnated on γ-Al_2O_3 have been reported as catalysts of a high selectivity for thymol formation in the vapor[3] and liquid phases.[1,2] However, the isopropylations over these catalysts are accompanied by multiple reaction steps; the Reaction Scheme below shows an example. So far as the isopropylation of I is concerned, there has been no systematic study of the reaction kinetics. In order to design a reactor, it is necessary to describe quantitatively the distribution of products under various reaction conditions.

"$FeSO_4$-Al_2O_3"[1a] is an excellent catalyst which has a selectivity as high as γ-Al_2O_3 and a catalytic activity 100 times as high as γ-Al_2O_3. In this paper, the rates of the formation of II and the by-products over "$FeSO_4$-Al_2O_3" catalysts will be determined, and then the apparent rate constants will be correlated to the surface acidity of the catalysts and the reaction conditions.

Experimental

Catalysts. A 47.3-g portion of $FeSO_4 \cdot 7H_2O$ of a guaranteed reagent grade was dissolved in 150 ml of distilled water at 40—60 °C, and then a 75-g portion of γ-Al_2O_3 (Nikki Chemicals Co., Ltd.) of 100—200 mesh was stirred into the solution. After standing for 15—16 h, the solid was filtered and washed 3 times with 200 ml of distilled water. The resultant solid was dried on a water bath, calcined in a stream of dry air or dry nitrogen at 500 or 450 °C, and used as a catalyst. No particular caution was taken to exclude traces of moisture. The BET surface area of the γ-Al_2O_3 was 205 m²/g. In a series of preparetive runs, the resultant catalysts varied in their impregnated amounts of $FeSO_4$; these amounts were 8.7 wt% (Catalyst No. 2), 4.3 wt% (No. 3), 5.0 wt% (No. 4), 5.9 wt% (No. 5), 4.3 wt% (No. 9), 4.1 wt% (No. 10).

Surface Acidity of Catalysts. The acid-base strength distribution of catalysts were measured by a titration method.[4]

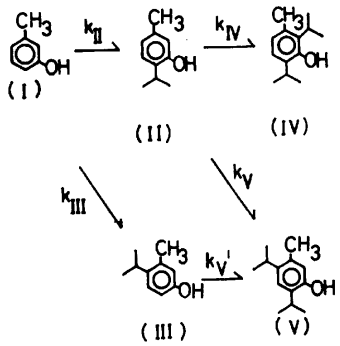
Isopropylation and the Analysis of the Products. Desired amounts of I (of guaranteed reagent grade) and of a catalyst were weighed into a reactor, which consisted of an autoclave with a capacity of 100 ml equipped with a magnetic stirrer and with gas inlet-outlet pipes. The pressure of VI (P) was kept constant at 9—25 kg/cm² by the incremental addition of VI. The reaction temperature was 240—280 °C and was kept constant within ±2 °C. The amount of catalyst (W) was 2.5—25 wt% of the initial amount of I. After an appropriate reaction period, the reactor was cooled rapidly in a cold-water stream, and the unreacted VI was released. The reaction mixture was dissolved with ether, washed with water, dried over Na_2SO_4, and concentrated.

The reaction mixture was analyzed by gas chromatography, using a Kotaki Model GU-21A on a 2 m×5 mm ϕ column packed with 20 wt% of silicone oil (D. C. 200) on Celite-545 (60—80 mesh), at 165 °C and with 1.2 kg/cm² of He as the carrier. Isopropyl benzoate was used as the internal standard. Some of the reaction mixture was fractionated into components by modified fractional gas chromatography, and each of the fractions was identified by IR absorption spectroscopy in a Nujol mull.

Isopropylations of II or III were carried out in the same way as above.

Results and Discussion

Rate Equations. The isopropylation of I was assumed to proceed *via* the following scheme. Ethers of



I and of the products were also formed, but the contents of isopropyl *m*-tolyl ether and of the total ethers in the reaction mixture were not more than 0.04 and 0.1 in mole fraction respectively. Therefore, their formation was excluded from the scheme. Figure 1 illustrates the composition-time plots of a reaction mixture. At 240—280 °C, the I content in the reaction mixture decreased monotonously with the time.

The overall reaction was well expressed by a set of irreversible rate equations:

$$dC_I/d\theta = -kC_I = -(k_{II} + k_{III})\, C_I \quad (1)$$

$$dC_{II}/d\theta = k_{II}C_I - (k_{IV} + k_V)\, C_{II} \quad (2)$$

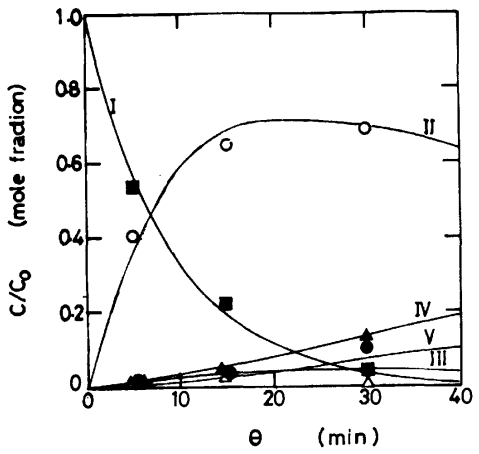


Fig. 1. Change in the composition of a reaction mixture with the reaction time at 260 °C, with 15 kg/cm² of propylene. *W* of the catalyst (No. 3) was 15 wt%. ○, II; △, III; ▲, IV; ●, V; □, I; ——, calculated value.

$$dC_{III}/d\theta = k_{III}C_I - k_V' C_{III} \quad (3)$$

$$dC_{IV}/d\theta = k_{IV} C_{II} \quad (4)$$

$$dC_V/d\theta = k_V C_{II} + k_V' C_{III} \quad (5)$$

where θ, C, and k represent the time, the concentration of the species defined by the suffix, and the apparent rate constant shown in the Reaction Scheme.

In each experimental run of the isopropylation using I, II, or III as the starting material, a linear correlation was found between {−log(1−conversion)} and θ.

Rate Constants. The apparent rate constants were determined as follows. 1) k_{II} and k_{III} were determined from the slopes of the curves of C_{II}/C_0 and C_{III}/C_0 against θ, at $\theta=0$; C_0 denotes C_I at $\theta=0$. 2) Replacing the left-hand sides of Eqs. 2—5 with the slopes of the concentration-time curves of II, III, IV, and V at any time, θ, and applying the corresponding concentrations, the rate constants were obtained. Their values are presented in Figs. 2 and 4.

Most of the compositions of the reaction mixtures which were calculated by integrating Eqs. 1 to 5 and by applying the rate constants at any time, θ, agreed within a deviation of less than 0.05 in mole fraction with the observed values over a full range of isopropylations, where the total conversion of I was from 0.17 to 0.95 in mole fraction. The composition-time curves in Fig. 1 are the calculated ones.

Each k value was proportional to the amount of catalyst (W).

From the Arrhenius plots of the rate constants in Fig. 2, the apparent activation energies in each step were determined to be 22 kcal/mol for Steps I→II, II→V, and III→V and 6.5 kcal/mol for Steps I→III and II→IV. Probably, the rate-determining step was different between these two groups of reactions. From Fig. 2, the apparent pre-exponential factors are in the order of I→II>III→V>II→V>II→IV>I→III.

Effect of the Pressure of Propylene. All of the rate constants were apparently proportional to the 2.2nd power of the pressure of VI (P).

Effect of the Surface Acidity. The acid-strength distributions of the catalysts used in this study are shown

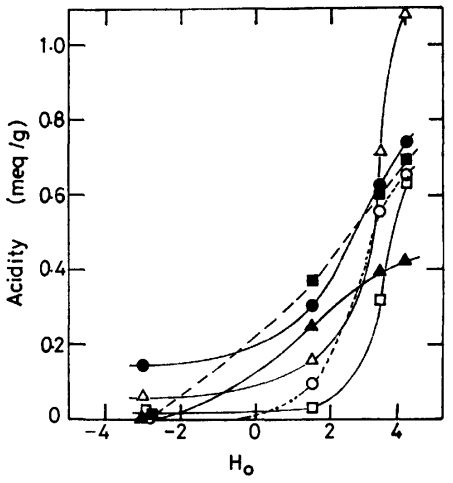

Fig. 3. Acid strength distributions of catalysts, No. 2 (▲), No. 3 (△), No. 4 (■), No. 5 (○), No. 9 (●), and No. 10 (□).

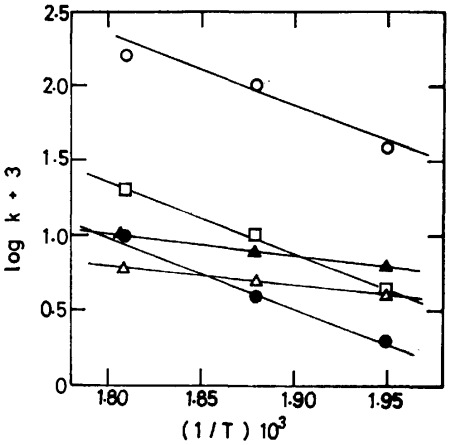

Fig. 2. Arrhenius plots of k_{II} (○), k_{III} (△), k_{IV} (▲), k_V (●), and k'_V (□). *W* of the catalyst (No. 3) was 15 wt% and propylene of 15 kg/cm² was used.

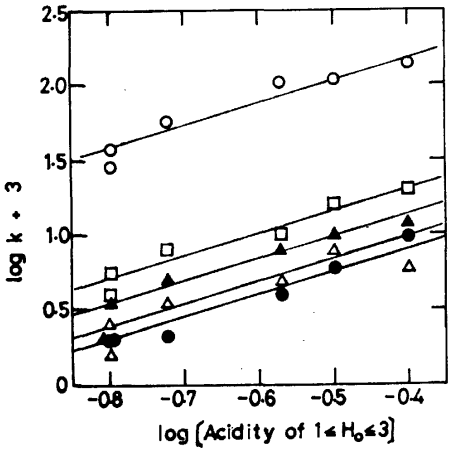

Fig. 4. Effect of the surface acidity of $1 \leq H_0 \leq 3$, α, of catalysts on k_{II} (○), k_{III} (△), k_{IV} (▲), k_V (●), and k'_V (□), at 260 °C, with 15 kg/cm² of propylene. *W* was 15 wt%.

in Fig. 3. The acidity at any H_0 value shows the amount of acidic sites whose acid strength is equal to or less than the H_0 value. Over most of the catalyst surfaces, the amount of acidic sites was at a maximum at $H_0=$ 1—4.

The rate constants were not correlated with the total amount of acidic sites of $H_0\leq 4$, or with the amount of acidic sites of any H_0 range other than $1\leq H_0\leq 3$. As is shown in Fig. 4, the rate constant in each step is similarly roughly proportional to the 1.5th power of the acidity of $1\leq H_0\leq 3$. It should be noticed that the efficient acidic sites seem not to be of $H_0<1$ but to be of $1\leq H_0\leq 3$, this will be interpreted in the following section.

Catalytic Actions. The isopropylation of I with VI has been reported to be catalyzed by solid acid catalysts *via* the formation of an isopropyl cation (HP^+).[3,5] The acidic sites of $1\leq H_0\leq 3$ will be Brönsted acidic sites and will protonate propylene. On the other hand, phenols were regarded as being adsorbed on the basic site of catalysts with the OH group.[3,6,7] On γ-Al_2O_3 used as the carrier, basic sites whose conjugate acids had H_0 values of less than 7 were observed.[4] These basic sites are probably exposed on the present catalysts' surface.[1a] The π-electron densities at C_2- and C_4-positions of the adsorbed *m*-cresol are greater than those of *m*-cresol in the liquid phase.[8] Hence, the isopropylation of I must take place between the adsorbed *m*-cresol and HP^+:

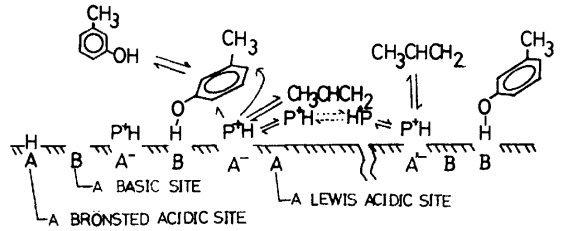
$$HA + VI \longrightarrow [HP^+ \cdots\cdots A^-] \text{ (VII)} \quad (6)$$

$$B + I \overset{K_I}{\rightleftharpoons} [I\cdots\cdots B] \text{ (VIII)} \quad (7)$$

$$VII + VIII \overset{k'_{II}}{\longrightarrow} II + HA + B \quad (8)$$

$$VII + VIII \overset{k'_{III}}{\longrightarrow} III + HA + B \quad (9)$$

where HA and B denote an acidic site of $1\leq H_0\leq 3$ and a basic site which are adjacent to each other. A^-, K, and k' denote the conjugate base of HA, an equilibrium constant, and a rate constant in the corresponding step respectively. A^- will facilitate the isopropylation by accepting a proton from the C_2- or C_4-position subsequently to the attack of HP^+.



Because the C_4-position of VII is more remote from the surface than C_2,[3,5] the migration of HP^+ to C_4 from the surface is less frequent than the direct attack of HP^+ on C_2. This is supported by the difference between the apparent pre-exponential factors of k_{II} and k_{III}. The diffusion of HP^+ has a lower activation energy than the surface reaction between HP^+ and the C_2-position of VIII. This is supported by the difference between the apparent activation energies in Steps I→II and I→III, which shows that the energy barrier in Step (9) is *ca.* 16 kcal/mol lower than that in Step (8).

Provided that the structures of the surface in the vicinity of B are almost the same, the amount of B will be proportional to the amount of HA.

The reason why acidic sites of $H_0<1$ seemed to have no effect on the rate constants is either that they were Brönsted acidic sites which were not adjacent to B or that they were Lewis acidic sites. These Brönsted acidic sites protonate propylene as well as those of $1\leq H_0\leq 3$. If HP^+ migrates rapidly and freely enough over the surface, HP^+, which are formed at the Brönsted acidic sites of $H_0\leq 3$, contribute to the activity of HP^+ as a whole. On the other hand, if HP^+ does not migrate, only the HA in the vicinity of B contributes to the activity of HP^+, which affects the rate constants. Therefore, the activity of HP^+ will be independent of the amount of HA over all the surface. In this case, the rate constants will be proportional to the amount of HA, which represents the amount of the reaction loci where the isopropylation is catalyzed by a set of HA and B. The dependency of the rate constants on the acidity of $1\leq H_0\leq 3$ by the 1.5th power suggests a restricted mobility of HP^+. For clarifying the behavior of HP^+ consistently with the behavior of propylene in gas- and liquid-phase, however, further investigations will be required interpreting the 2.2nd-power dependency of k on the P value.

Because the acid strengths of I, II, and III are estimated to be nearly equal,[9] the differences among their heats of adsorption will not be substantial. As Steps II→V and III→V had apparent activation energies equal to that of Step I→II, those steps must proceed *via* an activated state similar to that of VIII at the C_4-position of II and the C_2-position of III. The observed differences of the pre-exponential factors from that of Step I→II suggest a disadvantage in the steric factors of Steps II→V and III→V, *e.g.*, a disadvantageous entropy change in the adsorption of II because of the *ortho*-isopropyl group.

Between the competitive steps, II→V and II→IV, the relatively low activation energy and pre-exponential factor in Step II→IV indicate that the C_6-position of II is sterically unfavored, like the C_4-position of I.

We are grateful to the Takasago Perfumery Co., Ltd., for its permission to publish this article.

A CNDO-type MO Method of the Third Transition Metal Complexes and the Electronic Structure of Methylmercury(II) Halides

Shigeyoshi SAKAKI, Nobuo HAGIWARA, Noriko IWASAKI, and Akira OHYOSHI

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860

(Received February 23, 1976)

The parameters of a CNDO-type SCF-MO method are determined for some 5d transition metal complexes such as $IrCl_6^{3-}$, $AuCl_4^-$, and $HgCl_4^{2-}$ by comparing the calculated transition energies of these complexes with their experimental values. MO calculations with these established parameters are also carried out for $IrBr_6^{3-}$, $AuBr_4^-$, HgX_4^{2-}, HgX_2, and CH_3HgX (X=Cl, Br, and I). The transition energies and assignments obtained from MO calculations are in fair agreement with experimental ones, with a few exceptions. This MO method gives successful results for the electron density and the bond strength: (1) a linear relation is obtained between the calculated and observed net charges on the Hg atom of HgX_2 and CH_3HgX, and (2) similar linear relations are obtained between the bond index E_{M-X} values and the stretching force constant f_{M-X} and between the E_{Hg-C} value and the f_{Hg-C}. Some discussion is presented for the Hg-C bonding character of the CH_3HgX; the Hg-C bond is mainly contributed from the covalent interaction of the 6s and 6p orbitals of the Hg atom with the 2s and 2p orbitals of the C atom. The contributions of the Hg 5d orbitals and the electrostatic interaction are rather small.

There exist various organo-transition metal complexes which are interesting as model compounds of intermediates formed in reactions catalyzed by transition metal complexes.[1] These organometallic compounds have received many spectroscopic studies. There is, however, limited theoretical work on these complexes; such studies are especially few in the 5d organo-transition metal complexes.[2-5] Theoretical work is necessary to understand and discuss the electronic structures of organometallic complexes. Furthermore, theoretical studies can give us useful information on unstable and unisolable intermediates.[2-5,7] Thus, we should investigate a MO method powerful enough to achieve this purpose.

One of the authors presented a CNDO-type MO method which gave successful results in MO calculations of Pt-complexes.[5] By use of this method, he investigated the reaction mechanism and ligand effect in the ethylene insertion reaction into the Pt(II)-H bond.[5b] This MO method, therefore, can be expected to give us important information about organo-transition metal complexes. In the present study, we attemp to establish the parameters of Hg,Au,and Ir atoms by comparing the calculated transition energies of these metal complexes, such as $HgCl_4^{2-}$, $AuCl_4^-$, and $IrCl_6^{3-}$, with the observed ones. No MO calculation has been reported for HgX_4^{2-} and IrX_6^{3-} as far as we know; for $AuCl_4^-$, although an INDO-type MO calculation was carried out, neither d-d transition energies nor the bonding nature were discussed.[6]

Then, MO's of methylmercury(II) complexes are calculated by use of the established parameters. Although these complexes have been investigated in detail by means of various spectroscopic instruments, such as IR and Raman,[8-14] NMR,[15-18] and UV[19] spectroscopy, there has been reported only one theoretical work,[3] in which the extended Hückel MO calculations were carried out and the ligand effect on the ^{199}Hg-H coupling constant was interpreted theoretically. In the present study, the electronic spectra, the electron density, and the Hg-C bonding character are investigated.

Method, Parameters, and Geometries

Method and Parameters. The method used here is the CNDO-type approximate SCF-MO method which gave successful results in MO calculations of Pt complexes.[5] Details of this method are presented elsewhere.[20] Only the part of this method which concerns parametrization carried out in this work, is described here. The two-center Coulomb repulsion integrals are estimated by use of the modified Ohno's equation, which has been introduced in the previous paper:[5a]

$$\gamma_{rs} = 14.3986/(R_{rs}^2 + d^2)^{1/2} \quad (1)$$

$$14.3986/d = 0.5(\gamma_{rr} + \gamma_{ss}) - a_r \quad (2)$$

See Ref. 5 for the notation in the above equation. In the 3d and 4d transition metal series elements, values such as a_{4s}, a_{4p}, a_{5s}, and a_{5p} are determined from the atomic spectra. It has been found that there exist four linear relations between the atomic numbers and the a_{ns} values, and between the atomic numbers and a_{np} ones (n=4 and 5).[21] In the 5d transition metal elements, those values can not be obtained from the atomic spectra because there is not enough data to estimate those values. Thus, in the Pt atom, they have been determined as parameters so that the calculated transition energies agree with the observed ones.[5] In this work, the a_{6s} and a_{6p} values are also determined as parameters under consideration of the following conditions; the a_{6s} and a_{6p} values increase linearly with an increase in the atomic number, which is expected from the analogy to the 3d and 4d transition metal elements, and their two linear lines pass through the 1.5 and 2.5 eV[5a] at the Pt atom respectively. The values of the parameters are listed in Table 1.

Values of other parameters, such as the Wolfsberg-Helmholz parameter, K, and the orbital exponents, are taken as well to be those in the case of the Pt complexes.[5a] These parameters give good results for the transition energies, the electron densities, *etc.*

Bond Index. The energy contribution of the AB bond to the total energy, E_{AB}, is used as the bond index.[5,7,22,23] The negative value means the bonding

a) H. Basch and H. B. Gray, *Theor. Chim. Acta*, **4**, 367 (1966). b) For only the d-orbital, the double-ζ type orbitals are used. These values are their coefficients, which are re-normalized values, since the contributions of the 3d and 4d Slater type orbitals are neglected in this work. c) The calculated values from the atomic spectra (C. E. Moore, "Atomic Energy Levels," Natl. Bur. Std. Circ., No. 467 (1958). d) The estimated value.[7] e) In our previous paper,[5] these values are over-estimated. By the use of these correct values, the electronic spectra of $PtCl_4^{2-}$ are calculated successfully, and the differences between the correct and the previous calculation are very small; for example $^1B_{1g}$=1.97 eV in the present calculation and 1.99 eV in our previous report. f) R. D. Bach and H. F. Henneike, *J. Am. Chem. Soc.*, **92**, 5589 (1970). g) Ir's VSIP can not be calculated correctly from atomic spectra due to lack of experimental data. These values are estimated by assuming that the promotion energy from $^3F_4$ state of Ir(I) to the d^8 valence state is 1 eV. This assumption seems reasonable from considering that this energy is 0.87 eV for the isoelectronic Rh(I) atom.

interaction between the A and the B atoms, and the large absolute value shows the large interaction. The formula representing the E_{AB} under the used approximations has been given elsewhere.[5]

In order to investigate the detailed bonding character, the $E_{AB}^{(1)}$ and $E_{AB}^{(2)}$ which approximately represent the covalent interaction are divided into the $E_{AB(s)}^{(1)+(2)}$, $E_{AB(p)}^{(1)+(2)}$, and $E_{AB(d)}^{(1)+(2)}$ as has been described in the previous paper;[24] where the $E_{AB(s)}^{(1)+(2)}$, in which the suffix (1)+(2) denotes the sum of $E_{AB}^{(1)}+E_{AB}^{(2)}$, represents approximately the contribution of the s orbital of the B atom to the covalent interaction between the A and B atoms, and the $E_{AB(p)}^{(1)+(2)}$ and $E_{AB(d)}^{(1)+(2)}$ also represent similar meanings.

Geometries. The IrX_6^{3-}, AuX_4^-, HgX_4^{2-}, and HgX_2 belong to O_h, D_{4h}, T_d, and $D_{\infty h}$ symmetries, respectively. The following bond lengths are employed in MO calculations: Ir-Cl=2.47 Å,[25] Ir-Br=2.618 Å,[26] Au-Cl=2.42 Å,[25] Au-Br=2.57 Å,[25] Hg-Cl (in $HgCl_4^{2-}$)=2.50 Å,[27] Hg-Br (in $HgBr_4^{2-}$)=2.62 Å,[28] Hg-I (in HgI_4^{2-})=2.80 Å,[29] Hg-Cl(in $^1HgCl_2$)=2.252 Å,[30] Hg-Br (in $HgBr_2$)=2.41 Å,[31] and Hg-I(in HgI_2)=2.60 Å.[29] The CH_3HgX complex is known to have a linear structure. Its bond distance is taken as follows: for CH_3HgCl, Hg-C=2.052 Å, Hg-Cl=2.285 Å;[32] for CH_3HgBr, Hg-C=2.062 Å, Hg-Br=2.405 Å;[32] for CH_3HgI, Hg-C=2.070 Å, Hg-I=2.588 Å;[32] for $Hg(CH_3)_2$, Hg-C=2.083 Å;[33] for CH_3HgF, Hg-C=2.040 Å, and Hg-F=1.93 Å.[26] The methyl group is assumed to have the same structure in all the complexes because the kinds of the ligand can scarcely cause any structural change: ∠HCH=109.8° and C-H=1.096 Å.[33]

Results and Discussion

Parametrization and Electronic Spectra. $IrCl_6^{3-}$ and $IrBr_6^{3-}$: By considering the Pt's a_{6s}(=1.5 eV) and a_{6p}(=2.5 eV), the following values of the a_{6s} and a_{6p} were examined in MO calculations of $IrCl_6^{3-}$: a_{6s}=1.2, 1.4, and 1.6 eV, and a_{6p}=2.2, 2.4, and 2.6 eV. Results are given in Table 2.

In $IrCl_6^{3-}$, various values of a_{6s} and a_{6p} give only a small effect on the transition energies. The first and the second small bands observed at 2.99 and 3.48 eV have been assigned to the $^1T_{1g}$ and $^1T_{2g}$.[35] In the present MO calculations, the $^1T_{1g}$ and $^1T_{2g}$ transitions are calculated to be *ca.* 2.9 and 3.5 eV, respectively. The large band observed at 6.01 eV may be assigned to the $^1T_{1u}$ transition calculated at 4.8 eV, since the $^1T_{1u}$ one is the only allowed one. This transition is the charge-transfer (CT) one from the halogen's p_π orbital

a) eV unit. The transitions which satisfy both the following conditions are omitted for simplicity: (1) the transition is above the first CT one; (2) its transition moment is zero. These transitions do not relate to the present discussion. b) Ref. 35. c) Molar extinction coefficient (M^{-1} cm^{-1}). d) Transition moment (Å). Transition moments are zero in other transitions.

to the Ir's $5d_\sigma$ orbital. In all the calculations, these calculated transition energies roughly agree with the observed one, although the $^1T_{1u}$ transition energy is smaller than the observed one by *ca.* 1.2 eV.

Then, the a_{6s} and a_{6p} values can be determined. The small a_{6s} and a_{6p} values give better results for the observed $^1T_{1g}$, $^1T_{2g}$, and $^1T_{1u}$ transitions, as shown in Table 2. The a_{6s} and a_{6p} values, however, are determined as 1.4 and 2.4 eV respectively, by considering the linear relation between the atomic number and the a_{6s} and a_{6p} values (See Fig. 1, the previous discussion in method and parameter, and Ref. 49. This determination seems reasonable, since the calculated transition energies do not much depend on the a_{6s} and a_{6p} values.

By using these values of a_{6s} and a_{6p}, transition energies of $IrBr_6^{3-}$ are calculated, as is shown in Table 2. Three large bands are observed at 4.5—6 eV: the first is assigned to the transition from the weak π-antibonding and weak σ-bonding $3t_{1u}$ MO, mainly composed of the halogen's p_π orbital, to the $2e_g$ MO, mainly composed of the Ir's $5d_\sigma$ orbital; the second is that from the $1t_{2u}$ MO composed of the halogen's non-bonding p_π orbital to the

$2e_g$ MO; and the last is that from the weak π- and σ-bonding $2t_{1u}$ MO, mainly composed of the halogen's p_π orbital, to the $2e_g$ MO. The calculated transition energies roughly agree with experimental ones,[35] but the calculated transition moments are unreasonable. For the first small band observed at 2.78 eV, the calculated transition energy is smaller than the observed one. For the small band observed at 3.20 eV, there is an ambiguity whether the $^1T_{2g}$ calculated at 1.75 eV or that at 3.82 eV should correspond to this band. Thus, although there is insufficiency in the $^1T_{1g}$ and $^1T_{2g}$ results, roughly good results are obtained for the CT bands.[51]

$AuCl_4^-$ and $AuBr_4^-$: The following values of the a_{6s} and a_{6p} were examined: a_{6s}=1.5, 1.7, and 1.9 eV, and a_{6p}=2.5, 2.7, and 2.9 eV. The calculated transition energies are compared with the observed ones in Table 3.

The calculated transitin energies do not much depend on the a_{6s} and a_{6p} values.[34] The transitions calculated at *ca.* 3.8, 4.0, and 8.2 eV seem to correspond to the observed bands at 3.85, 5.47,[36,37] and 7.07 eV,[36] respectively.[38] These assignments agree well with the experimental ones which have been proposed from the MCD study.[37] The calculated transition energies also agree well with the experimental ones,[36,37] but the second ^1E_u transition calculated at 4.0 eV is smaller than the experimental one by *ca.* 1.5 eV.

The two bands observed at 2.72 and 3.29 eV have been assigned to the $^1A_{2g}$ and ^1E_g transitions, respectively.[36] In our calculations, the $^1A_{2g}$ and ^1E_g transitions are calculated at *ca.* 2.8 and 3.2 eV, respectively, and the other four transitions, $^1B_{2g}$, ^1E_g, $^1A_{2u}$, and $^1B_{2u}$ are also calculated about 2.8—3.5 eV. Thus, detailed study should be carried out for the assignments of these transitions.

Then, the values of the parameters a_{6s} and a_{6p} can be determined. With regard to the $^1A_{2g}$ transition observed at 2.72 eV, the small a_{6s} and the large a_{6p} values give a better result, whichever of the three transitions, $^1B_{2g}$, ^1E_g, and $^1A_{2g}$ (calculated at about 2.8 eV), correspond to this transition at 2.72 eV. On the other hand, with regard to three ^1E_u transitions, the large a_{6s} and the small a_{6p} values give better results. Thus, the a_{6s} and a_{6p} values are determined as 1.7 and 2.7 eV, respectively.

Using these determined values of a_{6s} and a_{6p}, a similar MO calculation was carried out for $AuBr_4^-$. The

results are also shown in Table 3. Calculated transition energies agree well with the observed ones, except for the second ^1E_u transition observed at 4.90 eV.[36] Reasonable assignments are also obtained,[36,37] except with the $^1A_{2u}$ band observed at 6.61 eV.[39b]

HgX_4^{2-} and HgX_2: Just as in the cases of the Ir and Au complexes, MO calculations of $HgCl_4^{2-}$ were carried out using various values of a_{6s} and a_{6p}: a_{6s}=1.6, 1.8, and 2.0 eV, and a_{6p}=2.6, 2.8, and 3.0 eV. Results are given in Table 4.

One large band is observed at 5.28 eV, which is assigned to the $^1T_2$ transition, since the $^1T_2$ transition is the only allowed one in the T_d symmetry.[40] Also in our calculation, the $^1T_2$ transition is calculated at 5.6 eV; the calculated value fairly agrees with the experimental one. As the a_{6s} value becomes large and the a_{6p} one becomes small, the calculated transition energy of the $^1T_2$ becomes small. Since this calculated value is slightly larger than the observed one,[40] the large value of the a_{6s} and the small one of the a_{6p} are preferable. The a_{6s} and a_{6p} values, however, are determined as 1.8 and 2.8 eV respectively, by considering the expected linear relation between the atomic number and the a_{6s} and a_{6p} values, and also by considering the a_{6s} and a_{6p} values of the Ir, Pt, and Au atoms. This determination seems reasonable, since the calculated transition energy does not depend so greatly on the a_{6s} and a_{6p} values, and since fairly good agreement with the experimental results is obtained in all the calculations.

By use of these values of a_{6s} and a_{6p}, MO calculations were carried out for HgX_4^{2-} (X=Br and I), and HgX_2 and CH_3HgX (X=Cl, Br, and I). Calculated transition energies are given in Table 5. Those of HgX_4^{2-} agree fairly well with the experimental ones,[40] where the large band is considered as the $^1T_2$ transition as is that of $HgCl_4^{2-}$. It has been proposed previously that these bands are the CT transitions.[40] The present calculation shows that these transitions are the $^1T_2$ CT ones from the $4t_2$ MO, mainly composed of halogen's p_π orbital, to the $3a_1$ MO, mainly composed of the Hg's 6s orbital.

In HgX_2, the moderately large bands observed at 4.5—6 eV are considered as the $^1A_{2u}$ transitions, since only this transition is allowed. Also, in the CH_3HgX, the moderately large bands are observed at 5.4—6 eV, and these are considered as similar to the $^1A_1$ transitions. These $^1A_{2u}$ and $^1A_1$ transitions calculated at 6—7 eV, are larger than the observed ones by *ca.* 1.5 eV.[41,42] The $^1A_{2u}$ transition of HgX_2 is the one electron transfer from the $2a_{1u}$ MO to the $4a_{1g}$ MO. Since the former MO is mainly composed of the halogen's p_σ orbital and the latter one mainly of the Hg's 6s orbital, this transition is the CT one, which agrees with the experimental proposal.[42] The $^1A_1$ transition of CH_3HgX is the one electron transfer from the $4a_1$ MO to the $5a_1$ MO; the former is largely contributed to from the p orbitals of the C and X atoms and the latter largely from the Hg's 6s orbital. Thus, this transition is also the CT one.

As described above, the results of the electronic spectra are reasonable, with a few exceptions. The values of the parameters established above are listed in Table 1. The a_{6s} and a_{6p} values are plotted against the atomic number in Fig. 1, where a nearly linear relation is obtained.

TABLE 6. ELECTRON DISTRIBUTION OF IrX^{3-}, AuX_4^-, HgX_4^{2-}, AND HgX_2

Cmpound	5d	6s	6p
$IrCl_6^{3-}$	6.776	0.527	0.927
$IrBr_6^{3-}$	6.812	0.560	0.963
$AuCl_4^-$	9.197	0.594	0.807
$AuBr_4^-$	9.327	0.612	0.807
$HgCl_4^{2-}$	9.989	0.704	0.722
$HgBr_4^{2-}$	9.989	0.783	0.755
HgI_4^{2-}	9.989	0.821	0.771
$HgCl_2$	9.933	0.915	0.456
$HgBr_2$	9.944	1.019	0.447
HgI_2	9.955	1.059	0.455

Electron Density. Electron densities are shown in Table 6. It is reasonable for all the complexes that the electron density of the central metal atom increases with a decrease in the electronegativity of the halogen.

Our calculations show that the net charge of the Au atom is +0.401 *e* in $AuCl_4^-$ and +0.254 *e* in $AuBr_4^-$, although these values have been reported to be negative from the Mössbauer spectroscopy:[43] −0.24 *e* in $KAuCl_4$ and −0.21 *e* in $KAuBr_4$. The authors wonder why the Mössbauer study reported that the net charge of the Au atom was −0.24 *e* in $KAuCl_4$ and +0.41 *e* in AuCl, although the formal net charge of the Au atom is +3 in the former complex and +1 in the latter one. Thus, these reported values should be re-investigated in more detail.

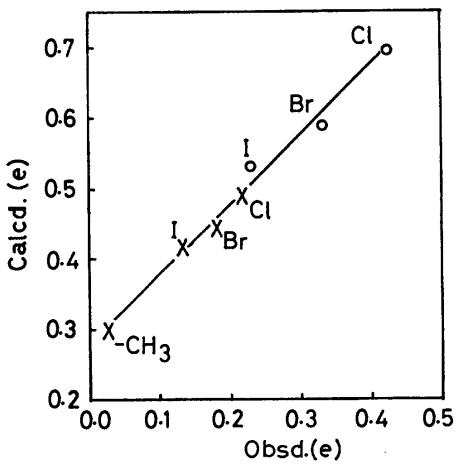

Fig. 2. The relation between the observed[a] and the calculated net charges of the Hg atom in HgX_2 and CH_3HgX. ○; HgX_2, ×; CH_3HgX. a) Ref. 44.

In HgX_4^{2-} and HgX_2, all the d orbitals seem to be of the non-bonding type, since they have about 10 electrons. The Hg–X bond is mainly contributed to from the 6s and 6p orbitals of the Hg atom. Our calculated net charges of the Hg atom are compared with the estimated ones from the ESCA study,[44] as is shown in Fig. 2. Although these two values do not agree with each other, a linear relation is obtained between these two values, and it should be further noted that its slope

is about 1.0. This result reveals that our method is at least qualitatively successful.

The ^{35}Cl NQR studies of $HgCl_2$ and CH_3HgCl give the unbalance in the p-electron population on the Cl atom, U_p, which is defined in Ref. 44. From MO calculations, the U_p values can be estimated: 0.526 for $HgCl_2$ and 0.474 for CH_3HgCl. These are in moderately good agreement with the experimental values: 0.402 for $HgCl_2$ and 0.383 for CH_3HgCl.[45] Since the quantity of U_p depends upon the electron populations of the p_σ and p_π orbitals of the Cl atom, it is suggested that the calculated electron distribution agrees with the experimental one.

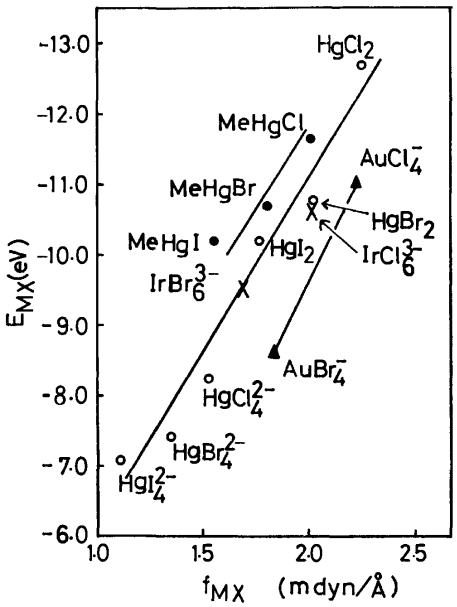

Fig. 3. The relation between the force constant f_{M-X}[a] and the E_{M-X} values.
a) HgX_2 and HgX_4^{2-}, Ref. 29; IrX_6^{3-}, Ref. 46; CH_3HgX, Ref. 8; AuX_4^-; Ref. 47.

Bond Strength. The E_{M-X} values are compared with the M-X force constants in Fig. 3, since the force constant and E_{M-X} approximately represent the bond strength. Three different linear relations are obtained: the first one concerning the HgX_2, HgX_4^{2-}, and IrX_6^{3-}, the second concerning the CH_3HgX, and the last concerning the AuX_4^-. Generally speaking, the value of the force constant depends upon their calculation method. The force constants of HgX_2 and HgX_4^{2-} were calculated with the simple method,[29] those of IrX_6^{3-} were done with the generalized force field,[46] those of CH_3HgX were done with a simple valence force field,[8] and those of AuX_4^- were done with an Urey-Bradley force field.[47] Thus, it seems reasonable that in all the calculations, a linear relation can not be obtained. It should be noted that linear relations do exist between the E_{M-X} values and the M-X force constants which are calculated by use of the same force field, and the three lines have almost the same slopes.

Similar relations are also obtained between the E_{Hg-C} values and the Hg-C force constants,[8] and between the E_{Hg-C} values and the Hg-C dissociation energies of CH_3HgX,[48] as are shown in Figs. 4 and 5. Thus, our

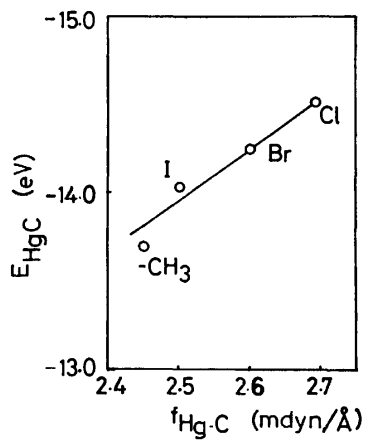

Fig. 4. The relation between the Hg-C force constant f_{Hg-C}[a] and the E_{Hg-C} value.

method gives successful results for the bond strength.

Electronic Structure of CH_3HgX. In this section, the electron distribution and bonding nature of the Hg-C and Hg-X of CH_3HgX are investigated. Results are given in Table 7.

First, the electron distribution is investigated in detail. The electron density of the 5d orbitals of the Hg atom is *ca.* 10 *e*, suggesting that the 5d orbitals hardly contribute to the Hg-C and Hg-X bonds in these complexes as well. On this point, a more detailed discussion will be presented in a following paragraph. The electron densities of the 6s and 6p orbitals of the Hg atom increase in the order $F<Cl<Br<I<CH_3$. This order accords with the decreasing order of the halogen's electronegativity. The electron density of the Hg atom in $Hg(CH_3)_2$ is larger than that in CH_3HgI by *ca.* 0.1 *e*, and larger than that in the corresponding dihalide HgX_2 by *ca.* 0.1—0.2 *e*. These results suggest that the methyl anion tends to donate electrons more than the halogen anion by *ca.* 0.1 *e*.

Then the nature of the Hg-C and Hg-X bonds will be investigated. As is shown in Table 7, the absolute values of $E^{(1)+(2)}_{Hg(s)-C}$ and $E^{(1)+(2)}_{Hg(p)-C}$ are remarkably large, and those of $E^{(1)+(2)}_{Hg(d)-C}$ and $E^{(3)}_{Hg-C}$ are less than one-tenth of $E^{(1)+(2)}_{Hg(s)-C}+E^{(1)+(2)}_{Hg(p)-C}$. Similar results are obtained with

Table 7. Electronic structures of CH_3HgX

E_{AB}: eV unit.

regard to the Hg–X bond. These results reveal that the Hg–C and Hg–X bonds are mainly contributed to from the covalent interaction of the 6s and 6p orbitals of the Hg atom with the C and X atoms. The 5d orbital of the Hg atom hardly contributes to these bonds, which is in conformity with the results that the 5d orbital has about 10 electrons, as has been described above.

Our MO method can give successful results for the electronic spectra, the electronic distribution, and the bond strength of the 5d transition metal complexes. It has been ascertained that this MO method is also useful in studying the electronic structures and the bonding nature of organometallic complexes.

These calculations were carried out with the FACOM 230-75 Computer of the Data Processing Center of Kyushu University.

49) As will be described below, the small a_{6p} value of the Hg atom gives good results. From the linear relation between the atomic number and the a_{6p} value (Fig. 1), the small a_{6p} value of the Ir atom brings about the large a_{6p} value of the Hg atom, which gives rather poorer results for $HgCl_4^{2-}$. Thus, the Ir's a_{6p} value is taken as 2.4 eV. For the a_{6s} value. if the Hg's a_{6s} value is taken as large (=2.0 eV) and that of the Ir atom as small (=1.2 eV), which gives rather good results, the slope of the linear line between the a_{6s} values and the atomic number is too high (=0.2) relative to that of the a_{5s} line (=0.11). The slope of the a_{6s} line in Fig. 1 is 0.1, which seems reasonable.

Singlet Excitation Energy Transfer in the Vinyl Polymers with Pendant Carbazolyl Groups

Akira ITAYA, Ken-ichi OKAMOTO, and Shigekazu KUSABAYASHI

Department of Chemical Engineering, Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube 755

(Received May 17, 1976)

The migration of electronic excitation energy in films of poly(*N*-vinylcarbazole) (PVCz) prepared by the radical and cationic polymerizations(PVCz(r) and PVCz(c) respectively), poly[2-(9-carbazolyl)ethyl vinyl ether] (PCzEVE), brominated PVCz(BPVCz), and poly(9-acryloylcarbazole) (PACz) has been studied by means of fluorescence-quenching experiments, using dimethyl terephthalate or perylene as a guest molecule. No clear difference in the concentration of the effective intrinsic trap sites was observed between PVCz(r) and PVCz(c) films. The concentration of the sandwich-like excimer site(c_E) in a PVCz(r) film was nearly equal to that in a PVCz(c) film, while the concentration of the second excimer site (c_S) in a PVCz(r) film was higher than that in a PVCz(c) film by a factor of about 1.6. The value of c_E was much larger than that of c_S for both films. The second excimer site seems to be a shallow trap. The number of carbazolyl chromophores covered by a singlet exciton during the lifetime was in the following order: PCzEVE$>$PVCz(r)$\approx$PVCz(c)$>$PACz$\approx$BPVCz. This order was explained by the concentration of the intrinsic trap sites depending on the distance between neighboring Cz chromophores, the lifetime of the singlet exciton, and the concentration of extrinsic trap sites.

Recently, the emission spectra of aromatic vinyl polymers have been extensively investigated. Studies of singlet energy transfer and migration in vinyl polymer films with large aromatic rings are very important in understanding their electric and optical properties. Klöpffer[1] has reported that the results of fluorescence-quenching experiments in an amorphous PVCz film are consistent with a hopping model of monomer exciton migration, in which excitons can migrate in a polymer film and both excimer-forming sites and guest molecules act competitively as exciton traps. From a lifetime quenching observed in PVCz film doped with perylene, Powell *et al.*[2] has recently proposed a model containing dimer sites besides guest molecules and excimer-forming sites. Concerning an undoped PVCz film, Offen *et al.*[3] suggested the presence of a dimer site as a result of measuring the fluorescence decay time of PVCz films at 77 K. Klöpffer *et al.*[4] showed that the two different types of the spectra were observed in the prompt fluorescence and phosphorescence at 77 K, independent of the polymerization methods.

Recently, we have ourselves revealed, from the NMR spectra and the glass-transition temperatures, that PVCz prepared by the cationic polymerization has a higher isotacticity than the PVCz prepared by the radical polymerization(PVCz(c) and PVCz(r) respectively).[5] It has also been reported that the difference in the tacticity of PVCz is reflected in the fluorescence spectra in fluid and rigid solutions and that the concentration of the second excimer site in a syndiotactic-rich polymer (PVCz(r)) is higher than that in an isotactic-rich polymer(PVCz(c)).[6] Therefore, it is of interest to investigate how the difference in the tacticity of PVCz samples affects the singlet-excitation-energy migration. The studies of singlet-excitation-energy migration in vinyl polymer films with carbazolyl(Cz) chromophores widely spaced on the skeletal chains is of interest in connection with that of PVCz films.

In the present research, we investigated the migration of the electronic-excitation energy in films of PVCz(r), PVCz(c), brominated PVCz(BPVCz), poly[2-(9-carbazolyl)ethyl vinyl ether] (PCzEVE), and poly(9-acryloylcarbazole) (PACz); in the latter two polymers, the Cz chromophores are widely spaced on the skeletal chains by $-O-CH_2-CH_2-$, and $-CO-$ bonds respectively. Dimethyl terephthalate (DMTP) or perylene was used as the guest molecule. In the case of perylene, the long-range resonant energy transfer is somewhat possible.[2,7] However, the long-range resonant energy transfer from a Cz chromophore to a DMTP molecule is quite impossible, because DMTP has no absorption in the wavelength region where the fluorescence of the PVCz film is observed.[7] Therefore, the DMTP is very useful in studying the phenomenon of the single-exciton migration.

Experimental

The vinyl polymers(PVCz(r), PVCz(c), BPVCz, PCzEVE, and PACz) were prepared by the methods described previously.[8,9] The DMTP and perylene were recrystallized twice from benzene and subsequently sublimed *in vacuo*. Doped films were cast onto quartz or Pyrex glass plates from a dichloroethane solution of the polymer containing a certain amount of the dopant and dried *in vacuo*. The thickness of the film was about 4 μm for PCzEVE and about 7 μm for the other polymers.

The fluorescence spectra were measured with the apparatus described in a previous paper.[8] The spectra at 293 K were measured for the coated plates *in vacuo* (0.1 Torr). The spectra at 77 K were measured for the coated plates immersed in liquid nitrogen. PACz films were excited by 315 nm light, and the others, by 335 nm light.

For the fluorescence-decay time measurements, the samples were excited with a N_2 gas laser. The sample fluorescence was chosen with appropriate glass filters before being detected by a biplanar phototube R 617. Responses from the phototube were led to a Tektronix 475 oscilloscope, and the decay curve was photographed.

Results and Discussion

Fluorescence Spectra of the Vinyl Polymer Films with Pendant Carbazolyl Groups. The fluorescence spectra of PVCz(r) and PVCz(c) films are shown in Figs. 1 and 2.

The difference in the spectra between PVCz(r) and PVCz(c) films observed at 293 and 77 K is similar to that observed in a fluid solution.[6] That is, the fluorescence intensity in the shorter-wavelength region of a PVCz(r) film is larger than that of a PVCz(c) film. Therefore, the emission band in the shorter-wavelength region was assigned to the second excimer fluorescence, and that in the longer wavelength region, to the sandwich-like excimer fluorescence. The fluorescence spectra of both polymer films were resolved into two individual

a) At 77 K.

bands. The resolution spectra thus obtained are also shown in Figs. 1 and 2. The intensity of the second excimer fluorescence relative to the sandwich-like excimer one and the fluorescence yields are listed in Table 1.

The presence of two kinds of emitting species in the fluorescence of PVCz(r) and PVCz(c) was also clarified by measuring the fluorescence decay curves of the polymers. The fluorescence decay curves of both polymer films in air at 293 K are clearly two-component (20 ± 3 and 6 ± 1 ns) in the shorter wavelength region, but one-component (22 ± 2 ns) in the longer wavelength region. The intensity of the short-lived component relative to the long-lived one for a PVCz(r) film in the shorter wavelength region is larger than that for a PVCz(c) film. Therefore, the long- and short-lived components correspond to the sandwich-like excimer fluorescence and the second excimer one respectively. Similar results were also obtained at 77 K; the long- and short-lived components are 17 ± 2 and 6 ± 2 ns respectively. These decay constants are roughly in agreement with the values reported by Powell *et al.* (20 and 10 ns).[2] The lifetime of the sandwich-like excimer fluorescence of PVCz films is shorter than that of PVCz in a fluid solution (*ca.* 40—42 ns)[6,10,11] and that of a PVCz film obtained by Offen *et al.* (43 ns).[3]

The fluorescence spectra of a PCzEVE film undoped and doped with DMTP are shown in Fig. 3. A PCzEVE film shows only a broad, structureless fluorescence spectrum with a peak at *ca.* 26050 cm^{-1}. The fluorescence decay curves in air are one-component in both the shorter and longer wavelength regions (4—5 and 10—11 ns respectively). A two-component decay curve is observed in the medium wavelength region. This fact indicates that the two kinds of emitting species are present in a PCzEVE film at 293 K. Although the fluorescence spectrum of a PCzEVE film at 77 K has the structure, it does not seem to be the monomeric fluorescence of a Cz chromophore because of the large Stokes shift (1540 cm^{-1}).

The fluorescence spectra of PACz and BPVCz films undoped and doped with DMTP or perylene are shown in Fig. 4. The fluorescence efficiency of a PACz film is extremely low (Table 1) because of the presence of the intersystem crossing from the lowest $^1\pi, \pi^*$ state to the lowest $^3n, \pi^*$ state due to a carbonyl group. A PACz film shows a fluorescence spectrum consisting of two components. The spectra of PACz and BPVCz films

change rapidly under irradiation by an exciting light.

Singlet Excitation Energy Transfer in the Vinyl Polymers with Pendant Carbazolyl Groups. The fluorescence spectra of PVCz(r), PVCz(c), and PCzEVE films doped with DMTP or perylene at 77 K are shown in Fig. 5. In the case of every polymer film studied at 293 and 77 K, by the doping of DMTP or perylene, the host fluorescence decreases and is replaced by the exciplex or guest fluorescence. The exciplex is formed between DMTP and a Cz chromophore. As DMTP has no absorption in the wavelength region where the host fluorescence of these polymers is observed, the dipole-dipole resonance cannot be responsible for the energy transfer to a DMTP molecule.[7] In fact, no decrease in the fluorescence lifetimes of PVCz(r) films upon doping of DMTP is observed. That is, the fluorescence lifetimes in the shorter-wavelength region of PVCz(r) films doped with a small amount of DMTP (*ca.* 3×10^{-3} mol/mol basic

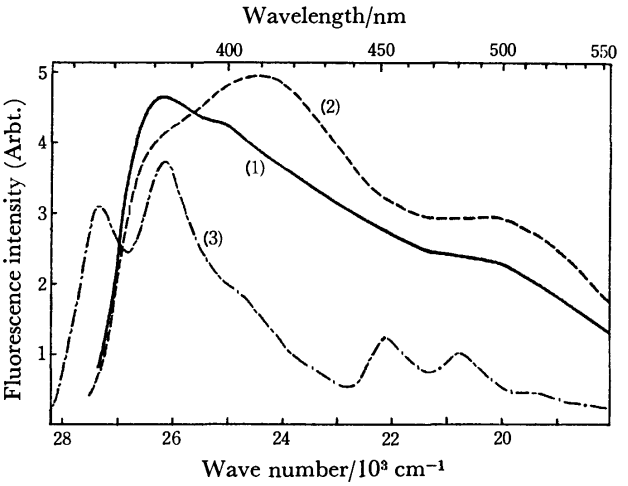

Fig. 5. Fluorescence spectra of PVCz(r), PVCz(c) and PCzEVE films doped with DMTP or perylene at 77 K. (1) PVCz(r) doped with DMTP (3.26×10^{-3} mol/VCz unit mol), (2) PVCz(c) doped with DMTP (3.02×10^{-3} mol/VCz unit mol), and (3) PCzEVE doped with perylene (1.15×10^{-4} mol/CzEVE unit mol).

unit) are 17 ± 3 and 5 ± 2 ns at 293 K and 19 ± 2 and 6 ± 1 ns at 77 K.

In the present case, therefore, the hopping model of monomer-exciton migration is applicable at 293 and 77 K. We should consider the case of the presence of two kinds of traps (for example; the sandwich-like excimer-forming sites, c_E [mol/mol basic unit], and the second excimer sites, c_S [mol/mol basic unit], in the case of a PVCz film) in a way similar to the treatment in Ref. 1. Then, the quenching factor of host fluorescence, Q_H, is expressed by the following equations:

$$Q_H = (\eta_{H,0} - \eta_H)/\eta_H = 0.66nc/[1 + 0.66n(c_E + c_S)],$$
$$n = n_S/(n_e + n_l)$$

where n_S, n_e, and n_l are the relative probabilities (per unit time) of jumping, radiative, and nonradiative decay, where $\eta_{H,0}$ and η_H are the quantum efficiencies of the host fluorescence in the absence and in the presence of the guest molecule in a concentration of c [mol/mol basic unit], and where n is the number of jumps during the lifetime without any trapping sites. The quenching factor of monomer fluorescence, Q_M, may be expressed by:

$$Q_M = 0.66n(c_E + c_S).$$

In the present case, where no monomer fluorescence can be observed, $Q_M \gg 1$. Therefore,

$$Q_H = c/(c_E + c_S). \quad (1)$$

The ratio of the fluorescence intensities guest/host (I_G/I_H) is:

$$I_G/I_H = c\eta_G/(c_E\eta_E + c_S\eta_S), \quad (2)$$

where η_G is the quantum efficiency of the guest fluorescence in the host film under direct excitation. The relative intensity of the second excimer fluorescence to the sandwich-like excimer one is expressed by

$$I_S/I_E = c_S\eta_S/c_E\eta_E. \quad (3)$$

Although the experimental values of Q_H scatter a little, the measurement of Q_H at various concentrations of a

a) The errors in (c_E+c_S) and n' are $\pm 5\%$ at 293 K and $\pm 10\%$ at 77 K. The error in $(I_G/I_H c)$ is $\pm 3\%$. b) At 77 K. c) The values are less reliable because of the large error in the I_S obtained by a resolution of the host fluorescence spectrum. d) $L=an'^{1/2}$, where L is the mean exciton migration length and a is the interchromophore separation (3.5 Å). e) The value were obtained from the value of Q_H, on the assumption that the fluorescence in the shorter and longer wavelength regions is emitted by some intrinsic trap site and an excimer respectively. f) The values were obtained from the ratio of $(I_G/I_H c)$, on the assumption that the fluorescence in the shorter and longer wavelength regions is emitted by a monomer and an excimer respectively. g) The values were obtained in a way similar to that used in the treatment in Ref. 1, on the assumption that the host fluorescence is emitted by one trap site.

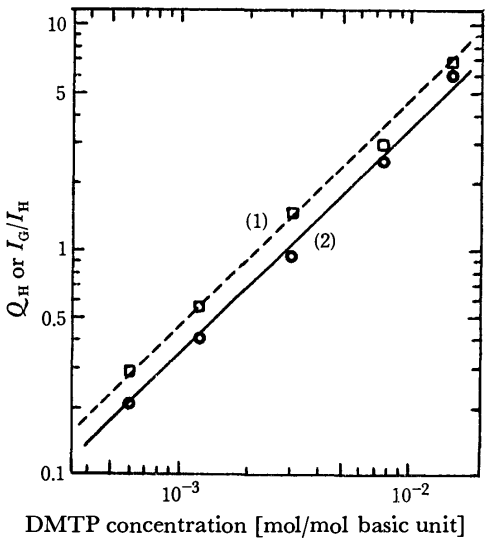

Fig. 6. Ratio of fluorescence intensities guest/host I_G/I_H (1) and quenching factor of host fluorescence Q_H (2) as a function of guest concentration for PVCz(c)-DMTP system at 293 K.

guest gives the values of c_E+c_S according to Eq. 1. The measurement of I_G/I_H at various concentrations of a guest gives the values of $c_E\eta_E$ and $c_S\eta_S$ according to Eqs. 2 and 3, using the values of η_G and I_S/I_E in Tables 1 and 2. Figure 6 shows the bilogarithmic plots of Q_H or I_G/I_H thus obtained and c, as example, in the case of the PVCz(c)-DMTP system. The values thus obtained are listed in Table 2.

In the case of the PVCz(r) and PVCz(c) films, the values of c_E+c_S, $c_E\eta_E$, and $c_S\eta_S$ are obtained by the method mentioned above. The value of c_E+c_S at 293 K is nearly equal to the value of c_E obtained by Okamoto *et al.* in a PVCz(r)-DMTP system, on the assumption that the host fluorescence is emitted only from the sandwich-like excimer.[7)] The value of c_E+c_S is almost the same for a PVCz(r) film and for a PVCz(c) film. The number of Cz chromophores covered by an exciton during the lifetime in the presence of trap sites (abbreviated hereafter to n') is nearly equal to the reciprocal of the concentration of the traps, $[1/(c_E+c_S)]$. This number is almost the same for a PVCz(r) film and for a PVCz(c) film. The value of $c_E\eta_E$ is almost the same for a PVCz(r) film and for a PVCz(c) film, while the value of $c_S\eta_S$ for a PVCz(r) film is higher than that for a PVCz(c) film. It can safely be considered that the fluorescence efficiencies of each fluorescence (η_E and η_S) of PVCz(r) are equal to those of PVCz(c). Therefore, the concentration of the sandwich-like excimer sites (c_E) in a PVCz(r) film is nearly equal to that in a PVCz(c) film. On the other hand, considering that the value of $c_S\eta_S$ for a PVCz(c) film at 293 K is less reliable, the concentration of the second excimer sites (c_S) in a PVCz(r) film is higher than that in a PVCz(c) film by a factor of about 1.6. This difference in the value of c_S does not clearly appear in the value of c_E+c_S. This fact suggests that the value of c_E is larger than that of c_S in both films.

The values of $c_E\eta_E$ for PVCz(r) and PVCz(c) films obtained at 77 K are larger than those obtained at 293 K by a factor of 4. It may safely be considered that the values of η_E and η_S for a PVCz(r) film change with the temperature in a manner similar as that for a PVCz(c) film. The value of c_E is considered to be determined by the casting temperature(T_{cast}) of the film because of the high glass-transition temperature of PVCz. Therefore, this increase in the value of $c_E\eta_E$ seems to be caused by a change in the value of η_E. On the other hand, the value of $c_S\eta_S$ obtained at 77 K is much larger than that obtained at 293 K. This increase in $c_S\eta_S$ with a decrease in the temperature is too large to be caused only by an increase in η_S. The value of c_S might be considered to vary apparently with the measuring temperature. In the previous paper, we have reported that the second excimer has a small binding energy.[6)] Therefore, this increase in $c_S\eta_S$ might be explained by the assumption that the second excimer site is a shallow trap. That is, the second excimer site acts more effectively as a trap at low temperatures.

It has been reported in a previous paper that the concentration of the trap sites for a triplet exciton in a

PVCz(c) film is somewhat larger than that in a PVCz(r) film.[8] On the other hand, as has been mentioned above, the concentration of the trap sites for a singlet exciton in a PVCz(c) film is nearly equal to that in a PVCz(r) film. This suggests that the conformation of intrinsic trap sites is not necessarily the same for singlet and for triplet excitons. This explanation might be supported by the presence of a conformational difference between the singlet and triplet excimers of 1,3-di(1-naphthyl)propane.[12]

The migration frequency, k'_{mig}, for the triplet exciton was estimated from the following equation:

$$k'_{mig} = 6\Lambda/a$$

where a is the interchromophore separation and Λ is the migration coefficient; the coefficients have been tabulated in Ref. 8. Assuming that $a=3.5$ Å, then $k'_{mig}=6\times10^3$ and 3.3×10^3 s^{-1} for PVCz(r) and PVCz(c) films. Therefore, the number of Cz chromophores covered by the triplet exciton during the lifetime ($2\tau_{df}$) are 600 and 330 for PVCz(r) and PVCz(c) films respectively. Although the conformation of intrinsic trap sites seems to be different for singlet and triplet excitons, the number of the Cz chromophores covered by both excitons in both PVCz films during the lifetimes ranges from 300 to 600 and the mean exciton diffusion length ranges from 60 to 80 Å.

The fluorescence of a PCzEVE film is also emitted from two kinds of traps, as has been mentioned above. The value of c_E+c_S for a PCzEVE film is much smaller than those for the PVCz(r) and PVCz(c) films. This suggests that it is difficult for Cz chromophores to form intrinsic trap sites because of the large distance between neighboring Cz chromophores. The value of n' for a PCzEVE film is expected to be smaller than the values of n' for PVCz(r) and PVCz(c) films, judging from the large distance between neighboring Cz chromophores. However, even in the case of a PCzEVE film, $Q_M \gg 1$, that is, the singlet exciton migration is limited by the intrinsic trap sites. Therefore, the value of n' for a PCzEVE film is larger than that for a PVCz film by a factor of *ca.* 5.

In the cases of the PACz and BPVCz films, the emitting species of the host fluorescence are ambiguous. Judging from the profile of the fluorescence spectrum of a PACz film, the broad fluorescence band with a peak at *ca.* 25000 cm^{-1} might be assigned to the excimer fluorescence. The fluorescence band in the shorter wavelength region might be attributable to a monomer or to some intrinsic trap site. The host fluorescence of a BPVCz film is considered to be emitted from some trap site. Irrespective of the treatments used to obtain the value of n' (Table 2), the values of n' for both polymer films are very small. This may be attributable to the short exciton lifetime because of the enhanced intersystem crossing and the presence of extrinsic trap sites(photoproducts and/or impurities introduced during a bromination reaction).

The number of Cz chromophores covered by a singlet exciton during the lifetime was in the following order; PCzEVE>PVCz(r)≈PVCz(c)>PACz≈BPVCz.

This work was supported in part by a Scientific Research Grant of the Ministry of Education.

Steric Effects of Alkyl Substituents on the N-H Stretching Absorptions and Rotational Isomerism of *N,N'*-Dialkylthioureas[1]

Yoshiyuki MIDO, Takashi YAMANAKA, and Ryoichi AWATA

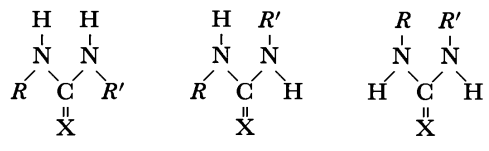
Department of Chemistry, Faculty of Science, Kobe University, Nada, Kobe 657

(Received May 21, 1976)

The fundamental N-H stretching absorptions of twenty nine *N,N'*-dialkylthioureas were observed in dilute solutions. The observed frequencies were classified into five groups assignable to the *out*, three different types of the *trans*, and the *cis* forms. The steric hindrance between the bulky *t*-butyl group and the thiocarbonyl sulfur, which is larger than for *N,N'*-dialkylureas, was suggested to cause the *out* form. Dialkylthioureas of *R*TU*t*B type seem to exist to a great extent in the *trans-out* conformation in solutions. It is suggested that it is not the N-H group with the bulky *t*-butyl group but the N-H group in the opposite part which is out of the skeletal plane. The energy difference between the *out* and the *trans* forms was found to be $\Delta H = 430 \pm 100$ cal mol^{-1}.

A number of studies have been carried out to elucidate the rotational isomerism of secondary amides in solutions in connection with the backbone-structures of polypeptides and proteins.[2,3] It was disclosed that the steric hindrance between two substituents and the C=X group (X=O or S) plays an important part in the isomerism.

On the other hand, some infrared studies of *N,N'*-disubstituted ureas (*R*U*R'*) and -thioureas (*R*TU*R'*) suggested the presence of *trans-cis* isomerism in solutions.[2,4,5] The isomeric conformations were considered to be the *trans-trans* and the *trans-cis* conformations since the *cis-cis* conformation was unlikely on steric grounds. Nevertheless, percentages of over 50% of the *cis* form[6] were estimated for the ureas with bulky groups; *s*-D*t*BU[4] and *s*-DPhU.[2] For the corresponding thioureas with the sulfur atom larger in effective size than the oxygen atom, *s*-D*t*BTU[5] and *s*-DPhTU,[2] the percentages of the *cis* form were estimated to be approximately 50 and 45%, respectively.



In systematic infrared studies on *R*U*R'* in solutions a correlation was found between the N-H frequencies and *R* and *R'*, the presence of a very small amount of a form differing from the *trans* form in *R*U*R'* being confirmed with either one *t*-butyl group or two.[7-10] From an examination of the infrared spectra of trialkylureas (D*R*U*R'*) in solutions it was suggested that the different form has the N-H group out of the skeletal plane (the *out* form) owing to the steric hindrance between the bulky substituents and the C=O group.[11] This necessitates a re-examination of the study of *R*TU*R'*.

The purpose of this study is (1) to examine the applicability of our established correlation to *R*TU*R'*, (2) to confirm an increase in the amount of the *out* form caused by the larger steric hindrance in *R*TU*R'* with a sulfur atom than that in the corresponding *R*U*R'* with an oxygen atom, and (3) to obtain information on the *out* form.

Experimental

Twenty nine *R*TU*R'* were prepared by the standard method (addition of *R*CNS to *R'*NH$_2$).[12] The crude samples were purified by repeated recrystallization from suitable solvents. The purified samples were identified by their melting points and infrared spectra. Each sample was examined as a 10^{-3} M solution in CCl_4 (2 cm NaCl cell) and as a 10^{-2} M solution in CS_2 and in $CHCl_3$ (2 mm NaCl cell). Solvents of spectroscopic grade were used.

The spectrometer, the experimental conditions in the recording of the spectra, and the calibration of band-positions were the same as given previously.[7] The spectra at different temperature were obtained with an electrically-heated and beam-transparent box in which the sample and the reference cells were placed and adjusted to each light axis.

Results and Discussion

Two fundamental N-H stretching bands from two N-H links should appear in the infrared spectra of *R*TU*R'* in the absence of rotational isomerism. However, in some spectra one or two extra bands are observed suggesting the rotational isomerism in solutions (Fig. 1). We examined some possibilities of over- and combination tones, and of Fermi resonance[13] for the extra bands. It was concluded from observation of the solution spectra of deuterated compounds that the extra bands are really the N-H fundamentals, and from comparison of the solution spectra with the solid spectra that there may be a little or no effect of Fermi resonance in such dilute solution.[14] We classified the observed bands into five groups, A—E, according to wave number (Table 1).

The trans *N-H Bands.* Although the N-H bands of *R*TU*R'*, as a whole, are lower by about 15 cm^{-1} than those of *R*U*R'*, three of the classified five groups, B, C, and D, correspond to the three groups characteristic of a substituent of the *trans-trans R*U*R'*;[7] the N-H group with a methyl group shows the highest frequency band, the group with other primary alkyl groups exhibits medium one,[15] and the group with branched alkyl groups shows the lowest one.

In connection with such a correlation it can be understood that, for example, the two bands of MTU*s*B result from two different types of N-H group; the higher com-

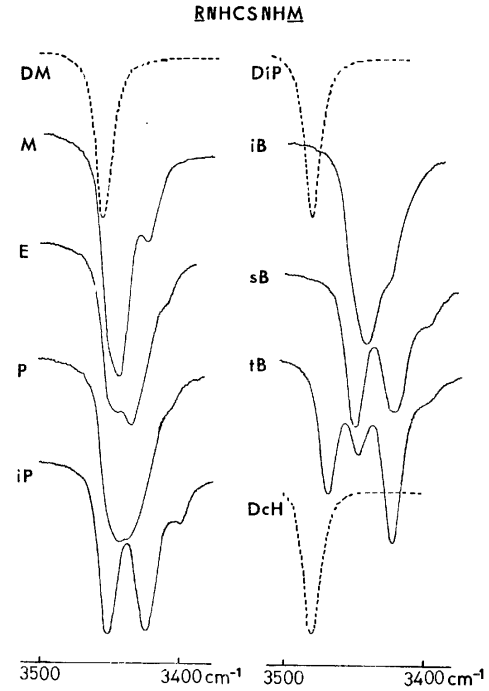

Fig. 1. The infrared spectra in the N-H stretching region of *R*TUM (the solid line) and D*R*TUM (the broken line) in CCl_4. *R*: see the abbreviations in Table 1; *c*H: cyclohexyl.

ponent resulting from the N-H group with the methyl group, and the lower component from the N-H group with the *s*-butyl group. In the case of the *R*TU*R'* showing only one band, the two components from the two different types of N-H group may be closer than those in the above example, or may overlap each other, thus appearing as only one band. This is suggested by the fact that *R*TU*R'* with only slightly different components such as MTUP (combinations of the B and C groups) give a band with lower apparent optical density and with larger half-intensity width than *R*TU*R'* with overlapped components such as *s*-DMTU (combinations of two groups belonging to the same type), as shown in Fig. 1.

It is concluded that these three kinds of bands originate from the *trans* form, and that the established *trans*-correlation for *R*U*R'* is applicable to *R*TU*R'*.

Out *N-H Bands.* Band A appears at the highest frequency and with medium or strong intensity without exception in *R*TU*R'* with a *t*-butyl group or groups. It probably corresponds to the very weak band at 3469 cm^{-1} of *s*-D*t*BU,[7] to the bands of *R*U*t*B which appear newly when the solvent is changed from CCl_4 to $CHCl_3$,[8] and to the 3478 cm^{-1} band of D*c*HU*t*B, being assignable to the *out* form.[11] It is suggested that the larger X atom of *R*TU*t*B enhances the steric hindrance between substituent and C=X group in comparison with *R*U*t*B since band A of *R*TU*t*B appears always and more

strongly than the corresponding band of *R*U*t*B.

Taking into account the N-H frequencies of D*R*U*R'* higher than those of *R*U*R'*,[11] the spectra of D*R*TU*R'* (broken lines, Fig. 1) indicate that DMTUM exist completely as the *trans* form, while D*i*PTUM and D*c*HTUM exist completely as the *out* form. It is concluded that the assignment of band A to the *out* form is reasonable from a steric point of view.

Out-of-plane N-H Group. The *out* N-H frequencies seem to be sensitive to the opposite alkyl group, *R*, in *R*TU*t*B; *R*TU*t*B with *R*=M or *i*B being the highest in frequency, *R*=other primary alkyls medium, and *R*=branched alkyls the lowest. The situation was the same for all three solvents.[16] MTU*t*B shows three bands and a shoulder E (Fig. 2). We assign band A=the *out*, B=the *trans* methyl, and D=the *trans* *t*-butyl N-H absorptions. Band B (the *trans* methyl) is considerably weaker than band D (the *trans* *t*-butyl), although in the absence of isomerism the *trans* methyl band of *RUR'*[9] and of secondary amides[17] have larger molar extinction coefficients than the other *trans* bands.

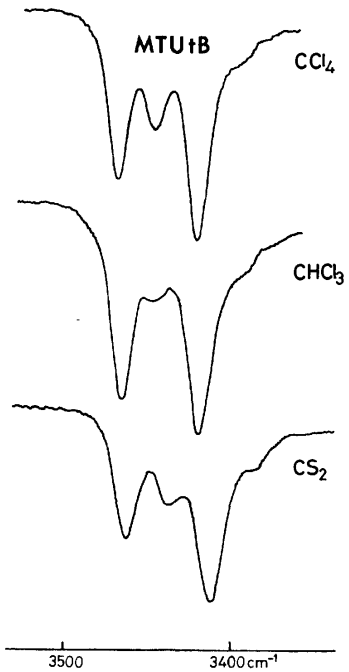

Fig. 2. Solvent effects on the infrared spectra of MTU*t*B.

By changing the solvent from CCl_4 to $CHCl_3$ the intensity of band A seems to increase at the expense of the weak band B (Fig. 2). The two bands were observed to be temperature dependent but in the opposite direction to each other. Other *R*TU*t*B with *R*=E, P, *i*B, and B were expected to show bands C and D. However, band C did not appear even as a shoulder. The component of band C is considered to be weakened by the appearance of band A.

From the facts mentioned above it is suggested that it is not the N-H group with the bulky *t*-butyl group but the N-H group in the opposite part that is predominantly out of the skeletal plane, though this seems to be unlikely. However, the suggestion may have validity if we consider that it is not the bulkiness of the substituent attached to the one N-H group, *R'*, but that of the opposite substituents, D*R*, in D*R*U*R'* that plays an important role in the rotational isomerism.[11] This can be interpreted in terms of the steric hindrance between the *t*-butyl group and the sulfur atom, and of the stronger electron-releasing inductive effect of the *t*-butyl group. The hindrance may weaken the resonance effect of the skeleton. While the inductive effect, which would be expected to increase the electron density on the nitrogen atom, may strengthen the double-bond character on the N-C link with the *t*-butyl group more strongly than that on the other N-C link. Accordingly, these effects would make only the N-H link with the *R* group out-of-plane (the *trans-out* conformation).

The amount of the *trans-out* conformation was roughly estimated from band-intensity data; (*R* in *R*TU*t*B, %) M or *i*B, 60%; E, P, or B, 70%; *i*P or *s*B, 75%; and *t*B (=*s*-D*t*BTU), 90%.

Energy Difference. We carried out the analysis on the *trans-out* equilibrium using the 3452 (the *out*) and 3418 cm^{-1} (the *trans*) bands of *s*-D*t*BTU in CCl_4 (15.5—85.3 °C). Each band-intensity curve was in good agreement with the corresponding Lorentz curve calculated for bands A and D except for a slight deviation on the lower frequency side of band D. The presence of band E (O. D. <0.05) and the slope of the overtone band near 3150 cm^{-1} (O. D. <0.02 at 3400 cm^{-1}) were analyzed to give the deviation. The energy difference between the *out* and the *trans* forms was found to be $\Delta H=430\pm100$ cal mol^{-1} from area-intensity data ($\Delta H=380\pm100$ cal mol^{-1} from peak-intensity data). The ΔH value is consistent with the value 500 ± 200 cal mol^{-1} of Rao *et al.*[5] for the *cis-trans* forms estimated in the first N-H overtone region.

Band E. Most of the spectra of *R*TU*R'* have this band as a shoulder. By examining the solution spectra at different temperatures and concentrations, band E was confirmed to be no associated band, being assignable to the N-H vibration from a certain form in a rotational isomer, probably the *cis* form. Despite some uncertainty in frequency the band of *R*TU*R'* with both primary alkyl groups is slightly higher than that of the other *R*TU*R'*.

The authors wish to express their thanks to Mr. M. Watanabe for his assistance.

Photochemistry in the Adsorbed Layer. VIII. Lifetimes of Excited Alkyl Ketones and Alkyl Radicals Adsorbed on Porous Vycor Glass

Masakazu ANPO, Toshiaki WADA, and Yutaka KUBOKAWA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Mozu-Umemachi, Sakai, Osaka 591

(Received June 7, 1976)

The photolyses as well as the absorption spectra of adsorbed 3-methyl-2-butanone and 3-methyl-2-pentanone have been investigated in the presence and absence of nitrogen monoxide. The Stern-Volmer relationship was applied to the decrease in the rate of photolysis caused by addition of nitrogen monoxide. From the results together with those for acetone, 2-butanone, and 2-pentanone, it has been concluded that in the adsorbed layer the more blue shifted, *i.e.*, the more strongly hydrogen bonded to the surface OH groups a ketone molecule, the shorter the lifetime of its excited state. It has been found that the lifetime of the alkyl radical on the surface increases with the decrease in its ionization potential, leading to the decrease in the strength of its interaction with the surface. Special features of the photolysis in the adsorbed layer have been described for 3-methyl-2-butanone photolysis.

In spite of its importance in many problems,[1] photochemistry in the adsorbed layer appears to be one of the most unexploited fields in photochemistry. We have investigated the photolysis of alkyl ketones such as acetone, 2-butanone, and 2-pentanone adsorbed on porous Vycor glass, as regards general characteristics of the photochemistry in the adsorbed layer, *e. g.*, the enhanced type I selectivity for the ketones having γ-hydrogen atoms, the importance of the reaction of the geminate radical pairs formed in the primary process, and the contribution of surface OH groups to the photochemical reactions.[2-8] Some information on the relative lifetimes of the excited triplet states as well as the radicals on the surface has been obtained from the effect of the addition of nitrogen monoxide upon the photolyses. In the present work, similar studies have been extended to 3-methyl-2-butanone and 3-methyl-2-pentanone in order to obtain more general information on the relative lifetimes of those species as well as the characteristics of the photolysis of adsorbed alkyl ketones.

Experimental

Materials. Commercial compounds (Tokyo Kasei Co., Ltd., Grade SG) were purified by means of preparatory chromatography, and then vacuum distilled bulb-to-bulb. Only those fractions were used which contained less than 0.5% impurity as determined by means of a vapor-phase chromatograph equipped with a flame ionization detector and a polyethylene glycol 1500 column. Porous Vycor glass (Corning, No. 746685-7930) was used as an adsorbent.

Apparatus and Procedure. Details of the apparatus and procedure used in the photolysis in the adsorbed layer were reported.[2-8] A conventional vacuum system was used in conjunction with a special quartz cell capable of studying the spectra and photolysis in the adsorbed layer. The specimen of porous Vycor glass, which had been heated in oxygen to remove carbonaceous impurities, was introduced into the cell and degassed at 500 °C for 7 h. After a certain amount of ketone had been adsorbed on the specimen, photolysis was carried out using an ultra high pressure mercury lamp without filter. Gas phase photolysis was carried out in a cylindrical quartz cell under the same irradiation conditions. The analytical system consisted of three traps and a modified Ward still. The gaseous products were separated by fractional distillation and analyzed by gas-chromatography using a flame ionization detector.

The absorption spectra of adsorbed ketones were determined with a Hitachi EPS 3T type spectrophotometer, measuring transmission through the sample. A quartz cell was placed just before the photomultiplier in order to minimize scattering error. Another porous Vycor glass sample was pretreated under the same conditions in a separate cell and used as a blank in the reference beam. The spectra of the adsorbed ketones increased in intensity proportional to the amounts adsorbed without changes in relative intensity for the bands from 250 to 340 nm.

Results

Photolysis of Adsorbed 3-Methyl-2-Butanone. The major products in the gas phase photolysis of 3-methyl-2-butanone (3-M-2-B) are propylene, propane, and hexane (Table 1). The following processes can be proposed[9,10] for the formation of these products.

$$i\text{-}C_3H_7COCH_3 + h\nu \longrightarrow \begin{cases} i\text{-}\dot{C}_3H_7 + \dot{C}OCH_3 \\ i\text{-}C_3H_7\dot{C}O + \dot{C}H_3 \end{cases} \quad (1)$$

$$i\text{-}\dot{C}_3H_7 + i\text{-}\dot{C}_3H_7 \longrightarrow C_3H_6 + C_3H_8 \text{ or } C_6H_{14} \quad (2)$$

where reaction (1) is α-cleavage of alkyl ketones (type I reaction) and reaction (2) is disproportionation or combination reaction of isopropyl radicals. The rate of propylene formation is larger than the rate of propane formation. Such behavior was found by Zaha and Noyes[9] who attributed it to the occurrence of the following reaction.

TABLE 1. RELATIVE YIELD OF PRODUCTS FROM PHOTOLYSIS OF 3-METHYL-2-BUTANONE AT 25°C

	CH_4	C_2H_6	C_3H_6	C_3H_8	C_4H_{10}	C_6H_{14}
Adsorbed layer[a]	0.005	0.001	10.9	88.7	$<$0.001	$<$0.001
Vapor phase[b]	0.015	6.50	42.1	24.1	5.80	19.4

a) Amount of adsorbed 3-methyl-2-butanone, 8.5×10^{-5} mol/g. Conversion per h, 12—15%. Irradiation time, 15—30 min. b) 3-Methyl-2-butanone pressure, 13.0$\pm$0.5 Torr.

$$\dot{R} + i\text{-}C_3H_7COCH_3 \longrightarrow RH + C_3H_6 + CH_3\dot{C}O \quad (3)$$

where R stands for any radicals formed in the primary processes.

In the adsorbed layer photolysis the rate of propane formation is much larger and that of propylene formation much smaller as compared to the corresponding values in the gas phase photolysis. Previous works[4,6] on the photolysis of adsorbed acetone or 2-pentanone show that methane or propane arises from hydrogen abstraction from the surface OH groups by methyl or propyl radicals as well as the disproportionation of the geminate radical pairs such as

$$\dot{C}H_3 + CH_3\dot{C}O \longrightarrow CH_4 + CH_2CO.$$

The reaction of alkyl radicals formed in the primary process with the ketone molecules hardly takes place. A similar situation would be expected for the propane and propylene formation from the photolysis of adsorbed 3-M-2-B. Thus, it can be concluded that in the adsorbed layer the contribution of reaction (3) to the propylene formation is negligible, most part of propylene arising from disproportionation reaction of the geminate radical pairs. It should be noted that the amounts of the radical recombination products such as ethane or hexane are very small in the adsorbed layer. Such behavior is one of the general characteristics of the photolysis of adsorbed alkyl ketones.[4]

In contrast to 3-M-2-B, 3-methyl-2-pentanone (3-M-2-P) undergoes the type II as well as the type I reaction, since it has a γ-hydrogen atom. The most significant feature of its photolysis in the adsorbed layer is a marked enhanced type I selectivity as compared to that in the gas phase photolysis. Details were previously reported[8] (Table 2).

Effect of the Addition of Nitrogen Monoxide upon Photolysis. In order to study the nature of the excited states as well as the radicals formed in the photolysis the effect of the addition of nitrogen monoxide on the photolysis of adsorbed 3-M-2-B and 3-M-2-P has been investigated. In the photolysis of the latter the rate of ethylene formation decreases with increase in the nitrogen monoxide pressure, levelling off to a constant value (Fig. 1). Considering the fact that nitrogen monoxide is an efficient triplet quencher, the amount of quenchable reaction (57%) can be attributed to reaction from the excited triplet state with the remainder of the reaction (43%) occurring from the excited singlet state. A similar nonquenchable fraction of the ethylene formation (44%) has been obtained with the photolysis of adsorbed 2-pentanone in the presence of nitrogen monoxide.[2]

The rate of propane formation from 3-M-2-B as well as that of butane formation from 3-M-2-P decreases markedly with increasing nitrogen monoxide pressure,

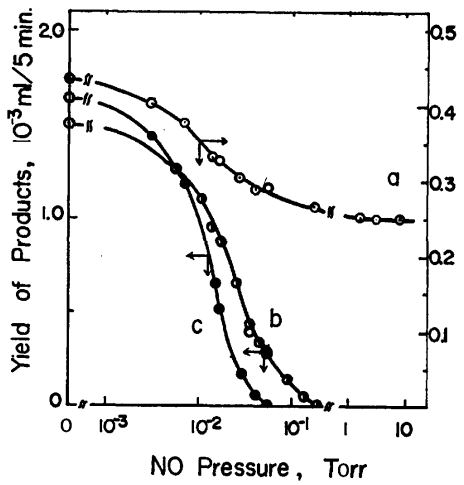

Fig. 1. Effect of nitrogen monoxide upon the rates of photolyses of 3-methyl-2-butanone and 3-methyl-2-pentanone adsorbed on porous Vycor glass.
The amounts of 3-methyl-2-butanone and 3-methyl-2-pentanone adsorbed were 7.5×10^{-5} and 8.5×10^{-5} mol/g, respectively. During the photolysis nitrogen monoxide was somewhat consumed; It was confirmed, however, that the resulting pressure decrease did not affect the value of the constants A and B in the Stern-Volmer equation. a: Ethylene (3-M-2-P), b: propane (3-M-2-B), c: butane (3-M-2-P).

finally approaching zero around 0.10 Torr for propane and 0.06 Torr for butane, as expected from the action of nitrogen monoxide as a radical scavenger (Fig. 1). In addition to such scavenging action, the decrease in the rate of formation is caused by quenching of the excited states with nitrogen monoxide.

Discussion

The photolysis of adsorbed 3-M-2-B and 3-M-2-P in the presence of nitrogen monoxide is as follows. Reactions (3) and (7) are included only in the case of 3-M-2-P.

$$P + h\nu \longrightarrow {}^1P$$

$$^1P \xrightarrow{k_1} P + \text{heat} \quad (1)$$

$$^1P \xrightarrow{k_2} \dot{R} + \dot{C}OR' \quad (2)$$

$$^1P \xrightarrow{k_3} C_2H_4 + CH_3COCH_3 \quad (3)$$

$$^1P \xrightarrow{k_4} P + h\nu' \quad (4)$$

$$^1P \xrightarrow{k_{isc}} {}^3P \text{ (isc)}$$

$$^3P \xrightarrow{k_5} P + \text{heat} \quad (5)$$

Table 2. Relative yield of products from the photolysis of 3-methyl-2-pentanone at 25°C

	C_2H_4	C_3H_8	C_4H_8	C_4H_{10}	C_5H_{12}	C_6H_{14}	type I/II
Absorbed layer[a]	14.1	4.12	3.19	72.6	2.90	3.12	6.0
Vapor phase[b]	73.3	3.15	1.14	12.2	4.18	6.01	0.35

a) Amount of adsorbed 3-methyl-2-pentanone, 4.5×10^{-5} mol/g. Conversion per h, 10—15%. Irradiation time, 15—30min. b) 3-Methyl-2-pentanone pressure, 18.0 ± 0.5 Torr. The selectivity of type type I was identified as follows; $I/II=(\phi_{C_1}+\phi_{C_4}+\phi_{C_5}+\phi_{C_6})/\phi_{C_4H_8}$.

Table 3. Values of A (τk_9) and B ($\tau' k_{11}$) for nitrogen monoxide quenching (M^{-1})

	Acetone[a)]	2-Butanone[a)]	3-Methyl-2-butanone	2-Pentanone[a)]	3-Methyl-2-pentanone

$$\dot{R} + NO \xrightarrow{k_{11}} RNO \longrightarrow \text{Stabilized} \quad (11)$$

$$\dot{R} + R'\dot{C}O \xrightarrow{k_{12}} \text{Recombination or disproportionation products} \quad (12)$$

The α-cleavage from the excited singlet state (reaction 2) can be neglected,[2] since there exists a striking difference in the reactivity of the excited singlet and triplet states toward α-cleavage of alkyl ketones.[11] Thus, the following quadratic Stern-Volmer equation is obtained by the steady state treatment for propane formation from 3-M-2-B and butane formation from 3-M-2-P.

$$Q_0/Q = (1+A[NO])(1+B[NO]) \quad (I)$$

where $A=k_9/(k_5+k_6+k_7+k_8)$, $B=k_{11}/([H]k_{10}+[R'CO]k_{12})$. Q and Q_0 are the rates of propane or butane formation in the presence and absence of nitrogen monoxide, respectively. The plot of Q_0/Q against nitrogen monoxide pressure is shown in Fig. 2. Constants A and B for both ketones are so determined to give the best fit to the experimental curves[2] (Table 3). Values of A and B for other ketones are also given in Table 3.

In the photolysis of 3-M-2-P, ethylene is formed from the singlet as well as the triplet state. The following equation holds for the rate of ethylene formation from the triplet state, which is determined by subtracting the nonquenchable amount of ethylene formed with nitrogen monoxide present from the total amount of ethylene formed without nitrogen monoxide present.

$$Q_0/Q = (1+A'[NO]) \quad (II)$$

where Q and Q_0 are the rates of ethylene formation from the excited triplet state in the presence and absence of nitrogen monoxide, respectively. From the slope of the Stern-Volmer plot (Fig. 2) the value of A' is found to be 5.2×10^5 l/mol, in agreement with that obtained from equation (I). This supports the assumption that the formation of propane and butane from the excited singlet state can be neglected.

Lifetime of Excited Ketone Molecules. The wavelengths of maximum absorption of (n, π^*) transition of adsorbed 3-M-2-B and 3-M-2-P together with the corresponding values of other ketones[3] are given in Table

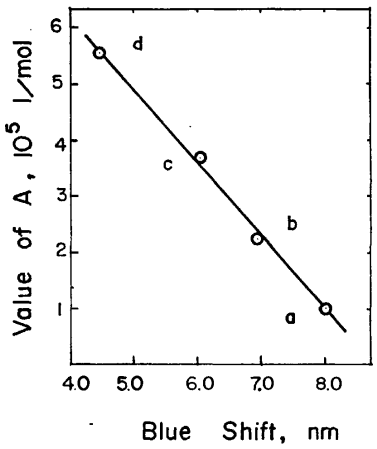

Fig. 3. The relationship between values of A and blue shift. The blue shift was identified as follows; $\Delta E=$ (λ_{max} on Vycor glass) − (λ_{max} in heptane).
a; 2-Butanone, b; 3-M-2-B, c; 2-pentanone, d; 3-M-2-P.

Table 4. Wavelengths of maximum absorption of alkyl ketones adsorbed on porous Vycor glass at 25 °C (nm)

	Acetone	2-Butanone	3-Methyl-2-butanone	2-Pentanone	3-Methyl-2-pentanone
$\lambda_{max.}$ on vycor glass	262.0	270.0	276.0	273.0	280.0
$\lambda_{max.}$ in heptane	276.5	278.0	283.0	279.0	284.5

Table 5. Relative lifetime of the alkyl radicals in the adsorbed layer (M^{-1})

	Methyl	Ethyl	Propyl	Isopropyl	*s*-Butyl
B ($\tau' k_{11}$)	0.054×10^6	0.24×10^6	4.9×10^6	6.1×10^6	7.0×10^6
Relative lifetime	1	11	1100	2800	6400

4. The blue shift of the (n, π^*) bands decreases in the order acetone>2-butanone>3-M-2-B>2-pentanone> 3-M-2-P. Values of A also decrease in the same order (Table 3). A linear relation exists between the values of A and blue shift (Fig. 3). The magnitude of A is mainly determined by the rate of radiationless deactivation k_5, *i.e.*, $k_5 \gg (k_6+k_7+k_8)$.[2] Thus, the results confirms the conclusion that the more blue shifted the ketone molecule, *i.e.*, the more strongly hydrogen bonded to the surface OH groups, the more efficient the radiationless deactivation (k_5).[2]

It is well-known[12] that there is a marked difference between the excited and ground states in the geometry, *e. g.*, the ground state of HCHO is planar, while in its excited singlet state the CO bond makes an angle of 20° to the CH_2 plane. According to the work of Iwata and Morokuma,[13] the hydrogen bond energy of HCHO with water depends upon the geometry in its excited (n, π^*) state, *i.e.*, the extent to which the excited state is non-planar. The Franck-Condon principle shows that the rate of radiationless decay depends upon the vibrational overlap factor.[14] It seems obvious that the overlap factor is expected to be larger the larger the differences in geometry between the ground and excited states. One explanation is as follows. In going from acetone to 3-M-2-P, the extent to which the excited (n, π^*) state is non-planar would decrease in the adsorbed layer, as reflected in the decrease in the strength of the hydrogen bond with the surface OH groups. Such a change in the excited state geometry would affect the rate of the radiationless decay.

Lifetime of Adsorbed Alkyl Radicals. Values of B ($\tau' k_{11}$), including the corresponding values for other ketones obtained previously,[3] are given in Table 5. Although it is expected that in the adsorbed layer the reactivity of the radicals differs from that in the gas phase,[15] it seems difficult to attribute such a large difference in the B values only to the difference in k_{11}.[2,5] It can be concluded that the alkyl radical lifetime increases in the order methyl<ethyl<propyl<isopropyl<*s*-butyl radicals in the adsorbed layer. Assuming that the relative reactivity of nitrogen monoxide toward the radicals in the adsorbed layer is approximately equal to that in the gas phase,[15] it is possible to estimate the relative lifetime of the radicals in the adsorbed layer as seen in Table 5. In the photolysis of adsorbed alkyl ketones the lifetime of alkyl radicals is mainly determined by the rate of recombination of the geminate radical pairs, k_{11}, the magnitude of which is expected to depend upon the surface mobility of the radicals.[6]

According to the work of Garbutt and Gesser,[16] the radicals are stabilized on the surface of porous Vycor glass by charge-transfer interaction where radicals play the role as electron-donors and the surface OH groups as electron-acceptors. In such cases it would be expected that the stabilization energy, *i.e.*, the adsorption energy

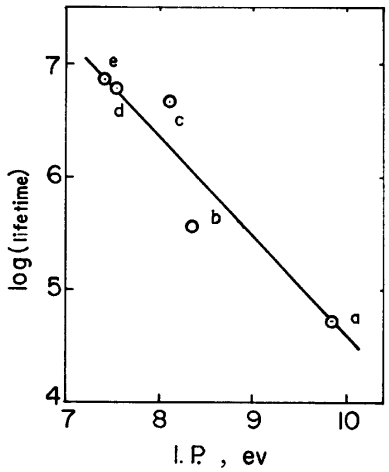

Fig. 4. The relationship between log(lifetime) and ionization potential (I.P.) of alkyl radicals.[17]
a: Methyl, b: ethyl, c: propyl, d: isopropyl, e: s-butyl radical.

of the radicals, E_{ads} decreases with increasing the ionization potential of the donors (radicals). The lifetime of the radical on the surface should increase with the decrease in its surface mobility, which will decrease with increasing adsorption energy of the radical. It is concluded that in the adsorbed layer the lifetime of the radical will increase with the decrease in its ionization potential, *i.e.*, with increasing strength of its interaction with surface. The results shown in Fig. 4 confirm the conclusion.

The Vibrational Spectra of Tetracyanothiophene

Jiro NAKANISHI and Tohru TAKENAKA
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received June 18, 1976)

The polarized infrared and far-infrared spectra of the tetracyanothiophene (TCNT) crystals were recorded by means of the normal and oblique incidence of radiation upon the (001) and (20$\bar{1}$) sample planes. The Raman spectra of the powdered sample and of a saturated solution in acetonitrile or 1,2-dichloroethane were also obtained. The observed bands were experimentally classified into the symmetry species of the free molecule (the point group C_{2v}) under the assumption of an oriented gas model. Assignments of the observed bands to individual fundamental vibrations were carried out with the aid of the spectral data of the analogous molecules and the normal coordinate analysis of the in-plane vibrations, which was made with a modified Urey-Bradley force field.

Although a number of vibrational studies have been carried out on such fully conjugated tetracyano compounds as tetracyanoethylene (TCNE),[1-7] 7,7,8,8-tetracyanoquinodimethane (TCNQ),[8-11] and 1,2,4,5-tetracyanobenzene (TCNB),[12,13] little attention has been paid to the heterocyclic tetracyano compounds. The present paper will deal with the vibrational spectra of tetracyanothiophene (TCNT), which was first synthesized and physicochemically studied by Simmons and his co-workers.[14]

The infrared and far-infrared spectra of the oriented crystals were measured with a polarized radiation incident, not only normally, but also obliquely upon the (001) and (20$\bar{1}$) sample planes. From the results obtained, the observed bands were classified into three infrared-active species—a_1, b_1 and b_2—of the free molecule (the point group C_{2v}) under the assumption of an oriented gas model. In order to distinguish the lattice vibrations from the molecular vibrations, the far-infrared spectrum of the molten sample was also obtained. The Raman spectra were recorded of the powdered sample and of solutions in acetonitrile and in 1,2-dichloroethane. The observed values of the depolarization ratios in the solutions confirmed the previous findings regarding the classification of the corresponding infrared bands into totally symmetric (a_1) and non-totally symmetric species.

The assignments of the observed bands to individual fundamental vibrations were made with the aid of the spectral data of the analogous molecules and the normal coordinate analysis. The analysis of the in-plane vibrations was carried out using a modified Urey-Bradley force field. The agreements between the observed and calculated frequencies were satisfactory.

Experimental

A sample of TCNT was prepared by the method of Simmons and his co-workers;[14] tetracyano-1,4-dithiin was heated up to 215 °C in 1,2,4-trichlorobenzene, and the products were recrystallized three times from benzene and then sublimed. The colorless crystalline needles of TCNT thus obtained melted at 201—202 °C, while the literature value is 198—199 °C. The ultraviolet spectrum,[14] the results of the elemental analysis, and the X-ray diffraction pattern[15] of this sample were identical with those previously reported. The infrared spectrum of the powdered sample was also the same as that previously reported,[14] except for the 700-cm^{-1} band, which is much weaker in our spectrum. Since this band is considered to be due to a trace of impurities, it may be concluded that our sample is of a higher purity than that of Simmons and his co-workers.[14]

The thin, oriented crystals used for infrared measurements were prepared by the slow, careful cooling of molten samples sandwiched between two potassium bromide plates with a small temperature gradient. The oriented crystals for far-infrared measurements were obtained in the same way between two quartz plates. The crystal structure of TCNT has been reported by Rychnovsky and Britton[15] to be a monoclinic system, $a=13.42$, $b=6.56$, $c=7.07$ Å and $\beta=137°$, with a space group of P_s-C_s^2 with two molecules in a unit cell. The present X-ray diffraction studies showed that the crystal planes developed were either the (001) or (20$\bar{1}$) plane, depending upon the degree of temperature gradient during the crystal preparations.

The infrared spectra between 4000 and 250 cm^{-1} were recorded on a Perkin-Elmer model 521 grating spectrophotometer. For far-infrared measurements between 400 and 30 cm^{-1}, a Hitachi model FIS-3 vacuum grating spectrophotometer was used. The spectrum of the melt in this region was obtained for a sample sandwiched between two silicon plates. In this measurement the double-chopping method was used to eliminate the emission from the heated sample. The polarization measurements in the infrared and far-infrared regions were made with the aid of wire grid polarizers of the silver bromide substrate and of the polyethylene substrate respectively. The Raman spectra of powdered sample and of saturated solutions in acetonitrile and 1,2-dichloroethane at 60 °C were recorded on a Japan Electron Optics Laboratory model JRS-Sl spectrophotometer equipped with an Ar^+ laser as a light source for excitation. A Glan-Thomson prism and polaroid were used for measurements of the depolarization ratios in the solutions.

Selection Rules and Observed Spectra

The TCNT molecule has been reported to have the C_{2v} molecular symmetry.[15] The selection rules for the free molecule and for the molecules in the crystal are given in the correlation diagram of Table 1. The vibrations belonging to the a_1 and b_2 species are of the in-plane mode, while those belonging to the a_2 and b_1 species are of the out-of-plane mode. Table 1 shows that each vibration of the free molecule splits in the crystal into two modes, which are both Raman- and infrared-active, and that there are nine lattice vibrations-three translational and six rotational.

The infrared spectra of the TCNT crystals obtained with the polarized radiation incident normally upon the

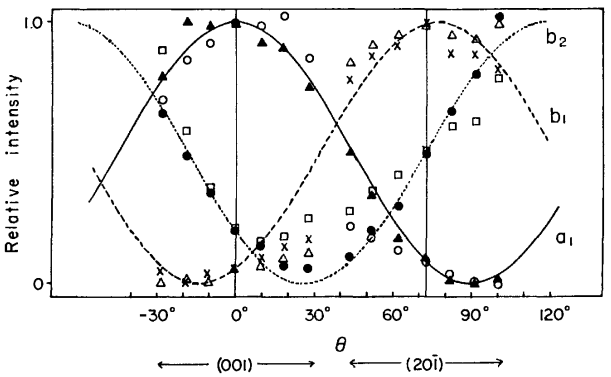

Fig. 2. Relative intensities of the infrared bands as a function of the angle θ between the a axis and the electric vector of the polarized radiation.
□: 1512, ○: 1443, ▲: 1406, ●: 1233, △: 604, ×: 504 cm^{-1} band.

(001) and (20$\bar{1}$) planes are given in Figs. 1A and 1B respectively. The solid lines refer to the orientation of the electric vector parallel to the b axis, while the broken lines refer to the electric vector perpendicular to it. The fact that the factor-group splitting is scarcely observed in Fig. 1 suggests that the effects of the crystal field on the molecular vibrations are small. The agreement between the two solid lines in Figs. 1A and 1B is fairly good, as expected, except for the relative intensity of the band at 1695 cm^{-1}, which may be due to impurities.

Although it is generally known that the observed bands can be classified into three infrared-active species—a_1, b_1, and b_2—by examining the dichroism in Figs. 1A and 1B, there often appear some ambiguities which are due to imperfections in the crystals as well as to experimental errors. To avoid these ambiguities, additional experimental data were introduced by the use of the tilting method, in which the sample plane was rotated in turn by certain angles about the b axis, and the polarized radiation with the electric vector parallel to the ac plane was incident upon the sample plane. The change in the relative intensities of the infrared bands of the a_1, b_1, and b_2 species with the change in the tilting angle was calculated from the crystal data[15] under the assumption of an oriented gas model. The results are given by the solid (a_1), broken (b_1), and dotted (b_2) lines in Fig. 2 as a function of the angle, θ, between the a axis and the electric vector of the polarized radiation. The angles are measured in terms of the rotation which transfers the a axis to the c axis through the obtuse angle.

Experimental data were obtained from the samples of both the (001) and (20$\bar{1}$) planes. The normal incidence of the polarized radiation upon the (001) and (20$\bar{1}$) planes gives the data at $\theta=0°$ and $\theta=72.3°$ in Fig. 2 respectively. The peak intensities of the bands obtained at various angles of θ for the (001) sample were normalized in such a way that the observed intensities at $\theta=0°$ fit into the corresponding calculated values. The same normalization of the observed intensities was carried out on the basis of the values calculated at $\theta=72.3°$ for the (20$\bar{1}$) sample. By the use of both the (001) and (20$\bar{1}$) planes, experimental data could be obtained over a wide range of θ, from $-30°$ to 100°. Although there are some departures of the experimental values from the calculated curves, a glance at the overall θ-dependence of the experimental values leads to unambiguous classifications of the most observed bands into the three infrared-active species. The results of this examination are summarized in Table 2.

Figures 3A and 3B represent the far-infrared spectra of the TCNT crystals recorded on the normal incidence of radiation upon the (001) and (20$\bar{1}$) planes respectively. The solid lines refer to the orientation of the electric vector parallel to the b axis, while the broken lines refer to the electric vector perpendicular to it. The agreements between the two solid lines in Figs. 3A and 3B are good. Figure 3C is the spectrum of TCNT in the molten state. The bands at 90, 83, 76, 74, 54, and 36 cm^{-1} in Fig. 3A or 3B disappear in Fig. 3C, suggesting that they are due to lattice vibrations. We observe

[C] Far-infrared spectrum of TCNT in the molten state.

some frequency shifts of the bands with the phase change from crystal to melt. As is apparent from Table 1, the lattice bands at 90, 74, and 54 cm^{-1}, found only in the solid lines of Figs. 3A and 3B, are to be assigned to the A″ vibrations of the factor group, while the bands at 83, 76, and 36 cm^{-1}, found only in the broken lines, are to be assigned to the A′ vibrations. The classification of the far-infrared bands due to molecular vibrations into the respective species was also made by means of the tilting method mentioned above. These results are given in Table 2. In this low-frequency region the factor-group splittings are observed at 226 and 223 cm^{-1} and at 188 and 181 cm^{-1}.

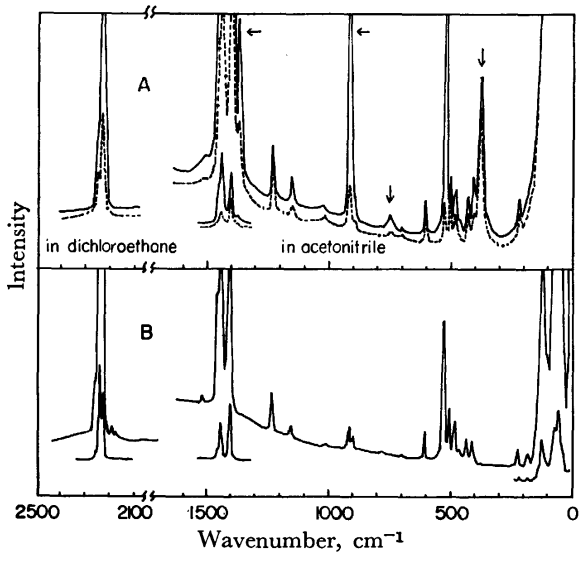

Fig. 4. [A] Raman spectra of TCNT in acetonitrile and in 1,2-dichloroethane. Bands marked with the arrow are due to solvents.
——: $I_{//}$, ------: $I_{\perp}$.
[B] Raman spectrum of TCNT powder.

Figure 4A represents the Raman spectra of the acetonitrile and the 1,2-dichloroethane solutions of TCNT. The bands marked with arrows are solvent bands. The solid and broken lines give the spectra of Raman scatterings with the electric vector parallel and perpendicular to that of the exciting light respectively. The observed values of the depolarization ratios confirmed the previous results regarding the classification of the corresponding infrared bands into the totally symmetric (a_1) and non-totally symmetric species (b_1 and b_2), as is seen in Table 2. The Raman spectrum of the powdered sample is also given in Fig. 4B and Table 2.

Assignments

In order to make the assignments of the observed bands to the individual fundamental vibrations, the following examinations were carried out besides the discussions in the previous section: (a) a comparison of the spectral data with those of the partly analogous molecules, such as TCNE,[1-7] TCNQ,[8-11] TCNB,[12,13] thiophene[16] and the bis(maleonitrile dithiolato) Ni(II) anion,[17] and (b) the normal coordinate analysis of the in-plane vibrations mentioned in the next chapter. In the following discussions, the mean values of the infrared frequencies of the crystal and Raman frequencies of the powder are used as the observed frequencies when both were found.

The assignments of the a_1 bands at 2247, 2228, 1444, 1407, 1153, and 525 cm^{-1} and of the b_2 bands at 2258, 2241, 1511, 1233, 983, 530, 223, and 126 cm^{-1} were straightforward.

The a_1 fundamental band ν_6, mainly due to the C–C stretching vibration, can be expected around 900 cm^{-1} by the normal coordinate analysis. Both the infrared bands at 916 and 896 cm^{-1}, which have been determined by the tilting method to belong to the a_1 species, are assignable to this vibration. Of the corresponding Raman bands in the solution, the low-frequency one at 897 cm^{-1} (900 cm^{-1} for the powder) was found to be polarized, although the high-frequency band (913 cm^{-1} for the powder) could not be observed because of the band overlap with the strong solvent band. Furthermore, in the process of the normal coordinate analysis, where the refinement of the force constants was carried out to get a better agreement between the calculated and the observed values for the above-mentioned fourteen bands which were assigned without ambiguities, it was found that the calculated frequency of the ν_6 vibration showed a tendency to decrease to *ca.* 900 cm^{-1}. Therefore, the 898 cm^{-1} band (on the average) was assigned to this vibration, and the 915-cm^{-1} band, to the combination tone [$\nu_3(a_1)-\nu_7(a_1)=919$ cm^{-1} (a_1)].

Thr b_2 fundamental band ν_{18} is thought to be present between 900 and 750 cm^{-1}. In this region, three infrared bands at 874, 820, and 770 cm^{-1} were found to belong to the b_2 species. Since, however, only one Raman band was observed at 777 cm^{-1}, corresponding to the infrared

band at 770 cm^{-1}, this band (774 cm^{-1} on the average) was assigned to the ν_{18} vibration, and the 874- and 820-cm^{-1} bands, to the combination tones [$\nu_7(a_1)+\nu_{21}(b_2)=$ 867 cm^{-1} (b_2) and $\nu_{16}(b_2)-\nu_9(a_1)=822$ cm^{-1} (b_2) respectively].

In the region from 500 to 400 cm^{-1}, two a_1 fundamental bands, ν_8 and ν_9 are to be expected. Apparently, four infrared bands of the a_1 species and four corresponding polarized Raman bands were found in this region. Since there is no further experimental evidence on the basis of which to choose two of them as the fundamentals, the assignments were carried out by reference to the tendency of the calculated frequency variation found in the refining process of the normal coordinate analysis, as has been mentioned above. Thus, the 464- and 411-cm^{-1} bands (on the average) were assigned to the ν_8 and ν_9 vibrations respectively. The 483-cm^{-1} band (on the average) was attributed to the combination tone [$\nu_6(a_1)-\nu_9(a_1)=487$ cm^{-1} (a_1)], and the 434-cm^{-1} band (on the average), to the overtone [$2\nu_{22}(b_2)=446$ cm^{-1} (a_1)].

The b_2 fundamental band ν_{20}, mainly due to the C-C≡N deformation vibration, can be expected in the same frequency region. Since only one infrared band of the b_2 species and the corresponding depolarized Raman band were observed in this region, this band (430 cm^{-1} on the average) was ascribed to the ν_{20} fundamental vibration.

The a_1 fundamental band ν_{10}, mainly due to the C=C-S bending vibration, and the b_2 fundamental band ν_{21}, mainly due to the C=C-C (ring) bending vibration, are to be expected between 400 and 300 cm^{-1}. Only two infrared bands, at 342 and 332 cm^{-1}, were observed in this region, except for the 374-cm^{-1}, which belongs to the b_1 species. Therefore, these bands were assigned to the ν_{21} and ν_{10} vibrations respectively, although they are very weak.

In the region from 150 to 100 cm^{-1}, three infrared bands of the a_1 species were observed at 146, 118, and 113 cm^{-1}. Correspondingly, two Raman bands were seen at 144 and 118 cm^{-1}; the latter seemed to include two components. By referring to the normal coordinate analysis, the 118- and 113-cm^{-1} bands were assigned to the ν_{11} and ν_{12} vibrations respectively. The 145-cm^{-1} band (on the average) was attributed to the combination tone [$\nu_8(a_1)-\nu_{10}(a_1)=132$ cm^{-1} (a_1)].

A weak infrared band of the a_1 species was observed at 58 cm^{-1} for the crystal and at 57 cm^{-1} for the melt, suggesting that it is due to the molecular vibration. Correspondingly, a very strong Raman band was observed at 59 cm^{-1} for the powdered sample. Since, however, no fundamental vibration belonging to the a_1 species was expected in this low-frequency region, it was assigned to the difference band [$\nu_7(a_1)-\nu_8(a_1)=61$ cm^{-1} (a_1)]. The strong intensity of the Raman band may be interpreted in terms of the overlap with the lattive vibration band.

In the region lower than 700 cm^{-1}, seven infrared bands of the b_1 species were observed at 604, 504, 487, 374, 185, 128, and 46 cm^{-1}, while five b_1 out-of-plane fundamentals (ν_{24}—ν_{28}) were expected. Almost all of these infrared bands had corresponding Raman bands. The assignments of these bands were carried out tentatively by comparison with the spectral data of the analogous molecules. The 605- and 374-cm^{-1} bands (on the average) were assigned without ambiguity to the ν_{24} (C-S torsion) and ν_{26} (C-C≡N deformation) vibrations respectively.

Either one of the infrared bands at 504 and 487 cm^{-1} can be expected to be the fundamental C-C≡N deformation band ν_{25}. The corresponding depolarized Raman bands were observed at 503 and 485 cm^{-1} for the solution (504 and 484 cm^{-1} for the powder). Since the infrared band at 487 cm^{-1} was very much stronger than that at 504 cm^{-1}, while the two Raman bands had nearly the same intensities, the 486-cm^{-1} band (on the average) was assigned to the ν_{25} vibration, and the 504 cm^{-1} band, to the combination tone [$\nu_8(a_1)+\nu_{28}(b_1)=$ 511 cm^{-1} (b_1)].

Although one fundamental vibration, ν_{27}, is thought to appear in the region from 200 to 100 cm^{-1}, two infrared bands of the b_1 species were observed at 185 cm^{-1} (the means value of the factor group splitting) and 128 cm^{-1}. The former band was found to remain in the melt (168 cm^{-1}), while its corresponding Raman band was observed at 184 cm^{-1}. For the latter band, however, the presence of an infrared band in the molten state and of a Raman band was not certain. Thus, the 185-cm^{-1} band was assigned to the ν_{27} vibration, and the 128-cm^{-1} band, to the combination tone [$\nu_{24}(b_1)-\nu_8(a_1)=141$ cm^{-1} (b_1)].

The lowest out-of-plane fundamental vibration, ν_{28}, seems to appear below 100 cm^{-1}. The weak infrared band was observed at 46 cm^{-1} for the crystal in both the solid and broken lines of Figs. 3A and 3B. Although the band could not be observed for the melt, the above fact may suggest that this is due to molecular vibration, because the lattice vibration should appear in either the solid or broken line. Furthermore, the use of the tilting method seemed to show that the crystal band at 46 cm^{-1} belonged to the b_1 species. Thus, this band (47 cm^{-1} on the average) was assigned to the ν_{28} vibration. The corresponding Raman band was found at 48 cm^{-1}. No Raman bands assignable to the five a_2 out-of-plane fundamentals were observed.

The observed infrared and Raman bands which have not been discussed yet were assigned to the overtone and combination tone according to the experimental results regarding the classification of the bands. The results of the discussion in this chapter are summarized in the last column of Table 2. The frequencies of the in-plane and

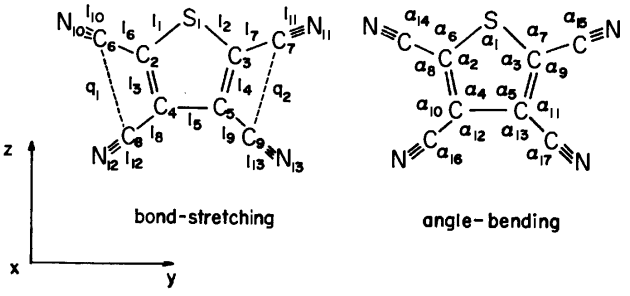

Fig. 5. In-plane internal coordinates of TCNT.

a) The mean values of the frequencies are cited whenever both the infrared band of the crystal and Raman band of the powder are observed or when factor group splitting occurs. b) Dev.$=100[\nu(\text{Calcd})-\nu(\text{Obsd})]/\nu(\text{Obsd})$. c) Only contributions greater than 25 per cent are included. d) The mark (I) refers to the C_2–$C_6{\equiv}N_{10}$ and C_3–$C_7{\equiv}N_{11}$ groups, and (II), to the C_4–$C_8{\equiv}N_{12}$ and C_5–$C_9{\equiv}N_{13}$ groups (see Fig. 5).

out-of-plane fundamentals are listed in Tables 3 and 4 respectively.

Normal Coordinate Analysis of In-plane Vibrations

Wilson's ***GF*** matrix method[18] was used for the normal coordinate analysis. The numerical calculations were carried out with the aid of a FACOM 230-75 digital computer of Kyoto University Data Processing Center. The internal coordinates of TCNT are given in Fig. 5. The equilibrium bond lengths and bond angles adopted are the mean values of those determined by Rychnovsky and Britton:[15] $l_1^\circ=l_2^\circ=1.71$ Å, $l_3^\circ=l_4^\circ=1.37$ Å, $l_5^\circ=1.40$ Å, $l_6^\circ=l_7^\circ=l_8^\circ=l_9^\circ=1.41$ Å, $l_{10}^\circ=l_{11}^\circ=l_{12}^\circ=l_{13}^\circ=1.17$ Å, $\alpha_1^\circ=89.1°$ $\alpha_2^\circ=\alpha_3^\circ=114.0°$, $\alpha_4^\circ=\alpha_5^\circ=111.3°$, $\alpha_6^\circ=\alpha_7^\circ=121.4°$, $\alpha_8^\circ=\alpha_9^\circ=124.6°$, $\alpha_{10}^\circ=\alpha_{11}^\circ=125.4°$ and $\alpha_{12}^\circ=\alpha_{13}^\circ=123.3°$. Furthermore, $\alpha_{14}^\circ=\alpha_{15}^\circ=\alpha_{16}^\circ=\alpha_{17}^\circ=180°$ are assumed for the sake of simplicity.

TABLE 4. OUT-OF-PLANE FUNDAMENTAL VIBRATIONS OF TCNT

a) See footnote a of Table 3. b) See footnote d of Table 3.

As the potential function for the in-plane vibrations, the modified Urey-Bradley force field (mod. UBFF) given by:

$$2V(\text{mod. UBFF}) = 2V(\text{UBFF}) + 2\alpha(\Delta l_3\Delta l_5+\Delta l_4\Delta l_5) + C\sum_i^2(\Delta q_i)^2 + 2C'\sum_i^2(\Delta q_i)q_i$$

was used. Here, q_i is the equilibrium non-bonded distance between C_6 and C_8 atoms and between C_7 and C_9 atoms. V(UBFF) consists of terms with five bond-stretching, seven angle-bending, and six non-bonded repulsion force constants; those constants are listed in the first column of Table 5. The force constant α is the coefficient of the cross terms between C=C and C–C (ring) stretching coordinates; it is introduced to take account of the presumed resonance interaction in the thiophene ring. The constant C is the coefficient of the *cis* non-bonded repulsion terms between two carbon

TABLE 5. FORCE CONSTANTS[a] (mdyn/Å) OF TCNT

	Force const (Initial)	Force const (Final)	Dispersion
K (C–S)	4.75	4.15	—[b]
K (C–C)	4.58	4.55	0.24

C		0.10	—[b]

a) The $F'=-0.10\,F$ and $C'=-0.1\,C$ relations were assumed. b) Fixed.

atoms. The $C'=-0.1C$ relation was assumed, as usual.

For the first calculation, the values of the force constants were transferred from the bis(maleonitrile dithiolato)Ni(II) anion,[17] diethyl ether,[19] TCNQ,[9] and TCNB.[12] These values are shown in the second column of Table 5, while the frequencies calculated with these values are given in the third column of Table 3. The agreements between the calculated and observed frequencies are not very good. For the purpose of obtaining a good agreement, after some refinements of the force constants by the trial-and-error method using the Jacobian matrix, repetitions of the calculations with several sets of force constants were carried out by the least-squares method. The converged set of the force constants and their dispersion values are given in Table 5. The frequencies calculated with this set of force constants are compared with the observed values in Table 3. The agreement is satisfactory. The last column of Table 3 represents the potential energy distribution.

It is apparent from Table 5 that the C–S and C–C (ring) single bonds acquire a partial double-bond character, while the C=C and C≡N bonds, on the other hand, lose their double- and triple-bond characters respectively. These facts, and the necessity of the cross terms with the α coefficient, suggest that the resonance takes place throughout the molecule of TCNT, as is to be expected from the configuration of the molecule.

The authors wish to express their gratitude to Professor Shinzaburo Oka of this institute for his guidance in the preparation of TCNT. Thanks are also due to Dr. Soichi Hayashi and Mr. Junzo Umemura of this laboratory for their helpful discussion.

Reactions of the Cation Radicals of Aromatic Diamines with Their Parent Molecules or Aliphatic Amines

Tadayoshi SAKATA,* Mitsuo HIROMOTO, Tomoko YAMAGOSHI, and Hiroshi TSUBOMURA

Department of Chemistry, Faculty of Engineering Science Osaka University, Toyonaka, Osaka 560

(Received June 23, 1976)

The chemical reactions of the cation radicals of some aromatic diamines with their parent molecules, aliphatic amines or sodium hydroxide have been studied spectroscopically. In the case of the cation radical of *p*-phenylenediamine (PPD), the main products are Bandrowski's base (BB) and PPD, *p*-benzoquinone diimine being found as an intermediate. This reaction are found essentially to be a disproportionation of PPD^+ to BB and PPD in which bases added enhance the reaction rate. The thermodynamical quantities of the initial step of the reaction, proton transfer from PPD^+, are estimated and the reaction mechanism is discussed. The reaction of the cation radical of *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD) with triethylamine (TEA) gives the parent molecule, TMPD. This reaction is concluded to be caused by an electron transfer from TEA to $TMPD^+$ followed by a reaction of TEA with a large negative free energy change. The reaction between the cation radical of *N,N*-dimethyl-*p*-phenylenediamine and its parent molecule has also been studied.

Cation radicals are expected to act as strong electron acceptors and interact with electron donating molecules. The charge resonance interaction between a cation radical and its parent molecule has been reported by several authors.[1-4] We reported the charge transfer (CT) interactions between some aromatic diamine cation radicals and aliphatic amines.[5]

The coexistence of a cation radical and an electron donating neutral molecule leads not only to the complex formation but often to chemical reaction at room temperature. For example, Würster's cations, though known to be rather stable, react easily with some electron donors. An ethanol solution of the *p*-phenylenediamine cation radical (PPD^+) changes from yellow to blue by adding *p*-phenylenediamine (PPD). Such chemical aspects of cation radicals have been relatively unexplored.

We had been interested in the physical aspects of the CT interaction between a cation radical and a neutral molecule. Recently we started work on the chemical reactions involving cation radical, because we recognized its importance for understanding the overall physical and chemical processes of these cation radicals which often play a substantial role as intermediates of various chemical reactions.

Experimental

Preparation of Material. *p*-phenylenediamine (PPD), *N,N*-dimethyl-*p*-phenylenediamine (DMPD) and *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD) were purified according to the method described previously.[5] Their cation radical salts were synthesized according to the literature.[6]

Bandrowski's base (BB, ) NH_2, N^1,N^4-bis(*p*-aminophenyl)-2,5-diamino-*p*-benzoquinone diimine) was produced by oxidizing PPD with hexacyanoferrate (III) under mild alkaline conditions.[7] Found: C, 67.33; H, 5.74; N, 25.9%. Calcd for $C_{18}H_{18}N_6$: C, 67.90; H, 5.70; N, 26.40%. When DMPD was oxidized similarly, the compound corresponding to *N*-methylated Bandrowski's base (BB', ) was obtained. Found: C, 69.60; H, 7.12; N, 20.82%. Calcd for $C_{24}H_{28}N_6$; C, 71.61; H, 7.51; N, 20.88%. Its electronic spectrum is quite similar to that of BB except for slight red shift and broadening. *p*-Benzoquinone di-imine[8] and 4,4'-bis(dimethylamino)azobenzene (AZ')[9] were prepared according to the literature. Triethylenediamine (1,4-diazabicyclo-[2.2.2]octane) was purified by recrystallization from ether and by sublimation under vacuum. Triethylamine of the commercial GR grade was used without further treatment.

Measurement. The infrared spectra were recorded with a Hitachi EPI-G3 grating infrared spectrophotometer or a Hitachi 215 grating infrared spectrophotometer. A Shimadzu Multipurpose recording spectrophotometer MPS-50L was used for the measurements of the electronic absorption spectra.

Results

The Reaction between PPD^+Br^- and PPD. When an ethanol solution of *p*-phenylenediamine bromide (PPD^+Br^-) and that of PPD were mixed, the color of the solution changed gradually from yellow to blue. Figure 1 shows the electronic absorption spectra. The solution became acidic with the color change. On evaporating the solvent, it yielded a blue precipitate, whose infrared (IR) spectrum showed prominent bands of *p*-phenylenediamine monohydrobromide (PPD·HBr). When the reaction mixture was neutralized with NaOH, it turned from blue to red. The main products separated by the thin layer chromatography (TLC) on silica gel with a 1 : 1 mixture of benzene and ether as a solvent were BB and PPD. A slight amount of 4, 4'-diaminoazobenzene (AZ) and a violet unknown substance were also separated as by-products. These were confirmed by comparison of their UV and IR spectra with those of the authentic samples.[10] In the case of AZ, the R_f values of TLC also agreed with that of the authentic sample. The yield of AZ was about 1/8 of BB in the mole ratio.

An ethanol solution of BB turns from red to blue by adding a slight amount of mineral acid. The absorption

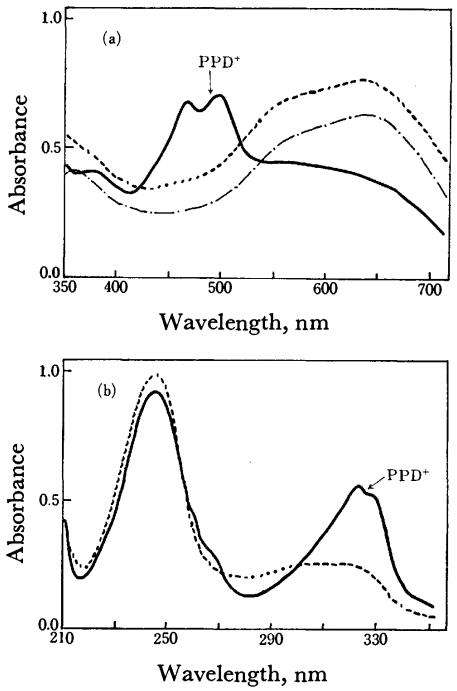

Fig. 1. The spectra of PPD+Br⁻–PPD system in ethanol at room temperature: ——; a few minutes after mixing, ------; 50 minutes after mixing.
(a) [PPD+Br⁻]=3.51×10⁻⁴ M, [PPD]=3.60×10⁻⁴ M. For reference the spectrum of the protonated Bandrowski's base in ethanol (-·-·-; [BB]/[HBr]=1) is shown in this figure.
(b) [PPD+Br⁻]=4.80×10⁻⁵ M, [PPD]=5.45×10⁻⁵ M.

of BB around 470 nm (21300 cm⁻¹) decreased by adding hydrobromic acid, while a new absorption appeared with a peak at 635 nm (15700 cm⁻¹). The intensity of the latter band showed a maximum at the molar ratio of HBr to BB of 1.17, and began to decrease by further addition of HBr as shown in Fig. 2. Therefore, the 635 nm band is assigned to the monoprotonated BB (BB·H⁺). This was also confirmed from the fact that the elemental analysis of the precipitate obtained by concentrating the solution agreed with calculated values.

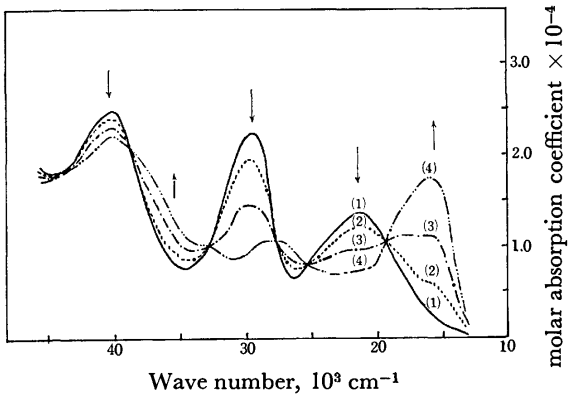

Fig. 2. The electronic absorption spectra of Bandrowski's base in ethanol with various content of HBr.
[HBr]/[BB]: (1), 0.0; (2), 0.34; (3), 0.69; (4), 1.17. The concentration of BB is constant; [BB]=7.0×10⁻⁵ M.

Found: C, 54.62; H, 4.78; N, 20.82%. Calcd for $C_{18}H_{19}N_6Br$: C, 54.14; H, 4.80; N, 21.05%. When a solution of BB and HBr at the mole ratio of 1: 1 was neutralized by adding an ethanol solution of NaOH, it returned from blue to red, showing the spectrum of BB. Thus, the reaction is a reversible acid-base reaction.

$$BB \underset{NaOH}{\overset{HBr}{\rightleftharpoons}} BB\cdot H^+$$

As seen in Fig. 1, the absorption spectrum of the reaction mixture in the longer wavelength region is quite similar to that of BB·H⁺ with regard to both the absorption shape and peak positions, showing that the blue color comes from BB·H⁺.

The absorption at 245 nm (in Fig. 1b) is attributable mainly to PPD and BB. This absorption increases a little with the progress of the reaction. The IR spectrum of the reaction products shows that PPD exists as a monoprotonated species (PPD·HBr).

The formation of BB was investigated spectroscopically varying the concentration of PPD and keeping the initial concentration of PPD⁺ constant. The amount of BB·H⁺ formed was found to be independent of the added PPD ranging from 0.28 to 7.46 molar equivalent to the PPD, though the rate of reaction increased with the concentration of PPD. The BB formed was about 1/6.5 of PPD⁺ in molar quantity.

Based on the above results, the following stoichiometric equation is set up.

$$6PPD^+Br^- \longrightarrow BB + 3PPD + 6HBr \qquad (1)$$

Since, this reaction is accelerated by added PPD, we add rather randomly 2 PPD, to both sides of Eq. 1. Then, we have

$$6PPD^+Br^- + 2PPD \longrightarrow BB + 5PPD + 6HBr \qquad (2)$$

We mixed PPD+Br⁻ and PPD at the molar ratio of 6: 2, and, after the reaction was completed, compared the spectrum of the reaction mixture with that of a solution containing BB, PPD and HBr at the concentrations as given by Eq. 2. The absorption spectra of the two solutions agreed very well with each other both in shape and in intensity (Fig. 3). This confirms that the stoichiometry of the reaction is like that of Eq. 1 or 2. As Eq. 1 shows, this reaction is considered essentially to be a disproportionation of PPD⁺ to BB and PPD in which

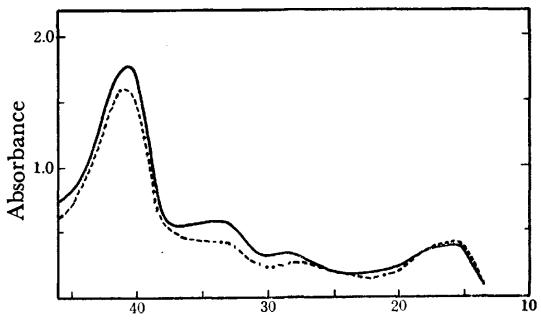

Fig. 3. The absorption spectrum of the reaction mixture of PPD+Br⁻ (1.46×10⁻⁴ M) and PPD (0.51×10⁻⁴ M) (——), and that of BB (0.24×10⁻⁴ M), PPD (1.23×10⁻⁴ M), and HBr (1.48×10⁻⁴ M) (------).

bases added enhances the rate of reaction.

When PPD was oxidized in ethanol with bromine, a blue solution was obtained. The blue precipitate formed from this solution showed the electronic and IR spectra quite similar to those of the products of the above reaction, indicating the formation of the same products as the reaction between PPD^+ and PPD.

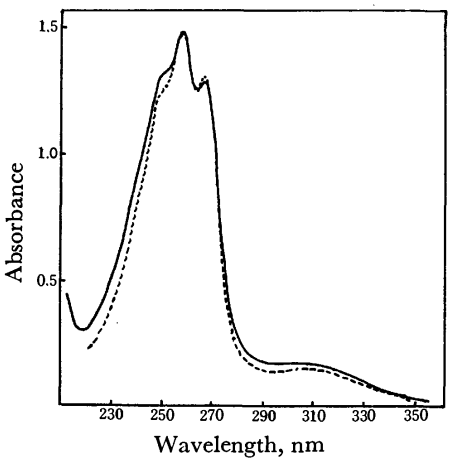

Fig. 4. The absorption spectrum of the reaction mixture of PPD^+Br^- (0.866×10^{-4} M) and NaOH (1.99×10^{-4} M) (——), and the theoretically calculated one (------) based on Eq. 3 and the spectral data of Fig. 5.

The Reaction of PPD^+Br^- with NaOH and Aliphatic Amines in Ethanol. Figure 4 shows the absorption spectrum of the reaction mixture of an ethanol solution of PPD^+Br^- (0.866×10^{-4} M) and NaOH (1.99×10^{-4} M). The dotted line shows the spectrum drawn by assuming the following dispropotionation reaction being completed.

$$2PPD^+ \longrightarrow PPD + HN=\langle\bigcirc\rangle=NH + 2H^+ \qquad (3)$$

The spectrum was drawn using the absorption spectra of PPD and *p*-benzoquinone diimine (Fig. 5). As seen in Fig. 4, the spectrum obtained experimentally agrees fairly well with the theoretically expected one, indicating that the reaction proceeds mainly as defined by Eq. 3.

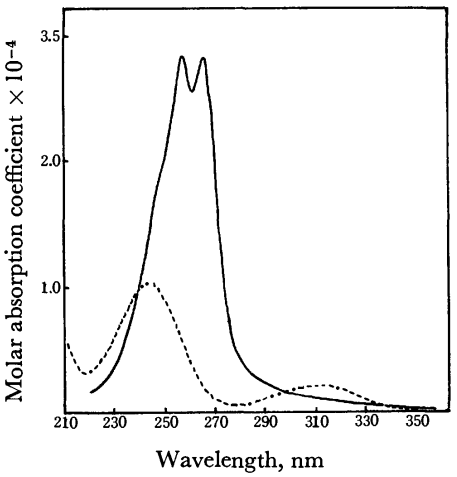

Fig. 5. The absorption spectra of *p*-phenylenediamine (------) and *p*-benzoquinone diimine (——).

The formation of the diimine was also observed when triethylamine was used instead of NaOH. The quantity in this case was about 80% of the expected one. In the case where triethylenediamine was used, the quantity of the diimine formed was still less. In both cases of amines, the diimine was unstable and changed into Bandrowski's base having the absorption peak at 470 nm, while it was fairly stable in the case of NaOH. When the amount of triethylamine was decreased to about 1/10 to 1/20 molar equivalent of PPD^+Br^-, the diimine was observed weakly, only as an absorption shoulder at 267 nm at the early stage of the reaction. Then the absorption spectra changed rapidly, showing the formation of $BB\cdot H^+$ with a peak at 635 nm. The spectrum in both the ultraviolet and visible regions agreed fairly well with that expected from Eq. 1, suggesting that the reaction mechanism in this case is essentially the same as in the case of the reaction between PPD^+ and PPD.

The Reaction between $DMPD^+ClO_4^-$ and DMPD. When an ethanol solution of *N,N*-dimethyl-*p*-phenylenediamine perchlorate ($DMPD^+ClO_4^-$) and that of DMPD were mixed, the color changed gradually from red (the color of the cation) to blue. Figure 6 shows the absorption spectra. After 4 days, the reaction mixture was neutralized with NaOH and was separated by TLC with the 3:1 mixture of benzene and ethanol. The main products separated were 4,4'-bis(dimethylamino)-azobenzene(AZ'), *N,N*-dimethylated Bandrowski's base (BB'), DMPD and an unknown substance (λ_{max}=590 nm, 650 nm). The latter two substances were produced more than BB' and AZ'. The amount of BB' formed was nearly equal to that of AZ'. The absorption at 660 nm which appeared in the course of the reaction (Fig. 6) might be attributable to the protonated species of BB' or AZ'. However it is not clear which contribution of the

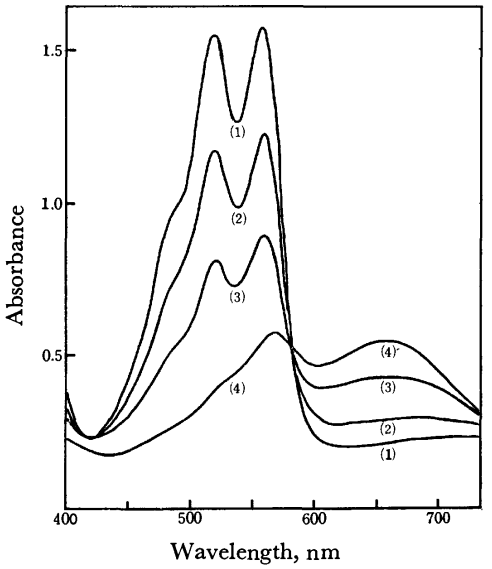

Fig. 6. Spectroscopic course of the reaction in $DMPD^+ClO_4^-$–DMPD system in ethanol.
$[DMPD^+ClO_4^-]=2.22\times10^{-4}$ M, [DMPD]=2.20×10^{-4} M.
(1) 4 min, (2) 14 min, (3) 44 min, (4) 170 min after mixing.

two is larger, because both of the protonated species have their absorption peaks at the same wavelength, 660 nm. The absorption at 660 nm decreased again with time and new absorptions appear at 590 nm and 650 nm, suggesting that BB'·H$^+$ or AZ'·H$^+$ reacts further. The similar phenomenon was observed, when DMPD was oxidized in ethanol with bromine.

The Reaction between TMPD$^+$ClO$_4^-$ and Triethylamine (TEA) in Ethanol. When TEA was added to an ethanol solution of TMPD$^+$ClO$_4^-$, the blue color characteristic of TMPD$^+$ disappeared and the solution became colorless. The absorption spectrum after the reaction showed a strong band at 263 nm which agreed very well with that of TMPD both in shape and position. An ether extract from the reaction mixture gave a colorless crystalline solid whose IR spectrum agreed with that of TMPD. Moreover, when bromine was added to the reaction mixture, it turned blue, giving the absorption spectrum of TMPD$^+$. From the absorption intensity the amount of TMPD$^+$ recovered was determined to about 80% of TMPD$^+$ before the reaction. This suggests that 80% of TMPD$^+$, at least, changes into TMPD by adding TEA. Figure 7 shows the spectrum of the reaction mixture together with the one which was obtained by assuming 100% conversion of TMPD$^+$, into TMPD.

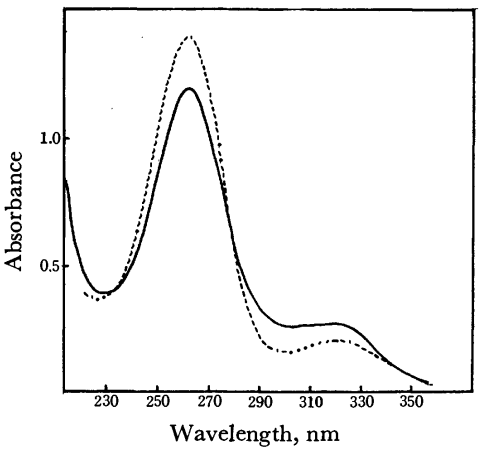

Fig. 7. The absorption spectrum of the reaction mixture of TMPD (0.885×10^{-4} M) and TEA (2.01×10^{-4} M) at 3 h after mixing (——), and the spectrum of TMPD (0.885×10^{-4} M) in EtOH (------).

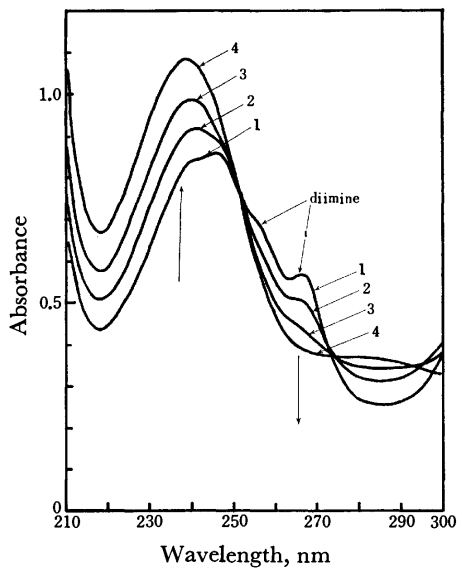

Fig. 8. Spectroscopic changes during the decomposition of PPD$^+$Br$^-$ in a 1:2 (volume ratio) mixture of water and ethanol at room temperature. (1) 4 min, (2) 9 min, (3) 13 min, (4) 31 min after mixing.

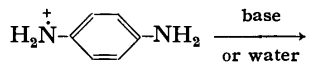
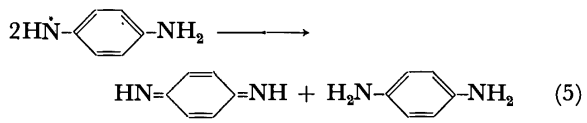
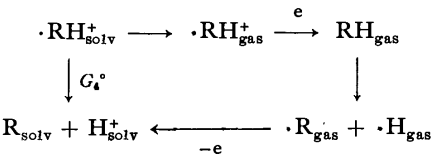
Discussion

The Reaction of PPD$^+$Br$^-$ with PPD, NaOH and Aliphatic Amines. When two molar equivalents of NaOH, triethylamine or triethylenediamine was added to an ethanol solution of PPD$^+$Br$^-$, the formation of *p*-benzoquinone diimine was observed clearly as shown in Fig. 4. In the case of the reaction of PPD$^+$ with triethylamine, the absorption intensity of the diimine in the region of 256—265 nm became weak with decreasing amount of triethylamine. When it was decreased to 1/10 molar equivalents of PPD$^+$, only a weak shoulder of the diimine was observed at about 270 nm. PPD$^+$Br$^-$ decomposes easily in water showing the absorption of the diimine, though it is fairly stable in ethanol. Figure 8 shows the spectra of the solution in a water-ethanol mixture, ethanol being added to decrease the rate of decomposition. In the reaction between PPD$^+$ and PPD, a shoulder at 267 nm was observed immediately after the mixing and disappeared in a while, as shown in Fig. 1. From these results, this absorption is attributable to *p*-benzoquinone diimine, which may be formed by a process shown below





Let us estimate the Gibbs's free energy change ΔG_4° for the Reaction 4 in the case without a base. It can be estimated by using the following Born-Haber cycle.



Here the cation radical of PPD is denoted as ·RH$^+$. ΔG_4° is expressed approximately by the equation

$$\Delta_4{}^\circ G_4^0 = -E_A^a(\text{PPD}^+) + S(\text{PPD}^+) + D(\text{N–H}) + I_P^a(\text{H}\cdot) - S(\text{H}^+) - S(\text{R}\cdot) \quad (6)$$

where $E_A{}^a$, S, D, and $I_P{}^a$ represent adiabatic electron affinity, solvation energy, bond energy and adiabatic ionization energy, respectively.

The following values are obtained from the literatures.

$$E_A^a(\text{PPD}^+) = I_P^a(\text{PPD}) = 6.8\text{ eV}.^{11)}$$

$$I_P^a(\text{H}\cdot) = 13.6\text{ eV},\quad D(\text{N–H}) = 4.0\text{ eV}.^{12)}$$

$S(H^+ \text{ in water}) \cong 11.5$ eV.[13,14]

$S(PPD^+ \text{ in water})$ is evaluated to be 2.2 eV using Born's equation with the dielectric constant of water at 25 °C, 78.5, and the effective radius of PPD^+, 3.24 Å.[15] Though the value of $S(R\cdot)$ is not certain, it can be taken to be the order of 0.1 eV. When these values are substituted in Eq. 6, $\Delta G_4°$ (in water) of 1.2 eV is obtained.

Since the solvation energy of a proton is smaller in ethanol than in water, $\Delta G_4°$ is calculated to be larger in ethanol than in water. This explains the fact that PPD^+-Br^- is fairly stable in ethanol though it is unstable in water.

It is important that the values of $\Delta G_4°$, though derived approximately, are positive and fairly large both in water and ethanol. It indicates that the equilibrium of Eq. 4 is inclined to the left and the concentration of the semiquinone $R\cdot$ is small. Nevertheless, the experimental fact that the diimine is formed easily from PPD^+ in water or water-ethanol mixture indicates that the free energy change of the reaction of Eq. 3 is nagative. Since $\Delta G_4°$ is positive, $\Delta G_5°$, the free energy for the formation of diimine from the semiquinone, must be a fairly large negative value to make up for $\Delta G_4°$.

In the presence of bases (B), one must take account of the reaction,

$$B + H^+ \rightleftarrows B\cdot H^+ \qquad (7)$$

the standard free energy change for this reaction in water, $\Delta G_7°$, at 25 °C are obtained as follows:[16]

$$\Delta G_7°(PPD) = -0.36 \text{ eV}, \quad \Delta G_7°(TEA) = -0.60 \text{ eV}$$
$$\Delta G_7°(OH^-) = -0.83 \text{ eV}$$

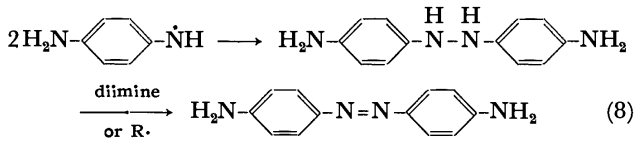
The standard free energy change of Eq. 4, $\Delta G_4°$, in the presence of a base, is reduced from that in water estimated above by these amounts.

Since the solvation energy of a proton is smaller in ethanol than in water, the equilibrium will shift to the right so that $\Delta G_7°$ becomes smaller in ethanol. Fairly large negative values of $\Delta G_7°$ are thought to be the reason why the reaction is enhanced by the addition of bases. Experimentally, the rates of decrease of the visible absorption band of PPD^+ at about 460 nm with various bases lie in the order OH^-, TEA and PPD, in agreement with that of their basicities.

In the actual reaction course, the interactions through the hydrogen bond are considered to be important. Since PPD^+ is thought to be a strong proton donor, a hydrogen bond complex between PPD^+ and PPD or aliphatic amines is formed. A proton will transfer easily through this hydrogen bond. The CT interaction between PPD^+ and TEA was reported previously.[5] Though we tried to find the dimer cation formed between PPD^+ and PPD in ethanol, we could not find it spectroscopically in the temperature range from room temperature to about −50 °C. Therefore the dimer cation may not play an important role.

With the addition of 2 molar equivalents of bases to an ethanol solution of PPD^+Br^-, the diimine produced reached about 100% of the theoretically expected quantity in the case of NaOH, while in the case of TEA it was about 80% and in the case of PPD a trace amount was detected as a shoulder of the absorption spectrum (Fig. 1). The diimine formed was stable in the case of NaOH, though in the case of both TEA and PPD it decomposed easily into Bandrowski's base. These observations can be explained as follows: Due to the relation, $\Delta G_7°(PPD) > \Delta G_7°(TEA) > \Delta G_7°(OH^-)$, the rate of the formation of the diimine is in the order of OH^-, TEA and PPD. Corbett studied the reaction of *p*-benzoquinone diimine with PPD in water and discussed the mechanism of the formation of Bandrowski's base.[17] According to his result, the rate of the reaction of the diimine with PPD increases greatly with lowering pH in the region of pH>6.[17] Since the basicity becomes lower in the order of PPD, TEA, and NaOH, the diimine formed is expected to be unstable in this order. The result is consistent with these expectations.

The result of TLC shows that 4,4′-diaminoazobenzene (AZ) is formed at the molar ratio of about 1/8 of BB. The following reaction is suggested for this.



(8)

As is seen from the comparison of the molecular structures of AZ and BB, thus, AZ is formed by the bonding between the N atoms of the amino groups, while BB is formed by the bonding between the C atom of the benzene ring and the N atom of the amino group. The fact that BB is formed more than AZ indicates that the C atom of the benzene ring is attacked more easily by the aminonitrogen, in the above reactions.

$TMPD^+ClO_4^-$+triethylamine (TEA). In this case, the first step of the reaction is considered to be an electron transfer.

$$TMPD^+ + TEA \rightleftarrows TMPD + TEA^+ \qquad (9)$$

The cation radical of TEA (TEA^+) produced is considered to be quite unstable and undergo further reaction, causing the shift in the equilibrium of Eq. 9 to produce TMPD.

The free energy change for the electron transfer reaction of Eq. 9 can be expressed approximately by

$$\Delta G_9° = I_P^a(TEA) - E_A^a(TMPD^+) + \Delta P \qquad (10)$$

The following values are obtained from the literature.

$$I_P^a(TEA) = 7.5 \text{ eV},^{18}$$
$$E_A^a(TMPD^+) = I_P^a(TMPD) = 6.20 \text{ eV}^{19}$$

ΔP represents the difference of the polarization energy before and after the reaction and it is expressed as

$$\Delta P = P(TEA^+) - P(TMPD^+)$$

The value is estimated to be −0.4 eV by using Born's equation, assuming 4.3 Å and 3.5 Å as the effective radii of $TMPD^+$ and TEA^+, respectively. When these valuie are substituted in Eq. 10, $\Delta G_9°$=0.9 eV is obtained. Since it is a large positive value, it seems improbable that the electron transfer reaction proceeds to the right without the second step of TEA^+ decomposition.

$DMPD^+ClO_4^-$+DMPD. In this case, a large amount of AZ′ was produced. The formation of AZ′ and BB′ would be explained by taking into consideration the similar reactions with those for PPD^+. However the reaction proceeds further to form an unknown product in this case.

Nature of Catalytically Active Sites over Solid Acids. II. Relationships between Acidic Properties of Silica-Alumina and Its Catalytic Activities for Olefin Polymerization

Jun-ichiro TAKE, Masanori IKEDA, and Yukio YONEDA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received June 29, 1976)

The influences of the degree of hydration of a silica-alumina surface on its Brönsted or Lewis acid content and on its catalytic activity for *cis*-2-butene polymerization were investigated at 30 °C as a function of the evacuation temperature. The raise in the evacuation temperature, *i.e.*, the decrease in the degree of hydration, gave rise to an increase in both the Lewis acid content and the catalytic activity but to a decrease in the Brönsted acid concent. A good linear relationship, which could not be extrapolated through the origin, was found between the Lewis acid content and the catalytic activity. Thus, the conclusion is drawn that only strong Lewis acid sites are active in olefin polymerization on silica-alumina at low temperature.

Olefins such as propylene or butenes produce an irreversibly adsorbed species on silica-alumina[1-6] or some Y zeolites[7-9] at near room temperature. This species gives rise to IR absorption bands characteristic of saturated hydrocarbons.[4-8] Recently, the species has been proved to act as the proton-donating center in olefin isomerization[10,11] and to comprise branched oligomers having about four monomer units on the average.[1-3] However, the nature of the active site for this polymerization still remains unsettled, in spite of several intensive investigations.[3,5,6,8]

In the previous study,[12] we investigated this problem by using a series of silica-alumina samples whose Lewis acid sites were selectively poisoned *in situ* with pyridine to different extents, and concluded that strong Lewis acid sites were active in the polymerization on silica-alumina at 30 °C. The present study intends to provide additional evidence for this conclusion by correlating the catalytic activities of partially hydrated silica-aluminas with their acidic properties.

Experimental

Materials and Apparatus. Silica-alumina (SA-1, 13% Al_2O_3),[13] pyridine,[12] and *cis*-2-butene[12] were those used earlier. The IR cell and the preparation of the self-supporting 20-mm diameter wafers of SA-1 are described in detail elsewhere.[12]

Procedures. Partially hydrated samples were prepared as follows. After the wafer had been mounted in the sample holder and pretreated in a dry oxygen stream for 2 h at 450 °C, it was cooled to 150 °C for 1 h in an oxygen stream containing 20—25 Torr of water vapor, and then evacuated in the IR cell for 2 h at different temperatures of 150—450 °C.

The wafer was exposed to pyridine vapor at about 16 Torr for 1 h at room temperature, and evacuated for 1 h at 110 °C. The spectrum of chemisorbed pyridine was recorded. The peak absorbances of the 1460 and 1540 cm^{-1} bands due to Lewis- (LPY) and Brönsted-bound pyridine (BPY), respectively, were taken as a measure of the total acid content for the corresponding acid type.

The reaction was carried out in a closed circulation system including the IR cell as a reactor at an initial olefin pressure of 5 Torr and 30 °C. Its progress was followed in the same way as in the previous study.[12]

The IR spectrometer and the operating conditions have previously been described.[12] Peak absorbances were all normalized so as to indicate the absorbance per unit optical thickness of the wafer. This normalized absorbance, AS/W (cm^2/g), corresponds to the quantity $\varepsilon M/W$, where A and ε are respectively the absorbance and the absorption coefficient of a band, M is the amount (mmol) of the responsible species, and S and W are the cross section (cm^2) and the weight (g) of the wafer, respectively.

Results and Discussion

Hydroxyl Groups on Surfaces. Figure 1 shows the IR spectra in the O-H stretching region of partially hydrated SA-1 samples. A sharp band at 3750 cm^{-1} is due to isolated surface silanol groups, and a broad band around 3600 cm^{-1} is due to hydrogen-bonded surface hydroxyl groups and adsorbed water.[14] As the evacuation temperature was raised, the 3600 cm^{-1} band decreased in intensity and the 3750 cm^{-1} band became more and more definite without a significant change in intensity. This fact implies that the adsorbed water is only slightly hydrogen-bonded to the isolated silanol groups.[14] Since the original SA-1 had previously been calcined at 550 °C for 8 h, and every wafer was heated to 450 °C before use, the wet oxygen treatment and the

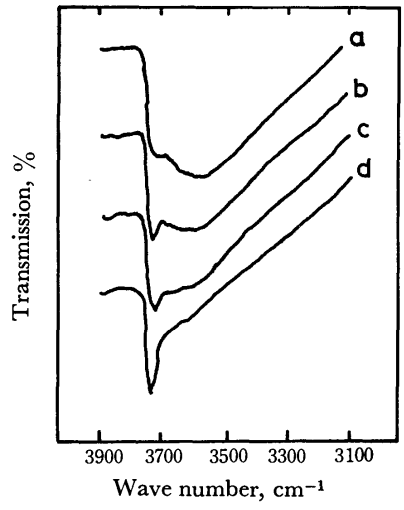

Fig. 1. IR spectra of surface hydroxyl groups on SA-1. A sample was evacuated for 2 h at 150 (a), 200 (b), 300 (c), or 450 °C (d).

subsequent evacuation probably bring about no drastic structural changes of the surface, except for hydration. The intensity of the band around 3600 cm^{-1} can therefore be taken as a qualitative measure of the degree of hydration of the surface. Thus, Fig. 1 indicates that a lowering in the evacuation temperature certainly results in an increase in the degree of hydration.

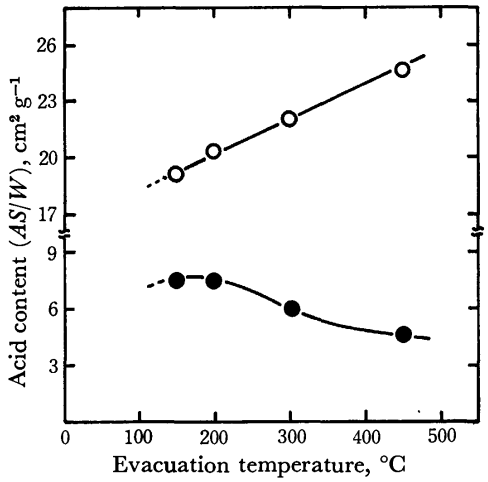

Fig. 2. Effect of evacuation temperature on surface acid content of Lewis (○) or Brönsted (●) type.

Acid Contents. Figure 2 illustrates the effects of the evacuation temperature, or, in other words, those of the added water, on the acid contents of SA-1. As the evacuation temperature was raised, the Lewis acid content increased while the Brönsted acid content decreased. Different values have been reported for the ratio of absorption coefficients of the LPY band to the BPY band: $\varepsilon_{1460}/\varepsilon_{1540} \approx 1$[15–17] or 2.6.[18] For our catalyst it was evaluated to be approximately unity from the differences in peak intensities resulting from the conversion of LPY to BPY upon dosing with quite small amounts of water. In view of this value, an increase in the Lewis acid content is compensated for with a decrease in the Brönsted acid content in the evacuation-temperature range of 200 to 450 °C. This implies that one Brönsted acid site is converted into one Lewis acid site when the surface is dehydrated. When the evacuation temperature was lowered from 200 to 150 °C, the Lewis acid content further decreased, while the Brönsted acid content remained approximately constant. It is quite reasonable to expect that comparatively large amounts of added water poison acid sites of both the Lewis and Brönsted types. Hence, a further lowering in the evacuation temperature may effect a decrease in the Brönsted acid content as well as in the Lewis acid content.

Polymerization Activity. *cis*-2-Butene produced, when it was introduced onto SA-1 at 30 °C, the polymeric species giving rise to IR absorption bands at 2960, 2930, and 2870 cm^{-1} in the saturated C–H stretching region and at 1470, 1385, and 1370 cm^{-1} in the saturated C–H bending region. The growth of each band occurred rapidly in the initial stage of the reaction, slowed down gradually, and finally ceased after 1—2 days. The peak intensity at 2960 cm^{-1} was well proportional to the amount of polymeric species formed.[12] The intensity of this peak after 1 min was therefore taken as the initial activity.

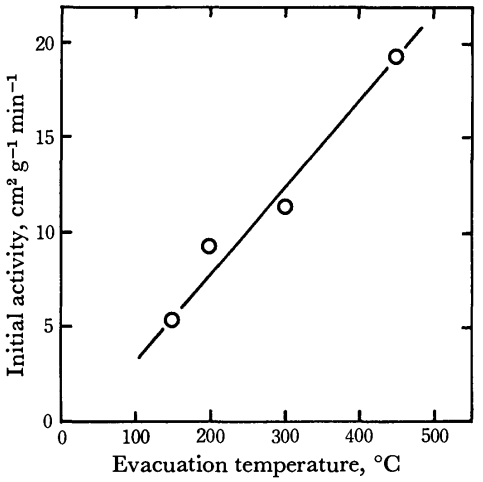

Fig. 3. Effect of evacuation temperature on catalytic activity for *cis*-2-butene polymerization at 30 °C.

Figure 3 is a plot of the initial activity against the evacuation temperature; it indicates that the initial activity decreases as the evacuation temperature is lowered, in other words, that added water certainly acts as an inhibitor for the formation of the polymeric species. This suggests that the Brönsted acid site is inactive in the present reaction. It can be seen from Figs. 2 and 3 that the influence of the evacuation temperature on the initial activity is similar to that on the Lewis acid content.

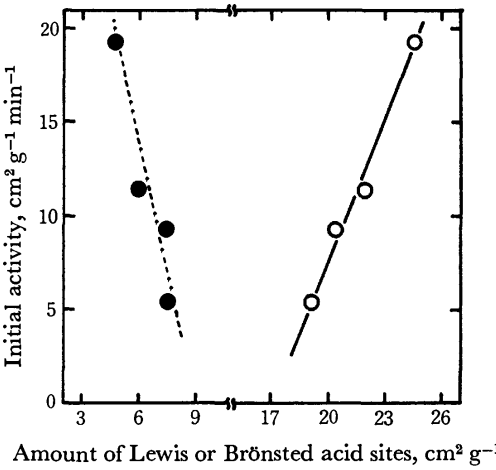

Fig. 4. Correlation of surface acidity with catalytic activity for *cis*-2-butene polymerization at 30 °C. ○: Lewis acidity, ●: Brönsted acidity.

Figure 4 shows correlations of the initial activity of SA-1 with its Lewis or Brönsted acid content. Since the initial activity decreases with an increase in the Brönsted acid content, this correlation is considered to be unreasonable. On the other hand, the initial activity decreases linearly with decreasing amounts of Lewis acid sites. This reasonable correlation probably indicates that the active acid site is of the Lewis type. Evidently, the straight line correlating the initial activity with the Lewis acid content does not extrapolate through the

origin. This is easily explained on the assumption that only part of the Lewis acid sites are active. According to this interpretation, the majority of the active Lewis acid sites are those which can be liberated, as a result of desorption of water (or hydroxyl groups) from the sites, by raising the evacuation temperature from 150 to 450 °C. Since such water probably is strongly adsorbed, the active Lewis acid sites are reasonably concluded to be high in acid strength. This conclusion agrees well with the previous one.[12)]

In addition, the previous study[12)] showed that, in *cis*-2-butene polymerization at the same temperature as in the present study, an upper limit for the amount of the active Lewis acid sites on SA-1 evacuated at 450 °C amounted to about 30% of the total Lewis acid content. The correlation in Fig. 4 may permit a similar estimate. The point of intersection of the solid straight line and the abscissa can be regarded as the point representing a sample whose active Lewis acid sites have been just blocked with added water. Accordingly, with respect to SA-1 evacuated at 450 °C, an upper limit for the amount of the active Lewis acid sites is again evaluated to be about 30% of the total Lewis acid content. Thus, we are again led to the conclusion that strong Lewis acid sites are active in olefin polymerization over silica–alumina at the low temperature of 30 °C.

Emission Spectra of the Vinyl Polymers with Pendant Phenanthryl Groups

Akira ITAYA, Ken-ichi OKAMOTO, and Shigekazu KUSABAYASHI

Department of Chemical Engineering, Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube 755

(Received June 30, 1976)

The emission properties of 9-ethylphenanthrene (EPh), poly(9-vinylphenanthrene) (PVPh), poly(9-phenanthryl methacrylate) (PPhMA), and poly[2-(9-phenanthryl)ethyl vinyl ether] were investigated in solution. These vinyl polymers showed no clear excimer fluorescence in the longer-wavelength region. Both the fluorescence quantum yield and the lifetime of PVPh decreased largely with an increase in temperature at higher temperatures. This suggests that PVPh forms an excimer which has a low fluorescence quantum yield. The fluorescence properties of PPhMA and PPhEVE, in which Ph chromophores are widely spaced on the skeletal chains, indicated little interaction between neighboring Ph chromophores in the singlet state. This results from the nature of Ph, in whith it is difficult to form an excimer. The phosphorescence spectrum and its lifetime of PPhEVE indicated a presence of a weak interaction between neighboring Ph chromophores in the triplet state. PVPh and PPhEVE showed a delayed fluorescence resulting from a T-T annihilation between two migrating triplet excitons.

Recently, emission spectra of aromatic vinyl polymers have been extensively investigated. It is known that aromatic vinyl polymers exhibit excimer fluorescences in dilute solutions due to the interaction between neighboring chromophores.

1-Ethylpyrene and 1-ethylnaphthalene show the excimer fluorescence in concentrated fluid solutions at room temperature. Poly(1-vinylpyrene)[1,2] and poly(1-vinylnaphthalene)[3-5] show almost exclusively the excimer fluorescence in dilute solutions. Poly(1-pyrenylmethyl vinyl ether) (PPyMVE),[1,6] poly(1-naphthylmethyl vinyl ether) (PNMVE),[6] and poly(1-naphthyl methacrylate) (PNMA),[7] in which the pyrenyl and naphthyl chromophores are widely spaced on the skeletal chains by $-O-CH_2-$ and $-CO-O-$ bonds, show both the structured monomer fluorescence and the excimer one in dilute solutions. On the other hand, *N*-ethylcarbazole (ECz) and 9-ethylacridine (EAcr) show no excimer fluorescence in concentrated solutions.[1,8] Poly(*N*-vinylcarbazole) (PVCz)[8] and poly(9-vinylacridine) (PVAcr),[1] however, show the excimer fluorescence. Poly[2-(*N*-carbazolyl)ethyl vinyl ether] (PCzEVE), in which the carbazolyl chromophores are widely spaced on a skeletal chain by $-O-CH_2-CH_2-$ bonds, shows a structureless fluorescence, which is different from both the monomeric structured fluorescence and the sandwich-like excimer one observed for the model compounds and PVCz respectively. This implies the presence of the excited-state interactions among the carbazolyl chromophores in PCzEVE.[9]

Phenanthrene crystal has only two molecules per unit cell arranged with their molecular planes almost perpendicular. It does not normally exhibit an excimer emission. However, this crystal under a high pressure does exhibit a broad emission with a peak at *ca.* 440 nm. This emission is assigned to the excimer fluorescence.[10] Despite extensive studies of the prompt and delayed fluorescence of phenanthrene, no excimer fluorescence has been observed in this compound at room temperature.[11] Studies of the emission of a phenanthrene sandwich dimer prepared by photolytic dissociation have also shown that phenanthrene does not form an excimer even under favorable condition.[12] Therefore, it is of interest to investigate the emission spectra of the vinyl polymers, where the phenanthryl (Ph) chromophores are directly connected to or widely spaced on the skeletal chains.

In the present paper, we have investigated the spectroscopic behaviors of poly(9-vinylphenanthrene) (PVPh), poly(9-phenanthryl methacrylate) (PPhMA), and poly[2-(9-phenanthryl)ethyl vinyl ether] (PPhEVE); in the latter two polymers, the phenanthryl chromophores are widely spaced on the skeletal chains by $-CO-O-$ and $-O-CH_2-CH_2-$ bonds respectively.

Experimental

Syntheses of 9-Ethylphenanthrene(EPh) and PVPh. EPh and 9-vinylphenanthrene(VPh) were prepared according to the literature.[13,14] The EPh was purified by recrystallization from methanol and sublimation *in vacuo*. The VPh was purified by recrystallization from ethanol and sublimation *in vacuo*. The PVPh was prepared by the polymerization of a 0.4 M benzene solution of the purified VPh in the presence of 0.2 mol% azobisisobutyronitrile in an evacuated sealed tube at 80 °C for 20 h and was reprecipitated three times from the benzene solution with methanol or hexane. The molecular weight measured by a vapor pressure osmometer was 3600. The degree of polymerization($\overline{DP}$) is about 18.

Synthesis and Polymerization of 2-(9-Phenanthryl)ethyl Vinyl Ether(PhEVE). 2-(9-Phenanthryl)ethanol(PhEtOH) was prepared from purified phenanthrene according to the literature[15] and purified by recrystallization from cyclohexane. The PhEVE was synthesized from the PhEtOH by the route similar to 2-(*N*-carbazolyl) ethyl vinyl ether[16] and was purified by recrystallization from ligroin and sublimation *in vacuo*. Yield, 30%; mp 82.0—84.0 °C, IR(KBr-disk): δ_{CH} of vinyl ether 960 and 820 cm^{-1}, NMR ($CDCl_3$): 1.4—1.6 τ (multiplet, two ring protons); 2.0—2.2 τ (multiplet, one ring proton); 2.3—2.7 τ (multiplet, six ring protons); 3.5—3.8 τ (quartet, $-O-C\underline{H}=CH_2$); 5.8—6.2 τ (multiplet, $-C\underline{H}_2-CH_2-O-CH=C\underline{H}_2$); 6.5—6.7 τ (triplet, $-CH_2-C\underline{H}_2-O-$). Found: C, 87.07; H, 6.52%. Calcd for $C_{18}H_{16}O$: C, 87.05; H, 6.51%.

The polymerization conditions are summarized in Table 1. The solvents were purified by ordinary methods.

Synthesis and Polymerization of Phenanthryl Methacrylate(PhMA). 9-Phenanthrol was prepared from the purified phenanthrene according to the literature.[17] The PhMA was synthesized by reacting methacryl chloride with the 9-phenanthrol by the route similar to naphthyl methacrylate.[18] The monomer was extracted with benzene, washed with water, and dried over Na_2SO_4. The PhMA was isolated by column chromatography

(silica gel, benzene); mp 53.5—55.0 °C, IR (KBr-disk); 1715 ($\nu_{C=O}$), 1615 ($\nu_{C=C}$), 920 ($\delta_{C=CH_2}$) cm^{-1}, NMR ($CDCl_3$); 1.35—1.61 τ (quartet, two ring protons); 2.03—2.32 τ (multiplet, two ring protons); 2.03—2.32 τ (multiplet, two ring protons); 2.36—2.62 τ (multiplet, five ring protons); 3.54 τ (singlet, terminal vinyl proton(*cis*)); 4.22 τ (singlet, terminal vinyl proton(*trans*)); 7.86 τ (singlet, methyl protons). This monomer was very labile and was polymerized often during the purification. The PPhMA used for spectral measurements was prepared by a thermal polymerization and was reprecipitated from the chloroform solution with methanol. This polymer was insoluble in some organic solvents, but soluble in chloroform. Found: C, 81.31; H, 5.40%. Calcd for $C_{18}H_{14}O_2$; C, 82.41; H, 5.39%.

Method. The sample of PPhEVE (No. 5 in Table 1), which had the highest value of $\overline{DP}$(87) was used for spectral measurements. All of the solvents used (tetrahydrofuran (THF), 2-methyltetrahydrofuran (MTHF), chloroform, and 1,4-dioxane) were purified by the usual methods. Solutions were completely degassed by freeze-pump-thaw cycles. The emission spectra and fluorescence decay times were measured with the apparatus described in the previous paper.[8]

Results and Discussion

Polymerization of PhEVE. The cationic polymerization results are shown in Table 1. The PPhEVE is obtained in fairly good yields at or below 0 °C. The yield decreases with an increase in the polymerization temperature above 0 °C. PhEVE is also polymerized by $AlEtCl_2$ in high yields. The PPhEVE is soluble in some organic solvents, such as tetrahydrofuran and 1,2-dichloroethane.

The PPhEVE prepared in the present study has a comparatively high molecular weight (22000, $\overline{DP}$=87). This value of $\overline{DP}$ for PPhEVE is higher than the values for PCzEVE, PPyMVE, and PNMVE (33, 10, and 22, respectively).[16,19] The rather low softening point (SP) of the PPhEVE suggests the enhanced flexibility of the skeletal chain as compared with the cases of PVPh (SP: 209—218 °C, $\overline{DP}$=18), PPyMVE (SP: 220—230 °C, $\overline{DP}$=10) and PCzEVE (SP: 137—148 °C, DP=33).[16,19] The reason why the PPhEVE with the comparatively high $\overline{DP}$ has the low SP value is that phenanthryl chromophores, being less bulky than carbazolyl and pyrenyl chromophores, are widely spaced on the skeletal chain.

Emission Spectra. 1,3-Di(*N*-carbazolyl)propane and *N*-vinylcarbazole oligomer ($\overline{DP}$=4), of which the monomer compound (ECz) shows no excimer fluorescence, show excimer fluorescence in dilute solution at room temperature.[7,20-22] Therefore, the PVPh(DP=18) sample has sufficient molecular weight to be used in order to examine the possibility of excimer formation.

Fluorescence spectra of PVPh, PPhMA, PPhEVE, and EPh in solutions at room temperature are shown in Fig. 1. The fluorescence spectrum of the concentrated EPh solution indicated that EPh does not form an excimer, as is the case of phenanthrene. The fluorescence spectrum of PPhEVE is similar to that of EPh. Although the fluorescence spectra of PVPh and PPhMA are broad as compared with those of EPh and PPhEVE, no clear excimer fluorescence in the longer-wavelength region is observed for PVPh and PPhMA. Therefore, it is suggested that the interaction between neighboring chromophores in these polymers is much weaker than that observed for other aromatic vinyl polymers.

Fluorescence spectra of PVPh, PPhEVE, and EPh in rigid glasses at 77 K are shown in Fig. 2. The fluorescence band shifts to lower frequencies in the order of EPh, PPhEVE, and PVPh. The clear vibrational structure bands observed for PVPh and PPhEVE are similar to that for EPh and the fluorescence lifetimes of PVPh and PPhEVE are also much the same as that of

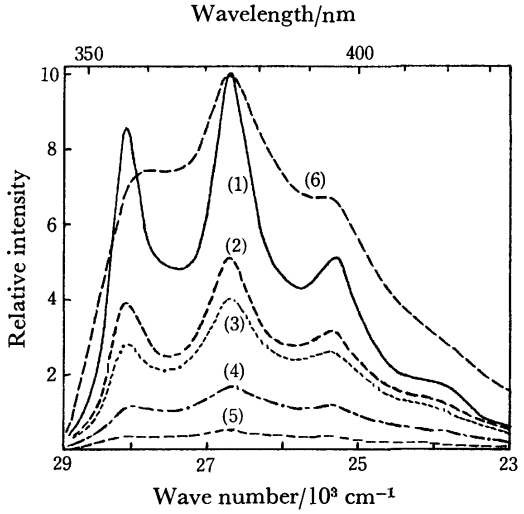

Fig. 3. Temperature dependence of fluorescence spectra of PVPh (5.1×10^{-4} M) in MTHF–THF solution. Excitation wavelength; 310 nm. (1) −130, (2) −86.5, (3) −37.7, (4) 6, and (5) 63.5 °C. The fluorescence (6) is 1.95 times the fluorescence (5).

EPh at 77 K (Table 2). These facts suggest that there is little interaction between neighboring Ph chromophores in PPhEVE and PVPh in rigid glasses at 77 K.

Table 2 shows the relative fluorescence quantum yields, taking the value of EPh as unity, and the fluorescence lifetimes. The fluorescence quantum yields and lifetimes of PVPh and PPhMA at room temperature are much lower than those of EPh and PPhEVE. The decay curve of PVPh has an initial fast component. The fluorescence spectra of PVPh in MTHF–THF solution at various temperatures are shown in Fig. 3. The fluorescence intensity decreases and the vibrational bands broaden with an increase in temperature. Temperature dependences of the fluorescence yields are shown in Fig. 4. The changes observed for EPh, PPhEVE, and PPhMA are small and they show a similar tendency. On the other hand, only PVPh shows a large decrease. The same tendency is observed for the temperature dependence of the fluorescence lifetimes (Table 2). Namely, the fluorescence lifetimes of EPh, PPhEVE, and PVPh in rigid glasses at 77 K are all equal. Only the lifetime of PVPh, however, decreases unusually with an increase in temperature.

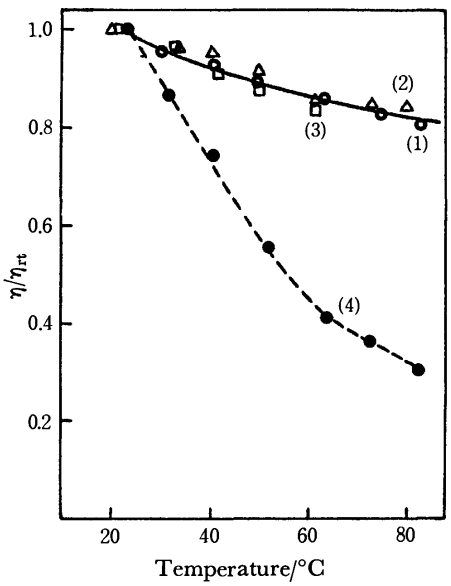

Fig. 4. Temperature dependence of the fluorescence yields. The value of η/η_{rt} exhibits the ratio of the fluorescence yield at some temperature to that at room temperature. (1) ○; EPh, (2) △; PPhEVE, (3) □; PPhMA, and (4) ●; PVPh. Solvent: (1), (2), (4); 1,4-dioxane, (3); chloroform containing 1.0% ethanol. These values were uncorrected for decrease in density of solvents with an increase in temperature.

As mentioned above, the vibrational structure of fluorescence and its lifetimes of PVPh and PPhEVE are similar to those of EPh in rigid solutions at 77 K. How-

ever, the phosphorescence of PVPh and PPhEVE is markedly different from that of EPh, as is shown in Fig. 5. The phosphorescence band shifts to lower frequency and the vibrational structure broadens in the order of EPh, PPhEVE, and PVPh. The phosphorescence lifetime shortens in the same order (Table 2). The red shift of the phosphorescence band is much larger than that of the fluorescence. These facts indicate that an interaction between neighboring Ph chromophores in the triplet state is much larger than that in the singlet state in rigid glasses at 77 K.

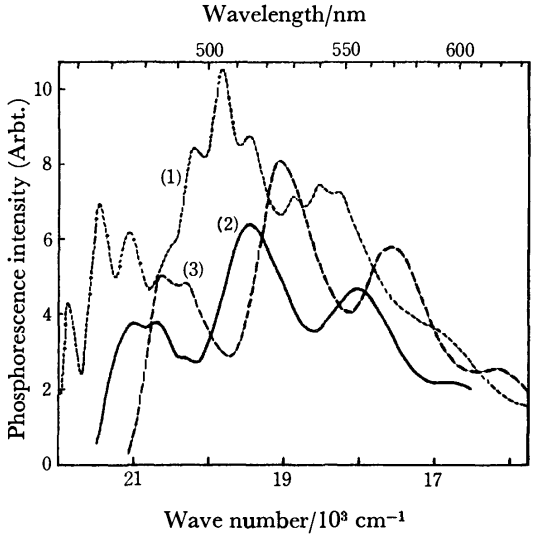

Fig. 5. Phosphorescence spectra of (1) EPh, (2) PPhEVE, and (3) PVPh in MTHF–THF rigid glasses at 77 K. Excitation wavelength; 310 nm.

The delayed emission, of which the position and profile are the same as those observed for the normal fluorescence at 77 K, is observed for PVPh and PPhEVE in rigid glasses at 77 K. The emission intensity depends quadratically on the phosphorescence intensity. The lifetime of this emission of PPhEVE is about 30 ms, while that of PVPh could not be determined because of the extremely low intensity. These facts indicate that this emission band can be assigned to the delayed fluorescence resulting from a T-T annihilation between two migrating triplet excitons.

PPhEVE resembles EPh very closely in fluorescence properties, forms no excimer, and does not show the anomalous fluorescence observed for PCzEVE.[9] The fluorescence spectra of PPhMA is markedly different from that of EPh and its lifetime is very short. The temperature dependence of the fluorescence yield, however, is similar to those of EPh and PPhEVE. This indicate that PPhMA forms no excimer. The fluorescence properties observed for PPhMA seems to be more likely to be affected by the substituent groups (-O-CO-). On the other hand, PPyMVE, PNMVE, and PNMA show the excimer fluorescence in dilute solutions at room temperature. Therefore, the failure of PPhEVE and PPhMA to form an excimer is considered to be attributable to the nature of Ph, which forms an excimer only with difficulty.

Emission properties of PVPh indicate clearly that interaction between neighboring Ph chromophores in PVPh is strongest in these polymers studied. It has been reported, from fluorescence yield and decay curve measurements, that phenanthrene does not show concentration quenching of fluorescence at room temperature.[23,24] Therefore, if PVPh forms no excimer, the fluorescence yield of PVPh is expected to be as large as that observed for EPh. The present result is not so. Namely, the fluorescence yield of PVPh is much lower than that of EPh (Table 2) and decreases largely with an increase in temperature (Fig. 4). These facts suggest that PVPh forms an excimer which has a low fluorescence quantum yield. This is reasonable from the fact that the phenanthrene excimer in the crystal state under a high pressure has a low fluorescence quantum yield.[10]

As mentioned above, ECz, EAcr, and EPh show no excimer fluorescence in concentrated solutions at room temperature. PVCz and PVAcr, however, show the excimer fluorescence in dilute solutions at room temperature. It is suggested from the above mentioned results that PVPh forms an excimer, although it does not show clearly an excimer fluorescence. Thus, the following conclusions were drawn: in the case of the vinyl polymers with the aromatic chromophores which form no excimer, an excimer is formed in the vinyl polymers in which the aromatic chromophores are directly connected to the skeletal chains, but it is not formed in the vinyl polymers in which the aromatic chromophores are widely spaced on the skeletal chains. PCzEVE is considered to be rather a special case.

Reaction of Recoil ^{35}S Atoms with Organic Compounds. Insertion Reaction of Recoil ^{35}S Atoms into the C-H and the C-C Bond

Kazuhiro NIISAWA and Ko TAKI

Faculty of Industrial Hygiene, Kitasato University, Asamizodai, Sagamihara-shi, Kanagawa 228

(Received July 7, 1976)

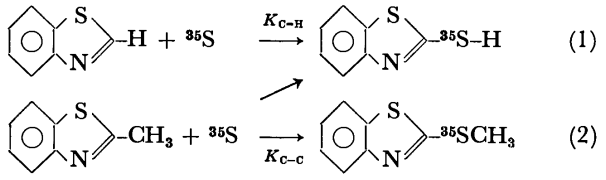
The insertion reactions of recoil sulfur atoms produced by the nuclear transformation of $^{35}Cl(n,p)^{35}S$ process into the C–H bond of benzothiazole and the C–C bond of 2-methylbenzothiazole have been examined. It has been found that the C–H insertion is a little easier than the C–C insertion by the energetic sulfur atoms, and that in thermal reaction the water used as a solvent seems to have some role in producing the C–H insertion product.

Sulfur atoms generated by the photolysis of COS react with organic compounds to produce insertion and addition products to the C–H and the C=C double bonds, such as the reaction of CH_2, oxygen and other carbenes.[1-4]

Church and Rowland[5] have studied the insertion reaction of recoil sulfur atoms into the primary and the secondary C–H bond in propane molecule to determine the spin states of the recoil sulfur atoms, and they have found that the sulfur atoms in the triplet state have inserted mainly into the secondary C–H bond. However, the insertion of diradicals into the C–C bond has not been reported.

In this study, the possibility of the insertion of recoil sulfur atoms produced by the nuclear transformation of $^{35}Cl(n, p)^{35}S$ process into the C–C bond was examined, with the aim of determining, if possible, the ratio of the insertion rate of the C–H bond to the C–C bond.

For the C–H and C–C bonds, the 2-position bond of benzothiazole (C–H compound) and the 2-position bond of 2-methylbenzothiazole (C–C compound) were respectively used. The insertion product of ^{35}S atoms to the 2-position of benzothiazole as in (1) leads to 2-mercaptobenzothiazole and to the 2-position of 2-methylbenzothiazole as in (2) leads to 2-(methylthio)benzothiazole. These compounds are well-known and stable substances.



(1)

(2)

Experimental

Materials. After the vacuum distillation of bezothiazole and 2-methylbenzothiazole (Tokyo Kasei Co.), hydrochloric acid was added. Then the hydrochlorides thus produced were purified by sublimation for benzothiazole and by recrystallization for 2-methylbenzothiazole. These starting materials were used as either an aqueous solution or a solid. Oxygen and nitrogen oxide (Takachiho Chem. Co.) were used as additives without further purification.

Thermal Neutron Irradiation. Thermal neutron irradiation of the starting material was performed in a quartz ampoule (about 0.5 ml) at a neutron flux of 3×10^{13} or 7×10^{13} n/cm^2/s for 20 min with JRR-2 or JRR-3 of the Japan Atomic Energy Research Institute.

Separation, Purification, and Radioactivity Measurement of the Reaction Products. The separation and the purification were performed chromatographically and the radioactivity measurements of the products were carried out as previously described.[6]

Nearly all the experimental data are averages of three runs; the errors are about 30% through all runs.

Results and Discussion

When the recoil sulfur atoms react with organic compounds, many reaction products labeled with ^{35}S may be produced by either the energetic process or the thermal one.[7] In order to distinguish between the two processes, radical scavengers such as O_2 and NO are added to the sample; thus the thermal atoms and their reactions may be eliminated.[7]

In this experiment, the total organic yield in aqueous solution was about 70%.[8]

The Effect of Scavengers. From Tables 1 and 2, the yield of the C–^{35}S–H product from the C–H compound in the aqueous solution is clearly inhibited in the presence of NO or O_2. However, the yield of the C–^{35}S–C product from the C–C compound was not affected in the presence of the scavenger. From these results, it may be said that the C–H insertion takes place in both the thermal and energetic reaction, but the C–C insertion takes place only in the energetic reaction. This experi-

	C-^{35}S-C	0.2	0.3	0.3	0.2	

mental fact may not conflict with the results of the reactions of the carbenes produced by the photochemical and thermal processes.[1,2]

The Effect of Solvents and Their Concentrations. The yield of the C-^{35}S-C from the C-C compound shows a constant value in various concentrations of the aqueous solution and the solid. On the other hand, the yields of the C-^{35}S-H product from the C-H and the C-C compounds are affected by the concentration of the aqueous solution, as shown in Fig. 1. But in the presence of scavengers, the yield is no longer affected by the solution concentration. Higher concentration of the C-H compound give higher yields of the C-^{35}S-H product. However, the energetic reaction is not affected by the concentration of the C-H compound.

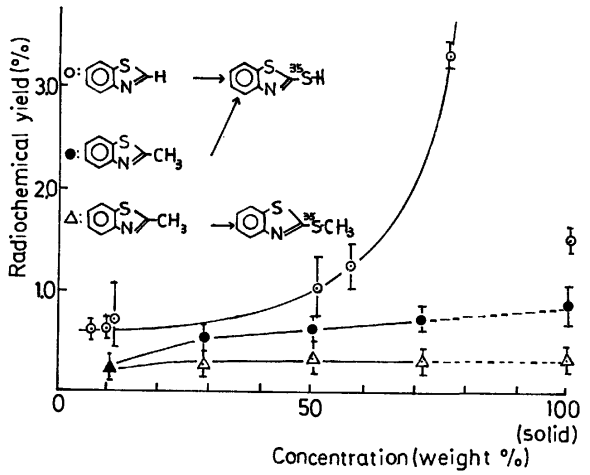

Fig. 1. Yields of the C-^{35}S-H and the C-^{35}S-C product from the C-H and the C-C compound in the aqueous solution.

Organic Solutions.[9] To elucidate the role of the solvent, various solvents such as methanol, benzene, and hexane were used. The results show that the yield of the C-^{35}S-H and the C-^{35}S-C were not affected in the presence of the scavenger nor by the variation of the concentration.

From these results, it seems that only the energetic reaction occurs in the organic solution; in this case thermal sulfur atoms may react easily with the organic solvent to give some other products.[3,4] Therefore, it is not suitable for the thermal reaction of recoil sulfur atoms to use the organic compounds as a solvent. Sulfur atoms seem to be more stable in water than the organic solutions.

The Annealing Effect on the Formation of the C-^{35}S-H Product.[10] After the neutron irradiation of the sample, the yield of the C-^{35}S-H products from the C-H compound in the aqueous solution increases by annealing. The result is shown in Table 1. Although the mechanism of this effect is not clear, it may be considered that the sulfur atoms give some other intermediate with the C-H compound or with water, and then it becomes the C-^{35}S-H product rather easily as a result of the annealing. It seems that the water plays some role in the reaction, because the annealing effect is found only in the aqueous solution and not in the organic solutions.

Table 3. Radiochemical yields of the C-^{35}S-C and the C-^{35}S-H products from the C-C and the C-H compound in various organic solutions

		16	0.3
		180	0.2

p-Dichlorobenzene was used as a chlorine source of the nuclear transformation in these organic systems.

The Radiation Effect on the Formation of the Products. Thiols are easily decomposed by the radicals induced by radiation in aqueous solution, as follows:[11]

$$H_2O \rightsquigarrow H + OH \quad (3)$$

$$R\text{-}SH + OH \longrightarrow RS + H_2O \quad (4)$$

$$R\text{-}SH + H \longrightarrow RS + H_2 \quad (5)$$

The contribution of radiation to the formation and the decomposition of the product during the thermal neutron irradiation could not be estimated exactly. But from the comparison of the rate constant for the decomposition (k_6)[12] with that for the formation (k_7)[13] and the comparison of the number of the sulfur atoms produced (8×10^{12} atoms) by the nuclear transformation with the number of the hydrogen and hydroxyl radicals (4×10^{19} species)[14] formed, the insertion product may quite influenced by the radiation.[15]

$$R\text{-}H + S \xrightarrow{k_6} R\text{-}SH \quad (6)$$

$$R\text{-}SH + H \text{ and } OH \xrightarrow{k_7} \text{decomp} \quad (7)$$

The rate of the R-SH formation may be roughly estimated as the difference of reactions 6 and 7 by the following equation: $d[R\text{-}SH]/dt = k_6[R\text{-}H][S] - k_7[R\text{-}SH][H \text{ and } OH]$

The ratio of the rate constant of the decomposition to that of the formation (k_7/k_6) is about 10^4.

So, if the radiation effect can be neglected, the yield of the C-^{35}S-H compound in the reaction of the recoil sulfur atoms may be about 10 times larger than the ex-

perimental results of the C-^{35}S-H yield. This assumption may be supported by the experimental result that the sulfur atoms produced by the photolysis of $CO^{35}S$ reacted with the C-H compound in the aqueous solution to give about 13% insertion product, based on the carbon monoxide produced.

The Ratio of the Rate Constant for the C-H to the C-C Insertion. Because of the low conversion of the reaction product, it can be considered that the ratio of the rate constant for the C-H to the C-C insertion may be equal to the ratio of the C-^{35}S-H to the C-^{35}S-C product yield.

The ratio of the rate constant of insertion (K_{C-H}/K_{C-C}) is about 1.5 in the energetic process. There are direct and indirect insertion reactions in the reaction of recoil sulfur atoms. One of the indirect insertion reaction is the addition to the -N=C- double bond to form -N-C(S·)-H as described by Grovenstein.[16] The other is the formation of C-^{35}S· intermediate by the reaction of energetic sulfur atoms with the C-H compound; this intermediate abstracts hydrogen from the surrounding molecules to form the C-^{35}S-H product.

The evidence for this reaction is shown by the formation of the C-^{35}S-H product from the C-C compound, as is shown in Table 2 and Fig. 1. Moreover, the hydrogen dissociation in the aqueous solution may be concerned with the production of the C-^{35}S-H, because the yield shows a higher value at the concentration of 75% than that of the solid state. In the reaction of carbon atoms using accelerated $^{14}C^+$ ions with benzene, toluene and cycloheptatriene were formed as synthetic products.[17] It was assumed that the energetic methylene must be involved in this reaction and gives C-H and C-C insertion products. The C-H insertion yield is higher than the C-C insertion in their experiments.

However, the photolytically generated $^{14}CH_2$ reacts with benzene to give toluene in which the methyl group is exclusively labeled (C-H insertion product).[18] And naturally it is possible that the relative populations of the spin states of the recoil sulfur atoms may decide the yield and radioactivity distribution of the insertion product.

From these considerations, it may be concluded that the formation of the C-^{35}S-C is a direct insertion, but the C-^{35}S-H formation involves both direct and indirect insertion.

The C-^{35}S-H product gives a slightly higher yield than the C-^{35}S-C in the aqueous solutions.

The authors wish to express their appreciation to Dr. M. Matsui for his helpful discussion and suggestions on the effects of radiation.

The Infrared Band Shapes of Methyl Iodide in Solutions

Shun-ichi IKAWA, Kohji FUKUSHI, Kenji FUJIWARA,* and Masao KIMURA
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received July 7, 1976)

The infrared band shapes of methyl iodide in solutions were simulated by the superposition of the Lorentzian functions. The a_1-type band was well repoduced by a single Lorentzian function. Its half-width was reasonably explained by the reorientational and vibrational relaxations. The e-type band was reproduced by two Lorentzian functions; one represents the central main peak of the band, while the other is much broader and appears like a background. The half-width of the former was nearly proportional to the Q-branch line spacing in the gas spectrum, while that of the latter seems to be related to the A_1-E-type Coriolis coupling.

The infrared band shape of a molecule in the liquid phase contains information about the rotational diffusion of the molecule.[1-12] However, in order to get insight into the details, it is necessary to take into account the vibrational relaxation of the resonant-exchange[9,10] and translational-diffusion types,[11,12] and the vibration-rotation interaction[6] as well. The effect of other overlapping vibrational transition can not be neglected, either.[11]

It is well-known that the e-type bands of methyl halides in the liquid phase have considerably greater widths than the a_1-type bands. Jones and Sheppard[13] attributed this fact to a large difference between the two kinds of moments of inertia of the molecules. They also suggested that the Coriolis interaction between the degenerate vibration and the rotation about the three-fold axis was operative on the e-type band widths, since a considerable degree of rotational freedom about the three-fold axis remained in solutions. On the other hand, Glass and Pullin[14] and also Bulanin and Tonkov[15] reported that no clear correlation was observed between various half-widths of the e-type bands and the Coriolis constants. Bulanin and Tonkov proposed that the broadening of the e-type band was caused, rather, by the splitting of the degenerate level as a result of the intermolecular force field. However, the observed splittings in a crystal[16] resulting from the intermolecular force field are too small to explain the various half-widths of the e-type bands in the liquid phase. Under these circumstances, more detailed analyses of the bands are necessary in order to clear up the character of the infrared band shape. In a previous paper we reported on the ν_3 band of methyl iodide.[11] In the present work, the simulation of the observed band shape by means of analytical functions has been extended to the eight a_1-type transitions and the five e-type transitions of the same molecule in solutions.

Experimental

The infrared transmission was measured at room temperature with a JASCO DS-701G Spectrophotometer. The spectral slit widths were set at 1.0—1.5 cm^{-1} and about 2 cm^{-1} in the measurement of the a_1- and e-type bands respectively. Under these conditions, no correction is needed for the effect of the finite slit width on the observed band-widths.[17] Uncertainties in the observed band-width were estimated, in the manner described in the previous report,[11] to be ± 0.3 cm^{-1} and ± 1 cm^{-1} for the a_1- and e-bands respectively. The concentrations of methyl iodide in solutions were arranged between 0.4 and 2.3 mol/l. They are in the same concentration range as was employed in the previous work,[11] where the observed band shapes in the ν_3 region were almost independent of the concentrations. Therefore, the concentration-dependence of band shapes was also ignored in the present work. Carbon disulfide and carbon tetrachloride were used as solvents. The two kinds of solutions yielded almost the same band-width wherever both solvents can be used for measurements.

* Present address: Canon Inc., Torite, Ibaragi.

Decomposition of Bands

The observed intensity was obtained by means of this equation:

$$I(\nu) = \ln (\mathbf{T}_0/\mathbf{T})_\nu [\nu(1-\exp(-hc\nu/kT))]^{-1}, \quad (1)$$

where $(\mathbf{T}/\mathbf{T}_0)_\nu$ is the transmittance at wavenumber ν and where T is the absolute temperature. The observed values are indicated by small circles in Figs. 1—5. If the random-reorientation model is adopted for the ensemble of molecules, the band-shape function (1) for a single vibrational transition centered at ν^0 is given by:[1]

$$I(\nu) \sim \sum_{i,f} \rho_i |\langle i|\boldsymbol{\varepsilon}\cdot\boldsymbol{m}^\nu|f\rangle|^2 \delta[(E_f-E_i)/hc-(\nu-\nu^0)] \quad (2)$$

From this equation, one can easily derive the following relationship:

$$I(2\nu^0-\nu) = \exp(-hc(\nu-\nu^0)/kT)\cdot I(\nu) \quad (3)$$

This is nothing but the condition of the detailed balance.[18] Such a function, $I(\nu)$, can be represented in terms of a symmetric function, $I_s(|\nu-\nu^0|)$, as follows:

$$I(\nu) = \exp(hc(\nu-\nu^0)/2kT)\cdot I_s(|\nu-\nu^0|) \quad (4)$$

Here, $I_s(|\nu-\nu^0|)$ represents the Fourier transform of a real autocorrelation function of the transition dipole moment. It is widely accepted that the dipole correlation function should show an exponential decay at a long time in the liquid phase. It follows from this that the central part of the infrared band should be described by a Lorentzian profile. Thus, $I_s(|\nu-\nu^0|)$ was assumed to be Lorentzian. The observed intensity in a given region is, then, expressed in general by:

$$I(\nu) = \sum_i \exp(hc(\nu-\nu_i^0)/2kT)\frac{p_i(\omega_i/2)^2}{(\nu-\nu_i^0)^2+(\omega_i/2)^2}, \quad (5)$$

where ν_i^0, ω_i, p_i denote the band center, the half band-width, and the peak height respectively for the i-th vibrational transition. The right-hand side of Eq. 5 is divergent on the high-frequency side. However, since the absorption regions in question were limited near the

band centers, no difficulty occurred in the band analysis. The parameter values fitted are summarized in Tables 1 and 2. Practically, the parameter values adjusted for bands with half-widths smaller than 30 cm^{-1} did not depend upon whether or not the exponential factor in Eq. 5 was ignored. Therefore, the values for the ν_3 band in Table 1 are taken from the previous report, in which this factor was ignored.[11]

Results and Discussion

a_1-Type Bands. The band shape of the fundamental a_1-type vibration is well reproduced by a single Lorentzian function, except for slight deviations from the Lorentzian functions in the lower-frequency wings, as may be seen in Fig. 1. A similar deviation was also found for the ν_3 fundamental band.[11] These deviations may be attributed to the vibration-rotation interaction, as was mentioned in the previous report on the ν_3 band.

The doublet in the region from 2740 to 2900 cm^{-1} was observed as parallel bands in the gas phase and was assigned to the Fermi doublet, $2\nu_5$ and $\nu_3+\nu_5+\nu_6$, by Matsuura and Shimanouchi.[19] The decomposition of the doublet was performed after subtracting the wings of the ν_1 and ν_4 bands from the total absorption. The results are shown in Fig. 2a.

In the absorption region of the $2\nu_2$ band, a small band is observed in the lower-frequency wing, as is shown in Fig. 2b. The best-fit parameter values of the two Lorentzian functions are $\nu_a^0=2464.2$ cm^{-1}, $\nu_b^0=2453.0$ cm^{-1}, $\omega_a=9.1$ cm^{-1}, and $\omega_b=9.0$ cm^{-1}, and the ratio of band areas, $p_b\omega_b/p_a\omega_a$, is 0.095, where the subscripts a and b denote the $2\nu_2$ and the small band respectively. The small band may be assigned to the hot band transition, $2\nu_2+\nu_3-\nu_3$, since its half-width is nearly equal to that of $2\nu_2$ and since the area ratio is in agreement with the theoretical values, $\exp(-hc\nu_3/kT)=0.081$, at $T=300$ K. The anharmonicity constant was estimated using the relation $x_{23}=(\nu_b^0-\nu_a^0)/2$ to be -5.6 cm^{-1}. This value is nearly equal to the value of -5 cm^{-1} obtained by using another relation, $x_{23}=(\nu_2+\nu_3)-\nu_2-\nu_3$, in a CCl_4 solution.[20] Although such a non-zero x_{23} should produce the $\nu_2+\nu_3-\nu_3$ hot band at the frequency lower than that of the ν_2 fundamental by about 5 cm^{-1}, it is impossible to resolve the observed band into the two components. However, the effect of the hot band on the parameter values obtained for the ν_2 fundamental band may be small and need not be taken into account in the following discussion.

••••••: Observed; ——: calculated.

The band width of the overtone, $2\nu_2$, is larger than that of the fundamental, ν_2. This is probably due to the difference between contributions from the vibrational relaxation of the translational-diffusion type,[12] as was pointed out in the case of the ν_3 transition.[11] If there is no other cause of the band broadening, the width due to the vibrational relaxation is estimated to be $\omega_2\ (0\rightarrow2)-\omega_2(0\rightarrow1)=1.4$ cm^{-1}; accordingly the width due to the reorientational relaxation becomes $\omega_2(0\rightarrow1)-1.4$ cm^{-1}

$=6.3\ cm^{-1}$. In order to estimate the reorientational relaxation for the ν_1 band, some Raman data is available. The width of the isotropic component of the Raman ν_1 band has been found to be $3.5\ cm^{-1}$ in CS_2 solutions (1.7 mol/l).[21] This width may be considered to be due to the vibrational relaxation and to be transferable to the infrared-band width.[11,22-25] Then, the band-width of the infrared ν_1 vibration due to the reorientational relaxation is estimated to be $\omega_1(0\rightarrow1)-3.5\ cm^{-1}=7.3\ cm^{-1}$. The widths of the ν_3 band due to the reorientational and vibrational relaxations have previously been estimated to be 6.3 and $2.0\ cm^{-1}$ respectively.[11]

The vibrational species of the same symmetry have transition dipole moments in the same direction in the molecular framework. Therefore, their band-widths based upon the reorientational relaxation should be identical to one another only if the effect of the vibration-rotation interaction is negligible. This is the case for the a_1-type band of CH_3I. The estimated band-widths due to the reorientational relaxation, 7.3, 6.3, and $6.3\ cm^{-1}$ for the ν_1, ν_2, and ν_3 vibrations respectively, agree approximately with one another in spite of a scattering of the observed total widths, 10.8, 7.7, and $8.3\ cm^{-1}$.[26]

The band-widths of the Fermi doublet, $2\nu_5$ and $\nu_3+\nu_5+\nu_6$, are much larger than those of the other a_1-type bands. Matsuura and Shimanouchi[19] have pointed out that the unperturbed $(\nu_3+\nu_5+\nu_6)^0$ band behaves as a quasi-perpendicular band with an effective Coriolis constant of -0.47, whereas the unperturbed $(2\nu_5)^0$ band has the normal profile of a parallel band. The band-widths observed in solutions are intermediate between those of the a_1-type and the e-type bands. It is probable that the vibration-rotation interaction is operative in solutions and that, as a result, the broadenings of the components of this doublet are much larger than those of the other a_1-type bands.

e-Type Bands. The absorption region of the e-type vibration is, as a rule, well reproduced by two Lorentzian functions. The narrower Lorentzian, designated as $\nu(L_1)$, and the broader one, designated as $\nu(L_2)$, represent the shape near the band center and a background-like absorption of a greater width respectively.

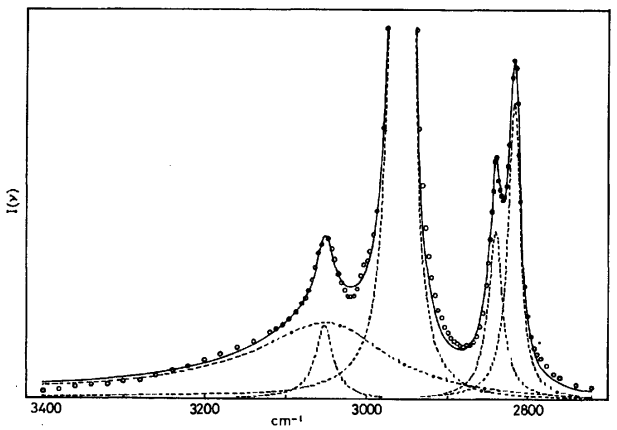

Fig. 3. The infrared absorption in the region from 2720 to 3400 cm^{-1} of methyl iodide in the carbon tetrachloride solution.
•••••: Observed; ——: calculated, total; ------: calculated, components.

Figure 3 shows the absorption ranging from 2720 to 3400 cm^{-1}, of methyl iodide in carbon tetrachloride. In addition to the e-type ν_4 band, there appear three a_1-type bands, ν_1, $2\nu_5$, and $\nu_3+\nu_5+\nu_6$. The absorption in this region is well reproduced by five Lorentzian functions. It should be noted that $\nu_4(L_2)$ is much broader than the others and spreads all over the region.

In the absorption region of ν_5, the combination band $\nu_3+\nu_6$ also appears. This region is well reproduced by three Lorentzian functions, as is shown in Fig. 4. It has

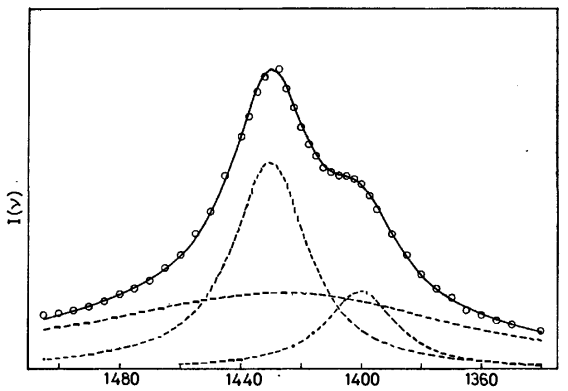

Fig. 4. The infrared absorption in the region of the Fermi doublet ν_5 and $\nu_3+\nu_6$ of methyl iodide in the carbon tetrachloride solution.
•••••: Observed; ——: calculated, total; ------: calculated, components.

been established that the Fermi-resonance occurs between the ν_5 and $\nu_3+\nu_6$ bands.[27] If the value of the Fermi-resonance parameter, $W=K_{356}/\sqrt{2}$, in the solution is assumed to be equal to that in the gas phase, 10.4 cm^{-1},[27d] the unperturbed frequencies may be estimated to be 1426.5 and 1403.8 cm^{-1} for ν_5^0 and $(\nu_3+\nu_6)^0$ respectively. The value of the anharmonicity constant, x_{36}, is, then, obtained to be as follows: $x_{36}=(\nu_3+\nu_6)^0-\nu_3-\nu_6=-4.8$ cm^{-1}. This value agrees with those obtained in the gas phase, -5.6[27d] and -5 cm^{-1}.[27b] Both the values of K_{356} and x_{36} seem to be almost unchanged on going from gas to solution.

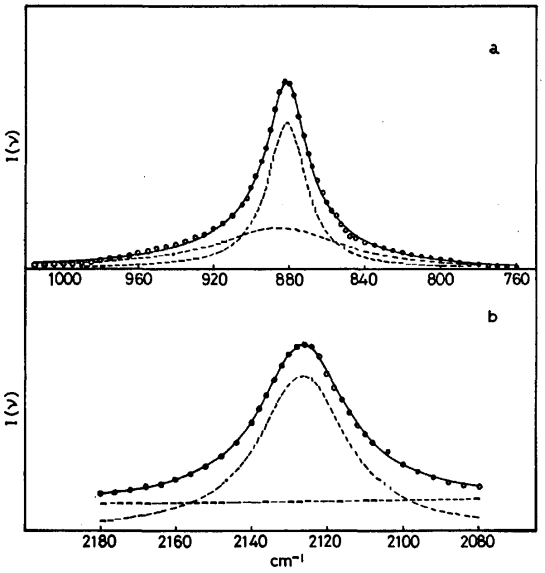

Fig. 5. The infrared bands of methyl iodide in solutions: (a) ν_6 in CS_2, (b) $\nu_2+\nu_6$ in CCl_4.
•••••: Observed; ——: calculated, total; ------: calculated, components.

The region of the ν_6 vibration is simply reproduced by two Lorentzian functions, as is shown in Fig. 5a. The combination band, $\nu_2+\nu_6$, is much weaker than the other e-type bands studied in the present work. The background-like absorption in Fig. 5b looks nearly constant throughout the region. This is probably because of the overlap of the wings of the neighboring bands. It is impossible to extract the $\nu(L_2)$ from the whole background.

The shapes of ν_4, ν_5, and ν_6 fundamental bands, each of which is composed of $\nu(L_1)$ and $\nu(L_2)$, are compared in Fig. 6. Their band-widths, ω(ap), are very different

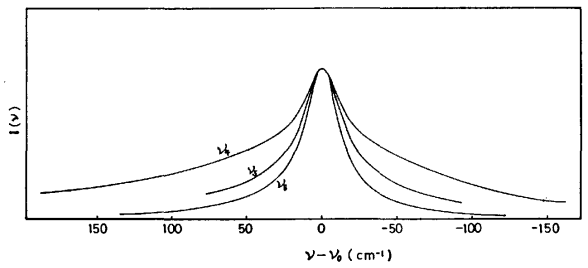

Fig. 6. Comparison of the normalized shapes of the ν_4, ν_5, and ν_6 bands, each of which is composed of $\nu(L_1)$ and $\nu(L_2)$.

from each other, as is shown in Table 2. Nevertheless, the half-widths of $\nu(L_1)$, $\omega(L_1)$, are much less dispersive and in the order of $\omega_5(L_1)>\omega_4(L_1)>\omega_6(L_1)$, in accordance with that of the Q-branch line spacings in the gas phase. The Q-branch line spacing of methyl iodide in the gas phase is nearly proportional to $1-\zeta$, where ζ is the Coriolis coupling constant. The values of ζ have been reported to be 0.060,[27a] -0.242,[27d] and 0.210[27d] for ν_4, ν_5, and ν_6 respectively. If a strong Fermi resonance occurs, the Q-branch line spacing of each Fermi component may be related to the mean value of ζ for the unperturbed vibrations, at least in the region near the band center. Therefore, we tentatively adopted the value of $\zeta=(\zeta_5+\zeta_6)/2$ for the Fermi doublet, by using ζ_6 in place of ζ_{36}. The values of $\omega(L_1)$ divided by $1-\zeta$ are given in the last column in Table 2. They are constant; in other words, $\omega(L_1)$ is proportional to the Q-branch line spacing.

The absorptions specified by $\nu(L_2)$ serve for the broadening of the observed bands; the percentage of each $\nu(L_2)$ occupying the band area and the broadening are much larger for ν_4 than ν_5 and ν_6. No definite conclusion can be drawn about their origin and precise shape at present. However, the $\nu(L_2)$ parts of the e-type bands seem to be related to the A_1-E-type Coriolis coupling, with the intense nondegenerate band in the neighborhood. The intensity perturbation due to the A_1-E-type Coriolis coupling is approximately proportional to $[J(J+1)-K(K+1)]$ in the gas phase.[28] This type of coupling probably intensifies the band-wing, even in the solutions. For methyl iodide, the separations between the degenerate bands and their nondegenerate intense neighbors are $\nu_4-\nu_1\approx90$ cm^{-1}, $\nu_5-\nu_2\approx170$ cm^{-1}, $\nu_2-\nu_6\approx360$ cm^{-1}, and $\nu_6-\nu_3\approx350$ cm^{-1}. Therefore, the A_1-E-type Coriolis coupling may affect the ν_4 band most strongly and the ν_6 band most weakly. This is consistent with the observed order of the magnitudes for $\omega(L_2)$.

The authors wish to thank Professors Osamu Yonemitsu and Kozo Tanabe of Hokkaido University for their permission to use the JASCO DS-701G infrared spectrophotometers.

Statistical Thermodynamic Theory of Liquid Water

Kiyoshi ARAKAWA, Kazuo TOKIWANO,* and Kazumitsu KOJIMA

Research Institute of Applied Electricity, Hokkaido University, Sapporo 060

** Faculty of Engineering, Hokkaido University, Sapporo 060*

(Received July 12, 1976)

A new statistical thermodynamic theory is presented for a model of liquid water, which consists of two components, *i.e.*, tetrahedrally-coordinated pentamers and non-hydrogen-bonded monomers. In the model the two components are assumed to be immersed in a uniform background potential which results from electrostatic, induction, and dispersion forces between water molecules. A partition function is given without assuming any specified lattice. A translational partition function is written into a simple and explicit expression which is derived from the Lebowitz solution of the Percus-Yevick equation for hard sphere mixtures. The mole fraction of each component and the density are determined by solving two equations, *i.e.*, the condition of free energy minimization and the equation of state derived from the partition function, simultaneously. Various thermodynamic quantities are calculated and the values determined are compared with those observed. Some discussions are carried out, together with the criticism of the earlier theories.

Various kinds of statistical thermodynamic theories of liquid water[1-3] have been proposed for about a decade since the presentation of the earlier theory by Némethy and Scheraga (1962). Many new experimental results have also been accumulated for nearly the same period of time and added a great deal of contributions to the knowledge of the structure of liquid water,[4] though no decisive conclusion about it has been obtained at present.[5]

Concerning the structure theories of liquid water, the situations are diversified nowadays certainly, but, as to the theoretical methods and models used, several distinguishable features are found in the studies carried out recently. Those are classified into three groups: 1) lattice and cell theories, 2) applications of the recent progress in the theory of liquids, *i.e.*, the Percus-Yevick and HNC equations *etc.*, 3) results in computer experiments, *i.e.*, molecular dynamics and Monte Carlo calculations.

Among the first group of studies we find lattice theories presented by Bell and others[6] and by Fleming and Gibbs,[7] a cell theory by Weissmann and Blum,[8] and an order-disorder theory by the authors.[9] Some of these theories[6,7,9] treated the theme of the cooperative character in the structure of liquid water, that is, the cooperative formation and breakage of the hydrogen-bonded structure, but the success of those is only qualitative, subjected to the limitation which is associated with the essential nature of the lattice theory. The studies in line with the second group are mainly promoted by Ben-Naim and others.[10] There seems to be a fair prospect of success of these theories, but the greatest problem lies in mathematical difficulties of solving integral equations for correlation functions. The most remarkable results in the third group are those of molecular dynamics given by Rahman and Stillinger.[11] They have made important contributions to the determination of the structure model for water. All the results described above give new possibilities, surely, to solve the important but difficult problem of the liquid structure of water. However, their successes remain to be qualitative and limited ones on the whole.

From the quantitative view-point of results, recent two theories presented by Weres and Rice[12] and by Scheraga and coworkers[13] are intensely interesting. The former one is a kind of lattice theory and the latter one is based on a mixture model (cluster model). They made a further forward step to the quantitative explanation of the equilibrium behavior of water. However, they are too solid-like. For example, it has been found in the calculation by Weres and Rice that the value of configurational entropy with respect to the arrangement of water molecules in basic cells remains quite unchanged throughout the temperature range from 0 to 100 °C. In the calculation by Scheraga *et al.* also, it has been found that $U_{\text{vib.}}$, the internal energy resulting from the intermolecular vibrational structure, increases from the value of 3.33 kcal/mol to 3.87 kcal/mol throughout the same range of temperature while $U_{\text{trans.}}$, the energy for translational motion, is very small, being within the range from 0.18 to 0.28 kcal/mol. These features of the two theories clearly show the too solid-like character, though it is found to be more intense in the theory by Weres and Rice than in the one by Scheraga *et al.*

Thus, the authors have attempted to propose a statistical thermodynamic theory of liquid water based on the recent progress in studies of liquids, in order to give the more adequate explanation of the properties of water. Details of the results are reported in the following sections.

Description of the Model

Since the proposition by Bernal and Fowler in 1933, the tetrahedral coordination has been considered to dominate in the local structure in liquid water. The results of X-ray studies from Morgan and Warren's (1938) to the recent Narten, Danford, and Levy's[14] has ascertained that the average coordination number in liquid water is slightly larger than four at ordinary temperatures, indicating the predominance of the local tetrahedral geometry. Recent spectroscopical studies by Walrafen[15] and others has also confirmed that the tetrahedrally-coordinated hydrogen-bonded configurations with C_{2v} symmetry constitute most of the structures present in water. This feature should be taken into consideration firstly in the formulation of the theoretical model for water.

In the recent presentation of a statistical thermodynamic theory for water, Lentz, Hagler, and Scheraga

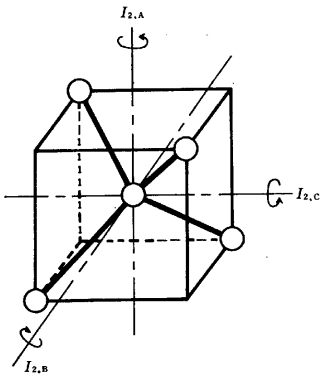

Fig. 1. Tetrahedrally-coordinated pentamer.

have used a model consisting of a distribution of small clusters from 1 to 9,[13] admitting the criticisms against the earlier theory of Némethy and Scheraga[16] (1962) that it used a model with very large clusters.

It is desirable that the basic model underlying a theory is as simple as possible if the theory can explain the behavior of the substance as objects with a sufficient accuracy. Thus, the authors assume that liquid water consists of two species which are tetrahedrally hydrogen-bonded pentamers (Fig. 1) and unbonded monomers. The character of the structure supposed to be intrinsic of water is attributed to the presence of the pentamers, and liquid water is regarded as an equilibrium mixture of the monomers and the pentamers.

In the formulation of the total partition function, we assume that attractive forces between molecules give rise to a uniform background potential, taking into consideration the treatment made first by Longuet-Higgins and Widom for liquid Argon,[17] by Scheraga and others for water,[13,18] and by the authors for normal liquid.[19] The magnitude of the background potential is determined by a direct calculation as described in later sections, while it was treated as an adjustable parameter in the calculation of Scheraga and others.

In order to give a translational partition function we regard the two species as hard spheres with diameters R_1 and R_2 ($R_1<R_2$), respectively, which are immersed in the background potential, and the translational partition function is derived from the analytical solution of the Percus-Yevick equation for hard sphere mixtures. Its details are described later.

The Partition Function

For the model used the total partition function is expressed as a product,

$$Z = Q_{\text{trans.}} Q_{\text{rot.}} Q_{\text{int.}} Q_{\text{BG}}, \tag{1}$$

in terms of the translational, rotational, internal, and background potential contribution, respectively.

i) Translational Partition Function. We can write the translational partition function $Q_{\text{trans.}}$ at given V and T for an assembly of N_1 non-hydrogen-bonded monomers (the mass m_1 and the diameter R_1) and N_2 pentamers (the mass m_2 and diameter R_2). The formula is derived from the analytical and explicit solution of the generalized Percus-Yevick equation given first by Lebowitz.[20,21] The details of the derivation are described in Appendix I.

$Q_{\text{trans.}}$ is expressed as

$$Q_{\text{trans.}} = \left[\left(\frac{2\pi m_1 kT}{h^2}\right)^{3/2} e v_1 f\right]^{N_1} \left[\left(\frac{2\pi m_2 kT}{h^2}\right)^{3/2} e v_2 f\right]^{N_2}, \tag{2}$$

and

$$f = (1-\xi)\exp\left[-\frac{9}{\pi}\frac{V}{N_1+N_2}\frac{1}{(1-\xi)^2}(2XY-2XY\xi+X^3)\right], \tag{3}$$

where

$$v_1 = V/N_1 = \rho_1^{-1},\ v_2 = V/N_2 = \rho_2^{-1},$$

$$X = \frac{\pi}{6}\rho_1 R_1^2 + \frac{\pi}{6}\rho_2 R_2^2,\ Y = \frac{\pi}{6}\rho_1 R_1 + \frac{\pi}{6}\rho_2 R_2,$$

and the packing fraction is

$$\xi = \frac{\pi}{6}\rho_1 R_1^3 + \frac{\pi}{6}\rho_2 R_2^3.$$

The Eqs. 2 and 3 are a generalization of Eqs. 4 and 6 in the previous paper[19] for an one component fluid into the formulas for a mixture of hard spheres, where ξ corresponds to y in the paper. Equation 2 is seen to have a form identical with that given in the free volume theory in general. Thus, $f \equiv$ Eq. 3 is defined as a generalized equivalent free volume fraction, which is similar to the case of an one component fluid.[19] This is extended to the general case for an m-component fluid as described in Appendix I. In the presentation of our theory no lattice is assumed, and the theory derived is free from the criticism against the lattice theory in general in its application to liquids.

ii) Rotational Partition Function. The contribution $Q_{\text{rot.}}$ from the rotational motions to the total partition function becomes

$$Q_{\text{rot.}} = \left[\frac{\pi^{1/2}}{\sigma_1}\left(\frac{8\pi^2 kT}{h^2}\right)^{3/2}(I_{1,A}I_{1,B}I_{1,C})^{1/2}\right]^{N_1} \times \left[\frac{\pi^{1/2}}{\sigma_2}\left(\frac{8\pi^2 kT}{h^2}\right)^{3/2}(I_{2,A}I_{2,B}I_{2,C})^{1/2}\gamma\right]^{N_2}, \tag{4}$$

where $I_{i,A}$, $I_{i,B}$, $I_{i,C}$, and σ_i are the moment of inertia and symmetry factor, respectively, of an i-th particle. γ is a reduction factor which results from the restriction of the over-all free rotation for a larger particle such as a pentamer. Though this factor γ is expected to be smaller than 1 for the pentamer, we take it as 1, for it is impossible to compute the reduced number of rotational configurations. Symmetry factors σ_1 and σ_2 are taken to be 2, as usual.

iii) Internal Partition Function. The internal partition function $Q_{\text{int.}}$ is

$$Q_{\text{int.}} = Q_{\text{vib.}} \exp\left(\frac{-4N_2\varepsilon}{kT}\right), \tag{5}$$

where $Q_{\text{vib.}}$ is the contribution from the vibrational degrees of freedom from N_2 pentamers and ε is the energy of hydrogen bonding within pentamers. In each pentamer four hydrogen bonds are formed between the central molecule and four tetrahedrally-coordinated molecules. We write the vibrational contribution $Q_{\text{vib.}}$ as

$$Q_{\text{vib.}} = \left[\prod_{j=1}^{24}\left\{\frac{\exp(-h\nu_j/2kT)}{1-\exp(-h\nu_j/kT)}\right\}\right]^{N_2}, \tag{6}$$

where ν_j is the frequency of intermolecular vibrational mode within a pentamer. $24(=6\times5-6)$ degrees of freedom are considered for the modes.

iv) Backbround Potential. The contribution Q_{BG} from the uniform background potential term to the total partition function becomes

$$Q_{BG} = \exp(-U_{BG}/kT) \tag{7}$$

As described in the previous section, each hard sphere molecule is assumed to be immersed in a uniform background potential U_{BG}, and no specific interactions are considered between hard spheres. U_{BG} for a molecule is considered to result from the dipole-dipole, dipole-induced dipole, and dispersion interactions between the molecule and all the other molecules as its medium. U_{BG} is expressed as inversely proportional to the volume of the liquid in the same way as Longuet-Higgins and Widon assumed,[17] and is written into a simple form as $U_{BG}=aN^2/V$, where a is a constant. This presupposes that, concerning electrostatic, induction, and dispersion interactions, water molecules behave similarly with each other, whether they are within pentamers or in unbonded state.

The dipolar interaction between permanent point dipoles is expressed as

$$U_{\mu\mu} = \frac{\mu^2}{\tilde{R}^3}[\sin\theta_A \sin\theta_B \cos(\phi_A-\phi_B) - 2\cos\theta_A\cos\theta_B], \tag{8}$$

where $\tilde{R}$ is the separation between a dipole A and a dipole B, θ_A and θ_B the polar angles for A and B (the line connecting A and B is regarded as a polar axis), and ϕ_A and ϕ_B the angles formed by the plane including the dipole and the polar axis with a reference plane. $U_{\mu\mu}$ is averaged for all configurations of two dipoles A and B with respects to angles θ_A, θ_B, ϕ_A, and ϕ_B, and the averaged value $\langle U_{\mu\mu}\rangle$ becomes a function of $\tilde{R}$ only.

$$\langle U_{\mu\mu}\rangle = \int U_{\mu\mu}\exp(-U_{\mu\mu}/kT)d\Omega \Big/ \int \exp(-U_{\mu\mu}/kT)d\Omega, \tag{9}$$

where $d\Omega=\sin\theta_A \sin\theta_B\, d\theta_A\, d\theta_B\, d\phi_A\, d\phi_B$.

The dipole-induced dipole interaction $U_{\mu\alpha}$ becomes

$$U_{\mu\alpha} = -\frac{2\mu^2\bar{\alpha}}{\tilde{R}^6}, \tag{10}$$

where $\bar{\alpha}$ is a average molecular polarizability, and the dispersion interaction between two molecules is

$$U_{disp.} = -\frac{c}{\tilde{R}^6}, \tag{11}$$

The background potential U_{BG} is determined by integration of the sum of Eqs. 9, 10, and 11 multiplied by $g(\tilde{R})$. The $g(\tilde{R})$ is a molecular correlation function[22] obtained from the observed radical distribution function by substracting intramolecular contributions.

Then, U_{BG} is written as

$$U_{BG} = \frac{N^2}{2V}\int[\langle U_{\mu\mu}\rangle + U_{\mu\alpha} + U_{disp.}]g(\tilde{R})4\pi\tilde{R}^2 d\tilde{R}. \tag{12}$$

A Monte Carlo method is used in the calculation of $\langle U_{\mu\mu}\rangle$. The details in the procedure of calculation of U_{BG} are described in Appendix II.

Thermodynamic Variables

In the present model the following equilibrium at given T is established in water,

$$5(H_2O) \rightleftarrows (H_2O)_5, \tag{13}$$

where the total number of water molecules N remains constant,

$$N = N_1 + 5N_2. \tag{14}$$

The free energy F is obtained from the total partition function Z (Eq. 1).

$$F = -kT\ln Z, \tag{15}$$

where N_1, N_2, and molar volume V^0 (density ρ) at equilibrium are determined at given T and N from the condition of Z maximization and the equation of state derived from Z. Under the association equilibrium condition (Eqs. 13 and 14), the following relation holds.[23]

$$\left(\frac{\partial F}{\partial T}\right)_{V,N} = \left(\frac{\partial F}{\partial T}\right)_{V,N_1,N_2}, \quad \left(\frac{\partial F}{\partial V}\right)_{T,N} = \left(\frac{\partial F}{\partial V}\right)_{T,N_1,N_2}. \tag{16}$$

This relation simplifies the formulas for various thermodynamic variables which are derived from Eq. 15.

The equation of state is given as

$$pV = \frac{kT}{(1-\xi)^3}\left[(N_1+N_2)(1+\xi+\xi^2) - \frac{\pi N_1 N_2}{2V}(R_2-R_1)^2 \times\left\{R_1+R_2+\frac{\pi}{6}\left(\frac{N_1R_1^2+N_2R_2^2}{V}\right)R_1R_2\right\}\right] + \frac{aN^2}{V}, \tag{17}$$

where the first term in the right of Eq. 17 is the same as that derived by Lebowitz[20] for hard sphere mixtures, and the second term comes from the background potential term.

The entropy S is expressed[24] as

$$S = S_{trans.} + S_{rot.} + S_{int.}, \tag{18}$$

$$S_{trans.} = k\ln Q_{trans.} + \frac{3}{2}(N_1+N_2)k$$

$$S_{rot.} = k\ln Q_{rot.} + \frac{3}{2}(N_1+N_2)k$$

$$S_{int.} = k\ln Q_{vib.} + kT\frac{\partial \ln Q_{vib.}}{\partial T} = S_{vib.}$$

The internal energy $U=F+TS$ is obtained from F and S as

$$U = 3(N_1+N_2)kT + 4N_2\varepsilon + kT^2\left(\frac{\partial \ln Q_{vib.}}{\partial T}\right) + \frac{aN^2}{V}. \tag{19}$$

$$U_{trans.} = U_{rot.} = \frac{3}{2}(N_1+N_2)kT$$

$$U_{kin.} = U_{trans.} + U_{rot.}$$

$$U_{vib.} = kT^2\left(\frac{\partial \ln Q_{vib.}}{\partial T}\right)$$

$$U_{HB} = 4N_2\varepsilon$$

$$U_{BG} = \frac{aN^2}{V}.$$

The heat capacity at constant pressure, C_p, is derived as follows,

$$C_p = \left(\frac{\partial U}{\partial T}\right)_p + p\left(\frac{\partial V}{\partial T}\right)_p$$
$$= \left(\frac{\partial U}{\partial T}\right)_{p,N_1,N_2} + \left(\frac{\partial U}{\partial N_2}\right)_{p,T}\left(\frac{\partial N_2}{\partial T}\right)_{p,N} + p\left(\frac{\partial V}{\partial T}\right)_p$$
$$= 3(N_1+N_2)k + 2kT\left(\frac{\partial \ln Q_{\text{vib.}}}{\partial T}\right) + kT^2\left(\frac{\partial^2 \ln Q_{\text{vib.}}}{\partial T^2}\right)$$
$$+ \left(\frac{\partial U_{\text{BG}}}{\partial T}\right)_p + \left[-12kT + 4\varepsilon + kT^2\left(\frac{\partial \ln q_{\text{vib.}}}{\partial T}\right)\right]$$
$$\times \left(\frac{\partial N_2}{\partial T}\right)_{p,N} + p\left(\frac{\partial V}{\partial T}\right)_p, \qquad (20)$$

where $(q_{\text{vib.}})=(Q_{\text{vib.}})^{1/N_2}$ is a molecular vibrational partition function for a pentamer.

Numerical Computations

i) Determination of Molecular Parameters. For the purpose of calculating thermodynamic quantities, the following values of molecular parameters are used, which have been determined from various sources. The magnitudes of hard sphere diameters and moments of inertia are tabulated in Table 1.

TABLE 1. MOLECULAR PARAMETERS

	Unbonded monomers	Pentamers
Diameter of hard spheres		
	$R_1=3.10$ Å	$R_2=5.50$ Å 5.55 Å
Polarizability $\bar{\alpha}$	1.44×10^{-24} cm^3	O-H···O distance 2.82 Å
Dipole moment μ	1.84 D	
Moments of inertia (10^{-40} g cm^2)		
	$I_{1,A}=1.0220$ $I_{1,B}=1.9187$ $I_{1,C}=2.9376$	$I_{2,A}=I_{2,B}$ $=I_{2,C}=634.332$

The R_1 is considered to correspond to the van der Waals diameter for water, which is used in the molecular dynamics calculation by Stillinger and Rahman.[11] The magnitudes of moments of inertia for monomers are those determined by Benedict and others[25] and cited by Eisenberg and Kauzmann.[26] Those of moments of inertia for a pentamer are calculated for the configuration shown in Fig. 1, where the hydrogen-bonded distance in liquid water is taken to be 2.82 Å[14,27] and the mass of four tetrahedrally-bonded molecules is assumed to be concentrated at their centers of mass. Calculated values of the moments of inertia for three rectangular axes shown in Fig. 1, *i.e.*, $I_{2,A}$, $I_{2,B}$, and $I_{2,C}$ are all equal in their magnitudes. This equality of these three moments of inertia shows high degree of symmetry of that configuration, which supports the idea that the pentamer is treated as a sphere in this work. Some uncertainly attaches to the determination of R_2. Lentz, Hagler and Scheraga[13] used about 5.3—5.4 Å as the values of R_2 for a pentamer. They determined the value by measuring the displaced volume of "foil-wrapped space-filling models" (by immersion of the models into liquid). Their values are those for "clusters as compact as possible, consistent with a maximum value of hydrogen bonding", and supposed to be a little smaller than that for the pentamer shown in Fig. 1. Thus, we have carried out calculations for two values of R_2, *i.e.* 5.50 and 5.55 Å.

As to the energy of the formation of hydrogen-bonding, the value of 2.5 kcal per mole of hydrogen bonds is used, various experimental sources of which are given in Table 2. This value of ε is assumed to correspond to the energy for the process of hydrogen-bond breakage during which the separation of the hydrogen-bonded pair of molecules remains nearly unchanged. The values determined by various different experimental techniques are seen to agree with each other. Davis and Litovitz used the value of 2.55 kcal/mol in their calculation.[27]

TABLE 2. THE ENERGY OF HYDROGEN-BONDING
ε (kcal/mol)

	ε	Authors	Bonding
R[a]	2.5_5	Walrafen[15]	O-H···O
IR[b]	2.5	Worley and Klotz[28]	O-H···O
R	2.4—2.5	Lindner[15]	O-D···O
IR	2.3	Senior and Verrall[29]	O-D···O
N[c]	≈2.5	Safford[15]	O-H···O
Average	2.5		

a) R: Raman. b) IR: infrared. c) N: neutron scattering.

Concerning the assignment of the frequency ν_j, there is still some uncertainty. We have assigned the values tabulated in Table 3 to each normal mode frequency $\nu_j(j=1—24)$, which are grouped as seen in the table. These values are taken from the sources[13,15,30,31] cited in Table 3 and are used as rounded-up values.

TABLE 3. NORMAL MODE FREQUENCIES
ν_j FOR PENTAMERS

	ν_j (cm^{-1})	Number of modes[a]
ν_L[b]	700	3
ν_L'	550	4
ν_L''	450	4
ν_T	200	3
ν_T'	150	3
$\nu_{tor.}$	100	2
ν_b	60	3
ν_b'	40	2

a) Refs. 13, 15, 30, 31. b) Suffix L, L', L'' are those for librational modes, T and T' for translational ones, tor. for torsional one, and b and b' for bending modes.

ii) Determination of Mole Fraction x for Hydrogen-Bonded Molecules and the Density of Liquid Water. In advance of calculating various thermodynamic quantities we must determine the equilibrium distribution for N_1 and N_2 at given T and V for a given total number N of molecules (Eq. 14). This can be carried out using the condition of the maximization of Z with respect to N_2, where the number of independent variables is only one under the condition of Eq. 14 for a given value of N and we take N_2 for the independent variable for convenience.

Thus,

$$\left(\frac{\partial F}{\partial N_2}\right)_{V,T} = \left(\frac{\partial F}{\partial N_2}\right)_{N_1,V,T} + \left(\frac{\partial F}{\partial N_1}\right)_{N_2,V,T}\left(\frac{\partial N_1}{\partial N_2}\right)_{V,T} = 0.$$

From Eq. 14 for a constant value of N,

$$\left(\frac{\partial N_1}{\partial N_2}\right)_{V,T} = -5.$$

Inserting this into the equation described above, we obtain

$$\left(\frac{\partial F}{\partial N_2}\right)_{N_1,V,T} = 5\left(\frac{\partial F}{\partial N_1}\right)_{N_2,V,T} \tag{21}$$

or $$\mu_2 = 5\mu_1, \tag{21'}$$

where μ_1 and μ_2 is the chemical potential for each species, respectively. Eq. 21 (*i.e.* Eq. 21') is the condition of thermodynamic equilibrium between pentamers and unbonded monomers.

In order to determine the density for the liquid theoretically, the equation of state, which is expressed as Eq. 17, is used, where the left hand side (pV) is safely regarded as zero under ordinary pressures (the so-called "vanishing external pressure condition"[19,32]).

The two procedures for the determination of the mole fraction and the density (*i.e.* molar volume) must be carried out simultaneously, because the two kinds of values to be determined are interrelated to each other in the two equations.

We use $x=5N_2/N$ as an independent variable instead of N_2, which is the mole fraction for hydrogen-bonded molecules in water. The following two equations are used in the determination of x and V for practical use. Eq. 21 becomes

$$\begin{aligned}
&-\left[\ln\left\{\left(\frac{2\pi m_2 kT}{h^2}\right)^{3/2}\frac{V}{N}\frac{5}{x}\right\} + \ln(1-\xi)\right.\\
&-\frac{1}{(1-\xi)}\frac{\pi}{6}\frac{N}{V}\left(1-\frac{4}{5}x\right)R_2^3 - \frac{3}{(1-\xi)}(R_2^2Y+R_2X)\\
&\left.-\frac{3}{(1-\xi)^2}\left(R_2^3XY+\frac{3}{2}R_2^2X^2\right) - \frac{3R_2^3X^3}{(1-\xi)^3}\right]\\
&-\left[\ln\left\{\frac{\pi^{1/2}}{\sigma_2}\left(\frac{8\pi^2kT}{h^2}\right)^{3/2}(I_{2,A}I_{2,B}I_{2,C})^{1/2}\gamma\right\}\right.\\
&\left.+\ln\left\{\prod_{j=1}^{24}\frac{\exp(-h\nu_j/2kT)}{1-\exp(-h\nu_j/kT)}\right\} - \frac{4\varepsilon}{kT}\right]\\
&+5\left[\ln\left\{\left(\frac{2\pi m_1 kT}{h^2}\right)^{3/2}\frac{V}{N}\frac{1}{(1-x)}\right\} + \ln(1-\xi)\right.\\
&-\frac{1}{(1-\xi)}\frac{\pi}{6}\frac{N}{V}\left(1-\frac{4}{5}x\right)R_1^3 - \frac{3}{(1-\xi)}(R_1^2Y+R_1X)\\
&\left.-\frac{3}{(1-\xi)^2}\left(R_1^3XY+\frac{3}{2}R_1^2X^2\right) - \frac{3R_1^3X^3}{(1-\xi)^3}\right]\\
&+5\left[\ln\left\{\frac{\pi^{1/2}}{\sigma_1}\left(\frac{8\pi^2kT}{h^2}\right)^{3/2}(I_{1,A}I_{1,B}I_{1,C})^{1/2}\right\}\right] = 0,
\end{aligned} \tag{22}$$

$$\xi = \frac{\pi}{6}\frac{N}{V}\left[R_1^3(1-x)+R_2^3\frac{x}{5}\right]$$

$$X = \frac{\pi}{6}\frac{N}{V}\left[R_1^2(1-x)+R_2^2\frac{x}{5}\right]$$

$$Y = \frac{\pi}{6}\frac{N}{V}\left[R_1(1-x)+R_2\frac{x}{5}\right],$$

and, from Eq. 17 with the vanishing external pressure condition, we obtain

$$\begin{aligned}
&\frac{kT}{(1-\xi)^3}\left[N\left(1-\frac{4}{5}x\right)(1-\xi)^2\right.\\
&\left.+\frac{18}{\pi}V\{XY(1-\xi)+X^3\}\right] + U_{BG} = 0
\end{aligned} \tag{23}$$

after some calculations (see Appendix I). For given values of various molecular parameters, the two simultanious equations are solved numerically to determine the values of x and V (*i.e.*, the density ρ).

iii) Numerical Calculations of Thermodynamic Variables. The computations of thermodynamic variables, F, U, S, C_p are carried out for each temperature, using the values of U_{AB} given in Appendix II as well as those of x and V determined according to the procedures in the previous section. The values of F, U, S, C_p are tabulated in Table 4 for the case of R_2=5.50 Å, including observed values. The calculated values of x and ρ also are given in Table 5.

We have taken the state of ice at 0 K in its ground intermolecular and intramolecular vibrational levels as the thermodynamic standard states. The values of U_{BG} have been calculated employing the state of infinitely dilute vapor at 0 K as the zero of energy. Then, we have added the value of 11.3−1.4=9.9 kcal/mol to those of U and F calculated from Eqs. 15 and 19, where

11.3 kcal/mol is the value of sublimation energy from ice at 0 K[33] and 1.4 kcal/mol is the shift in intramolecular zero-point energy[34] for the process of sublimation.

Results and Discussion

i) Temperature Dependence of x *and* ρ. Values of x calculated are plotted against temperature in Fig. 2, where the two calculations for R_2=5.50 Å (Table 5) and for R_2=5.55 Å are given. The curves given in Fig. 2 shows that magnitude of x, which is regarded as a measure of the "structure" in liquid water, is large at lower temperatures (about 80% for R_2=5.50 Å and about 60% for R_2=5.55 Å) and decreases rapidly with increase of temperature. The inflection point where $\partial^2 x/\partial T^2=0$ and the decreasing rate is maximum is about 40 °C for R_2=5.50 Å. This supports the idea that the structure of water varies a great deal at about 40—50 °C. It is observed experimentally that compressibility becomes minimum near about the temperatures and also that the third peak of the radial distribution curve nearly disappeares above the temperatures.[14,35] The rapid decrease of x at the temperatures is supposed to be associated with those observed facts. The calculation for R_2=5.50 Å is expected to give a more adequate result than that for R_2=5.55 Å.

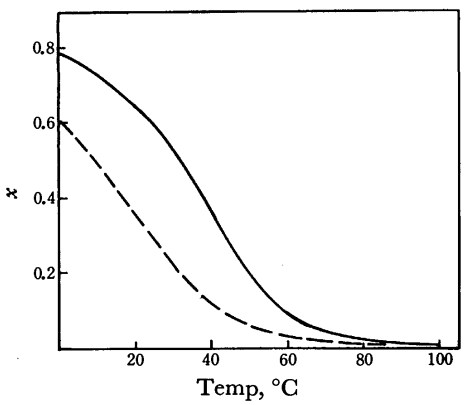

Fig. 2. The temperature dependence of mole fraction of hydrogen-bonded molecules.
——: R_2=5.50 Å,
------: R_2=5.55 Å.

The mole fraction of unbroken hydrogen bonds, x_{HB}, which is calculated from the value of x, is given in Table 6, and is compared with the values of Lentz, Hagler and Scheraga[13] (LHS) and those of Weres and Rice[12] (WR). Our values decrease more rapidly and are found to be smaller than those of LHS and WR. The values of WR are seen to be constant throughout the range of temperature from 0 to 100 °C, and those of LHS also are nearly constant. This is unreasonable, considering from the variation of various properties of water with temperature, *i.e.*, the disappearance of some features in the radial distribution curve at higher temperatures, *etc.* The temperature dependence of x_{HB} found in our work may be reasonably accepted as showing the behavior of water, though the magnitudes are too small at higher temperatures.

Table 6. Mole fraction of unbroken hydrogen bonds x_{HB}

Temp (°C)	This work (R_2=5.50 Å)	LHS	WR
0	0.32	0.47	0.68[a]
20	0.26	0.46	
40	0.14_5	0.45	
100	0.00_2	0.43	

a) Nearly constant from 0 to 100 °C.

Values of ρ calculated are plotted against temperature in Fig. 3 in comparison with observed values. The temperature dependence in the calculated ρ *vs.* T curve is seen to be too large compared with that observed. The curve becomes fairly flat at about 0—10 °C range (R_2= 5.50 Å), though the temperature of maximum density (TMD) is not observed.

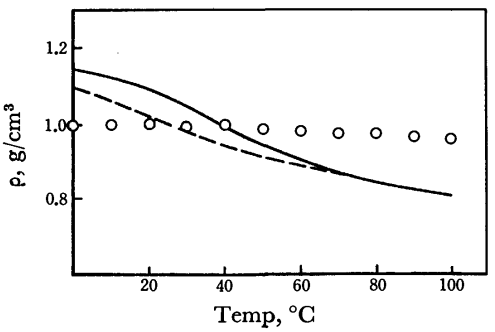

Fig. 3. The temperature dependence of density ρ.
——: R_2=5.50 Å,
------: R_2=5.55 Å,
○: observed values.

In the recent study by Lentz, Hagler, and Scheraga[13] they did not calculate the density and used the observed values as given ones in their calculation. Weres and Rice gave a calculated ρ *vs.* T curve (in Fig. 6 in their paper[12]), but their values of ρ is determined only semi-empirically as a direct result of their assumption that "the dimensions of the basic cell vary linearly with temperature."

In our calculation the density is determined theoretically without any additive assumptions by solving directly a simultaneous equation (Eqs. 22 and 23). The

agreement of the calculated values of ρ with observed ones is fairly good on the whole, which proves the essential usefulness of the procedures for the determination of ρ in this work.

Fleming and Gibbs[7] have presented a lattice gas theory of water and carried out a theoretical determination of ρ. Their values are found to be too large by a factor of 1.4. They also have not succeeded in giving TMD in the range of temperatures from 0 to 100 °C, though a possibility of the presence of TMD below 0 °C has been stated. To give TMD in the calculated ρ *vs.* T curve is the problem of further studies.

ii) Temperature Dependence of Thermodynamic Variables. The values of F, U, and S are plotted against temperature in Figs. 4, 5, and 6, including the values calculated for the case of R_2=5.55 Å and those observed for comparison. The calculated F *vs.* T curve is seen to be in good agreement with the observed curve. Concerning the S *vs.* T given in Fig. 6, the deviation from the observed curve is small at lower temperatures, and it ascends more rapidly with temperature, being above the observed curve through all the range of temperatures from 0 to 100 °C. The behavior is similar to the U *vs.* T curve as given in Fig. 5. As clearly seen in Figs. 2—5, the calculation for R_2=5.50 Å gives better results than that for R_2=5.55 Å.

As expressed in Eqs. 18 and 19, the thermodynamic quantities calculated are regarded as consisting of several terms which are attributed to various kinds of degrees of freedom. Those are tabulated in Tables 7 and 8. It is very interesting to investigate the variation of the contribution from each degree of freedom with temperature, in order to compare the features of various theories.

Thus, our results (Tables 7 and 8) are compared with those of LHS[13] (Table 9) and WR[12] (Table 10) in

Table 7. Values of various terms in Eq. 18 (cal/deg mol)

Temp (°C)	$S_{trans.}$	$S_{rot.}$	$S_{int.}$[a]	S_{total}
0	1.9	6.5	7.6_5	16.0_5
10	2.7_5	6.8_5	7.2_5	16.8_5
20	4.0_5	7.3	6.5_5	17.9

a) The sublimation energy at 0 K, 11.3 kcal/mol, has been added to the sum to obtain U_{total}.

details. It is noticed that as to the entropy, each term in our theory corresponds to that in LHS theory when $S_{int.}$ of ours is regarded as equivalent to $(S_{vib.}+S_H)$ in LHS, and also noticed that it is not the case in the comparison with WR theory.

It is easily seen that the temperature dependence of entropy in our results is greater than that in WR and LHS theories. In the case of WR the calculated values of S_{total} are smaller than observed, being in sharp contrast to the authors' values. At lower temperatures the largest contribution to S_{total} comes from the vibrational motion in all three theories, but the behaviors are different at higher temperatures. In the authors calculation, $S_{trans.}$ increases fairly rapidly and amounts to about a half of the total entropy at about 50—60 °C, while $S_{trans.}$ in LHS theory increases only slightly with increasing temperature. As to the internal energy, the similar behavior is observed in the comparison between $U_{kin.}$ in our calculation and that in LHS.

We can see another noticeable feature in the comparison of $S_{vib.}$ and $U_{vib.}$, the contributions from the vibrational degrees of freedom. They both decrease with increasing temperature in our calculation, while in the calculations by LHS as well as WR they increase on the contrary.

From the two features described above, it is tentatively said that the theory of LHS as well as that of WR is possessed of too solid-like character so far as the temperature dependence of thermodynamic variables is concerned.

In the calculation of WR, the configurational entropy which is attributed to the number of ways for the arrangement of molecules within a basic unit cell is kept constant throughout the range of temperatures from 0 to 100 °C. This is unreasonable, because it shows that the local structure in liquid water remains thoroughly unchanged with the variation of temperatures.

In our calculation the magnitudes of $U_{vib.}$, $S_{int.}=S_{vib.}$, $U_{HB.}$, and $S_{trans.}$ vary most rapidly at 40—50 °C with increasing temperature. This is ascribed to the rapid decrease of the mole fraction of water molecules forming pentamers, as seen in Fig. 2, at the temperatures.

iii) Heat Capacity. In using Eq. 20 for the calculation of C_p, the term $p(\partial V/\partial T)_p=pV\alpha$ has been safely ignored in comparison with the term $(\partial U/\partial T)_p$, where $pV<1$ cal/mol and the thermal expansion coefficient $\alpha\lesssim 10^{-3}$ deg.$^{-1}$. Among the remaining terms in Eq. 20, the temperature derivatives of $x=5N_2/N$ and U_{BG} are determined graphically using the curves given in Figs. 2 and AII-2, respectively, and the terms including $Q_{vib.}$ are calculated using Eq. 6.

Our values (the eighth column in Table 4) becomes 27.3_5 cal/deg mol in the average throughout the range of temperatures, 0—100 °C, which is about 9 cal/deg mol larger than the average of $C_{p.obsd.}$. This is in sharp contrast to the feature found in the calculations of LHS[13] and WR,[12] where $C_{p.calcd}$ is smaller than $C_{p.obsd.}$

It is noted that a shallow minimum is observed at about 40 °C in the $C_{p.calcd}$ *vs.* T relation in this work. This corresponds to the presence of a minimum at about 35 °C in the $C_{p.obsd}$ *vs.* T relation. In the calculation of LHS and WR, $C_{p.calcd}$ *vs.* T curves are monotonously increasing throughout the range of temperatures, 0—100 °C. The contribution to C_p from each degree of freedom can be determined from the corresponding values of internal energy (Eq. 19) given in Table 8. Each contribution averaged in the range 0—100 °C is shown in Table 11.

Table 11. Average contributions to the total heat capacity C_p (cal/deg mol)

Kinetic	16.1_5
Vibrational	−26.8
Hydrogen-Bonding	15.7
Background Potential	22.3
$C_{p.total}$	27.3_5

iv) Equivalent Free Volume Fraction f. In the formulation of our theory we have used Eq. 2 as the translational partition function. The partition function

has a form which is similar in its appearance to the formula used in cell theories of fluid mixtures. Then, we have defined f (Eq. 3) as an equivalent free volume fraction, which is a generalization of the authors' proposition[19] with respect to a pure liquid into multi-conponent fluids. In our theory no lattice which is necessary for cell theories is assumed.

The translational partition function for hard sphere mixtures is shown as a comparatively simple explicit expression similar to usual free volume theories. This is expected to give a good promise for further use.

We have calculated the values of f according to Eq. 3 and the values are compared with those calculated by Weissmann and Blum[8] for water using the Monte Carlo method. The values are given in Table 12. Our values are found to be larger than those of Weissmann and Blum. However, in their calculations, the contribution from the rotational degree of freedom is included, and the magnitude of f is expected to be of nearly the same order compared with ours if that contribution to the phase integral is substracted as stated in their paper.

Table 12. Free volume fraction f and packing fraction ξ

Temp (°C)	f		ξ	
	This work	Weissmann-Blum[8]	R_2=5.50 Å	5.55 Å
4	5.80×10^{-5}	0.60×10^{-7}	0.64_5	0.61
50	7.14×10^{-3}	0.34×10^{-6}	0.50	0.48
100	2.95×10^{-2}	1.19×10^{-6}	0.42	0.42

As for the magnitudes of the packing fraction ξ given together in Table 12, the large value of ξ at 4 °C is supposed to result from the too large value of ρ_{calcd} obtained at the temperature.[19,36]

Concluding Remarks

The purpose of this paper has been to formulate a statistical thermodynamic theory for liquid water without using adjustable parameters to obtain the best fit with observed data as ordinarily carried out. We have used a model consisting of tetrahedrally hydrogen-bonded pentamers and unbonded monomers which are immersed in a uniform background potential. The feature in the theory and its results are outlined as follows: (a) the translational partition function for the model has been derived from the analytical solution of the Percus-Yevick equation for hard sphere mixtures, (b) U_{BG} has been calculated directly as the sum of dipole-dipole, dipole-induced dipole, and dispersion interactions, (c) the mole fraction x of hydrogen-bonded species and the density ρ have been determined by solving a simultaneous equation numerically, and calculated values of ρ are found to be of the right order in their magnitudes, compared with observed values, though the TMD is not observed, (d) the magnitude of x is found to be large (about 80%) at 0 °C which shows the predominance of the "structure" in liquid water at lower temperatures, (e) calculated thermodynamic properties are found to vary rapidly at 40—50 °C with increase in temperature, which is attributed to the rapid decrease of x at the range of temperatures, (f) the magnitude of x becomes very small above about 60 °C (Table 5).

The success in the present theory, though it is qualitative and limited, has put a support to the so-called small cluster model, and the better fit of results with observed data is expected through making some improvements of the model used. The first of those is an introduction of one more species, *i.e.* "hydrogen-bonded ring hexamer" as a structure unit. In that model, water is assumed to be a mixture of unbonded monomers, tetrahedrally-coordinated pentamers, and ring hexamers immersed in a uniform background potential. This three-component model is expected to improve the results.

Appendix I. An Analytical Expression of the Partition Function for the Mixture of Hard Spheres

For a system consisting of m components with number densities ρ_i, $i=1,\cdots\cdots m$,

$$F = G - pV = \sum_{i=1}^{m} N_i\mu_i - pV, \tag{AI-1}$$

where μ_i is the chemical potential of the i-th species and $N_i = \rho_i V$. The exact analytical solution of the generalized Percus-Yevick equation for the mixture of hard spheres was given by Lebowitz, and the μ_i becomes, following Lebowitz and Rowlinson,[20]

$$\beta\mu_i = \ln\left[\frac{\rho_i h^3}{(2\pi m_i kT)^{3/2}}\right] - \ln(1-\xi) + \frac{\pi}{6}\beta p R_i^3 + \frac{3}{(1-\xi)}(R_i^2 Y + R_i X) + \frac{9}{2}\frac{R_i^2 X^2}{(1-\xi)^2}, \tag{AI-2}$$

where R_i is the diameter of a particle of the i-th species and $\beta = 1/kT$, and

$$\xi = \sum_{i=1}^{m}\frac{\pi}{6}\rho_i R_i^3, \quad X = \sum_{i=1}^{m}\frac{\pi}{6}\rho_i R_i^2, \quad Y = \sum_{i=1}^{m}\frac{\pi}{6}\rho_i R_i.$$

Substitution of Eq.AI-2 into Eq.AI-1 gives

$$F = \beta^{-1}\sum_{i=1}^{m}\ln\left[\frac{\rho_i h^3}{(2\pi m_i kT)^{3/2}}\right]^{N_i} - \beta^{-1}\ln(1-\xi)^{\sum N_i} + \frac{9}{\pi}\beta^{-1}V\frac{1}{(1-\xi)^2}\left[-\frac{\pi}{9}\beta p(1-\xi)^3 + 4XY - 4XY\xi + 3X^3\right]. \tag{AI-3}$$

The equation of sate (Eq. 2.8 in Ref. 20) which was given associated with the generalized compressibility relation is

$$\beta p = \frac{1}{(1-\xi)^3}\left[(\sum_{i=1}^{m}\rho_i)(1+\xi+\xi^2) - \frac{\pi}{2}\sum_{i<j}\rho_i\rho_j(R_i-R_j)^2(R_i+R_j+R_iR_jX)\right]. \tag{AI-4}$$

Using the relations,

$$\frac{\pi}{2}\sum_{i<j}\rho_i\rho_j(R_i-R_j)^2(R_i+R_j) = 3\xi(\sum_i\rho_i) - \frac{18}{\pi}XY$$

and

$$\frac{\pi}{2}\sum_{i<j}\rho_i\rho_j(R_i-R_j)^2R_iR_j = \frac{18}{\pi}(Y\xi - X^2),$$

we obtain from Eq. AI-4

$$\beta p = \frac{1}{(1-\xi)^3}\left[(\sum_i\rho_i)(1-\xi)^2 + \frac{18}{\pi}(XY - XY\xi + X^3)\right]. \tag{AI-5}$$

Inserting Eq. AI-5 into Eq. AI-3, we obtain

$$F = \beta^{-1}\sum_i \ln\left[\frac{\rho_i h^3}{(2\pi m_i kT)^{3/2}}\right]^{N_i} - \beta^{-1}\ln(1-\xi)^{\sum_i N_i} - \beta^{-1}\sum_i N_i + \frac{9}{\pi}\beta^{-1}V\frac{1}{(1-\xi)^2}(2XY - 2XY\xi + X^3). \quad \text{(AI-6)}$$

From Eq. AI-6 we give the following partition function Z which is expressed as a form with the equivalent free volume fraction f for an m-component mixture of hard spheres,

$$Z = \exp(-\beta F) = \prod_{i=1}^{m}\left[\left(\frac{2\pi m_i kT}{h^2}\right)^{3/2} e v_i f\right]^{N_i} = \frac{(\sum_i N_i)!}{\prod_i N_i!}\prod_{i=1}^{m}\left[\left(\frac{2\pi m_i kT}{h^2}\right)^{3/2} e v f\right]^{N_i} \quad \text{(AI-7)}$$

where f has the form

$$f = (1-\xi)\exp\left[-\frac{9}{\pi}\frac{v}{(1-\xi)^2}(2XY - 2XY\xi + X^3)\right], \quad \text{(AI-8)}$$

and $v_i = V/N_i, v = V/\sum_i N_i$.

For a one-component system, Eqs. AI-7 and AI-8 lead us to the same analytical expression as given in the previous paper by the two of the authors,[19] in which the concept of an equivalent free volume was proposed on the basis of Wertheim's solution for the Percus-Yevick equation of pure liquid.

Appendix II. The Calculation of the Background Potential

Two steps of numerical integrations are required in carrying out the calculation of the background potential U_{BG}. The first step is the integration in obtaining $\langle U_{\mu\mu}\rangle$ (Eq. 9), as follows,

$$\langle U_{\mu\mu}\rangle = \int_0^{\pi}\int_0^{\pi}\int_0^{2\pi}\int_0^{2\pi} d\theta_A d\theta_B d\phi_A d\phi_B \exp\left[-\frac{U_{\mu\mu}(\theta_A,\theta_B,\phi_A,\phi_B)}{kT}\right] \times U_{\mu\mu}\sin\theta_A \sin\theta_B \Big/ \int_0^{\pi}\int_0^{\pi}\int_0^{2\pi}\int_0^{2\pi} d\theta_A d\theta_B d\phi_A d\phi_B \times \exp\left[-\frac{U_{\mu\mu}(\theta_A,\theta_B,\phi_A,\phi_B)}{kT}\right]\sin\theta_A \sin\theta_B, \quad \text{(AII-1)}$$

where

$$U_{\mu\mu} = \frac{\mu^2}{\bar{R}^3}[\sin\theta_A \sin\theta_B \cos(\phi_A - \phi_B) - 2\cos\theta_A \cos\theta_B].$$

The numerical evaluation of multidimentional integral such as Eq. AII-1 is usually carried out by means of the Monte Carlo method which gives as an estimate for the integral the sum,

$$\langle U_{\mu\mu}\rangle = \frac{1}{M}\sum_{i=1}^{M}\exp\left[-\frac{U_{\mu\mu}(\theta_{Ai},\phi_{Ai},\theta_{Bi},\phi_{Bi})}{kT}\right]U_{\mu\mu}\sin\theta_{Ai}\sin\theta_{Bi} \Big/ \frac{1}{M}\sum_{i=1}^{M}\exp\left[-\frac{U_{\mu\mu}(\theta_{Ai},\phi_{Ai},\theta_{Bi},\phi_{Bi})}{kT}\right]\sin\theta_{Ai}\sin\theta_{Bi}, \quad \text{(AII-2)}$$

where M is the number of the points X_i (θ_{Ai}, ϕ_{Ai}, θ_{Bi}, ϕ_{Bi}), and θ_{Ai}, ϕ_{Ai}, θ_{Bi}, and ϕ_{Bi} are chosen at random in the range of integration.

The error of such an estimate is of the order of $M^{-1/2}$ as a standard deviation. In carrying out the evaluation we have used the Monte Carlo method using the technique devised by Haselgrove.[37] It is shown that the error in the method is convergent asymptotically to the order of $O(M^{-1})$ and $O(M^{-2})$ under certain conditions, and also shown that the method is superior to the usual Monte Carlo method. The magnitude of M has been taken as 15000, when the convergence in the integration is very well.

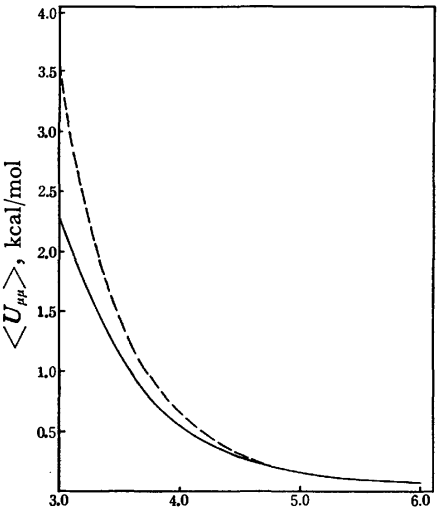

Fig. AII-1. $\langle U_{\mu\mu}\rangle$ *vs.* R curves at 25 °C.
——: Exact, ------: approximated (Eq. AII-3).

The calculated values of $\langle U_{\mu\mu}\rangle$ for 25 °C are plotted against the separation $\bar{R}$ in Fig. AII-1, including the values calculated from the following approximate formula which should be used under the condition that kT is much greater than the difference of the maximum and minimum value of $U_{\mu\mu}$.

$$\langle U_{\mu\mu}\rangle = -\frac{2}{3kT}\frac{\mu^4}{\bar{R}^6} \quad \text{(AII-3)}$$

The curve for this approximate formula is observed to deviate from the exact curve discriminately within the range of $\bar{R}$ smaller than 4—5 Å.

The second step is the numerical evaluation of the integral in Eq. 12, where the magnitudes of $\bar{\alpha}$ and μ are given in Table 1 and the value of c is taken to be 60×10^{-60} erg cm^6.[38]

Then, the background potential is

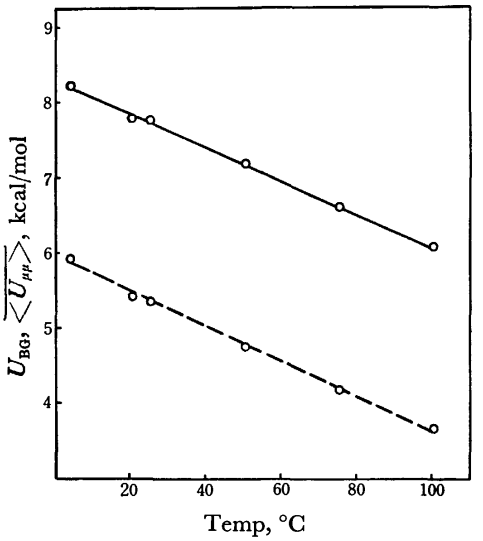

Fig. AII-2. The temperature dependence of U_{BG} and $\overline{\langle U_{\mu\mu}\rangle}$.
——: U_{BG}, ------: $\overline{\langle U_{\mu\mu}\rangle}$.

$$U_{BG} = \frac{N^2}{2V}\int_{\tilde{R}_0}^{\infty}[\langle U_{\mu\mu}\rangle + U_{\mu\alpha} + U_{disp.}]g(\tilde{R})4\pi\tilde{R}^2 d\tilde{R}$$
$$= \overline{\langle U_{\mu\mu}\rangle} + \bar{U}_{\mu\alpha} + \bar{U}_{disp.}, \quad \text{(AII-4)}$$

where the value of $\tilde{R}_0$ is taken to be 3.1 Å.[3,11] We have estimated the integral by means of the Simpson rule. The values of U_{BG} and $\overline{\langle U_{\mu\mu}\rangle}$ thus calculated are given in Fig. AII-2. Throughout the range of temperatures from 0°C to 100 °C, the values of $\bar{U}_{\mu\alpha}$ and $\bar{U}_{disp.}$ are found to remain constant within the range of 0.34 ± 0.01 and 2.05 ± 0.05 kcal/mol, respectively.

22) A. H. Narten and H. Levy, *J. Chem. Phys.*, **55**, 2263 (1971).
23) δF is written as
$$\delta F = \left(\frac{\delta F}{\delta T}\right)_{V,N_1,N_2}\delta T + \left(\frac{\delta F}{\delta V}\right)_{T,N_1,N_2}\delta V + \left(\frac{\delta F}{\delta N_1}\right)_{V,T,N_2}\delta N_1 + \left(\frac{\delta F}{\delta N_2}\right)_{V,T,N_1}\delta N_2,$$
for small variations δT, δV, δN_1, and δN_2. We obtain $\delta N_1 + 5\delta N_2 = 0$ from Eq. 14 for a given N. Then, at the equilibrium condition of Eq. 13 for a given N,
$$(\delta F)_N = \left(\frac{\delta F}{\delta T}\right)_{V,N_1,N_2}(\delta T)_N + \left(\frac{\delta F}{\delta V}\right)_{T,N_1,N_2}\delta(V)_N.$$
Thus, we obtain Eq. 16.
24) In Eq. 18, the contribution from the temperature variation of a is ignored. The magnitude of a was determined from the values of U_{BG} (Table 8) and those of V° obtained from ρ_{calcd} (Table 4). It was found to be $-(1.35\pm0.03)\times10^5$ cal cm^3/mole^2 throughout the range of temperatures, 0—100 °C. Thus, the assumption, $\partial a/\partial T = 0$ is considered to be adequate.

(Received July 12, 1976)

The ENDOR spectra of several alkylated biphenyl anions with *para*- and *meta*-substitutions were observed, and the relation between the molecular size and the optimum temperature of *ortho*-proton ENDOR were investigated in terms of the electron-nuclear dipole-dipole interaction. On the basis of the Stokes-Einstein model, a linear relation was found between the inverse of the effective radius and the cubic root of the η/T value at the optimum temperature of the *ortho*-proton ENDOR, under the assumption that the radical anion undergoes rotation accompanied by the solvent shell. In this situation, the separation between the radical anion and the counter cation thus estimated is more than 8.3 Å and the ion pair exists as a solvent-separated ion pair.

It is known that the optimum ENDOR enhancement in a solution can usually be observed in the temperature region close to the freezing point of the solvent. In identical physico-chemical environments, the optimum temperature varies with the proton species, *e.g.*, the aromatic protons and the aliphatic protons; the electron-nuclear hyperfine interaction affects a shift of the optimum temperature. A larger spin density on aromatic carbon usually displaces the optimum enhancement toward higher temperatures. Such an effect is successfully interpreted under the assumption that the electron-nuclear dipole-dipole interaction (END) plays the dominant role in the relaxation process, when the Heisenberg spin-exchange interaction in negligible in dilute solution systems;[1] that is, the desaturation of the ESR by NMR exciation is most effectively established when the lattice-induced nuclear-spin transition probability, W_n, has a certain value comparable to the lattice-induced electron-spin transition probability, W_e. W_n is proportional to the molecular rotational correlation time, τ_R, and the square of spin density. The τ_R value can be also related to the molecular volume and, therefore, the molecular volume, as well as the spin density, should affect the optimum temperature for ENDOR enhancement.

Alkylated biphenyls with *meta*- or *para*-substituents are some of the most suitable systems for investigating this point, because the spin densities at the *ortho*-position are only slightly perturbed by alkyl substitution,[2] and ENDOR observation has already been established.[3-5] In the present paper, the relation between the molecular radius and the temperature dependence of the ENDOR enhancement is investigated for anion radicals such as biphenyl (BP), 4,4′-bitolyl (*p*-Me), 4,4′-diethylbiphenyl (*p*-Et), 4,4′-di-*t*-butylbiphenyl (*p*-Bu), 3,3′,5,5′-tetramethylbiphenyl (*m*-Me), and 3,3′,5,5′-tetra-*t*-butylbiphenyl (*m*-Bu). The effective radii of the solvated radical anions are estimated and the structures of the ion-pairs are discussed.

Experimental

Commercial biphenyl was recrystallized from ethanol and the alkylbiphenyls employed was synthesized and purified in the manner described in a previous paper.[6]

The anion radicals were prepared by reduction with potassium metal in 1,2-dimethoxyethane (DME). The ENDOR spectra were recorded using a JEOL-type ES-EDX-1 spectrometer for a constant rate of microwave output (3.2 mW) from a JES-ME3-ESR spectrometer. The operating power of NMR excitation was maintained constant (120 W). The viscosity of the solvent for all temperatures was calculated using the formula given in the table.[7]

Results and Discussion

Hyperfine Coupling Constants and Optimum Temperature of the ENDOR Signal Intensity. Figure 1 shows the ENDOR spectra of biphenyl and the 3,3′,5,5′-tetra-*t*-butylbiphenyl anion radical. With reference to the previous work, the signals for the biphenyl anion radical observed at 14.43, 17.63, and 21.46 MHz can be easily assigned to the *meta*-, *ortho*-, and *para*-ring protons. The ENDOR spectrum of the 3,3′,5,5′-tetra-*t*-butylbiphenyl anions clearly resolved the *t*-butyl proton splittings, which have never been detected in previous ESR studies.[8] The proton hyperfine splittings for the alkylbiphenyls determined in the same manner are summarized in Table 1, where it is seen that the magnitude of the *ortho*-ring proton splitting more or less close to that of the biphenyl anion radicals. A typical example of the temperature dependence of the ENDOR intensities (F) are shown in Fig. 2. For biphenyl anion radicals, the maximum ENDOR signals for the *meta*-, *ortho*-, and *para*-ring protons appear at −95, −90, and −80 °C, respectively, in order of increasing spin densities; that is, $\rho_m < \rho_o < \rho_p$.

For 9,10-anthraquinone, similar effects due to the different spin densities have already been studied by Kotake and Kuwata, who demonstrated the importance

a) Methyl proton. b) Ethyl proton. c) Butyl proton.

of the END mechanism.[9] A similar tendency was also seen for the *para*- and *ortho*-positions of the 3,3′,5,5′-tetra-*t*-butylbiphenyl anion radical, except for the anomalous optimum temperature of the *t*-butyl proton, which has often been reported for the hindered phenoxyl radicals.[10] In the case of 3,3′,5,5′-tetra-*t*-butylbiphenyl, however, the optimum temperatures for both the *para*- and *ortho*-positions (−40 °C, −73 °C) were displaced to higher temperatures in comparison with those (−80 °C, −95 °C) for biphenyl. Actually, the ENDOR of the *para*-ring proton of biphenyl anion radicals was clearly recorded at −78 °C, but that of 3,3′,5,5′-tetra-*t*-butylbiphenyl could hardly be detected and the signal intensity gradually increased with elevation of the observing temperature, up to −40 °C.

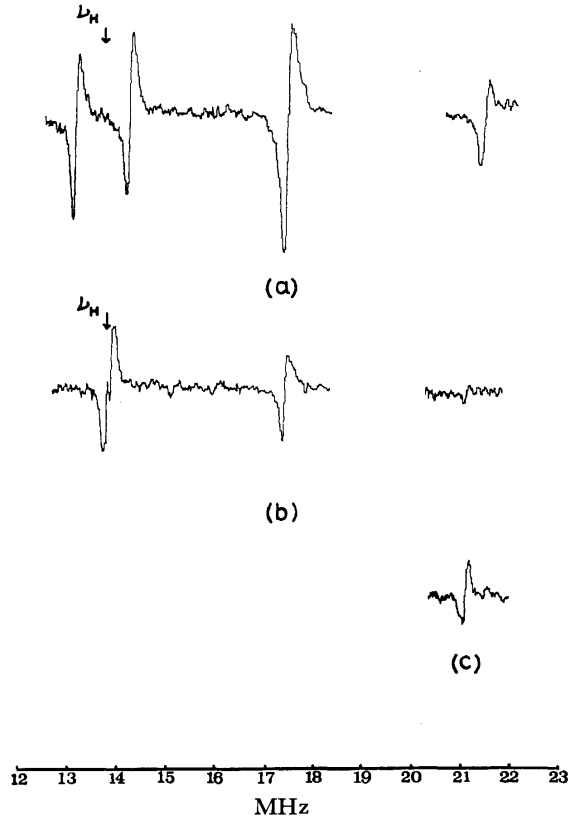

Fig. 1. The ENDOR spectra of biphenyl (a) and 3,3′,-5,5′-tetra-*t*-butylbiphenyl anion radical (b). (a) and (b) were observed at −78 °C. (c) is the ENDOR of *para*-protons of 3,3′,5,5′-tetra-*t*-butylbiphenyl observed at −40 °C.

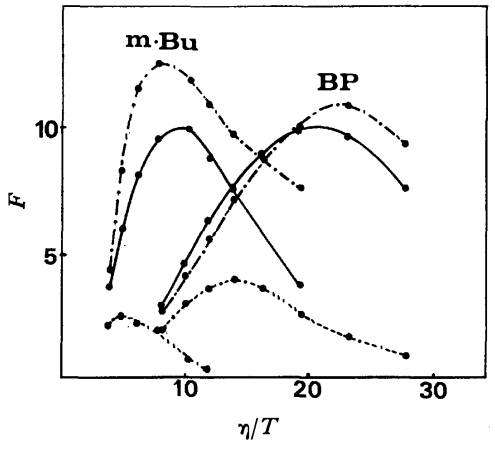

Fig. 2. Temperature dependence of the ENDOR enhancement for biphenyl and 3,3′,5,5′-tetra-*t*-butylbiphenyl anion radicals.
------: *para*, ——: *ortho*, -·-·-: *meta*.
F denotes the ENDOR enhancement calculated to be $F=I_{ENDOR}/I_{ESR}$, where I_{ENDOR} and I_{ESR} are the peak height of the ENDOR and ESR signal at any temperature.

Because the spin densities on the *para*- and the *ortho*-positions are close together in both radicals, alterations of the optimum temperature could be attributed to the differences of the molecular radii. This is true, because the optimum temperature of the *ortho*-proton ENDOR increases with an increase in the number of substituents and their spherical bulkiness as shown in Table 2.

Table 2. Optimum temperatures (°C) of *ortho*-proton ENDOR

BP	*p*-Bu	*p*-Me	*m*-Me	*p*-Et	*m*-Bu
−95	−79	−87	−86	−86	−73

Molecular Radius and Optimum Temperature. Under ordinary ENDOR conditions in solution, the electron-spin transition probability, W_e, and that of the nuclear spin, W_n, can be expressed as functions of the rotational correlation time, τ_R, as follows:[1]

$$W_e = A(1/\tau_R), \quad (1)$$

$$W_n = B\tau_R \quad (2)$$

Where A is the constant related to the magnitude of the g-factor and hyperfine anisotropies, and B is related to that of hyperfine anisotopy only. According to the END approximation, optimum ENDOR enhancement is observed when the ratio

$$b = W_n/W_e = (B/A)\tau_R^2 \quad (3)$$

has a certain value. Because B is proportional to the expectation value of the END term over the molecular wave function, the rotational correlation time at the optimum ENDOR enhancement, τ_R^{opt}, should become shorter for an increase of the spin density on the carbon atom to which the observing proton is bonded. In alkylbiphenyl anion radicals studied here, τ_R^{opt}, corresponding to the optimum ENDOR of the *ortho*-ring proton may have a constant value for each anion radical, because the spin densities, ρ_2^{π}, at the *ortho*-position have more or less the same values regardless of the alkyl substitutions. On the other hand, τ_R^{opt}, can be expressed by the Stokes-Einstein relationship:

$$\tau_R^{opt} = \frac{4\pi r^3}{3k}(\eta/T)_{opt}. \quad (4)$$

One may thus expect that a linear relation holds between the inverse of the effective radius, $1/r$, and the cubic root of the (η/T) value calculated for the optimum temperature of the *ortho*-proton ENDOR. If the radical ions are subject to a tumbling motion accompanied by the solvent shell, which has an averaged thickness, r_s, the following relation can be derived;

$$(r'+r_s)/(r+r_s) = (\eta'/T')^{-1/3}/(\eta/T)^{-1/3}, \quad (5)$$

Where r and r' are the averaged radius of the alkylbiphenyl and the biphenyl anion radical, respectively, and η and η' are the viscosity coefficient at the optimum ENDOR temperature for the derivative (T') and for the biphenyl anion radical (T). The averaged radii, r, of the alkylated biphenyl, which is regarded to be an ellipsoid, were calculated by taking the geometrical average of the three axes a, b, and c. The length of each axis was estimated using the following interatomic bond distances R and bond angles θ:[11]

R_{C-C}(aromatic) = 1.40 Å, $R_{C_1-C_1'}$(bridgehead) = 1.49 Å,
R_{C-C}(aliphatic) = 1.54 Å, R_{C-H} = 1.08 Å,
θ_{sp^2} = 120° and θ_{sp^3} = 109°.

The total length of each shorter and longer axes a and b was estimated by summing the Van der Waals radii of the ring, the aliphatic (1.20 Å) and terminal methyl protons (2.00 Å), and the thickness of the phenyl group, c, was assumed to be 3.40 Å. As is shown in Fig. 3, a

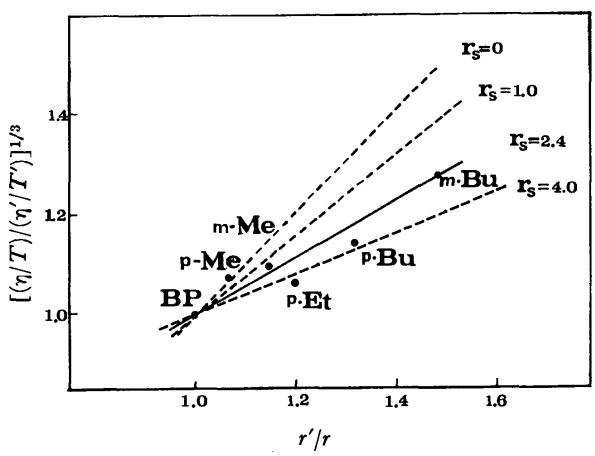

Fig. 3. Relation between the molecular radii and the cubic root of η/T value.

linear rotation can be seen between the (r/r') and the $[(\eta/T)/(\eta'/T')]^{1/3}$ values of each derivative, and r_s is thus estimated to be 2.4 Å, as calculated from the slope of the plot. The rotational correlation times of the anions at the optimum ENDOR, τ_R^{opt}, calculated using the effective radius $r+r_s$ have more or less constant values, which are close to 1.0×10^{-9} s, as summarized in Table 3.

Table 3. Molecular radii, molecular volumes and rotational correlation times at optimum ENDOR enhancement

	BP	*p*-Me	*p*-Et	*p*-Bu	*m*-Me	*m*-Bu
r (10^{-8} cm)	3.16	3.36	3.79	4.16	3.60	4.69
V (10^{-24} cm)	132	159	228	307	200	432
τ_R^{opt} (10^{-9} s)	1.08	0.98	1.28	1.19	1.05	1.07

The τ_R^{opt} values were calculated assuming that the thickness of the solvent shell is 2.4 Å

Since the τ_R^{opt} value thus determined may contain inaccuracies attributable to the crude estimation of the molecular volume and neglect of the contribution due to the anisotropic rotational diffusion,[12] the numerical values cannot be taken too seriously. Nevertheless, the large effective radius of the anion radical demonstrated here, is quite interesting, because this suggests that the distance between the radical anion and the alkali metal cation should be large, at least 8.3 Å in the case of biphenyl$^-$–K$^+$ system, in which case the radius of K$^+$ is assumed to be 1.5 Å.[13] Previous NMR studies of the biphenyl$^-$–K$^+$ system confirmed that the interaction between the anion and the cation is rather weak in DME, and the ion pair is considered to be a solvent separated ion pair.[14] According to conductance studies of biphenyl$^-$–Na$^+$ ion pairs in DME, the dissociation energy is reduced by lowering the temperature, that is, $\Delta H_{20°C} = -2.5$ kcal and $\Delta H^-_{55°C} = 0$ kcal.[15] This means that the cation and the anion are completely separated by the solvent molecules at low temperature. Indeed, no important change was observed in the temperature dependence of the ENDOR enhancement for the biphenyl anion radical, even through the alkali metal cation is replaced by sodium in the present investigation.

Hydrocracking of Tetralin on Supported Nickel-Tungsten Catalysts

Shoko YAMADAYA, Masaaki OBA, and Yasuo MIKI

National Chemical Laboratory for Industry, Mita, Meguro-ku, Tokyo 153

(Received July 16, 1976)

The hydrocracking of tetralin was carried out over supported nickel-tungsten (NiO 3%, WO_3 20%) on silica-alumina, alumina, and silica catalysts at a hydrogen pressure of 100 atm and in the temperature range from 325 to 375 °C. The total conversion of tetralin and the product composition of hydrocracking were measured for the catalysts. The influence of pretreatment of the catalysts with H_2 and H_2S on the conversion and product composition was investigated for each catalyst. The hydrocracking of decalin was also carried out under the same conditions. It is found that the hydrocracking of tetralin proceeds along two reaction paths: (A) hydrogenation to decalin followed by conversion to methylperhydroindenes and C_{10}-naphthenes, (B) isomerization to methylindans followed by cracking to butylbenzene. The selectivity of each reaction path and the catalytic properties are discussed.

Catalytic hydrocracking is of considerable importance in petroleum refining. In the course of the commercial growth of the petroleum industry, the chemistry of hydrocracking over various catalysts has been studied with pure hydrocarbons. Most hydrocracking catalysts of commercial interest are of dual nature, consisting of both a hydrogenation-dehydrogenation component and an acidic support.

Recently, the chemistry of hydrocracking of typically pure hydrocarbons has been reviewed by Langlois and Sullivan,[1] and the mechanism for hydrocracking of polynuclear aromatic hydrocarbons on silica-alumina based dual-functional catalysts (CoS, MoS_2, NiS, WS_2, *etc.*) has been investigated by Qader.[2] Hydrocracking is found to proceed through sequential hydrogenation, isomerization and cracking reactions. Also, the reaction is found to follow first-order kinetics and the data are found compatible with the dual-site mechanism of Langmuir-Hinshellwood.

Sullivan *et al.*[3] have found considerable cyclization of the side chain when certain aromatic hydrocarbons (phenanthrene, anthracene, pyrene, *etc.*) are hydrocracked over a nickel sulfide on silica-alumina catalyst. The product is found to be predominantly tetrahydronaphthalene (tetralin) of lower moleculer weight than that of the reactant.

In this paper, the hydrocracking of tetralin was carried out as a test reaction to clarify the selectivity of hydrocracking catalysts. Supported nickel-tungsten on silica-alumina, alumina and silica catalysts were used. Effect of the carrier in the supported catalysts on the selectivity of hydrocracking was observed to significant extent. Also, the product composition changed extensively with catalyst pretreatment. On sulfiding the silica-alumina supported catalyst with H_2S, the principal reaction was found to be the hydrogenation to perhydronaphthalene (decalin), which was further converted to methylperhydroindenes and C_{10}-naphthenes. While for the catalysts pretreated with H_2, isomerization to methylindans and cracking to butylbenzene occurred predominantly.

The selectivity of each reaction path seems to depend on the relative strength of the acidic and hydrogenation components on the catalysts.

Experimental

Equipment. The experiments were performed in a continuous flow system with a fixed bed reactor, a flow diagram of which is shown in Fig. 1. The catalyst (16—32 mesh, 5 ml) was supported inside a 12 mm i.d. by 680-mm long stainless-steel tube which was surrounded by an electric furnace. The catalyst temperature was measured by a chromel-alumel thermocouple located in a thermowell in the catalyst bed.

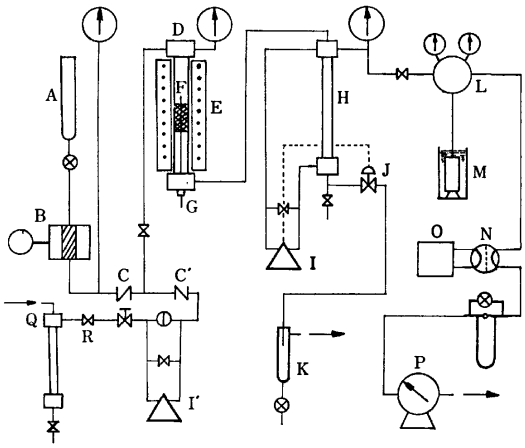

Fig. 1. Reaction apparatus.
A: Reactant vessel, B: plunger pump, C,C': non return valve, D: reactor, E: furnace, F: catalyst bed, G: thermocouple, H: separator, I,I': D.P. cell, J: level control valve, K: reservoir, L: pressure control valve, M: standard pressure vessel, N; six way valve, O: gas chromatograph, P: gas meter, Q: gas purifier, R: flow control valve.

Tetralin or decalin was fed by a plunger pump, and purified hydrogen was fed through a needle valve. The effluent from the reactor was taken to a gas-liquid separator. The liquid from the separator was automatically effluent by a revel control valve. The gas, passing through a six-way valve, was measured with a gas meter. Both the gas and liquid were analyzed by a gas chromatograph.

The reaction was carried out in the temperature range from 325 to 375 °C at a pressure of 100 atm. The liquid hourly space velocity (LHSV) was 8 per h and the molar ratio of hydrogen to the hydrocarbon was 10. In order to collect products representative of steady-state reaction conditions, the first hour was taken as off-stream time for bringing the reaction system to a steady state.

Analysis. The products were analyzed with a Hitachi Model K-53 gas chromatograph with flame-ionization detectors and with a squalan capillary column (90 m × 0.25 mm) at 90 °C. In the identification of each product on the chromatogram, the information[4,5] from the capillary gas chromatographic method for determining the C_3–C_{12} hydrocarbons in full-range moter gasolins was applied.

The peak areas in the chromatograms were measured with a Hewlett-Packerd Model 3380A reporting integrator.

Catalysts and Chemicals. The catalysts consisted of supported nickel-tungsten (3% NiO, 20% WO_3) on commercial alumina (Ketjenfine pure alumina), silica-alumina (25% Al_2O_3, Nikki Kagaku N 633H) and silica carriers. These catalysts were prepared by impregnating the carriers with a solution of nickel nitrate and ammonium paratungstate. The impregnated materials were oven-dried and calcined in air at 500 °C for 10 h.

Prior to reaction, they were reduced in flowing hydrogen at 500 °C for 16 h. In some experiments, they were sulfided with 10% H_2S in H_2 after the reduction.

Surface areas, determined by the standard BET method, were 226 m^2/g for the silica-alumina supported catalyst, 186 m^2/g for the alumina-supported catalyst, 156 m^2/g for the silica-supported catalyst.

Tetralin and decalin were commercial extra-pure reagents (Kokusan Kagaku, 99% purity) and were used without further purification. The decalin consisted of 54% *trans*-decalin and 45% *cis*-decalin.

Results and Discussion

Product Composition and Reaction Path. The total conversions of tetralin and the product compositions for hydrocracking on a nickel-tungsten-silica-alumina catalyst pretreated with H_2S are shown in Table 1. At

TABLE 1. HYDROCRACKING OF TETRALIN ON A SULFIDED NICKEL–TUNGSTEN–SILICA–ALUMINA CATALYST

Hydrogen pressure, 100 atm; LHSV, 8; H_2/Tetralin, 10.

Decalin	4.4	5.2	4.5
Tetralin	90.2	87.4	77.4
Naphthalene	0.8	1.3	1.5

a temperature of 325 °C, the main product is decalin, and the other products are divided into methylindans, methylperhydroindenes, C_{10}-naphthenes, C_6-compounds,[6] butylbenzene, and naphthalene. The selectivities of each product (the ratio of the yield to the total conversion) were calculated from this table and are shown in Fig. 2. At higher temperatures,[7] the selectivity for decalin and methylperhydroindenes decreased, whereas both the yields and selectivities of other products increased.

In Table 2, the conversions and the product compositions for the hydrocracking of decalin are shown under

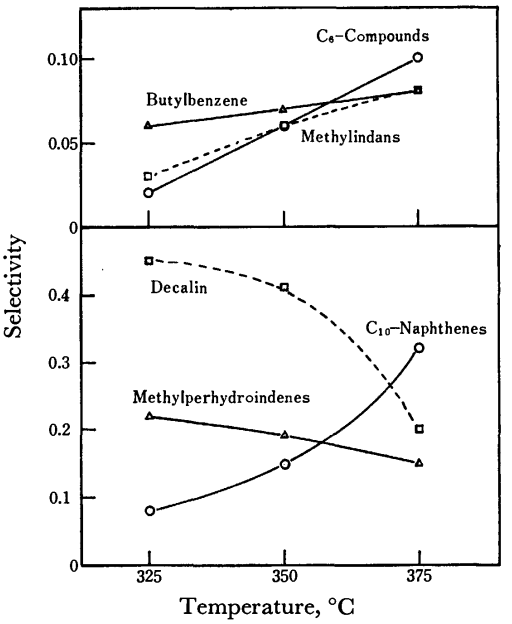

Fig. 2. Selectivity for hydrocracking of tetralin.

TABLE 2. HYDROCRACKING OF DECALIN ON A SULFIDED NICKEL–TUNGSTEN–SILICA–ALUMINA CATALYST

Hydrogen pressure, 100 atm; LHSV, 8; H_2/Decalin, 10.

Temperature °C	325	350	375
Total conversion mol %	6.3	18.2	33.5
Product composition mol/100 mol charge			
C_{10}-Naphthenes	2.6	10.8	22.5
Methylperhydroindenes	3.7	7.4	11.0
Decalin	93.7	81.2	66.5

the same conditions and catalyst as for the tetralin reaction (in Table 1). The principal products are methylperhydroindenes and C_{10}-naphthenes.

From a comparison of the above product compositions for the hydrocracking of tetralin and decalin, it is suggested that hydrogenation to decalin occurred predominantly in the first step during the reaction at a lower temperature and then the isomerization of decalin to methylperhydroindenes occurred in the second step. Then the methylperhydroindenes were further converted to C_{10}-naphthenes in the third step. At higher temperatures, the isomerization to methylindans and cracking to butylbenzene also occurred to a significant extent.

These data indicate that the hydrocracking of tetralin is divided into two types of reaction paths as shown in

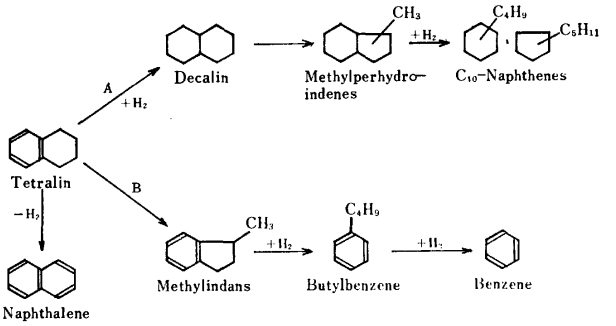

Fig. 3. Mechanism of hydrocracking of tetralin.

Fig. 3: (A) hydrogenation to decalin followed by conversion to methylperhydroindenes and C_{10}-naphthenes, and (B) isomerization to methylindans and cracking to butylbenzene followed by conversion to benzene.

Effect of Pretreatment and Carriers of Catalysts. In the hydrocracking of tetralin, the influence of pretreatment of the supported nickel-tungsten catalysts with H_2 and H_2S on the product composition was investigated. In Table 3, the conversions of tetralin and the product compositions on three supported catalysts, silica-alumina-, alumina-, and silica-supported catalysts, were measured at 350 °C. The conversion of tetralin and the product composition for each sulfided catalyst were quite different from those of the reduced catalyst. The conversion on the reduced catalyst was lower than that on the sulfided catalyst in each case.

The decalin yield on the silica-alumina supported catalyst treated with H_2S was higher than that on the reduced catalyst, and the yield of methylperhydroindenes and C_{10}-naphthenes were also higher. However, the yield of methylindans and C_6-compounds on the reduced catalyst were higher than those on the sulfided catalyst.

In the hydrocracking of decalin, the influence of the pretreatment of these catalysts on the decalin conversion was investigated. In Table 4, the conversions on the silica-alumina- and alumina-supported catalysts treated with H_2 and H_2S are compared. The conversion on the silica-alumina-supported catalyst treated with H_2 was about seven times that on the catalyst treated with H_2S. On the alumina-supported catalyst, the reaction was extensively inhibited by the sulfidation. The conversion for the silica-alumina catalyst alone was comparable to that on the sulfided silica-alumina-supported catalyst.

Hydrogen pressure, 100 atm, Temperature, 350 °C, LHSV, 8, H_2/Decalin, 10.

Catalysts	Nickel-Tungsten-Silica-Alumina		Nickel-Tungsten-Alumina		Silica-Alumina
Pretreatment	H_2S	H_2	H_2S	H_2	H_2
Total conversion mol %	6.3	42.4	—	36.2	7.0
Product composition mol/100 mol charge					
C_{10}-Naphthenes	2.6	29.0		23.8	2.0
Methyl-perhydroindenes	3.7	13.2	No reaction	12.3	5.0
Decalin	93.7	57.6		63.8	93.0

From the above observation for hydrocracking on these catalysts, the selectivity of catalysts is discussed in relation to several recent reports.

Selectivity of Hydrocracking Catalysts. Some data have been reported on tetralin hydrocracking over nickel sulfide on silica-alumina catalysts.

Flinn *et al.*[8] have reported that ring opening and hydrogenation are the predominant reactions at 68 atm and 412 °C, and light alkanes are produced with a high ratio of branched to unbranched alkanes.

Sullivan *et al.*[3] have reported that the fused bicyclic cycloalkanes as main products are produced by the hydrocracking of tetralin at 288 °C and 82 atm.

However, the reaction path of the hydrocracking was not discussed in these reports.

Table 5. Selectivity for hydrocracking of tetralin on supported nickel-tungsten catalysts

Catalysts	Nickel-Tungsten-Silica-Alumina		Nickel-Tungsten-Alumina		Nickel-Tungsten-Silica
Pretreatment	H_2S	H_2	H_2S	H_2	H_2S

Naphthalene	*0.09*	*0.14*	*0.02*	*0.05*	*0.01*

In the present paper, it was demonstrated that the hydrocracking of tetralin proceeds along two reaction paths (A and B) as shown in Fig. 3. According to the mechanisms, the selectivity calculated from the product composition in Table 3 are shown in Table 5. The selectivity for all naphthenes produced for path A was 0.74 on the sulfided silica-alumina supported catalyst, whereas it was 0.36 on the reduced catalyst. On the alumina-supported catalyst treated with H_2S and H_2, the selectivities were 0.98 and 0.64, respectively. The selectivity for the sulfided silica-supported catalyst was 0.99.

The total conversion of tetralin on each catalyst treated with H_2S was generally higher than that on the reduced catalyst. As shown in Table 4, the activity of the sulfided catalyst for decalin hydrocracking was lower than that of the reduced catalyst.

It is suggested from the above observations that the active sites for hydrogenation of tetralin on the catalyst are produced by means of sulfidation, while the acid sites producing isomerization and the cracking of tetralin and decalin are decreased upon sulfidation.

Langlois *et al.*[9] have found that, with sulfiding a nickel on silica-alumina catalyst, the total conversion of decane hydrocracking greatly increased and the predominant reaction changed from isomerization to cracking. They postulated that the catalyst before sulfidation contained both nickel metal and nickel salts at the silica-alumina acid site, and upon sulfidation the nickel metal was converted to nickel sulfide, and the H_2S reacted with the nickel-silica-alumina salt to regenerate the original strong acid sites of the silica-alumina support.

In this paper, it is suggested that on the silica-alumina supported catalyst treated with H_2S, the original acid sites of the silica-alumina carrier are effective for the isomerization and cracking of tetralin. Also, by reducing the catalyst, acidic sites are formed on the surface of the supported tungsten oxide. Upon sulfidation of the alumina supported catalyst, no hydrocracking of decalin occurs. However, the hydrocracking activity of the reduced catalyst is higher. Therefore, the acidic properties of the catalyst are assumed to be formed by reduction with H_2.

The sulfidation of tungsten oxide supported on silica-alumina catalysts has been studied by Massoth and Bidlack.[10] Supported catalysts and bulk WO_3 were sulfided with mixture of H_2S and H_2 at temperatures between 260 and 594 °C and at a H_2S partial pressure of 0.1—5 atm. Studies of partially reacted samples show the sulfided species to be WS_2 and the unconverted oxide to be $W_{20}O_{58}$, suggesting that partial reduction precedes sulfidation. The salient findings of their study are: (1) reduction of bulk WO_3 by H_2 proceeds rapidly to $W_{20}O_{58}$ and then more slowly to W metal, (2) the sulfidation of bulk WO_3 by H_2S–H_2 mixtures proceeds rapidly through the formation of $W_{20}O_{58}$, followed by a slower reaction to WS_2, and (3) the mechanisms of sulfidation for bulk and supported WO_3 are similar.

The catalytic structure of nickel-tungsten sulfide as a hydrogenation catalyst has been investigated by Voorhoeve[11] using the ESR technique. It was concluded that the active sites for benzene hydrogenation in a wide variety of tungsten-disulfide based catalysts are tungsten ions, probably in the trivalent state. Nickel appears to have an indirect influence on the hydrogenation activity in Ni-W-S rather than acting as the active center.

It is apparent that the state of tungsten on the sulfided catalyst surface in the present study is probably attributable to WS_2. According to the above conclusions reported by Voorhoeve,[11] it is apparent that the active sites for the hydrogenation of tetralin are the tungsten ions of tungsten disulfide crystals on the catalyst.

On the reduced alumina-supported catalyst, the acidic catalyzed isomerization and cracking activity is attributed to the acidic hydroxyl groups over the partially-reduced surface of tungsten oxide supported on alumina.

Appreciation is expressed to Dr. T. Kabe for a significant contribution to this work and to Mr. T. Hasegawa for assistance with the experimental work.

The Distribution of Higher Alcohols in Aqueous Micellar Solutions

Kohji HAYASE and Shigeo HAYANO

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received July 22, 1976)

The distribution coefficients, K, for 1-butanol, 1-pentanol, 1-hexanol, and 1-heptanol between the sodium dodecyl sulfate (SDS) micellar and aqueous phases were measured directly, with the gas chromatographic technique was used to measure the vapor pressure of the alcohols. The standard free energy change of penetration, ΔG_p°, of the alcohol from the aqueous to the micellar phase was obtained using the equation: $\Delta G_p^\circ = -RT\ln K$. There is a linear relation between ΔG_p° and the carbon number of the alcohol.

The change in the standard free energy of an alcohol for a transition from the aqueous to the micellar phase, ΔG_p°, is indispensable to the study of solubilization of additives in surfactant solutions. In spite of the necessity of evaluating ΔG_p°, no values of ΔG_p° have yet been reported for an aqueous alcohol solution. Though Kaufman[1] and Dalen, Gerritsma, and Wijkstra[2] have reported the solubilization of organic additives in organic solvents, they were unable to calculate the distribution coefficient because of a lack of an accurate knowledge of the critical micelle concentration (CMC) in the organic solvent.

Concerning the effect of alcohol on decreasing the CMC, Ward[3] and Herzfed, Corrin, and Harkins[4] have pointed out the importance of evaluating ΔG_p°. Shirahama and Kashiwabara[5] have discussed thermodynamically the relation between ΔG_p° and the CMC decrease of systems containing alcohol. However, since the ΔG_p° were not measured but were estimated values deduced from the physical constants of the alcohols, the theoretical equation does not correspond to their experimental results. Thus, an experimental determination of the ΔG_p° values would be useful in their thermodynamical discussion.

In this paper, experimental work on the distribution coefficients is reported. These experiments are thought to be very important for the discussion of the interaction of surfactants and additives. The distribution coefficients were evaluated by measuring the vapor pressure of the alcohol in an aqueous alcohol solutions both in the presence and absence of sodium dodecyl sulfate (SDS) employing a gas chromatograph. This technique, to the best of the authors' knowledge, has not yet been applied to this kind of problem.

Experimental

Method. 5 ml vapor samples equilibrated with alcohol solutions were introduced from a gas loop by means of a six-way sampling valve into a Shimadzu GC-3BF gas chromatograph equipped with a flame ion detector. Helium was used as the carrier gas at flow rates of 50, 80, and 100 ml/min through a 3 mm×2 m column. The column packing was 5 or 10% polyethylene glycol 6000 on a 30—60 mesh Flusin T support, and 5% Versamid 900 on a 60—80 mesh Uniport KS support. The operating temperature was 120—160 °C.

The experimental arrangement for the gas chromatographic measurements is shown in Fig. 1. The measuring process was similar to the reported by Kaufman.[1] To prevent foam from overflowing to the outer part of the bottle, the helium was passed for four minutes in order to saturate the vapor, which

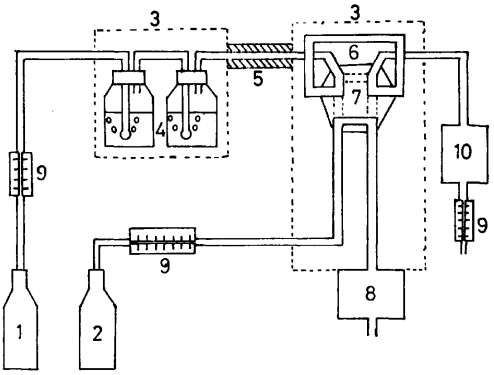

Fig. 1. Experimental arrangement for measuring vapor pressure by gas chromatograph.
(1): Helium cylinder for saturator, (2): helium cylinder for gas chromatograph, (3): thermostat, (4): saturator, (5): ribbon heater, (6): sampling loop, (7): sampling valve, (8): gas chromatograph, (9): flow meters, (10): ballast.
(Solid lines in the sampling valve denote a standby position; dotted lines denote a sampling position.)

was then introduced into the gas chromatograph. The helium flow was stopped for twelve minutes in order to reduce the quantity of foam. The sampling procedure was standardized to allow a uniform 1.5 min period for the valve in the sampling position.

The 1-butanol, 1-pentanol, 1-hexanol, and 1-heptanol peaks were well-resolved, symmetrical and only slightly tailed.

The measurement of the electric conductivity of the SDS solution was made using a Towa Denpa Co., Ltd. Model CG-201PL universal bridge. An electric conductivity cell of the dip type was bright-platinized and immersed in a 100-ml polyethylene beaker which was maintained at 25 °C in a thermostat.

The SDS concentration was varied by adding portions of a concentrated SDS solution containing an alcohol.

Materials. Wako Pure Chemical Industries, Ltd. SDS for biochemical use was carefully dried in a vacuum for twenty hours. The 1-butanol, 1-pentanol, 1-hexanol, and 1-heptanol of high purity (higher than 99%) were used. The water used was passed through a Nihon Millipore Co., Ltd. Milli-Q2 Systems until its specific conductivity fell below 10^{-7} Ω^{-1} cm^{-1}.

Results and Discussion

Figure 2 displays two curves obtained directly from the gas chromatographic measurements. In Fig. 2, 1-heptanol is shown as an example. The upper or calibration curve represents the data taken from a series

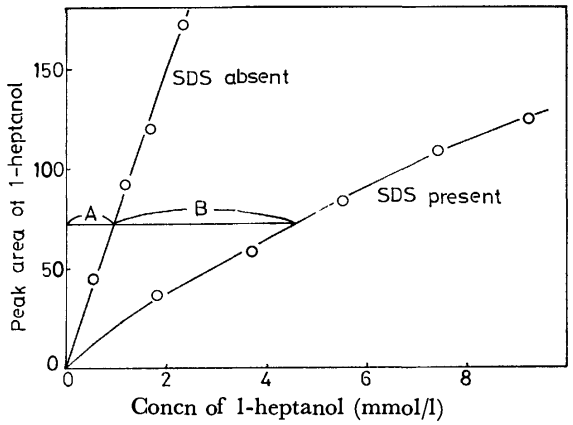

Fig. 2. Calibration curve for the aqueous 1-heptanol solution and typical results for the same solution in the presence of SDS (at 25 °C).
(A): 1-Heptanol fraction remaining in the aqueous phase, (B): 1-heptanol fraction existing in the micellar phase.

of solutions without SDS, while the lower curve shows the data for a similar solution to which a specific amount of SDS was added.

For the purposes of this study, it is unnecessary to know the absolute concentration of the alcohol in the vapor phase, provided that a relationship between the peak area and the compositions of the solutions has once been established. Owing to the self association of the alcohol in the solution, the slopes of the curves decrease as the concentration of the alcohol increases.

The horizontal separation between the two curves at any ordinate represents A and B. B corresponds to the alcohol fraction existing in the micellar phase and A to the alcohol fraction remaining in the aqueous phase. From these curves, the distribution coefficient was calculated from the following equations:

$$Y_a = (18 \times A)/1000, \quad (1)$$

$$X_a = B/(S - \mathrm{CMC}(C_a) + B), \quad (2)$$

and

$$K = X_a/Y_a, \quad (3)$$

where Y_a is the molar fraction of the alcohol in the aqueous phase, X_a the molar fraction of the alcohol in the micellar phase, S the total concentration of SDS added, C_a the concentration of the alcohol in the solution, CMC (C_a) the CMC of SDS in the presence of the alcohol, and K the distribution coefficient of the alcohol (the ratio of the concentration in the micellar phase to that in the aqueous phase).

In Fig. 3, the molar fractions of the alcohol(1-heptanol, for example) in the micellar phase are plotted against the mole fractions of the alcohol in the aqueous phase. The amount of SDS was 40 mmol/l. From these results, we evaluated the distribution coefficients using the least-squares method.

The values of K and ΔG_p° calculated from

$$\Delta G_p^\circ = -RT \ln K \quad (4)$$

are shown in Table 1.

Some work[1,2] has been reported on the solubilization of organic additives by surfactant micelles in organic solvents. Kaufman[1] has given the solubilization ratios

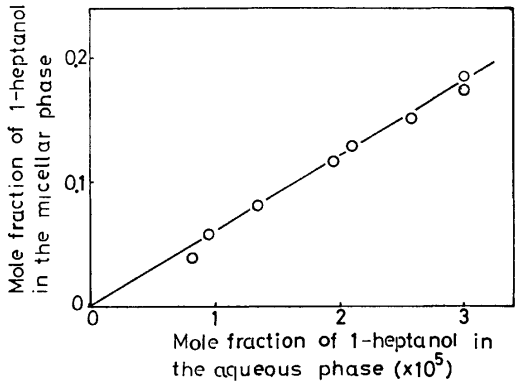

Fig. 3. Distribution of 1-heptanol between the aqueous and the micellar phases (at 25 °C).

Table 1. The distribution coefficients (K) of alcohol between the aqueous and micellar phases and the standard free energy changes of penetration of the alcohols (ΔG_p°) (at 25 °C)

	1-Butanol	1-Pentanol	1-Hexanol	1-Heptanol
K	3.00×10^2	7.22×10^2	2.25×10^3	6.02×10^3
ΔG_p° (kcal/mol)	−3.38	−3.90	−4.57	−5.16

computed for the sodium, cesium, barium, magnesium, and zinc salts of 1,8- dinonyl-4-naphthalene sulfonic acid as a function of methanol, propylamine, and acetic acid in toluene. However, because an accurate value of the CMC was inacessible for organic solvents containing organic additives, no concentration of micellized surfactant was reported. Therefore, an accurate distribution coefficient could not be obtained, because the total surfactant concentration was employed instead of the micellized surfactant concentration.

Table 2. CMC values for SDS in water to which a small amount of alcohol was added (at 25 °C)

Alcohol concn (mmol/l)		CMC (mmol/l)
Pure water		8.01
1-Butanol	43.74	6.96
	116.9	5.32
	204.4	4.18
1-Pentanol	15.41	6.86
	31.15	5.70
	64.45	4.17
1-Hexanol	2.683	7.32
	5.584	6.61
	9.227	5.89
1-Heptanol	0.7354	7.54
	1.918	6.89
	3.178	6.45

Since, in this experiment, accurate values of the CMC using the conductivity method were obtained, as given in Table 2, it is now possible to evaluate the distribution coefficients. Our results for the CMC values both in pure water and in the presence of 1-butanol agree ap-

proximately with those of Shirahama and Kashiwabara.[5]

As shown in Table 1, ΔG_p° is a linear function of the carbon number of the alcohol. As the carbon number of the alcohol increases, the ΔG_p° decreases. Similarly, the standard free energy change of micellization, ΔG_m°, decreases as the carbon number of the surfactant increases.[6] This can be understood since an increase in the carbon number of the alcohol is expected to result in an increased hydrophobic interaction with the surfactant micelles. In other words, penetration of the alcohol into the micellar phase becomes more favorable for an increase in the carbon number of the alcohol. Thus, it is reasonable that this tendency of the ΔG_p° to decrease parallels the tendency of solubility of the alcohol in water to decrease.

ΔG_p° is linearly related to the carbon number of the alcohol as follows:

$$\Delta G_p^\circ = -0.60n - 0.95, \quad (5)$$

where n is the carbon number of the alcohol.

The increment of ΔG_p° per methylene group is -0.60 kcal/mol. Kresheck and Hargraves[6] have investigated the ΔG_m° of the sodium octyl-, decyl-, and dodecyl sulfate series and found that the increment of the ΔG_m° per methylene group was approximately from -0.55 to -0.32 kcal/mol. The absolute value of the increment of the ΔG_p° per methylene group is a little larger than that of the ΔG_m° per methylene group.

Mankowich[7] has reported on the solubilization of Orange OT in aqueous sodium dodecyl benzene sulphonate solutions. In his paper, the standard free energy changes of the solubilization of Orange OT from the non-micellar phase to the micellar phase were reported to be from -5.4 to -5.8 kcal/mol in the range 25—50 °C. In his method, the solubilities of Orange OT both above the CMC and at the CMC were measured. The concentration (mol/l) of Orange OT in the micellar phase was calculated from the solubility of Orange OT above the CMC, and the concentration (mol/l) of Orange OT in the non-micellar phase was calculated from the solubility of Orange OT at the CMC. Then, the standard free energy change was computed from these two concentrations. However, his method is inconvenient for evaluating ΔG_p°, because the solubilities of 1-butanol, 1-pentanol, 1-hexanol, and 1-heptanol are much higher than that of Orange OT, and the CMC values are altered in the presence of the alcohols.

Aveyard and Lawrence[8] and Larsen and Magid[9] reported the standard enthalpy change of penetration, ΔH_p°, of the alcohol from the aqueous phase to the micellar phase obtained using the calorimetric method. If the ΔH_p° of their results (1-butanol: 0.5 kcal/mol, 1-pentanol: 0.4 kcal/mol, 1-hexanol: 0.4 kcal/mol) are employed, it is possible to estimate the standard entropy change of penetration, ΔS_p°, of the alcohol using the following equation:

$$\Delta G_p^\circ = \Delta H_p^\circ - T\Delta S_p^\circ. \quad (6)$$

The results are 13.0, 14.4, and 18.7 cal/mol K for 1-butanol, 1-pentanol, and 1-hexanol, respectively. From these results, it may be considered that penetration of the alcohol from the aqueous to the micellar phases exhibits entropy dependence rather than enthalpy dependence. This is similar to the case of micellization of surfactants, namely, penetration of the alcohol from the aqueous to the micellar phases may be attributed to the release of the compact iceberg structure of water molecules around the hydrophobic parts of the alcohol.

Acidic Properties of SiO_2–MoO_3 and MoO_3, and Their Catalytic Activities

Kazumasa MARUYAMA, Hideshi HATTORI, and Kozo TANABE

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received August 9, 1976)

MoO_3, SiO_2, and SiO_2–MoO_3 of different compositions were prepared and their surface and catalytic properties examined. A large number of acid sites were generated by mixing SiO_2 with MoO_3, while each component oxide by itself did not exhibit any appreciable acidic properties. The oxidizing property of MoO_3 was enhanced by mixing with SiO_2. No new compounds were detected in the oxide mixture by X-ray diffraction. The activity for depolymerization of 2,4,6-trimethyl-1,3,5-trioxane correlated well with the surface acidity. In the isomerization of 1-butene, both MoO_3 and SiO_2–MoO_3 were active. The active sites on MoO_3 were poisoned by CO_2 but not by NH_3, while those on SiO_2–MoO_3 were poisoned by NH_3 but not by CO_2.

Among the metal oxides most widely used as a component of the multicomponent metal oxide catalysts is MoO_3, which is usually mixed with other oxides such as SiO_2, Al_2O_3, Bi_2O_3, and SnO_2. Many metal oxides are known to exhibit acidic properties when they are mixed with other oxides.[1,2] The acidic sites play an important role not only in reactions recognized as acid-base catalyzed reactions, but also in those of other types. For instance, the selectivity in the oxidation of olefins depends strongly on the surface acid-base properties.[3–6] However, the acid-base properties of the catalysts containing MoO_3 as a component oxide have not been subjected to extensive study except for MoO_3–Al_2O_3.[7]

We have prepared SiO_2–MoO_3 in various molar ratios and examined their acid-base properties. Two typical acid-base catalyzed reactions, depolymerization of 2,4,-6-trimethyl-1,3,5-trioxane and isomerization of butenes, were studied.

Experimental

Catalyst Preparation. SiO_2 and MoO_3 were prepared by precipitation from an isopropanol solution of ethyl orthosilicate and an aqueous solution of ammonium molybdate, respectively, with nitric acid followed by aging at 70—80 °C for 16 h and drying at 110 °C for 24 h.

SiO_2–MoO_3 was prepared as follows. A mixture of ethyl orthosilicate and 10% aqueous solution of ammonium molybdate was dissolved in isopropanol. To the solution was added dilute nitric acid (pH=1) and the solution was heated at 70—80 °C for 16 h to facilitate gelation. The resulting gel was dried at 110 °C for 24 h. Amounts of the reagents are given in Table 1.

Table 1. Amounts of reagents used for the preparation of MoO_3–SiO_2 with different compositions

Composition mol ratio (MoO_3: SiO_2)	$(C_2H_5)_4SiO_4$ ml	$(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ g	$(CH_3)_2CHOH$ ml
MoO_3	0	160	0
9: 1	13.2	159	14
1: 1	167	129	170
1: 9	402	35.3	400
SiO_2	400		400

Acidity and Basicity Measurements. Acidity was measured at 55 °C by titration of the suspension in benzene with 0.1 N butylamine benzene solution. The indicators used were dicinnamilideneacetone ($pK_a=-3.0$), *p*-(phenylazo)diphenylamine (1.5), Dimethyl Yellow (3.3), Methyl Red (4.8), and Neutral Red (6.8). The existence of basic sites was monitored by dropping a series of benzene solutions of nitroaniline indicators onto a sample.

Surface Area, X-Ray Analysis, DTA, and TG, ESR Measurements. Specific surface areas were determined by applying the BET equation to nitrogen adsorption isotherms at −196 °C. X-Ray diffraction patterns were recorded on a Toshiba ADG-301 with a powdered sample over the range of $2\theta=10°$—$60°$. Cu$K\alpha$ was used as the radiation source.

DTA and TG were performed on a Rigakudenki standard model over the range from room temperature to 720 °C. The rate of temperature rise was 20 °C/min.

For ESR measurements, 20 mg of the sample in a cell with a breakable seal was evacuated at the desired temperature for 3 h and sealed off. ESR spectra of these samples were measured at −196 °C and room temperature. After recording the spectra, samples were exposed to butene, oxygen, nitrobenzene or a benzene solution of perylene through a breakable seal. All the spectra were measured on a Varian E-4 ESR spectrometer.

Reaction Procedure. The benzene solution of 2,4,6-trimethyl-1,3,5-trioxane (paraldehyde) (0.0495 mol/l) was used as a reactant for the depolymerization of paraldehyde. Powdered catalyst was calcined at 500 °C for 3 h in air. To 40 ml of the reactant in a 100 ml flask with a cap was added 0.24 g of catalyst followed by magnetic stirring at 30 °C. Portions of the reaction mixture were periodically withdrawn from the system and subjected to analysis of acetaldehyde by the following method. Excess amount of 0.1 N $NaHSO_3$ was added to 10 ml of reaction mixture to form a complex with acetaldehyde. After titration of residual $NaHSO_3$ with I_2, the $NaHSO_3$–acetaldehyde complex was dissociated by the addition of $NaHCO_3$. The amount of $NaHSO_3$ required for the formation of the complex was determined by titration with I_2.

A microcatalytic pulse reactor was employed for the isomerization of butenes. The catalyst was sieved to 20—35 mesh and calcined at 500 °C for 3 h. A quarter grams of the catalyst was placed in the reactor and pretreated at 500°C under a helium stream for 1 h prior to reaction. All the reactions were carried out at 250 °C. Butene (*ca.* 40μ mol) was introduced into a helium carrier ahead of the catalyst by manipulating a stop cock. Effluent products were directly introduced into a gas chromatographic column for analysis. The flow rate of the carrier was kept constant (1.1 ml/s). In some experiments, CO_2 or NH_3 was introduced in order to examine a poisoning effect after reaching a steady activity, which was usually attained after 7 or 8 injections.

Results

Surface Area, X-Ray, DTA, and TG. The specific

Table 2. Specific surface area (m^2/g) of MoO_3–SiO_2 after calcination at various temperatures[a)]

Composition (MoO_3: SiO_2)	Calcination temperature, °C			
	300	400	500	600
MoO_3	4.5	4.8	4.3	2.8
9: 1	5.4	4.5	4.0	2.2
1: 1	143	92	81	40
1: 9	440	376	240	93
SiO_2	—	—	520	375

a) Before measurement, sample was evacuated at 150—170 °C for 1 h.

surface areas ot catalysts are given in Table 2. They decrease with an increase in percentage of MoO_3 and with a rise in calcination temperature.

X-Ray diffraction patterns show that all the peaks obtained for SiO_2–MoO_3 of different compositions calcined at 400, 500, and 600 °C are due to those of MoO_3, strong peaks being observed at $2\theta=10.17$, 19.90, and 29.80°. The samples calcined at 300 °C did not show this set of peaks. The peak intensity increases with a rise in calcination temperature and with an increase in MoO_3 content in SiO_2–MoO_3. No peaks other than those ascribed to MoO_3 were found.

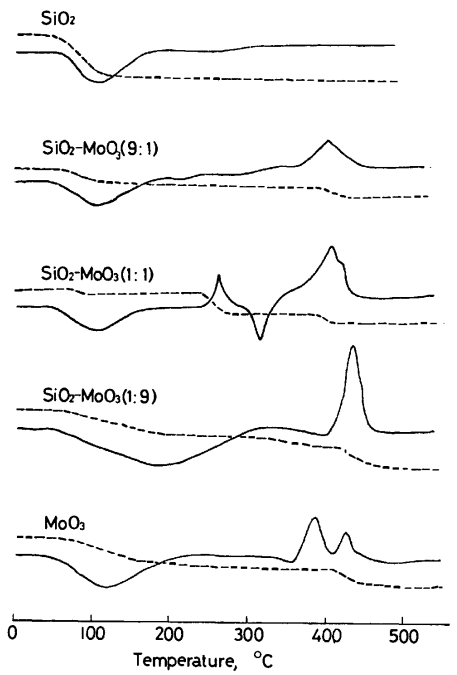

Fig. 1. DTA-TG curves of catalysts. DTA, solid line; TG, broken line.

DTA-TG curves are shown in Fig. 1. All the samples show endothermic peaks by DTA around 50—200 °C with loss of weight. These peaks can be ascribed to desorption of physically adsorbed water. The samples containing MoO_3 show exothermic peaks around 400 °C also accompanied a weight loss.

ESR. SiO_2–MoO_3 and MoO_3 show ESR signals assigned to Mo^{5+}. The signal for SiO_2–MoO_3 (9: 1) after evacuation at 500 °C is shown in Fig. 2. On exposure to nitrobenzene, the amplitude of the signal decreased considerably but no signal for nitrobenzene anion radical was observed. On admission of a benzene solution of perylene, a strong signal appeared which could be assigned to perylene cation radical. The signals observed for SiO_2–MoO_3 9: 1 and 1: 1 showed hyperfine splitting into nine peaks. On the other hand, the signals for SiO_2–MoO_3 (1: 9) and MoO_3 were broad singlets. The variation of the integrated signal amplitude of perylene cation radicals with composition is shown in Fig. 3.

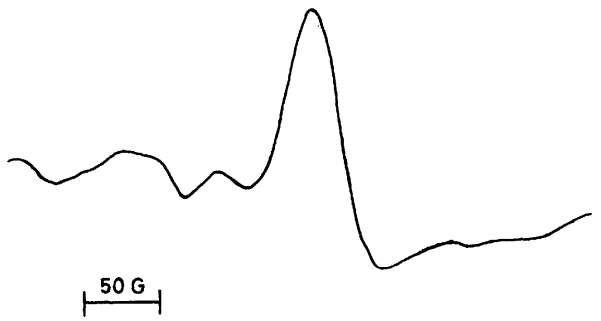

Fig. 2. ESR signal of SiO_2–MoO_3 (9: 1) evacuated at 500 °C.

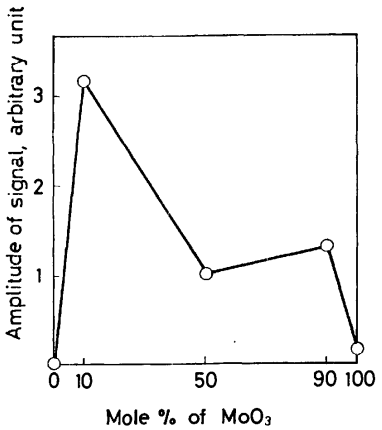

Fig. 3. Numbers of perylene cation radicals on SiO_2–MoO_3 of different composition. Catalysts had been evacuated at 500 °C.

Admission of butene at 200 °C to SiO_2–MoO_3 (9: 1) evacuated at 500 °C resulted in an increase in the signal amplitude of Mo^{5+}, and the successive admission of O_2 after the excess butene had been trapped in liquid nitrogen resulted in a decrease in the amplitude of the Mo^{5+} signal and the production of O^{2-}.

Acidity. Figure 4 shows the acidity of SiO_2–MoO_3 having compositions of 9: 1, 1: 1, and 1: 9 as well as that of SiO_2 and MoO_3, when calcined at 500 °C in air. Although SiO_2 and MoO_3 showed negligible amounts of acid sites stronger than $H_0=3.3$, SiO_2–MoO_3 with composition 9: 1 and 1: 1 showed considerable amounts of these acid sites. Change in calcination temperature caused no great change in acidity. An example is shown in Fig. 5 for SiO_2–MoO_3 (9: 1).

Depolymerization of 2,4,6-Timethyl-1,3,5-trioxane. The reaction rate equation was of first order in concen-

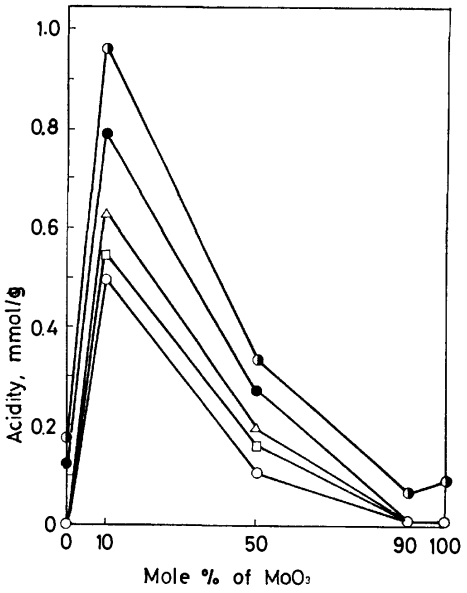

Fig. 4. Acidity of SiO_2–MoO_3 of different composition. $H_0 = -3.0$ (○), $+1.5$ (□), $+3.3$ (△), $+4.8$ (●), $+6.8$ (◑).

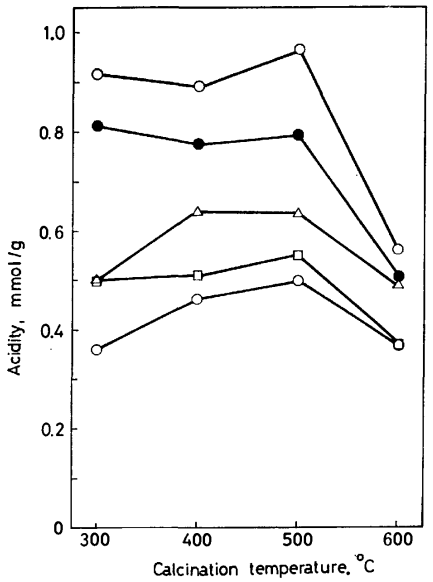

Fig. 5. Changes in acidity of SiO_2–MoO_3 (9: 1) with calcination temperature $H_0 = -3.0$ (○), $+1.5$ (□), $+3.3$ (△), $+4.8$ (●), $+6.8$ (◑).

tration of reactant. Activity of the catalyst was expressed by a first order rate constant, k, per unit weight of catalyst. The variation of the activity with composition is shown in Fig. 6, where the catalysts are calcined at 500 °C in air. A similarity in the change in activity to that in acidity with composition of the catalyst suggests that the acid sites are active sites for the decomposition of 2,4,6-trimethyl-1,3,5-trioxane to produce acetaldehyde. The activity of the catalysts is more than 10 times greater than that of $NiSO_4$ and $CuSO_4$.[7]

Isomerization of Butene. The conversion of *cis*-2-butene over MoO_3 and SiO_2–MoO_3 (9: 1) is plotted against the pulse number in Figs. 7 and 8. The decrease in conversion with the pulse number is greater for MoO_3 than SiO_2–MoO_3 (9: 1). After the conversion had

attained a constant value, CO_2 or NH_3 was introduced. The active sites of MoO_3 were poisoned by CO_2, but not substantially by NH_3. On the other hand, the active

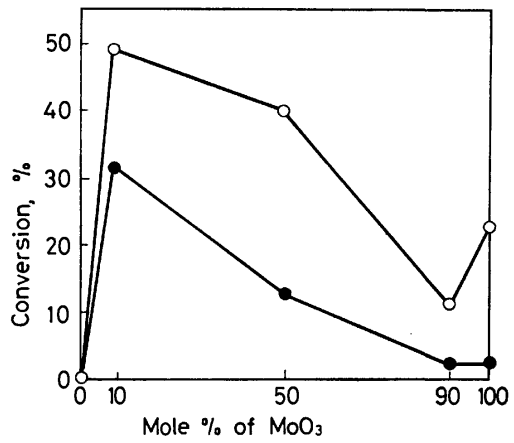

Fig. 9. Initial activity (○) and steady state activity (●) for isomerization of *cis*-2-butene.

sites of SiO_2–MoO_3 were poisoned by NH_3, but not by CO_2.

The conversion at the first pulse and that after several pulses (the constant conversion) are shown in Fig. 9. Except for MoO_3, the change in conversion with the composition of catalyst is similar to that in acidity.

Discussion

Mixing of SiO_2 and MoO_3 gave rise to new surface and catalytic properties not found in either component oxide, though X-ray and DTA-TG data showed no formation of a new compound. Of these properties acidity is important. A good correlation of acidity with activity for depolymerization of 2,4,6-trimethyl-1,3,5-trioxane indicates that the active sites for the reaction are the acid sites generated by mixing SiO_2 and MoO_3.

For the isomerization of butene, MoO_3 showed considerable activity though it had no acidic sites stronger than $H_0=4.8$. The catalyst was not poisoned by NH_3. Thus, the active sites are not acidic. Since CO_2 is an acidic molecule and can be adsorbed on basic sites, and CO_2 actually poisons the catalyst, the active sites on MoO_3 for the butene isomerization seem to be basic. On the other hand, the activity of the mixed oxides correlates with the acidity and NH_3 poisons the active sites. Thus, the active sites on SiO_2–MoO_3 are suggested to be acidic sites and the reaction proceeds *via* a carbenium ion mechanism.

An increase in the amplitude of the ESR signal for Mo^{5+} by the admission of butene to SiO_2–MoO_3 (9: 1) indicates that reduction occurred during the course of isomerization of butene. The activity also decreased with successive pulses. It seems that the active sites become less active by reduction. The mechanism of generation of acid sites in a mixed oxide was proposed by one of the authros,[1,2] and the concept can be applied to the SiO_2–MoO_3 system. Acid sites are caused by the excess positive charge on Si^{4+} in the SiO_2–MoO_3. The reduction of Mo^{6+} reduces the excess positive charge on Si^{4+} by the transfer of negative charge to Si^{4+} through oxygen bridging. This weakens the strength of acid sites or eliminates the acid sites.

Complexes between Nucleotide Base and Amino Acid. III. Crystal Structure of 5-Bromocytosine:Phthaloyl-DL-glutamic Acid Complex Hemihydrate

Minoru OHKI, Akio TAKENAKA, Hirotaka SHIMANOUCHI, and Yoshio SASADA

Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received August 25, 1976)

5-Bromocytosine and phthaloyl-DL-glutamic acid co-crystallize from their aqueous solution in space group $P\bar{1}$, with dimensions of $a=10.578(2)$, $b=19.640$ (4), $c=9.890$ (3) Å, $\alpha=88.13$ (2), $\beta=107.86$ (3), $\gamma=104.26$ (1)°. Two molecular complexes and one water molecule are in an asymmetric unit. The structure was solved by the heavy atom method and refined by a block-diagonal least-squares method. The 5-bromocytosine molecule binds with γ-carboxyl group of the amino acid through NH···O and OH···O hydrogen bonds. In spite of largely different molecular environment in the crystal from that of 5-bromocytosine:*N*-tosyl-L-glutamic acid complex, the mode of interaction between the nucleotide base and the amino acid is the same. Thus, it is suggested that the present geometry is a typical binding mode between cytosine and acidic side group of amino acid.

The present structure determination is a part of the serial studies on specific binding patterns of nucleotide base-amino acid interactions.

As reported in Part II on the 5-bromocytosine:*N*-tosyl-L-glutamic acid complex (BCTG),[1] we have found a specific hydrogen bond of cytosine with γ-carboxyl group of glutamic acid, not with α-carboxyl group. In cytidine:*N*-benzyloxycarbonyl-L-glutamic acid complex dihydrate,[2] on the other hand, cytosine binds with α-carboxyl group of glutamic acid. As α-carboxyl group is used for peptide bond formation in protein except for its C-terminal, the hydrogen bonds between cytosine and γ-carboxyl group may represent a more general mode of interaction. So, it must be examined whether the interaction mode found in BCTG complex is preserved or not, when the molecular environment in a crystal is altered. We have investigated this by the structure analysis of the title complex which has a different *N*-protective group of glutamic acid from BCTG.

Experimental

Plate crystals were obtained from an aqueous solution containing equimolar quantities of the two components. The complex formation was confirmed by IR spectroscopy and an elementary analysis of these crystals. Found: C, 43.12; H, 3.39; N, 12.28%. Calcd for $C_4H_4N_3OBr\cdot C_{13}H_{11}NO_6\cdot 1/2H_2O$: C, 42.87; H, 3.39; N, 11.77%. Diffraction pattern of the crystal indicated the crystal system to be triclinic. The unit-cell dimensions were determined by least-squares calculations from 89 reflexions recorded on equator Weissenberg photographs about the three different axes, calibration being made with superposed silicon lines ($a=5.43075$ Å). These results are listed in Table 1.

Table 1. Crystal data

5-Bromocytosine: phthaloyl-DL-glutamic acid hemihydrate
$C_4H_4N_3OBr\cdot C_{13}H_{11}NO_6\cdot \frac{1}{2}H_2O$
F.W.=476.2
Crystal system: triclinic
Space group: $P\bar{1}$
$a=10.578$ (2) Å $b=19.640$ (4) Å $c=9.890$ (3) Å
$\alpha=88.13$ (2)° $\beta=107.86$ (3)° $\gamma=104.26$ (1)°
$U=1893.3$ (7) Å^3 $Z=4$
$D_x=1.671$ g cm^{-3} $D_m=1.69$ g cm^{-3}
μ (Cu$K\alpha$)=38.11 cm^{-1}

Diffraction data were collected on equi-inclination Weissenberg photographs (0*kl*-7*kl* and *hk*0-*hk*7) using Ni-filtered Cu$K\alpha$ radiation and the intensities were measured by a TV densitometer.[3] The crystals used for the a- and c-axis rotations were $0.1\times0.2\times0.3$ mm and $0.07\times0.19\times0.36$ mm in size, respectively. Corrections were made for Lorentz and polarization effects and spot size, but not for absorption. A total of 7649 independent reflexions was obtained, of which zero-reflexions numbered 3908. The $N(z)$ test[4] indicated the crystal to be centro-symmetric; this is reasonable because the amino acid derivatives is racemic, thus the space group being decided to be $P\bar{1}$. The density, measured by flotation in a $CHBr_3$–CCl_4 mixture, indicated that there are two molecular complexes and one water molecule in an asymmetric unit.

Structure Determination and Refinement

The structure was solved by the heavy atom method, and refined by a block-diagonal least-squares method, the minimized function being $\sum w\Delta F^2$ where $\Delta F=|F_o|-|F_c|$. In this refinement, the zero-reflexions were assumed to have the value of $|F_o|_{min}$ (=4.31). The zero-reflexions for which $|F_c|$ values were smaller than $|F_o|_{min}$ were omitted in each cycle of refinement. The weight function used was as follows: $w=\exp(-as^2-bt^2-cst-ds-et-f)$ for $|F_o|>|F_o|_{min}$, where $s=|F_o|$ and $t=\sin\theta/\lambda$; $w=1/\langle\Delta F^2\rangle$ for $|F_o|=|F_o|_{min}$. The coefficients, *a*—*f*, were evaluated by least-squares at each cycle of the structure refinement so that $\langle w\Delta F^2\rangle=1$. The refinement was terminated when the maximum shift of parameters was less than 0.04σ and 0.06σ for positional and thermal parameters, respectively. At the final cycle, the coefficients of weight function were 0.00006012, 23.72, −0.05158, 0.04557, −21.35, and 5.304, respectively, and weight for $|F_o|_{min}$ was 0.0763. The final value of *R* is 0.13 ($R_w=0.11$). For reflexions of $|F_o|>3\sigma$ ($\sigma=1/\sqrt{w}$), *R* is 0.078. The comparison between observed and calculated structure factors is given in Table 2.[5] Atomic scattering factors used were taken from "International Tables for X-Ray Crystallography."[6] The final positional and thermal parameters are given in Table 3.

TABLE 3. FINAL POSITIONAL AND THERMAL PARAMETERS

Standard deviations are given in parentheses. The temperature factor has the form $\exp[-(\beta_{11}h^2+\beta_{22}k^2+\beta_{33}l^2+\beta_{12}hk+\beta_{13}hl+\beta_{23}kl)]$. All parameters have been multiplied by 10^4.

Results and Discussions

Bond lengths and angles of the two independent molecules are listed in Table 4. The values for corresponding bonds are in good agreement, and their averages are given in Fig. 1. The effects of bromine substitution on the bond lengths and angles of pyrimidine ring is not so large; somewhat longer C(2)-O(2) bond and shorter C(2)-N(3) bond are observed as compared with the authentic values of neutral cytosine,[7] but these should be attributable partly to the effects of strong hydrogen bonds involving O(2) (Table 5), which are also observed in BCTG complex.[1] The crystallographically independent molecules are shown in Fig. 2.

The molecules are arranged in layers parallel to the (021) plane (Fig. 3). As shown in Fig. 4, four α-carboxyl groups and two water molecules constitute a 14-membered ring around the center of symmetry at 1/2, 1/2, 1/2 by hydrogen bonds, O(4A)H···O(9), O(9)H···O

(3B), and O(4B)H···O(3A). Distance of O(4A)··· O(9) is fairly shorter than those of the other OH···O hydrogen bonds (Table 5). Similar short O···O distances are also observed in oxalic acid dihydrate (2.512 Å)[8] and pyromellitic acid dihydrate (2.549 Å).[9] Furthermore, this ring is connected with those in the neighboring unit-cells by the hydrogen bond between water molecule and O(8) atom of phthaloyl group in the A molecule, to complete a three-dimensional network. The structure is further stabilized by the overlapping of the phthaloyl groups; the dihedral angle between the mean planes of the two independent phthaloyl groups is 5.1° and the spacing is about 3.4 Å.

The hydrogen bonding arrangements in the layer is illustrated in Fig. 5, relevant distances and angles being listed in Table 5. The 5-bromocytosine molecules are linked by the hydrogen bonds, N(1A)H···O(2B), N (1B)H···O(2A), N(4A)H···N(3B), and N(4B)H···N (3A), to form a ribbon elongated along [100] direction. To the ribbon, γ-carboxyl group of a glutamic acid is bound through hydrogen bonds in which O(5) atom is a donor to O(2) of 5-bromocytosine and at the same time an acceptor from N(4) of the neighboring base. In addition, O(6) seems to make a CH···O type interaction with C(6) of the base A′. The other crystallographically independent glutamic acid also interacts to the ribbon

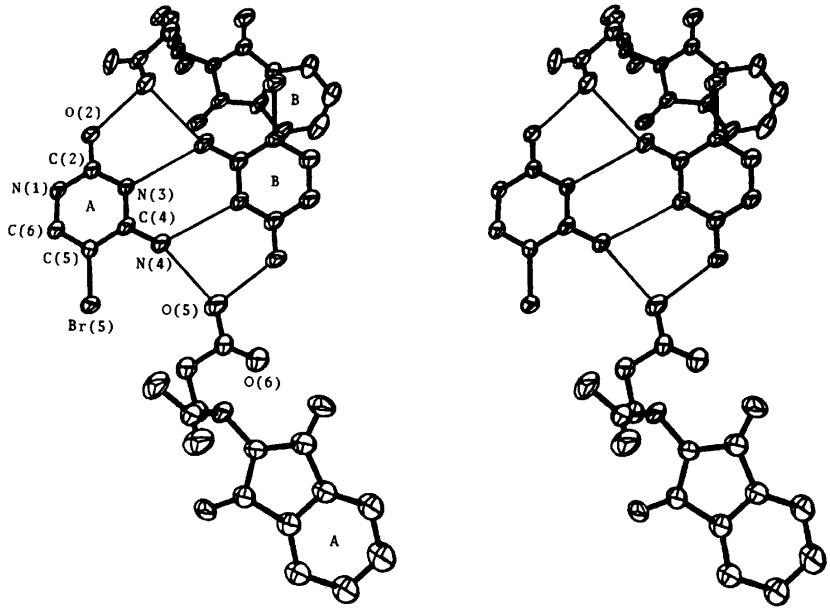

Fig. 2. A stereoscopic view of 5-bromocytosine: phthaloylglutamic acid.
Thermal ellipsoids are drawn at the 50% probability level.

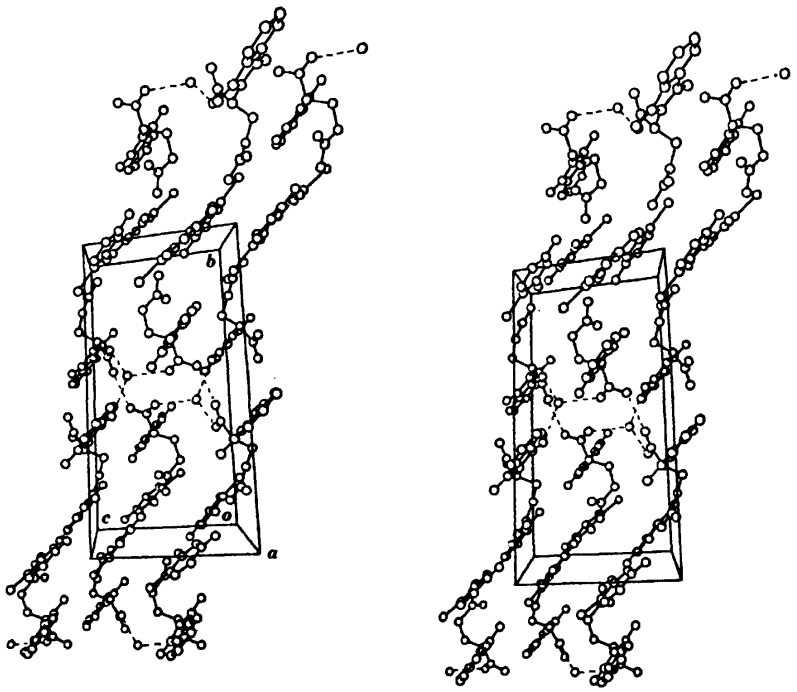

Fig. 3. A stereoscopic view of the crystal structure.

in the same way. It is interesting to note that amino acids bound to one cytosine's ribbon are the same optical isomers.

As seen from the hydrogen bond scheme described above, the N(3) atom of cytosine is not protonated; the C(2)–N(3)–C(4) bond angle of cytosine 119.6° is close to unprotonated form,[7] and the distances and angles of α- and γ-carboxyl groups of glutamic acid correspond to those of undissociated acid.

Each pyrimidine ring is planar within 0.02 Å and each bromine atom also lies in the plane. The dihedral angle between these mean planes is 11.5°.

The conformations of two glutamic acids A and B are different to each other mainly in torsions around the C(7)–C(8) and C(8)–C(9) bonds, as shown in Table 6. In the molecule A, the C(8)–N(5) bond is nearly parallel to α-carboxyl plane and the torsion angle of C(7)–C(8)–C(9)–C(10) is a nearly right angle, while in the molecule B, the C(8)–C(9) bond is parallel to α-carboxyl plane and C(7), C(8), C(9), and C(10) are nearly coplanar.

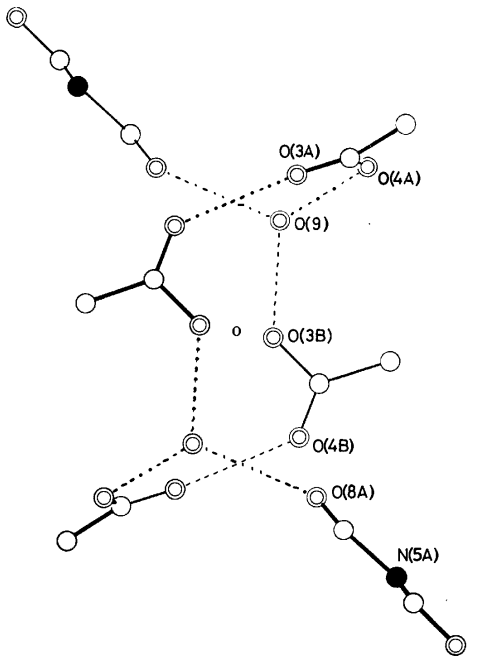

Fig. 4. The hydrogen bonding network around the center of symmetry at 1/2, 1/2, 1/2 viewed along the a axis.

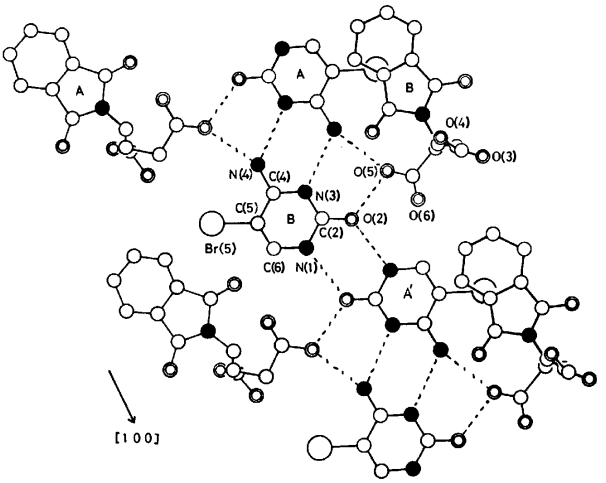

Fig. 5. A projection of one layer of 5-bromocytosine: phthaloyl-DL-glutamic acid onto the (021) plane. This illustrates the hydrogen bonding arrangement in the complex. The crystallographically independent molecules are labeled as A and B.

The side chains of glutamic acids are folded by the rotations around C(9)–C(10) bonds, in contrast to the extended form found in BCTG complex.[1]

As described above, the present crystal structure is different from that of BCTG in a mode of interlayer interaction, in hydrogen bonds of the α-carboxyl groups, and in the conformations of glutamic acids. In spite of these differences, binding scheme between 5-bromocytosine and γ-carboxyl group of glutamic acid is the same as that of BCTG, suggesting that this binding is a typical mode between 5-bromocytosine and the acidic amino acid.

The other type of complex formation between cytosine and glutamic acid has been reported for cytidine: *N*-benzyloxycarbonyl-L-glutamic acid complex dihydrate,[2] in which cytosine moiety interacts with dissociated α-carboxyl group. Such a difference may be attri-

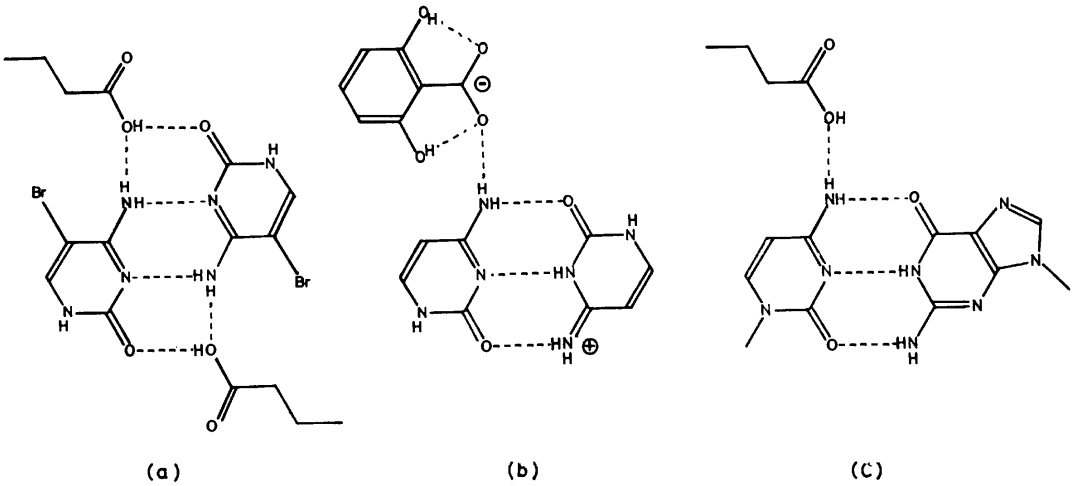

Fig. 6. The hydrogen bond scheme of (a) present and BCTG complexes, (b) cytosine: resorcylic acid 2: 1 complex monohydrate, and (c) a model of interaction between acidic side group of amino acid and the Watson-Crick G: C pair.

buted to the bromine substitution at C(5) of cytosine. Bromine at C(5) decreases the basicity of cytosine, so that a protonation to N(3) is inhibited; pK_a of 5-bromocytosine is 3.04 while those of cytosine and cytidine are 4.61 and 4.1,[10] respectively. In cytidine:*N*-benzyloxycarbonyl-L-glutamic acid, cytosine base is protonated and then hydrogen-bonded with stronger acid, α-carboxyl group of glutamic acid, while in the present and BCTG complexes, the protonation of the base is inhibited so that it becomes possible to interact with milder γ-carboxyl group. This argument is supported by the recent structure analysis of cytosine:phthaloyl-DL-glutamic acid complex,[11] in which cytosine binds with α-carboxyl group of glutamic acid.

Schematic drawing of complex molecules found in the present and BCTG complexes in Fig. 6(a) shows that the mode of three parallel hydrogen bonds of cytosine resembles the triple hydrogen bond in the Watson-Crick guanine:cytosine pair. A similar feature is also found in cytosine: resorcylic acid 2: 1 complex monohydrate[12] (Fig. 6(b)), in which the triple hydrogen bond is formed between neutral and protonated cytosines; furthermore, dissociated carboxyl group of resorcylic acid binds through a hydrogen bond to cytosine in the same geometry as those in the present and BCTG complexes. Thus, if the base on the right side in Fig. 6 (a) and (b) is replaced by guanine as in Fig. 6(c), it might provide a model of interaction between paired cytosine and acidic side group of amino acid. Recently, some model building[13,14] concerning mutual recognition between double helical nucleic acid and protein have been reported, but the present model is the first one based on the observed interaction between nucleotide base and amino acid in the crystal. It is known that elongation factors T_u and G, and initiation factor F_2 in protein synthesis are all acidic protein. Therefore, the present structure might be effected if some acidic side groups of these factors would interact with tRNA, mRNA, and rRNA.

Part of the cost of this research was met by a Scientific Research Grant from the Ministry of Education to which the authors' thanks are due.

(Received September 20, 1976)

On the basis of the second-order Jahn-Teller theorem, we propose a criterion for predicting the stable ground-state geometrical structures of open-shell conjugated hydrocarbons. It is found that in contrast with the cases of the parent closed-shell hydrocarbons no molecular symmetry reduction occurs in the ion radicals of the C_mH_{m-2} cata-condensed nonalternant hydrocarbons, such as pentalene and heptalene. On the other hand, it is revealed that the ion radicals of fulvalene systems suffer the molecular symmetry reduction from D_{2h} to C_{2v}. In addition, the electronic spectra were calculated using the stable geometrical structures obtained by use of the semiempirical open-shell SCF MO method.

It is well known that the ground states of odd cyclic polyene radicals, *e.g.* the cyclopentadienyl radical, and ion radicals of even cyclic polyenes, *e.g.* the benzene positive ion, are unstable in the fully symmetrical nuclear arrangements and undergo the first-order Jahn-Teller distortions.[1] Further, the closed-shell C_mH_{m-2} cata-condensed nonalternant hydrocarbons, considered to be formed by the introduction of a cross-link between the two carbon atoms of like parity in even cyclic polyenes with $4n$ π-electrons, such as pentalene and heptalene, are found to suffer the second-order (pseudo) Jahn-Teller effects in the fully symmetrical nuclear arrangements and to be unstable with respect to the nuclear deformation of bond alternation type.[2] Our present interest is to examine whether the second-order Jahn-Teller distortions occur or not in the ground states of the ion radicals of C_mH_{m-2} cata-condensed nonalternant systems.

In order to predict the stable molecular shapes of closed-shell conjugated hydrocarbons, we have proposed a symmetry rule on the basis of the so-called pseudo Jahn-Teller theorem,[3-5] assuming that only the lowest-lying excited state plays a dominant role for the problem of a molecular symmetry reduction. In spite of the very drastic approximation, this rule has been shown to hold for a large number of conjugated hydrocarbons.[2,3,6-8]

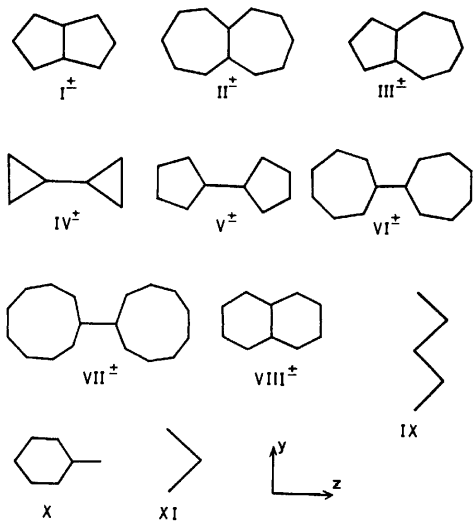

Fig. 1. Carbon skeletons and choice of axes for some open-shell conjugated hydrocarbons. The + or − sign of the superscript refers to the cation or the anion radical, respectively. I: Pentalene, II: heptalene, III: azulene, IV: triafulvalene, V: pentafulvalene, VI: heptafulvalene, VII: nonafulvalene, VIII: naphthalene, IX: pentadienyl radical, X: benzyl radical, XI: allyl radical.

In this paper, we derive a criterion for a molecular symmetry reduction in open-shell conjugated systems, and examine the stable molecular shapes of some ion radicals of (a) C_mH_{m-2} cata-condensed nonalternant systems, (b) $C_{4n+2}H_{4n}$ fulvalene systems, and (c) alternant systems (Fig. 1). Moreover, we calculate the electronic spectra using the stable geometrical structures obtained by use of the open-shell SCF MO method.

Theoretical

The Second-order Jahn-Teller Effect. The method for predicting the stable molecular shapes of conjugated hydrocarbons is based on the second-order Jahn-Teller theorem. First we assume a fully symmetrical nuclear arrangement as the unperturbed nuclear configuration for an open-shell conjugated hydrocarbon. We further assume that in the unperturbed nuclear configuration all the fully symmetrical bond distortions take place until the first-order energy equilibrium is reached. The unperturbed doublet electronic wavefunctions ϕ_0, ϕ_1, $\cdots$, ϕ_n, $\cdots$ and the corresponding eigenvalues E_0, E_1, $\cdots$, E_n, $\cdots$ are assumed to be known. We now distort the nuclei from the fully symmetrical (first-order) nuclear arrangement by means of the ith normal coordinate of nuclear motion Q_i. On the basis of the same approximation as used previously,[3] the energy of the ground state after the deformation may be written as

$$E(Q_i) = E_0 + \frac{1}{2}\left\{k - 2\sum_{n(\neq 0)} \frac{|\langle\phi_n|(\partial v/\partial Q_i)_0|\phi_0\rangle|^2}{(E_n - E_0)}\right\} Q_i^2$$

where k and v represent the force constant for an sp^2 hybridized C–C σ-bond and the operator of one electron nuclear-electron potential energy, respectively.

According to the above equation, the curvature of $E(Q_i)$ with respect to the nuclear deformation Q_i, that is, $\{k - 2\sum_{n(\neq 0)}|\langle\phi_n|(\partial v/\partial Q_i)_0|\phi_0\rangle|^2/(E_n - E_0)\}$, can be identified as the force constant for the nuclear deformation Q_i. If a given matrix element $\langle\phi_n|(\partial v/\partial Q_i)_0|\phi_0\rangle$ is nonvanishing and the associated energy gap $E_n - E_0$ is sufficiently small, the force constant can be negative and the initial nuclear configuration would be unstable with respect to the nuclear deformation Q_i.

Such a nuclear deformation is called the pseudo, or the second-order Jahn-Teller effect.

Criterion for a Molecular Symmetry Reduction. In order to estimate the value of the force constant, we make the following approximation: the infinite sum over the excited states is replaced by one term corresponding to the lowest excited state, ϕ_1. It has been shown that this approximation is amply justified at least in the closed-shell conjugated hydrocarbons.[2,3,6-8]

We now focus our attention on the matrix element, $\langle\phi_1|(\partial v/\partial Q_i)_0|\phi_0\rangle$, called the relaxability of the molecule along the nuclear displacement Q_i.[9] It is obvious from the symmetry argument that this integral is nonvanishing, only if the symmetry of the direct product $\Gamma(\phi_0)\times\Gamma(\phi_1)$ is identical with that of the nuclear deformation Q_i. We can thus determine the symmetry of nuclear deformation effective for the molecular symmetry reduction. It should be noted that in the closed-shell systems the ground state is, in principle, totally symmetric, the symmetry of nuclear deformation Q_i is identical with that of the lowest excited singlet state.

In order to calculate electronic states of open-shell conjugated hydrocarbons, we employ Longuet-Higgins and Pople's method.[10] According to their method, a doublet ground state wavefunction is written as

$$\phi_0 = |\varphi_1\bar{\varphi}_1 \cdots \varphi_{m-1}\bar{\varphi}_{m-1}\varphi_m|$$

where φ_m is the molecular orbital of an odd α electron. As the main electron configuration of the lowest excited doublet state, the following two types of electron excitation are possible:

(i) The excitation of the β electron in φ_{m-1} to φ_m, which gives rise to the doublet wavefunction

$$\phi_A = |\varphi_1\bar{\varphi}_1 \cdots \varphi_{m-1}\bar{\varphi}_m\varphi_m|$$

(ii) The excitation of the odd electron to φ_{m+1}, which gives rise to the doublet wavefunction

$$\phi_B = |\varphi_1\bar{\varphi}_1 \cdots \varphi_{m-1}\bar{\varphi}_{m-1}\varphi_{m+1}|$$

Since $(\partial v/\partial Q_i)_0$ is the one-electron operator, the matrix element $\langle\phi_1|(\partial v/\partial Q_i)_0|\phi_0\rangle$ is reduced to $\int\rho_{01}\cdot(\partial v/\partial Q_i)_0 d\tau$, where ρ_{01} is the so-called transition density. The value of this integral may become very large if the transition density is localized in the regions near nuclei which are involved in the motion. The transition density between the ground and the lowest excited doublet state is given by $\varphi_{m-1}\varphi_m$, if the latter state is ϕ_A, or $\varphi_m\cdot\varphi_{m+1}$ if it is ϕ_B.

It should be noted in this connection that for closed-shell systems the transition density between the ground and the lowest excited singlet state corresponding to the orbital jump $\varphi_i\rightarrow\varphi_j$, in which φ_i and φ_j are respectively the highest occupied and the lowest vacant molecular orbitals, is given by $\sqrt{2}\,\varphi_i\varphi_j$. Therefore, in so far as the transition densities for both open and closed-shell systems are assumed not to vary significantly according to the molecular orbitals concerned, the square of the matrix element, $|\langle\phi_1|(\partial v/\partial Q_i)_0|\phi_0\rangle|^2$, for open-shell systems should be about one half as that for closed-shell systems. As for closed-shell systems, it should be kept in mind that the following criterion[3] for the molecular symmetry reduction holds for a variety of molecules: if the lowest excitation energy of a molecule, calculated assuming the full molecular symmetry, is smaller than *ca.* 1.2 eV, the force constant for a certain antisymmetrical nuclear vibration should be negative, and the molecule would be distorted into a less symmetrical nuclear arrangement.

From the above arguments, we may now draw a criterion for a molecular symmetry reduction in open-shell conjugated hydrocarbons, which states: if the lowest doublet excitation energy of a given molecule, calculated assuming the full molecular symmetry, is smaller than a critical value, *ca.* 0.6 eV, the initial nuclear arrangement is unstable with respect to a certain antisymmetrical C–C nuclear deformation, and the molecule would be distorted into a less symmetrical nuclear arrangement. As to the actual type of nuclear deformation Q_i, it is predicted by examining the distributions of the transition density ρ_{01}.

Since it is based on the second-order Jahn-Teller theorem, the above criterion gives only the type of the most favorable bond distortion. In order to obtain the equilibrium C–C bond-length at which the nuclei of the real molecule will settle, we use the semiempirical open-shell SCF MO method in conjunction with the variable bond-length technique.[11,12]

Results and Discussion

In Table 1 are listed the lowest excitation energies, calculated by using the semiempirical open-shell SCF

Table 1. The lowest excitation energies and symmetries of the ground and the lowest excited doublet states of open-shell conjugated hydrocarbons

Molecule (Point group and ground state symmetry)	Lowest Excited State	
	ΔE (eV)	Symmetry

a) The + or − sign refers to the cation or the anion radical, respectively.

MO CI method and the symmetries of the ground and the lowest excited doublet states at the fully symmetrical nuclear arrangements.

The Ion Radicals of C_mH_{m-2} Cata-condensed Nonalternant Systems. It is found in a previous paper[2] that in the $C_{4n}H_{4n-2}$ closed-shell systems which has a cross-link between the two carbon atoms of like parity all the lowest excitation energies calculated assuming the fully symmetrical structures are significantly smaller than the critical value, which results in the molecular symmetry reduction accompanied by a marked double-bond fixation in the peripheral carbon skeleton. On the other hand, in $C_{4n+2}H_{4n}$ with a cross-link between the two carbon atoms of like parity the lowest excitation energies are predicted to be considerably larger than the critical value for small members and a molecular symmetry reduction would not occur until the number of carbon atoms increases to a certain value. Pentalene (1-methylpentalene) and heptalene, both having $4n$ carbon atoms, have successfully been synthesized by Bloch *et al.*[13] and Dauben and Bertelli,[14] respectively, and are known to exhibit the polyolefinic characters. The theoretical studies on both molecules revealed that at the fully symmetric D_{2h} configuration the lowest excited singlet state (B_{3g}) is nearly degenerate with the ground state (A_g) and therefore the stable geometrical structure is predicted to be of C_{2h} symmetry, showing a marked double-bond fixation in the periphery.

In the cation radicals of pentalene, heptalene, and nonalene, the distributions of the transition densities are of b_{3g} symmetry and they have a tendency to distort into a skew structure corresponding to one of the Kekulé type structures (Fig. 2). However, since the energy gaps of these radicals are considerably larger than the critical value, *ca.* 0.6 eV, we cannot expect such a molecular symmetry reduction as observed in the parent closed-shell hydrocarbons.

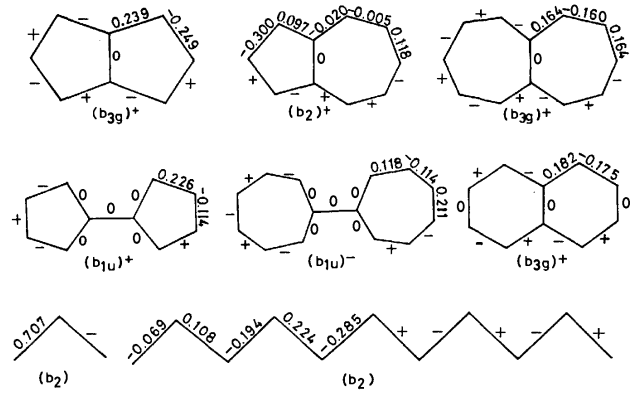

Fig. 2. Symmetries and distributions of the two-center components of transition densities (ρ_{01}). The + or − sign of the superscript written after the parentheses refers to the cation or the anion radical, respectively.

Moreover, in the anion radicals of the above molecules, the situation is the same as that seen in the cation radicals, *i.e.*, no molecular symmetry reduction occurs.

In the cation and anion radicals of azulene belonging to $C_{4n+2}H_{4n}$ system, there is no possibility of a molecular symmetry reduction from C_{2v} to C_s through the nuclear deformation of b_2 symmetry, because of the relatively large energy gap.

Results of SCF MO calculations agree that all these ion radicals, independent of the number of carbon atoms, undergo no molecular symmetry reduction (Fig. 3).

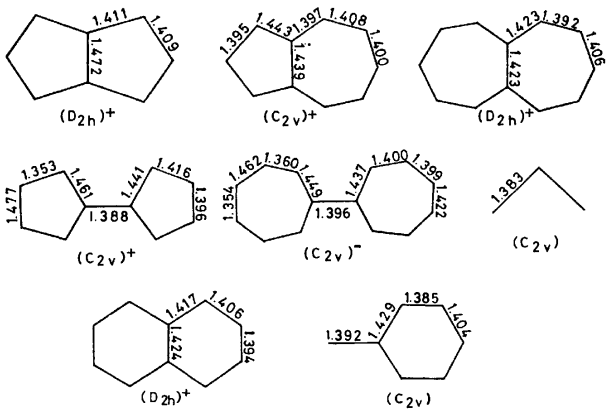

Fig. 3. Molecular symmetry groups and C-C bond lengths (in Å unit).

TABLE 2. TRANSITION ENERGIES AND INTENSITIES

a) Ref. 15. b) Refs. 21 and 22.

It should be noted that using the fully symmetric C_{2v} geometrical structures obtained, we can well reproduce the observed electronic spectra[15] for both ion radicals of azulene (Table 2).

The Ion Radicals of Fulvalene Systems. Of fulvalene systems, $C_{4n+2}H_{4n}$, pentafulvalene ($n=2$), heptafulvalene ($n=3$), and the ion radicals of heptafulvalene have been prepared, and their UV and ESR spectra have been reported.[16,17] Sevilla *et al.* have found that in the cation radical of heptafulvalene the unpaired spin density is delocalized throughout the molecule, while in the anion radical, the spin density is localized essentially on a single seven-membered ring. In a previous paper[18] we have explained the origin of the sharp contrast between the spin density distributions of the cation and anion radicals of heptafulvalene, by examining the energetically favorable molecular symmetry groups and C–C nuclear arrangements, using the open-shell SCF MO method (Fig. 3).

In the cation radicals of triafulvalene ($n=1$) and heptafulvalene ($n=3$), the ground state is of B_{3u} symmetry and the lowest excited doublet state is of A_u one in the fully symmetric D_{2h} configuration. The associated energy gaps of interest (1.55 and 1.22 eV, respectively) are considerably larger than the critical value, so that we cannot expect the molecular symmetry reduction to occur from D_{2h} to C_{2h} through the nuclear deformation of b_{3g} symmetry. On the other hand, in the anion radicals for both molecules, the ground state is of B_{1g} symmetry and the lowest excited state, nearly degenerate with the ground state, is of A_u one. It is therefore expected that in the anion radicals the molecular symmetry reduction occurs from D_{2h} to C_{2v} through the nuclear deformation of b_{1u} symmetry. Of the several nuclear deformation with the b_{1u} symmetry, the one actually effective for the molecular symmetry reduction is predicted by examining the distributions of the transition density shown in Fig. 2.

Further, in the cation radicals of pentafulvalene ($n=2$) and nonafulvalene ($n=4$), the lowest excited state (B_{1g}) is very close to the ground state (A_u). Both ion radicals are predicted to undergo the second-order Jahn-Teller distortions from D_{2h} to C_{2v} through the nuclear deformation of b_{1u} symmetry, whereas in the anion radicals, the situation is found to be the same as that seen in the cation radicals of triafulvalene and heptafulvalene.

From the above results, we can deduce the following rules concerning the molecular symmetry reduction in the ion radicals of $C_{4n+2}H_{4n}$ fulvalene systems: (i) When n is odd, a molecular symmetry reduction occurs in the anion radicals, while (ii) when n is even, it occurs in the cation radicals. These rules are interpreted in terms of Hückel MO energy level diagrams as follows: if n is odd, the lowest vacant molecular orbitals of fulvalene systems, whose symmetries are b_{1g} and a_u, are accidentally degenerate with each other. On the other hand, if n is even, the highest occupied molecular orbitals of b_{1g} and a_u symmetries are also accidentally degenerate. Hence for anion radicals of case (i), there are two ways of assigning one electron to the doubly degenerate molecular orbitals, which results in the degeneracy of the ground state in the simple one-electron picture. If we take into account the electron repulsion, this degeneracy is removed, but the energy gap between the two split states is still small as can be seen in Table 1. In a similar manner, for cation radicals of case (ii), there also occurs the degeneracy of the ground state in the one-electron approximation.

The Odd Alternant and Other Ion Radicals. As to $C_{2n+1}H_{2n+3}$ odd linear polyene radicals, we deal with those with $n=1$ to 8. In smaller systems, the energy gaps are significantly larger than the critical value, and there would be no possibility for the molecular symmetry reduction to occur. However, since as n increases, the energy gap tends to decrease and since in the hypothetical infinite odd cyclic polyene radical, which is mathematically equivalent to the infinite odd linear polyene radical,[19,20] the nuclear distortion of bond alternation type should certainly occur, it may be expected that in molecules with n larger than a certain limiting value there is a possibility of the second-order Jahn-Teller distortions to take place through the nuclear deformation of bond alternation type (Fig. 2).

In benzyl radical, the symmetry of the lowest excited state is the same as that of the ground state and the second excited state is located at the appreciably higher region, *i.e.*, 2.63 eV, so that there is no possibility for the molecular symmetry reduction to occur.

In the cation and anion radicals of naphthalene, they undergo no molecular symmetry reduction, since the calculated energy gaps are larger than the critical value.

Results of SCF MO calculations support the above predictions, and the transition energies calculated at the fully symmetric D_{2h} configurations for both ion radicals of naphthalene and those at the fully symmetric C_{2v} configuration of benzyl radical reproduce well the respective observed transition energies (Table 2).[15,21,22]

Conclusion

The problem of a molecular symmetry reduction in the open-shell conjugated systems are discussed on the basis of the second-order Jahn-Teller theorem. In contrast with the cases of the parent closed-shell hydrocarbons, the ion radicals of C_mH_{m-2} cata-condensed nonalternant hydrocarbons having $4n$ carbon atoms undergo no pseudo Jahn-Teller distortions. In the ion radicals of fulvalene systems, $C_{4n+2}H_{4n}$, a molecular symmetry reduction from D_{2h} to C_{2v} occurs in the cation radicals if n is even, and in the anion radicals if n is odd. It is found further that in odd linear polyene radicals, $C_{2n+1}H_{2n+3}$, with n larger than a certain critical value the nuclear configuration with the full molecular symmetry group should be unstable with respect to the nuclear deformation of bond alternation type.

Finally, it should be noted that the success of the predictions based on the energy-gap law is due to the assumption that the transition density does not vary significantly according to the molecular orbitals concerned, *i.e.*, the value of the matrix element, $\langle\phi_1|(\partial v/\partial Q_i)_0|\phi_0\rangle$, called the relaxability of the molecule along the nuclear displacement is almost constant from molecule to molecule. In view of the good agreement between theory and experiment obtained in this paper, we believe

that this assumption does hold at least for a variety of conjugated hydrocarbons considered in this paper.

The numerical calculation was carried out at Tohoku University with an NEAC 2200-700 electronic computer.

Vibration Spectra and Rotational Isomerism of Chain Molecules. II.[1] Butane, Pentane, Hexane, Pentane-d_{12}, and Hexane-d_{14}

Issei HARADA, Hideo TAKEUCHI,* Masaaki SAKAKIBARA, Hiroatsu MATSUURA, and Takehiko SHIMANOUCHI

Department of Chemistry, Faculty of Science, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received July 26, 1976)

The Raman spectra of butane, pentane, hexane, pentane-d_{12}, and hexane-d_{14} and infrared spectra of pentane-d_{12} and hexane-d_{14} were measured for the liquid and solid states. The rotational isomerism of normal paraffins was studied on the basis of the spectral observations and the normal coordinate calculations. The spectra of the deuterated compounds were useful in the confirmation of the less stable isomers and the establishment of the local symmetry force field of normal paraffins. The enthalpy differences among the rotational isomers were studied on pentane and hexane, which yielded some important data for the study of the conformations and properties of longer hydrocarbons.

The study of the vibrational spectra and rotational isomerism of normal paraffins was started by Mizushima and coworkers[2] and Sheppard and coworkers[3] about thirty years ago.

More recently, Snyder *et al.*[4] treated this problem by the use of the newly observed infrared data and normal coordinate analysis and obtained the refined valence force field that could correlate the calculated frequencies with the observed frequencies satisfactorily for various isomers of normal paraffins. As the result, it has become clear that some bands that had been used for the determination of the enthalpy differences are possibly assigned to more than one vibrations of one form or different forms. The enthalpy difference between the *trans-gauche* (TG) and the *trans-trans* (TT) forms and that between the *gauche-gauche* (GG) and the TG forms of pentane have been estimated to be 600±100 cal/mol and 670±100 cal/mol, respectively.[4c]

Verma *et al.*[5] studied the temperature dependence of the Raman spectra of gaseous butane, 2-methylbutane and 2,3-dimethylbutane. They could resolve the Raman bands which had been observed as single bands and obtained the enthalpy difference of 966±54 cal/mol between the G and T forms of butane.

In pursuit of the studies on the vibration spectra and rotational isomerism of chain molecules,[1,6,7] we investigated the vibration spectra of normal paraffins and perdeuterated normal paraffins and obtained the refined local symmetry force field that explained the frequencies

of both species. In the course of the research, several new findings including the identification of the less stable rotational isomers and the determination of the enthalpy differences among the isomers of pentane and hexane in the liquid state have been obtained. The present paper describes the rotational isomerism and vibrational assignments of butane, pentane, hexane, pentane-d_{12}, and hexane-d_{14}.

Experimental

Butane (stated purity of 98%) was supplied by Tokyo Kasei Kogyo Co., Ltd. and was used without further purification. Highly pure samples (stated purity of 99.9%) of pentane and hexane were purchased from Tokyo Kagaku Seiki Co., Ltd. and were distilled prior to the measurements. Pentane-d_{12} and hexane-d_{14} (stated purity of 98%) were obtained from Merck, Sharp, and Dohme of Canada and were transferred to ampoule Raman cells by the use of a vacuum system. The spectrometers used are the same as those in the previous study.[1]

The Raman spectra were recorded in the region below 1600 cm^{-1}. The measurements of the spectra at low temperatures were performed in the same way as that in a previous study.[8] Liquid nitrogen and liquid-nitrogen cooled ethanol were used as the cooling agent. For the determination of the enthalpy difference, the Raman spectra were recorded twice

at each of ten different temperatures between −111 and 23 °C for pentane and at each of eight different temperatures between −89 and 23 °C for hexane.

Infrared spectra of pentane-d_{12} and hexane-d_{14} in the solid and liquid states were measured in the region 1600—400 cm⁻¹.

Normal Coordinate Treatment

The normal coordinate treatment of normal paraffin molecules was carried out in a way similar to the case of the ethers.[1] The molecules treated are: butane, pentane, hexane, pentane-d_{12}, hexane-d_{14}, poly(ethylene), and poly(ethylene-d_4). Detailed results including structural parameters, symmetry coordinates, and force constants are reported in a separate paper.[9]

A total of 45 force constants of normal paraffins were determined from 254 Raman and infrared frequencies of 14 forms of the seven molecular species.**

** Some of the observed frequencies were assigned to more than one vibrations of the same isomer or different isomers. However each of these frequencies was counted as one.

a) The observed bands are assigned to the individual vibrations of the TT and TG forms. The vibration of the GG form is identified in the table when the band is assigned only to this form. There is a possibility that the bands observed only in the solid state are components of crystal field splittings. For the notation and definition of the local symmetry coordinates, see Ref. 10. VS: very strong, S: strong, M: medium, W: weak, VW: very weak, sh: shoulder. b) Observed at room temperature.

Results and Discussion

Figures 1—7 show the Raman and infrared spectra in the liquid and solid states of the molecules. In Figs. 2 and 4, the comparatively isolated bands for which the dependence of the relative intensities on temperature has been examined are identified by letters a through e for pentane and f through m for hexane. The observed frequencies and the assignments based on the calculated potential-energy distributions are listed in Tables 1—5. In the column of assignment in each table, the conformation symbol given by boldface indicates that the corresponding frequency is definitely assigned to the rotational isomer based solely on the experimental result or almost definitely assigned based on the combined results of the experiments and normal vibration calculations. The apparent enthalpy differences calculated by assuming that the intensity of each of the bands is due to one rotational isomer are tabulated in Table 6 and possible assignments of the bands a through m are listed in Table 7. Part of the observed spectra and calculated frequencies of pentane-d_{12} are compared in Fig. 8.

Butane (See Fig. 1 and Table 1). Verma *et al.*[5)] studied the Raman spectra of this molecule in the gaseous and solid states for the purpose of determining the enthalpy difference between the rotational isomers, but reported only the spectra in the regions 900—750 cm^{-1} and 450—300 cm^{-1}. Figure 1 and Table 1 give the Raman frequency data below 1600 cm^{-1} obtained in the present measurements and the assignments. The band

at 421 cm^{-1} observed and assigned to the G form by Verma *et al.*[5] is missing in the spectrum in the liquid state at −70 °C. By comparison of the relative intensities of the band and other *gauche* bands, this band is assigned to a hot band or combination band of the T form. The two bands at 842 and 833 cm^{-1} observed in the gaseous state[5] are also resolved at 837 and 829 cm^{-1} in the liquid state at −70 °C. The bands at 1475 and 1464 cm^{-1} observed in the solid state may be due to the Fermi resonance between the CH_3 ip-d-deformation vibration (a_g) and the overtone of the CH_2 rocking vibration (a_u).

Pentane and Pentane-d_{12} *(See Figs. 2, 3, 6 and 8, and Tables 2 and 3).* The possible conformations are TT, TG, GG, and GG′, of which GG′ may be the least stable because of the steric hindrance. The spectra in the solid state are consistent with the calculated frequencies for the TT form. The spectra in the liquid state are mostly explained by the coexistence of the TT and TG forms. The intensities of the bands at 659 and 592 cm^{-1} of pentane-d_{12} observed at room temperature decrease significantly on cooling compared with those of the TG

	j	k	52(18)
	m	l	661(51)

a) $\Delta H_{x-y}=H_x-H_y$. The value in parentheses is the standard deviation.

bands. These bands are explained only by the calculated frequencies of the GG form. Hence, it is certain that the GG form exists at room temperature to some extent.

Hexane and Hexane-d_{14} (See Figs. 4, 5, and 7 and Tables 4 and 5). The spectra in the solid state are explained

Table 7. Possible assignments of the bands used in the calculation of enthalpy differences

Molecule	Raman band	Frequency (cm^{-1})	Possible assignments
Pentane	a	337	TG
	b	403	TT, GG
	c	471	TG, GG
	d	841	TG, GG
	e	868	TT, TG, GG
Hexane	f	372	TTT, GTG[a]
	g	402	TTG, TGG[a]
	h	456	TTG
	i	520	TGT
	j	824	TGT, TGG
	k	870	TTG, GTG, GTG′
	l	952	GTG, GTG′
	m	975	TTG, TGG

a) The value of the enthalpy difference between the TTT and TTG forms depends on the relative amounts of the contributions from these forms to the intensities of the bands f and g (see text).

by the calculated frequencies for the TTT form. Among the liquid-state bands that are due to forms other than the TTT form, the bands at 456 and 520 cm^{-1} of hexane and the bands at 350 and 294 cm^{-1} of hexane-d_{14} are assigned only to the TTG and TGT forms, respectively. The temperature dependence of the intensity of the Raman band at 952 cm^{-1} of hexane is much more significant than those of the above bands. Since this frequency matches the calculated frequencies for the GTG and GTG′ forms, the existence of one or both of these forms is evident.

Enthalpy Differences (See Figs. 2 and 4 and Tables 6 and 7). *Pentane*: As the intensity of the band b in the solid state is very strong, the contribution, if any, from the vibration of the GG form to this band in the liquid state may be small. Hence, the apparent enthalpy difference obtained for the band pair of b and a, 581 cal/mol, may be a good approximate value of the enthalpy difference between the TG and TT forms.

Hexane: It is evident from the value of ΔH_{i-h} that the TGT form is as stable as the TTG form. The great difference between the values of ΔH_{g-f} and ΔH_{h-f} indicates the fair amount of the contribution from the TGG form to the band g. From these values, it is apparent that the enthalpy difference between the TTG and TTT forms lies in the range between 400 and 600 cal/mol. However, since the relative amount of the contribution from the GTG form to the band f is considered to be far less than that from the TGG form to the band g, it may be safely concluded that the enthalpy difference between the TTG and TTT forms is on the side of 400 cal/mol. Moreover, by assuming that the TGG, GTG, and GTG′ forms are approximately of the same stability, it may be concluded from the value of ΔH_{l-m} that the GTG form is less stable than the TTG form by 650 cal/mol.

In conclusion, the present study shows that the TGT form is as stable as the TTG form in the liquid state of hexane and that $\Delta H_{TTG-TTT}$ (400 cal/mol) of hexane is less than ΔH_{TG-TT} (600 cal/mol) of pentane. These results add to the data for the understanding of the stable structure and properties of longer hydrocarbon molecules. It is to be noted that these enthalpy-difference values are appreciably smaller than ΔH_{G-T} (966 cal/mol) reported for gaseous butane.[5]

Vibration Spectra and Rotational Isomerism of Chain Molecules. III.[1] Ethyl Methyl Sulfide and Deuterium Compounds

Masaaki SAKAKIBARA, Hiroatsu MATSUURA, Issei HARADA, and Takehiko SHIMANOUCHI

Department of Chemistry, Faculty of Science, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received July 26, 1976)

The Raman spectra of ethyl methyl sulfide and its three deuterated compounds $CD_3SC_2H_5$, $CH_3SCH_2CD_3$, and $CH_3SC_2D_5$ were measured for the liquid and crystalline states. The Raman spectra of the undeuterated species in the gaseous state were measured at different temperatures. The normal vibration frequencies were calculated by using a consistent set of force constants for aliphatic sulfides. The combination of the spectral observations of the deuterated compounds and the normal vibration calculations showed that only the *gauche* form exists in the crystalline state and the *trans* and *gauche* forms coexist in the liquid and gaseous states. The enthalpy difference between the *gauche* and *trans* forms in the gaseous state, ΔH_{G-T}, was obtained as -30 ± 50 cal/mol.

Ethyl methyl sulfide is the simplest sulfide with one internal rotation axis associated with the rotational isomerism. It has long been accepted that this molecule takes the *trans* form in the crystalline state and the *trans* and *gauche* forms in the liquid and gaseous states, although some ambiguities have been left out.[2]

Recently, Nogami *et al.*[3] compared the spectra of ethyl methyl sulfide with those of related molecules and reached the conclusion that the crystalline ethyl methyl sulfide takes the *gauche* form but not the *trans* form as had been thought.

In the series of studies to establish the intramolecular force field as well as to clarify the existing rotational isomers of chain molecules,[1,4-6] we have investigated the Raman spectra of ethyl methyl sulfide and its deuterium compounds of $CD_3SC_2H_5$, $CH_3SCH_2CD_3$, and $CH_3SC_2D_5$ and determined the rotational isomerism and vibrational assignments for these molecules. The temperature dependence of the Raman spectra of the undeuterated species in the gaseous state has also been examined. The results are reported in the present paper.

Experimental and Calculation

The deuterium compounds were prepared from sodium salts of appropriate thiols and deuterium compounds of methyl iodide or ethyl bromide and the undeuterated compound was purchased from Tokyo Kasei Kogyo Co., Ltd. All of the samples were purified by fractional distillations. The Raman spectra were recorded on a JEOL JRS-400D spectrometer. The Raman spectra in the gaseous state were measured at five different temperatures between 21 and 112 °C. Temperature measurements of the vapor in the laser beam were made by using nitrogen gas as a thermometer.[7]

The Raman spectra in the liquid and crystalline states in the region below 1500 cm^{-1} are shown in Figs. 1—4. The Raman spectra and the calculated frequencies in the 400—150 cm^{-1} region are compared in Fig. 5.* The gaseous-state Raman spectrum of the undeuterated species is shown in Fig. 6. The

* The relative intensities of the low-frequency bands (below 400 cm^{-1}) in the crystalline-state spectra are often found to vary depending on the condition of solidification (compare Figs. 1—4 and 5). It is certain that only one isomer exists in the crystalline state as is evident from the complete disapperance of some of the bands in the CS stretching vibration region. One possible explanation of the above observations is that the sample is composed of partially oriented crystallites and gives different intensity patterns due to the different orientation with respect to the polarization direction of the incident light.

observed frequencies and assignments on the basis of the calculated potential-energy distributions are listed in Tables 1—4.

The normal vibration frequencies were calculated by using a consistent set of force constants for aliphatic sulfides.[5] Detailed results of the calculations and the force constants are reported in a separate paper.[6]

Results and Discussion

Spectra below 400 cm^{-1} and Rotational Isomerism. In the frequency region below 400 cm^{-1}, five normal vibrations are expected for each isotopic species, two skeletal deformation (bending) and three torsional vibrations. As seen from Fig. 5, the frequencies calculated for the *trans* and *gauche* forms of $CH_3SC_2H_5$ or $CD_3SC_2H_5$ are not much different from each other. On the other hand, $CH_3SCH_2CD_3$ and $CH_3SC_2D_5$ give the frequencies which are distinctly different between the two forms.

The comparison between the observed and calculated frequencies of these isotopic species shows clearly that the crystalline-state spectra are explained only by the *gauche* form and the liquid-state spectra by the *trans* and *gauche* forms. Thus, the Raman spectra of the deuterium compounds are found to be important in studying the rotational isomerism of ethyl methyl sulfide.

As shown in Tables 1—4, the SCC deformation and CSC bending modes are highly coupled in all of the isotopic species. Such vibrational couplings are known to yield conformation-sensitive frequencies. However, the frequencies of the *trans* and *gauche* forms of $CH_3SC_2H_5$ or $CD_3SC_2H_5$ resemble each other (Fig. 5). This is explained by a further coupling of the CSC bending

mode with the CH_2-CH_3 torsional mode in the *gauche* form of these isotopic species. This coupling is removed, however, in $CH_3SCH_2CD_3$ or $CH_3SC_2D_5$ owing to the downward frequency shift of the CH_2-CD_3 or CD_2-CD_3 torsional vibration.

The calculated frequencies of the CH_3-S torsion (160—150 cm^{-1}), the CD_3-S torsion (120—110 cm^{-1}) and the S-CH_2 or S-CD_2 torsion (lower than 100 cm^{-1}) do not differ between the *trans* and *gauche* forms.

It is noted for all of the isotopic species that the Raman band at 270—250 cm^{-1} shifts appreciably to higher frequency in going from the liquid to the crystalline state. The magnitude of the shift is larger for the vibration with a larger contribution from the C-C torsional mode. This large difference between the frequencies of the two states have led previously to misinterpretation of the spectra.[2b] The shifting of this band is confirmed in the present study by observing the Raman spectra of the liquid state at several low temperatures; namely the observed frequency is higher at lower temperature and approaches the crystalline-state value. It is also noted that the *gauche* bands of $CH_3SC_2H_5$ at 232 cm^{-1} and of $CD_3SC_2H_5$ at 215 cm^{-1} are clearly resolved in the low-temperature spectra (Fig. 5).

Sectra in Higher-Frequency Regions. In the 800—600 cm^{-1} region, the bands due to the C-S stretching, CH_2 rocking and CD_3 rocking vibrations are expected. The C-S stretching vibration is known to give rise to much stronger Raman bands than the rocking vibrations.

In the crystalline state, all of the isotopic species exhibit two strong Raman bands separated by 70—100 cm^{-1} (Figs. 1—4). The results of the normal coordinate treatment indicate that the higher-frequency band is assigned to the CH_3-S (CD_3-S) stretching vibration and the lower-frequency band to the S-CH_2 (S-CD_2) stretching vibration, respectively, of the *gauche* isomer.

The 678 cm^{-1} Raman band of liquid $CH_3SC_2H_5$ which disappears on crystallization is assigned to the S-CH_2 stretching vibration of the *trans* isomer. On the other hand, the CH_3-S stretching vibration of the *trans* form has been considered to overlap with the *gauche* band at 725 cm^{-1}.[3] This assignment is confirmed by the present experimental observation that the corresponding bands for $CH_3SCH_2CD_3$ and $CH_3SC_2D_5$ are split into two components in the liquid state. It is seen from the observed spectra of the various isotopic species that the C-S stretching frequencies of the *trans* form are slightly higher than those of the *gauche* form.

The vibrational assignments in other frequency regions have also been established in this study on the basis of the systematic treatment of normal coordinates (see Tables 1—4). The observed Raman frequencies of the deuterated species were found to be important in determining the force field of aliphatic sulfides.[5]

Enthalpy Difference in the Gaseous State. The enthalpy difference between the *gauche* and *trans* forms in the gaseous state, ΔH_{G-T}, has been determined to be -30 ± 50 cal/mol through the analysis of the temperature dependence of the intensities of the band pairs at 682 (*trans*) and 657 cm^{-1} (*gauche*) of the undeuterated species. It is of interest to compare the ΔH_{G-T} values of butane, ethyl methyl ether, and ethyl methyl sulfide. They are 966 ± 54,[7] 1500 ± 200,[9] and -30 ± 50 cal/mol, respectively. The differences in the bond nature of CC-XC (X=C, O, S) groups, as is evident from the above values of enthalpy difference together with those of XC-CY (Y=C, O, S) groups, yield a variety of the structures and properties of longer chain molecules.

The Effect of Axial Ligands on the Reductions of Co(III) Complexes with a Macrocyclic Schiff-base Ligand by $Fe(edta)^{2-}$

Yoshimi KURIMURA, Hiroshi SAITO, Ikuko NAKAJIMA, and Yuki FUJII

Department of Chemistry, Ibaraki University, Bunkyo, Mito, Ibaraki 310

(Received March 11, 1976)

The second-order rate constants for the reduction of cobalt(III) complexes with a macrocylic Schiff-base ligand, $Co(dop)L_2^{2+}$ (dop=*N,N'*-bis(2-hydroxyimino-1-methylpropylidene)-1,3-propanediamine and L=primary amine), by Fe (edta)$^{2-}$ are very sensitive to the nature of the axial ligands. The rate increases with a decreases in the basicity of the axial ligands: the order is methylamine, ethylamine, 2-aminoethanol, toluidine, aniline, and bromoaniline derivatives. It is shown that there is a linear relationship between the logarithmic second-order rate constant and the pK_a of the axial primary amine ligand. Among the series of primary amine derivatives, the differences in the free energy of the activation for the reduction can be considered to be mainly dependent upon those in the enthalpy of the activation for the bond stretching of the Co–N (axial ligand) prior to the electron-transfer.

Various kinetic and thermodynamic properties of cobalt(III) complexes with macrocyclic Schiff-base ligands have been well studied in view of the similarities of numerous chemical properties of these with those of the derivatives of coenzyme B_{12}.[1–16] In the ligand-substitution process of such complexes it is demonstrated that the reactive sites are essentially those in the axial ligand resulting from a very high stability of the coordination bonds between the cobalt(III) ion and the equatorial ligands.[15]

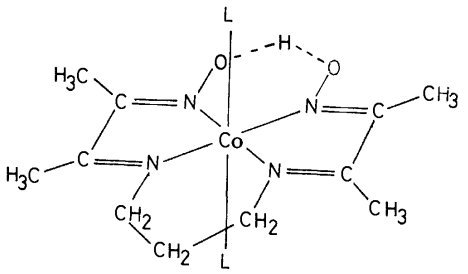

Fig. 1. $Co(dop)L_2^{2+}$.

In the redox process of the cobalt(III)–macrocyclic-ligand complexes, a linear relationship has been found between the polarographic halfwave potential of the first reduction wave and the pK value of the axial Lewis base ligands of the $Co(salen)L_2^+$(salen=*N,N'*-disalicylidene-ethylenediamine) and $Co(dop)L_2^{2+}$ (dop =*N,N'*-bis(2-hydroxyimino-1-methylpropylidene)-1,3-propanediamine).[14] The rate constants for the outer-sphere oxidation of $Co^{II}(N_4)X_2$(N_4=a tetradentate macrocyclic ligand) have been shown to be experimentally correlated to the standard free energy of the reactions.[17] There have been few investigations concerning the effect of the nature of the axial and equatorial ligands on the rate of the reductions of the cobalt(III) complexes with a macrocyclic Schiff-base ligand.

We wish now to report and discuss the influence of axial ligands on the reduction rate of the cobalt(III) complex ions of the $Co(dop)L_2^{2+}$ type by Fe(edta)$^{2-}$. The Fe(edta)$^{2-}$ has been shown to be a good reducing agent for several cobalt(III) complexes in the neutral pH region, and the mechanisms of these reductions have been investigated.[18]

Experimental

Materials. $[Co(dop)Cl_2]$ was prepared after the literature procedure.[19] Complexes of the $[Co(dop)L_2](ClO_4)_2$ type were synthesized by a manner similar to that used in the preparation of $[Co(dop)(NH_3)_2](ClO_4)_2$ described elesewhere.[19] The analytical data of the cobalt(III) chelates prepared are presented in Table 1. The NMR spectra were recorded in DMSO-d_6, with tetramethylsilane as the internal standard. The *trans*-structure of all the chelates were confirmed by their NMR spectra (Table 2). The buffer components, inorganic salts, and disodium salt of ethylenediamine-*N,N,N',N'*-tetraacetic acid were of a guaranteed grade and were used without further purification. The iron(II) chelate solution was prepared by a manner similar to that described previously.[18] The solutions of the iron(II) chelate and the cobalt(III) complexes were adjusted to the described pH and ionic strength by the use of acetate-buffer and potassium-chloride solutions respectively.

Kinetic Measurements. The reduction of the cobalt(III)

a) Broad signal.

complexes by the iron(II) chelate were carried out under an atmosphere of nitrogen which had been purified by passing it through acidic chromium(II) ion solutions. Kinetic runs were made under pseudo-first-order conditions in which the concentration of the iron(II) calculate was at least twenty times that of cobalt(III). For relatively slow reactions, the rate was monitored by the measurement of the absorption change (≈500 nm) of the reaction mixture in a thermostated cell compartment of a Union Giken SM-101 spectrophotometer. The cobalt(III) and the iron(II) chelate solutions were mixed by means of a Union Giken MX-7 mixing apparatus. Reaction which were too rapid to be followed by the conventional technique were studied with a Yanagimoto SPS-1 stopped-flow spectrophotometer. The spectral change of the reaction mixture, shown in Fig. 2, was observed by means of a Union Giken RA-1300 rapid-scan spectrophotometer.

Results and Discussion

It was estimated from the known values of the formation constants of the iron(II) chelate species[20] that the predominant species of the iron(II) chelate in the reaction mixture was the normal form of Fe(edta)$^{2-}$ under the conditions employed. The iron(III) chelate species produced in the reaction mixture by the oxidation of Fe(edta)$^{2-}$ could also be estimated to be the normal form of Fe(edta)$^{-}$.[20] A gradual increase in the absorbance at about 510 nm due to the cobalt(II) chelate was observed upon the addition of a solution of the iron(II) chelate to that of the cobalt(III) chelate under a nitrogen atmosphere. In the wave-length region between 500 and 600 nm, the molar extinction coefficients of the cobalt(III), iron(II), and iron(III) in the reaction mixture were very small compared with that of the cobalt(II) chelate under the present conditions. An example of the spectral change for Co(dop)$(HOC_2H_4NH_2)_2^{2+}$ is presented in Fig. 2. It is considered that the reductions of cobalt(III) chelates by Fe(edta)$^{2-}$ all give a product of the cobalt(II) which has a square planar configuration. It has been reported that the cobalt(II)-macrocyclic Schiff-base complexes with a square planar configuration have one or two absorption peaks (log ε= 10^3-10^4) in the visible region.[22,23]

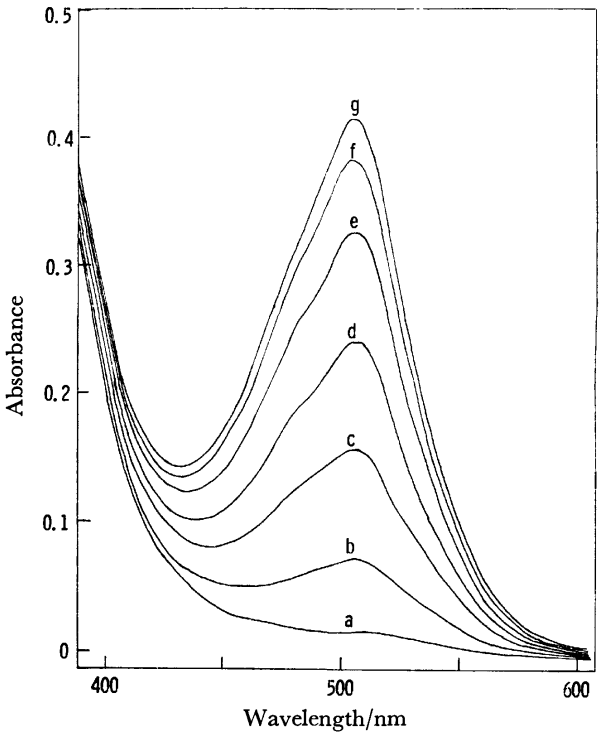

Fig. 2. Spectral change of the reaction mixture.
Initial concentrations: $[Co(dop)L_2^{2+}]_0=1.0\times10^{-4}$ M, L=2-aminoethanol, $[Fe(edta)^{2-}]_0=1.0\times10^{-3}$ M, pH=5.0, μ=0.2, room temp, Scan time: 20 nm/s, a: initial stage, b: 110 s, c: 240 s, d: 420 s, e: 720 s, f: 1200 s, g: final stage.

Table 3. Rate constants for the Fe(edta)$^{2-}$ reductions of $Co(dop)L_2^{2+}$ at μ=0.2 and 25°C[a]

L	k/M^{-1} s^{-1}
CH_3NH_2	$(6.8\pm0.5)\times10^{-2}$
	7.1×10^{-2} [b]
$C_2H_5NH_2$	$(1.4\pm0.06)\times10^{-1}$
$HOC_2H_4NH_2$	1.9 ± 0.04
	1.9[c]
	2.0[d]
$C_6H_5NH_2$	$(3.4\pm0.05)\times10^3$
	3.1×10^3 [e]
	3.2×10^3 [f]
$CH_3C_6H_4NH_2$	$(1.3\pm0.04)\times10^3$
$BrC_6H_4NH_2$	$(5.3\pm0.5)\times10^3$

a) Unless otherwise stated, the experimental conditions were $[Co(dop)L_2^{2+}]_0=1.0\times10^{-4}$M, $[Fe(II)]_0=2.0\times10^{-3}$M, $[X]_f$=0M ($[X]_f$ is the concentration of free amine), and pH=5.0. b) $[X]_f/[Co(III)]_0$= 100. c) pH=4.5. d) pH=5.4. e) $[Fe(II)]_0/[Co(III)]_0$=48. f) $[Fe(II)]_0/[Co(III)]_0$=98.

Plots of $\log(A_\infty-A_t)$ *vs.* time were linear for at least three half-lives for the saturated amine derivatives and two half-lives for the aromatic amine derivatives, where A_∞ is the absorbance when the reaction is completed and A_t, that at time t. The second-order rate constants can be calculated by means of this equation: $k=2.303\times m/[Fe(II)]$, where m is the value of the slope of the straight line. The second-order rate constants for the primary amine derivatives are summarized in Table 3. The second-order rate constants were kept essentially constant by varying the initial concentration of the iron(II) chelate from 2.0×10^{-3} to 1.0×10^{-2} M; they were independent of the hydrogen-ion concentration in the pH region between 4.5 and 5.4. A rate law consistent with the experimental results is given by:

$$d[Co(II)]/dt = k[Co(III)][Fe(edta)^{2-}] \quad (1)$$

where k is the second-order rate constant.

It may safely be assumed that the rate constants obtained correspond to those of Reaction 2, because the reaction is first-order with respect to the concentration of the iron(II) chelate and the rate is not affected by the initial addition of the corresponding free amine to the reaction mixture:

$$Co(dop)L_2^{2+} + Fe(edta)^{2-} \rightleftharpoons Co(dop)L_2^{+} + Fe(edta)^{-} \quad (2)$$

$$Co(dop)L_2^{+} \rightleftharpoons Co(dop)^{+} + 2L \quad (3)$$

That is, the rate-determining step of the reaction is Reaction 2, not the ligand-substitution process represented by 3.

The rate data summarized in Table 3 show that the rate is very sensitive to the nature of the axial ligands: the value of the rate constants vary from 6.8×10^{-2} M^{-1} s^{-1} for methylamine to 5.3×10^{3} M^{-1} s^{-1} for bromoaniline. The reduction rate is enhanced by a decrease in the donor ability of the axial Lewis-base ligand. For a series of runs while varying the axial ligands, a linear relationship between the logarithmic rate constant and the pK_a of the amines was found to hold for the reactions investigated (Fig. 3).

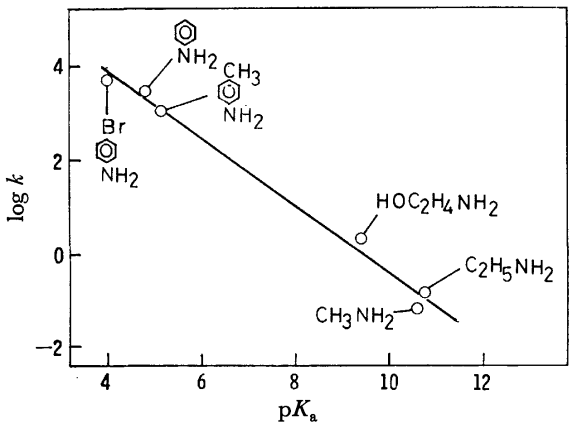

Fig. 3. Relationship between pK_a of axial amine ligand and logarithmic rate constant of the reduction of Co(dop)L_2^{2+} by Fe(edta)$^{2-}$.

Based on the Franck-Condon principle, for the reductions of the cobalt(III) complexes, the reorganization of the cobalt(III) complex would occur prior to the electron-transfer to lower the energy level of the acceptor orbital, which may be d_{z^2} one.[24-26] In the present case, the amounts of free energy for the reorganization may be considered to be dependent upon that for stretching the axial ligands, since the free energy for the reorganization of these ligands would be small as compared with that of the equatorial tetradentate ligand, which is tightly coordinated to the cobalt(III) ion. Such bond stretching energy may increase with an increase in the bond strength between the cobalt(III) ion and the donor atom of the primary amine. It is considered that the Co–N (axial ligand) bond is strengthened when the value of pK_a of the amine increases, since it has substantially the σ bonding nature. It might be concluded that the linear relationship shown in Fig. 3 holds in the electron-transfer reactions, since the predominant factor controlling the activation free energy is the free energy for the reorganization of the axial ligands.

Table 4. Activation parameters for the reduction of Co(dop)L_2^{2+}

L	$\Delta H^{\ddagger}$/kcal mol^{-1}	$\Delta S^{\ddagger}$/e.u.
CH_3NH_2	22.9	8.6
$C_2H_5NH_2$	23.9	18.0
$HOC_2H_4NH_2$	18.4	13.2
$C_6H_5NH_2$	16.2	12.0
$CH_3C_6H_4NH_2$	17.5	13.7
$BrC_6H_4NH_2$	15.0	10.0

The activation parameters for the reactions obtained from the temperature dependence of the rate constant are presented in Table 4. The relatively small variation in the activation entropy as compared with that in the activation enthalpy seems to indicate that the large change in the rate constant upon the variation in the axial ligands is mostly attributable to the relatively large variation in the activation enthalpy.

Synthesis and Magnetic Properties of Iron(III) Complexes with Several Quadridentate Schiff Bases[1)]

Yuzo NISHIDA, Shuhei OSHIO, and Sigeo KIDA

Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka 812

(Received May 29, 1976)

New iron(III) complexes containing quadridentate Schiff bases, $[Fe(L)AB]^{n+}$, were prepared, where H_2L represents a quadridentate Schiff base, and A and B, unidentate ligands, such as imidazole, pyridine derivatives, and cyanide ions. The magnetic moments of the complexes are in the range of 1.9—6.0 B.M. at room temperature. Based on the magnetic susceptibilities at various temperatures (90—295 K), these compleses were classified into four types: (1) high-spin ($S=5/2$), (2) low-spin ($S=1/2$), (3) intermediate spin ($S=3/2$), and (4) cross-over complexes, the last of which have a ligand-field strength near the cross-over point of high-spin and low-spin types. From the ESR spectra obtained, the existence of a spin-equilibrium was established for the cross-over complexes.

Iron(III) complexes have a $(3d)^5$ electronic configuration and the energy levels in the octahedral ligand field have been calculated by Tanabe and Sugano.[2)] According to their diagram, three types of iron(III) complexes can be expected in the octahedral field, depending upon the strength of the ligand field, that is, high-spin ($S=5/2$), low-spin ($S=1/2$), and cross-over complexes, the last of which have a ligand-field strength near the cross-over point of high-spin and low-spin types. In fact, complexes of these types are known for six-coordinated iron(III) complexes.[3)]

For the iron(III) complexes of porphyrin derivatives (abbreviated as H_2por), $[Fe(por)AB]^{n+}$, the magnetic moments depend greatly upon the axial ligands, A and B, and fall in the range of 2.2—5.9 B.M. at room temperature. In seeking to explain the variation in magnetic moments, some authors have claimed the existence of a spin-equilibrium of two spin states in these porphyrin derivatives.[4)] However, Harris has carried out numerous calculations on the magnetic properties of iron(III) complexes with tetragonal symmetry and concluded that the anomalous magnetic behavior of heme derivatives should be elucidated in terms of "spin-mixed states."[5,6)] For the interpretation of the magnetic properties of the cross-over complexes in more detail, systematic data on many other complexes are necessary. Accordingly, we have attempted to prepare iron(III) complexes with a tetragonal symmetry, by the use of quadridentate Schiff bases (abbreviated as H_2L) as the planar ligands. The prepared complexes have the general formula of $[Fe(L)AB]^{n+}$, where A and B are unidentate ligands, such as imidazole, pyridine derivatives, and cyanide ions.

The Schiff bases and other ligands used in this study are listed in Tables 1 and 2 with their abbreviations, while the structural formulas of their representative Schiff bases are shown in Fig. 1.

Table 1. Abbreviations of the Schiff bases
(Skeletal structures are depicted in Fig. 1.)

Type	X	R	Y	Abbreviation (L)
(a)	H	$-CH_2CH_2-$		salen
	H	$1,2-C_6H_4$		salphen
	$3-CH_3O$	$-CH_2CH_2-$		vanen
(b)		$-CH_2CH_2-$	CH_3	acen
		$-CH_2CH_2-$	C_6H_5	bzacen

Table 2. Abbreviations of the unidentate ligands

Ligands	Abbreviation
Imidazole	im
Pyridine	py
4-Aminopyridine	apy
β-Picoline	β-pic
γ-Picoline	γ-pic

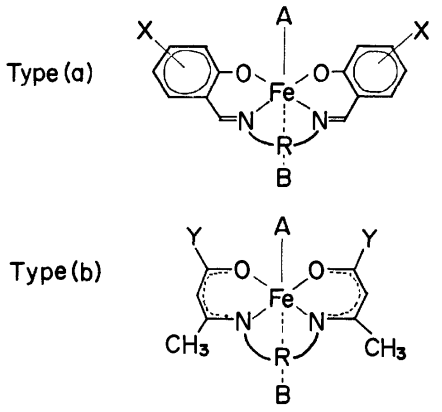

Fig. 1. Iron(III) Schiff base complexes (*cf.* Table 1).

Experimental

Preparations. The quadridentate Schiff bases used in this study were prepared according to the methods described in the literatures.[7)]

[Fe(salen)Cl]: This complex was prepared according to the method of Pfeiffer *et al.*[8)]

[Fe(acen)Cl]: The H_2acen ligand (1.1 g) dissolved in absolute methanol (20 ml), was added to anhydrous iron(III) chloride (0.8 g) dissolved in absolute methanol (20 ml). To this mixture, triethylamine (1.0 g) was then added. The resulting solution was warmed at 60 °C for ten minutes and subsequently allowed to stand for five hours at room temperature. The purple crystals yielded were filtered and washed with cold absolute methanol.

$[Fe(salen)(im)_2]B(ph)_4$: The [Fe(salen)Cl] complex was suspended in absolute methanol (40 ml), and then imidazole (0.6 g) was added to this solution. The solution was warmed at 60 °C for ten minutes and then filtered. Sodium tetraphenylborate (0.7 g) dissolved in absolute methanol (10 ml) was added to the filtrate, and the solution was allowed to

stand overnight at room temperature. The reddish-brown crystals separated were filtered and washed with cold ethanol.

[Fe(vanen)(im)$_2$]B(ph)$_4$ and [Fe(salphen)(im)$_2$]B(ph)$_4$: These complexes were prepared according to a procedure similar to that described for [Fe(salen)(im)$_2$]B(ph)$_4$.

[Fe(acen)(im)$_2$]B(ph)$_4$, [Fe(acen)(py)$_2$]B(ph)$_4$, [Fe(acen)(β-pic)$_2$]B(ph)$_4$, [Fe(acen)(apy)$_2$]ClO$_4$, and [Fe(acen)(γ-ipic)$_2$]ClO$_4$: These complexes were prepared according to a method similar to that described above, except that [Fe(acen)Cl] was used, instead of [Fe(salen)Cl], and $NaClO_4$ instead of NaB(ph)$_4$.

[Fe(salen)CN]·CH$_3$OH: Sodium cyanide (0.05 g) dissolved in absolute methanol (15 ml) was added to an absolute methanol solution (15 ml) of [Fe(salen)(im)$_2$]B(ph)$_4$(0.8 g). This solution was allowed to stand five hours at room temperature. The black precipitate thus yielded was filtered and washed with absolute methanol.

Na[Fe(salen)(CN)$_2$]·CH$_3$OH: Sodium cyanide (0.1 g) dissolved in absolute methanol (15 ml) was added to an absolute methanol solution containing 0.55 gram of [Fe(salen)Cl], and then the solution was warmed at 60 °C for ten minutes. The solution was evaporated under reduced pressure, and the dicyano complex thus separated was recrystallized from hot absolute methanol. The green crystals thus obtained were filtered and washed with absolute ethanol.

Na[Fe(acen)(CN)$_2$] and [Fe(bzacen)(im)CN]: These complexes were prepared by methods similar to those described for Na[Fe(salen)(CN)$_2$] and [Fe(salen)CN]·CH$_3$OH respectively.

[Fe(bzacen)(im)$_2$]B(ph)$_4$: To a hot absolute methanol solution (40 ml) of anhydrous ferric chloride (0.85 g), H_2bzacen (1.73 g) and imidazole (2.00 g) were added, the solution was then warmed at 60 °C for ten minutes and filtered. To this filtrate, NaB(ph)$_4$ (1.0 g) was added, and the solution was allowed to stand for five hours. The dark green crystals thus precipitated were filtered and washed with cold absolute methanol.

Measurements. Magnetic susceptibilities were measured over the range from the temperature of liquid nitrogen to room temperature by the Faraday method, Pascal's constants being used for diamagnetic correction. Mercury(II) tetrathiocyanatocobaltate(II), $HgCo(NCS)_4$ was employed as the standard for magnetic susceptibility. The effective magnetic moments at room temperature were calculated from the expression:

$$\mu_{eff} = 2.828\sqrt{T \cdot \chi_A}$$

where χ_A is the susceptibility per gram atom of iron.

The ESR spectra of polycrystalline samples and DMSO-frozen solutions were measured with a JEOL ESR spectrometer model, JES-ME-3X using an X-band. DPPH was used as the standard marker.

The absorption spectra were measured with a recording spectrophotometer model, Hitachi EPS-2, at room temperature.

Results and Discussion

Characterization of New Complexes. Table 3 gives the analytical data, color, and magnetic moments of the complexes. The structures of the new complexes are assumed to be *trans* (A, B)-[Fe(L)AB]$^{n+}$, because the quadridentate Schiff bases used in this study prefer the planar coordination, furthermore, Na[Fe(salen)(CN)$_2$] shows only one sharp band, at 2105 cm^{-1}, in the infrared spectrum.

The magnetic moments of the complexes depend greatly on the Schiff bases and axial ligands; they fall in the range of 1.9—6.0 B.M. at room temperature. On the basis of magnetic susceptibilities at various temperatures (90—295 K), the **1**—**3** and **4**—**8** complexes are high-spin and low-spin types, respectively. The **9**—**13** complexes show intermediate magnetic moments (2.5—5.0 B.M.) between high-spin and low-spin values; accordingly, they may be assumed to be cross-over complexes. The interpretation of the magnetic data on the assumption of a dimeric structure such as [Fe(salen)Cl]$_2$[9] is impossible, because all the complexes can assume six-coordination without any bridged structure.

Judging from the magnetic data of the series [Fe(L)(im)$_2$]$^{n+}$ complexes shown in Table 3, the spin-pairing abilities of planar Schiff bases appear to be of the following order: H_2acen>H_2bzacen>H_2salen≈H_2salphen. Thus, it was revealed that a small change in the planar

Table 3. Analytical data and magnetic moments

1: 244 K, 2: 184 K, 3: 77 K.

ligands exerts a large effect on the electronic configuration of the ground state of the iron(III) ion. From the magnetic data of the series of acen complexes shown in Table 3, the order of spin-pairing ability is: CN> imidazole>apy>β-pic>py>γ-pic. The order of the pyridine derivatives agrees with neither the order of basicity of pyridine nitrogen nor the spectrochemical series. These facts suggest that the choice of the spin state of [Fe(L)AB]$^{n+}$ depends not only on the ligand field strength, but also on the crystal lattice energy and the steric effect of the ligands.

Cross-over Complexes. In Fig. 2, the ESR spectra of [Fe(vanen)(im)$_2$]B(ph)$_4$ at various temperatures are shown. In Fig. 3, the ESR spectra of [Fe(salen)(im)$_2$]-B(ph)$_4$(high-spin type) and Na[Fe(salen)(CN)$_2$](low-spin type) are shown. In the ESR spectrum of [Fe-(salen)(im)$_2$]B(ph)$_4$, some absorptions are observed over the wide range of 1000—3000 G. This is characteristic of high-spin complexes.[10,11] On the other hand, in the case of Na[Fe(salen)(CN)$_2$], some peaks are observed at about 3000 gauss. The small anisotropy of g-values suggests that the electronic configuration of the ground state is $(d_{xz})^2(d_{yz})^2(d_{xy})^1$.[12]

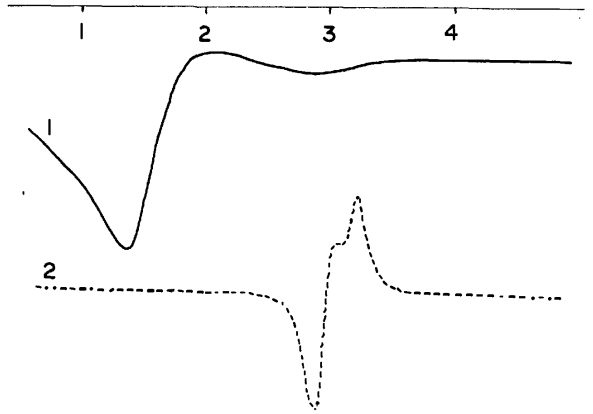

Fig. 3. Powder ESR spectra (X-band, at 244 K).
1: [Fe(salen)(im)$_2$]B(ph)$_4$ (high-spin complex),
2: Na[Fe(salen)(CN)$_2$] (low-spin complex).

In the ESR spectra of [Fe(vanen)(im)$_2$]B(ph)$_4$ and [Fe(bzacen)(im)$_2$]B(ph)$_4$,[1] some peaks are observed at about 3000 gauss and in the range of 1000—2700 G. As the temperature is lowered, the relative intensities of the absorptions change dramatically, as may be seen in Fig. 2, although the positions of the absorptions do not change. This fact indicates two or more spin states exists in these complexes in the temperature range investigated; undoubtedly one of them is $S=1/2$.

Harris[5,6] investigated the magnetic properties of heme derivatives and concluded that the magnetic behavior of complexes with intermediate magnetic moments at room temperature should be explained in terms of "spin-mixed states." However, the presently obtained ESR spectra are not compatible with his prediction. Rather, the magnetic behavior of the **9—13** complexes should be interpreted in terms of a spin-equilibrium between two or more spin states. We further attempted to confirm the spin-equilibrium by the use of the Mössbauer spectra. However, clear peaks were not observed for high-spin complexes; therefore, the existence of spin-equilibrium could not be verified by the Mössbauer spectra.

Absorption Spectra. As shown in Table 3, the colors of the low-spin complexes differ from those of the high-spin complexes. In general, the Lambert-Beer law can not be applied to solutions of these complexes, probably because of the partial dissociation of axial ligands. Therefore, a small excess of axial ligands was added to the methanol solutions of the complexes. In Fig. 4, the absorption spectra of [Fe(salen)(im)$_2$]B(ph)$_4$, Na[Fe(acen)(CN)$_2$], and [Fe(bzacen)(im)$_2$]B(ph)$_4$ are shown. The low-spin Schiff base complexes are generally green or blue, perhaps because of the absorptions at

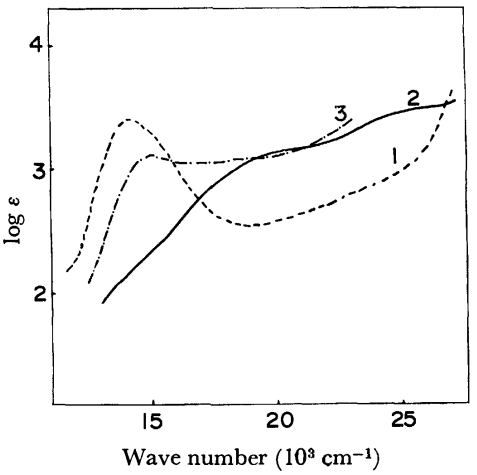

Fig. 4. Absorption spectra of iron(III) Schiff base complexes (at 295 K, in methanol solution).
1: Na[Fe(acen)(CN)$_2$] (low-spin type, 1.9×10^{-4} M),
2: [Fe(salen)(im)$_2$]B(ph)$_4$ (high-spin type, 2.7×10^{-4} M),
3: [Fe(bzacen)(im)$_2$]B(ph)$_4$ (cross-over complex, 4.4×10^{-4} M).

14—16 $\times 10^3$ cm^{-1} (log $\varepsilon \approx 3$). Such absorptions are not observed for high-spin complexes. These bands may be attributed to the charge-transfer transitions between metal and Schiff bases, because this absorption is independent of axial ligands. On the other hand, the absorption spectrum of $[Fe(bzacen)(im)_2]B(ph)_4$ seems to be a superposition of high-spin and low-spin types; this is consistent with the results of the ESR spectra.

Gas Chromatographic Studies of the Thermal Decompositions of Hexaammine-, Chloropentaammine-, and *trans*-Dichlorotetraammine-cobalt(III) Chloride in the Solid State

Sukeo ONODERA*

Department of Chemistry, Faculty of Science, Tokyo University of Science, Kagurasaka, Shinjuku-ku, Tokyo 162

(Received June 2, 1976)

This paper will describe gas chromatographic studies of the thermal decomposition of cobalt(III) ammine complexes in the solid state. The sample is pyrolyzed in a chamber in a helium atmosphere at a heating rate of 1 °C/min. The evolved products are directly led into a chromatographic separation column at periodic intervals of 10 °C. The preliminary gaseous product for these compound is ammonia. The gas evolution(GE) curves for each compound could be made as function of the temperature on the basis of the various gas chromatograms. These GE curves show two maximum peaks; the first is a sharp peak at about 250 °C, while the second is a broad peak in the 280—340 °C temperature range. The combination of these GE curves with the results of TG and DTA studies allows more complete interpretations of the thermal-decomposition reactions of the cobalt(III) ammine complexes.

Thermogravimetric analysis(TG) and differential thermal analysis (DTA) have been widely used by earlier investigators for studying the thermal-decomposition reactions of some transition metal complexes. These techniques gives information concerning the weight loss or the thermal changes in the compounds during the thermal reactions, but they do not give information on the species and the composition of the produced gases.

When the metal complexes are heated under various experimental conditions, volatile ligands or their gaseous decomposition product are usually liberated from the compounds. Thus, gas evolution analysis (GEA) is required for the above reactions in order to obtain exact information on the decomposition processes of the compounds. The combination of GEA with a TG or DTA apparatus allows more complete interpretations of their curves.

The simultaneous measurements of TG and DTA have been reported by Logers, Yamada and Zinn,[1] and, those of DTA and GEA, by Ayres and Bens,[2] Langer and Gohlke,[3] and Wendlandt *et al.*[4]

In earlier studies by Wendlandt *et al.*,[4] GEA curves were obtained by the use of a thermister thermal conductivity cell, and the composition of the pyrolyzed gases was determined by such conventional techniques as mass spectrometry, gas chromatography, and infrared absorption spectroscopy. Further works by Wendlandt *et al.*[3] have reported the method of leading the evolved product gases directly into a mass spectrometer for studying the thermal decomposition reactions of $[Cu(NH_3)_4]SO_4 \cdot H_2O$, some metal-cupferron chelates, and halogenopentaamminecobalt(III) complexes.

This paper will describe a method of leading the evolved product gases directly into a gas chromatograph, the so-called pyrolysis-gas chromatograph, for studying the thermal decomposition reactions of some chloroammine cobalt(III) complexes in the temperature range of 25—400 °C; on the basis of the GEA curves, the stoichiometries of the thermal-decomposition reactions of these compounds will be presented.

* Present adress: Faculty of Pharmaceutical Science, Tokyo University of Science, Ichigaya-funagawara, Shinjuku-ku, Tokyo 162.

Experimental

Materials. The hexaammine-,[6] chloropentaammine-,[7] and *trans*-dichlorotetraamminecobalt(III) chloride[8] were prepared according to the methods given in the literature. They were identified by the measurements of the infrared absorption spectra. Sample ranging in perticle size between 100—200 mesh were used in these studies. These chloroammine cobalt(III) chlorides were selected because they are the ammine complexes most extensively studied by earlier workers.

J: Gas chromatograph. K: Reference column. L: Separation column. M: Thermistor thermal conductivity cell. N: Gas chromatogram recorder.

GEA Apparatus. A schematic diagram of the GEA apparatus is given in Fig. 1, while the pyrolysis part of the apparatus is illustrated in Fig. 2.

The GEA apparatus consisted of a pyrolysis chamber(E), a furnace(F), a furnace temperature controller(G), a sample temperature recorder (H), and a Shimadzu model GC-2C gas chromatograph (J) with a thermal conductivity detector (M). Helium from a cylinder (A) and a pressure regulator (B) was passed through into reference column (K), into the pyrolysis chamber (E), and then into a separation column(L) packed with a 20% Silicon oil SF-96 on Fluoro Pack-80 (60—80 mesh) in a Teflon tube 5 m long by 0.3 cm in diameter.

The pyrolysis chamber consisted of a U-type Pyrex glass tube 15 cm long by 0.4 cm in diameter, which was terminated

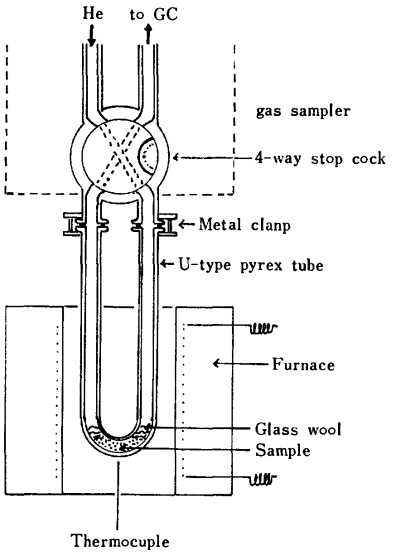

Fig. 2. Pyrolysis part of the apparatus.

on both ends by a 0.4-cm-inner-diameter "O"-ring joint (silicon gem). Two "O" -ring joints were attached to the joint of the gas sampler of the gas chromatograph by means of a metal clamp. The Pyrex tube was electrically heated by Nichrom wire enclosed in the furnace. The furnace was made by an asbestos tube, 15 cm long by 4.0 cm in diameter, which was wound by Nichrom heater wire and then insulated by additional asbestos paper so as to make a layer about 1.0 cm thick. The temperature of the wall of the Pyrex tube was measured by means of a chromel–alumel thermocouple. The pyrolysis temperature rise was controlled by means of the transformer(G).

The glass tubing from the pyrolysis chamber to the gas sampler of the gas chromatograph was maintained at about 60 °C by means of external heating jackets.

Procedure for Pyrolysis of Sample. Twenty mg of a sample was placed in the Pyrex tube and fixed with glass wool. The air in the system was swept out with a helium gas at a flow rate of 40 ml/min for about 30 min. During this time, gas-chromatographic conditions were allowed to be stabilized.

After the flow of helium had been directly passed through into the gas sampler by the changing of the stop cock, the heating of the furnace was begun. Usually, a furnace heating rate of 1 °C/min was employed, but this could be varied at will. The temperature-rising curve was recorded on the strip-chart recorder (H).

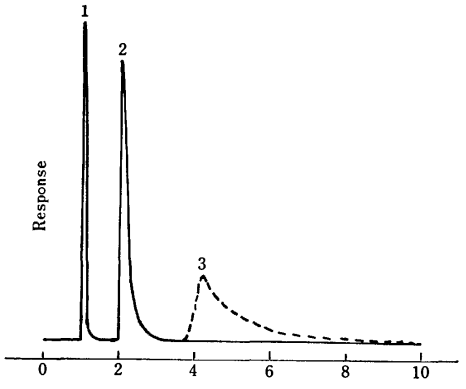

Fig. 3. Gas chromatogram of nitrogen (1), ammonia (2) and water (3) using 20% silicon SF-96 on fluoro Pack-80.

Procedure for the Analysis of the Gaseous Products. The gaseous products evolved during the above pyrolysis procedure were quickly swept into the chromatographic separation column at periodic intervals of 10 °C by changing the stop cock. Thus, the various gas-chromatographic patterns for the evolved gases could be obtained as a function of the temperature.

The peaks appearing on the gas chromatograms were identified by the use of the retention times of various pure substances which may be expected to be formed during the decomposition of the sample. From the peak areas of the various peaks, the amount of the decomposition product could be ascertained as a function of the temperature. The chromatographic patterns for various pure substances are shown in Fig. 3.

Results and Discussion

The GEA curves of the cobalt(III) ammine complexes in the temperature range of 25—400 °C in a helium atmosphere are given in Fig. 4, while the data on gaseous decomposition products are summarized in Table 1. These results were reproducible under the experimental conditions employed in the present work.

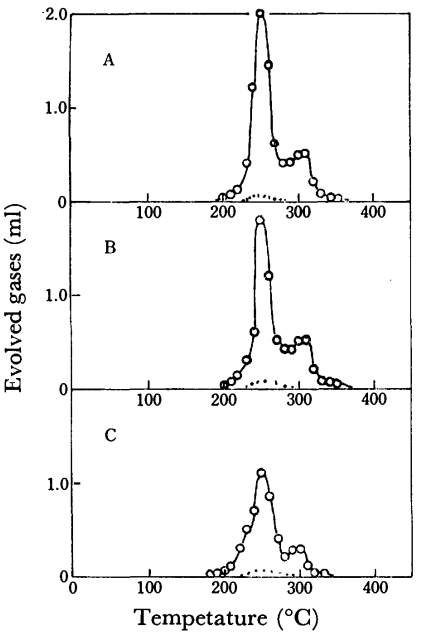

Fig. 4. Gas evolution curves for $[Co(NH_3)_6]Cl_3$ (A), $[CoCl(NH_3)_5]Cl_2$(B) and *trans*-$[CoCl_2(NH_3)_4]Cl$(C) in helium atmosphere.
N_2; ·····, NH_3; -•-•-•-.

Table 1. Data on gaseous decomposition products

Compound	Moles of NH_3/mol of compound	Moles of N_2/mol of compound
$[Co(NH_3)_6]Cl_3$	4.75	0.18
$[CoCl(NH_3)_5]Cl_2$	3.80	0.15
$[CoCl_2(NH_3)_4]Cl$	2.70	0.15

$[Co(NH_3)_6]Cl_3$. Clark, Quick, and Harkins[9] have reported that the evolution of ammonia from this compound *in vacuo* began at about 173 °C, while a sublimate of ammonium chloride was observed at 181 °C.

They also confirmed, on the basis of an analysis of a solid mixture and the gaseous products (for ammonia only), that the stoichiometry of the thermal dissociation of this compound given as;

$$6[Co(NH_3)_6]Cl_3 \longrightarrow 6CoCl_2 + 6NH_4Cl + N_2 + 28NH_3 \quad (1)$$

The TG curves of this compound in a nitrogen atmosphere reported by Watt[10] and by Tanaka and Nanjo[11] indicated that the first mass-loss (evolution of ammonia) began at about 250 °C. On the other hand, the DTA curves of this compound in a helium or nitrogen atmosphere reported by Wendlandt[12] and Watt[10] show that the endothermic peak began at about 200 °C, resulting in a peak with a ΔT_{min} of 280 °C, and that this was followed by a second broad endothermic peak in the 300—375 °C temperature range.

The GEA curve given in Fig. 4A shows that the evolution of ammonia from this compound began at about 200 °C, the maximum intensity for gas evolution being obtained at 250 °C, and that this was followed by a second broad peak in the 280—340 °C temperature range. These temperature ranges and the number of peaks observed in this curve are in agreement with those appearing on the DTA curves reported by Watt[10] and Wendlandt,[12] but the first and second peak maxima were somewhat lower than those appearing on the DTA curves.[10,12]

The stoichiometry of the thermal decomposition of this compound, based on the data given in Table 1, agrees with that previously proposed by Clark *et al.*,[9] Watt,[10] and Wendlandt,[12] as given in Eq. 1.

$[CoCl(NH_3)_5]Cl_2$. The TG curves of this compound have been reported by a number of investigators. Wendlandt[13] found that the compound began to loss mass at 180 °C. However, the TG curves reported by Kawakubo[14] and Watt[10] indicated that the mass-loss of this compound began at 200 °C.

The DTA curves for this compound have been reported by Lavanov *et al.*,[15] Kawakubo,[14] Watt[10] and Wendlandt and Smith.[16] The DTA curves in a nitrogen atmosphere reported by the above investigators contained two endothermic peaks; the first began at about 200 °C, with a ΔT_{min} value of about 280 °C, while second began with a ΔT_{min} value of about 320 °C.

Watt[10] confirmed, from his TG and DTA curves and an analysis of the gaseous decomposition products, that the over-all reaction leading to the formation of $CoCl_2$ is:

$$6[CoCl(NH_3)_5]Cl_2 \longrightarrow 6CoCl_2 + 6NH_4Cl + N_2 + 22NH_3 \quad (2)$$

The GEA curve given in Fig. 4B shows that the evolution of ammonia from this compound began at about 200 °C, the corresponding maximum intensity for gas evolution being found at about 250 °C, and that this was followed by a second broad peak in the 280—320 °C temperature range. These temperature ranges and the number of peaks observed in this curve are in agreement with those appearing on the DTA curves reported by Watt[10] and Wendlandt and Smith.[16]

The stoichiometry of the thermal decompositions of this compound, based on the data given in Table 1, agrees with that previously proposed by Watt[10] and Wendlandt and Smith[16] as given in Eq. 2.

trans-*$[CoCl_2(NH_3)_4]Cl$.* Ocone *et al.*[17] have reported the TG curves for *cis*- and *trans*-types of this compound in a nitrogen atmosphere. The curve for the *trans*-type indicated that the mass-loss began at 181 °C, corresponding to the loss of three moles of ammonia in the over all reaction. Also, the curve for the *trans*-type of this compound was essentially in agreement with that obtained by Watt.[10]

The DTA curve for the *trans*-type of this compound in nitrogen reported by Watt[10] was very similar to that for $[CoCl(NH_3)_5]Cl_2$, exhibiting well-defined endothermal minima at 283 and 347 °C. Watt[10] also confirmed, from his TG and DTA curves, and based on an analysis of the gaseous decomposition products, that the stoichiometry of the thermal dissociation reaction of this compound given as:

$$6[CoCl_2(NH_3)_4]Cl \longrightarrow 6CoCl_2 + 6NH_4Cl + N_2 + 16NH_3 \quad (3)$$

The GEA curve given in Fig. 4C shows that the thermal decomposition of this compound begins with the evolution of ammonia at about 180 °C, the maximum intensity of the gas evolution appearing at 250 °C, and that this followed by a second broad peak in the 280—340 °C temperature range. These temperature ranges and the number of the peaks observed in this curve are in agreement with those appearing on the DTA curves reported by earlier researchers.[10,11]

The stoichiometry of the thermal dissociation of this compound, based on the data given in Table 1, agrees with that previously proposed by Watt[10] given in Eq. 3.

From the GEA curves in Fig. 4 and the results obtained by earlier investigators,[10,11,18-20] it may be seen that the starting of the thermal decomposition reactions of chloroammine cobalt(III) chlorides in a helium atmosphere at a slow heating rate takes place by means of the following competition reactions:

$$[Co^{III}(NH_3)_6]Cl_3 \longrightarrow \begin{cases} [Co^{III}Cl(NH_3)_5]Cl_2 + NH_3 \\ \text{low ammine cobalt(II) complexes} \end{cases}$$

$$[Co^{III}Cl(NH_3)_5]Cl_2 \longrightarrow \begin{cases} [Co^{III}Cl_2(NH_3)_4]Cl + NH_3 \\ \text{low ammine cobalt(II) complexes} \end{cases}$$

$$[Co^{III}Cl_2(NH_3)_4]Cl \longrightarrow \begin{cases} [Co^{III}Cl_3(NH_3)_3] + NH_3 \\ \text{low ammine cobalt(II) complexes} \end{cases}$$

Although the peak maximum temperature is dependent upon the furnace heating rate, the sample size, the carrier gas flow rate, the furnace atmosphere, and so on, the use of simultaneous GEA-gas chromatographic analysis gives exact data concerning the thermal decomposition reactions of metal complexes.

The author wishes to thank Professor Masaakira Iguchi, Tokyo University of Science, for his valuable advice.

Binuclear Metal Complexes. XVI.[1] Hetero Metal Binuclear Complexes with *N,N'*-Bis(3-carboxysalicylidene)ethylenediamine[2]

Hisashi OKAWA, Yuzo NISHIDA, Mitsunori TANAKA,* and Sigeo KIDA

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812
**Faculty of Education, Kagawa University, Takamatsu, Kagawa 760*

(Received June 17, 1976)

Hetero metal binuclear complexes, MM' (fsaen)·nH_2O (M=Cu(II) and Ni(II); M'=Cu(II), Ni(II), Co(II), Fe(II), and Mn(II); n=1—3), with *N,N'*-bis(3-carboxysalicylidene)ethylenediamine (H_4fsaen) have been synthesized and characterized, where M and M' denote the metal ion coordinated by the N_2O_2-coordinating atoms and the O_4-coordinating atoms, respectively. The magnetism of CuNi(fsean)·$3H_2O$ and CuCo(fsaen)·$3H_2O$ is explained in terms of the Heisenberg model. The magnetism of NiCu(fsaen)·H_2O, NiCo(fsaen)·$2H_2O$, and NiMn(fsaen)·$2H_2O$ obeys the Curie-Weiss law, demonstrating the binuclear structure to be composed of one diamagnetic nickel(II) and one paramagnetic M'(II) ions. CuFe(fsaen)·$2H_2O$, NiFe(fsaen)·$2H_2O$, and CuMn(fsaen)·H_2O each shows unusual magnetic property.

Binuclear metal complexes containing two different metal ions are of interest in connection with spin-exchange and charge-transfer between metal ions and in the domain of metalloenzymes and homogeneous catalysis. One method for the synthesis of hetero metal binuclear and polynuclear complexes is to use the reaction of a simple metal salt with a metal chelate ligand such as a quadridentate Schiff base complex[3-5] or a sulfur-ligand complex.[6,7] Binuclear and polynuclear complexes such as V(IV)O-Cu(II)[3,4] and Cu(II)-M(II)-Cu(II)[5] have been obtained by this method. The success in synthesizing hetero metal binuclear complexes depends on the stability of the starting metal chelate and the solubility of the hetero metal complex. Thus, application of this method to other hetero metal polynuclear complexes is limited.

Another method for obtaining hetero metal binuclear complexes is to use a step-wise reaction of two different metal ions with a coordinatively selective binucleating ligand, in which two coordinating sites differ from each other in the ligand field strength or in the stereochemistry of coordination. A few such ligands have recently been reported.[1,8,9]

In previous papers of this series,[1,8] it was shown that the Schiff bases derived from 3-formylsalicylic acid and diamines are binucleating ligands with coordinative selectivity. They formed a hetero metal complex of Cu(II)-Ni(II)[8] and binuclear nickel(II) complexes with one diamagnetic and one paramagnetic nickel(II) ions.[1] This report deals with the synthesis and characterization of hetero metal binuclear complexes with *N,N'*-bis(3-carboxysalicylidene)ethylenediamine (abbreviated to H_4 fsaen). The complexes are represented by MM'(fsaen)·nH_2O (M(II)=Cu(II) and Ni(II); M'=Cu(II), Ni(II), Co(II), Fe(II), and Mn(II); n=1—3),

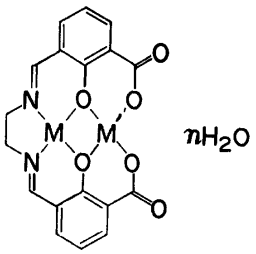

Fig. 1.

where M is an "inside" metal ion coordinated by the N_2O_2-coordinating atoms and M' is an "outside" metal ion coordinated by the O_4-coordinating atoms (Fig. 1). A part of this work has been reported,[8] which is the first report on hetero metal binuclear complexes with H_4 fsaen. Recently some hetero metal binuclear complexes such as Cu(II)-U(VI)O_2 and Ni(II)-Th(IV) were obtained using H_4 fsaen.[10] However, no hetero metal binuclear complexes with first transition metal ions have been obtained.

Experimental

Syntheses. The syntheses of mononuclear complexes, Cu(H_2fsaen)·$0.5H_2O$ and Ni(H_2fsaen)·$0.5H_2O$, have been described in the previous paper.[1]

CuNi(fsaen)·$3H_2O$. Cu(H_2fsaen)·$0.5H_2O$ (107 mg) was dissolved in an aqueous solution (50 ml) of lithium hydroxide monohydrate (21 mg) by warming. A small amount of insoluble particles was separated by filtration. To this solution was added an aqueous solution (10 ml) of nickel(II) chloride hexahydrate (60 mg) and the resulting red-purple solution was left to stand overnight at room temperature to give reddish purple prisms, which were collected, washed with water, and dried over P_2O_5 in a vacuum desiccator.

Found: C, 40.65; H, 3.45; N, 5.27; Cu, 12.27; Ni, 10.74%. Calcd for $C_{18}H_{12}N_2O_6CuNi·3H_2O$: C, 40.90; H, 3.43; N, 5.30; Cu, 12.02; Ni, 11.10%.

CuCo(fsaen)·$3H_2O$. To an aqueous solution prepared from Cu(H_2fsaen)·$0.5H_2O$ (107 mg) and lithium hydroxide monohydrate (21 mg), was added an aqueous solution (10 ml) of cobalt(II) chloride hexahydrate (80 mg) to give a red-purple solution. After the reaction mixture was left to stand overnight at room temperature, purple prisms separated were collected, washed with water, and dried over P_2O_5 *in vacuo*.

Found: C, 40.94; H, 3.58; N, 5.32; Co, 11.41; Cu, 12.28%. Calcd for $C_{18}H_{12}N_2O_6CoCu·3H_2O$: C, 40.88; H, 3.43; N, 5.30; Co., 11.14; Cu, 12.02%.

CuFe(fsaen)·$2H_2O$. This complex was obtained as yellowish brown prisms by reacting Cu(H_2fsaen)·$0.5H_2O$ (107 mg) with iron(II) sulfate heptahydrate (70 mg) in the presence of lithium hydroxide monohydrate (21 mg).

Found: C, 42.25; H, 3.18; N, 5.50; Cu, 12.60; Fe, 10.65%. Calcd for $C_{18}H_{12}N_2O_6CuFe·2H_2O$: C, 42.58; H, 3.18; N, 5.52; Cu, 12.52; Fe, 11.00%.

CuMn(fsaen)·H_2O. This complex was obtained as pink-purple prisms by reacting Cu(H_2fsaen)·$0.5H_2O$ (107 mg)

with manganese(II) sulfate hexahydrate (65 mg) in the presence of lithium hydroxide monohydrate (21 mg).

Found: C, 44.06; H, 2.63; N, 5.72; Cu, 12.52; Mn, 11.51%. Calcd for $C_{18}H_{12}N_2O_6CuMn \cdot H_2O$: C, 44.23; H, 2.89; N, 5.73; Cu, 13.00; Mn, 11.24%.

NiCu(fsaen)·H_2O. $Ni(H_2fsaen) \cdot 0.5H_2O$ (106 mg) was dissolved in an aqueous solution (60 ml) of lithium hydroxide monohydrate (21 mg) by warming. To the resulting red solution was added an aqueous solution (10 ml) of copper(II) chloride dihydrate (34 mg). Immediately pinkish orange prisms separated. After the reaction mixture had been warmed at 50 °C for 10 min, the product was isolated, washed with water, and dried over P_2O_5 *in vacuo*.

Found: C, 43.53; H, 2.52; N, 5.62; Cu, 12.72; Ni, 12.30%. Calcd for $C_{18}H_{12}N_2O_6CuNi \cdot H_2O$: C, 43.89; H, 2.86; N, 5.69; Cu, 12.90; Ni, 11.92%.

NiCo(fsaen)·$2H_2O$. This complex was obtained as yellowish brown micro-crystals from $Ni(H_2fsaen) \cdot 0.5H_2O$ (106 mg), cobalt(II) chloride hexahydrate (65 mg) and lithium hydroxide monohydrate (21 mg).

Found: C, 43.13; H, 2.92; N, 5.67; Co, 11.98; Ni, 12.16%. Calcd for $C_{18}H_{12}N_2O_6CoNi \cdot 2H_2O$: C, 42.73; H, 3.19; N, 5.54; Co, 11.65; Ni, 11.60%.

NiFe(fsaen)·$2H_2O$. This complex was obtained as reddish orange micro-crystals from $Ni(H_2fsaen) \cdot 0.5H_2O$ (106 mg) and iron(II) sulfate heptahydrate (70 mg) in the presence of lithium hydroxide monohydrate (21 mg).

Found: C, 43.24; H, 2.75; N, 5.49; Fe, 11.46; Ni, 12.02%. Calcd for $C_{18}H_{12}N_2O_6FeNi \cdot 2H_2O$: C, 42.99; H, 3.21; N, 5.57; Fe, 11.11; Ni, 11.67%.

NiMn(fsaen)·$2H_2O$. This complex was obtained as yellow needles from $Ni(H_2fsaen) \cdot 0.5H_2O$ (106 mg), manganese(II) sulfate hexahydrate (65 mg) and lithium hydroxide monohydrate (21 mg).

Found: C, 42.74; H, 2.82; N, 5.45; Mn, 10.91; Ni, 11.31%. Calcd for $C_{18}H_{12}N_2O_6MnNi \cdot 2H_2O$: C, 43.07; H, 3.22; N, 5.58; Mn, 10.95; Ni, 11.70%.

Measurements. C, H, and N elemental analyses were carried out at the Service Center of Elemental Analysis, Kyushu University. Metal analyses were carried out with a Shimadzu Atomic Absorption-Flame Spectrophotometer Model AA-610S. The aqueous solution for the measurement was prepared by thermally decomposing a complex in the presence of sulfuric acid and dissolving the resulting metal sulfate in dilute hydrochloric acid or sulfuric acid. Infrared spectra were measured with a Hitachi Infrared Spectrophotometer Model 215 on a KBr disk. Electronic spectra were measured with a Shimadzu Multipurpose Spectrophotometer Model MSP-5000 by the reflection on a powder sample. Magnetic susceptivility was measured by the Faraday method, where diamagnetic correction was carried out by means of Pascal's constants.

Results and Discussion

Infrared spectra of the complexes resemble each other and are similar to those of $Cu_2(fsaen) \cdot 3H_2O$ and $Ni_2(fsaen) \cdot 3H_2O$, whose binuclear structures have been characterized.[1] No band was found in the region 1750—1650 cm^{-1}. Instead a broad and strong band was found around 1550 cm^{-1}, which is attributable to the coordinated carboxylate group.

Because of the low solubility of the complexes in most solvents, the electronic spectra were measured by reflection on a solid sample. The electronic spectra are given in Figs. 2 and 3. The room temperature magnetic moments of the complexes are given in Table 1.

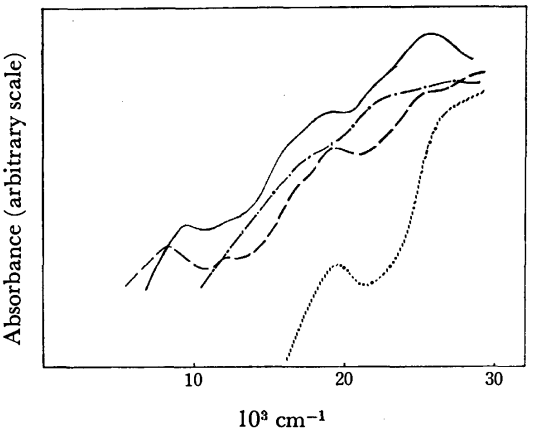

Fig. 2. Electronic spectra of (——)CuNi(fsaen)·$3H_2O$, (— —)CuCo(fsaen)·$3H_2O$, (—·—)CuFe(fsaen)·$2H_2O$, and (·····)CuMn(fsaen)·H_2O.

Table 1. Magnetic moments of complexes at room temperature

	μ_{eff} (T(K)) (Bohr magneton)	
CuNi(fsaen)·$3H_2O$	3.05[a] (292.6)	$N\alpha = 200 \times 10^{-6}$ e.m.u.
CuCo(fsaen)·$3H_2O$	4.76[a] (295.4)	$N\alpha = 450 \times 10^{-6}$ e.m.u.
CuFe(fsaen)·$2H_2O$	2.76[b] (297.8)	
CuMn(fsaen)·H_2O	5.17[b] (293.2)	
NiCu(fsaen)·H_2O	1.87[a] (294.7)	$N\alpha = 60 \times 10^{-6}$ e.m.u.
NiCo(fsaen)·$2H_2O$	5.15[a] (293.1)	$N\alpha = 400 \times 10^{-6}$ e.m.u.
NiFe(fsaen)·$2H_2O$	2.29[b] (297.8)	
NiMn(fsaen)·$2H_2O$	5.71[b] (293.0)	

a) Magnetic moment was calculated by the equation $\mu_{eff} = 2.828\sqrt{(\chi_M - N\alpha)T}$ using the estimated $N\alpha$ given in the Table. b) Calculated by the equation $\mu_{eff} = 2.828\sqrt{\chi_M T}$.

The electronic spectrum of CuNi(fsaen)·$3H_2O$ possesses ligand field bands (9500, 16000, and 19000 cm^{-1}) in the visible region. The band at 19000 cm^{-1} seems substantially the same as the band found for $Cu(H_2fsaen) \cdot 0.5H_2O$ and tentatively assigned to the "inside" copper(II). The bands at 9500 and 16000 cm^{-1}, on the other hand, may be assigned to the nickel(II) in an

octahedral environment. The molar magnetic moment of this complex is subnormal (3.05 Bohr magnetons (μ_B)). It has been shown[1] that this magnetic behavior can be explained on the basis of the Heisenberg model by the equation,

$$\chi_M = \frac{Ng^2\beta^2}{4kT}\cdot\frac{10+\exp(-3J/kT)}{2+\exp(-3J/kT)} + N\alpha \qquad (1)$$

where J is the exchange integral, k the Boltzmann constant, N the Avogadro number, β the Bohr magneton and g the Lande g-factor. The magnetic parameters, J, g_{ave}, and $N\alpha$(temperature-independent paramagnetism), determined from the best fit of the experimental χ_M values to the Eq. 1 are -75 cm^{-1}, 2.19 and 200×10^{-6} e.m.u./mol, respectively.[1]

The electronic spectrum of CuCo(fsaen)·3H$_2$O shows the ligand field bands at 8300, 11000, 17000, and 19200 cm^{-1}. The band at 19200 cm^{-1} is attributed to the copper(II) in the "inside" coordination site. The remaining bands may be assigned to the cobalt(II) ion. The spectrum resembles that of hexaaquacobalt(II). Therefore, coordination of water molecule to the cobalt(II) from an apical direction is presumed. On assuming an octahedral configuration around the cobalt(II), the band at 8300, 11000, and 17000 cm^{-1} are assigned to the $^4T_{2g}\leftarrow{}^4T_{1g}$, $^2E_g\leftarrow{}^4T_{1g}$, and $^4A_{2g}\leftarrow{}^4T_{1g}$ transitions, respectively. The transition $^4T_{1g}$ (P)$\leftarrow{}^4T_{1g}$ (F) can be superposed by the band of the copper(II) ion.

The magnetic moment for a cobalt(II) ion under octahedral symmetry is, in general, larger than the spin-only value because of the contribution from an orbital angular momentum, and is in the range 4.3—5.2 μ_B. The magnetic moment of CuCo(fsaen)·3H$_2$O is 4.76 μ_B which seems common to a magnetically noninteracting Cu(II)-Co(II) system if we take into account the 1.85 μ_B of Cu(H$_2$fsaen)·0.5H$_2$O. However, the magnetic moment of this complex markedly depends on temperature, indicating the spin-spin exchange interaction between the metal ions (Fig. 4). Based on the Heisenberg model, spin-spin coupling between copper(II) ($s_1=1/2$) and cobalt(II) ($s_2=3/2$) would result in two spin states, $s=1$ and $s=2$. The spin-quintet state is separated by $-4J$ from the supposed spin-triplet ground state, where J is the exchange integral. The molar magnetic susceptibility for this system is expressed by the equation,

$$\chi_M = \frac{Ng^2\beta^2}{kT}\cdot\frac{10+2\exp(-4J/kT)}{5+3\exp(-4J/kT)} + N\alpha \qquad (2)$$

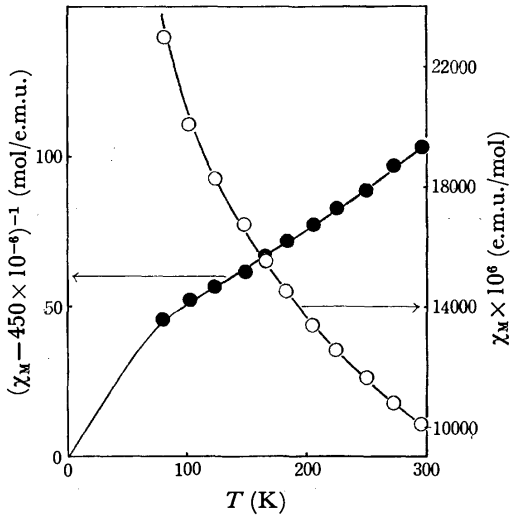

Fig. 4. Variations of molar susceptibility and inverse molar susceptibility for CuCo(fsaen)·3H$_2$O as a function of temperature.

As is seen in Fig. 4, the magnetic susceptibility (and the inverse magnetic susceptibility) is in accordance with the theoretical value when average g-value, J and $N\alpha$ are estimated at 2.45, -35 cm^{-1} and 450×10^{-6} e.m.u./mol, respectively. It is likely that the orbital contribution from the cobalt(II) to the total magnetic susceptibility is small. This implies that the geometry around the cobalt(II) is not exactly octahedral. The $^4T_{1g}$ ground state of cobalt(II) in an octahedral environment should split into two or three states under a low symmetry. If the first excited state were thermally accessible, the temperature dependence of magnetic susceptibility would become much complicated, and could not be interpreted in terms of Eq. 2. Thus, the ground state for the cobalt(II) in CuCo(fsaen)·3H$_2$O is orbitally singlet and the first excited state is above the ground state more than 1000 cm^{-1}. According to Sinn[11] the orbital contribution to magnetic susceptibility of a poly-nuclear cluster, in general, can be ignored. Thus the geometry around the cobalt in CuCo(fsaen)·3H$_2$O is pseudo-octahedral; it is supposed that the water molecules in the apical positions are elongated.

Electronic spectrum of CuFe(fsaen)·2H$_2$O shows a band at 22000 cm^{-1} in addition to the band (19000 cm^{-1}) attributable to the "inside" copper(II). In general, high-spin iron(II) in an octahedral crystal field should show the spin-allowed transition $^5E_g\leftarrow{}^5T_{2g}$ around 11000 cm^{-1}. However, such a band could not be found for CuFe(fsaen)·2H$_2$O. The molar magnetic moment decreases with lowering of temperature from 2.76 μ_B at 297.8 K to 1.90 μ_B at 79.9 K (Table 2). This behavior can not be explained in terms of the spin-exchange interaction between a copper(II) and a high-spin iron(II). It might be possible to explain the magnetism in terms of a spin-equilibrium between high-spin (or intermediate-spin) and low-spin states of iron(II). Based on this assumption, the band at 22000 cm^{-1} is attributable to a low-spin iron(II). However, most iron(II) cross-over complexes are restricted to those containing imine-nitrogen ligands[12–18] and no iron(II) cross-over complex with only oxygen-ligands has yet been obtained.

In the spectrum of CuMn(fsaen)·H$_2$O no characteristic band was found except the band at 19400 cm^{-1}, which is attributable to the "inside" copper(II). This seems natural since a high-spin manganese(II) shows no spin-allowed d-d transition. The molar magnetic moment is 5.17 μ_B which is much lower than the value expected for only high-spin manganese(II). This indicates an antiferromagnetic spin-exchange interaction between copper(II) and manganese(II).

In composition, color, infrared spectrum, electronic spectrum and magnetic property NiCu(fsaen)·H$_2$O differs from CuNi(fsaen)·3H$_2$O. The reflectance spec-

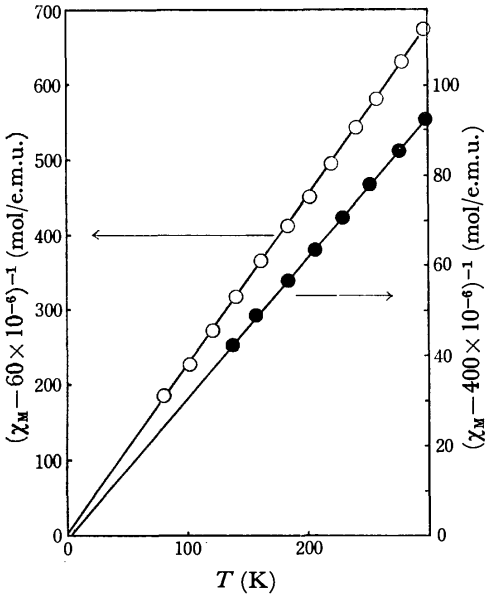

Fig. 5. The inverse magnetic susceptibilities for (○) NiCu(fsaen)·H_2O and (●) NiCo(fsaen)·$2H_2O$.

trum of NiCu(fsaen)·H_2O possesses two ligand field bands at 12000 and 19000 cm^{-1}. The first band seems to be essentially the same as the band (13400 cm^{-1}) found for Cu_2(fsaen)·$2H_2O$. The bands at 12000 and 19100 cm^{-1} are tentatively assigned to the "outside" copper(II) and the "inside" nickel(II), respectively. The molar magnetic moment at room temperature is 1.87 μ_B and the inverse magnetic susceptibility obeys the Curie-Weiss law in the temperature range 78—300 K. Spectral and magnetic properties indicate that NiCu(fsaen)·H_2O is composed of one diamagnetic nickel(II) and one copper(II) ions.

The electronic spectrum of NiCo(fsaen)·$2H_2O$ resembles that of CuCo(fsaen)·$3H_2O$. Therefore, the assignment of the ligand field bands was tentatively done by an assumption of a pseudo-octahedral configuration around the cobalt(II); 8100 ($^4T_{2g} \leftarrow {}^4T_{1g}$), 12000 ($^2E_g \leftarrow {}^4T_{1g}$), 16200 ($^4A_{2g} \leftarrow {}^4T_{1g}$), and 19500 cm^{-1} ($^4T_{1g}(P) \leftarrow {}^4T_{1g}(F)$). The band at 19500 cm^{-1} may be overlapped by the band due to the "inside" nickel(II). The supposed structure of planar nickel(II)-octahedral cobalt(II) is supported by magnetic measurements. The magnetic moment at room temperature is 5.15 μ_B, which is common to high-spin cobalt(II) complexes. The plot of the inverse magnetic susceptibility against temperature obeys the Curie-Weiss law as is shown in Fig. 5.

NiFe(fsaen)·$2H_2O$ resembles CuFe(fsaen)·$2H_2O$ in spectral and magnetic properties. The magnetic susceptibility and magnetic moments at various temperature are given in Table 2. Since the electronic spectrum indicates that the nickel(II) has a planar configuration, unusual magnetic property of this complex is attributed to the iron(II).

From the electronic spectrum it is apparent that the configuration around the nickel(II) in NiMn(fsaen)·$2H_2O$ is also planar. The fact that the room temperature magnetic moment is 5.71 μ_B which is common to high-spin manganese(II) supports the binuclear structure composed of planar nickel(II) and high-spin manganese(II).

Consequently the nickel(II) in NiM'(fsaen)·nH_2O is always planar. This finding is compatible with the fact that the "inside" nickel(II) is always diamagnetic in Ni_2(fsaen)·$3H_2O$ and its homologues. The ligand field band due to the "inside" metal ion in the present complexes shifts to higher energy as compared with the band of the corresponding monomeric complex. This implies that the binuclear complex formation enhances the coplanarity of the "inside" metal plane.[19]

A New Spectrophotometric Method for the Determination of Some Reducible Compounds by the Reduction with Chromium(II) Ion

Kikuo TERADA, Hiromi HONNAMI,* and Toshiyasu KIBA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received July 6, 1976)

A number of reducible compounds, such as nitrates, nitrites, nitro, nitroso, azoxy compounds, aldehydes, carbon tetrachloride, oximes, and chloramine T, can be determined by reducing them with chromium(II) ion prepared in an aqueous solution in a special vessel and measuring the absorbance of the resulting chromium(III) in the solution. In this reducing process, nitrate and nitrite are reduced to hydroxylamine quantitatively in hydrochloric acid at room temperature; carbon tetrachloride, nitrobenzene, and chloramine T each consume definite amounts of chromium(II) in an acidic medium at room temperature; propionaldehyde and azoxybenzene react with the reagent only in a basic solution; dimethylglyoxime and 1-nitroso-2-naphthol react only under heating at 80 °C in an basic medium. The absorbance of the resulting chromium(III) ion in the presence of the excess chromium(II) is found to obey Beer's law at the wavelengths of 410—425 nm over the range of 4×10^{-3}—8×10^{-2} mol/l of chromium(III). This concentration range corresponds to about 10^{-5}—10^{-4} mol of the reducible compounds mentioned above. A rapid and precise method has been established with few disadvantages.

Although the spectrophorometric method for nitrite with Griess-Romijin reagent[1] is strikingly simple and accurate, for nitrate we have few methods of accurate determination. Most of the spectrophotometric methods for nitrate are based on the nitration of some organic reagents; these are often difficult to perform, since some methods are only applicable to a solid nitrate sample (*e.g.*, the phenoldisulfonic acid method[2-6]) and others give hardly linear calibration curves at the wavelengths of maximal absorption of the colored compound (*e.g.*, the brucine method[7-8]). This may be caused by the fact that nitration is apt to be affected by the presence of chloride, bromide, or nitrite, and also by other experimental conditions.

On the other hand, both nitrate and nitrite were also found to be readily reduced to hydroxylamine by low valence ions such as Cr(II).[9] It has also been known that some organic compounds containing nitro,[10-12] nitroso,[11] and diazo groups[11] react with some low valence ions such as Cr(II), Ti(III), and V(II); furthermore, chloroform, carbon tetrachloride,[13] and oximes[14] are also reducible with these ions. In the titrimetric process a sample is put into a solution containing an excess of these ions and allowed to react perfectly under an optimum condition of acidity or temperature; then the unconsumed reducing agent is back-titrated with iron(III) standard solution using thiocyanate as an indicator. In this case, however, the color change at the end point was not precisely detectable. Chromium(II) ions are preferred as a reducing agent because the blue color changes to green by the oxidation, so if we can measure the absorbance of the green color of chromium(III) resulting after the reduction of the sample, even minute amounts of the above inorganic and organic compounds could be determined spectrophotometrically.

This paper describes a rapid and simple method based on the above principle with some devices to prevent the oxidation of the remaining chromium(II) by air: we use a new air-shielded vessel that resembles the ordinary reductor vessel with liquid amalgam. The vessel is also useful for pipetting an aliquot of the solution for measuring the absorbance of chromium(III). The absorbance at the wavelength of 420 nm gives the concentration of chromium(III) and is not affected by the excess chromium(II). Beer's law is obeyed over the range of 4×10^{-3}—8×10^{-2} mol/l of chromium(III).

Experimental

Reagents. Potassium dichromate standard solution (0.1 M): Potassium dichromate of the guaranteed reagent grade (29.422 g) was dissolved in 1000 ml of 1.5 M hydrochloric acid. This solution was diluted again with 1.5 M hydrochloric acid to prepare 0.01 M solution.

Standard Nitrate Stock Solution (0.03 M): Potassium nitrate of the guaranteed reagent grade was dried, weighed (3.033 g), and dissolved in 1000 ml of distilled water. A standard nitrate solution in desired concentration was prepared by diluting the stock solution appropriately.

Standard Nitrite Stock Solution (0.18M): In distilled water 12.42 g of sodium nitrite of the guaranteed reagent grade was dissolved and the solution was diluted to 1000 ml. A 100 ml portion of the solution was diluted again to 1000 ml with distilled water and standardized as follows:[15] 50 ml of the 0.05 M potassium permanganate solution, 1 ml of concentrated sulfuric acid, and 50.00 ml of the sodium nitrite solution were taken in a glass-stoppered bottle. The reaction was made to proceed completely under occasional shaking for 15 min, then 2 g of potassium iodide were put into the solution. The liberated iodine was titrated with 0.025 M sodium thiosulfate standard solution using starch as an indicator. From the amount of potassium permanganate consumed by the sodium nitrite the concentration of the standard solution of nitrite was determined. A standard solution of a suitable concentration was prepared by diluting the stock standard solution.

Zinc Amalgam: 3—4 g of mossy zinc metal were washed with 1 M sulfuric acid and the metal pieces were put into 100 g of mercury placed in a porcelain casserole; then they were covered with 20 ml of 1 M sulfuric acid. The casserole was placed on a boiling water-bath to amalgamate the zinc with the mercury under occasional stirring; the liquid zinc amalgam thus prepared was separated from the solid by means of a separating funnel. The liquid zinc amalgam was stored in a glass stoppered bottle which contained 1 M sulfuric acid, enough to cover the amalgam.

* Present address: Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158.

Organic Compounds: Carbon tetrachloride, chloroform, nitrobenzene, and propionaldehyde, all of the guaranteed reagent grade, were submitted to analysis without any purification.

Chloramine T: 0.845 g of chloramine T (guaranteed reagent grade) was dissolved in 10 ml of distilled water.

Dimethylglyoxime: 0.363 g of dimethylglyoxime was dissolved in 20 ml of 3 M sodium hydroxide.

1-Nitroso-2-naphthol: 0.733 g of 1-nitroso-2-naphthol (guaranteed reagent grade) was dissolved in 20 ml of benzene.

Other Chemicals: Sulfuric acid, sodium hydrogensulfide, and amidosulfuric acid were of the guaranteed reagent grade.

Apparatus. A Hitachi 239 type digital spectrophotometer and Hitachi 323 type recording spectrophotometer with 1 cm glass cells were used.

The devised reductor is shown in Fig. 1, where (A) is a 300-ml glass vessel similar to a separating funnel, with the glass stopcock (E), fitted with a 10-ml glass reservior (C) through a rubber tube (B). (F) is the sample inlet.

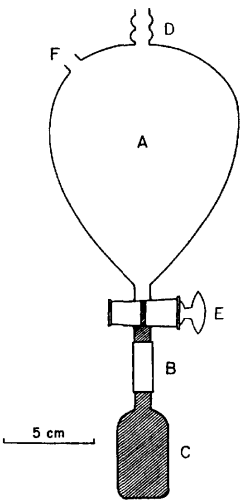

Fig. 1. Amalgam reductor.
A: Amalgam reductor, B: rubber tube, C: glass reservior, D: N_2-gas inlet, E: stopcock, F: sample inlet and outlet.

Procedure. The liquid zinc amalgam was introduced into the vessel (A) through the inlet (D) and dropped into the reservoir to fill out (C) up to the upper level of the stopcock (E). After the stopcock (E) was closed, and excess of the amalgam was rejected through (D) by turning the vessel upside down. The vessel was then returned to the normal position. For the determination of nitrate and nitrite, 10 ml of 0.02 M potassium dichromate solution (in 1.5 M hydrochloric acid) was pipetted into the reductor. Nitrogen gas was introduced through an alkaline pyrogallol washing solution into the reductor for 2—3 min to displace the air in the vessel completely; the gas flowed through the vessel from (D) to (F); (F) and (D) were then closed respectively with small silicon rubber stoppers. The zinc amalgam in the reservoir (C) was transferred back to the reductor by turning the vessel upside down, the stopcock (E) was closed, and the reductor was shaken for about 5 min till the orange color of the solution completely changed to sky blue. After the vessel was returned to normal, the zinc amalgam was completely restored to the reservoir through the cock (E) by pushing on the side of the rubber tube (B) with one's fingers; then the stopcock (E) was sclosed. Ten milliliters of a sample solution were introduced through the inlet (F), under the passage of nitrogen gas from (D) through the vessel. The reductor was shaken for about 5 min. About 5 ml of the solution were carefully sucked up into a 10-ml injector through the silicone rubber stopper and transferred into a 1-cm glass cell placed in a newly designed enclosed vessel, in Fig. 2, which was filled with nitrogen gas from the continuous passage of the gas. The cell was closed with a glass cover plate to protect it from the air. The absorbance of chromium(III) in the solution was measured at 420 nm with distilled water as the reference.

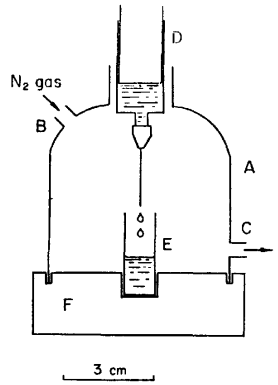

Fig. 2. New designed air-shielded vessel.
A: Air-shielded vessel made of 500 ml polyethylene bottle, B: N_2-gas inlet, C: N_2-gas outlet, D: 10 ml glass injector, E: absorption cell, F: base, made of wood.

Carbon tetrachloride, nitrobenzene, and chloramine T were found to react with chromium(II) ion in 1.5 M hydrochloric acid solution at room temperature. A suitable amount of the sample was introduced to the chromium(II) solution by means of a microsyringe through the inlet rubber stopper (F). After the reductor was shaken for 30 min, the absorbance of the resulting chromium(III) was measured.

Propionaldehyde and azoxybenzene were reduced very slowly in acidic solution at room temperature, whereas they react smoothly in a weak alkaline solution. Five milliliters of 3 M sodium hydroxide solution were slowly introduced with a pipette through (F) into the reductor containing 10 ml of 0.02 M chromium(II) under nitrogen gas flow, and at that time a greyish blue precipitate appeared in the solution. A suitable amount of the sample solution was injected into the reductor with a microsyringe through the rubber stopper (F). After the reductor was shaken for about 30 min, the solution was made acidic by adding 5 ml of 6 M hydrochloric acid with a pipette through (F) under nitrogen gas flow. The absorbance of the resulting chromium(III) was measured in the same way as described above.

Dimethylglyoxime and 1-nitroso-2-naphthol react with chromium(II) ions in a weak alkaline solution at 80 °C. After 5 ml of 3 M sodium hydroxide was introduced into the reductor which contained chromium(II) solution, a suitable amount of the sample was injected with a microsyringe in the same way as above. Then, the reductor was warmed at 80 °C in a thermostat for about 30 min. After the reductor was cooled to room temperature, the solution was made acidic with 5 ml of 6 M hydrochloric acid, and the absorbance of the resulting chromium(III) was measured.

Results and Discussion

Absorption Curves of Chromium(II) and Chromium(III). Twenty milliliters of 0.01 M potassium dichromate solution were reduced to chromium(II) with zinc amalgam

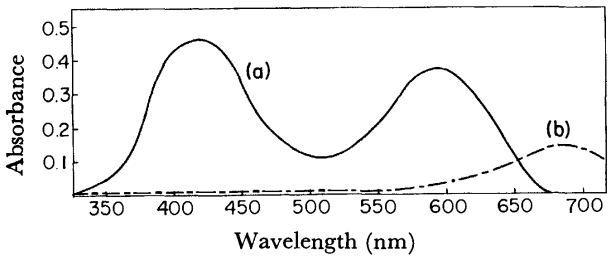

Fig. 3. Absorption spectra of chromium(II) and chromium(III) (0.02 M of metals in 1.5 M hydrochloric acid).
(a): Chromium(III), (b): chromium(II).

in the reductor according to the above procedure, and the absorption spectrum of a portion of the resulting chromium(II) solution was measured using a recording spectrophotometer. The solution which remained in the reductor was allowed to come in contact with air in order to change chromium(II) to chromium(III) completely; then the absorption spectrum of this solution was measured. As shown in Fig. 3, the absorption spectra exhibit the absorption maxima at 420 nm and 590 nm for chromium(III) and at 690 nm for chromium (II). From this figure it can be seen that the absorption maxima of the chromium(III) are isolated from that of chromium(II) and the spectrophotometric determination of the former is unaffected by the latter. These absorption curves almost coincide with those determined by Kranz and Duczmal[16] in 0.5 M sulfuric acid. Although it has been pointed out that chromium(III) forms a wide variety of complex ions, depending on the concentration of chromium, pH, and other ionic species present, the complication due to polynuclear compounds of chromium(III) is minimized in an acidic solution such as 1.0—1.5 M and the chromium(III) ion species seem rather invariable.

Calibration Curve for Chromium(III). The chromium(III) solutions in various concentrations were prepared in a similar way to that described above: chromium(VI) of varying concentrations was reduced to chromium(II) with zinc amalgam and oxidized to chromium(III) by exposing the solution to air. The absorbances of the resulting solutions were measured at 420 nm with a spectrophotometer. Beer's law was obeyed over the range of 4×10^{-3}—8×10^{-2} mol/l of chromium(III), with notably higher precision in the range of 4×10^{-3}—2×10^{-2} mol/l.

TABLE 1. RELATIONSHIP BETWEEN ABSORBANCE OF Cr(III) AT 420 nm AND CONCENTRATION OF NITRATE AND NITRITE

Nitrate taken[a] 10^{-5} mol	Absorbance	Cr(III) produced 10^{-5} mol	Nitrite taken[a] 10^{-5} mol	Absorbance	Cr(III) produced 10^{-5} mol
2.4	0.159	14.1	3.6	0.158	14.0
3.6	0.238	21.2	5.4	0.243	21.7
4.8	0.318	28.2	7.2	0.318	28.4
6.0	0.399	35.7	9.0	0.403	36.0
6.5	0.435	38.9			

a) Both nitrate and nitrite ions are present in 30 ml of the solution, respectively.

Nitrate and Nitrite. In Table 1 are shown the relations between the concentration of nitrate and nitrite ions and the absorbances measured. From this data it is found that 1 mol of nitrate oxidized exactly 6 mol of chromium(II) to chromium(III), and nitrite exactly 4 mol. Therefore, the reactions can be written as follows:

$$NO_3^- + 6Cr^{2+} + 7H^+ \longrightarrow NH_2OH + 6Cr^{3+} + 2H_2O$$

$$NO_2^- + 4Cr^{2+} + 5H^+ \longrightarrow NH_2OH + 4Cr^{3+} + H_2O$$

Hydroxylamine may be the final product, because no further reduction was found when an aqueous solution of hydroxylamine was put in the chromium(II) solution.

Determination of nitrate and nitrite in their mixture: From the above equations, under the present conditions 6.67×10^{-4}—3.3×10^{-3} mol/l of nitrate and 1.00×10^{-3}—5.00×10^{-3} mol/l of nitrite will be determined by measuring the absorbance of the resulting chromium(III). Therefore, if both nitrate and nitrite are present in a sample solution, their sum can be determined by the method. Then, if the nitrite can be removed from the sample by an appropriate reagent, the nitrate alone may be determined by this method. Thus the nitrite could be calculated as the difference between the total and the nitrate. Brasted[17] reported that nitrite was decomposed by amidosulfuric acid in the following process:

$$NaNO_2 + HSO_3NH_2 \longrightarrow N_2 + NaHSO_4 + H_2O$$

In the present study this reaction was employed. A definite volume of a sample solution containing both nitrate and nitrite was put into an Erlenmeyer flask and a suitable amount of amidosulfuric acid(solid) was added to decompose the nitrite. When the violent evolution of gas bubbles ceased, an aliquot of the solution was submitted to the reduction with chromium(II) ions, followed by the spectrophotometric measurement of the resulting chromium(III) ions. When the reaction between nitrite and amidosulfuric acid was performed in the air, the value of the resulting nitrate was often higher than the theoretical one, and was subject to wide fluctuations in every case. This fact is assumed to be caused by the following side reactions:

$$2NO_2^- + 2H^+ \longrightarrow N_2O_3 + H_2O$$

$$2N_2O_3 + O_2 \longrightarrow 4NO_2$$

$$2NO_2 + H_2O \longrightarrow NHO_3 + HNO_2$$

Thus, an appreciable amount of nitrate may be produced and consumes chromium(II) ions, yielding a higher value in the determination of the nitrate. The decomposable percentage of sodium nitrite varies with the concentration of the salt taken initially: about 2% of nitrite for 0.1—0.3 mol/l and about 10% for above 0.5 mol/l are decomposed in the way described above. In order to overcome this difficulty, the nitrite was decomposed under a nitrogen atmosphere in a glass-stoppered Erlenmeyer flask. The results indicated that satisfactory analyses were possible with solutions containing as much as 0.4 g sodium nitrite, but the concentration should not exceed 0.25 mol/l NO_2^-. Moreover, it was found that the amidosulfuric acid treatment did not affect nitrate ions in the range of concentration between 6.67×10^{-4} and 3.33×10^{-3} mol/l, and the chromium(II) reduction process could also be carried out without any trouble.

Table 2. Determination of nitrate and nitrite in their mixture

No.	NO_3^- taken 10^{-5} mol	NO_2^- taken 10^{-5} mol	Absorbance for $(NO_3^-+NO_2^-)$	Absorbance for (NO_3^-)	NO_3^- found 10^{-5} mol	NO_2^- found 10^{-5} mol
1	1.80	1.80	0.203	0.122	1.82	1.78
2	1.80	2.70	0.242	0.125	1.85	2.61
3	2.40	3.60	0.320	0.165	2.44	3.49
4	1.80	2.01	0.105	0.126	1.85	2.05
5	1.80	1.96	0.102	0.123	1.83	2.22

Therefore, one part of nitrate can be determined in the presence of about 350 parts of nitrite. The results for samples containing various amounts of nitrate and nitrite are shown in Table 2. Samples 4 and 5 in the table were diluted 10 and 100 times, respectively, prior to the determination of nitrite. A small amount of nitrite ions can be removed by the amidosulfuric acid method even in the air.

Determination of Nitrate Ions Present as Impurities in a Commercial Sodium Nitrite Reagent: It is well known that bulk nitrite reagents being used in the laboratory are not so stable and always contain some nitrate after the exposure to the air. By the method proposed so far, it is impossible to determine a small amount of nitrate contained in such a large amount of nitrite, since nitrite interferes with the determination of nitrate in many cases. Hence there have not been any reports on this subject. As described above, it seems possible to determine the nitrate impurity in a commercial sodium nitrite by the present method.

0.345 g of dried, ground sodium nitrite was weighed accuralately and dissolved in 20 ml of distilled water in a 200-ml glass-stoppered Erlenmeyer flask. After nitrogen gas was introduced into the flask sufficiently to replace the air, about 2 g of amidosulfuric acid were put in the flask. After 2—3 min the flask was warmed on a water bath (about 60 °C) for 5—10 min to make the reaction complete. The solution was diluted to 25 ml with distilled water in a measuring flask. Ten milliliters of an aliquot was taken in the reductor containing 10 ml of 0.04 M chromium(II) solution and the procedure was carried out as described in the Procedure section.

Table 3. Determination of nitrate ions in a commercial sodium nitrite reagent

$NaNO_2$ taken g	NO_3^- found g	NO_3^- content %
0.34503	0.00333	0.97
0.34493	0.00341	0.99
0.34514	0.00336	0.97
0.34544	0.00324	0.94

The results obtained are shown in Table 3. It was found that the nitrite reagent contained about 0.97% of nitrate. These results agree with that obtained by the gravimetric method with nitron carried out as follows: 1.380 g of sodium nitrite was dissolved in 100 ml of distilled water. 1.80×10^{-4} mol of nitrate was also added in order to obtain the precipitate of nitron which was filterable in the conventional manner. The solution was divided into four nearly equal portions (*ca.* 25 ml), which were put in four separate Erlenmeyer flasks. Two grams of amidosulfuric acid were added in each flask. After the nitrite was removed, each solution was collected together in a beaker, 10% nitron solution (in 5% acetic acid) was added in the solution, and the beaker was cooled in an ice bath to precipitate the nitron nitrate completely. The precipitate was filtered off onto a previously weighed glass-fiber filter paper (Toyo Roshi, GB-100), washed, dried at 110 °C for about 3 h, and weighed. This value coincided with that obtained by the recommended reduction method; the latter method is accurate and more simple and rapid than the former gravimetric one.

Interferences: Some oxidizing salts, such as chlorate, bromate, periodate, iodate, selenate, and selenite, oxidize chromium(II) to chromium(III) and thus interfere with this method; perchlorate, chloride, bromide, iodide, sulfate, and arsenate ions do not (Table 4). Some metal ions, such as copper(II) and iron(III), also interfere. Chlorate, bromate, and periodate and iodate ions are reduced to chloride, bromide, and iodide with chromium(II) ion, while selenate and selenite and copper(II) ions are reduced to their metals and iron(III) ion to iron(II) ion. However, periodate and iodate can be reduced by the addition of a small amount of hydrogensulfite to their 0.01 M hydrochloric acid solution; excess hydrogensulfite can be removed by gently boiling the solution. In this case, however, if the sample solution is

Table 4. Effect of diverse substances

more acidic than 0.1 M, a loss of nitrite occurs along with the evolution of gaseous nitric oxide. Nitrite and nitrate are not affected at all by the hydrogensulfite treatment under the present conditions. Some interfering metal ions, such as copper(II) and iron(III), can be removed by passing the sample solution through a column of cation exchange resin, Dowex 50 W×8 in hydrogen form, 100—200 mesh. Chlorate, selenate, and selenite ions can not be removed by any treatment, but as these ions seem to exist in commerical nitrites in only trace concentrations, and therefore except for some special cases, they may not give a serious error to the determination on a semi-micro scale.

Determination of Organic Compounds. The recommended procedures were carried out as described in the Procedure section. In the case of azoxybenzene, it is reduced with chromium(II) ions and gives azobenzene as a precipitate. Then, after acidifying the solution, the solution must be filtered through a dried absorbent cotton on the funnel to remove the precipitate, the filtrate is then received in a photometric cell. The results obtained are shown in Table 5 (1)—(7) together with the wavelength at which the measurement of the absorbance should be made.

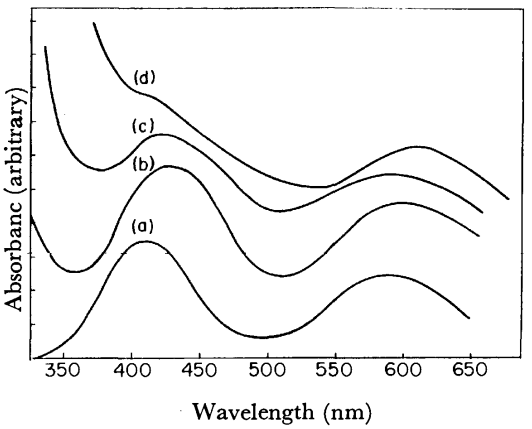

Fig. 4. Absorption spectra of chromium(III) complexes resulted by reaction between chromium(II) and some organic compounds.
(a): Carbon tetrachloride, nitrobenzene, and chloramine T, (b): propionaldehyde, azoxybenzene, and dimethylglyoxime, (c): 1-nitroso-2-naphthol, (d): *p*-benzoquinone and propiophenone oxime.

The absorption spectra of the resulting chromium(III) complex solutions are shown in Fig. 4. The spectra for carbon tetrachloride, nitrobenzene, and chloramine T (a) are very close to the standard one (Fig. 3), while those for propionaldehyde, azoxybenzene, and dimethylglyoxime (b) somewhat deviate from the standard one. On the other hand, the absorption spectra for 1-nitroso-2-naphthol (c) and *p*-benzoquinone and propiophenone oxime (d) exhibit another strong absorption peak at a wavelength shorter than 400 nm, which contributes to the absorption of chromium(III) at 420 nm. This absorption may be attributed to the reaction product in the solution. Consequently, the determined values are higher than the theoretical one, but in the case of 1-nitroso-2-naphthol an approximately linear relationship exists between the concentration of the sample and the absorbance of the resulting solution. Therefore, the determination of 1-nitroso-2-naphthol can be performed satisfactorily (Table 5(7)). However, in the case of *p*-benzoquinone and propiophenone oxime, the absorbance at about 420 nm is difficult to measure because the absorption peak is hindered by a strong absorption at a wavelength shorter than 400 nm. The absorption at 420 nm very quickly decreases, so the determination is impossible.

According to Kiba and Terada,[13] carbon tetrachloride and chloroform were assumed to be reduced to methane by chromium(II) ions. However, in the present study, as the results of the gaschromatographic measurement of the resulting aqueous solution and of the gas phase remained after the reaction in the reductor, it was found that tetrachloroethylene could be detected in the solution and carbon monooxide in the gas phase, but not any methane at all. The mechanism for this reac-

tion remains still obscure.

Carbon tetrabromide also can be determined in the same way, while chloroform reacts completely with chromium(II) under heating at 80 °C.

From the results in Table 5, which shows the mol number of chromium(III) produced by oxidation of chromium(II) with 1 mol of the sample, the reaction stoichiometry can be speculated about:

Nitrobenzene:

$$C_6H_5NO_2 + 6Cr^{2+} + 6H^+ \longrightarrow C_6H_5NH_2 + 6Cr^{3+} + 2H_2O$$

Although 1 mol of nitrobenzene oxidized only 4.5 mol of chromium(II), aniline was detected as a reaction product by gaschromatographic measurements. Consequently, it may be assumed that this reaction will proceed to the extent of 75% under these conditions. However, as an exact linear relationship was obtained between the concentration of the sample and the absorbance of the resulting chromium(III) solution, determination of nitrobenzene should be carried out satisfactorily in the range of 10^{-5}—2×10^{-4} mol.

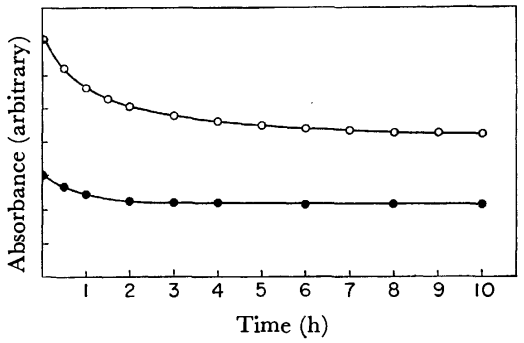

Fig. 5. Change of the absorbance of chromium(III) at 410 nm on the elapse of time.
—○—: 1-Nitroso-2-naphthol, —●—: azoxybenzene.

Chloramine T:

$$CH_3C_6H_4SO_2N\cdot ClNa + 2Cr^{2+} + 2H^+ \longrightarrow CH_3C_6H_4SO_2NH_2 + 2Cr^{3+} + Na^+ + Cl^-$$

Propionaldehyde:

$$CH_3CH_2CHO + 2Cr(OH)_2 + 2H_2O \longrightarrow CH_3CH_2CH_2OH + 2Cr(OH)_3$$

Azoxybenzene:

$$C_6H_5N(O)=NC_6H_5 + Cr(OH)_2 + H_2O \longrightarrow C_6H_5N=NC_6H_5 + 2Cr(OH)_3$$

Dimethylglyoxime:

$$[(CH_3)C=NOH]_2 + 8Cr(OH)_2 + 6H_2O \longrightarrow [(CH_3)CHNH_2]_2 + 8Cr(OH)_3$$

1-Nitroso-2-naphthol:

$$C_{10}H_6(OH)NO + 4Cr(OH)_2 + 3H_2O \longrightarrow C_{10}H_6(OH)NH_2 + 4Cr(OH)_3$$

As shown in Fig. 5, the reaction of the last three compounds is not fast, so the contents must be kept standing for about 3, 1, and 6—7 h, to obtain invariable results for azoxybenzene, dimethylglyoxime, and 1-nitroso-2-naphthol, respectively.

Synthesis and X-Ray Structure of Triethylenetetraminepalladium(II) Complex

Fumio Hori, Keiji Matsumoto, Shun'ichiro Ooi, and Hisao Kuroya
Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558
(Received July 12, 1976)

The triethylenetetraminepalladium(II) perchlorate and the potassium triethylenetetraminepalladium(II)tris-(hexafluorophosphate) were prepared; the X-ray structure analysis has been carried out for the latter compound. The crystal of $[Pd(trien)](PF_6)_2 \cdot KPF_6$ is orthorhombic, with space group Pbca: $a=21.645$ (5), $b=20.873$ (5), $c=9.541$ (2) Å, and $Z=8$. The structure has been determined from X-ray diffractometer data and refined to $R=0.091$ (1166 reflections). The Pd atom has a planar coordination of 4N atoms disposed in a somewhat trapezoidal form. The complex cation has a pseudo symmetry plane which is perpendicular to the 4 N plane and bisects the H_2N–Pd–NH_2 angle. In the quadridentate triethylenetetramine ligand, each of the terminal H_2N–CH_2–CH_2–NH– fragments forms a 5-membered chelate ring with the asymmetric envelope conformation, whereas the chelate ring formed by the middle –NH–CH_2–CH_2–NH– fragment has the symmetric envelope conformation. The electronic spectrum of $[Pd(trien)]^{2+}$ is presented.

A number of metal chelates, in particular Co(III) chelates, of the triethylenetetramine (trien) have been prepared and characterized as regards various properties. In 1949 Jonassen *et al.* synthesized the Magnus-type $[Pd(trien)][PdCl_4]$, which was the first isolated salt of the $[Pd(trien)]^{2+}$ ion.[1] However, no detailed studies have yet been made of the complex cation. We report here the synthesis, electronic spectrum, and X-ray structure of the Pd(II) chelate of the trien.

Experimental

Preparation of the Compounds. *$[Pd(trien)](PF_6)_2 \cdot KPF_6$*: Triethylenetetramine (58 mg) was added with stirring to a solution of K_2PdCl_4 (107 mg) in 10 ml of water. An orange precipitate was formed but it dissolved immediately. The yellow solution was warmed at 50 °C for 1 h, then $AgPF_6$ (345 mg) dissolved in 5 ml of water was added to the solution. The mixture was stirred for another 0.5 h in the dark and then filtered to remove AgCl. The filtrate was evaporated to dryness under reduced pressure and the residue was dissolved in 10 ml of ethanol. After filtering off the precipitated KPF_6, the filtrate was concentrated to 2 ml, to which 5 ml of water was added. The resulting solution was allowed to stand for 5 days at room temperature. It turned pasty, and yellow needle-like crystals separated out. These crystals were washed with small amounts of cold ethanol and water. Recrystallization was made from ethanol-water solution. Yield, 33%.

Found: C, 9.84; H, 2.40; N, 7.48%. Calcd for $C_6H_{18}N_4PdKP_3F_{18}$: C, 9.92; H, 2.50; N, 7.71%.

$[Pd(trien)](ClO_4)_2$: Triethylenetetramine (202 mg) was added to a solution of $[Pd(NH_3)_4](ClO_4)_2$ (515 mg) in 10 ml of water. The solution was stirred at 50 °C for 2 h and then filtered. The filtrate was evaporated to 5 ml under reduced pressure and the concentrated solution was allowed to stand for 5 days at room temperature. Yellow needle-like crystals were obtained and these were recrystallized from water. Yield, 55%.

Found: C, 15.57; H, 4.12; N, 12.18%. Calcd for $C_6H_{18}N_4PdO_8Cl_2$: C, 15.96; H, 4.03; N, 12.41%.

X-Ray Data Measurement. *Crystal Data*: $C_6H_{18}N_4PdKP_3F_{18}$, F.W.=726.7, Orthorhombic, $a=21.645$ (5), $b=20.873$ (5), $c=9.541$ (2) Å, $U=4311$ (3) Å^3, $D_m=2.18$, $Z=8$, $D_c=2.23$ g cm^{-3}. μ(Mo$K\alpha$)=15.0 cm^{-1}, Mo$K\alpha$ radiation ($\lambda=0.71069$ Å), Space group Pbca. The space group and the approximate cell dimensions were determined from oscillation and Weissenberg photographs taken with Cu$K\alpha$ radiation. The cell dimensions were refined by the least-squares analysis of 38 θ values accurately measured on a Philips PW 1100 four circle diffractometer with Mo$K\alpha$ radiation.

Data Collection: Intensity data for one octant of the reciprocal space were collected by the ω-2θ scan technique with graphite-monochromated Mo$K\alpha$ radiation; the dimensions of the specimen used were $0.13\times0.10\times0.11$ mm. A scan speed of 0.017° s^{-1} in ω, a scan width $(0.8+0.2\tan\theta)$°, and stationary background measurements of 20 s were chosen. A total of 1166 reflections having intensity $I_t-2\sqrt{I_t}>I_b$ was collected in the range of $6°\leq2\theta\leq50°$ (I_t: intensity (counts/s) measured at the peak of reflection during the scan; I_b: mean background intensity (counts/s) obtained from preliminary background measurements of 5 s at each side of the scan). The number of the reflections collected is no more than *ca.* 27% of that of the reciprocal lattice points investigated in the data collection. Three standard reflections (10 0 0, 0 8 0, 0 0 2), monitored every 4 h throughout the data collection, showed no significant variation in intensity. Intensity data were processed by the use of the computer program of Hornstra and Stubbe.[2] No absorption correction was applied.

Structure Determination and Refinement. The crystal structure was solved by the heavy atom technique. The positional and thermal parameters were refined by the block-diagonal least-squares method, with anisotropic temperature factors used for Pd, K, and P atoms. The minimized function was $\sum w(|F_o|-|F_c|)^2$. A weighting scheme of the type suggested by Hughes[3] was applied using $w=0.70$ for $F_o<F_{min}$, $w=1$ for $F_{min}\leq F_o\leq F_{max}$, and $w=(F_{max}/F_o)^2$ for $F_o>F_{max}$; $F_{min}=11.0$ and $F_{max}=31.2$ were found to be optimum. The final R was 0.091 ($R'=[\sum w(|F_o|-|F_c|)^2/\sum wF_o^2]^{1/2}=0.117$). The temperature factors for lighter atoms, especially those for F atoms, are rather high. This is indicative of the disorder in the arrangment of those atoms. In the final cycle of the refinement all parameter shifts were $<(1/5)\sigma$. The atomic coordinates and the temperature factors are listed in Table 1, along with their estimated standard deviations. A complete list of the observed and calculated structure factors is preserved by the Chemical Society of Japan (Document No. 7702).

Atomic scattering factors of neutral Pd, P, F, N, and C, and K^+ were taken from Ref. 4. The real part of the anomalous dispersion correction was applied for the Pd atom. Computer programs used in the calculations were as follows: RSSFR-4 (Fourier synthesis), HBLS-4 (least-squares calculation), and DAPH (interatomic distances and angles, least-squares

planes, and coordinates of H atoms), all of which were adapted to the FACOM 270—30 computer at Osaka City University.

In order to confirm the structure, further least-squares calculations were carried out by the use of the anisotropic temperature factors for all atoms, here the weighting scheme $w=(7.6+F_o+0.013F_o^2)^{-1}$ was employed. The R and R' reached 0.054 and 0.072, respectively. The difference Fourier map calculated at this point showed no peaks>0.55 e Å^{-3}. Of the residual peaks, nine could be identified as H atoms.

Electronic Spectra and Electric Conductivity. The absorption spectra were recorded at room temperature using a Hitachi EPS-3T Recording Spectrophotometer. The electric conductivity was measured in water by means of an MY-8 apparatus of the Yanagimoto Seisakusho, Ltd.

Results and Discussion

The projection and elevations of the complex cation are shown in Figs. 1 and 2, respectively. The Pd atom is surrounded by 4 N atoms disposed in trapezoidal form. The complex has a pseudo mirror plane which is perpendicular to the plane defined by the 4 N atoms and bisects the N(1)-Pd-N(4) angle. The 5-membered chelate rings A and C assume the asymmetric envelope conformation, whereas the middle ring B has the symmetric one: the -NH-CH_2-CH_2-NH- fragment in B has an almost eclipsed conformation, with the torsional angle of 9°. This conformation of the trien ligand is essentially identical with that found in [Cu(SCN)(trien)](NCS),[5] though the corresponding torsional angle in the Cu complex (49°) is rather large as compared with that of the Pd complex. In the present $[Pd(trien)]^{2+}$ all C atoms lie on the upper side of the 4 N plane, while the Pd atom deviates slightly downward from the plane, by 0.06 Å. The F(4) atom is in close contact with the Pd atom, at a distance of 3.15 Å. The equations of some least-squares planes are given in Table 2.

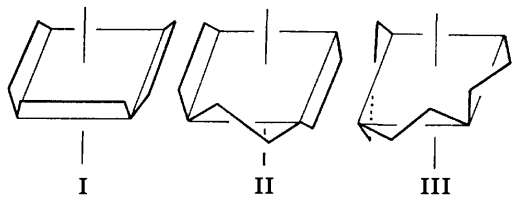

Fig. 3. Possible conformers for a planar disposition of the trien ligand.

Bosnich *et al.* studied the strain energy in the metal chelates of the trien which has a planar disposition. They suggested that the most stable conformations of the ligand are those shown in Figs. 3 I and II.[6] The conformer I has C_s symmetry, while the symmetries of the conformers II and III are C_2. The conformations of trien in the Pd and Cu complexes can be classified as I. The conformation II has not yet been found in the crystal structures of the trien complexes. Although the conformer III was predicted to be less stable than I and II, it is believed that in $(+)_D$-*trans*-$[CoCl_2(trien)]^+$ the chelating ligand assumes the conformation III.[7]

The bond lengths and angles are given in Table 3. The N(1)–Pd–N(4) bond angle is somewhat larger than 90°, showing considerable strain in the complex. However, it is comparable to those in the [Cu(SCN)(trien)](NCS) (98.9°)[5] and $(-)_D$-*trans*-$[Co(NO_2)_2(L\text{-}3,8\text{-dimetrien})](ClO_4)$ (101.6°).[8] The bond length of Pd–N (primary amino group) seems to be somewhat longer than that of the Pd–N (secondary): the mean value of the former is 2.08 Å, whereas that of the latter is 1.98 Å. However, such a difference in metal–nitrogen bonds is less pronounced in the Co complex,[8] and is not found in the Cu one.[5]

groups participate in the hydrogen bonding, while none of the –NH– groups do.

Figure 5 shows the electronic spectra of the triethylenetetraminepalladium(II) perchlorate and the potassium triethylenetetraminepalladium(II) tris(hexafluorophosphate) in an aqueous solution. These spectra agree with each other and indicate that the species in the solution are identical. The spectra of these compounds resemble those of $[Pd(NH_3)_4](ClO_4)_2$[9] and $[Pd(R\text{-pn})_2]Cl_2$.[10] Accordingly, on the basis of D_{4h} symmetry the absorption band at 33.7×10^3 cm^{-1} may be assigned to the transitions $^1A_{1g} \rightarrow {}^1A_{2g}$, ^1E_g, and $^1B_{1g}$.[9] The peak position of the trien complex is almost equal to that of the ammine complex, but is displaced to a slightly lower energy relative to the band maximum of the R-pn complex. However, the absorption in the present complexes is about three times as intense as those in the complexes cited for comparison. The ion pairing which gives a 5-coordinate complex sometimes results in an enhancement of the absorption intensity.[11] The molar conductance of the perchlorate is 250 ohm^{-1} cm^2 mol^{-1} at 25 °C in 5.90×10^{-4} M aqueous solution. The concentration of this solution is almost equal to those of the solutions used for the measurements of the spectra. The value of conductance is typical for a 1:2 electrolyte: there seems to be no appreciable interaction between the cation and the anion in 10^{-3}—10^{-4} M solution.

The PdN_4 chromophore in the $[Pd(NH_3)_4]^{2+}$ and $[Pd(R\text{-pn})_2]^{2+}$ have an effective symmetry of D_{4h}, and therefore the d→d transition is Laporte-forbidden. On the other hand, the configuration of 4 N atoms in the $[Pd(trien)]^{2+}$ is trapezoidal and the symmetry of the chromophore can be regarded as C_{2v}. Since this group contains no inversion center, Laporte's rule is relaxed. Furthermore, symmetry considerations imply that the C_{2v} symmetry is favorable to the mixing of d→d transitions with some allowed transitions through configuration interaction, as compared with the case of D_{4h} symmetry. Some of these might be responsible for the enhancement of the intensities in the ligand fields bands. The orbitals in the plane of the ligator atoms are most sensitive to the change of the disposition of these atoms. Consequently, the intensity of the $a_1(d_{xy}) \rightarrow b_1(d_{x^2-y^2})$ transition may be the most enhanced of the d→d transitions.

Studies on Mixed Chelates. VI. Mixed Copper(II) Chelates with *N,N,N',N'*-Tetraethylethylenediamine and Various β-Diketones

Yutaka FUKUDA, Yukiko MIURA, and Kozo SONE

Department of Chemistry, Faculty of Science, Ochanomizu University, Otsuka, Tokyo 112

(Received July 27, 1976)

Ten new mixed copper(II) chelates containing *N,N,N',N'*-tetraethylethylenediamine and various β-diketones were prepared and the cause of the large variations of ν_{max} values observed in the visible absorption spectra of their organic solutions was discussed in comparison with similar variations of the corresponding tetramethyl chelates.

In previous papers,[1,2] the authors reported on the mixed copper(II) chelates containing *N,N,N',N'*-tetramethylethylenediamine(tmen) and various β-diketonate ions. It was found that the position of the d-d band of such chelates depends remarkably upon the coordination ability of the solvent and counter anion, and upon the nature of the substituent groups in the diketonate ions. The present study on the preparation and spectra of the corresponding chelates containing *N,N,N',N'*-tetraethylethylenediamine(teen) was undertaken to see how the bulkiness of the *N*-alkyl groups affects the structure and spectra of these types of chelates.

Experimental

Preparation of the Chelates. *(I) [Cu(teen)aca]ClO_4*: Acetone solutions of $Cu(ClO_4)_2 \cdot 6H_2O$ and aca* (10 mmol each) were mixed together with teen** (15 mmol) with vigorous stirring. After the mixture had been filtered and concentrated, an excess of diethyl ether was added. Crystals of the chelate began to separate out when the vessel wall was scratched with a glass rod. They were washed with an acetone–diethyl ether mixture and dried in a vacuum.

(II) Other Chelates: Acetone solutions of $Cu(ClO_4)_2 \cdot 6H_2O$ (or $Cu(NO_3)_2 \cdot 3H_2O$) and a β-diketone (10 mmol each) were mixed together with teen (15 mmol) as in (I), and the filtered mixture was evaporated to dryness. The raw chelate thus obtained was purified by repeated crystallization from 1,2-dichloroethane, and dried in a vacuum.

The colors, magnetic moments, and analytical data of the new chelates are listed in Table 1. All the chelate perchlorates and nitrates are apparently similar to the tmen chelates reported before; however it was impossible to prepare [Cu(teen)hfa]NO_3, and a green chelate [Cu(teen)hfa_2] was obtained instead. For the physical measurements *cf.* previous papers.[1,2]

Discussion

Electronic Spectra. As in the case of the corresponding tmen chelates, all the teen chelates obtained are fairly soluble in a variety of organic solvents. Measurements of the visible absorption spectra in solution, and the reflection spectra in the solid state, revealed a close resemblance between these spectra and those of the corresponding tmen chelates. Here again it seems that the position of the d-d band depends on two factors, (1) the nature of the substituent groups in the β-diketonate ions, which controls the magnitude of the in-plane ligand field strength, and (2) the strength of the axial bonds formed between the central copper(II) and the counter anions or solvent molecules.

The data in organic solutions are of special interest. Fig. 1 shows some examples of the obtained spectra, *i.e.*, the spectra of [Cu(teen)aca]ClO_4 in five solvents. The variations of the ν_{max} value of the d-d band of each chelate in organic solutions are summarized in Fig. 2.

The spectral variations among the chelate perchlorates are especially similar to those of the corresponding tmen chelates. Thus the ν_{max} value for each chelate decreases in the following order of solvent,

$$1,2\text{-}C_2H_4Cl_2 > \text{acetone} > \text{MeOH} > \text{DMF} > \text{DMSO}$$

and the ν_{max} value in one particular solvent decreases in the following order of the β-diketonate ion,

$$\text{dpm} > \text{aca} > \text{bza} > \text{dbm} \gg \text{hfa}$$

just as in the case of the tmen chelates.

TABLE 1. COLORS, ANALYTICAL DATA,[a] MAGNETIC MOMENTS AND MOLAR CONDUCTIVITIES OF THE CHELATES

No.	Chelate	Color	C%	H%	N%	μ_{eff} (B.M.)	Λ_M[b]

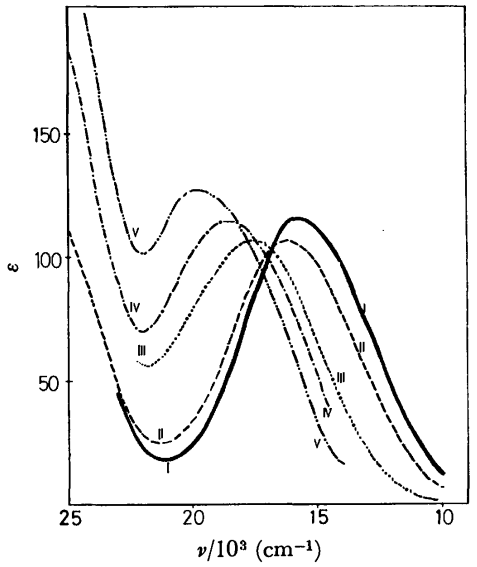

Fig. 1. Electronic absorption spectra of [Cu(teen)aca]-ClO_4 in various solvents. (*Cf.* also Fig. 2).

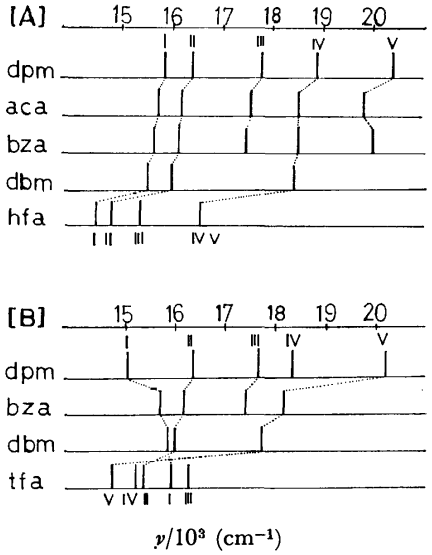

Fig. 2. Variations of the ν_{max} values of the chelates [Cu(teen)β-dik]X in various solvents. [A]: X=ClO_4, [B]: X=NO_3. The solvents studied in Figs. 1 and 2 are: DMSO(I), DMF(II), MeOH(III), acetone (IV) and 1,2-dichloroethane (V); concn ≈5 mM.

The variations among the chelate nitrates seem to be more complicated, poor solubility and the appearance of shoulder-like curves sometimes hindering the correct locating of the bands. However, it can be recognized that the ν_{max} in 1,2-dichloroethane and acetone decrease drastically in going from dpm to tfa, probably for the same reason as that for a similar spectral anomaly observed among the spectra of the tmen chelates in 1,2-dichloroethane, *i.e.*, the coordination of NO_3^- to the chelate cation.

The general features shown in Fig. 2 are thus fairly similar to the corresponding figure of the tmen chelates,[2] but the spectra of the teen chelates seem to be more sensitive to the changes of solvent, anion and substituent groups. For example, in going from DMSO to 1,2-dichloroethane, the ν_{max} of [Cu(tmen)dpm]ClO_4 changes from 16600 to 18900 cm^{-1}, while that of [Cu(teen)dpm]ClO_4 changes from 15800 to 20400 cm^{-1}. One can also compare the complicated pattern of Fig. 2 [B] with the corresponding figure of the tmen chelates, which looks more regular except for the above-mentioned anomaly of 1,2-dichloroethane solutions.

This spectral sensitivity of the teen chelates seems strange, since the four bulky *N*-ethyl groups in teen can be expected to hinder the approach of the solvents and anions more strongly than the *N*-methyl groups of tmen, so that the electronic structure of the teen chelate should be more insensitive to the changes of environment. In fact, the mixed nickel(II) chelates of teen and β-diketonate ions were found to be much more reluctant to combine with solvent molecules and change from square planar to octahedral than the corresponding tmen chelates.[3]

The cause of this spectral sensitivity might be found in the fact that copper(II), unlike nickel(II), tends to form axial bonds even with ligands lying far away from it, and even when they lie considerably outside the z-axis. That is, the axial bonds are considerably elastic or flexible in nature.[4]

It is thus conceivable that the above-mentioned steric hindrance in the teen chelates works only when the coordination ability of the solvent or anion is very low and the in-plane l.f.s. is sufficiently large; in such a case a highly planar chelate structure will result, and its ν_{max} may be higher than that of its tmen analogue. On the other hand, when the coordination ability of the solvent or anion becomes higher and the in-plane l.f.s. lower, the steric hindrance will be readily overcome, and a more or less deformed tetragonal structure will result. The effective l.f.s. in such a structure may be somewhat weaker, and its ν_{max} lower, than that of its tmen analogue, because there will be larger interligand repulsions and structural deformations in the teen system. The observed larger spectral variations among the teen chelates may be a reflection of all these effects.

It should be added that the chelate [Cu(teen)hfa_2] shows only a small variation of ν_{max} in various solvents

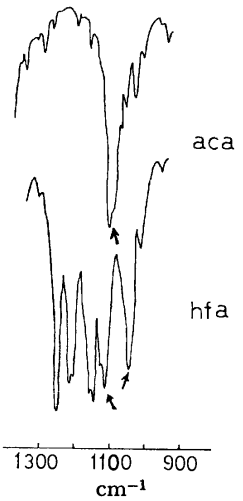

Fig. 3. IR spectra of [Cu(teen)β-dik]ClO_4 in Nujol mulls.

(14080 to 14580 cm^{-1} in DMSO, methanol and 1,2-dichloroethane) probably owing to its 6-coordinate structure which somewhat resembles the chelate [Cu bip hfa_2] reported by Veidis *et al.*[5]

Evidence of Perchlorate Coordination. The data in Fig. 2 suggest that, in 1,2-dichloroethane with very poor coordination ability, and with hfa with the weakest l.f.s. among the diketonate ions used, even ClO_4^- gets coordinated to some extent, since the ν_{max} of [Cu(teen)-hfa]ClO_4 in this solvent is remarkably low and nearly the same as that of the same chelate in acetone. This leads further to the supposition that the same kind of perchlorate coordination will also occur in the crystals of this chelate. The conductivity data in Table 1, and the fact that the IR main peak of ClO_4^- which appears single in other chelates is apparently split in the spectrum of this chelate (Fig. 3) support these suppositions. Similar observations have been made on the tmen system.[2]

The authors are grateful to Dr. Ichiro Fujita and Mrs. Etsuko Fujita, Georgia Institute of Technology (Atlanta, USA), for the supply of a sample of teen.

Optical Resolution and Ternary System Solubility Isotherms of Cobalt(III) Complex Salts

Yoichi SHIMURA and Katsuyuki TSUTSUI

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received July 28, 1976)

The characteristics of three-component phase diagrams consisting of water and a pair of enantiomeric or diastereomeric cobalt(III) complex salts have been clarified experimentally by constructing the solubility isotherms of the following 6 ternary systems at 25 °C: H_2O–Δ-[Co(ox)$(en)_2$]X–Λ-[Co(ox)$(en)_2$]X, where X stands for Cl^-, I^-, (*R,R*)-$C_4H_5O_6^-$, Δ-[Co(edta)]$^-$, $^1/_2[Sb_2\{(R,R)\text{-}C_4H_2O_6\}_2]^{2-}$ or *d*-$C_{10}H_{14}OBrSO_3^-$. It has been found that the latter two anions form an active racemate, *rac*-[Co(ox)$(en)_2]_2[Sb_2\{(R,R)\text{-}C_4H_2O_6\}_2]\cdot 5H_2O$ and *rac*-[Co(ox)$(en)_2$]-(*d*-$C_{10}H_{14}OBrSO_3)\cdot H_2O$, respectively. Solubility of the [Co(ox)$(en)_2]^+$ salts containing optically active counter-ions was determined at 5—60 °C in water.

The solubility isotherm for a multi-component system consisting of an optically inactive solvent and a pair of enantiomers or diastereomers seems to give useful information on optical resolution.[1,2] However, no such isotherm seems to have been reported for the system of metal complexes and water. The present paper deals with some solubility isotherms for the ternary systems, H_2O–Δ-[Co(ox)$(en)_2$]X–Λ-[Co(ox)$(en)_2$]X, where X stands for univalent anions such as (a) Cl^-, (b) I^-, (c) (*R,R*)-$C_4H_5O_6^-$, (d) Δ-[Co(edta)]$^-$, (e) $^1/_2[Sb_2\{(R,R)\text{-}C_4H_2O_6\}_2]^{2-}$ or (f) *d*-$C_{10}H_{14}OBrSO_3^-$. The monohydrate and tetrahydrate of the chloride (a) are spontaneously resolved,[3–5] but the iodide (b) forms a solid racemic compound.[4] Anions (c) and (d) represent the successful cases of optical resolution, and (e) and (f) the unsuccessful ones.

Experimental

Materials. *[Co(ox)$(en)_2$]I*: Racemic chloride monohydrate was prepared by the method of Dwyer *et al.*[6] and was optically resolved by two kinds of resolving agents: $(+)_{589}$-(*R,R*)-tartrate(1−) ion (abbreviated to *d*-$C_4H_5O_6^-$), which gave the $\Lambda(+)_{589}$ iodide through the less soluble diastereomer Λ-[Co(ox)$(en)_2$](*d*-$C_4H_5O_6)\cdot H_2O$,[7] and $\Delta(+)_{546}$-[Co(edta)]$^-$, which gave the $\Delta(-)_{589}$ iodide through the less soluble diastereomer Δ-[Co(ox)$(en)_2]\cdot\Delta$-[Co(edta)]$\cdot H_2O$. The $\Lambda(+)_{589}$ iodide showed $\Delta\varepsilon_{523}=+2.55$ (lit,[7] $\Delta\varepsilon_{520}=+2.64$), and the $\Delta(-)_{589}$ iodide −2.53.

[Co(ox)$(en)_2$]Cl·H_2O: The recemic complex was also prepared by the method of Dwyer *et al.* The $\Lambda(+)_{589}$ and $\Delta(-)_{589}$ isomers were obtained from the corresponding iodides by treating with AgCl; $\Delta\varepsilon_{523}=+2.57$ and −2.60, respectively.

[Co(ox)$(en)_2$](d-$C_4H_5O_6)\cdot nH_2O$: The Λ-complex salt monohydrate was obtained by the method of Jordan *et al.*,[7] and recrystallized from water; $\Delta\varepsilon_{523}=+2.60$ (lit,[7] $\Delta\varepsilon_{520}=+2.65$). Found: C, 27.46; H, 5.36; N, 12.89%. Calcd for Λ-[Co(ox)$(en)_2$](*d*-$C_4H_5O_6)\cdot H_2O$: C, 27.65; H, 5.35; N, 12.90%. The Δ-complex salt 2.5-hydrate was separated by the method of Froebe[8] from the filtrate from the Λ-complex diastereomer in the procedure of Jordan *et al.*[7] and purified by repeated recrystallizations from hot water; $\Delta\varepsilon_{523}=-2.67$, the yield was almost 1/10 of the corresponding Λ-complex diastereomer. Found: C, 26.20; H, 5.67; N, 11.95%. Calcd for Δ-[Co(ox)$(en)_2$](*d*-$C_4H_5O_6)\cdot 2.5H_2O$: C, 26.03; H. 5.69; N, 12.15%.

[Co(ox)$(en)_2]_2[Sb_2$(d-$C_4H_2O_6)_2]\cdot nH_2O$: The diastereomers were obtained by the reaction of an aqueous suspension (0.1 mol, 50 °C) of $\Lambda(+)_{589}$- or $\Delta(-)_{589}$-[Co(ox)$(en)_2$]I, or *rac*-[Co(ox)$(en)_2$]Cl·H_2O with freshly prepared silver antimony(III) $(+)_{589}$-tartrate, which was precipitated in advance from a cold aqueous solution of tatar emetic $K_2[Sb_2(d\text{-}C_4H_2O_6)_2]\cdot 3H_2O$ (0.05 mol) by adding the equivalent amount of silver nitrate solution. Recrystallization was carried out from warm water; $\Delta\varepsilon_{523}$ per the complex cation was +2.59, −2.48, and 0 for the Λ-, Δ-, and *rac*-complex diastereomers, respectively. Found: C, 19.82; H, 4.04; N, 9.58%. Calcd for Λ-[Co(ox)-$(en)_2]_2[Sb_2(d\text{-}C_4H_2O_6)_2]\cdot 6H_2O$: C, 20.39; H, 4.12; N, 9.51%. Found: C, 20.56; H, 3.85; N, 9.56%. Calcd for Δ-[Co(ox)-$(en)_2]_2[Sb_2(d\text{-}C_4H_2O_6)_2]\cdot 4H_2O$: C, 21.03; H, 3.89; N, 9.81%. Found: C, 20.21; H, 4.02; N, 9.76%. Calcd for *rac*-[Co-(ox)$(en)_2]_2[Sb_2(d\text{-}C_4H_2O_6)_2]\cdot 5H_2O$: C, 20.71; H, 4.00; N, 9.66%.

[Co(ox)$(en)_2$](d-$C_{10}H_{14}OBrSO_3)\cdot nH_2O$: Ammonium $(+)_{589}$-(1*R*,3*S*,4*S*,7*R*)-3-bromocamphor-9-sulfonate (the anion is abbreviated to *d*-$C_{10}H_{14}OBrSO_3^-$) was converted into silver salt by treatment with silver nitrate in a cold aqueous solution. The $\Lambda(+)_{589}$- or $\Delta(-)_{589}$-[Co(ox)$(en)_2$]I, or *rac*-[Co(ox)$(en)_2$]-Cl·H_2O was suspended in warm water and treated with Ag-(*d*-$C_{10}H_{14}OBrSO_3$). The diastereomers obtained were recrystallized from warm water; $\Delta\varepsilon_{523}=+2.54$, −2.58, and 0 for the Λ-, Δ-, and *rac*-complex diastereomers, respectively. Anal. Found: C, 31.56; H, 5.42; N, 9.83%. Calcd for Λ-[Co(ox)-$(en)_2]$(*d*-$C_{10}H_{14}OBrSO_3)\cdot H_2O$: C, 32.27; H, 5.43; N, 9.41%. Found: C, 30.74; H, 5.66; N, 9.01%. Calcd for Δ-[Co(ox)-$(en)_2]$(*d*-$C_{10}H_{14}OBrSO_3)\cdot 2.5H_2O$: C, 30.87; H, 5.68; N, 9.00%. Found: C, 32.00; H, 5.46; N, 9.52%. Calcd for *rac*-[Co(ox)$(en)_2]$(*d*-$C_{10}H_{14}OBrSO_3)\cdot H_2O$: C, 32.27, H, 5.43; N, 9.41%.

[Co(ox)$(en)_2]\cdot\Delta$-[Co(edta)]$\cdot nH_2O$: The less soluble diastereomer was obtained by the method of Dwyer *et al.*;[6] $[\alpha]_{589}=-550°$ (lit,[6] +550° for the enantiomer trihydrate). Found: C, 30.30; H, 4.77; N, 13.35%. Calcd for Δ-[Co-(ox)$(en)_2]\cdot\Delta$-[Co(edta)]$\cdot H_2O$: C, 30.39; H, 4.78; N, 13.29%.

The more soluble diastereomer was prepared from Λ-[Co-

$(ox)(en)_2]I$ and Δ-$Ag[Co(edta)]$, the latter being obtained by the method given by Maricondi and Douglas.[9] Recrystallization was carried out from warm water; $\Delta\varepsilon_{538}=+2.25$. Found: C, 28.42; H, 5.07; N, 12.53%. Calcd for Δ-$[Co(ox)(en)_2]\cdot\Delta$-$[Co(edta)]\cdot 3H_2O$: C, 28.75; H, 5.13; N, 12.57%.

Measurements. Mutual solubility of the Δ and Λ complex salts in water was measured at 25 °C as follows: A mixed aqueous solution of the Δ and Λ complex salts containing an excess of the solid complex salt(s) in a conical flask was stirred mechanically for about 2 h at 25 °C in a thermostat regulated within ±0.1 °C. After the resulting saturated solution had been left to stand for a while, a portion of the supernatant solution was sucked into a weighing bottle through a cotton plug and then weighed. This was diluted to a known volume, and its optical density and CD were measured at the wave lengths 497 and 523 nm, respectively, except for the case of X=Δ-$[Co(edta)]^-$. The optical density value is related to the total amount of enantiomers (or diastereomers) and the CD value the difference in amounts of Δ and Λ complexes, since no counter ions influence the absorption or CD spectra in the visible region regardless of whether they are optically active or not. Thus, the absorption and CD maximum values of the complex salts (Table 1) enable us to calculate the amounts of both Δ and Λ complexes separately.

In the case of X=Δ-$[Co(edta)]^-$, the total amount of diastereomers was calculated from the observed optical density at 524 nm, where the absorption maximum of $[Co(ox)(en)_2]$-$[Co(edta)]$ salt lies, and the difference in the amount of diastereomers from the observed CD at 538 nm, where the CD curve of Δ-$[Co(edta)]^-$ ion intersects the zero line; the complex salt has a value of $\Delta\varepsilon=\pm 2.25$ at this wavelength. The observed CD value at 561 nm, where the CD curve of Λ-$[Co(ox)(en)_2]\cdot\Delta$-$[Co(edta)]$ diastereomer intersects the zero line, was also used for calculation of the dissolved amount of the Δ-$[Co(ox)(en)_2]\cdot\Delta$-$[Co(edta)]$ diastereomer.

The solid phases were identified from the elemental analyses and measurements of CD or optical rotation (solvent: H_2O). The solubility of complexes in water at 5—60 °C (Table 2) was determined in the same way as previously reported.[4] Optical densities were measured with a Jasco UVIDEC-1 spectrophotometer, CD with a Jasco MOE-1 spectropolarimeter, and optical rotation with a Jasco DIP-4 digital polarimeter.

Results and Discussion

The ternary system data obtained are given in Table 3 and Figs. 1—6. In the triangular isotherms the top part (H_2O corner) is enlarged for the sake of convenience and the tie lines omitted.

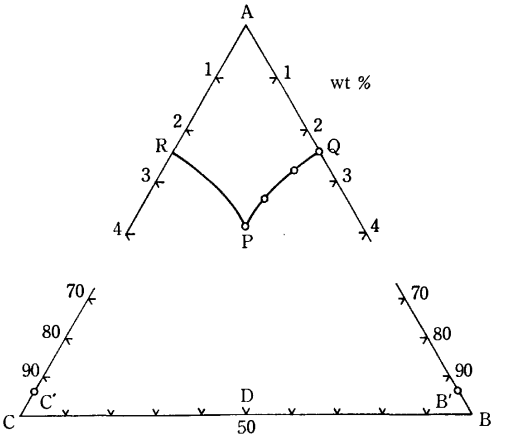

Fig. 1. Solubility isotherm of the ternary system H_2O-(A)-Δ-$[Co(ox)(en)_2]Cl$(B)-Λ-$[Co(ox)(en)_2]Cl$(C) at 25 °C. The solid phase B′ or C′ is monohydrate of B or C, respectively.

Spontaneous Resolution. *$[Co(ox)(en)_2]Cl$*: Figure 1 shows the ternary phase diagram at 25 °C for the system consisting of Δ and Λ isomers of chloride and water. One invariant point P is found. The triangular area PB′C′ represents the compositions consisting of Δ chloride monohydrate, Λ chloride monohydrate and a saturated solution of composition P, which is identical to a saturated solution of the racemic complex. This is the case of spontaneous resolution. The molar solubility in point P should be identical to or larger than $\sqrt{2}/2$ of that in point Q or R.[4]

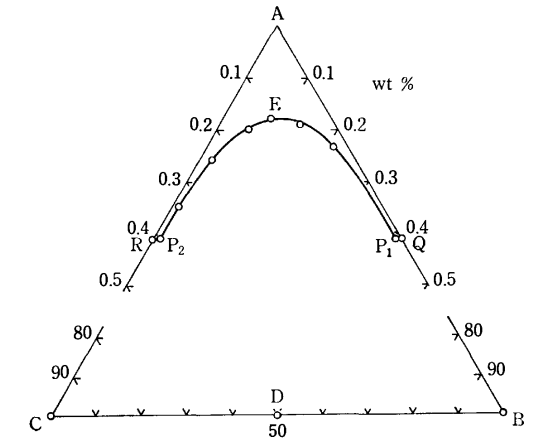

Fig. 2. Solubility isotherm of the ternary system H_2O-(A)-Δ-[Co(ox)$(en)_2$]I(B)-Λ-[Co(ox)$(en)_2$]I(C) at 25 °C.

Formation of Racemic Compound. [*Co(ox)(en)*$_2$]*I*: Figure 2 shows the case of Δ and Λ isomers of iodide and water. Two invariant points P_1 and P_2 appear, the curve P_1EP_2 representing the solubility of the racemic compound Δ-[Co(ox)$(en)_2$]I·Λ-[Co(ox)$(en)_2$]I (D). The solubility curve of the Δ or Λ complex, QP_1 or RP_2, is greatly suppressed in the diagram.

Optical Resolution by Solubility Difference between Diastereomers. [*Co(ox)(en)*$_2$]*X*(*X*=d-$C_4H_5O_6^-$ *and* Δ-[*Co(edta)*]$^-$): The optically active [Co(ox)$(en)_2$]$^+$ ion was first obtained by the substitution reaction[10] of optically active *cis*-[$CoCl_2(en)_2$]$^+$ with oxalate ion, or by preferential crystallization by seeding[11] some optically active complex salts into a concentrated aqueous solution of the racemic bromide [Co(ox)$(en)_2$]Br. The optical resolution through its diastereomer was first performed by Dwyer *et al.*[6] with the use of optically active [Co(edta)]$^-$ ion as the resolving agent. Later, Jordan *et al.*[7] reported a fine procedure of resolution through the $(+)_{589}$-tartrate(1—) diastereomer, [Co(ox)$(en)_2$]-(*d*-$C_4H_5O_6$).

Figure 3 shows the isotherm for the complex of X= *d*-$C_4H_5O_6^-$. Invariant point P appears near the right

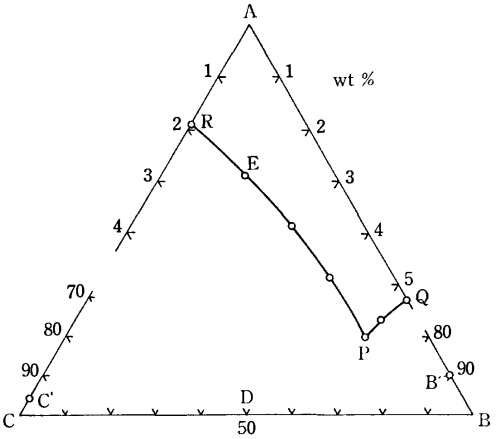

Fig. 3. Solubility isotherm of the ternary system H_2O-(A)-Δ-[Co(ox)$(en)_2$](*d*-$C_4H_5O_6$)(B)-Λ-[Co(ox)$(en)_2$](*d*-$C_4H_5O_6$) (C) at 25 °C. The solid phase B′ is 2.5 hydrate of B, and C′ monohydrate of C.

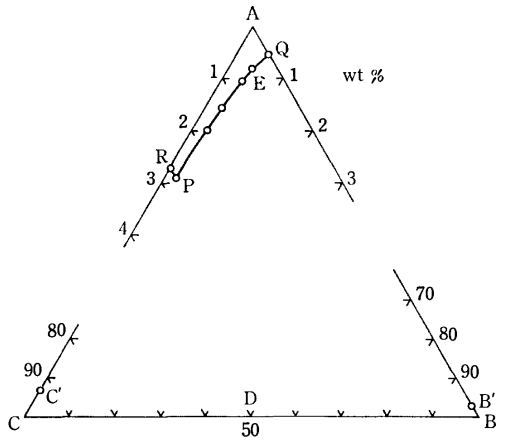

Fig. 4. Solubility isotherm of the ternary system H_2O-(A)-Δ-[Co(ox)(en)$_2$]·Δ-[Co(edta)](B)-Λ-[Co(ox)(en)$_2$]·Δ-[Co(edta)](C) at 25 °C. The solid phase B′ is monohydrate of B, and C′ 2.5 hydrate of C.

hand side. If an aqueous solution of equimolar mixture of the two diastereomers is concentrated at this temperature, the less soluble diastereomer Λ-[Co(ox)(en)$_2$](*d*-$C_4H_5O_6$)·H_2O would crystallize out first and the solution composition would change along the solubility curve EP. The solid phase consists of both the diastereomers at P. Figure 4 shows the case of X=Δ-[Co(edta)]$^-$, the invariant point P appearing near the left hand side. It is expected that the nearer the invariant point to the right or left hand side, the higher the relative yield of the less soluble diastereomer. The relative composition of the saturated solution at point P is Δ: Λ=3.75: 50 and 50: 10.6 for the X=Δ-[Co(edta)]$^-$ and X=*d*-$C_4H_5O_6^-$, respectively.

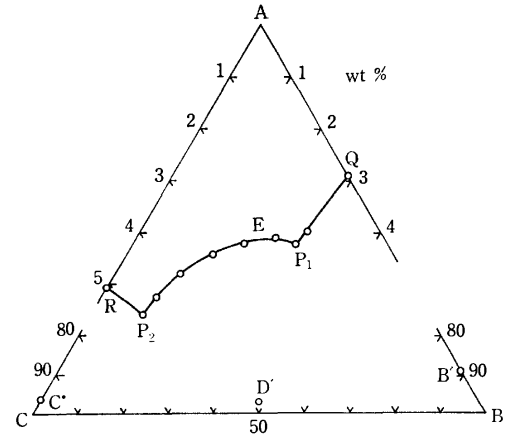

Fig. 5. Solubility isotherm of the ternary system H_2O-(A)-Δ-[Co(ox)(en)$_2$](*d*-$C_{10}H_{14}OBrSO_3$)(B)-Λ-[Co(ox)-(en)$_2$](*d*-$C_{10}H_{14}OBrSO_3$)(C) at 25 °C. The solid phase B′ is tetrahydrate of B, C′ monohydrate of C, and D′ *rac*-[Co(ox)(en)$_2$](*d*-$C_{10}H_{14}OBrSO_3$)·H_2O.

Optically Active Racemate Formed between Diastereomers. [*Co(ox)(en)*$_2$]*X* (*X*=$^1/_2$[*Sb*$_2$(d-$C_4H_2O_6$)$_2$]$^{2-}$ *and* d-$C_{10}H_{14}OBrSO_3^-$): Figure 5 shows the isotherm for the system consisting of Δ and Λ diastereomers of the $(+)_{589}$-(1*R*,3*S*,4*S*,7*R*)-3-bromocamphor-9-sulfonate salt and water. Two invariant points P_1 and P_2 appear, the curve P_1EP_2 representing the solubility of a new solid compound formed between the two diastereomers. This solid compound was isolated from the system and characterized by elemental analysis, visible and ultraviolet absorption, CD, ORD, and IR spectra. It was confirmed that the compound is an optically active racemate, Δ-[Co(ox)-(en)$_2$](*d*-$C_{10}H_{14}OBrSO_3$)·Λ-[Co(ox)(en)$_2$](*d*-$C_{10}H_{14}O$-$BrSO_3$)·$2H_2O$ = *rac*-[Co(ox)(en)$_2$](*d*-$C_{10}H_{14}OBrSO_3$)·H_2O. The same compound was obtained by treating *rac*-[Co(ox)(en)$_2$]Cl·H_2O with silver *d*-bromocamphorsulfonate (see Experimental). If an aqueous solution of this active racemate is concentrated at 25 °C, its composition would change along AE (Fig. 5) and the racemate monohydrate (D′) would crystallize out at point E. Thus the separation of Δ and Λ diastereomers by fractional crystallization is impossible, though the solubility of the two diastereomers in water differs greatly (Table 2).

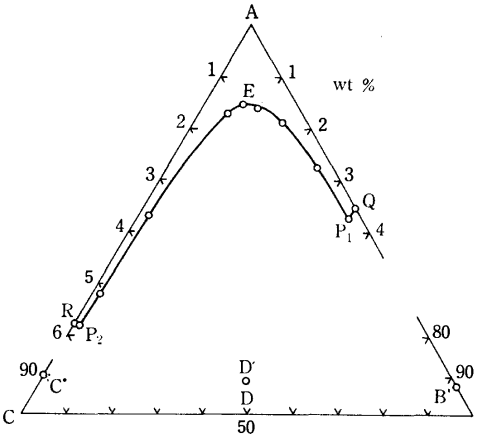

Fig. 6. Solubility isotherm of the ternary system H_2O-(A)-Δ-[Co(ox)(en)$_2$]$_2$[Sb$_2$(*d*-$C_4H_2O_6$)$_2$](B)-Λ-[Co(ox)-(en)$_2$]$_2$[Sb$_2$(*d*-$C_4H_2O_6$)$_2$](C) at 25 °C. The solid phase B′ is tetrahydrate of B, C′ hexahydrate of C, and D′ *rac*-[Co(ox)(en)$_2$]$_2$[Sb$_2$(*d*-$C_4H_2O_6$)$_2$]·$5H_2O$.

Figure 6 shows the case of X=$^1/_2$[Sb$_2$(*d*-$C_4H_2O_6$)$_2$]$^{2-}$. Here, the solubility curve of the active racemate is spread over a wide region and those of the pure Δ and Λ diastereomers are much suppressed. The racemate has the composition Δ-[Co(ox)(en)$_2$]·Λ-[Co(ox)(en)$_2$]·[Sb$_2$(*d*-$C_4H_2O_6$)$_2$]·$5H_2O$=*rac*-[Co(ox)(en)$_2$]$_2$[Sb$_2$(*d*-$C_4H_2O_6$)$_2$]·$5H_2O$.

It is generally thought that the so-called inadequate resolving agent is the one which gives a pair of diastereomers with a smaller difference in solubility. The present solubility data, however, show that the formation of an optically active racemate is also an important cause for unsuccessful optical resolution. A few such active racemates have been reported: a *d*-tartrate(2−) racemate, *rac*-[Co(en)$_2$(1,10-phenanthroline)]$_2$(*d*-$C_4H_4O_6$)$_3$·$9H_2O$, which has been named by Jaeger[12] a "partial racemoid."

Temperature Dependence of Solubility in Water. Table 2 shows temperature dependence of solubility of the [Co(ox)(en)$_2$]$^+$ salts containing optically active counter ions in water. Most of the salts show a temperature dependence similar to that of the halide salts.[4] Thus the solubility at 25 and 60 °C is 1.5—2 and 3—5 times larger than that at 5 °C, respectively. An exceptional

case is found in Λ-[Co(ox)$(en)_2$]·Δ-[Co(edta)]·2.5H_2O, its solubility at 60 °C being about 9 times greater than that at 5 °C. The solubility difference between the Δ and Λ diastereomers of Δ-[Co(edta)]$^-$ salt becomes very large at higher temperatures.

The solubility curve of Δ-[Co(ox)$(en)_2$](d-$C_{10}H_{14}OBrSO_3$) has an inflection point at about 35 °C, where the solid phase changes from 4-hydrate (below 35 °C) to 2.5-hydrate (above 35 °C). However, no such inflection was found in the corresponding Λ diastereomer or the active racemate. The solid phases of both salts consist of the monohydrate in 5—60 °C.

Kinetic Studies of the Inversion of η^2-*trans*-2-Butene in Platinum(II) Complexes Containing Various Amino Carboxylates

Yoshiro TERAI, Hiroaki KIDO, Kazuo KASHIWABARA,* Junnosuke FUJITA,* and Kazuo SAITO

Chemistry Department, Faculty of Science, Tohoku University, Sendai 980

(Received August 9, 1976)

Platinum(II) complexes containing *S,S*- or *R,R*-*trans*-2-butene and various L-amino carboxylate, *i.e.* *cis*(*N*, olefin)[PtCl (L-prolinate)(*S,S*-*trans*-2-butene)] and *trans*(*N*,olefin)[PtCl (L-am)(*S,S*- or *R,R*-*trans*-2-butene)], were synthesized (L-am=L-prolinate, *N*-methyl-L-prolinate, *N*-benzyl-L-prolinate, L-alaninate and L-valinate). The kinetics of the inversion reaction of the coordinated *S,S*- or *R,R*-*trans*-2-butene was investigated in acetone in the presence of an excess of *trans*-2-butene at 8.0 °C. Second order rate law was obeyed with respect to the concentrations of the complex and free olefin, and no solvent path was observed. In the *trans*(*N*,olefin) complexes, interactions steric around the coordinated nitrogen atoms seems to be responsible in determining the ease of inversion *via* an associative mechanism. On the other hand, smaller rate for the *cis*(*N*,olefin) complex than the corresponding trans isomer seems to be due to the trans effect.

The substitution reaction of various olefins for the η^2-*trans*-2-butene in [PtCl(L-pro)(*S,S*-*trans*-2-butene)] (L-pro=L-prolinate) in acetone gave a variety of rate and activation entropy,[1,2] and we pointed out the importance of the steric effect between the nucleophilic olefin and the coordinated amino carboxylate and/or olefin.[1] This paper deals with further kinetic studies of the exchange of *trans*-2-butene with inversion of configuration by use of *cis*(*N*,olefin)[PtCl(L-pro)(*S,S*-*trans*-2-butene)] and various *trans*(*N*,olefin)[PtCl(L-am)(*S,S*- or *R,R*-*trans*-2-butene)] in acetone, where L-am stands for various amino carboxylates, *i.e.* L-prolinate, *N*-methyl-L-prolinate (*N*-Me-L-pro), *N*-benzyl-L-prolinate (*N*-Bz-L-pro), L-alaninate (L-ala), and L-valinate (L-val).

Experimental

Materials. *N*-Methyl- and *N*-benzyl-L-proline were prepared from L-proline.[3] Guaranteed grade L-proline, L-alanine and L-valine and pure grade *trans*-2-butene (Nihon Tokushu Gas Co.) were used without further purification.

Preparation of the Complexes: The *trans*(*N*, olefin) complexes, *trans*(*N*, olefin)[PtCl(L-am)(olefin)] (olefin=ethylene and *trans*-2-butene) were synthesized by the reported methods.[4] The cis complex *cis*(*N*, olefin)[PtCl(L-pro)(C_2H_4)] was prepared by a new method with tin(II) chloride as a catalyst. Three mol dm^{-3} hydrochloric acid (15 cm^3) and K[$PtCl_2$(L-pro)](2 g)[5] were sealed in a 50 cm^3 flask with a rubber stopper, and nitrogen was bubbled for 30 min. A suspension of *ca.* 30 mg tin(II) chloride dihydrate in deoxygenated water (2—3 cm^3) was added with a syringe and ethylene was bubbled slowly with a vigorous stirring. Colorless crystals precipitated within 20 min. After 30 min the flask was cooled by ice, and the precipitate was filtered off, washed with water, air-dried at room temperature, and recrystallized from *N,N*-dimethylformamide (DMF) or acetonitrile (AN). Yield *ca.* 67%.
cis(*N*, olefin)[PtCl(L-pro)(*trans*-2-butene)] was obtained by replacing the coordinated ethylene by *trans*-2-butene in AN, and recrystallized from AN by adding diethyl ether.

All the *trans*-2-butene complexes were resolved by repeated fractional recrystallization until the CD spectra remained unchanged in a mixture of acetone and petroleum ether (trans complex) or of AN and diethyl ether (cis complex).

Identification of Geometrical Isomers: Elemental analysis of carbon, hydrogen, and nitrogen of all the new complexes agreed with the calculated values as shown in Table 1. It was claimed that the *trans*(*N*, olefin) complexes are pale-yellow and *cis*(*N*, olefin) complexes are colorless.[4] The present new complexes seem to obey this empirical rule, when the geometrical isomerism of the prepared complexes is assigned on the basis of the route of synthesis (for the formation of the cis complexes *vide infra*). The pale-yellow and colorless [PtCl(L-pro)(*trans*-2-butene)] gave IR absorption at 350 and 340 cm^{-1}, respectively, which can be assigned to Pt-Cl stretching vibration. This correspondence is also in accord with the empirical rule.[4] The trans complexes are soluble in acetone, AN, and DMF, whereas the cis complexes are very sparingly soluble in acetone and AN and soluble in DMF. Thus the geometrical

TABLE 1. ANALYTICAL DATA OF THE NEW COMPLEXES, *trans*(*N*, olefin) [PtCl(L-am)(olefin)]

* Present Address: Department of Chemistry, Faculty of Science, Nagoya University, Nagoya 464.

isomers can be distinguished by the color of crystals, synthetic route, IR absorption, and solubility.

Kinetic Runs. The decrease in CD strength of the complexes with time was recorded in acetone by the following method. The complexes were dissolved in acetone to give *ca.* 10^{-3} mol dm^{-3} solution, cooled and mixed with cold *trans*-2-butene in acetone (10^{-2} to 1 mol dm^{-3}). The solution was placed in a cell box of a spectrometer, which had been cooled to 8.0±0.3 °C, and the decrease in CD strength at the CD peak (360—385 nm) was continuously recorded. The rate of decrease obeyed the first order kinetic law and the observed rate constant k_{obsd} is expressed by Eq. 1.

$$k_{obsd} = -\ln[(\alpha_t-\alpha_\infty)/(\alpha_0-\alpha_\infty)]/t \quad (1)$$

Where α's are the CD strength at the time denoted by the suffices. The concentrations of the complex and free olefin at 8.0 °C were calculated by taking the density of acetone into consideration.

Measurements. The CD spectra were recorded with a JASCO Model ORD/UV-5 Spectrometer with CD attachment. Visible and UV spectra and IR spectra were recorded with a Hitachi 323 and a JASCO DS-403 G, respectively, A Komatsu-Yamato Coolnics thermostat was used for keeping the temperature at 8.0 °C.

Results and Discussion

Preparation of cis(N,*olefin*)[*PtCl*(L-*pro*)(trans-*2-butene*)]. *cis*(*N*, olefin)-complexes of platinum(II) containing prochiral olefin have been known only for the type [$PtCl_2$(*S*- or *R*-α-methylbenzylamine)(*S,S*- or *R,R*-*trans*-2-butene)].[6] We have succeeded in preparing *cis*(*N*, olefin)[PtCl(L-pro)(*trans*-2-butene)] by the substitution of *trans*-2-butene for the ethylene in *cis*(*N*,olefin)[PtCl(L-pro)(C_2H_4)] in AN. Several *cis*(*N*,olefin)[PtCl(am)-(C_2H_4)] had been prepared by the reaction of amino carboxylate with $[PtCl_4]^{2-}$ followed by the action of concentrated hydrochloric acid and ethylene in aqueous solution. However, the corresponding L-prolinate complex was not obtained by this method.[4]

We have found that tin(II) chloride was a useful catalyst for the synthesis of *cis*(*N*,olefin)[PtCl(L-pro)-(C_2H_4)]. Belluco *et al.* studied the mechanism of the catalytic action of tin(II) chloride in the substitution of aquo-soluble olefins for the chloride in $[PtCl_4]^{2-}$ in hydrochloric acid.[7] They considered the formation of some reactive intermediates containing $SnCl_3^-$ ligand. In the present synthesis, $[PtCl_3$(L-proH)$]^-$ (L-proH is coordinated as a unidentate on nitrogen) may have been formed from $[PtCl_2$(L-pro)$]^-$,[5] and reacted with tin(II) chloride in deoxygenated concentrated hydrochloric acid solution, to give *cis*-$[PtCl_2$(L-proH)(C_2H_4)$]^-$ *via* similar intermediates containing $SnCl_3^-$. This *cis* complex must be in equilibrium with *cis*(*N*,olefin)-[PtCl(L-pro)(C_2H_4)] in aqueous solution and the less soluble latter complex was precipitated as colorless crystals. The corresponding L-alaninato complex *cis*(*N*, olefin)[PtCl(L-ala)(C_2H_4)] was not obtained by this method, presumably because of its solubility in aqueous solution.

UV Absorption and CD Spectra. Spectral data of UV absorption of all the trans complexes give d-d transition absorption around 25000 cm^{-1}, whereas the cis complexes at *ca.* 28000 cm^{-1} (Table 2). The CD maxima of all the trans complexes in this region are 26.0—27.0×10^3 cm^{-1}, and that of the cis complex is at 27.8×10^3 cm^{-1}. The diastereoisomers with plus CD in this region are assigned to *S,S*- and those with minus CD to *R,R*-configuration of coordinated *trans*-2-butene, in accordance with Scott and Wrixon's empirical rule.[8]

Table 2. The UV absorption spectral data of *trans*- and *cis*(*N*, olefin) [PtCl(L-am)(olefin)] in ethanol

	Olefin	Absorption maxima/10^3 cm^{-1} (logε)		
trans-Complex	C_2H_4	*ca.* 25* (1.6—1.8)	*ca.* 33.5 (≈3)	37—38 (3.2—3.3)
	trans-2-Butene	*ca.* 25* (1.5)	35—36* (≈3)	*ca.* 39* (3.1—3.3)
cis-Complex	C_2H_4	*ca.* 28* (1.5)	*ca.* 35* (2.9)	*ca.* 38 (3.3)
	trans-2-Butene	*ca.* 28* (1.5)	*ca.* 33.5* (2.4)	*ca.* 39* (3.3)

* shoulder

Table 3. The Δε values of CD maxima in d-d region of the completely resolved *trans* (*N*, olefin)[PtCl(L-am)(*S,S*- or *R,R*-*trans*-2-butene)] and that of the corresponding ethylene complexes in ethanol

L-am	ν (CD max) 10^{3}cm^{-1}	Δε(C_4H_8) (a,c)	Δε(C_2H_4) (b,c)	δΔε[d]	C_4H_8[e]
L-ala	27.0	+1.13	0	+1.13	*S,S*
L-val	26.7	−1.0	0	−1.0	*R,R*
L-pro	27.0	+1.05	−0.05	+1.10	*S,S*
N-Me-L-pro	26.3	−1.06	+0.02	−1.08	*R,R*
N-Bz-L-pro	26.0	+1.00	−0.19	+1.19	*S,S*
L-pro[f]	27.8	+1.14	+0.12	+1.02	*S,S*

a) Δε value of the *trans*-2-butene complex b) Δε value of the ethylene complex, c) at the CD maxima of the *trans*-2-butene complexes at *ca.* 27000 cm^{-1}, d) Δε (*trans*-2-butene complex)-Δε(C_2H_4 complex), e) absolute configuration of coordinated *trans*-2-butene, f) *cis* (*N*, olefin)[PtCl(L-pro)(olefin)].

Table 3 gives the CD strength of all the completely resolved complexes at the peak of the *trans*-2-butene complexes in the d-d transition band region. These complexes are the diastereoisomers first crystallized on fractional crystallization. It also shows the difference in CD strength between the *trans*-2-butene- and the ethylene complexes at the wave length mentioned above. The δΔε is almost equal for all the complexes, suggesting that the contribution of asymmetrically coordinated *trans*-2-butene to the CD strength is not affected by the variety of the coordinated amino carboxylates.

Kinetics of the Inversion of trans-*2-Butene.* When *trans*-2-butene was added to the *trans*- and *cis*(*N*,olefin)-[PtCl(L-am)(*S,S*- or *R,R*-*trans*-2-butene)] complexes in acetone at 8.0 °C, the UV absorption remained unchanged for at least two days, whereas the CD strength at the peak in 360—385 nm region decreased obeying Eq. 1. This reaction should be the substitution with inversion of *trans*-2-butene ligand, *i.e.* the epimerization of the complex on the substitution.

The k_{obs} increased linearly with increase in free *trans*-2-butene concentration to give Eq. 2.

$$k_{obsd} = k_2[\textit{trans}\text{-2-butene}] \quad (2)$$

The k_2 is related to the rate constant of the inversion reaction, k_2^{inv}, by the relation $k_2=2k_2^{inv}$. However, the k_2 values are used in the following discussion. By use of *cis*-2-butene in place of *trans*-2-butene as nucleophile the same relation holds. Absence of intercept on the k_{obsd} *vs.* free ligand concentration diagram indicates no participation of the solvent molecule in the rate determining process.

trans(N,*olefin*) *Complexes*: The second order rate constant decreases in the following sequence as the amino carboxylate was changed. (Table 4).

TABLE 4. RATE CONSTANTS OF THE EPIMERIZATION REACTION OF *trans*(*N*, olefin)[PtCl(L-am)(*S,S*- or *R,R-trans*-2-butene)] IN ACETONE AT 8.0 °C

L-am	Config.[a]	Added olefin	$k_2/10^{-3}$ s^{-1} mol^{-1} dm^3
L-ala	*S,S*	*trans*-2-Butene	30 ± 3
L-val	*R,R*	*trans*-2-Butene	39 ± 4
L-pro	*S,S*	*trans*-2-Butene	9.7 ± 0.6[b,c]
L-pro	*R,R*	*trans*-2-Butene	7.6 ± 0.3
L-pro	*S,S*	*cis*-2-Butene	350 ±13[b,d]
N-Me-L-pro	*R,R*	*trans*-2-Butene	0.54± 0.01
N-Me-L-pro	*R,R*	*cis*-2-Butene	26 ± 5[d]
N-Bz-L-pro	*R,R*	*trans*-2-Butene	<0.01
L-pro[e]	*S,S*	*trans*-2-Butene	<0.3

a) Configuration of coordinated *trans*-2-butene. b) Ref. 1. c) The datum was obtained by the different method (see Ref. 1). d) The rate is not epimerization, but substitution rate. e) *cis*(*N*, olefin)[PtCl(L-pro)(*S,S-trans*-2-butene)].

$$\text{L-val, L-ala} > \text{L-pro} > \textit{N}\text{-Me-L-pro} > \textit{N}\text{-Bz-L-pro} \quad (3)$$

No appreciable difference is seen between the rate for the L-alaninato and L-valinato complex, indicating little influence of the substituents on the asymmetric carbon atoms. Hence, the discussion is to be made among complexes containing various substituents on the coordinated nitrogen atom.

The difference among k_2 values can be interpreted either by the electronic or the steric effect brought about by the amino carboxylates. The most important electronic effect affecting the rate of substitution reaction around square planar complexes is the trans effect. Various factors can give influence upon this effect, but the basicity of the nitrogen atom should be looked upon as predominating in the present complexes. L-Proline has larger pK_a (10.64 at 25 °C) than L-alanine and L-valine (9.64 and 9.72, respectively), and the L-prolinato complex gives much smaller k_2 than the L-alaninato- and L-valinato complexes do. On the other hand, *N*-methyl-L-proline can be expected to be more basic than *N*-benzyl-L-proline (because pK_a of methylamine and benzylamine are 10.68 and *ca.* 9.6, respectively at 25 °C), but the k_2 value of *N*-methyl-L-prolinato complex is larger than that of *N*-benzyl-L-prolinato complex. Thus no regular relationship is observed between the basicity of the amino nitrogen and the second order rate constant, suggesting that the electronic effect is not very important in determining the ease of inversion of *trans*-2-butene.

Parametrization of steric effect is far more difficult. We will use the overall bulkiness of ligands around the platinum(II) ion as influencing the ease of formation of the transition state with coordination number 5 containing two moles of *trans*-2-butene. The k_2 values do not differ much by use of a pair of diastereomers containing *R,R*- and *S,S-trans*-2-butene. Thus, our tentative representation of the overall bulkiness by molecular model studies would not be very inappropriate. Studies with molecular models indicate that the bulkiness of the coordinated amino carboxylate around the platinum(II) ion increases in the sequence of Fig. 1. This sequence is equal to the sequence (3). Thus, presence of bulky substituents on the nitrogen atom may hinder the formation of the transition state with coordination number 5, to result in slower substitution of the olefin.

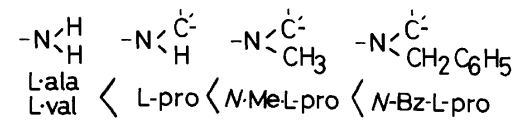

Fig. 1. Sequence of the bulkiness of the coordinated amino nitrogen.

Moreover, Table 4 includes the rate of substitution of *cis*-2-butene for the coordinated *trans*-2-butene. *cis*-2-Butene is not prochiral and its substitution always brings about decrease in CD strength,[1] so that the rate indicates the ease of substitution. When the L-prolinato and the *N*-methyl-L-prolinato complexes are compared, the ratio of their k_2 values is almost equal for both the substitution of *cis*-2-butene and the inversion of *trans*-2-butene. This fact suggests that the bulkiness of the coordinated amino carboxylate affects the rate of the substitution of *cis*-2-butene in a similar manner.

cis(N,*olefin*) *Complex*: Studies with molecular models suggest no significant difference in overall bulkiness around the platinum(II) ion between the *cis*(*N*,olefin)- and the *trans*(*N*,olefin)-L-prolinato complexes. On the other hand, a significant difference in electronic effect is expected, since the pK_a value of the carboxylate oxygen (1.99 at 25 °C) is far smaller than that of the nitrogen (*loc. cit.*). Such a difference is reflected in the frequency of Pt–Cl streching vibration; *i.e.* the *cis*(*N*,-olefin) complex with nitrogen trans to chloride gives an IR absorption peak at 340 cm^{-1}, whereas *trans*(*N*,olefin) with the oxygen trans to chloride at 350 cm^{-1}. Thus a basic ligand at the trans position seems to make the Pt–Cl bond loose. The nature of metal–ligand bond between Pt(II) and η^2-olefin should be significantly different from that between Pt(II) and chloride. However, the ease of exchange of olefins in [PtCl(L-am)(olefin)] seems to be mainly governed by the strength of σ-bond between Pt(II) and olefin.[2] *trans*-2-Butene–Pt(II) bond can be made loose by the trans influence of basic nitrogen in the *trans*(*N*,olefin) complex, so that the k_2 value becomes greater than that of the *cis*(*N*,olefin) complex.

The authors' thanks are due to the Takeda Science Foundation for financial support.

Studies on Mixed Chelates. VII. Mixed Nickel(II) Chelates Containing *N,N'*- or *N,N*-Dialkylethylenediamines and Acetylacetone

NGUYEN Thi Nga, Yutaka FUKUDA, and Kozo SONE

Department of Chemistry, Faculty of Science, Ochanomizu University, Otsuka, Bunkyo-ku, Tokyo 112

(Received August 19, 1976)

Twelve mixed nickel(II) chelates with *N,N'*- or *N,N*-dimethyl (or diethyl)ethylenediamines and acetylacetonate ion (acac) were prepared, and their properties were compared with those of the similar chelates with *N,N,N',N'*-tetramethyl(or tetraethyl)ethylenediamine. With the decrease of the number and bulkiness of the *N*-alkyl groups in the diamine, the tendency of forming 6-coordinated mixed chelates remarkably increases. The chelates of the type [Ni(diamine)(acac)]X, formed when X is $B(Ph)_4$, which are essentially similar to the corresponding chelates with *N,N,N',N'*-tetraalkylethylenediamines, but more apt to combine with solvent molecules and to go over into 6-coordinated structures than the latter.

In the previous papers,[1,2] the authors reported that *N,N,N',N'*-tetramethylethylenediamine (tmen) and various β-diketonate ions form two kinds of nickel(II) chelates, *i.e.*, the blue, 6-coordinate, high-spin $[Ni(tmen)(\beta\text{-dik})(OH_2)_2]ClO_4$, $[Ni(tmen)((\beta\text{-dik})NO_3]$ and $[Ni(tmen)(\beta\text{-dik})_2]$ and red, planar 4-coordinate, low-spin $[Ni(tmen)(\beta\text{-dik})]ClO_4$ and $[Ni(tmen)(\beta\text{-dik})]B(Ph)_4$, and an equilibrium is established in organic solutions of the latter chelates:

$$\underset{\text{Red}}{[Ni(tmen)(\beta\text{-dik})]^+} + 2Solv. \rightleftarrows \underset{\text{Blue}}{[Ni(tmen)(\beta\text{-dik})(Solv.)_2]^+}$$

(Solv.=solvent molecule). They also studied the chelates containing *N,N,N',N'*-tetraethylethylenediamine (teen) instead of tmen and found generally similar results, but here the planar chelates are more reluctant to go over into 6-coordinate structures, owing to the increased steric hindrance of the larger N-alkyl groups.

In this paper the authors will report on the preparation and properties of similar mixed chelates containing *N,N'*-dimethyl, *N,N*-dimethyl, *N,N'*-diethyl, and *N,N*-diethylethylenediamines (abbreviated as sym-dmen, unsym-dmen, sym-deen and unsym-deen,[3] respectively) and acetylacetonate ion (acac).

Experimental

Preparation of the Chelates. Chelates of the Type [Ni(diamine)(acac)$_2$] (No. I—No. IV in Table 1): To an aqueous solution of $Ni(ClO_4)_2 \cdot 6H_2O$ (10 mmol), acetylacetone (20 mmol) and an aqueous solution of Na_2CO_3 (5 mmol) are added with stirring. The precipitate formed is dissolved in methanol, and dmen or deen (10 mmol) is added. A blue solution is obtained, from which blue crystals separate out upon concentration and standing. They are recrystallized from 1,2-dichloroethane.

The sym-dmen and sym-deen chelates prepared in this way contain one molecule of crystal water, but the unsym-dmen and unsym-deen chelates are anhydrous.

Chelates of the Type [Ni(diamine)$_2$(acac)]ClO$_4$ (No. V—No. VIII): To a methanolic solution of $Ni(ClO_4)_2 \cdot 6H_2O$ (10 mmol), acetylacetone (10 mmol), Na_2CO_3 (5 mmol), and dmen or deen (10 mmol) are added in succession. The blue solution is filtered, concentrated and let stand, until crystals separate out, which are recrystallized from 1,2-dichloroethane.

Chelates of the Type [Ni(diamine)(acac)]B(Ph)$_4$ (No. IX—No. XII): To a methanolic solution of $Ni(NO_3)_2 \cdot 6H_2O$ (10 mmol), acetylacetone (10 mmol), Na_2CO_3 (5 mmol) and sym- or unsym-dmen (10 mmol) are added with stirring in succession. The blue solution is evaporated to driness, and the residue is dissolved in 1,2-dichloroethane and filtered. To this solution, which is expected to contain $[Ni(dmen)(acac)NO_3]$ (*cf.* the preparations of $[Ni(tmen)(acac)NO_3]$ and $[Ni(teen)(acac)NO_3]$ reported before[1,2]), $NaB(Ph)_4$ (14 mmol) is added. A red solution is obtained, which is filtered, concentrated and let stand, until red crystals separate out, which are recrystallized from 1,2-dichloroethane.

The chelates with sym- and unsym-deen are more difficult to prepare. Their 1,2-dichloroethane solutions can be obtained in the same way, but they become syrupy upon concentration. Precipitating with diethyl ether, powder-like mixed chelates can be obtained from them.

Physical Measurements. The methods and instruments used in this study were the same as those in the previous studies of this series.[1,2]

Results and Discussion

The formulas, colors, compositions, and effective magnetic moments of the obtained chelates are shown in Table 1. It is clear that the blue chelates, No. I—No. VIII, are all high-spin, and the red ones, No. IX—No. XII, are all low-spin, and each of them should be formulated as shown. The small magnetic moments of the red chelates are probably due to impurities, since all of them were rather difficult to prepare and purify, and may contain small amounts of high spin chelates.

Formation and Preparation of the Chelates. Although it was tried to get all kinds of mixed chelates corresponding to those obtained before,[1,2] it was found that, with the four dialkyl diamines used in this study, the formation of the chelate species $[Ni(diamine)(acac)_2]$ and $[Ni(diamine)_2(acac)]^+$, *i.e.*, blue, 6-coordinate, high-spin chelates containing three typical chelating ligands, seems to be strongly favored in the reaction mixtures, even when their compositions differ considerably from those of such chelates (*cf.* Experimental), so that only these chelates (the latter in the form of the perchlorates) could be obtained readily in crystalline state. Only in the case where the counter anion is tetraphenylborate, red, planar 4-coordinate and low-spin chelates $[Ni(diamine)(acac)]B(Ph)_4$ were obtained with some

TABLE 1. COLORS, COMPOSITIONS[a], AND MAGNETIC MOMENTS OF THE CHELATES OBTAINED

No.	Chelate	Color	C%	H%	N%	μ_{eff}(B.M.)

a) Calculated values in parentheses.

difficulty.*

It may be noted that the chelates of the type [Ni(diamine)$_2$(acac)]X can be prepared with dmen's and deen's but not with tmen and teen, while those of the type [Ni(diamine)(acac)$_2$] can be prepared with any of these diamines. This is undoubtedly due to the fact that the stability of a former type chelate depends critically on the magnitude of the large steric repulsion between two bulky diamines in it, while that of a latter type chelate does not depend so strongly on the bulkiness of the diamine since acac is a ligand of much smaller steric requirement.

Electronic Spectra. As in the case of the tmen and teen chelates, all these chelates are soluble in most organic solvents. The ν_{max} and ε_{max} values in the electronic spectra of such solutions, and the ν_{max} values in the reflection spectra of the solid chelates, are summarized in Tables 2 and 3.

The features of these spectra are in general very similar to those of the tmen- and teen-containing chelates.[1,2] All the high-spin chelates show two weak bands in the visible and near infrared regions, which move only little in going from the solid to the solutions

			15.72[b](16.1)	16.23(7.1)	16.29(7.6)
	20.70	20.62(122)	20.92 (36.0)	20.88 sh	

a) In parentheses. b) These very low values may be taken as an indication for the large interligand repulsion in the chelate [Ni(unsym-deen)(acac)(acetone)$_2$] which weakens the Ni–acetone bonds so much.

* The possibility that the chelates X and XII with unsym-diamines are, in fact, Schiff base chelates, *e.g.*, [Ni{NR_2-$(CH_2)_2$N=C(CH_3)CHCOCH_3}(OH_2)]$B(Ph)_4$ with the same compositions as the mixed chelates, can be ruled out, because the NMR spectra of these chelates are clearly in support of the mixed chelate formulation.[4]

in various solvents.** This fact shows that the structures of these 6-coordinate chelates are stable enough in solution and not influenced sensitively by the solvents used.

Comparison of the spectra in 1,2-dichloroethane, in which the interaction with the solutes will be the least, shows that, in each of the two series of the 6-coordinate chelates, the ν_{max} of the two bands decrease in the order (1) of the diamines:

$$\text{sym-dmen} > \text{sym-deen} \gtrsim \text{unsym-dmen} > \text{unsym-deen} \quad (1)$$

indicating that the ligand field strength (l.f.s.) in these chelates also decreases in this order. It may also be noted that, among the chelates of the type $[Ni(diamine)_2(acac)]X$, the decrease in ν_{max} is quite large (10590 cm^{-1} to 8420 cm^{-1} in ν_1, which is a direct measure of 10Dq), while among those of the type $[Ni(diamine)(acac)_2]$ it is much smaller (10000 to 9620 in ν_1), showing that the l.f.s in a former type chelate is much more sensitive to the steric change of its diamine than that in a latter type one, in comformity with the view on their ease of formation mentioned above.

On the other hand, the spectra of the red, 4-coordinate and low-spin chelates are influenced strongly by the solvent, but the mode of the spectral change observed is essentially the same as that observed among the corresponding chelates of tmen or teen, indicating that here again the equilibrium

$$\underset{\text{I}}{[Ni(diamine)(acac)]^+} + 2Solv. \rightleftarrows \underset{\text{II}}{[Ni(diamine)(acac)(Solv.)_2]^+}$$

is established in solution, which is shifted from the left hand side to the right as follows (Figs. 1 and 2):

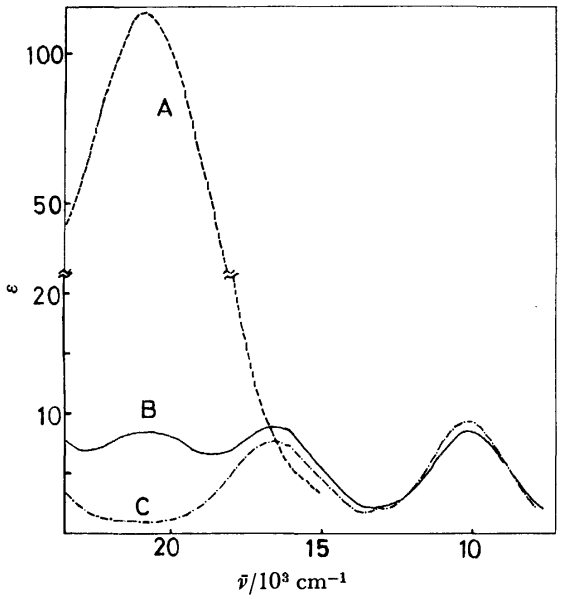

Fig. 1. Electronic spectra of the chelate IX in three solvents.
A: 1,2-Dichloroethane; B: acetone; C: DMF.

** The solid reflection spectra could be measured only up to 700 nm so that the first band is lacking in them.

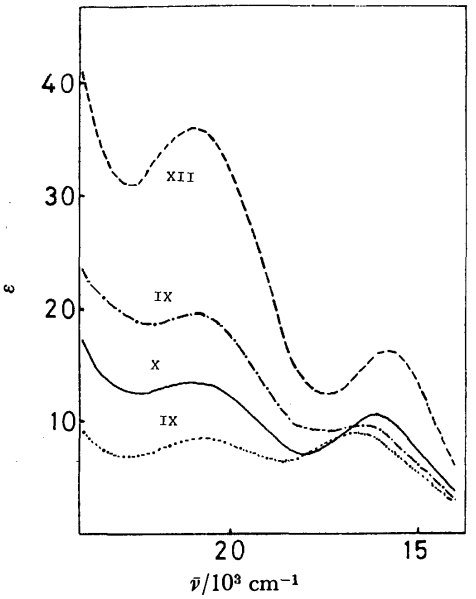

Fig. 2. Comparison of the electronic spectra of the chelates IX—XII in acetone.

TABLE 4. PERCENTAGES OF $[Ni(diamine)(acac)]^+$, REMAINING UNSOLVATED IN THE EQUILIBRIUM MIXTURES PRODUCED BY DISSOLVING THE CHELATES IX—XII AND THEIR tmen- AND teen- CONTAINING ANALOGUES IN ACETONE

IX	7.5%	$[Ni(tmen)(acac)]B(Ph)_4$ [a]	21%
X	11.0	$[Ni(teen)(acac)]B(Ph)_4$ [a]	82
XI	18.0		
XII	30.4		

a) *Cf.* Ref. 2.

$$\underset{\approx 100\%\ \text{I}}{\text{1,2-dichloroethane}} \longrightarrow \underbrace{\text{Acetone} \longrightarrow \text{Ethanol}}_{\text{I+II}} \longrightarrow \underset{\approx 100\%\ \text{II}}{\text{DMF}}$$

Increase in II (dearease in I) $\longrightarrow$

As in the case of the teen chelates,[2] it is possible to calculate the percentages of I in the equilibrium mixtures. From the data in Fig. 1, the values in Table 4 are obtained. The values for the corresponding tmen and teen chelates are also shown. It can be seen that the tendencies of these chelates to combine with solvent molecules and to go over into 6-coordinate structures decrease in the order:

$$\text{sym-dmen} > \text{unsym-dmen} > \text{sym-deen} \approx \text{tmen} > \text{unsym-deen} \gg \text{teen} \quad (2)$$

It is interesting to note that this order (2) is nearly the same as the order (1) of the decreasing l.f.s. in octahedral chelates.*** The relative positions of tmen and teen in the order (1), which can be found by comparing the data of the chelates of the type $[Ni(diamine)(acac)_2]$ with those of $[Ni(tmen)(acac)_2]$ and $[Ni(teen)(acac)_2]$,[1,2] are also nearly the same as their positions in the order (2), except that tmen lies between teen and unsym-deen.

*** In fact, there is also a slight shift of ν_{max} values of the planar $[Ni(diamine)(acac)]B(Ph)_4$ chelates in 1,2-dichloroethane in the order (1), showing that here too the l.f.s. decreases in this order.

These facts can be understood as follows: the total volume of the *N*-alkyl groups in a diamine increase naturally in the order:

teen > unsym-deen, sym-deen > unsym-dmen, sym-dmen

The position of tmen in this series will be somewhere near the deen's. Now if it is assumed that the amount of steric hindrance, which a neighboring ligand suffers from such groups in an unsym-diamine chelate, is somewhat larger than that in its sym-diamine analogue, the order (1) or (2) can be taken as the inverse order of such steric hindrance in each case. Thus the order (1) indicates that the l.f.s. in an octahedral chelate is weakened owing to the increasing interligand repulsion, and the order (2) that the coordination of solvent molecules above and below a planar chelate is hindered more and more owing to the increasing ligand-solvent repulsion.

It is also of interest to note that a weak band at 20000 to 21000 cm^{-1} is observed in some spectra of the chelates VI and VIII, indicating the formation of the species $[Ni(diamine)(acac)]^+$, or, in other words, the dissociation of a diamine molecule from the chelate cation, in solvents of lower coordination ability. Only the chelates of the type $[Ni(diamine)_2(acac)]X$ (and not those of the type $[Ni(diamine)(acac)_2]$) show such a band, and only the unsym-diamine chelates do so,

Table 5. Examples of ν_{CO}, $\nu_{C=C}$, and $\Delta\nu$ in the two types of chelates (cm^{-1})

Chelate	ν_{CO}	$\nu_{C=C}$	$\Delta\nu$	Spin type
II	1604	1514	90	High Spin
IV	1596	1516	80	
V	1597	1525	72	
VI	1586	1507	79	
XI	1578	1528	50	Low Spin
XII	1570	1525	45	

suggesting that here also interligand repulsion is playing a role.

Infrared Spectra. As in the case of the tmen and teen chelates, there are two strong bands at 1500—1600 cm^{-1}, which are ascribed to the C=C and C=O vibrations of acac, and their separations ($\Delta\nu$) are much larger in the 6-coordinate chelates than in 4-coordinate ones (Table 5). It was also found that ClO_4^- ions are not coordinated. In addition, there is N-H stretching absorption at *ca.* 3200 cm^{-1}, which is a single peak in the sym-, but split into two or three peaks in unsym-diamine chelates. The hydrated chelates show also O-H stretching absorption superposed on it, broadening the peak considerably.

In conclusion it can be said that, in going from tmen and teen to the dmen's and deen's, both the l.f.s. in octahedral chelates and their ease of formation (either from component ligands, or from a planar chelate and solvent molecules) remarkably increase, owing to the decrease in steric hindrance caused by the *N*-alkyl groups.

Sincere thanks of the authors are due to Prof. Hiroshi Kakizawa of Tokyo Kyoiku University, for his kind permission to use the Hitachi spectrophotometer in his laboratory. The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Fundamental Studies on the Ion-Exchange Separation of Boron Isotopes

Hidetake KAKIHANA, Masahiro KOTAKA, Shohei SATOH, Masao NOMURA, and Makoto OKAMOTO

Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received August 20, 1976)

The single-stage separation factors for boron isotopes between an ion-exchange resin and an external solution were determined, using an ion-exchange breakthrough operation. The lighter isotope boron-10 was considerably enriched in the anion-exchange resin phase. The separation factor was very much influenced by the boric acid concentration in the external solution, but not as much influenced by the kind of the anion exchange resin used and operation temperature. The separation factor increased with a decrease in the boric acid concentration of external solution from 1.008 (0.501 mol/l)to 1.016 (0.010 mol/l). The value of the separation factors obtained experimentally were compared with those estimated on the basis of the theory of the two-phase distribution of isotopes.

Naturally occurring boron contains 19.8% boron-10 and 80.2% boron-11. The absorption cross section of natural boron for thermal neutrons is 752 barns; for pure boron-10 and boron-11, the corresponding values are 3837 and 0.005 barns, respectively.[1] This means that isotopically pure boron-10 is five times more effective as a neutron shield than natural boron. The large cross section of boron-10 for thermal neutrons and the α particle emission subsequent to neutron capture have suggested the possible use of boron compounds (enriched in boron-10) for neutron therapy of malignant tissue. This kind of nuclear approach is being actively pursued in the world, especially for treatment of brain tumors[2] and melanotic cancer.[3] In view of this characteristic of boron-10, it is not surprising that a demand for the separation of boron isotopes arose in very early stage of the nuclear era.

The first experiment on ion-exchange separation of boron isotopes had been done by Makishima and coworkers in 1959.[4] In this experiment, boric acid solution was passed through a column packed with a strong-base anion exchange resin (Amberlite CG-400-I) in hydroxide form. The boric acid concentration and the atomic fraction of boron-10 in each fraction of the effluent were measured. It was found that the lighter isotope boron-10 was enriched in the resin phase. and that the values of the single-stage separation factors were 1.010 for aqueous 0.03 mol/l boric acid, and 1.016 for 0.1 mol/l boric acid in 8% glycerol–water solution. Large-scale experiments stimulated by Makishima's work were carried out in France[5] and Spain.[6] Nowadays, at the Isobor company in France isotopically pure boron-10 and 11 are being produced from natural boron by means of ion-exchange chromatography, using a strong-base anion exchange resin.

The present authors have pointed out that this process can be greatly improved by using a weak-base resin in free-base form or a strong-base resin in fluoride form, and thus dispensing with regeneration of the resin in the column.[7-9] In these experiments, a high porosity type weak-base anion exchange resin (Diaion WA 21) in the free-base form, and a gel type strong-base anion exchange resin (Diaion SA 20A) in the fluoride form were used. An aqueous solution containing 5 mmol of boric acid was passed through columns packed with these resins, and the borate band formed in the column was eluted with pure water. It was found that:

(1) Boron-10 was considerably enriched in the rear part of the band, and depleted in the frontal part.

(2) The boric acid charged to the column was completely eluted with pure water.

The remarkable feature of this separation system is that it is scarcely necessary to regenerate the resin in the column. Recently, one of the authors has discussed the further possibility of ion-exchange separation of isotopes, giving the case of boron isotopes as an example.[10]

The purpose of the present research is to determine the effects of temperature, the concentration of boric acid charged to the column, and the kind of resin used, on the single-stage separation factor of boron isotopes between the resin and the external solution phases.

Experimental

The ion-exchange resins used were Diaion WA 21, WA 30, WA 10, PA 312, SA 20A, and PK 224. Diaion WA 21 is a high porosity type weak-base anion exchange resin with primary and secondary amine groups. Diaion WA 30 is a high porosity type weak-base anion exchange resin with tertiary amine groups. Diaion WA 10 is a gel type weak-base anion exchange resin with tertiary amine groups. Diaion PA-312 is a porous type strong-base anion exchange resin with quaternary amine groups. Diaion SA 20A is a gel type strong-base anion exchange resin with quaternary amine groups. Diaion PK 224 is a porous type strong-acid cation exchange resin with sulfonic groups. It is known that the increasing order of resin-basicity is as follows:

$$\text{Diaion WA 21} < \text{Diaion WA 10} < \text{Diaion WA 30} < \text{Diaion SA 20A} < \text{Diaion PA 312}$$

The boric acid used in these experiments was recrystallized twice from aqueous solution. The other chemicals were analytical grade materials used without further purification.

Equilibrium Experiment. The columns used were about 20 cm in length and 1 cm in diameter, surrounded by a jacket through which water from a thermostat was circulated so that the columns were maintained at constant temperature within ± 0.2 °C. The resins described above were packed in the columns, and subjected to chloride–hydroxide or sodium–hydrogen cycles in a usual manner to ensure regeneration and uniform packing. The columns were thoroughly washed with distilled water after converting the resins into the hydroxide or the hydrogen forms. A boric acid solution was placed in a reservoir above the columns which was connected to the columns with a polyolefin tube. In order to establish isotopic equilibrium between the resin in the column and the boric acid solution, the amount of boric acid charged to the column

was more than 50 times the total exchange capacity of the column. The flow rate of the boric acid solution was controlled with a screw cock at the bottom of the column.

After equilibrium was established between the resin and the external solution phases, some samples of the resin in the column were extracted with a pipette, filtered through a sintered glass disk with suction for 10 min, and weighed. Then the boric acid absorbed by the resin was eluted with pure water or other suitable eluting agents, and the concentration of boric acid in the effluent was measured with a Varian Tectron Model 1100 flame photometer and the amount of boric acid absorbed by the resin was calculated. The resin was weighed after being dried in an air bath with autometic controller at 50—60 °C for about 48 h and kept in a desiccator (with silica gel as a drying agent) for 24 h.

The isotopic analysis of boric acid absorbed by the resin was carried out using a Varian Mat CH 5 mass spectrometer by means of the surface ionization method.[11] The mass peaks used were those at *m/e* 88 ($Na_2{}^{10}BO_2^+$) and 89 ($Na_2{}^{11}BO_2^+$). This mass region was repeatedly scanned about 40 times for each sample, and the ratio of peak heights at *m/e* 88 to *m/e* 89 was calculated as an average of these scans. The atomic fraction of boron-10 was determined from the ratio of the peak-heights. The standard deviation of the isotopic analysis of boron-10 was less than ± 0.0002 in every case. Some other samples of the resin in the column, in equilibrium with the external solution of boric acid, were pipetted together with the external solution into eight test tubes. A few drops of an indicator were added to each of these test tubes. The indicators used were methyl red, phenol red, thymol blue, phenolphthalein, cresolphthalein, thynolphthalein, alizarin yellow R. and the Kolthoff's universal indicator. The pH of the resin phase was roughly estimated by comparing the color of the resin with that of standard buffer solutions.

Breakthrough Experiment. A boric acid solution was passed through the same column as used in the equilibrium experiment. The superficial velocity of the boric acid solution was 13 ml h^{-1} cm^{-2}. A number of 20 ml fractions of the effluent were successively collected in 20 ml measuring flasks, and the boric acid concentration and the atomic fraction of boron-10 in these fractions were determined by the methods used in the equilibrium experiment.

Results and Discussion

The results obtained from the equilibrium and breakthrough experiments are summarized in Table 1 along with the experimental conditions. Some examples of the elution graphs obtained from the breakthrough experiment are shown in Figs. 1 through 4. The ${}^{10}_{11}S$ shown in Table 1 is the single-stage separation factor for boron isotopes between the resin and the external solution phases, defined in the following equation:

$$ {}^{10}_{11}S = \frac{\text{Total amount of boron-10 in the resin phase}}{\text{Total amount of boron-11 in the resin phase}} \times \frac{\text{Total amount of boron-11 in the external solution phase}}{\text{Total amount of boron-10 in the external solution phase}} \quad (1) $$

In the case of the equilibrium experiment, the first term of the right hand side of Eq. 1 is the value of isotope ratio measured for the boric acid absorbed by the resin at the equilibrium, and the second term is that of the external solution which is simply the natural isotope ratio. In the case of the breakthrough experiment, ${}^{10}_{11}S$ can be calculated from the experimental data by means of the following equation,[12]

$$ {}^{10}_{11}S = 1 + \frac{1}{Q} \cdot \frac{1}{R_0(1-R_0)} \cdot (R_0 - R_i) \cdot f_i \quad (2) $$

where Q is the total amount of boron in the resin phase (mmol), R_0 the atomic fraction of boron-10 in the feed solution, R_i the atomic fraction of boron-10 in fraction i of the effluent, and f_i the total amount of boron

cases using Diaion WA 21, Diaion WA 10, and other resins, the values of ${}^{10}_{11}S$ were determined from the equilibrium experiment only. Of the other symbols in Table 1, q is the mass concentration of boron absorbed in the resin phase (mmol/g-dry resin), and W is the weight fraction of water in the resin phase, defined as

$$W = \frac{W_w}{W_r + W_w} \tag{3}$$

where W_r is the weight of the dry resin, and W_w the weight of water in the resin. M is the molar concentration of boric acid in the resin phase, which can be calculated by means of the following equation:

$$M = \frac{1-W}{W} \times q \tag{4}$$

The following can be seen from Table 1 and Figs. 1—4 under the present experimental conditions:

(1) The lighter isotope boron-10 is considerably enriched in the anion exchange resin phase, while in the case of the cation exchange resin no isotope effect is found within our limits of experimental accuracy.

(2) The separation factor is very much influenced by the boric acid concentration in the external solution, but not so much influenced by the kind of anion exchange resins used nor by the operating temperature. The separation factor increases with a decrease in the boric acid concentration.

(3) The amount of boron absorbed in the weak-base anion exchange resins (Diaion WA 21 and 10) increases with a decrease in temperature at a certain concentration of boric acid in the external solution.

(4) The amount of boron absorbed in the weak-base anion exchange resins (Diaion WA 21, 10, and 30) increases remarkably with an increase of the boric acid concentration in the external solution, while in the case of the strong-base anion exchange resins (Diaion PA 312 and SA 20A) it reaches the maximum value at the relatively low concentration of boric acid.

(5) The boric acid concentration in the anion exchange resin phase is very high; that is, at an operating temperature of 25 °C, when the boric acid concentration in external solution is 0.5 mol/l its value reaches about 10 mol/l in the resin.

(6) The pH of the anion exchange resin phase in equilibrium with the external solution shows a considerably higher value (8—12) than that of boric acid solutions; 4.9 at 0.01 mol/l, 4.7 at 0.1 mol/l, 4.3 at 0.5 mol/l.

(7) The breakthrough graph is influenced effectively by the boric acid concentration of the external solution and operating temperature: Its features become sharper with a decrease in the boric acid concentration of the external solution and with an increase in the operating temperature.

The values of the separation factor obtained from the present research agree closely with those obtained for a strong-base anion exchange resin by Rosset and coworkers[5]: 1.018 at 0.0098 mol/l; 1.014 at 0.103 mol/l; 1.011 at 0.249 mol/l; 1.009 at 0.555 mol/l boric acid. This would seem to confirm the correctness of the present results.

The boron-isotope exchange reaction,

$$^{10}B(OH)_3 + {}^{11}B(OH)_4^- = {}^{11}B(OH)_3 + {}^{10}B(OH)_4^-, \tag{5}$$

occurs in aqueous solutions of boric acid. The isotope effect between a trigonal planar structure ($B(OH)_3$) and a tetrahedral structure[13,14] ($B(OH)_4^-$) as calculated from spectroscopic data on molecular vibrations, based on statistical mechanics with quantum corrections, is remarkable.[7,15,16]

The value of equilibrium constant is 1.0194 at 298.1 K as shown in Table 2. This means that boron-10 is enriched in the anionic species $B(OH)_4^-$.

It has been reported by Ingri[17] that the main species formed in aqueous solutions of boric acid are $B(OH)_3$, $B(OH)_4^-$, $B_3O_3(OH)_4^-$, $B_3O_3(OH)_5^{2-}$. That is, the following equilibria exist in the solutions:

$$B(OH)_3 + OH^- \overset{K_1}{=} B(OH)_4^- \tag{6}$$

$$3B(OH)_3 + OH^- \overset{K_2}{=} B_3O_3(OH)_4^- + 3H_2O \tag{7}$$

$$3B(OH)_3 + 2OH^- \overset{K_3}{=} B_3O_3(OH)_5^{2-} + 3H_2O \tag{8}$$

where K_1, K_2, and K_3 are the stability constants; the respective values at 25 °C are $\log K_1 = 5.27$, $\log K_2 = 7.41$, and $\log K_3 = 11.67$. The distribution of the hydrolyzed

species in the boric acid solution, calculated at the total boron concentration of 0.5 mol/l from the values of the stability constants described above, is represented graphically in Fig. 5. Figure 5 shows that the main species are $B(OH)_3$ at pH less than 6, $B(OH)_3$ and $B_3O_3(OH)_4^-$ in the pH range 7—8, $B(OH)_3$, $B_3O_3(OH)_4^-$, and $B(OH)_4^-$ in the pH range 8—9, $B(OH)_3$, $B_3O_3(OH)_4^-$, $B(OH)_4^-$, $B_3O_3(OH)_5^{2-}$ in the pH range 9—10, and $B(OH)_4^-$ at pH greater than 10. As mentioned above, in aqueous solution $B(OH)_3$ has a trigonal planar structure and $B(OH)_4^-$ has a tetrahedral structure. It has been also reported[18] that polyborate ions, $B_3O_3(OH)_4^-$ and $B_3O_3(OH)_5^{2-}$, have both trigonal planar and tetrahedral structure: $B_3O_3(OH)_4^-$ is composed of two triangular groups and a tetrahedral group joined by three common oxygen atoms; $B_3O_3(OH)_5^{2-}$ is composed of a triangular group and two tetrahedral groups joined by three common oxygen atoms (Fig. 6).

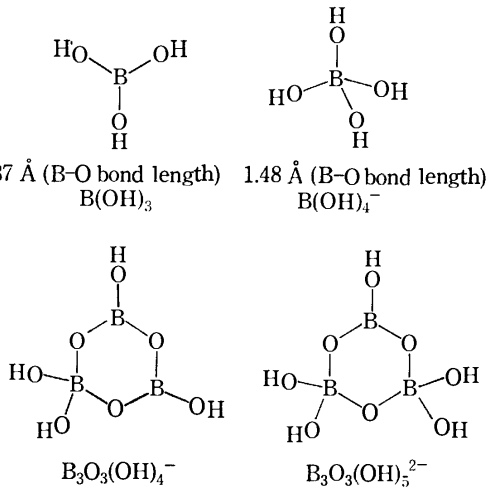

Fig. 6. Structure of boron species.

From the facts mentioned above, the main species present in the anion exchange resin phase in equilibrium with the external solution, could be $B(OH)_4^-$, $B_3O_3(OH)_4^-$, and $B_3O_3(OH)_5^{2-}$, while the main species in the external solution phase is $B(OH)_3$ only. Consequently, the high value of the separation factor for boron isotopes between the two phases is caused by the structure change between boron species existing in the two phases: from trigonal planar structure to tetrahedral structure. The high concentration of boric acid in the resin phase may be caused by the formation of polyborate anions. In the case of the cation exchange resin, the only species present in the two phases is $B(OH)_3$, and therefore, the value of the separation factor is approximately unity.

The separation factor (${}^{10}_{11}S$) for boron isotopes between the anion exchange resin and the external solution phases can be estimated on the basis of the theory of the two phase distribution of isotopes proposed by Kakihana,[19,20] that is, expressed by the following equation,[7]

$$
\begin{aligned}
{}^{10}_{11}S &= \{({}^{10}\overline{[B(OH)_3]} + {}^{10}\overline{[B(OH)_4^-]} + {}^{10}\overline{[B_3O_3(OH)_4^-]} \\
&\quad + {}^{10}\overline{[B_3O_3(OH)_5^{2-}]})/({}^{11}\overline{[B(OH)_3]} + {}^{11}\overline{[B(OH)_4^-]} \\
&\quad + {}^{11}\overline{[B_3O_3(OH)_4^-]} + {}^{11}\overline{[B_3O_3(OH)_5^{2-}]})\} \\
&\quad \times ({}^{11}[B(OH)_3]/{}^{10}[B(OH)_3]) \qquad (9)
\end{aligned}
$$

$$
\begin{aligned}
&= [\bar{X}_{{}^{11}B(OH)_3} + \bar{f}_{B(OH)_3} \cdot \bar{f}^{-1}_{B(OH)_4^-} \cdot \bar{X}_{{}^{11}B(OH)_4^-} \\
&\quad + \bar{f}_{B(OH)_3} \cdot \bar{F}^{-1}_{B_3O_3(OH)_4^-} \cdot \bar{X}_{{}^{11}B_3O_3(OH)_4^-} \\
&\quad + \bar{f}_{B(OH)_3} \cdot \bar{F}^{-1}_{B_3O_3(OH)_5^{2-}} \cdot \bar{X}_{{}^{11}B_3O_3(OH)_5^{2-}}] \\
&\quad \times f^{-1}_{B(OH)_3} \cdot f_{B(OH)_3} \qquad (10)
\end{aligned}
$$

where the bracket [ ] denotes the molar concentration of boron isotopes involved in the corresponding species, the symbol $\bar{}$ the resin phase, X the atomic fraction of a given boron isotope in the form of the specified chemical species, f the reduced partition function ratio, and F the reduced partition function ratio of polyborate anion. Since the difference of the reduced partition function ratios of the same chemical species between the resin and the external solution phase is very small, we can make the approximations $\bar{f}_{B(OH)_3} = f_{B(OH)_3}$, $\bar{f}_{B(OH)_4^-} = f_{B(OH)_4^-}$, $\bar{F}_{B_3O_3(OH)_4^-} = F_{B_3O_3(OH)_4^-}$, $\bar{F}_{B_3O_3(OH)_5^{2-}} = F_{B_3O_3(OH)_5^{2-}}$.

The atomic fraction of boron isotope in a chemical species can be approximated by the mole fraction of the corresponding chemical species.[21] As mentioned above, $B_3O_3(OH)_4^-$ is composed of two triangular groups and a tetrahedral group joined by three common oxygen atoms, while $B_3O_3(OH)_5^{2-}$ a triangular group and two tetrahedral groups joined by three common oxygen atoms. Therefore, the reduced partition function ratios can be approximated by the following equations,

$$F_{B_3O_3(OH)_4^-} = \frac{2f_{B(OH)_3} + f_{B(OH)_4^-}}{3} \qquad (11)$$

$$F_{B_3O_3(OH)_5^{2-}} = \frac{f_{B(OH)_3} + 2f_{B(OH)_4^-}}{3} \qquad (12)$$

Equation 10 is reduced to

$$
\begin{aligned}
{}^{10}_{11}S &= \bar{X}_{B(OH)_3} + f_{B(OH)_3} \cdot f^{-1}_{B(OH)_4^-} \cdot \bar{X}_{B(OH)_4^-} \\
&\quad + f_{B(OH)_3} \cdot \left\{\frac{2f_{B(OH)_3} + f_{B(OH)_4^-}}{3}\right\}^{-1} \cdot \bar{X}_{B_3O_3(OH)_4^-} \\
&\quad + f_{B(OH)_3} \cdot \left\{\frac{f_{B(OH)_3} + 2f_{B(OH)_4^-}}{3}\right\}^{-1} \cdot \bar{X}_{B_3O_3(OH)_5^{2-}} \qquad (13)
\end{aligned}
$$

Thus, ${}^{10}_{11}S$ is calculated as a function of pH and boric acid concentration in the resin phase from Eq. 13, using the stability constants of boron species determined by Ingri and the calculated reduced partition function ratios for $B(OH)_3$ and $B(OH)_4^-$ (Fig. 7 and Table 1). It is apparent from Fig. 7 and the calculated values of ${}^{10}_{11}S$ in Table 1 *i.e.*:

(1) The calculated separation factor increases with an increase of the boric acid concentration in the resin at pH below 8.7, but has the contrary tendency at pH above 8.7, and is independent of the boric acid concentration in the resin at pH 8.7. The formation of polyborate anions containing the tetrahedral groups may contribute to the high values of the separation factor at pH below 8.7.

(2) The calculated separation factors show roughly agreement with those obtained experimentally. The discrepancy between the calculated values and the

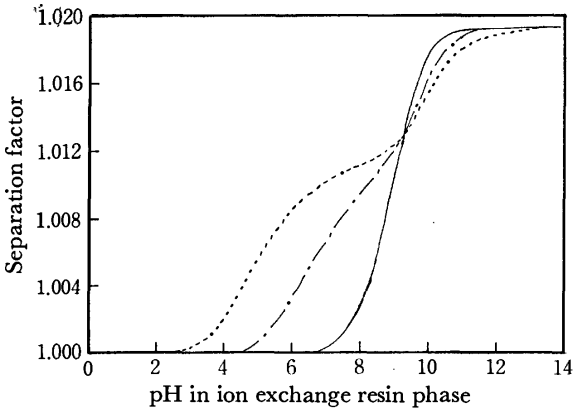

Fig. 7. Separation factor of boron isotopes calculated as a function of pH and boric acid concentration in resin phase at 25 °C.
——: The total boron concentration of 0.05 mol/l.
-•---: The total boron concentration of 1.20 mol/l.
------: The total boron concentration of 8.50 mol/l.

experimental values may be caused mainly by the insufficient accuracy of the resin-phase pH measurement and the use of the stability constants in such a high concentration range (up to 10 molarity), and subsidiarily by the use of the approximate values of the reduced partition function ratio for the polyborate ion. ${}^{10}_{11}S$ was also calculated at 40 °C by the use of the stability constants of boron species determined by Mesmer[22] (Table 1), and the values had a same tendency as these of ${}^{10}_{11}S$ at 25 °C.

The separation system of boron isotopes by means of weak-base anion exchange resins such as Diaion WA 21 may indeed be one of the best separation systems, because the separation factor is as high as that for the system using a strong-base anion exchange resin, the boric acid charged to the column is absorbed in the resin to a high concentration, and it can be completely eluted with pure water. The advantages of the boric acid charged to the column being easily eluted with pure water are that it is scarcely necessary to regenerate the resin in the column, and that the boric acid is free from contamination by any other chemicals.

The authors would like to express their thanks to Professor Y. Marcus of the Hebrew University of Jerusalem for his valuable discussions and to Professor I. Okada for his kind comments and to Mr. D. Dickeson of the University of Washington of the U. S. A. for reading the manuscript.

The Conformations of Nickel(II) Complexes with edda-Type Optically Active Polyamino Carboxylic Acids in Aqueous Solutions

Tasuku MURAKAMI, Ichiro HIRAKO, and Masahiro HATANO

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, 2-1-1 Katahira, Sendai 980

(Received August 30, 1976)

Circular dichroism (CD) and proton magnetic resonance (PMR) spectra of nickel(II) complexes containing a series of ethylenediamine-*N*,*N*′-diacetic acid(H_2edda)-type optically active quadridentate ligands were measured in aqueous solutions. The epro complex which is an edda-type optically active ligand containing L-proline residues is found to exhibit the same CD spectrum as complexes of other edda-type ligands containing L-alanine, L-valine, L-phenylalanine, and L-serine residues. The CD and PMR spectra of the mixed complexes of these edda-type ligands having an oxalate ion was also measured. From the CD and PMR spectral data, it is concluded that these complexes stereospecifically take the *Δ-s-cis* form in solution. The large contact shift observed for the a protons of the amino acidate moieties indicates that the substituent groups become axial to the chelate plane.

In a previous paper,[1] we reported the preparation and solid state character of nickel(II) complexes having a series of ethylenediamine-*N*,*N*′-diacetic acid (H_2edda)-type optically active polyamino carboxylic acids, as is shown in Fig. 1;[2] the stretching frequencies of the coordinated carboxylate groups and the thermal stability suggested that the structure of the edda-type complexes in the solid state is different from that of bis(amino acidato) complexes. In this paper, we wish to report the circular dichroism (CD) and proton magnetic resonance (PMR) spectra measured in order to obtain information about the structure of the nickel(II) complexes with the edda-type optically active ligands in aqueous solutions.

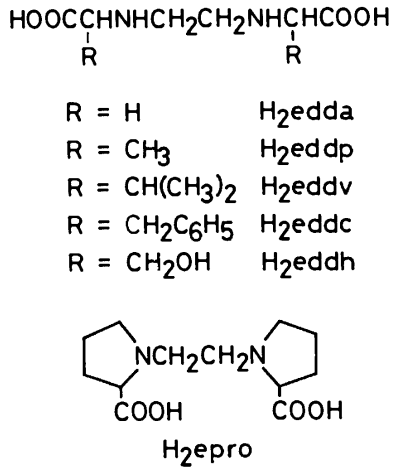

Fig. 1. The edda-type polyamino carboxylic acids. Except for H_2edda these acids possess two asymmetric carbon atoms with the *S* configuration.

Since the investigation of Milner and Pratt,[4] PMR studies have been found to be very useful for the conformational analysis of chelate rings in paramagnetic nickel(II) complexes.[5–9] However, most of subsequent work has involved optically inactive nickel(II) complexes. As is well-known, CD is an effective technique for the conformational analysis of optically active complexes. The combination of PMR and CD should lead to a more detailed understanding of the stereochemistry of paramagnetic nickel(II) complexes with optically active ligands.

Cobalt(III) complexes containing edda and its analogs have been extensively studied.[10–13] Schoenberg *et al.*,[14] have prepared cobalt(III) complexes with eddp, which is an optically active edda-type acid (see Fig. 1), and obtained the *Δ-s-cis* and *Λ-s-cis* isomers as main products and a small amount of the *Δ-uns-cis* isomer.[15,16] Since the yields of the two *s-cis* isomers were nearly equal, the stereospecificity of eddp does not appear to be very large. In the case of the nickel(II) ion, however, eddp-type quadridentate ligands may form only the most stable isomer in solution due to the labile characteristic of the nickel(II) ion. Thus, there is the possibility of displaying their essential stereospecificity by forming labile complexes. One of the purposes of this paper is to clarify this problem. Especially, the epro ion has two pyrrolidinyl groups in its interior (Fig. 1) and hence is expected to coordinate to a metal ion with a large stereospecificity. Even for the copper(II) ion, the epro ion is reported to coordinate with an *uns-cis* configuration.[3] The conformations of the nickel(II) complexes with these edda-type ligands are discussed on the basis of the CD and PMR spectra.

Experimental

Materials. The edda-type optically active polyamino carboxylic acids shown in Fig. 1 and their nickel(II) complexes were prepared as described in a previous paper.[1] Mixed ligand complexes of these acids having an oxalate ion were prepared by adding an amount of sodium oxalate two times in excess to the complex solutions.[17] Sodium 3-(trimethylsilyl)-1-propanesulfonate (TMS*) was used as an internal reference for the chemical-shift measurements for the PMR.

Samples for PMR measurements were prepared as follows. The isolated complex was dissolved in D_2O (99.75%). To reduce the size of the HDO signal, the solution was evaporated to dryness at 50 °C, and dried solid was again dissolved in D_2O. After this procedure had been repeated, the dried solid was dissolved in D_2O containing TMS*. The final concentration of each solution was about 0.02 M. In the case of complexes mixed having an oxalate ion, the complex solutions containing amount of sodium oxalate two times in excess were similarly treated. The concentration was about 0.2 M.

Measurements. Absorption spectra from the near-infrared to the near-ultraviolet regions were measured with a Hitachi EPS-3T spectrophotometer. CD spectra from 250 to 1200 nm were measured with a Jasco J-20A recording

spectropolarimeter (250—1000 nm) and a Jasco J-200 grating spectropolarimeter (900—1200 nm). The PMR spectra were obtained with a Varian CFT-20 spectrometer at 80 MHz. To obtain high signal-to-noise ratios for PMR, each signal was repeatedly accumulated using a Fourier transform (FT) technique or a water-eliminated FT technique.

Results and Discussion

Figure 2 shows the absorption and CD spectra of [Ni(eddp)(H_2O)$_2$], [Ni(eddh)(H_2O)$_2$], and [Ni(epro)-(H_2O)$_2$] in the region of 7000 to 38000 cm^{-1}. These complexes exhibit CD curves with similar shapes, which have a large negative band in the first (lowest energy) absorption band region, two negative bands in the second absorption region, and two bands of oppsite sign in the third absorption region. The diaquanickel-(II) complexes of eddv and eddc also exhibit analogous CD spectra. Of the diaquabis(L-amino acidato)nickel-(II) complexes, on the other hand, it has been reported that only the L-prolinato complex exhibits a quite different CD spectrum from those of other L-amino acidato complexes in methanol[18] and water.[19] This is considered to be due mostly to the large contribution of the asymmetric secondary nitrogen atom of proline to the optical activity. Therefore, the fact that the CD spectrum of the epro complex containing the two proline residues is the same as those of other eddp-type complexes is very interesting. This will be significant in the discussion of the structure of these complexes.

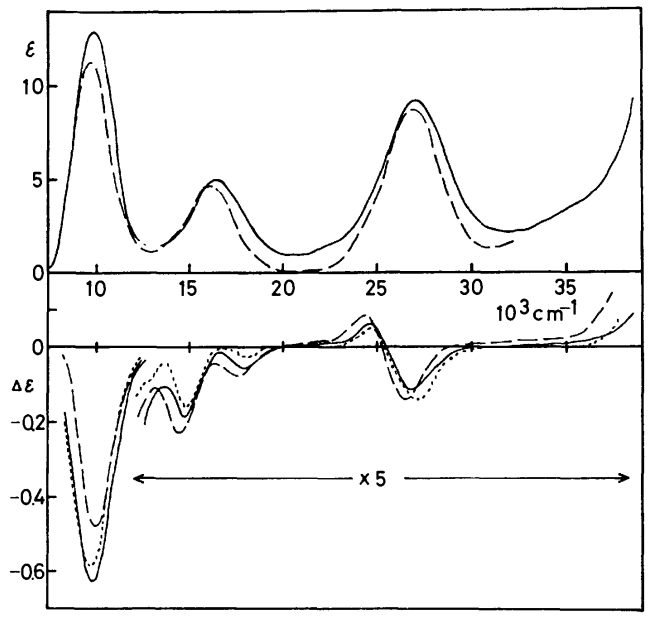

Fig. 2. Absorption and CD spectra of [Ni(eddp)(H_2O)$_2$] (——), [Ni(eddh)(H_2O)$_2$] (------), and [Ni(epro)(H_2-O)$_2$] (----) in aqueous solutions.

For the edda-type complexes, three geometrical isomers, *trans*, *s-cis*, and *uns-cis*, are possible and further there are two optical isomers of Δ and Λ for both the *s-cis* and *uns-cis* forms. Considering the asymmetry of chelate rings, the number of possible conformations increases to many more. Contributions to the CD spectrum observed for the octahedral nickel(II) complexes having edda-type optically active quadridentate ligands arise from (i) the configurational effect based on the arrangement of chelate rings around the nickel ion, (ii) the vicinal effect of the asymmetric nitrogen, (iii) the conformational effect of the central ethylenediamine(en)-type chelate ring, (iv) the conformational effect of the amino acidate chelate ring, and (v) the vicinal effect of the asymmetric carbon. Of these five effects, the contributions from the absolute configuration around the nickel ion and the asymmetric nitrogen are expected to be much more significant. Therefore, the similarity of the CD spectra observed for all the edda-type complexes suggests that these complexes have at least the same absolute configuration and an asymmetric nitrogen atom with the same configuration.

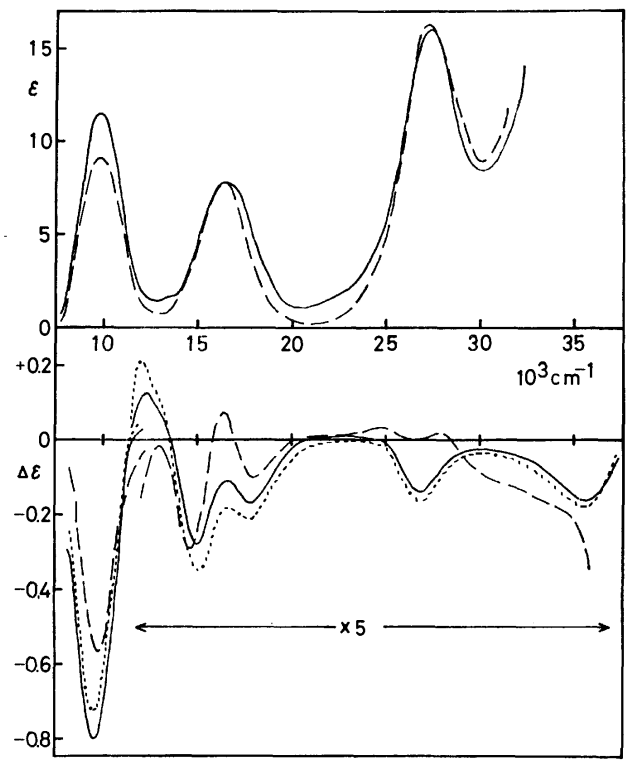

Fig. 3. Absorption and CD spectra of [Ni(eddp)(ox)]$^{2-}$ (——), [Ni(eddh)(ox)]$^{2-}$ (------), and [Ni(epro)(ox)]$^{2-}$ (----) in aqueous solutions.

The edda-type polyamino carboxylic acids appear primarily to have the particular character that they hardly coordinate to a metal ion in a plane.[12] For example, so far, no cobalt(III) complex with an edda-type acid in the planar configuration has been reported. Only *s-cis* and *uns-cis* isomers have actually been obtained.[10-14,20-22] This also appears to be the case for the nickel(II) complexes. The fact that the CD spectra of the nickel(II) complexes are not so greatly influenced when mixed complexes having an oxalate ion are formed (Fig. 3) indicates that these complexes are of the *cis*-type form to which the oxalate ion can coordinate without changing the configuration of the quadridentate ligands.

Among the edda-type ligands, especially the epro ion which has two pyrrolidinyl rings is expected to coordinate with large stereospecificity. Even to the copper(II)

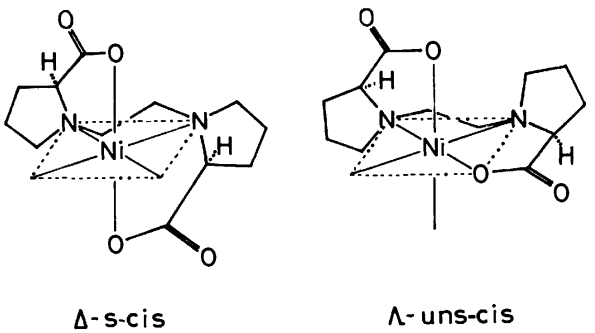

Fig. 4. Schematic drawing of the *Δ-s-cis* and *Λ-uns-cis* forms possible for the epro complex.

ion, which is generally thought to form planar complexes, epro appears to coordinate with a *Λ-uns-cis* configuration.[3] In addition, some tetraamines, which have two pyrrolidinyl groups in their interior as well as epro, do not form planar species of nickel(II) ions, but form only octahedral species.[23-25] An examination of the molecular models shows that the possible *cis* forms for epro are only two, *Δ-s-cis* and *Λ-uns-cis*, because of the rigid pyrrolidine rings. These two forms are illustrated in Fig. 4. The configuration of all the tertiary nitrogen atoms is *R*.[26] The central en-like chelate ring is a *δ gauche* in the *Δ-s-cis* form, while it appears to be an envelope in the *Λ-uns-cis* form. The epro complex will exist in either the *Δ-s-cis* or the *Λ-uns-cis* form in solution. Therefore, other eddp-type complexes are also considered to have a structures similar to either of these two forms on the basis of the similarity of the CD spectra.

The PMR spectra of $[Ni(eddp)(H_2O)_2]$ and $[Ni(eddh)(H_2O)_2]$, and complexes of these mixed with oxalate ions in D_2O are shown in Fig. 5. The signal due to the residual HDO of the solvent is not shown. The large peak at about −5.5 ppm observed for the eddp complex is assigned to the methyl protons on the basis of its relative area. The methylene protons in the hydroxymethyl group of the eddh complex appear at −7.2 ppm. Three other broad peaks, with almost the same intensity, observed at lower fields for each complex correspond to the central ethylene protons and the α protons in the amino acidate moieties, assuming the assignments for the edda complex.[6] Since the protons of the ethylene linkage of the edda complex were found to appear at −26 and −116 ppm, the α proton of the eddp complex could be assigned to either of the two bands at −126 and −103 ppm. Similarly, the α proton of the eddh complex corresponds to either of the two peaks at −121 and −102 ppm. The other of these two peaks is assigned to the equatorial protons of the ethylene linkage. In any case, the α protons of the eddp and eddh complexes would appear at a field lower than −100 ppm. This is significant when examining the ring conformation, as will be described below.

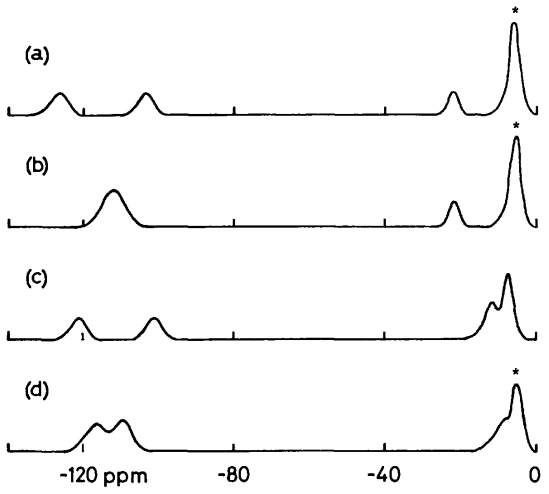

Fig. 5. PMR spectra of (a) $[Ni(eddp)(H_2O)_2]$, (b) $[Ni(eddp)(ox)]^{2-}$, (c) $[Ni(eddh)(H_2O)_2]$, and (d) $[Ni(eddh)(ox)]^{2-}$ in D_2O at 34 °C. The chemical shift is relative to the internal standard, TMS*. The signal from the residual HDO of the solvent is not shown. The signals with the sign (*) overlap with the signal of HDO.

The coordination of an oxalate ion appears to have some influence on the contact shifts of the ethylene and α protons (Fig. 5); in the eddh complex the signal of the equatorial proton of the ethylene moiety and that of the α proton approach each other, and in the eddp complex the two signals overlap to become a single broad band. Since the coordination of an oxalate ion does not change the configuration of the quadridentate ligand, this finding suggests that the coordinated oxalate ion might change the magnetic environment around the protons, or might even affect detailed conformations of the chelate rings.

The simplicity of the PMR spectra suggests that the eddp and eddh complexes exist not as equilibrium mixtures, but almost all in *s-cis* form. In the *s-cis* form, there is a C_2-symmetry axis passing through the central ethylene linkage and the nickel atom which makes the two chelate rings of the amino acidate equivalent. Consequently, it may be concluded that the nickel(II) complexes of edda-type optically active ligands are of *Δ-s-cis*-type absolute configuration. The CD spectra observed for mixed complexes having an oxalate ion afford some evidence to support this conclusion. As can be seen in Fig. 3, a new positive CD band emerges at higher wavenumbers in the first adsorption-band region when mixed complexes are formed. This CD pattern in the first absorption region, with negative and positive components from low wavenumbers, is characteristic of the absolute *Δ* configuration.[27-29] That the mixed complexes clearly indicate the *Δ*-type CD spectra is probably attributable to an increase in *Δ*-type ring pairing due to the addition of the oxalate chelate ring. That is to say, the contribution of the *Δ*-type configurational effect to the optical activity becomes relatively greater.

As described above, the PMR and CD spectral data indicate that these edda-type optically active ligands should stereospecifically ccordinate to a nickel(II) ion to form only the *Δ-s-cis* isomer in solution. Then, the steric factor for which ligands other than epro are forced to coordinate with the *Δ-s-cis* form must be examined. The four possible *s-cis* forms for the eddp-type complexes are depicted in Fig. 6. The symbols *δ* and *λ* represent the *gauche* form of the central en-type

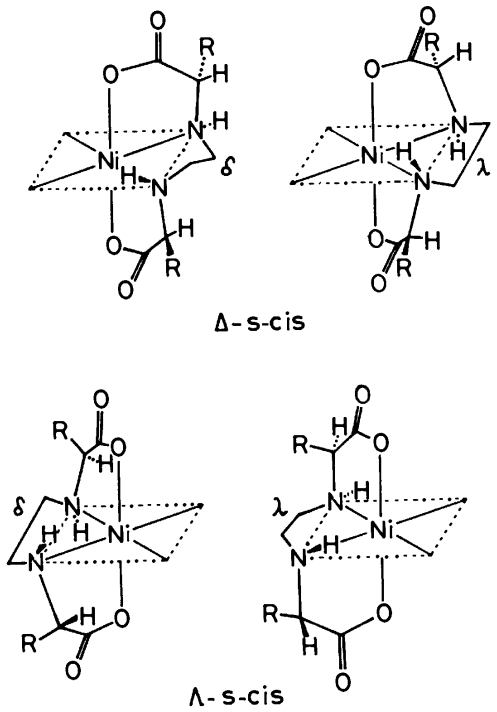

Fig. 6. Schematic drawing of the *cis*-type structures possible for the eddp-type complexes.

chelate ring. The substituent groups are denoted by R. The configuration of the secondary nitrogen atoms is *R* in the *Δ-s-cis* forms and *S* in the *Λ-s-cis* forms.

In the *Δ-s-cis* forms, both substituent groups are axial to the N-Ni-O chelate plane but point away from the central en-like chelate ring(*exo*), while in the *Λ-s-cis* forms, they point toward the central chelate ring(*endo*). Since the interaction between the non-bonding atoms is probably smaller in the *exo*-form than in the *endo*-form,[30] the *Δ-s-cis* form is considered to be thermodynamically more stable than the *Λ-s-cis* form. This may be the reason why these quadridentate ligands coordinate to a labile nickel(II) ion to form stereospecifically the *Δ-s-cis* isomer. For the cobalt(III) complex of eddp, however, both *Δ-s-cis* and *Λ-s-cis* isomers are obtained with almost the same yield, and hence the stereospecificity of eddp is not so large toward the inert cobalt(III) ion.[14] Thus, it can be said that the eddp-type ligands display their essential stereospecificity by forming labile nickel(II) complexes.

As has been pointed out by many other investigators,[4-7,31-33] the contact shift of the α protons in the amino acidate chelate ring depends on the relative axial-equatorial nature of the protons, that is, on the dihedral angle between the planes of the Ni-N-C and N-C-H groups; the equatorial proton appears at a very low value of the field (*ca.* −100 ppm) while the axial proton appears at a field higher than −40 ppm. The α protons of the eddp and eddh complexes are observed at fields lower than −100 ppm, indicating that the α protons are equatorial and hence the substituent groups are axial. Thus, this PMR finding supports the expectation that these complexes should be of Δ-*s-cis* form.

From an empirical correlation between the dihedral angle and the contact shift,[5] the α protons observed at

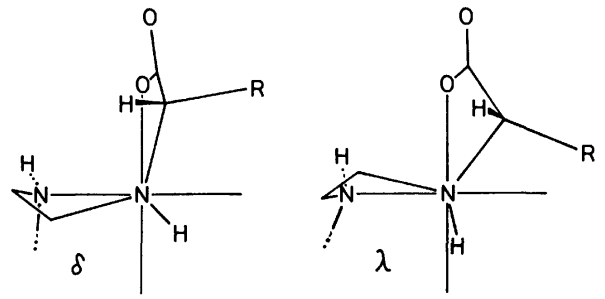

Fig. 7. The ring conformations in the *Δ-s-cis* forms as viewed from the Ni-N bond axis. δ and λ represent the conformations of the central en-type chelate ring. R designates the substituent groups. Another amino acidate chelate ring is not shown for clarity.

about −100 ppm for the eddp and eddh complexes are considered to be on a pseudo-*gauche* form of the amino acidate chelates. Figure 7 shows the ring conformations of the two *Δ-s-cis* forms illustrated in Fig. 6 as viewed from the Ni-N bond axis. The lower amino acidate chelate ring is omitted for clarity. The δ and λ symbols represent the conformation of the central en-type chelate ring. In the case of the λ conformation, the amino acidate ring becomes a highly strained envelope and, moreover, the substituent group designated as *R* closely approaches the neighboring coordination site. Therefore, the λ form is considered to be very unstable. In the δ form, on the other hand, the amino acidate ring is pseudo-*gauche* (λ). The observed contact shift is indicative of the δ form, in fair agreement with the relative stability expected for the two forms.

In conclusion, the eddp-type ligands would stereospecifically coordinate to the nickel(II) ion to form the *Δ-s-cis* isomer, in which the secondary nitrogen atoms are in an *R* configuration and the central en-type chelate ring is *δ-gauche*. This structure is exactly the same as the *Δ-s-cis* form expected for the epro complex except for the minor difference between the secondary and tertiary nitrogens. Thus, it can be said that the stereospecificity of eddp-type ligands is identical to that of epro containing L-proline residues.

The authors wish to thank Dr. K. Aoki of the NEC-Varian Co., Ltd., for the PMR measurements. The authors also acknowledge the Mitsubishi Foundation for the gift of the Jasco J-200 grating spectropolarimeter used in these studies.

The Synthesis of Several Octose Derivatives Related to Octosyl Acids A and B

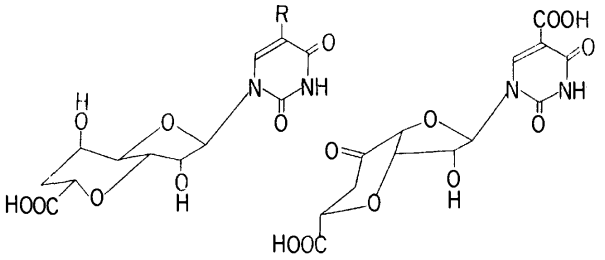
Kentaro ANZAI and Tsuneo SAITA

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received May 10, 1976)

Starting from 1,2: 5,6-di-*O*-isopropylidene-α-D-allofuranose (**3a**), the sugar portion of octosyl acids **A** and **B** (**1a** and **1b**) was synthesised, though with some protecting groups. Compound **7a**, thus obtained, was found to be acid-liable, and treatment of **7a** in a dilute hydrochloric acid in methanol resulted in furanose-ring opening, affording an isopropylidene compound **8**.

Octosyl acids **A**, **B**, and **C**, which have been isolated from the fermentation broth of a polyoxin-producing microorganism *Streptomyces cacaoi* var. asoensis,[1] have been reported to have the structures **1a**, **1b**, and **2** by Isono, Crain, and McClosky.[2]



1a R=COOH
1b R=CH_2OH

2

These compounds are considered to be carbo-analogues of cyclic AMP,[2] and exploitation of a synthetic route to them may also contribute to the synthesis of other cyclic AMP analogues. We wish to report here the synthesis of the sugar portion of octosyl acids **A** and **B** with some protecting groups.

1,2: 5,6-Di-*O*-isopropylidene-α-D-allofuranose(**3a**)[3] was chosen as the starting material. Reaction of **3a** with methyl bromoacetate in the presence of sodium hydride in tetrahydrofuran afforded the methyl ester **3b**. Similarly, the ethyl ester **3c** was prepared.

To construct the bicyclic skeleton of octosyl acids, bond formation between the carbon at 3-O and C_6 in **3c** is necessary; for this purpose, an attempt was made to convert **3c** to a malonic acid derivative **3d** in order to activate the carbon atom at 3-O in **3c**.

Reaction of the ester **3c** with diethyl carbonate in the presence of one equivalent of sodium hydride in refluxing tetrahydrofuran afforded two products, which were separated by silica gel chromatography. The less polar compound, which was indistinguishable from the starting material on TLC, was actually found to be the required malonic acid derivative **3d**, showing two carbonyl bands at 1770 and 1740 cm^{-1} in the IR spectrum, a mass fragment ion at *m/e* 403 corresponding to M^+-CH_3, and a singlet a δ 4.78 in the NMR spectrum corresponding to one methine proton at 3-O-C. The more polar compound was found to be a Claisen condensation product **4**, showing a mass fragment ion at *m/e* 631 corresponding to M^+-CH_3. Though **4** was homogeneous on TLC, and the NMR spectrum showed a methine proton singlet at δ 4.78, the anomeric proton signal appeared as a multiplet (δ 5.68—5.88), suggesting that **4** was a mixture of the stereoisomers at the carbon atom flanked by two carbonyl groups. The yield ratio of **3d** to **4** varied markedly in several experiments, though the latter was predominant in every case. However, if the reaction was carried out in refluxing diethyl carbonate (bp 127 °C) instead of refluxing tetrahydrofuran (bp 66 °C), the formation of **3d** was predominant and the ratio of **3d** to **4** was found constantly to be 9: 1. On the contrary, **4** was formed exclusively when the reaction was carried out at 0 °C.

Treatment of **3d** in 70% acetic acid at 37 °C for 3 h was effective in obtaining the monoacetonated compound **5a** in a good yield. Reaction of **5a** with an equimolar amount of tosyl chloride afforded the 6-*O*-tosylate **5b** almost exclusively; a small amount of the ditosylate **5d** as well as the starting material were also isolated from the reaction mixture. With excess tosyl chloride, the ditosylate **5d** was formed exclusively. Reaction of **5b** with acetic anhydride in pyridine afforded the acetyl tosyl compound **5c**, whose proton signal at C-5 appeared in a lower field (δ 5.31) than that of **5b** (δ 3.8), showing the correctness of the assignment of **5b** as the 5-hydroxy compound.

The monotosylate **5b** was treated with an equimolar amount of sodium hydride in tetrahydrofuran at room temperature to give two products, which were separated by silica gel chromatography. The less polar one was the epoxy compound **6a**, the NMR spectrum of which still showed a singlet at δ 4.68, corresponding to one methine proton of the malonic acid moiety. The shifts of the proton signals at C_5 and C_6 in **6a** to higher fields showed the formation of an epoxide ring. The mass spectrum of **6a** showed intense peaks at *m/e* 345, 302, and 169 corresponding to M^+-CH_3, $M^+-CH_3-CH_2CH(-O-)$, and $M^+-CH_3-(C_2H_5OOC)_2CHO-H$.

The more polar one was found to have the same molecular formula as **6a** (M^+-CH_3 *m/e* 345) and was identified as the required **7a**, which showed an IR absorption at 3500 cm^{-1} corresponding to a hydroxyl group. The methine proton signal at δ 4.68 in the NMR spectrum in **5b** was lost **7a**, showing the bond formation between 3-O-C and C_6. The yield ratio of **6a** to **7a** was 1/2 to 1/3 throughout several experiments. Attempts at the conversion of **6a** to **7a** in the presence of varying amounts of sodium hydride (0.1 to 1.0 equivalent) failed, suggesting that the reaction to **6a** and **7a** from **5b** proceeded independently.

Similarly, the ditosylate **5d** and the acetyl tosylate **5c** were converted into two ring-formation compounds, **7c** and **7b**. In the latter case, the reaction conditions were

more vigorous (under reflux in tetrahydrofuran for 2 days) than in the former case (at room temperature in tetrahydrofuran for 20 h).

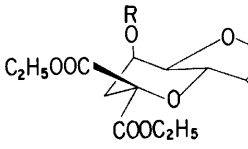
Attempts were made to construct the bicyclic system of octosyl acids by intramolecular cyclization of the monocarboxylic acid ethyl ester **5f** and its cyanomethyl analogue **5k**. As in the case of the tosylate **5b**, the tosylate **5f** was prepared from the partially deacetonated product **5e** of **3c**; **5e** was also converted into the ditosylate **5h** with excess tosyl chloride.

The cyanomethyl derivative **3e** was obtained in a moderate yield on treatment of **3a** with chloroacetonitrile or bromoacetonitrile in the presence of sodium hydride. Partial deacetonation of **3e** in 70% acetic acid afforded **5j**, which was then converted to the mono- and ditosylate, **5k** and **5l**.

The ester **5f** and the nitrile **5k** gave exclusively the epoxy compounds **6b** and **6c**; the required products were not obtained.

The benzoyl tosylate **5g**, the ditosylate **5h** and the iodo compound **5i**, which had been prepared from **5h** by treatment with sodium iodide in ethyl methyl ketone, were found to be inert to sodium hydride or lithium bis(trimethylsil)amide at room temperature or under reflux. These results were somewhat surprising, because, as has been mentioned previously, the diacetonated compound **3c** was converted into **4** even at 0 °C by treatment with sodium hydride.



7a R=H
7b R=CH_3CO
7c R=*p*-$CH_3C_6H_4SO_2$

Attempts at acetolysis of **7a**, followed by reaction with bis(trimethylsilyl)uracil using a $SnCl_4$ catalyst[4] to obtain a nucleoside related to octosyl acids, failed. The failure may be attributable to the susceptibility of the 3,7-anhydrooctose skeleton of **7a** to acids, which was also shown by the following results: in a dilute methanolic solution of hydrochloric acid (0.01 M) **7a** was converted into the ring-opened acetonate **8**, and under more vigorous conditions (0.5 M) the deacetonated product **9** was obtained. We feel now that the binding of the aglycon should be prior to the formation of the bicyclic system of the sugar portion in the synthesis of octosyl acids.

Experimental

1,2:5,6-Di-O-isopropylidene-3-O-ethoxycarbonylmethyl-α-D-allofuranose (3c). Sodium hydride (550 mg, 23 mmol), freshly prepared from a commercially available oil-coated product (NaH content, 50%) by washing with hexane, was added to a solution of **3a** (5.2 g, 20 mmol) in dry tetrahydrofuran (20 mmol). After the evolution of hydrogen had ceased, the mixture was cooled to 0 °C and ethyl bromoacetate (5 g, 30 mmol) was added dropwise. The mixture was stirred overnight at room temperature. The remaining sodium hydride was quenched by adding ethanol at 0 °C, and a few drops of acetic acid were added to keep the mixture acidic during processing. After the mixture had been concentrated, it was distributed between ethyl acetate and water. The organic layer was washed with water and then concentrated to dryness to give a crude product, which was crystallized from hexane; yield, 5.8 g (84%); mp 89—90 °C; ν_{CO}^{KBr} 1750 cm^{-1}; M^+-CH_3 *m/e* 331; NMR (100 MHz, $CDCl_3$) δ: 1.30 (t, 3H, ethyl ester J=7 Hz), 1.38 and 1.46 (2s, 6H, two

methyls of one isopropylidene group), 1.38 and 1.58 (2s, 6H, two methyls of one isopylropyidene group), 4.78 (t, 1H, H-2, $J_{1,2}$=4 Hz, $J_{2,3}$=4 Hz), 5.76 (s, 1H, H-1, $J_{1,2}$=4 Hz).

Found: C, 55.87; H, 7.69%. Calcd for $C_{16}H_{26}O_8$: C, 55.48; H, 7.57%.

*1,2:5,6-Di-O-isopropylidene-3-O-methoxycarbonylmethyl-α-D-allofuranose (**3b**).* Compound **3a** (5.2 g, 20 mmol) was treated with methyl bromoacetate (4.6 g, 30 mmol) and sodium hydride (550 mg, 23 mmol) in dry tetrahydrofuran (50 ml) as has been described in the preceding section. The product was crystallized from hexane; yield, 4.7 g (70%). Silica gel chromatography, developed with a mixture of benzene and ethyl acetate (2: 1), gave an analytically pure sample; mp 80—81 °C; ν_{CO}^{KBr} 1760 cm^{-1}; M$^+$−CH_3 *m/e* 317; NMR (100 MHz, $CDCl_3$) δ: 1.36 and 1.46 (2s, 6H, two methyls of one isopropylidene group), 1.36 and 1.58 (2s, 6H, two methyls of one isopropyridene group), 3.75 (s, 3H, methyl ester), 4.76 (t, 1H, H-2, $J_{1,2}$=4 Hz, $J_{2,3}$=4 Hz), 5.76 (d, 1H, H-1, $J_{1,2}$=4 Hz).

Found: C, 54.06; H, 7.16%. Calcd for $C_{15}H_{24}O_8$: C, 54.21; H, 7.28%.

*3-O-Bis(ethoxycarbonyl)methyl-1,2:5,6-di-O-isopropylidene-α-D-allofuranose (**3d**).* A suspension of sodium hydride (500 mg, 20 mmol) in diethyl carbonate (150 ml) previously dried over sodium was heated to reflux, and then the reaction vessel was taken off from the heater. Immediately, the ester **3c** (6.92 g, 20 mmol) was added portionwise. The mixture was further heated under reflux for 2 h and cooled to −15 °C. Ethanol (10 ml) and then acetic acid (2 ml) were added and the mixture was concentrated below 35 °C.

Silica gel chromatography of the ethyl acetate extracts, developed with mixtures of benzene and ethyl acetate (2—1: 1), afforded 6.6 g (80%) of the main product as a syrup, which was subsequently crystallized from ether and hexane; yield, 5.50 g; mp 50—51 °C; 1770 and 1740 cm^{-1}; M$^+$−CH_3 *m/e* 403; NMR (100 MHz, $CDCl_3$) δ: 4.70 (t, 1H, H-2, $J_{1,2}$=4 Hz, $J_{2,3}$=4 Hz), 4.80 (s, 1H, $H_5C_2OOCC\underline{H}COOC_2H_5$), 5.80 (d, 1H, H-1, $J_{1,2}$=4 Hz).

Found: C, 54.71; H, 7.19%. Calcd for $C_{19}H_{30}O_{10}$: C, 54.53; H, 7.23%.

From the reaction mixture was also isolated the Claisen condensation product **4**, which was more polar than **3d**; yield, 0.70 g.

*The Claisen Condensation Product **4**.* The ester **3c** (500 mg, 1.45 mmol) was treated with sodium hydride (40 mg, 1.65 mmol) in tetrahydrofuran (30 ml) first at 0 °C for 8 h and at room temperature for 16 h. The mixture was cooled again at 0 °C. After ethanol (1 ml) and a few drops of acetic acid had been added, it was concentrated and the product was extracted with ethyl acetate. Silica gel chromatography developed with a mixture of benzene and ethyl acetate (1: 1) afforded 310 mg (70%) of a syrup, which was fractionally precipitated from ethyl acetate and hexane for analysis; ν_{CO}^{KBr} 1740 cm^{-1}; M$^+$−CH_3 *m/e* 631; NMR (100 MHz, $CDCl_3$) δ: 4.72 (s, 1H, $OC\underline{H}COOC_2H_5$), 5.68—5.88 (m, 2H, two anomeric protons).

Found: C, 55.72; H, 7.17%. Calcd for $C_{30}H_{46}O_{15}$: C, 55.73; H, 6.98%.

The same reaction was carried out in a mixture of tetrahydrofuran and diethyl carbonate (9: 1) at room temperature. However, no trace of **3d** could be detected as was shown by IR. Note that the separation of **3d** from **3c** on TLC was unsucessful by any combination of solvents.

*3-O-Bis(ethoxycarbonyl)methyl-1,2-O-isopropylidene-α-D-allofuranose (**5a**).* A solution of **3d** (1.9 g) in 70% acetic acid (100 ml) was allowed to stand at 37 °C for 3 h and was evaporated to dryness keeping the temperature below 37 °C. To the residue was added an ice-cooled solution of sodium hydrogencarbonate, and the products were extracted with chloroform. TLC showed the presence of trace amounts of the starting material as well as one major and one minor product, the latter presumably being the di-deacetonated product, 3-*O*-bis(ethoxycarbonyl)methyl-D-allose.

The major one was isolated by silica gel chromatography, developed first with a mixture of benzene and ethyl acetate (1: 1) and then with ethyl acetate; yield, 1.4 g (82%). For further purification it was fractionally precipitated from benzene and hexane to give a syrup, which, on standing, was gradually converted into a solid melting at 53 °C; ν_{CO}^{KBr} 1773 and 1738 cm^{-1}; M$^+$−CH_3 *m/e* 363; NMR (100 MHz, $CDCl_3$) δ: 1.32 (t, 6H, ethyl ester, J=7 Hz), 1.35 and 1.56 (two s, 6H, two isopropylidene methyls), 4.64 (t, 1H, H-2, $J_{1,2}$=4 Hz, $J_{2,3}$=4 Hz), 4.74 (s, 1H, $H_5C_2OOCC\underline{H}COOC_2H_5$), 5.80 (d, 1H, H-1, $J_{1,2}$=4 Hz).

Found: C, 51.07; H, 6.58%. Calcd for $C_{16}H_{26}O_{10}$: C, 50.79; H, 6.93%.

*3-O-Bis(ethoxycarbonyl)methyl-1,2-O-isopropylidene-6-O-tosyl-α-D-allofuranose (**5b**).* Tosyl chloride (0.8 g, 4.2 mmol) was added all at once to a solution of **5a** (1.4 g, 3.7 mmol) in pyridine (50 ml) cooled at −15 °C, after which the mixture was allowed to stand at room temperature overnight. An ice-cooled solution of sodium hydrogencarbonate was added and the products were extracted with ethyl acetate. The main product was isolated by silica gel chromatography, developed with a mixture of benzene and ethyl acetate (2: 1); yield, 1.35 g (70%); M−CH_3 *m/e* 517; NMR (100 MHz, $CDCl_3$) δ: 1.30 (t, 6H, ethyl ester, J=7 Hz), 1.32 and 1.52 (two s, 6H, two isopropylidene methyls), 2.44 (s, 3H, one methyl of the tosyl group), 4.67 (s, 1H, $H_5C_2OOCC\underline{H}COOC_2H_5$), 5.72 (d, 1H, H-1, $J_{1,2}$=4 Hz), 7.33 and 7.82 (two d, 4H, four aromatic protons of the tosyl group, J_{ortho}=9 Hz).

Found: C, 51.93; H, 6.00; S, 5.97%. Cacld for $C_{23}H_{32}O_{12}S$: C, 51.87; H, 6.06; S, 6.02%.

*3-O-Bis(ethoxycarbonyl)methyl-5,6-di-O-tosyl-1,2-O-isopropylidene-α-D-allofuranose (**5d**).* Treatment of **5a** (500 mg) with tosyl chloride (1 g) in pyridine (20 ml) at 37 °C for 2 days afforded a single product. The pyridine was removed by evaporation, and an ice-cooled solution of sodium hydrogencarbonate was added. Extraction with ethyl acetate and silica gel chromatography, developed with a mixture of benzene and ethyl acetate (4: 1), gave a syrup; yield, 700 mg; NMR (100 MHz, $CDCl_3$) δ: 1.23 and 1.28 (two t, 6H, ethyl ester), 1.27 and 1.43 (two s, 6H, two isopropylidene methyls), 2.41 (s, 6H, two methyls of the tosyl group), 4.51 (t, 1H, H-2), 4.59 (s, 1H, $H_5C_2OOCC\underline{H}COOC_2H_5$), 5.11 (m, 1H, H-5), 5.46 (d, 1H, H-1, $J_{1,2}$=4 Hz).

Found: C, 53.05; H, 5.49; S, 9.01%. Calcd for $C_{30}H_{38}O_{14}S_2$: C, 52.47; H, 5.58; S, 9.34%.

*5-O-Acetyl-3-O-bis(ethoxycarbonyl)methyl-1,2-O-isopropylidene-6-O-tosyl-α-D-allofuranose (**5c**).* A solution of **5b** (700 mg) in a mixture of acetic anhydride (5 ml) and pyridine (2 ml) was allowed to stand at 37 °C for 3 h; after it was evaporated to dryness, the product was precipitated from ether and hexane to give a syrup; yield, 650 mg; NMR (100 MHz, $CDCl_3$) δ: 1.30 (t, 6H, ethyl ester, J=7 Hz), 1.32 and 1.52 (two s, 6H, two isopropylidene methyls), 2.03 (s, 3H, acetyl), 2.44 (s, 3H, one methyl of the tosyl group), 4.62 (t, 1H, H-2, $J_{1,2}$=4 Hz, $J_{2,3}$=4 Hz), 4.64 (s, 1H, $H_5C_2OOCC\underline{H}COOC_2H_5$), 5.31 (q, 1H, H-5), 5.70 (d, 1H, H-1, $J_{1,2}$=4 Hz), 7.35 and 7.82 (two d, 4H, four aromatic protons of the tosyl group, J_{ortho}=9 Hz).

Found: C, 52.36; H, 6.11; S, 5.56%. Calcd for $C_{25}H_{34}O_{13}S$: C, 52.25; H, 5.96; S, 5.58%.

5,6-Anhydro-3-O-bis(ethoxycarbonyl)methyl-1,2-O-isopropylidene-

*α-D-allofuranose (**6a**) and 3,7-Anhydro-7-bis(C-ethoxycarbonyl)-6-deoxy-1,2-O-isopropylidene-α-D-allo-heptose (**7a**).* To a solution of **5b** (700 mg, 1.3 mmol) in dry tetrahydrofuran (20 ml), cooled at −15 °C, has been added sodium hydride (34 mg, 1.4 mmol). After the mixture had been stirred for 20 h at room temperature, it was cooled again to −15 °C. Ethanol (1 ml) was added to quench the remaining sodium hydride, and acetic acid (1 ml) was added to keep the reaction mixture acidic during processing. Concentration, extraction with ethyl acetate, and developing on a silica gel column with mixtures of benzene and ethyl acetate (4—1: 1) afforded two products.

The less polar compound (132 mg) was identified as the epoxide **6a** and was obtained as a syrup by precipitation from benzene and hexane; MS (75 eV) *m/e*: 345 (M^+-CH_3), 302 ($M^+-CH_3-CH_2CH(-O-)$), 169 ($M^+-CH_3-H_5C_2OOCCH(O)COOC_2H_5-H$), 127 ($M^+-CH_3-H_5C_2OOCCH(O)COOC_2H_5-CH_2CH(-O-)$); NMR (100 MHz, $CDCl_3$) δ 1.31 and 1.38 (two t, 6H, ethyl ester, J=7 Hz), 1.36 and 1.56 (two s, 6H, two isopropylidene methyls), 2.82 (t, 1H, H_a-6, J_{gem}=4.5 Hz, $J_{5,6a}$=4.5 Hz), 3.10 (q, 1H, H_b-6, J_{gem}=4.5 Hz, $J_{5,6b}$=3 Hz), 3.32 (m, 1H, H-5), 3.81 (q, 1H, H-3, $J_{3,4}$=8 Hz, $J_{2,3}$=4 Hz), 4.28 and 4.29 (two q, 4H, two methylenes of the ester groups, J=7 Hz), 4.41 (q, 1H, H-4, $J_{3,4}$=8 Hz, $J_{4,5}$=2 Hz), 4.63 (t, 1H, H-2, $J_{1,2}$=4 Hz, $J_{2,3}$=4 Hz), 4.68 (s, 1H, $H_5C_2OOCCHCOOC_2H_5$), 5.80 (d, 1H, H-1, $J_{1,2}$=4 Hz).

Found: C, 53.10; H, 6.48%. Calcd for $C_{16}H_{24}O_9$: C, 53.33; H, 6.71%.

The more polar compound (387 mg) was obtained as a syrup by precipitation from benzene and hexane and was identified as **7a**: IR (KBr) cm^{-1}: 3500 (OH), 1770, sh and 1743 (CO); M^+-CH_3 *m/e* 345 (intense); NMR (100 MHz, $CDCl_3$) δ: 1.27 and 1.29 (two t, 6H, ethyl ester), 1.37 and 1.59 (two s, 6H, two isopropylidene methyls), 2.15 (broad, 1H, OH), 2.31 and 2.77 (two dd, 2H, H_a-6 and H_b-6, $J_{5,6a}$=3 Hz, $J_{5,6b}$=4 Hz, J_{gem}=15 Hz), 3.92 (dd, 1H, H-4, $J_{3,4}$=12 Hz, $J_{4,5}$=3 Hz), 4.29 (q, 4H, two methylenes of the ester groups, J=7 Hz), 4.35 (dd, 1H, H-3, $J_{2,3}$=4 Hz, $J_{3,4}$=12 Hz), 4.49 (broad, 1H, H-5), (4.79 (t, 1H, H-2, $J_{1,2}$=4 Hz, $J_{2,3}$=4 Hz), 5.77(d, 1H, H-1, $J_{1,2}$=4 Hz).

Found: C, 53.64; H, 6.67%. Calcd for $C_{16}H_{24}O_9$: C, 53.33; H, 6.71%.

*5-O-Acetyl-3,7-anhydro-7-bis(C-ethoxycarbonyl)-6-deoxy-1,2-O-isopropylidene-α-D-allo-heptose (**7b**).* A mixture of **5c** (535 mg, 0.93 mmol) and sodium hydride (30 mg, 1.3 mmol) in dry tetrahydrofuran (10 ml) was refluxed for 2 days and cooled to −15 °C. Ethanol (0.5 ml) and a few drops of acetic acid were added, and the mixture was concentrated. The product was extracted with ethyl acetate and purified by silica gel chromatography, developed with a mixture of benzene and ethyl acetate (2: 1); yield, 255 mg. For analysis it was fractionally precipitated from ethyl acetate and hexane to give a syrup; M^+-CH_3 *m/e* 387 (intense): NMR (100 MHz, $CDCl_3$) δ: 1.26 and 1.30 (two t, 6H, ethyl ester, J=7 Hz), 1.35 and 1.58 (two s, 6H, two isopropylidene methyls), 2.00 (s, 3H, acetyl), 2.39 and 2.90 (two dd, 2H, H_a-6 and H_b-6, $J_{5,6a}$=3 Hz, $J_{5,6b}$=4 Hz, J_{gem}=15 Hz), 3.95 (dd, 1H, H-4, $J_{3,4}$=10 Hz, $J_{4,5}$=3 Hz), 4.1—4.5 (m, 5H, H-3 and four methylene protons of the ester groups), 4.80 (t, 1H, H-2, $J_{1,2}$=4 Hz, $J_{2,3}$=4 Hz), 5.52 (m, 1H, H-5), 5.78 (d, 1H, H-1, $J_{1,2}$=4 Hz).

Found: C, 53.91; H, 6.55%. Calcd for $C_{18}H_{26}O_{10}$; C, 53.72; H, 6.51%.

*3,7-Anhydro-7-bis(C-ethoxycarbonyl)-6-deoxy-1,2-O-isopropylidene-6-O-tosyl-α-D-allo-heptose (**7c**).* A mixture of **5d** (710 mg, 1.03 mmol) and sodium hydride (38 mg, 1.5 mmol) in dry tetrahydrofuran (20 ml) was stirred at room temperature overnight and was treated as has been described in the preceding section. Silica gel chromatography, developed with a mixture of benzene and ethyl acetate (4: 1) followed by crystallization from ethyl acetate and hexane, afforded 318 mg of **7c**; mp 146—147 °C; MS (75 eV) *m/e*: 499 (M^+-CH_3), 427 ($M^+-CH_3-COOC_2H_5+H$), 342 ($M^+-CH_3C_6H_4SO_3H$); NMR (100 MHz, $CDCl_3$) δ: 1.26 and 1.31 (two t, 6H, ethyl ester), 1.33 and 1.52 (two s, 6H, two isopropylidene methyls), 2.42, (s, 3H, tosyl), 2.46 and 3.06 (two dd, 2H, H_a-6 and H_b-6, $J_{5,6a}$=3 Hz, $J_{5,6b}$=4 Hz, J_{gem}=15 Hz), 3.82 (dd, 1H, H-4, $J_{3,4}$=10 Hz, $J_{4,5}$=3 Hz), 4.1—4.5 (m, 5H, H-3 and four methylene protons of the ester groups), 4.72 (t, 1H, H-2, $J_{1,2}$=4 Hz, $J_{2,3}$=4 Hz), 5.09 (broad, 1H, H-5), 5.54 (d, 1H, H-1, $J_{1,2}$=4 Hz).

Found: C, 53.61; H, 5.83; S, 6.33%. Calcd for $C_{23}H_{30}O_{11}S$: C, 53.68, H, 5.88; S, 6.23%.

*3-O-Ethoxycarbonylmethyl-1,2-O-isopropylidene-α-D-allofuranose (**5e**).* A solution of **3c** (5 g, 14.5 mmol) in 70% acetic acid (100 ml) was allowed to stand at 37 °C for 3 h and was evaporated to dryness. An ice-cooled solution of sodium hydrogencarbonate was added, and the product was extracted with chloroform. TLC showed the presence of one major product as well as a small amount of the starting material and a by-product, the latter being presumably the di-deacetonated product, 3-*O*-ethoxycarbonylmethyl-D-allose.

Silica gel chromatography, developed with a mixture of ethyl acetate and methanol (9: 1), afforded 2.51 g (8.2 mmol, 57%) of **5e**, which was fractionally precipitated from benzene and hexane for analysis; M^+-CH_3 *m/e* 291; NMR (100 MHz, $CDCl_3$) δ: 1.30 (t, 3H, ethyl ester, J=7 Hz), 1.36 and 1.58 (2s, 6H, two isopropylidene methyls), 4.68 (t, 1H, H-2, $J_{1,2}$=4 Hz, $J_{2,3}$=4 Hz), 5.77 (d, 1H, H-1, $J_{1,2}$=4 Hz).

Found: C, 50.99; H, 7.18%. Calcd for $C_{13}H_{22}O_8$: C, 50.97; H, 7.24%.

*3-O-Ethoxycarbonylmethyl-1,2-O-isopropylidene-6-O-tosyl-α-D-allofuranose (**5f**).* Compound **5e** (828 mg, 2.7 mmol) was treated with tosyl chloride (420 mg, 2.7 mmol) much as in the preparation of **5b**. The main product was isolated by silica gel chromatography, developed with mixtures of benzene and ethyl acetate (2—1: 1); it was obtained as a syrup from ethyl acetate and hexane; yield, 810 mg; IR (KBr) cm^{-1}: 3470 (OH), 1735 (ester); M^+-CH_3 *m/e* 445; NMR (100 MHz, $CDCl_3$) δ: 1.26 (t, 3H, ethyl ester, J=7 Hz), 1.33 and 1.52 (2s, 6H, two isopropylidene methyls), 2.42 (1s, 3H, methyl of the tosyl group), 5.71 (d, 1H, H-1, $J_{1,2}$=4 Hz), 7.32 and 7.80 (two d, 4H, four aromatic protons of the tosyl group).

Found: C, 52.23; H, 5.95; S, 6.95%. Calcd for $C_{20}H_{28}O_{10}S$: C, 52.16; H, 6.13; S, 6.96%.

*5,6-Di-O-tosyl-3-O-ethoxycarbonylmethyl-1,2-O-isopropylidene-α-D-allofuranose (**5h**).* Compound **5e** (306 mg, 1 mmol) was treated with tosyl chloride (760 mg, 4 mmol) much as in the preparation of **5d**. Silica gel chromatography, developed with mixtures of benzene and ethyl acetate (4—1: 1), afforded 450 mg of the product, which was crystallized from ethyl acetate and hexane; mp 115—116 °C; NMR (100 MHz, $CDCl_3$) δ: 1.26 (t, 3H, ethyl ester, J=7 Hz), 1.31 and 1.48 (2s, 6H, two isopropylidene methyls), 2.44 (s, 6H, two methyls of the tosyl group), 4.58 (t, 1H, H-2, $J_{1,2}$=4 Hz, $J_{2,3}$=4 Hz), 5.07 (m, 1H, H-5), 5.47 (d, 1H, H-1, $J_{1,2}$=4 Hz), 7.33 and 7.72 (two d, 4H, four aromatic protons of one tosyl group, J_{ortho}=8 Hz), 7.33 and 7.76 (two d, 4H, four aromatic protons of one tosyl group, J_{ortho}=8 Hz).

Found: C, 52.79; H, 5.56; S, 10.42%. Calcd for $C_{27}H_{34}O_{12}S_2$: C, 52.75: H, 5.58; S, 10.43%.

*5-O-Benzoyl-3-O-ethoxycarbonylmethyl-1,2-O-isopropylidene-6-O-tosyl-α-D-allofuranose (**5g**).* To a solution of **5f** (3 g,

6.6 mmol) in pyridine (50 ml), cooled at −15 °C, was added benzoyl chloride (3 g, 21 mmol), after which the solution was stirred for 1 h at room temperature. An ice-cooled solution of sodium hydrogencarbonate was added, and the product was extracted with ethyl acetate. Precipitation from ether and hexane afforded 3.10 g of a syrup (83%); M^+-CH_3 *m/e* 549; NMR (100 MHz, $CDCl_3$) δ: 1.20 (t, 3H, ethyl ester, J=7 Hz), 1.32 and 1.55 (2s, 6H, two isopropylidene methyls), 2.34 (s, 3H, methyl of the tosyl group), 4.68 (t, 3H, H-2, $J_{1,2}$=4 Hz, $J_{2,3}$=4 Hz), 5.5—5.7 (m, 2H, H-1 and H-5), 7.18 and 7.72 (2d, 4H aromatic protons of the tosyl group, J_{ortho}=8 Hz), 7.3—7.6 (m, 3H, *meta* and *para* protons of the benzoyl group), 7.94 (dd, 2H, *ortho* protons of the benzoyl group, J_{ortho}=8 Hz, J_{meta}=1.5 Hz).

Found: C, 57.51; H, 5.73; S, 5.48%. Calcd for $C_{27}H_{32}O_{11}S$: C, 57.43; H, 5.71; S, 5.68%.

5-O-Benoyl-z6-deoxy-3-O-ethoxycarbonylmethyl-6-iodo-1,2-O-isopropylidene-α-D-allofuranose (5i). A solution of **5g** (2.46 g, 4.6 mmol) and sodium iodide (3 g, 20 mmol) in ethyl methyl ketone (50 ml) was refluxed for 17 h. After the solvent had been evaporated to dryness, the residue was distributed between water and ethyl acetate. The organic layer was washed with an aqueous solution of sodium hydrogensulfite. TLC showed the formation of a sigle product, which was isolated by silica gel chromatograpy developed with mixtures of benzene and ethyl acetate (9—4: 1) yield, 1.65 g. For analysis it was fractionally precipitated from ether and hexane. It gradually decomposed at 56 °C *in vacuo*; MS (75 eV) *m/e*: 505 (M^+-CH_3), 393 (M^+-1); NMR (100 MHz, $CDCl_3$) δ: 1.20 (t, 3H, ethyl ester, J=7 Hz), 1.34 and 1.59 (two s, 6H, two isopropylidene methyls), 4.71 (t, 1H, H-2, $J_{1,2}$=4 Hz, $J_{2,3}$=4 Hz), 5.35 (q, 1H, H-5, $J_{4,5}$=6 Hz, $J_{5,6}$=6 Hz), 5.71 (d, 1H, H-1, $J_{1,2}$=4 Hz), 7.3—7.7 (m, 3H, *meta* and *para* protons of the benzoyl group), 8.08 (dd, 2H, *ortho* protons of the benzoyl group, J_{ortho}=8 Hz, J_{meta}=1.5 Hz).

Found: C, 46.98; H, 4.95; I, 23.76%. Calcd for $C_{20}H_{25}O_8I$: C, 47.20; H, 5.09; I, 32.75%.

5,6-Anhydro-3-O-ethoxycarbonylmethyl-1,2-O-isopropylidene-α-D-allofuranose (6b). A mixture of **5f** (689 mg, 1.5 mmol) and sodium hydride (36 mg, 1.5 mmol) in dry terahydrofuran (10 ml) was refluxed for 2 h and then cooled to −15 °C. Ethanol (1 ml) and a few drops of acetic acid were added, and the mixture was concentrated to dryness. The product was extracted with chloroform, and crystallized from ether and hexane; yield, 227 mg; mp 55—57 °C; ν_{CO}^{KBr} 1755 cm^{-1}; MS (75 eV) *m/e*: 273 (M^+-CH_3), 169 ($M^+-CH_3-C_2H_5OOCCH_2O-H$), 127 ($M^+-CH_3-C_2H_5OOCCH_2O-CH_2CH(-O-)$); NMR (100 MHz, $CDCl_3$) δ: 1.32 (t, 3H, ethyl ester, J=7 Hz), 1.39 and 1.60 (2s, 6H two isopropylidene methyls), 2.84 (t, 1H, H_a-6, $J_{5,6a}$=5 Hz, J_{gem}=5 Hz), 3.01 (q, 1H, H_b-6, $J_{5,6b}$=3 Hz, J_{gem}=5 Hz), 3.26 (m, 1H, H-5), 3.82 (q, 1H, H-4, $J_{3,4}$=9 Hz, $J_{4,5}$=5 Hz), 4.71 (t, 1H, H-2, $J_{1,2}$=4 Hz, $J_{2,3}$=4 Hz), 5.79 (d, 1H, H-1, $J_{1,2}$=4 Hz).

Found: C, 54.28; H, 6.81%. Calcd for $C_{13}H_{20}O_7$; C, 54.16; H, 6.99%.

3-O-Cyanomethyl-1,2:5,6-di-O-isopropylidene-α-D-allofuranose (3e). To a stirred mixture of **3a** (19.5 g, 7.5 mmol) and sodium hydride (1.8 g, 7.5 mmol) in dry tetrahydrofuran (200 ml), cooled at −15 °C, was added bromoacetonitrile (10 g, 8.3 mmol) dropwise. The mixture gradually became dark and was stirred at room temperature for 3 h. Ethanol (10 ml) was added at 0 °C to quench any remaining sodium hydride. After concentration of the mixture, the products were extracted with ethyl actate. TLC showed the presence of one major product as well as a few minor ones. Silica gel chromatography, developed with mixtures of benzene and ethyl actate (4—2: 1), and crystallization from ethyl actate and hexane, afforded 7.5 g (33%) of **3e**: mp 109 °C. Similarly, from 13 g of **3a** and 10 g of chloroacetonitrile, 5.1 g of **3e** was obtained; M^+-CH_3 *m/e* 284 (base peak); NMR (100 MHz, $CDCl_3$) δ: 1.36 and 1.49 (2s, 6H,two methyls of one isopropylidne group), 1.36 and 1.57 (2s, 6H two methyls of one isopropylidene group), 4.41 and 4.54 (two d, 2H, OCH_2CN, J_{gem}=16 Hz), 5.81 (d, 1H, H-1, $J_{1,2}$=4 Hz).

Found: C, 55.78; H, 6.96; N, 4.56%. Calcd for $C_{14}H_{21}O_6N$: C, 56.17; H, 7.07; N, 4.68%.

3-O-Cyanomethyl-1,2-O-isopropylidene-α-D-allofuranose (5j). A solution of **3e** (1 g) in 70% acetic acid (50 ml) was allowed to stand at room temperature overnight and was concentrated below 37 °C to dryness. The residue was well dried over phosphorous pentoxide and sodium hydroxide; it was subsequently chromatographed on silica gel developed with ethyl acetate and with a mixture of ethyl acetate and methanol (9: 1) to give a syrup; yield, 730 mg (76%); MS (75 eV) *m/e*: 244 (M^+-CH_3), 198 (M^+-HOCH_2CHOH); NMR (100 MHz, $CDCl_3$) δ: 1.36 and 1.55 (two s, 6H, two isopropylidene methyls), 5.84 (d, 1H, H-1, $J_{1,2}$=4 Hz).

Found: C, 50.68; H, 6.52; N, 5.21%. Calcd for $C_{11}H_{17}NO_6$: C, 50.96; H, 6.61; N, 5.40%.

3-O-Cyanomethyl-1,2-O-isopropylidene-6-O-tosyl-α-D-allofuranose (5k) and 3-O-Cyanomethyl-5,6-di-O-tosyl-1,2-O-isopropylidene-α-D-allofuranose (5l). A mixture of **5j** (1.84 g, 7.1 mmol) and tosyl chloride (2.6 g, 13.6 mmol) in pyridine (30 ml) was allowed to stand at room temperature overnight, and ice water was added. TLC of the chloroform extract showed the formation of two products, which were separated by silica gel chromatography developed with mixtures of benzene and ethyl acetate (4—1: 1).

The less polar compound, identified as the ditosylate **5l**, was obtained as a syrup (1.3 g) by precipitation from benzene and hexane; M^+-CH_3 *m/e* 552; NMR (100 MHz, $CDCl_3$) δ: 1.32 and 1.49 (2s, 6H, two isopropylidene methyls), 2.43 (s, 6H, methyls of two tosyl groups), 4.35 (s, 2H, OCH_2CN), 4.69 (t, 1H, H-2, $J_{1,2}$=4 Hz, $J_{2,3}$=4 Hz), 4.90 (m, 1H, H-5), 5.55 (d, 1H, H-1, $J_{1,2}$=4 Hz).

Found: C, 52.72; H, 5.15; N, 2.48; S, 11.11%. Calcd for $C_{25}H_{29}O_{10}NS_2$: C, 52.90; H, 5.15; N, 2.47; S, 11.30%.

The more polar compound, identified as the monotosylate **5k**, was obtained as a syrup by precipitation from benzene and hexane; M^+-CH_3 *m/e* 398; NMR (100 MHz, $CDCl_3$) δ: 1.34 and 1.52 (two s, 6H, two isopropylidene methyls), 2.44 (s, 3H, methyl of the tosyl group), 4.35 and 4.43 (two d, 2H, OCH_2CN, J=16 Hz), 4.72 (t, 1H, H-2, $J_{1,2}$=4 Hz, $J_{2,3}$=4 Hz), 5.77 (d, 1H, H-1, $J_{1,2}$=4 Hz), 7.34 and 7.80 (2d, 4H four aromatic protons of the tosyl group, J_{ortho}=8 Hz).

Found: C, 52.26; H, 5.63; N, 3.23; S, 7.53%. Calcd for $C_{18}H_{23}O_8NS$: C, 52.29; H, 5.61; N, 3.39; S, 7.76%.

5,6-Anhydro-3-O-cyanomethyl-1,2-O-isopropylidene-α-D-allofuranose (6c). A mixture of **5k** (306 mg, 0.74 mmol) and sodium hydride (21 mg, 0.87 mmol) in dry tetrahydrofuran (10 ml) was stirred at room temperature for 20 h. TLC showed the formation of a single product. Ethanol (1 ml) and a few drops of acetic acid were added, and, after the mixture had been concentrated, the product was extracted with ethyl acetate. Precipitation from ether and hexane afforded 152 mg of a syrup; MS (75 eV) *m/e*: 226 (M^+-CH_3), 169 ($M^+-CH_3-CNCH_2O-H$), 127 ($M^+-CH_3-CNCH_2O-CH_2CH(-O-)$), NMR (100 MHz, $CDCl_3$ δ: 1.35 and 1.54 (2s, 6H two isopropylidene methyls), 2.73 (q, 1H, H_a-6, $J_{5,6a}$=3 Hz, J_{gem}=5 Hz), 2.88 (t, 1H, H_b-6, $J_{5,6b}$=5 Hz, J_{gem}=5 Hz), 3.20 (q, 1H, H-5), 3.88 (q, 1H, H-3, $J_{2,3}$=4 Hz, $J_{3,4}$=8 Hz), 4.08 (q, 1H, H-4, $J_{3,4}$=8 Hz, $J_{4,5}$=3.5 Hz), 4.38

and 4.47 (two d, 2H, OCH_2CN, $J_{gem}=16$ Hz), 4.72 (t, 1H, H-2, $J_{1,2}=4$ Hz, $J_{2,3}=4$ Hz), 5.82 (d, 1H, H-1, $J_{1,2}=4$ Hz).

Found: C, 54.65; H, 6.25; N, 5.71%. Calcd for $C_{11}H_{15}NO_5$: C, 54.76; H, 6.27; N, 5.81%.

Methyl 3,7-Anhydro-7-bis(C-ethoxycarbonyl)-6-deoxy-1,2-O-isopropylidene-D-allo-heptoside (8). A solution of **7a** (270 mg) in methanol containing dry HCl (0.01 M, 10 ml) was allowed to stand at room temperature for 7 h and concentrated while keeping the temperature below 40 °C. An ice-cooled solution of sodium hydrogencarbonate was added, and the product was extracted with ethyl acetate. Silica gel chromatography, developed with a mixture of benzene and ethyl acetate (1:1), and crystallization from benzene and hexane afforded 177 mg of **8**; mp 90 °C; MS (75 eV) *m/e*: 377 (M^+-CH_3), 361 (M^+-OCH_3); NMR (100 MHz, $CDCl_3$) δ: 1.23 and 1.29 (two t, 6H, ethyl ester $J=7$ Hz), 1.47 and 1.49 (two s, 6H, two isopropylidene methyls), 2.23 and 2.76 (two dd, 2H, H_a-6 and H_b-6, $J_{5,6a}=3$ Hz, $J_{5,6b}=4$ Hz, $J_{gem}=15$ Hz), 3.41 (s, 3H, OCH_3), 5.33 (d, 1H, H-1, $J_{1,2}=1$ Hz).

Found: C, 50.61; H, 7.08%. Calcd for $C_{17}H_{28}O_{10}$: C, 50.29; H, 6.63%.

3,7-Anhydro-7-bis(C-ethoxycarbonyl)-6-deoxy-D-allo-heptose Dimethyl Acetal (9). A solution of **7a** (193 mg) in methanol containing dry HCl (0.5 M, 10 ml) was allowed to stand at room temperature overnight; subsequently it was concentrated while keeping the temperature below 40 °C. An ice-cooled solution of sodium hydrogencarbonate was added, and the product was extracted with ethyl acetate. Silica gel chromatography, developed with ethyl acetate followed by a mixture of ethyl acetate and methanol (9:1), afforded 60 mg of an amorphous solid. For analysis it was fractionally precipitated from ethyl acetate and hexane. It showed no definite mp; NMR (100 MHz, $CDCl_3$) δ: 1.25 and 1.29 (two t, 6H, ethyl ester, $J=7$ Hz), 2.21 and 2.77 (two dd, 2H, H_a-6 and H_b-6, $J_{5,6a}=3$ Hz, $J_{5,6b}=4$ Hz, $J_{gem}=15$ Hz), 3.44 and 3.76 (two s, 6H, $2OCH_3$).

Found: C, 49.11; H, 6.90%. Calcd for $C_{15}H_{26}O_{10}$: C, 49.17; H, 7.15%.

Direct Measurement of the Rates of Ionic Dissociation by Dynamic NMR Technique. Dissociation of α-Chlorodibenzyl Sulfides

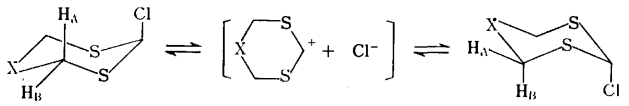
Kazutaka ARAI and Michinori ŌKI*

Department of Chemistry, Faculty of Science, The University of Tokyo, Tokyo 113

(Received May 15, 1976)

Exchange processes of diastereotopic protons of α-chlorodibenzyl sulfides were observed by means of dynamic nuclear magnetic resonance. Polar effects of solvents and substituent effects on the ease of the exchange process of protons in *p,p'*-disubstituted α-chlorodibenzyl sulfides indicate that the process occurs with the dissociation of the compounds into benzylic cations and chloride ion. It is possible to measure the rates of ionic dissocation by observing the change in the line shape of signals in ^{1}H NMR spectra. The scope of the method is discussed.

In a previous paper a report was given on the observation of ionic dissociation of 2-chloropolythianes (**1**) by dynamic nuclear magnetic resonance technique.[1] In this case, inversion of the six-membered ring is the required process to average the chemical shifts of the protons in question. Thus, the energetics of the ring inversion might be included in the energetics of ionic dissociation, when the compound requires small energy for the dissociation.

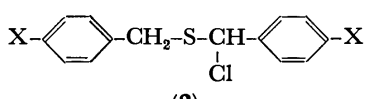


(*1*) (*1'*)

We have undertaken an extension of the above technique in order to generalize the method for determination of the rates and/or energetics for ionic dissociation of certain organic compounds. Since the ionic dissociation is a crucial step in S_N1 reactions, a knowledge of the rates of ionization would help understand such reactions.

For application of dynamic NMR technique, the compound should satisfy the following three conditions. a) It can produce a stable cation since NMR technique can detect neither very slow nor very fast exchange processes. b) It possesses a pair of diastereotopic protons. c) It is desirably an acyclic compound, direct measurement of the rates of ionization being possible, since ring inversion is not necessary for the averaging of protons.

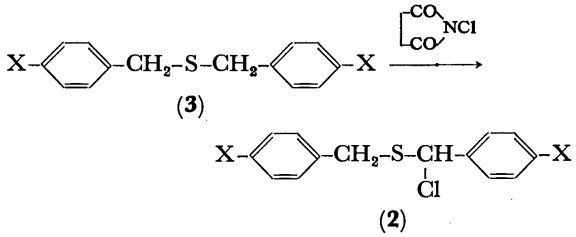
Suitable samples are α-chloro sulfides since they produce stable cations due to the presence of sulfur atoms, as confirmed for chloropolythianes. After several trials we found that α-chlorodibenzyl sulfides (**2**) satisfy the conditions: the cation produced receives additional stabilization due to the presence of a benzene ring. This paper describes the determination of free energies for ionic dissociation of these compounds and discusses the effects of substituents and solvents on ionic dissociation.



(**2**)

Experimental

Syntheses. The compounds required for the measurements were prepared by chlorination of substituted dibenzyl sulfides (**3**) with *N*-chlorosuccinimide. All the sulfides were known compounds but two were prepared by modified methods.



(**3**) (**2**)

*Bis(*p*-chlorobenzyl) Sulfide (**3**, X=Cl).* To a methanolic solution of sodium methoxide prepared from 4.0 g (0.17 mol) of sodium and 150 ml of methanol was added 25 g (0.16 mol) of *p*-chlorophenylmethanethiol and then 25 g (0.16 mol) of *p*-chlorobenzyl chloride during a 10 min period with stirring. The resulting mixture was heated under reflux for 3 h and the solvent was evaporated under reduced pressure. The residue was taken up in benzene and washed with 6 M sodium hydroxide and then with water. After drying over magnesium sulfate, the solvent was evaporated *in vacuo* and the residue was kept overnight at —5 °C to induce crystallization. Washing twice with small amounts of hexane gave pure **3** (X=Cl), mp 42 °C (lit,[2] mp 42 °C), in 90% yield.

*Bis(*p*-methylbenzyl) Sulfide (**3**, X=CH$_3$)*, mp 77 °C (lit,[3] mp 76 °C), was prepared similarly in 90% yield.

^{1}H NMR spectral data of the sulfides are summarized in Table 1.

Table 1. ^{1}H NMR spectral data of *p,p'*-disubstituted dibenzyl sulfides (**3**) in carbon tetrachloride (δ)

a) Data with a $CDCl_3$ solution.

Chlorination of p,p'*-Disubstituted Dibenzyl Sulfides.* To a solution of 1.0 g of a *p,p'*-disubstituted dibenzyl sulfide in 10 ml of carbon tetrachloride was added 1.1 equivalents of powdered *N*-chlorosuccinimide at 35 °C with stirring during a 5 min period under nitrogen atmosphere. Stirring was continued for 1—2 h after completion of the addition. The reaction mixture was filtered in order to remove insoluble materials, contact with moisture being avoided as completely as possible. From ^{1}H NMR spectral data of the filtrate, the

purity and yield of *p,p'*-disubstituted α-chlorodibenzyl sulfides were estimated to be 90—95% and 85—90%, respectively.

The nitro compound, being sparingly soluble in carbon tetrachloride, was chlorinated in benzene by essentially the same procedure.

^{1}H NMR spectral data of the *p,p'*-disubstituted α-chlorodibenzyl sulfides are given in Table 2.

Table 2. ^{1}H NMR spectral data of *p,p'*-disubstituted α-chlorodibenzyl sulfides (**2**) in carbon tetrachloride (δ)

Substituent (X)	Benzylic δ	CH_2 J	Methine H	Aromatic H	Others

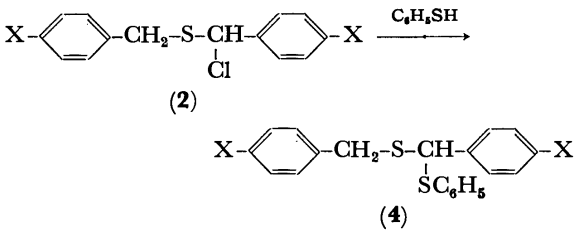
a) Data with a $CDCl_3$ solution. b) It was impossible to determine which of the two pairs at the higher field forms the AB quartet with a pair of signals at the lower field. The coupling constants for the two AB quartets were 9.0 Hz.

Benzenethiolyses of p,p'*-Disubstituted α-Chlorodibenzyl Sulfides.* The solutions of *p,p'*-disubstituted α-chlorodibenzyl sulfides obtained above were treated with 2—3 equivalents of benzenethiol at room temperature for 8—10 h and the resulting mixture was evaporated *in vacuo* Chromatography of the residue on silica gel afforded pure *p,p'*-disubstituted α-phenylthiodibenzyl sulfides (**4**). The pertinent data are summarized in Table 3.



^{1}H NMR Measurement. ^{1}H NMR spectra were recorded on a Hitachi R 20B spectrometer, operating at 60 MHz, with a temperature variation accessory. The temperature reading was calibrated by measuring the chemical shift difference between methylene and hydroxy protons of ethylene glycol for the higher temperatures and that between methyl and hydroxy protons of methanol for the lower temperatures.

Kinetic Parameters. The rate constants of the exchange processes at the coalescence temperature were obtained by application of the following equation,[7] where J_{AB} is the coupling constant of the diastereotopic protons and $\Delta\nu_{AB}$ the chemical shift difference of these protons.

$$k_c = \frac{\pi}{\sqrt{2}}\sqrt{6J_{AB}^2+\Delta\nu_{AB}^2} \quad (1)$$

Free enrgies of activation at the coalescence temperature were obtained by substituting k_c into the following equation.

$$\Delta G_c^{\ddagger} = 4.57T_c\left\{10.319+\log\frac{T_c}{k_c}\right\} \quad (2)$$

Results and Discussion

Confirmation of the Structure of p,p'*-Disubstituted α-Chlorodibenzyl Sulfides.* Since the *p,p'*-disubstituted α-chlorodibenzyl sulfides (**2**), key compounds in this paper, are reactive toward moisture, their structures must be confirmed by other means. This is accomplished by a) the chemical method and b) ^{1}H NMR spectral data. In a), since the method of preparation is generally applied to α-chlorination of sulfides,[8] a chlorine atom is expected to enter at a benzylic position. The ease of reaction of these compounds with benzenethiol is supporting evidence for the structure, since other normal halides would not be so reactive as these compounds. The substituted α-phenylthiodibenzyl sulfides (**4**) are analyzed correctly. In b) the two benzylic protons turn to a methine proton

which gives a signal at a low field. In addition, the benzylic protons in the chloro compounds **2** and in phenylthio compounds **4** give AB quartets: it would not be possible to explain if a chiral center were not present in the proximity of these protons.

Dynamic NMR and the Rate Process. The ^{1}H NMR spectra of the chlorides **2** were found to be dependent on solvents and temperature. Typical examples of temperature-dependence of the spectra are shown in Fig. 1. Since a quartet signal of a diastereotopic pair of protons does not usually coalesce below 200 °C, the temperature-dependent spectra suggest that a certain exchange process involving bond breaking takes place under these conditions. The process should be such that chirality due to asymmetric carbon is lost.

Survey of solvent and substituent effects on the coalescence temperature and free energies of activation will shed light on the nature of the process. The temperature dependence of the spectra of α-chlorodibenzyl sulfide was investigated in various solvents. The results are given in Table 4. Nitrobenzene showed no tendency of line broadening even at 0 °C. The coalescence temperature is lower when the solvent is more polar, the free energies of activation being lower. The cases of chloroform and deuteriochloroform are exceptions. We wish to attribute this anomaly to the hydrogen bond effect. Chloroform is known to form hydrogen bond[9] which should stabilize an anion.[10] No such stabilization is expected in the other solvents used. Deuteriochloroform would stabilize the anion to a greater extent, since deuterium compounds are known to form a stronger hydrogen bond than the corresponding ^{1}H compounds.[11]

a) 1-Chloronaphthalene. b) J_{AB} and $\Delta\nu_{AB}$ in chlorobenzene are diverted.

The results obtained by changing the solvent are consistent with the idea that the loss of the chiral center is of polar nature. Heterolysis of the C–S bond requires much energy. Then, in principle, the following two modes of dissociation are possible.

$$\mathrm{ArCH_2S\underset{\displaystyle Cl}{\underset{|}{C}}HAr \rightleftarrows ArCH_2S\overset{+}{C}HAr + Cl^-} \qquad (3)$$

$$\mathrm{ArCH_2S\underset{\displaystyle Cl}{\underset{|}{C}}HAr \rightleftarrows ArCH_2S\underset{\displaystyle Cl}{\underset{|}{\bar{C}}}Ar + H^+} \qquad (4)$$

Although it may seem that Eq. 3 is a more plausible process, Eq. 4 may not be ruled out without convincing evidence. Such evidence should be provided when the substituent effect is examined: if the process is represented by Eq. 3, electron-releasing groups should facilitate the exchange, and the reverse is true if the process is represented by Eq. 4.

The results of changing the substituent are given in Table 5, in which σ_m values are included as a measure of electron-donating or electron-withdrawing ability. The results are in line with the idea that the electron-donating substituent facilitates the process. Thus the exchange of proton spins occurs following Eq. 3.

Rate Constants of the Ionic Dissociation. Although the planar cation itself erases the non-equivalency of the CH_2 protons due to its planar structure, we observe no NMR spectra of the cation because of its transient nature. Thus the equivalency of the methylene protons at a higher temperature is caused by the rapid mixing of one stereoisomer with another. The mixing or interconversion of one stereoisomer with another can occur in one or more of the following steps. If the compound dissociates into a free cation and a free anion, recombination to produce the mother compound would proceed from either side of the plane of the cation, thus producing a 1 : 1 mixture of the enantiomers. If the cation undergoes internal rotation about the S–C$^+$ axis while the anion remains immobile, the stereoisomer is formed, or else, the anion will recombine with the cation from the other side than that where the former departed. These cases are possible when the ions form a loose ion pair. If the ions form a tight ion pair, it is not possible to invert the stereochemistry directly. However, we might consider the cation to be of pyramidal shape and inversion of the pyramid followed by recombination with an anion derived from another molecule leads to the formation of a stereoisomer.

It is difficult to determine to what extent the above

a) The signal due to benzyl protons of *p,p'*-dimethyl-α-chlorodibenzyl sulfide was sharper than that of α-chlorodibenzyl sulfide.

factors are responsible. To a first approximation, however, we may take a model in which the probability of the ion pairs returning to the original stereochemistry and forming the other stereochemistry are 50: 50 as a result of many factors. The rate of the dissociation of the chloride **2** must then be twice the rate of the exchange process. The results are included in Table 5.

It is of interest that the barriers to the ionic dissociation of these compounds are comparable to or smaller than that of triphenylmethyl chloride. The enthalpy and the entropy of activation for the reaction of triphenylmethyl chloride in aqueous acetone were reported to be 12.5 kcal/mol and −17 e.u. at temperatures between −34 °C and −14 °C.[12] The free energy of activation is then calculated to be *ca.* 17 kcal/mol at about −20 °C. If we assume this to be the pure S_N1 reaction, the energy should correspond to that for ionic dissociation. Since the polarity of the solvent is high in this case, the ionic dissociation of the chloro compound **2** may be taken as an easy one. The enthalpy and entropy of activation for the exchange process of chloride ion in benzene are reported to be 12.4 kcal/mol and −39 e.u. respectively, at 50 °C for triphenylmethyl chloride[13] and the free energy is calculated as 25 kcal/mol at that temperature.

Conclusion. The method described here for determining the rates of ionic dissociation seems to be of value in kinetic studies. For the tranditional chemical method, racemization or isotope exchange had to be used. This necessitates an optically active compound or isotopically enriched ions. As an example, the rate of ionization of triphenylmethyl chloride was estimated from the exchange of the chloro group with isotopically labelled tetraalkylammonium chloride,[13] but the method is hampered by the fact that the concentration of the ammonium chloride affects the rates. The method described here needs no expensive isotopes, optical isomers nor a nucleophile to react. Thus the rate of ionization can be obtained without perturbation of the excess of other materials. Since the ionization of an organic compound into a stable cation and an anion is an important step in S_N1 reactions and many stable cations show substantial barriers for reaction with another anion,[14] dynamic NMR method provides an important means for understanding such a reaction.

If a compound possesses a good leaving group at a chiral or prochiral center and diastereotopic protons close to the center, and produces a fairly stable carbonium ion, then the rates of the dissociation can be determined by dynamic NMR technique.[15] As one example, the case of α-chlorodibenzyl sulfides is presented.

The Intramolecular OH---π Bonding in [n]Paracyclophanols[1)]

Nobuo MORI, Tetsuo TAKEMURA, and Takayoshi OHKUMA

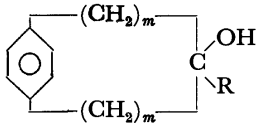
Department of Chemistry, Science University of Tokyo, Kagurasaka 1-3, Shinjuku-ku, Tokyo 162

(Received June 3, 1976)

The intramolecular OH···π bonding, the probable conformations, and the internal rotation in two series of [n]-paracyclophanols, I (**1**—**4**) and II (**5**—**8**), are investigated by means of IR, UV, and PMR spectroscopies. The IR results indicate that (1) there is the OH···π bonding in **1**, **2**, **3**, **5**, and **7** in CCl_4, and (2) the integrated intensity ratio of the π-bonded OH species to the free OH, (A_b/A_f), hardly changes in going from **1** to **3**, while it decreases in going from **5** to **7**. The ratio is, then, related to both ΔH and ΔS. In the PMR spectra, aliphatic-proton signals are assigned by means of the spin-decoupling and/or the shift-reagent technique; the results agree with those predicted, with a few exceptions. In the aromatic region, **3**, **4**, and **8** show singlets, while the others show AB-like quartets. These results are discussed in relation to the internal rotation of the benzene ring and/or the alkylene chain.

Intramolecular hydrogen bondings have been observed in many systems of open chains and medium-size rings,[2)] and the spectral shifts of the bonded OH bands have been measured. There have, though, been surprisingly few reports on thermodynamic measurements for the intramolecular hydrogen-bond formations, and these have been for only a few acylic systems of β-phenylalkanols,[3)] 1,3-diols,[4)] and ω-methoxyalkanols.[5)] Only the last system has been examined in relation to the alkylene-chain length. In this system, the loss of entropy accompanying the hydrogen-bond formation increases greatly with the increasing chain length, but the enthalpy term hardly changes at all.

In the present work, we will examine the intramolecular OH···π bonding in two series of [n]paracyclophanols, I and II, by means of IR spectroscopy, and thermodynamic parameters, ΔH and ΔS, for the hydrogen-bond formation will be obtained from measurements of the temperature dependence of the ν_{OH} spectra.



m = 4—7
Series I: R=H
Series II: R=CH_3

The reasons why paracyclophanols are selected are that their conformations are partially fixed around the benzene rings and that at least some of them are expected to be internally hydrogen-bonded with a relatively slight loss of entropy.

On the other hand, there have been presented several experimental or theoretical approaches to estimate the probable conformations of [5]—[12]paracyclophane compounds. These include an examination of molecular models,[6)] a free-electron model calculation,[7)] X-ray diffraction,[8,9)] and a force-field calculation.[10)]

In the present work concerning probable conformations in Series I and II, the degrees of bending of the benzene rings are predicted by a comparison of the UV spectral shifts with the theory,[11)] and the magnitudes of magnetic shielding for the aliphatic protons are estimated by a calculation using the Johnson and Bovey method.[12)] Furthermore, the PMR spectra of the aromatic protons are simulated by assuming an A_2B_2 type of proton system, and the internal rotation of the benzene rings and/or the alkylene chains is discussed.

Experimental

Samples. All the paracyclophanols examined were unknown compounds, except for [9]paracyclophane-5-ol,[13)] **1**. [11]Paracyclophane-6-ol, **2**, and its 6-methyl derivative, **6**, were prepared by the $LiAlH_4$ reduction or by the Grignard reaction of the corresponding ketone, which had itself been obtained by the Dieckmann reaction[14)] of dimethyl benzene-1,4-dihexanoate. The others were similarly obtained from the corresponding known ketones.[13,14)] The alcohols thus obtained were purified by recrystallization from hexane; their melting points and analytical results are summarized in Table 1.

IR Spectra. The ν_{OH} spectra were recorded on a JASCO DS-403G spectrometer; the solvent used was CCl_4, and the concentrations selected were *ca.* 0.003 mol/l or less so as to give apparent peak intensities of *ca.* 1.4 and to avoid an intermolecular association (cell length: 50 mm). The tem-

Table 1. Melting points and analytical data of the paracyclophanols

a) A waxy solid which was homogeneous according to its GC and TLC and according to its PMR spectrum,

perature dependence of the spectra was also examined at different temperatures ranging from 10 to 60 °C (error: ±1 °C in each case); correction was made for the thermal expansion of the solvent at each temperature. The calculated spectral slit width was 1.5 cm^{-1} at about 3600 cm^{-1}.

UV Spectra. Measured in concentrations of *ca.* 0.002 mol/l in hexane, using a Hitachi EPS-3T spectrometer.

PMR Spectra. Recorded in concentrations of 5—10 w/v% in CCl_4 on a JEOL JNM4H-100 spectrometer operating at 100 MHz; TMS was used as an internal reference and a lock signal. Dilution experiments were carried out in the concentration range of 1—20 w/v%, and the chemical shifts for concentration-dependent protons were obtained at an infinite dilution. Lanthanoid-induced shift measurements were performed by the step-by-step addition of either $Pr(fod)_3$ or $Eu(fod)_3$ to $CDCl_3$ solutions of substrates in the molar-ratio ranges of 0—0.6, until enough magnitudes of the induced shifts were obtained to assign the proton signals. The temperature dependence of the aromatic proton spectra was examined in dimethyl-d_6 sulfoxide or acetone-d_6 which proved to be suitable for obtaining an appropriately high resolution at the higher or lower temperatures examined.

The above measurements were carried out at room temperature (*ca.* 25 °C) unless otherwise noted.

Results and Discussion

IR Spectra. Three paracyclophanols, **4**, **6**, and **8**, show single, unsymmetric or symmetric OH bands characteristic of the monomers of ordinary secondary or tertiary alkanols.[15] The other paracyclophanols show doublets, which are ascribed to the presence of at least two OH species, free and internally bonded, but to other causes such as Fermi resonance, overtone, conformational heterogeneity, or intermolecular association. If the latter causes were predominant, **4**, **6**, and **8** could be expected to show similar doublets. Each doublet can be graphically separated into two almost symmetric bands; the higher-frequency band corresponds to the free OH group, so the lower-frequency one should then be assigned to the π-bonded one. The integrated intensity of each band is calculated using the following equation:

$$A = (\pi/2cl) \ln (I_0/I)_{max} \Delta\nu_{1/2} \quad (\text{in l mol}^{-1}\,\text{cm}^{-2})$$

The spectra of **1**, **4**, and **5** are shown in Fig. 1 as typical examples, and the results are summarized in Table 2.

a) A_b and A_f denote the integrated intensities of bonded and free OH bands respectively.

The A values for **1**, **2**, and **3** may be less accurate than those for the others, because their doublet-components so overlap that it is not easy to separate them. On raising the temperature, ν_{OH} becomes slightly higher and the sum of A_b and A_f becomes smaller, as is usually observed.[16] From these data, the thermodynamic parameters can then be calculated using the following equation:[16]

$$\ln A_b/A_f = -\Delta H/RT + (\Delta S/R - \ln a)$$

where a is the ratio of the true molecular extinction coefficients of the bonded and the free OH groups. Good linear relationships are obtained between $\ln A_b/A_f$ and $1/T$, as Fig. 2 shows. The results are summarized in Table 3.

It can be seen in Table 2 that, in Series I (**1**—**3**), the shifts ($\Delta\nu_{OH}$) of the π-bonded OH frequencies from the

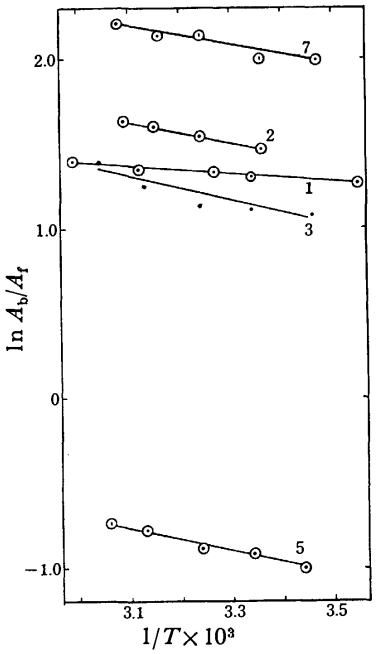

Fig. 2. Linear relationship between $\ln A_b/A_f$ and $1/T$.

corresponding free OH ones are almost the same, *ca.* 20 cm^{-1}, comparable to those in α-phenylalkanols.[17] In Series II (**5** and **7**), $\Delta\nu_{OH}$ is *ca.* 40 or 50 cm^{-1}; these values correspond to those in β- and γ-phenylalkanols.[3,18] The difference in $\Delta\nu_{OH}$ must be related to the distance (r) between the π-bonded OH group and the π-site.[2] However, the relationship between $\Delta\nu_{OH}$ and r can not be examined in the present case, because the paracyclophanols are in very complicated conformations with sterically unfavorable dihedral and bond angles[9,10] and the geometries of the internally bonded conformations can not be estimated.

As an approximate measure of the r, one may assume a magnitude of magnetic shielding for the OH proton. However, the observed magnitude ($\Delta\delta_{OH}=\delta_{ref.OH}-\delta_{OH}$) is not related to the $\Delta\nu_{OH}$, probably because each δ is the weight-average for all the OH species in all conformations.

An inspection of Table 3 reveals that, in Series I, both $-\Delta H$ and $-\Delta S$ tend to increase in going from **1** to **3** and are, therefore, contributable to the A_b/A_f ratio. In Series II also, the ratio is related to ΔH and ΔS, because $-\Delta H$ decreases in going from **5** to **7**, while $-\Delta S$ increases. In this connection, it is noteworthy in Table 2 that, in I and II, the A_b/A_f ratios alternate with m. The alternation in I is noticeable and is attributable to the ΔH's, but not to the ΔS's, because $-\Delta H$ in **5** is greater than that in **1** and $-\Delta H$ in **7** is less than that in **3**, while the ΔS's in **5** and **7** are almost the same as those in **1** and **3**. In **6**, ΔS is expected to be not greatly different from the ΔS in **3**; therefore, the absence of hydrogen bonding should be attributable to ΔH, which would be negligibly small or be positive in sign.

Table 3. Thermodynamic data for the internally bonded paracyclophanols

	Compound No.	$-\Delta H$ (kcal/mol)	$-(\Delta S/R-\ln a)$	$-\Delta S$[a] (e.u.)	$-AI$ (kcal/mol)	RI (kcal/mol)
I	**1**	0.4±0.1	2.1±0.1	4.2	0.94	0.54
	2	1.2±0.1	3.6±0.1	7.2	0.95	−0.25
	3	1.3±0.2	3.3±0.1	6.6	0.95	−0.35
II	**5**	1.4±0.1	1.5±0.1	3.0	1.22	−0.18
	7	0.5±0.1	3.8±0.2	7.6	1.42	0.92

a) Approximate values, assuming $a=1$.[16]

We will now discuss the ΔH by separating it into its two components: the interaction between the OH group and the π-site (AI) and the combined interactions between the other non-bonded atoms (RI). AI can be approximately estimated from $\Delta\nu_{OH}$, using the Joesten and Drago equation[19] for intermolecular hydrogen bonds:

$$-AI \pm 0.5(\text{kcal/mol}) = 0.016\,\Delta\nu_{OH} + 0.63$$

The values of AI and RI calculated in this manner are also listed in Table 3. The accuracy of these values is considerably poor, but it is at least possible to ascertain the tendency of their change through the whole series. Of interest is the fact that, in I and II, $-\Delta H$ is inversely proportional to RI. In other words, the OH···π bond formation is less exothermic in **1**, but more exothermic in **2** and **3**, than expected, because RI increases in **1** but decreases in **2** and **3**. This means that, the longer the alkylene chain is, the more feasible it is for the conformational change in forming the hydrogen bond to occur; this could be a reflection of the theoretical results[10] that, in [5]—[10]paracyclophanes, the conformation is less strained when the alkylene chain is longer.

In Series II, the reverse is true and the OH···π bond formation is more exothermic in **5**, but much less exothermic in **7**, than expected. This may be explained in terms of the flexibility of the alkylene chain being more decreased in II than in I. Because of the methyl group attached to the central bridge atom, the alkylene chains in II are more rigid than those in I. Taking this expectation together with the A_b/A_f ratios into consideration, it seems reasonable that the conformation of **5** is so fixed that the OH···π bond formation is accompanied by only a slight change in RI and that the conformation of **6** is so fixed that the hydrogen-bond formation requires an excessively large increase in RI. The large RI in **7**, as compared to that in **3**, may similarly be explained in terms of the less flexible conformation. This is supported by the observation that the internal rotation of the benzene ring and/or the alkylene chain is more restricted in **7** than in **3**, as will be described later. An examination of molecular models indicates that the C–OH bond in **5** is situated inside the alkylene loop, with its O–H toward the face of the benzene ring, while the C–OH bonds in the other paracyclophanols must be in such conformations as to be less favorable for the OH···π interaction.

Table 4. UV data in hexane solutions

a) Not observed. b) [9]Paracyclophane. c) [10]-Paracyclophane. d) *p*-Diethylbenzene. The data for b), c), and d) are taken from Ref. 9.

UV Spectra. The spectra of **1**—**8** are quite similar to those of the corresponding [n]paracyclophanes;[20,21] hence, the OH and/or CH_3 substituents at the central bridge carbon and also the OH···π bonding involved seem to have no detectable effect on the electronic transitions. Table 4 lists the spectral properties of the 1st and 2nd electronic transitions. As m decreases from 7 to 4, the absorption maxima shift toward longer wavelengths with lower intensities. This tendency is associated with an increasing bending of the benzene ring from planarity,[9,20] the extent of which is related to the magnitude of

the red shift from the λ_{max} of *p*-diethylbenzene.[11] According to this relationship, the angles of bending of the benzene rings in I and II are equal to those in the parent hydrocarbons[11] and may be less than 5 degrees with $m=6$ and 7, equal to *ca.* 5° with $m=5$, and *ca.* 15° with $m=4$.[22]

PMR Spectra. In the aliphatic region, the OH, CH, and CH_3 signals could easily be confirmed by their characteristic patterns, chemical shifts, relative intensities, and/or concentration-dependence. For the CH_2 signals, **1** and **2** (and also **9**, for comparison) were first examined by spin-decoupling. The signals thus assigned showed lanthanoid-induced shifts (LIS) obeying the general rule[23] that, in alkanols, CH_2 groups at greater distances from their positions of attachment to an OH group have smaller LIS values. For this reason, the CH_2 signals of the other paracyclophanols were assigned by means of the shift-reagent technique. The results are summarized in Table 5, while the spectra of **1**, **3**, and **5** are shown in Fig. 3 as typical examples.

A calculation was then made using the Johnson and Bovey method[12] in order to estimate the probable conformations. The magnitudes of chemical shielding for the 1-CH_2 and the other protons were assumed to be equal to the averaged chemical shifts (δ: 2.11 ppm) for the 3-CH_2 groups of cycloheptene and cyclooctene and to those for the corresponding protons in **13** and **14** respectively. The magnitudes of shielding for all the aliphatic protons by the π-current were predicted by constructing molecular models[24] to establish the probable conformation of the alkylene bridge and by measuring the positions of the protons involved. After this procedure has been repeated several times, the average positions were finally obtained. The angles of bending of the benzene rings were taken as 15 and 5 degrees for only $m=4$ and 5 respectively. However, the Johnson

and Bovey method was employed with no modification, because there was no appreciable effect of the ring bending upon the aromatic proton resonance (see Table 6). Furthermore, the three possible rotamers of the OH group around the C–O axis were assumed to be equal in population, but the proportion of the rotamers which would be able to interact with the π-site was taken to be equal to the $A_b/(A_b+A_f)$ ratio, when the paracyclophanol in question was internally bonded. The values thus

predicted are summarized in Table 5. They are in fairly good agreement with the observed ones, except for the OH protons of **1**, **2**, and **5**. Figure 4 shows the conformations constructed in the above manner, where **1**, **2**, **4**, and **8** each have two conformers with respect to the positions of OH and H or CH_3, while the others have only one conformer. The conformations of **1** and **2** were used in the calculation of **9** and **11** for comparison.

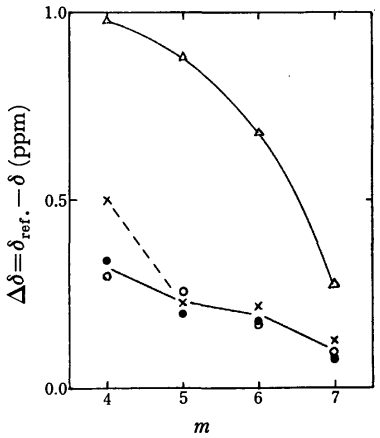

Fig. 5. Plots of m *vs.* $\Delta\delta$. △: CH; ●: CH_3; ×: OH in Series I; ○: OH in Series II.

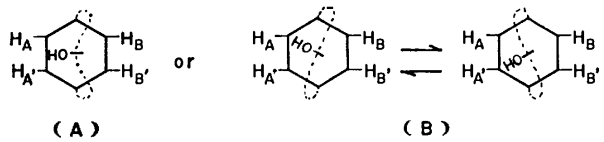
Of particular interest in Table 5 are the π-current shieldings ($\Delta\delta=\delta_{ref}-\delta$) for OH, CH, and CH_3 at the central bridge carbons. Figure 5 indicates the plots of $\Delta\delta$ *vs.* m. In both Series I and II, except for the pair with $m=4$, the $\Delta\delta_{OH}$'s and $\Delta\delta_{CH_3}$ lie on almost the same curve; therefore, $\Delta\delta_{OH}$ is not related to the population of the π-bonded OH species involved. In other words, a possible deshielding for the OH proton by the π-bonding is not detectable,[25] probably because of the relatively low population of the π-bonded OH species. In the case of $m=4$, however, the $\Delta\delta_{OH}$ for **5** is less by 0.2 ppm than that for **1** (0.5 ppm). The reason for this is not clear, but the much higher population of the π-bonded OH species in **5** might be, at least in part, responsible for it.

In the aromatic region, simple AB-like quartets were observed for the lower paracyclophanols, but not for the higher homologs which showed sharp singlets, as could be confirmed by their five- or ten-fold expanded spectra. The results are listed in Table 6. In order to elucidate the difference, the temperature dependence of the spectra of **1** and **3** was examined in dimethyl-d_6 sulfoxide and acetone-d_6 respectively. On warming, the quartet of **1** changed to a broad triplet and coalesced into a relatively broad singlet at 130 °C (T_c), which thereafter further changed to a sharp singlet. On the other hand, the singlet of **3** changed, in the course of cooling down to −65 °C, to a broad singlet at −47 °C (T_c) and then split into a broad doublet which was further transformed to a broad quartet at −60 °C. These phenomena may be associated with the internal rotation of the benzene ring and/or the alkylene chain, as in substituted paracyclophanes,[26] paracyclophenes,[27] and similar heteraphanes.[28] That is, the signal splitting may be due to the spin-coupling of the aromatic protons rendered distinguishable on the NMR time scale by the slow rotation of the benzene ring and/or the alkylene chain (or by inhibition of the rotation). In the case of **1**, the rotation is slow at room temperature because of the shorter alkylene bridge, but on warming it becomes so fast as to render the protons indistinguishable. Contrary, in **3** the rotation is fast at room temperature because of the longer alkylene bridge, while on cooling it becomes so slow as to render them distinguishable. The internal rotation is expected to be more restricted in II than in I, because the methyl group at the central bridge carbon in II will play a role in restricting the rotation. In fact, **3** shows a singlet, while **7** shows a quartet. The free energy barriers, $\Delta G^{\ddagger}$, to rotation are 22.4 in **1** and 12.3 kcal/mol in **3**, as can be estimated by putting the observed $\Delta\delta$ (2.6 for **1** and 3 Hz for **3**) and T_c into the Calder and Garratt equation;[29] they are reasonable compared with those in other cyclophanes.[26,28]

The cause of the simple AB-like splitting is the closer approach of the C–O bond to the protons on one side of the benzene ring, as is shown below:



Here, two forms of B interconvert so fast as to render the two pairs of H_A/H_B and $H_{A'}/H_{B'}$ indistinguishable on the NMR time scale. In A and B, if H_A and $H_{A'}$ are immersed in the deshielding cone of the C–O bond, they may be expected to be slightly deshielded compared with H_B and $H_{B'}$. It is, then, safe to assume that the aromatic proton system is an A_2B_2 type, and that the two J_{AB}'s (meta and para) have small, but significant, values. These assumptions may explain the observed resonance pattern, because a rather complicated AA'BB' pattern would otherwise be expected. A computer simulation, performed under these assumptions, gave a good agreement with the observed results. The three typical examples are shown in Fig. 3, and the chemical-shift differences ($\Delta\delta_{A-B}$) and the J values used are listed in Table 6.

The authors wish to thank Dr. Shoichi Kondo of our university for his valuable suggestions and assistance in the computer simulation and also Messrs Mitsuo Yoshifuji and Yasuo Ishitomo of our university for their assistance in the synthesis of the compounds.

A Reductive Elimination of Steroidal Diol Monoesters with Zinc Giving the Corresponding Olefins

Giichi GOTO

Central Research Division, Takeda Chemical Industries, Ltd., Yodogawa-ku, Osaka 532

(Received June 5, 1976)

Steroidal *cis*-diol monoacetates (**1, 9, 11,** and **13**) were refluxed with zinc powder in acetic acid to give the corresponding olefins (**2, 10, 12,** and **14**) in good yield. Under the reaction conditions, no reaction occurred with diol diacetates (**1b**: $R_1=R_2=H$, $R_3=R_4=Ac$ and **1m**: $R_1=C_6H_5$, $R_2=H$, $R_3=R_4=Ac$) and *trans*-diol monoacetates (**15** and **16**). Acyclic erythro and threo diol monoacetates (**17** and **19**) underwent highly stereoselective reduction affording **18** and **20**, respectively. The olefin-forming elimination proceeded with *syn*-elimination of a cyclic orthoacetate intermediate (**21**). The effect of some metals on the reduction and the behavior of a number of esters (**26**) and orthoesters (**27**) were also investigated.

In connection with mechanistic studies on the Serini reaction,[1,2] the addition of a catalytic amount of acetic acid accelerate was reported to the Serini rearrangement.[2] During the course of an investigation of the effect of acetic acid on the rearrangement, it was found that increase in the amount of acetic acid resulted in the formation of olefinic products. Thus, treatment of 16,-17-dihydroxy steroid monoacetates (**1**) with zinc powder in toluene in the presence of an excess acetic acid at 130 °C for 8 h gave the olefinic compounds (**2**) as a major product and a trace of the Serini rearrangement products (**3**). The finding has led to an investigation of the reductive elimination of diol monoesters to olefins. This paper describes the scope of this new reaction using a variety of steroidal diol monoesters.

Results and Discussion

The solution of steroidal 16,17-*cis*-diol monoacetates (**1**)[2] in acetic acid was refluxed with freshly activated zinc powder[3] under nitrogen for 4—6 h. After removal of the zinc by filtration, the filtrates were extracted with ether to give the corresponding steroidal 16-enes (**2**). Of various *cis*-diol monoacetates, secondary-tertiary diol monoesters were smoothly converted into olefins in high yields, together with a small amount (<5%) of the dehydrated compounds (**4**) as a by-product. Secondary-secondary diol monoacetates were reduced in lower yield and a large amount of diacetate (**1b**: $R_1=R_2=H$, $R_3=R_4=Ac$) was formed.[4] The corresponding diacetates (**1b** and **1m**: $R_1=C_6H_5$, $R_2=H$, $R_3=R_4=Ac$) were not affected under the reaction conditions.[6]

In order to investigate the participation of the neighbouring double bond, 16α-vinyl-16β,17β-diol 17-monoacetate (**1i**)[2] was heated with zinc in acetic acid to afford 16-vinyl-16-ene (**2i**) in 25% yield, coupled with 16β-vinyl-17β-acetate (**5**), its 16α-isomer (**6**) and (*E*)-16-ethylidene-17β-acetate (**7**) in 22, 26, and 17% yields, respectively. The (*E*)-configuration of 16-ethylidene group in **7** was confirmed by the conversion (hydrolysis and then oxidation) of **7** into the known (*E*)-16-ethylidene-17-one derivative.[2] An allenium ion intermediate (**8**) leading to the formation of **5, 6,** and **7** may be involved in this reaction. The results are summarized in Table 1 and the spectral data of **2** are given in Table 2.

In the androstane series, *cis*-diol monoacetates **9**[2] and **11**[8] were treated with zinc in acetic acid to give the corresponding steroidal olefins **10** and **12**, respectively, without elimination of the 3β-acetyl group. Diol monoacetate (**13**)[2] having a 4-en-3-one system was refluxed with zinc in acetic acid to give 3,16-diene (**14**) accompanied by concomitant Clemmensen type reduction[9] of the system.

On the other hand, when *trans*-diol monoacetates (**15** and **16**)[2] were refluxed with zinc in acetic acid for a prolonged reaction time, most of the starting materials were recovered unchanged, along with a small amount (<5%) of the olefinic products (**2e**: $R_1=H$, $R_2=Me$, and **2l**: $R_1=C_6H_5$, $R_2=H$) even after 56 h.

The following results demonstrate that the olefin-

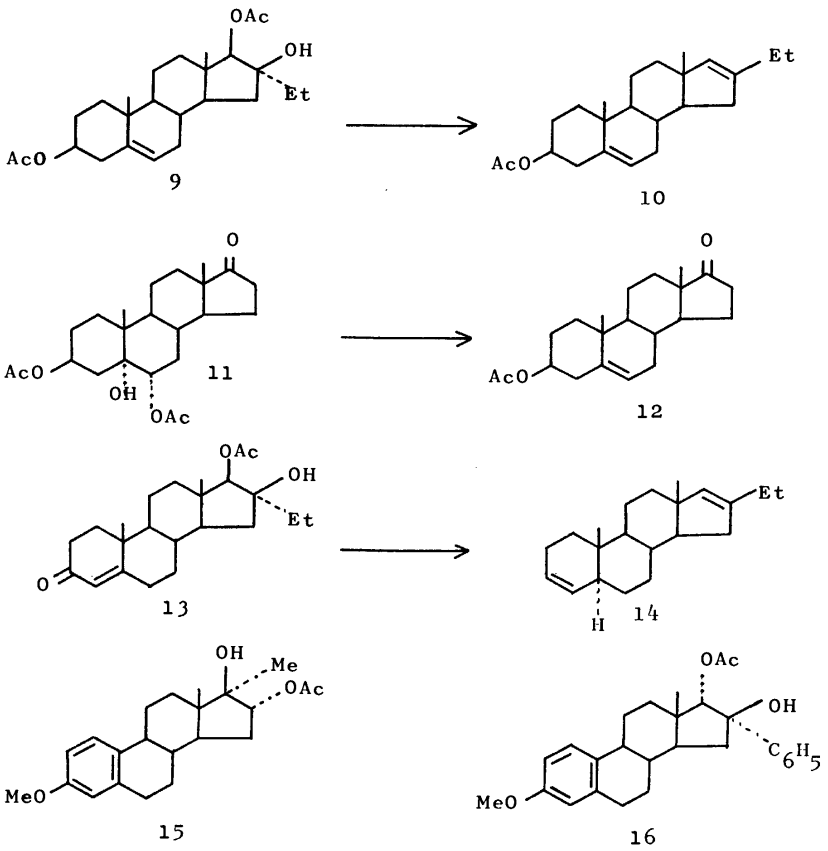
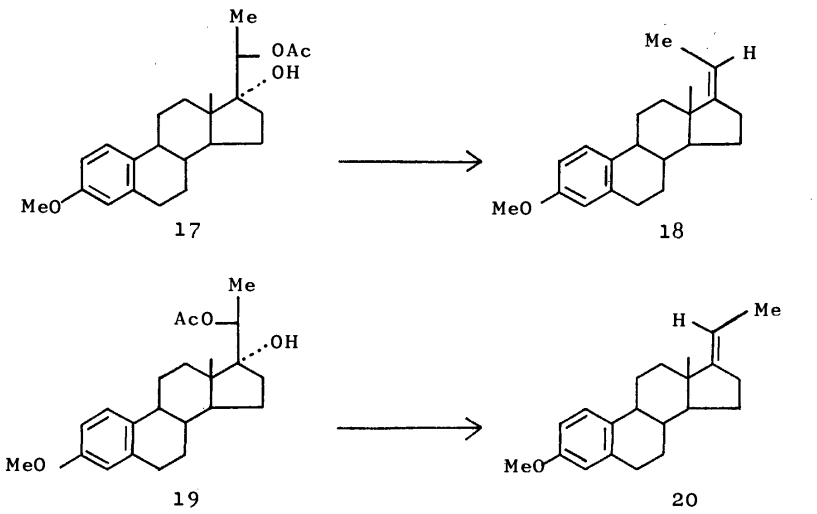
forming elimination of acyclic erythro and threo diol monoacetates proceeded stereoselectively and in good yield. 17α,20α-Diol monoacetate (**17**), when treated with zinc in acetic acid for 8 h at 120 °C, afforded stereoselectively (93%) (*Z*)-17-ethylidene derivative (**18**)[10] in 92% yield, whereas 20β-epimer (**19**) gave stereoselectively (94%) (*E*)-17-ethylidene isomer (**20**)[11] in 93% yield.

The results suggest that the dideoxygenation reaction proceeds with reductive *cis*-elimination of a cyclic ortho-



Scheme 3.



Scheme 4.

acetate intermediate (**21**),[2] which is in accord with the recent *syn*-elimination[12-14] of 1,3-dioxolan derivatives.

The explanation is supported by the following results. The cyclic orthoacetate (**23**), prepared from diol (**22**)[2] and trimethyl orthoacetate,[15] was refluxed with zinc in acetic acid to yield **2f** in 93% yield. It should be noted that heating of **23** with acetic acid gave (*Z*)-16-ethylidene-17β-acetate (**24**)[16] *via trans*-elimination of methanol quantitatively. Furthermore, treatment of **23** under the conditions of the Serini reaction (zinc in toluene)[1] gave 16β-ethyl-17-one (**25**) and **24** in 83% yield with a ratio of 1 : 5. Assignment of the configuration of 16-ethylidene group in **24** was made by comparison of the NMR spectrum with that of (*E*)-16-ethylidene isomer (**7**).

In order to investigate the behavior of esters other than acetates, several esters were subjected to the reaction conditions. The esters (**26**) were smoothly converted into the olefin (**2f**) in a range of 70—90% yield. This means that the reaction is not restrict-

Table 4. Effect of metal on the reduction of 16,17-dihydroxysteroid monoacetate (**1f**)

Metal used	Solvent	Reaction time (h)	Products (%)[c]		
			2f	**24**	**25**
Zn	AcOH	4	92	2	trace
Sn[a]	AcOH	6	24	17	40
Mg[b]	AcOH–Toluene (1: 3)	2	trace	3	7
Al[2]	AcOH–Toluene (1: 3)	2	7	5	12

a) Sn dust was activated by washing with 5% HCl. b) Mg and Al powders were washed with 3% NaOH and then water. c) Isolated yield.

ed to acetate. The corresponding orthoesters (**27**) were also reduced into the olefin (**2f**) in a good yield. The results are summarized in Table 3.

The olefin-forming elimination of diol monoesters was also effected by the use of activated tin powder, but considerable amount of by-products were formed. Other metal powders such as magnesium and aluminium gave no satisfactory results. The effect of metals on the reduction is shown in Table 4. We see that zinc is the most suitable reducing agent in this reaction.

The new dideoxygenation reaction is restricted to the case in which one hydroxyl group is tertiary. However, the reaction may be of general applicability to the stereoselective synthesis of trisubstituted olefins (**29**) from diastereomeric trisubstituted 1,2-glycol monoesters (**28**).

Experimental

All melting points were determined on a micro hot-stage apparatus and were uncorrected. UV spectra were measured in EtOH on a Hitachi EPS-3T spectrophotometer, IR spectra on a Hitachi 215 spectrophotometer. NMR spectra were determined on a Varian HA-100 spectrometer using $CDCl_3$ as a solvent, chemical shifts (δ) being given in ppm relative to internal TMS. The mass spectra were determined on a Hitachi RMU-6D mass spectrometer equipped with a direct inlet system. Silicagel GF_{254} (E. Merck) was used for TLC analysis.

Reaction of Diol Monoacetates with Zinc in Acetic Acid. General Procedure: To a solution of **1** in acetic acid was added a 5—10 fold mol. of freshly activated zinc powder. The mixture was refluxed on an oil bath (at 150 °C) with stirring under nitrogen for 2—6 h. After cooling, ether was added and the solid was removed by filtration. The ether was successively washed with satd $NaHCO_3$ aq solution, water and satd NaCl aq solution, followed by drying, and then concentrated to give crude crystals. Recrystallization from MeOH afforded pure **2**. The mother liquor was treated with column chromatography using silica gel (E. Merck); eluted with benzene: ether (5: 1) to give **4** in 2—5% yield. The mps of **2** are given in Table 1 and IR, UV and NMR spectral data in Table 2. The results of elemental analyses are as follows.

*16-Methyl-3-methoxyestra-1,3,5(10),16-tetraene (**2d**).* Found: C, 85.09; H, 9.29%. Calcd for $C_{20}H_{26}O$: C, 85.05; H, 9.28%.

*17-Methyl-3-methoxyestra-1,3,5(10),16-tetraene (**2e**).* Found: C, 85.01; H, 9.30%. Calcd for $C_{20}H_{26}O$: C, 85.05; H, 9.28%.

*16-Ethyl-3-methoxyestra-1,3,5(10),16-tetraene (**2f**).* Found: C, 85.07; H, 9.63%. Calcd for $C_{21}H_{28}O$: C, 85.08; H, 9.52%.

*16-Ethyl-17-deuterio-3-methoxyestra-1,3,5(10),16-tetraene (**2h**).* Found: C, 84.81; H, 9.80%. Calcd for $C_{21}H_{27}DO$: C, 84.79; H, 9.83%.

*16-Vinyl-3-methoxyestra-1,3,5(10),16-tetraene (**2i**).* Found: C, 85.58; H, 8.90%. Calcd for $C_{21}H_{26}O$: C, 85.66; H, 8.90%.

*16-Allyl-3-methoxyestra-1,3,5(10),16-tetraene (**2j**).* Found: C, 85.70; H, 9.23%. Calcd for $C_{22}H_{28}O$: C, 85.66; H, 9.15%.

*16-(3-Butenyl)-3-methoxyestra-1,3,5(10),16-tetraene (**2k**).* Found: C, 85.80; H, 9.40%. Calcd for $C_{23}H_{30}O$: C, 85.66; H, 9.38%.

*16-Phenyl-3-methoxyestra-1,3,5(10),16-tetraene (**2l**).* Found: C, 87.14; H, 8.20%. Calcd for $C_{25}H_{28}O$: C, 87.16; H, 8.19%.

*Reaction of **1i** with Zinc in Acetic Acid.* To a solution of **1i** (2.4 g) in acetic acid (25 ml) was added activated zinc powder (4.8 g). The mixture was refluxed under nitrogen for 2 h with stirring. Work-up of the reaction mixture in the same way as for **2** gave a mixture of the products which were separated by preparative TLC impregnated with $AgNO_3$ (developed with hexane: ether 5: 1). The product with R_f value 0.89 was **2i** (477 mg). The other products with R_f values 0.47, 0.43 and 0.33 were **5** (505 mg), **7** (390 mg) and **6** (597 mg), respectively.

*17β-Acetoxy-16β-vinyl-3-methoxyestra-1,3,5(10)-triene (**5**).* Mp 107—108 °C (from petroleum ether); IR (KBr) 1730, 1640, 1610 cm^{-1}; NMR 0.83 (3H, s, 18-Me), 1.96 (3H, s, OAc), 3.73 (3H, s, OMe), 4.72 (1H, d, J=9 Hz, 17α-H),[16] 5.0—6.2 (3H, m, vinyl H), 6.6—7.3 (3H, m, Ar); MS *m/e* 354 (M^+), 312, 294. Found: C, 77.90; H, 8.62%. Calcd for $C_{23}H_{30}O_3$: C, 77.93; H, 8.53%.

*17β-Acetoxy-16α-vinyl-3-methoxyestra-1,3,5(10)-triene (**6**).* Mp 109 °C; IR (KBr) 1730, 1640, 1610 cm^{-1}; NMR 0.86 (3H, s, 18-Me), 1.98 (3H, s, OAc), 3.73 (3H, s, OMe), 4.50 (1H, d, J=7 Hz, 17α-H),[16] 4.9—6.2 (3H, m, vinyl H), 6.6—7.3 (3H, m, Ar); MS *m/e* 354 (M^+), 312, 294. Found: C, 77.99; H, 8.52%. Calcd for $C_{23}H_{30}O_3$: C, 77.93; H, 8.53%.

*17β-Acetoxy-(E)-16-ethylidene-3-methoxyestra-1,3,5(10)-triene (**7**).* Mp 99—100 °C; IR (KBr) 1730 cm^{-1}; NMR 0.75

(3H, s, 18-Me), 1.50 (3H, d, J=7 Hz, =CMe), 2.14 (3H, s, OAc), 3.75 (3H, s, OMe), 5.27 (1H, s, 17α-H), 5.2—5.3 (1H, m, =CH), 6.6—7.3 (3H, m, Ar); MS *m/e* 354 (M^+), 312, 294. Found: C, 77.85; H, 8.31%. Calcd for $C_{23}H_{30}O_3$: C, 77.93; H, 8.53%.

*3β-Acetoxy-16-ethylandrosta-5,16-diene (**10**).* Reaction of **9** (3.5 g) with zinc powder (8 g) in acetic acid (25 ml) was carried out by the same procedure as for **2**: **10** (2.6 g), mp 128 °C; IR (KBr) 1730, 1625 cm^{-1}; NMR 0.78 (3H, s, 18-Me), 1.00 (3H, t, J=6 Hz, Me), 1.05 (3H, s, 19-Me), 2.01 (3H, s, OAc), 4.4—4.8 (1H, m, 3α-H), 5.3—5.5 (2H, m, 6-H and 16-H); MS *m/e* 342 (M^+), 327, 282, 267. Found: C, 80.60; H, 10.01%. Calcd for $C_{23}H_{34}O_2$: C, 80.65; H, 10.01%.

*Stereoselective Conversion of 17α,20-Dihydroxy Monoacetates (**17** and **19**) into (Z)- and (E)-17-Ethylidene Derivatives (**18** and **20**).* Reaction of diol monoacetates (**17** and **19**) with zinc in acetic acid was carried out by the same procedure as for **1**. The purity of the products was estimated by gas chromatography on a column with 10% OV-17 (2 m, 265 °C).

Preparation of Orthoesters.[15] *General Procedure*: To a solution of diol (**22**) in CH_2Cl_2 was added trialkyl orthoester and a catalytic amount of *p*-TsOH. After being stirred at room temperature for 2 h, the reaction mixture was poured into 5% $NaHCO_3$ aq solution and extracted with CH_2Cl_2. The extracts were washed with water, dried, and concentrated to give a resinous material. Recrystallization from petroleum ether gave the steroidal orthoesters. The following compounds were prepared.

*Methyl Orthoacetate of **22** (**23**).* Mp 63 °C; IR (KBr) 1610 cm^{-1}; NMR 0.86 (3H, s, 18-Me), 1.04 (3H, t, J=7 Hz, Me), 1.57 (3H, s, Me), 3.25 (3H, s, OMe), 3.73 (3H, s, OMe), 3.84 (1H, s, 17α-H), 6.6—7.3 (3H, m, Ar); MS *m/e* 386 (M^+), 354, 312. Found: C, 74.60; H, 8.80%. Calcd for $C_{24}H_{34}O_4$: C, 74.57; H, 8.87%.

*Methyl Orthoformate of **22** (**27a**).* IR (KBr) 1610 cm^{-1}; NMR 0.83 (3H, s, 18-Me), 1.01 (3H, t, J=7 Hz, Me), 3.27 (3H, s, OMe), 3.71 (3H, s, OMe). 3.86 (1H, s, 17α-H), 5.74 (1H, s, -OCHO-), 6.6—7.3 (3H, m, Ar); MS *m/e* 372 (M^+), 344, 341. Found: C, 74.20; H, 8.60%. Calcd for $C_{23}H_{32}O_4$: C, 74.16; H, 8.66%.

*Ethyl Orthoformate of **22** (**27b**).* IR (KBr) 1610 cm^{-1}; NMR 0.82 (3H, s, 18-Me), 1.00 (3H, t, J=6 Hz, Me), 1.20 (3H, t, J=7 Hz, Me), 3.52 (2H, q, J=7 Hz, $-CH_2-$), 3.73 (3H, s, OMe), 3.78 (1H, s, 17α-H), 5.73 (1H, s, -OCHO-), 6.6—7.3 (3H, m, Ar); MS *m/e* 386 (M^+), 357, 341. Found: C, 74.59; H, 8.90%. Calcd for $C_{24}H_{34}O_4$: C, 74.57; H, 8.87%.

*Ethyl Orthoacetate of **22** (**27c**).* IR (Neat) 1610 cm^{-1}; NMR 0.87 (3H, s, 18-Me), 3.56 (2H, q, J=7 Hz, $-CH_2-$), 3.72 (3H, s, OMe), 3.80 (1H, s, 17α-H), 6.6—7.3 (3H, m, Ar); MS *m/e* 400 (M^+, $C_{25}H_{36}O_4$ requires: 400), 385, 354.

*Ethyl Orthopropionate of **22** (**27d**).* IR (Neat) 1610 cm^{-1}; NMR 0.86 (3H, s, 18-Me), 3.60 (2H, q, J=7 Hz, $-CH_2-$), 3.71 (3H, s, OMe), 3.84 (1H, s, 17α-H), 6.6—7.3 (3H, m, Ar); MS *m/e* 414 (M^+, $C_{26}H_{38}O_4$ requires: 414), 399, 368.

Ethyl Orthobenzoate[17] *of **22** (**27e**).* IR (Neat) 1615, 1610 cm^{-1}; NMR 0.90 (3H, s, 18-Me), 3.70 (3H, s, OMe), 3.72 (2H, q, J=7 Hz, $-CH_2-$), 3.93 (1H, s, 17α-H), 6.6—7.6 (8H, m, Ar); MS *m/e* 462 (M^+, $C_{30}H_{38}O_4$ requires: 462), 447, 434.

Treatment of Orthoesters with Zinc in Acetic Acid. General Procedure: To a solution of orthoester (0.4 g) in acetic acid (5 ml) was added activated zinc powder (1.3 g). The mixture was refluxed under nitrogen for 4—6 h with stirring. Work-up of the reaction mixture gave **2f** which was crystallized from MeOH.

*17β-Acetoxy-(Z)-16-ethylidene-3-methoxyestra-1,3,5(10)-triene (**24**).* A solution of **23** (0.34 g) in acetic acid (10 ml) was heated under reflux for 30 min. The solvent was evaporated under reduced pressure to give crude crystals. Recrystallization from ether: hexane (5: 1) afforded **24** (0.3 g), mp 161—162 °C; IR (KBr) 1730, 1610 cm^{-1}; NMR 0.81 (3H, s, 18-Me), 1.56 (3H, d, J=7 Hz, =CMe), 2.11 (3H, s, OAc), 3.75 (3H, s, OMe), 5.24 (1H, s, 17α-H), 5.49 (1H, m, =CH), 6.6—7.3 (3H, m, Ar); MS *m/e* 354 (M^+), 312, 297, 294. Found: C, 77.85; H, 8.31%. Calcd for $C_{23}H_{30}O_3$: C, 77.93; H, 8.53%.

*Treatment of **23** under the Conditions of the Serini Reaction.* To a solution of **23** (0.77 g) in dried toluene was added freshly activated zinc powder. The mixture was refluxed for 6 h with stirring. Zinc was removed by filtration. The filtrates were evaporated under vacuum to give a residue which was separated by preparative TLC (developed with benzene: ether 10: 1). The product with higher R_f value (0.42) was **24** (490 mg). The other product with R_f value (0.33) was 16β-ethyl-3-methoxyestra-1,3,5(10)-trien-17-one (**25**)[2] (86 mg).

*17β-Formyloxy-16β-hydroxy-16α-ethyl-3-methoxyestra-1,3,5(10)-triene (**26a**).* Formylation of **22** with Ac_2O-HCOOH gave **26a**: IR (KBr) 3500, 1720, 1610 cm^{-1}; NMR 0.97 (3H, s, 18-Me), 3.71 (3H, s, OMe), 4.59 (1H, s, 17α-H), 6.6—7.3 (3H, m, Ar), 8.15 (1H, s, CHO); MS *m/e* 358 (M^+), 312. Found: C, 73.76; H, 8.43%. Calcd for $C_{22}H_{30}O_4$: C, 73.71; H, 8.44%.

*17β-Propionyloxy-16β-hydroxy-16α-ethyl-3-methoxyestra-1,3,5-(10)-triene (**26b**).* Treatment of **22** with propionic anhydride in pyridine gave **26b**: IR (KBr) 3500, 1730, 1610 cm^{-1}; NMR 0.98 (3H, s, 18-Me), 3.75 (3H, s, OMe), 4.58 (1H, s, 17α-H), 6.6—7.3 (3H, m, Ar); MS *m/e* 386 (M^+), 357, 312. Found: C, 74.59; H, 8.80%. Calcd for $C_{24}H_{34}O_4$: C, 74.57; H, 8.87%.

*17β-Benzoyloxy-16β-hydroxy-16α-ethyl-2-methoxyestra-1,3,5-(10)-triene (**26c**).* Treatment of **22** with benzoyl chloride in pyridine afforded **26c**: IR (KBr) 3350, 1695, 1610, 1600 cm^{-1}; NMR 0.95 (3H, t, J=7 Hz, Me), 1.08 (3H, s, 18-Me), 3.74 (3H, s, OMe), 4.85 (1H, s, 17α-H), 6.6—7.3 (3H, m, Ar), 7.4—8.3 (5H, m, Ar); MS *m/e* 434 (M^+), 312. Found: C, 77.40; H, 7.80%. Calcd for $C_{28}H_{34}O_4$: C, 77.39; H, 7.89%.

*Reaction of **26** with Zinc in Acetic Acid. General Procedure*: To a solution of **26** in acetic acid was added freshly activated zinc powder. The mixture was refluxed under nitrogen for 4—6 h with stirring. Work-up by the usual procedure gave **2f**.

*Reaction of **1f** with Tin in Acetic Acid.* To a solution of **1f** (1.2 g) in acetic acid (15 ml) was added tin powder (3 g) which had been washed with acid. The mixture was heated under reflux for 6 h. To the cooled solution was added ether (200 ml) and the solid was removed by filtration. The filtrate was washed with satd $NaHCO_3$ aq, satd NaCl aq solution in succession and then dried. The ether was concentrated to give a residue which was separated by preparative TLC using benzene: ether (10: 1) as an eluent. The product with R_f value 0.86 was **2f** (229 mg). The other products with R_f values 0.42 and 0.33 were **24** (194 mg) and **25** (403 mg), respectively.

The author would like to thank Drs. E. Ohmura, H. Morimoto, T. Miki, and K. Hiraga of this Division for their advice and encouragement.

(Received June 10, 1976)

Seven 2-hydroxy-4-methoxybenzophenones were oxidized with manganese(III) acetate to give 9-xanthenones (24—65%). 2-Hydroxy-3',4,4',6-tetramethoxybenzophenone gave 1,3,6,7-tetramethoxy-9-xanthenone in a 5% yield. 2-Hydroxy-3',4,4',5-tetramethoxybenzophenone yielded 2,5-dihydroxy-3',4,4'-trimethoxybenzophenone (9%). The oxidation of the 2-hydroxybenzophenones with lead tetraacetate also gave the 9-xanthenones, but in poor yields.

In a previous paper,[1] it has been reported that the reactions of 2-hydroxy-4-methoxy- and 2-hydroxy-4,4'-dimethoxybenzophenones with metal salts gave rise to dimeric compounds and 2,5-dihydroxybenzophenones. It was also reported that 2-hydroxy-2',4,4'-trimethoxy- and 2-hydroxy-3',4,4'-trimethoxybenzophenones yielded 3,6-dimethoxy- and 2,3,6-trimethoxy-9-xanthenones respectively. We have now continued our investigation of the reaction in the hope that this can lead to a new synthesis of 9-xanthenones.

The 2-hydroxybenzophenones were prepared by the known method,[2] while the reactions of the 2-hydroxybenzophenones with manganese(III) acetate and lead tetraacetate were carried out in boiling acetic acid. The structures of the reaction products were determined by examining their IR, NMR, and mass spectra, and by elemental analyses.

When 2-hydroxy-2',4,5'-trimethoxybenzophenone (Ie) was oxidized with manganese(III) acetate, 2,6-dimethoxy-9-xanthenone (IIb) (65%) was obtained. This indicates that an intramolecular coupling between the hydroxyl group and the carbon (2') in Ie took place and that the 2'-methoxyl group on that position was removed.

When Ie was oxidized with lead tetraacetate, 2,6-dimethoxy-1-methyl-9-xanthenone (IIe) (3%) and 1-acetoxymethyl-2,6-dimethoxy-9-xanthenone (IIIe) (6%) were obtained, together with IIb (11%). The NMR spectrum of IIe in CF_3COOH showed the presence of a methyl group {δ 2.96 (s, 3H)}, two methoxyl groups {δ 4.10 (s, 3H) and δ 4.15 (s, 3H)}, three aromatic protons {δ 7.24 (d, J=2 Hz), δ 7.34 (dd, J=9, 2 Hz) and δ 8.45 (d, J=9 Hz)}, and two aromatic protons {δ 7.78 (d) and 7.99 (d), AB system, J=9 Hz}. The methyl group at δ 2.96 can be located at the 1-position on the basis of its extraordinary lower shift[3] and on the basis of the presence of the lower-field doublet at δ 8.45 (J=9 Hz) as a result of the hydrogen adjacent to the carbonyl group. The presence of the aromatic AB system (J=9 Hz) further confirmd the IIe structure. A similar methylation of aromatic compounds and the acetoxylation of an aromatic methyl group have been reported in the reaction of lead tetraacetate.[4] The oxidation of 2-hydroxy-2',4-dimethoxybenzophenone (Ia) and 2-hydroxy-2',4,4'-trimethoxybenzophenone (Ic), both with a 2'-methoxyl group, gave 3-methoxy-9-xanthenone (IIa) (49% with $Mn(OAc)_3$ and 16% with $Pb(OAc)_4$) and 3,6-dimethoxy-9-xanthenone (IIc) (45% with $Mn(OAc)_3$ and 12% with $Pb(OAc)_4$, with the loss of the 2'-methoxyl group, respectively. In the oxidation of Ic with manganese(III) acetate, IV (9%) was isolated; however, its structure could not be determined.

When 2-hydroxy-3',4,4',5'-tetramethoxybenzophenone (If) was subjected to oxidation with manganese(III) acetate, 2,3,4,6-tetramethoxy-9-xanthenone (IIf) was obtained in a 48% yield, whereas the oxidation of If with lead tetraacetate afforded IIf in only a 7% yield, plus 1-acetoxymethyl-2,3,4,6-tetramethoxy-9-xanthenone (IIIf) (6%). 2-Hydroxy-3',4-dimethoxybenzophenone (Ib) and 2-hydroxy-3',4,4'-trimethoxybenzophenone (Id) gave IIb (24%) and 2,3,6-trimethoxy-9-xanthenone (IId) (40%) respectively, showing that the coupling occurred preferentially at the less hindered position.

When 2,4'-dihydroxy-3',4,5'-trimethoxybenzophenone (Ig) was oxidized with manganese (III) acetate, 2,6-dimethoxy-*p*-benzoquinone (V) (13%) was the only isolable product. There were many unidentified compounds in the reaction mixture, suggesting that the oxidation of dihydroxybenzophenones is not useful for the synthesis of 9-xanthenone. A monoacetate of Ig, 2-hydroxy-4'-acetoxy-3',4,5'-trimethoxybenzophenone (Ih), did, however, give 3-acetoxy-2,4,6-trimethoxy-9-xanthenone (IIh) (31%). This may indicate that hydroxy-9-xanthenones can be prepared from dihydroxybenzophenones *via* their acetate.

The manganese (III) acetate oxidation of 2-hydroxy-3',4,4',6-tetramethoxybenzophenone (Ii), which possesses a phloroglucinol nucleus, yielded 1,3,6,7-tetramethoxy-9-xanthenone (IIi) (5%) and 2,6-dimethoxy-3-(3,4-dimethoxybenzoyl)-*p*-benzoquinone (VIi) (5%). The lead tetraacetate oxidation of Ii afforded IIi in a better yield (11%), plus VIi (7%) and 2,6-dimethoxy-3-(3,4-dimethoxybenzoyl)-5-methyl-*p*-benzoquinone(VIi') (7%). A similar methylation is often observed in the reaction of a quinone with lead tetraacetate.[4]

Finally, we examined the oxidation of 2-hydroxy-3',4,4',5-tetramethoxybenzophenone (Ij). 2,5-Dihydroxy-3',4,4'-trimethoxybenzophenone (Ik) (9%) was obtained, together with many unidentified products.

Although 9-xanthenones have been synthesized in a number of ways, *i.e.*, by the dehydration of 2,2'-dihydroxybenzophenones,[2] the base-catalysed cyclization of 2-hydroxy-2'-methoxybenzophenones,[5] the cyclization of *o*-phenoxybenzoic acids,[6] and the oxidative couplings

of polyhydroxybenzophenones with potassium permanganate,[6] potassium ferricyanide[7] and dichlorodicyano-*p*-benzoquinone,[8] it is now demonstrated that 9-xanthenones can be synthesized from 2-hydroxy-4-methoxy- and 2-hydroxy-4,6-dimethoxybenzophenones in moderate yields, by the reaction of manganese(III) acetate, but not from 2-hydroxy-4,5-dimethoxybenzophenone. Acetoxy-9-xanthenones, which could not be obtained by the previous methods, can also be prepared by the oxidation of 2-hydroxyacetoxybenzophenones.

Experimental

All the ^1H NMR spectra were recorded for the deuteriochloroform solution, unless otherwise stated, with a Hitachi R 24 NMR spectrometer, with tetramethylsilane as the internal reference. The IR spectra were recorded for the chloroform solution with a JASCO IRA-1 grating spectrometer, while the UV spectra were measured for the methanol solution with a Hitachi EPS-3T spectrophotometer. The mass spectrum was recorded with a Hitachi RMU-6M spectrometer. The melting points were determined with a Yanagimoto hot-stage apparatus and were uncorrected.

Preparations of 2-Hydroxybenzophenones (Ia,Ib,Ie—Ii). The 2-hydroxybenzophenones (Ia Ib, Ie, and Ig) were prepared by the reaction of 3-methoxyphenol (8 mmol) and a benzoic acid (8 mmol) with phosphoryl chloride (7 ml) containing fused zinc chloride (3 g), with heating at 65—70 °C for 2 h. The reaction mixture was poured into water and extracted with chloroform. After the removal of the chloroform, the crude 2-hydroxybenzophenone was purified on a silica gel column (Wakogel C 100) (100 g), eluting with benzene, followed by recrystallization from methanol.

2-Hydroxy-2',4-dimethoxybenzophenone (Ia): Mp 88.5—89 °C, 68%, ν_{max}: 1630 cm^{-1} (C=O), λ_{max} (ε): 286 (14400) and 325 nm (9550), δ: 3.75 (s, OCH_3), 3.81 (s, OCH_3), 6.15—6.5 (m, 2H), 6.8—7.6 (m, 5H), and 12.6 (s, OH). Found: C, 69.68; H, 5.37%. Calcd for $C_{15}H_{14}O_4$: C, 69.75; H, 5.46%.

2-Hydroxy-3',4-dimethoxybenzophenone (Ib): $Bp_{0.3}$ 165—170 °C (bath temp), 54%, ν_{max}: 1630 cm^{-1} (C=O), λ_{max} (ε): 292 (8970) and 325 nm (6780), δ: 3.81 (s, $2\times OCH_3$), 6.2—6.5 (m, 2H), 6.9—7.6 (m, 5H) and 12.4 (s, OH). Found: C, 69.55; H, 5.47%. Calcd for $C_{15}H_{14}O_4$: C, 69.75; H, 5.46%.

2-Hydroxy-2',4,5'-trimethoxybenzophenone (Ie): Mp 110 °C, 21%, ν_{max}: 1628 cm^{-1} (C=O), λ_{max} (ε): 230 (s) (12300), 287 (15000) and 327 nm (9700), δ: 3.66 (s, OCH_3), 3.72 (s, OCH_3), 3.79 (s, OCH_3), 6.2—6.5 (m, 2H), 6.7—7.3 (m, 4H) and 12.5 (broad s, OH). Found: C, 66.65; H, 5.57%. Calcd for $C_{16}H_{16}O_5$: C, 66.66; H, 5.59%.

2,4'-Dihydroxy-3',4,5'-trimethoxybenzophenone (Ig): Ig was prepared by the reaction of 3-methoxyphenol (8 mmol) and

3,4,5-trimethoxybenzoic acid (8 mmol) with phosphoryl chloride (7 ml) containing fused zinc chloride (3 g); mp 142—143 °C, 32%, ν_{max}: 1620 cm^{-1} (C=O), λ_{max} (ε): 241 (s) (10900), 920 (11400) and 344 nm (14600), δ: 3.79 (s, OCH_3), 3.84 (s, $2\times OCH_3$), 6.0 (broad s, OH), 6.2—6.45 (m, $H_{(3)}$ and $H_{(5)}$), 6.84 (s, $H_{(2')}$ and $H_{(6')}$), 7.45 (d, J=8.5 Hz, $H_{(6)}$) and 12.5 (broad s, OH). Found: C, 63.24; H, 5.36%. Calcd for $C_{16}H_{16}O_6$: C, 63.15; H, 5.30%.

2-Hydroxy-3',4,4',5'-tetramethoxybenzophenone (If): A mixture of Ig (6 g), dimethyl sulfate (3 ml), potassium carbonate (5 g), and acetone (50 ml) was heated under reflux for 30 min. After the removal of the acetone, the resulting mixture was extracted with benzene. The benzene was evaporated *in vacuo*, and the resulting liquid was allowed to crystallize from methanol to give If (3.6 g, 57%); mp 106—107 °C, ν_{max}: 1630 cm^{-1} (C=O), λ_{max} (ε): 293 (16300) and 328 nm (15200), δ: 3.81 (s, OCH_3), 3.84 (s, $2\times OCH_3$), 3.88 (s, OCH_3), 6.25—6.55 (m, $H_{(3)}$ and $H_{(5)}$), 6.83 (s, $H_{(2')}$ and $H_{(6')}$), 7.50 (d, J=8.5 Hz, $H_{(6)}$) and 12.50 (s, OH). Found: C, 64.11; H, 5.77%. Calcd for $C_{17}H_{18}O_6$: C, 64.14; H, 5.74%.

2-Hydroxy-4'-acetoxy-3',4,5'-trimethoxybenzophenone (Ih): A mixture of Ig (1.30 g), acetic anhydride (480 mg), and pyridine (8 ml) was kept at room temperature for 24 h. The reaction mixture was then poured into water, and the resulting precipitates were collected and recrystallized from ethanol to give Ih (1.18 g, 80%); mp 124—125 °C, ν_{max}: 1630 (C=O) and 1770 cm^{-1} (OAc), λ_{max} (ε): 294 (13500) and 325 nm (11100), δ: 2.37 (s, OAc), 3.88 (s, $3\times OCH_3$), 6.3—6.8 (m, $H_{(3)}$ and $H_{(5)}$), 6.93 (s, $H_{(2')}$ and $H_{(6')}$), 7.65 (d, J=8.5 Hz, $H_{(6)}$) and 12.40 (s, OH). Found: C, 62.24; H, 5.51%. Calcd for $C_{18}H_{18}O_7$: C, 62.42; H, 5.24%.

2-Hydroxy-3',4,4',6-tetramethoxybenzophenone (Ii): A mixture of 3,5-dimethoxyphenol (4 g), 3,4-dimethoxybenzoyl chloride (5.5 g), aluminium chloride (12 g), and ether (50 ml) was stirred at room temperature for 48 h. By working up in a similar manner to the above, Ii (4.0 g, 49%) was obtained; mp 134 °C, ν_{max}: 1625 cm^{-1} (C=O), λ_{max} (ε): 233 (21900), 286 (11900) and 313 nm (12600), δ: 3.55 (s, OCH_3), 3.86 (s, OCH_3), 3.90 (s, OCH_3), 3.95 (s, OCH_3), 5.99 (d, 1H) and 6.19 (d, 1H) (AB system, J_{AB}=2.0 Hz), 6.19 (d, J=8.5 Hz, $H_{(5')}$), 6.75—6.90 (m, $H_{(2')}$ and $H_{(6')}$), and 11.60 (s, OH). Found: C, 64.22; H, 5.75%. Calcd for $C_{17}H_{18}O_6$: C, 64.14; H, 5.70%.

Oxidation of 2-Hydroxybenzophenones (Ia—Ii) with Manganese (III) Acetate. A mixture of 2-hydroxybenzophenone (1 mmol), manganese(III) acetate dihydrate[13] (4 or 5 mmol), and acetic acid (30 ml) was heated under reflux for the period of time shown in the Table. After the removal of the acetic acid *in vacuo*, the resulting solid was triturated with water and extracted with chloroform. The chloroform was removed *in vacuo* and the resulting products were purified on TLC (Wakogel B 10) and by recrystallization.

Ia gave 3-methoxy-9-xanthenone (IIa); mp 125—126 °C (EtOH) (lit,[10] mp 128—129 °C), 49%, ν_{max}: 1660 cm^{-1} (C=O), λ_{max} (ε): 239 (44100), 270 (12000) and 303 nm (17300), δ: 3.85 (s, OCH_3), 6.7—7.0 (m, 2H), 7.1—7.85 (m, 3H) and 8.1—8.45 (m, 2H).

Ib yielded 2,6-dimethoxy-9-xanthenone (IIb); mp 162 °C (EtOH) (lit,[11] mp 163.5—164.5 °C), 24%, ν_{max}: 1650 cm^{-1} (C=O), λ_{max} (ε): 243 (36500) and 312 nm (15700), δ: 3.88 (s, $2\times OCH_3$), 6.7—7.0 (m, $H_{(5)}$ and $H_{(7)}$), 7.0—7.5 (m, $H_{(3)}$ and $H_{(4)}$), 7.63 (d, J=2 Hz, $H_{(1)}$) and 8.20 (d, J=8 Hz, $H_{(8)}$).

Ic gave 3,6-dimethoxy-9-xanthenone (IIc) [mp 185 °C (EtOH) (lit,[1] mp 182—183 °C), 45%) and IV (mp 157 °C (benzene), 9%, ν_{max}: 1650, 1698 and 1758 cm^{-1}, λ_{max} (ε): 229 (24500), 267 (17400) and 290 nm (9670), δ: 3,75 (s, OCH_3), 3.82 (s, OCH_3), 5.50 (d, J=2 Hz, 1H), 6.16 (dd, J=10, 2 Hz, 1H), 6.40 (d, J=2 Hz, 1H), 6.64 (dd, J=8.2 Hz, 1H), 6.80 (d, J=10 Hz, 1H) and 7.81 (d, J=8 Hz, 1H). *m/e*: 288 (M^+), 150, 122 and 107. Found: C, 62.45; H, 4.21%. Calcd for $C_{15}H_{12}O_6$: C, 62.50; H, 4.20%].

Id yielded 2,3,6-trimethoxy-9-xanthenone (IId); mp 216—217 °C (EtOH) (lit,[1] mp 216—217 °C), 40%.

Ie gave IIb; mp 162 °C, 65%.

If yielded 2,3,4,6-tetramethoxy-9-xanthenone (IIf); mp 130 °C (EtOH), 48%, ν_{max}: 1655 cm^{-1} (C=O), λ_{max} (ε): 246 (38600), 272 (14000) and 313 (21100), δ: 3.92 (s, $2\times OCH_3$), 4.00 (s, OCH_3), 4.02 (s, OCH_3), 6.75—7.05 (m, $H_{(5)}$ and $H_{(7)}$), 7.46 (s, $H_{(1)}$) and 8.14 (d, J=8.5 Hz, $H_{(8)}$). Found: C, 64.35; H, 5.02%. Calcd for $C_{17}H_{16}O_6$: C, 64.55; H, 5.10%.

Ig yielded 2,6-dimethoxy-*p*-benzoquinone (V); mp 255 °C (EtOH) lit,[14] mp 255—256 °C), 12%, ν_{max}: 1660 and 1720 cm^{-1}, δ: 3.82 (s, $2\times OCH_3$) and 5.87 (s, $H_{(3)}$ and $H_{(5)}$).

Ih gave 3-acetoxy-2,4,6-trimethoxy-9-xanthenone (IIh); mp 166—167 °C (EtOH), 31%, ν_{max}: 1660 (C=O) and 1772 cm^{-1} (OAc), λ_{max} (ε): 247 (34000), 274 (12900) and 312 nm (16100), δ: 2.43 (s, OAc), 3.93 (s, $2\times OCH_3$), 4.08 (s, OCH_3), 6.9—7.1 (m, $H_{(5)}$ and $H_{(7)}$), 7.57 (s, $H_{(1)}$) 8.22 (d, J=8.5 Hz, $H_{(8)}$). Found: C, 62.74; H, 4.59%. Calcd for $C_{18}H_{16}O_7$: C, 62.79; H, 4.68%.

Ii yielded 1,3,6,7-tetramethoxy-9-xanthenone (IIi) (mp 202 °C (benzene) (lit,[12] mp 185—190 °C), 5%, ν_{max}: 1650 cm^{-1} (C=O), λ_{max} (ε): 256 (33100), 270 (s) (7100), 305 (11300) and 351 nm (9000), δ: 3.86 (s, OCH_3), 3.94 (s, $3\times OCH_3$), 6.30 (d, 1H) and 6.42 (d, 1H) (AB system, J=2 Hz, $H_{(2)}$ and $H_{(4)}$), 6.76 (s, $H_{(5)}$), and 7.62 (s, $H_{(8)}$)], and 2,6-dimethoxy-3-(3,4-dimethoxybenzoyl)-*p*-benzoquinone (VIi) [mp 161 °C (benzene), 5%, ν_{max}: 1655, 1688 and 1718 cm^{-1}, λ_{max} (ε): 236 (17600) and 289 nm (16200), δ: 3.85 (s, $2\times OCH_3$), 3.95 (s, $2\times OCH_3$), 5.90 (s, $H_{(5)}$), 6.85 (d, J=8.5Hz, $H_{(5')}$), 7.38 (dd, J=8.5, 2 Hz, $H_{(6')}$) and 7.55 (d, J=2 Hz, $H_{(2')}$). Found: C, 61.15; H, 4.89%. Calcd for $C_{17}H_{16}O_7$: C, 61.44; H, 4.85%].

Ij gave 2,5-dihydroxy-3',4,4'-trimethoxybenzophenone (Ik); mp 208—209 °C (EtOH), 9%, ν_{max}: 1630 cm^{-1} (C=O), λ_{max} (ε): 239 (14800), 253 (14600), 287 (10600), and 372 nm (9850), δ: 3.95 (s, OCH_3), 3.97 (s, $2\times OCH_3$), 5.24 (s, OH), 6.58 (s, $H_{(3)}$), 6.95 (d, J=8.5 Hz, $H_{(5')}$), 7.23 (s, $H_{(6)}$), 7.2—7.45 (m, $H_{(2')}$ and $H_{(6')}$) and 12.30 (s, OH). Found: C, C, 63.06; H, 5.30%. Calcd for $C_{16}H_{16}O_6$: C, 63.15; H, 5.30%.

Oxidation of 2-Hydroxybenzophenones (Ia, Ic, Ie, If, and Ii) with Lead Tetraacetate. A mixture of a 2-hydroxybenzophenone (5 mmol), lead tetraacetate[15] (15 mmol), and acetic acid (30 ml) was heated under reflux for the period of time shown in the Table. After the removal of the acetic acid *in vacuo*, the resulting products were triturated with 2M-hydrochloric acid and then extracted with chloroform. The chloroform solution was washed with aqueous sodium hydrogencarbonate, and the chloroform was evaporated again *in vacuo* to give crude products which were purified on TLC (Wakogel B 10) and by recrystallization. Ia gave IIa; mp 125—126 °C (EtOH), 16%. Ic yielded IIc; mp 185 °C (EtOH), 12%. Ie gave IIb (mp 162 °C (EtOH), 11%), 2,6-dimethoxy-1-methyl-9-xanthenone (IIe) [mp 173 °C (EtOH), 3%, ν_{max}: 1655 cm^{-1} (C=O), λ_{max} (ε): 244 (34300), 273 (s) (12200), 309 (13300), and 355 nm (4600), Found: C, 70.92; H, 5.25%. Calcd for $C_{16}H_{14}O_4$: C, 71.10; H, 5.22%], and 1-acetoxymethyl-2,6-dimethoxy-9-xanthenone (IIIe) [mp 196 °C (benzene–light petroleum), 6%, ν_{max}: 1660 (C=O) and 1745 cm^{-1} (OAc), λ_{max} (ε): 242 (38200), 271 (s) (8900), 314 (14200) and 359 nm (5700), δ: 2.05 (s, OAc), 3.87 (s, $2\times OCH_3$), 5.85 (s, 2H, $-CH_2-$), 6.75 (d, J=2 Hz, $H_{(5)}$), 6.85 (dd, J=8.5, 2 Hz, $H_{(7)}$), 7.30 (d, 1H) and 7.43 (d, 1H) (AB system, J_{AB}=

8 Hz, $H_{(3)}$ and $H_{(4)}$), and 8.12 (d, J=8.5 Hz, $H_{(8)}$). Found: C, 65.88; H, 4.93%. Calcd for $C_{18}H_{16}O_6$: C, 65.85; H, 5.19%]. If gave IIf [mp 130 °C (EtOH), 7%] and 1-acetoxymethyl-2,3,4,6-tetramethoxy-9-xanthenone (IIIf) [mp 120—121 °C (benzene), 6%, ν_{max}: 1660 (C=O) and 1745 cm^{-1} (OAc), λ_{max} (ε): 248 (36500), 275 (10200), and 311 nm (17500), δ: 2.05 (s, OAc), 3.86 (s, 2×OCH_3), 4.03 (s, OCH_3), 4.06 (s, OCH_3), 5.72 (s, $-CH_2-$), 6.80 (d, J=2 Hz, $H_{(5)}$), 6.80 (dd, J=8.5, 2 Hz, $H_{(7)}$) and 8.00 (d, J=8.5 Hz, $H_{(8)}$). Found: C, 61.58; H, 5.21%. Calcd for $C_{20}H_{20}O_8$: C, 61.85; H, 5.19%]. The Reactions of Sodium 1-Benzyl-1,4-dihydronicotinamide-4-sulfinate with Halogen Compounds

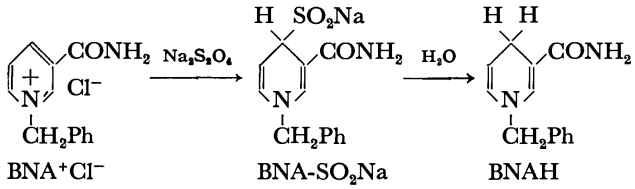
Hiroo INOUE, Nobuaki INOGUCHI, and Eiji IMOTO

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka 591

(Received June 18, 1976)

Sodium 1-benzyl-1,4-dihydronicotinamide-4-sulfinate (BNA-SO_2Na) reacts with various halogen compounds, YZCHBr, through the cleavage of the carbon-sulfur bond to give sulfones, $(YZCH)_2SO_2$, in Y=Ph or PhCH=CH and Z=H; *trans*-stilbene in Y=Ph and Z=CH(Br)Ph or $CH(OCH_3)Ph$; and the reduction products, $YZCH_2$ and $(YZCH)_2$, in Y=Ph, Z=Br, and Y=H, Z=PhCO. The BNA-SO_2Na is converted to 1-benzylnicotinamide bromide, while sulfur dioxide or sulfite ions are formed.

Sodium 1-benzyl-1,4-dihydronicotinamide-4-sulfinate (BNA-SO_2Na) is a bright-yellow intermediate isolated in the course of the reduction of 1-benzylnicotinamide chloride (BNA^+Cl^-) with sodium dithionite to 1-benzyl-1,4-dihydronicotinamide (BNAH).[1] The BNA-SO_2Na was characterized by NMR spectroscopy as an addition compound with the sulfinate group at the 4-position of BNAH.[2]



The reaction of BNA-SO_2Na with organic compounds has not yet been reported except for the reduction of pyridinium salts to dihydropyridines.[1] On the other hand, the reducing agents with a sulfinate group, such as sodium dithionite,[3] sodium hydroxymethanesulfinate,[4] and thiourea dioxide,[5] are well known. In view of the reducing action of these agents and BNAH, BNA-SO_2Na might also serve as a reducing agent with the cleavage of the carbon-sulfur bond of BNA-SO_2Na. Our interest in the reactivity of BNA-SO_2Na has led us to examine the reactions of BNA-SO_2Na with organic halogen compounds, of which the carbon-halogen bond reductions with metals[6] and metal complexes[7] and by electrolysis[8] have been studied extensively. In this paper, we wish to report on the reactions of BNA-SO_2Na with halogen compounds which have a phenyl, cinnamyl, or carbonyl group at the same carbon position as that of the halogen atom.

Results and Discussion

Formation of Sulfones. As Table 1 shows, the reaction of BNA-SO_2Na with benzyl bromide (**1**) in methanol or *N,N*-dimethylformamide (DMF) at 60 °C afforded dibenzyl sulfone, together with BNA^+Br^-. This reaction did not occur at 25 °C. The reduction products, such as toluene and 1,2-diphenylethane, were not obtained at all. Thus, the carbon-sulfur bond of BNA-SO_2Na was cleaved by the action of **1** to form BNA^+Br^-. The production of dibenzyl sulfone with BNA^+Br^- in equimolar amounts indicates that the Na^+ or BNA^+ salt of phenylmethanesulfinic acid (**2**) is formed as an intermediate, and that it then reacts with **1** to give dibenzyl sulfone:

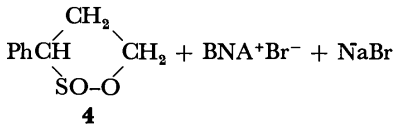
$$PhCH_2Br + BNA\text{-}SO_2Na \longrightarrow$$
1

$$PhCH_2SO_2^-Na^+ \text{ (or } BNA^+) + BNA^+ \text{ (or } Na^+)Br^-$$
2

$$\xrightarrow{1} PhCH_2SO_2CH_2Ph + BNA^+Br^- + NaBr$$

A substitution by the sulfinate group was found to take place in the reaction of BNA-SO_2Na with 1,3-dibromo-1-phenylpropane (**3**). As Table 1 shows, a cyclic sulfinate (**4**) was produced by ring-closure in amounts corresponding approximately to those of BNA^+Br^-:

$$PhCHCH_2CH_2Br + BNA\text{-}SO_2Na \longrightarrow$$
3



+ BNA^+Br^- + NaBr

4

Cinnamyl bromide (**5**) also reacted with BNA-SO_2Na in 80 vol% aqueous acetone or DMF, even at 25 °C, to give dicinnamyl sulfone in a high yield, together with BNA^+Br^-, as Table 1 shows.

TABLE 1. REACTIONS OF BNA-SO_2Na WITH **1**, **3**, AND **5**[a]

Halogen compd	Reaction conditions	$-SO_2-$ or $-SO-O-$ %[b]	BNA^+Br^- %[b]
1	MeOH, 60 °C, 6 h	67	62
1	DMF, 60 °C, 3 h	69	—[c]
3	EtOH, 60 °C, 3 h	55	64
3	DMF, 60 °C, 3 h	64	71
5	$(CH_3)_2CO$-H_2O (4:1) 25 °C, 3 h	83	86
5	DMF, 25 °C, 3 h	99	96

a) BNA-SO_2Na; 5—5.1 mmol. Solvent; 50 cm^3. BNA-SO_2Na/halogen compd molar ratio; 1. b) Based on the halogen compound (2 × product or BNA^+Br^- (mol)/halogen compd (mol) × 100). The products obtained from **1**, **3**, and **5** are dibenzyl sulfone, **4**, and dicinnamyl sulfone respectively. c) Identified, but not quantified.

Formation of Olefins. When a solution of *dl* or *meso*-1,2-dibromo-1,2-diphenylethane (*dl* or *meso*-**6**) in ethanol containing BNA-SO_2Na was heated at 60 °C, the *dl* and *meso*-**6** were converted to *trans*-stilbene in high yields, as Table 2 shows. On the other hand, *cis*-stilbene was not obtained at all. The BNA-SO_2Na was converted to BNA^+Br^- with the generation of sulfur dioxide. The addition of water to the reaction system

(80 vol% aqueous ethanol) did not affect the yield of *trans*-stilbene. When DMF was used as the solvent, the reaction occurred rapidly, even at 20 °C. Furthermore, the isomerization of *cis*-stilbene to *trans*-stilbene was not observed under the reaction conditions.

threo-1-Bromo-2-methoxy-1,2-diphenylethane (*threo*-**7**) reacted also with BNA-SO_2Na in ethanol and DMF at 60 °C to give, selectively, *trans*-stilbene, although the reaction took place slowly (Table 2). Thus, BNA-SO_2Na underwent the debromination of the *dl* and *meso*-**6** and *threo*-**7**, resulting selectively, in *trans*-stilbene, with BNA$^+$Br$^-$ and sulfur dioxide also formed.

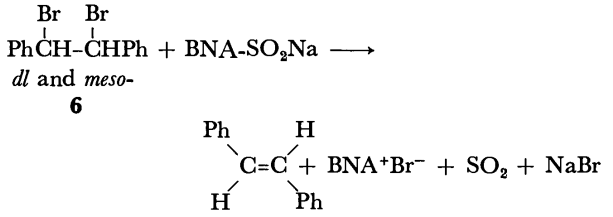


Table 2. Reactions of BNA–SO_2Na with *dl* and *meso*-**6** and *threo*-**7**[a]

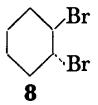
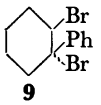
6 or **7**	Molar ratio[b]	Solvent	Product, % PhCH=CHPh	Product, % BNA$^+$Br$^-$	Product, % SO_2
dl[c]	1	EtOH	73[e]	80	57
dl	1	DMF	76	78	—[f]
meso	2	EtOH	94	—[f]	50
meso	2	DMF	99	—[f]	—[f]
threo[d]	2	EtOH	48[g]	—	—
threo	1	DMF	39[g]	—	—

a) **6** or **7**; 3 mmol. Solvent; 50 cm^3. Reaction time; 2 h. Temperature; 60 °C. The yields were calculated by means of product (mol)/**6** or **7** (mol) × 100. b) BNA-SO_2Na/**6** or **7**. c) In the case of the molar ratio of 2, *trans*-stilbene was obtained in a 100% yield. d) Reaction time; 3 h. e) Recovery % of *dl*-**6**; 27%. f) Identified, but not quantified. g) Recovery % of *threo*-**7**; 40% (EtOH) and 55% (DMF).

In order to investigate whether or not the existence of the phenyl group in *vic*-dibromides is required for debromination, the reactions of BNA-SO_2Na with *trans*-1,2-dibromocyclohexane (**8**) and *trans*-1-phenyl-1,2-dibromocyclohexane (**9**) in ethanol at 60 °C were carried out. The **8** was recovered unchanged after a reaction of 6 h, but the **9** was converted to 1-phenylcyclohexene in a 77% yield after 2 h. BNA$^+$Br$^-$ was obtained in a 86% yield, together with 90% of the sulfur dioxide. Thus, the phenyl group attached to the carbon atom with the bromine atom favors the debromination of *vic*-dibromides by BNA-SO_2Na.



8



9

The debromination of *dl* and *meso*-**6** by many dehalogenating agents has been studied extensively.[9] Among these reagents, the benzenesulfinate ion has been known to undergo the debromination of *dl*-**6** to give *cis*-stilbene as the major product.[9] Thus, the reactivity of BNA-SO_2Na to *dl*-**6** would differ essentially from that of the benzenesulfinate ion.

Reduction. Benzylidene dibromide (**10**) was converted to *dl*-**6** and *trans*-stilbene by the action of BNA-SO_2Na in water-free DMF at 20 °C, as Table 3 shows. This reaction was accompanied by the conversion of BNA-SO_2Na to BNA$^+$Br$^-$ and sulfur dioxide. When the molar ratio of BNA-SO_2Na to **10** was 2, *trans*-stilbene was obtained as the only product. The *trans*-stilbene must be produced by the debromination of *dl*-**6** by BNA-SO_2Na, as has been described above. In 80 vol% aqueous methanol, however, dibenzyl sulfone was obtained without any formation of *dl*-**6** or *trans*-stilbene. Thus, it is possible that the formation of **1** is the intervening process in the conversion of **10** to dibenzyl sulfone and that, in the process, BNA-SO_2Na undergoes the two-electron reduction of **10** to give **1**. In an aprotic solvent, the PhCHBr produced by the two-electron reduction could react with **10** to give *dl*-**6**.

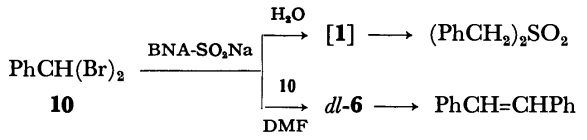


Table 3. Reaction of BNA-SO_2Na with **10**[a]

Reaction conditions[b]	Product, %[c]
DMF, 20 °C, 3 h (1)	*dl*-**6** (26); PhCH=CHPh (36)
DMF, 20 °C, 3 h (2)	PhCH=CHPh (69)
MeOH–H_2O (80%), 60 °C, 3 h (2)	$(PhCH_2)_2SO_2$ (36)

a) **10**; 5—6 mmol. Solvent; 50 cm^3. b) The parentheses represent the molar ratio of BNA-SO_2Na to **10**. c) Based on **10** (2 × product (mol)/**10** (mol) × 100. BNA$^+$Br$^-$ and sulfur dioxide were identified, but not quantified.

α-Bromoacetophenone (**11**) was reduced with BNA-SO_2Na in 80 vol% aqueous methanol at 30 °C to give acetophenone in a good yield, as Table 4 shows. In the reaction, BNA$^+$Br$^-$ and a sulfite ion were produced from BNA-SO_2Na in amounts corresponding to those of acetophenone. No further reduction of acetophenone with BNA-SO_2Na occurred at all. As BNA-SO_2Na is known to be converted to BNAH and a sulfite ion by the action of water, there is a possibility that BNAH acts as a reducing agent. Therefore, the reduction of **11** with BNAH was carried out under similar conditions. Consequently, it was found that the rate of the reduction by BNAH is much slower than that by BNA-SO_2Na: the reduction of **11** with BNAH in 80 vol% aqueous methanol at 25 °C gave acetophenone in a 16% yield after a reaction of 24 h. Furthermore, the reaction of **11** with BNA-SO_2Na was carried out using water-free DMF as the solvent. As Table 4 shows, 1,2-dibenzoylethane was obtained as the reduction product in a high yield, without any formation of 2,4-diphenylfuran, which is produced in the dehalogenation of **11** with Cr(II) or Cu(I) salt[10] in DMF or DMSO. BNA-SO_2Na was converted to BNA$^+$Br$^-$ with the generation of sulfur dioxide. The selective formation of acetophenone or 1,2-dibenzoylethane suggests that the reaction of **11** with BNA-SO_2Na proceeds *via* the formation of **12**, which reacts as a carbanion, PhCO-

Table 4. Reactions of BNA-SO_2Na with α-bromo carbonyl compounds[a]

YZCHBr Y	YZCHBr Z	Reaction conditions[b]	Reduction product, %	BNA^+Br^- %	SO_3^{2-}, SO_2 %
H	PhCO	M-W, 30 °C, 6 h	$PhCOCH_3$ (67)	67	61

a) YZCHBr; 3—5 mmol. Solvent; 50 cm^3. BNA-SO_2Na/YZCHBr molar ratio=1. b) M-W represents 80 vol% MeOH-H_2O. c) Identified, but not quantified.

CH_2^-, followed by a reaction with water to give acetophenone or with **11** in DMF to give 1,2-dibenzoylethane.

$$PhCOCH_2Br \xrightarrow{BNA\text{-}SO_2Na} \underset{\mathbf{11}}{}$$

$$[PhCOCH_2\text{-}SO_2Na] \quad \mathbf{12} \quad \begin{cases} \xrightarrow{H_2O} PhCOCH_3 \\ \xrightarrow[DMF]{\mathbf{11}} (PhCOCH_2)_2 \end{cases}$$

α-Bromodeoxybenzoin, ethyl α-bromophenylacetate, and diethyl α-bromomalonate were all reduced with BNA-SO_2Na in 80 vol% aqueous methanol at 20 °C to the corresponding parent carbonyl compounds in high yields. These reactions were accompanied by the formation of equimolar amounts of BNA^+Br^- and a sulfite ion. Thus, the carbonyl group attached to the carbon atom with a bromine atom favors the reductive debromination by BNA-SO_2Na.

Experimental

Materials. All the halogen compounds, except for **1**, were prepared according to the methods described in the literature.[11] The BNA-SO_2Na was prepared from BNA^+Cl^- and sodium dithionite (85—90% purity) according to the method reported by Biellmann and Callot,[1] and was purified in the following manner: BNA-SO_2Na was dissolved in a 1 M sodium hydroxide solution at 40 °C, and the solution was allowed to cool to 0 °C to give yellow crystals. After the mixture had then been filtered under nitrogen, the crystals were washed with cold water and dried under a reduced pressure of 1 Torr for 4—6 h. All the procedures were carried out in an atmosphere of nitrogen. The purified BNA-SO_2Na was immediately submitted to the reactions with halogen compounds. The UV and NMR spectra (1 M sodium hydroxide solution) of the BNA-SO_2Na used here were identical with those reported by Caughey and Schellenberg.[2]

*Reactions of BNA-SO_2Na. Benzyl Bromide (**1**)*: To a solution of 5.05 mmol of **1** in 50 cm^3 of methanol, we added 5.13 mmol of BNA-SO_2Na. The suspension was stirred under nitrogen at 60 °C for 6 h. After the methanol had then been removed *in vacuo*, the residue was suspended in 150 cm^3 of benzene, and heated under reflux, and the mixture was filtered. The benzene solution was concentrated to 10—15 cm^3. The concentrate was submitted to chromatography on silica gel. Elution with benzene gave 0.42 g (67%) of dibenzyl sulfone; mp 149—150 °C (lit, [12] 149.5—150 °C). Its IR spectrum was identical with that of the authentic specimen. IR (KBr): 1110 and 1300 cm^{-1} (SO_2). The precipitate was then added to 50 cm^3 of methanol, and heated under reflux, and the mixture was filtered. After methanol removal *in vacuo*, the residue was again added to 50 cm^3 of acetone containing a small amount of ethanol and refluxed. The insoluble material was separated from the solution by filtration. The removal of the solvent *in vacuo* gave 0.45 g (62%) of BNA^+Br^-; mp 207—209 °C. Its melting point and IR spectrum were identical with those of the authentic specimen prepared from **1** and nicotinamide. Similar procedures were used in the experiment employing DMF as a solvent.

*1,3-Dibromo-1-phenylpropane (**3**)*: The reaction of BNA-SO_2Na (5.05 mmol) with **3** (5.11 mmol) was carried out, employing ethanol (50 cm^3) as the solvent, under conditions similar to those used in the case of **1**. The reaction products were isolated in a manner similar to that described above to yield 0.5 g (55%) of **4** and 0.93 g (64%) of BNA^+Br^-. The **4** exhibited NMR (CCl_4) signals at δ=2.6 (m, 2H, CH_2), 4.3 (m, 2H, CH_2O), 4.9 (m, 1H, CH), and 7.3 ppm (s, 5H, aromatic protons), and an IR (KBr) peak at 1120 cm^{-1} (SO_2). MS, *m/e*, 182 (parent peak).

Found: C, 59.02; H, 5.66%. Calcd for $C_9H_{10}SO_2$: C 59.33; H, 5.53%.

*Cinnamyl Bromide (**5**)*: A solution of 5.03 mmol of **5** and 5.09 mmol of BNA-SO_2Na in 50 cm^3 of DMF was stirred under nitrogen at 25 °C for 3 h. The reaction mixture was then poured into 300 cm^3 of water to give 0.74 g (99%) of dicinnamyl sulfone; mp 199—200 °C: NMR (CCl_4) δ=3.72 (d, CH_2SO_2) (total 4H), 6.40 (m, =CH) (total 2H), and 7.14 ppm (s, C_6H_5CH=) (total 12H); IR (KBr) 970 (HC=CH) and 1050 and 1180 cm^{-1} (SO_2); MS, *m/e*; 64 (SO_2), 117 (C_6H_5-CH=$CHCH_2$), and 234 [$(C_6H_5CH$=$CHCH_2)_2$].

Found: C, 72.53; H, 6.17%. Calcd for $C_{18}H_{18}SO_2$: C, 72.46; H, 6.08%.

After the water and DMF had been removed *in vacuo*, the residue was extracted with methanol to yield 0.71 g (96%) of BNA^+Br^- in a manner similar to that described above.

vic-*Dibromides (*dl *and* meso-***6***, **8**, *and* **9**) *and* threo-**7**: A typical experiment was as follows: to a solution of 3 mmol of *dl*-**6** in 50 cm^3 of ethanol, we added 3.04 mmol of BNA-SO_2Na. The mixture was stirred at 60 °C for 2 h while nitrogen was being bubbled through the solution. The sulfur dioxide thus evolved was absorbed by 50 cm^3 of a 1 M sodium hydroxide solution. To the alkaline solution we added 20 cm^3 of a 30% hydrogen peroxide solution, and then an excess of a barium chloride solution. The precipitate of barium sulfate was obtained by filtration. Yield: 0.4 g (57%). After the ethanol had been removed *in vacuo*, the residue was extracted with ether. The material, which was insoluble in ether, was then added to methanol. BNA^+Br^- was isolated from the methanol solution by procedures similar to those used in the case of **1**. Yield: 0.71 g (80%). The crude product obtained by the evaporation of the ethereal phase was chromatographed on silica gel to yield *trans*-stilbene (0.394 g, 73%) (mp 118—120 °C), and *dl*-**6** (0.28 g, 27% recovery). Similar procedures were used for

the reactions of BNA-SO_2Na with *meso*-**6**, *threo*-**7**, **8**, and **9**.

*Benzylidene Dibromide (**10**).* *DMF Solvent*: To a solution of 6.06 mmol of **10** in 50 cm^3 of DMF, we added 6.07 mmol of BNA-SO_2Na. The solution was stirred under nitrogen for 3 h at 20 °C, poured into 300 cm^3 of water, and extracted with ether. After the removal of the water and DMF from the aqueous layer, BNA^+Br^- was isolated in a 75% yield by procedures similar to those used in the case of **1**. The ethereal extract was dried on magnesium sulfate, and the ether was removed. The residue was submitted to chromatography on alumina. Elution with hexane and benzene gave 0.195 g (36%) of *trans*-stilbene and 0.26 g (26%) of *dl*-1,2-dibromo-1,2-diphenylethane respectively.

80 Vol% Aqueous Methanol: To a solution of 5.04 mmol of **10** in 50 cm^3 of 80 vol% aqueous methanol, we added 10.1 mmol of BNA-SO_2Na. The solution was then stirred under nitrogen for 3 h at 60 °C. After methanol removal *in vacuo*, 50 cm^3 of water was added to the concentrate. The resulting solution, containing the precipitate, was extracted with ether. The ethereal extract was dried over magnesium sulfate. The subsequent removal of the ether gave 0.22 g (36%) of dibenzyl sulfone.

α-Halo Ketones and Esters: A typical experiment was as follows: A solution of a mixture of 3.02 mmol of **11** and 3.01 mmol of BNA-SO_2Na in 50 cm^3 of 80 vol% aqueous methanol was stirred under nitrogen at 30 °C for 6 h. Then water (200 cm^3) was added, and the resulting solution was extracted with benzene. The benzene phase was dried over magnesium sulfate, and the benzene was then removed. The residue was chromatographed on silica gel to yield 0.244 g (67%) of acetophenone. The aqueous phase, containing a sulfite ion, was acidified by means of 30 vol% hydrobromic acid to bring about the evolution of sulfur dioxide. The sulfur dioxide thus evolved was absorbed by a 1 M sodium hydroxide solution and determined in a manner similar to that described above. Yield of sulfite ions: 61%. The crude product obtained by solvent evaporation was determined by the method described above to contain 0.59 g (67%) of BNA^+Br^-.

Similar procedures were used for the reactions of BNA-SO_2Na with α-bromodeoxybenzoin, ethyl α-bromophenylacetate, and ethyl α-bromomalonate.

The reaction of BNA-SO_2Na (5.05 mmol) with **11** (5 mmol) in DMF (50 cm^3) at 30 °C for 3 h yielded 0.48 g (80%) of 1,2-dibenzoylethane (mp 143—144 °C (lit,[13] 145 °C)), and 0.62 g (86%) of BNA^+Br^-. 1,2-Dibenzoylethane exhibited an IR (KBr) peak at 1675 cm^{-1} (C=O). (Found: C, 80.88; H, 5.88%. Calcd for $C_{16}H_{14}O_2$: C, 80.64; H, 5.92%).

Synthesis of Corticotropin Peptides. XIV. The Synthesis of Two Octadecapeptides Corresponding to the Amino Acid Sequence 22—39 of Porcine and Human Corticotropins*

Kunio WATANABE and Ken INOUYE

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka 553

(Received June 29, 1976)

The syntheses are described of two octadecapeptides, H-Val-Tyr-Pro-Asn-Gly-Ala-Glu-Asp-Glu-Leu-Ala-Glu-Ala-Phe-Pro-Leu-Glu-Phe-OH (Ip) and H-Val-Tyr-Pro-Asn-Gly-Ala-Glu-Asp-Glu-Ser-Ala-Glu-Ala-Phe-Pro-Leu-Glu-Phe-OH (Ih), corresponding to a tryptic fragment (positions 22—39) of porcine corticotropin (α_p-ACTH) and that of human hormone (α_h-ACTH), respectively. The porcine peptide and the corresponding human peptide are prepared simultaneously by an identical synthetic procedure except for the introduction of amino acid residue in position 31. Synthetic peptide Ip is compared with the authentic α_p-ACTH (22—39), which has been isolated from a tryptic hydrolysate of natural α_p-ACTH, in terms of chemical and physicochemical properties to establish their identity. These data as well as those obtained with human peptide Ih prove the satisfactory synthesis of the two octadecapeptides.

In corticotropin (ACTH) lysine 21 is the only basic amino acid residue in the C-terminal half of the hormone molecule (Fig. 1). Thus, the tryptic hydrolysis of ACTH yields a peptide fragment comprising the amino acid residues 22—39 of the hormone;[7] H-Val-Tyr-Pro-Asn-Gly-Ala-Glu-Asp-Glu-Leu-Ala-Glu-Ala-Phe-Pro-Leu-Glu-Phe-OH (Ip) from porcine ACTH (α_p-ACTH)[8] and H-Val-Tyr-Pro-Asn-Gly-Ala-Glu-Asp-Glu-Ser-Ala-Glu-Ala-Phe-Pro-Leu-Glu-Phe-OH (Ih) from human ACTH (α_h-ACTH).[8] The present paper describes the synthesis of octadecapeptides Ip and Ih, which has been performed as a step of our total synthesis of α_p-ACTH and α_h-ACTH.[9] The porcine peptide and the corresponding human peptide were prepared in parallel and there was employed an identical synthetic procedure except for the introduction of the amino acid residue in position 31, which makes the only structural difference between the two mammalian hormones.

Fig. 2. Synthesis of amino acid sequence 28—39 of α_p-ACTH and α_h-ACTH.

Protected dodecapeptides XIIp and XIIh, corresponding to positions 28—39 of α_p-ACTH and α_h-ACTH, respectively, were synthesized as shown in Fig. 2, in which the carboxyl groups were protected as their *t*-butyl esters and the α-amino function was temporarily blocked by a benzyloxycarbonyl group in combination with the subsequent deblocking by catalytic hydrogenolysis. The coupling reactions to lead to the production of porcine peptide XIIp were carried out in a step-by-step manner by the *p*-nitrophenyl ester method throughout, following the strategy employed by Schwyzer and Sieber[10] in their synthesis of the originally proposed amino acid sequence of porcine ACTH.[1,2] This was also applied to our present synthesis of human peptide XIIh with an exception of serine 31 which was introduc-

ed by the azide procedure rather than the active ester method. Among the intermediate compounds involved in the synthesis of XIIp and XIIh, compounds II, III, IV and VII (for structures see Experimental) were obtained in crystalline form. Compounds VIII and IXh separated out of the medium during the coupling reaction. They were amorphous but easily purified by reprecipitation. In the other cases the coupling product had to be chromatographed on a silica gel column for purification, in which methanol-chloroform systems were successfully employed as solvent.

A further extension of the peptide chain at the N-terminal of XIIh produced a tridecapeptide Z-Ala-Glu-(OBu^t)-Asp(OBu^t)-Glu(OBu^t)-Ser-Ala-Glu(OBu^t)-Ala-Phe-Pro-Leu-Glu(OBu^t)-Phe-OBu^t, but its low solubility did not allow us to perform chromatographic purification. Therefore, we synthesized a hexapeptide derivative corresponding to the amino acid residues in positions 22—27 and combined it with dodecapeptides XIIp and XIIh to obtain the desired octadecapeptides. The synthesis of this hexapeptide, Z-Val-Tyr-Pro-Asn-Gly-Ala-NHNH$_2$ (XIX), was carried out as illustrated in Fig. 3. Starting with the dicyclohexylcarbodiimide (DCC)-mediated coupling of Z-Ala-OH with *t*-butyl carbazate, the step-by-step lengthening of peptide chain yielded a tetrapeptide *t*-butoxycarbonyl (Boc)-hydrazide (XVI). The benzyloxycarbonyl (Z) group of XVI was removed by catalytic hydrogenolysis and the resulting N^{α}-free compound was coupled with Z-Val-Tyr-N_3, derived from the corresponding hydrazide[11,12] by the treatment with an alkyl nitrite in an anhydrous acid solution,[13] to give a crystalline hexapeptide derivative (XVIII) in a moderate yield. The subsequent treatment of XVIII with hydrogen chloride in acetic acid to remove the Boc group gave the hydrazide hydrochloride (XIX).

Fig. 3. Synthesis of amino acid sequence 22—27 of ACTH.

Hydrazide XIX obtained above was treated with an alkyl nitrite,[13] and the resulting azide was allowed to react with the N^{α}-free dodecapeptides, derived from XIIp and XIIh by catalytic hydrogenolysis, to give the protected octadecapeptides (XXIp and XXIh). The partially purified preparations of XXIp and XXIh were submitted to catalytic hydrogenolysis and the products were purified on silica gel columns with ethyl acetate–acetic acid–water (4: 1: 1) as solvent to give the N^{α}-free octadecapeptides H-Val-Tyr-Pro-Asn-Gly-Ala-Glu(OBu^t)-Asp(OBu^t)-Glu(OBu^t)-Leu-Ala-Glu(OBu^t)-Ala-Phe-Pro-Leu-Glu(OBu^t)-Phe-OBu^t (XXIIp) and H-Val-Tyr-Pro-Asn-Gly-Ala-Glu-(OBu^t)-Asp(OBu^t)-Glu(OBu^t)-Ser-Ala-Glu(OBu^t)-Ala-Phe-Pro-Leu-Glu(OBu^t)-Phe-OBu^t (XXIIh). Compounds XXIIp and XXIIh have proved to serve as intermediates for the total synthesis of α_p-ACTH and α_h-ACTH, respectively.[9]

Octadecapeptide XXIIh was also synthesized by an alternative route, in which dodecapeptide XIIh was acylated consecutively with Z-Pro-Asn-Gly-Ala-N_3, derived from XVII (Fig. 3), and Z-Val-Tyr-N_3 in combination with the removal of the N^{α}-Z group by catalytic hydrogenolysis. The azides were prepared from the corresponding hydrazides by means of the alkyl nitrite procedure.[13]

Partially protected peptides XXIIp and XXIIh obtained above were deprotected with trifluoroacetic acid in the presence of 2-mercaptoethanol followed by treatment with Amberlite CG-400 (acetate form) to liberate the free octadecapeptides α_p-ACTH(22—39) (Ip) and α_h-ACTH(22—39) (Ih), respectively. The crude preparations of Ip and Ih were purified by partition chromatography on a column of Sephadex LH-20 with 1-butanol–acetic acid–water (4: 1: 2) as solvent. The synthetic octadecapeptides thus obtained were found to be homogeneous in TLC and their acid hydrolysates contained the constituent amino acids in the ratios predicted by theory except for tyrosine, whose recovery was 70—80% as compared with the other amino acids.

In order to obtain the authentic sample of α_p-ACTH-(22—39), a purified preparation of natural α_h-ACTH[9] was submitted to tryptic hydrolysis at pH 8.2 and 37 °C for 60 min. The desired octadecapeptide was isolated from the hydrolysate by chromatography on a column of silica gel with ethyl acetate–acetic acid–water (4: 1: 1) as solvent. This was further purified by partition chromatography on a Sephadex LH-20 column with 1-butanol–acetic acid–water (4: 1: 2) as solvent. Thin-layer chromatography and amino acid analysis revealed the homogeneity of the preparation obtained above, although the tyrosine content was found to be considerably lower than the theoretical value. The low tyrosine content was also observed with the synthetic peptides as described above.[14] The synthetic porcine peptide (Ip) was found to be identical with this authentic octadecapeptide in TLC and in optical rotation within the precision of measurement. It is known that asparagine 25 is the only site of alkaline deamidation in the

ACTH molecule; the Asn-Gly bond (positions 25—26) being transformed into the Asp-α/β-Gly bond by way of the formation of a succinimide intermediate.[15] Upon treatment with 0.1 M ammonia at 37 °C overnight, the authentic α_p-ACTH(22—39) and synthetic peptide Ip yielded an identical product which was clearly distinguished from the intact peptide in TLC with 1-butanol-acetic acid-water (4: 1: 2) as solvent. Thus, the identity between the synthetic peptide and the authentic sample from natural origin has now been established on a sound basis. This would also prove the satisfactory synthesis of human peptide Ih, since peptide Ih was prepared in parallel with Ip using the identical synthetic procedure and conditions except for the introduction of serine 31 in place of leucine 31 in Ip.

Human peptide Ih was found to be more soluble in aqueous acetic acid than porcine peptide Ip and also found to be distinguishable from Ip in TLC with 1-butanol-acetic acid-water (4: 1: 2) as solvent (Ip, R_f= 0.27; Ih, R_f=0.22). These observations may be explained as a reflection of the structural difference between Ip and Ih.

Experimental

Thin-layer chromatography (TLC) was performed on silica gel plates (Kieselgel GF_{254} or precoated Kieselgel $60F_{254}$, Merck) with the following solvent systems: A, chloroform-methanol (8: 2); B, chloroform-methanol-acetic acid (95: 5: 3); C, chloroform-methanol-acetic acid (90: 10: 3); D, ethyl acetate-acetic acid-water (4: 1: 1); E, 1-butanol-acetic acid-water (4: 1: 2).

Z-Glu(OBu^t)-Phe-OBu^t (II). Z-Glu(OBu^t)-OH [derived from the dicyclohexylamine salt (14.3 g, 27.6 mmol) in the usual manner][16] and H-Phe-OBu^t (6.1 g, 27.6 mmol)[17] were coupled with dicyclohexylcarbodiimide (DCC; 5.7 g, 27.6 mmol) in ethyl acetate-dichloromethane (1: 1) to give II, which was crystallized from ether-petroleum ether; yield 12.4 g (83%), mp 132—134 °C, $[\alpha]_D^{22}$ −17.5±0.3° (*c* 2.0, methanol), −14.1±0.3° (*c* 2.0, 95% ethanol). TLC: a single component (sulfuric acid) in system B. Found: C, 66.43; H, 7.42; N, 5.41%. Lit, mp 131.5—132.5 °C, $[\alpha]_D$ −14.0±0.5° (*c* 2, 95% ethanol);[10] mp 131.0—131.5 °C, $[\alpha]_D^{22}$ −11.2° [*c* 0.99, *N,N*-dimethylformamide (DMF)].[18]

Z-Leu-Glu(OBu^t)-Phe-OBu^t (III). Compound II (11.5 g, 21.2 mmol) was hydrogenolyzed over palladium in methanol containing acetic acid to give the N^α-free dipeptide ester, which was coupled with Z-Leu-ONp (8.2 g, 21.2 mmol) in DMF. The product was crystallized from ethyl acetate-ether; yield 13.1 g (94%), mp 109—110 °C, $[\alpha]_D^{22}$ −25.5±0.4° (*c* 2.0, 95% ethanol). TLC: a single component (sulfuric acid) in system C. Found: C, 65.98; H, 7.82; N, 6.52%. Lit, mp 116—117.5°C, $[\alpha]_D$ −26.3±0.6° (*c* 2.0, 95% ethanol);[10] mp 113—115 °C, $[\alpha]_D^{22}$ −14.3° (*c* 1.04, DMF).[18]

Z-Pro-Leu-Glu(OBu^t)-Phe-OBu^t (IV). Compound III (7.60 g, 11.6 mmol) was hydrogenolyzed to give the N^α-free tripeptide ester, which was coupled with Z-Pro-ONp (4.30 g, 11.6 mmol) in DMF. The product was crystallized from ether; yield 8.00 g (92%), mp 160—161°C, $[\alpha]_D^{23}$ −58.7±0.5° (*c* 2.0, 95% ethanol). TLC: a single component (sulfuric acid) in system C. Found: C, 65.68; H, 7.79; N, 7.38%. Lit, mp 152—153 °C, $[\alpha]_D$ −56.8±0.6° (*c* 2, 95% ethanol).[10]

Z-Phe-Pro-Leu-Glu(OBu^t)-Phe-OBu^t (V). Compound IV (12.4 g, 16.5 mmol) was hydrogenolyzed to give the N^α-free tetrapeptide ester, which was coupled with Z-Phe-ONp (6.94 g, 16.5 mmol) in DMF. The crude product was purified on a column of silica gel (100 g, Kieselgel H, Merck) with 2% methanol in chloroform as solvent; yield 14.75 g (97.5%), $[\alpha]_D^{23}$ −54.8±1.0° (*c* 1.0, methanol). TLC: a single component (sulfuric acid) in system C. Found: C, 66.76; H, 7.53; N, 7.87%. Lit, $[\alpha]_D$ not given.[10]

Z-Ala-Phe-Pro-Leu-Glu(OBu^t)-Phe-OBu^t (VI). Compound V (14.1 g, 15.7 mmol) was hydrogenolyzed to give the N^α-free pentapeptide ester, which was coupled with Z-Ala-ONp (5.40 g, 15.7 mmol) in DMF. The crude product was purified on a silica gel column with 1% methanol in chloroform as solvent; yield 11.9 g (77%), $[\alpha]_D^{22}$ −67.9±1.1° (*c* 1.0, methanol). TLC: a single component (sulfuric acid) in system C. Found: C, 64.74; H, 7.55; N, 8.60%. Lit, $[\alpha]_D$ not given;[10] $[\alpha]_D^{22}$ −38.6° (*c* 1.01, DMF).[18]

Z-Glu(OBu^t)-Ala-Phe-Pro-Leu-Glu(OBu^t)-Phe-OBu^t (VII). Compound VI (5.80 g, 5.9 mmol) was hydrogenolyzed to give the N^α-free hexapeptide ester, which was coupled with Z-Glu(OBu^t)-ONp (2.74 g, 5.9 mmol) in DMF. The product was crystallized from ethyl acetate-ether; yield 5.30 g (78%), mp 178—180 °C, $[\alpha]_D^{24}$ −64.8±1.1° (*c* 1.0 methanol). TLC: a single component (sulfuric acid) in system C. Found: C, 64.01; H, 7.73; N, 8.51%. Lit, mp 172—173 °C, $[\alpha]_D$ not given;[10] mp 168—170 °C decomp., $[\alpha]_D^{21}$ −34.4° (*c* 1.03, DMF).[18]

Z-Ala-Glu(OBu^t)-Ala-Phe-Pro-Leu-Glu(OBu^t)-Phe-OBu^t (VIII). Compound VII (4.0 g, 3.64 mmol) was hydrogenolyzed to give the N^α-free heptapeptide ester, which was coupled with Z-Ala-ONp (1.25 g, 3.64 mmol) in ethyl acetate. The product which had separated was filtered off and reprecipitated from ethyl acetate-ether; yield 4.02 g (90%), mp 145—147 °C, $[\alpha]_D^{24}$ −63.8±1.0° (*c* 1.0, methanol). TLC: a single component (sulfuric acid) in system C. Found: C, 62.82; H, 7.68; N, 9.30%. Lit, no data given;[10] mp 185—186 °C decomp., $[\alpha]_D^{23}$ −34.9° (*c* 1.05, DMF).[18]

Z-Leu-Ala-Glu(OBu^t)-Ala-Phe-Pro-Leu-Glu(OBu^t)-Phe-OBu^t (IXp). Compound VIII (2.45 g, 2.0 mmol) was hydrogenolyzed to give the N^α-free octapeptide ester, which was coupled with Z-Leu-ONp (0.85 g, 3.3 mmol) in DMF-ethyl acetate (1: 2). The crude product was purified on a silica gel column (70 g) with 3% methanol in chloroform as solvent; yield 2.40 g (90%), mp 125—130 °C, $[\alpha]_D^{28}$ −60.0 ±1.0° (*c* 1.0, methanol). TLC: a single component (sulfuric acid) in system C. Found: C, 63.17; H, 7.73; N, 9.29%. Lit, no data given.[10]

Z-Ser-Ala-Glu(OBu^t)-Ala-Phe-Pro-Leu-Glu(OBu^t)-Phe-OBu^t (IXh). The N^α-octapeptide ester, derived from VIII (2.65 g, 2.2 mmol) as above, and Z-Ser-N_3 [derived from the corresponding hydrazide (0.84 g, 3.3 mmol) by the treatment with nitrous acid in the usual manner] were coupled in ethyl acetate at 4 °C overnight. The product which had separated was filtered off and reprecipitated from ethyl acetate-ether; yield 2.60 g (90%), mp 187—189 °C, $[\alpha]_D^{24}$ −55.9 ±1.0° (*c* 1.0, methanol). TLC: a single component (sulfuric acid) in system C. Found: C, 61.99; H, 7.63; N, 9.45%. Lit, no data given;[15] mp 181—183 °C decomp., $[\alpha]_D^{28}$ −32.9° (*c* 1.04, DMF).[18]

Z-Glu(OBu^t)-Leu-Ala-Glu(OBu^t)-Ala-Phe-Pro-Leu-Glu-(OBu^t)-Phe-OBu^t (Xp). Compound IXp (2.37 g, 1.8 mmol) was hydrogenolyzed over palladium in acetic acid to give the N^α-free nonapeptide ester. This was then coupled with Z-Glu(OBu^t)-ONp (0.82 g, 1.8 mmol) in DMF in the presence of triethylamine (0.25 ml, 1.8 mmol) at 4 °C overnight. The crude product was purified on a silica gel column (70 g) with 3% methanol in chloroform as solvent; yield 2.32 g (86%), mp 185—190 °C, $[\alpha]_D^{25}$ −57.4±0.9° (*c* 1.0, methanol).

TLC: single component (sulfuric acid) in system C.

Found: C, 62.71; H, 7.79; N, 9.03%. Calcd for $C_{80}H_{118}N_{10}O_{19}$: C, 63.05; H, 7.81; N, 9.19%.

Z-Glu(OBu^t)-Ser-Ala-Glu(OBu^t)-Ala-Phe-Pro-Leu-Glu(OBu^t)-Phe-OBu^t (Xh). Compound IXh (2.62 g, 2.0 mmol) was hydrogenolyzed to give the N^{α}-free nonapeptide ester, which was coupled with Z-Glu(OBu^t)-ONp (0.92 g, 2.0 mmol) in DMF. The crude product was purified on a silica gel column with 3—5% methanol in chloroform as solvent; yield 2.60 g (90%), mp 135—137 °C, $[\alpha]_D^{24}$ −48.9 ±0.9° (*c* 1.0, methanol). TLC: a single component (sulfuric acid) in system C. Found: C, 61.20; H, 7.48; N, 9.45%. Lit, no data given;[15] mp 189—190 °C decomp., $[\alpha]_D^{23}$ −29.7° (*c* 0.98, DMF).[18]

Z-Asp(OBu^t)-Glu(OBu^t)-Leu-Ala-Glu(OBu^t)-Ala-Phe-Pro-Leu-Glu(OBu^t)-Phe-OBu^t (XIp). Compound Xp (2.00 g, 1.32 mmol) was hydrogenolyzed over palladium in acetic acid to give the N^{α}-free decapeptide ester. This was then coupled with Z-Asp(OBu^t)-ONp (0.59 g, 1.32 mmol) in DMF in the presence of triethylamine (0.20 ml, 1.43 mmol) at 4 °C for 2.5 days. The crude product was purified on a silica gel column (70 g) with 3% methanol in chloroform as solvent; yield 2.10 g (94%), mp 224—225 °C decomp., $[\alpha]_D^{26}$ −48.9±0.9° (*c* 1.0, methanol).

Found: C, 61.91; H, 7.67; N, 8.84%. Calcd for $C_{83}H_{131}H_{11}O_{22}$: C, 62.35; H, 7.79; N, 9.09%.

Z-Asp(OBu^t)-Glu(OBu^t)-Ser-Ala-Glu(OBu^t)-Ala-Phe-Pro-Leu-Glu(OBu^t)-Phe-OBu^t (XIh). Compound Xh (2.80 g, 1.87 mmol) was hydrogenolyzed to give the N^{α}-free decapeptide ester, which was coupled with Z-Asp(OBu^t)-ONp (0.84 g, 1.87 mmol) in DMF. The crude product was purified on a silica gel column with 5% methanol in chloroform as solvent; yield 2.98 g (96%), mp 193—195 °C decomp., $[\alpha]_D^{28}$ −48.1±0.5° (*c* 1.0, methanol). TLC: a single component (sulfuric acid) in system C. Found: C, 60.80; H, 7.65; N, 8.94%. Lit, no data given;[15] mp 194—195 °C decomp., $[\alpha]_D^{28}$ −29.8° (*c* 1.05, DMF).[18]

Z-Glu(OBu^t)-Asp(OBu^t)-Glu(OBu^t)-Leu-Ala-Glu(OBu^t)-Ala-Phe-Pro-Leu-Glu(OBu^t)-Phe-OBu^t (XIIp). Compound XIp (2.00 g, 1.18 mmol) was hydrogenolyzed over palladium in acetic acid to give the N^{α}-free undecapeptide ester. This was then coupled with Z-Glu(OBu^t)-ONp (0.55 g, 1.20 mmol) in DMF in the presence of triethylamine (0.20 ml, 1.43 mmol) at 4 °C for 2.5 days. The crude product was purified on a silica gel column (50 g) with 3% methanol in chloroform as solvent; yield 2.10 g (95%), mp 230 °C decomp., $[\alpha]_D^{28}$ −41.2±0.8° (*c* 1.0, methanol). Amino acid ratios in acid hydrolysate (theoretical values are given in parentheses): Asp 0.92 (1), Glu 3.89 (4), Pro 0.92 (1), Ala 1.95 (2), Leu 2.00 (2), Phe 1.82 (2).

Found: C, 61.55; H, 7.82; N, 8.91%. Calcd for $C_{97}H_{146}N_{12}O_{25}$: C, 61.96; H, 7.83; N, 8.94%.

Z-Glu(OBu^t)-Asp(OBu^t)-Glu(OBu^t)-Ser-Ala-Glu(OBu^t)-Ala-Phe-Pro-Leu-Glu(OBu^t)-Phe-OBu^t (XIIh). Compound XIh (2.10 g, 1.26 mmol) was hydrogenolyzed to give the N^{α}-free undecapeptide ester, which was coupled with Z-Glu(OBu^t)-ONp (0.58 g, 1.27 mmol) in DMF. The crude product was purified on a silica gel column with 4% methanol in chloroform as solvent; yield 2.10 g (94%), mp 220—221 °C decomp., $[\alpha]_D^{24.5}$ −26.9±0.7° (*c* 1.0, DMF). TLC: a single component (sulfuric acid) in system C. Amino acid ratios in acid hydrolysate: Asp 1.00 (1), Ser 0.91 (1), Glu 4.11 (4), Pro 1.07 (1), Ala 2.04 (2), Leu 1.00 (1), Phe 1.89 (2). Found: C, 60.77; H, 7.55; N, 8.97%. Lit, no data given;[15] mp 215—216 °C decomp., $[\alpha]_D^{23}$ −27.2° (*c* 1.07, DMF).[18]

Z-Ala-NHNH-Boc (XIII). Z-Ala-OH (11.15 g, 50 mmol) and *t*-butyl carbazate (6.60 g, 50 mmol) were dissolved in ethyl acetate (100 ml) and to this was added DCC (10.35 g, 50 mmol) at 0 °C with ethyl acetate as solvent. The mixture was stirred at 4 °C overnight followed by evaporation *in vacuo*. The residue was submitted to a silica gel column (150 g) with 2% methanol in chloroform as solvent. The fractions (17 g/tube) were examined by TLC in system C and those containing the desired compound as a single component (tubes 39—70) were combined and evaporated *in vacuo* to give a residue which was crystallized from ether-petroleum ether; yield 15.9 g (94%), mp 93—95 °C, $[\alpha]_D^{28}$ −48.2±0.9° (*c* 1.0, methanol).

Found: C, 55.84; H, 6.60; N, 12.34%. Calcd for $C_{16}H_{23}N_3O_5$: C, 56.96; H, 6.87; N, 12.46%.

Z-Gly-Ala-NHNH-Boc (XIV). Compound XIII (3.37 g, 10 mmol) was hydrogenolyzed over palladium in methanol. The resulting N^{α}-free compound and Z-Gly-OH (2.09 g, 10 mmol) were coupled with DCC (2.06 g, 10 mmol) in ethyl acetate (40 ml) at 4 °C overnight. The reaction mixture was worked up in the usual manner to isolate the crystalline product, which was recrystallized from aqueous methanol; yield 4.10 g (99%), mp 110—112 °C, $[\alpha]_D^{22}$ −45.8 ±0.9° (*c* 1.0, methanol).

Found: C, 52.60; H, 7.00; N, 13.38%. Calcd for $C_{18}H_{26}N_4O_6\cdot H_2O$: C, 52.42; H, 6.84; N, 13.59%.

Z-Asn-Gly-Ala-NHNH-Boc (XV). Compound XIV (3.94 g, 9.6 mmol) was hydrogenolyzed over palladium in methanol. The resulting N^{α}-free dipeptide derivative was then coupled with Z-Asn-ONp (3.87 g, 10 mmol) in DMF (10 ml) at 4 °C overnight. The product isolated as amorphous solid was reprecipitated from methanol-ether; yield 4.50 g (92%), mp 146—149 °C decomp., $[\alpha]_D^{28}$ −24.6±0.7° (*c* 1.0, methanol).

Found: C, 52.13; H, 6.52; N, 15.89%. Calcd for $C_{22}H_{32}N_6O_8$: C, 51.96; H, 6.34; N, 16.53%.

Z-Pro-Asn-Gly-Ala-NHNH-Boc (XVI). Compound XV (4.30 g, 8.5 mmol) was hydrogenolyzed over palladium in methanol containing acetic acid to give the N^{α}-free tripeptide derivative, which was coupled with Z-Pro-ONp (3.13 g, 8.5 mmol) in DMF. The product, dissolved in water-saturated 1-butanol-ethyl acetate (1: 1), was washed with 1M acetic acid followed by evaporation *in vacuo*. The residue was precipitated from ethyl acetate-ether (2: 1) and then from methanol-ethyl acetate (1: 3) to give XVI in pure form; yield 4.40 g (83%), mp 145—147 °C, $[\alpha]_D^{24.5}$ −68.1±1.1° (*c* 1.0, methanol). TLC: a single component (sufuric acid) in system A.

Found: C, 51.52; H, 6.63; N, 15.53%. Calcd for $C_{27}H_{39}N_7O_9\cdot H_2O$: C, 52.00; H, 6.63; N, 15.72%.

Z-Pro-Asn-Gly-Ala-NHNH$_2$·HCl (XVII). Compound XVI (4.70 g) was treated with 1M hydrogen chloride in acetic acid (50 ml) at room temperature for 60 min followed by evaporation *in vacuo*. The residue was triturated with ethyl acetate-ether (1: 1) and the resulting precipitates were filtered off and reprecipitated from ethanol (30 ml) two times; yield 2.75 g (65%), mp 145—147 °C decomp., $[\alpha]_D^{24}$ −63.9 ±1.5° (*c* 0.7, methanol).

Found: C, 47.83; H, 6.15; N, 17.28; Cl, 5.71%. Calcd for $C_{22}H_{31}N_7O_7\cdot HCl\cdot H_2O$: C, 47.18; H, 6.12; N, 17.51; Cl, 6.33%.

Z-Val-Tyr-Pro-Asn-Gly-Ala-NHNH-Boc (XVIII). Compound XVI (2.33 g, 3.7 mmol) was hydrogenolyzed over palladium in methanol to give H-Pro-Asn-Gly-Ala-NHNH-Boc (1.96 g) as amorphous solid.

A solution of Z-Val-Tyr-NHNH$_2$ (1.76 g, 4.1 mmol)[11,12] in DMF (18 ml) was chilled to −15—−20 °C and 3.66 M hydrogen chloride in dioxane (4.5 ml) was introduced. To this was added dropwise isopentyl nitrite (0.59 ml, 4.5 mmol)

and the mixture was stirred at the same temperature for 10 min. The resulting azide solution was chilled to −40——50 °C and there were added triethylamine (2.9 ml, 20.6 mmol) and the N^{α}-free tetrapeptide derivative obtained above with DMF (20 ml) as solvent. The bath was removed and the temperature was allowed to rise to 4 °C at which the reaction mixture was stirred for 20 h followed by evaporation *in vacuo*. The residue was shaken with a mixture of 1-butanol–ethyl acetate (1: 1, 20 ml) and 1M acetic acid (20 ml). The organic phase separated was further washed with 1M acetic acid three times followed by evaporation *in vacuo*. The residue was then chromatographed on a silica gel column (70 g) with 15% methanol in chloroform as solvent. The fractions (7 g/tube) were examined by TLC (system A) and those containing the desired compound as a single component were combined and evaporated *in vacuo* to give a residue which was crystallized from ethyl acetate; yield 1.8 g (56%), mp 166—167 °C decomp., $[\alpha]_D^{24}$ −66.4±1.0° (*c* 1.0, methanol).

Found: C, 55.89; H, 6.85; N, 14.34%. Calcd for $C_{41}H_{57}N_9O_{12}$: C, 56.74; H, 6.62; N, 14.53%.

Z-Val-Tyr-Pro-Asn-Gly-Ala-NHNH$_2$·HCl (XIX). Compound XVIII (1.80 g) was treated with 1M hydrogen chloride in acetic acid at room temperature for 60 min in the presence of anisole (0.2 ml) as scavenger. The solvent was evaporated *in vacuo* to give a residue which was triturated with ether; yield 1.70 g, mp 143—145 °C. Amino acid ratios in acid hydrolysate: NH_3 0.99 (1), Asp 1.04 (1), Pro 0.89 (1), Gly 1.04 (1), Ala 1.04 (1), Val 1.00 (1), Tyr 0.87 (1).

Z-Pro-Asn-Gly-Ala-Glu(OBu^t)-Asp(OBu^t)-Glu(OBu^t)-Ser-Ala-Glu(OBu^t)-Ala-Phe-Pro-Leu-Glu(OBu^t)-Phe-OBu^t (XX). Compound XIIh (1.20 g, 0.65 mmol) was hydrogenolyzed over palladium in acetic acid to give the N^{α}-free dodecapeptide ester. A solution of XVII (0.56 g, 1.0 mmol) in tetrahydrofuran containing 1M hydrochloric acid (1.5 ml) was chilled in an ice bath and 2 M sodium nitrite (0.55 ml) was added. The mixture was stirred at 0 °C for 4 min. To this were then introduced ice-cold ethyl acetate (20 ml) and ice-cold 50% potassium carbonate (8 ml). The organic phase separated was dried over magnesium sulfate at 0 °C and was combined with a DMF solution of the dodecapeptide ester obtained above. The mixture was concentrated *in vacuo* at a bath temperature of 5—10 °C to remove ethyl acetate and was stirred at 4 °C for 20 h. The product which was precipitated by the addition of ether and petroleum ether was lyophilized from acetic acid. The resulting soft powder was suspended in aqueous ethanol and the insoluble precipitates were filtered off (1.1 g). Reprecipitation from a mixture of methanol (40 ml) and water (20 ml) afforded hexadecapeptide XX; yield 0.88 g (62%), $[\alpha]_D^{24.5}$ −20.6±0.6° (*c* 1.0, DMF). TLC: almost homogeneous (ninhydrin, after pretreatment with hydrobromic acid) in systems A and E. Amino acid ratios in acid hydrolysate: NH_3 0.93 (1), Asp 1.94 (2), Ser 0.95 (1), Pro 1.96 (2), Glu 4.01 (4), Gly 0.98 (1), Ala 3.00 (3), Leu 1.07 (1), Phe 2.15 (2).

H-Val-Tyr-Pro-Asn-Gly-Ala-Glu(OBu^t)-Asp(OBu^t)-Glu(OBu^t)-Leu-Ala-Glu(OBu^t)-Ala-Phe-Pro-Leu-Glu(OBu^t)-Phe-OBu^t (XXIIp). Compound XIIp (0.98 g, 0.52 mmol) was hydrogenolyzed over palladium in acetic acid to give the N^{α}-free dodecapeptide ester.

A solution of XIX (0.45 g, 0.57 mmol) in DMF (5 ml) was chilled to −20——30 °C and 3.66 M hydrogen chloride in dioxane (0.47 ml) was introduced. To this was added dropwise isopentyl nitrite (0.082 ml, 0.63 mmol) and the mixture was stirred at the same temperature for 10 min. The azide solution thus obtained was chilled to −40——50 °C and triethylamine (0.4 ml, 2.87 mmol) was added. This was then combined with a DMF solution of the N^{α}-free dodecapeptide obtained above and the mixture was stirred for 24 h, while the temperature was allowed to rise to 4 °C. After the solvent had been removed by evaporation *in vacuo* the residue was triturated and washed with water and lyophilized from acetic acid. The resulting powder was suspended in 50% ethanol and the insoluble precipitates were filtered off, washed and dried to give the protected octadecapeptide (XXIp, 1.09 g, 84%), which was almost homogeneous in TLC in system A; mp 232—233 °C decomp.

Compound XXIp (1.40 g) prepared as described above was hydrogenolyzed over palladium in acetic acid. The resulting N^{α}-free peptide was purified on silica gel columns (150—250 g, Kieselgel 60, Merck) with ethyl acetate–acetic acid–water (4: 1: 1) as solvent. The resulting pure material was lyophilized from acetic acid; yield 1.09 g (67%), $[\alpha]_D^{23.5}$ −37.0 ±0.7° (*c* 1.0, acetic acid). TLC: a single component (ninhydrin) in system D. Amino acid ratios in acid hydrolysate: NH_3 0.90 (1), Asp 1.90 (2), Glu 3.95 (4), Pro 1.96 (2), Gly 1.04 (1), Ala 2.97 (3), Val 0.95 (1), Leu 2.00 (2), Tyr 0.86 (1), Phe 1.90 (2).

H-Val-Tyr-Pro-Asn-Gly-Ala-Glu(OBu^t)-Asp(OBu^t)-Glu(OBu^t)-Ser-Ala-Glu(OBu^t)-Ala-Phe-Pro-Leu-Glu(OBu^t)Phe-OBu^t (XXIIh). *a) By (22—23)+(24—39):* Compound XX (0.83 g, 0.38 mmol) was hydrogenolyzed over palladium in acetic acid to give the N^{α}-free hexadecapeptide ester. This was then coupled with Z-Val-Tyr-N_3 [derived from the corresponding hydrazide (0.21 g, 0.5 mmol)[11,12] by the treatment with nitrous acid in the usual manner] in DMF at 4 °C for 2.5 days. The product was repeatedly precipitated from ethanol–water to give a partially purified preparation of the protected octadecapeptide (XXIh, 0.77 g).

Compound XXIh obtained above was hydrogenolyzed over palladium in acetic acid and the resulting N^{α}-free peptide was purified on silica gel columns in the manner described above for XXIIp. The pure material was lyophilized from acetic acid; yield 0.39 g (43%). TLC: a single component (ninhydrin) in system D.

b) By (22—27)+(28—39). Compound XIIh (1.06 g, 0.57 mmol) was hydrogenolyzed over palladium in acetic acid to give the N^{α}-free dodecapeptide ester. This was then coupled with the acyl hexapeptide azide [derived from XIX (0.52 g, 0.65 mmol) in exactly the same manner as described above] in DMF in the presence of triethylamine (0.45 ml, 3.25 mmol) at 4 °C for 24 h. The crude product was lyophilized from acetic acid and the resulting powder was suspended in 50% ethanol and the insoluble material was collected to give XXIh (1.20 g, 87%), which was almost homogeneous in TLC in system A; mp 224—225 °C decomp.

Compound XXIh (2.20 g) prepared as described above was hydrogenolyzed over palladium in acetic acid. The resulting N^{α}-free peptide was purified on silica gel columns as described above; yield 1.71 g (70%), $[\alpha]_D^{23.5}$ −34.3±0.7° (*c* 1.0, acetic acid). TLC: a single component (ninhydrin) in system D. Amino acid ratios in acid hydrolysate: NH_3 0.91 (1), Asp 1.99 (2), Ser 0.87 (1), Glu 4.01 (4), Pro 1.78 (2), Gly 1.04 (1), Ala 3.09 (3), Val 0.99 (1), Leu 1.00 (1), Tyr 0.90 (1), Phe 1.98 (2).

H-Val-Tyr-Pro-Asn-Gly-Ala-Glu-Asp-Glu-Leu-Ala-Glu-Ala-Phe-Pro-Leu-Glu-Phe-OH (Ip). *a) Synthetic Preparation:* Compound XXIIp (100 mg) was dissolved in trifluoroacetic acid (1 ml) together with 2-mercaptoethanol (0.1 ml) and the mixture was kept at room temperature for 60 min. The precipitates which formed upon addition of ether were filtered off and dissolved in 3 M acetic acid (5 ml). The aqueous solution was passed through a column (0.9×7 cm) of Amberlite CG-400 (acetate form) with additional portions

of 3 M acetic acid and the eluates combined were lyophilized. The product was then submitted to partition chromatography on a column of Sephadex LH-20 (3.0×70 cm) with 1-butanol–acetic acid–water (4: 1: 2) as solvent. Five-ml fractions were collected and their absorption at 275 nm was measured. The fractions corresponding to a main peak (tubes 36—60) were pooled and evaporated *in vacuo* at a bath temperature of 45 °C. Lyophilization of the residue from acetic acid afforded Ip; yield 60 mg, $[\alpha]_D^{22}$ −41.6±2.0° (*c* 0.4, acetic acid) TLC: a single component (ninhydrin) in system E. Amino acid ratios in acid hydrolysate: NH_3 1.24 (1), Asp 2.00 (2), Glu 3.83 (4), Pro 2.09 (2), Gly 1.12 (1), Ala 2.99 (3), Val 0.93 (1), Leu 2.03 (2), Tyr 0.70 (1), Phe 2.00 (2).

b) Isolation from Natural α_p-ACTH. To a solution of the purified natural α_p-ACTH (*ca.* 15 mg)[9] in 0.2 M ammonium hydrogencarbonate (pH 8.2, 3.75 ml) was added 0.51 ml of 0.2% trypsin (chymotrypsin-free, in 0.001 M hydrochloric acid) and the mixture was incubated at 37 °C for 60 min. After addition of acetic acid (0.25 ml) the mixture was lyophilized. The tryptic hydrolysate thus obtained was submitted to chromatography on a column of silica gel (5 g, Kieselgel H, Merck) with ethyl acetate–acetic acid–water (4: 1: 1) as solvent. One half-ml fractions were collected and their absorption at 275 nm was measured. The fractions corresponding to a peak (tubes 16—22) were combined, evaporated *in vacuo* at a bath temperature of 40 °C and lyophilized from acetic acid (5 mg). This was further purified on a Sephadex LH-20 column (3.0×74 cm) with 1-butanol–acetic acid–water (4: 1: 2) as solvent. Five-ml fractions were collected and their absorption at 275 nm was measured to reveal the presence of a single component. The fractions corresponding to the peak (tubes 25—29) were combined and evaporated *in vacuo*, and the residue was lyophilized from acetic acid; yield 4 mg, $[\alpha]_D^{22}$ −42.7±3.5° (*c* 0.2, acetic acid). TLC: a single component (ninhydrin) in system E. Amino acid ratios in acid hydrolysate: NH_3 1.11 (1), Asp 2.01 (2), Glu 3.90 (4), Pro 1.91 (2), Gly 1.05 (1), Ala 2.95 (3), Val 0.96 (1), Leu 2.00 (2), Tyr 0.81 (1), Phe 1.83 (2).

H-Val-Tyr-Pro-Asn-Gly-Ala-Glu-Asp-Glu-Ser-Ala-Glu-Ala-Phe-Pro-Leu-Glu-Phe-OH (Ih). Compound XXIIh (100 mg) was treated with trifluoroacetic acid (1 ml) at room temperature for 60 min in the presence of 2-mercaptoethanol (0.1 ml). The precipitates which formed upon addition of ether were passed through an Amberlite CG-400 column with 1M acetic acid as solvent, followed by purification on a Sephadex LH-20 column with 1-butanol–acetic acid–water (4: 1: 2) as solvent in exactly the same manner as described above for Ip; yield 70 mg, $[\alpha]_D^{22}$ −41.4±1.6° (*c* 0.5, acetic acid). TLC: a single component (ninhydrin) in system E. Amino acid ratios in acid hydrolysate: NH_3 1.31 (1), Asp 2.03 (2), Ser 0.93 (1), Glu 3.98 (4), Pro 2.20 (2), Gly 1.08 (1), Ala 3.00 (3), Val 0.95 (1), Leu 1.00 (1), Tyr 0.78 (1), Phe 2.03 (2).

14) In this connection, we should mention that in the amino acid analysis of the full-length ACTH preparations the recovery of tyrosine was excellent.[9] Thus, the extent of decomposition of tyrosine during acid hydrolysis seems to depend on the amino acid composition of a peptide to be hydrolyzed, and some amino acid (*e.g.* methionine) may play a role to protect tyrosine from its decomposition.

(Received June 29, 1976)

An undecapeptide derivative, Z-Lys(Mhoc)-Pro-Val-Gly-Lys(Mhoc)-Lys(Mhoc)-Arg-Arg-Pro-Val-Lys-(Mhoc)-$NHNH_2$, corresponding to the amino acid sequence 11—21 of corticotropin (ACTH) is synthesized. In the course of the synthesis a key intermediate H-Arg(NO_2)-Arg(NO_2)-Pro-OH is derived from Z-Arg(NO_2)-Arg-(NO_2)-Pro-OBzl by the treatment with hydrogen bromide in acetic acid. This procedure eliminates the danger of racemization associated with the use of alkali for saponification. The synthesis is also described of a nonapeptide derivative, Z-Lys(Mhoc)-Pro-Val-Gly-Lys(Mhoc)-Lys(Mhoc)-Arg(NO_2)-Arg(NO_2)-Pro-OH (amino acid sequence 11—19 of ACTH), in which a new protecting group, 9-methyl-9-fluorenyloxycarbonyl (Mfoc), is utilized for the temporary protection of an α-amino function.

In the preceding paper[1] we described the syntheses of the amino acid sequence 22—39 of porcine corticotropin (α_p-ACTH) and that of the human hormone (α_h-ACTH). In the present communication we wish to report the synthesis of an undecapeptide derivative, Z-Lys(Mhoc)-Pro-Val-Gly-Lys(Mhoc)-Lys(Mhoc)-Arg-Arg-Pro-Val-Lys(Mhoc)-$NHNH_2$ (VII), and a nonapeptide derivative, Z-Lys(Mhoc)-Pro-Val-Gly-Lys(Mhoc)-Lys(Mhoc)-Arg(NO_2)-Arg(NO_2)-Pro-OH (XI), corresponding to the amino acid sequences 11—21 and 11—19, respectively, of ACTH which has been performed as a step of the total synthesis of α_p-ACTH and α_h-ACTH.[2]

Synthesis of Undecapeptide Derivative VII. The synthetic procedure of undecapeptide VII is outlined in Fig. 1. The ε-amino function of lysines and the guanidino function of arginines were protected by the 1-methylcyclohexyloxycarbonyl (Mhoc) group and by the nitro group, respectively. The Mhoc group is much the same as the *t*-butoxycarbonyl (Boc) group in susceptibility toward acid reagents.[3] The dicyclohexylcarbodiimide (DCC)-mediated coupling of Boc-Arg(NO_2)-OH with proline benzyl ester yielded a dipeptide (I), which was purified on a silica gel column with a chloroform–methanol system as solvent. Compound I was treated with trifluoroacetic acid and the resulting N^{α}-free peptide was allowed to react with the pentachlorophenyl ester[4] of Z-Arg(NO_2)-OH. The product was purified by chromatography to give a tripeptide (II) in a 70% yield. Compound II was treated with hydrogen bromide in acetic acid for the simultaneous removal of benzyloxycarbonyl (Z) and benzyl ester groups to yield III. This was then coupled with Z-Lys(Mhoc)-OSu[5] to give a tetrapeptide (IV) in an 82% yield after chromatographic purification on a silica gel column with a chroloroform–methanol–acetic acid system as solvent.

A dipeptide derivative Z-Val-Lys(Mhoc)-OMe[5] was hydrogenolyzed to remove its Z group and the product was coupled with IV by the DCC method in the presence of 1-hydroxybenzotriazole (HOBt)[6] to produce a hexapeptide (V) in an excellent yield. Catalytic hydrogenolysis of V yielded H-Lys(Mhoc)-Arg-Arg-Pro-Val-Lys(Mhoc)-OMe. This compound, which was found to be homogeneous in TLC and found to have no appreciable absorption owing to the presence of nitro group, was allowed to react with the azide derived from Z-Lys(Mhoc)-Pro-Val-Gly-Lys(Mhoc)-$NHNH_2$[5] in

Fig. 1. Synthesis of amino acid sequence 11—21 of ACTH.
Mhoc: 1-methylcyclohexyloxycarbonyl; HOPcp: pentachlorophenol.

* All the amino acid residues mentioned in this communication are of the L-configuration. Abbreviations used are those recommended by the IUPAC-IUB Commission of Biochemical Nomenclature [*Biochemistry*, **5**, 2485 (1966); *ibid.*, **6**, 362 (1967); *ibid.*, **11**, 1726 (1972)], and include Mhoc: 1-methylcyclohexyloxycarbonyl, Mfoc: 9-methyl-9-fluorenyloxycarbonyl, and HOPcp: pentachlorophenol.

the usual manner. The product was purified on a silica gel column with chloroform–methanol–acetic acid systems as solvent to give an undecapeptide ester (VI) in a pure form. The hydrazinolysis of ester VI yielded the desired undecapeptide hydrazide (VII) whose sufficient purity was confirmed by TLC and elemental analysis. The acid hydrolysates of VI and VII were also found to contain the constituent amino acids in the correct ratios expected by theory.

In the above synthesis of VII the three peptide subunits, which were respectively synthesized in the step-by-step manner from their C-terminal, were connected by the azide procedure and the DCC–HOBt method[6] to form a Lys–Lys bond and a Pro–Val bond, respectively. In addition, there was not employed any alkaline treatment throughout the synthesis. Thus, the cause of racemization associated with chemical processes was fully eliminated. Compound VII has successfully been employed as an intermediate in the total synthesis of α_p-ACTH and α_h-ACTH.[2]

Synthesis of Nonapeptide Derivative XI. The synthetic route to XI was illustrated in Fig. 2. In introducing a lysine residue to position 16, its N^{α}-protecting group was required to be the one selectively removable in the presence of the N^{ε}-Mhoc and the N^{G}-nitro groups. A purpose of the present synthesis is to examine if a new protecting group 9-methyl-9-fluorenyloxycarbonyl (Mfoc), which has been introduced by us recently,[3] meets this requirement.

Fig. 2. Synthesis of amino acid sequence 11—19 of ACTH.
Mhoc: 1-methylcyclohexyloxycarbonyl; Mfoc: 9-methyl-9-fluorenyloxycarbonyl.

First, H–Lys(Mhoc)–OH[3] was acylated with 9-methyl-9-fluorenyl azidoformate[3] in the presence of Triton B (benzyltrimethylammonium hydroxide) as base and under anhydrous conditions[7] to give Mfoc–Lys(Mhoc)–OH, from which the *p*-nitrophenyl ester (VIII) was derived by the DCC method in the usual manner. A tripeptide derivative Z–Arg(NO_2)–Arg(NO_2)–Pro–OMe[5] was treated with hydrogen bromide in acetic acid and the resulting N^{α}-free compound isolated in the form of acetic acid salt was allowed to react with VIII. The product was purified on a silica gel column with a chloroform–methanol system as solvent to give a tetrapeptide (IX) in pure form. The subsequent treatment of IX with 20% formic acid in acetic acid achieved the selective removal of the N^{α}-Mfoc group. The removal was complete within 7 h, in which any appreciable cleavage of the Mhoc group was not observed. The N^{α}-free tetrapeptide thus obtained was then coupled with the pentapeptide azide, derived from Z–Lys(Mhoc)–Pro–Val–Gly–Lys(Mhoc)–$NHNH_2$[5] by the treatment with nitrous acid in the usual manner, to give a protected nonapeptide ester (X) in an excellent yield. In the final step ester X was saponified with alkali under the same conditions as those employed for the saponification of Z–Lys(Mhoc)–Arg(NO_2)–Arg(NO_2)–Pro–OMe, in which no appreciable racemization seemed to occur,[5] and the product was purified on a silica gel column with a chloroform–methanol system as solvent to give the desired compound (XI). The purity of XI was confirmed by TLC and elemental analysis. Nonapeptide XI has been utilized as an intermediate in our first synthesis of α_h-ACTH.[2]

Experimental

Thin-layer chromatography (TLC) was performed on silica gel plates (Kieselgel GF_{254} or precoated Kieselgel $60F_{254}$, Merck) with the following solvent systems: A, chloroform–methanol (85: 15); B, chloroform–methanol (3: 1); C, chloroform–methanol–acetic acid (90: 10: 3); D, chloroform–methanol–acetic acid (80: 20: 3); E, ethyl acetate–acetic acid–water (4: 1: 1); F, 1-butanol–acetic acid–water (4: 1: 2).

Boc–Arg(NO_2)–Pro–OBzl (I). An aqueous solution of H–Pro–OBzl·HCl (2.42 g, 10 mmol) was treated with 50% potassium carbonate (5 ml) at 0 °C in the presence of dichloromethane. The organic phase separated was dried over magnesium sulfate and evaporated *in vacuo* at a bath temperature of 20 °C. The resulting proline ester free base and Boc–Arg(NO_2)–OH (3.19 g, 10 mmol) were coupled with dicyclohexylcarbodiimide (DCC; 2.06 g, 10 mmol) in *N,N*-dimethylformamide (DMF)–ethyl acetate in the presence of 1-hydroxybenzotriazole (HOBt; 1.35 g, 10 mmol) at 4 °C; for 20 h. The crude product was purified on a column of silica gel (100 g, Kieselgel H, Merck) with chloroform–methanol (93: 7) as solvent. The fractions (10 g/tube) were examined by TLC in system A and those containing the desired compound as a single component (tubes 62—70) were combined and evaporated *in vacuo* to afford I as a sirupy residue.

Z–Arg(NO_2)–Arg(NO_2)–Pro–OBzl (II). Compound I obtained above was treated with trifluoroacetic acid (10 ml) at room temperature for 60 min. The precipitates which separated upon addition of ether were dissolved in DMF (30 ml) together with HOBt (1.3 g, 10 mmol) and triethylamine (1.4 ml, 10 mmol) and to this was added Z–Arg(NO_2)–OPcp (6.0 g, 10 mmol)[4] at 0 °C. The mixture was stirred at 4 °C overnight followed by evaporation *in vacuo* at a bath temperature of 45 °C. The oily residue was dissolved in aqueous ethyl acetate and the solution was washed with 1M acetic acid and evaporated *in vacuo*. The crude product thus obtained was submitted to a silica gel column (140 g, Kieselgel H, Merck) with chloroform–methanol (90: 10) as solvent. The fractions (12 g/tube) were examined by TLC in system A and those containing the desired product as a single component (tubes 41—60) were combined and evaporated *in vacuo*. The residue was precipitated from ethyl acetate–ether; yield 5.35 g (70%), $[\alpha]_D^{26}$ $-48.4\pm0.9°$

(*c* 1.0, methanol).

Found: C, 51.79; H, 6.04; N, 20.17%. Calcd for $C_{33}H_{43}N_{11}O_{11}$: C, 51.49; H, 5.63; N, 20.02%.

Z-Lys(Mhoc)-Arg(NO_2)-Arg(NO_2)-Pro-OH (IV). Compound II (1.49 g, 1.93 mmol) was treated with 25% hydrogen bromide in acetic acid (20 ml) at room temperature for 3 h. The precipitates which separated upon addition of ether were dissolved in DMF (10 ml) together with triethylamine (1.33 ml, 9.7 mmol) and to the resulting solution was added Z-Lys(Mhoc)-OSu[5] prepared from the dicyclohexylamine salt of Z-Lys(Mhoc)-OH (1.16 g, 1.93 mmol).[3] The mixture was kept at 4 °C for 2.5 days followed by evaporation *in vacuo*. To the residue were added 1-butanol-ethyl acetate (1: 1, 20 ml) and 1M acetic acid (20 ml), and the mixture was shaken vigorously. The organic phase separated was evaporated *in vacuo* (1.6 g). This was purified on a column of silica gel (70 g, Kieselgel H, Merck) with chloroform-methanol-acetic acid (80: 20: 3) as solvent to give IV in pure form; yield 1.50 g (82%), mp 138—140 °C, $[\alpha]_D^{25}$ −37.5 ±0.8° (*c* 1.0, methanol).

Z-Lys (Mhoc)-Arg (NO_2)-Arg (NO_2)-Pro-Val-Lys (Mhoc)-OMe (V). A solution of Z-Val-Lys(Mhoc)-OMe (0.54 g, 1 mmol)[5] in 10% acetic acid in methanol was submitted to hydrogenolysis over palladium for 2 h followed by evaporation *in vacuo*. The residue was dissolved in dichloromethane and the solution was shaken with 50% potassium carbonate at 0 °C. The organic phase was dried over magnesium sulfate at 0 °C and evaporated *in vacuo* at a bath temperature of 20 °C. The resulting dipeptide ester free base and IV (0.94 g, 1 mmol) were coupled with DCC (0.41 g, 2 mmol) in DMF in the presence of HOBt (0.27 g, 2 mmol). The reaction was allowed to proceed at 4 °C for 2.5 days. The crude product was repeatedly precipitated from methanol-ether to give a pure preparation of V; yield 1.26 g (95%), mp 125—130 °C, $[\alpha]_D^{28}$ −55.6±0.9° (*c* 1.0, methanol). TLC: homogeneous (sulfuric acid) in system D.

Found: C, 53.63; H, 7.48; N, 17.13%. Calcd for $C_{59}H_{96}N_{16}O_{17}\cdot H_2O$: C, 53.70; H, 7.49; N, 16.99%.

Z-Lys(Mhoc)-Pro-Val-Gly-Lys(Mhoc)-Lys(Mhoc)-Arg-Arg-Pro-Val-Lys(Mhoc)-OMe (VI). Compound V (0.90 g, 0.69 mmol) was hydrogenolyzed over palladium in acetic acid to give the partially deblocked hexapeptide ester (acetate); no appreciable absorption at 275 nm. TLC: homogeneous (ninhydrin and Sakaguchi reagents) in system F.

An ethyl acetate solution of the azide, derived from Z-Lys(Mhoc)-Pro-Val-Gly-Lys(Mhoc)-$NHNH_2$ (0.73 g, 0.76 mmol) in the same manner as described previously,[5] was combined with a solution of the hexapeptide ester obtained above and triethylamine (0.5 ml, 3.5 mmol) in DMF (3 ml). The mixture was, after removal of ethyl acetate by evaporation at a bath temperature of 5 °C, stirred at 4 °C for 2.5 days. After addition of another quantity of the pentapeptide azide, freshly prepared from the hydrazide (0.33 g, 0.35 mmol), the mixture was stirred for one more day followed by evaporation *in vacuo*. The residue was dissolved in aqueous ethyl acetate and the solution was washed with 1M acetic acid and evaporated. The crude product thus obtained (1.50 g) was then purified on a silica gel column (50 g, Kieselgel 60, Merck) with chloroform-methanol-acetic acid system (90: 10: 3, 100 ml; 80: 20: 3, 100 ml; 60: 40: 3, 200 ml) as solvent to give a pure preparation of VI; yield 1.04 g (76%), mp 129—130 °C, $[\alpha]_D^{24}$ −58.7±1.0° (*c* 1.0, methanol). TLC: a single component (ninhydrin, after preheating at 150 °C) in systems D, E, and F. Amino acid ratios in acid hydrolysate (theoretical values are given in parentheses): Lys 4.00 (4), Arg 1.92 (2), Pro 1.84 (2), Gly 1.00 (1), Val 2.01 (2).

Z-Lys (Mhoc)-Pro-Val-Gly-Lys (Mhoc)-Lys (Mhoc)-Arg-Arg-Pro-Val-Lys(Mhoc)-$NHNH_2$ (VII). Compound VI (0.98 g, 0.49 mmol) was treated with hydrazine hydrate (0.25 ml) in DMF (5 ml) at 37 °C for 40 h. The solvent was evaporated *in vacuo*. To the resulting residue were added 1M acetic acid (15 ml) and 1-butanol-ethyl acetate (1: 1, 15 ml) and the mixture was shaken vigorously. The organic phase was separated and evaporated *in vacuo* (0.95 g). A 0.85 g portion of this product was dissolved in aqueous ethyl acetate and the solution was repeatedly extracted with 1 M acetic acid. The aqueous solutions combined were lyophilized to afford VII; yield 0.79 g (90%), $[\alpha]_D^{24.5}$ −55.4 ±1.1° (*c* 0.9, methanol). TLC: almost homogeneous (ninhydrin, after preheating at 150 °C) in system F. Amino acid ratios in acid hydrolysate: Lys 4.07 (4), Arg 2.01 (2), Pro 1.95 (2), Gly 1.00 (1), Val 2.10 (2).

Found: C, 55.49; H, 8.41; N, 14.78%. Calcd for $C_{97}H_{165}N_{23}O_{21}\cdot 2CH_3COOH\cdot 4H_2O$: C, 55.60; H, 8.36; N, 14.77%.

Mfoc-Lys(Mhoc)-ONp (VIII). N^{ϵ}-Mhoc-lysine (1.43 g, 5 mmol)[3] and 40% benzyltrimethylammonium hydroxide in methanol (Triton B, 2.4 ml) were dissolved in DMF (4 ml) and the solvent was evaporated *in vacuo* at a bath temperature of 45 °C. The residue was redissolved in DMF (10 ml) and 9-methyl-9-fluorenyl azido-formate (1.85 g, 7 mmol)[3] was added. The reaction mixture was stirred at 4 °C for 24 h followed by evaporation *in vacuo*. The residue was dissolved in ethyl acetate and the solution was washed with 1M citric acid and water, dried over magnesium sulfate and evaporated *in vacuo*. The residue was purified on a column of silica gel (50 g, Kieselgel H, Merck) with chloroform-methanol (95: 5) as solvent to give Mfoc-Lys(Mhoc)-OH as an oil; yield 1.65 g (59%).

The diacyllysine thus obtained was dissolved in ethyl acetate along with *p*-nitrophenol (0.42 g, 3 mmol) and to this was added DCC (0.62 g, 3 mmol). The mixture was stirred at 4 °C for 20 h followed by evaporation *in vacuo*. The resulting oily residue was precipitated from methanol-petroleum ether to give VIII; yield 1.95 g (97%). This was used for the subsequent coupling reaction without further purification.

Mfoc-Lys(Mhoc)-Arg(NO_2)-Arg(NO_2)-Pro-OMe (IX). Z-Arg(NO_2)-Arg(NO_2)-Pro-OMe (2.05 g, 3 mmol)[5] was treated with 28% hydrogen bromide in acetic acid (10 ml) at room temperature for 60 min. The precipitates which formed upon addition of ether (1.40 g) were dissolved in water (10 ml) and Amberlite CG-400 (acetate form, wet vol. 10 ml) was added. The mixture was shaken for 30 min and then filtered off. The filtrate was evaporated to give a residue which was dried over sodium hydroxide pellets and phosphorus pentoxide *in vacuo* (1.30 g).

The tripeptide methyl ester obtained above was allowed to react with VIII (1.95 g, 2.88 mmol) in DMF (5 ml) in the present of triethylamine (0.6 ml, 4.4 mmol) at 4 °C for 24 h. The crude product was chromatographed on a column of silica gel (70 g, Kieselgel H, Merck) with chloroform-methanol (95: 5) as solvent to give IX in pure form; yield 2.10 g (92%) mp 135—140 °C decomp., $[\alpha]_D^{25}$ −60.9±1.0° (*c* 1.0, methanol). TLC: homogeneous (sulfuric acid) in system A.

Found: C, 54.55; H, 6.66; N, 17.15%. Calcd for $C_{47}H_{67}N_{13}O_{13}\cdot H_2O$: C, 54.27; H, 6.69; N, 17.51%.

Z-Lys(Mhoc)-Pro-Val-Gly-Lys(Mhoc)-Lys(Mhoc)-Arg-(NO_2)-Arg(NO_2)-Pro-OMe (X). Compound IX (0.52 g, 0.5 mmol) was dissolved in 20% formic acid in acetic acid (6 ml) and the solution was allowed to stand at room temperature for 7 h. The solvent was evaporated and the residue was triturated with ether. The resulting precipitates were filtered off and dried over potassium hydroxide pellets *in vacuo*. To this were added ethyl acetate (15 ml) and 1M

acetic acid (15 ml) and the mixture was shaken vigorously. The organic phase was extracted again with 1M acetic acid. The combined aqueous solution was washed with ethyl acetate, concentrated *in vacuo* and lyophilized.

The N^{α}-free tetrapeptide obtained above was dissolved in DMF and triethylamine (0.07 ml, 0.5 mmol) was added. To this was added an ethyl acetate solution of Z-Lys(Mhoc)-Pro-Val-Gly-Lys(Mhoc)-N_3, derived from the corresponding hydrazide (0.72 g, 0.75 mmol),[5] and the mixture was concentrated *in vacuo* at a bath temperature of 0—5 °C to remove ethyl acetate. The resulting solution was stirred at 4 °C for 20 h followed by evaporation *in vacuo*. The precipitates which formed upon addition of ether were reprecipitated from ethyl acetate to yield X in pure form; yield 0.83 g (96%), mp 130—135 °C, $[\alpha]_D^{23}$ $-52.7\pm0.9°$ (*c* 1.0, methanol). TLC: homogeneous (ninhydrin, after pretreatment with hydrobromic acid) in system A.

Found: C, 55.71; H, 7.68; N, 15.37%. Calcd for $C_{80}H_{130}N_{20}O_{22}$: C, 55.73; H, 7.60; N, 16.25%.

Z-Lys(Mhoc)-Pro-Val-Gly-Lys(Mhoc)-Lys(Mhoc)-Arg-(NO_2)-Arg(NO_2)-Pro-OH (XI). Compound X (0.83 g, 0.48 mmol) in methanol (2 ml) was treated with 2 M sodium hydroxide (0.48 ml) at room temperature for 2 h. The mixture was neutralized by the addition of ice-cold 1M hydrochloric acid (0.96 ml) and then diluted with water. This was repeatedly extracted with 1-butanol–ethyl acetate (1: 1). The organic solutions were combined, washed three times with water and evaporated *in vacuo*. The residue was chromatographed on a column of silica gel (30 g, Kieselgel 60, Merck) with chloroform–methanol (95: 5) as solvent for the first 20 fractions (10 ml/tube) and with chloroform–methanol (80: 20) for the rest. The fractions containing the desired product as a single component (tubes 37—55), as examined by TLC in system B, were combined and evaporated *in vacuo*. The residue was solidified by tritutation with ether to afford XI; yield 0.43 g (50%), mp 160—170 °C, $[\alpha]_D^{24.5}$ $-35.5\pm0.8°$ (*c* 1.0, methanol). TLC: homogeneous (ninhydrin, after pretreatment with hydrobromic acid) in system B.

Found: C, 53.12; H, 7.53; N, 15.40%. Calcd for $C_{79}H_{128}N_{20}O_{22}\cdot 4H_2O$: C, 53.24; H, 7.69; N, 15.72%.

Synthesis of Corticotropin Peptides. XVI. The Total Syntheses of Porcine and Human Corticotropins*

Ken INOUYE, Kunio WATANABE, and Hideo OTSUKA

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka 553

(Received June 29, 1976)

The syntheses are described of two nonatriacontapeptides corresponding to the primary structure of porcine corticotropin (α_p-ACTH) and that of human hormone (α_h-ACTH). The porcine peptide is synthesized by assembling three fragment peptides corresponding to ACTH(1—10), ACTH(11—21) and α_p-ACTH (22—39). The Synthetic product is compared with natural α_p-ACTH in terms of chemical, physicochemical, and biological properties to establish their identity. The human peptide is synthesized *via* two different routes, one of which is the same as that employed for the synthesis of porcine peptide. The two synthetic preparations of human peptide are not only indistinguishable from each other, but also very similar to α_p-ACTH in various items of physicochemical measurements and in the *in vivo* steroidogenesis assay. The collected data prove the satisfactory synthesis of α_h-ACTH as well as α_p-ACTH.

The thirty-nine amino acid sequence of porcine corticotropin (α_p-ACTH) was first proposed by Shepherd *et al.*[1] in 1956 and its total synthesis was accomplished by Schwyzer and Sieber[2] in 1963. The primary structure tentatively proposed for the human hormone (α_h-ACTH)[3] was synthesized by Bajusz *et al.*[4] in 1967.

Natural α_p-ACTH was known to be deamidated upon mild alkaline treatment.[5] Recently, it has also been found by Gráf *et al.*[6] and Riniker *et al.*[7] that the natural preparations of α_p-ACTH and α_h-ACTH undergo deamidation at the same rate in dilute aqueous ammonia. However, the synthetic product of α_p-ACTH[2,7] and that of α_h-ACTH[4,6] were stable under the same conditions. These synthetic peptides contained a single amide group in the form of Gln 30. The inconsistency observed between the natural and the synthetic preparations prompted them to reexamine the structures of these two mammalian hormones. As a result, the primary structure of α_p-ACTH was revised in 1971.[6,7] At the same time, the correct amino acid sequence 22—39 (a tryptic fragment) of α_h-ACTH was also presented.[7] Subsequent to the above revisions, the 1—20 sequence of α_h-ACTH, which had been proposed only on the homology with the hormones from other species, was confirmed by Bennett *et al.*[8] Figure 1 shows the amino acid sequences of porcine and human hormones thus established; note that the only structural difference between the two mammalian hormones resides in position 31, Leu in α_p-ACTH and Ser in α_h-ACTH, and that these structures contain a single amide group in the form of Asn 25. The synthesis of the revised structure of α_h-ACTH was reported by Sieber *et al.*[9] Kisfaludy *et al.*[10] and Nishimura *et al.*[11] A solid-phase synthesis was described by Yamashiro and Li.[12] Very recently Yajima *et al.* have accomplished the synthesis of α_p-ACTH.[13] We wish now to report the total syntheses of α_p-ACTH and α_h-ACTH performed on the basis of our own strategy.

Fig. 1. Primary structures of porcine corticotropin (α_p-ACTH)[1,6,7] and human corticotropin (α_h-ACTH).[3,7,8]

In the preceding papers, we described the synthesis of an undecapeptide derivative corresponding to ACTH-(11—21),[14] and that of octadecapeptides, α_p-ACTH-(22—39) and α_h-ACTH(22—39).[15] The two octadecapeptides were obtained simultaneously with an identical synthetic procedure, except for the introduction of the amino acid residue in position 31. The fully deblocked porcine peptide was identified with the α_p-ACTH(22—39) isolated from a tryptict digest of

natural α_p-ACTH.[15] This proved the satisfactory synthesis of porcine peptide and that of human peptide as well. The synthesis of the decapeptide derivative corresponding to ACTH(1—10) was reported previously.[16] The present paper describes the formation of the nonatriacontapeptides, corresponding to α_p-ACTH and α_h-ACTH, from these fragment peptides according to the route illustrated in Fig. 2. An alternative synthesis of α_h-ACTH is also described, in which a nonapeptide derivative corresponding to ACTH(11—19)[14] is utilized as an intermediate (Fig. 3).

Synthesis of Porcine Hormone, α_p-ACTH (Ip). The synthesis started with the coupling of the C-terminal octadecapeptide derivative (IVp, Fig. 2) and the undecapeptide azide, derived from III (Fig. 2) by the treatment with an alkyl nitrite in an anhydrous acid solution,[17] to give a nonacosapeptide Z-Lys(Mhoc)-Pro-Val-Gly-Lys(Mhoc)-Lys(Mhoc)-Arg-Arg-Pro-Val-Lys(Mhoc)-Val-Tyr-Pro-Asn-Gly-Ala-Glu(OBu^t)-Asp(OBu^t)-Glu(OBu^t)-Leu-Ala-Glu(OBu^t)-Ala-Phe-Pro-Leu-Glu(OBu^t)-Phe-OBu^t (IXp). The crude preparation of IXp was purified by partition chromatography on a column of Sephadex LH-20 with 1-butanol-acetic acid-water (4: 1: 2) as solvent. The sufficient purity was confirmed by TLC and by amino acid analysis of the acid hydrolysate. The yield was 64%. Compound IXp thus obtained was then submitted to catalytic hydrogenolysis and the product was chromatographed on a silica gel column with ethyl acetate-acetic acid-water (4: 1: 1) as solvent to give the N^{α}-free nonacosapeptide (Xp) corresponding to α_p-ACTH-(11—39).

The protected decapeptide (II, Fig. 2) corresponding to ACTH(1—10) was synthesized as reported previously,[16] except that in the azide couplings involved Boc-Ser-Tyr-$NHNH_2$ and Boc-Ser-Tyr-Ser-Met-$NHNH_2$ were converted into the corresponding azides by the treatment with an alkyl nitrite,[17] instead of nitrous acid formerly used, to improve the coupling yields significantly. The crude preparation of II was purified on a silica gel column with ethyl acetate-acetic acid-water (4: 1: 1) as solvent. The final reaction connecting the N-terminal decapeptide with the rest of the molecule of α_p-ACTH was performed by the *N*-hydroxysuccinimide (HOSu) ester method.[18] The same procedure had been employed in our synthesis of the ACTH peptides with shorter chain lengths.[19] The decapeptide active ester derived from II was allowed to react with Xp obtained above to give a protected nonatriacontapeptide Boc-Ser-Tyr-Ser-Met-Glu(OBu^t)-His-Phe-Arg-Trp-Gly-Lys(Mhoc)-Pro-Val-Gly-Lys(Mhoc)-Lys(Mhoc)-Arg-Arg-Pro-Val-Lys(Mhoc)-Val-Tyr-Pro-Asn-Gly-Ala-Glu(OBu^t)-Asp(OBu^t)-Glu(OBu^t)-Leu-Ala-Glu(OBu^t)-Ala-Phe-Pro-Leu-Glu(OBu^t)-Phe-OBu^t. The crude product was, without purification, deprotected with trifluoroacetic acid in the presence of anisole and 2-mercaptoethanol as scavengers, followed by the treatment with Amberlite CG-400 (acetate form). Purification of the product was achieved by repeated chromatography on a carboxymethyl cellulose column using an ammonium acetate buffer with a linear concentration gradient of 0—0.4 M (Figs. 4 and 5). The synthetic α_p-ACTH (Ip) thus obtained was found to be homogeneous in TLC and its acid hydrolysate contained the constituent amino acids in the ratios predicted by theory with an exception of tryptophan. The Tyr/Trp ratio in intact Ip was 2.06,

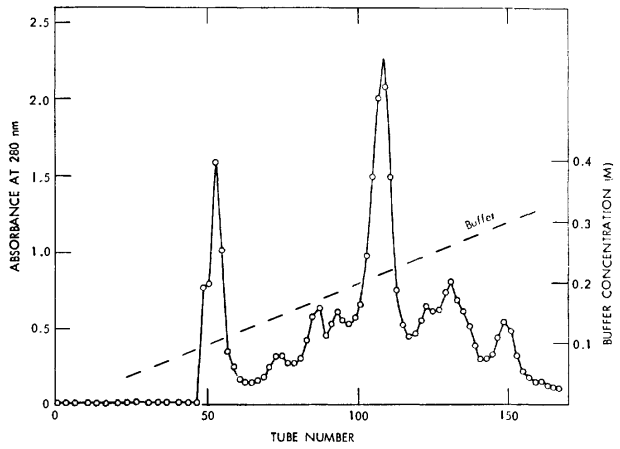

Fig. 4. Carboxymethyl cellulose column chromatography of crude synthetic α_p-ACTH: sample, 0.46 g; column, CM-52 (Whatman), 2.1×22 cm; buffer, 0—0.4 M ammonium acetate (pH 6.5), 1800 ml; fractionation, 9 ml/tube.

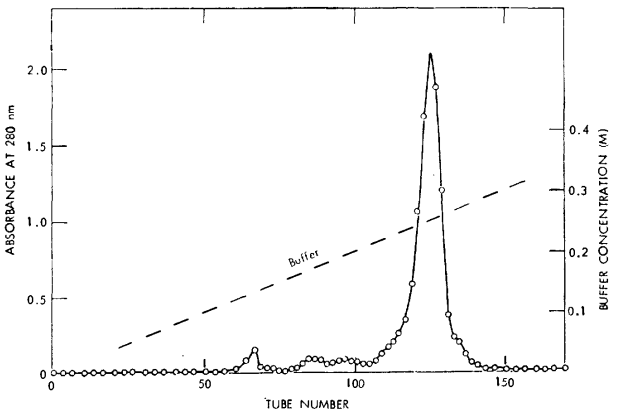

Fig. 5. Rechromatography of partially purified synthetic α_p-ACTH on a carboxymethyl cellulose column: sample, 0.15 g, derived from Fig. 4 (for details see Experimental); column, CM-52 (Whatman), 2.8×22 cm; buffer, 0—0.4 M ammonium acetate (pH 6.5), 1800 ml; fractionation, 9 ml/tube.

as determined spectrophotometrically.[20] The overall yield of Ip for the final coupling, deprotection and purification processes was 26%, when the molecular weight of 5050, estimated from ultraviolet absorption on the assumption that $E^{1\%}_{1cm}=17.7$ (at $\lambda^{0.1MHCl}_{max}=276$ nm) for 100% peptide content,[9] was employed.

An authentic sample of α_p-ACTH to be compared with the synthetic peptide was obtained by purification of a commercial preparation from porcine origin. The crude preparation (Sigma)[21] was submitted to chromatography on a column of carboxymethyl cellulose, in which 0.1 M sodium acetate (pH 6.2) was used as a buffer and the elution of peptide was effected by increasing the concentration of sodium chloride added to the buffer. The fractions containing the desired material were combined and passed through an Amberlite XAD-2 column to remove inorganic salts. The peptide remained on the column was eluted with a mixture of ethanol–0.1 M acetic acid (1: 1) quantitatively. The purified porcine hormone was found to be homogeneous in TLC and amino acid analysis also confirmed its sufficient purity. The Tyr/Trp ratio in intact peptide was 1.94, as determined spectrophotometrically.[20]

The synthetic peptide (Ip) and the natural hormone, obtained as described above, were indistinguishable from each other by electrophoresis on polyacrylamide gel at pH 4.0 (Fig. 6)[22] and pH 9.4 (Fig. 7)[23] and by TLC (cellulose) with 1-butanol–acetic acid–pyridine–water (30: 6: 20: 24) as solvent. The ultraviolet absorption spectra of the synthetic and natural preparations were identical within the precision of measurements. The optical rotatory dispersion and circular dichroism spectra of the synthetic peptide were virtually identical with those of the natural hormone as shown in Tables 1 and 2.[24]

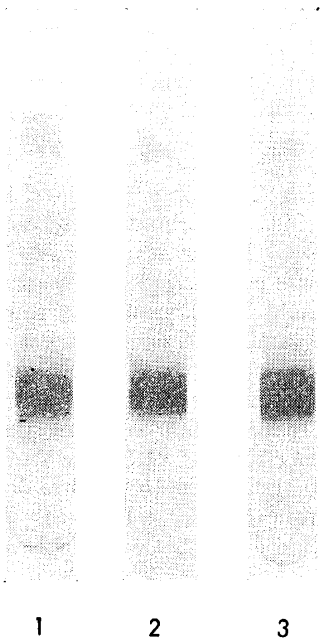

Fig. 6. Electrophoresis of α_p-ACTH and α_h-ACTH preparations on 15% polyacrylamide gel at pH 4.0: 1, natural α_p-ACTH, 60 μg; 2, synthetic α_p-ACTH, 60 μg; 3, synthetic α_h-ACTH, 60 μg. Detection, by staining with Amido-Black 10B.

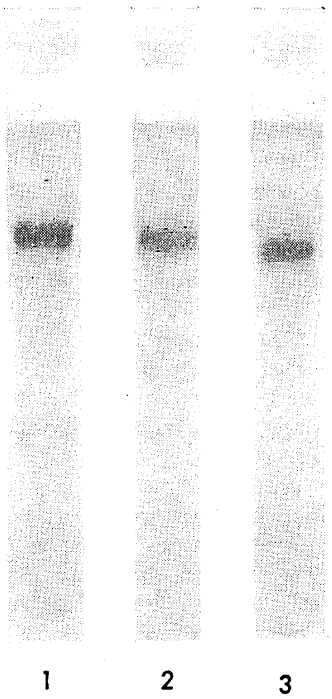

Fig. 7. Electrophoresis of α_p-ACTH and α_h-ACTH preparations on 7.5% polyacrylamide gel at pH 9.4: 1, natural α_p-ACTH, 20 μg; 2, synthetic α_p-ACTH, 20 μg; 3, synthetic α_h-ACTH, 20 μg. Detection, by staining with Amido-Black 10B.

Electrophoretic patterns of a tryptic hydrolysate of the synthetic material were identical with those obtained with the natural hormone. The tryptic digestion

[substrate: enzyme=50 (w/w)] was carried out at pH 8.2 and 37 °C for 60 min and the electrophoresis on a cellulose plate (Cellulose F, Merck) was performed at pH 6.9 in 0.1 M collidine acetate. Recently, it has been shown that natural α_p-ACTH undergoes alkaline deamidation at the asparagine residue in position 25 to form the corresponding aspartyl-α/β-peptide[6,7] which can be distinguished from the intact hormone by electrophoresis on polyacrylamide gel at pH 9.[6] This was equally observed with our synthetic and natural preparations of porcine ACTH, when they were treated with 0.1 M ammonia at 37 °C according to Gráf *et al.*[6] Their electrophoretic patterns are not shown here, since they were virtually the same as those obtained with our synthetic human hormone which are shown in Fig. 12.

Finally, the synthetic material and the authentic porcine hormone were compared for the *in vivo* steroidogenic activity to demonstrate that the former was as active as the latter, when the assays were performed by a method based on the elevated levels of 11-hydroxycorticosteroids in the adrenal venous blood of the hypophysectomized rat in response to intravenous administration of a test sample (Table 3).[25]

TABLE 3. *In vivo* STEROIDOGENIC ACTIVITY OF NATURAL AND SYNTHETIC CORTICOTROPINS[25]

Peptide		Activity[a] (units/mg)
α_p-ACTH	Natural	94.2
	Synthetic	98.1
α_h-ACTH	Synthetic (route A)[b]	98.6
	Synthetic (route B)[c]	98.7

a) The Third USP Corticotropin Reference Standard was used as reference. b) See Fig. 2. c) See Fig. 3.

In view of the correspondence between our synthetic α_p-ACTH and the natural hormone in terms of chemical, physicochemical and biological properties, we conclude that their identity has now been established.

Synthesis of Human Hormone, α_p-ACTH (Ih). The human hormone was synthesized by two different routes A (Fig. 2) and B (Fig. 3). Route A is exactly the same as that employed for the synthesis of the porcine hormone, except that the octadecapeptide derivative (IVh, Fig. 2) was used as a starting material. The intermediate nonacosapeptide, Z-Lys(Mhoc)-Pro-Val-Gly-Lys(Mhoc)-Lys(Mhoc)-Arg-Arg-Pro-Val-Lys(Mhoc)-Val-Tyr-Pro-Asn-Gly-Ala-Glu(OBu^t)-Asp(OBu^t)-Glu(OBu^t)-Ser-Ala-Glu(OBu^t)-Ala-Phe-Pro-Leu-Glu(OBu^t)-Phe-OBu^t (IXh), corresponding to α_h-ACTH(11—39) was obtained in a 63% yield after purification on a Sephadex LH-20 column. Catalytic hydrogenolysis of IXh yielded the N^α-free peptide, which was coupled with the decapeptide (II) by the HOSu ester method[18] to give a protected nonatriacontapeptide Boc-Ser-Tyr-Ser-Met-Glu(OBu^t)-His-Phe-Arg-Trp-Gly-Lys(Mhoc)-Pro-Val-Gly-Lys(Mhoc)-Lys(Mhoc)-Arg-Arg-Pro-Val-Lys(Mhoc)-Val-Tyr-Pro-Asn-Gly-Ala-Glu(OBu^t)-Asp(OBu^t)-Glu(OBu^t)-Ser-Ala-Glu(OBu^t)-Ala-Phe-Pro-Leu-Glu(OBu^t)-Phe-OBu$_t$. The crude product was deblocked with trifluoroacetic acid

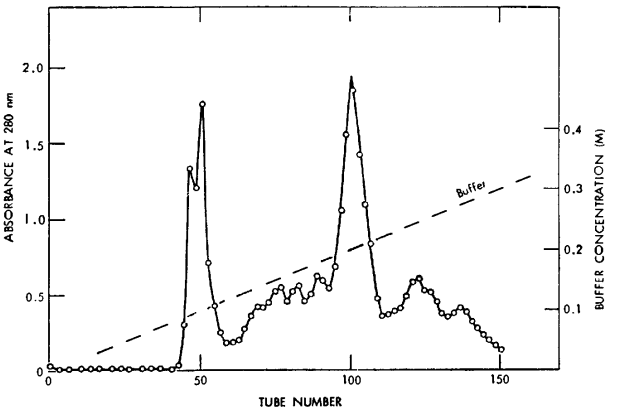

Fig. 8. Carboxymethyl cellulose column chromatography of crude α_h-ACTH synthesized *via* route A: sample, 0.45 g; column, CM-52 (Whatman), 2.1×22 cm; buffer, 0—0.4 M ammonium acetate (pH 6.5), 1800 ml; fractionation, 9 ml/tube.

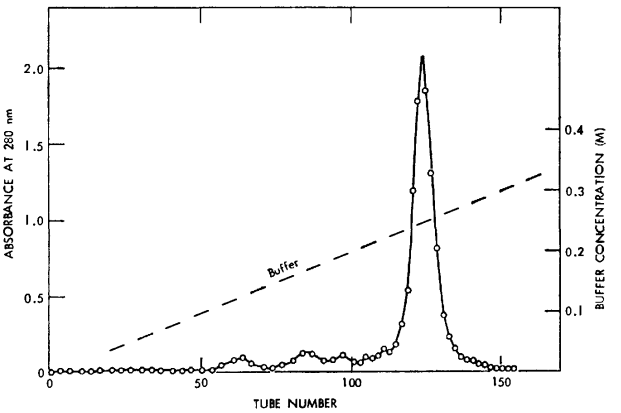

Fig. 9. Rechromatography of partially purified synthetic α_h-ACTH on a carboxymethyl cellulose column: sample, 0.13 g, derived from Fig. 8 (for details see Experimental); column, CM-52 (Whatman), 2.8×22 cm; buffer, 0—0.4 M ammonium acetate (pH 6.5), 1800 ml; fractionation, 9 ml/tube.

and the resulting free peptide isolated in the form of acetate was purified on carboxymethyl cellulose columns (Figs, 8 and 9). The synthetic α_h-ACTH (Ih) thus obtained by route A behaved as a single component in TLC and its acid hydrolysate was found to contain the constituent amino acids in correct ratios with an exception of tryptophan. The Tyr/Trp ratio in intact Ih was 1.98, as determined spectrophotometrically,[20] The overall yield of Ih for the final coupling, deprotection and purification processes was 21.5%, when the molecular weight of 4960, estimated from ultraviolet absorption on the assumption that $E^{1\%}_{1cm}=17.7$ (at $\lambda^{0.1MHCl}_{max}=276$ nm) for 100% peptide content,[9] was employed.

Route B, shown in Fig. 3, represents an alternative synthesis of α_h-ACTH. First, the N^α-free octadecapeptide (IVh, Fig. 2) was acylated with Z-Val-Lys(Mhoc)-N_3, derived from the corresponding hydrazide (Fig. 3)[19c] by the treatment with nitrous acid in the usual manner, to give a protected eicosapeptide (VI) in a 91% yield. Compound VI was submitted to catalytic hydrogenolysis and the resulting N^α-free eicosapeptide was coupled

with nonapeptide V (Fig. 3) corresponding to ACTH-(11—19) by means of DCC in the presence of 1-hydroxybenzotriazole.[26] The product was purified on a silica gel column with chloroform–methanol (9: 1) as solvent to afford a nonacosapeptide, Z-Lys(Mhoc)-Pro-Val-Gly-Lys (Mhoc) - Lys (Mhoc) - Arg (NO_2) - Arg (NO_2)-Pro-Val-Lys (Mhoc)-Val-Tyr-Pro-Asn-Gly-Ala-Glu-(OBu^t)-Asp (OBu^t) -Glu (OBu^t) -Ser-Ala-Glu (OBu^t)-Ala-Phe-Pro-Leu-Glu(OBu^t)-Phe-OBu^t (VII), in a 47% yield. Simultaneous removal of the benzyloxycarbonyl (Z) and two nitro groups from VII was attempted by catalytic hydrogenolysis. However, the reaction gave a product which was reactive to ninhydrin but not to the Sakaguchi reagent. The product was also found to have a maximum absorption at 270 nm ($E^{1\%}_{1cm}$=62.3). These observations strongly suggest that the nitro groups had remained almost intact even after extensive hydrogenolysis. The N^{α}-free nonacosapeptide (VIII) thus obtained was then allowed to react with the HOSu ester of decapeptide II (Fig. 2) to give a protected nonatriacontapeptide Boc-Ser-Tyr-Ser-Met-Glu-(OBu^t)-His-Phe-Arg-Trp-Gly-Lys (Mhoc)-Pro-Val-Gly-Lys (Mhoc) - Lys (Mhoc) - Arg (NO_2) - Arg (NO_2) - Pro-Val-Lys (Mhoc)-Val-Tyr-Pro-Asn-Gly-Ala-Glu-(OBu^t) - Asp(OBu^t) - Glu(OBu^t) - Ser-Ala - Glu(OBu^t)-Ala-Phe-Pro-Leu-Glu(OBu^t)-Phe-OBu^t. The crude product was deprotected by the hydrogen fluoride treatment in the presence of anisole as scavenger[27] to liberate α_h-ACTH as the hydrofluoride. This was treated with Amberlite CG-400 (acetate) in the usual manner. The crude material was purified by chromatography on a carboxymethyl cellulose column using an ammonium acetate buffer (Figs. 10 and 11). The purity of α_h-ACTH (Ih) thus synthesized by route B was confirmed by TLC and by amino acid analysis. The overall yield of Ih for the final coupling, deprotection and purification processes was 29%, as based on the molecular weight of 4960 which was determined spectrophotometrically.

The two synthetic preparations of α_h-ACTH obtained above were indistinguishable from each other by chromatographic and electrophoretic behavior. Their ultraviolet absorption spectra and optical rotations were virtually identical. In addition, they exhibited an identical adrenal-stimulating potency, when assayed for the *in vivo* steroidogenic activity, as shown in Table 3.[25]

Figures 6 and 7 exhibit the electrophoretic patterns of the synthetic human hormone on polyacrylamide gel at pH 4.0 and pH 9.4, respectively, in which those of the porcine hormone preparations are also shown for comparison. There is no significant difference between the two mammalian hormones. Our synthetic preparations of α_h-ACTH obtained above were treated with 0.1 M ammonia at 37 °C according to Gráf *et al.*[6] and the product was submitted to polyacrylamide gel electrophoresis at pH 9. A typical result is shown in

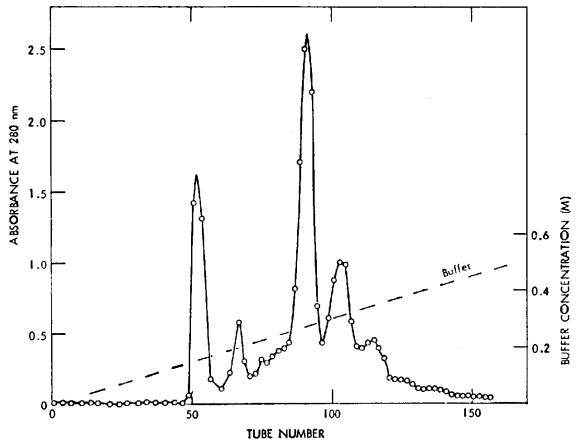

Fig. 10. Carboxymethyl cellulose column chromatography of crude α_h-ACTH synthesized *via* route B: sample, 0.34 g; column, CM-52 (Whatman), 2.1×28 cm; buffer, 0—0.6 M ammonium acetate (pH 6.5), 2000 ml; fractionation, 10 ml/tube.

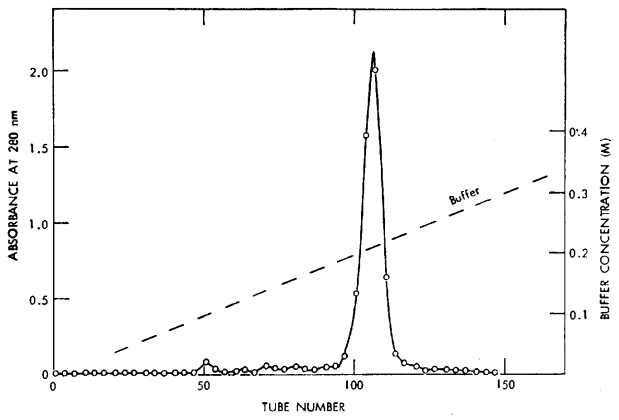

Fig. 11. Rechromatography of partially purified synthetic α_h-ACTH on a carboxymethyl cellulose column: sample, 0.13 g, derived from tubes 75—87 in Fig. 10; column, CM-52 (Whatman), 2.1×28 cm; buffer, 0—0.4 M ammonium acetate (pH 6.5), 2000 ml; fractionation, 10 ml/tube.

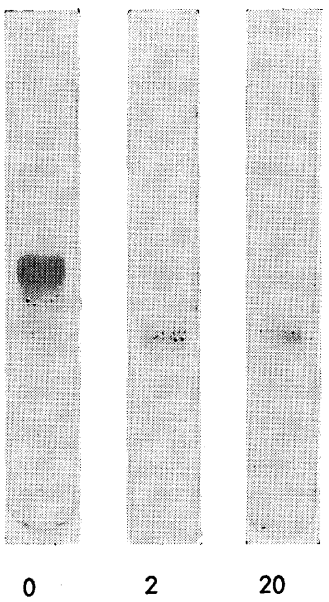

Fig. 12. Electrophoretic patterns of synthetic α_h-ACTH after 0, 2, and 20 h of incubation in 0.1 M ammonia at 37 °C: electrophoresis, on 7.5% polyacrylamide gel at pH 9.4; detection, by staining with Amido-Black 10B.

Figure 12, in which the electrophoretic patterns demonstrate that the synthetic hormone is mostly converted into the deamidated form in 2 h and the complete conversion is attained within 20 h. Virtually the same patterns were obtained with our synthetic as well as natural preparations of α_p-ACTH as described above. These results clearly indicate that the labile Asn 25 is present intact in our synthetic preparations of both α_p-ACTH and α_h-ACTH. The optical rotatory dispersion and circular dichroism of synthetic α_h-ACTH were very similar to those of the α_p-ACTH preparations as shown in Tables 1 and 2.[24] In addition, the *in vivo* steroidogenic potencies of the synthetic α_h-ACTH preparations were identical with those of the natural and synthetic preparations of porcine hormone (Table 3). These close similarities observed between the synthetic α_h-ACTH and the porcine hormone are consistent with the fact that the primary structure of α_h-ACTH is identical with that of α_p-ACTH except for Ser 31 (Fig. 1). Although there is no direct evidence to support the identity of our synthetic α_h-ACTH with the natural human hormone, the above observations may allow us to conclude that our synthesis of α_h-ACTH has been accomplished satisfactorily.

Experimental

Thin-layer chromatography was performed on "silica gel" plates (Kieselgel GF_{254} or precoated Kieselgel $60F_{254}$, Merck) or "cellulose" plates (precoated Cellulose G_{254}, Merck) with the following solvent systems: A chloroform–methanol (85: 15); B, ethyl acetate–acetic acid–water (4: 1: 1); C, 1-butanol–acetic acid–water (4: 1: 2); D, 1-butanol–acetic acid–pyridine–water (30: 6: 20: 24).

Z–Val–Lys(Mhoc)–Val–Tyr–Pro–Asn–Gly–Ala–Glu(OBu^t)–Asp(OBu^t)–Glu(OBu^t)–Ser–Ala–Glu(OBu^t)–Ala–Phe–Pro–Leu–Glu(OBu^t)–Phe–OBu^t (VI). Compound IVh (Fig. 2; 0.39 g, 0.016 mmol)[15] was dissolved in dimethyl sulfoxide (DMSO)–*N,N*-dimethylformamide (DMF) (4: 1, 2.5 ml) and to this was added a solution of Z–Val–Lys(Mhoc)–N_3 [derived from the corresponding hydrazide (Fig. 3; 0.22 g, 0.4 mmol)[19c] by the treatment with nitrous acid in the usual manner] in ethyl acetate (10 ml). The mixture was concentrated *in vacuo* at a bath temperature of 5—10 °C to remove ethyl acetate and then stirred at 4 °C overnight. The precipitates which formed upon addition of water were filtered off, washed thoroughly with water and lyophilized from acetic acid. The resulting powder was suspended in ethyl acetate (30 ml) and the suspension was kept at room temperature overnight. The insoluble precipitates were filtered off and dried *in vacuo* to give VI; wt 0.41 g (91%), $[\alpha]_D^{24.5}$ $-16.3\pm1.5°$ (*c* 0.4, DMF). TLC (silica gel): almost homogeneous (ninhydrin, after pretreatment with hydrobromic acid) in system A. Amino acid ratios in acid hydrolysate (theoretical values are presented in parentheses): Asp 2.00 (2), Ser 0.69 (1), Glu 3.89 (4), Pro 2.23 (2), Gly 1.09 (1), Ala 2.98 (3), Val 2.01 (2), Leu 1.00 (1), Tyr 0.61 (1), Phe 1.90 (2).

Z–Lys(Mhoc)–Pro–Val–Gly–Lys(Mhoc)–Lys(Mhoc)–Arg–(NO$_2$)–Arg(NO$_2$)–Pro–Val–Lys(Mhoc)–Val–Tyr–Pro–Asn–Gly–Ala–Glu(OBu^t)–Asp(OBu^t)–Glu(OBu^t)–Ser–Ala–Glu(OBu^t)–Ala–Phe–Pro–Leu–Glu(OBu^t)–Phe–OBu^t (VII). Compound VI (0.40 g, 0.14 mmol) was hydrogenolyzed palladium in water-saturated 1-butanol for 20 h. The solvent was removed by evaporation *in vacuo* at a bath temperature of 45 °C and the residue was treated with ether to yield the N^{α}-free eicosapeptide derivative as an amorphous powder. This was dissolved in DMF (5 ml) along with V (Fig. 3; 0.25 g, 0.14 mmol)[14] and 1-hydroxybenzotriazole (0.080 g, 0.6 mmol), and dicyclohexylcarbodiimide (DCC, 0.12 g, 0.6 mmole) was added. The reaction mixture was stirred at 4 °C for 2 days followed by evaporation *in vacuo*. The residue was treated with ethyl acetate and the insoluble material was filtered off and dried *in vacuo* (0.53 g). The crude product thus obtained was chromatographed on a column of silica gel (30 g, Kieselgel H, Merck) with chloroform–methanol (90: 10) as solvent. Five-g fractions were collected and they were examined by TLC (silica gel, in system A, and sulfuric acid for detection). Tubes 21—50 were pooled and rechromatographed in almost the same manner as above. The fractions containing the desired product as a single component were combined and evaporated *in vacuo* to give a residue which was solidified by trituration with ether; wt 0.30 g (47%), mp 200—205 °C decomp., $[\alpha]_D^{25}$ $-50.5\pm1.8°$ (*c* 0.5, acetic acid).

H–Lys(Mhoc)–Pro–Val–Gly–Lys(Mhoc)–Lys(Mhoc)–Arg–(NO$_2$)–Arg(NO$_2$)–Pro–Val–Lys(Mhoc)–Val–Tyr–Pro–Asn–Gly–Ala–Glu(OBu^t)–Asp(OBu^t)–Glu(OBu^t)–Ser–Ala–Glu(OBu^t)–Ala–Phe–Pro–Leu–Glu(OBu^t)–Phe–OBu^t (VIII). Compound VII (0.30 g) was hydrogenolyzed over palladium in acetic acid (10 ml) for 24 h. The catalyst was filtered off and the filtrate was lyophilized to give the product which was almost homogeneous in TLC (silica gel, in system B, and ninhydrin as reagent for detection). The product was unreactive to the Sakaguchi reagent wt. 0.29 g, λ_{max}^{MeOH} 270 nm ($E_{1cm}^{1\%}$ 62.3). Amino acid ratios in acid hydrolysate: Lys 4.50 (4),[28] Arg 1.67 (2),[28] Asp 1.99 (2), Ser 0.91 (1), Glu 3.94 (4), Pro 4.23 (4), Gly 2.06 (2), Ala 3.02 (3), Val 3.00 (3), Leu 0.94 (1), Tyr 0.74 (1), Phe 1.93 (2).

Z–Lys(Mhoc)–Pro–Val–Gly–Lys(Mhoc)–Lys(Mhoc)–Arg–Arg–Pro–Val–Lys(Mhoc)–Val–Tyr–Pro–Asn–Gly–Ala–Glu(OBu^t)–Asp(OBu^t)–Glu(OBu^t)–Leu–Ala–Glu(OBu^t)–Ala–Phe–Pro–Leu–Glu(OBu^t)–Phe–OBu^t) (IXp). Compound III (Fig. 2; 0.33 g, 0.15 mmol)[14] was dissolved in a mixture of DMSO–DMF (1: 3, 4 ml). The solution was chilled to −20——30 °C and 3.66 M hydrogen chloride in dioxane (0.41 ml) was added. To this was then added isopentyl nitrite (0.022 ml, 0.165 mmol) and the mixture was stirred at −20—−30 °C for 15 min. The resulting azide solution was neutralized with triethylamine (0.23 ml, 1.65 mmol) at −40—−50 °C and combined with a solution of IVp (Fig. 2; 0.24 g, 0.1 mmol)[15] in DMSO–DMF (1: 4, 2.5 ml). The reaction mixture was stirred at 4 °C for 2 days and then evaporated *in vacuo* at a bath temperature of 45 °C to give a residue which was triturated with water. The crude product (0.54 g) was submitted to partition chromatography on a column (2.8×75 cm) of Sephadex LH-20 with 1-butanol–acetic acid–water (4: 1: 2) as solvent. Three-ml fractions were collected and those containing the desired product as a single component (tubes 46—56), as examined by TLC (silica gel, in system C), were combined, evaporated *in vacuo* at a bath temperature of 45 °C and lyophilized from acetic acid (0.21 g). Tubes 57—61 were combined and rechromatographed in the same manner as above to give an additional quantity of the pure peptide (0.08 g). Thus, the total yield of IXp amounted to 0.29 g (64%); $[\alpha]_D^{23.5}$ $-49.6\pm1.0°$ (*c* 0.9, acetic acid). Amino acid ratios in acid hydrolysate: Lys 3.94 (4), NH_3 1.50 (1), Arg 2.00 (2), Asp 1.90 (2), Glu 4.07 (4), Pro 4.01 (4), Gly 1.94 (2), Ala 2.96 (3), Val 2.89 (3), Leu 2.00 (2), Tyr 0.87 (1), Phe 1.96 (2).

Z–Lys(Mhoc)–Pro–Val–Gly–Lys(Mhoc)–Lys(Mhoc)–Arg–Arg–Pro–Val–Lys(Mhoc)–Val–Tyr–Pro–Asn–Gly–Ala–Glu(OBu^t)–Asp(OBu^t)–Glu(OBu^t)–Ser–Ala–Glu(OBu^t)–Ala–Phe–Pro–Leu–Glu(OBu^t)–Phe–OBu^t (IXh). Compound III (Fig.

2; 0.33 g, 0.15 mmol)[14] was converted into the corresponding azide by the treatment with isopentyl nitrite in an acid solution in the same manner as described above. The azide solution [in DMSO–DMF (1: 3, 4 ml)] was neutralized with triethylamine (0.23 ml, 1.65 mmol) at −40—−50 °C and combined with a solution of IVh (Fig. 2; 0.23 g, 0.1 mmol)[15] in DMSO–DMF (1: 3, 4 ml). The reaction was allowed to proceed at 4 °C for 2 days. The crude product (0.53 g) was purified by partition chromatography on a column of Sephadex LH-20 with 1-butanol–acetic acid–water (4: 1: 2) as solvent, in the manner described above for IXp, to give IXh; wt 0.28 g (63%), $[\alpha]_D^{28.5}$ −47.3±1.0° (*c* 0.8, acetic acid). Amino acid ratios in acid hydrolysate: Lys 3.98 (4), NH_3 1.48 (1), Arg 2.00 (2), Asp 1.99 (2), Ser 0.86 (1), Glu 4.03 (4), Pro 4.11 (4), Gly 2.04 (2), Ala 3.06 (3), Val 3.09 (3), Leu 1.00 (1), Tyr 0.91 (1), Phe 1.92 (2).

H–Lys(Mhoc)–Pro–Val–Gly–Lys(Mhoc)–Lys(Mhoc)–Arg–Arg–Pro–Val–Lys(Mhoc)–Val–Tyr–Pro–Asn–Gly–Ala–Glu(OBu^t)–Asp(OBu^t)–Glu(OBu^t)–Leu–Ala–Glu(OBu^t)–Ala–Phe–Pro–Leu–Glu(OBu^t)–Phe–OBu^t (Xp). Compound IXp (0.53 g) was hydrogenolyzed over palladium in acetic acid for 2 days. The catalyst was filtered off and the filtrate was lyophilized. The product was chromatographed on a column of silica gel [50 g, Kieselgel 60 (100—230 mesh), Merck] with ethyl acetate–acetic acid–water (4: 1: 1) as solvent. Three-ml fractions were collected and examined by TLC (silica gel, in system C). The fractions containing the desired product as a single component (tubes 33—40) were combined, evaporated *in vacuo* and lyophilized from acetic acid (0.20 g). Tubes 13—32, containing the starting material which had remained intact, were combined, evaporated *in vacuo* and hydrogenolyzed for 24 h. This was combined with tubes 41—47 and chromatographed in the same manner as described above to give an additional quantity of Xp from tubes 44—60 (0.14 g). The total yield amounted to 0.34 g (65%); $[\alpha]_D^{21}$ −46.8±1.4° (*c* 0.6, acetic acid). Amino acid ratios in acid hydrolysate: Lys 4.00 (4), NH_3 1.38 (1), Arg 2.08 (2), Asp 2.00 (2), Glu 4.24 (4), Pro 3.99 (4), Gly 2.08 (2), Ala 3.07 (3), Val 2.94 (3), Leu 2.00 (2), Tyr 0.96 (1), Phe 2.00 (2).

H–Lys(Mhoc)–Pro–Val–Gly–Lys(Mhoc)–Lys(Mhoc)–Arg–Arg–Pro–Val–Lys(Mhoc)–Val–Tyr–Pro–Asn–Gly–Ala–Glu(OBu^t)–Asp(OBu^t)–Glu(OBu^t)–Ser–Ala–Glu(OBu^t)–Ala–Phe–Pro–Leu–Glu(OBu^t)–Phe–OBu^t (Xh). Compound IXh (0.45 g) was hydrogenolyzed over palladium in acetic acid for 2 days. The product was chromatographed on a silica gel column [70 g, Kieselgel 60 (100—230 mesh), Merck] in exactly the same manner as described above for Xp. The desired product was obtained from tubes 56—77 (0.12 g). Tubes 11—55 combined were evaporated and the residue was hydrogenolyzed again. This was rechromatographed as above to give an additional quantity of Xh (0.24 g). The total yield amounted to 0.36 g (82%); $[\alpha]_D^{25.5}$ −41.5±1.6° (*c* 0.5, acetic acid). Amino acid ratios in acid hydrolysate: Lys 3.89 (4), NH_3 1.17 (1), Arg 1.97 (2), Asp 2.09 (2), Ser 0.98 (1), Glu 4.28 (4), Pro 4.36 (4), Gly 2.13 (2), Ala 3.13 (3), Val 3.03 (3), Leu 1.00 (1), Tyr 0.96 (1), Phe 2.06 (2).

H–Ser–Tyr–Ser–Met–Glu–His–Phe–Arg–Trp–Gly–Lys–Pro–Val–Gly–Lys–Lys–Arg–Arg–Pro–Val–Lys–Val–Tyr–Pro–Asn–Gly–Ala–Glu–Asp–Glu–Leu–Ala–Glu–Ala–Phe–Pro–Leu–Glu–Phe–OH, α_p-ACTH (Ip). A solution of II (Fig. 2; 0.15 g, 0.09 mmol) in DMF (2 ml) was chilled in an ice-bath and 1M hydrochloric acid (0.2 ml) was added. This was introduced into an ice-cold mixture of ethyl acetate–ether (1: 1, 50 ml) and the resulting precipitates were collected by filtration, washed with ether and dried *in vacuo*. The decapeptide hydrochloride thus obtained was dissolved in DMF (3 ml) together with *N*-hydroxysuccinimide (0.041 g, 0.36 mmol) and DCC (0.080 g, 0.39 mmol) was added. The mixture was stirred at 4 °C for 20 h, after which it was introduced into ethyl acetate–ether (1: 1, 70 ml). The precipitates which formed were filtered off, washed with ethyl acetate and ether, and dried *in vacuo* to give the decapeptide active ester hydrochloride.

Compound Xp (0.30 g, 0.069 mmol) was dissolved in DMF (5 ml) and to this was added the active ester obtained above. The mixture was stirred at room temperature for 20 h. Removal of the solvent by evaporation *in vacuo* followed by treatment with ether yielded a crude preparation of the protected nonatriacontapeptide (0.46 g). The crude product obtained above was then treated with trifluoroacetic acid (5 ml) at room temperature for 90 min in the presence of anisole (0.46 ml) and 2-mercaptoethanol (0.46 ml). The precipitates which formed upon addition of ether were filtered off, washed with ether and dried *in vacuo*. The crude deblocked peptide thus obtained was dissolved in water and the solution was passed through a column (1.5×11 cm) of Amberlite CG-400 (acetate). The column was washed with additional portions of water. The aqueous solutions combined were lyophilized to give a crude preparation of Ip (0.46 g).

The crude peptide was submitted to chromatography on a column of carboxymethyl cellulose with an ammonium acetate buffer (Fig. 4). The fractions corresponding to a major peak (tubes 98—117) were combined, evaporated *in vacuo* at a bath temperature of 45 °C and lyophilized to a constant weight (0.12 g). Tubes 81—97 and 118—140 were combined and rechromatographed in the same manner as above. The fractions corresponding to the peak of desired peptide were combined, evaporated and lyophilized (0.03 g). These preparations were combined (0.15 g) and chromatographed again on a carboxymethyl cellulose column (Fig. 5). The fractions corresponding to a major peak (tubes 119—130) were combined, evaporated and lyophilized to give a pure preparation of Ip; wt 0.090 g (26%), $[\alpha]_D^{25}$ −88.0±2.4° (*c* 0.5, 2% acetic acid). Lit, $[\alpha]_D^{27}$ −80.2° (*c* 0.3, 1% acetic acid).[13] $\lambda_{max}^{0.1M\ HCl}$ 276 nm ($E_{1cm}^{1\%}$ 16.0), $\lambda_{shoulder}^{0.1M\ HCl}$ 289 nm ($E_{1cm}^{1\%}$10.3); $\lambda_{max}^{0.1M\ NaOH}$ 282.5 nm ($E_{1cm}^{1\%}$ 17.7), 289 nm ($E_{1cm}^{1\%}$ 18.2). TLC (cellulose): homogeneous to ninhydrin and the Ehrlich reagent in system D. Amino acid ratios in acid hydrolysate: Lys 3.73 (4), His 1.09 (1), Arg 2.79 (3), Asp 1.97 (2), Ser 1.91 (2), Glu 5.26 (5), Pro 4.53 (4), Gly 3.11 (3), Ala 3.00 (3), Val 3.02 (3), Met 1.04 (1), Leu 2.00 (2), Tyr 2.08 (2), Phe 3.07 (3). The Tyr/Trp ratio in intact Ip was 2.06, as determined spectrophotometrically.[20]

H–Ser–Tyr–Ser–Met–Glu–His–Phe–Arg–Trp–Gly–Lys–Pro–Val–Gly–Lys–Lys–Arg–Arg–Pro–Val–Lys–Val–Tyr–Pro–Asn–Gly–Ala–Glu–Asp–Glu–Ser–Ala–Glu–Ala–Phe–Pro–Leu–Glu–Phe–OH, α_h-ACTH (Ih). *a) From Compound Xh*: In the same manner as described above for α_p-ACTH (Ip), the *N*-hydroxysuccinimide ester hydrochloride, derived from II (Fig. 2; 0.16 g, 0.1 mmol), was coupled with Xh (0.33 g, 0.075 mmol) in DMF (5 ml) at room temperature for 20 h to give the protected nonatriacontapeptide (0.46 g). This was submitted to deprotection with trifluoroacetic acid (5 ml) at room temperature for 90 min in the presence of anisole (0.46 ml) and and 2-mercaptoethanol (0.46 ml) and the product was treated with Amberlite CG-400 (acetate) in water to give a crude preparation of Ih (0.45 g).

The crude peptide was chromatographed on a carboxymethyl cellulose column using an ammonium acetate buffer (Fig. 8). The fractions corresponding to a major peak (tubes 93—111) were combined, evaporated *in vacuo* and lyophilized (0.11 g). Tubes 81—92 and 112—140 were combined and rechromatographed in the same manner as above to afford an additional quantity of the desired peptide

(0.02 g). These preparations combined (0.13 g) were chromatographed again on a carboxymethyl cellulose column (Fig. 9) and the fractions corresponding to a major peak (tubes 119—130) were combined, evaporated and lyophilized to give a pure preparation of Ih; wt 0.080 g (21.5%), $[\alpha]_D^{25}$ $-87.2\pm2.8°$ (*c* 0.5, 2% acetic acid). Lit, $[\alpha]_D^{24}$ $-87.6°$ (*c* 0.26, 2% acetic acid).[11] $\lambda_{max}^{0.1M\ HCl}$ 276 nm ($E_{1cm}^{1\%}$ 16.2), $\lambda_{shoulder}^{0.1M\ HCl}$ 289 nm ($E_{1cm}^{1\%}$ 10.6); $\lambda_{max}^{0.1M\ NaOH}$ 282.5 nm ($E_{1cm}^{1\%}$ 17.3), 289 nm ($E_{1cm}^{1\%}$ 18.0). TLC (cellulose): homogeneous to ninhydrin and the Ehrlich reagent in system D. Amino acid ratios in acid hydrolysate: Lys 4.02 (4), His 1.00 (1), Arg 3.23 (3), Asp 2.04 (2), Ser 2.84 (3), Glu 5.08 (5), Pro 4.42 (4), Gly 3.14 (3), Ala 3.05 (3), Val 3.13 (3), Met 0.98 (1), Leu 1.00 (1), Tyr 2.01 (2), Phe 3.03 (3). The Tyr/Trp ratio in intact Ih was 1.98, as determined spectrophotometrically.[20]

b) From Compound VIII. To a solution of VIII (0.31 g, 0.069 mmol) in DMF (5 ml) was added the *N*-hydroxysuccinimide ester hydrochloride, derived from II (0.14 g, 0.089 mmol) in the same manner as described above. The mixture was stirred at room temperature for 20 h and then introduced to ethyl acetate–ether (1: 1, 50 ml) to afford a crude preparation of the protected nonatriacontapeptide (0.43 g). This was then treated with being hydrogen fluoride (20 ml) at 0 °C for 60 min in the presence of anisole (0.5 ml) in the usual manner.[27] Hydrogen fluoride was evaporated *in vacuo* at 0 °C. The resulting residue was dissolved in ice-cold water and the solution was, after being washed with chloroform, passed through a column (1.4×14 cm) of Amberlite CG-400 (acetate). The column was washed with additional portions of water. The aqueous solutions combined were lyophilized to give a crude preparation of Ih (0.34 g).

The crude product thus obtained was chromatographed on a column of carboxymethyl cellulose using an ammonium acetate buffer (Fig. 10). The fractions corresponding to a major peak (tubes 75—87) were combined, concentrated and lyophilized (0.13 g). This was again chromatographed on a carboxymethyl cellulose column in almost the same manner as above (Fig. 11). The fractions corresponding to a single peak (tubes 101—112) were combined and evaporated *in vacuo*. Repeated lyophilization of the residue yielded the desired Ih as colorless fluffy powder: wt 0.100 g (29%), $[\alpha]_D^{24}$ $-86.5\pm4.0°$ (*c* 0.3, 2% acetic acid). $\lambda_{max}^{0.1M\ HCl}$ 276 nm ($E_{1cm}^{1\%}$ 16.0), $\lambda_{shoulder}^{0.1M\ HCl}$ 289 nm ($E_{1cm}^{1\%}$ 10.0); $\lambda_{max}^{0.1M\ NaOH}$ 282.5 nm ($E_{1cm}^{1\%}$ 17.0), 289 nm ($E_{1cm}^{1\%}$ 17.6). TLC (cellulose): homogeneous to ninhydrin and the Ehrlich reagent in system D. Amino acid ratios in acid hydrolysate: Lys 3.75 (4), His 1.14 (1), Arg 2.88 (3), Asp 1.96 (2), Ser 2.51 (3), Glu 4.91 (5), Pro 4.10 (4), Gly 3.12 (3), Ala 2.87 (3), Val 2.97 (3), Met 0.97 (1), Leu 1.00 (1), Tyr 1.99 (2), Phe 2.96 (3). The Tyr/Trp ratio in intact Ih was 1.97, as determined spectrophotometrically.[20]

Purification of Natural α_p-ACTH. A commercial preparation of α_p-ACTH (45 mg)[21] was chromatographed for purification on a column (1.7×10 cm) of carboxymethyl cellulose (CM-52, Whatman) with a 0.1 M sodium acetate buffer (pH 6.2, 1000 ml). The elution was performed by increasing the sodium chloride concentration of buffer linearly from 0 to 0.2 M. Five-ml fractions were collected and their absorption at 280 nm was measured. The fractions corresponding to a major peak (tubes 63—75) were combined and passed through a column (1.1×7 cm) of Amberlite XAD-2, which had been equilibrated with 0.1 M acetic acid, at a flow rate of 35 ml/h. The column was washed with 0.1 M acetic acid (100 ml) and the peptide adsorbed on the column was then eluted with ethanol–0.1M acetic acid (1: 1). Ten ml-fractions were collected and those corresponding to a single peak (tubes 19—33) were combined, evaporated *in vacuo* at a bath temperature of 45 °C and lyophilized; wt 18 mg (recovery 40%),[29] $[\alpha]_D^{21}$ $-84.6\pm3.5°$ (*c* 0.4, 2% acetic acid). $\lambda_{max}^{0.1M\ HCl}$ 276 nm ($E_{1cm}^{1\%}$ 15.5), $\lambda_{shoulder}^{0.1M\ HCl}$ 289 nm ($E_{1cm}^{1\%}$ 10.3); $\lambda_{max}^{0.1M\ NaOH}$ 282.5 nm ($E_{1cm}^{1\%}$ 16.8), 289 nm ($E_{1cm}^{1\%}$ 17.2). TLC (cellulose): homogeneous to ninhydrin and the Ehrlich reagent in system D. Amino acid ratios in acid hydrolysate: Lys 3.84 (4), His 1.05 (1), Arg 2.90 (3), Asp 2.05 (2), Ser 1.79 (2), Glu 4.96 (5), Pro 3.82 (4), Gly 3.11 (3), Ala 3.04 (3), Val 3.00 (3), Met 1.02 (1), Leu 2.06 (2), Tyr 1.98 (2), Phe 3.00 (3). The Tyr/Trp ratio in intact hormone was 1.94 as determined spectrophotometrically.[20]

The authors wish to thank Dr. Akira Tanaka and Mr. Kunihiro Odaguchi for biological assays and Dr. Kaoru Kuriyama and Mr. Tatsuo Iwata for the measurements of optical rotatory dispersion and circular dichroism spectra. They also thank Miss Yoshie Sumitomo for able technical assistance.

28) Upon acid hydrolysis nitroarginine will decompose to give arginine and ornithine. The latter amino acid overlaps the lysine peak under the conditions used.

29) There were found two major peaks, tubes 18—40 and tubes 63—75, in CM-52 column chromatography of the commercial α_p-ACTH preparation. The desired pure hormone was obtained from tubes 63—75, as described avobe. Tubes 18—40 afforded an adrenocorticotropically inactive material (15 mg) and its amino acid ratios in acid hydrolysate were found to be greatly different from those expected for α_p-ACTH.

The Efficient Oxidation of Thiols to Disulfides with Thallium(III) Acetate

Sakae UEMURA,* Sakuya TANAKA, and Masaya OKANO
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received July 2, 1976)

The treatment of various kinds of alkane- and arenethiols with thallium(III) acetate in chloroform at 20—30 °C readily affords the corresponding disulfides almost quantitatively, without affecting other functional groups, such as the hydroxyl, amino, and carboxyl in the thiols. Under similar conditions, the reaction of thiobenzoic *S*-acid with thallium(III) acetate gives thallium(III) thiobenzoate, while that of thioacetic *S*-acid yields diacetyl disulfide and thallium(I) thioacetate.

It is generally known that a large variety of metal ions and oxides oxidize thiols to disulfides.[1] However, although the oxidation with lead(IV) acetate has been fully studied,[2,3] there have been no reports on that with thallium(III) salt, which is also a good oxidizing reagent and which shows some resemblance to lead(IV) salt in many organic reactions.[4] We wish now to describe a facile oxidation of thiols to disulfides with thallium(III) acetate.

Table 1. The oxidation of butanethiol with various oxidants in chloroform[a]

Oxidant (mmol)		*n*-BuSH (mmol)	Temp (°C)	Time (h)	Yield (%)[b] of *n*-BuSS-*n*-Bu
$Tl(OAc)_3$	10	30	25—35	1	104[c,d]
$Tl(OAc)_3$	5	10	20—27	1	100[e]

a) $CHCl_3$ (15 ml). b) Based on the amount of oxidant charged and determined by GLC. c) Isolated yield. d) TlOAc (91%) was isolated. e) TlOAc (95%) was isolated as TlCl by the addition of aq NaCl to the reaction mixture.

First, the oxidation of 1-butanethiol was examined with various thallium salts and lead(IV) and mercury(II) acetate as oxidants in chloroform. The results are shown in Table 1. It is clear that thallium(III) acetate is a more effective reagent than lead(IV) and mercury(II) acetate for disulfide formation, and also that the stoichiometric reduction of thallium(III) acetate to thallium(I) one occurs thus (Scheme 1):

$$2RSH + Tl(OAc)_3 \longrightarrow RSSR + TlOAc + 2AcOH \quad (1)$$

Since thallium(III) acetate was revealed to be a good oxidizing reagent for disulfides, the reaction was applied to various alkane- and arenethiols. It was found that the oxidation proceeded almost quantitatively without affecting other functional groups, such as the hydroxyl, amino, and carboxyl in the thiols. Some typical results are summarized in Table 2, together with some data obtained using lead(IV) acetate. In the case of 2-methyl-2-propanethiol, the oxidation with thallium(III) acetate gave disulfide selectively, while a further oxidized compound, sulfone, was obtained as the major product

Table 2. The oxidation of thiol with thallium(III) and lead (IV) acetates[a]

a) RSH (10 mmol), $M(OAc)_n$ (5 mmol), $CHCl_3$ (15 ml) at 20—30 °C. b) Isolated yield unless otherwise stated. The values in parentheses are from Ref. 2. c) Determined by GLC. d) Other product: *t*-$BuSO_2S$-*t*-Bu (50% yield). e) More than 90% of the lead (IV) salt was recovered (by iodometry).

by the use of lead(IV) acetate. In the case of *o*-aminobenzenethiol, it has been reported that the oxidation with lead(IV) acetate gave disulfide in a low yield, probably because of the oxidation of the amino group by lead(IV) salt.[2] The oxidation with thallium(III) acetate, however, yielded only disulfide quantitatively. In the case of L-cysteine, the oxidation by lead(IV) acetate was very slow compared to that by thallium(III) acetate under nearly the same reaction conditions.

In the oxidation of arenethiols, when the reaction was carried out in the presence of more than two equivalents of thiols to one of thallium(III) acetate, yellow thallium(I) thiolate was formed as well as disulfide, as has previously been reported in the cases with lead(IV) acetate[3] (See Experimental section). The stoichiometry (using three mol of thiols) is shown in Scheme 2. On the other hand, in the cases of alkanethiols, no such thiolate was formed and thallium(I) salt was obtained as the acetate.

$$3ArSH + Tl(OAc)_3 \longrightarrow ArSSAr + TlSAr + 3AcOH \quad (2)$$

Although thiocarboxylic *S*-acids have reacted with lead(IV) acetate to yield diacetyl disulfides,[2,3] the reaction of them with thallium(III) acetate gave slightly different results. That is, the reaction of thiobenzoic

* To whom correspondence should be addressed.

S-acid with thallium(III) acetate in chloroform at room temperature resulted in the formation of thallium(III) thiobenzoate in a good yield (Scheme 3), while that of thioacetic *S*-acid gave diacetyl disulfide and thallium(I) thioacetate (Scheme 4). In the latter case, unstable thallium(III) thioacetate seemed to be formed at first; it then decomposed to give the products. In fact, thallium(III) thiobenzoate also decomposed to thallium-(I) salt and dibenzoyl disulfide upon heating in chloroform or carbon tetrachloride, or even upon standing at room temperature for several days.

$$3PhCOSH + Tl(OAc)_3 \longrightarrow Tl(SCOPh)_3 + 3AcOH \quad (3)$$

$$3CH_3COSH + Tl(OAc)_3 \longrightarrow TlSCOCH_3 + (CH_3COS)_2 + 3AcOH \quad (4)$$

Experimental

The NMR spectra were taken with a Varian EM-360 spectrometer, using $CDCl_3$ as the solvent. The IR and mass spectra were recorded on Hitachi EPI-S2 and JEOL JMS-01SG spectrometers respectively. The GLC analyses were carried out on a Shimadzu 4BMPF apparatus, using an EGSS-X (30%)-Chromosorb W (1 m or 3 m) column. Commercial organic and inorganic materials were used without further purification. The thallium(III) acetate was prepared from thallium(III) oxide and acetic acid.[5]

Reaction of Thiols with $Tl(OAc)_3$. The following is a typical example. To a stirred chloroform (15 ml) solution of 1-butanethiol (2.7 g, 30 mmol) we added solid thallium(III) acetate (3.81 g, 10 mmol) in several portions at 25 °C over a 10-min period. The reaction was exothermic, and the temperature rose to 35 °C during the addition. The resulting yellowish orange mixture was stirred for 1 h. The subsequent evaporation of the chloroform by means of a vacuum evaporator at room temperature left white thallium(I) acetate (2.4 g, 9.1 mmol; mp 130 °C) and organic products, the latter of which was distilled to afford acetic acid (0.5 g, 8.3 mmol; bp 25—35 °C/22 Torr) and dibutyl disulfide (1.85 g, 10.4 mmol; bp 110—118 °C/22 Torr).

Reaction of Benzenethiol with $Tl(OAc)_3$. To a chloroform (15 ml) solution of benzenethiol (3.3 g, 30 mmol) we added several portions of solid thallium(III) acetate (3.81 g, 10 mmol) at 25 °C over a 10-min period. The temperature of the mixture rose to 30 °C during the addition, and a yellow solid of thallium(I) benzenethiolate was precipitated. After 1 h, the solid was filtered off [C_6H_5STl, 2.90 g, 9.3 mmol, 93% yield; mp 255—260 °C (lit,[6] mp 258—260 °C)] and the filtrate was concentrated to give diphenyl disulfide [2.18 g, 10 mmol, 100% yield; mp 59—60 °C (lit,[2] mp 59—61 °C)]. When benzenethiol (20 ml) was added, drop by drop, to a suspension of thallium(III) acetate (10 mmol) in chloroform (15 ml), diphenyl disulfide and thallium(I) acetate were obtained quantitatively. The further addition of the thiol in this case resulted in the formation of thallium(I) benzenethiolate instead of the acetate.

Reaction of Thiobenzoic S-Acid with $Tl(OAc)_3$. The addition of thallium(III) acetate (1.15 g, 3 mmol) to a chloroform (8 ml) solution of thiobenzoic *S*-acid (1.38 g, 10 mmol) at 20—25 °C readily afforded a yellow heterogeneous mixture. After 20 mins' stirring a yellow solid was filtered off and washed with ether. It was revealed to be thallium-(III) thiobenzoate [1.55 g, 2.5 mmol, 84% yield; mp (decomp) 113—114 °C]. IR (hexachlorobutadiene and paraffin mulls), 3070 (w), 1660 (s), 1630 (m), 1590 (m), 1575(m), 1445 (m), 1310 (w), 1195 (s), 1170 (s), 1000 (w), 900 (s), 890 (s), 765 (m), and 675 (s) cm^{-1}. Found: C, 41.10; H, 2.51%. Calcd for $C_{21}H_{15}O_3S_3Tl$: C, 40.95; H, 2.45%. Dibenzoyl disulfide was not detected in the organic extract.

By heating thallium(III) thiobenzoate (0.61 g, 1 mmol) in CCl_4 (15 ml) under reflux for 3 h, dibenzoyl disulfide [0.24 g, 0.88 mmol, mp 125 °C (lit,[3] mp 125—127 °C)] and thallium-(I) thiobenzoate (0.33 g, 0.97 mmol) were isolated. The latter thallium(I) salt was also prepared by the reaction of equimolar amounts of thallium(I) acetate and thiobenzoic acid in ethanol at room temperature for 2 h: mp (decomp) 200—202 °C; Found: C, 24.52; H, 1.30%. Calcd for C_7H_5OSTl: C, 24.60; H, 1.46%.

Reaction of Thioacetic S-Acid with $Tl(OAc)_3$. To a stirred chloroform (10 ml) solution of thioacetic *S*-acid (1.14 g, 15 mmol), we added several portions of solid thallium(III) acetate (1.90 g, 5 mmol) at 25—30 °C. The color of the mixture soon became bright yellow and then gradually changed to pale yellow. After 5 h, a pale yellow solid was filtered off. It was revealed to be thallium(I) thioacetate (1.35 g, 4.82 mmol, 96% yield; mp 76—78 °C). IR (hexachlorobutadiene and paraffin mulls), 1645 (s), 1638(s), 1565 (s), 1545 (sh), 1410 (w), 1348 (m), 1150 (w), 1130 (m), 1110 (s), 950 (m), and 865 (m) cm^{-1}. Found: C, 8.64; H, 1.21%. Calcd for C_2H_3OSTl: C, 8.60; H, 1.08%. The evaporation of chloroform from the organic filtrate left 0.4 g of a residue which was revealed by NMR to consist of almost pure diacetyl disulfide. The distillation of the residue, accompanied by a slight decomposition, gave diacetyl disulfide (0.2 g, 1.33 mmol, 27% yield; bp 40—65 °C/3 Torr), the NMR and IR spectra being identical with those of an authentic sample prepared by the oxidation with $Pb(OAc)_4$.[2]

Reaction of 2-Methyl-2-propanethiol with $Pb(OAc)_4$. The oxidation of 2-methyl-2-propanethiol (0.9 g, 10 mmol) with lead(IV) acetate [2.46 g (90% purity), 5 mmol] in chloroform (15 ml) was carried out at 25—30 °C for 5 h, as in the case with thallium(III) acetate. The lead(II) acetate thus formed (1.40 g, 4.31 mmol) was filtered off, and the subsequent GLC analysis of the filtrate revealed the presence of di-*t*-butyl disulfide (1.85 mmol, 37% yield) and *S*-*t*-butyl 2-methyl-2-propanethiosulfonate, *t*-$BuSO_2S$-*t*-Bu (2.50 mmol, 50% yield). Even when the reaction was stopped within 1 h, the yield of each compound was nearly the same to that described above. The reaction with PbO_2 in place of $Pb(OAc)_4$ was sluggish, and only disulfide was formed. Pure thiosulfonate was isolated by the distillation of the filtrate after the solvent had been removed. Thiosulfonate: bp 122 °C/35 Torr; NMR δ 1.37 (s); MS, (*m/e*) 210 (M^+); IR 1362 (s, ν_{as} SO_2), 1165 (s, ν_s SO_2); Found: C, 45.59; H, 8.92%. Calcd for $C_8H_{18}O_2S_2$: C, 45.68; H, 8.62%. Disulfide: NMR δ 1.30 (s); MS, (*m/e*) 178 (M^+).

(Received July 5, 1976)

Under UV irradiation in the presence of an inorganic base, aqueous formaldehyde was found to give pentaerythritol and 2-hydroxymethylglycerol as the main products, accompanied by the concomitant formation of a mixture of sugars and sugar alcohols. The results indicate that this photochemical formose reaction is considerably different in product distribution from the thermal formose reaction using the $Ca(OH)_2$ catalyst. The detailed examination of the photochemical formose reaction was carried out in the presence of Na_2CO_3, and a possible scheme for the formation of pentaerythritol and 2-hydroxymethylglycerol is proposed.

The formose reaction, which is essentially the autocondensation of formaldehyde by a base catalyst, resulting in the formation of a complex mixture of monosaccharides, has been studied by many investigators. Among various inorganic and organic bases, $Ca(OH)_2$ has been recognized as an excellent catalyst, for this reaction,[1-4] while the mechanism of the sugar formation has been discussed mainly in terms of the aldol condensation between formaldehyde and lower saccharide intermediates.[4-7] In the majority of the reports, the complexity of this reaction has been emphasized. The number of products amounts to more than 30,[8] and this complexity has made it difficult to utilize the method for common carbohydrate resources.

Formose can also be synthesized photochemically. The photochemical sugar formation from formaldehyde was found by Moore *et al.*,[9] who observed the sugar formation under sunlight or irradiation by a mercury lamp in the presence of $FeCl_3$ or uranium compounds as sensitizer. Since Baly *et al.*[10,11] reported that the irradiation of 40% formalin with ultraviolet light in the presence of $CaCO_3$ gives reducing sugars in *ca.* an 8% yield, no significant report on the photochemical formose reaction has appeared. The purpose of the present work is to obtain further information on the effect of additives on the product distribution in the photochemical formose reaction as well as to contribute to the elucidation of the mechanism.

Experimental

Materials. Aqueous formaldehyde solutions were prepared from paraformaldehyde (Merck Co.).[12] All of the inorganic bases used as catalysts were of an analytical grade.

Irradiation Procedure. An aqueous formaldehyde solution (230 ml) containing 15 g of a basic catalyst was irradiated internally with a 450-W high-pressure mercury lamp in a Pyrex tube equipped with a water jacket under stirring in air. The temperature of the solution was maintained at 28—30 °C. After irradiation, the reaction mixture was slightly acidified with 1 M HCl. The formaldehyde consumption and the sugar yield were determined by the methods described in an earlier paper.[12] The amount of the organic acids was determined for acidified 10 ml aliquots by back titration with 2 M KOH.

Thermal Formose Reaction. The reaction was carried out by the method previously described.[12] The sugar products were trimethylsilylated and analyzed by gas chromatography (Fig. 1).

Gas Chromatography. The reaction mixture was evaporated to dryness *in vacuo* at 40 °C by the repeated addition and concentration of water in order to remove formaldehyde as possible. The residue was trimethylsilylated in the usual manner[13] and extracted with chloroform. A Shimadzu GC-5A chromatograph, equipped with a hydrogen-flame ionization detector, was used under the following conditions: coiled glass column of 3 m by 0.3 in. o.d., adsorber, 5% silicon gum SE-30 on 60—80 mesh Chromosorb-W; nitrogen flow rate, 60 ml/min; temperature, 100—250 °C, rising at the rate of 4 °C/min.

Separation and Identification of Products. An aqueous solution (230 ml) containing formaldehyde (55.2 g) and Na_2CO_3 (15.0 g) was irradiated as above for 50 h. The consumption of formaldehyde, the sugar yield, and the yield of organic acid (as formic acid) were determined to be 42.8, 7.5, and 2.5% respectively, based on the starting formaldehyde. The reaction mixture was then passed through columns of Amberlite IR120(H) (120 ml) and Amberlite IRA400 (OH) (500 ml) successively, after which the columns were washed with water (200 and 500 ml respectively). The whole eluate was concentrated *in vacuo* to dryness by the repeated addition and concentration of water in order to remove the formaldehyde. The residue was dissolved in water (50 ml) and diluted with acetone (50 ml) to separate pentaerythritol(I), corresponding to the GLC peak 9 (Fig. 2) (8.8 g; 38% based on the consumed formaldehyde) as colorless crystals (mp 255—256 °C), which were identical with an authentic sample (IR).

The mother liquor was evaporated to a sirup which was chromatographed in 2 g portions as follows. On the top of a column (20 cm by 2.8 cm o.d.) packed with dry cellulose powder, the sample, which had been mixed with a small amount of cellulose powder (Whatman CF-11) and dried in a desiccator, was placed; it was eluted successively with the following solvents: acetone, 500 ml; acetone–methanol (9: 1, v/v), 300 ml; acetone–methanol (8: 2, v/v), 300 ml; acetone–methanol (7:3, v/v), 200 ml; acetone–methanol (5: 5, v/v), 200 ml; methanol, 100 ml. The eluate was then collected in 50 ml portions and was analyzed by GLC and PPC. All the eluates were then divided into two fractions. Fraction A consisted of products corresponding to GLC peaks 1, 2, 3, 4, 5, 6, and 10 (Fig. 2) and amounted to 3.0 g (13%, based on the consumed formaldehyde); the second fraction consisted mainly of a product corresponding to the GLC peak 7 (2.8 g; 12%, based on the consumed formaldehyde). Part of the latter fraction was purified by paper chromatography as follows: Toyo filter paper No. 50; the upper layer of a mixture of 1-butanol–acetic acid–water (4: 1: 5) as the developing solvent; detection by an ammoniacal silver nitrate solution.[14] The chromatogram was extracted with methanol to give 2-hydroxymethylglycerol(II) (GLC peak 7) as a colorless sirup; it was identified from its spectral and analytical data: IR (KBr)

3400, 2950, 1460, 1120, 1040, 910 cm^{-1}; MS 122, 91, 73, 61, 45 *m/e*; Found: C, 39.43; H, 8.16%. Calcd for $C_4H_{10}O_4$: C, 39.34; H, 8.25%. The acetate of 2-hydroxymethylglycerol, NMR ($CDCl_3$) 2.07 (9H, s), 2.08 (3H, s), 4.13 (6H, s).

Amberlite IRA400 (OH) which had been treated with the total reaction mixture was washed with 0.2 M HCl (1 liter), and the washings was concentrated *in vacuo* (Fraction B), (8.5 g; 37%, based on the consumed formaldehyde). Fraction B consisted of products corresponding to GLC peaks (Fig. 2) 8, 14, 15, 20, 21, 23, 24, 27, 29, and organic acids.

Formation of 2-Hydroxymethylglycerol(II) from Glycolaldehyde and Formaldehyde. An aqueous formaldehyde solution (30 ml; 1.7 g) containing 0.75 g of glycolaldehyde and 0.48 g of Na_2CO_3 was stirred at 30 °C without irradiation. At intervals an aliquot was taken up and slightly acidified (pH, 5—6) with 1 M HCl to stop the reaction. The reaction mixture was evaporated to dryness as above, and the residue was trimethylsilylated and analyzed by gas chromatography. The results are shown in Fig. 6.

Photochemical Formation of Pentaerythritol (I). To 20 ml of an aqueous solution of 2-hydroxymethylglycerol (II), concd formalin, Na_2CO_3, and water were added so as to bring the concentrations of II, formaldehyde, and Na_2CO_3 to 0.1 M, 6M, and 0.62 M respectively, and the final volume to 25 ml. A quartz tube containing the solution was irradiated externally with a 450-W high-pressure mercury lamp at 30 °C. At intervals an aliquot was taken up and analyzed as above. The results are shown in Fig. 7.

Results and Discussion

The sugar yields in the photochemical formose reactions with various catalysts are summarized in Table 1.

Table 1. Effect of inorganic base catalyst on the photochemical formose reaction[a)]

Inorganic base	Concentration of base (M)	Sugar yield as glucose (%)
$CaCO_3$	0.86	5.8
$Ca(OH)_2$	0.88	5.2
Na_2CO_3	0.62	8.7
$NaHCO_3$	0.78	4.5
NaOH	1.63	2.0
$Mg(OH)_2$	1.12	6.4

a) Light source, 450-W high-pressure mercury lamp (Pyrex); irradiation time, 72 h; [HCHO]=12.3M; temperature, 30 °C.

In the absence of a basic catalyst, the consumption of formaldehyde became negligible under UV irradiation for 50 h. When $CaCO_3$ was used as the catalyst, the sugar yield (5.8%) was lower than that (8%) reported by Baly.[11)] The discrepancy between these two experimental results might be attributed to differences in the irradiation conditions. The sugar yield was relatively high when Na_2CO_3 was used. The gas chromatogram of the trimethylsilylated products obtained by the use of the Na_2CO_3 catalyst is shown in Fig. 2. It is apparent that the product distribution of the photochemically synthesized formose is simpler than that of the formose prepared by the usual thermal method (Fig. 1). In experiments with the other catalysts listed in Table 1, the GLC patterns were similar to that of Fig. 2, but the product corresponding to peak 9 was obtained in the highest yield in case of the Na_2CO_3 catalyst. Therefore, the detailed studies of the photochemical formose reactions were made using the Na_2CO_3 catalyst.

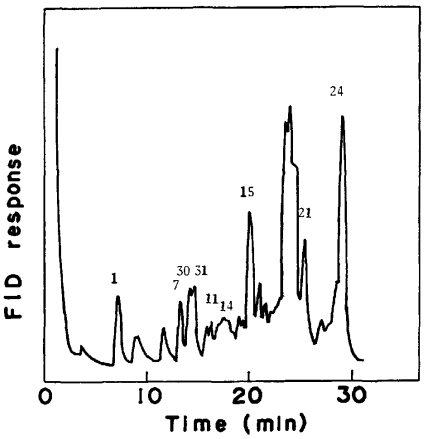

Fig. 1. Gas chromatogram of TMS derivatives of thermosynthesized formose.
[HCHO]=2.0 M; [$Ca(OH)_2$]=0.2 M; Temp, 60 °C; Total volume; 880 ml.[12)]

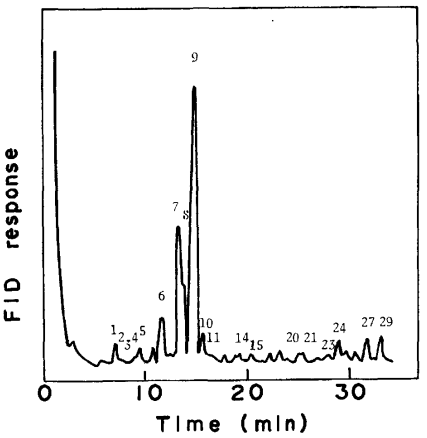

Fig. 2. Gas chromatogram of TMS derivatives of photochemically synthesized formose.
[HCHO]=8.0 M; [Na_2CO_3]=0.62 M; Temp, 30 °C; Light source, 450-W high-pressure mercury lamp; Irradiation time, 50 h; Total volume, 230 ml.

The main products, corresponding to GLC peaks 7 and 9 of Fig. 2, were separated and identified as 2-hydroxymethylglycerol (II) and pentaerythritol (I) respectively. The compound I formed amounts to *ca.* 40% of the total products (by GLC), and the II, to 13%. Fractions A and B are most probably sugar alcohols and sugars respectively, judging from their behavior in the Benedict test (A: negative; B: positive) and the adsorption on the IRA400(OH) resin.

The formaldehyde consumption and the sugar yield in the photochemical formose reaction were found to depend on the formaldehyde concentration, which is shown in Fig. 3. At higher formaldehyde concentrations, both the formaldehyde consumption and the sugar yield increase. At concentrations less than 3 M, the reaction proceeded very slowly under a high-pressure mercury lamp (Pyrex), resulting in a formaldehyde consumption of less than 10% and a negligible formation of the sugars. However, when a 10-W low-pressure mercury

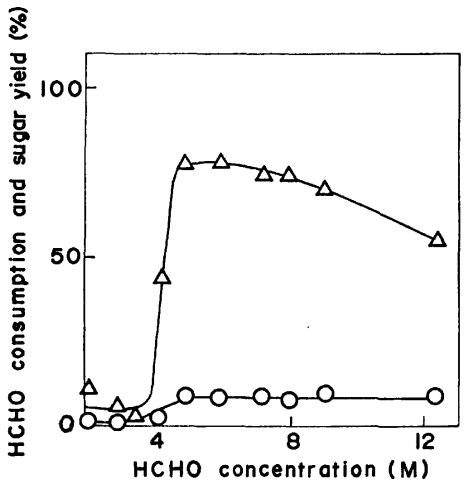

Fig. 3. Effect of HCHO concentrations on the HCHO consumption and the sugar yield.
$[Na_2CO_3]=0.62$ M; Temp, 30 °C; Light source, 450-W high-pressure mercury lamp; Irradiation time, 72 h; Total volume, 230 ml; △, HCHO consumption; ○, Sugar yield.

lamp (quartz tube) was used at a 2 M formaldehyde concentration, the consumption of formaldehyde and the sugar yield were raised to 70 and 5.4% respectively. The gas chromatogram of the products exhibited more than 30 peaks, and no selective formation of I and II was observed.

The sugar yield (usually *ca.* 50%) in the $Ca(OH)_2$-catalyzed formose reaction, in which the Cannizzaro reaction competes with the sugar formation,[5,6] is known to improve upon the addition of methanol because of its inhibitory action on the Cannizzaro reaction.[15] The fact that the sugar yield was low regardless of the formaldehyde concentrations in the photochemical formose reaction (Fig. 3) may be ascribed to the accumulation of formic acid resulting from the Cannizzaro reaction, as may be seen in the decrease in the pH in the course of the reaction (Fig. 5). However, the addition of methanol to the photochemical reaction system

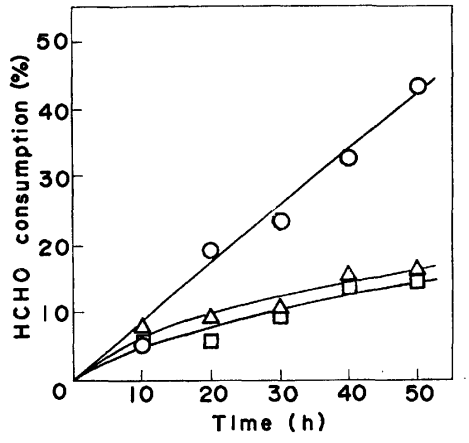

Fig. 4. Effect of methanol addition on the HCHO consumption.
[HCHO]=8.0 M; $[Na_2CO_3]=0.62$ M; Temp, 30 °C; Light source, 450-W high-pressure mercury lamp; [MeOH] (v/v): ○, 0%; △, 50%; □, 100%.

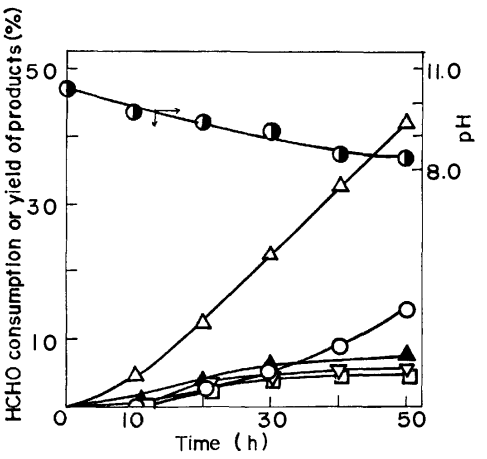

Fig. 5. Time course of the photochemical formose reaction.
[HCHO]=8.0 M; $[Na_2CO_3]=0.62$ M; Temp, 30 °C; Light source, 450-W high-pressure mercury lamp; Total volume, 230 ml; ◑, pH; △, HCHO consumption; ▽, Organic acid (as formic acid); ○, Pentaerythritol; □, 2-hydroxymethylglycerol; ▲, HCHO consumption by dark reaction.

resulted in a decrease in the formaldehyde consumption rate (Fig. 4), and the sugar yield became negligible. This shows that methanol has rather an inhibitory effect on the photochemical formose reaction.

The time course of a typical run of the photochemical formose reaction is shown in Fig. 5. In the earlier stages of the reaction, the yield of pentaerythritol (I) is equal to that of 2-hydroxymethylglycerol (II), but after 40 h the former appreciably exceeds the latter. A lowering of the pH due to the formation of organic acids was also observed. In a control experiment without UV irradiation, formaldehyde was consumed only to a small extent, and it was converted into organic acids nearly quantitatively by the Cannizzaro reaction.

Mechanistic Consideration. The compound I is usually prepared by treating acetaldehyde with about five equivalents of formaldehyde in an aqueous $Ca(OH)_2$ suspension. The reactions proceeds *via* the addition of three molecules of formaldehyde to acetaldehyde, followed by the Cannizzaro reaction of tris(hydroxymethyl)acetaldehyde, leading to I.[16] An attempt was made to detect acetaldehyde in the present photoreaction mixture with morpholine and sodium nitroprusside,[17] but acetaldehyde could not be detected in any stage of the reaction. The gaseous material evolved during the reaction was found by GLC analysis to be O_2 and CO_2 derived from the Na_2CO_3 catalyst.

On the basis of the facts that glycolaldehyde is a product of the first step of the thermal formose synthesis using basic catalysts,[18] and that 2-hydroxymethylglycerol is detected in the final products by GC-MS,[19] the photochemical formose reaction must be: formaldehyde→glycolaldehyde (III)→2-hydroxymethylglycerol (II)→pentaerythritol (I). The following experiments support this sequence.

When an aqueous solution of glycolaldehyde (0.42 M), formaldehyde (1.9 M), and Na_2CO_3 (0.15 M) was allowed to stand at 30 °C, II was formed in *ca.* a 30%

[HCHO]=1.9 M; [Glycolaldehyde]=0.42 M; [Na_2CO_3]=0.15 M; Temp, 30 °C; Total volume, 30 ml; △, HCHO consumption; □, 2-hydroxymethylglycerol; ○, Pentaerythritol; Products analysis, GLC of TMS derivatives.

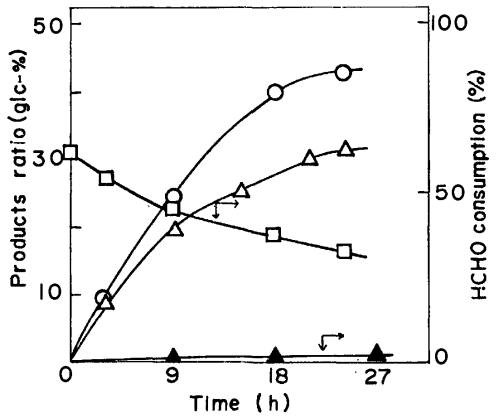

Fig. 7. Photochemical formation of pentaerythritol from 2-hydroxymethylglycerol and formaldehyde.
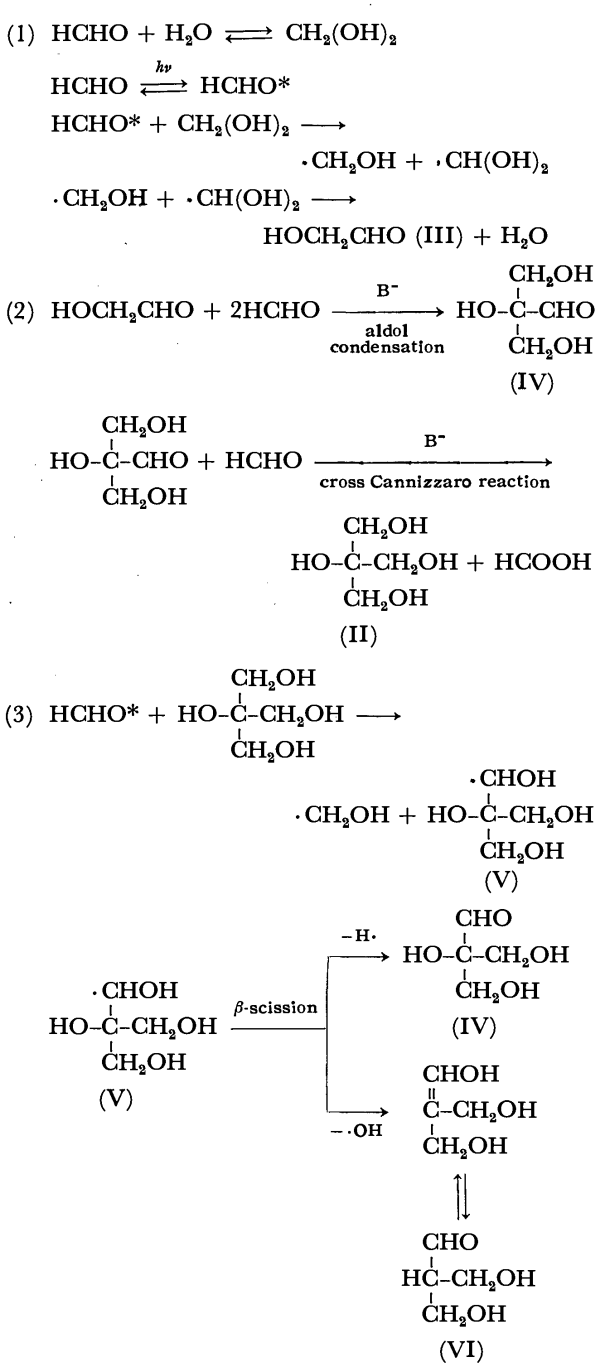
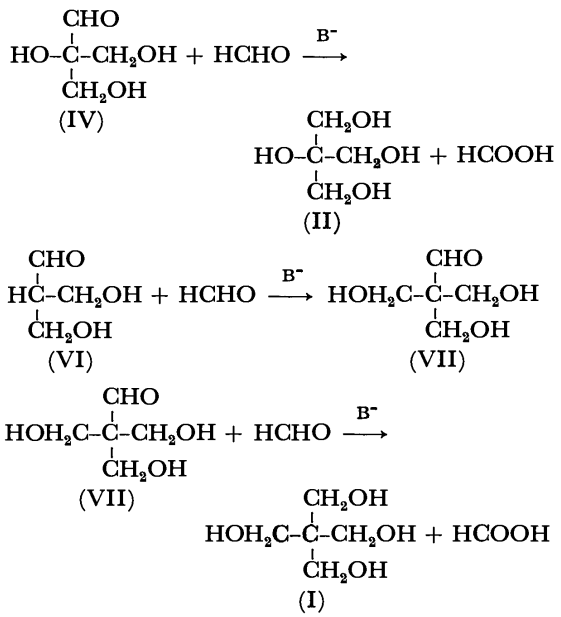
[HCHO]=6.0 M; [2-hydroxymethylglycerol]=0.1 M; [Na_2CO_3]=0.62 M; Temp, 30 °C; Light source, 450-W high-pressure mercury lamp; Total volume, 25 ml; △, HCHO consumption; ○, Pentaerythritol; □, 2-hydroxymethylglycerol; ▲, HCHO consumption in the absence of Na_2CO_3 (pH=6.6); Product analysis, GLC of TMS derivatives.

yield (by GLC), while formaldehyde was consumed, but no formation of I was detected (Fig. 6). The compound III disappeared rapidly at an early stage of this reaction and was no longer detectable by GLC analysis after 30 min. On the other hand, when an aqueous solution of glycolaldehyde and formaldehyde at the same concentrations was irradiated for 20 h in the absence of Na_2CO_3, the consumption of formaldehyde was less than that in the thermal Na_2CO_3-catalyzed reaction (*ca.* 30%), and neither II nor I was formed. These results indicate that, in the presence of a base and formaldehyde, glycolaldehyde (III) smoothly gives rise to 2-hydroxymethylglycerol (II) by means of a reaction in the dark.

The lack of pentaerythritol formation in the experiment shown in Fig. 6 suggests that the step of pentaerythritol formation in the photochemical formose reaction might require UV irradiation. This was shown by a photochemical formation from II (0.1 M) in the presence of formaldehyde (6 M) and Na_2CO_3 (0.62 M) (Fig. 7). In the course of irradiation, pentaerythritol (I) increases with a decrease in the formaldehyde and II; when UV irradiation was omitted or when the reaction was carried out at pH 5, little formaldehyde was consumed and the formation of I was not observed. At a low concentration of formaldehyde (0.6 M), the yield of I decreases dramatically under a 20 h irradiation.

Now, the pathway of the formation of I and II from formaldehyde under UV irradiation in the presence of a base catalyst can be formulated as is shown in the following scheme:





(1) The first step is the formation of glycolaldehyde (III) from formaldehyde with light, as has already been reported by Pribram.[20] An n-π^* excited state of formaldehyde [$\lambda_{max}^{H_2O}$ 288 nm (log ε 1.13)[21]] abstracts hydrogen from its hydrated form,[22] methanediol; this is followed by the coupling of the two radical species.

(2) The second step may consist of thermal processes. In the presence of a base, glycolaldehyde (III) smoothly undergoes aldol condensation with formaldehyde, followed by a cross-Cannizzaro reaction between 2-formylglycerol (IV) and formaldehyde to yield 2-hydroxymethylglycerol (II).

(3) The final step probably involves a photochemical process. An excited state of formaldehyde may abstract hydrogen from a methylene group of II, giving a substituted hydroxymethyl radical (V). The radical may then undergo β-scission to yield either 2-formylglycerol (IV) or bis(hydroxymethyl)acetaldehyde (VI). The oxygen evolved during the reaction may come from the hydroxyl radicals. In the presence of a base and formaldehyde, the former (IV) undergoes a cross-Cannizzaro reaction to revert back to II. The latter (VI) undergoes an aldol condensation with formaldehyde, followed by a cross-Cannizzaro reaction of the tris(hydroxymethyl)-acetaldehyde (VII) thus formed, to yield, finally, pentaerythritol (I).

The Synthesis of Dimethyl *dl*-3-Ethyl-4-methyl-1,2-cyclopentanedicarboxylates[1]

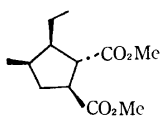
Shosuke Ito and Yoshimasa Hirata

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

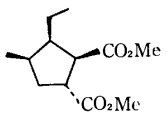
(Received July 6, 1976)

The four 3,4-*cis*-stereoisomers of dimethyl *dl*-3-ethyl-4-methyl-1,2-cyclopentanedicarboxylates (**1a**, **1b**, **1c**, and **1d**) have been synthesized and their configurations established. A comparison of the spectral data and the GLC behaviors has shown that the corresponding ester, one of the key degradation products of ikarugamycin, has the *r*-1, *t*-2, *c*-3, *c*-4-configuration (**1a**). The *r*-1, *t*-2, *c*-3, *t*-4-stereoisomer (**1f**) has also been prepared.

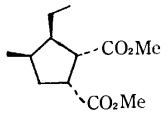
Ikarugamycin[2] is an antibiotic with a unique *as*-hydrindacene skeleton. On permanganate oxidation followed by esterification it yielded a monocyclic ester **1**, $C_8H_{14}(CO_2Me)_2$, along with a number of esters.[2b] The structure of the ester **1** was determined as dimethyl 3-ethyl-4-methyl-1,2-cyclopentanedicarboxylate by spectral data and the concomitant formation of dimethyl 2-ethyl-3-methylglutarate.[2b] Furthermore, the *r*-1, *t*-2, *c*-3, *c*-4 stereochemistry was suggested by the facts: the configuration of the ethyl and methyl groups in the isolated dimethyl 2-ethyl-3-methylglutarate was *erythro*, and the base-catalyzed equilibration of the ester **1** resulted in the recovery of **1** as the major product.[2b]



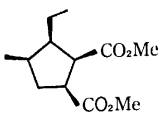
1a



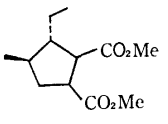
1b



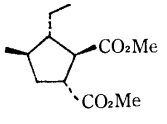
1c



1d

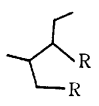


1e



1f

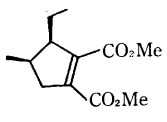
Since the ester **1** contained four of the nine asymmetric carbons in ikarugamycin, it became necessary to unequivocally confirm the relative configuration of the ester **1** through its synthesis. We describe here the synthesis and the stereochemistry of the four isomeric 3,4-*cis*-3-ethyl-4-methyl-1,2-cyclopentanedicarboxylates (**1a**, **1b**, **1c**, and **1d**). Two 3,4-*trans*-stereoisomers (**1e** and **1f**) were also prepared.



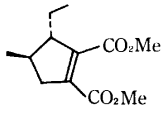
2a: R=CO_2H
2b: R=CH_2OH
2c: R=CH_2OTs
2d: R=CH_2CN
2e: R=CH_2CO_2H
2f: R=$CHBrCO_2Me$

There have been extensive works on the synthesis of nepetic acids, 3-methyl-1,2-cyclopentanedicarboxylic acids.[3] However, none of them seemed applicable for the synthesis of 3,4-disubstituted 1,2-cyclopentanedicarboxylic acids. The cyclization reaction by McDonald and Reitz[4] appeared to be the most convincing method for our purpose. As the starting material was chosen 2-ethyl-3-methylglutaric acid (**2a**) which was prepared by a known method[5] as a mixture (1: 2 ratio) of *erythro*- and *threo*-isomers.

Lithium aluminum hydride reduction of the acid **2a** gave a diol **2b**. The corresponding ditosylate (**2c**) was treated with sodium cyanide in dimethyl sulfoxide to yield a dinitrile **2d**, which was then hydrolyzed with potassium hydroxide in aqueous ethylene glycol to give a dicarboxylic acid **2e**. Bromoesterification[6] of **2e** yielded a dibromo diester **2f**, whose structure was confirmed by the mass spectrum and elemental analysis (see Experimental). The cyclization of **2f** with sodium hydride in *N*,*N*-dimethylformamide[4] proceeded smoothly, giving the two expected cyclopentene derivatives **3a** and **3b** in 5: 7 ratio. They were separated without difficulty by chromatography on silver nitrate impregnated silica gel followed by preparative gas-liquid chromatography (GLC). In order to confirm the relative configurations of the ethyl and methyl groups in the esters (**3a** and **3b**), the latter (**3b**) was submitted to ozonolysis and yielded *threo*-2-ethyl-3-methylglutaric acid.[7]



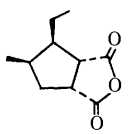
3a



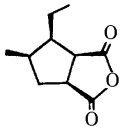
3b

Hydrogenation of the unsaturated 3,4-*cis*-ester (**3a**) proved to be very difficult. However, this was overcome by repeating hydrogenation in acetic acid over platinum oxide. The products, free of unsaturated esters, were separated by preparative GLC, giving three saturated esters **1d**, **1a**,[8] and **1e**[8] in 33, 7, and 13% yields, respectively.

On equilibration by heating with methanolic sodium methoxide, the ester **1d** disappeared to give the isomeric ester **1a** as the major product, along with two new esters **1b** and **1c** (ratio of **1a**, **1b**, and **1c**; 89: 2: 9). This indicates that the isomer **1a** has the most stable *r*-1, *t*-2, *c*-3, *c*-4-configuration.[9]



4a



4b

The two isomeric 1,2-*cis*-esters (**1c** and **1d**) were also prepared *via* their anhydrides (**4a** and **4b**) as follows. The ester **1d** was equilibrated, hydrolyzed, and then

treated under reflux with acetic anhydride containing *p*-toluenesulfonic acid. Preparative GLC of the product afforded the 2,3-*trans*-anhydride (**4a**) and the 2,3-*cis*-anhydride (**4b**) in 4: 1 ratio. Methanolysis of **4a** and **4b** followed by esterification with diazomethane gave the corresponding esters (**1c** and **1d**), respectively. Thus, the second most stable isomer **1c** must have the *r*-1, *c*-2, *t*-3, *t*-4-configuration and the least stable isomer **1d** the *r*-1, *c*-2, *c*-3, *c*-4-configuration.

The remaining isomer whose configuration was to be confirmed was then the *r*-1, *t*-2, *t*-3, *t*-4-ester (**1b**). It was prepared from the anhydride **4b** by essentially the same method as used for the preparation of *t*-3-methyl-*r*-1, *t*-2-cyclopentanedicarboxylic acid.[10] The anhydride (**4b**) was converted to a mixture of half methyl esters, which was equilibrated with base and esterified. The product consisted mostly of the ester **1b** which was isolated in 50% yield by preparative GLC.

Thus, all of the four stereoisomers of dimethyl 3,4-*cis*-3-ethyl-4-methyl-1,2-cyclopentanedicarboxylates were prepared with high purities and their stereochemistry established.

Consequently, the isomer **1e**, obtained by the catalytic hydrogenation of **3a** (described above), must have 3,4-*trans*-configuration.[8] In fact, equilibration of **1e** yielded predominantly the sixth isomer **1f** whose stereochemistry was most likely *r*-1, *t*-2, *c*-3, *t*-4.

A comparison of the IR and NMR spectra and retention times on GLC showed that the ester **1**, obtained from ikarugamycin, was identical with the synthetic sample of dimethyl *c*-3-ethyl-*c*-4-methyl-*r*-1,*t*-2-cyclopentanedicarboxylate (**1a**).

Experimental

The IR spectra were taken on a JASCO IR-S spectrophotometer and the UV spectra on a Perkin-Elmer 202 UV-VIS spectrophotometer. The NMR spectra were recorded on Nihondenshi JNM-C60H and 4H-100 spectrometers using CCl_4 as the solvent; the chemical shifts are given in ppm relative to the internal TMS, and the coupling constants given in Hz. The mass spectra were obtained with a Hitachi RMU-6D spectrometer, operating with an ionization energy of 70 eV. The preparative gas-liquid chromatography (GLC) were carried out on a Varian 1828-4 instrument, using a column packed with 10% OV-17 on Chromosorb W at 170 °C.

Synthesis of Dimethyl 2,6-Dibromo-3-ethyl-4-methylpimelate (2f). *(a) 3-Ethyl-4-methyl-1,5-pentanediol (2b)*: A solution of 2-ethyl-3-methylglutaric acid (**2a**: 17.4 g) in ether (100 ml) was added dropwise during 2 h to a stirred suspension of lithium aluminum hydride (11.2 g) in ether (200 ml) at 0 °C. The mixture was stirred at room temperature for an additional 4 h. After cooling to 0 °C ethyl acetate (20 ml) and then water were carefully added. After 1 h a mixture of ice-water (150 ml) and concd sulfuric acid (45 ml) was added and the mixture was extracted with ether (600 ml). The ether extract was washed with saturated sodium hydrogen carbonate solution and saturated sodium chloride solution, and dried over magnesium sulfate. Evaporation of the solvent afforded 12.2 g (83%) of a colorless oil, $\nu_{max}^{CHCl_3}$ 3670, 3600—3200 cm^{-1}.

(b) Ditosylate (2c) of 2b: To a stirred solution of *p*-toluenesulfonyl chloride (38.2 g) in pyridine (70 ml) at 0 °C was added dropwise a solution of the diol **2b** (12.1 g) in pyridine (20 ml) during 20 min. After standing at 5 °C for 18 h the mixture was poured into ice-water (200 ml) and extracted with chloroform (500 ml). The chloroform extract was washed with concd hydrochloric acid (100 ml) and water, and then dried over sodium sulfate. Evaporation of the solvent gave 31.9 g (84%) of a colorless oil, $\nu_{max}^{CHCl_3}$ 1603, 1360, 1170 cm^{-1}. The crude ditosylate was immediately used for the next experiment without a further purification.

(c) 3-Ethyl-4-methylpimelonitrile (2d): A mixture of the ditosylate **2c** (31.9 g) and sodium cyanide (10.3 g) in dimethyl sulfoxide (350 ml) was heated with stirring at 100 °C for 2 h under an atmosphere of nitrogen. After cooling the mixture was poured into a solution of ammonium chloride (40 g) in water (400 ml) and extracted with dichloromethane (800 ml). The dichloromethane extract was washed throughly with water and dried over sodium sulfate. Removal of the solvent gave a reddish residue, which was distilled to furnish 8,7 g (76%) of **2d** as a pale pink oil: bp 132—155 °C/3 mmHg; $\nu_{max}^{CCl_4}$ 2260, 1427 cm^{-1}; *m/e* 165 (M^++1), 163 (M^+−1). Found: C, 73.22; H, 10.27; N, 17.06%. Calcd for $C_{10}H_{16}N_2$: C, 73.12; H, 9.82; N, 17.06%.

(d) 3-Ethyl-4-methylpimelic Acid (2e): A mixture of the nitrile **2d** (9.8 g) and potassium hydroxide (32 g) in ethylene glycol (225 ml)–water (25 ml) was heated with stirring at 110 °C for 16 h. After cooling the mixture was poured into ice-water (200 ml) and extracted with benzene (200 ml). The aqueous layer was acidified with concd hydrochloric acid (60 ml) and extracted throughly with chloroform (600 ml). The chloroform extract was washed with water and dried over sodium sulfate. Evaporation of the solvent left 7.3 g (62%) of **2e** as a pale yellow viscous oil, $\nu_{max}^{CHCl_3}$ 1713 cm^{-1}. which was used for the next experiment without a further purification.

(e) Dimethyl 2,6-Dibromo-3-ethyl-4-methylpimelate (2f): The dicarboxylic acid **2e** (8.7 g) was heated with thionyl chloride (20 ml) under reflux for 2 h and then bromine (5 ml) was added dropwise to the mixture at 90 °C during 1 h. After heating the mixture for 17 h at 90 °C, it was cooled, poured into methanol (60 ml), and kept for 1 h at room temperature. The mixture was then diluted with water and extracted with ethyl acetate (250 ml). The ethyl acetate extract was washed successively with saturated sodium hydrogen sulfite solution, saturated sodium hydrogencarbonate solution, water, and then saturated sodium chloride solution. The extract was dried over sodium sulfate and the solvent evaporated under reduced pressure. The reddish residue was distilled to give 12.3 g of a pale brown oil, bp 153—171 °C/4 mmHg, which was then chromatographed on silica gel (200 g). Elution with hexane–ether (6: 1) gave 9.4 g (38%) of **2f** as a pale yellow oil: $\nu_{max}^{CCl_4}$ 1753 cm^{-1}; *m/e* 359, 357, 355 (M^+−OMe), 309, 307 (M^+−Br). Found: C, 37.18; H, 4.29%. Calcd for $C_{12}H_{16}O_4Br_2$: C, 37.52; H, 4.20%.

Dimethyl cis- *and* trans-*3-ethyl-4-methyl-1-cyclopentene-1,2-dicarboxylates (3a and 3b).* To a stirred solution of sodium hydride (55% mineral oil dispersion; 445 mg) in *N,N*-dimethylformamide (8 ml) at 0 °C was added dropwise a solution of the dibromodiester **2f** (1.97 g) in *N,N*-dimethylformamide (8 ml). The mixture was stirred at 0 °C for 1 h and at room temperature for another 2 h. Aqueous 10% potassium hydroxide (10 ml) was then added and the mixture was stirred at 0 °C for 1 h and at room temperature for 14 h. The mixture was extracted with ether to remove the mineral oil and the ether extract was washed with water. The combined aqueous layer was acidified with 6M hydrochloric acid and extracted with ethyl acetate (200 ml). The ethyl acetate extract was washed throughly with water, saturated sodium chloride solution, and dried over sodium sulfate. Evaporation of the solvent gave a mixture of dicarboxylic acid, which was then

esterified with diazomethane and the product distilled to yield a mixture (966 mg) of **3a** and **3b**, bp 150 °C/6 mmHg. The unsaturated esters were roughly separated by column chromatography on 13% silver nitrate impregnated silica gel (18 g) with hexane–ethyl acetate (6: 1) as an eluent. Further purification by preparative GLC furnished 283 mg (25%) of **3a** and 392 mg (35%) of **3b** as colorless oil.

*Unsaturated 3,4-*cis*-Dimethyl Ester (3a)*: $\nu_{max}^{CCl_4}$ 1728, 1642 cm^{-1}; λ_{max}^{MeOH} 235 nm (ε 6300); *m/e* 226 (M$^+$), 195, 166; δ 0.91 (3H, t, 6.8), 1.01 (3H, d, 6.3), 1.5 (2H, m), 2.2—3.1 (4H, m), 3.65 (3H, s), 3.68 (3H, s). Found: C, 63.40; H, 8.14%. Calcd for $C_{12}H_{18}O_4$: C, 63.70; H, 8.02%.

*Unsaturated 3,4-*trans*-Dimethyl Ester (3b)*: $\nu_{max}^{CCl_4}$ 1727, 1646 cm^{-1}; λ_{max}^{MeOH} 235 nm (ε 5700); *m/e* 226 (M$^+$), 195, 166; δ 0.90 (3H, t, 6.8), 1.10 (3H, d, 6.9), 1.3—2.7 (6H, m), 3.64 (3H, s), 3.65 (3H, s). Found: C, 63.84; H, 7.93%. Calcd for $C_{12}H_{18}O_4$: C, 63.70; H, 8.02%.

*Ozonolysis of Unsaturated 3,4-*trans*-Dimethyl Ester (3b).* The ester **3b** (72 mg) in dichloromethane (4 ml) was saturated with ozone (5 min) at −70 °C. To it 10% sodium hydroxide (2 ml) and 35% hydrogen peroxide (2 ml) were added, and the mixture was vigorously stirred for 20 hr at room tem perature. After extraction with ether the aqueous layer was acidified with 6 M hydrochloric acid and extracted with ether (30 ml). The crude acid (49 mg) obtained was crystallized from ether–hexane, giving 21 mg (38%) of *threo*-2-ethyl-3-methylglutaric acid, mp 98—99 °C. The IR spectrum of this acid was identical with that of an authentic sample, mp 99—100 °C.[7]

*Catalytic Hydrogenation of Unsaturated 3,4-*cis*-Dimethyl Ester (3a): Preparation of Dimethyl Esters 1a, 1d, and 1f.* A solution of **3a** (123 mg) in acetic acid (5 ml) was hydrogenated for 40 h in the presence of platinum oxide (57 mg). The catalyst was filtered and the acetic acid was evaporated under reduced pressure. Although the oil obtained was free of the starting material **3a** (GLC), it contained isomeric unsaturated ester(s) (IR and mass spectra). Therefore, it was again hydrogenated for 12 h in acetic acid (4 ml) over platinum oxide (54 mg). The resulting mixture of saturated esters was separated by preparative GLC into three dimethyl esters, **1a**, **1d**, and **1e**.

Dimethyl c-*3-Ethyl*-c-*4-methyl*-r-*1*, t-*2-Cyclopentanedicarboxylate (1a)*: 8.8 mg (7%); $\nu_{max}^{CCl_4}$ 1742 cm^{-1}; *m/e* 228 (M$^+$), 168,109; δ 0.87 (3H, d, 6.8), 0.90 (3H, t, 7.0), 1.2—2.4 (6H, m), 2.81 (1H, t, 8.0), 3.11 (1H, ddd, 9.0, 8.0, 7.2), 3.61 (3H, s), 3.62 (3H, s). Found: C, 62.73, H, 9.20%. Calcd for $C_{12}H_{20}O_4$: C, 63.13; H, 8.83%.

Dimethyl c-*3-Ethyl*-c-*4-methyl-r-1*, c-*2-Cyclopentanedicarboxylate (1d)*: 40.9 mg (33%); $\nu_{max}^{CCl_4}$ 1746 cm^{-1}; *m/e* 228 (M$^+$), 168, 109; δ 0.93 (3H, d, 5.8), 0.95 (3H, t, 7.5), 1.4 (2H, m), 1.9—2.5 (4H, m), 2.82 (1H, m), 3.10 (1H, t, 6.6), 3.60 (6H, s).

*3,4-*trans*-Dimethyl Ester (1e)*: 16.2 mg (13%); $\nu_{max}^{CCl_4}$ 1742 cm^{-1}; *m/e* 228 (M$^+$), 168, 109; δ 1.02 (3H, d, 5.9), 1.02 (3H, t, 7.1), 1.0—2.5 (6H, m), 3.2 (2H, m), 3.62 (6H, s).

Base-catalyzed Equilibration of 1d Formation of Dimethyl Esters 1a, 1b, and 1c. A solution of **1d** (72 mg) in 1 M sodium methoxide–methanol (5 ml) was heated under reflux for 8 h. The methanol was removed under reduced pressure, the residue was acidified with 6 M hydrochloric acid and extracted with ethyl acetate (30 ml). The ethyl acetate extract was dried over sodium sulfate and concentrated to give an oil, from which three dimethyl esters, **1a**, **1b**, and **1c**, were isolated by preparative GLC.

r-*1*, t-*2*, c-*3*,c-*4-Dimethyl Ester (1a)*: 36.9 mg (51%).

r-*1*, t-*2*, t-*3*, t-*4-Dimethyl Ester (1b)*: 0.8 mg (1%) (described later).

Dimethyl t-*3-Ethyl*-t-*4-methyl*-r-*4*,c-*2-cyclopentanedicarboxylate (1c)*: 3.8 mg (5%): $\nu_{max}^{CCl_4}$ 1747 cm^{-1}; *m/e* 228 (M$^+$), 168, 109; δ 0.85 (3H, d, 7.0), 0.93 (3H, t, 7.2), 1.2—1.7 (3H, m), 2.0—2.5 (3H, m), 2.72 (1H, dd, 10.0, 8.4), 3.10 (1H, dt, 10.0, 8.0), 3.58 (3H, s), 3.59 (3H, s).

Acid Anhydrides 4a and 4b. Preparation of Dimethyl Esters 1c and 1d. The diester **1d** (40 mg) was heated with 1 M sodium methoxide–methanol (5 ml) under reflux for 12 h. Water (1 ml) was added and the mixture was heated under reflux for an additional 2 h. The methanol was evaporated, the aqueous solution was acidified with 6 M hydrochloric acid and extracted with ethyl acetate (50 ml). The ethyl acetate extract was dried over sodium sulfate and evaporated to dryness, yielding a mixture of dicarboxylic acids (33 mg). The oily mixture was dissolved in xylene (1 ml), to which acetic anhydride (1 ml) and *p*-toluenesulfonic acid (3 mg) were added. The mixture was heated at 140 °C for 14 h and then concentrated under reduced pressure. The residue was subjected to preparative GLC, giving two isomeric acid anhydrides **4a** and **4b**

t-*3-Ethyl*-t-*4-methyl*-r-*1*, c-*2-Cyclopentanedicarboxylic Anhydride (4a)*: 11.2 mg (35%); $\nu_{max}^{CCl_4}$ 1865, 1791 cm^{-1}; *m/e* 182 (M$^+$), 154, 140, 110, 81; δ 0.96 (3H, d, 5.6), 1.02 (3H, t, 6.0), 1.0—2.5 (6H, m), 2.9—3.6 (2H, m).

c-*3-Ethyl*-c-*4-methyl*-r-*1*, c-*2-Cyclopentanedicarboxylic Anhydride (4b)*: 2.5 mg (8%); $\nu_{max}^{CCl_4}$ 1865, 1790 cm^{-1}; *m/e* 182 (M$^+$), 154, 140, 110, 81; δ 0.82 (3H, d, 6.3), 1.05 (3H, t, 7.0), 1.1—2.6 (6H, m), 2.9—3.8 (3H, m).

The *r*-1, *c*-2, *t*-3, *t*-4-acid anhydride (**4a**; 9.7 mg) was treated with methanol followed by diazomethane. Purification by preparative GLC gave 8.4 mg (69%) of the corresponding dimethyl ester (**1c**). A similar treatment of the *r*-1, *c*-2, *c*-3, *c*-4-anhydride (**4b**) yielded the corresponding ester (**1d**).

Preparation of r-*1*, t-*2*, t-*3*, t-*4-Dimethyl Ester (1b).* A solution of *r*-1, *c*-2, *c*-3, *c*-4-acid anhydride (**4b**; 27.3 mg) in methanol (1 ml) was heated under reflux for 1 h. Evaporation of the methanol gave a mixture of monocarboxylic acids, $\nu_{max}^{CCl_4}$ 1744, 1706 cm^{-1}. It was heated with 1 M sodium methoxide–methanol (2 ml) under reflux for 2 h. The methanol was evaporated, the residue was acidified with dil hydrochloric acid, and extracted with ethyl acetate. The extract was dried over sodium sulfate and evaporated to dryness, leaving an oil, which was esterified with diazomethane. A mixture of the dimethyl esters **1a** and **1b** was formed, which was separated by preparative GLC, yielding 17.2 mg (50%) of *dimethyl* t-*3-ethyl*-t-*4-methyl*-r-*1*, t-*2-cyclopentanedicarboxylate (1b)* in 97% purity (contaminated by 3% of **1a**): $\nu_{max}^{CCl_4}$ 1742 cm^{-1}; *m/e* 228 (M$^+$), 168, 109; δ 0.89 (3H, t, 6.8), 0.92 (3H, d, 6.8), 1.3 (2H, m), 1.85 (2H, m), 2.2 (2H, m), 3.3 (2H, m), 3.64 (3H, s), 3.66 (3H, s). A mixture (3.4 mg) of **1a** and **1b** was also obtained.

Base-catalyzed Equilibration of 1e: Preparation of Dimethyl Ester 1f. The 3,4-*trans*-dimethyl ester **1e** (11.3 mg) was equilibrated in the same way as used for the equilibration of **1d**. Preparative GLC of the resulting mixture gave 5.3 mg (47%) of *dimethyl* c-*3-ethyl*-t-*4-methyl*-r-*1*, t-*2-cyclopentanedicarboxylate (1f)*: $\nu_{max}^{CCl_4}$ 1743 cm^{-1}; *m/e* 228 (M$^+$), 168, 109; δ 0.90 (3H, t, 6.8), 1.02 (3H, d, 6.0), 1.1—2.2 (6H, m), 2.5—3.3 (2H, m), 3.63 (3H, s), 3.64 (3H, s). A mixture (0.8 mg) of **1f** and other isomers was also obtained.

Studies of Peptide Antibiotics. XXXIV.[1] Syntheses of Tyrocidine A and Its Analogs Containing Glycine

Kouji OKAMOTO,* Kazuhiko NONAKA, and Nobuo IZUMIYA

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received July 15, 1976)

The synthesis of Tyrocidine A (TA), an antibiotic cyclic decapeptide, was achieved by a revised conventional method. Two analogs of TA, 6-glycine-TA and 7-glycine-TA, were synthesized by a similar method to investigate the contribution of L-phenylalanine[6] and D-phenylalanine[7] residues in TA to its antibacterial activity. The properties of synthetic TA were identical to natural TA. The antibacterial activities of the two analogs were weaker when compared with TA; the activity of 6-glycine-TA being weaker than 7-glycine-TA. The three cyclic peptides synthesized were subjected to droplet countercurrent chromatography (DCCC) and optical rotatory dispersion (ORD), and the elucidation of the difference in the activities between the two analogs was followed with DCCC and ORD.

Tyrocidine A (TA) is an antibiotic cyclic peptide isolated from *Bacillus brevis* and its structure has been proposed to be that of **18a** (Fig. 1). It is of interest to note that the pentapeptide sequence, L-Val-L-Orn-L-Leu-D-Phe-L-Pro, is found in gramicidin S (GS). In 1966, Ohno *et al.* synthesized a cyclic peptide corresponding to the sequence of TA by a conventional solution-phase method, and showed the synthetic peptide to be identical to natural TA.[2] Recently, we synthesized TA and its analogs by a solid-phase method.[3] As has been generally recognized for a solid-phase method, we observed that the procedure to synthesize the cyclic peptides, including TA, was easier compared with a solution-phase method; however the purity of the TA synthesized was inferior to that synthesized by the solution-phase method.[3] In the present study, therefore, we selected the solution-phase method for peptide synthesis.

	X	Y
TA (**18a**)	L-Phe	D-Phe
[Gly[6]]-TA (**18b**)	Gly	D-Phe
[Gly[7]]-TA (**18c**)	L-Phe	Gly

Fig. 1. Structure of TA and its analogs.

First we intended to synthesize pure TA through a revised route in a solution-phase method. In the previous paper,[2] Ohno *et al.* cyclized a decapeptide active intermediate, H-Phe[6]-D-Phe-Asn-Gln-Tyr-Val-Orn(Z)-Leu-D-Phe-Pro[5]-ONp,[4] as the key step. Recently, we carried out the cyclization reaction of a pentapeptide *via* several active intermediates and observed that the azide and *N*-hydroxysuccinimide intermediates were excellent ones in regards to high yield, experimental simplicity and absence of racemization.[5] By applying a mechanism of biosynthetic cyclization, Tanaka *et al.*[6] and Abe *et al.*[1] indicated that GS and its analogs could be obtained in excellent yields by the cyclization reaction of linear peptides. In *B. brevis*, TA is biosynthesized with the cyclization of a linear decapeptide (H-D-Phe[4]-Pro-Phe-D-Phe-Asn-Gln-Tyr-Val-Orn-Leu[3]-OH).[7] Considering the facts previously mentioned, a route of TA synthesis was chosen which would place a L-Leu[3] residue at the C-terminal and which would activate the carboxyl as an azide as shown in Fig. 2. As described later, the route was effective, giving pure TA in good yield.

Second, we intended to clarify the contribution of L-Phe[6] and D-Phe[7] residues in the TA molecule to its biological activity. For this purpose, we designed the following syntheses of two analogs, [Gly[6]]-TA and [Gly[7]]-TA (Fig. 1). The route for syntheses of these analogs was similar to that of TA synthesis shown in Fig. 2. The present paper reports the syntheses, and physicochemical and antibacterial properties of TA and its analogs.

For the syntheses of the three cyclic peptides (**18a—c**), a hexapeptide ester (**13**) was prepared by stepwise elongation from the carboxyl toward the amino end, and this same component (**13**) was used throughout the syntheses (Fig. 2). Boc-tetrapeptide-hydrazides

Table 1. Antibacterial activity of cyclic peptides (Minimum inhibitory concentration, μg/ml[a])

Compound	*Escherichia coli*	*Staphylcoccus aureus*	*Bacillus subtilis*	*Mycobacterium Takeo*
GS	>50 (>50)	5 (10)	5 (5)	>50 (>50)
Natural TA	>50 (>50)	20 (50)	10 (10)	>50 (>50)
Synthetic TA (**18a**)	>50 (>50)	20 (20)	10 (10)	>50 (>50)
[Gly[6]]-TA (**18b**)	>50 (>50)	>50 (>50)	50 (50)	>50 (>50)
[Gly[7]]-TA (**18c**)	>50 (>50)	50 (50)	20 (20)	>50 (>50)

a) The assays were carried out with a bouillon agar medium. Numbers in parentheses represent the concentration with a synthetic agar medium.

* Present address: Laboratory of Molecular Biophysics, University of Alabama, Birmingham, Alabama, U. S. A.

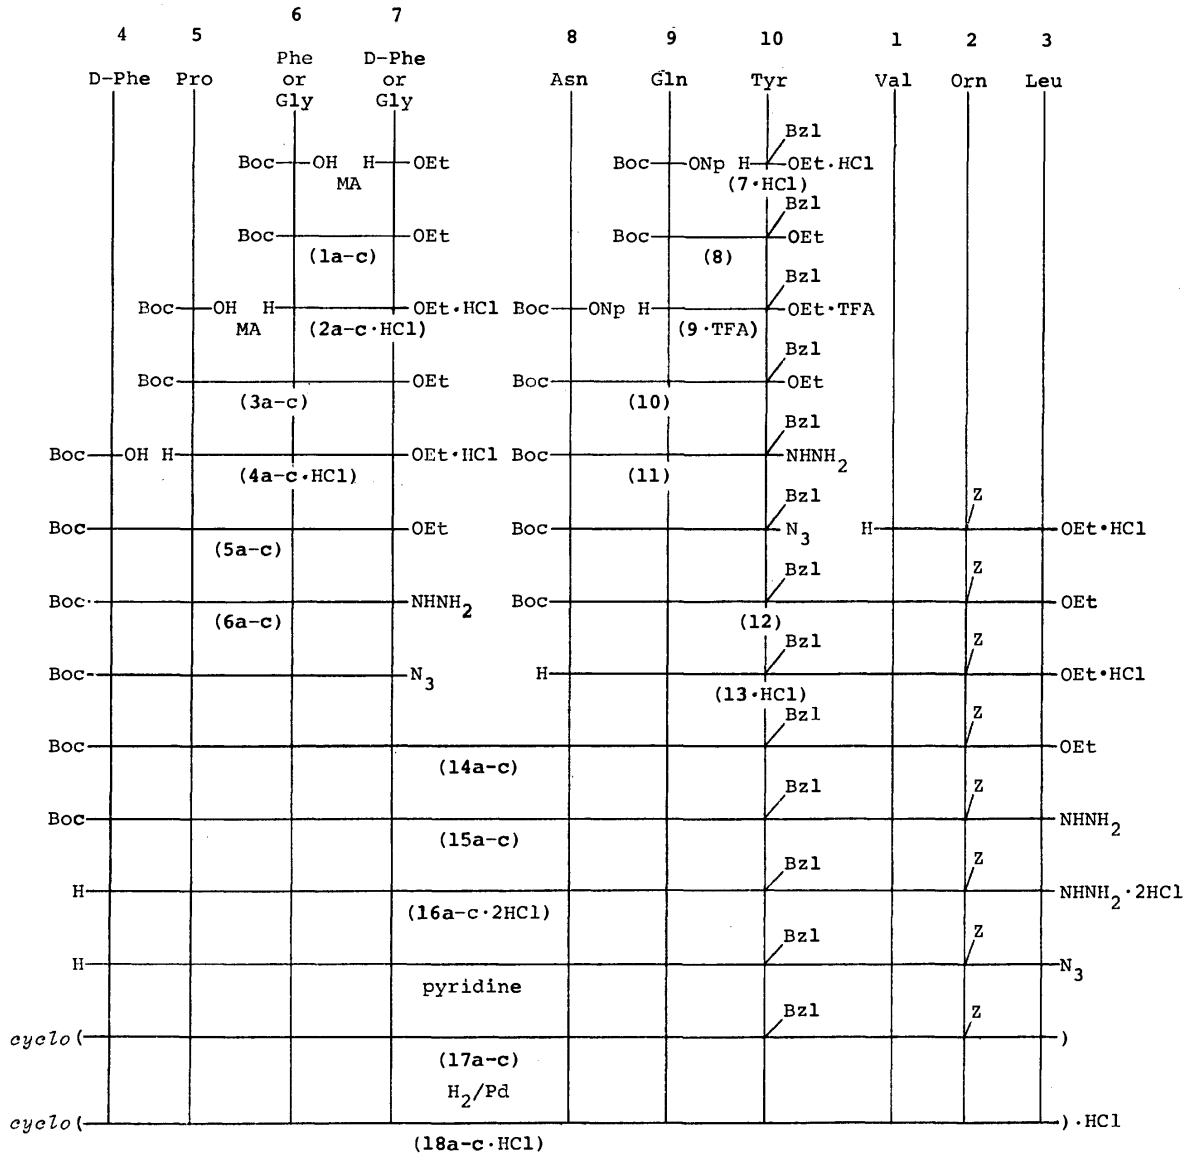

Fig. 2. Synthesis of TA and its analogs. **a**, -Phe^6-D-Phe^7-; **b**, -Gly^6-D-Phe^7-; **c**, -Phe^6-Gly^7-.

(**6a**—**c**) were also prepared by stepwise elongation. Boc-decapeptide ester (**14a**—**c**) was prepared by the coupling of **13** and each azide derived from **6a**—**c**; and a protected cyclic decapeptide (**17a**—**c**) was prepared by the cyclization reaction of each decapeptide azide derived from **16a**—**c**.

For the syntheses of TA (**18a**) and its analogs (**18b**—**c**), **17a**—**c** were subjected to hydrogenolysis, and the cyclic peptides were obtained as crystalline hydrochlorides (**18a**—**c**·HCl). In a previous paper,[8] we indicated that droplet countercurrent chromatography (DCCC) was very effective in the isolation of a desired peptide in a mixture of compounds of similar structures. Here, we applied DCCC for the detection of possible impurities in synthetic TA and the analogs. As shown in Fig. 3, each cyclic peptide (**18a**—**c**) gave a single peak without any additional peaks due to impurities.[9] The synthetic TA gave a single peak at the same position as natural TA. It is of interest to note that **18c** eluted faster than **18b** because **18c** is more hydrophobic in the organic phase in DCCC in spite of the fact that **18b** or **18c** is an analog which replaced only one Phe residue (position 6 or 7) with a Gly residue. The homogeneity of **18a**—**c** was further ascertained by paper and thin-layer chromatographies, paper electrophoresis, and elemental and amino acid analyses.

The antibacterial activities of **18a**—**c** toward several microorganisms were tested, the results shown in Table 1. It was proved that the specific activity of synthetic TA was identical to that of natural TA. Both analogs (**18b**—**c**) exhibited weak activity against *S. aureus* and *B. subtilis*; the results indicating that the aromatic side chain of Phe residue at position 6 and 7 was important for full activity, but not quite essential. At the beginning of this study, we expected that [Gly^7]-TA (**18c**) which the D-Phe^7 residue is replaced might possess weaker activity than [Gly^6]-TA (**18b**) which the L-Phe^6 is replaced because we assumed that the D-configuration at position 7 was more meaningful than L at position 6. Contrary to our expectation, the activity of **18c** was

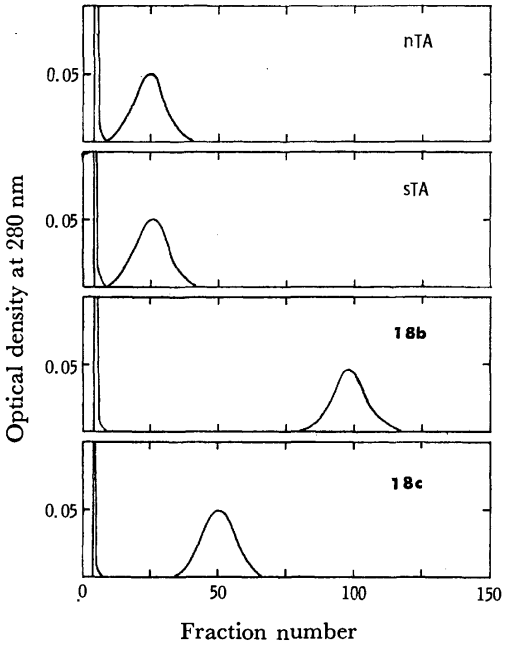

Fig. 3. Droplet countercurrent chromatography of the cyclic peptides. nTA, natural TA; sTA, synthetic TA (**18a**).

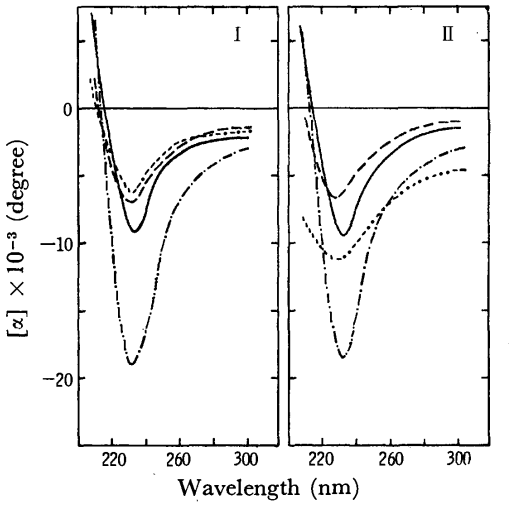

Fig. 4. ORD curves of the cyclic peptides. Solvent: I, 50% EtOH; II, 6 M urea in 50% EtOH. ——, nTA and sTA; – – –, [Gly⁶]-TA (**18b**); ------, [Gly⁷]-TA (**18c**); ·····, GS.

slightly greater than **18b** (Table 1). We can give no definite explanation for the difference of specific activities between **18b** and **18c** from the standpoint of molecular structure, but we can show by the DCCC results that hydrophobicity of **18c** is greater than **18b** and is close to TA (Fig. 3).

The ORD curves of the peptides in 50% ethanol are shown in Fig. 4-I. The curve of synthetic TA was identical with that of natural TA. The negative troughs of the two analogs were shallower than that of TA, but the position at 233 nm was similar to TA and GS. In a solution of 6 M urea, causing denaturation of some polypeptides, the position of the troughs of the two analogs shifted slightly to 229 nm while that of TA and GS remained constant. We showed that conformations of the analogs are different (Fig. 4-I) from TA and more flexible (Fig. 4-II) than TA, and consequently the biological activities of the two analogs are lower than TA.

Experimental

Melting points were uncorrected. TLC was performed on Merck silica gel G with the following solvent systems: R_f^1, BuOH–AcOH–pyridine–H_2O (15: 3: 10: 12, v/v); R_f^2, $CHCl_3$–MeOH (5: 1, v/v); R_f^3, BuOH–AcOH–H_2O (4: 1: 5, v/v). Paper chromatography was performed on Toyo Roshi No. 52 with the following solvent systems: R_f^4, same solvent as that used for R_f^1; R_f^5, BuOH–formic acid–H_2O (15: 3: 2, v/v). Optical rotations were determined with a Union high sensitivity polarimeter PM-71.

*Boc–Phe–D-Phe–OEt (**1a**).* To a chilled solution of Boc–Phe–OH (3.98 g, 15 mmol) and Et_3N (2.1 ml, 15 mmol) in THF (22 ml) was added isobutyl chloroformate (1.97 ml, 15 mmol) at −5 °C. After 10 min, a chilled solution of H–D-Phe–OEt·HCl (3.45 g, 15 mmol) and Et_3N (2.1 ml, 15 mmol) in $CHCl_3$ (22 ml) was added. The mixture was left to stand at room temperature overnight, evaporated *in vacuo*, and the oily residue was dissolved in AcOEt. The solution was washed successively with 4% $NaHCO_3$, 10% citric acid and water, dried (Na_2SO_4), and evaporated. The resulting solid was recrystallized from EtOH–ether–petroleum ether; yield, 4.82 g (73%); mp 91—93 °C; $[\alpha]_D^{25}$ +1.6° (*c* 1, MeOH); R_f^1 0.98, R_f^2 0.90.

Found: C, 68.34; H, 7.35; N, 6.35%. Calcd for $C_{25}H_{32}O_5N_2$: C, 68.16; H, 7.32; N, 6.36%.

*Boc–Gly–D-Phe–OEt (**1b**).* This was prepared from Boc–Gly–OH (3.50 g) and H–D-Phe–OEt·HCl (4.59 g) as described for the preparation of **1a**; yield of oil, 6.42 g (92%); R_f^1 0.89, R_f^2 0.69.

*Boc–Phe–Gly–OEt (**1c**).* This was prepared from Boc–Phe–OH (3.90 g) and H–Gly–OEt·HCl (2.05 g) as described for the preparation of **1a**; yield, 3.64 g (71%); mp 100—101 °C (lit, mp 89.5—90 °C,[10] 88—89.5 °C[11]); $[\alpha]_D^{25}$ −5.0° (*c* 2, EtOH) (lit, $[\alpha]_D^{25}$ −4.3°,[10] −4.2°[11]); R_f^1 0.86, R_f^2 0.62.

*H–Phe–D-Phe–OEt·HCl (**2a**·HCl).* Compound **1a** (4.41 g, 10 mmol) was dissolved in 0.1 M hydrogen chloride in formic acid (120 ml). After being left to stand at room temperature for 20 min, the solution was evaporated to dryness, and the resulting solid was collected by filtration with the aid of ether–petroleum ether. The product was recrystallized from EtOH–ether–petroleum ether; yield, 3.56 g (94%); mp 103—106 °C; $[\alpha]_D^{25}$ +14.0° (*c* 0.5, MeOH); R_f^1 0.87, R_f^2 0.86.

Found: C, 63.40; H, 6.72; N, 7.37%. Calcd for $C_{20}H_{25}O_3N_2Cl$: C, 63.74; H, 6.69; N, 7.43%.

*H–Gly–D-Phe–OEt·HCl (**2b**·HCl).* Compound **1b** (3.68 g, 10.5 mmol) was treated with 0.1 M hydrogen chloride in formic acid (126 ml) as described for the preparation of **2a**·HCl; yield, 2.60 g (86%); mp 131—134 °C; $[\alpha]_D^{25}$ −11.2° (*c* 1, MeOH); R_f^1 0.72, R_f^2 0.24.

Found: C, 54.25; H, 6.71; N, 9.62%. Calcd for $C_{13}H_{19}O_3N_2Cl$: C, 54.45; H, 6.68; N, 9.77%.

*H–Phe–Gly–OEt·HCl (**2c**·HCl).* This was prepared from **1c** (3.50 g) as described for the preparation of **2a**·HCl; yield of oil, 2.80 g (98%); R_f^1 0.75, R_f^2 0.25.

*Boc–Pro–Phe–D-Phe–OEt (**3a**).* Boc–Pro–OH (1.94 g, 9 mmol) and **2a**·HCl (3.39 g, 9 mmol) were coupled by the mixed anhydride method as described for the preparation of **1a**. The product was recrystallized from AcOEt–ether–petro-

leum ether; yield, 2.95 g (61%); mp 103—105 °C; $[\alpha]_D^{25}$ −48.0° (*c* 1, MeOH): R_f^1 0.96, R_f^2 0.81.

Found: C, 66.83; H, 7.40; N, 7.86%. Calcd for $C_{30}H_{39}O_6N_3$: C, 67.02; H, 7.31; N, 7.82%.

*Boc-Pro-Gly-D-Phe-OEt (**3b**).* This was prepared from Boc-Pro-OH (1.72 g) and **2b**·HCl (2.29 g) as described above; yield, 2.81 g (78%); mp 117—119 °C; $[\alpha]_D^{25}$ −45.0° (*c* 1, MeOH); R_f^1 0.88, R_f^2 0.76.

Found: C, 62.12; H, 7.43; N, 9.42%. Calcd for $C_{23}H_{33}O_6N_3$: C, 61.72; H, 7.43; N, 9.39%.

*Boc-Pro-Phe-Gly-OEt (**3c**).* This was prepared from Boc-Pro-OH (2.0 g) and **2c**·HCl (2.66 g); yield, 2.88 g (69%); mp 109—111 °C; $[\alpha]_D^{25}$ −54.4° (*c* 0.25, MeOH); R_f^1 0.82, R_f^2 0.50.

Found: C, 61.42; H, 7.22; N, 9.32%. Calcd for $C_{23}H_{33}O_6N_3$: C, 61.72; H, 7.43; N, 9.39%.

*H-Pro-Phe-D-Phe-OEt·HCl (**4a**·HCl).* Compound **3a** (2.16 g, 4.02 mmol) was dissolved in 3.5 M hydrogen chloride in dioxane (34.3 ml). After being left to stand at room temperature for 2 h, the solution was evaporated, and the resulting hygroscopic solid was collected by filtration with the aid of ether-petroleum ether. The product was recrystallized from EtOH-ether-petroleum ether; yield, 1.37 g (72%); mp 93 °C; $[\alpha]_D^{25}$ −23.0° (*c* 0.5, MeOH); R_f^1 0.72, R_f^2 0.52.

Found: C, 63.74; H, 7.07; N, 8.56%. Calcd for $C_{25}H_{32}O_4N_3Cl$: C, 63.35; H, 6.81; N, 8.87%.

*H-Pro-Gly-D-Phe-OEt·HCl (**4b**·HCl).* Compound **3b** (2.51 g, 5.6 mmol) was treated with 3.5 M hydrogen chloride in dioxane (48.0 ml) as described above; yield of oil, 2.0 g (93%); R_f^1 0.78, R_f^2 0.30.

*H-Pro-Phe-Gly-OEt·HCl (**4c**·HCl).* This was prepared from **3c** (2.73 g) as described above; yield of oil, 1.96 g (84%); R_f^1 0.79, R_f^2 0.52.

*Boc-D-Phe-Pro-Phe-D-Phe-OEt (**5a**).* Boc-D-Phe-OH (0.76 g, 2.86 mmol) and **4a**·HCl (1.36 g, 2.86 mmol) were coupled by the mixed anhydride method as described for the preparation of **1a**; yield of oil, 1.81 g (92%); R_f^1 0.94, R_f^2 0.70.

*Boc-D-Phe-Pro-Gly-D-Phe-OEt (**5b**).* This was prepared from Boc-D-Phe-OH (1.38 g) and **4b**·HCl (2.0 g) as described above. The product was recrystallized from AcOEt-ether-petroleum ether; yield, 2.08 g (67%); mp 128—130 °C; $[\alpha]_D^{25}$ −36.2° (*c* 1, MeOH); R_f^1 0.82, R_f^2 0.53.

Found: C, 63.86; H, 7.02; N, 9.39%. Calcd for $C_{32}H_{42}O_7N_4 \cdot 1/2\ H_2O$: C, 63.66; H, 7.18; N, 9.28%.

*Boc-D-Phe-Pro-Phe-Gly-OEt (**5c**).* This was prepared from Boc-D-Phe-OH (1.35 g) and **4c**·HCl (1.96 g) as described above; yield, 2.28 g (75%); mp 139—141 °C; $[\alpha]_D^{25}$ −72.6° (*c* 1, MeOH); R_f^1 0.86, R_f^2 0.66.

Found: C, 63.29; H, 7.29; N, 9.35%. Calcd for $C_{32}H_{42}O_7\ N_4 \cdot 1/2H_2O$: C, 63.66; H, 7.18; N, 9.28%.

*Boc-D-Phe-Pro-Phe-D-Phe-NHNH$_2$ (**6a**).* A solution of **5a** (0.685 g, 1 mmol) and hydrazine hydrate (2.9 ml, 60 mmol) in MeOH (12 ml) was allowed to stand at 36 °C for 12 h. The solution was evaporated, water was added, and the resulting solid was collected. The product was recrystallized from MeOH-water; yield, 0.302 g (45%); mp 117—120 °C; $[\alpha]_D^{25}$ −67.0° (*c* 0.2, MeOH); R_f^1 0.89, R_f^2 0.83.

Found: C, 64.20; H, 6.85; N, 11.93%. Calcd for $C_{37}H_{46}O_6N_6 \cdot H_2O$: C, 64.51; H, 7.02; N, 12.20%.

*Boc-D-Phe-Pro-Gly-D-Phe-NHNH$_2$ (**6b**).* Compound **5b** (0.357 g) was treated with hydrazine hydrate (0.58 ml) in MeOH (5 ml) as described above. The solution was evaporated, and the residue was dissolved in AcOEt. The solution was washed with a small volume of water, dried (Na_2SO_4), and evaporated. The residual oil was crystallized by the addition of ether-petroleum ether; yield, 0.264 g (76%); mp 100—102 °C; $[\alpha]_D^{25}$ −6.0° (*c* 1, MeOH); R_f^1 0.87, R_f^2 0.74.

Found: C, 60.39; H, 6.97; N, 14.32%. Calcd for $C_{30}H_{40}O_6N_6 \cdot H_2O$: C, 60.18; H, 7.07; N, 14.04%.

*Boc-D-Phe-Pro-Phe-Gly-NHNH$_2$ (**6c**).* This was prepared from **5c** (0.357 g) and hydrazine hydrate (0.58 ml) as described above; yield, 0.284 g (82%); mp 110—113 °C; $[\alpha]_D^{25}$ −73.0° (*c* 1, MeOH); R_f^1 0.94, R_f^2 0.69.

Found: C, 60.01; H, 6.92; N, 13.89%. Calcd for $C_{30}H_{40}O_6N_6 \cdot H_2O$: C, 60.18; H, 7.07; N, 14.04%.

*H-Tyr(Bzl)-OEt·HCl (**7**·HCl).* To a solution of H-Tyr(Bzl)-OH[12] (2.71 g, 10 mmol) in EtOH (20 ml) was added $SOCl_2$ (0.872 ml, 12 mmol). The reaction mixture was stirred at 40 °C for 0.5 h and at room temperature overnight, and evaporated. The resulting oil was crystallized by the addition of ether-petroleum ether; yield, 2.34 g (70%); mp 190—192 °C; $[\alpha]_D^{25}$ +7.1° (*c* 1, MeOH); R_f^1 0.75, R_f^2 0.74.

Found: C, 63.95; H, 6.68; N, 4.17%. Calcd for $C_{18}H_{22}O_3NCl$: C, 64.37; H, 6.60; N, 4.17%.

*Boc-Gln-Tyr(Bzl)-OEt (**8**).* To a solution of **7**·HCl (2.02 g, 6 mmol) and Et_3N (0.924 ml, 6.6 mmol) in DMF (70 ml) were added Boc-Gln-ONp (2.20 g, 6 mmol) and 1-hydroxybenzotriazole (0.081 g, 0.6 mmol). After being left to stand at room temperature for 12 h, several drops of 1-(2-aminoethyl)piperazine[13] were added. The solution was diluted with water (2 l), and the resulting solid was collected, washed with 10% citric acid, 4% $NaHCO_3$, and water; yield, 2.82 g (89%); mp 138—141 °C; $[\alpha]_D^{25}$ −3.9° (*c* 1, DMF); R_f^1 0.96, R_f^2 0.80.

Found: C, 63.56; H, 7.16; N, 7.85%. Calcd for $C_{28}H_{37}O_7N_3$: C, 63.74; H, 7.07; N, 7.97%.

*H-Gln-Tyr(Bzl)-OEt·TFA (**9**·TFA).* A solution of **8** (1.58 g, 3 mmol) in TFA (30 ml) was allowed to stand at room temperature for 10 min and evaporated. The resulting oil was solidified by the addition of ether-petroleum ether. The product was recrystallized from EtOH-ether-petroleum ether; yield, 1.48 g (91%); mp 112—116 °C; $[\alpha]_D^{25}$ +14.6° (*c* 1, MeOH), R_f^1 0.80, R_f^2 0.57.

Found: C, 55.37; H, 5.75; N, 7.52%. Calcd for $C_{25}H_{30}O_7N_3F_3$: C, 55.45; H, 5.58; N, 7.76%.

*Boc-Asn-Gln-Tyr(Bzl)-OEt (**10**).* Boc-Asn-ONp (0.897 g) was coupled with **9**·TFA (1.38 g), Et_3N (0.391 ml), and 1-hydroxybenzotriazole (0.034 g) as described for the preparation of **8**. The product was recrystallized fromDMF-ether; yield, 1.31 g (80%); mp 240—241 °C (dec); $[\alpha]_D^{25}$ −22.0° (*c* 0.6, DMF); R_f^1 0.91, R_f^2 0.72.

Found: C, 59.70; H, 6.88; N, 10.91%. Calcd for $C_{32}H_{43}O_9N_5$: C, 59.89; H, 6.75; N, 10.91%.

*Boc-Asn-Gln-Tyr(Bzl)-NHNH$_2$ (**11**).* A solution of **10** (1.28 g, 3 mmol) and hydrazine hydrate (1.94 ml, 40 mmol) in DMF (40 ml) was allowed to stand at room temperature overnight. The solution was evaporated, water (1000 ml) was added, and the resulting solid was collected; yield, 1.09 g (87%); mp 215—216 °C (dec); $[\alpha]_D^{25}$ −41.0° (*c* 1, DMF); R_f^1 0.72, R_f^2 0.16.

Found: C, 56.54; H, 6.70; N, 15.35%. Calcd for $C_{30}H_{41}O_8N_7 \cdot 1/2H_2O$: C, 56.59; H, 6.65; N, 15.40%.

*Boc-Asn-Gln-Tyr(Bzl)-Val-Orn(Z)-Leu-OEt (**12**).* To a solution of **11** (1.06 g, 1.69 mmol) in DMF (15 ml) was added 3.5 M hydrogen chloride in dioxane (1.49 ml) and isopentyl nitrite[14] (0.262 ml, 1.86 mmol) at −50 °C. After being left to stand at −20 °C for 10 min, the solution was cooled to −60 °C and neutralized with Et_3N (0.731 ml, 5.22 mmol). To this solution was added a chilled solution of H-Val-Orn(Z)-Leu-OEt·HCl (1.10 g, 2.02 mmol)[1] and Et_3N (0.283 ml, 2.02 mmol) in DMF (8 ml). The reaction mixture was allowed to stir at 0 °C for 3 days and evaporated. After the addition of 0.02 M citric acid (300 ml), the solid was

collected and washed with water; yield, 1.59 g (85%); mp 279—281 °C (dec); $[\alpha]_D^{25}$ −41.0° (*c* 0.2, DMF); R_f^1 0.84, R_f^2 0.67.

Found: C, 60.37; H, 7.30; N, 11.28%. Calcd for $C_{56}H_{79}O_{14}N_9 \cdot 1/2H_2O$: C, 60.52; H, 7.26; N, 11.34%.

H-Asn-Gln-Tyr(Bzl)-Val-Orn(Z)-Leu-OEt·HCl (**13**·HCl). Compound **12** (1.70 g, 1.54 mmol) was treated with 0.1 M hydrogen chloride in formic acid (23 ml) as described for the preparation of **2a**·HCl; yield, 1.48 g (92%); mp 265—267 °C (dec); $[\alpha]_D^{25}$ −29.0° (*c* 0.2, DMF); R_f^1 0.81, R_f^2 0.34.

Found: C, 58.01; H, 6.95; N, 11.78%. Calcd for $C_{51}H_{72}O_{12}N_9Cl \cdot H_2O$: C, 57.97; H, 7.06; N, 11.93%.

Boc-D-Phe-Pro-Phe-D-Phe-Asn-Gln-Tyr(Bzl)-Val-Orn(Z)-Leu-OEt (**14a**). Compound **6a** (0.257 g, 0.383 mmol) and **13**·HCl (0.437 g, 0.421 mmol) were coupled by the azide method as described for the preparation of **12**; yield, 0.522 g (83%); mp 243—245 °C (dec); $[\alpha]_D^{25}$ −29.0° (*c* 0.5, AcOH); R_f^1 0.98, R_f^2 0.58.

Found: C, 61.33; H, 6.80; N, 10.54%. Calcd for $C_{88}H_{113}O_{18}N_{13} \cdot 4H_2O$: C, 61.70; H, 7.12; N, 10.63%.

Boc-D-Phe-Pro-Gly-D-Phe-Asn-Gln-Tyr(Bzl)-Val-Orn(Z)-Leu-OEt (**14b**). This was prepared from **6b** (0.222 g) and **13**·HCl (0.418 g) as described above; yield, 0.482 g (81%); mp 253—255 °C (dec); $[\alpha]_D^{25}$ −27.0° (*c* 1, AcOH); R_f^1 0.98, R_f^2 0.63.

Found: C, 60.26; H, 6.92; N, 11.36%. Calcd for $C_{81}H_{107}O_{18}N_{13} \cdot 3H_2O$: C, 60.62; H, 7.10; N, 11.35%.

Boc-D-Phe-Pro-Phe-Gly-Asn-Gln-Tyr(Bzl)-Val-Orn(Z)-Leu-OEt (**14c**). This was prepared from **6c** (0.222 g) and **13**·HCl (0.418 g); yield, 0.505 g (85%); mp 252—254 °C (dec); $[\alpha]_D^{25}$ −43.0° (*c* 0.5, AcOH); R_f^1 0.98, R_f^2 0.64.

Found: C, 61.26; H, 7.01; N, 11.51%. Calcd for $C_{81}H_{107}O_{18}N_{13} \cdot 2H_2O$: C, 61.31; H, 7.05; N, 11.47%.

Boc-D-Phe-Pro-Phe-D-Phe-Asn-Gln-Tyr(Bzl)-Val-Orn(Z)-Leu-NHNH$_2$ (**15a**). Compound **14a** (0.523 g, 0.319 mmol) was treated with hydrazine hydrate (1.55 ml, 31.9 mmol) as described for the preparation of **11**; yield, 0.42 g (81%); mp 252—254 °C (dec); $[\alpha]_D^{25}$ −28.0° (*c* 0.5, AcOH); R_f^1 0.91, R_f^2 0.41.

Found: C, 60.51; H, 6.81; N, 12.22%. Calcd for $C_{86}H_{111}O_{17}N_{15} \cdot 4H_2O$: C, 60.79; H, 7.06; N, 12.37%.

Boc-D-Phe-Pro-Gly-D-Phe-Asn-Gln-Tyr(Bzl)-Val-Orn(Z)-Leu-NHNH$_2$ (**15b**). This was prepared from **14b** (0.183 g) and hydrazine hydrate (0.572 ml) as described above; yield, 0.162 g (90%); mp 254—255 °C (dec); $[\alpha]_D^{25}$ −27.0° (*c* 1, AcOH); R_f^1 0.90, R_f^2 0.30.

Found: C, 59.41; H, 6.93; N, 13.55%. Calcd for $C_{79}H_{105}O_{17}N_{15} \cdot 3H_2O$: C, 59.65; H, 7.03; N, 13.21%.

Boc-D-Phe-Pro-Phe-Gly-Asn-Gln-Tyr(Bzl)-Val-Orn(Z)-Leu-NHNH$_2$ (**15c**). This was prepared from **14c** (0.476 g) and hydrazine hydrate (1.49 ml); yield, 0.437 g (93%); mp 254—256 °C (dec); $[\alpha]_D^{25}$ −29.0° (*c* 0.5, AcOH); R_f^1 0.92, R_f^2 0.36.

Found: C, 60.02; H, 6.86; N, 13.38%. Calcd for $C_{79}H_{105}O_{17}N_{15} \cdot 2H_2O$: C, 60.33; H, 6.99; N, 13.36%.

H-D-Phe-Pro-Phe-D-Phe-Asn-Gln-Tyr(Bzl)-Val-Orn(Z)-Leu-NHNH$_2$·2HCl (**16a**·2HCl). Compound **15a** (0.163 g, 0.1 mmol) was treated with 0.1 M hydrogen chloride in formic acid (1.5 ml) as desctibed for the preparation of **2a**·HCl; yield, 0.147 g (92%); mp 235—237 °C (dec); $[\alpha]_D^{25}$ −35.0° (*c* 0.5, AcOH); R_f^1 0.85, R_f^2 0.38.

Found: C, 59.81; H, 6.75; N, 12.83%. Calcd for $C_{81}H_{105}O_{15}N_{15}Cl_2 \cdot H_2O$: C, 60.14; H, 6.67; N, 12.99%.

H-D-Phe-Pro-Gly-D-Phe-Asn-Gln-Tyr(Bzl)-Val-Orn(Z)-Leu-NHNH$_2$·2HCl (**16b**·2HCl). This was prepared from **15b** (0.141 g) as described above; yield, 0.129 g (93%); mp 237—240 °C (dec); $[\alpha]_D^{25}$ −15.0° (*c* 0.2, AcOH); R_f^1 0.83, R_f^2 0.38.

Found: C, 57.99; H, 6.72; N, 13.37%. Calcd for $C_{74}H_{99}O_{15}N_{15}Cl_2 \cdot H_2O$: C, 58.18; H, 6.66; N, 13.75%.

H-D-Phe-Pro-Phe-Gly-Asn-Gln-Tyr(Bzl)-Val-Orn(Z)-Leu-NHNH$_2$·2HCl (**16c**·2HCl). This was prepared from **15c** (0.17 g) as described above; yield, 0.148 g (88%); mp 238—241 °C (dec); $[\alpha]_D^{25}$ −63.0° (*c* 0.5, AcOH); R_f^1 0.87, R_f^2 0.44.

Found: C, 58.12; H, 6.65; N, 13.40%. Calcd for $C_{74}H_{99}O_{15}N_{15}Cl_2 \cdot H_2O$: C, 58.18; H, 6.66; N, 13.75%.

cyclo(-D-Phe-Pro-Phe-D-Phe-Asn-Gln-Tyr(Bzl)-Val-Orn(Z)-Leu-) (**17a**). Compound **16a**·2HCl (146 mg, 0.091 mmol) was dissolved in a mixture of DMF (4 ml), AcOH (0.2 ml) and 1 M HCl (0.19 ml). To the solution at −10 °C was added 1 M $NaNO_2$ (0.096 ml). After being left to stand at −10 °C for 15 min, the solution was added into pyridine (100 ml) at −5 °C. The solution was allowed to stir at −5 °C for 3 h and at 0 °C for 45 h, and evaporated. The residue was dissolved in a mixture (100 ml) of MeOH–dioxane–water (5: 3: 1), an insoluble material being removed by filtration. The filtrate was passed successively through columns (1.5×12 cm) of Amberlite IRC-50 (H^+ form) and Amberlite IR-45 (OH^- form). The effluent (250 ml) was evaporated, and the resulting solid was collected by filtration with the aid of water; yield, 68 mg (50%); mp 245—248 °C (dec); $[\alpha]_D^{25}$ −95° (*c* 0.1, DMF); R_f^1 0.98, R_f^2 0.70, R_f^3 0.74.

Found: C, 62.57; H, 6.78; N, 12.01%; mol wt, 1493.[15] Calcd for $C_{81}H_{99}O_{15}N_{13} \cdot 3H_2O$: C, 62.81; H, 6.83; N, 11.76%; mol wt, 1549.

cyclo(-D-Phe-Pro-Gly-D-Phe-Asn-Gln-Tyr(Bzl)-Val-Orn(Z)-Leu-) (**17b**). This was prepared from **16b**·2HCl (133 mg) as described above; yield, 65 mg (52%); mp 236—239 °C (dec); $[\alpha]_D^{25}$ −83° (*c* 0.1, DMF); R_f^1 0.95, R_f^2 0.64, R_f^3 0.74.

Found: C, 60.90; H, 6.92; N, 12.32%; mol wt, 1475. Calcd for $C_{74}H_{93}O_{15}N_{13} \cdot 3H_2O$: C, 60.93; H, 6.84; N, 12.48%; mol wt, 1459.

cyclo(-D-Phe-Pro-Phe-Gly-Asn-Gln-Tyr(Bzl)-Val-Orn-(Z)-Leu-) (**17c**). This was prepared from **16c**·2HCl (156 mg); yield, 83 mg (57%); mp 232—235 °C (dec); $[\alpha]_D^{25}$ −85° (*c* 0.1, DMF); R_f^1 0.98, R_f^2 0.64, R_f^3 0.79.

Found: C, 61.23; H, 6.69; N, 12.50%; mol wt, 1445. Calcd for $C_{74}H_{93}O_{15}N_{13} \cdot 3H_2O$: C, 60.93; H, 6.84; N, 12.48%; mol wt, 1459.

cyclo(-D-Phe-Pro-Phe-D-Phe-Asn-Gln-Tyr-Val-Orn-Leu-)·HCl (**18a**·HCl). A solution of **17a** (60 mg, 0.04 mmol) in 0.43 M hydrogen chloride (0.14 ml) in MeOH was hydrogenated in the presence of Pd black. After 20 h, the filtrate was evaporated, and the resulting crystals were collected by filtration with the aid of ether; yield of air-dried product (**18a**·HCl·7H_2O), 48 mg (92%); mp 240—243 °C (dec); $[\alpha]_D^{25}$ −111° (*c* 0.14, 50% EtOH) (lit. $[\alpha]_D^{25}$ −111°,[16] −112°[8]); R_f^1 0.78, R_f^2 0.03, R_f^4 0.98, R_f^5 0.87. Amino acid ratios in acid hydrolysate; Asp 1.02, Glu 1.00, Pro 0.93, Val 0.99, Leu 1.02, Tyr 0.92, Phe 3.19, Orn 0.96.

Found: C, 55.78; H, 6.79; N, 12.25%. Calcd for $C_{66}H_{87}O_{13}N_{13} \cdot HCl \cdot 7H_2O$: C, 55.32; H, 7.17; N, 12.71%.

cyclo(-D-Phe-Pro-Gly-D-Phe-Asn-Gln-Tyr-Val-Orn-Leu-)·HCl (**18b**·HCl). This was prepared from **17b** (56 mg) as described above; yield of air-dried product (**18b**·HCl·8H_2O), 46 mg (94%); mp 232—234 °C (dec); $[\alpha]_D^{25}$ −95° (*c* 0.17, 50% EtOH); R_f^1 0.77, R_f^2 0.03, R_f^4 0.96, R_f^5 0.85. Amino acid ratios in acid hydrolysate; Asp 1.00, Glu 1.00, Pro 0.97, Gly 1.03, Val 1.05, Leu 1.04, Tyr 1.04, Phe 1.93, Orn 1.02.

Found: C, 51.74; H, 6.96; N, 13.74%. Calcd for $C_{59}H_{81}$-

$O_{13}N_{13}\cdot HCl\cdot 8H_2O$: C, 52.07; H, 7.26; N, 13.38%.

*cyclo(-D-Phe-Pro-Phe-Gly-Asn-Gln-Tyr-Val-Orn-Leu-)·HCl (**18c**·HCl).* This was prepared from **17c** (70 mg); yield of air-dried product (**18c**·HCl·$7H_2O$), 56 mg (92%); mp 230—232 °C (dec); $[\alpha]_D^{25}$ −98° (*c* 0.14, 50% EtOH); R_f^1 0.97, R_f^2 0.03, R_f^4 0.97, R_f^5 0.85. Amino acid ratios in acid hydrolysate; Asp 1.03, Glu 1.00, Pro 1.06, Gly 1.06, Val 1.11, Leu 1.09, Tyr 1.00, Phe 1.93, Orn 1.06.

Found: C, 52.31; H, 6.93; N, 13.95%. Calcd for $C_{59}H_{81}O_{13}N_{13}\cdot HCl\cdot 7H_2O$: C, 52.76; H, 7.21; N, 13.56%.

Droplet Countercurrent Chromatography. An apparatus made by Seikagaku Kogyo Co., Tokyo, was used. It consists of 300 columns of glass tubing (0.24×60 cm) connected by teflon tubing (I. D., 0.05 cm). The solvent used was $CHCl_3$–MeOH–0.1 M HCl (19: 19: 12, v/v).[17] The upper phase of the solvent was loaded into 150 glass columns as the stationary phase. The 5 mg samples each of **18a—c** and natural TA were dissolved in the lower phase (1 ml) and placed at the top of first column. The lower phase, as the moving phase, was pumped with nitrogen pressure through the top of the first column at a flow rate of 15 ml/h. Fractions (4 g) from the last column were collected and their absorbances were determined at 280 nm. The results are shown in Fig. 3.

Paper Electrophoresis. This was carried out with Toyo Roshi No. 52 and a solvent system of formic acid–ACOH–MeOH–water (1: 3: 6: 10, v/v; pH 1.8) for 2.5 h at 500 v/30 cm. Fig. 5. showed that each of **18a—c** revealed a single spot.

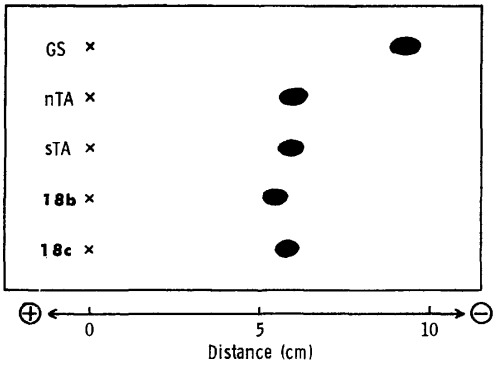

Fig. 5. Paper electrophoresis of the cyclic peptides.

Microbiological Assays,[18] *ORD Measurements.* These were carried out as described in a previous paper,[1] the results being shown in Table 1 and Fig. 4.

The authors wish to express their thanks to Dr. T. Kato, Dr. M. Ohno, Dr. M. Waki, and Mr. K. Sato of this laboratory for their helpful discussions and assistances.

17) Natural TA used in this study was prepared following Ref. 8. In Ref. 8, we reported the use of a solvent system, benzene–$CHCl_3$–MeOH–0.1 M HCl=11: 5: 10: 4, for the separation of gramicidin A and tyrocidine family, and recognized a mistake of the description after the publication of Ref. 8. We wish to correct that the solvent system used was benzene–$CHCl_3$–MeOH–0.1 M HCl=5: 10: 11: 4.

18) We are indebted to the staff of Takeda Chemical Industries, Ltd. for the assay.

The Reaction of Nucleophilic Reagents at the β-Position of 3-Bromo-4-nitropyridine *N*-Oxides

Eizo MATSUMURA and Masahiro ARIGA

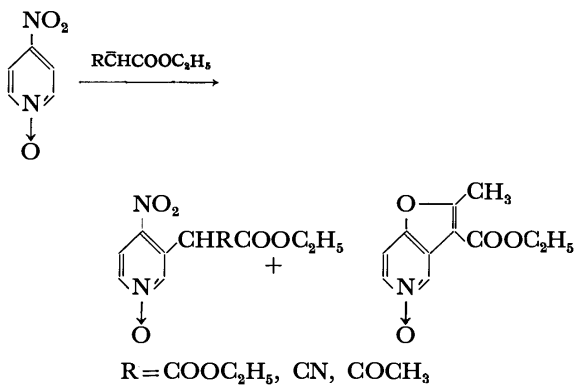
Department of Chemistry, Osaka Kyoiku University, Tennoji-ku Osaka 543

(Received July 16, 1976)

The reactions of 3-bromo-4-nitro-2-R_1-6-R_2-5-X-pyridine *N*-oxides (**1a**: R_1=H, R_2=Me, X=H; **1b**: R_1=R_2=Me, X=H; **1c**: R_1=R_2=H, X=Br) with diethyl sodiomalonate, ethyl sodiocyanoacetate, and ethyl sodioacetoacetate have been carried out. The treatment of **1a**, **1b**, and **1c** with diethyl sodiomalonate gives 3-[bis(ethoxycarbonyl)methyl]-4-nitro-2-R_1-6-R_2-5-X-pyridine *N*-oxides (**2a**, **2b**, and **2c**) and 4-[bis(ethoxycarbonyl)methyl]-3,5-dibromopyridine *N*-oxide (**3c**). With ethyl sodiocyanoacetate, 3-[cyano(ethoxycarbonyl)methyl]-4-nitro-2-R_1-6-R_2-pyridine *N*-oxides (**4a** and **4b**) and 4-[cyano(ethoxycarbonyl)methyl]-3,5-dibromopyridine *N*-oxide (**5c**) are obtained. With ethyl sodioacetoacetate, **1a** and **1c** give 3-[acetyl(ethoxycarbonyl)methyl]-6-methyl-4-nitropyridine *N*-oxide (**6a**) and/or 3-ethoxycarbonyl-2-methyl-6-R_1-7-X-furo[3,2-*c*]pyridine *N*-oxides (**7a** and **7c**), but **1b** is unaffected by ethyl sodioacetoacetate under the given conditions. The electronic and steric effects of methyl and bromo groups for the reactions are discussed.

The nucleophilic substitution reactions of pyridine homologues and their *N*-oxides have widely been studied for a long time,[1-4] but these studies dealt almost exclusively with the α or γ-position of the ring, with only a few exceptions.[5-7]

In the previous paper[8] of this series, the authors reported the nucleophilic substitution at the β-position of the pyridine ring. Thus, 3-bromo-4-nitropyridine *N*-oxide reacted with diethyl sodiomalonate, ethyl sodiocyanoacetate, and ethyl sodioacetoacetate to yield 3-[bis(ethoxycarbonyl)methyl]-4-nitropyridine *N*-oxide, 3-[cyano(ethoxycarbonyl)methyl]-4-nitropyridine *N*-oxide, and 3-[acetyl(ethoxycarbonyl)methyl]-4-nitropyridine *N*-oxide, respectively, and with ethyl sodioacetoacetate, when treated at a higher temperature, to yield 3-ethoxycarbonyl-2-methylfuro[3,2-*c*]pyridine *N*-oxide; the ring closure reaction was assumed to occur at the γ-position of the pyridine ring by the intramolecular nucleophilic attack of the mesomeric *O*-anion, which was produced by the loss of a proton from the substituted 3-methyl group of the intermediate, 3-[acetyl(ethoxycarbonyl)methyl]-4-nitropyridine *N*-oxide.



R=$COOC_2H_5$, CN, $COCH_3$

It seems of interest to investigate further the scope of this reaction. This paper deals with the reactions of the above nucleophiles with 3-bromo-6-methyl-4-nitropyridine *N*-oxide (**1a**), 3-bromo-2,6-dimethyl-4-nitropyridine *N*-oxide (**1b**), and 3,5-dibromo-4-nitropyridine *N*-oxide (**1c**). With the former two, the reactivity may be weakened by the inductive effects of the methyl groups located *ortho* and/or *para* to the site of the substitution, and the steric effect of the 2-methyl group also should be taken into consideration in the case of **1b**. With the latter, the resonance effect of the nitro group may be enfeebled by steric compression, and it is supposed that the nitro group, itself, may also be displaced by a nucleophilic substitution reaction.

Results and Discussion

On the treatment of 3-bromo-6-methyl-4-nitropyridine *N*-oxide (**1a**), 3-bromo-2,6-dimethyl-4-nitropyridine *N*-oxide (**1b**), and 3,5-dibromo-4-nitropyridine *N*-oxide (**1c**) with diethyl sodiomalonate in diethyl carbonate at 50 °C, 3-substituted products, 3-[bis(ethoxycarbonyl)methyl]-6-methyl-4-nitropyridine *N*-oxide (**2a**), 3-[bis(ethoxycarbonyl)methyl]-2,6-dimethyl-4-nitropyridine *N*-oxide (**2b**), and 3-[bis(ethoxycarbonyl)methyl]-5-bromo-4-nitropyridine *N*-oxide (**2c**), respectively, were obtained in good yields. These were analogous to the results of the reaction of 3-bromo-4-nitropyridine *N*-oxide with diethyl sodiomalonate in our previous paper.[8] Besides, in the case of the reaction of **1c**, a small amount of **3c** was isolated in addition to **2c**. The compound, **3c**, had the empilical formula $C_{12}H_{13}NO_5Br_2$. The NMR spectra of **3c** showed nearly the same pattern as that of **2c** with exception of the paramagnetic shift of the methin proton in 0.68 ppm. The IR spectra of **3c** indicated the existence of a carbonyl group (1746 cm^{-1}) and an *N*-oxide (1260 cm^{-1}), and the lack of a nitro group. On the basis of these data, **3c** was proved to be 4-[bis(ethoxycarbonyl)methyl]-3,5-dibromopyridine *N*-oxide (**3c**).

The fact that the 4-substituted product, **3c**, was given, though in poor yield, indicated that the potential ability of the 4-nitro group as a leaving group was promoted by the inductive effect of the two bromine atoms, seated in both ortho places, on the nitro group.

The reactions of **1a**, **1b**, and **1c** with ethyl sodiocyanoacetate were performed at different temperature in pyridine. At 5 °C, 3-[cyano(ethoxycarbonyl)methyl]-6-methyl-4-nitropyridine *N*-oxide (**4a**) was obtained from **1a** in a good yield, but at this temperature, **1b** gave 3-[cyano(ethoxycarbonyl)methyl]-2,6-dimethyl-4-nitropyridine *N*-oxide (**4b**) in only 32% yield, and **1c** was

b: R_1=R_2=Me, X=H
c: R_1=R_2=H, X=Br

TABLE 1. REACTIONS WITH DIETHYL SODIOMALONATE

Substrates	Temp °C	Time h	Solvent	Products (Yields %)
1a	50	5	Diethyl carbonate	**2a** (97.3)
1b	50	5	Diethyl carbonate	**2b** (87.1)
1c	50	5	Diethyl carbonate	**2c** (88.9) **3c** (2.2)

recovered intact. At 50 °C **1b** was converted to **4b** in a satisfactory yield, but **1c** was still unaffected, **1c** berely underwent the reaction at 75 °C to give 3,5-dibromo-4-[cyano(ethoxycarbonyl)methyl]pyridine *N*-oxide (**5c**). However, 5-bromo-3-[cyano(ethoxycarbonyl)methyl]-4-nitropyridine *N*-oxide (**4c**), analogous to **4a** and **4b**, was not obtained. The yield of **5c** was not enhanced even if the reaction temperature was raised.

With ethyl sodioacetoacetate, **1a** gave 3-[acetyl-(ethoxycarbonyl)methyl]-6-methyl-4-nitropyridine *N*-oxide (**6a**) at the lower temperature (35 °C), and when the reaction was followed by further treatment at the higher temperature (75 °C), the anticipated 3-ethoxycarbonyl-2,6-dimethylfuro[3,2-*c*]pyridine *N*-oxide (**7a**) was obtained. The identity of both products was confirmed by the IR, NMR, and elemental analytical data, and by analogy with the results in the previous paper.[8] Similarly, 7-bromo-3-ethoxycarbonyl-2-methylfuro[3,2-*c*]pyridine *N*-oxide (**7c**) was easily obtained by treatment of **1c** with ethyl sodioacetoacetate at 35 °C, and 5-bromo-3-[acetyl(ethoxycarbonyl)methyl]-4-nitropyridine *N*-oxide (**6c**), analogous to **6a**, was not isolated even under the mild conditions in which a part of **1c** was recovered. The reaction of **1b** with ethyl sodioacetoacetate was examined under several conditions, but resulted in either the recovery of the starting material or the formation of resinous matters.

Examination of the above results as a whole reveals that **1a** is more liable to undergo the reaction with the anions than **1b**. Thus, whereas **1a** can be allowed to react under as mild conditions as 3-bromo-4-nitropyridine *N*-oxide[8] allows, **1b** required more severe conditions to give the same results. These facts are consistent with the results which are expected by considering the electronic effects of the second substituents (2 and/or 6-methyl groups). The inductive and steric effects of the 2-methyl group of **1b** appear to play an important role in preventing the formation of the 3-substituted product on treatment with ethyl sodioacetoacetate. The nucleophilicity of ethyl sodioacetoacetate is intermediate between those of ethyl sodiomalonate and ethyl sodiocyanoacetate (the pK_a value of these esters are about 11, 13, and 9, respectively). The steric requirement of ethyl sodioacetoacetate is also located between those for the other (stericaly favorable -CN,>-$COCH_3$,>-$COOC_2H_5$). Taking into account the operation of these characters a and effects, the lower reactivity of **1b** with ethyl sodioacetoacetate may be reasonable.

It appears that **7a** and **7c** are formed *via* **6a** and **6c**, as shown in the following scheme. This is quite analogous to the formation of 3-ethoxycarbonyl-2-methylfuro[3,2-*c*]pyridine *N*-oxide in the previous paper.[8] This account is supported by the facts that 3-[acetyl(ethoxycarbonyl)-methyl]-4-nitropyridine *N*-oxide was converted to

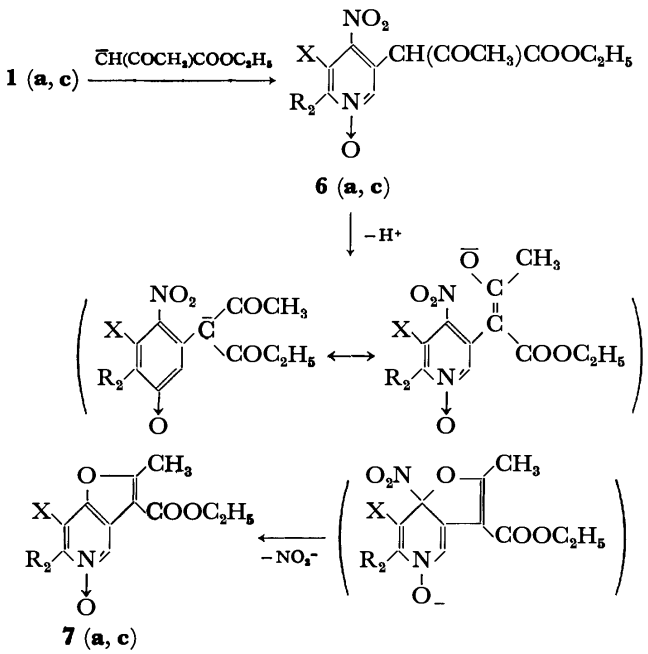
3-ethoxycarbonyl-2-methylfuro[3,2-*c*]pyridine *N*-oxide either by treating with dilute ethanolic sodium ethoxide or only the prolonged storage.



7 (a, c)

a: R_2=Me, X=H; b: R_2=H, X=Br

On reaction of **1c** with ethyl sodioacetoacetate, an anticipated **6c** as an intermediate for **7c** was not isolated even under the mild conditions in which the starting material was recovered as shown in Table 3. This result may be interpreted as follows. The nitro group in the anticipated product, **6c**, was not coplanar with the pyridine ring on account of the steric hindrance by a bromine atom and newly introduced group situated at both *ortho* positions to the nitro group, and **6c**, even if formed, becomes labile and converts to **7c** as soon as it is formed.

Experimental

All the melting points were uncorrected. The IR spectra were obtained on a Hitachi Infrared Spectrophotometer, EPI-S2, as Nujol mulls with the exception of some liquid samples. The NMR spectra were recorded on a Hitachi High Resolution NMR Spectrometer, 20-B, with TMS as the internal standard.

3-Bromo-6-methyl-4-nitropyridine N-*Oxide (1a).* 3-Bromo-6-methylpyridine[9] was treated according to the manner described in our paper[8] to give 3-bromo-6-methylpyridine *N*-oxide (mp 117.5—118 °C) in 86.8% yield. 3-Bromo-6-methyl-4-nitropyridine *N*-oxide (**1a**) (mp 137.5—138 °C) was obtained from 3-bromo-6-methylpyridine *N*-oxide by application of Jujo's method[10] in 76.3% yield.

3-Bromo-2,6-dimethyl-4-nitropyridine N-*Oxide (1b).* 3-Bromo-2,6-dimethylpyridine[11] was managed in the same manner as above to give 3-bromo-2,6-dimethyl-4-nitropyridine *N*-oxide **1b** (mp 111.5—113 °C) in 64.8% total yield.

3,5-Dibromo-4-nitropyridine N-*Oxide (1c).* 3,5-Dibromopyridine[12] was treated as above to give 3,5-dibromopyridine *N*-oxide in 93.5% yield. The *N*-oxide was treated as reported in the literature[13] to give 3,5-dibromo-4-nitropyridine *N*-oxide **1c** in 91.3% yield.

General Procedure of the Reaction of 1a, 1b, and 1c. To a solution of the pyridine **1** in a three necked flask were added three equimolar amounts of sodium salt in appropriate solvents dropwise over a period of an hour, at 15—20 °C with few exceptions, then the mixture were stirred at the required temperature for 5—10 h. The solvent was evaporated under reduced pressure, and the solution were neutralized with dil hydrochloric acid to pH 3—4; when diethyl carbonate is used as a solvent, the evaporation of the solvent may be omitted. The resulting mixture was extracted with chloroform. After drying over anhydrous sodium sulfate the solvent was distilled off, and the residual oil disolved in a small

amount of chloroform and refined through a silica gel (Wakogel C-300) column.

The Reaction of ***1a*** *with Diethyl Sodiomalonate.* A diethyl carbonate solution of 1.0 g of 3-bromo-6-methyl-4-nitropyridine *N*-oxide (**1a**) was treated as general procedure with a solution of diethyl sodiomalonate which had been formed from 0.3 g of sodium and 2.2 g diethyl malonate in 50 ml of diethyl carbonate. After the elution of diethyl malonate with chloroform on the chlomatograph, evaporation of the ethereal elute gave 1.30 g of 3-[bis(ethoxycarbonyl)methyl]-6-methyl-4-nitropyridine *N*-oxide (**2a**) as an oily syrup. Found: C, 49.90; H, 4.92; N, 8.37%; Calcd for $C_{13}H_{16}N_2O_7$: C, 50.00; H, 5.16; N, 8.97%. IR: 1750 cm^{-1} (C=O), 1525 and 1345 (NO_2), 1240 (N→O). NMR ($CDCl_3$): δ 1.27 (6H, t) 4.25 (4H, q), 2.52 (3H, s), 5.26 (1H, s), 8.02 (1H, s), 8.25 (1H, s).

The Reaction of ***1b*** *with Diethyl Sodiomalonate.* From 1.0 g of 3-bromo-2,6-dimethyl-4-nitropyridine *N*-oxide (**1b**), 1.15 g of 3-[bis(ethoxycarbonyl)methyl]-2,6-dimethyl-4-nitropyridine *N*-oxide (**2b**) was obtained as an oily syrup. Found: C, 51.66; H, 5.70; N, 8.19%. Calcd for $C_{14}H_{18}N_2O_7$: C, 51.38; H, 5.54, N. 8.56%. IR: 1745 cm^{-1} (C=O), 1530 and 1340 (NO_2), 1245 (N→O). NMR ($CDCl_3$): δ 1.26 (6H, t), 4.24 (4H, q), 2.54 (3H, s), 2.58 (3H, s), 5.21 (1H, s), 7.84 (1H, s).

The Reaction of ***1c*** *with Diethyl Sodiomalonate.* From the reaction of 1.0 g of **1c** with diethyl sodiomalonate, 1.12 g of 3-[bis(ethoxycarbonyl)methyl]-5-bromo-4-nitropyridine *N*-oxide (**2c**) was obtained from ethereal elution; mp 79—80 °C (acetone–diisopropyl ether). Found: C, 38.08; H, 3.37; N, 7.16%. Calcd for $C_{12}H_{13}N_2O_7Br$: C, 38.22; H, 3.47; N, 7.43%. IR: 1760 cm^{-1} (C=O), 1560 and 1355 (NO_2), 1240 (N→O). NMR ($CDCl_3$): δ 1.29 (6H, t), 4.26 (4H, q), 5.64 (1H, s), 8.37 (2H, s). From the succesive acetone–ether elution was obtained 0.03 g of 4-[bis(ethoxycarbonyl)methyl]-3,5-dibromopyridine *N*-oxide (**3c**); mp 124—125 °C (diisopropyl ether). Found: C, 34.72; H, 3.04; N, 3.16%; Calcd for $C_{12}H_{13}NO_5Br_2$: C, 35.02; H, 3.16; N, 3.40%. IR: 1746 cm^{-1} (C=O), 1254 (N→O). NMR ($CDCl_3$): δ 1.28 (6H, t), 4.26 (4H, q), 5.32 (1H, s), 8.40 (2H, s).

The Reaction of ***1a*** *with Ethyl Sodiocyanoacetate.* From 1.0 g of **1a**, 1.04 g of 3-[cyano(ethoxycarbonyl)methyl]-6-methyl-4-nitropyridine *N*-oxide (**4a**) was obtained: mp 177—177.5 °C (ethanol). Found: C, 49.62; H, 4.01; N, 15.63%. Calcd for $C_{11}H_{11}N_3O_5$: C, 49.81; H, 4.18; N, 15.84%. IR: 2230 cm^{-1} (CN), 1746 (C=O), 1260 (N→O). NMR ($CDCl_3$): δ 1.33 (3H, t), 4.32 (2H, q), 2.52 (3H, s), 5.51 (1H, s), 8.13 (1H, s) 8.43 (1H, s).

The Reaction of ***1b*** *with Ethyl Sodiocyanoacetate.* Under the suitable conditions, 50 °C, 3-[cyano(ethoxycarbonyl)-methyl]-2,6-dimethyl-4-nitropyridine *N*-oxide (**4b**) was obtained in 93.0% yield: mp 118.5—119.0 °C (acetone–diisopropyl ether). Found: C, 51.53; H, 4.46; N, 14.80%. Calcd for $C_{12}H_{13}N_3O_5$: C, 51.61; H, 4.69; N, 14.80%. IR: 2224 cm^{-1} (CN), 1745 (C=O), 1530 and 1342 (NO_2), 1270 (N→O). NMR ($CDCl_3$): δ 1.32 (3H, t), 2.54 (3H, s), 2.60 (3H, s), 4.30 (3H, q), 6.50 (1H, s), 7.97 (1H, s). The starting material, **1b**, when it was recovered, was obtained from chloroform elution following after the reagemt.

The Reaction of ***1c*** *with Ethyl Sodiocyanoacetate.* In this case ethyl sodiocyanoacetate was added at 75 °C over a period of 5 h, then the mixture was managed according to the general procedure. From 1.0 g of 3,5-dibromo-4-nitropyridine *N*-oxide (**1c**), after the collection of unreacted **1c** from ether–acetone elution 0.18 g of 4-[cyano(ethoxycarbonyl)methyl]-3,5-dibromopyridine *N*-oxide (**5c**) was obtained: mp 182—183 °C (ethanol). Found: C, 33.14; H, 2.29; N, 7.84%. Calcd for $C_{10}H_8N_2O_3Br_2$: C, 33.00; H, 2.22; N, 7.70%. IR: 2235 cm^{-1} (CN), 1745 (C=O), 1246 (N→O). NMR ($CDCl_3$): δ 1.33 (3H, t), 4.32 (2H, q), 5.52 (1H, s), 8.30 (1H, s).

The Reaction of ***1a*** *with Ethyl Sodioacetoacetate at 35 °C.* One gram of **1a** was treated with ethyl sodioacetoacetate according to the general procedure; the reaction temperature was kept at 35 °C for 5 h, and from ethereal elution 1.05 g of 3-[acetyl(ethoxycarbonyl) methyl]-6-methyl-4-nitropyridine *N*-oxide (**6a**) was obtained as yellow leaflets; mp 106—107 °C (diethyl ether). Found: C, 51.18; H, 4.87; N, 9.78%. Calcd for $C_{12}H_{14}N_2O_6$: C, 51.08; H, 5.00; N, 9.93%. IR: 1720 cm^{-1} (C=O), 1730 (C=O), 1560 and 1335 (NO_2), 1260 (N→O). NMR ($CDCl_3$): δ 1.12 (3H, t), 1.93 (3H, s), 2.54 (3H, s), 4.11 (2H, m), 7.96 (1H, s), 8.04 (1H, s), 12.98 (1H, s).

The Reaction of ***1a*** *with Ethyl Sodioacetoacetate at 75 °C.* The reaction mixture of the above reaction was further heated at 75 °C for an additional 5 h. The resulting mixture was treated by the same procedure, and from the alcoholic elute, 0.9 g of 3-ethoxycarbonyl-2,6-dimethylfuro[3,2-*c*]-pyridine *N*-oxide (**7a**) was obtained as colorless prisms; mp 120—121 °C (ethanol). Found: C, 61.44; H, 5.58; N, 5.57%. Calcd for $C_{12}H_{13}NO_4$: C, 61.27; H, 5.58; N, 5.95%. IR: 1720 cm^{-1} (C=O), 1246 (N→O). NMR ($CDCl_3$): δ 1.42 (3H, t), 2.58 (3H, s), 2.74 (3H, s), 4.38 (2H, q), 7.28 (1H,s), 8.83 (1H, s).

The Reaction of ***1c*** *with Ethyl Sodioacetoacetate.* When the reaction was carried out at 50 °C, 7-bromo-3-ethoxycarbonyl-2-methylfuro[3,2-*c*]pyridine *N*-oxide (**7c**) was obtained from ethanol elution as colourless prisms; mp 194—195 °C (acetone). Found: C, 44.07; H, 3.24; N, 4.48%. Calcd for $C_{11}H_{10}NO_4Br$: C, 44.02; H, 3.36; N, 4.67%. IR: 1705 cm^{-1} (C=O), 1250 (N→O). NMR ($CDCl_3$): δ 1.43 (3H, t), 2.83 (3H, s), 4.42 (2H, q), 8.28 (1H, s), 8.70 (1H, s).

3-Ethoxycarbonyl-2-methyl[3,2-c]pyridine N-Oxide. The mixture of 0.5 g of 3-[acetyl(ethoxycarbonyl)methyl]-4-nitropyridine *N*-oxide and 0.2 g of sodium ethoxide in 100 ml of ethanol was heated at 50 °C for 5 h. The deep violet color of the mixture faded with time. The solvent was evaporated, and the residue was neutralized with dil hydrochloric acid to pH 4, then extracted with chloroform. After drying over anhydrous sodium sulfate, evaporation of the solvent gave 0.22 g (53.4%) of 3-ethoxycarbonyl-2-methylfuro-[3,2-*c*]pyridine *N*-oxide, semihydrate; mp 150 °C, which was identified by mixed melting point determination and by comparing the IR and NMR spectra data with those of an authentic sample.[8]

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira-2, Sendai 980

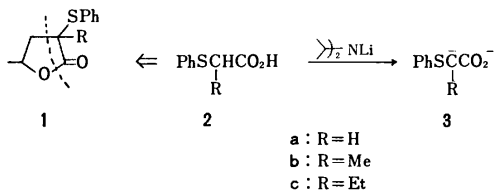
(Received July 20, 1976)

A combination of the reaction of dianions of (phenylthio) acetic acid and its homologs with epoxides, the conjugate addition reaction of 3-phenylthio-2-(5*H*)-furanones with carbanion species, and the α-alkylation reaction of α-phenylthio-γ-butyrolactones is shown to provide a general method for the synthesis of a variety of substituted α-phenylthio-γ-butyrolactones. Oxidation of these α-phenylthiolactones to the corresponding sulfoxides, followed by pyrolysis furnishes all the types of substituted (3-, 4-, and 5-mono-; 3,4-, 3,5- 4,5-, and 5,5-di-; 3,4,5-tri-) 2(5*H*)-furanones in good overall yields.

Recently a number of methods for the synthesis of 2(5*H*)-furanones (γ-crotonolactones, 2-buten-4-olides, $\Delta^{\alpha,\beta}$-butenolides) have been reported,[1] in view of their abundance in nature[2] and usefulness as synthetic intermediates.[1d,3] Concerning the synthesis of natural products by the application of photocycloaddition reactions of 2(5*H*)-furanones to olefins,[3f] we became interested in the development of a convenient method for the synthesis of a variety of 2(5*H*)-furanones.[4]

Results

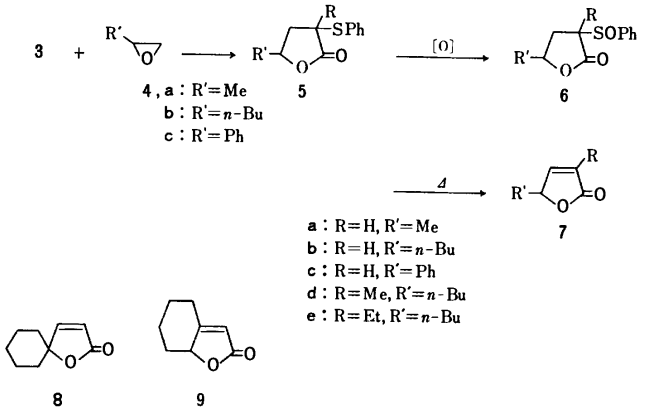
The method includes α-phenylthio-γ-butyrolactones **1** as the key intermediate. (Phenylthio)acetic acid (**2a**) might be suitable as the starting material for the construction of the C-2, 3 unit in 2(5*H*)-furanones (indicated by a dotted line in **1**). The phenylthio group was chosen since it appears (1) to facilitate the generation of the adjacent carbanion species which would have sufficient nucleophilicity to react with epoxides or alkyl



halides before or after the construction of γ-lactone ring, and (2) to be oxidized easily to the sulfinyl group which would be further transformed into other useful intermediary functional groups (vinyl sulfide or sulfoxide) through the Pummerer rearrangement and serve as a facile eliminating group to produce a double bond in the final products.

The dianion **3a** was easily prepared by treating **2a** with lithium diisopropylamide, and reacted smoothly with methyl iodide and ethyl bromide to give α-(phenylthio)propionic acid (**2b**) and -butyric acid (**2c**) in quantitative yields, respectively.[5] The homologous acids **2b** and **2c** also produced the corresponding dianions **3b** and **3c** in the same manner.

The reactions of the dianions **3** with epoxides **4** and subsequent transformation into 5-mono- and 3,5-disubstituted 2(5*H*)-furanones are shown in Scheme 1. The reactions of **3** with propylene oxide (**4a**), 1-hexene oxide (**4b**), or styrene oxide (**4c**) proceeded smoothly to give the corresponding phenylthiobutyrolactones **5** in excel-



Scheme 1.

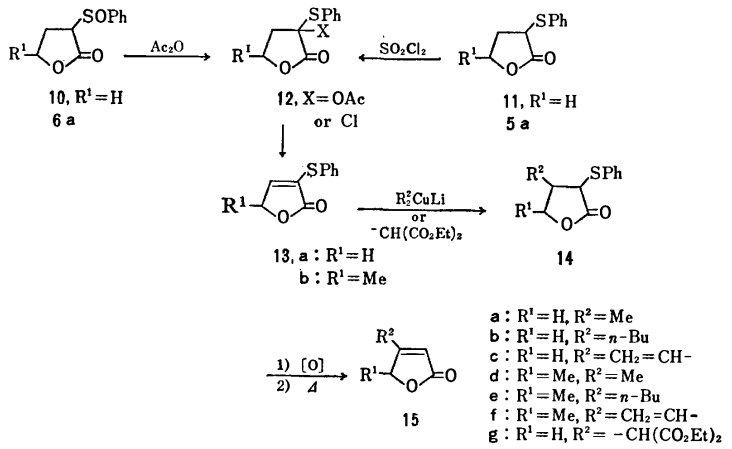
lent yields. Each lactone **5** was obtained as a mixture of stereoisomers. On treatment of **5** with *m*-chloroperbenzoic acid, hydrogen peroxide, or sodium periodate, the corresponding sulfoxides **6** were obtained quantitatively and were pyrolyzed (at *ca.* 110 °C for **6a—c** and *ca.* 70 °C for **6d**, **e**) to give 5-mono- and 3,5-disubstituted 2(5*H*)-furanones **7** in high yields. It should be noted that, in the cases of **6d** and **6e**, a double bond was exclusively introduced into an endocyclic position, neither α-methylene- nor α-ethylidene- γ-butyrolactone being detected.[1g]

In a similar way, the use of methylenecyclohexane oxide (1,1-disubstituted epoxide) or cyclohexene oxide (symmetrical 1,2-disubstituted epoxide) gave 5,5-pentamethylene-2(5*H*)-furanone (**8**) (5,5-disubstituted) and 4,5-tetramethylene-2(5*H*)-furanone (**9**) (4,5-disubstituted), respectively.

An attempt to use the anion of the ester of **2a**, PhS-$\bar{C}$HCO$_2$Et, for the reaction with **4a** gave an unsatisfactory result, **5a** being obtained in a low (30%) yield. Thus, the present α-phenylthio carboxylic acid dianion procedure would be very useful for the synthesis of 5-mono, 3,5-di, 5,5-di, and 4,5-di (the same substituents)-substituted 2(5*H*)-furanone derivatives, because of ready availability of the starting materials, simple operation of the reactions, and high yield of the products.

Among the number of methods for the synthesis of 2(5*H*)-furanones,[1] the procedure for 4-substituted derivatives has so far been very limited. Thus the development of a convenient synthetic method for them would be of considerable interest.

In order to introduce a substituent to the C-4 position

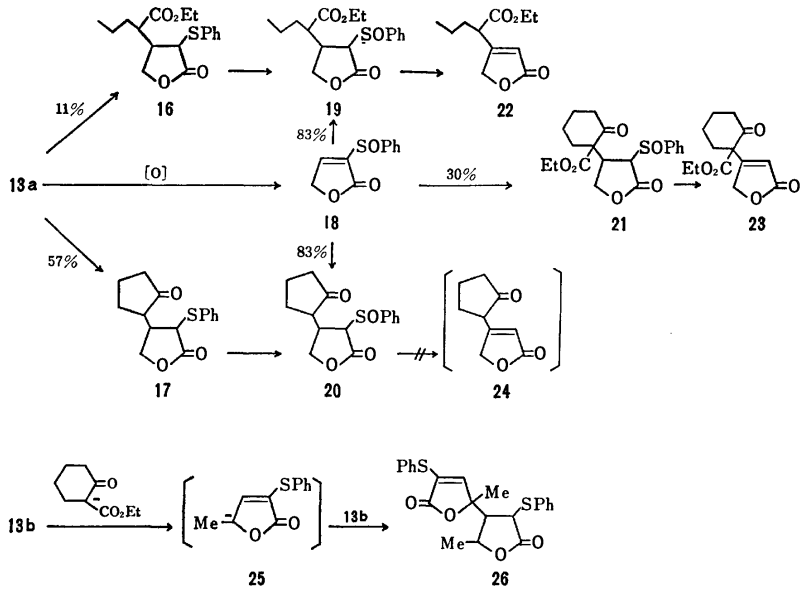


Scheme 2.

of 2(5*H*)-furanone system, we adopted the 1,4-conjugate addition reaction of 3-phenylthio- (**13**) or 3-phenylsulfinyl-2(5*H*)-furanones (**18**). The preparation of **13** was satisfactorily accomplished in two ways through the intermediates **12**: one by the Pummerer rearrangement[6] of α-phenylsulfinyl-γ-butyrolactones (**10** and **6a**) and the subsequent elimination of acetic acid by heating in acetic anhydride (60—70 °C and then 150 °C) (86 and 93% overall) and the other by the chlorination of α-phenylthio-γ-butyrolactones (**11** and **5a**) with sulfuryl chloride, followed by dehydrochlorination (93 and 88% overall) (Scheme 2). Phenylthiofuranones **13** thus obtained underwent conjugate addition with lithium dialkylcuprates (dialkyl=dimethyl, dibutyl, or divinyl) to give the adducts **14a—f** in good yields. These could be converted into the expected 4-mono- and 4,5-disubstituted 2(5*H*)-furanones **15a—f** in good yields. Combined use of the Grignard reagent and cuprous iodide for the conjugate addition gave an unsatisfactory result (low yields of **14** due to formation of a considerable amount of by-products).

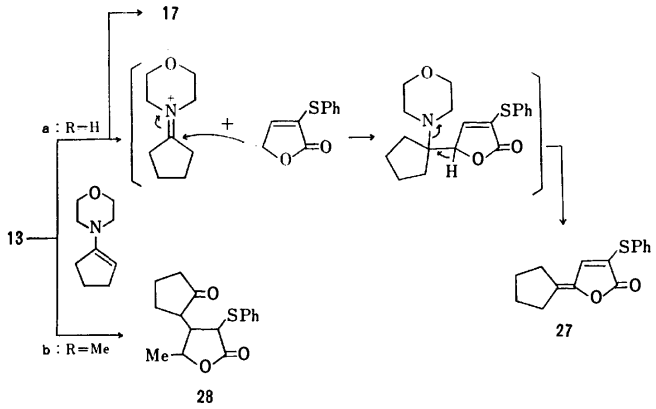
In contrast to the successful addition of dialkylcuprate to **13**, the reaction of **13a** with other enolates (diethyl malonate, ethyl valerate, or cyclopentanone) did not necessarily give good results, the low yields of the adducts: 60% for **14g**, 11% for **16**, and 57% for **17**, presumably because of an unfavorable equilibrium (Scheme 3). Hence, the more effective stabilization of the α-anion in the adducts would favor the equilibration to the adduct side, facilitating the conjugate addition reaction of enolates. In fact, 3-phenylsulfinyl-2(5*H*)-furanone (**18**) underwent smoothly the conjugate addition with the enolates of ethyl valerate and cyclopentanone to give the desired adducts **19** and **20**, respectively, in good yields.[7] Unlike **13a**, **18** also reacted with ethyl 2-oxocyclohexanecarboxylate to afford a 30% yield of the adduct **21**. Pyrolysis of **19** and **21** furnished the 4-substituted 2(5*H*)-furanones **22** and **23**, respectively, in good yields, but the 2(5*H*)-furanone **24** derived from **20** was extremely unstable, polymerizing during the course of isolation. The reaction of **13a** with ethyl 2-oxocyclohexanecarboxylate produced only the polymers of **13a** itself, which would arise from self-addition of the 5-anion of **13a** (such as **25**). Actually, the dimer **26** was isolated in the reaction of **13b** in 38% yield.

The preferential abstraction of the 5-hydrogen atom



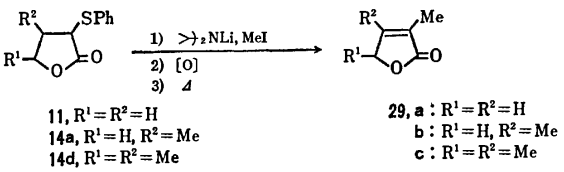
Scheme 3.

was also observed in the reaction of **13a** with an enamine. The reaction of **13a** with 1-morpholino-1-cyclopentene gave, in addition to a 22% yield of **17**, 5-cyclopentylidene-3-phenylthio-2(5*H*)-furanone (**27**) (30%), which would be formed through the reaction of the 5-anion of **13a** with the protonated enamine and the subsequent elimination of morpholine as depicted in Scheme 4. The 5-methyl derivative **13b** gave only the conjugate addition product **28** in low yield.



Scheme 4.

Finally, the application of α-alkylation to the α-phenylthio-γ-butyrolactones,[1g] through the subsequent oxidation and dehydrosulfenylation, led to the remaining 3-mono-, 3,4-di-, and 3,4,5-trisubstituted 2(5*H*)-furanone derivatives. Typical examples are shown in Scheme 5.



Scheme 5.

The procedures we gave provide useful methods for the synthesis of all types of substituted 2(5*H*)-furanones starting from readily available substances through simple and high-yield operations.

Experimental

All the melting points were taken on a Yamato melting point apparatus and are uncorrected. Distillation of the liquid products was usually carried out evaporatively using a modified sublimation apparatus and the oil bath temperatures were recorded. IR spectra were taken on a Hitachi EPI-S2 or G2 spectrometer. NMR spectra were obtained on a JEOL C-60HL (60 MHz) instrument using TMS as an internal standard. Reported values are given in the δ scale. Both spectra were recorded in CCl_4 solution unless otherwise stated. Elementary analyses were carried out in the microanalytical laboratory of this Institute. Progress of all the reactions was followed by TLC, silica gel (Merck GF_{254} Typ 60). The developing solvent system was petroleum ether–ether mixture, visualization being effected with a fluorescent lamp or concd H_2SO_4 spray.

Generation of the Dianion (3) of (Phenylthio)acetic Acid and its Homologs (2). To a solution of freshly prepared lithium diisopropylamide (0.02 mol) in THF–ether was added dropwise a solution of (phenylthio)acetic acid (**2a**)[8] (1.68 g, 0.01 mol) in THF (7 ml) at 0 °C under nitrogen. The mixture was stirred at 0—4 °C for 1 h. An aliquout (3 ml) was taken with a syringe and quenched with D_2O. Incorporation of one deuterium atom at the α-position in the recovered **2a** (acidification and extraction) was confirmed from the NMR spectrum: δ 3.58 (1H, s).

In the same manner, solutions of the dianions (**3b**) and (**3c**) of the propionic (**2b**) and butyric acid derivatives (**2c**) could be prepared.

Alkylation of the Dianion (3a). A solution of excess methyl iodide (17.6 g) in THF (5 ml) was added dropwise at −60——70 °C to a solution of the dianion (**3a**) (0.01 mol) under nitrogen, and the mixture was stirred overnight and warmed gradually to room temperature. A saturated solution of NH_4Cl and then 30% H_2SO_4 (to Congo Red) were added, and the mixture was extracted with $CHCl_3$. The combined extracts were washed with saturated brine and freed from the solvent. A small amount of ether was added to the residue and the insoluble material was removed by filtration. Evaporation of the solvent, and distillation (100—140 °C/<1 Torr) of the pale yellow oil remaining afforded 1.70 g (93%) of α-(phenylthio)propionic acid (**2b**). NMR 1.50 (3H, d, J=7 Hz, $-CHC\underline{H}_3$), 3.60 (1H, q, J=7 Hz, $-C\underline{H}CH_3$), 7.10—7.60 (5H, m, Ph), and 12.0 (1H, s, COOH).

In the same manner, the alkylation of **3a** with ethyl bromide gave α-(phenylthio)butyric acid (**2c**) in 99% yield. Bp 100—140 °C/<1 Torr; NMR 1.55 (3H, t, J=7.5 Hz, $-CH_2C\underline{H}_3$), 1.60—2.15 (2H, m, $-\dot{C}HC\underline{H}_2CH_3$), 3.47 (1H, t, J=7.2 Hz, $-\dot{C}\underline{H}CH_2-$), 7.10—7.60 (5H, m, Ph), and 11.4 (1H, s, COOH).

Compound **2b** was also prepared by the reaction of ethyl α-bromopropionate with sodium thiophenolate as in the preparation of **2a**. To a stirred slurry of sodium thiophenolate (1.4 g) in THF (20 ml) was added a solution of ethyl α-bromopropionate (1.18 g) in THF (10 ml) at 0 °C, and the mixture was stirred at room temperature for 6 h. After the removal of inorganic salt and solvent, distillation of the residual oil gave 2.0 g (95%) of ethyl α-(phenylthio)propionate. A mixture of this ester (1.8 g) and aqueous potassium hydroxide (720 mg in 10 ml) was heated under reflux for 3 h. At this stage the mixture became homogeneous. The cooled mixture was acidified with 30% H_2SO_4 turing to Congo Red and extracted with ether. The combined extracts were washed with saturated brine and dried. After evaporation of the solvent, distillation of the residue afforded 1.56 g (99%) of **2b**.

General Procedure for Reaction of the Dianions (3) with Epoxides. To a solution of dianion **3** was added a solution of the freshly purified epoxide (a slightly excess molar amount except propylene oxide) in dry THF at *ca.* −60 °C under nitrogen, and the reaction mixture was stirred at this temperature for 1 h and then gradually warmed to room temperature within a period of *ca.* 15 h. For 1 g of an epoxide, *ca.* 3 ml of THF was used. Aqueous NH_4Cl was added to the mixture and the solvent was then removed under reduced pressure. The residue was poured into a mixture of ether and dil H_2SO_4 (sufficient amount for neutralization), and the water layer was thoroughly extracted with ether. The combined ether layers were washed with water and saturated brine, and dried. After removal of the solvent, the residual oil was heated in benzene (*ca.* 10 ml for 1 g) containing a trace of concd H_2SO_4 under reflux for 3 h using a water-separator. The cooled reaction mixture was diluted with ether and successively washed with dil NaOH, water, and saturated brine. Removal of the solvent gave a mixture of *cis* and *trans* γ-substituted α-phenylthio-γ-butyrolactones (**5**) in 70—94% yield, which

were usually separable by chromatography on silica gel using petroleum ether–ether as an eluting agent. In the cases of **5d** and **5e**, the extraction was carried out with $CHCl_3$, and the concentration of the extracts at 80 °C under ordinary pressure resulted in complete lactonization.

General Procedure for Oxidation of α-Phenylthio-γ-butyrolactones. To a solution of the α-phenylthiolactone derivative in CH_2Cl_2 (*ca.* 20 ml for 1 g of the lactone) was added a solution of *m*-chloroperbenzoic acid (MCPBA, 85%, 1.0—1.2 equiv) in CH_2Cl_2 (*ca.* 30 ml for 1 g of the peracid) at 0 °C. The reaction mixture was stirred at 0 °C for 0.5—1 h, diluted with CH_2Cl_2, successively washed with dil $NaHCO_3$ solution and saturated brine, and dried. Evaporation of the solvent under reduced pressure left the α-phenylsulfinyl-γ-butyrolactone derivative in nearly quantitative yield.

The α-phenylthiolactone derivative was treated at room temperature with either $NaIO_4$ (*ca.* 1.2 equiv) in 40—50% methanol (*ca.* 20 ml for 1 g of the lactone) for 12 h or 30% hydrogen peroxide (*ca.* 2 ml) in 50% methanol for 4 days, and the usual work-up (extraction with CH_2Cl_2) gave also the α-phenylsulfinyllactone derivative (**6**) in excellent yield. In all cases, the sample thus obtained was sufficiently pure for the subsequent pyrolysis.

General Procedure for Pyrolysis of α-Phenylsulfinyl-γ-butyrolactones. A solution of the α-phenylsulfinyllactone derivative in toluene (10—20 ml for 1 g of the lactone) or in pyridine (*ca.* 5 ml) was heated under reflux for 0.5—1 h. After removal of the solvent under reduced pressure, the residue was chromatographed on silica gel using petroleum ether–ether as an eluting agent to give the 2(5*H*)-furanone derivative, which was purified by evaporative distillation.

*α-Phenylthio-γ-butyrolactone (**11**).* A solution of α-bromo-γ-butyrolactone[9] (15.1 g) in THF (30 ml) was added dropwise to a suspension of sodium thiophenolate (12.1 g) in THF (70 ml) at room temperature, and the reaction mixture was stirred for 2 days. After the removal of insoluble material and solvent, distillation (165—175 °C/1 Torr) of the residual oil afforded 17.1 g (96%) of **11**. Found: C, 61.56; H, 5.20%. Calcd for $C_{10}H_{10}O_2S$: C, 61.85; H, 5.15%.

*α-Phenylsulfinyl-γ-butyrolactone (**10**)*, yield 86% ($NaIO_4$): mp 100—104 °C from $CHCl_3$–CCl_4. Found: C, 57.11; H, 4.82%. Calcd for $C_{10}H_{10}O_3S$: C, 57.14; H, 4.80%.[10]

*3-Phenylthio-2(5H)-furanone (**13a**).* (a) A solution of **10** (4.4 g) in acetic anhydride (25 ml) was heated at 60—70 °C overnight and then refluxed for 2 h. After the removal of acetic anhydride and acetic acid under reduced pressure, the residue was recrystallized from ethanol to give 3.3 g (86%) of **13a**; mp 57.5—59 °C; IR ($CHCl_3$) 1760 and 1600 cm^{-1}; NMR ($CDCl_3$) 4.84 (2H, d, J=2.2 Hz), 6.75 (1H, t, J=2.2 Hz), and 7.40—7.80 (5H, m). Found: C, 62.57; H, 4.05%. Calcd for $C_{10}H_8O_2S$: C, 62.50; H, 4.20%. When the reaction was stopped at the stage of 70 °C heating, a small amount of α-acetoxy-α-phenylthio-γ-butyrolactone (**12**, R^1=H, X=OAc) was isolated.

(b) A solution of sulfuryl chloride (9.8 g) in CCl_4 (30 ml) was added dropwise (1 h) to a solution of **11** (11.9 g) in CCl_4 (70 ml) at 0 °C under nitrogen. The reaction mixture was stirred at 0 °C for 2 h, poured into aqueous $NaHCO_3$, and extracted with CH_2Cl_2. The combined extracts were successively washed with $NaHCO_3$ solution, water, and saturated brine, and dried. Evaporation of the solvent under reduced pressure left 13.2 g of α-chloro-α-phenylthio-γ-butyrolactone (**12**, R^1=H, X=Cl). The crude product, dissolved in THF (60 ml), was added to a mixture of LiBr (17 g) and Li_2CO_3 (13 g) in THF (60 ml) at room temperature. The reaction mixture was refluxed for 30 min under nitrogen. After the removal of inorganic salts and solvent, the residue was dissolved in CH_2Cl_2, and the solution was washed with $NaHCO_3$ solution and saturated brine, and dried. Evaporation of the solvent gave 9.94 g (93%) of **13a**.

*5-Methyl-3-phenylthio-2(5H)-furanone (**13b**).* This compound was prepared from either of **6a** or **5a** as in the preceding experiment. (a) from **6a**. Yield 93%; (b) from **5a**. Yield 88%. Bp 160—170 °C/1 Torr; IR 1770 and 1600 cm^{-1}; NMR 1.35 (3H, d, J=6.8 Hz), 4.98 (1H, dq, J=1.5 and 6.8 Hz), 6.60 (1H, d, J=1.5 Hz), and 7.20—7.80 (5H, m). Found: C, 63.71; H, 5.15%. Calcd for $C_{11}H_{10}O_2S$: C, 64.07; H, 4.89%.

*General Procedure for the Reaction of **13** with Lithium Dialkylcuprates.* To a freshly prepared solution of lithium dimethyl, dibutyl, or divinylcuprate[11] (2 equiv) in ether or ether–hexane was added dropwise a solution of **13** in ether (60 ml for *ca.* 1.5 g) under nitrogen. The reaction temperature and time for each cuprate are as follows: 0 °C for 2—3 h for dimethylcuprate; −78 °C for 3—4 h for dibutylcuprate; −60—−50 °C for 1.5—2 h for divinylcuprate. The reaction mixture was poured into a cold NH_4Cl solution and thoroughly extracted with ether. The combined extracts were washed with water and saturated brine, and dried. After removal of the solvent, the residual oil was chromatographed on silica gel using petroleum ether–ether as an eluting agent. Yields of **14** were 75—100%.

*β-[Bis(ethoxycarbonyl)methyl]-α-phenylthio-γ-butyrolactone (**14g**).* A mixture of diethyl malonate (350 mg) and lithium hydride (25 mg) in THF (15 ml) was stirred at room temperature for 30 min under nitrogen. To this solution was added a solution of **13a** (384 mg) in THF (10 ml) at room temperature, and the reaction mixture was stirred for 2 h and then refluxed for 30 min. The cooled mixture was poured into a cold NH_4Cl solution and the solvent was removed under reduced pressure. The organic residue was extracted with ether. The extract was washed with saturated brine and evaporated. The oil remaining was chromatographed on silica gel (10 g) using petroleum ether–ether to give 423 mg (60%) of **14g**.

*β-(1-Ethoxycarbonylbutyl)-α-phenylthio-γ-butyrolactone (**16**).* To a solution of lithium diisopropylamide (1 equiv) in THF (10 ml) was added a solution of ethyl valerate (390 mg) in THF (10 ml) at −78 °C under nitrogen, and the mixture was stirred at −78 °C for 1 h. A solution of **13a** (576 mg) in THF (10 ml) was added to this solution, and the reaction mixture was stirred at −78 °C for 20 h and then warmed to room temperature within a period of 8 h. A cold NH_4Cl solution was added, and the mixture was extracted with CH_2Cl_2. The extracts were washed with water and saturated brine, and dried. After removal of the solvent, chromatography of the residual oil on silica gel (100 g) using 1: 1 petroleum ether–ether as an eluent gave 110 mg (11%) of **16** accompanied by the recovery of 140 mg of **13a**.

*β-(2-Oxocyclopentyl)-α-phenylthio-γ-butyrolactone (**17**).* A solution of cyclopentanone (280 mg) in THF (10 ml) was added to a solution of lithium diisopropylamide (1 equiv), and the mixture was stirred for 1 h. To this solution was added a solution of **13a** (576 mg) in THF (15 ml), and the reaction mixture was stirred for 4 h. All the operations were carried out at −78 °C under nitrogen. A cold NH_4Cl solution was added to the mixture, and the solvent was removed under reduced pressure. The residue was extracted with CH_2Cl_2. The combined extracts were washed with saturated brine. After removal of the solvent, the residual oil was chromatographed on silica gel (100 g) using 2: 1 petroleum ether–ether as an eluent to give 500 mg (57%) of **17**.

*γ-Methyl-β-(2-oxocyclopentyl)-α-phenylthio-γ-butyrolactone (**28**).* The reaction of **13b** with cyclopentanone or its morpholine enamine was carried out in the same manner as **13a**. Yields:

64% (cyclopentanone) and 31% (enamine).

3-Phenylsulfinyl-2(5H)-furanone (18). Oxidation of **13a** was carried out using MCPBA (−20—−10 °C for 1 h) and work-up was carried out as described earlier. Yield. 80%. Mp 86—88 °C from ether. IR ($CHCl_3$) 1770 cm^{-1}; NMR ($CDCl_3$) 5.00 (2H, br. s), 7.50—8.00 (5H, m), and 8.10 (1H, br. s). Found: C, 57.62; H, 4.01%. Calcd for $C_{10}H_8O_3S$: C, 57.69; H, 3.87%.

β-(1-Ethoxycarbonylbutyl)-α-phenylsulfinyl-γ-butyrolactone (19). The reaction of **18** with ethyl valerate was carried out in the same manner as for **13a** except for quenching at −78 °C Yield 83%. The compound was also obtained by MCPBA oxidation of **16**.

β-(2-Oxocyclopentyl)-α-phenylsulfinyl-γ-butyrolactone (20). The reaction of **18** with cyclopentanone was carried out in the same manner as for **13a**. Yield 82%.

β-(1-Ethoxycarbonyl-2-oxocyclohexyl)-α-phenylsulfinyl-γ-butyrolactone (21). To a solution of lithium diisopropylamide (1 equiv) in THF (15 ml) was added a solution of ethyl 2-oxocyclohexanecarboxylate (425 mg) in THF (15 ml), and the mixture was stirred for 1 h. A solution of **18** (520 mg) in THF (15 ml) was added to the above enolate solution, and the reaction mixture was stirred for 3 h. All the operations were carried out at −78 °C under nitrogen. A cold NH_4Cl solution was added, and the solvent was removed under reduced pressure. The residue was extracted with CH_2Cl_2, and the combined extracts were washed with saturated brine. After removal of the solvent under reduced pressure, the residue was chromatographed on silica gel (80 g) using 1: 5 petroleum ether–ether as an eluent to give 280 mg (30%) of **21**.

Reaction of 13b with Ethyl 2-Oxocyclohexanecarboxylate. To a solution of the enolate of ethyl 2-oxocyclohexanecarboxylate (374 mg) in THF, prepared according to the manner described earlier, was added a solution of **13b** (412 mg) in THF (10 ml) at −50 °C under nitrogen, and the reaction mixture was gradually warmed to −20 °C within a period of 3 h under stirring. Aqueous NH_4Cl was added, and the solvent was removed under reduced pressure. The organic residue was extracted with ether, and the extracts were washed with saturated brine and dried. After removal of the solvent, the residue was chromatographed on silica gel (60 g) using 1: 1 petroleum ether–ether as an eluent to give 155 mg (38%) of 2,2′-dimethyl-4,4′-bis(phenylthio)-2,2′,3′,4′,5,5′-hexahydro-2,3′-bifuran-5,5′-dione (**26**), bp 200 °C/1 Torr; IR ($CHCl_3$) 1760 cm^{-1}; NMR ($CDCl_3$) 1.20 (3H, d, J=6.8 Hz), 1.43 (3H, s), 2.30 (1H, dd, J=6.8 and 8.2 Hz), 3.35 (1H, d, J=8.2 Hz), 4.48 (1H, quint, J=6.8 Hz), 6.05 (1H, s) and 7.20—7.80 (10H, m). Found: C, 63.88; H, 5.01%. Calcd for $C_{22}H_{20}O_4S_2$: C, 64.07; H, 4.89%.

5-Cyclopentylidene-3-phenylthio-2(5H)-furanone (27). To a solution of 1-morpholino-1-cyclopentene (306 mg)[12] in MeCN (5 ml) was added a solution of **13a** (384 mg) in MeCN (5 ml) at room temperature under nitrogen, and the reaction mixture was stirred at room temperature for 5 h. Dilute HCl (2 M, 10 ml) was added, and the resulting solution was stirred for 1 h, then poured into water, and extracted with ether. The combined extracts were washed with water several times and then saturated brine. After removal of the solvent, the residue was chromatographed on preparative TLC of silica gel with 1: 1 petroleum ether–ether to give 120 mg (22%) of **17** and 165 mg (30%) of **27**, mp 138—139 °C from ethanol; IR ($CDCl_3$) 1750 cm^{-1}; NMR ($CDCl_3$) 1.40—2.00 (4H, m), 2.20—2.80 (4H, m), 6.85 (1H, s), and 7.50 (5H, m). Found: C, 69.55; H, 5.48%. Calcd for $C_{15}H_{14}O_2S$: C, 69.75; H, 5.46%.

Methylation of α-Phenylthio-γ-butyrolactones. A solution of the α-phenylthiobutyrolactone derivative (**11**, **14a**, **14d**) in THF (10 ml for 1 g) was added to a solution of lithium diisopropylamide (1.3 equiv) in THF at −60 °C under nitrogen. After being stirred for 1 h, methyl iodide (large excess) was added, and the mixture was stirred at −60 °C overnight. The usual work-up (quenching, extraction, distillation) gave the α-methylated product in quantitative yield.

α-Phenylthio-γ-butyrolactones. All the α-phenylthio-γ-butyrolactones (**5**, **14**, **16**, **17**, the γ,γ-pentamethylene-, β,γ-tetramethylene-, α-methyl, α,β-dimethyl-, and α,β,γ-trimethyl-derivatives) gave satisfactory analytical and spectral results.

Yield (from the corresponding α-phenylthio-γ-butyrolactones), Bps (Torr), ν_{CO}, Proton Chemical Shifts, and Analytical Data of 2-(5H)-Furanones.

5-Methyl- (7a) (β-Angelica Lactone). 74%. Identified with the authentic sample.[13]

5-Butyl- (7b). 82%. 130—140 °C/2. 1770 cm^{-1}. δ 0.70—2.00 (9H, m), 4.80—5.20 (1H, m), 6.00 (1H, dd, J= 1.5 and 6 Hz), and 7.55 (1H, dd, J=1.5 and 6 Hz). Found: C, 67.94; H, 8.28%. Calcd for $C_8H_{12}O_2$: C, 68.54; H, 8.63%.

5-Phenyl- (7c). 57%, in addition to 23% of 2(3*H*)-isomer, after chromatographic separation. 90—120 °C/1. 1790, 1760, and 1700 cm^{-1}. δ 5.90 (1H, t, J=2.3 Hz), 6.10 (1H, dd, J=2.3 and 6 Hz), 7.30 (5H, s), and 7.45 (1H, dd, J=2.3 and 6 Hz). Found: C, 75.15; H, 5.01%. Calcd for $C_{10}H_8O_2$: C, 74.99; H, 5.03%.

5-Butyl-3-methyl- (7d). 63%. 90—110 °C/1. 1760 cm^{-1}. δ 0.70—1.80 (9H, m), 1.87 (3H, t, J=2.3 Hz), 4.65—5.00 (1H, m), and 7.15 (1H, m). Found: C, 70.27; H, 9.01%. Calcd for $C_9H_{14}O_2$: C, 70.10; H, 9.15%.

5-Butyl-3-ethyl- (7e). 78% (in this case the pyrolysis was carried out in boiling CCl_4 containing 2-mercaptobenzothiazole).[14] 70—90 °C/1. 1760 cm^{-1}. δ 0.70—2.00 (9H, m), 1.13 (3H, t, J=7.5 Hz), 2.25 (2H, tq, J=1.6 and 7.5 Hz), 4.65—5.00 (1H, m), and 7.05 (1H, dt, J=1.6 and 1.6 Hz). Found: C, 71.49; H, 9.49%. Calcd for $C_{10}H_{16}O_2$: C, 71.39; H, 9.59%.

5,5-Pentamethylene- (8). 83%. 130—140 °C/4. 1770 cm^{-1}. δ 1.70 (10H, br. s), 5.92 (1H, d, J=6 Hz), and 7.52 (1H, d, J=6 Hz). Found: C, 71.24; H, 7.68%. Calcd for $C_9H_{12}O_2$: C, 71.02; H, 7.95%.

4,5-Tetramethylene- (9). 82%. 70—90 °C/1. 1780 and 1760 cm^{-1}. δ 0.90—3.10 (8H, m), 4.40—4.90 (1H, m), and 5.60 (1H, m). Found: C, 69.68; H, 7.08%. Calcd for $C_8H_{10}O_2$: C, 69.54; H, 7.30%.

4-Methyl- (15a). 87%. Identified with the authentic sample.[15]

4-Butyl- (15b). 80%. 140 °C/1. 1780 and 1750 cm^{-1}. δ 0.95 (7H, m), 2.45 (2H, br. t, J=7.2 Hz), 4.75 (2H, br. s), and 5.75 (1H, br. s). Found: C, 68.51; H, 8.79%. Calcd for $C_8H_{12}O_2$: C, 68.54; H, 8.63%.

4-Vinyl- (15c).[16] 51%. 1780 and 1760 ($CHCl_3$) cm^{-1}. δ ($CDCl_3$) 5.06 (2H, br. d, J=1.5 Hz), 5.70 (1H, d, J=10.5 Hz), 5.70 (1H, d, J=18 Hz), 6.05 (1H, br. t, J= 1.5 Hz), and 6.82 (1H, dd, J=10.5 and 18 Hz). This compound is unstable, and decomposed partially on distillation. The sample, which was chromatographically and spectroscopically homogeneous, did not give satisfactory analytical results.

4,5-Dimethyl- (15d). 87%. 85 °C/1. 1780 and 1760 cm^{-1}. δ 1.40 (3H, d, J=7.1 Hz), 2.08 (3H, br. s), 4.95 (1H, br. q. J=7.1 Hz), and 5.75 (1H, br. s). Found: C, 64.59; H, 6.80%. Calcd for $C_6H_8O_2$: C, 64.27; H, 7.19%.

4-Butyl-5-methyl- (15e). 82%. 140 °C/1. 1770 cm^{-1}. δ 0.95—1.19 (7H, m), 1.36 (3H, d, J=6.8 Hz), 2.10—2.60 (2H, m) 4.90 (1H, br. q, J=6.8 Hz), and 5.67 (1H, br. s). Found: C, 69.87; H, 8.98%. Calcd for $C_9H_{14}O_2$: C, 70.10;

H, 9.15%.

*5-Methyl-4-vinyl- (**15f**).* 89%. 1780 and 1760 cm^{-1}. δ 1.55 (3H, d, J=7.5 Hz), 5.30 (1H, q, J=7.5 Hz), 5.72 (1H, d, J=18 Hz), 5.75 (1H, d, J=10.5 Hz), 6.07 (1H, s), and 6.73 (1H, dd, J=10.5 and 18 Hz). The thermal property of **15f** is similar to that of **15c**.

*4-[Bis(ethoxycarbonyl)methyl]- (**15g**).* 68%. 140—160 °C/1. 1780, 1750, and 1740 cm^{-1}. δ 1.30 (6H, t, J=7 Hz), 4.30 (4H, q, J=7 Hz), 4.70 (1H, br. s), 5.02 (2H, d, J=2.3 Hz), and 6.20 (1H, br. s). Found: C, 54.68; H, 5.72%. Calcd for $C_{11}H_{14}O_6$: C, 54.54; H, 5.83%.

*4-(1-Ethoxycarbonylbutyl)- (**22**).* 90%. 140—150 °C/1. 1780, 1750, and 1735 cm^{-1}. δ 0.70—2.10 (7H, m), 1.30 (3H, t, J=7.2 Hz), 3.50 (1H, br. t, J=7.5 Hz), 4.15 (2H, q, J=7.2 Hz), 4.80 (2H, br. d, J=1.9 Hz), and 5.87 (1H, br. s). Found: C, 62.22; H, 7.75%. Calcd for $C_{11}H_{16}O_4$: C, 62.25; H, 7.60%.

*4-(1-Ethoxycarbonyl-2-oxocyclohexyl)- (**23**).* 83%. 160 °C/1. 1780, 1750, and 1720 ($CHCl_3$) cm^{-1}. δ ($CDCl_3$) 1.30 (3H, t, J=7.5 Hz), 1.10—3.00 (8H, m), 4.32 (2H, q, J=7.5 Hz), 4.80 (1H, dd, J=18 and 2.1 Hz), 5.10 (1H, dd, J=18 and 2.1 Hz), and 6.00 (1H, m). Found: C, 61.48; H, 6.45%. Calcd for $C_{13}H_{16}O_5$: C, 61.89; H, 6.39%.

*3-Methyl- (**29a**).* 65%. Identified with the authentic sample.[1g,17]

*3,4-Dimethyl- (**29b**).* 75%, in addition to 8% of the *exo*-methylene isomer. 70 °C/1. 1760 cm^{-1}. δ 1.75 (3H, br. s), 2.02 (3H, br. s), and 4.60 (2H, br. s). Found: C, 64.18; H, 7.51%. Calcd for $C_6H_8O_2$: C, 64.27; H, 7.19%.

*3,4,5-Trimethyl- (**29c**).* 93%. 60—80 °C/1. 1760 cm^{-1}. δ 1.38 (3H, d, J=6.8 Hz), 1.77 (3H, br. s), 2.00 (3H, br. s), and 4.78 (1H, br. q, J=6.8 Hz). Found: C, 66.73; H, 8.03%. Calcd for $C_7H_{10}O_2$: C, 66.64; H, 7.99%.

Formations and Reactions of Cation Radicals from Compounds Possessing a *p*-Dimethylaminophenyl Group by Reactions with *o*-Sulfobenzoic Anhydride

Toshikazu NAGAI, Tadao SHINGAKI, and Hirokazu YAMADA*

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received July 26, 1976)

It was found that cation radicals were formed from a number of substrates bearing a *p*-dimethylaminophenyl group, such as *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD) and *N,N,N',N'*-tetramethylbenzidine (TMB), by reactions with *o*-sulfobenzoic anhydride (*o*-AH). The systems, bis(*p*-dimethylaminophenyl)methane (BMM) and tris (*p*-dimethylaminophenyl)methane (TMM) with *o*-AH, gave their cations in the presence of oxygen, showing that the oxygen eliminates the hydrogen atoms of the cation radicals derived from BMM and TMM. The reactions of *N,N*-dimethylaniline (DMA) with *o*-AH gave rise to isolations of BMM and *N*-methylaniline, along with the formations of the cation radical of TMB and the crystal violet cation (TMM^+). The mechanisms of the reactions are proposed.

Cation radicals are familiar as transient species in mass spectrometry or anodic oxidation.[1] However, the chemical behaviors of cation radicals have not, until recently, received much attention.[2] Previously, we reported that the radical cations of some aromatic hydrocarbons, triethylamine, triphenylamine or *N*-vinylcarbazole arose in liquid sulfur dioxide in the presence of oxygen; in these cases, the existence of the radical cations was proved from the electronic or ESR spectra and from the chemical follow-up reactions.[3] The values of the electron affinity and the dielectric constant of liquid sulfur dioxide are not so much higher than those of the usual acceptors or polar solvents. Hence, sulfur dioxide probably plays a role of a polarizable electrophilic reagent, using the available 3d orbitals of the sulfur atom, rather than that of a polar solvent. Keeping these consideration in mind, we have examined the reaction of some sulfones with substrates possessing a *p*-dimethylaminophenyl group. It was found that mixed sulfonic-carboxylic anhydrides provided a convenient means of generating cation radicals from the substrates.

Results and Discussion

Formation of Cation Radicals and Cations. In the reactions of *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD), *N,N,N',N'*-tetramethylbenzidine (TMB) and tetrakis(*p*-dimethylaminophenyl)ethylene (TMPE) with *o*-sulfobenzoic anhydride (*o*-AH) in acetonitrile, the formations of their cation radicals were investigated spectrophotometrically. The absorption maxima in the 340—1400 nm range for the cation radicals or dication are summarized in Table 1, being compared with those reported by some authors.

These values were in fair agreement with those reported,[4-11] though the peak positions for TMPE shifted slightly. The reaction of TMPE with *o*-AH in acetonitrile underwent double electron transfer to form the diamagnetic dication ($TMPE^{2+}$), whose absorption band was in essential agreement with that observed in the reaction of TMPE with iodine in acetonitrile.[11] These results are coincident with those reported by Foster and Thomson:[12] that the ease of the complete

electron transfer is TMPE>TMPD>TMB.

An investigation by ESR also was undertaken for the reaction of TMPD with *o*-AH in acetonitrile. The hyperfine coupling constants of TMPD$^+$ were assigned as follows: a_{CH_3}=6.65 G; a_N=6.85 G; $a_{ring H}$=1.98 G. These couplings are very similar to those reported by Carrington[13] and Taft.[14]

The reactions of bis(*p*-dimethylaminophenyl)methane (BMM) and tris(*p*-dimethylaminophenyl)methane (TMM) with *o*-AH were investigated spectrophotometrically in acetonitrile. The absorption maxima observed are due to those of bis(*p*-dimethylaminophenyl)methyl cation (BMM$^+$) and tris(*p*-dimethylaminophenyl)methyl cation (TMM$^+$, Crystal Violet cation) by reference to the literature values (Table 2). These cations are to be derived from the corresponding cation radicals (BMM$^+$ and TMM$^+$): the cation radicals are then able to release a hydrogen atom to afford highly stabilized BMM$^+$ and TMM$^+$ respectively.

Table 3. Effect of oxygen on formation of cation species

Amine	Cation species	Yield (mol %)[a] undegassed	degassed
TMPD	TMPD$^+$	20	18
TMM	TMM$^+$	59	29

a) Calculated from molar extinction coefficients. TMPD$^+$: 1.1×10^4 at 615 nm.[7] TMM$^+$: 1.1×10^5 at 592 nm.[18,19]

An intervention of oxygen, here, was considered important for the elimination of the hydrogen atoms. Influences of oxygen on the formation of such cation species have not been investigated to date, though they have been mentioned in Refs. 2b and 9. And so, the reactions with *o*-AH were carried out under a degassed condition. As shown in Table 3, the reaction of TMM with *o*-AH gave a decreased yield of the cation under a degassed atmosphere, in contrast to that of TMPD. Effects of oxygen on the formation rates of the cation species were also studied for the reactions of TMPD, BMM, and TMM with *o*-AH in acetonitrile (Fig. 1). The formation rates of the cations were remarkably accelerated in the presence of oxygen, in contrast to those of the cation radical (TMPD$^+$). These results show that the cations are formed from the cation radicals, which are derived from BMM and TMM which have some available hydrogen atoms, by hydrogen

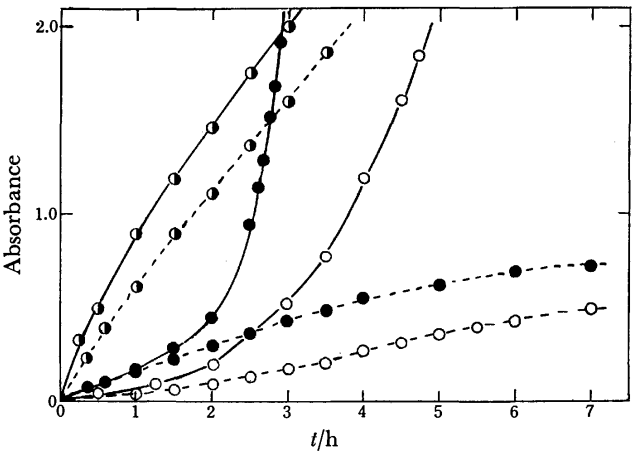

Fig. 1. Effect of oxygen on the rate of formation of cation species in acetonitrile at 8 °C. [TMPD], [BMM], and [TMM]: 7.6×10^{-3} M, [*o*-AH]: 1.3×10^{-3} M. ◑: TMPD$^+$, ○: BMM$^+$, ●: TMM$^+$. ——: under undegassed, ------: under degassed.

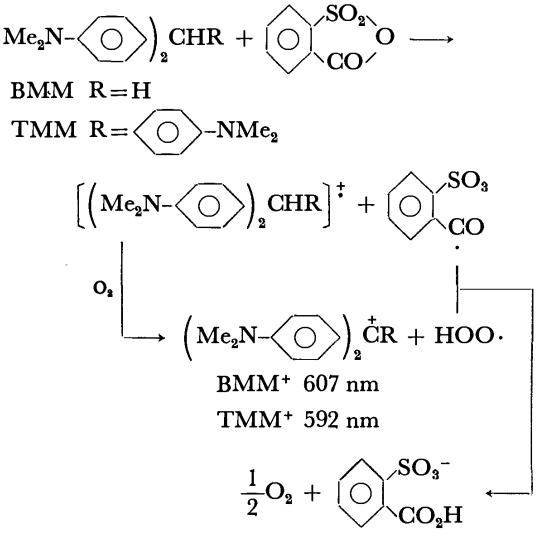

Scheme 1.

abstraction with oxygen (Scheme 1). To explain the retarded formation of the cations under the degassed atmosphere, a following alternative pathway can be considered: the cation radicals (BMM$^+$ and TMM$^+$) give their protons to the counter anion radical shown in Scheme 1, and are transformed into the radicals (BMM· and TMM·), which are then oxidized by *o*-AH to the highly stabilized cations (BMM$^+$ and TMM$^+$).

Reaction of N,N-*Dimethylaniline with* o-*AH.* *N,N*-Dimethylaniline (DMA) has no blocked *para*-position in contrast to the amines used so far. Studies of the cation radical (DMA^+) formation from DMA have been done by many researchers.[2b,9,19-23] In their studies,[2b,19] it was recognized that the cation radical converted to tris(*p*-dimethylaminophenyl)methyl cation (Crystal Violet cation). However, none of the reports clarified the reaction path to the Crystal Violet cation from the cation radical (DMA^+) at all.

TABLE 4. EQUIMOLECULAR REACTIONS BETWEEN DMA AND ANHYDRIDES

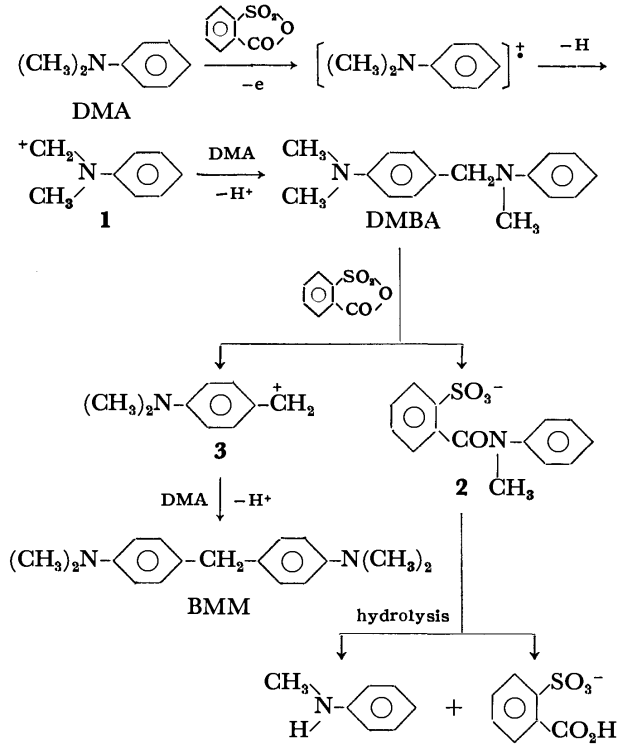
			O_2	13	7

a) Calculated based on triple the molar quantity of the amine used.

An equimolar amount of DMA and *o*-AH was allowed to react in a solvent. Table 4 shows the results. These products are the same as those obtained from the gamma-radiolysis[20] of DMA. This fact and the formation of TMB^+, as described below in detail, suggest that DMA^+ is formed in this reaction. A reaction of DMA with *β*-sulfoisobutyric anhydride (*β*-AH) also gave the same products as the reaction with *o*-AH (Table 4).



Scheme 2.

The mechanism for this reaction, outlined in Scheme 2, is similar to that reported previously by Grodowski and Latowski[21] from the study of the photoxidation of DMA with bromobenzene. A hydrogen atom of the cation radical derived from DMA is abstracted by oxygen to give *N*-methylanilinomethyl cation (**1**). This cation attacks the *para*-position of unoxidized DMA to afford *N*-(*p*-dimethylaminobenzyl)-*N*-methylaniline (DMBA). In a subsequent reaction step, DMBA is decomposed by sulfonic carboxylic anhydride giving the anilide derivative (**2**) and *p*-dimethylaminobenzyl cation (**3**). This carbocation (**3**), in the presence of DMA, forms the isolated product BMM. The anilide derivative **2** is hydrolyzed by treatment in an alkali solution to yield *N*-methylaniline. On the other hand, when DMA was treated with *o*-AH in the presence of authentic DMBA, the same products, BMM and *N*-methylaniline, were also obtained. In this reaction, it was confirmed by means of NMR and thin-layer chromatography that the DMBA used had been consumed completely. These results support the reaction mechanism shown in Scheme 2.

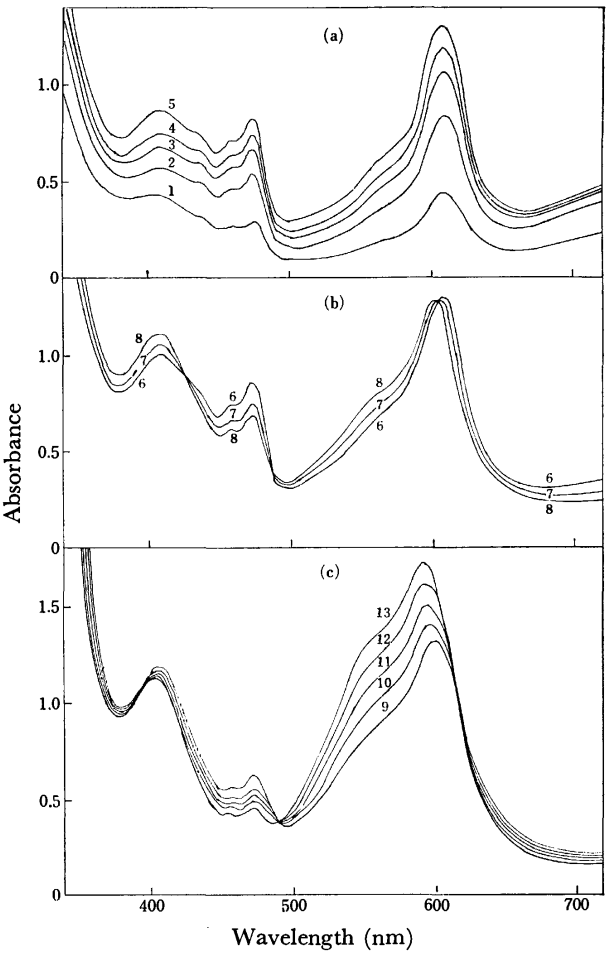


Fig. 2. Spectroscopic course of the reaction of DMA with *o*-AH in acetonitrile. [DMA]=4.1×10^{-2} M, [*o*-AH]=4.1×10^{-2} M. After mixing:
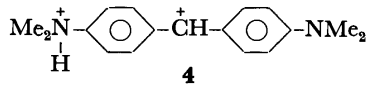
(a) 1, 10 min; 2, 20 min; 3, 30 min; 4, 40 min; 5, 60 min;
(b) 6, 110 min; 7, 160 min; 8, 210 min;
(c) 9, 300 min; 10, 420 min; 11, 540 min; 12, 660 min; 13, 900 min.

Reaction Course from DMA to TMM⁺. In the reaction of DMA with *o*-AH, it was confirmed by the optical spectra that *N,N,N′,N′*-tetramethylbenzidine cation radical (TMB†) and Crystal Violet cation (TMM⁺) were formed. When an acetonitrile solution of DMA was mixed with an acetonitrile solution of *o*-AH, the reaction mixture rapidly assumed a yellowish-green color, then turned to a green color (stage 1). The green color gradually changed to a bluish-green color (stage 2) and finally to a purple color (stage 3). Figure 2 shows the absorption spectra of the reaction mixture of DMA and *o*-AH corresponding to stages 1, 2, and 3.

The addition of an acetonitrile solution of *o*-AH to an acetonitrile solution of DMA gave rise to a new series of absorptions in the visible region at 438, 458, and 472 nm, due to the TMB†, and at 607 nm due to BMM⁺. In addition, a new absorption at 408 nm was also observed. This band was assigned to a dication (**4**) protonated at one nitrogen atom of BMM⁺, because the same absorption band was also obtained by the addition of *o*-sulfobenzoic acid to an acetonitrile solution of BMM⁺, which had been prepared by the reaction of BMM and *o*-AH.



4

In stage 1, each of these absorptions due to TMB†, BMM⁺, and the dication (**4**) increased in intensity over a period of one hour, as shown in Fig. 2a. In stage 2 (Fig. 2b), it was observed that the intensity of the absorption at 592 nm due to TMM⁺ increased while those of TMB† and BMM⁺ decreased, showing the isosbestic points at 426, 490, and 602 nm. In stage 3 (Fig. 2c), the absorption of TMM⁺ showed further increased intensity, with an isosbestic point at 490 nm, with the lapse of time, while the absorptions in the 430—480 nm region, on the contrary, decreased in intensity. Such spectral changes were observed as well by the use of *β*-AH instead of *o*-AH.

From these changes of the absorption spectra, it is suggested that the oxidation of DMA to TMM⁺ by the sulfonic carboxylic anhydrides proceeds through BMM⁺ and TMB†. On the other hand, the addition of DMA to the solution of BMM⁺, which had been prepared by the reaction of BMM with *o*-AH in acetonitrile, showed a new absorption band at 592 nm due to TMM⁺, together with a decrease in the intensity of the absorption at 607 nm due to BMM⁺. The presence of the isosbestic point at 490 nm, in Fig. 2c, shows that a one-electron transfer reaction occurs between TMM and TMB†. This was confirmed also from the result that the spectrum of a mixture of TMM and TMB†, which had come from the reaction of TMB with *o*-AH in acetonitrile, changed with the isosbestic point at 492 nm, as shown in Fig. 3.

Finally, we here propose a mechanism for the oxidation of DMA to TMM⁺ by the sulfonic carboxylic anhydrides, as shown in Scheme 3, which is different

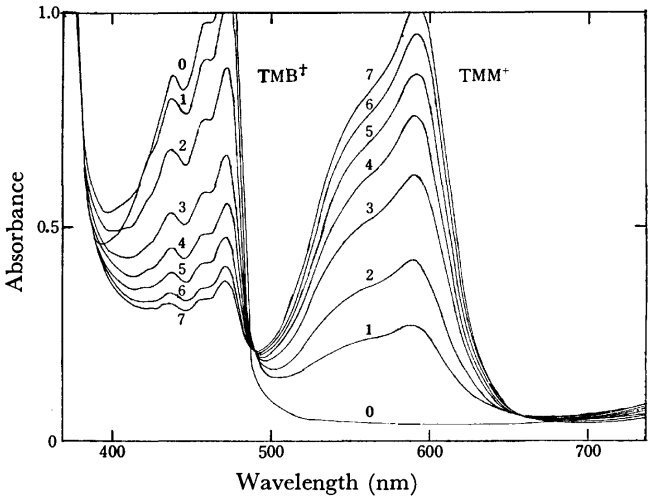


Fig. 3. Spectroscopic course of the reaction of TMB† with TMM in acetonitrile. 0, TMB† alone. After addition of TMM: 1, immediately; 2, 10 min; 3, 20 min; 4, 30 min; 5, 40 min; 6, 50 min; 7, 60 min.

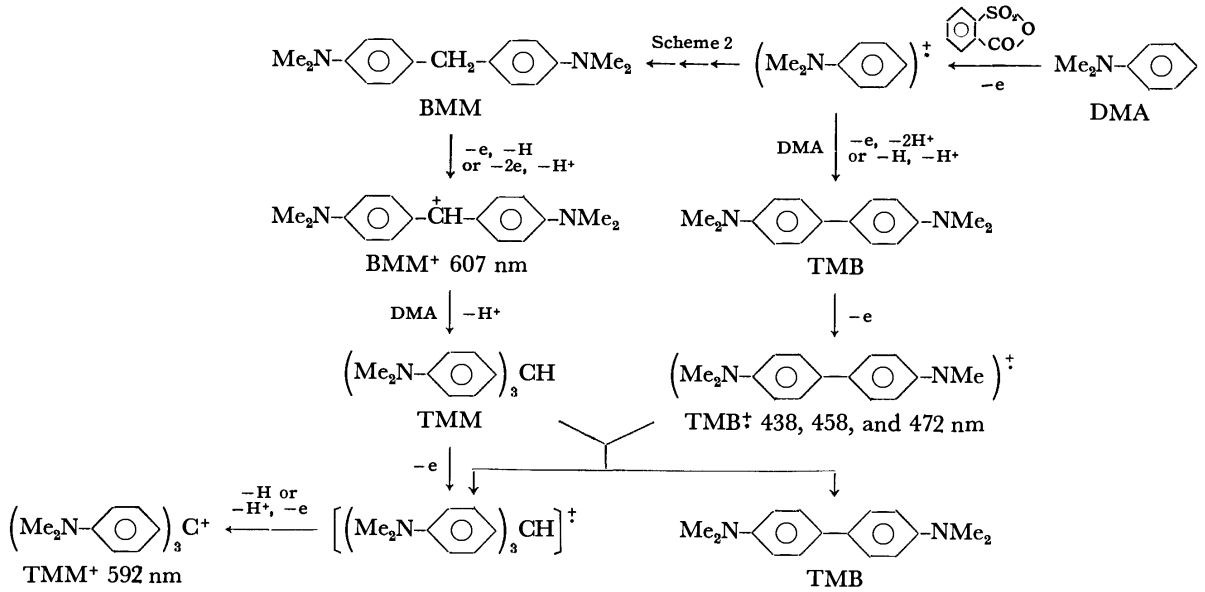
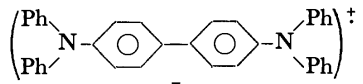


Scheme 3.

from the mechanism proposed in the system of DMA and chloranil.[24] The BMM^+ derived from BMM attacks the *para*-position of the unoxidized DMA, giving TMM. Alternatively, the cation radical of DMA dimerizes or reacts with the parent to form TMB^+. Then, the one-electron transfer reaction between TMM and TMB^+ occurs to afford TMM^+.

Reaction of Triphenylamine with o-*AH.* A reaction of triphenylamine with *o*-AH was studied spectrophotometrically in a similar manner. An absorption band appeared at 480 nm. This broad band is apparently due to the *N,N,N',N'*-tetraphenylbenzidine cation radical (**5**), whose spectral assignment has been reported by Hasegawa,[25] Dollish, and Hall.[26]



5

Triphenylamine is not blocked at the *para*-positions and doesn't contain a labile hydrogen atom such as the *N*-methyl group of DMA. Thus, the cation radical derived from triphenylamine recombines or reacts with the parent exclusively at the *para*-position to give the cation radical **5**.

Experimental

The optical absorption spectra in the 340—740 nm and 650—1400 nm ranges were recorded on a Union SM-401 and a Shimadzu MPS-50L recording spectrophotometer. The quartz cell used was 1.0 cm in length. If necessary, each of the sample solutions of an electron donor and an acceptor was mixed into the cell after repeated freeze-pump-thaw-cycles. The NMR spectra were obtained on a Varian EM-360 (60 MHz) analytical spectrometer with tetramethylsilane as an internal standard. The IR and ESR spectra were taken on an Hitachi EP-S and a JEOL JES-NE2X instrument. Gas chromatography was done on a Yanagimoto GCG-5DH unit, employing as adsorbent 10% Apiezon Grease M on Celite (60—80 mesh).

Solvents. Acetonitrile, benzene, and dioxane were used after the commercial reagents were purified according to the published directions.[27]

Materials. *o*-Sulfobenzoic anhydride (*o*-AH) was prepared from acid ammonium *o*-sulfobenzoate,[28] which had been obtained by the hydrolysis of *o*-sulfobenzoic imide (saccharin insoluble);[29] mp 127 °C (lit,[28] 128 °C). The preparation of *β*-sulfoisobutyric anhydride (*β*-AH) was the same as that reported by Kharasch *et al.*[30] *N,N,N',N'*-Tetramethyl-*p*-phenylenediamine (TMPD) was obtained by alkalizing an aqueous solution of its dihydrochloride salt with a potassium hydroxide aqueous solution. The amine was purified by means of sublimation; mp 51 °C (lit,[31] 51 °C). The white crystalline solid thus obtained was kept at about −20 °C in the dark until used. *N,N,N',N'*-Tetramethylbenzidine (TMB) was recrystallized twice from 1-pentanol; mp 196 °C (lit,[12] 196 °C). Tetrakis(*p*-dimethylaminophenyl)ethylene (TMPE) was prepared according to the method given in the literature,[32] and recrystallized from a benzene–ligroin mixture; mp 314.5—315.0 °C (lit,[32-33] 314—316 °C). Bis and tris(*p*-dimethylaminophenyl)methanes (BMM and TMM) respectively were recrystallized twice from ethanol. BMM: mp 90 °C (lit,[34] 91 °C). TMM: mp 176 °C (lit,[35,36] 177—178 °C). *N,N*-Dimethylaniline (DMA) was refluxed with acetic anhydride, followed by neutralization, separation of the organic layer, and repeated distillation under reduced pressure. The colorless oil was dried over pellets of sodium hydroxide, and distilled *in vacuo* before use. Triphenylamine was recrystallized from absolute ether, followed by recrystallization from ethanol; mp 127 °C (lit,[37] 128 °C). *N*-(*p*-Dimethylaminobenzyl)-*N*-methylaniline (DMBA) was prepared in the following way. A solution of benzoyl peroxide (12 g) in benzene (100 ml) was added dropwise to a solution DMA (24 g) in benzene (20 ml) with stirring, keeping the temperature at 25 °C. The reaction mixture was refluxed for 14 h. The benzene solution was washed with a sodium hydroxide solution, followed by washing with water and drying with sodium sulfate. Then the benzene and unchanged DMA were removed by distillation under a pressure of 2 Torr. The residue (6 g) was chromatographed on alumina (90 g), and DMBA (1.5 g) was eluted with light petroleum ether. The white crystal was recrystallized from ethanol; mp 67.5—68.0 °C (lit,[23] 68 °C). NMR (CCl_4, δ): 2.80 (s, 6H, $-CH_3$), 2.85 (s, 3H, $-CH_3$), 4.30 (s, 2H, $-CH_2-$) and 6.50—7.20 (m, 9H, aromt.).

Reaction of DMA with Sulfonic Carboxylic Anhydrides. A solution of 3 g of DMA in an absolute solvent (25 ml) was added to an equimolecular solution of sulfonic carboxylic anhydride in the absolute solvent (25 ml). The reaction mixture, protected in the usual way from atmospheric moisture, was stirred for a week in the dark at room temperature. The reaction mixture was evaporated to a deep green syrup under reduced pressure. A sodium hydroxide solution was added to the residue and an insoluble oily substance was extracted with ether; the ether extract was dried over sodium hydroxide. Removal of the solvent gave a brown crystalline residue, which was recrystallized from ethanol. The IR, NMR, and mass spectra of this product were identical with those of the authentic sample, BMM. On the other hand, after the alkali aqueous solution was heated at about 90 °C for 6 h, the solution was extracted with ether. Concentration of the ether solution gave an oily substance, which was analyzed by the use of gas chromatography. The IR and NMR spectra of the product were identical with those of the authentic sample, *N*-methylaniline.

Reaction of DMA with o-*AH in the Presence of DMBA.* A solution of *o*-AH (38.5 mg) in anhydrous acetonitrile (2 ml) was added to a solution of DMA (20 mg) and DMBA (8.6 mg) in absolute acetonitrile (2 ml). The reaction mixture was introduced into a cell and then sealed. The visible spectrum of the final product was identical to that of TMM^+, whose yield was five times that of the reaction in the absence of DMBA. A procedure similar to that described above was carried out.

Synthesis of Alanyl-1-aminoethanesulfonic Acid[1)]

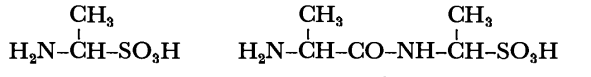
Tetsuo SHIBA, Kenichi MIYOSHI, and Shoichi KUSUMOTO
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received August 14, 1976)

For the purpose of the verification of an expectation that the structural analogs of D-alanyl-D-alanine which participates in the biosynthesis of cell wall peptides might inhibit the growth of microorganisms, alanyl-1-aminoethanesulfonic acid was synthesized by the mixed anhydride method. Four diastereomers were separated and their absolute configurations were deduced on the basis of X-ray analysis. None of these dipeptide analogs and their benzyloxycarbonyl or *t*-butoxycarbonyl derivatives showed appreciable activity against *E. coli*.

α-Amino sulfonic acids can often act as antagonists of α-amino carboxylic acids. In 1941, McIlwain[2)] prepared several α-amino sulfonic acids which were found to possess antimicrobial activities. Thereafter, another author reported antivial activity of some amino sulfonic acids.[3)] The analogy between amino carboxylic acid and amino sulfonic acid in biological effect was also proved in meaty taste of γ-sulfonic acid analog of L-glutamic acid.[4)] In this line, an activity as antagonist will be expected in a structural analog of a biologically significant peptide where one of the component amino acids is replaced with the corresponding amino sulfonic acid.

From studies on the biosynthesis of bacterial cell wall,[5)] it has been revealed that D-alanyl-D-alanine is incorporated as a dipeptide unit into a peptidoglycan precursor in an early step and the C-terminal D-alanine residue finally splits off for completion of the network structure of the peptidoglycan through transpeptidation. If an amino sulfonic acid peptide acts as an antagonist of D-alanyl-D-alanine, it may possibly inhibit either the incorporation of the dipeptide or the formation of the cross linkage of the peptide chain.[6)]

On the basis of above consideration, we planned to prepare the compounds in which one alanine residue of the dipeptide is replaced with 1-aminoethanesulfonic acid (Aes) (**1**).[7)] In this paper, the synthesis and separation of four stereoisomers of alanyl-1-aminoethanesulfonic acid (**4** and **6**) are described.



1 **4, 6**

Although Frankel and Moses[8)] reported the preparation of some (*N*-benzyloxycarbonylglycyl)amino sulfonic acids, problems remained to be solved on the stereochemistry of amino sulfonic acids. Mild conditions for deprotection also seemed to have to be investigated.

Results and Discussion

As a preliminary experiment, benzyloxycarbonyl derivative of 1-aminoethanesulfonic acid (**1**) was prepared in order to examine the chemical properties of acylated α-amino sulfonic acid and to investigate the method of deprotection. 1-(Benzyloxycarbonylamino)-ethanesulfonic acid (**2**) was isolated as crystalline anilinium salt which was readily characterized.[9)] Isolation of this sulfonic acid (**2**) as its sodium salt was not preferable since removal of inorganic salt from it became very difficult because of the similar solubilities in water. When benzyloxycarbonyl derivative was hydrogenolyzed in the presence of palladium catalyst, free 1-aminoethanesulfonic acid (**1**) was obtained, though in a low yield (12%). This indicates that the amino sulfonic acid structure can survive more or less through hydrogenolysis depending on the reaction conditions. Thus, the benzyloxycarbonyl group could be used as appropriate protecting group for the synthesis of the amino sulfonic acid peptides.

In a similar manner to the usual peptide synthesis, benzyloxycarbonyl-D-alanine was coupled with sodium salt of 1-aminoethanesulfonic acid (**1**) using ethyl chloroformate to afford benzyloxycarbonyl-D-alanyl-1-aminoethanesulfonic acid (**3**), which was isolated as crystalline anilinium salt. Since racemic **1** was employed as the starting material, the product (**3**) should be a mixture of diastereomers, *i.e.*, benzyloxycarbonyl-D-alanyl-D-1-aminoethanesulfonic acid and its D-L isomer.[10)] However, this product showed no sign of heterogenity either on TLC or on recrystallization.

Catalytic hydrogenolysis of **3** gave free D-alanyl-1-aminoethanesulfonic acid (**4**) by removal of the benzyloxycarbonyl group in a good yield. This product (**4**) showed two ninhydrin positive spots on TLC or paper chromatography (PC). Both components (**4a** and **4b**) which were separated each other by preparative PC had the same molecular formula and thus could be assigned to be the diastereoisomers of D-alanyl-1-aminoethanesulfonic acid, though the configurations of the amino sulfonic acid residues were not clarified at this stage.

In order to confirm this result, the same reactions were carried out starting from benzyloxycarbonyl-L-alanine. Thus, deprotection of benzyloxycarbonyl-L-alanyl-1-aminoethanesulfonic acid (**5**) followed by separation with preparative PC afforded the diastereomers of L-alanyl-1-aminoethanesulfonic acid (**6a** and **6b**). Purities of **6a** and **6b** were well monitored by means of NMR spectra, since slight but distinct differences of chemical shifts between the two compounds are observed at the protons of L-alanine residues (see experimental section). The NMR spectrum of the deprotection product (**6**) before separation corresponds to that expected for a 1 : 1 mixture of **6a** and **6b**.

X-Ray analysis of **6a**[11)] established the *R* configuration for the asymmetric carbon atom of the 1-aminoethanesulfonic acid residue in this diastereomeric form by taking account of the *S* configuration of the L-alanine residue in the same molecule as reference. If D, L re-

presentation for amino acid is applied to the configuration of aminoethanesulfonic acid, **6a** should be termed as L-alanyl-L-1-aminoethanesulfonic acid. Accordingly, the stereostructures of the other three "dipeptides" were unequivocally assigned by comparison of their physical constants each other. These results are summarized in Table 1.

Consequently, we could thus obtain two pairs of optically active alanyl-1-aminoethanesulfonic acids and determine their absolute configurations. Furthermore, it was also revealed that the configuration of the α-carbon atom in an α-amino sulfonic acid residue is retained stable if its amino group is acylated, although it is generally accepted that α-amino sulfonic acids are unstable, thus being readily dissociated to the parent aldehydes, ammonia and bisulfite in aqueous solution. There has been reported only one case of securing an optically active α-amino sulfonic acid derivative by Neelakantan so far.[12] On reaction of ephedrine with sodium hydrogen sulfite adduct of benzaldehyde, he obtained one of the two possible diastereomers of the amino sulfonic acid derivative and another isomer could not be obtained which was immediately transformed *via* intramolecular cyclization. Therefore, our result in this investigation would be the first and significant example in the determination of stereochemistry of α-amino sulfonic acid.

For further synthesis of more complex peptide analogs containing amino sulfonic acid, applicability of other protecting groups should be examined. *t*-Butoxycarbonyl group was shown to be satisfactorily useful. Thus, *t*-butoxycarbonyl-D and L-alanines were condensed with 1-aminoethanesulfonic acid (**1**) to yield *t*-butoxycarbonyl-D and L-alanyl-1-aminoethanesulfonic acids (**7** and **8**) respectively. Removal of *t*-butoxycarbonyl group was carried out by means of dry hydrogen chloride in ethyl acetate. From the anilinium salt of **8** was obtained free L-alanyl-1-aminoethanesulfonic acid (**6**), which was identified by means of TLC and IR spectra with the sample obtained above by hydrogenolysis of benzyloxycarbonyl-L-alanyl-1-aminoethanesulfonic acid (**5**). When the anilinium salt of the benzyloxycarbonyl derivative (**5**) was treated with anhydrous hydrogen bromide in acetic acid, the protecting group was readily removed and the product was identified with **6** by TLC. However, separation of pure substance from contaminating anilinium bromide was hardly effected.

Finally, antimicrobial activity was tested for the four diastereomers of alanyl-1-aminoethanesulfonic acid (**4a**, **4b**, **6a**, and **6b**) and sodium salts of benzyloxycarbonyl- as well as *t*-butoxycarbonyl-D and L-alanyl-1-aminoethanesulfonic acids (**3**, **5**, **7**, and **8**). Unfortunately, none of them showed appreciable activity against *E. coli* in a modified Henderson-Snell medium free from alanine even in high concentrations of 500—1000 μg/ml.

Experimental[13]

1-Aminoethanesulfonic Acid (1). This compound was prepared through the reaction of acetaldehyde either with ammonium sulfite[2a] or with sodium hydrogen sulfite and ammonia;[14] mp 171—172 °C dec. Use of the former reagent was more convenient though the yield was somewhat lower than the latter. The product was used to the following coupling reaction without recrystallization because of its lability toward decomposition on heating or even on standing at room temperature in an aqueous solution.

1-(Benzyloxycarbonylamino)ethanesulfonic Acid (2) Anilinium Salt. To an ice-cooled solution of **1** (1.25 g, 10 mmol) and Na_2CO_3 (1.17 g, 11 mmol) in water (10 ml), there was added benzyloxycarbonyl chloride (2.1 g, 12 mmol) dropwise with stirring. Stirring was continued at room temperature overnight and excess of the chloride was extracted with ether. After the aqueous layer was concentrated *in vacuo*, aniline (0.93 g, 10 mmol) was added and the mixture was adjusted to pH 6 with 6 M HCl under ice cooling. The crystalline anilinium salt of **2** was collected by filtration; yield 1.35 g (38%). Recrystallization was effected from methanol–ether; mp 164—166 °C dec.

Found: C, 54.34; H, 5.68; N, 7.91; S, 9.09%. Calcd for $C_{16}H_{20}O_5N_2S$: C, 54.53; H, 5.72; N, 7.95; S, 9.10%.

Hydrogenolytic Deprotection of 2. The anilinium salt of **2** (0.70 g, 2 mmol) was dissolved in methanol (20 ml), and hydrogenolyzed in the presence of Pd black and acetic acid (0.12 ml, 2 mmol) at room temperature. After 3 h, the catalyst and the white precipitates formed were filtered and the latter were extracted with water at 40 °C. The aqueous extract was concentrated *in vacuo* and allowed to stand in a refrigerator to form colorless crystals; yield, 30 mg (12%); mp 170—172 °C dec. The IR spectrum of this product was completely identical with that of **1**.

Benzyloxycarbonyl-D-alanyl-DL-1-aminoethanesulfonic Acid (3) Anilinium Salt. Ethyl chloroformate (0.24 ml, 2.5 mmol) was added to a solution of benzyloxycarbonyl-D-alanine (0.53 g, 2.4 mmol) and *N*-methylmorpholine (0.29 ml, 2.6 mmol) in anhydrous tetrahydrofuran (5 ml) at −13 °C with stirring. After 10 min, a solution of **1** (0.45 g, 3.6 mmol) in 2 M aqueous NaOH (1.8 ml) was added dropwise during 5 min, while the mixture was stirred at −13 °C. Stirring was continued at this temperature for further 3 h. After tetrahydrofuran was evaporated *in vacuo*, the mixture was diluted with water, treated with aniline (0.35 ml, 3.8 mmol) and adjusted to pH 6 with 2 M HCl under ice cooling. The crystals of anilinium salt of **3** were filtered; yield, 0.47 g (46%). Recrystallization was effected from methanol–ether; mp 201—204 °C dec.

Found: C, 53.88; H, 5.94; N, 9.93; S, 7.67%. Calcd for $C_{19}H_{25}O_6N_3S$: C, 53.88; H, 5.95; N, 9.92; S, 7.57%.

D-Alanyl-DL-1-aminoethanesulfonic Acid (4). The anilinium salt of **3** (1.27 g, 3.0 mmol) was dissolved in methanol and hydrogenolyzed in the presence of Pd black at room temperature. After the catalyst was filtered off and solvent

was evaporated *in vacuo*, the residue was recrystallized from water–methanol–ether; yield, 0.46 g (77%); mp 220—224 °C dec; R_f 0.23, 0.27 (Toyo No. 51 filter paper, 1-butanol–acetic acid–water 4: 1: 2).

Separation of D-*Alanyl*-D *and* L-*1-aminoethanesulfonic Acids (**4a** and **4b**).* The mixture (400 mg) of the diastereomers (**4**) obtained above was dissolved in a small amount of water and subjected to a preparative PC on Toyo No. 50 filter paper (40×40 cm, 4 pieces) by developing twice with 1-butanol–acetic acid–water (4: 1: 2). The three portions of a ninhydrin positive band were extracted with water separately. From each extract, pure **4a** (75 mg), pure **4b** (40 mg), and a mixture of them (105 mg) were obtained respectively by crystallization from water–methanol–ether.

D-*Alanyl*-D-*1-aminoethanesulfonic Acid (**4a**)*: Physical constants; see Table 1.

Found: C, 27.70; H, 6.62; N, 13.07; S, 14.85%. Calcd for $C_5H_{12}O_4N_2S \cdot H_2O$: C, 28.03; H, 6.59; N, 13.08; S, 14.97%.

D-*Alanyl*-L-*1-aminoethanesulfonic Acid (**4b**)*: Physical constants; see Table 1.

Found: C, 29.91; H, 6.11; N, 13.98; S, 15.86%. Calcd for $C_5H_{12}O_4N_2S \cdot 1/4H_2O$: C, 29.92; H, 6.28; N, 13.96; S, 15.97%.

Benzyloxycarbonyl-L-*alanyl*-DL-*1-aminoethanesulfonic Acid (**5**) Anilinium Salt.* Ethyl chloroformate (1.60 ml, 17 mmol) was added to a solution of benzyloxycarbonyl-L-alanine (3.40 g, 15 mmol) and *N*-methylmorpholine (1.80 ml, 16 mmol) in anhydrous tetrahydrofuran (35 ml) at −9 °C with stirring. After 8 min, there was added a solution of **1** (2.50 g, 20 mmol) in 1.5 M aqueous NaOH (13 ml) with stirring at −9 °C. The mixture was stirred at room temperature for 3 h. The product was converted into its anilinium salt as described above for **3** and recrystallized from methanol–ether; yield 1.90 g (30%); mp 193—194 °C dec. Its IR spectrum was identical with that of the anilinium salt of **3**.

Found: C, 53.51; H, 5.82; N, 9.92; S, 7.56%. Calcd for $C_{19}H_{25}O_6N_3S$: C, 53.88; H, 5.95; N, 9.92; S, 7.57%.

L-*Alanyl*-DL-*1-aminoethanesulfonic Acid (**6**).* The anilinium salt of **5** (1.27 g, 3.0 mmol) was hydrogenolyzed as described above for **4** and the product was recrystallized from water–methanol–ether; yield 0.58 g (97%); mp 224—226 °C dec. NMR[15]: δ 1.51 (3H, d, J=7, CH_3 of Aes), 1.55 and 1.57 (each 1.5H, d, J=7, CH_3 of Ala), 4.11 and 4.12 (each 0.5H, q, J=7, CH of Ala), 5.02 (1H, q, J=7, CH of Aes). The IR spectrum was identical with that of **4**.

Found: C, 29.99; H, 6.23; N, 13.88; S, 16.10%. Calcd for $C_5H_{12}O_4N_2S \cdot 1/4H_2O$: C, 29.92; H, 6.28; N, 13.96; S, 15.97%.

Separation of L-*Alanyl*-L *and* D-*1-aminoethanesulfonic Acids (**6a** and **6b**).* The mixture (400 mg) of the diastereomers obtained above was subjected to preparative PC as described for **4a** and **4b**, affording pure **6a** (130 mg), pure **6b** (130 mg), and a mixture of them (90 mg).

L-*Alanyl*-L-*1-aminoethanesulfonic Acid (**6a**)*: Physical constants; see Table 1. NMR[15]: δ 1.51 (3H, d, J=7, CH_3 of Aes), 1.57 (3H, d, J=7, CH_3 of Ala), 4.12 (1H, q, J=7, CH of Ala), 5.02 (1H, q, J=7, CH of Aes).

Found: C, 27.88; H, 6.66; N, 13.01; S, 14.72%. Calcd for $C_5H_{12}O_4N_2S \cdot H_2O$: C, 28.03; H, 6.59; N, 13.08; S, 14.97%.

L-*Alanyl*-D-*1-aminoethanesulfonic Acid (**6b**)*: Physical constants; see Table 1. NMR[15]: δ 1.51 (3H, d, J=7, CH_3 of Aes), 1.55 (3H, d, J=7, CH_3 of Ala), 4.11 (1H, q, J=7, CH of Ala), 5.02 (1H, q, J=7, CH of Aes).

Found: C, 29.95; H, 6.24; N, 14.11; S, 15.97%. Calcd for $C_5H_{12}O_4N_2S \cdot 1/4H_2O$: C, 29.92; H, 6.28; N, 13.96; S, 15.97%.

t-*Butoxycarbonyl*-D-*alanyl*-DL-*1-aminoethanesulfonic Acid (**7**).* Ethyl chloroformate (0.53 ml, 5.5 mmol) was added to a solution of *t*-butoxycarbonyl-D-alanine (0.95 g, 5.0 mmol) and *N*-methylmorpholine (0.60 ml, 5.5 mmol) in anhydrous tetrahydrofuran (15 ml) at −8 °C with stirring. After 10 min, there was added a solution of **1** (0.95 g, 7.6 mmol) in 1 M aqueous NaOH (7.5 ml) dropwise with stirring at −8 °C. Stirring was continued at this temperature for 1 h and at room temperature for further 3 h. Tetrahydrofuran was removed *in vacuo* and the product was isolated as its anilinium salt as described for **3** and recrystallized from methanol–ether; yield, 0.84 g (43%); mp 163 °C dec. An analytical sample was further recrystallized from the same solvents; mp 179—181 °C dec.

Found: C, 49.09; H, 7.02; N, 10.77; S, 8.22%. Calcd for $C_{16}H_{27}O_6N_3S$: C, 49.34; H, 6.99; N, 10.79; S, 8.23%.

t-*Butoxycarbonyl*-L-*alanyl*-DL-*1-aminoethanesulfonic Acid (**8**).* This compound was prepared as described above for **7** by using *t*-butoxycarbonyl-L-alanine (0.95 g, 5.0 mmol) in place of *t*-butoxycarbonyl-D-alanine. The product was isolated as its anilinium salt; yield, 0.50 g (26%); mp 162—166 °C dec. Its IR spectrum was identical with that of the anilinium salt of **7**.

*Deprotection of **8**.* To a suspension of anilinium salt of **8** (100 mg, 0.26 mmol) in ethyl acetate (3 ml), there was added a saturated solution of dry hydrogen chloride in ethyl acetate (2 ml). While the mixture was stirred at room temperature for 90 min, the initial crystals dissolved and the product separated out. The latter was collected by filtration and recrystallized from water–methanol–ether; yield, 20 mg (40%); mp 220—223 °C dec. Its IR spectrum was identical with that of **6**.

*Sodium Salts of **3**, **5**, **7**, and **8**.* These compounds were prepared by dissolving the corresponding anilinium salt in water containing one equivalent of NaOH, followed by extraction with ether and evaporation of the aqueous phases *in vacuo*.

The authors are deeply indebted to Prof. M. Kakudo and his coworkers, Protein Research Institute, Osaka University for X-ray analysis and to Daiichi Seiyaku Co., Ltd. for the test of antimicrobial activity.

Deacylations and Syntheses of Some 9-Acylfluorenes

Takao KIMURA, Masahiro MINABE,* Motohiro TSUBOTA, and Kazuo SUZUKI

Department of Industrial Chemistry, Faculty of Engineering, Utsunomiya University, Ishiicho, Utsunomiya 321-31

(Received August 14, 1976)

Deacylations of substituted 9-acetyl-, 9-propionyl-, 9-benzoyl-fluorene, and 9-fluorenyl 9-methyl-9-fluorenyl ketones were studied; the reactivity of deacylation was enhanced by the substitution of the 9-hydrogen atom on 9-acetylfluorene. The reaction of 9-acetylfluorene with ethyl nitrate afforded 9-*aci*-nitrofluorene.

Deacylation promoted by a base has been known already to occur in the active methylene to which an acyl group is attached. In fluorene derivatives, 9-benzoylfluorene (**1**) gave fluorene (**2**) and benzoic acid,[1] and 9-chloro-9-acetylfluorene (**3**) afforded 9,9′-bifluorenyl (**4**).[2] The present work deals with the deacylation of 9-acylfluorenes in order to clarify the reactivities on the 9-carbon atom of fluorenes.

Deacetylation of 9-acetylfluorene (**5**)[3] yielded **2** and ethyl acetate; the yield of **2** increased (28—96%) with the increase of base concentration (1—20%) and with the extension of the reaction time (1—10 h). The deacetylation may be explained by the nucleophilic attack of ethoxide anion on the cationic carbon atom of carbonyl in **5** to form the intermediary carbanion (A) as the reverse-Claisen-type condensation (Scheme 1).

The deacylation of some 9-acylfluorenes was carried out as shown in Table 1. The substituent effect in the deacylation of 9-propionyl- (**6**),[4] 2-ethyl-9-acetyl- (**7**), and 2-bromo-9-acetylfluorene (**8**) was observed to be less significant in comparison with that of **5**. The reaction of 9,9-dibenzoylfluorene (**9**)[5] with base afforded **1**, which was further converted to **2** by debenzoylation.

The elimination was accelerated remarkably in the deacetylation of **3**, 9-methyl- (**10**),[6] and 9-hydroxy-9-acetylfluorene (**11**).[7] The ethoxide anion may be able to attack on the two positions of **5**, that is, the 9-carbon and the carbonyl carbon atoms. The 9-acetylfluoren-9-ide anion would be stabilized by resonance as enolate anion and **5** is less reactive under these conditions. The substitution on the 9-position of **5** prevents the attack on this position and results in the significant formation of the elimination product.

The reaction of **5** with ethyl nitrate in the presence of sodium ethoxide gave pure 9-*aci*-nitrofluorene[8] in good yield. The ethoxide anion removes a proton from the 9-position on the **5**. The resulting carbanion may afford the intermediary 9-nitro-9-acetylfluorene by an attack of ethyl nitrate, and this was converted to 9-*aci*-nitrofluorene by the action of a second ethoxide anion and by the tautomeric effect of the nitro group (Scheme 2).

The deacetylation of the substrate containing an electron-attracting group proceeds more readily than that having an electron-releasing group. Actually, the progress of the deacylations for **3** and also for **10** was followed by means of gas chromatography; the **10** still remained in a considerable amount (37%) at the reaction step in which all the **3** had been consumed. Chloride **3** gave 9,9′-bifluorenylidene (46%) and **4** (trace), and the ethylene was reduced to **4** under similar conditions.

The reactivity of the carbonyl group in 9-*t*-butyl-9-acetylfluorene (**12**) is hindered by the bulky substituent

from the approach of an attacking ethoxide ion, therefore, the yield of 9-*t*-butylfluorene[9] decreased. No deacetylation was observed in the cases of 9-acetonylfluorene (**13**)[10] and 2-acetylfluorene.[11] This finding shows that deacylation occurs when the acyl group is attached directly to the active 9-position of fluorenes. The anomalous lower field (2.19 ppm) of the methyl chemical shift of **13** compared with that (1.60 ppm) of **5** is ascribed to the predominant conformation of **13** and **5**; the mobile methyl group of **13** may be located further away from the shield zone of the aromatic rings than that of **5**.

The reaction of 9,9′-diacetyl-9,9′-bifluorenyl (**14**)[2] afforded dehydrate compound **15** accompanied by **4** (Scheme 3); **15** would be formed by the intramolecular aldol-type condensation.

The same reaction of 9-fluorenyl 9-methyl-9-fluorenyl ketone (**16**) yielded **2**, 9-methylfluorene, 9-methylfluorene-9-carboxylic acid (**17**),[12] and its ethyl ester (**18**),[13] as summarized in Table 2. The ester **18** gave 9-methylfluorene and **17**. Similarly, methyl fluorenyl-9-carboxylate (**19**) yielded **2**, the corresponding carboxylic acid (**20**), and its ethyl ester. The ratio of the yields of these products indicates that **16** cleaves into 9-fluorenide anion and **18**, but not into 9-methylfluoren-9-ide anion and an ester of **20**; this may be attributed to the stability of the 9-fluorenide anion formed, which is greater than that of the methyl derivative.

Experimental

All the melting points are uncorrected. The instruments used in this experiment have been described elsewhere.[11]

Deacylation of 9-Acylfluorene. General Procedure: Sodium metal (1.15 g) was treated with 33 ml of dry ethanol, then 5 mmol of substrate was added, and the mixture was refluxed for 10 h under an atmosphere of dry nitrogen. Upon cooling, the reaction mixture was poured into 150 ml of 3% hydrochloric acid and the resulting precipitate was purified by a combination of alumina-column chromatography, vacuum sublimation, and recrystallization.

*Reaction of **14** with Sodium Ethoxide.* A 2.070 g portion of **14** was refluxed with 3.4 g of sodium ethoxide in 330 ml of dry benzene for 10 h to give 0.450 g of 3-methyl-4,5-bis(2,2′-biphenylylene)-2-cyclopenten-1-one (**15**), 0.012 g of **4**, and 0.010 g of fluorenone. Mp of **15**: 233.5—234.5 °C. IR: (C=O) 1694 cm^{-1}. Mass: *m/e* 396 (M^+), 381, and 352. NMR (benzene-d_6): δ 1.29 (3H, s), 6.47 (1H, s), and 6.65—7.35 (16H, m) ppm. Found: C, 90.96; H, 5.17%. Calcd for $C_{30}H_{20}O$: C, 90.88; H, 5.09%.

*Reaction of **5** with Ethyl Nitrate.* A soln of 2.08 g of **5**, 1.82 g of ethyl nitrate, and 0.68 g of sodium ethoxide in 20 ml of dry ethanol was refluxed for 2 h. Upon cooling, 100 ml of

benzene and 150 ml of water were added to the reaction mixture and the aqueous layer was neutralized with hydrochloric acid to yield 1.53 g of 9-*aci*-nitrofluorene, mp 154 °C (dec). IR: (OH) 2770; (NO_2) 1653, 1441 cm^{-1}.

2-Ethyl-9-acetylfluorene (7). Compd **7** was prepared by means of the same procedure as used for **5** in a 34% yield, bp 142—144 °C/2 Torr (uncorr.). Mass: *m/e* 236 (M^+).

2,4-Dinitrophenylhydrazone, mp 200—202 °C. IR: (NH) 3320; (NO_2) 1614, 1589 cm^{-1}. Found: C, 66.68; H, 4.95; N, 13.58%. Calcd for $C_{23}H_{20}O_4N_4$: C, 66.33; H, 4.84; N, 13.46%.

2-Bromo-9-acetylfluorene (8). The title compd was obtained by the same method as described above, yield 30%, mp 66—67 °C. Mass: *m/e* 288, 286 (M^+), 245, 243, and 207. Found: C, 62.95; H, 3.64%. Calcd for $C_{15}H_{11}OBr$: C, 62.74; H, 3.86%.

9-t-Butyl-9-acetylfluorene (12). Compd **12** was obtained by a procedure similar to that of **10** in a 39% yield, mp 76.5—77 °C. Mass: *m/e* 264 (M^+), 249, 221, 208, 206, 191, and 165. Found: C, 86.73; H, 7.77%. Calcd for $C_{19}H_{20}O$: C, 86.32; H, 7.63%.

9-Acetonylfluorene (13). This compd was synthesized by the reaction of α-(9-fluorenyl)acetyl chloride with methylmagnesium iodide in the presence of cadmium chloride: yield 58%, mp 62—63 °C (lit,[10] mp 57 °C). Mass: *m/e* 222 (M^+), 179, and 165.

9-Fluorenyl 9-Methyl-9-fluorenyl Ketone (16). To a soln of 9-methyl-9-lithiofluorene (prepared from 0.96 g of lithium chips, 9.4 g of butyl bromide, and 10.3 g of 9-methylfluorene in 100 ml of xylene) was added dropwise 12.0 g of 9-fluorenylcarbonyl chloride in 60 ml of xylene at 0 °C with stirring for 30 min, then the mixture was boiled for 1 h to afford 6.45 g of **16**, mp 226—227.5 °C. Mass: *m/e* 372 (M^+), 179, and 165. Found: C, 90.27; H, 5.57%. Calcd for $C_{28}H_{20}O$: C, 90.29; H, 5.41%.

Oxidation of Cinnamyl Alcohol with Peracetic Acid in Acidic Solvents[1)]

Yoshiro OGATA* and Kohtaro TOMIZAWA

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received April 25, 1976)

Peracetic acid oxidation of cinnamyl alcohol(**1**) in tetrahydrofuran(THF) at room temperature has been found to give phenylacetic acid(**2**), benzaldehyde(**4**) and cinnamyl acetate(**5**) as major products. A probable first-formed intermediate, 2,3-epoxy-3-phenyl-1-propanol(**7**), was detected as its derivative (1-phenyl-1,2,3-propanetriol), and also a probable second intermediate, 1-hydroxy-3-phenyl-2-propanone (**3**), was detected. **3** was found to be converted to **2** by the Baeyer-Villiger reaction. On the other hand, the peracetic acid oxidation of **1** in methanol gave a methanolysis product of oxirane ring, 3-methoxy-3-phenyl-1,2-propanediol (**6a**), a small amount of a rearrangement product and benzaldehyde. The peracid oxidation of **1** in various solvents was also studied. A probable reaction mechanism is discussed.

We have previously reported that peracid oxidation of vitamin A alcohol, $Me_3C_6H_6$-CH=CH-CMe=CH-CH=CH-CMe=CH-CH_2OH, yielded 11,12-epoxy-vitamin A aldehyde, $Me_3C_6H_6$-CH=CH-CMe=CH-$\overset{O}{\overset{/\backslash}{CH-CH}}$-CMe=CH-CHO, *via* oxidation of primary alcohol group to aldehyde as well as epoxidation of an ethylenic bond.[2)] In the present paper, we intended to study the peracetic acid oxidation of cinnamyl alcohol (**1**), which have an α,β-unsaturated alcohol group.

The present study showed that the peracid oxidation of **1** had a behaviour different from that of vitamin A alcohol. In this paper we wish to report the mechanism of peracid oxidation of **1** which was speculated from the products of an assumed intermediary epoxide, 2,3-epoxy-3-phenyl-1-propanol (**7**).

It was reported that the perbenzoic acid oxidation of in $CHCl_3$ at 0 °C gave **7**, which could be converted to phenylacetaldehyde, formaldehyde and 1-hydroxy-3-phenyl-2-propanone (**3**) on pyrolysis in the presence of kieselguhr,[3-5)] but resinous material on pyrolysis in the presence of H_2SO_4 or $ZnCl_2$.[3,4)] The pyrolysis products of **7** and the migratory aptitude of the epoxide rearrangement were studied only in the absence of peracid at high temperature[3,6-8)] and little was known on the peracid oxidation of **1** and the subsequent reactions in solution and at lower temperature.

Also peracid oxidation of α,β-unsaturated secondary alcohol was reported to yield the epoxides and its derivative,[9,10)] but no report is available on the mechanism of formation of these derivatives.

Results and Discussion

Oxidation of cinnamyl alcohol(**1**) with an equivalent of peracetic acid in tetrahydrofuran(THF) and in some solvents containing acetic acid at room temperature gave a distribution of products as shown in Table 1. In addition of products listed in the table, a trace of cinnamaldehyde, PhCH=CHCHO, and significant amounts of unknown products were formed but the expected products, 2,3-epoxy-3-phenylpropanal, Ph$\overset{O}{\overset{/\backslash}{CH-CH}}$CHO(**8**), was not detected. Most of these products were identified by the comparison of IR and NMR spectra and GLC peaks with those of the corresponding authentic specimens.

A trace of cinnamaldehyde formed during this oxidation cannot be the precursor to **8**, because the peracetic acid oxidation of cinnamaldehyde did not proceed under these conditions. Furthermore, we observed that **8** was very unstable, thus **8** could not be synthesised by oxidation of cinnamaldehyde by H_2O_2 or *t*-BuOOH even according to the reported procedure in alkaline media[11)] as described in Experimental part. In the case of oxidation of vitamin A alcohol, the steric selectivity of attacking site seems to play an important role,[2)] thus the observed oxidation of unsaturated alcohol to epoxy aldehyde can occur because of the chemical driving force for the formation of its α,β-unsaturated aldehyde in acidic media. Whereas, the peracetic acid oxidation of cinnamyl alcohol (**1**) to **8** is unfavourable because of the

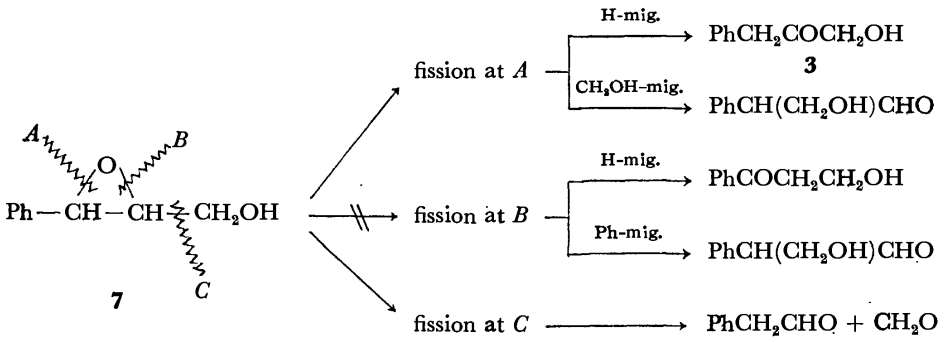
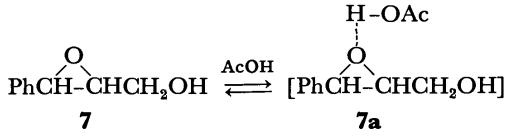
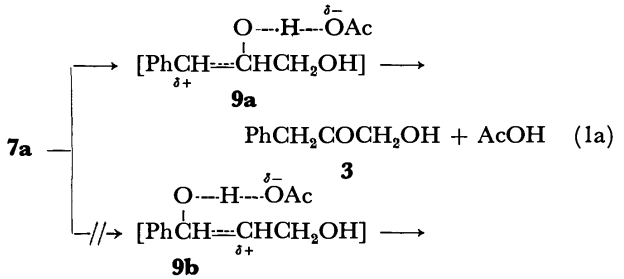


Scheme 1.

faster ring opening of its intermediate epoxide **7** as discussed below.

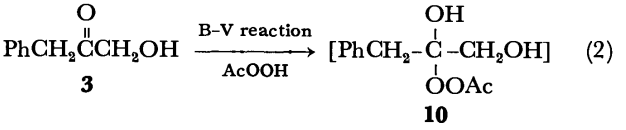
1-Hydroxy-3-phenyl-2-propanone (**3**) should be a rearrangement product of the initially formed 2,3-epoxy-3-phenyl-1-propanol (**7**) from **1** as shown in Eq. (1a). The epoxide (**7**) may afford by fissions at *A* and *B* three isomers, and by fission at *C*, products of cleavage at C–C as shown in Scheme 1, but actually the catalytic pyrolysis of **7** was reported to give phenylacetaldehyde, formaldehyde and **3**, which may be products of radical reactions.[3,4] Also our pyrolysis of alternatively synthesised **7** at 200—250 °C at the injection temperature of GLC yielded phenylacetaldehyde (25%) and **3** (29%) and unknown products. On the other hand, during the column chromatography with silica gel ($SiO_2 \cdot xH_2O$), **7** was completely changed to give 1-phenyl-1,2,3-propanetriol, $PhCH(OH)CH(OH)CH_2OH$, and no phenylacetaldehyde and **3** was detected by GLC. The present peracetic acid oxidation of **1** gave **3** and a little phenylacetaldehyde, which were identified by GLC, but 1-phenylpropane-1,2,3-triol was obtained instead of phenylacetaldehyde by the column chromatography with silica gel. The above fact suggests that **7** is a primary intermediate formed in this oxidation and that **7** is converted to **3** by the following ionic path (Eq. 1a) which involves no radical species.

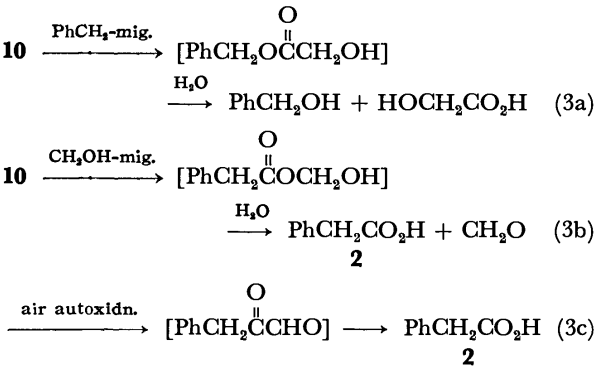




On account of the more resonance delocalization of the positive charge in **9a**, the pathway (Eq. 1a) *via* **9a** leading to **3** should be favoured rather than the pathway (Eq. 1b) *via* **9b** leading to *β*-hydroxypropiophenone.

The authentic **3**, which was prepared alternatively,[4,12] gave phenylacetic acid (**2**) on the peracetic acid oxidation under similar conditions. Hence, **3** may be an intermediate in the formation of **2** from **1**. Three paths from **3** (Eqs. 3a—c) are conceivable for this oxidation, but the Baeyer-Villiger reaction of Eq. 3a is negligible because of the formation of little benzyl alcohol which is fairly stable under these conditions as evidenced in Experimental part. Further, the autoxidation of **3**(Eq. 3c) is less probable, because peracetic acid is necessary for this reaction forming **2** which proceeds even under N_2. Hence, **2** is probably formed *via* Eq. 3b alone, where the preferential migration of methylol group of **10** occurs. The Taft σ^* values are 0.225 for benzyl group and 0.555 for hydroxymethyl group.[13] In





most Baeyer-Villiger reactions, a more electron-releasing group tends to migrate preferentially, but in this case the more electron-attracting hydroxymethyl group must migrate. This migration of methylol group may be due to the formation of hydrogen bonding which facilitates O–O fission in the transition state of migration as shown in **11**. The similar migration of an electron-attracting phenyl group was reported for acetophenone, where

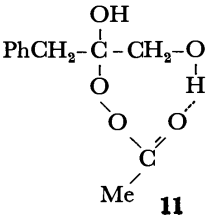


Table 2. Effect of molar ratio of reactants ($PhCH=CHCH_2OH$: AcOOH)

Solvent	Mole ratio[a]	Reaction time h	Conversion %	Product % 2	3[b]	4	5

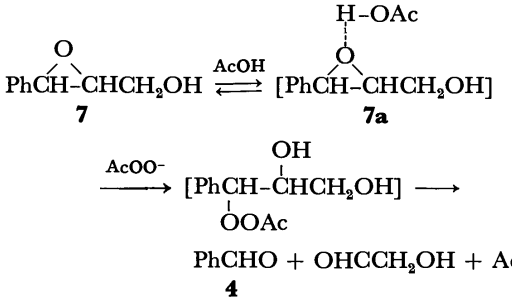
a) Ratio of cinnamyl alcohol (**1**) and peracetic acid. b) The value for **3** was determined in the same way as Table 1.

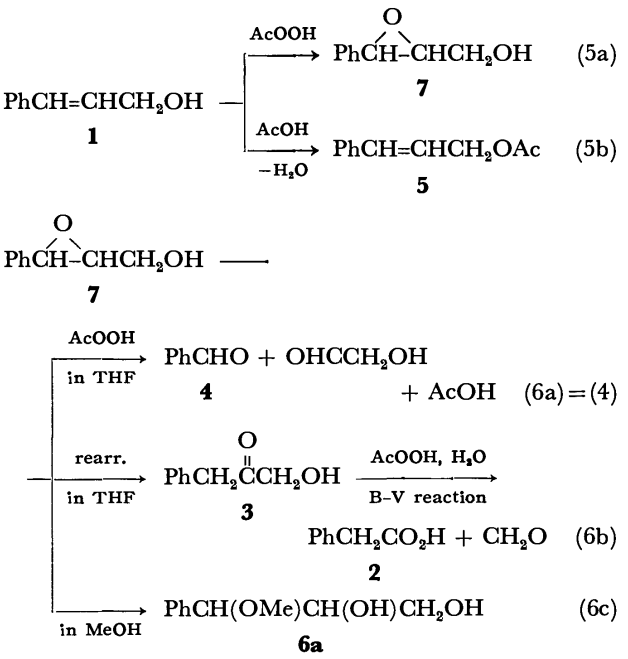
bridged phenonium ion assists the migration.[14]

The formation of benzaldehyde (**4**) can also be explained by assuming the H-bonded neutral intermediate **7a**, which is cleaved to give **4** by the addition of peracetic acid to its oxirane ring (Eq. 4) in view of the acid catalysis as will be discussed below. The similar mechanism was reported for the peracetic acid oxidation of ketene.[15]

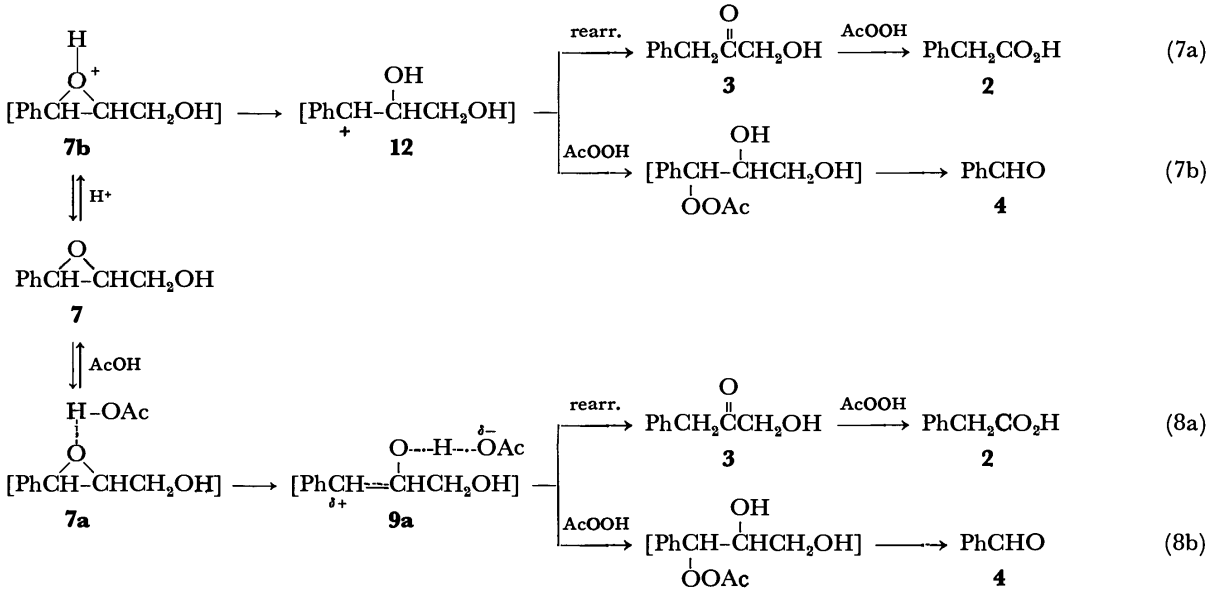


Observed products and pathways in various solvents for the oxidation of **1** are shown in Scheme 2. The structure of **6a** was supported by comparison with 1,3-dimethoxy-1-phenyl-2-propanol (**14**) which was prepared by peracid oxidation of cinnamyl methyl ether (**13**) in MeOH.

The yield of phenylacetic acid (**2**) from **1** increases with increasing amount of peracetic acid, while the yield of benzaldehyde (**4**) decreases (Table 2). On the other hand, when a small amount of mineral acid is added to a mixture of **7** and peracetic acid, the yield ratio [**4**]/[**2**] increases significantly. The above facts may be explained as follows: (i) In the presence of mineral acid, benzaldehyde (**4**) should be obtained as a major product *via* **12** (Eq. 7b), because the greater electro-



Scheme 2.



philicity of **12** than that of **7a** accelerates an attack of nucleophiles on **12** and thus favours this addition (Eq. 7b) rather than the rearrangement (Eq. 7a). (ii) In the absence of mineral acid, the precursor of **2**, $PhCH_2COCH_2OH$(**3**), is probably formed as a main product via neutral intermediate **7a** (Eq. 8a), because the carbonium ion from **7a**, if formed, is very unstable and hence the rearrangement (Eq. 8a) is preferred to an attack of nucleophiles ($AcOO^-$, AcOOH) on **9a**. The decrease of the yield of **4** with increasing amount of peracid seems to be curious, but the increase would accelerate the Baeyer-Villiger reaction (Eq. 8a) more than the C–C cleavage (Eq. 8b), which does not involve peracid in the rate-determining step. The increase of acidity on addition of mineral acid promotes the formation of **7b** and increases the yield of **4** by the acceleration of an attack of peracid on **12**. Whereas, in the absence of mineral acid, there is formed no **7b** but H-bonded **7a**, which is much weaker electrophile and thus the rate of Eq. (8a) going to **3** is much faster than the rate of Eq. (8b) going to **4**, and then the increase of concentration of peracid increases the ratio of [**2**]/[**4**].

Experimental

Mps were measured by a Yanagimoto micro-melting point apparatus and they were corrected. IR spectra were measured by a Perkin-Elmer Model 337 grating infrared spectrophotometer. GLC analysis was carried out by a Yanagimoto gas chromatograph with FID, Model GCG-550F, employing two sorts of 2 m×2.5 mm columns(one of which was packed with 2.5% PEG-20 M on Chamelite CS of 80—100 mesh and another packed with 13% DEGS on Chromosorb W of 80—100 mesh), using N_2 as a carrier gas. NMR spectra were recorded by a Japan Electron Optic Laboratory Co., C60 HL NMR instrument. The yield of products are listed in Table 1.

Materials. Peracetic acid was prepared by the reaction of Ac_2O (205 g) with 60% aq. H_2O_2 (50 g) added with concd H_2SO_4 (0.5 ml) at 35—40 °C.[16] The peracid concentration was 3.0—3.1 M in average. THF was purified by distillation over Na, bp 66 °C/760 Torr. 2,3-Epoxy-3-phenyl-1-propanol, PhCH(O)CHCH$_2$OH (**7**), was obtained by the oxidation of cinnamyl alcohol (**1**) (0.105 mol) with perbenzoic acid (0.105 mol) in $CHCl_3$ at 0 °C in a yield of 38%: bp 117.5—118.5 °C/1.5 Torr (lit,[17] 117—118 °C/1.5 Torr), IR (liquid film): 3450—3350, 2920, 2860, 1240, 1025, 880, 750, and 700 cm^{-1}; NMR (CCl_4): δ 3.17 (1H, m, 2-H), 3.65 (1H, s, OH), 3.80 (1H, d, J=6 Hz, 3-H), 3.88 (2H, d, J=3 Hz, 1-H), and 7.40 (5H, s, aromatic). 1-Hydroxy-3-phenyl-2-propanone, $PhCH_2COCH_2OH$ (**3**), was synthesised by the reaction of $HOCH_2CN$ (19.7 g) with $PhCH_2MgCl$ in ether and recrystallized from ethanol–petroleum ether,[4,12] in a yield of 5% based on the used nitrile, mp 49.5—50.5 °C (lit,[4] mp 47—48 °C), IR (KBr disk): 3450—3350, 1720, 750, and 695 cm^{-1}; NMR ($CDCl_3$): δ 3.08 (1H, s, OH), 3.35 (2H, s, 3-H), 4.18 (2H, s, 1-H), and 7.17 (5H, s, aromatic). Cinnamyl methyl ether, $PhCH{=}CHCH_2OMe$ (**13**), was obtained by the reaction of cinnamyl alcohol (**1**) (25 g) with Me_2SO_4 and $NaNH_2$ in ether in a yield of 78%, bp 115—117 °C/20 Torr (lit,[18] 111—112.5 °C/15 Torr), IR (liquid film): 2815, 965, 742, and 690 cm^{-1}; NMR (CCl_4): δ 3.26 (3H, s, OMe), 3.97 (2H, d, J=7 Hz, 1-H), 6.10 (1H, m, 2-H), 6.55 (1H, d, J=16 Hz, 3-H), and 7.20 (5H, s, aromatic). Cinnamyl acetate, $PhCH{=}CHCH_2OAc$ (**5**), was prepared by the acetylation of **1** with Ac_2O, (68%), bp 104—106 °C/3 Torr (lit,[19] 141 °C/18 Torr).

Oxidation of Cinnamyl Alcohol (1). Product Isolation. For the reaction of **1** with peracetic acid, **1** (4.33×10^{-2} mol) was treated with peracetic acid (4.31×10^{-2} mol) in THF (100 ml) at room temperature. The produced solution was condensed under vacuum (50 °C at 30 Torr), and the residue was chromatographed on a 60×2 cm column slurry packed with silica gel (benzene and benzene–ethyl acetate). The first substance eluted was benzaldehyde (**4**) and the second was cinnamyl acetate (**5**). The third was colourless crystals, 1-hydroxy-3-phenyl-2-propanone (**3**), and the fourth was recovered **1** and the fifth was colorless crystals, phenylacetic acid (**2**), mp and mmp 77—78 °C. The sixth was a colourless liquid, which was identified to be 1-phenyl-1,2,3-propanetriol, IR (liquid film): 3400—3300, 2920, 2860, 1460, 1100, 1025, 760, and 695 cm^{-1}; NMR ($CDCl_3$): δ 3.30 (1H, m, 2-H), 3.58 (2H, d, 1-H), 4.25 (3H, s, OH), 4.62 (1H, d, 3-H), and 7.25 (5H, s, aromatic).

Oxidation of 1 in Methanol. Product Isolation. The similar oxidation of **1** in MeOH and the similar work up gave products which were chromatographed through a 60×2 cm column of silica gel and developed by the gradient method of benzene–ethyl acetate. The first eluted substance was benzaldehyde (**4**) (trace). The second one was cinnamyl acetate (**5**) and the third was recovered **1** and the fourth was phenylacetic acid (**2**). The fifth was 3-methoxy-3-phenyl-1,2-propanediol (**6a**) which was identified by IR and NMR spectra, IR (liquid film): 3450—3350, 2820, 1200, 760, and 700 cm^{-1}; NMR (CCl_4): δ 3.06 (3H, s, OMe), 3.47 (2H, s, 1-H), 3.58 (1H, m, 2-H), 3.89 (2H, s, OH), 4.00 (1H, d, J=7 Hz, 3-H), and 7.20 (5H, s, aromatic). Found: C, 66.21; H, 7.74%. Calcd for $C_{10}H_{14}O_3$: C, 65.91; H, 7.74%. The sixth was 2-methoxy-1-phenyl-1,3-propanediol (**6b**) which was identified by IR and NMR spectra, IR (liquid film): 3450—3400, 2815, 1210, 760, and 700 cm^{-1}; NMR (CCl_4): δ 3.15 (3H, s, OMe), 3.30 (2H, d, 1-H), 3.66 (1H, m, 2-H), 3.83 (2H, s, OH), 4.19 (1H, d, 3-H), and 7.30 (5H, s, aromatic).

The peracetic acid oxidation of cinnamyl methyl ether (**13**) in MeOH affords 1,3-dimethoxy-1-phenyl-2-propanol (**14**). The comparison of NMR spectra of $PhCH(OMe)CH(OH)CH_2OH$ (**6a**) with those of $PhCH(OH)CH(OMe)CH_2OH$ (**6b**) and **14** confirms the structure of **6a** and **6b**.

In addition, the structure of **6a** was assured by the structure of product (**15**) by H_2SO_4-catalysed dehydration of **6a**; *i.e.*, **15** was identified to be 1-methoxy-1-phenyl-2-propanone, PhCH(OMe)COMe, IR (liquid film): 1715, 755, and 700 cm^{-1}; NMR (CCl_4): δ 2.05 (3H, s, 3-H), 3.35 (3H, s, OMe), 4.48 (1H, s, 1-H), and 7.27 (5H, s, aromatic).

Oxidation of Cinnamyl Methyl Ether (13) in Methanol. The similar oxidation of **13** and the similar work up afforded 1,3-dimethoxy-1-phenyl-2-propanol (**14**), which was identified by IR and NMR spectra, IR (liquid film): 3450—3400, 2820, 1200, 1140, 755, and 695 cm^{-1}; NMR (CCl_4): δ 2.60 (1H, s, OH), 3.16 (3H, s, 3-OMe), 3.27 (3H, s, 1-OMe), 3.30 (2H, d, J=7 Hz, 1-H), 3.76 (1H, m, 2-H), 4.08 (1H, d, J=7 Hz, 3-H), and 7.22 (5H, s, aromatic).

Oxidation of 1-Hydroxy-3-phenyl-2-propanone (3). Two THF solutions of **3**, one of which contained peracetic acid but the other no peracid, were warmed to 20 °C for 24 h and the resulting solutions were analysed similarly by GLC. In this experiment, the former gave phenylacetic acid (**2**) but the latter did not. Also two THF solutions of **3** and peracetic acid, one of which was filled with air and the other filled with N_2 after deaerated under −78 °C, were warmed to 20 °C for 24 h and the products were analysed similarly. Both of them gave **2** in a good yield. Therefore, **2** was formed from the reaction of **3** with peracetic acid and no autoxidation occurs during the reaction.

Pyrolysis of 2,3-Epoxy-3-phenyl-1-propanol (7). **7** was pyrolysed at 200—250 °C at the injection temperature of GLC. Phenylacetaldehyde and **3** were obtained in yields of 25 and 29%, respectively, together with two unknown products. In the present pyrolysis, neither phenylacetic acid (**2**) nor benzaldehyde (**4**) was formed. Further, phenylacetaldehyde was not oxidised to form **2** during this pyrolysis.

Column Chromatography of 2,3-Epoxy-3-phenyl-1-propanol (7). **7** was chromatographed on a 60×2 cm column slurry packed with silica gel. A large portion of the substance eluted with benzene–ethyl acetate (50: 50) was a colourless liquid and it was identified to be 1-phenyl-1,2,3-propanetriol by IR and NMR spectra. In this column chromatography **7** was not recovered and a small amount of unknown material was obtained. Further, neither phenylacetaldehyde nor **3** was obtained.

Oxidation of 2,3-Epoxy-3-phenyl-1-propanol (7). **7** was oxidised similarly with peracetic acid in THF at room temperature for 24 h and the formation of **2** and **4** established by GLC, since the pyrolysis of **7** at 200—250 °C gave neither **2** nor **4** thus their contamination could be avoided. By the reaction with an equivalent of peracetic acid **7** yielded **2** and **4** in yields of 16 and 12%, respectively. Whereas the reaction with two equivalents of peracid gave **2** and **4** in yields of 24 and 13%, respectively. On addition of a small amount of mineral acid, the peracid oxidation of **7** gave **2** (8%) and **4** (32%).

Oxidation of Benzyl Alcohol in THF. Benzyl alcohol was treated with peracetic acid in THF at room temperature by a work up similar to the oxidation of **1**, the resulting products were identified by GLC using two columns by comparing those of authentic samples. The products and their yields were shown in Table 3.

Table 3. The peracetic acid oxidation of benzyl alcohol in THF

Reaction time h	Conversion %	Product %		
		PhCHO (**4**)	$PhCO_2H$	$PhCH_2OAc$
24	23.8	8.8 (1.5)[a)]	2.4	88.7
48	34.0	10.3 (1.7)[a)]	2.5	87.2

a) Yield by autoxidation.

Oxidation of Cinnamaldehyde. Cinnamaldehyde was oxidised with method (1) H_2O_2 in aq. MeOH at pH 8—8.5 and method (2) *t*-BuOOH in MeOH at pH 10.5±0.2, where pH was controlled with a glass electrode pH meter. The reaction solution was condensed under N_2 *in vacuo* and distilled. In both methods 1 and 2, a considerable amount of cinnamaldehyde was recovered and unknown products were obtained. Further, an attempt to oxidise cinnamaldehyde with peracetic acid in THF under conditions similar to that for **1** gave mostly recovered starting material.

The authors are grateful to Dr. K. Takagi for his helpful discussions.

Synthesis of Taxodione, Royleanone, Cryptojaponol, and Methyl 11-Hydroxy-12-methoxy-7-oxoabieta-8,11,13-trien-18-oate

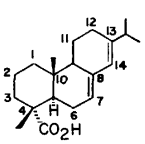
Takashi MATSUMOTO, Yasuo OHSUGA, Shogo HARADA, and Kenji FUKUI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

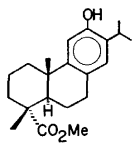
(Received August 30, 1976)

Oxidation at the C-11 position of methyl 12-hydroxyabieta-8,11,13-trien-18-oate (II) and ferruginol (XXXII) were successfully carried out using benzoyl peroxide, and the resulting phenols (VII and XXXVII) were further converted into taxodione (III), royleanone (IV), cryptojaponol (V), and methyl 11-hydroxy-12-methoxy-7-oxoabieta-8,11,13-trien-18-oate (VI).

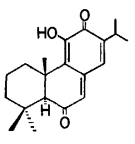
There have been reported the isolation and structural elucidation of many naturally-occurring tricyclic diterpenes possessing an abietane skeleton. As a part of our synthetic studies on natural terpenes, we attempted the conversion of (—)-abietic acid (I) which was easily obtained from pine rosin, into several 11-oxygenated tricyclic diterpenes. This paper[1] describes the conversion of methyl 12-hydroxyabieta-8,11,13-trien-18-oate (II)[2] prepared from I into taxodione (III)[3,4] which has shown significant tumor-inhibiting activity, royleanone(IV),[3-7] cyptojaponol (V),[4,8,9] and methyl 11-hydroxy-12-methoxy-7-oxoabieta-8,11,13-trien-18-oate (VI).[10] Since (—)-abietic acid (I) has already been synthesized, the present conversion can be regarded as the total syntheses of these natural compounds (III, IV, V, and VI).



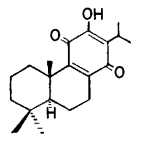
I



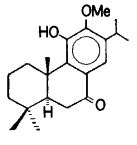
II



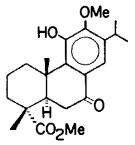
III



IV



V

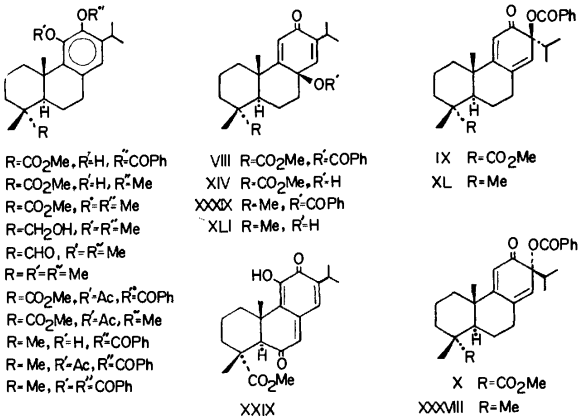


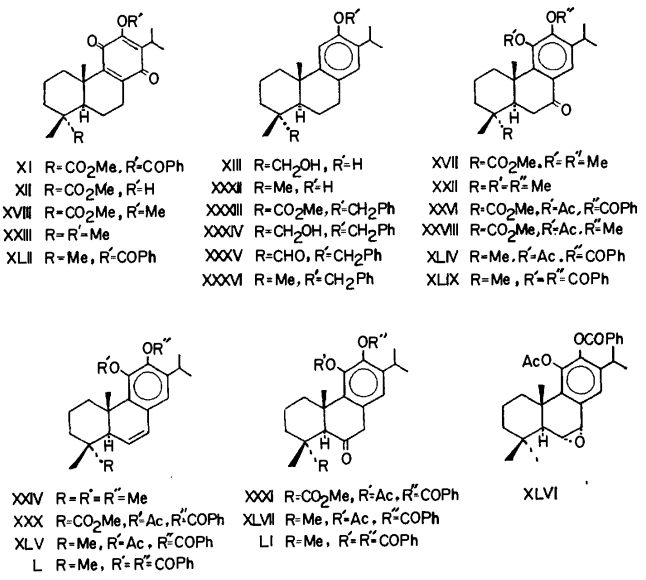
VI

The oxidation of II with benzoyl peroxide in refluxing chloroform afforded a phenol (VII), with three dienones (VIII, IX, and X) as minor products. The structures of these products (VII—X) were assigned on the basis of the following evidence. The phenol (VII) responded positively to the Gibbs test[15] which suggested the presence of an aromatic proton para to a phenolic hydroxyl group. The oxidation of VII with *m*-chloroperbenzoic acid gave a benzoyloxy-*p*-benzoquinone (XI) which was hydrolyzed to give the corresponding hydroxy-*p*-benzoquinone (XII). The NMR spectrum of VII showed a signal at δ 6.57 ppm due to C_{14}–H, while for those of XI and XII no corresponding signal was observed. Thus, the structure of VII was identified to be methyl 12-benzoyloxy-11-hydroxyabieta-8,11,13-trien-18-oate.[16] The treatment of VIII, IX, and X with lithium aluminum hydride in refluxed ether gave the same product, abieta-8,11,13-trien-12,18-diol (XIII).[17,18] This suggests that each of these dienones has an oxygen-function at the C-12 position. From the IR and UV spectra (see Experimental section) of these dienones, it is obvious that IX and X were ortho-substituted dienones,[19] while VIII was a para-substituted dienone.[19] The NMR spectrum of IX was also very similar to that of X, and both IX and X showed two non-equivalent secondary methyl group signals at δ 0.93 and 1.15 ppm and at δ 0.92 and 1.15 ppm, respectively. On the other hand, VIII showed an equivalent signal at δ 1.05 ppm due to the methyls of the isopropyl group. Thus, IX and X should be epimeric isomers with respect to the C-13 position. Hydrolysis of the para-dienone VIII in aqueous methanol with potassium carbonate under reflux gave the corresponding alcohol (XIV). In the NMR spectrum of XIV, the downfield shift of the signal (δ 1.42 ppm) due to the methyl group at the C-10 position relative to the corresponding signal (δ 1.12 ppm) for VIII (or δ 1.17 ppm for II) suggested a 1,3-diaxial-*cis*-relationship between the methyl group and the hydroxyl group at the C-8 position. Thus, the benzoyloxyl group in VIII was stereochemically assigned to be the β-configuration. In order to determine the stereochemistry of the benzoyloxyl group at the C-13 position in the ortho-dienones IX and X, the following thermal rearrangements were carried out. A solution of X in toluene was refluxed for 2 h to give VII (18%) together with the starting substance (X: 80%). However, a similar treatment of IX gave VII (14%) and VIII (16%) along with IX (67%). From this rearrangement of IX into VIII, the stereochemical structure of the benzoyloxyl group in IX was assigned to be the β-configuration, and therefore, that in X to be the α-configuration. The methylation of VII in refluxing methanol with dimethyl sulfate in the presence of aqueous potassium hydroxide gave a monomethyl ether (XV) which responded positively to the Gibbs test. XV was further methylated with dimethyl sulfate and anhydrous potassium carbonate in refluxing methyl ethyl ketones to give methyl 11,12-dimethoxyabieta-8,11,13-trien-18-oate (XVI) which was oxidized with chromium trioxide in acetic acid to afford the corresponding 7-oxo compound (XVII) along with a small amount of methyl 12-methoxy-11,14-dioxoabieta-8,12-dien-18-oate (XVIII). This quinone (XVIII) was also obtained by the oxidation of XV with *m*-chloroperbenzoic acid in a moderate yield. The demethylation of XVIII with hydrochloric acid afforded XII. Subsequently, the conversion of a methoxycarbonyl group at the C-4 position in XVI into a methyl group was carried out in the following manner. The ester XVI was reduced with lithium aluminum hydride to give the

corresponding alcohol (XIX) which by oxidation with a chromium trioxide–pyridine complex gave an aldehyde (XX). Huang-Minlon reduction of XX gave 11,12-dimethoxyabieta-8,11,13-triene (XXI).[3,11,20] The conversion of XXI into taxodione (III) *via* 11,12-dimethoxyabieta-6,8,11,13-tetraene (XXIV) has been achieved by Mori and Matsui.[11] In the present study, XXIV was prepared by an alternate method. The oxidation of XXI with chromium trioxide gave 11,12-dimethoxyabieta-8,11,13-trien-7-one (XXII)[8,9] together with a small amount of royleanone methyl ether (XXIII)[5] which was demethylated to give royleanone (IV). The reduction of XXII with lithium aluminum hydride gave the corresponding alcohol which was immediately dehydrated with *p*-toluenesulfonic acid in refluxing toluene to give XXIV.[11] The conversion of VII and XV into VI was also carried out as follows. Acetylation of VII with isopropenyl acetate in the presence of *p*-toluenesulfonic acid gave an acetate (XXV),[16] which was then submitted to oxidation with chromium trioxide in acetic acid to give the corresponding 7-oxo derivative (XXVI).[16] Alkaline hydrolysis of XXVI, followed by methylation with diazomethane gave VI. This phenol (VI) was also obtained from XV by a similar treatment *via* an acetate (XXVII) and a ketone (XXVIII). Methyl 11-hydroxy-6,12-dioxoabieta-7,9(11),13-trien-18-oate (XXIX), a taxodione analogue, was also synthesized from XXVI. The reduction of a carbonyl group in XXVI with sodium borohydride and subsequent dehydration of the resulting alcohol gave a tetraene derivative (XXX) which was then oxidized with *m*-chloroperbenzoic acid to give a 6-oxo derivative (XXXI). Alkaline hydrolysis of XXXI followed by oxidation gave XXIX.

Next, the above benzoyl peroxide oxidation was applied to ferruginol (XXXII) which was prepared in the following manner. The treatment of II with benzyl chloride in refluxing *N,N*-dimethylformamide in the presence of anhydrous potassium carbonate gave a benzyl ether (XXXIII), which, on reduction with lithium aluminum hydride followed by oxidation of the resulting alcohol (XXXIV) with a chromium trioxide–pyridine complex, yielded a formyl derivative (XXXV). Huang-Minlon reduction of XXXV gave ferruginol benzyl ether (XXXVI) which was then hydrogenolyzed using Pd–C in acetic acid to give ferruginol (XXXII). The oxidation of XXXII with benzoyl peroxide in chloroform at room temperature gave a phenol (XXXVII) and three dienones (XXXVIII-XL), whose structures were also assigned on the basis of spectral and chemical studies (see Experimental section), as in the case of VII—X. The phenol XXXVII was easily converted into royleanone (IV) by *m*-chloroperbenzoic acid oxidation and subsequent alkaline hydrolysis *via* royleanone benzoate (XLII). Further, acetylation of XXXVII gave an acetate (XLIII) and this was then oxidized with chromium trioxide in acetic acid to give the corresponding 7-oxo compound (XLIV). The hydrolysis of XLIV followed by methylation with diazomethane gave cryptojaponol (V). Finally, taxodione (III) was also synthesized from the ketone XLIV *via* a tetraene (XLV), an epoxide (XLVI), and a 6-oxo compound (XLVII), and from the phenol XXXVII *via* a dibenzoate (XLVIII),[21] a 7-oxo compound (XLIX), a tetraene (L), and a 6-oxo compound (LI).





Experimental

All melting points are uncorrected. The IR and UV spectra were taken in chloroform and ethanol, respectively. The NMR spectra were obtained in carbon tetrachloride at 60 MHz with tetramethylsilane as an internal standard, unless otherwise stated. The chemical shifts are presented in the δ values; s: singlet, bs: broad singlet, d: doublet, bd: broad doublet, dd: double doublet, t: triplet, m: multiplet. The optical rotations were measured in chloroform using a Yanaco OR-50D. Column chromatography was performed using Merck silica gel (0.063 mm).

Oxidation of Methyl 12-Hydroxyabieta-8,11,13-trien-18-oate (II) with Benzoyl Peroxide. A solution of the phenol II (5.00 g) and benzoyl peroxide (3.70 g) in chloroform (60 ml) was gently refluxed for 2 h in a stream of nitrogen. The solution was diluted with ether containing a small amount of acetic acid, and washed successively with aqueous potassium iodide, aqueous sodium thiosulfate, aqueous sodium hydrogencarbonate, and water. After drying over sodium sulfate, the solvent was evaporated and the residue was chromatographed on silica gel using benzene and benzene–ether (97: 3 and 95: 5) as eluents, giving four products (VII—X).

a): Methyl 12-benzoyloxy-11-hydroxyabieta-8,11,13-

trien-18-oate (VII: 61%), which responded positively to the Gibbs test;[15] mp 155—157 °C (from methanol), $[\alpha]_D$ +83.1°, IR: 3575, 3375, 1735, 1718 cm^{-1}, NMR: 1.16 and 1.19 (each d and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.29 (s, C_4-CH_3), 1.38 (s, $C_{10}-CH_3$), 3.64 (s, $-CO_2CH_3$), 5.26 (s, -OH), 6.57 (s, $C_{14}-H$), 7.4—8.2 (m, $-C_6H_5$). Found: C, 74.86; H, 7.71%. Calcd for $C_{28}H_{34}O_5$: C, 74.64; H, 7.61%.

b): Methyl 8β-benzoyloxy-12-oxoabieta-9(11),13-dien-18-oate (VIII: 2%); mp 157—158.5 °C (from methanol), $[\alpha]_D$ −81.8°, IR: 1722, 1668, 1638 cm^{-1}, UV: λ_{max} 236 nm (ε 18600), NMR: 1.05 (d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.12 (s, $C_{10}-CH_3$), 1.22 (s, C_4-CH_3), 3.65 (s, $-CO_2CH_3$), 6.11 and 6.25 (each s, $C_{11}-H$ and $C_{14}-H$), 7.2—8.1 (m, $-C_6H_5$). Found: C, 74.46; H, 7.67%. Calcd for $C_{28}H_{34}O_5$: C, 74.64; H, 7.61%.

c): Methyl 13β-benzoyloxy-12-oxoabieta-8(14),9(11)-dien-18-oate (IX: 6%); mp 140—141 °C (from methanol), $[\alpha]_D$ −196°, IR: 1715, 1663 cm^{-1}, UV: λ_{max} nm (ε) 232 (19800), 321 (2280), NMR ($CDCl_3$): 0.93 and 1.15 (each d and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.28 (s, C_4-CH_3 and $C_{10}-CH_3$), 3.68 (s, $-CO_2CH_3$), 5.92 (bs, $C_{14}-H$), 6.07 (s, $C_{11}-H$), 7.2—8.2 (m, $-C_6H_5$). Found: C, 74.37; H, 7.65%. Calcd for $C_{28}H_{34}O_5$: C, 74.64; H, 7.61%.

d): Methyl 13α-benzoyloxy-12-oxoabieta-8(14),9(11)-dien-18-oate (X: 11%); mp 167—168 °C (from methanol), $[\alpha]_D$ +280°, IR: 1715, 1663 cm^{-1}, UV: λ_{max} nm (ε) 232 (19700), 321 (2740), NMR ($CDCl_3$): 0.92 and 1.15 (each d and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.23 and 1.29 (each s, C_4-CH_3 and $C_{10}-CH_3$), 3.67 (s, $-CO_2CH_3$), 5.90 (bs, $C_{14}-H$), 6.07 (s, $C_{11}-H$), 7.2—8.2 (m, $-C_6H_5$). Found: C, 74.34; H, 7.75%. Calcd for $C_{28}H_{34}O_5$: C, 74.64; H, 7.61%.

Methyl 12-Benzoyloxy-11,14-dioxoabieta-8,12-dien-18-oate (XI). A solution of VII (360 mg) and *m*-chloroperbenzoic acid (290 mg) in dichloromethane (15 ml) was allowed to stand at room temperature for 22 h and then diluted with ether. The solution was washed successively with aqueous potassium iodide, aqueous sodium thiosulfate, aqueous sodium hydrogencarbonate, and water. After drying over sodium sulfate, the solvent was evaporated and the crude product was purified by column chromatography on silica gel using benzene as the eluent producing the recovered VII (104 mg: 29%) and a quinone (XI) (166 mg: 45%), which was recrystallized from ethanol; mp 121—123 °C, $[\alpha]_D$ +32.4°, IR: 1740, 1720, 1658, 1646 sh, 1602 cm^{-1}, UV: λ_{max} nm (ε) 235.5 (17300), 264.5 (17700), NMR: 1.22 (s, C_4-CH_3), 1.22 and 1.25 (each d and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.30 (s, $C_{10}-CH_3$), 3.64 (s, $-CO_2CH_3$), 7.4—8.3 (m, $-C_6H_5$). Found: C, 72.39; H, 7.02%. Calcd for $C_{28}H_{32}O_6$: C, 72.39; H, 6.94%.

Methyl 12-Hydroxy-11,14-dioxoabieta-8,12-dien-18-oate (XII). *a)*: A mixture of XI (110 mg), sodium hydrogencarbonate (500 mg), water (4 ml), and methanol (20 ml) was refluxed for 1 h. After removal of the solvent, the residue was extracted with ether, washed with water, and then dried over sodium sulfate. The crude product was chromatographed on silica gel (20 g) using benzene–ether (99: 1) as the eluent to give XII (53 mg; 62%), which was recrystallized from petroleum ether; mp 149—150 °C, $[\alpha]_D$ +93.1°, IR: 3375, 1720, 1640, 1633, 1603 cm^{-1}, NMR: 1.20 (d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.22 (s, C_4-CH_3), 1.28 (s, $C_{10}-CH_3$), 3.66 (s, $-CO_2CH_3$), 7.15 (s, -OH). Found: C, 69.95; H, 7.77%. Calcd for $C_{21}H_{28}O_5$: C, 69.97; H, 7.83%.

b): A mixture of methyl 12-methoxy-11,14-dioxoabieta-8,12-dien-18-oate (XVIII: 113 mg) and concentrated hydrochloric acid (5 ml) in methanol (15 ml) was refluxed for 15 h. After the usual work-up, the product was purified using column chromatography and subsequent crystallization to give XII (mp 149—150 °C) which was shown to be identical to a sample of *a)* from a comparison of the IR and NMR spectra.

Reductions of Dienones (VIII, IX, and X) with Lithium Aluminum Hydride. *a)*: A mixture of VIII (100 mg) and lithium aluminum hydride (100 mg) in dry ether (15 ml) was refluxed for 1.5 h. After the usual work-up, the product was recrystallized from a mixture of acetone and petroleum ether to give abieta-8,11,13-trien-12,18-diol (XIII: 60 mg),[17,18] mp 180—181 °C, $[\alpha]_D$ +72.1° (ethanol), which was identical to an authentic sample prepared from II by lithium aluminum hydride reduction. Found: C, 79.71; H, 10.05%. Calcd for $C_{20}H_{30}O_2$: C, 79.42; H, 10.00%.

b): Each of the benzoates (IX and X) was also reduced with lithium aluminum hydride as described in *a)* above producing XIII.

Methyl 8β-Hydroxy-12-oxoabieta-9(11),13-dien-18-oate (XIV). A mixture of VIII (65 mg), potassium carbonate (200 mg), water (2 ml), and methanol (8 ml) was refluxed for 2 h. After the usual work-up, the crude product was chromatographed on silica gel (20 g) using benzene–ether (9: 1) as the eluent to give XIV (46 mg: 92%) which was recrystallized from a mixture of ether and petroleum ether; mp 74—77 °C, $[\alpha]_D$ −60.0°, IR: 3588, 3413, 1720, 1665, 1635 cm^{-1}, UV: λ_{max} 241 nm (ε 12900), NMR: 1.00 and 1.04 (each d and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.27 (s, C_4-CH_3), 1.42 (s, $C_{10}-CH_3$), 3.64 (s, $-CO_2CH_3$),5.81 and 6.28 (each s, $C_{11}-H$ and $C_{14}-H$).

Thermal Rearrangement of Dienones (IX and X). *a)*: A solution of IX (100 mg) in toluene (3 ml) was refluxed for 2 h and the crude product, after evaporation of the solvent, was purified by column chromatography on silica gel (20 g) using benzene–ether (99: 1) as the eluent giving VII (14 mg: 14%), VIII (16 mg: 16%), and the recovered IX (67 mg: 67%).

b): A solution of X (130 mg) in toluene (3 ml) was refluxed for 2 h. Chromatographic purification gave VII (23 mg: 18%) and the recovered X (103 mg: 80%).

Methyl 11-Hydroxy-12-methoxyabieta-8,11,13-trien-18-oate (XV). A mixture of VII (2.5 g), 30% aqueous potassium hydroxide (4.5 ml), and methanol (50 ml) was refluxed for 10 min in a stream of nitrogen. To the cold solution, dimethyl sulfate (4.5 ml) was added and the mixture was refluxed for 4.5 h. The reaction mixture was further treated with 30% aqueous potassium hydroxide under reflux for 20 min, cooled, acidified with dilute hydrochloric acid, and then extracted with ether. After the usual work-up, the product was chromatographed on silica gel (300 g) using benzene as the eluent and recrystallized from methanol giving XV (1.6 g: 80%), mp 146—147 °C, $[\alpha]_D$ +68.8°, IR: 3500, 1720 cm^{-1}, NMR: 1.20 (d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.24 (s, C_4-CH_3), 1.32 (s, $C_{10}-CH_3$), 3.61 (s, $-CO_2CH_3$), 3.69 (s, $-OCH_3$), 5.85 (s, -OH), 6.30 (s, $C_{14}-H$). Found: C, 73.07; H, 8.96%. Calcd for $C_{22}H_{32}O_4$: C, 73.30; H, 8.95%. The phenol XV responded positively to the Gibbs test.[15]

Methyl 11,12-Dimethoxyabieta-8,11,13-trien-18-oate (XVI). A mixture of XV (136 mg), anhydrous potassium carbonate (5 g), dimethyl sulfate (0.6 ml), and methyl ethyl ketone (20 ml) was refluxed for 24 h. After the usual work-up, the product was chromatographed on silica gel (30 g) using benzene as the eluent and recrystallized from methanol giving XVI (134 mg: 95%), mp 92—92.5 °C, $[\alpha]_D$ +82.8°, NMR: 1.16 and 1.18 (each d and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.24 (s, C_4-CH_3), 1.30 (s, $C_{10}-CH_3$), 3.60 (s, $-CO_2CH_3$), 3.68 and 3.79 (each s, 2-OCH_3), 6.46 (s, $C_{14}-H$). Found: C, 73.80; H, 9.14%. Calcd for $C_{23}H_{34}O_4$: C, 73.76; H, 9.15%.

Methyl 12-Methoxy-11,14-dioxoabieta-8,12-dien-18-oate (XVIII). A solution of XV (210 mg) and *m*-chloroperbenzoic acid (220 mg) in dichloromethane (10 ml) was treated as described above for XI. The crude product was purified by column chromatography on silica gel (20 g) with benzene giving XVIII (128 mg: 59%) which was recrystallized from

petroleum ether; mp 139—140 °C, $[\alpha]_D$ −70.7°, IR: 1718, 1653, 1638, 1600 cm^{-1}, NMR: 1.16 (bd, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.20 (s, C_4-CH_3), 1.30 (s, $C_{10}-CH_3$), 3.58 (s, $-CO_2CH_3$), 3.82 (s, $-OCH_3$). Found: C, 70.85; H, 8.16%. Calcd for $C_{22}H_{30}O_5$: C, 70.56; H, 8.08%.

Oxidation of XVI with Chromium Trioxide. A mixture of XVI (183 mg) and chromium trioxide (90 mg) in acetic acid (4 ml) was allowed to stand at room temperature for 18 h and then diluted with ether. The mixture was washed successively with water, aqueous sodium hydrogencarbonate, and water. After removal of the solvent, the residue was chromatographed on silica gel (20 g) using benzene–ether (97: 3) as the eluent to give a quinone (29 mg: 16%) which was shown to be identical to XVIII from IR and NMR spectral comparisons. Further elution gave a ketone (XVII) (147 mg: 77%) which was recrystallized from petroleum ether; mp 101.5—102 °C, $[\alpha]_D$ +48.1°, IR: 1720, 1675 cm^{-1}, NMR: 1.22 and 1.26 (each d and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.30 (s, C_4-CH_3), 1.39 (s, $C_{10}-CH_3$), 3.62 (s, $-CO_2CH_3$), 3.77 and 3.78 (each s, 2-OCH_3), 7.60 (s, C_{14}–H). Found: C, 70.84; H, 8.53%. Calcd for $C_{23}H_{32}O_5$: C, 71.10; H, 8.30%.

11,12-Dimethoxyabieta-8,11,13-trien-18-ol (XIX). A mixture of XVI (393 mg) in dry ether (10 ml) and lithium aluminum hydride (80 mg) was refluxed for 2 h. After the usual work-up, the product was chromatographed on silica gel (40 g) using benzene–ether (99: 1) as the eluent to give an alcohol (XIX: 380 mg), $[\alpha]_D$ +79.7°, IR: 3620, 3450 cm^{-1}, NMR: 0.81 (s, C_4-CH_3), 1.13 and 1.18 (each d and J=6.5 Hz, $-CH(C\underline{H}_3)_2$), 1.28 (s, $C_{10}-CH_3$), 3.65 and 3.75 (each s, 2-OCH_3), 6.42 (s, C_{14}–H).

11,12-Dimethoxyabieta-8,11,13-triene (XXI). a): A solution of XIX (380 mg) in pyridine (6 ml) was added to the Sarett reagent prepared from chromium trioxide (450 mg) and pyridine (6 ml). The mixture was stirred at room temperature for 50 min and then filtered. The filtrate was acidified with dilute hydrochloric acid, extracted with ether, and the extract was washed with brine. The crude product was purified by column chromatography on silica gel (40 g) using hexane–benzene (1: 9) as the eluent to give an aldehyde (XX) (234 mg: 62%), $[\alpha]_D$ +73.5°, IR: 1718 cm^{-1}, NMR: 1.13 (s, C_4-CH_3), 1.16 and 1.18 (each d and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.32 (s, $C_{10}-CH_3$), 3.68 and 3.78 (each s, 2-OCH_3), 6.47 (s, C_{14}–H), 9.17 (s, –CHO).

b): A mixture of XX (234 mg) in diethylene glycol (6 ml) and 80% hydrazine hydrate (0.6 ml) was refluxed for 2 h and powdered sodium hydroxide (0.6 g) was then added. The mixture was heated at 200 °C for 3 h, cooled, extracted with ether, and the extract was washed with brine. Removal of the solvent and subsequent chromatography on silica gel (20 g) using hexane–benzene (1: 9) as the eluent gave XXI (179 mg: 80%); mp 89.5—90.5 °C, $[\alpha]_D$ +92.0° (EtOH), NMR ($CDCl_3$): 0.93 (s, $-C(CH_3)_2$), 1.18 and 1.21 (each d and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.30 (s, $C_{10}-CH_3$), 3.70 and 3.78 (each s, 2-OCH_3), 6.55 (s, C_{14}–H). Found: C, 79.74; H, 10.25%. Calcd for $C_{22}H_{34}O_2$: C, 79.95; H, 10.37%.

Oxidation of XXI with Chromium Trioxide. A solution of XXI (570 mg) and chromium trioxide (300 mg) in acetic acid (20 ml) was allowed to stand at room temperature for 48 h. After the mixture had been treated as described above, the product was chromatographed on silica gel (150 g) and eluted with benzene to give a small amount of royleanone methyl ether (XXIII)[5] (19 mg: 3%) which was recrystallized from methanol; mp 117.5—118.5 °C, $[\alpha]_D$ −113°, IR: 1654, 1643, 1602 cm^{-1}, NMR: 0.92 (s, $-C(CH_3)_2$), 1.17 and 1.19 (each d and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.30 (s, $C_{10}-CH_3$), 3.86 (s, $-OCH_3$).

Further elution with benzene–ether (98: 2) gave 11,12-dimethoxyabieta-8,11,13-trien-7-one (XXII)[8,9] (406 mg: 64%); $[\alpha]_D$ +35.5°, IR: 1672 cm^{-1}, NMR: 1.00 (s, $-C(CH_3)_2$), 1.21 and 1.27 (each d and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.38 (s, $C_{10}-CH_3$), 3.80 (s, 2-OCH_3), 7.60 (s, C_{14}–H).

11,12-Dimethoxyabieta-6,8,11,13-tetraene (XXIV). A mixture of XXII (203 mg) in dry ether (10 ml) and lithium aluminum hydride (40 mg) was refluxed for 2 h. After the usual work-up, the crude alcohol was further treated under reflux with *p*-toluenesulfonic acid (20 mg) in toluene (20 ml) for 3 h, and then cooled. After the addition of sodium hydrogencarbonate, the mixture was stirred for 30 min, filtered, and the filtrate was evaporated. The crude product was chromatographed on silica gel (50 g) using hexane–benzene (1: 1) as the eluent producing XXIV[11] (165 mg: 85%), $[\alpha]_D$ −99.6°, NMR ($CDCl_3$): 0.96 and 1.03 (each s, $-C(CH_3)_2$), 1.13 (s, $C_{10}-CH_3$), 1.18 and 1.22 (each d and J=7 Hz, $-CH(CH_3)_2$), 2.19 (t, J=3 Hz, C_5–H), 3.77 (s, 2-OCH_3), 5.86 (dd, J=3 and 9 Hz, C_6–H), 6.41 (dd, J=3 and 9 Hz, C_7–H), 6.63 (s, C_{14}–H). Found: C, 80.18; H, 9.88%. Calcd for $C_{22}H_{32}O_2$: C, 80.44; H, 9.83%.

Methyl 11-Acetoxy-12-benzoyloxyabieta-8,11,13-trien-18-oate (XXV). A mixture of VII (300 mg) in toluene (4 ml), *p*-toluenesulfonic acid (30 mg), and isopropenyl acetate (0.6 ml) was refluxed for 5 h. After the usual work-up, the product was recrystallized from methanol containing a small amount of acetone producing XXV (300 mg: 92%), mp 191—192 °C, $[\alpha]_D$ +88.7°, IR: 1763, 1740, 1720 cm^{-1}, NMR: 1.78 (s, $-OCOCH_3$). Found: C, 72.92; H, 7.36%. Calcd for $C_{30}H_{36}O_6$: C, 73.14; H, 7.37%.

Methyl 11-Acetoxy-12-benzoyloxy-7-oxoabieta-8,11,13-trien-18-oate (XXVI). A mixture of XXV (700 mg) and chromium trioxide (350 mg) in acetic acid was allowed to stand at room temperature for 26 h. The crude product was chromatographed on silica gel (70 g) and eluted with benzene–ether (95: 5) giving XXVI (586 mg: 82%), mp 178—180 °C (from methanol), $[\alpha]_D$ +72.0°, IR: 1765, 1738, 1720, 1682 cm^{-1}, NMR: 7.95 (s, C_{14}–H). Found: C, 70.85; H, 6.71%. Calcd for $C_{30}H_{34}O_7$: C, 71.13; H, 6.77%.

Methyl 11-Hydroxy-12-methoxy-7-oxoabieta-8,11,13-trien-18-oate (VI). a): A mixture of XXVI (135 mg) in methanol (7 ml) and 30% aqueous potassium hydroxide (0.6 ml) was refluxed for 2 h in a stream of nitrogen. After removal of the solvent, the residue was acidified, extracted with ether, and the extract was washed with water. The crude product was methylated with diazomethane and then chromatographed on silica gel (20 g) using benzene–ether (99: 1) as the eluent giving VI[10] (68 mg: 68%), which was recrystallized from petroleum ether containing a small amount of acetone; mp 202.5—203.5 °C, $[\alpha]_D$ +33.8°, IR (CCl_4): 3500, 1730, 1685, 1607 cm^{-1}, NMR ($CDCl_3$): 1.25 (d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.32 (s, C_4-CH_3), 1.41 (s, $C_{10}-CH_3$), 3.62 (s, $-CO_2CH_3$), 3.78 (s, $-OCH_3$), 6.13 (s, –OH), 7.59 (s, C_{14}–H). Found: C, 70.51; H, 8.12%. Calcd for $C_{22}H_{30}O_5$: C, 70.56; H, 8.08%.

b): Similarly, XV (109 mg) was acetylated with isopropenyl acetate (0.1 ml) and *p*-toluenesulfonic acid (10 mg) in toluene (5 ml) giving the corresponding acetate (XXVII) (94 mg: 77%), IR: 1760, 1720 cm^{-1}.

Oxidation of XXVII (94 mg) with chromium trioxide (50 mg) in acetic acid (3 ml) gave methyl 11-acetoxy-12-methoxy-7-oxoabieta-8,11,13-trien-18-oate (XXVIII) (71 mg: 73%), IR: 1760, 1720, 1680 cm^{-1}, which was then hydrolyzed under reflux for 2 h with 30% aqueous potassium hydroxide (0.3 ml) in methanol (7 ml) yielding VI (44 mg: 69%). IR and NMR spectra of the synthetic VI were identical with those of a natural sample.

Methyl 11-Acetoxy-12-benzoyloxyabieta-6,8,11,13-tetraen-18-oate (XXX). A mixture of XXVI (1.26 g) in methanol

(20 ml) and sodium borohydride (190 mg) was allowed to stand at 0 °C for 3.5 h. After the usual work-up, the crude alcohol (1.26 g) was refluxed with *p*-toluenesulfonic acid (130 mg) in toluene (40 ml) for 1.5 h. The product was chromatographed on silica gel (120 g) using benzene–ether (99: 1) as the eluent giving XXX (1.11 g: 91%), which was recrystallized from ethanol; mp 128—129 °C, $[\alpha]_D$ +29.3°, IR: 1758, 1735, 1720 cm^{-1}, NMR: 3.03 (t, J=2.5 Hz, C_5–H), 5.59 (dd, J=2.5 and 9.5 Hz, C_6–H), 6.42 (dd, J=2.5 and 9.5 Hz, C_7–H). Found: C, 73.36; H, 6.99%. Calcd for $C_{30}H_{34}O_6$: C, 73.45; H, 6.99%.

Methyl 11-Acetoxy-12-benzoyloxy-6-oxoabieta-8,11,13-trien-18-oate (XXXI). A mixture of XXX (210 mg) in dichloromethane (20 ml) and *m*-chloroperbenzoic acid (88 mg) was allowed to stand at 0 °C for 4 h, and then extracted with ether. The ether extract was washed with aqueous sodium hydrogencarbonate and water. Evaporation of the solvent and subsequent chromatography on silica gel (20 g) using benzene–ether (98: 2) as the eluent gave XXXI (46 mg: 22%), which was recrystallized from a mixture of acetone and methanol; mp 253—255 °C, $[\alpha]_D$ +164°, IR: 1760, 1732, 1725, 1710 sh cm^{-1}, NMR ($CDCl_3$): 1.23 and 1.25 (each d and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.28 and 1.47 (each s, C_4–CH_3 and C_{10}–CH_3), 1.96 (s, $-OCOCH_3$), 3.48 (s, C_5–H), 3.65 (s, $-CO_2CH_3$), 3.71 (s, $-COCH_2-$), 7.00 (s, C_{14}–H), 7.3—8.4 (m, $-C_6H_5$). Found: C, 70.85; H, 6.81%. Calcd for $C_{30}H_{34}O_7$: C, 71.13; H, 6.77%.

Methyl 11-Hydroxy-6,12-dioxoabieta-7,9(11),13-trien-18-oate (XXIX). A mixture of XXXI (298 mg) in methanol (54 ml), sodium hydrogencarbonate (200 mg), and water (6 ml) was refluxed for 40 min, and then extracted with ether. The extract was washed with water, dried over sodium sulfate, and evaporated. The crude product was chromatographed on silica gel (20 g) using benzene–ether (99: 1) as the eluent giving XXIX (127 mg: 61%), which was recrystallized from methanol; mp 57.5—59 °C, $[\alpha]_D$ −80.3°, IR: 3345, 1723, 1667, 1642, 1627, 1617, 1600 cm^{-1}, UV: λ_{max} nm (ε) 325 (20000), 335 (21400), 405 (3020), NMR: 1.22 (d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.32 (s, C_4–CH_3), 1.46 (s, C_{10}–CH_3), 3.49 (s, C_5–H), 3.66 (s, $-CO_2CH_3$), 6.21 (s, C_7–H), 6.92 (s, C_{14}–H), 7.62 (s, –OH).

Methyl 12-Benzyloxyabieta-8,11,13-trien-18-oate (XXXIII). A mixture of II (500 mg) in *N,N*-dimethylformamide (2 ml), benzyl chloride (250 mg), and anhydrous potassium carbonate (2 g) was refluxed with stirring for 1 h, cooled, diluted with ether, and then acidified with dilute hydrochloric acid. The ether solution was washed with brine, dried over sodium sulfate, and evaporated. The residue was chromatographed on silica gel using benzene as the eluent giving XXXIII (617 mg: 97%), which was recrystallized from ethanol, mp 76.5—77 °C, $[\alpha]_D$ +70.4°. Found: C, 80.13; H, 8.57%. Calcd for $C_{28}H_{36}O_3$: C, 79.96; H, 8.63%.

12-Benzyloxyabieta-8,11,13-trien-18-one (XXXV). A mixture of XXXIII (4.60 g) in dry ether (50 ml) and lithium aluminum hydride (1.0 g) was refluxed for 4 h. After the usual work-up, the crude alcohol XXXIV (4.05 g) in pyridine (40 ml) was oxidized at room temperature for 1.5 h with Sarett reagent prepared from chromium trioxide (3.09 g) and pyridine (30 ml). The product was recrystallized from ethanol giving XXXV (2.13 g: 69%), mp 135—136.5 °C, $[\alpha]_D$ +73.9°, IR: 1720 cm^{-1}, NMR: 9.15 (s, –CHO). Found: C, 82.83; H, 8.64%. Calcd for $C_{27}H_{34}O_2$: C, 83.03; H, 8.78%.

12-Benzyloxyabieta-8,11,13-triene (Ferruginol Benzyl Ether) (XXXVI). A mixture of XXXV (2.06 g) in diethylene glycol (62 ml) and 80% hydrazine hydrate (8.2 ml) was refluxed for 2 h. After the addition of powdered sodium hydroxide (8.2 g), the mixture was further heated at 195—200 °C for 3 h. After the usual work-up, the product was purified by column chromatography on silica gel (200 g) using hexane–benzene (1: 3) as the eluent giving XXXVI (1.82 g: 92%), which was recrystallized from ethanol, mp 63—64 °C, $[\alpha]_D$ +68.2°. Found: C, 86.37; H, 9.80%. Calcd for $C_{27}H_{36}O$: C, 86.11; H, 9.64%.

Ferruginol (XXXII). A mixture of XXXVI (2.26 g) in acetic acid (150 ml), 5% Pd-C (750 mg), and concentrated hydrochloric acid (1.0 ml) was stirred at room temperature for *ca.* 3 h in an atmosphere of hydrogen. After the usual work-up, the product was chromatographed on silica gel (150 g) using hexane–benzene (2: 3) as the eluent giving XXXII (1.69 g: 98%), $[\alpha]_D$ +57.5°, IR: 3605, 3350 cm^{-1}, NMR: 0.90 and 0.92 (each s, $-C(CH_3)_2$), 1.08 (s, C_{10}–CH_3), 1.17 (d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 5.18 (s, –OH), 6.37 and 6.65 (each s, C_{11}–H and C_{14}–H).

Oxidation of Ferruginol (XXXII) with Benzoyl Peroxide. A solution of XXXII (5.73 g) and benzoyl peroxide (5.60 g) in chloroform (30 ml) was allowed to stand at room temperature for 4 h. The crude product was purified by column chromatography on silica gel giving four products (XXXVII-XL).

a): 12-Benzoyloxyabieta-8,11,13-trien-11-ol (XXXVII: 44%), which responded positively to Gibbs test;[15] mp 132.5—133 °C, (from petroleum ether), $[\alpha]_D$ +81.2°, IR: 3575, 3350, 1740 cm^{-1}, NMR: 0.97 (s, $-C(CH_3)_2$), 1.17 and 1.19 (each d and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.33 (s, C_{10}–CH_3), 5.17 (s, –OH), 6.50 (s, C_{14}–H), 7.4—8.3 (m, $-C_6H_5$). Found: C, 80.02; H, 8.56%. Calcd for $C_{27}H_{34}O_3$: C, 79.76; H, 8.43%.

b): 12-Oxoabieta-8(14),9(11)-dien-13α-yl benzoate (XXXVIII: 6%); mp 134.5—135.5 °C (from methanol), $[\alpha]_D$ +270°, IR: 1714, 1664 cm^{-1}, UV: λ_{max} nm (ε) 233 (15400), 321 (2230), NMR: 0.90 and 1.11 (each d and J=7 Hz, $-CH(C\underline{H}_3)_2$), 0.96 (s, $-C(CH_3)_2$), 1.19 (s, C_{10}–CH_3), 5.81 and 5.89 (each s, C_{11}–H and C_{14}–H), 7.2—8.1 (m, $-C_6H_5$). Found: C, 79.56; H, 8.55%. Calcd for $C_{27}H_{34}O_3$: C, 79.76; H, 8.43%.

c): 12-Oxoabieta-9(11),13-dien-8β-yl benzoate (XXXIX: 2%); mp 139—140 °C (from methanol), $[\alpha]_D$ −119°, IR: 1721, 1665, 1630 cm^{-1}, UV: λ_{max} 235 nm (ε 20900), NMR: 0.92 (s, $-C(CH_3)_2$), 1.05 (d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.11 (s, C_{10}–CH_3), 6.09 and 6.26 (each s, C_{11}–H and C_{14}–H). Found: C, 79.60; H, 8.51%. Calcd for $C_{27}H_{34}O_3$: C, 79.76; H, 8.43%.

d): 12-Oxoabieta-8(14),9(11)-dien-13β-yl benzoate (XL: 3%); mp 135—136 °C (from methanol), $[\alpha]_D$ −214°, IR: 1715, 1663 cm^{-1}, UV: λ_{max} nm (ε) 233 (17000), 321 (2350), NMR: 0.88 and 1.11 (each d and J=7 Hz, $-CH(C\underline{H}_3)_2$), 0.94 and 0.97 (each s, $-C(CH_3)_2$), 1.27 (s, C_{10}–CH_3), 5.80 and 5.88 (each s, C_{11}–H and C_{14}–H), 7.2—8.1 (m, $-C_6H_5$). Found: C, 80.03; H, 8.63%. Calcd for $C_{27}H_{34}O_3$: C, 79.76; H, 8.43%.

Reduction of XXXVIII, XXXIX, and XL with Lithium Aluminum Hydride. A mixture of XXXVIII (83 mg) in dry ether (5 ml) and lithium aluminum hydride (100 mg) was refluxed for 1.5 h. After the usual work-up, the product was purified by column chromatography to give ferruginol (XXXII) (53 mg: 91%).

By similar treatments, XXXIX and XL were also converted to XXXII.

Thermal Rearrangement of Dienones (XXXVIII and XL).

a): A solution of XXXVIII (119 mg) in toluene (5 ml) was refluxed for 2 h, and then evaporated. The residue was chromatographed on silica gel to give XXXVII (8 mg: 7%) and the recovered XXXVIII (106 mg: 89%).

b): A similar treatment of XL (129 mg) in refluxing toluene (5 ml) for 2 h gave XXXVII (22 mg: 17%), XXXIX (15 mg: 12%), and the recovered XL (86 mg: 67%).

8β-Hydroxyabieta-9(11),13-dien-12-one (XLI). A mixture of XXXIX (90 mg) in methanol (16 ml), anhydrous potassium carbonate (200 mg), and water (2 ml) was refluxed

for 2 h and the solvent was removed in a vacuum. After the residue had been extracted with ether, the extract was washed with water, dried, and then evaporated. The crude product was chromatographed on silica gel (20 g) using benzene–ether (95: 5) as the eluent to give the recovered XXXIX (14 mg: 16%) and an alcohol (XLI) (56 mg: 83%), which was recrystallized from methanol, mp 181—182.5 °C, $[\alpha]_D$ −142°, IR: 3580, 3400, 1662, 1630 cm^{-1}, UV: λ_{max} 242 nm (ε 12700), NMR ($CDCl_3$): 0.90 and 0.95 (each s, $-C(CH_3)_2$), 1.05 (d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.38 (s, $C_{10}-CH_3$), 1.86 (s, -OH), 5.98 and 6.38 (each s, C_{11}-H and C_{14}-H). Found: C, 79.40; H, 10.12%. Calcd for $C_{20}H_{30}O_2$: C, 79.42; H, 10.00%.

12-Benzoyloxyabieta-8,12-dien-11,14-dione (Royleanone Benzoate) (XLII). A solution of XXXVII (205 mg) and *m*-chloroperbenzoic acid (155 mg) in dichloromethane (7 ml) was allowed to stand at room temperature for 25 h. After the usual work-up, the crude product was chromatographed on silica gel (30 g) using hexane–benzene (1: 1) as the eluent to give the recovered XXXVII (78 mg: 38%) and XLII (100 mg: 45%), which was recrystallized from ethanol; mp 196—197 °C, $[\alpha]_D$ +52.3°, IR: 1740, 1659 cm^{-1}, UV: λ_{max} nm (ε) 235 (15900), 265 (16400), NMR: 0.93 (s, $-C(CH_3)_2$), 1.24 (d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.28 (s, $C_{10}-CH_3$), 7.4—8.2 (m, $-C_6H_5$). Found: C, 76.88; H, 7.66%. Calcd for $C_{27}H_{32}O_4$: C, 77.11; H, 7.67%.

Royleanone (IV). *a)*: A mixture of the benzoate XLII (96 mg) in methanol (40 ml), sodium hydrogencarbonate (300 mg), and water (7 ml) was refluxed for 1 h. After removal of the solvent under vacuum, the residue was extracted with ether and the extract was washed with water, dried, and then evaporated. The crude product was chromatographed on silica gel using benzene as the eluent to give royleanone (IV)[5] (62 mg: 84%), which was recrystallized from hexane; mp 181.5—183 °C, $[\alpha]_D$ +137°, IR: 3375, 1674, 1636, 1602 cm^{-1}, UV: λ_{max} nm (ε) 277 (14100), 403 (440), NMR: 0.95 (s, $-C(CH_3)_2$), 1.20 (d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.26 (s, $C_{10}-CH_3$), 7.16 (s, -OH). Found: C, 76.21; H, 9.04%. Calcd for $C_{20}H_{28}O_3$: C, 75.91; H, 8.92%.

b): A solution of the methyl ether XXIII (31.8 mg) in methanol (5 ml) and 10% hydrochloric acid (1.0 ml) was refluxed for 16 h. After the usual work-up, the product was purified by column chromatography to give royleanone (IV) (11.7 mg: 38%), mp 180.5—182 °C. The IR and NMR spectra of the synthetic royleanone were identical to those of a natural sample.

11-Acetoxy-12-benzoyloxyabieta-8,11,13-triene (XLIII). A solution of XXXVII (710 mg) in dry toluene (10 ml), *p*-toluenesulfonic acid (40 mg), and isopropenyl acetate (2 ml) was refluxed for 5 h. After the usual work-up, the crude product was chromatographed on silica gel (70 g) using benzene as the eluent to give XLIII (730 mg: 93%), which was recrystallized from methanol; mp 179—179.5 °C, $[\alpha]_D$ +80.0°, IR: 1760, 1738 cm^{-1}, NMR: 0.91 and 0.96 (each s $-C(CH_3)_2$), 1.18 and 1.20 (each d and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.26 (s, $C_{10}-CH_3$), 1.81 (s, $-OCOCH_3$), 6.82 (s, C_{14}-H), 7.2—8.3 (m, $-C_6H_5$). Found: C, 77.36; H, 8.01%. Calcd for $C_{29}H_{36}O_4$: C, 77.64; H, 8.09%.

11-Acetoxy-12-benzoyloxyabieta-8,11,13-trien-7-one (XLIV). A solution of XLIII (985 mg) in acetic acid (20 ml) was oxidized with chromium trioxide (450 mg) at room temperature for 22 h. The product was purified by column chromatography on silica gel (100 g) using benzene–ether (99: 1) as the eluent to give XLIV (833 mg: 82%), which was recrystallized from ethanol; mp 160—162 °C, $[\alpha]_D$ +56.9°, IR: 1768, 1740, 1680 cm^{-1}, NMR: 0.98 (s, $-C(CH_3)_2$), 1.25 and 1.29 (each d and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.34 (s, $C_{10}-CH_3$), 1.87 (s, $-OCOCH_3$), 7.5—8.3 (m, $-C_6H_5$), 7.98 (s, C_{14}-H). Found: C, 75.54; H, 7.44%. Calcd for $C_{29}H_{34}O_5$: C, 75.30; H, 7.41%.

Cryptojaponol (V). A mixture of XLIV (250 mg) in methanol (18 ml), sodium hydrogencarbonate (600 mg), and water (2 ml) was refluxed for 1 h. After the usual work-up, the crude product was methylated with diazomethane and then purified by column chromatography on silica gel (20 g) using benzene–ether (99: 1) as the eluent to give cryptojaponol (V)[8,9] (145 mg: 81%), which was recrystallized from methanol; mp 205—206.6 °C, $[\alpha]_D$ +20.0°, IR: 3505, 1670, 1605 cm^{-1}, NMR: 0.98 (s, $-C(CH_3)_2$), 1.26 (d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.39 (s, $C_{10}-CH_3$), 3.77 (s, $-OCH_3$), 6.02 (s, -OH), 7.48 (s, C_{14}-H). Found: C, 76.09; H, 9.13%. Calcd for $C_{21}H_{30}O_3$: C, 76.32; H, 9.15%.

11-Acetoxy-12-benzoyloxyabieta-6,8,11,13-tetraene (XLV). A solution of XLIV (263 mg) and sodium borohydride (120 mg) in methanol (7 ml) was allowed to stand at 0 °C for 4 h. After the usual work-up, the product (251 mg) was dehydrated with *p*-toluenesulfonic acid (90 mg) in dry toluene (15 ml) under reflux for 3.5 h to afford a tetraene derivative along with the corresponding 11-hydroxy-12-benzoyloxy derivative. The above mixture was then acetylated with isopropenyl acetate (1 ml) in the presence of *p*-toluenesulfonic acid (20 mg) in refluxing toluene (10 ml) and chromatographed on silica gel to give XLV (148 mg: 56%), which was recrystallized from methanol; mp 157—158 °C, $[\alpha]_D$ −80.8°, IR: 1758, 1737 cm^{-1}, NMR: 0.98 and 1.02 (each s, $-C(CH_3)_2$), 1.15 (s, $C_{10}-CH_3$), 1.20 and 1.24 (each d and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.84 (s, $-OCOCH_3$), 2.32 (t, J=2.5 Hz, C_5-H), 5.92 (dd, J=2.5 and 9.5 Hz, C_6-H), 6.48 (dd, J=2.5 and 9.5 Hz, C_7-H), 6.84 (s, C_{14}-H), 7.4—8.3 (m, $-C_6H_5$). Found: C, 78.15; H, 7.59%. Calcd for $C_{29}H_{34}O_4$: C, 77.99; H, 7.67%.

11-Acetoxy-12-benzoyloxyabieta-8,11,13-trien-6-one (XLVII). A solution of XLV (589 mg) and *m*-chloroperbenzoic acid (320 mg) in dichloromethane (10 ml) was allowed to stand at room temperature for 24 h. After the usual work-up, the crude epoxide was chromatographed on silica gel (60 g) using benzene–ether (99: 1) as the eluent to give XLVII (475 mg: 78%), which was recrystallized from methanol; 222—224 °C, ($[\alpha]_D$ +111°, IR: 1762, 1740, 1717 cm^{-1}, NMR: 1.05 and 1.30 each s, $-C(CH_3)_2$), 1.19 and 1.23 (each d and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.30 (s, $C_{10}-CH_3$), 1.87 (s, $-OCOCH_3$), 2.64 (s, C_5-H), 3.60 (bs, $-COCH_2-$), 6.90 (s, C_{14}-H), 7.5—8.3 (m, $-C_6H_5$). Found: C, 75.06; H, 7.54%. Calcd for $C_{29}H_{34}O_5$: C, 75.30; H, 7.41%.

The above crude epoxide was recrystallized from a mixture of acetone and petroleum ether giving pure epoxide (XLVI), mp 199—201 °C, $[\alpha]_D$ +6.5°, IR: 1765, 1740 cm^{-1}, NMR ($CDCl_3$): 1.13 (s, $-C(CH_3)_2$), 1.21 and 1.26 (each d and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.33 (s, $C_{10}-CH_3$), 1.93 (s, $-OCOCH_3$), 3.54 (t, J=4.5 Hz, C_6-H), 3.92 (d, J=4.5 Hz, C_7-H), 7.38 (s, C_{14}-H), 7.4—8.3 (m, $-C_6H_5$). Found: C, 75.45; H, 7.49%. Calcd for $C_{29}H_{34}O_5$: C, 75.30; H, 7.41%.

11,12-Bis(benzoyloxy)abieta-8,11,13-triene (XLVIII). A solution of XXXVII (244 mg), benzoyl chloride (0.2 ml), and pyridine (4 ml) was heated at 80—100 °C for 2 h. The product was purified by column chromatography on silica gel using benzene as the eluent to give XLVIII[21] (279 mg: 91%), which was recrystallized from a mixture of acetone and petroleum ether; mp 207—208 °C, $[\alpha]_D$ +76.2°, IR: 1735 cm^{-1}, NMR: 0.92 and 0.97 (each s, $-C(CH_3)_2$), 1.22 (d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.28 (s, $C_{10}-CH_3$), 6.90 (s, C_{14}-H), 7.0—8.1 (m, 2-C_6H_5). Found: C, 79.82; H, 7.53%. Calcd for $C_{34}H_{38}O_4$: C, 79.97; H, 7.50%.

11,12-Bis(benzoyloxy)abieta-8,11,13-trien-7-one (XLIX). A solution of XLVIII (8.40 g) in acetic acid (300 ml) was oxidized at room temperature for 24 h with chromium trioxide

(7.0 g). The crude product was purified by chromatography on silica gel (300 g) using benzene as the eluent to give XLIX (6.15 g: 69%), which was recrystallized from methanol; mp 150—151 °C, $[\alpha]_D$ +23°, IR: 1742, 1682 cm^{-1}, NMR: 8.03 (s, C_{14}-H). Found: C, 77.56; H, 6.94%. Calcd for $C_{34}H_{36}O_5$: C, 77.83; H, 6.92%.

11,12-Bis(benzoyloxy)abieta-6,8,11,13-tetraene (L). A solution of XLIX (5.55 g) in methanol (120 ml) was reduced at 0 °C for 4 h with sodium borohydride (1.2 g). The crude alcohol was then dehydrated for 2 h with *p*-toluenesulfonic acid (1.8 g) in refluxing toluene (100 ml). The product was purified by chromatography on silica gel (300 g) using hexane–benzene (1: 9) as the eluent to give L (4.40 g: 76%), which was recrystallized from a mixture of acetone and methanol; mp 182.5—183 °C, $[\alpha]_D$ −308°, IR: 1740 cm^{-1}, NMR: 2.33 (t, J=3 Hz, C_5-H), 5.96 (dd, J=3 and 9.5 Hz, C_6-H), 6.52 (dd, J=3 and 9.5 Hz, C_7-H). Found: C, 80.55; H, 7.24%. Calcd for $C_{34}H_{36}O_4$: C, 80.28; H, 7.13%.

11,12-Bis(benzoyloxy)abieta-8,11,13-trien-6-one (LI). A solution of L (501 mg) in chloroform (5 ml) was treated at room temperature for 3 h with *m*-chloroperbenzoic acid (207 mg). The epoxide was chromatographed on silica gel (50 g) using benzene–ether (98: 2) as the eluent to give LI (340 mg: 66%), which was recrystallized from a mixture of acetone and methanol; mp 207—208 °C, $[\alpha]_D$ +58.3°, IR: 1740, 1718 cm^{-1}, NMR: 1.04 and 1.30 (each s, $-C(CH_3)_2$), 1.25 (d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.30 (s, C_{10}-CH_3), 2.65 (s, C_5-H), 3.64 (bs, $-COCH_2-$), 6.93 (s, C_{14}-H), 7.0—8.1 (m, 2-C_6H_5). Found: C, 78.12; H, 7.03%. Calcd for $C_{34}H_{36}O_5$: C, 77.83; H, 6.92%.

Taxodione (III). *a)*: A mixture of XLVII (150 mg) in methanol (10 ml), sodium hydrogencarbonate (450 mg), and water (1 ml) was refluxed for 1 h. The crude phenol was chromatographed on silica gel (20 g) using benzene as the eluent to give taxodione (III) (62 mg: 60%), which was recrystallized from petroleum ether; mp 97.5—98 °C, $[\alpha]_D$ +40°, IR: 3345, 1671, 1642, 1626, 1614, 1598 cm^{-1}, UV: λ_{max} nm (ε) 323 (23400), 335 (24500), 405 (3240), Mass: *m/e* 314 (M^+), NMR ($CDCl_3$): 1.12 and 1.27 (each s, $-C(CH_3)_2$), 1.18 (d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.27 (s, C_{10}-CH_3), 2.61 (s, C_5-H), 2.96 (m, $-CH(C\underline{H}_3)_2$), 6.20 (s, C_7-H), 6.87 (s, C_{14}-H), 7.57 (s, -OH). Found: C, 76.23; H, 8.39%. Calcd for $C_{20}H_{26}O_3$: C, 76.40; H, 8.34%.

b): A mixture of LI (340 mg) in methanol (25 ml), sodium hydrogencarbonate (1.0 g), and water (7 ml) was treated as described under *a)* above to give taxodione (III) (120 mg: 59%). The IR and NMR spectra of the synthetic taxodione were identical with those of a natural sample.

The authors are grateful to Arakawa Rinsan Kogyo Co., Ltd. for a generous gift of rosin. Thanks are also due to Professor S. Morris Kupchan, University of Virginia, to Professor O. E. Edwards, National Research Council, Ottawa, and to Professor J. F. Biellmann, Institute of Louis Pasteur, for kindly supplying the natural samples and their spectra.

The Temperature and Solvent Effects on the $AlCl_3$-catalyzed Cyclization of 3,3′-Diphenyl-2,2′-biindenyl-1,1′-dione

Fumio Toda and Yozo Todo

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Matsuyama 790

(Received August 30, 1976)

Upon the $AlCl_3$-catalyzed cyclization of the title biindenone (**1**) into benz[*c*]indeno[2,1-*a*]fluorene-13,14-dione (**2**) and 3,3′: 3,3′-di(*o*-phenylene)-2,2′-biindenylidene-1,1′-dione (**3**), the **2**: **3** ratio increased when the reaction temperature was raised and decreased when the polarity of the solvent was increased.

During the course of our study of the $AlCl_3$-catalyzed cyclization of the title biindenone (**1**) into benz[*c*]-indeno[2,1-*a*]fluorene-13,14-dione (**2**) and 3,3′:3,3′-di-(*o*-phenylene)-2,2′-biindenylidene-1,1′-dione (**3**), we found that the **2**: **3** ratio is remarkably affected by the reaction temperature and the polarity of the solvent.

Results

The yields of the products under various reaction conditions are summarized in Table 1. Of the products, **2**—**6**, **2**[1] and **6**[2] are known compounds. The spectral and analytical data of **3**, 3,3′-(*o*-phenylene)-3,3′-diphenyl-2,2′-biindenylidene-1,1′-dione (**4a**), and its halo derivatives (**4b**—**c** and **5b**—**c**) are summarized in Table 2.

Table 1. Reaction conditions and yields of products[a]

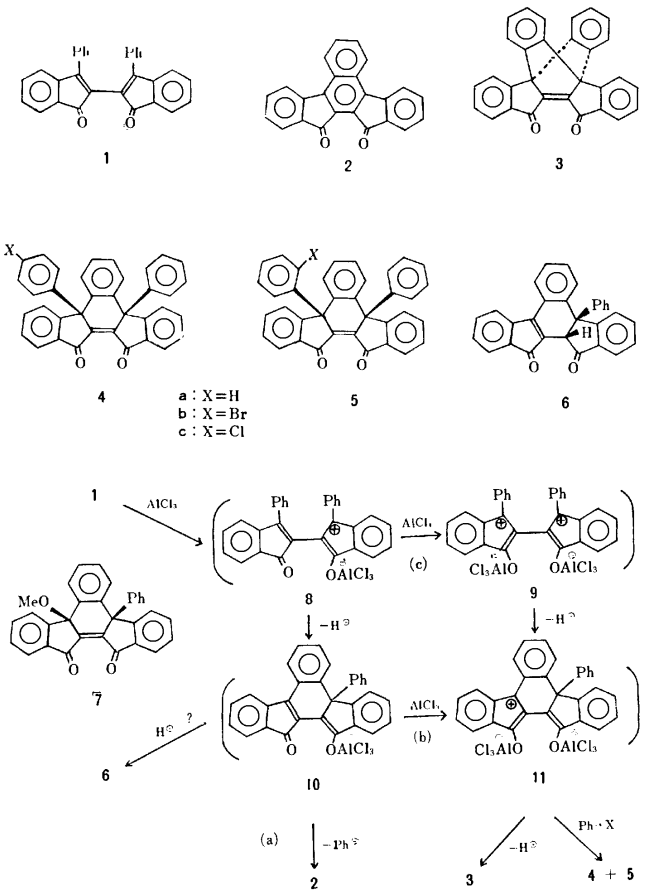
Reaction conditions			Yields (%) of products				
Solvent	Dielectric constant	Reaction temperature (°C)	**2**	**3**	**4**	**5**	**6**
C_6H_6	2.3	20	38		37 (**4a**)		
		80	74				
CS_2	2.6	20	22	6			28
		46	49				28
C_6H_5Br	5.4	20	20	8	19 (**4b**)	12 (**5b**)	
		80	49	14	15 (**4b**)		
C_6H_5Cl	5.6	20	12	8	24 (**4c**)	22 (**5c**)	
		80	30	16	16 (**4c**)		
CH_2Cl_2	8.9	20		70			
		40	89				
$C_6H_5NO_2$	34.8	20		60			
		80		60			

a) The yields are based on the product of the reaction which was carried out for 3 h; within this period all the reactions were completed.

Table 2. Melting points, and spectral and analytical data of **3**, **4**, and **5**[a]

Compound	Mp (°C)	ν_{max}^{Nujol} (cm^{-1})	$\lambda_{max}^{CHCl_3}$ nm ($\varepsilon \times 10^{-2}$)	*m/e* (rel intensity)	Found (Calcd) (%) C	H
3	292	1710 (C=O) 1640 (C=C)	296(375), 308(70), 409(91), 464(16)	408 (M^+, 100), 380 (M^+-CO, 30), 332 ($M^+-C_6H_4$, 85), 176 ($C_{14}H_8^+$, 30)	87.95 (88.22	3.87 3.95)
4a	>310	1710 (C=O) 1645 (C=C)	298(196)	486(M^+, 100), 409 (M^+-Ph, 33), 381 (409−CO, 40), 332 (409−Ph, 10)	88.63 (88.86	4.36 4.56)
4b	276—277	1720 (C=O) 1640 (C=C) 820 (1,4-C_6H_4)	296(191)	564 (M^+, 100), 566 ($(M+2)^+$, 98), 485 (M^+-Br, 50), 409 ($M^+-C_6H_4Br$, 20), 381 (409−CO, 40),	76.24 (76.46	3.55 3.74)
4c	295—296	1720 (C=O) 1640 (C=C) 820 (1,4-C_6H_4)	298(176)	520 (M^+, 100), 522 ($(M+2)^+$, 33), 485 (M^+-Cl, 45), 409 ($M^+-C_6H_4Cl$, 20)	82.79 (82.99	3.82 4.06)
5b	>310	1720 (C=O) 1640 (C=C)	297(194)	564 (M^+, 100), 566 ($(M+2)^+$, 98), 485 (M^+-Br, 50), 409 ($M^+-C_6H_4Br$, 20), 381 (409−CO, 20)	76.31 (76.46	3.66 3.74)
5c	>310	1720 (C=O) 1640 (C=C)	294(182)	520 (M^+, 100), 522($(M+2)^+$, 33) 485 (M^+-Cl, 45), 409 ($M^+-C_6H_4Cl$, 20)	82.71 (82.99	3.97 4.06)

a) All the melting points are uncorrected. The mass spectra were measured with an ionization energy of 75 eV. The NMR spectra showed aromatic protons only.



The structures of **4** and **5** were characterized by comparing their spectral data with those of **7**.[2] The structure of **3** was mainly characterized by means of the mass spectrum, which showed the fragmentation of the benzyne from the molecular ion and the formation of an anthracene cation radical (Table 2). The UV spectral bands of **3** in the remarkably longer-wave length region are presumably due to its internal strain. Of the halogen-substituted products (**4b—c** and **5b—c**), **4b** and **4c** were identified as 4-halo derivatives on the basis of their IR bands of 1,4-disubstituted benzene (820 cm^{-1}). Therefore, **5b** and **5c** are probably 2-halo derivatives.

Discussion

Temperature Effect. In the cases of all the reactions except in nitrobenzene with an extremely high dielectric constant, the **2**: **3** ratio increased when the reaction temperature was raised. This was remarkable in dichloromethane, the products at 20 and 40 °C being **3** and **2** respectively. Of course, no thermal conversion of **3** into **2** under the conditions described in Table 1 was observed. The temperature effect can be interpreted as follows: there are two competing reaction pathways, leading to **2** and **3** respectively. One of them proceeds through the elimination of the benzenide anion and $AlCl_3$ from **10**, which was formed by an intramolecular cyclization of the $AlCl_3$-coordinated intermediate (**8**), giving **2** (Path (a)). Another one proceeds through the further coordination of $AlCl_3$ to **10** (Path (b)); cyclization followed by the ketonization of the resulting intermediate (**11**) finally affords **3**. Such a dehydrogenating ketonization of vinyl alcohol has long been known to occur under the influence of $AlCl_3$.[3] At higher temperatures, Path (a) would be much more accelerated than would Path (b). Because of the increase in the steric and then the electrostatic repulsions at higher temperatures, **11** is less favored and Path (b) is relatively retarded. A similar interpretation has recently been reported with regard to the $AlCl_3$-catalyzed dimerization of indenone in boiling dichloromethane (40 °C) and ethylene chloride (83 °C), which afford endo and exo head-to-tail dimers respectively.[4]

The formation of **4** and **5** can be interpreted in terms of arylation on **11**. At 80 °C, the yields of **4** and **5** decreased. Again, this is due to the retardation of Path (b) for the reason presented above. In addition, the approach of the 2-position of halobenzene to the cationic center of **11** is fully inhibited at 80 °C because of the large steric repulsion.

The additional pathway which proceeds *via* **9** (Path (c)) could also be applied to the interpretation of the formation of **3**—**5**. However, this would be unreasonable, because the cyclization of **9** to **11** should overcome large electrostatic and steric repulsions in a transition state. The pathway of the formation of **6** is not clear. Although the ketonization of **10** can give **6**, this consideration disagrees with the finding that the yield of **6** is not affected by the reaction temperature. If **6** is derived directly from **10**, the yield of **6** should decrease at higher temperatures, because the yield of **2** increases when the temperature is raised.

Solvent Effect. Both the **2**: **3** ratio and the ratio of **2** to the total of **3**, **4**, and **5** at 20 °C decreased as the polarity of the solvent increases. This is remarkable in the cases of the reactions in dichloromethane and nitrobenzene; in both cases **3** was the sole isolable product. Especially, nitrobenzene of an extremely high dielectric constant strongly controlled the reaction causing it to proceed through Path (b) even at 80 °C and to produce **3** only. In a polar solvent, **11** would be stabilized by solvation, and thus Path (b) would be enhanced. If **9** is formed in this reaction, **9** would also be stabilized by the polar solvent. Nevertheless, there still remains the question of why **6** was formed only in the reaction in carbon disulfide.

Experimental

Preparation of 1. A mixture of 2,3-bis(diphenylmethylene)succinyl chloride[5] (10 g), benzene (50 ml), ether (50 ml), and $AlCl_3$ (5 g) was stirred at room temperature for 3 h. The reaction mixture was decomposed with water, and then extracted with benzene. The benzene solution was washed with water and dried over anhyd Na_2SO_4. The crude crystals left after the evaporation of the solvent were recrystallized from AcOEt to afford **1** as red prisms; 7 g (82%): mp 214 °C (lit,[6] mp 213—214 °C).

General Procedure of the $AlCl_3$-catalyzed Cyclization of 1. A mixture of **1** (0.5 g), the solvent (50 ml), and $AlCl_3$ (2 g) was stirred for 3 h. The reaction mixture was decomposed with water and then extracted with benzene. During the extraction, **2** was crystallized out as orange needles; it was then recrystallized from AcOEt to afford a pure sample of **2**; mp

306—308 °C (lit,[1] mp 309—310 °C). The benzene solution was washed with water and dried over anhyd Na_2SO_4. The crude crystals left after the evaporation of the solvent were recrystallized from AcOEt to afford **3** or **4**. In the cases of the reaction in halobenzene, **3**, **4**, and **5** were separated by fractional recrystallization from AcOEt. In the cases of the reaction in carbon disulfide, **3** and **6** were separated mechanically.

Studies on the Nitration of *m*-Cresol. A New Selective Method for the Preparation of 3-Methyl-6-nitrophenol

Mitsuru SASAKI, Katsuji NODERA, Kunio MUKAI, and Hirosuke YOSHIOKA

Research Department, Pesticides Division, Institute for Biological Science, Sumitomo Chemical Co., Ltd., Takatsukasa, Takarazuka, Hyogo 665

(Received August 30, 1976)

A new selective method for the nitration of *m*-cresol has been established. 3-Methyl-6-nitrophenol was most efficiently prepared by nitration of 3-methyl-4-sulfophenyl carbonate or phosphate and subsequent hydrolysis and desulfonation. Steric effects on the attacks of sulfonium or nitronium ion to the phosphate are discussed.

Certain mononitro derivatives of *m*-cresol are important intermediates for the preparation of organophosphorus pesticides such as Fenitrothion (*O,O*-dimethyl *O*-(3-methyl-4-nitrophenyl) phosphorothioate)[1] and herbicide Metacrephos (*O*-ethyl *N*-*s*-butyl *O*-(3-methyl-6-nitrophenyl) phosphoramidothioate).[2] The preparative value of direct nitration of *m*-cresol is limited due to a number of side reactions, *i.e.*, non-selective isomer formation together with oxidation with nitric acid and poor yield.[3] Various modifications were studied in order to overcome the defects of direct nitration.[4-7] Nitration after the introduction of a suitable protecting functional group to the hydroxyl group was the most common procedure. As an example, tri-*m*-tolyl phosphate was nitrated with a mixed acid, followed by hydrolysis, to yield 3-methyl-4-nitrophenol selectively.[6] 4-Hydroxy-6-methyl-1,3-benzenedisulfonic acid was nitrated and the subsequent desulfonation gave 3-methyl-2-nitrophenol in a good yield.[7] However, no report seems to have been given on an efficient method for selective preparation of 3-methyl-6-nitrophenol in a high yield.

This paper describes the formation of the three isomers of mononitro-3-methylphenols under various conditions, establishing a new selective method for the preparation of 3-methyl-6-nitrophenol. The mechanism of the formation of the product is also discussed.

Results

Syntheses of the Three Isomers of Mononitro-3-methylphenol. The results are given in Table 1. When *m*-cresol was sulfonated at 120 °C for 2 h with a slight excess of sulfuric acid, nitrated with a mixed acid and then desulfonated with diluted sulfuric acid, 3-methyl-6-nitrophenol(6-nitro isomer) was obtained as the major product and 3-methyl-2-nitrophenol (2-nitro isomer) as

a) A mixture of tri-*m*-tolyl phosphate (0,5 mol) and 96% H_2SO_4 (10 mol) was kept at 20—30 °C for 24 h. The resulting solution was divided into 4 portions. Mixed acid (70% HNO_3, calculated amount plus 96% H_2SO_4, 2 equiv. weight) was added dropwise to each portion at −5—0 °C. b) Molar ratio; 70% HNO_3/tri-*m*-tolyl phosphate.

a minor one. The ratio of formation of the 2- to the 6-nitro isomer was about 1 : 2. When a large excess of sulfuric acid was used, the 2-nitro isomer was obtained as the major product. Direct nitration of *m*-cresol with a mixed acid at −5—0 °C yielded about 50% of nitro-3-methylphenols and dinitro isomers accounted for 12%. Although tri-*m*-tolyl borate appeared to be a poor substrate owing to its rapid hydrolytic nature, the yield of the nitro isomers was 76.8%, the 2-nitro isomer being a main product.[8] Direct nitration of di-*m*-tolyl carbonate or tri-*m*-tolyl phosphate gave 3-methyl-4-nitrophenol (4-nitro isomer) as the major product (Nos. 5 and 7). In contrast, when both compounds were sulfonated, nitrated and followed by hydrolysis and desulfonation, the 6-nitro isomer was a predominant product (Nos. 6 and 8). The yield of the 6-nitro isomer from tri-*m*-tolyl phosphate was higher in comparison with that of the carbonate.

Selective Synthesis of the 6-Nitro Isomer. We see from Table 1 that tri-*m*-tolyl phosphate is the most favorable substrate for the preparation of the 6-nitro isomer. The following optimum conditions for selective preparation of the 6-nitro isomer were selected (Table 2). 96% Sulfuric acid was a better sulfonating reagent than 90% sulfuric acid or 10% oleum. We see from Table 3 that a small excess of nitric acid to the tolyl phosphate was effective for the most selective formation of the 6-nitro isomer (for No. 4, the ratio of the mono-nitro isomer was 1 : 1 : 28). Pure 6-nitro isomer was obtained from the crude mixture by dissociation extraction with a dilute alkaline solution.[9]

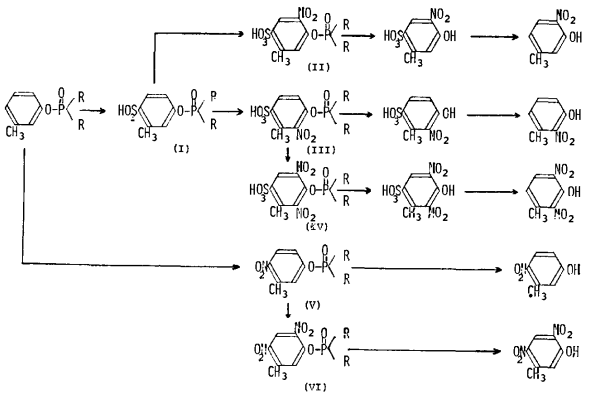
Identification of the Sulfonated Intermediates. All attempts to isolate the intermediates such as sulfo-*m*-tolyl phosphate or nitro-sulfo-*m*-tolyl phosphate after sulfonation or nitration were unsuccessful since they hydrolyze too easily. After nitration, the reaction mixture was poured onto ice and allowed to stand at room temperature for 48 h to give a yellow solid product. The product was extremely soluble in water and identical (mp and NMR) with an authentic specimen of 4-hydroxy-2-methyl-5-nitrobenzenesulfonic acid.[10] Desulfonation of the sulfonated nitrophenol with 60% sulfuric acid gave the 6-nitro isomer. 4-Hydroxy-2-methyl-5-nitrobenzenesulfonic acid (87.2%) and 4-hydroxy-2-methyl-3-nitrobenzenesulfonic acid (10.7%) were also detected by HLC analysis. 3-Methyl-4-nitrophenol was detected in the dephosphorylated solution by TLC on silica gel and quantitatively determined by GLC.

Discussion

The 4-nitro isomer was a dominant product of direct nitration of di-*m*-tolyl carbonate and tri-*m*-tolyl phosphate.[4,6] Haworth and Lapworth reported that the 4-position of *m*-cresol was predominantly sulfonated at 120 °C.[11] This was confirmed by the fact that the *o*-nitro isomers, *viz.*, 2- and 6-nitro isomers, occurred after subsequent nitration in a 1 : 2 ratio.

The use of a large excess of sulfuric acid at low temperature resulted in the selective formation of the 2-nitro isomer. This seems to be due to the formation of 4-hydroxy-6-methyl-1,3-benzenedisulfonic acid as an intermediate.

On the other hand, when the carbonate or the phosphate was monosulfonated, nitrated and followed by hydrolysis and desulfonation, the 6-nitro isomer was selectively obtained.



R: *m*-tolyl, nitro-*m*-tolyl, or nitro-sulfo-*m*-tolyl group

Fig. 1.

Selective formation of the 6-nitro isomer from tri-*m*-tolyl phosphate can be illustrated by the reaction sequence shown in Fig. 1. Tri-*m*-tolyl phosphate is sulfonated to give the 4-sulfo derivative (I), which is nitrated to yield the corresponding 6-nitro derivative (II) and 2-nitro derivative (III). It appears that attack of a nitronium ion takes place predominantly at the 6-position of I, since the 2-position of I is apparently hindered by the bulky ditolyloxyphosphinyl group and the 3-methyl group which may be inclined toward the 2-position by a buttressing effect from the 4-sulfonyl group. The higher selectivity of the nitration at the 6-position in the 4-sulfonated intermediates may be due to the peculiar geometry. A small excess of nitronium ion predominantly attacks the 6-position of the intermediate (III) to give the dinitro derivative (IV). IV is hydrolyzed, followed by desulfonation, to yield 2,6-dinitro-3-methylphenol. The unaffected *m*-tolyl group of the phosphate is directly nitrated to give the 4-nitro derivative (V), which undergoes nitration to give the 4,6-dinitro derivative (VI). Hydrolysis of VI produces 4,6-dinitro-3-methylphenol.

In conclusion, the present method of nitration after the specifically controlled sulfonation to the phosphate or the carbonate of *m*-cresol can provide the respective *o*-nitro derivatives in high yields in a convenient "one-pot-procedure." 3-Methyl-6-nitrophenol in particular can be efficiently prepared.

Experimental

Materials. Di-*m*-tolyl carbonate and tri-*m*-tolyl borate were prepared according to the procedures previously reported.[4,8] Tri-*m*-tolyl phosphate (99% pure) and *m*-cresol (98% pure) were prepared at Sumitomo Chemical Co. Ltd., Oita Works and used without further purification. Authentic specimens of 3-methyl-2-nitrophenol, 3-methyl-4-nitrophenol, 3-methyl-6-nitrophenol, 4,6-dinitro-3-methylphenol, 2,6-dinitro-3-methylphenol and 2,4,6-trinitro-3-methylphenol were prepared by the method given in the respective references.[3,10] 2,4-Dinitro-3-methylphenol was prepared by nitration of 3-methyl-2-nitrophenol in acetic acid, whose melting point was quite different from that in the literature.[10] Mp 130 °C (lit, 74 °C). Found: C, 42.56; H, 3.25; N, 14.20%. Calcd for $C_7H_6N_2O_5$: C, 42.43; H, 3.06; N, 14.14%. Physical and spectral data of these nitrophenols are given in Table 4. The following sulfonated nitro-3-methylphenols were prepared.[10] 4-Hydroxy-2-methyl-5-nitrobenzenesulfonic acid, mp 131—132 °C, NMR (D_2O): 2.60 (3H, s, CH_3), 7.10 (1H, S, H-5), and 8.50 (1H, s, H-2). 4-Hydroxy-2-methyl-3-nitrobenzenesulfonic acid, mp 78—79 °C, NMR (D_2O): 2.50 (3H, s, CH_3), 7.00 (1H, d, H-6, J=9.0 Hz), and 7.90 (1H, d, H-5, J=9.0 Hz).

TABLE 4. PHYSICAL AND SPECTRAL DATA OF NITRO-3-METHYLPHENOLS

Compound	Mp[a] (°C)	pK_a	UV in EtOH λ max (nm)	log ε
3-Methyl-2-nitrophenol	41 (39)	7.20	212 235 270	4.08 3.29 3.25

c) Determined in 5% EtOH.

Analysis. Identification and quantitative analysis of the nitro isomers were carried out on a GLC(Yanagimoto G-80 or Yanagimoto GCG-550 F, FID detecter) and a GC-Mass spectrometer (Shimadzu LKB-9000). Products were identified with authentic samples by GC retention time on at least two different columns (2% XE-60 on chromosorb W, 3 mm × 1.5 m, glass column programmed at 110—220 °C; 10% PEG-20M on Chromosorb W, 3 mm × 1.0 m, glass column programmed at 150—200 °C; 2% FFAP on Shimalite TPA, 3 mm × 1.0 m, glass column programmed at 170—200 °C). Neither 2,4-dinitro-3-methylphenol nor 2,4,6-trinitro-3-methylphenol were detected under the conditions described above. Mass spectra of peaks obtained from GLC were determined at 70 eV as follows; 3-methyl-6-nitrophenol (*m/e* 153 M^+), 3-methyl-2-nitrophenol (*m/e* 153 M^+), 3-methyl-4-nitrophenol (*m/e* 153 M^+), 2,6-dinitro-3-methylphenol (*m/e* 198 M^+) and 4,6-dinitro-3-methyl-phenol (*m/e* 198 M^+). 4-Methyl-3-nitrophenol (*m/e* 153 M^+) was obtained among other minor products by the nitration of *p*-cresol, a major impurity in the starting material. The sulfonated nitro-3-methylphenols formed as intermediates were analyzed as follows. The

reaction mixture occurring after nitration was poured onto ice and then neutralized with aqueous sodium hydroxide to pH 7.40. One μl of the solution was subjected to HLC. Operating conditions are follows; instrument, Shimadzu Du Pont 830 liquid chromatograph; column SAX 2 mm × 1.0 m; column temp, 40 °C; column pressure, 70 kg/cm²; mobile phase, distilled water at pH 7.40 with 0.2 M $NaNO_3$; detector, UV photometer at 254 nm; flow rate, 1 ml/min; retention time 4-hydroxy-2-methyl-5-nitrobenzenesulfonic acid (4.0 min', 4-hydroxy-2-methyl-3-nitrobenzenesulfonic acid (6.0 min). Concentrations of sulfuric acid and nitric acid were determined by alkaline titration or specific gravity. pK_a values of the nitro isomers were measured by alkaline titration on a pH meter. UV was recorded with a Shimazu double beam spectrophotometer UV-200. NMR was recorded on a Hitachi NMR spectrometer R-20B (60 Mz).

Preparation of the Mononitro-3-methylphenols. A typical procedure for preparation of the mononitro-3-methylphenols is as follows (see No. 8, Table 1). A mixture of 96% sulfuric acid (200 g, 2.0 mol) and tri-*m*-tolyl phosphate (36.8 g, 0.1 mol) was kept under stirring at 20—30 °C for 24 h. A mixed acid consisting of 70% nitric acid (28.0 g, 0.315 mol) and 96% sulfuric acid (50.0 g 0.5 mol) was added to the solution at −5—0 °C. After 2 h, the reaction mixture was poured onto ice (150 g). The resulting solution was heated and distilled with steam at 140—170 °C until no oily distillate was detected in the steam condensate. The distillate was extracted 3 times with 50 ml portions of chloroform. The combined chloroform extract dried over anhydrous sodium sulfate, chloroform was evaporated *in vacuo*. The yellow residue (41.0 g) was subjected to GLC for analysis. The crude mixture was again distilled with steam at 100 °C. The distillate dissolved in 100 ml of toluene was washed 3 times with 100 ml portions of 0.8% aqueous sodium hydroxide. Removal of toluene gave pure 3-methyl-6-nitrophenol (26.0 g). In experiments Nos. 3, 5, and 7 in Table 1 the mixed acid was added to the reaction mixture immediately after the starting material had been mixed with 96% sulfuric acid. The reaction conditions are summarized in Tables 1, 2, and 3.

Synthesis of a Peptide Lactone, *N*-(3-Hydroxypicolinyl)-threonyl-D-leucyl-prolylsarcosyl-leucyl-alanyl-alanine Threonine Lactone

Hideki KINOSHITA and Hiroshi KOTAKE

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received September 3, 1976)

The synthesis of a peptide lactone, *N*-(3-hydroxypicolinyl)-threonyl-D-leucyl-prolylsarcosyl-leucyl-alanyl-alanine Threonine Lactone (**21**) is described. The *t*-butoxycarbonyl group of *t*-butyl *O*-(*t*-butoxycarbonyl-alanyl)-*N*-benzyloxycarbonyl-threonyl-D-leucyl-prolylsarcosinate (**12**) was deblocked selectively with formic acid in good yield. The coupling of **12** with the azide derived from *t*-butoxycarbonyl-leucyl-alanine hydrazide (**15**) with isopentyl nitrite gave a heptapeptide ester **17**. Deblocking, cyclization, and hydrogenation gave a heptapeptide lactone **20** which was coupled with 3-hydroxypicolinic acid yielding **21**.

In a previous paper,[1] it was reported that the *t*-butoxycarbonyl group was cleaved selectively in the presence of the *t*-butyl ester group using 85% formic acid and the application of this selective deprotection method for the synthesis of peptides.

In this paper, the usefulness of this method for the synthesis of the peptide lactone[2] is reported.

In the past several years, the structures of a number of new antibiotics have been reported in the literature with the common feature of a lactone that is formed from the carboxyl function of an amino acid with the hydroxyl group of an amino acid. Moreover, in most of the cases, the amino function of the latter is acylated by a heterocyclic acid.[3-6] Examples of this class of compounds are the antibiotic actinomycin,[7] etamycin,[5] echinomycin,[8] *etc.* Synthetic approaches in this field of naturally occurring peptide lactone antibiotics have been limited only to actinomycin[9-11] and etamycin.[12]

Because of the difficulties of synthesis, the authors are interested in finding a new method of synthesizing this class of peptides in the utility of the selective deblocking method[1] described previously. For this purpose an attempt was made to synthesize a peptide lactone **21** as a model (Fig. 1).

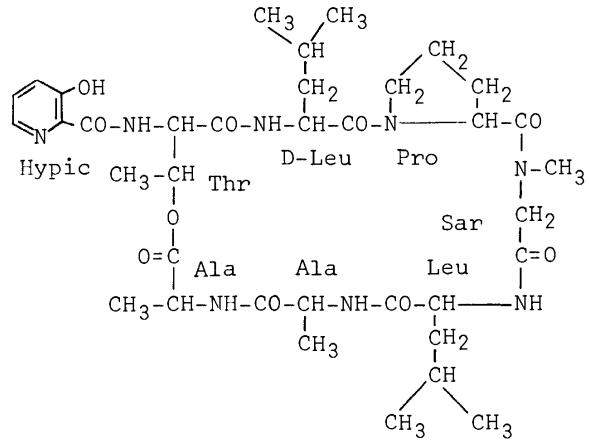

Fig. 1.

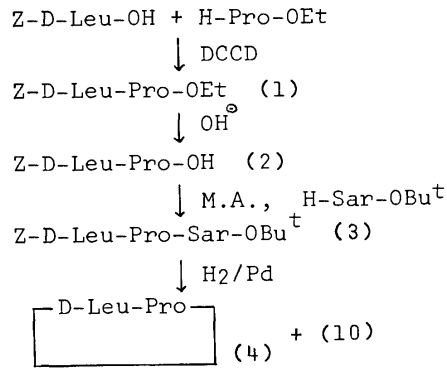
In the synthesis of a peptide lactone, it is usual to prepare initially the ester bond followed by cyclization by the formation of an amide bond. For example, in the case of 6-proline-staphylomycin S[13] and etamycin,[12] initially the linear peptide ester containing a 3-hydroxypicolinic acid moiety was prepared and then cyclization was provided by the amide bond formation. However a new route was designed in which the formation of peptide lactone **19** is obtained by cyclization of the linear peptide ester **18** and finally a 3-hydroxypicolinic acid moiety is introduced into the amino group of threonine, as illustrated in Scheme 2. This synthetic approach has not been reported in the literature to date as far as the present authors are aware, because it is necessary to use various protecting groups in this case.

The amide bond between sarcosine and leucine was selected for the cyclization step because of the stability of sarcosine toward racemization. For this approach, it was necessary to synthesize a chain that would include the desired ester bond between alanine and threonine (Scheme 2).

The preparation of the deprotected tripeptide (*t*-butyl D-leucyl-prolylsarcosinate (**10**)) was attempted in two different ways. Catalytic hydrogenation of *t*-butyl benzyloxycarbonyl-D-leucyl-prolylsarcosinate (**3**) derived from the coupling of benzyloxycarbonyl-D-leucyl-proline (**2**) with *t*-butyl sarcosinate, gave a tripeptide ester **10**, but D-leucyl-proline anhydride (**4**) was always produced as a by-product (Scheme 1). Therefore, it was



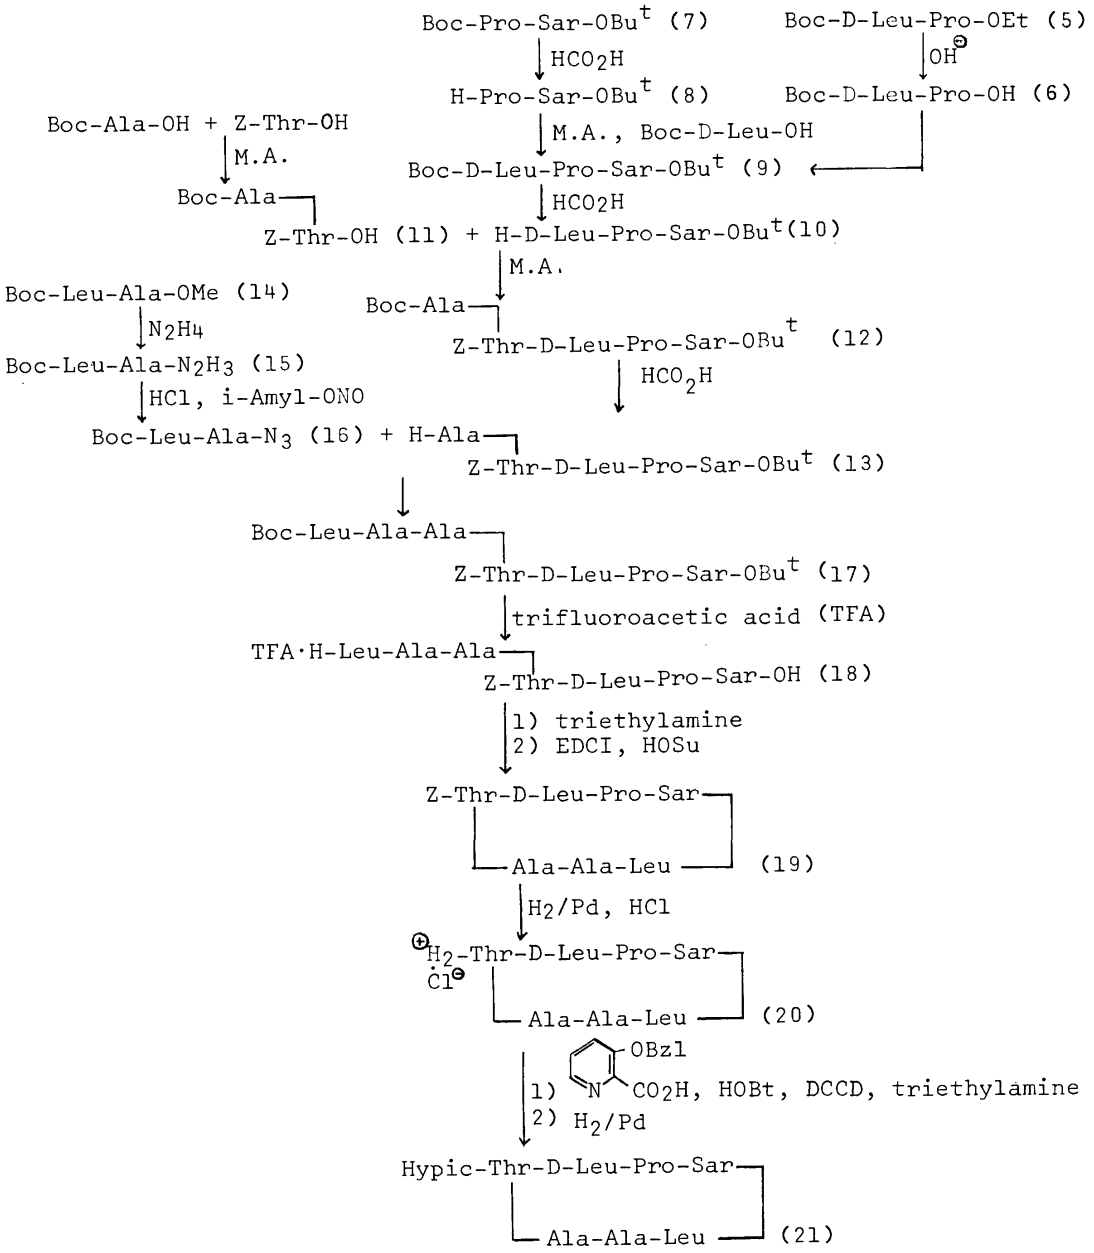
Scheme 1.

thought that the selective deblocking method[1] may be superior for this purpose. The cleavage of the *t*-butoxycarbonyl group of the protected dipeptide ester **7** by formic acid gave a dipeptide ester **8** in a 90% yield, which was condensed with *t*-butoxycarbonyl-D-leucine to give the desired protected tripeptide ester **9** in a 96% yield. Alternatively, compound **9** was obtained only in the low yield of 59% by coupling of *t*-butoxycarbonyl-D-leucyl-proline (**6**) with *t*-butyl sarcosinate. The cleav-

age of the *t*-butoxycarbonyl group of the protected tripeptide ester **9** by formic acid gave a tripeptide ester **10** in an 86% yield with no by-products such as anhydride.

The formation of the ester bond between alanine and threonine was mediated by the mixed anhydride method. The product was separated from the reaction mixture by gel filtration on Sephadex LH-20 to give the desired ester **11** in a 64% yield, which was isolated as dicyclohexylammonium salt. The coupling of the peptide **11** with the tripeptide *t*-butyl ester **10** using the mixed anhydride method gave the pentapeptide ester **12** in an 80% yield.

The selective cleavage of compound **12** by formic acid, a key step in the elongation of the peptide bond to the *N*-terminus, was realized successfully to give the desired deprotected pentapeptide ester **13** in good yield of 87%, which was condensed with the azide **16** derived from *t*-butoxycarbonyl-leucyl-alanine hydrazide (**15**) with isopentyl nitrite[14] to give a 91% yield of the desired heptapeptide ester **17**. A short treatment of the linear heptapeptide ester **17** with anhydrous trifluoroacetic acid is sufficient to remove both of the amino- and the carboxyl-protecting groups to give a trifluoroacetate **18** in a 93% yield. After neutralization with triethylamine, cyclization of the deprotected peptide ester was achieved in a highly dilute solution using five times excess amounts of EDCI and *N*-hydroxysuccinimide,[15] followed by separation of the reaction mixture by preparative TLC to give the desired peptide lactone **19** in good yield (45%). A mass spectrum of compound **19** showed the expected molecular weight. Debenzyloxycarbonylation of the heptapeptide lactone **19** was carried out in an acidic medium containing hydrogen chloride to avoid intramolecular acylation, the so-called O→N acyl



Scheme 2. Synthesis of Peptide Lactone.

migration.[16-18]

The introduction of a 3-hydroxypicolinic acid moiety to the *N*-terminus was at first carried out by the reaction of the deprotected cyclic peptide **20** with the 3-benzyloxypicolinic acid *p*-nitrophenyl ester[19] with slow neutralization, followed by catalytic hydrogenation giving only a poor yield of the desired acylated peptide lactone (20%). Alternatively, condensation of the heptapeptide lactone **20** with the active ester, derived from 3-benzyloxypicolinic acid[19] and HOBt using dicyclohexylcarbodiimide under the same reaction conditions (as described above) gave the desired cyclic octapeptide ester **21** in good yield (68%). The presence of 3-hydroxypicolinic acid was confirmed by spectroscopically[12,13] and by the color reaction[20] of the hydrolysate with an aqueous ferric chloride solution.

As mentioned above, the selective deblocking method has proved useful for the synthesis of a peptide lactone.

Experimental

All melting points are uncorrected. The NMR, IR, and UV spectra were recorded on a JEOL JNH-60, a JASCO IRA-1 spectrometer and a Union Giken SM-401 spectrometer, respectively. The optical rotation values were measured with a JASCO DIP-SL polarimeter.

Z-D-Leu-Pro-OEt (1). To a solution of benzyloxycarbonyl-D-leucine (13.3 g, 0.05 mol) and ethyl prolinate hydrochloride (7.57 g, 0.05 mol) in chloroform (80 ml), triethylamine (5.5 g, 0.055 mol) was added at 0 °C, followed, after 1 h, by dicyclohexylcarbodiimide (10.3 g, 0.05 mol). The reaction mixture was stirred for 3 h below 0 °C and allowed to stand overnight at room temperature. After a precipitate of dicyclohexylurea was filtered off, the filtrate was concentrated to dryness under reduced pressure. The residue was dissolved in ethyl acetate and the organic layer was washed with 1M-hydrochloric acid, 10% sodium hydrogencarbonate and water, and dried over anhydrous sodium sulfate. The solvent was removed *in vacuo* to give an oily product. Yield, 16.3 g (83.6%).

Z-D-Leu-Pro-OH (2). To a solution of **1** (16.3 g, 41.8 mmol) in EtOH (50 ml), 46 ml of 1M-aqueous sodium hydroxide was added with stirring at 0 °C for 3 h, followed by standing overnight at room temperature. The EtOH was removed *in vacuo* and water was added to the reaction mixture. The aqueous residue was extracted with ethyl acetate, and the alkaline aqueous layer was adjusted to pH 3 to afford a crude crystalline product (12.9 g, 81.2%) with a melting point of 98—102 °C, which was recrystallized from ethyl acetate–hexane. Yield, 10.81 g (68%); mp 103—104 °C; $[\alpha]_D^{27}$ −21.3° (1.05, abs EtOH). Found: C, 60.03; H, 7.38; N, 7.21%. Calcd for $C_{19}H_{26}O_5N_2 \cdot H_2O$: C, 59.98; H, 7.38; N, 7.36%.

Z-D-Leu-Pro-Sar-OBu^t (3). To a solution of **2** (7.24 g, 0.02 mol) in dry tetrahydrofuran (40 ml) was added triethylamine (2.02 g, 0.02 mol), followed, after 2 min, by isobutyl chloroformate (2.73 g, 0.02 mol) at −15 °C with stirring. A solution of *t*-butyl sarcosinate (2.90 g, 0.02 mol) in dry tetrahydrofuran (20 ml) was added. The solution was stirred for 2 h below 0 °C and allowed to stand overnight. The solvent was evaporated under reduced pressure and the residual oil was partitioned between ethyl acetate and water. The organic layer was washed with 1M-hydrochloric acid, 10% sodium hydrogencarbonate and water, and dried over anhydrous sodium sulfate. The ethyl acetate was evaporated *in vacuo* to give an oily product. Yield, 8.30 g (84.9%). M^+ 489.

Boc-D-Leu-Pro-OEt (5). *t*-Butoxycarbonyl-D-leucine monohydrate (8.34 g, 33.5 mmol) was dissolved in ethyl acetate (30 ml) and dry tetrahydrofuran (15 ml), and then to this solution was added dicyclohexylcarbodiimide (6.89 g, 33.5 mmol) at 0 °C. After 20 min, a solution of ethyl prolinate (4.97 g, 33.5 mmol) in ethyl acetate (10 ml) was added for a period of 20 min and the reaction mixture was stirred for 2 h at 0 °C and allowed to stand overnight at room temperature. After dicyclohexylurea was filtered off, the filtrate was concentrated to dryness *in vacuo* and the residue was dissolved in ethyl acetate. The organic layer was washed with 1M-hydrochloric acid, 10% sodium hydrogencarbonate and water, and dried over anhydrous sodium sulfate. The solvent was removed *in vacuo* to give an oily product. Yield, 10.8 g (90.6%).

Boc-D-Leu-Pro-OH (6). To a solution of **5** (10.8 g, 30.3 mmol) in EtOH (31 ml) was added 32 ml of 1M-aqueous sodium hydroxide (32 mmol) for a period of 40 min with stirring at −2 °C. The solution was stirred for 2.5 h below 0 °C and allowed to stand overnight. The EtOH was removed *in vacuo* and water was added to the reaction mixture. The aqueous residue was treated with ethyl acetate, and the alkaline aqueous layer was adjusted to pH 3 to afford an oily product, which was extracted with ethyl acetate. The ethyl acetate was removed *in vacuo* to give an oily product in quantitative yield, which was isolated in the form of a crystalline substance, dicyclohexylammonium salt, from ethyl acetate–hexane; 12.58 g (81.6%); mp 168.0—170.5 °C. Recrystallization from ethyl acetate gave a pure crystalline product with a melting point of 172—173 °C; yield, 11.98 g (77.7%); $[\alpha]_D^{31}$ −23.0° (1.02, abs EtOH). Found: C, 65.91; H, 9.92; N, 8.17%. Calcd for $C_{28}H_{51}O_5N_3$: C, 65.97; H, 9.92; N, 8.24%.

For the conversion to the free acid, the dicyclohexylammonium salt 3.50 g (6.87 mmol) was dissolved in a mixture of water and ethyl acetate. After the acidification with 1M-hydrochloric acid (8 ml) the precipitate of dicyclohexylammonium hydrochloride was filtered off. The ethyl acetate extract was dried over anhydrous sodium sulfate and concentrated to dryness *in vacuo*. Yield, 2.24 g (99.6%).

Boc-Pro-Sar-OBu^t (7). To a solution of *t*-butoxycarbonyl proline (1.29 g, 6 mmol) in dry tetrahydrofuran (5 ml) and ethyl acetate (10 ml) were added *t*-butyl sarcosinate (870 mg, 6 mmol) and dicyclohexylcarbodiimide (1.24 g, 6 mmol) with stirring at 0 °C. The reaction mixture was allowed to stand overnight at room temperature. The dicyclohexylurea precipitate was filtered off and the filtrate was concentrated to dryness *in vacuo*. The residue was dissolved in ethyl acetate and the organic layer was washed with 1M-hydrochloric acid, 10% sodium hydrogencarbonate and water. After drying over anhydrous sodium sulfate, the solvent was removed *in vacuo*. A crude crystalline substance (1.66 g, 80%) with a melting point of 70—75 °C was obtained, which was recrystallized from heptane. Yield, 1.48 g (72.7%); mp 73—75 °C. The second crop was obtained from the main solution, 60 mg; mp 72—73 °C. Total yield, 1.54 g (76.8%); $[\alpha]_D^{28}$ −52.1° (1.06, abs EtOH); NMR (CCl_4): δ 1.37 (s, 9H), 1.44 (s, 9H). Found: C, 59.63; H, 9.02; N, 8.08%. Calcd for $C_{17}H_{30}O_5N_2$: C, 59.62; H, 8.83; N, 8.18%.

H-Pro-Sal-OBu^t (8). Compound **7** (300 mg, 0.877 mmol) was dissolved in 7 ml of 85% formic acid, and after the solution had been maintained for 4.5 h at 19 °C, the solvent was removed *in vacuo*. The residual oil was dissolved in chloroform and ammonia was passed through the solution. The precipitate of ammonium formate was filtered off and the filtrate was concentrated to dryness *in vacuo*. The residue was dissolved in ethyl acetate and an insoluble material was filtered off. The organic layer was dried over anhydrous sodium sulfate and removed *in vacuo* to give an oily product.

Yield, 190 mg (89.6%); NMR (CCl_4): δ 1.45 (s, 9H).

Boc-D-Leu-Pro-Sar-OBu^t (9). *Method A*: To a solution of **6** (2.24 g, 6.84 mmol) in dry tetrahydrofuran (15 ml) was added triethylamine (690 mg, 6.84 mmol) and the mixture was cooled to −15 °C. To the solution, isobutyl chloroformate (934 mg, 6.84 mmol) was added followed, after 5 min, by a solution of *t*-butyl sarcosinate (1.00 g, 6.89 mmol) in dry tetrahydrofuran (1 ml). The reaction mixture was stirred for 2 h at 0 °C and allowed to stand overnight at room temperature. The solvent was removed *in vacuo* and the residue was partitioned between ethyl acetate and water, the organic layer was washed with 1 M-hydrochloric acid, 10% sodium hydrogencarbonate and water, and then dried over anhydrous sodium sulfate. The ethyl acetate was removed *in vacuo* to give a crude oil, which was subjected to column chromatography on silica gel using hexane-ethyl acetate (2: 1 v/v). Yield, 1.83 g (58.8%). NMR (CCl_4): δ 1.38 (s, 9H), 1.43 (s, 9H); M^+ 455.

Method B: To a stirred solution of *t*-butoxycarbonyl-D-leucine monohydrate (195 mg, 0.783 mmol) in dry tetrahydrofuran (2 ml) at −10 °C, was added triethylamine (79 mg, 0.783 mmol) followed by isobutyl chloroformate (107 mg, 0.783 mmol). After 5 min a solution of **8** (190 mg, 0.783 mmol) in dry tetrahydrofuran (1 ml) was stirred for 3.5 h below 0 °C and allowed to stand overnight at room temperature. The solvent was evaporated *in vacuo* and the residue was partitioned between ethyl acetate and water. The ethyl acetate layer was washed with 1 M-hydrochloric acid, 10% sodium hydrogencarbonate and water. After drying over anhydrous sodium sulfate, the ethyl acetate was removed *in vacuo* to give a pure oil. Yield, 340 mg (95.7%). The physical properties of this oil were similar to those of the product obtained according to method A.

H-D-Leu-Pro-Sar-OBu^t (10). *Catalytic Hydrogenation Method*: Catalytic hydrogenation of **3** (1.00 g, 2.04 mmol) with palladium (50 mg) in EtOH (25 ml) afforded the desired tripeptide (**10**) contaminated with a ninhydrin-negative compound. It was found that this compound was D-leucylproline anhydride (**4**), which was confirmed by its IR spectrum and elemental analysis. mp 148—149 °C; $[\alpha]_D^{21}$ −105.5° (0.50, abs EtOH). Found: C, 62.67; H, 8.44; N, 13.04%. Calcd for $C_{11}H_{18}O_2N_2$: C, 62.83; H, 8.63; N, 13.32%.

Selective Cleavage Method: Compound **9** (3.36 g, 7.41 mmol) was dissolved in 100 ml of 85% formic acid, and after the solution had been maintained for 3.5 h at 18 °C, the solvent was removed *in vacuo*. The residual oil was dissolved in chloroform, and ammonia was passed through it. After a short cooling, the precipitate was filtered off and the filtrate was evaporated *in vacuo*. The residual oil was dissolved in ethyl acetate and an insoluble material was filtered off. The organic layer was dried over anhydrous sodium sulfate. The solvent was removed *in vacuo* to give an oily product. Yield, 2.24 g (85.9%). NMR (CCl_4): δ 1.44 (s, 9H); M^+ 355.

Z-Thr-OH (11). *t*-Butoxycarbonyl-alanine (7.56 g, 40 mmol) and triethylamine (4.04 g, 40 mmol) were dissolved in dry tetrahydrofuran (12 ml), and the solution was cooled to −5 °C. Isobutyl chloroformate (5.44 g, 40 mmol) was added, followed, after 5 min of stirring in the cold bath, by a solution of benzyloxycarbonyl threonine (20.24 g, 80 mmol) and triethylamine (12.12 g, 120 mmol) in dry tetrahydrofuran (80 ml). The reaction mixture was allowed to stand with stirring at room temperature. The salt was filtered off and washed well with ethyl acetate. The filtrate was concentrated to dryness, and the residual oil was partitioned between ethyl acetate and water. The ethyl acetate layer was washed with 1 M-hydrochloric acid and water and dried over anhydrous sodium sulfate. The ethyl acetate was evaporated *in vacuo* to afford an oily product. The crude reaction mixture so obtained was separated by gel filtration on Sephadex LH-20, using chloroform as the elution solvent to give the desired product (16 g), which was isolated in the form of a crystalline product, dicyclohexylammonium salt, from ethyl acetate. Yield, 15.45 g (63.8%) with a melting point of 165—166 °C; $[\alpha]_D^{32}$ −10.5° (1.04, abs EtOH). Found: C, 63.15; H, 8.62; N, 6.83%. Calcd for $C_{32}H_{51}O_8N_3$: C, 63.45; H, 8.49; N, 6.93%.

Z-Thr-D-Leu-Pro-Sar-OBu^t (12). Triethylamine (674 mg, 6.67 mmol) and **11** (2.83 g, 6.67 mmol) were dissolved in dry tetrahydrofuran (30 ml) and the solution was cooled to −15 °C with stirring. Isobutyl chloroformate (911 mg, 6.67 mmol) was added, followed, after 5 min of stirring in the cold bath, by a solution of **10** (2.24 g, 6.36 mmol) in dry tetrahydrofuran (20 ml). The reaction mixture was kept at −10 °C for 1 h, then at 0 °C for 1.5 h and allowed to stand overnight at room temperature. The residual oil was partitioned between ethyl acetate and water. The ethyl acetate layer was washed with 1 M-hydrochloric acid, 10% sodium hydrogencarbonate and water and dried over anhydrous sodium sulfate. Evaporation afforded a crude oily product (4.51 g) and this oil was subjected to column chromatography on silica gel using ethyl acetate-hexane (2: 1 v/v) to give an 80% yield of the desired product (3.88 g); $[\alpha]_D^{28}$ −36.4° (1.20, abs EtOH); NMR (CCl_4): δ 1.37 (s, 9H), 1.47 (s, 9H); M^+ 761. Found: C, 59.60; H, 7.91; N, 8.95%. Calcd for $C_{38}H_{59}O_{11}N_5 \cdot 1/2H_2O$: C, 59.20; H, 7.84; N, 9.06%. Amino acid analysis showed the presence of threonine, sarcosine, proline, leucine and alanine in ratios of 0.8: 1.2: 1.3: 0.8: 1.0.

Boc-Leu-Ala-OMe (14). Methyl alaninate hydrochloride (3.14 g, 25 mmol) was suspended in chloroform (30 ml), followed by the addition of triethylamine (2.78 g, 27.5 mmol) at 0 °C. To the solution, dicyclohexylcarbodiimide (5.15 g, 25 mmol) were added. After cooling in a cold bath for 2 h, the reaction mixture was allowed to stand overnight. Dicyclohexylurea was filtered off and the organic layer was washed with 1 M-hydrochloric acid, 10% sodium hydrogencarbonate and water and dried over anhydrous sodium sulfate. The solvent was removed *in vacuo* to give a crystalline substance, (6.80 g, 86%) with a melting point of 113—115 °C, which was recrystallized from benzene-hexane. Yield, 6.36 g (80.5%); mp 113—115 °C; $[\alpha]_D^{28}$ −48.3° (1.20, abs MeOH). Found: C, 57.10; H, 8.84; N, 8.67%. Calcd for $C_{15}H_{28}O_5N_2$: C, 56.94; H, 8.92; N, 8.85%.

Boc-Leu-Ala-N_2H_3 (15). To a solution of **14** (3.9 g, 12.3 mmol), was added hydrazine monohydrate (2.4 g, 48 mmol) in MeOH (10 ml), and the solution was allowed to stand overnight at room temperature. Evaporation *in vacuo* afforded the crude product (3.77 g, 96.7%) with a melting point of 175—177 °C, which was recrystallized from ethyl acetate. Yield, 3.46 g (88.7%); mp 178—179 °C; $[\alpha]_D^{24}$ −51.9° (0.94, abs MeOH). Found: C, 52.90; H, 8.89; N, 17.37%. Calcd for $C_{14}H_{28}O_4N_4$: C, 53.14; H, 8.92; N, 17.74%.

Z–Thr–D-Leu–Pro–Sar–Ala–Ala–Leu (**19**). Compound **17** (1.10 g, 1.16 mmol) was dissolved in 15 ml of trifluoroacetic acid and allowed to stand for 1 h at room temperature. Excess trifluoroacetic acid was removed *in vacuo* and the residue was triturated with dry ether to give a salt (**18**) in a 92.3% yield (975 mg). The salt (600 mg, 0.664 mmol) was suspended in dry dichloromethane (10 ml) and triethylamine (133 mg,1.32 mmol) was added with ice cooling, after 50 min, followed by evaporation and drying under reduced pressure. The residue was taken up in 1.2 l of dry dichloromethane and cooled to 0 °C. *N*-Hydroxysuccinimide (381 mg, 3.32 mmol) was added and after a short delay, a solution of EDCI (515 mg, 3.32 mmol) in dry dichloromethane (10 ml) was added. The reaction mixture was stirred for 30 h at 0 °C and then the stirring was continued for 60 h at 5 °C. The solution was evaporated *in vacuo* and the residue was partitioned with ethyl acetate and water. The organic layer was washed with 0.1 M hydrochloric acid, 10% sodium hydrogencarbonate and water, dried over anhydrous sodium sulfate, and evaporated. The product was subjected to preparative TLC first using ethyl acetate–EtOH (6: 1 v/v) and once more using benzene–EtOH (5: 2 v/v). The desired product was obtained in a 44.5% yield (233 mg) which was recrystallized from ethyl acetate–hexane to give a crystalline product with a melting point of 176—178 °C. Yield, 224 mg; $[\alpha]_D^{24}$ +59.7° (1.17, abs EtOH); M^+ 771. Found: C, 58.01; H, 7.60; N, 12.41%. Calcd for $C_{38}H_{57}O_{11}N_7 \cdot H_2O$: C, 57.78; H, 7.27; N, 12.41%.

Hypic–Thr–D-Leu–Pro–Sar–Ala–Ala–Leu (**21**). Compound **19** (70 mg, 0.09 mmol) was dissolved in abs EtOH (15 ml) containing 0.04 ml of 4.62 M-HCl in dioxane and hydrogenated for 1 h over 10% palladium on charcoal (30 mg). The catalyst was filtered off and the solution was evaporated *in vacuo* to give a salt (**20**). 3-Benzyloxypicolinic acid sesquihydrate hydrochloride[19] (30 mg, 0.1 mmol) was suspended in 2 ml of dichloromethane followed by the addition of triethylamine (40 mg) with ice cooling. After 1 h the solution was evaporated *in vacuo* and dried. The residue was taken up in 1 ml of dry tetrahydrofuran followed by the addition of HOBt (13.5 mg, 0.1 mmol) and dicyclohexylcarbodiimide (20.6 mg, 0.1 mmol) and stirring for 1 h at 0 °C. To the solution prepared above was added a solution of **20** in tetrahydrofuran (1 ml) and a solution of triethylamine (9.1 mg, 0.09 mmol) in dry tetrahydrofuran (5 ml) was added dropwise over a 2.5 h period. The reaction mixture was stirred for 5 h at room temperature and evaporated. The residue was subjected to preparative TLC using benzene–EtOH (100: 35 v/v) to give the protected product in a 68.1% yield (52 mg), which was hydrogenated for 1 h over 10% palladium on charcoal (40 mg). After filtration of the catalyst the solvent was evaporated *in vacuo* to give the desired product in a 64.5% yield (44 mg); $[\alpha]_D^{22}$ +40.8° (0.98, CH_2Cl_2); IR (KBr): 1740, 1630, 1520 cm^{-1}; λ_{max} 304 nm (log ε 3.77).[12,13] Found: C, 54.87; H, 7.12; N, 14.44%. Calcd for $C_{36}H_{54}O_{10}N_8 \cdot 3/2H_2O$: C, 55.01; H, 7.31; N, 14.25%. The product showed a single spot using various solvents with TLC. Amino acid analysis showed the presence of threonine, sarcosine, proline, leucine, and alanine in ratios of 0.9: 1.0: 1.0: 1.9: 2.0.

Reactions of Benzyne with Substituted Benzenes

Iwao TABUSHI, Hidenori YAMADA, Zenichi YOSHIDA,* and Ryohei ODA*

Department oe Pharmaceutical Sciences, Kyashu University, Fukuoka 812

* *Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606*

(Received April 26, 1976)

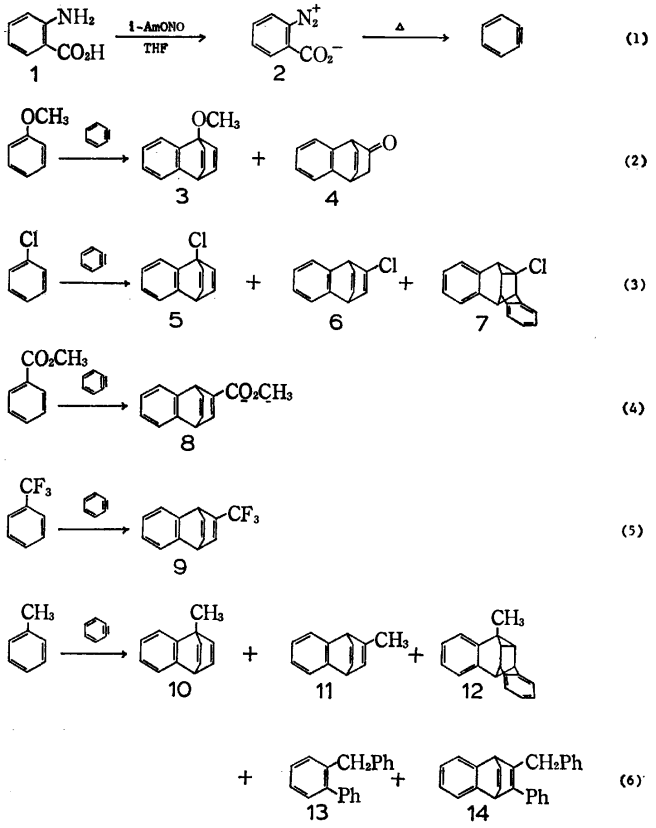
The reactions of benzyne with substituted benzenes(anisole, chlorobenzene, methyl benzoate, benzylidyne trifluoride and toluene) giving the Diels-Alder adducts were investigated, where two positionally isomeric adducts were possible, *i.e.*, a geminal-para adduct (1,4-adduct with respect to the substituent) and an ortho-meta adduct (2,5-adduct). From the competition reactions, relative reactivities of benzyne to substituted benzenes were estimated for the 1,4-addition and 2,5-addition. Markedly different substituent effects were observed. For the 1,4-addition, large negative ρ value (−1.79) was observed, but for the 2,5-addition, substituent effect was small. From benzyne and toluene, *o*-benzylbiphenyl (**13**) and 2-benzyl-3-phenylbenzo[5,6]bicyclo[2.2.2]octatriene (**14**) were obtained as the successive "ene" products together with the normal Diels-Alder adducts.

Reactions of halogenated benzynes with substituted benzenes were studied well where the Diels-Alder adducts were obtained in good yield.[1] But the reactions of benzyne with substituted benzenes have been scarcely studied probably because of the low reactivity. Only the reactions of benzyne, generated from the thermolysis of benzenediazonium-2-carboxylate, with benzene[2,3] and some alkylbenzenes[4] and that, generated from the pyrolysis of phthalic anhydride, with *o*-dichlorobenzene[5] have been reported. Stiles reported that the reaction of benzyne with benzene gave three one to one adducts, biphenyl, benzocyclooctene and benzobicyclo-[2.2.2]octatriene, together with a two to one adduct **15**.[2] Friedman, however, showed that the former two products were formed only in the presence of a catalytic amount of silver cation and their formations were reduced to near zero in the reaction where the starting benzenediazonium-2-carboxylate was prepared from anthranilic acid(**1**) and pentyl nitrite in the absence of a silver salt.[3,6] We also reported that the addition of several metal salts changed the products of the reaction of benzyne with benzene.[7]

In this paper we report the products and the relative reactivities of substituted benzenes treated with benzyne, generated from benzenediazonium-2-carboxylate, in the absence of a metal salt.

Results

The thermolysis of benzenediazonium-2-carboxylate (**2**) was carried out in a substituted benzene(anisole, chlorobenzene, methyl benzoate, benzylidyne trifluoride or toluene). The products are shown in Scheme 1 and their compositions are listed in Table 1.[8]



Scheme 1. The products of the reactions of benzyne with substituted benzenes.[9]

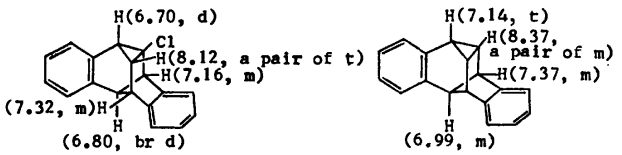
Table 1. THE PRODUCT COMPOSITIONS OF THE REACTIONS OF BENZYNE WITH SUBSTITUTED BENZENES[a]

Substrate (ml)	1 (g)	Product compositions (%)				
Anisole (500)	10	**3** 82.9	**4** 17.1			
Chlorobenzene (500)	3	**5** 17.8	**6** 44.4	**7** 37.8		
Methyl benzoate (225)	3	**8** ≈100				
Benzylidyne trifluoride (75)	3	**9** ≈100				
Toluene (500)	3	**10** 13.9	**11** 28.4	**12** 4.1	**13** 37.1	**14** 16.5

a) The product compositions were determined by means of gas chromatography (PEG 20M and Silicon DC 550 columns) and/or NMR spectroscopy.

The reaction of benzyne with anisole gave 1-methoxybenzo[2,3]bicyclo[2.2.2]octatriene(**3**) and benzobicyclo-[2.2.2]octadienone(**4**) in 25(32) and 6(8)% yields, respectively, on the basis of anthranilic acid used (yields in the parentheses were based on benzyne generated).[10] **4** was determined on the basis of its IR spectrum identical with that reported in literature[11] in every detail.

Chlorobenzene gave 1-chlorobenzo[2,3]bicyclo-[2.2.2]octatriene(**5**), 2-chlorobenzo[5,6]bicyclo[2.2.2]-octatriene (**6**) and compound **7** together with biphenylene(19% of the total products)[9] and phenyl benzoate



7 15

Fig. 1. H^1 NMR spectra of **7** and **15** (τ-value). Abbreviations are: d, doublet; t, triplet; m, multiplet; br, broad.

(4% of the total products).[9] The molecular peak of mass spectrum of **7** was observed at 264 (*m/e*) with relative intensity 12, indicating that **7** was the two to one adduct of benzyne and chlorobenzene. The 60 MHz NMR spectrum of **7** in CCl_4 consisted of aromatic absorptions as a multiplet at 2.55—3.05 τ (8H) and aliphatic absorptions at 6.70 τ(doublet, 1H), 6.80 τ(broad doublet, 1H), 7.16 τ(multiplet, 1H), 7.32 τ(multiplet, 1H), and 8.12 τ(a pair of triplet, 1H). No olefinic proton was observed. The 60 MHz spin-decoupling experiments showed that the original signal at 8.12 τ was coupled with the signal at 6.70 τ with J value of 7.2 Hz and also coupled with the signal at 6.80 τ with J value of 1.8 Hz. The NMR spectrum of **7** compared with that of unsubstituted compound **15**[2b] is shown in Fig. 1. Observed NMR spectrum of **7** was fully interpreted on the basis of the assigned structure.

Methyl benzoate gave 2-methoxycarbonylbenzo[5,6]bicyclo[2.2.2]octatriene (**8**), biphenylene and phenyl benzoate. No 1-substituted benzobicyclo[2.2.2]octatriene was obtained in a detectable amount.

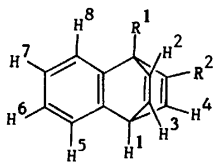
From benzylidyne trifluoride, 2-trifluoromethylbenzo[5,6]bicyclo[2.2.2]octatriene (**9**), biphenylene and phenyl benzoate were obtained.

From toluene, three products, 1-methylbenzo[2,3]bicyclo[2.2.2]octatriene (**10**), 2-methylbenzo[5,6]bicyclo[2.2.2]octatriene (**11**) and *o*-benzylbiphenyl (**13**) were obtained as was reported elswhere.[4] In addition, unknown compounds **12** and **14** were obtained. Structure of **12** was tentatively determined as shown in Scheme 1 on the basis of NMR spectrum which consisted of the signals at 8.95 τ(singlet), 7.4 τ(broad singlet), and 7.0 τ(broad singlet). The molecular peak of the mass spectrum of **14** was observed at 320 (*m/e*) indicating **14** to be the three to one adduct of benzyne and toluene. Its NMR spectrum showed the olefinic multiplet at 3.06—3.25 τ(2H) and aliphatic signals at 4.99 τ (doublet of doublet, 1H), 5.50 τ (doublet of doublet, 1H), and 6.40 τ (AB quartet, 2H). According to the decoupling experiment, no appreciable coupling was observed between the signals at 4.99 and 5.50 τ. The most probable structure of **14** and NMR assignment are shown in Fig. 2.

The NMR spectra of other benzobicyclo[2.2.2]octatriene derivatives are summarized in Table 2.

Competition reactions were carried out to estimate the relative reactivities of benzyne toward substituted benzenes. In each run, 0.5 g of anthranilic acid and 20—30 g of substituted benzenes were used. Results are shown in Table 3.

TABLE 2. ^{1}H NMR SPECTRA OF BENZOBICYCLO[2.2.2]OCTATRIENE DERIVATIVES[a]



Compounds	R^1	R^2	τ-value									
			R^1	H^1	R^2	H^2	H^3	H^4	H^5	H^6	H^7	H^8
3	OCH_3	H	6.25 (s)	5.35 (tt)				2.95—3.45 (m)				2.65—2.83 (m)

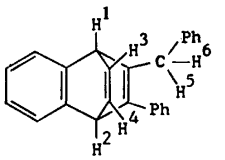
a) With 1% TMS as an internal standard, 5—10% in CCl_4, 60 MHz. Abbreviations are: s, singlet; d, doublet; dd, doublet of doublet; tt, triplet of triplet; m, multiplet.



Aromatic H: 2.65—3.06 τ (m, 14H)
H^3, H^4: 3.06—3.25 τ (m, 2H)
H^2: 4.99 τ (dd, 1H), J_{H^1,H^4}=5.4 Hz, J_{H^1,H^3}=2.8 Hz
H^1: 5.50 τ(dd, 1H), J_{H^1,H^3}=5.4 Hz, J_{H^1,H^2}=2.6 Hz
H^5, H^6: 6.40 τ (center, AB quartet, 2H), J_{H^5,H^6}=16.5 Hz

Fig. 2. The NMR spectrum of **14**. With 1% TMS as an internal standard, 10% in CCl_4, 60 MHz. Abbreviations are: dd, doublet of doublet; m, multiplet.

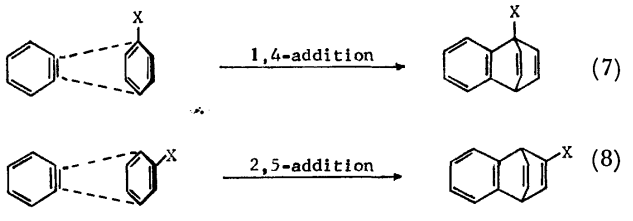
Table 3. Competition reactions of a series of substituted benzene toward benzyne[a]

Run	Substrate (g)	Ratio of products derived from two substrates	k_R/k_H[b]
1	{Benzene (30) {Anisole (20)	1 3.82	1 7.93
2	{Benzene (25) {Toluene (25)	1 3.61	1 4.25
3	{Benzene (20) {Chlorobenzene (30)	1 0.862	1 0.794
4	{Benzene (20) {Benzylidyne trifluoride (30)	1 0.466	1 0.580
5[c]	{Chlorobenzene (20) {Methyl benzoate (30)	1 1.45	0.794 0.993

a) The products from benzene were benzobicyclo[2.2.2]-octatriene (**16**) and **15**. b) Relative reactivities of substituted benzenes to benzene. c) Product compositions derived from chlorobenzene were slightly changed from those shown in Table 1 to **5**, 6.1% and **6**+**7**, 93.9%. The cause of these differences was not clear but it may be due to solvent effect.

Discussion

Regioselectivity of the Diels-Alder Addition. The reaction of benzyne with substituted benzene gave the Diels-Alder adducts[12] where two positional isomers were possible, a geminal-para adduct(1,4-addition; Eq. 7) and an ortho-meta adduct(2,5-addition; Eq. 8) with respect to a substituent.



The isomer compositions are shown in Table 4.[13] As shown in the table, the predominant product was systematically changed from the 1,4-adduct for anisole to the 2,5-adduct for methyl benzoate or benzylidyne trifluoride depending on the electron-donating(withdrawing) property of substituent.[14] If the steric factor alone is important, it should reduce the amount of the 1,4-adduct relative to the 2,5-adduct.[15] But our results indicated that the regioselectivity of the Diels-Alder addition could not be so simply explained as only the steric repulsion in the transition state was important (*vide infra*).

Table 4. The isomer compositions of the Diels-Alder adducts (%)

Substrate	1,4-Adduct	2,5-Adduct
Anisole	82.9	17.1
Toluene	28.6	71.4
Chlorobenzene	17.8	82.2
Methyl benzoate	≈0	≈100
Benzylidene trifluoride	≈0	≈100

Table 5. The relative reactivities of benzyne toward substituted benzenes with respect to 1,4-addition and 2,5-addition[a]

Substituent	OCH_3	CH_3	H	Cl	CO_2CH_3	CF_3
1,4-Addition	19.1	2.32	1	0.436	≈0	≈0
2,5-Addition	2.36	2.90	1	0.973	1.49	0.870

a) Statistical factors are corrected.

The Relative Reactivities of Benzyne toward Substituted Benzenes. The relative reactivities of benzyne toward substituted benzenes were estimated from the competition experiments. In Table 5, the relative reactivities of benzyne toward substituted benzenes with respect to 1,4-addition and 2,5-addition are shown. The reactivity of 1,4-addition changed more than 40-fold with changing a substituent, while that of 2,5-addition changed only 3.5-fold. Hammett plots of the relative reactivities of 1,4-addition and 2,5-addition of benzyne toward substituted benzenes are shown in Figs. 3 and 4, respectively. For 1,4-addition, the plot of the logarithms of the relative reactivities *vs.* σ_p^+ gave a straight line and the reaction constant, ρ, was estimated to be −1.79. A comparison of ρ values for several reactions is made in Table 6. As is seen, the absolute value of the present ρ is much smaller than that for the nitration of substituted benzenes but slightly larger than that for cationic phenylation of substituted benzenes.[19] This fact indicates that some positive charge may be induced in benzyne in the transition state of 1,4-addition.

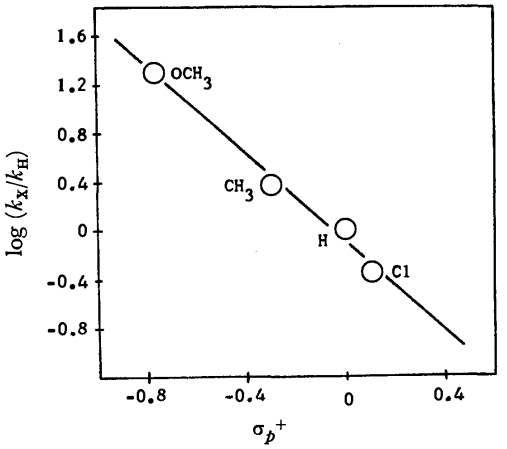


Fig. 3. Hammett plots for 1,4-addition.

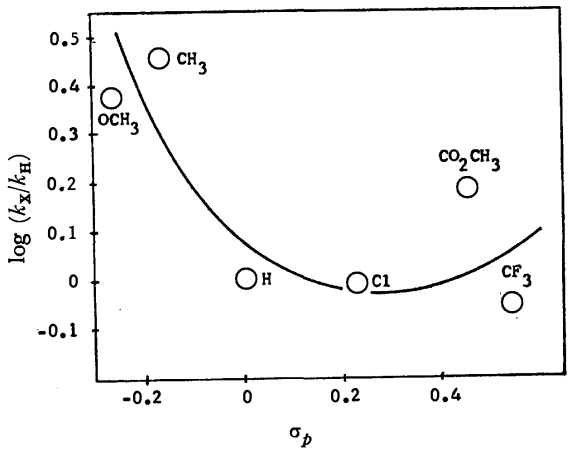

Fig. 4. Hammett plots for 2,5-addition.

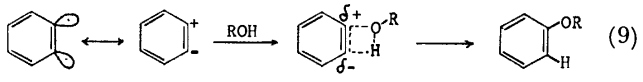
TABLE 6. REACTION CONSTANTS FOR SEVERAL REACTIONS OF SUBSTITUTED BENZENES

Reagent	Product	Kind of substituent constant	ρ	Reference
HNO_3–H_2SO_4 (in CH_3NO_2 or Ac_2O, 25 °C)	O_2N–C$_6$H$_4$–X	σ^+	−6.53	16
$PhN_2^+BF_4^-$ (40 °C)	Ph–C$_6$H$_4$–X	σ^+	−1.0	17
$(PhCO_2)_2$ (80 °C)	Ph–C$_6$H$_4$–X	σ_m	0.05	18
Benzyne (≈45 °C)		σ_p^+	−1.79	this work

To a marked contrast, for 2,5-addition, no clear correlation was observed between logarithms of the relative reactivities and σ_p, although some electrophilic nature of benzyne may be seen from Fig. 4. And present substituent effect seems to be similar to that of the radical decomposition of symmetrically disubstituted benzoyl peroxide.[20]

A possible explanation of these results can be made by a concerted mechanism of benzyne with substituted benzenes. Most stable electronic state of benzyne is considered to be a nonbonding diradical.[21] But benzyne is also considered to be strongly polarized in the transition state of the reactions with the nucleophiles[22] as shown for the case of alcohol (Eq. 9). In the transition state of



(9)

1,4-addition, because of the steric repulsion between substituent of substituted benzene and hydrogen of benzyne, two bond formations may be unequal. Therefore, the charges are induced in benzyne in the transition state as shown in Fig. 5 and the large substituent effect is observed. On the contrary, for 2,5-addition, this steric repulsion can be negligible, and two bond formations may be equal. Therefore, relatively small charges are

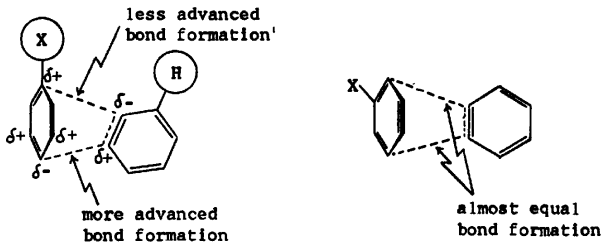


Fig. 5. Unequal bond formations of 1,4-addition and almost equal bond formations of 2,5-addition in the transition states.

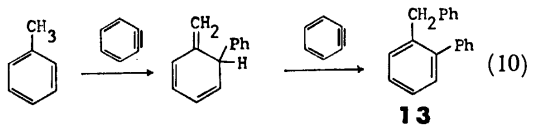
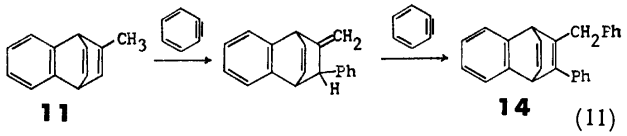
induced in benzyne in the transition state (Fig. 5) and the substituent effect appears small. This mechanism also explains the substituent effect of 2,5-addition to be similar to those of the radical reactions. Radical or cationic two step mechanism can neither explain both substituent effects of 1,4- and 2,5-additions satisfactorily at the same time, nor explain no formation of 1,2-adduct(benzocyclooctene derivative).

Double "Ene" Reaction of Benzyne with Toluene. Toluene gave, together with the normal Diels-Alder adducts, the abnormal products *o*-benzylbiphenyl (**13**) and 2-benzyl-3-phenylbenzo[5,6]bicyclo[2.2.2]octatriene (**14**). The formation of **13** was explained by the successive "ene" reactions of two benzyne molecules to one toluene molecule[4] as shown in Eq. 10. The forma-



(10)



(11)

tion of **14** can be also explained by the successive "ene" reactions of two benzyne molecules to one molecule of **11** (Eq. 11).[23] The fact that intermediates proposed here could not be isolated may be due to the fast second "ene" reactions. The reactions of halogenated benzynes with toluene gave exclusively the Diels-Alder adducts.[1] Thus, there is a remarkable difference between benzyne and halogenated benzyne.

Experimental

Benzenediazonium-2-carboxylate (2). Benzenediazonium-2-carboxylate (**2**) was prepared by the Friedman's method.[3] To a stirring soln of 3 g of anthranilic acid (**1**) in 20 ml of tetrahydrofuran (THF) in the presence of a catalytic amount of trichloroacetic acid was added dropwise 5 g of isopentyl nitrite. The mixture was stirred for 1 h and then cooled with ice bath. After the pale yellow solid of **2** was precipitated, upper liquid was carefully pipetted out, and immediately cold THF was added to the ppt. The mixture was stirred for a moment and kept standing with external cooling until the ppt was settled. Then, the upper THF layer was again removed from the ppt this procedure was repeated until the THF layer became prac-

tically colorless (3—4 times). Then the ppt was similarly washed with dichloromethane twice to remove THF.[10] The ppt, benzenediazonium-2-carboxylate (**2**), thus obtained was used directly for the reaction.

General Procedure of the Reaction of Benzyne with a Substituted Benzene. A mixture of benzenediazonium-2-carboxylate (**2**), prepared from 3—10 g of anthranilic acid (**1**), and 75—500 ml of a substituted benzene was stirred at about 45 °C. After gas evolution had ceased (20—48 h), the mixture was washed with aq sodium hydrogencarbonate soln and water, dried and then concd. The residue was analyzed by gas chromatography (Silicon DC 550, PEG 20M and Golay column of silicon oil). After distillation of the mixture, products were separated by preparative gas chromatography and identified by means of their IR, NMR, and mass spectra.

Reaction of Benzyne with Anisole. Anisole used for the reaction was dried on sodium. Gas chromatographic analysis of the concd crude mixture showed the presence of two products, 1-methoxybenzo[2,3]bicyclo[2.2.2]octatriene (**3**) and benzobicyclo[2.2.2]octadienone (**4**). Distillation of the concd crude mixture at 55—66 °C/0.7 Torr afforded the mixture of **3** and **4**. They were separated by preparative gas chromatography (PEG 20 M). **3** was a colorless oil, n_D^{16} 1.5840; MS, *m/e* (rel intensity) 184 (M^+, 90), 169 (100), 158 (24), 141 (87), 115 (84), and 94 (37); IR (neat), 1330, 1080, 1015, 860, 745, 695, and 680 cm^{-1}. Calcd for $C_{13}H_{12}O$: C, 84.75; H, 6.57%. Found: C, 84.52; H, 6.82%.

4 was the known compd and its IR spectrum was completely consistent with the reported one.[11]

Gas evolution was measured in the reaction of **2**, prepared from 1 g (7.30 mmol) of **1**, with 200 ml of anisole at 48 °C for 9 h, which amounted to 268 ml on water at 16.2 °C, indicating that 5.62 mmol of benzyne to be generated (77% based on **1** used). Gas chromatographic analysis of the crude mixture calibrated with the weighed internal standard (biphenyl) showed that the yields of **3** and **4** were 25 (32) and 6 (8)%, respectively based on **1** used (yields in the parentheses were based on benzyne generated).

Reaction of Benzyne with Chlorobenzene. The concd crude mixture was analyzed by gas chromatography on PEG 20 M which revealed the presence of 1-chlorobenzo[2,3]bicyclo[2.2.2]octatriene (**5**), 2-chlorobenzo[5,6]bicyclo[2.2.2]octatriene (**6**) and a compd **7** together with phenyl benzoate (4% of the total products), biphenylene (19% of the total products) and a small amount of ester not yet characterized. The distillate of the mixture at 70—73 °C/7 Torr consisted of **5**, **6**, biphenylene and phenyl benzoate. Isolations of **5** and **6** were carried out by preparative gas chromatography. **5** was obtained as white crystals, mp 47—48 °C, from ether; MS, *m/e* (rel intensity) 190 (M+2, 12), 188 (M^+, 35), 162 (14), 154 (18), 153 (100), 152 (39), 151 (19), 127 (16), and 126 (10); IR (neat), 1450, 1320, 990, 830, 750, and 685 cm^{-1}. Calcd for $C_{12}H_9Cl$: C, 76.40; H, 4.81; Cl, 18.79%. Found: C, 76.24; H, 5.08; Cl, 18.59%.

6 was obtained as white crystals, mp 47 °C, from ether; MS, *m/e* (rel intensity) 190 (M+2, 17), 188 (M^+, 41), 154 (27), 153 (100), 152 (100), 151 (27), 128 (14), 127 (18), and 126 (13); IR (neat), 1460, 1305, 1005, 820, 810, 750, and 710 cm^{-1}. Calcd for $C_{12}H_9Cl$: C, 76.40; H, 4.81; Cl, 18.79%. Found: C, 76.20; H, 4.77; Cl, 18.58%.

The distillate of the mixture at 116—130 °C/0.9 Torr afforded **7** which was further purified through a column of silica gel (eluted with petroleum ether) and with recrystallization from hexane, mp 128 °C; MS, *m/e* (rel intensity) 266 (M+2, 4), 264 (M^+, 12), 230 (23), 229 (100), 228 (53), 227 (13), 226 (23), 114 (24), 113 (18), 102 (12), and 101 (14); IR (neat), 1490, 1460, 1290, 1250, and 750 cm^{-1}. Calcd for $C_{18}H_{13}Cl$: C, 81.66; H, 4.95; Cl, 13.39%. Found: C, 81.95; H, 5.13; Cl, 13.67%.

Reaction of Benzyne with Methyl Benzoate. Gas chromatographic analysis (Silicon DC 550) of the concd crude mixture showed the presence of 2-methoxycarbonylbenzo[5,6]bicyclo[2.2.2]octatriene (**8**) together with biphenylene (21% of the total products) and phenyl benzoate (25% of the total products). Distilled **8** at 82—90 °C/4 Torr was further purified by preparative gas chromatography, followed by recrystallization from hexane, mp 63.5 °C; MS, *m/e* (rel intensity) 212 (M^+, 58), 169 (12), 154 (20), 153 (100), 152 (70), 151 (19), 128 (20), and 127 (20); IR (neat), 1700, 1240, 1200, 1060, 725, and 690 cm^{-1}. Calcd for $C_{14}H_{12}O_2$: C, 79.23; H, 5.70; O, 15.08%. Found: C, 78.94; H, 5.62; O, 14.79%.

Reaction of Benzyne with Benzotrifluoride. Gas chromatographic analysis (PEG 20 M) of the concd crude mixture showed the presence of 2-trifluoromethylbenzo[5,6]bicyclo[2.2.2]octatriene (**9**) together with biphenylene (45% of the total products) and phenyl benzoate (18% of the total products). Preparative gas chromatography of the distillate at 64—67 °C/3 Torr afforded **9** as a colorless oil, n_D^{16} 1.5092; MS, *m/e* (rel intensity) 222 (M^+, 100), 201 (17), 196 (16), 154 (31), 153 (95), 152 (76), 151 (28), 146 (22), 128 (44), and 127 (19); IR (neat), 1465, 1340, 1260, 1150, 1110, 1015, 740, and 685 cm^{-1}. Calcd for $C_{13}H_9F_3$: C, 70.27; H, 4.08; F, 25.65%. Found: C, 70.81; H, 4.35; F, 25.27%.

Reaction of Benzyne with Toluene. The mixture of **2**, prepared from 3 g of **1**, and 500 ml of toluene in 500 ml of dichloromethane was refluxed for 2 days. After usual work-up, gas chromatographic analysis (PEG 20 M) of the concd crude mixture showed the presence of 1-methylbenzo[2,3]bicyclo[2.2.2]octatriene (**10**), 2-methylbenzo[5,6]bicyclo[2.2.2]octatriene (**11**), small amounts of biphenylene (9% of the total products) and phenyl benzoate (4% of the total products), together with *o*-benzylbiphenyl (**13**) and **12**. The distillate at 68—69 °C/17 Torr consisted of **10** and **11** which were separated by preparative gas chromatography. **10** and **11** were reported elsewhere but their properties were not described.[4] **10** was a colorless oil; MS, *m/e* (rel intensity) 168 (M^+, 96), 167 (68), 165 (36), 153 (100), 152 (49), 149 (81), 141 (45), 128 (73), and 115 (41); IR (neat), 1460, 1445, 1330, 1010, 920, 740, 700, and 680 cm^{-1}. **11** was a colorless oil; MS, *m/e* (rel intensity) 168 (M^+, 100), 167 (71), 155 (38), 153 (97), 152 (54), 149 (62), 141 (45), 128 (85), and 115 (84); IR (neat), 1460, 1310, 805, 735, and 670 cm^{-1}.

The distillate at 64—74 °C/8 Torr consisted of biphenylene, phenyl benzoate and small amounts of **10** and **11**.

The distillate at 70—110 °C/0.8 Torr consisted of **12**, **13**, and **14** in a ratio of 1 : 9 : 4. The mixture was chromatographed through a column of silica gel. Elution with hexane gave a mixture of **12** and **13**. **13** was purified by recrystallization from carbon tetrachloride, melted at 54—55 °C (lit,[24] 54—56 °C). Although **12** was not purified, its structure was tentatively determined on the basis of the NMR spectrum of the mixture of **12** and **13** (**12** was isolated satisfactorily neither by gas chromatography nor by column chromatography). Further elution with a mixture of hexane and benzene gave **14**, recrystallized from hexane; mp 69—71 °C; MS, *m/e* (rel intensity) 320 (M^+, 41), 229 (100), 228 (25), 129 (37), 128 (98), 116 (40), 115 (40), and 105 (28); IR (neat), 1460, 1450, 740, and 690 cm^{-1}. Calcd for $C_{25}H_{20}$: C, 93.71; H, 6.29%. Found: C, 93.53; H, 6.07%.

Even if dichloromethane as a solvent was not used, the products and product composition were scarcely changed.

Competition Reactions of a Series of Substituted Benzenes toward Benzyne. Competition reactions of a series of substituted benzenes toward benzyne were carried out using **2**, prepared

from 0.5 g of **1**, and the following combinations of substituted benzenes: A) benzene 25 g, toluene 25 g; B) benzene 30 g, anisole 20 g; C) benzene 20 g, chlorobenzene 30 g; D) benzene 20 g, benzylidyne trifluoride 30 g; E) chlorobenzene 20 g, methyl benzoate 30 g. Relative reactivities were estimated from the calibrated gas chromatographic analysis and/or NMR analysis of the crude mixtures.

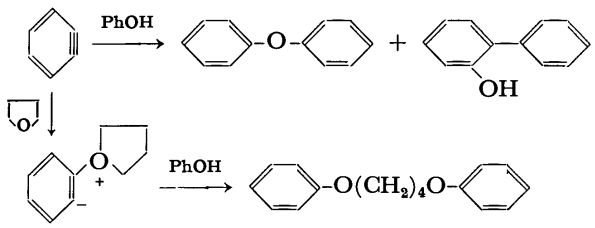
8) The products **10**, **11**, and **13** from toluene were already reported by L. Friedman, see Ref. 4.

9) In each case except anisole, biphenylene (9—45% of the total products) and phenyl benzoate (4—25% of the total products) were obtained. But obviously they are not the reaction products of benzyne with substituted benzenes.

10) Anisole distilled on sodium metal was used. In a run where anisole distilled on phosphorus pentoxide was used, diphenyl ether and *o*-hydroxybiphenyl were obtained together with **3** and **4**, and in the presence of tetrahydrofuran, 1,4-diphenoxybutane was also obtained. These products seem to be formed from phenol as follows.



Wolthuis *et al.* reported that from benzyne, tetrahydrofuran and water, 1,4-diphenoxybutane was also obtained. See, E. Wolthuis, B. Bouma, J. Modderman, and L. Sytsma, *Tetrahedron Lett.*, **1970**, 407.

11) K. Kitahonoki and Y. Takano, *Tetrahedron Lett.*, **1963**, 1597. We wish to thank Dr. Takano for his showing us the NMR spectrum of **4** for comparison.

12) In the presence of a silver salt, the reactions of benzyne with substituted benzenes gave mainly biphenyl and/or benzocyclooctene derivatives. See, I. Tabushi, H. Yamada, Z. Yoshida, and R. Oda, *Bull. Chem. Soc. Jpn.*, **50**, 291 (1977).

13) As for toluene, the product **14** was included in 2,5-adduct and the product **12** was included in 1,4-adduct. Similarly for chlorobenzene, the product **7** was included in 2,5-adduct.

14) For anisole and toluene, the results of benzyne were very similar to those of halogenated benzynes. For example, in the case of tetrafluorobenzyne, 86% of 1,4-adduct and 14% of 2,5-adduct from anisole, and 23% of 1,4-adduct and 77% of 2,5-adduct from toluene were obtained. See Ref. 1a.

15) Actually the ratios of 1,4-adducts to 2,4-adducts in reactions of tetrahalogenated benzynes with *t*-butylbenzene were reported to be markedly affected by the bulkiness of halogens. See Ref. 1i.

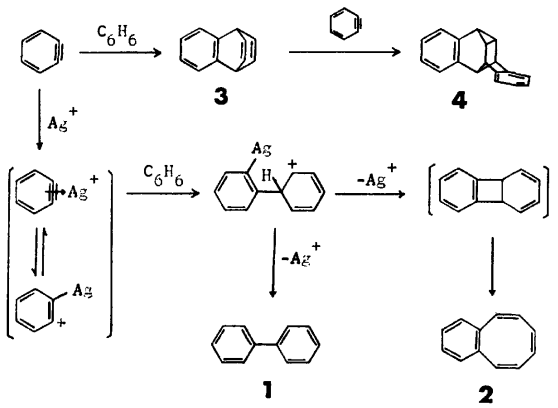
(Received April 26, 1976)

The presence of silver perchlorate changed the products in the reaction of benzyne with substituted benzene (anisole, toluene, chlorobenzene or methyl benzoate) to increase biphenyl and/or benzylidyne trifluoride derivatives by the sacrifice of benzobicyclo[2.2.2]octatriene derivatives. In the case of toluene, *o*-methylbiphenyl (**15**) and 6-methylbenzocyclooctene (**14**) were considered to be formed *via* common intermediate. These results were well explained by an assumption of benzyne-silver cation complex. From competition experiments, it was concluded that benzyne·silver cation complex assumed here had a stronger electrophilicity than benzyne itself.

In the previous paper, we reported the reactions of benzyne with substituted benzenes in the absence of a silver salt to yield benzobicyclo[2.2.2]octatriene derivatives.[1] Stiles *et al.* reported the reaction of benzyne with benzene giving biphenyl (**1**), benzocyclooctene (**2**), benzobicyclo[2.2.2]octatriene (**3**) and one two to one adduct **4**.[2] The addition of Ag^+ in the reaction of benzyne with benzene was reported by Friedman to increase **1** and **2** by the sacrifice of **3**.[3] We also reported that the addition of Hg^+, Hg^{2+}, Sn^{2+}, Co^{2+}, or V^{3+} changed the product distribution in the reaction of benzyne with benzene.[4] Friedman proposed a cationic mechanism of benzyne-silver cation complex to explain the change of the product distribution in the reaction of benzyne with benzene in the presence of a silver salt (Eq. 1).[3] Vedejs



(1)

et al. supported the cationic nature of benzyne-silver cation complex from the result of the reaction of benzyne with cyclooctatetraene in the presence of a silver salt.[5]

In this paper, we wish to report the products and the relative reactivities of substituted benzenes treated with benzyne in the presence of silver perchlorate and to discuss the nature of benzyne in the presence of silver cation.

Results

The thermolysis of benzenediazonium-2-carboxylate (**6**), prepared from anthranilic acid (**5**), was carried out in an excess of substituted benzene (anisole, toluene, chlorobenzene, methyl benzoate or benzylidyne trifluoride) in the presence of silver perchlorate. The products are shown in Scheme 1 and the product compositions in the typical runs are summarized in Table 1.

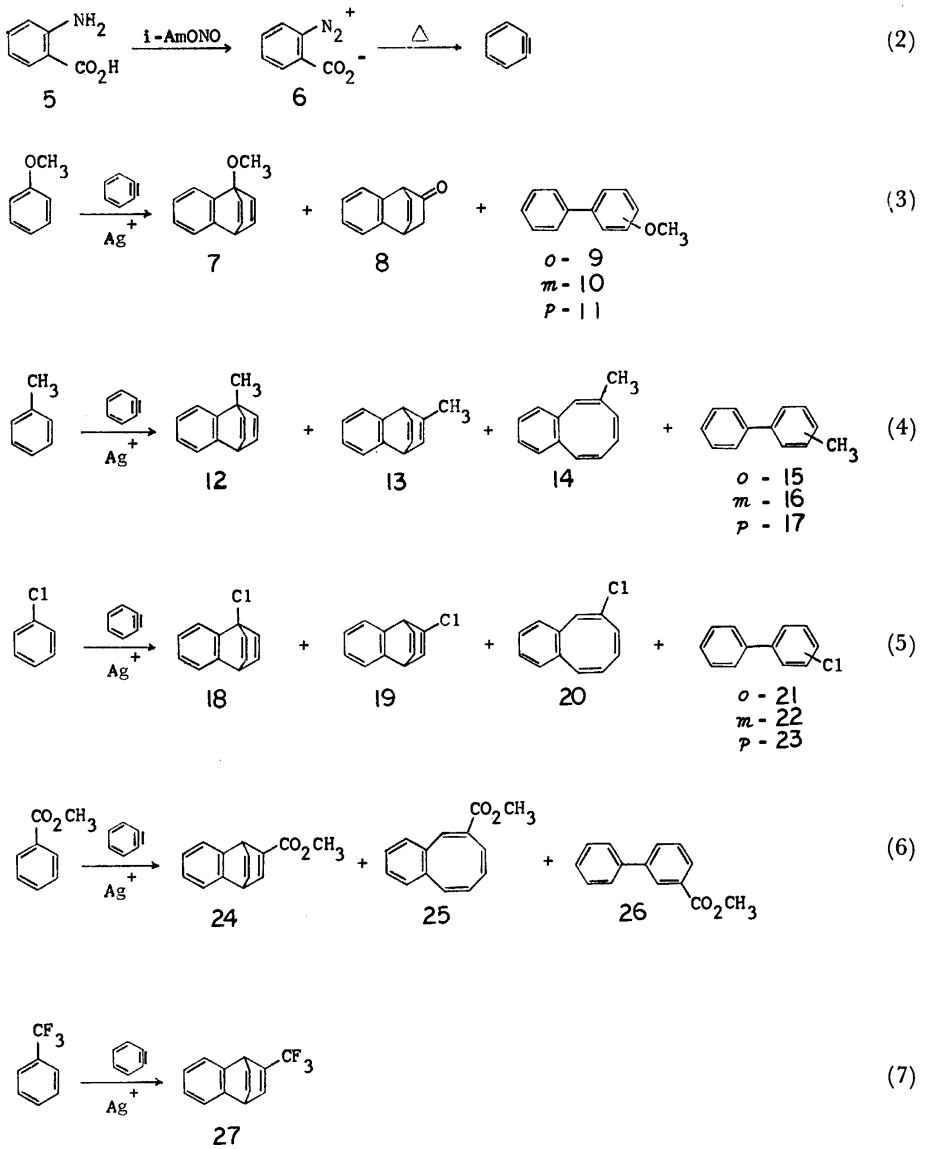
The reaction of benzyne with anisole in the presence of silver perchlorate gave methoxybiphenyls (**9**—**11**), 1-methoxybenzo[2,3]bicyclo[2.2.2]octatriene (**7**) and benzobicyclo[2.2.2]octadienone (**8**) but did not give benzocyclooctene derivatives.

Toluene gave methylbiphenyls (**15**—**17**), 1-methylbenzo[2,3]bicyclo[2.2.2]octatriene (**12**), 2-methylbenzo[5,6]bicyclo[2.2.2]octatriene (**13**) and hydrocarbon **14**. **14** was a colorless oil and the molecular peak of its mass spectrum was observed at 168 (*m/e*), indicating **14** to be an one to one adduct of benzyne and toluene. IR spectrum of this compound was similar to that of benzocyclooctene (**2**)[6] in the range of 850—650 cm^{-1}. NMR spectrum of **14** in CCl_4 with 100 MHz showed the ratio of aromatic, olefinic and aliphatic protons to be 4: 3: 3. These observations may indicate **14** to be one of methylbenzocyclooctenes. For comparison, NMR spectra of **14** and **2**[7] are shown in Table 2. Only 6-methylbenzocyclooctene can well explain the NMR spectrum of **14**.

TABLE 1. THE PRODUCT COMPOSITIONS OF THE REACTIONS OF BENZYNE WITH SUBSTITUTED BENZENES IN THE PRESENCE OF SILVER PERCHLORATE[a]

Substrate (ml)	**5**(g)	$AgClO_4$ (mg)	Product composition (%)					
Anisole(500)	3	75.0	**7** 10.3	**8** 2.7	**9** 74.5	**10** 1.4	**11** 11.1	
Toluene(170)	3	35.7	**12** 3.3	**13** 7.8	**14** 7.7	**15** 54.3	**16** 18.6	**17** 8.1
Chlorobenzene(200)	1	166	**18** 1.5	**19** 11.1	**20** 68.0	**21** 15.8	**22** 1.0	**23** 2.6
Methyl benzoate(50)	1	115.7	**24** 7.5	**25** 59.6	**26** 32.9			
Benzylidyne trifluoride(50)	1	301	**27** 100					

a) The product compositions were determined by means of gas chromatography (PEG 20M and Silicon DC 550).



Scheme 1. The products of the reactions of benzyne with substituted benzenes in the presence of silver perchlorate.

The yields of **12**+**13**, **14**, **15**, **16**, and **17** were 2, 4, 31, 10, and 5%, respectively, based on benzyne generated.

From chlorobenzene, 1-chlorobenzo[2,3]bicyclo-[2.2.2]octatriene (**18**), 2-chlorobenzo[5,6]bicyclo[2.2.2]-octatriene (**19**), chlorobiphenyls (**21**—**23**) and compound **20** were obtained. On the basis of the NMR spectrum (Table 2), **20** was determined to be 6-chlorobenzocyclooctene.

In the case of methyl benzoate, the decomposition of benzenediazonium-2-carboxylate (**6**) was markedly retarded by silver perchlorate. Heating of a mixture of **6** prepared from 1 g of **5**, 50 ml of methyl benzoate and 115 mg of silver perchlorate at 55 °C for 13 h did not decompose the precipitates of **6** appreciably and additional heating of the mixture at 90 °C for 9 h gave only small amounts of products. Gas chromatographic analysis of the reaction mixture showed the presence of six products, methylbenzo[5,6]bicyclo[2.2.2]octatriene-2-carboxylate (**24**), methyl 3-biphenylcarboxylate (**26**), compound **25**, one undetermined compound, phenyl benzoate and phenyl salicylate.[2] The latter two products were not the products from benzyne and methyl benzoate,[1] and the undetermined compound was not considered to be a one to one adduct of benzyne and methyl benzoate because of its long retention time in gas chromatography. Compound **25** was considered to be benzocyclooctene derivative based on the NMR and IR spectra, and we determined **25** to be methyl 6-benzocyclooctenecarboxylate, tentatively (Table 2).

From benzylidyne trifluoride, only 2-trifluoromethylbenzo[5,6]bicyclo[2.2.2]octatriene (**27**), biphenylene and phenyl benzoate were obtained, but biphenyl or benzocyclooctene derivatives were not obtained.

The effects of the concentration of silver perchlorate on the distributions of the products of biphenyl and/or benzocyclooctene derivatives were examined, in the cases of anisole, toluene and chlorobenzene. The results

are shown in Tables 3—5.

Competition reactions were carried out to investigate the relative reactivities of benzyne toward substituted benzenes in the presence of silver perchlorate. The relative reactivities were calculated from the amounts of biphenyl and benzocyclooctene derivatives produced, since they were considered to be the products concerned with silver perchlorate (*vide infra*). The results are shown in Table 6.

Discussion

In the presence of silver perchlorate, the reactions of benzyne with anisole, toluene, chlorobenzene and methyl benzoate, as well as benzene,[3] gave predominantly biphenyl and/or benzocyclooctene derivatives, in marked contrast to the results in the absence of silver perchlorate where the main products were benzobicyclo[2.2.2]octatriene derivatives.[1] In the case of benzylidyne trifluoride having a strong electron-withdrawing

a) Relative reactivity of substituted benzene to benzene.

group, silver perchlorate did not change the product. Thus, it is concluded that silver cation catalyzes the formations of biphenyl and/or benzocyclooctene derivatives in the reactions of benzyne with substituted benzenes, unless the substituent is a strong electron-withdrawing group such as CF_3.

For toluene, the distribution of 6-methylbenzocyclooctene (**14**) and *o*-methylbiphenyl (**15**) was affected by the concentration of silver perchlorate, but the sum of **14** and **15** was almost constant (Table 4). This may indicate that 6-methylbenzocyclooctene and *o*-methylbiphenyl are formed *via* a common intermediate. Similar situation was observed in the distribution of 6-chlorobenzocyclooctene (**20**) and *o*-chlorobiphenyl (**21**) in the case of chlorobenzene (Table 5). These observations can be well explained by benzyne-silver cation complex proposed by Friedman[3] (Eq. 1). Namely benzyne-silver cation complex attacks ortho position of a substituted benzene(toluene or chlorobenzene) forming the common intermediate **28** and then leaving of silver cation together with carbon-carbon bond formation gives 6-substituted benzocyclooctene (Eq. 9) or leaving of silver cation together with proton transfer gives *o*-substituted biphenyl (Eq. 8). In this mechanism the formation of 5-substituted benzocyclooctene is also possible, but it may be inhibited by the steric effect of a substituent. There is no satisfactory explanation of the effect of the concentration of silver perchlorate on the distribution of **14** and **15**.

Orientations of Benzyne-Silver Cation Complex to Substituted Benzenes. In the case of toluene, both of 6-methylbenzocyclooctene (**14**) and *o*-methylbiphenyl (**15**) should be included in ortho oriented products, since they were considered to be formed *via* the common intermediate. Similar situation was present in 6-chlorobenzocyclooctene (**20**) and *o*-chlorobiphenyl (**21**) from chlorobenzene. Table 7 shows the orientations of benzyne-silver cation complex to anisole, toluene and chlorobenzene, together with those of phenyl cation[8] and phenyl radical.[9-11] Obviously, the orientations of benzyne-silver cation complex were mostly ortho and very different from those of phenyl cation and phenyl radical. Therefore, we can not discuss the nature of benzyne-silver cation complex only from the distribution of the products from substituted benzene, although Friedman suggested that the distribution of isomeric methylbiphenyls should reveal the nature of benzyne–silver cation complex.[3]

TABLE 8. THE RELATIVE REACTIVITIES OF BENZYNE–SILVER CATION COMPLEX TOWARD THE ORTHO POSITIONS OF SUBSTITUTED BENZENES (F_o)

Substituent	OCH_3	CH_3	H	Cl
F_o	16.5	7.6	1	0.247

Relative Reactivities of Benzyne-Silver Cation Complex toward Substituted Benzenes. From Tables 6 and 7, the relative reactivities of benzyne-silver cation complex toward the ortho positions of substituted benzenes (partial rate factor, F_o) were estimated (Table 8).[12] As is seen, F_o changed about 65-fold with changing substituent from Cl to OCH_3. Hammett plots of log F_o *vs.* σ_p^+ are shown in Fig. 1. A linear relationship was roughly observed between log F_o and σ_p^+, and the reaction constant, ρ, was estimated to be -2.0. A comparison of ρ values for several reactions is made in Table 9. The absolute value of the present ρ is much smaller than that for nitration of substituted benzenes but twice as large as that for cationic phenylation of substituted benzenes and slightly larger than that for 1,4-addition of

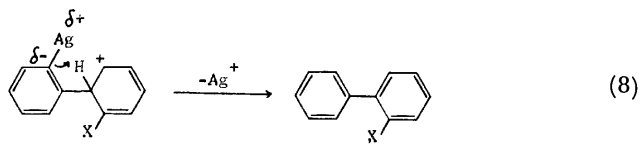
c) Biphenyl (**1**).

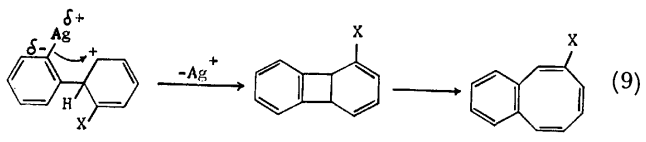
benzyne to substituted benzenes. Thus, it is concluded that benzyne-silver cation complex has a larger electrophilicity than phenyl cation and benzyne itself. This supports the cationic mechanism proposed by Friedman (Eq. 1).[3]

Substituent Effect on the Formation of Benzocyclooctene vs. Biphenyl Derivatives. Table 10 shows the percentages of 6-substituted benzocyclooctene (6-BCOT) and *o*-substituted biphenyl (*o*-BP) from the reactions of benzyne–silver cation complex with substituted benzenes, together with those of benzocyclooctene and biphenyl from benzene. Obviously, the formation of 6-BCOT or *o*-BP depends on the electron-donating (or electron-withdrawing) nature of a substituent of a substituted benzene. Namely, anisole having an electron-donating substituent gave exclusively *o*-methoxybiphenyl, while chlorobenzene having an electron-withdrawing substituent gave predominantly 6-chlorobenzocyclooctene. These results can be explained by the following way.



(8)

28



(9)

28

An electron-donating substituent stabilizes the intermediate cyclohexadienyl cation **28** and may reduce the electrophilicity of the cation to the carbon attached to silver. Thus, elimination of silver cation with proton transfer becomes predominant to increase the formation of *o*-substituted biphenyl (Eq. 8). On the other hand, an electron-withdrawing substituent may be reduce the electrophilicity of the cation **28** and elimination of silver cation with cyclization becomes more predominant to increase the formation of 6-substituted benzocyclooctene (Eq. 9). A very strong electron-withdrawing substituent like CF_3 destabilizes the intermediate cyclohexadienyl cation and the cation may not be formed. Thus, the fact that benzylidyne trifluoride did not give biphenyl or benzocyclooctene derivatives could be understood.

Experimental

General Procedure of the Reaction of Benzyne with Substituted Benzene in the Presence of Silver Perchlorate. Benzenediazonium-2-carboxylate (**6**), prepared from 1—3 g of anthranilic acid (**5**) by the method described elsewhere,[1] was stirred in 25—500 ml of a substituted benzene in the presence of a proper amount of silver perchlorate at about 45 °C. After gas evolution had ceased (20—64 h), the mixture was washed with aq sodium hydrogencarbonate soln and water, and dried on calcium chloride. After removal of the most of substituted benzene, the residue was analyzed by gas chromatography (PEG 20 M, Silicon DC 550).

Reaction of Benzyne with Anisole in the Presence of Silver Perchlorate. After the treatment as described above, gas chromatographic analysis (PEG 20 M, Silicon DC 550) of the concd crude mixture showed the presence of 1-methoxybenzo[2,3]bicyclo[2.2.2]octatriene (**7**), benzobicyclo[2.2.2]octadienone (**8**), methoxybiphenyls (**9**—**11**) and a small amount of phenyl benzoate (6% of the total products). All products were consistent with the authentic samples on the basis of the IR spectra and the retention times on gas chromatography, respectively.

Reaction of Benzyne with Toluene in the Presence of Silver Perchlorate. After the treatment as described above, gas chromatographic analysis (PEG 20 M, Silicon DC 550) of the concd crude mixture revealed the presence of 1-methylbenzo[2,3]bicyclo[2.2.2]octatriene (**12**). 2-methylbenzo[5,6]bicyclo[2.2.2]octatriene (**13**), methylbiphenyls (**15**—**17**) and 4-methyl-1,2-benzocyclooctene (**14**). **14** was isolated by preparative gas chromatography (PEG 20 M) from the distillate of the crude mixture at 57 °C/8 Torr. **14** was a colorless oil: MS, *m/e* (rel intensity) 168 (M^+, 92), 167 (49), 165 (28), 153 (100), 152 (50), 141 (21), 128 (44), and 115 (30); IR (neat), 1490, 1430, 830, 790, 760, 725, and 690 cm^{-1}.

Other products were all consistent with the authentic samples on the basis of the IR spectra and the retention times on gas chromatography (PEG 20 M, Silicon DC 550), respectively.

In another experiment using **6** prepared from 2 g (14.6 mmol) of **5**, 200 ml of toluene and 54 mg of silver perchlorate, evolution of 14.4 mmol of gases (N_2 and CO_2, 50% yield of benzyne based on **5** used) was observed. Gas chromatographic analysis of the crude mixture added with weighed diphenylmethane indicated the yields of **12**+**13**, **14**, **15**, **16**, and **17** to be 2, 4, 31, 10, and 5%, respectively, based on benzyne generated.

Reaction of Benzyne with Chlorobenzene in the Presence of Silver Perchlorate. Gas chromatographic analysis (PEG 20 M) of the concd crude mixture indicated the presence of 1-chloro-

benzo[2,3]bicyclo[2.2.2]octatriene (**18**), 2-chlorobenzo[5,6]-bicyclo[2.2.2]octatriene (**19**), 6-chlorobenzocyclooctene (**20**) and chlorobiphenyls (**21**—**23**) together with phenyl benzoate (10—20% of the total products). After distillation of the crude mixture at 47—53 °C/3 Torr, **20** was isolated by preparative gas chromatography (PEG 20 M) as a pale yellow oil: n_D^{16} 1.6226; MS, *m/e* (rel intensity) 190 (M+2, 16), 188 (M^+, 47), 154 (28), 153 (100), 152 (58), 151 (36), 150 (14), 128 (11), 127 (14), and 126 (13); IR (neat), 1495, 1100, 830, 795, 770, and 725 cm^{-1}. Calcd for $C_{12}H_9Cl$: C, 76.40; H, 4.81; Cl, 18.79%. Found: C, 76.38; H, 4.74; Cl, 18.52%.

Other products were all consistent with the authentic samples on the basis of the IR spectra and the retention times on gas chromatography (PEG 20 M), respectively.

Reaction of Benzyne with Methyl Benzoate in the Presence of Silver Perchlorate. A mixture of **6** prepared from 1 g of **5**, 116 mg of silver perchlorate and 50 ml of methyl benzoate was heated at 55 °C for 13 h and then 90 °C for 9 h, but only small amount of **6** was decomposed. The most of methyl benzoate was distilled off at 100 °C using 10 cm of packed column and then the residue was dissolved in ether. The ether soln was washed with aq ammonia and sat sodium chloride soln and dried on sodium sulfate, and then concd. Gas chromatographic analysis (Silicon DC 550) of the residue showed six peaks. First three peaks were due to phenyl benzoate (29% of the total products), 2-methoxycarbonylbenzo[5,6]bicyclo-[2.2.2]octatriene (**24**) (3% of the total products) and phenyl salicylate (13% of the total products), in the order of retention time. These products were all consistent with the authentic samples on the basis of the IR spectra and the retention times on gas chromatography (Silicon DC 550), respectively. The fourth peak (22% of the total products) was tentatively determined to be that of methyl 6-benzocyclooctenecarboxylate (**25**) which was isolated by preparative gas chromatography (Silicon DC 550) after column chromatography through silica gel with benzene. **25** was a pale yellow oil: IR (neat), 1715, 1240, 1065, 800, 755, 730, and 710 cm^{-1}. The fifth peak was that of methyl 3-biphenylcarboxylate (**26**) which was consistent with authentic sample on the basis of the IR spectrum and the retention time on gas chromatography. The last peak (20% of the total products) had a 2—3 times longer retention time than the other five peaks. This compd had a IR absorption at 1730 cm^{-1} but the structure was uncertain.

Reaction of Benzyne with Benzylidyne Trifluoride in the Presence of Silver Perchlorate. Reaction of **6** prepared from 1 g of **5**, with 50 ml of benzylidyne trifluoride in the presence of 301 mg of silver perchlorate gave 2-trifluoromethylbenzo[5,6]bicyclo-[2.2.2]octatriene (**27**) (30% of the total products), biphenylene (38% of the total products) and phenyl benzoate (32% of the total products). All products were consistent with authentic samples based on the IR spectra and the retention times on gas chromatography (PEG 20 M, Silicon DC 550).

Competition Reactions of a Series of Substituted Benzenes toward Benzyne in the Presence of Silver Perchlorate. Competition reactions of a series of substituted benzenes toward benzyne in the presence of silver perchlorate were carried out under usual conditions. Relative reactivities of substituted benzenes were estimated from the calibrated gas chromatographic analyses (PEG 20 M, Silicon DC 550) of the crude reaction mixtures. The results are shown in Table 6.

Fluorescence of 9-Aminoacridine Bound to Polynucleotides

Yukio KUBOTA and Yasuo FUJISAKI
Department of Chemistry, Yamaguchi University, Yamaguchi 753

(Received August 26, 1976)

Synopsis. The fluorescence of 9-aminoacridine is completely quenched when bound to poly (dG)·poly (dC), the quantum yield of fluorescence being nearly equal to that of free dye when bound to poly d(A–T). The dye bound to DNA shows a weak fluorescence for which the AT pair is responsible.

The interaction of 9-aminoacridine (9-AA) with DNA is of special interest because of its strong mutagenic activity.[1] In a previous paper,[2] it was reported that the fluorescence of 9-AA bound to DNA is almost completely quenched. In order to elucidate the interaction between 9-AA and the binding sites, fluorescence properties of 9-AA bound to DNA, poly d(A–T) and poly (dG)·poly (dC) were examined as a function of nucleotide to dye (P/D) ratio.

Experimental

9-AA (Tokyo Kasei) was purified by repeated crystallization and chromatography. Calf thymus DNA (Worthington Biochemical Corporation), poly d(A–T) and poly (dG)·poly (dC) (Miles Laboratories) were used.

Fluorescence and fluorescence-excitation (FE) spectra were measured with a Hitachi MPF-2A fluorescence spectrophotometer. Both spectra were corrected for the sensitivity of the detector system and the spectral-energy distribution of the exciting light. The fluorescence quantum yields were measured according to the method of Parker and Rees.[3] Fluorescence lifetimes were determined by the phase-shift measurements.[2] All the measurements were carried out in a 0.005 M phosphate buffer (pH 6.9) at 25 °C.

Results and Discussion

The results of fluorescence lifetimes (τ) and quantum yields (Φ_F) of 9-AA bound to DNA, poly d(A–T) and poly (dG)·poly (dC) are summarized in Table 1. The fluorescence of 9-AA is remarkably quenched when bound to DNA or poly (dG)·poly (dC), whereas the fluorescence quantum yield is approximately equal to that of free dye when bound to poly d(A–T). The fluorescence and FE spectra of 9-AA bound to polynucleotides were examined to obtain information on the fluorescing species. The fluorescence spectra of 9-AA bound to DNA and poly d(A–T) are almost the same, showing a red shift when compared to that of free dye (Fig. 1). We see that the fluorescence and FE spectra of 9-AA bound to poly (dG)·poly (dC) are superimposable on the corresponding fluorescence and FE spectra of free dye, respectively. Each FE spectrum was the same as the corresponding absorption spectrum except for 9-AA–poly (dG)·poly (dC) system. The fluorescence lifetimes of 9-AA–poly (dG)·poly (dC) system are almost the same as the lifetime of free dye (Table 1). In view of these findings, the following

Table 1. Fluorescence lifetimes (τ) and quantum yields (Φ_F) of 9-AA bound to polynucleotides

P/D	DNA		Poly d(A–T)		Poly (dG)·poly (dC)	
	τ(ns)	Φ_F	τ(ns)	Φ_F	τ(ns)	Φ_F
0	17.5	0.98	17.5	0.98	17.5	0.98
590	14.9	0.03				
250			34	0.82		
200	15.1	0.03				
100	15.4	0.03	37	0.81	15.3	0.00_6
50	14.8	0.03_5	38	0.81	15.7	0.01
20	15.0	0.03_5	38	0.77	17.0	0.04_5
10[a]	15.5	0.07	29	0.74	17.5	0.14

a) The contribution of free dye is not negligible.

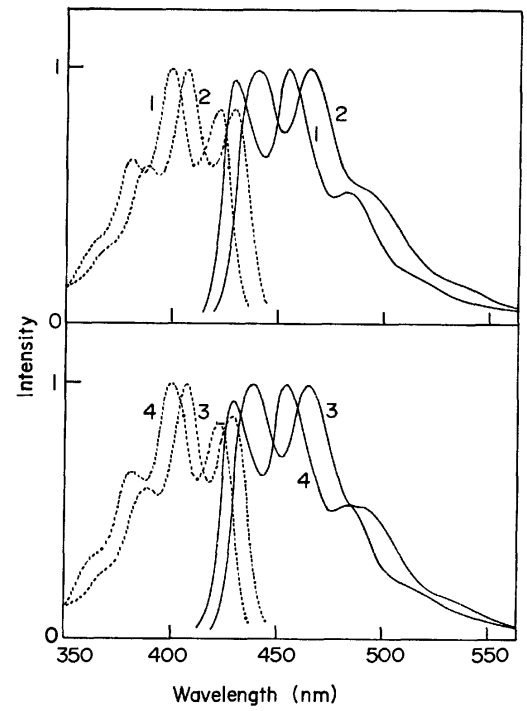

Fig. 1. Normalized corrected fluorescence (——) and FE (------) spectra of 9-AA (6.0×10^{-6} M) in 0.005 M phosphate buffer (pH 6.9) at 25 °C: (1) free, (2) bound to DNA (P/D=590), (3) bound to poly d(A–T) (P/D=250) and (4) bound to poly (dG)·poly (dC) (P/D=50). The excitation and emission wavelengths were 390 and 460 nm, respectively.

conclusions can be drawn: (1) the fluorescence of 9-AA–poly (dG)·poly (dC) system originates from free dye present in solutions;[4] the GC pair completely quenches the fluorescence of bound dye; (2) the AT pair is responsible for a weak fluorescence of 9-AA bound to DNA.

On the other hand, the fluorescence lifetime (34—38 ns) of 9-AA bound to poly d(A-T) is about twice that of free dye (Table 1). Our value is in agreement with the value obtained by nanosecond pulse fluorometry.[5] Such a long lifetime, however, seems to be reasonable on the basis of the strong hypochromicity of bound dye. The area under the absorption spectrum of bound dye plotted against wave number is reduced to about half the corresponding value of free dye. According to the method of Strickler and Berg,[6] the radiative lifetimes (τ_0) of free 9-AA and 9-AA bound to poly d(A-T) were calculated to be 17 and 37 ns, respectively. The τ/τ_0 value is approximately equal to the corresponding Φ_F value for both free and bound dye.

The results of 9-AA bound to DNA are somewhat surprising when compared to those of proflavine (PF). If PF is intercalated between adjacent AT pairs of DNA, the fluorescence quantum yield is nearly equal to that of PF bound to poly d(A-T).[2,7-9] However, the GC pair in the vicinity of bound PF gives rise to an almost complete quenching of the fluorescence.[2,7-9] From the results, it seems that 9-AA behaves similarly to PF with respect to the fluorescence properties. If this is the case, the fluorescence quantum yield of 9-AA bound to DNA should be about 0.3 in the case of calf thymus DNA (GC content of 42%).[2,10] Contrary to expectation, the observed quantum yield is much smaller (Table 1). The reason why the behavior of 9-AA is different from that of PF is not clear.

10) Φ_F (bound to adjacent AT pairs)$=\Phi_F$ (bound to poly d(A-T))$\times$(mole fraction of AT: AT pair). The mole fraction of AT: AT pair is 0.3364 on the assumption that the base pairs are randomly distributed. Then the fluorescence quantum yield of 9-AA bound to adjacent AT pairs can be estimated to be about 0.3 (0.82×0.3364) by assuming that the bound dye molecules are randomly distributed.

Excited-State Dipole Moments of Picrates of Pyridine, 2-Methylpyridine, 3-Methylpyridine, and 4-Methylpyridine

Osamu SEDOYAMA, Miwako HIGASHI, Yoshinori AKIMOTO, and Hiroyuki YAMAGUCHI*

Department of Chemistry, Kumamoto University, Kumamoto 860

(Received May 13, 1976)

Synopsis. Measurements of the excited-state dipole moments for picrates of pyridine and methylpyridines have been carried out by spectrophotometry. The contribution of the dative structure $\Psi(D^+A^-)$ in the excited state of these picrates is larger than the contribution of $\Psi(D^+A^-)$ in the ground state.

The excited-state dipole moments of electron donor–acceptor (EDA) complexes provide valuable information on the nature of binding in the excited state of the complexes. Recently, Rao and Dwivedi[1] have investigated the excited-state dipole moments of several EDA complexes by using the expression of McRae[2] to describe solvent shifts of electronic spectra. In the case of weak EDA complexes, they have observed red shifts of the CT bands and have concluded that the excited-state dipole moments μ_e are larger than the ground-state dipole moments μ_g. In the case of strong EDA complexes, they have observed solvent blue shifts and $\mu_e < \mu_g$. A lower μ_e compared to μ_g in strong EDA complexes was indeed a new observation.

Under these circumstances, it seems important to obtain experimental knowledge concerning the excited-state dipole moments of strong EDA complexes. We used picrates of pyridine, 2-methylpyridine, 3-methylpyridine, and 4-methylpyridine as strong EDA complexes. The purpose of our research was to determine the μ_e of these picrates from solvent shifts of electronic spectra and to investigate the contribution of the dative structures $\Psi(D^+A^-)$ and $\Psi(D^-A^+)$ in the excited-states of such strong EDA complexes.

Experimental

Materials and Their Purification. According to the procedure described by Raman and Soundararajan,[3] picrates of pyridine, 2-methylpyridine, 3-methylpyridine, and 4-methylpyridine were synthesized. All four picrates were recrystallized from ethyl alcohol three times. The 1:1 complexes precipitated from the solution.[4] The solvents used were carefully purified according to the descriptions in Ref. 5.

Measurements. The dielectric contants were determined with a home-made resonance-method apparatus. The refractive indices were measured by means of a Pulfrich refractometer. The dielectric constant (ε) and the refractive index (n_D) at the sodium D line of the solvents agreed with the values cited in Ref. 5. The densities of the solutions were measured by the use of a pycnometer for volatile liquids. The absorption spectra were taken with a Shimadzu UV-200 recording spectrophotometer equipped with a thermostated cell holder. Matched pairs of stopped silica cells of 1 cm path lengths were used. All measurements were made on deaerated samples at 20 °C.

Determination of Excited-state Dipole Moments. When two polar solvents I and II of similar n_D are used, the solvent shifts ($\Delta\nu$) of electronic spectra can be simplified from the expression of McRae[2] in the following manner:

$$\Delta\nu = \nu_{max}(\mathrm{I}) - \nu_{max}(\mathrm{II}) = C\{[(\varepsilon-1)/(\varepsilon+2)]_\mathrm{I} - [(\varepsilon-1)/(\varepsilon+2)]_\mathrm{II}\} \quad (1)$$

The constant C is given by Eq. 2:

$$C = (2/hc)[\mu_g(\mu_g-\mu_e)/a^3] \quad (2)$$

where a is the cabity radius in Onsager's theory[6] of the reaction field and is estimated from the molal volume on the assumption of the spherical radius of the complexes.

Rao and Dwivedi[1] have shown that the acetonitrile-diethyl ether solvent system can be used to obtain μ_e of EDA complexes from Eq. 1. When we used this solvent system, all four picrates dissociated completely into their donor and acceptor components in acetonitrile.[7] Instead of the acetonitrile-diethyl ether solvent system, we employed the acetone-diethyl ether solvent system. The validity of this solvent system was confirmed from the fact that the μ_e value, 9.8 D, for the hexamethylbenzene–chloranil complex was almost identical to the value, 10.0 D[1], obtained in the acetonitrile-diethyl ether solvent system.

Results and Discussion

The absorption spectra of pyridine picrate are shown in Fig. 1. The absorption band around 410 nm was assigned as the CT band of the picrate. The method of continuous variation was employed at 410 nm to establish the stoichiometry of the complex in the solvent. When the sum of the pyridine and picric acid concentrations was kept constant at 6.70×10^{-3} M, the Job curves showed a distinct maximum for equal concentrations of donor and acceptor, characteristic of a 1:1 complex (see Fig. 2). The results thus obtained for the picrates of three methylpyridines were the same as the above results for pyridine picrate. Since the IR spectra of the four picrates are the same as the IR spectra of the complexes between 2,4,6-trinitroanisole and pyridine and the three methylpyridines, and the complexes show the CT bands at almost the same

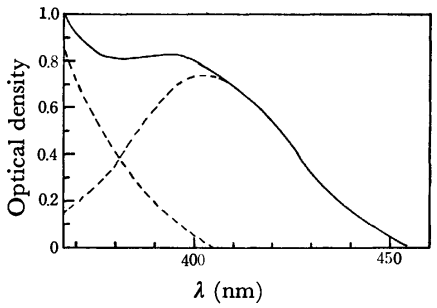

Fig. 1. The absorption spectra of pyridine picrate in diethyl ether at 30 °C. The dashed line shows the best fit of Gauss-curve for the CT band.

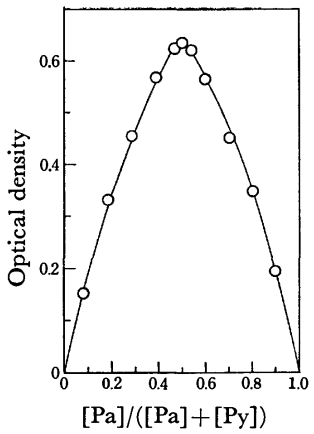

Fig. 2. The continuous variation of pyridine picrate in diethyl ether at 410 nm. The sum of the pyridine (Py) and picric acid (Pa) concentrations was kept constant at 6.70×10^{-3} M.

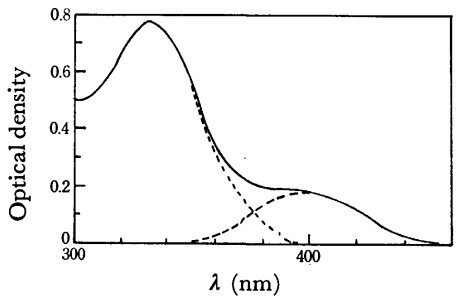

Fig. 3. The absorption spectra of 2,4,6-trinitroanisole-pyridine in diethyl ether at 30 °C. The dashed line shows the best fit of Gauss-curve for the CT band.

wavelength as the CT band of pyridine picrate (*e.g.*, see Figs. 1 and 3), all four picrates are not proton-transfer-typed complexes but EDA complexes. The CT bands of all four picrates were analyzed assuming Gauss-type absorption bands with the method described by Badoz *et al.*[8] (*e.g.*, see Fig. 1). The results are summarized in Table 1.

Table 1. Excited state dipole moments

Complex	ν_{CT}(cm^{-1}) (in ether)	C (cm^{-1})	a (Å)[a]	μ_g (D)[b]	μ_e (D)
Pyridine picrate	24750	−542	4.30	8.70	9.6
2-Methylpyridine picrate	24670	−476	4.25	9.25	10.1
3-Methylpyridine picrate	24650	−610	4.41	9.55	10.4
4-Methylpyridine picrate	24690	−596	4.33	9.60	10.4

a) Estimated from the apparent molal volume in 1,4-dioxane. b) Measured in 1,4-dioxane. See Ref. 3.

As the wave function Ψ_e for the excited state is given by Eq. 3,[1]

$$\Psi_e = C_1\Psi(DA) + C_2\Psi(D^+A^-) + C_3\Psi(D^-A^+) + C_4\Psi(D^*A) + C_5\Psi(DA^*) \quad (3)$$

the μ_e of the complex is proportional to $|C_2^2-C_3^2|$.

It is concluded from the μ_e thus obtained that the contribution of the dative structure $\Psi(D^+A^-)$ in the excited state of the present picrates is larger than the contribution of $\Psi(D^-A^+)$ is negligible even in the excited state of strong complexes such as the present complexes.

The differences of the ground state dipole moments between pyridine picrate and the picrates of 2-methylpyridine, 3-methylpyridine, and 4-methylpyridine are 0.55, 0.85, and 0.90 D, respectively. The differences of the excited-state dipole moments between pyridine picrate and the three picrates of methylpyridines are 0.5, 0.8, and 0.8 D, respectively. From these facts, it is concluded that the methyl groups of methylpyridines do not play any decisive role in the excited state on CT excitation.

The authors are greatly indebted to Professor Hitoshi Takeshita of Kyushū University for the elemental analysis. One of the present authors (H. Y.) especially wishes to thank Professor F. Yoneda of Kumamoto University for the supply of 2,4,6-trinitroanisole.

Selective Hydrogen Atom Abstraction by Hydrogen Atoms in Photolysis of Cyclohexane-Pentane Mixtures at 77 K

Tetsuo MIYAZAKI,*, Selma M. L. GUEDES, Leonardo G. de A. e SILVA, and Lizete FERNANDES

Instituto de Energia Atômica, C.P. 11049 (Pinheiros), 01000 São Paulo, SP, Brazil

(Received August 9, 1976)

Synopsis. The reaction of H atoms, produced by the photolysis of HI, has been studied in *c*-C_6H_{12}–*n*-C_5H_{12} mixtures at 77K. H atoms in *c*-C_6H_{12} matrix react more effectively with solute *n*-C_5H_{12} than with solvent *c*-C_6H_{12}, while H atoms in *n*-C_5H_{12} matrix react more effectively with solute *c*-C_6H_{12} than with solvent *n*-C_5H_{12}.

Recently, quite interesting phenomena have been reported concerning the hydrogen atom abstraction reaction by H atoms in the solid alkane at 77 K.[1)] When H atoms are produced at 77 K by the photolysis of a hydrogen halide or the radiolysis of a solvent alkane, such as neopentane, the H atoms react selectively with the solute alkane which exists in the neopentane matrix as an additive. The experimental bases of the selective hydrogen atom abstraction reaction by H atoms were described fully in a previous paper.[1b)] The same selective reaction has been found also in the matrices of 2,2,3,3-tetramethylbutane, isobutane, and cyclopropane.[1c)] The selective hydrogen atom abstraction reaction by H atoms has proposed new problems in reaction kinetics in the solid phase at 77 K. When H atoms are hot, we must assume that they migrate a long distance at 77 K through the alkane crystal without losing their kinetic energies. When H atoms are thermal, we must assume that the activation energy for the hydrogen atom abstraction reaction is nearly zero in the alkane matrix at 77 K, though the value amounts to 7—10 kcal/mol in the gas phase.[2,3)]

The previous examples of this reaction have the following characteristics: H atoms react selectively with the solute alkane, denoted as B, in the solvent alkane, denoted as A, where the combination of B in A is fixed. The selective reaction was not observed in the reverse combination, *i.e.* A in B. Here we will report a new type of combination in the case of cyclohexane and normal pentane mixtures. When A contains a small amount of B, H atoms react selectively with B. On the contrary, when B contains A, H atoms react selectively with A.

Experimental

Experimental procedures were identical with those described in the previous studies.[1)] Cyclohexane, >99.7 mol%, and pentane, >99 mol%, were passed through a 1-m column packed with freshly activated alumina and then distilled on a vacuum line before use. UV illumination was provided by a Toshiba medium-pressure mercury lamp at 77 K. The esr measurement was done at 77 K on a JES-ME-3 esr spectrometer.

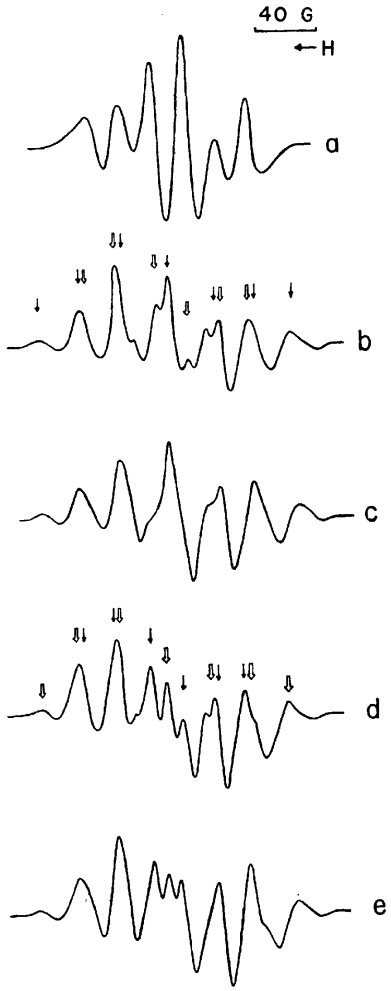

Fig. 1. a: ESR spectrum of UV-illuminated *c*-C_6H_{12}–HI (0.5 mol %) at 77 K. b: ESR spectrum of UV-illuminated *c*-C_6H_{12}–*n*-C_5H_{12} (5%)–HI (0.5%) at 77 K. c: ESR spectrum of UV-illuminated *n*-C_5H_{12}–HI (0.5%) at 77 K. d: ESR spectrum of UV-illuminated *n*-C_5H_{12}–*c*-C_6H_{12} (5%)–HI(0.5%) at 77 K. e: Simulated ESR spectrum of a mixture of C_5H_{11} radicals (60%) and *c*-C_6H_{11} radicals (40%). The relative sensitivities of the spectrometer for a, b, c, and d are approximately the same. The microwave power is 0.2 mW and the modulation width is 5 G. The area of double integration of the first-derivative ESR signal of each radical was used for simulation of the mixed spectra of the two radicals.

Results and Discussion

Figure 1a is the ESR spectrum obtained by UV-illumination of c-C_6H_{12}–HI (0.5 mol%) at 77 K. The spectrum is consistent with the reported spectrum for cyclohexyl radical.[4] The H atom produced by the photolysis of HI abstracts the hydrogen atom from cyclohexane to produce a cyclohexyl radical. When c-C_6H_{12} containing n-C_5H_{12} (5 mol%) and HI (0.5 mol %) is illuminated at 77 K by ultraviolet light, quite a different esr spectrum is obtained (Fig. 1b). Figure 1c shows the esr spectrum obtained by the photolysis of n-C_5H_{12}–HI (0.5 mol %) at 77 K. The H atom produced by the photolysis of HI abstracts the H atom from n-C_5H_{12} to produce a C_5H_{11} radical. The spectrum of Fig. 1c is ascribed to a pentyl radical.[5] It is clear that the spectrum of Fig. 1b contains largely the spectrum due to the C_5H_{11} radical. The spectrum of Fig. 1b is ascribed to a mixture of C_5H_{11} radicals, indicated by ↓, and c-C_6H_{11} radicals, indicated by ⇩. Therefore the H atoms produced by the photolysis of HI in cyclohexane react effectively with solute pentane to form C_5H_{11} radicals.

When n-C_5H_{12} containing c-C_6H_{12} (5 mol %) and HI (0.5 mol %) is illuminated at 77 K by ultraviolet light, the esr spectrum of Fig. 1d is obtained. This spectrum is different from that of Fig. 1c which is obtained by the photolysis of n-C_5H_{12}–HI (0.5 mol %). The simulated spectrum of a mixture of C_5H_{11} radical (60%) and c-C_6H_{11} radical (40%) is shown in Fig. 1e. The spectrum of Fig. 1d is approximately similar to that of Fig. 1e. ⇩ and ↓ in Fig. 1d represent C_5H_{11} and c-C_6H_{11} radicals respectively. Therefore H atoms produced by the photolysis of HI in n-C_5H_{12} react effectively with the solute cyclohexane to form cyclohexyl radicals.

In order to obtain the ratio of the solute radical yield to the total radical yield, the esr spectrum in the photolysis of c-C_6H_{12}–n-C_5H_{12}–HI mixture is compared with the simulated spectrum of the mixture of c-C_6H_{11} and C_5H_{11} radicals. The formations of the solute radicals in c-C_6H_{12} and n-C_5H_{12} matrices are shown in Fig. 2 and 3 respectively. In both cases the fraction of solute radical yield is much higher than the concentration of the solute. Therefore, it is concluded that H atoms in the c-C_6H_{12} matrix react more effectively with solute n-C_5H_{12} than with solvent c-C_6H_{12} (Fig. 2), while H atoms in the n-C_5H_{12} matrix react more effectively with solute c-C_6H_{12} than with solvent n-C_5H_{12} (Fig. 3).

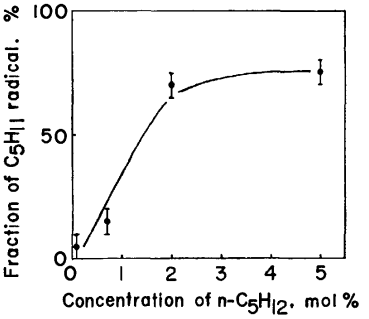

Fig. 2. Formation of solute pentyl radical in the photolysis of c-C_6H_{12}–HI (0.5 mol %) against concentration of n-C_5H_{12}.

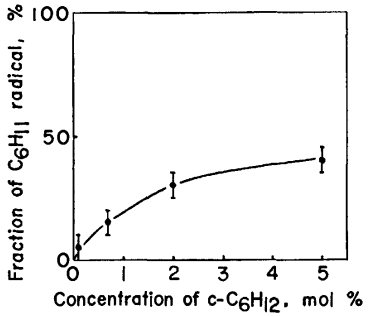

Fig. 3. Formation of solute cyclohexyl radical in the photolysis of n-C_5H_{12}–HI (0.5 mol %) against concentration of c-C_6H_{12}.

The solute alkane may form some active sites in the solid alkane at 77 K and be subjected selectively to H atom attack.

(Received August 28, 1976)

Synopsis. The directly-bonded nuclear spin-spin coupling constants were calculated by a perturbation method involving the summing over singly-excited states using localized orbitals. It is shown that a localized representation of orbitals in the perturbation expansion can be of considerable value both for interpretative purposes and for assessing the rate at which the pertubation expansion converges.

Although the Hartree-Fock (HF) variational condition selects the occupied and virtual manifolds, it does not completely determine the individual orbitals belonging to each manifold.[1] This orbital ambiguity yields the possibility of obtaining a new set of orbitals, within unitary transformations, which may be more suitable for the investigation of a particular physical problem than the original set of canonical molecular orbitals (CMO). The most interesting case is that of a transformation in which the orbitals are localized as much as possible.

One can employ the perturbation theory starting with a wave function constructed from localized molecular orbitals (LMO) as easily as CMO constructed wave functions. There is a theoretical advantage in using LMO- rather than CMO-based wave functions, since the LMO can often be chosen to be localized in a particular region of space, whereas the CMO are usually delocalized. If the perturbation can be expressed as a series of local perturbations which affect only a relatively small region of space, then there may be some advantages in choosing the original orbitals to reflect this localization.[2,3]

The second-order property of a system may be calculated in the perturbation approach employing a summing over excited states from the second-order energy $E^{(2)}$ or the first-order wave function $\Psi^{(1)}$:

$$E^{(2)} = \langle \Psi_0 | H' | \Psi^{(1)} \rangle$$

$$\Psi^{(1)} = \sum_n{}' C_n \Psi_n, \quad C_n = \langle \Psi_0 | H' | \Psi_n \rangle / (E_0 - E_n) \qquad (1)$$

where H' is the operator describing the perturbation and $\{\Psi_n\}$ is a complete set of eigenfunctions of the zeroth-order Hamiltonian H_0 with the set of eigenvalues $\{E_n\}$

$$H_0 \Psi_n = E_n \Psi_n \quad (n=0, 1, \cdots). \qquad (2)$$

Here the sum in Eq. 1 is over an infinite number of excited states. However, since it is impossible to obtain a set of exact wave functions satisfying Eq. 2, some approximation must be introduced. The most frequent approximation to Eq. 1 is to replace Ψ_0 by the HF wave function and Ψ_n by singly-excited configurations, cutting off from the sum other excited configurations. To this approximation, $E^{(2)}$ depends on the unitary transformation of the singly-excited configurations. It would be expected that an LMO set would guarantee a more rapid convergence of the perturbation expansion than a CMO set.

a) R.M.Lynden Bell and N. Sheppard, *Proc. R. Soc. London, Ser. A*, **269**, 385 (1962). b) CMO-SOSP results. c) unconstrained LMO-SOSP results. d) FP results. e) σ-π constrained LMO-SOSP results.

In order to test the LMO effects, model calculations were made of nuclear spin-spin coupling constants using INDO-MO[4] and the sum-over-singly excited-state perturbation (SOSP) method. Computational details have been described in a previous paper.[5] The LMO are obtained by minimizing the off-diagonal exchange energy according to the Edminton-Ruedenberg procedure.[6] The virtual orbitals were also transformed in the same manner. The calculated nuclear spin-spin coupling constants are summarized in Table 1. In the table, LMO denotes the SOSP values with a complete LMO set (*i.e.*, banana-type CC bonding orbitals are obtained for C_2H_4 and C_2H_2) and σ-π denotes the results of σ-π constrained LMO. In order to examine the refinement of LMO perturbation approximation, the coupling constants calculated with the SOSP method using CMO and those using the finite perturbation (FP) method[7] are also listed. It is to be noted here that the FP treatment which is equivalent to the coupled HF perturbation theory is the most accurate of the three different approaches, since in the FP approximation some doubly-excited states, in addition to the singly-excited states, can be included in the perturbed wave function.[8]

The LMO and σ-π results for CH coupling constants show a significant shift towards the FP results. Especially LMO values for CH_4 and C_2H_6 (saturated molecules) are in good agreement with the FP values. The Fermi

contributions calculated using the FP method are always larger than those obtained using the SOSP method. It has been suggested that the difference in the second-order properties calculated by the FP method and those by the SOSP method is essentially due to the fact that in the FP treatment one cannot introduce singly-excited states without introducing at the same time doubly-excited states in a restricted manner.[8] That is, if we take the Ψ_n to be singly-excited triplet states, ${}^3\Psi_{i\to a}$, for spin-dependent perturbations like the Fermi interaction, the approximate equation for C_{ia} in Eq. 1 is

$$C_{ia} = -\langle\Psi_0|H'|{}^3\Psi_{i\to a}\rangle/({}^3\Delta E_{i\to a}) \quad (3)$$

in the SOSP method. Here ${}^3\Delta E_{i\to a}$ is the triplet excitation energy. On the other hand, in the FP approximation, C_{ia} takes the first-order form

$$C_{ia} = -\langle\Psi_0|H'|{}^3\Psi_{i\to a}\rangle/({}^3\Delta E_{i\to a} - K_{ia}), \quad (4)$$

where the exchange integral K_{ia} comes from the doubly-excited configuration. Taking this into consideration, the reproduced trend in the CH coupling which is that the LMO-SOSP results are shifted from the CMO-SOSP results toward the FP values, would indicate that an LMO set gives a more rapid convergence of the perturbation expansion than a CMO set.

In CC couplings, σ-π constrained LMO results are also shifted towards the FP results, although the former exceed the latter in magnitude, while unconstrained LMO values are somewhat too large.

A comparison with the FP results indicates that better results would be obtained for C_2H_4 and C_2H_2 with σ-π constrained LMO than those obtained with banana-type LMO, although the latter agree well with the experimental results. In view of the energy localization criterion, the banana-type LMO are more localized than the σ-π constrained LMO. Nevertheless, maintaining the σ-π constraint and hence using less localized orbitals appears to be a better starting point of the perturbation expansion based on HF wave functions.

Next, let us examine the electronic origin of the coupling mechanisms. In the conventional perturbation theory with delocalized orbitals, the calculated result are determined by a very complicated cancellation of a number of large values and hence it is not easy to interpret the results. However, the LMO perturbation theory allows an easier qualitative interpretation of the results. As summarized in Table 2, the Fermi term for the CH couplings are determined by only one transition from the localized CH bonding orbital to the corresponding antibonding orbital. That is, the CH coupling can be expressed as a "local" contribution. The same is true for CC couplings. In the σ-π constrained LMO perturbation method, the transition from a localized CC bonding orbital to an antibonding orbital determines the Fermi term of the CC coupling. For the perturbation with banana-type orbitals, the transitions from banana-type CC bonding orbitals to the corresponding antibonding orbitals play an important role. Moreover, each contribution has the same sign, implying that there is no partial cancellation. Thus, the results can always be expressed as the sum of "local" contributions. Namely, the LMO perturbation results are useful for describing local properties and are of conceptual simplicity. This is an essential advantage in employing LMO perturbation theory. From this point of view, the σ-π constrained LMO appear to be more suitable than the unconstrained LMO.

Table 2. Contributions of "local" transitions to the Fermi term

Molecule		Local transitions[a]	Transition energy (eV)	Contribution of local transition (Hz)	Total Fermi term (Hz)
CH coupling					
CH_4	LMO	ω (2.67)[b] $\to\omega^*$ (3.38)	16.74	117.3	117.1

The C-Se Stretching Vibrations and Molecular Conformations of Dialkyl Selenides

Keiichi OHNO, Takeshi HIROKAWA, Seiro AONO, and Hiromu MURATA
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi Hiroshima 730
(Received September 16, 1976)

Synopsis. The Raman spectra of dialkyl selenides were measured in the liquid and solid states. The most intense Raman lines observed in the 500—700 cm^{-1} region were assigned to the C–Se stretching vibrations. Correlations of the C–Se stretching frequencies to the molecular conformations were found.

Recently, the rotational isomers about the C–Se bond have been confirmed in our laboratory to exist in ethyl methyl selenide and isopropyl methyl selenide.[1] For dialkyl disulfides[2] and dialkyl sulfides[3] of a homologous series, useful correlations of the C–S stretching frequencies to the molecular conformations about the C–C bonds adjacent to the C–S bond have been found, similar to the C–Cl stretching frequencies of alkyl chlorides.[4]

In the present note, therefore, we will study the C–Se stretching frequencies of dialkyl selenides in relation to their molecular conformations.

Results and Discussion

The Raman spectra of dimethyl selenide, ethyl methyl selenide, isopropyl methyl selenide, diethyl selenide, methyl propyl selenide, and *s*-butyl methyl selenide are measured in the liquid and solid states. For these selenides, the C–Se stretching vibrations are expected in the region of 600 cm^{-1} on the basis of the assignments of dimethyl selenide.[5] The most intense Raman lines assigned to the C–Se stretching vibrations are observed in the 500—700 cm^{-1} region; the other vibrations are not expected in this region. Figure 1 shows the liquid and solid spectra in this region, together with the results of the corresponding dialkyl sulfides.[6–8] Although only two Raman lines are expected for one isomer, too many Raman lines are observed in the liquid state for these selenides except for dimethyl selenide. Rotational isomers, therefore, coexist in the liquid state, and only one isomer persists in the solid state. For ethyl methyl selenide, isopropyl methyl selenide, and diethyl selenide, the patterns of the spectral changes from the liquid to the solid states are the same as those of the sulfides. It is estimated that the *gauche* (G) form for ethyl methyl selenide, the molecular form with the C_1 symmetry for isopropyl methyl selenide, and the TT form for diethyl selenide persist in the solid state, in analogy with the cases of the corresponding sulfides.[6–8] For methyl propyl selenide, the CH_3–Se stretching vibrations of all the isomers may be assigned to the Raman line at 591 cm^{-1}. The CH_3–Se stretching vibration is considered to be less affected by a residual part of a molecule, because the frequency difference between the C–Se stretching vibrations of dimethyl selenide (14 cm^{-1}) is considerably smaller than that of dimethyl sulfide (53 cm^{-1})[5] and for methyl propyl selenide the Raman intensity at 591 cm^{-1} is relatively strong, in comparison with that of methyl propyl sulfides.[9] For methyl propyl selenide, by analogy with the case of methyl propyl sulfide pre-

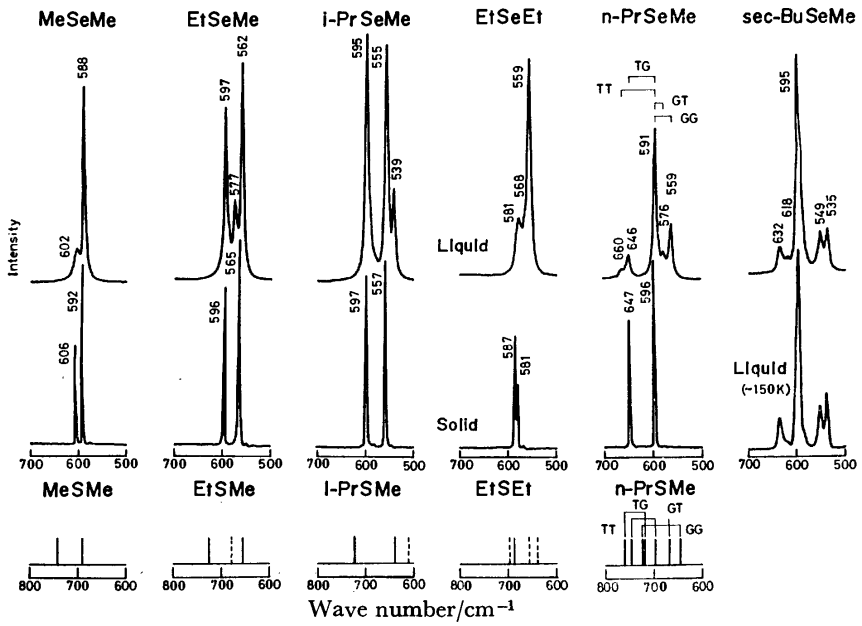

Fig. 1. The Raman spectra of the C–Se stretching vibrations of the dialkyl selenides in the liquid and solid states, together with the results of the dialkyl sulfides. Solid and dotted lines indicate the Raman lines persisting and disappearing in the solid state respectively.

Table 1. Characteristic C–Se stretching frequencies (cm^{-1}) of dialkyl selenides

Molecules	ν (CH_3–Se)	ν (–CH_2–Se)				ν (>CH–Se)				ν (>C–Se)
		P_H–P_H	P_H–P_C	P_C–P_H	P_C–P_C	S_{HH}–P_H	S_{HH}–P_C	S_{CH}–P_H	S_{CH}–P_C	T_{HHH}
CH_3SeCH_3	588*, 602*	—	—	—	—	—	—	—	—	—
$CH_3SeCH_2CH_3$	597*	562*	577	—	—	—	—	—	—	—
$(CH_3CH_2)_2Se$	—	559, 568	581*	—	—	—	—	—	—	—
$CH_3SeCH_2CH_2CH_3$	591*	559	576	646*	660	—	—	—	—	—
$CH_3SeCH(CH_3)_2$	595*	—	—	—	—	539	555*	—	—	—
$CH_3SeCH(CH_3)CH_2CH_3$	595	—	—	—	—	535	549	618	632	—
$((CH_3)_3C)_2Se$[12]	—	—	—	—	—	—	—	—	—	527
	588—602	559—581		646—660		535—555		618—632		527
Alkyl bromides[10]	611	557—617		635—649		529—588		608—617		506—524

viously investigated in detail,[9] it is estimated that the TG (-CH–CH–Se-) form persists in the solid state and that the TT, TG, GT, and GG forms coexist in the liquid state. At present, the solid spectrum of *s*-butyl methyl selenide is not obtained. However, the rotational isomers may coexist in the liquid state, since the changes in the Raman intensities are observed at different temperatures. The most intense Raman line at 595 cm^{-1} may be assigned to the CH_3–Se stretching vibrations of all the isomers, in a manner similar to that used for methyl propyl selenide.

Table 1 summarizes the observed frequencies of the Raman lines due to the C–Se stretching vibrations of the dialkyl selenides in the liquid state; asterisks indicate the Raman lines persisting in the solid state. The P_H, P_C, S_{HH}, S_{CH}, and T_{HHH} values in this table are the same as those used in previous papers.[2,4] For the notation of the molecular form, the first symbol refers to the internal rotation about the C–C bond adjacent to the C–Se bond, and the second symbol, to that about the C–Se bond. The frequency differences in the C–Se stretching vibrations caused by the conformation about the C–C bond adjacent to the C–Se bond (83—85 cm^{-1}) are larger than those caused by the conformation about the C–Se bond (14—22 cm^{-1}). On the other hand, for the C–S stretching vibrations, the frequency differences about the C–C bond have been reported to be 51—105 cm^{-1}, which are similar in magnitude to those in the case of the selenides; those about the C–S bond are 26—35 cm^{-1}, a little larger than those of the selenides.[2,3] The characteristic CH_3–Se stretching vibrations are observed in the 588—602 cm^{-1} region of dimethyl selenide. In the case of the primary selenides, the C–Se stretching vibrations due to the P_H and P_C forms about the C–C bond lie in the regions of 559—581 cm^{-1} and 646—660 cm^{-1} respectively. For the secondary selenides, the C–Se stretching vibrations due to the S_{HH} and S_{CH} forms about the C–C bond lie in the regions of 535—555 cm^{-1} and 618—632 cm^{-1} respectively. The observed frequencies for the dialkyl selenides, in general, correspond very well to the C–Br stretching frequencies of alkyl bromides,[10] much as in the case between dialkyl sulfides and alkyl chlorides.[3]

Experimental

The samples were prepared according to the methods previously reported[11] and were purified by fractional distillation. The resulting purities were estimated to be higher than 98%, as confirmed by gas-chromatographic analysis. All the boiling points are uncorrected. CH_3SeCH_3: bp 57 °C (reported bp[11] 56—57 °C); NMR (CCl_4): δ 1.93 (6H, s, Se ($C\underline{H}_3$)$_2$). $C_2H_5SeCH_3$: bp 85 °C; NMR (CCl_4): δ 1.37 (3H, t, J=7 Hz, $CH_2C\underline{H}_3$), 1.91 (3H, s, $SeC\underline{H}_3$), 2.48 (2H, q, J=7 Hz, $SeC\underline{H}_2$). $(C_2H_5)_2Se$: bp 108 °C (reported bp[11] 107—108 °C); NMR (CCl_4): δ 1.38 (6H, t, J=7 Hz, Se ($CH_2C\underline{H}_3$)$_2$), 2.52 (4H, q, J=7 Hz, Se ($C\underline{H}_2CH_3$)$_2$). *i*-$C_3H_7SeCH_3$: bp 103 °C; NMR (CCl_4): δ 1.40 (6H, d, J=7 Hz, $CH(C\underline{H}_3)_2$), 1.92 (3H, s, $SeC\underline{H}_3$), 2.96 (1H, quintet, J=7 Hz, $SeC\underline{H}$). $C_3H_7SeCH_3$: bp 113 °C; NMR (CCl_4): δ 0.99 (3H, t, J=7 Hz, $CH_2C\underline{H}_3$), 1.65 (2H, sex, J=7 Hz, $C\underline{H}_2CH_3$), 1.90 (3H, s, $SeC\underline{H}_3$), 2.46 (2H, t, J=7 Hz, $SeC\underline{H}_2$). *s*-$C_4H_9SeCH_3$: bp 128 °C; NMR (CCl_4): δ 0.97 (3H, t, J=7 Hz, $CH_2C\underline{H}_3$), 1.36 (3H, d, J=7 Hz, $CHC\underline{H}_3$), 1.57 (2H, quintet, J=7 Hz, $C\underline{H}_2CH_3$), 1.87 (3H, s, $SeC\underline{H}_3$), 2.75 (1H, sex, J=7 Hz, $SeC\underline{H}$).

The Raman spectra were recorded on a JEOL Raman Spectrometer (Model JRS-400D) with an argon-ion laser. For measurements of the solid spectra, samples in ampoules were held on a copper block cooled with liquid nitrogen in a vacuum.

The authors are grateful to Dr. Sachihico Imai of Hiroshima University for the NMR measurements.

Studies of Nitrogen-Phosphorus Compounds. XXVIII.[1] The Thermal Decomposition and Fireproofing Effect of Trimeric and Tetrameric Phosphorus Diamide Nitride

Etsuro KOBAYASHI and Tadao KANAYAMA

National Chemical Laboratory for Industry, Hon-machi, Shibuya-ku, Tokyo 151

(Received June 25, 1976)

Synopsis. The thermal decomposition of $N_3P_3(NH_2)_6 \cdot H_2O$ and $N_4P_4(NH_2)_8 \cdot H_2O$ and their fireproofing effects for cellulose have been investigated by means of DTA and TG. These compounds dehydrated at 113 and 124 °C and deammonated at 265 and 271 °C. The activation energies of the dehydration and deammonation were 27 and 42 kcal/mol in the trimer, and 37 and 40 kcal/mol in the tetramer. The cellulose impregnated with either of these compounds flamed up at lower temperatures than did the pure cellulose, but its carbonized product remakably resisted combustion.

The amidated derivatives of the lower polymers of phosphorus dichloride nitride have drawn interest as fireproof materials.[2,3] The present authors had prepared $N_3P_3(NH_2)_6$[4] and $N_4P_4(NH_2)_8$[5] and investigated their hydrolysis behaviors under various conditions.[5-7] In this study, the thermal decomposition of $N_3P_3(NH_2)_6 \cdot H_2O$ and $N_4P_4(NH_2)_8 \cdot H_2O$ was investigated by means of the differential thermal analysis (DTA) and thermogravimetric (TG) measurements; the incombustibility of the cellulose impregnated with either of these compounds was also examined and compared with that of the pure cellulose.

Experimental

$N_3P_3(NH_2)_6 \cdot H_2O$ and $N_4P_4(NH_2)_8 \cdot H_2O$ for the DTA and TG measurements were prepared by the procedures reported previously.[4,5] DTA and TG were performed simultaneously by the use of macro-type and micro-type thermal analysers. The conditions of the thermal analysis are indicated along with Figs. 1 and 3. The cellulose impregnated with $N_nP_n(NH_2)_{2n}$ (n=3,4) was formed as follows: a filter paper (Toyo Roshi Co., Ltd. No. 5B) was immersed in an aqueous solution of $N_nP_n(NH_2)_{2n}$ (n=3,4). It was drawn up, pressed, and dryed. The incombustibility was also examined by using the micro-thermal analyser.

Results and Discussion

The DTA and TG curves for trimeric and tetrameric phosphorus diamide nitride are shown in Fig. 1. In the DTA curve for $N_3P_3(NH_2)_6 \cdot H_2O$, endothermic peaks appeared at 113 and 265 °C: these seemed to be due to the dehydration of the water of crystallization and the deammonation from the amido-groups. In the DTA curve for $N_4P_4(NH_2)_8 \cdot H_2O$, two endothermic peaks also appeared. The height of the first peak was lower than that of the trimer variety, and was shifted to the higher temperature side. Therefore, it may be expected that the water of crystallization of the tetramer is bound more strongly than in the case of the trimer. On the other hand, the weight losses in two steps, which

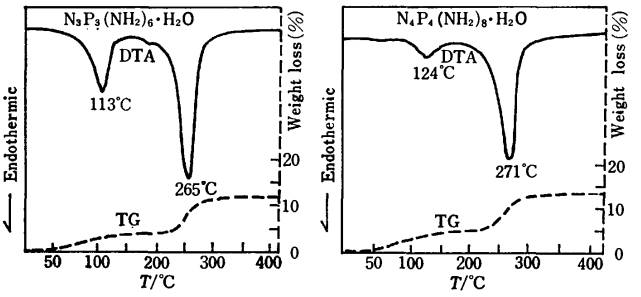

Fig. 1. DTA and TG curves for trimeric and tetrameric phosphorus diamide nitride.
Sample: 100 mg, heating rate: 5 °C/min, DTA: ±250 μV, current gas: N_2 gas 0.3 l/min.

proved the dehydration and deammonation, were recognizable on each TG curve. The activation energies in these reactions were calculated in accordance with Kissinger's method.[8] The peak temperatures (T_{max}) related to the reactions were measured at the heating rates (ϕ) of 5, 10, 20, and 40 °C/min. The activation energies, which were obtained from the relation between the reciprocal of the T_{max} and the log ϕ/T_{max}^2 shown in Fig. 2, were 27 and 37 kcal/mol for the dehydrations in $N_3P_3(NH_2)_6 \cdot H_2O$ and $N_4P_4(NH_2)_8 \cdot H_2O$, and 42 and 40 kcal/mol for their deammonations. It had already been known that the lower polymers of phosphorus diamide nitride decomposed at the elevated temperatures, and then were converted into phospham $(PN_2H)_n$.[4] In this study, it was confirmed by the use of the thermal analyser that a heating product of $N_nP_n(NH_2)_{2n} \cdot H_2O$ (n=3, 4) lost weight quickly at 800 °C, melted at about 900 °C, and immediately sublimed in nitrogen gas, although it burned in air.

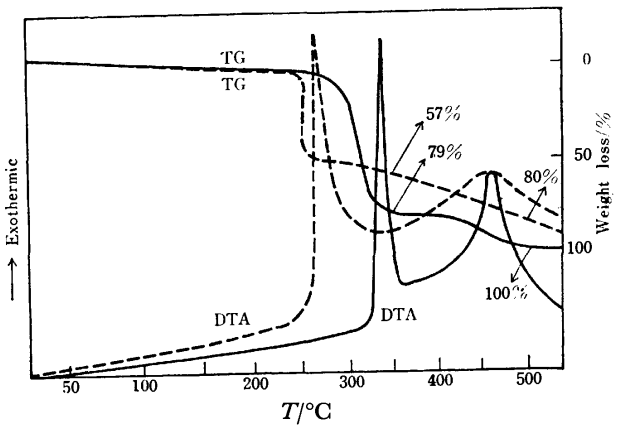

Fig. 3. DTA and TG curves for cellulose and cellulose including $N_4P_4(NH_2)_8$.
Sample: 20 mg, heating rate: 10 °C/min, DTA: ±100 μV, current gas: air 150 ml/min, ——: cellulose, – – –: cellulose impregnated with $N_4P_4(NH_2)_8$ (P: 2.9%).

The DTA and TG curves for the filter paper of pure cellulose and that treated with the aqueous solution of $N_4P_4(NH_2)_8$ are shown in Fig. 3. In the DTA curve for the pure cellulose, exothermic peaks appeared at 333 and 461 °C. The cellulose flamed up at the temperature of the first peak. The weight loss reached 79% at 350 °C, and a carbonized product was incinerated completely at 500 °C. In the DTA curve for the cellulose including $N_4P_4(NH_2)_8$, two exothermic peaks also appeared at 261 and 461 °C. The first peak shifted to the lower temperature side compared with that of the pure cellulose. In this case, the weight of the carbonized residue increased with the increase of the content of phosphorus in it. When the samples of cellulose including 2.0, 2.9, and 3.7% P were heated at 500 °C, the weight % of the residues were 11, 20, and 25%, respectively. The fireproofing effects of the trimer and tetramer varieties were almost the same. From the present results, it may be concluded that these compounds effectively retard the combustion of the cellulose.

The Formation and Properties of Solid Solutions in the $PbTiO_3$–$Pb(Ni_{1/2}W_{1/2})O_3$ System

Yasuyoshi Torii

Government Industrial Research Institute, Nagoya, Hirate-machi, Kita-ku, Nagoya 462

(Received July 5, 1976)

Synopsis. By usual and high-pressure techniques, a series of $PbTiO_3$–$Pb(Ni_{1/2}W_{1/2})O_3$ solid solution was formed with a perovskite structure. With an increase in the $Pb(Ni_{1/2}W_{1/2})O_3$ content, the Curie point shifted to lower temperatures and the degree of tetragonality decreased. The thermal-expansions were also measured, showing anomalies at the Curie point.

$PbTiO_3$ is a ferroelectric perovskite with a high Curie point of 490 °C.[1] However, its inability to produce dense $PbTiO_3$ ceramics and the relatively high conductivity of pure $PbTiO_3$ ceramics have restricted its usefulness.[2] On the other hand, $Pb(Ni_{1/2}W_{1/2})O_3$ has been synthesized only by high-pressure technique, and it has been suggested that it exhibits an antiferroelectric behavior.[3] The corresponding perovskites, $Pb(Mg_{1/2}W_{1/2})O_3$ and $Pb(Co_{1/2}W_{1/2})O_3$, have been prepared by usual solid-state reactions, and solid-solution series were formed over the whole composition range in the $PbTiO_3$–$Pb(Mg_{1/2}W_{1/2})O_3$ and $PbTiO_3$–$Pb(Co_{1/2}W_{1/2})O_3$ systems.[4,5] Much attention has been paid, from the physical and crystallographic points of view, to how solid solutions between $PbTiO_3$ and $Pb(Ni_{1/2}W_{1/2})O_3$ are formed. The present paper will report on the structural, dielectric, and thermal-expansion properties of this system.

Experimental

For the sample preparations, PbO, TiO_2, NiO, and WO_3 of high purities were used. Prefiring was done at 800 °C for 3 h in air. When the samples were then fired at temperatures of 850—1000 °C for 2 h, dense bodies were obtained. For samples which were not obtained as a single phase, high-pressure and high-temperature experiments (850 °C, 30 kb, 1 h) were made using a tetrahedral anvil apparatus. The sample was sealed by thin platinum foil to avoid contamination of the sample during the run. The sample container also served as a heating element. The room-temperature structure and the lattice constants of the samples were determined by the X-ray diffraction technique. The dielectric properties were measured on an universal bridge at 1 kHz. The thermal expansions of the sintered 0.7 cm-diameter specimen were measured with an automatic-plotting fused-quartz dilatometer.

Results and Discussion

In the $PbTiO_3$–$Pb(Ni_{1/2}W_{1/2})O_3$ system, tetragonal perovskite solid solutions were formed as a single phase up to the composition containing 50 mol% $Pb(Ni_{1/2}W_{1/2})O_3$, although $Pb(Ni_{1/2}W_{1/2})O_3$ was not synthesized by usual solid-state reaction. Superstructural lines were not observed in powder X-ray patterns. The lattice constants and the tetragonality $(c/a-1)$ are

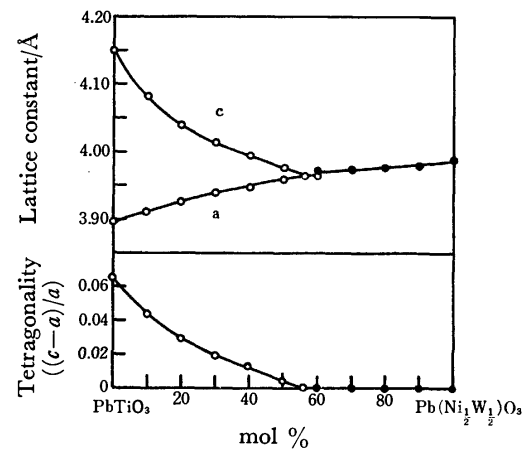

Fig. 1. Lattice constants and the tetragonality in the $PbTiO_3$–$Pb(Ni_{1/2}W_{1/2})O_3$ system.
○: sample obtained by usual solid state reaction.
●: sample obtained by high pressure reaction.

shown in Fig. 1. The tetragonality is continuously decreased by the substitution of the 1/2Ni+1/2W ions for the Ti ions. In a 60 mol% $Pb(Ni_{1/2}W_{1/2})O_3$ sample, other phases were observed to be formed in small amounts besides a cubic perovskite phase. The substitutional limitation of $Pb(Ni_{1/2}W_{1/2})O_3$ for $PbTiO_3$, as estimated from the dependence of the tetragonality on the composition, was *ca.* 56 mol%. In fact, a sample with this composition showed a single-phase pattern with the cubic perovskite structure, and its lattice constant was in good agreement with that in the sample with 60 mol% $Pb(Ni_{1/2}W_{1/2})O_3$. For samples contain-

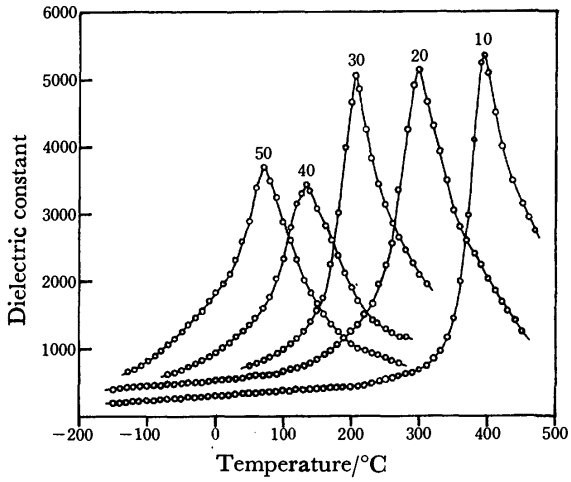

Fig. 2. Temperature dependence of dielectric constant in the $PbTiO_3$–$Pb(Ni_{1/2}W_{1/2})O_3$ system. Numbers on curves refer to $Pb(Ni_{1/2}W_{1/2})O_3$ content in mole percent.

ing more than 60 mol% $Pb(Ni_{1/2}W_{1/2})O_3$, a high-pressure technique was applied. Consequently, all the samples showed single-phase patterns of cubic perovskite. The lattice constant gradually increases with the increase in $Pb(Ni_{1/2}W_{1/2})O_3$, as is shown in Fig. 1. Superstructural lines indicating the NaCl-type ordering were observed for samples containing 70 mol% $Pb(Ni_{1/2}W_{1/2})O_3$.

Figure 2 shows the temperature dependence of the dielectric constant from −190 to 500 °C. High values of the dielectric constant are noticeable in these samples. A dielectric-constant peak characteristic of the ferroelectric substance was observed for each sample. With the increase in $Pb(Ni_{1/2}W_{1/2})O_3$, the sharp peak shifted to lower temperatures. This is attributed to the decrease in tetragonal distortion. The loss tangent for these samples was less than 0.05 below 200 °C and then rapidly increased with the temperature.

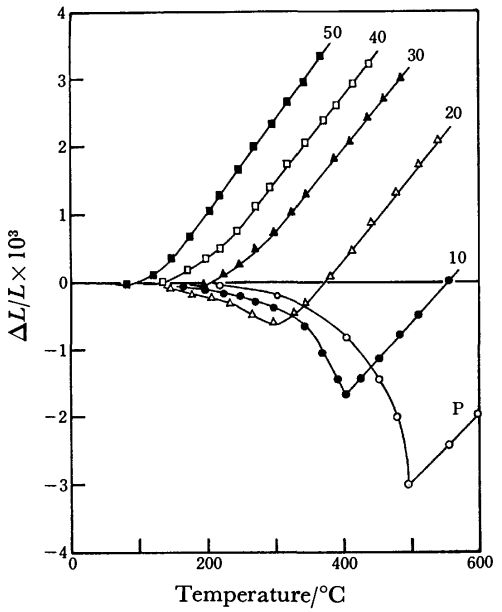

Fig. 3. Linear thermal-expansion curves in the $PbTiO_3$–$Pb(Ni_{1/2}W_{1/2})O_3$ system. Numbers on curves refer to $Pb(Ni_{1/2}W_{1/2})O_3$ content in mole percent and the symbol P means a sample of $PbTiO_3$ with 0.1 mol % CaF_2.

The thermal-expansion curves are shown in Fig. 3. Tien and Carlson have reported that $PbTiO_3$ with a 0.1 mol% addition of CaF_2 shows a net length expansion through a net length contraction at the Curie point.[6] Such a tendency appeared in these samples. With an increase in the $Pb(Ni_{1/2}W_{1/2})O_3$ content, the dilatometric anomaly also shifted to lower temperatures and the total quantity of contraction at the transition temperature became significantly lower. The phase-transition temperature obtained by dielectric and dilatometric measurements agree well. The linear thermal-expansion coefficients above the transition temperature were of the same order of magnitude, 10^{-5} per °C, for all the samples.

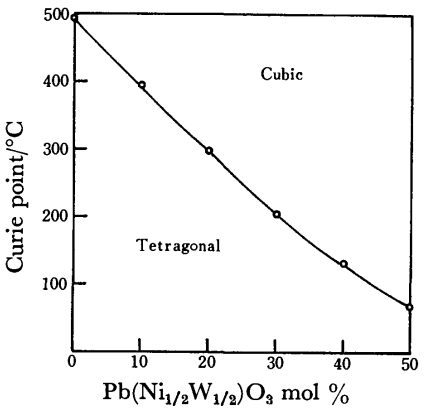

Fig. 4. Dependence of the Curie point on composition of $PbTiO_3$–$Pb(Ni_{1/2}W_{1/2})O_3$ solid solutions.

It may be concluded from these results that solid solutions containing less than 50 mol% $Pb(Ni_{1/2}W_{1/2})O_3$ are transformed from a tetragonal(ferroelectric) to a cubic(paraelectric) structure at the transition temperature. In this range of compositions, the arrangements of the cations in the octahedrally coordinated positions are at random, and the combination of Ni^{2+} and W^{6+} ions lowers the Curie point as is shown in Fig. 4. In samples containing more than 70 mol% $Pb(Ni_{1/2}W_{1/2})O_3$, the Ni^{2+} and W^{6+} ions show a partial ordering of the same type as in $Pb(Ni_{1/2}W_{1/2})O_3$.[3] With the increase in $Pb(Ni_{1/2}W_{1/2})O_3$, the intensities of the superstructural lines increase and the lattice expands. This expansion is probably due to an increase in the mean size of the cations occupying oxygen octahedra (according to Shannon *et al.*,[7,8] the ionic sizes of Ti^{4+}, Ni^{2+}, and W^{6+} ions being 0.605 Å, 0.69 Å, and 0.60 Å respectively). The dielectric anomaly would exist below room temperature, since perovskite solid solutions obtained by high-pressure technique are cubic at room temperature.

The structural and dielectric properties of this system have a tendency similar to those of the $PbTiO_3$–$Pb(Mg_{1/2}W_{1/2})O_3$ and $PbTiO_3$–$Pb(Co_{1/2}W_{1/2})O_3$ systems.[4,5]

Quantitative Analysis of Polybutadiene by Means of Pulse FT Carbon-13 NMR

Chizuko SHIBATA, Mitsuru YAMAZAKI,* and Tsugio TAKEUCHI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464
**Department of Medical Analysis, School of Pharmacy, Hokuriku University, Kanagawa-cho, Kanazawa 920-11*

(Received July 9, 1976)

Synopsis. ^{13}C NMR was applied to the determination of the vinyl content in polybutadiene by means of the internal standard method. Under optimum experimental conditions, it was found that ^{13}C NMR is applicable to the quantitative analysis of polymer by use of acetonitrile as an internal standard.

Experimental

^{13}C NMR spectra were obtained at 25.2 MHz on a Varian XL-100-15 spectrometer equipped with a VFT-100 Fourier Transform accessory. All the samples had natural isotopic abundance. Noise decoupling of the proton was achieved with a V-3508 decoupler modified to hold its frequency in a field to the frequency of the master crystal of the spectrometer. 1,2-addition polybutadiene and the blends of 1,2-addition polybutadiene and 1,4-*cis* polybutadiene were used as samples (supplied by Asahi Chemical Co., Ltd.). The sample temperature was maintained at about 37 °C. The samples were dissolved in $CDCl_3$ (analytical grade) for field/frequency in 12 mm tubes. TMS and acetonitrile were added to the polymer solution (1—6 wt%) as a chemical shift and an internal standard, respectively. Acetonitrile was selected as an internal standard from the fact that the peak height of methyl carbon of acetonitrile added is comparable to that of the carbon in question and the error in weighing acetonitrile is small. The optimum conditions for polymer analysis were determined by changing pules width, pulse delay and dynamic range, so as to get the best signal to noise ratio (s/n).

Results and Discussion

The peaks were assigned by comparison of the decoupled and coupled spectra.

In order to select the optimum conditions for analysis, first only the pulse width was changed to see the pulse width effect on s/n, the other conditions being kept constant. The results are shown in Fig. 1. s/n decreased rapidly above 130 μs pulse width where spins would flip over 90 degree. 100 μs was therefore taken as the appropriate pulse width.[2]

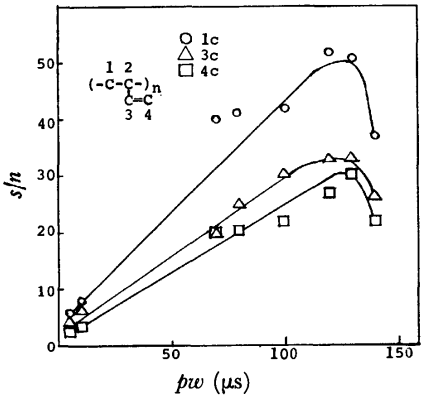

Fig. 1. Effect of pulse width on s/n.

The pulse delay effect on s/n measured is shown in Fig. 2. We see that a 2.4 s pulse delay is long enough to relax the methylene carbon in the main chain, but not the vinyl carbon. In this study, 2.4 s pulse delay was used for pulse delay.

The dynamic range effect on s/n is shown in Fig. 3. It was found that s/n has a maximum around 1 V/cm. This (1 V/cm) was used for dynamic range. The other conditions are follows: sweep width 5000 Hz, acquisition time 0.4 s, data points 4096. Three factors can be

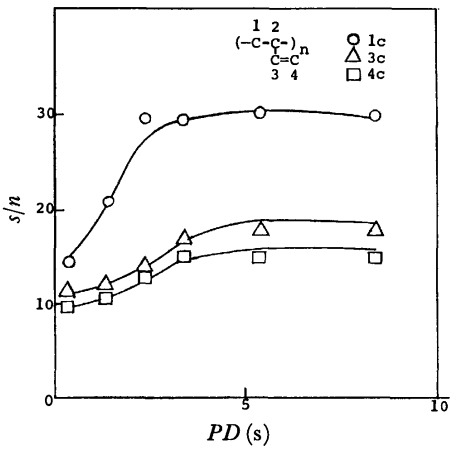

Fig. 2. Effect of pulse delay on s/n.

Table 1. Results of ^{13}C NMR method applied to 1,2-addition polybutadiene in blend

Vinyl content		Sample number 1	2	3	4
Calcd (%)		56.1	68.4	78.7	81.6
^{13}C NMR (%)	C_m	56.5	73.4	77.4	86.0
	C_v	55.4	74.6	77.4	94.0
Relative error (%)	C_m	0.71	7.31	1.65	5.39
	C_v	1.24	9.06	1.65	15.2

considered to effect ^{13}C signal intensity. They are relaxation time, Nuclear Overhauser Effect and polymer concentration. Relaxation time in the case of polymer is generally so short[3] that it can be neglected. The plots of intensity ratio (I_{C_1}/I_{CH_3CN} and I_{C_3}/I_{CH_3CN}) observed *vs.* polybutadiene weight are given in Fig. 4. By calculating the error statistically, standard deviations were found to be 0.10 except for the sample having the lowest concentration with standard deviation 0.15. The plots of the intensity ratio are linear. If the degree of NOE depends upon the polymer concentration, the relation (Fig. 4) would not be linear. It can be concluded that NOE is independent of polymer concentration at least in the range of the concentration examined. Since signal intensity is now known to depend upon only polymer concentration, quantitative analysis of polybutadiene can be expected.

Results of the determination of vinyl content in the physical blends between 1,2-addition polybutadiene and 1,4-*cis* polybutadiene are summarized in Table 1. Each sample is determined on the basis of two different relations, one obtained by the plots of intensity ratio $R_1(I_{C_1}/I_{CH_3CN}$, C_1; methylene carbon) and the other by the plots of $R_3(I_{C_3}/I_{CH_3CN}$, C_3; vinyl carbon) in Fig. 4. The result determined by means of methylene carbon is found to be applicable to quantitative analysis, but not that by means of vinyl carbon. This might be explained in terms of experimental conditions suitable for methylene carbon described under pulse delay conditions. It was confirmed that the internal standard method using acetonitrile is applicable to quantitative analysis by ^{13}C NMR under suitable conditions, since NOE is independent of polymer concentration.

Studies on Mixed Chelates. VIII. Mixed Copper(II) Chelates with *N,N'*- and *N,N*-Dialkylethylenediamines and Acetylacetone

Yutaka FUKUDA, Hiroko OKAMURA, and Kozo SONE

Department of Chemistry, Faculty of Science, Ochanomizu University, Otsuka, Tokyo 112

(Received August 20, 1976)

Synopsis. Mixed chelates [Cu(diamine)(acac)]X (diamine: *N,N'*- and *N,N*-dialkylethylenediamines) were studied. Two such chelates with diethyl ligands were obtained in crystalline state, while the formation of chelate cations $[Cu(diamine)(acac)]^+$ in 80% dioxane was studied with dimethyl ligands, and their formation constants estimated. The importance of steric effect in the bis-diamine chelates on the ease of formation of this type of chelate was pointed out.

The authors have studied the mixed chelates of the type [Cu(diamine)(acac)]X, with diamines such as 2,2'-bipyridine, 1,10-phenanthroline, and *N,N,N',N'*-tetramethyl- and tetraethylethylenediamines (bpy, phen, tmen and teen; acac=acetylacetonate ion)[1-4] and observed that (i) they are formed quite easily in appropriate organic solutions, *i.e.*, their formation constants are quite high; (ii) the ν_{max} values of their d-d band often do not obey the rule of Kida[5], which says that the ν_{max} of a mixed chelate CuAB is the mean of the values of its parent chelates CuA_2 and CuB_2; and (iii) the ν_{max} of the tmen and teen chelates are influenced strongly by the nature of the solvents used.

Extending these studies, the authors studied similar mixed chelates with *N,N'*-dimethyl, *N,N*-dimethyl-, *N,N'*-diethyl- and *N,N*-diethylethylenediamines (abbreviated as sym-dmen, unsym-dmen, sym-deen and unsym-deen, respectively).

Experimental

Preparation of the Chelates. [Cu(sym-deen)(acac)]ClO_4 and [Cu(unsym-deen)(acac)]ClO_4 are prepared as follows. $Cu(ClO_4)_2 \cdot 6H_2O$ (5 mmol) is dissolved in ethanol, and acetylacetone (5 mmol), Na_2CO_3 (2.5 mmol) and deen (5 mmol) are added successively. The crystals which separate out from the mixture are recrystallized from ethanol.

Physical Measurements. The methods and instruments used in this work were the same as those in the previous papers of this series.[1-4]

Results and Discussions

Crystalline Chelates. Although it was tried to prepare the chelates with all the four diamines, using several anions of low coordination power, it was found that many of such chelates are very hard to crystallize, and only the two in Table 1 could be obtained with sufficient purity, which are apparently very similar to the chelate [Cu(tmen)(acac)]ClO_4 studied before.

The values of ν_{max} in their electronic spectra (Table 2) show a strong solvent effect, which is comparable to that observed with [Cu(tmen)(acac)]ClO_4,[1,2] and that the unsym-deen chelate is a little more sensitive than the sym-deen chelate toward solvent change.

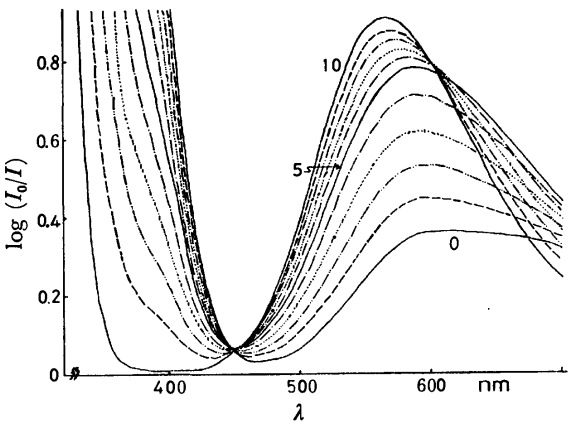

Fig. 1. Electronic spectra of the mixtures of [Cu(sym-dmen)$_2$](ClO_4)$_2$(CuA_2) and [Cu(acac)$_2$](CuB_2) in 80% dioxane at 18 °C. Total chelate concentration 0.91×10^{-2} M, cell thickness 1 cm. The ratio [CuA_2]: [CuB_2] in each sample is 10: 0 (Curve 10), 9: 1, 8: 2, 7: 3, 6: 4, 5: 5 (Curve 5), 4: 6, 3: 7, 2: 8, 1: 9, and 0: 10 (Curve 0).

TABLE 2. $\nu_{max}/10^3$ cm^{-1} AND ε_{max} (IN PARENTHESES) OF THE CHELATES IN VARIOUS SOLVENTS

No.	CH_3NO_2	$ClCH_2CH_2Cl$	CH_3CN	H_2O	80%-Dioxane	DMF	DMSO
I	18.18(87)	17.79(83)	17.12 (92)	16.69 (85)	16.69 (93)	16.56 (92)	16.37 (98)
II	18.28(95)	17.64(98)	17.09(106)	16.50(103)	16.47(108)	16.39(108)	16.05(117)

Stability Studies in Solution. The formation of the mixed chelates were also studied in solution. [Cu(sym-(or unsym-)dmen)$_2$](ClO$_4$)$_2$ and [Cu(acac)$_2$] were dissolved in 80% dioxane (v/v), and the method of continuous variation was applied to the visible spectra of their mixtures (Fig. 1). The plots clearly indicate the formation of 1 : 1 mixed chelates in solution, with formation constant $K([CuAB]^2/[CuA_2][CuB_2])$ estimated to be 500—600 at 18 °C. The same method applied to the system [Cu(sym-deen)$_2$](ClO$_4$)$_2$–[Cu(acac)$_2$] yielded similar results with a still higher value of K(*ca.* 2500 at 18 °C).

Although the accuracy of this estimation is not high,[6] comparison of these values with the K of [Cu(en)(acac)]$^+$ in 75% dioxane reported formerly by Kida (2.6)[5] clearly shows that K increases strongly with the increase in the bulkiness of the *N*-alkyl groups in the diamine.* Now the expression for K can be written as follows:

$$K = (k_{AB} \cdot k_{BA})/(k_{2A} \cdot k_{2B})$$

Here $k_{AB}=[CuAB]/[CuA][B]$, $k_{BA}=[CuAB]/[CuB][A]$, $k_{2A}=[CuA_2]/[CuA][A]$, and $k_{2B}=[CuB_2]/[CuB][B]$.

If A and B are identified with a diamine (en, dmen or deen) and acac, respectively, the data in the literature (*cf.* Table 3) show that k_{2A} decreases remarkably in going from en to dmen's and deen's (to *ca.* 1/150 and 1/3500 of the original value, respectively), owing to the increasing interligand repulsion in the bis-chelate. On the other hand, k_{2B} is naturally independent of A, and model study indicates that the interligand repulsion in CuAB will be nearly absent, so that the changes of k_{AB} and k_{BA} accompanying the change in A will be small. Thus it can be expected that the value of K is determined chiefly by $1/k_{2A}$, which increases about 150 and 3500 times in going from en to dmen's and deen's, respectively. The changes observed among the experimental values of K given above (*ca.* 200 and 1000 times) are not far from this expectation. These considerations thus give further support to the previously expressed view that the stability of the bpy-, phen- and tmen-containing mixed chelates is, to a large part, due to such an effect.[1]

Table 3. Values of k_2 for various diamines (25 °C, $I \rightarrow 0$)[7]

Diamine	k_{2A}	Diamine	k_{2A}
en	9.07	sym-deen	5.57
sym-dmen	6.94	unsym-deen	5.47
unsym-dmen	6.83		

It may be added that, if it is assumed that the spectra of the solutions containing the parent chelates in 1 : 1 ratio are very nearly those of the mixed chelates themselves (the fairly large K values support this view), their ν_{max} values satisfy Kida's rule approximately, indicating that the interligand repulsion in the bis-diamine chelates is not so strong to distort them remarkably from common tetragonal symmetry** (Table 4).

Table 4. $\nu_{max}/10^3$ cm^{-1} of the chelates [Cu(diamine)$_2$]$^{2+}$ and [Cu(diamine)-(acac)]$^+$ in 80% dioxane

Diamine	ν_{max} (bis-chelate)	ν_{max} (mixed chelate)
sym-dmen	17.61	16.98(16.87[a])
unsym-dmen	17.73	16.75(16.93)
sym-deen	17.24	16.69(16.69)
unsym-deen	17.04	16.50(16.59)

a) Values calculated with Kida's rule (ν_{max} for [Cu(acac)$_2$]: 16130 cm^{-1}) are in parentheses.

* K for [Cu(unsym-deen)(acac)]$^+$ could not be estimated with reasonable accuracy, possibly owing to the errors introduced by the smaller stability of [Cu(unsym-deen)$_2$]$^{2+}$ than those of the other bis-chelates. On the other hand, the values of K for the [Cu(diamine)(acac)]$^+$-type chelates with *N*-methyl- and *N*-ethylethylenediamines were found to be 9—10 (75% dioxane, 20 °C), lying between those of [Cu(en)(acac)]$^+$ and [Cu(dmen)(acac)]$^+$ (Y. Kuma, unpublished study).

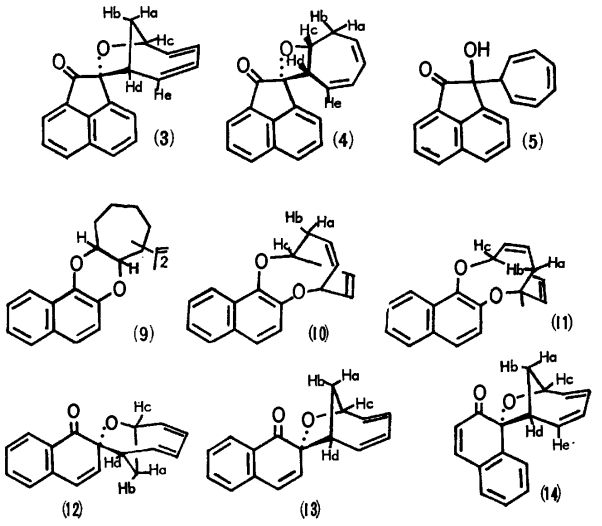
Synopsis. The photoaddition reaction of acenaphthenequinone and 1,2-naphthoquinone to cycloheptatriene was investigated. In contrast to acyclic α-diketones, various cycloadducts were formed from both quinones; the former giving the (2+2)π-, and (2+6)π-cycloadducts together with the ene-product, and the latter the (2+6)π-, (4+2)π-, and (4+4)π-cycloadducts.

A report was given on the results of the photoaddition reaction of cycloheptatriene (tropylidene, **1**) to some acyclic α-diketones.[2] The adduct solely isolated was found to be 7-tropyl-α-ketol derivative, an ene-product in every case. The absence of any cycloadducts is of interest. For comparison, we have examined the reaction of **1** to another type of 1,2-diketo derivatives, cyclic α-diketones.

Irradiation of a dioxane solution of acenaphthenequinone (**2**) and **1** by means of a 500 W tungsten lamp gave three products (**3**, **4**, and **5**) which were isolated by silica gel column chromatography. The first product (**3**, 18% yield) was shown to be a (6+2) π-adduct from the NMR[3] [δ: 2.69 (Ha, d, J=12.0 Hz), 2.96 (Hd, dd, J=7.6, 6.0 Hz), 3.61 (Hb, ddd, J=12.0, 8.0, 6.0 Hz), 4.90 (Hc, ddm, J=8.0, 6.0 Hz), 5.48 (He, dm, J=7.6 Hz), 6.00 (3H, m), and 7.85 (6H, m)] spectral analysis; the coupling patterns of the protons Ha, Hb, Hc and Hd ruled out other possibilitits. Furthermore, the appearance of an isolated signal due to He from the rest of the olefinic proton signals provided an evidence for its stereochemistry.[4]

The second product (**4**, 37%), colorless crystals, was a (2+2) π-adduct since the NMR [δ: 2.73 (Ha, ddm, J= 11.5, 4.5 Hz), 3.18 (Hb, tdm, J=11.5, 2.5 Hz), 4.14 (Hd, dt, J=8.0, 2.0 Hz), 5.31 (He, dd, J=11.5, 2.0 Hz), 5.57 (Hc, ddd, J=11.5, 8.0, 4.5 Hz), 5.6—6.1 (3H, m), and 7.6—8.1 (6H, m)] spectrum showed a signal ascribable to the proton of ethereal carbon (Hc), being spin-coupled to methylene protons (Ha and Hb) and also to Hd. The signal for He appearing in a higher field than for the rest of the protons is utilized to deduce the stereochemistry.



The third product (**5**, 38%), yellow crystals, was found to be the ene-product by the NMR [δ: 2.26 (1H, t, J=6.0 Hz), 5.01 (1H, dd, J=9.5, 6.0 Hz), 5.57 (1H, dd, J=9.5, 6.0 Hz), 6.17 (2H, m), 6.62 (2H, t, J=3.0 Hz), and 7.4—8.3 (6H, m)] spectrum.

When irradiation was carried out under aerial conditions, the products were formed in nearly the same ratio as above, although the main product in this case was 1,8-naphthalenedicarboxylic anhydride (31.3%).

These products must be formed independently, since **3** and **4** were quite stable for further irradiation, but **5** gradually decomposed into 7,7′-bitropyl (**6**),[5] 2-hydroxyacenaphthenenone (**7**),[6] and the starting material (**2**). A similar transformation has been observed in the irradiation of the ene-products derived from **1** and some benzil derivatives.[2] No interconversion of the products (**3**, **4**, and **5**) occurred.

1,2-Naphthoquinone (**8**) and **1** were similarly irradiated in benzene by use of a 500 W tungsten lamp, the products isolated after the column chromatography being a (4+2) π-adduct (**9**, colorless crystals), a pair of (4+4) π-isomers (**10** and **11**, pale yellow oils), a pair of (6+2) π-adducts (**12** and **13** yellow oils) and another (6+2) π-adduct (**14**, a yellow oil). No ene-product was detectable.

9, **10**, and **11** showed neither ν_{OH} nor $\nu_{C=O}$ in their IR spectra, indicating them to be cyclic ethers. The splitting patterns of the proton signals of sp^3-carbon in the NMR of **9** [δ: 2.74 (2H, m), 4.24 (1H, td, J=8.0, 4.6 Hz), 4.66 (1H, d, J=8.0 Hz), 5.95 (4H, m), 7.03 (1H, dd, J=8.0, 3.8 Hz), 7.28 (3H, m), 7.64 (1H, dd, J=8.0, 2.5 Hz), and 8.01 (1H, dd, J=8.0, 2.5 Hz)] was compatible to a (4+2) π-structure. **10** and **11** were stereoisomers which could be separated by high-pressure liquid chromatography. By catalytic reduction, they were converted into the same tetrahydro derivative (**15**) which differs from the tetrahydro derivative (**16**) of **9**. Thus, **10** and **11** were deduced to be the (4+4) π-adducts. Although the NMR spectra of **10** [δ: 2.55 (Ha, dm, J=16.0 Hz), 2.92 (Hb, dddd, J=16.0, 9.0, 3.0, 1.5 Hz), 4.63 (Hc, dt, J=9.0, 3.0 Hz), 4.81 (1H, br. s), 5.93 (4H, m), 6.94 (1H, d, J=9.5 Hz), 7.32 (3H, m), and 7.5—8.0 (2H, m)] and **11** [δ: 2.48 (Ha, dm, J=16.0 Hz), 2.83 (Hb, ddm, J=16.0, 8.0 Hz), 4.51 (Hc, dt, J=8.0, 3.0 Hz), 4.85 (1H, br. s), 5.88 (4H, m), 6.97 (1H, d, J=9.5 Hz), 7.28 (3H, m), and 7.5—8.1 (2H, m)] closely resembled each other, locations of the methylene group were tentatively assigned as depicted from the difference in chemical shifts of Ha, Hb, and Hc.

The NMR spectra of **12** and **13** were considerably different: **12** [δ: 2.53 (Ha, d, J=11.5 Hz), 2.71 (Hb, dt, J=11.5, 6.0 Hz), 2.88 (Hd, td, J=6.0, 1.5 Hz), 4.78 (Hc, tm, J=6.0 Hz), 5.40 (He, m), 5.84 (3H, m), 6.32 (2H, s), and 7.42 (4H, m)] revealed a high field shift for one of the olefinic protons (He); in contrast, **13** [δ: 2.35 (Ha, dt, J=12.0, 3.0 Hz), 2.96 (Hb and Hd, overlapped m), 4.86 (Hc, ddm, J=7.0, 6.5 Hz), 5.90 (4H, m), 6.50 (2H, s), and 7.40 (4H, m)] revealed combined signals for olefinic protons. The absence of α,β-unsaturated carbonyl group was also clear from the chemical shifts of the vinylic protons. Furthermore, the difference in chemical shift between each proton of methylene groups, $\delta_{Ha}-\delta_{Hb}$: 0.18 for **12**, and 0.61 for **13**, was interpreted in terms of the magnetic anisotropy of the carbonyl group on Hb. Thus, the stereochemistry for **12** and **13** was determined as depicted.

The structure of another type of (6+2) π-adduct (**14**) was also clarified from the NMR [δ: 2.41 (1H, d, J=12.0 Hz), 2.86 (1H, dt, J=12.0, 5.8 Hz), 3.24 (1H, dd, J=8.0, 5.8 Hz), 4.88 (1H, tm, J=6.0 Hz), 4.98 (He, tm, J=8.0 Hz), 5.7—6.2 (3H, m), 6.01 (1H, d, 10.0 Hz), 7.36 (1H, d, J=10.0 Hz), and 7.0—8.4 (4H, m)] spectrum. The presence of α,β-unsaturated carbonyl group in **14** is clear from the signals appearing at δ: 6.01 and 7.36. The isolated signal for He, revealing a high field shift, suggests the stereochemistry as depicted.

Formation of the (6+2) π-adducts resembles the mode of reaction of **1** with p-quinones. However, no cycloaddition took place at the C=C part of the quinones in contrast to the case with p-quinones. It is of interest that conjugated olefins, generally regarded to be good triplet quenchers, afforded various types of cycloadducts by irradiations with visible light.[1]

Experimental

*Photoaddition Reaction of Cycloheptatriene (**1**) with Acenaphthenequinone (**2**): Formation of the Cycloadducts (**3**, and **4**) and the Ene-Product (**5**).* A dioxane solution (30 ml) of **1** (2 ml) and **2** (220 mg) was externally irradiated by means of a 500 W tungsten lamp under nitrogen atmosphere for 18 h. After evaporation of the solvent, the residue was fractionated by silica gel column chromatography; **6** was obtained as colorless crystals from the least polar fractions, mp 61—63 °C (lit,[5] 61—62 °C), 17 mg. With the use of benzene as an eluent, three products were obtained consecutively. First, pale yellow crystals (**3**) were eluted, mp 123—125 °C (from ethanol), 23.2 mg [Found: C, 83.12; H, 5.17%. Calcd for $C_{19}H_{14}O_2$: C, 83.20; H, 5.15%. λ_{max}^{MeOH}: 225 nm (ε: 55600), 255.5 (sh., 13800), 308 (6600), 348 (4700)]. Then, colorless crystals (**4**), mp 163—164 °C (from methanol), 47.6 mg [Found: C, 82.91; H, 5.15%. λ_{max}^{MeOH}: 227 nm (ε: 29000), 285 (2700), 319 (2500), 347 (2200)], and pale yellow crystals (**5**), mp 146—147 °C (from methanol), 48.6 mg [Found: C, 83.29; H, 5.10%. λ_{max}^{MeOH}: 223 nm (ε: 47500), 256 (14700), 321 (5100), 345 (4700). ν: 3570, 1735 cm^{-1}] were obtained along with recovered **2** (134 mg).

*Photoaddition Reaction of **1** with **2** in the Presence of Oxygen.* A dioxane solution (16 ml) of **1** (0.5 ml) and **2** (464 mg) was irradiated with a tungsten lamp as above but under aerial conditions for 18.5 h. After evaporation of the solvent, the mixture was washed with a small amount of cold chloroform to recover unreacted **2** (278 mg) from the less soluble portion. Silica gel column chromatography of the soluble portion afforded **3** (38.2 mg), **4** (74.0 mg), colorless crystals, mp 274—275 °C (identified as 1,8-naphthalenedicarboxylic anhydride, 64.5 mg), and **5** (50.1 mg).

*Further Irradiation of **3** and **4**.* **3** (25 mg/3 ml of dioxane) and **4** (33 mg/4 ml of dioxane) were separately irradiated with a tungsten lamp for 9 h. No reaction took place according to the NMR analysis.

*Further Irradiation of **5**.* **5** (15 mg) was dissolved in benzene (10 ml) and irradiated with a tungsten lamp for 17 h. By preparative thin layer chromatography, regenerated **2** ($\approx$1 mg) and **7** ($\approx$1 mg, mp 236—238 °C (lit,[6] 238—239 °C)) were isolated together with **6** which was characterized by gas-liquid chromatographic analysis.

*Photoaddition Reaction of **1** and 1,2-Naphthoquinone (**8**): Formation of Cycloadducts (**9**, **10**, **11**, **12**, **13**, and **14**).* A benzene solution (25 ml) of **1** (1 ml) and **8** (780 mg) was irradiated by means of a 500 W tungsten lamp for 70 h. The product mixture was then separated by silica gel column chromatography. After elution of **6** (9 mg), **9** (colorless crystals, mp 93—94 °C from methanol, 113 mg) [Found: C, 81.29; H, 5.74%. Calcd for $C_{17}H_{14}O_2$: C, 81.58; H, 5.64%. λ_{max}^{MeOH}: 242 nm (ε: 38200)], an oily mixture of **10** and **11** (233 mg), **12** (a colorless oil, bp 120 °C/0.5 Torr (bath temp), 14 mg) [Found: m/e: 250.09509 (M^+). Calcd for $C_{17}H_{14}O_2$: m/e: 250.09938. λ_{max}^{MeOH}: 238 nm (ε: 24200), 275 (sh., 7100)]. **13** (a colorless oil, bp 120 °C/0.5 Torr (bath temp), 72.2 mg) [Found: m/e: 250.09987. λ_{max}^{MeOH}: 240 nm (ε: 40800), 275 (7290)], and **14** (a colorless oil, bp 120 °C/0.5 Torr (bath temp), 47.5 mg) [Found: m/e: 250.10205. λ_{max}^{MeOH}: 238 nm (ε: 14000)] were obtained by elution with benzene.

*Preparative Liquid Chromatographic Separation of a Mixture of **10** and **11**.* The mixture was fractionated by Micropolasil column (2 m) with chloroform: hexane (5: 95) using ALC 202/401 Model of Waters Co., from less polar fractions, a colorless oil (**10**) [Found: m/e: 250.09433. λ_{max}^{MeOH}: 220.5 nm (ε: 24600), 241.5 (38400)] was obtained and from more polar fractions a colorless oil (**11**) [Found: m/e: 250.10009. λ_{max}^{MeOH}: 219.5 nm (ε: 25500), 241.7 (43000)].

*Catalytic Reduction of **10**.* **10** (12 mg) was dissolved in ethyl acetate (2 ml) and reduced by palladium carbon (5%, 4 mg). After the usual work-up, a tetrahydro-derivative (**15**, 8 mg) was obtained as a colorless oil [Found: m/e=254.13292. Calcd for $C_{17}H_{18}O_2$: 254.13068.], whose homogeneity was confirmed by liquid chromatographic analysis.

*Catalytic Reduction of **11**.* Similarly, **11** (25.8 mg) was reduced to give a colorless oil (26 mg) which was identical with **15** in IR and liquid chromatographic comparison.

*Catalytic Reduction of **9**.* **9** (25.6 mg) was dissolved in ethanol (4 ml) and dioxane (1 ml) and reduced by palladium carbon (5%, 7.5 mg). Isolation by the usual work-up afforded colorless crystals, mp 120—121 °C (from methanol) (**16**), 17 mg [Found: C, 79.79; H, 7.18%. Calcd for $C_{17}H_{18}O_2$: C, 80.28; H, 7.13%].

Absolute Rate Constants for Hydrogen Abstraction from Some Aromatic Hydrocarbons by *p*-Chlorophenylthiyl Radical

Tokuji MIYASHITA, Masashi IINO, and Minoru MATSUDA
Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira, Sendai 980

(Received June 25, 1976)

Synopsis. The absolute rate constants for hydrogen abstraction from cumene, *p*-cymene, and tetralin by *p*-chlorophenylthiyl radical have been determined by means of flash-photolysis and kinetic absorption spectrophotometry. The results are discussed in comparison with those reported for other types of free radicals.

Thiyl radical can abstract hydrogen atom from hydrocarbons[1,2] containing reactive hydrogen atom and also from compounds containing functional groups such as aldehyde and alcohol.[1] However, few kinetic studies on these reactions have been carried out because of the difficulty of elimination of the reverse reaction under the usual steady state reaction conditions:

$$RS\cdot + R'H \underset{k_{-H}}{\overset{k_H}{\rightleftharpoons}} RSH + R'\cdot \qquad (1)$$

This difficulty has been overcome by using tritium-labeled thiol as a solvent[2] for obtaining the relative rate constants for hydrogen abstraction in the case of the cyclohexylthiyl radical.

We have determined the absolute rate constants for hydrogen abstraction from some hydrocarbons by *p*-chlorophenylthiyl radical by following the decay of a short-lived and a very small amount of the free thiyl radical by means of flash-photolysis and kinetic absorption spectrophotometry;[3] this can effectively eliminate such a reverse reaction. The flash apparatus delivered a flash with an energy of 125 J from xenon-filled lamps. The flash exhibited a half-peak duration of 10 μs.

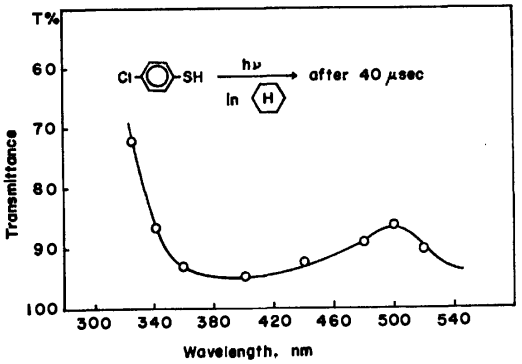

Fig. 1. Electronic spectrum of *p*-chlorophenylthiyl radical produced by flash photolysis of *p*-chlorophenylthiol.

Figure 1 shows the absorption spectrum of *p*-chlorophenylthiyl radical in cyclohexane recorded after 40 μs of the flash. The same spectrum has been reported by Thyrion,[4] and Tagami *et al.*[5] The decay of the *p*-chlorophenylthiyl radical has been followed by monitoring the absorbance at 500 nm. The behavior of the decay observed for *p*-chlorophenylthiyl radical in solutions can be divided into the following three patterns. (a) In cyclohexane and toluene solutions the thiyl radical decays according to second-order kinetics, indicating the occurrence of recombination of the thiyl radical in both the solvents:

$$2RS\cdot \xrightarrow{k_t} RS\text{-}SR \qquad (2)$$

Table 1. Decay kinetics of *p*-chlorophenylthiyl radical in various hydrocarbons (23 °C)

Solvent	Decay order	Rate constant (1 mol^{-1} s^{-1})
Cyclohexane	2 nd	$2k_t/\varepsilon = 4.1 \times 10^{6}$ [a]
		$2k_t = 1.4 \times 10^{9}$ [a]
Cyclohexane	2 nd	$2k_t/\varepsilon = 4.1 \times 10^{6}$
		$2k_t = 1.2 \times 10^{9}$ [b]
Toluene	2 nd	$2k_t/\varepsilon = 4.8 \times 10^{6}$
		$2k_t = 1.4 \times 10^{9}$ [b]
Ethylbenzene	2 nd—1 st	—
Tetralin	1 st	$k_H = 1.50 \times 10^{2}$
Cumene	1 st	$k_H = 1.20 \times 10^{3}$
p-Cymene	1 st	$k_H = 1.42 \times 10^{3}$

a) Ref. 4, the rate constant for the phenylthiyl radical. b) Calculated by using the reported ε[5] (280 dm^3/mol cm at 510 nm) for the *p*-chlorophenylthiyl radical.

The relevant second-order rate constants determined are given in Table 1. A similar recombination rate constant was reported for phenylthiyl radical in cyclohexane[4] (Table 1). (b) The decay in large excess of tetralin, cumene, and *p*-cymene, obeys pseudo first-order kinetics. (c) In the ethylbenzene solution, competitive reactions between the pseudo first-order reaction (hydrogen abstraction from the solvent, the forward reaction in Eq. 1) and recombination take place. The pseudo first-order rate constants were reduced to absolute second-order rate constants per reactive hydrogen atom. These results are also given in Table 1.

Ingold gave the absolute rate constants for hydrogen

Table 2. Absolute rate constants for hydrogen abstraction from cumene by short-lived radicals

Radical	Absolute rate constant k_H (1 mol^{-1} s^{-1})
OH·	Diffusion controlled[a]
Br·	1.2×10^{7} (40 °C)[a]
C_6H_5·	$\simeq 10^{7}$ (60 °C)[a]
t-C_4H_9O·	4.3×10^{4} (40 °C)[a]
p-ClC_6H_4S·	1.2×10^{3} (23 °C)[b]
Cl_3C·	1.3×10^{2} (40 °C)[a]
t-C_4H_9OO·	3.3×10^{-1} (30 °C)[a]
$-CH_2(C_6H_5)CH$·[c]	1.3×10^{-3} (60 °C)[a]

abstraction by a variety of radicals.[6] These absolute rate constants for α-hydrogen atom abstraction from cumene by various types of free radicals are summarized together with ours in Table 2. We see that the *p*-chlorophenylthiyl radical abstracts about 30 times faster than the trichloromethyl radical, and about 20 times slower than the *t*-butoxyl radical at 23 °C. Activation energies[6] of 6 kcal/mol and 12 kcal/mol, in the abstraction of *t*-butoxyl and trichloromethyl radicals, respectively, from toluene, were used in the calculation of the rate constants at 23 °C. Zwet and Kooyman reported that the triphenylmethylthiyl radical is more reactive in hydrogen abstraction reactions than the trichloromethyl radical, but less reactive than the *t*-butoxyl radical or chlorine atom.[8] Their findings agree with ours. The slightly greater reactivity toward *p*-cymene than cumene (Table 1) is reasonable in the light of electrophilicity of the thiyl radicals.[2,7]

The authors wish to thank Asst. Prof. Dr. H. Kokubun and Dr. K. Kikuchi, Tohoku University, for their introduction to flash photolysis technique and for the use of the apparatus.

Synthesis of New Heptacyclic Propellanes

Yoshito TOBE, Hirofumi OMURA, Atsutaka KUNAI, Koji KIMURA, and Yoshinobu ODAIRA

Department of Petroleum Chemistry, Faculty of Engineering, Osaka University, Suita-shi, Osaka 565

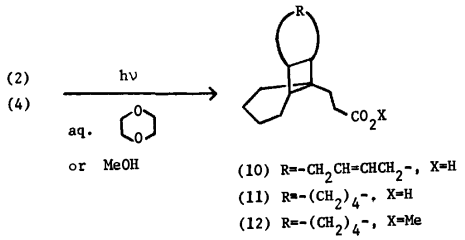
(Received June 28, 1976)

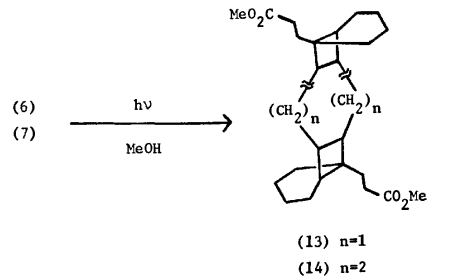
Synopsis. The heptacyclic propellanes, **8** and **9**, having two propellane rings in each molecule, were synthesized by the stepwise photocycloaddition of bicyclo[4.3.0]non-1(6)-en-7-one (**1**) to cyclohexadiene or cyclooctadiene followed by the Wolff-Kishner reduction of the resulting propellanones **6** and **7**. The photosolvolytic behavior of some of the cycloadducts is also described.

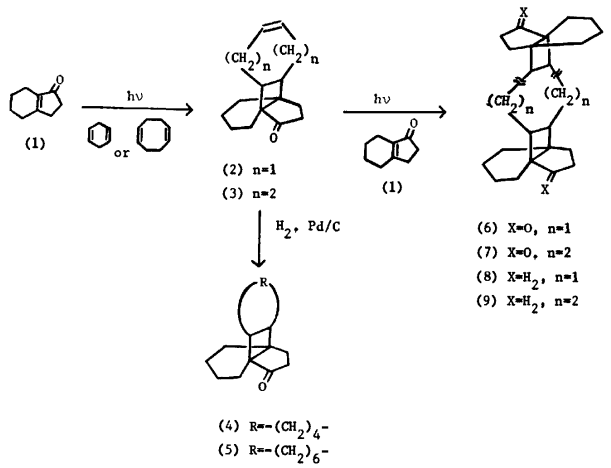
As part of a study of the synthesis of polycyclic propellanes,[1] we report that the tetracyclic *trans*-fused cycloadduct (**4** or **5**) was easily derived from the photocycloaddition of bicyclo[4.3.0]non-1(6)-en-7-one (**1**) to cyclohexene or cyclooctene.[2] The present investigation was undertaken to synthesize some new heptacyclic propellanes, having two propellane rings in each molecule, by a similar but stepwise photocycloaddition between the enone (**1**) and two kinds of alicyclic dienes.

First, **1** was irradiated in the presence of 10 molar excess of 1,4-cyclohexadiene or 1,5-cyclooctadiene through a Pyrex filter, until it was almost consumed, giving the sole cycloadduct, **2** or **3**, respectively in 74% or 80% yield. Catalytic hydrogenation of **2** and **3** over Pd/C led to the formation of **4** and **5**, respectively, compounds identical with the cycloadducts. The stereochemistry around the junction of the cyclobutane ring in the compounds **2**, **3**, and **4** has been determined to be *trans* by means of X-ray analysis.[3] Next, the cycloadduct (**2** or **3**) was irradiated with 4 molar excess of the enone (**1**), under similar conditions to those described above, to afford the heptacyclic cycloadduct, **6** or **7**, respectively in 25% or 31% yield. Thus, it seems reasonable to assume that the stereochemistry about the second cyclobutane ring in **6** and **7** is also *trans*, though the stereochemical relation between two bicyclo[4.3.0]-nonan-7-one skeltons in each molecule is still uncertain. Finally, the heptacyclic propellanes (**8** and **9**), having two propellane rings in each molecule, were obtained by the Wolff-Kishner reduction of the corresponding propellanones (**6** and **7**), in 37% and 56% yields, respectively.[4]

Photolyses of the propellanones **2**, **4**, **6**, and **7** were carried out, in an attempt to transform the cycloadducts of [4.3.2]propellane system into polycyclic compounds of another system. Photolyses of **2** and **4** in aqueous dioxane gave the acids, **10** and **11**, respectively, almost quantitatively. Irradiation of **4**, **6**, and **7** in methanol gave the esters **12**, **13**, and **14**, respectively.







Experimental

Bicyclo[4.3.0]non-1(6)-en-7-one(1). Enone (**1**) was prepared according to the procedure of Dev.[5]

Photocycloaddition of 1 with 1,4-Cyclohexadiene. A solution of **1** (0.800 g, 5.88 mmol) in 1,4-cyclohexadiene (59 mmol) was irradiated through a Pyrex filter under nitrogen at room temperature until enone (**1**) was almost comsumed. After removal of the diene, distillation gave 0.938 g of the cycloadduct (**2**) (74%), as the sole adduct (GLPC). Recrystallization from methanol gave an analytical sample, mp 80—81 °C; ν_{max} 1725, 660 cm^{-1}; δ (CCl_4) 0.60—2.65 (m, 18H), 6.55 (s, 2H); *m/e* 216 (M^+), 137; 2,4-dinitrophenylhydrazone, mp 174—175 °C; Found: C, 63.47; H, 6.03; N, 14.30%. Calcd for $C_{21}H_{24}O_4N_4$: C, 63.62; H, 6.10; N, 14.13%.

Photocycloaddition of 1 with 1,5-Cyclooctadiene. A solution of **1** (0.493 g, 3.62 mmol) in 1,5-cyclooctadiene (36 mmol) was irradiated and work-up as above gave 0.711 g of the cycloadduct (**3**) (80%), mp 88—89.5 °C; ν_{max} 1715, 725 cm^{-1}; δ (CCl_4) 0.60—1.75 (m, 14H), 1.90—2.50 (m, 8H), 6.40—6.65 (m, 2H); *m/e* 244 (M^+), 137; Found: C, 83.59; H, 9.95%. Calcd for $C_{17}H_{24}O$: C, 83.55; H, 9.90%.

Photocycloaddition of 1 with 2. A solution of **1** (2.825 g, 28.1 mmol) and **2** (1.355 g, 6.27 mmol) in 50 ml of pentane

was irradiated as above. After removal of the solvent, the residue was chromatographed on silica gel. The benzene eluate was collected and recrystallized from ethanol to give 0.55 g of the cycloadduct (**6**) (25% based on **2** used), mp 265—267 °C; ν_{max} 1720 cm^{-1}; δ (CCl_4) 0.60—2.40 (m, 28H), 2.40—2.70 (m, 4H); *m/e* 352 (M^+), 137; Found: C, 81.41; H, 9.05%. Calcd for $C_{24}H_{32}O_2$: C, 81.77; H, 9.15%.

*Photocycloaddition of **1** with **3**.* A solution of **1** (5.20 g, 38.2 mmol) and **3** (2.39 g, 9.80 mmol) in 50 ml of pentane was irradiated and work-up as above gave 1.15 g of the cycloadduct (**7**) (35% based on **3** used), mp 239—240 °C; ν_{max} 1715 cm^{-1}; δ ($CDCl_3$) 0.40—2.30 (m, 32H), 2.30—2.70 (m, 4H); *m/e* 380 (M^+), 137; Found: C, 81.79; H, 9.56%. Calcd for $C_{26}H_{36}O_2$: C, 82.06; H, 9.54%.

*Wolff-Kishner Reduction of **6** and **7**.* The Wolff-Kishner reduction of **6** and **7** was carried out according to the procedure of Huang-Minlon.[6] The products were isolated by vacuum distillation and purified by preparative GLPC. They showed no carbonyl absorption in infrared spectra. Reduction of **6** gave **8** (37%), mp 173—175 °C; δ (CCl_4) 0.70—2.30 (m): *m/e* 324 (M^+), 122; Found: C, 88.81; H, 11.43%. Calcd for $C_{24}H_{36}$: C, 88.82; H, 11.18%. Reduction of **7** gave **9** (56%), mp 132—134 °C; δ (CCl_4) 0.70—2.00 (m); *m/e* 352 (M^+), 122; Found: C, 88.16; H, 11.77%. Calcd for $C_{26}H_{40}$: C, 88.56; H, 11.44%.

*Photolysis of **2** and **4** in Aqueous Dioxane.* A solution of **2** or **4** in 90% aq dioxane irradiated in a quartz vessel until the ketone was almost consumed. After removal of the solvent, distillation gave the acid, **10** or **11**, respectively. Recrystallization from hexane gave an analytical sample. **10** (78%); mp 97—99 °C; ν_{max} 3050, 1700, 660 cm^{-1}; δ (CCl_4) 0.80—2.50 (m, 19H), 5.65 (s, 2H), 10.30—11.60 (broad s, 1H); *m/e* 234(M^+). **11** (84%); mp 100—101 °C; ν_{max} 3050, 1700 cm^{-1}; *m/e* 236 (M^+); Found: C, 76.10; H, 10.25%. Calcd for $C_{15}H_{24}O_2$: C, 76.22; H, 10.24%. Catalytic hydrogenation of **10** over Pd/C gave **11**.

*Photolysis of **4**, **6**, and **7** in Methanol.* A solution of **4** or **6** or **7** in methanol was irradiated as above. After removal of the solvent, the ester (**12**) was isolated by distillation, and esters (**13** and **14**) were isolated by column chromatograph on silica gel. **12** (86%); ν_{max} 1740 cm^{-1}; δ (CCl_4) 0.80—2.30 (m, 23H), 3.55 (s, 3H); *m/e* 250 (M^+); Found: C, 77.06; H, 10.75%. Calcd for $C_{16}H_{26}O_2$: C, 76.75; H, 10.74%. **13** (43%); mp 159—161 °C; ν_{max} 1730 cm^{-1}; δ (CCl_4) 0.90—2.40 (m, 34H), 3.60 (s, 6H); *m/e* 416 (M^+); Found: C, 74.81; H, 9.72%. Calcd for $C_{26}H_{40}O_4$: C, 74.96; H, 9.68%. **14** (35%); ν_{max} 1740 cm^{-1}; δ (CCl_4) 0.80—2.40 (m, 38H), 3.60 (s, 6H); *m/e* 444 (M^+).

We are grateful to Prof. N. Kasai and co-workers for the X-ray analysis.

A Convenient Two-Step Synthesis of Bis(polyalkylphenyl) Disulfides from Polyalkylbenzenes[1)]

Hitomi SUZUKI and Misao SHINODA*

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima 730

(Received June 30, 1976)

Synopsis. Heating of polyalkyliodobenzenes with copper(I) thiocyanate in phosphoric tris-dimethylamide at 180—190 °C for a short period of time gives the corresponding bis(polyalkylphenyl) disulfides in high yields.

Although the reaction of aryl halides with copper(I) thiocyanate was reported as early as in 1920 to yield a mixture of aryl cyanide, arenethiol, diaryl sulfide, and diaryl disulfide rather than the expected aryl thiocyanates,[2)] no attempts seem to have been made so far to extend the original work to synthetic purpose. This is probably due to the incomplete conversion coupled with the tedious work-up involved in the separation of the products.[3)]

We have found, however, that this reaction can be modified to provide a simple two-step method for the conversion of polyalkylbenzenes into the corresponding diaryl disulfides, which are otherwise less easy of access. Reported preparation of bis(polyalkylphenyl) disulfides is based on the mild oxidation of polyalkylbenzenethiols,[4)] the action of sulfur monochloride on polyalkylbenzenes,[5)] and the reaction of the diazonium compounds of polyalkylanilines with sodium polysulfide.[6)] Almost all these procedures, however, suffer from either difficulty of access to appropriate starting materials or the lack of generality.

A mixture of a polyalkyliodobenzene and copper(I) thiocyanate (mole ratio, *ca.* 1.0: 1.1) in phosphoric tris-dimethylamide was heated in an oil bath and kept at 180—190 °C for a short period of time until the mixture turned dark and homogeneous. After cooling, the thick mixture was diluted with water and the precipitate was filtered off and extracted with hexane or benzene, giving the corresponding diaryl disulfides in good yields. Neither the replacement of iodoarene by bromoarene nor the use of other dipolar aprotic solvents such as *N*-methyl-2-pyrrolidone and *N*,*N*-dimethylformamide gave better results.

This method of preparation of diaryl disulfides has certain advantages, complementing the existing methods for disulfide synthesis: 1) It is a two-step synthesis from hydrocarbon. Each operation is quite simple and overall process can be carried out in half a day. 2) Starting materials are easily available and reagents are cheap. 3) Products are pure and yields are good, although no attempts have yet been made to optimize them.

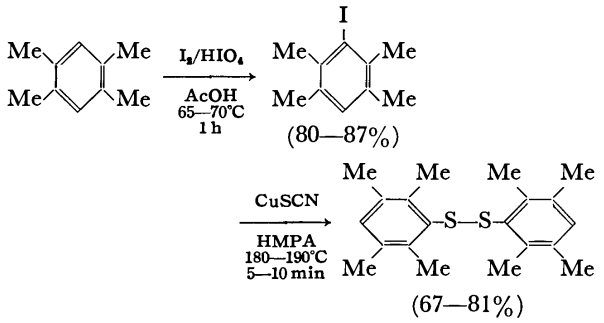
a) Based on the isolated product. b) Numerals in parentheses refer to the number of methyl groups.
c) Principal peaks in the region 650—1350 cm^{-1}.



Experimental

All melting points were determined on a hot stage and are uncorrected. The PMR spectra were recorded on a Varian T-60 spectrometer using deuteriochloroform solutions and TMS as internal standard. The IR spectra were measured in Nujol mulls with a Hitachi 215 spectrophotometer.

Iodoarenes were prepared by the direct iodination of arenes with iodine/periodic acid.[7] The structures of all the products were characterized by PMR and IR spectroscopy and elemental analysis. Physical properties and yields of some bis(polymethylphenyl) disulfides obtained are given in Table 1.

The general procedure is illustrated below with the preparation of *bis(2,3,4-trimethylphenyl) disulfide* from 4-iodo-1,2,3-trimethylbenzene:

A mixture of 4-iodo-1,2,3-trimethylbenzene (3.8 g), copper (I) thiocyanate (2.0 g), and phosphoric tris-dimethylamide (6 ml) was stirred and heated in an oil bath. At 180—190 °C the mixture rapidly turned dark and homogeneous. Heating was then stopped and the mixture was allowed to cool with stirring. The black viscous mixture was diluted with water and the precipitated solid was collected by filtration and washed thoroughly with water. It was sucked as dry as possible and then placed in a filter thimble and extracted with hexane with a Soxhlet extractor. The extract was evaporated and the residue was crystallized from ethanol to give bis(2,3,4-trimethylphenyl) disulfide as fine prisms, mp 127—129 °C. Yield, 2.12 g (91%).

Photochemical Ethoxycarbonylmethylation of Toluene with Ethyl Chloroacetate[1]

Yoshiro OGATA and Eiji HAYASHI

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received July 30, 1976)

Synopsis. UV irradiation of a toluene solution of ethyl chloroacetate under N_2 gave an isomeric mixture of ethyl tolylacetates: ortho, 5.2%, meta, 9.6%, para, 0.9% and a trace of diethyl succinate. The reaction under air increased the yields of all the products. Addition of $AlCl_3$ also increased the yields, especially that of ortho; *i. e.*; 17.9%; meta, 26.5%; para, 10.6%.

In the ordinary aromatic Friedel-Crafts reaction of carboxylic acids and esters, the site of electrophilic reagents is a carbonyl carbon atom because of the addition of $AlCl_3$ to carbonyl; thus the aromatic substitution by CH_2COOH or CH_2COOR is usually difficult and only a few reports are available on this sort of reaction.[2] However, UV irradiation can overcome this difficulty, the following examples being reported; ethoxycarbonylmethylation of benzene (PhH) giving $PhCH_2COOEt$[3] and carbamolymethylation of phenols (ArH) giving $ArCH_2CONH_2$.[4] The present note deals with the ethoxycarbonylmethylation of toluene with ethyl chloroacetate and a disccussion on its orientation.

Results and Discussion

Irradiation of 0.3 M ethyl chloroacetate solution in toluene under N_2 atmosphere for 40 h gave ethyl tolylacetates, the yields being ortho (I), 5.2%; meta (II), 9.6% and para (III), 0.9%. A trace of diethyl succinate (IV) and an unidentified product were also observed by GLC. Consumption of the chloroacetate was 25%.

$$\underset{\text{excess}}{C_6H_5CH_3} + ClCH_2CO_2Et \xrightarrow{h\nu}$$

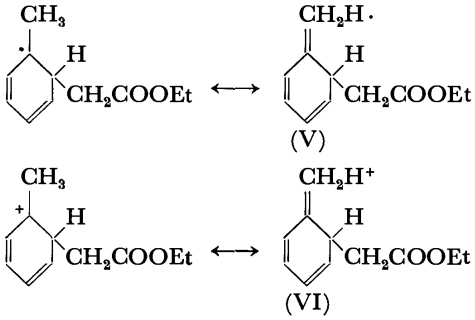
$$o\text{-}CH_3C_6H_4CH_2COOEt\ (\text{I}),\quad m\text{-}CH_3C_6H_4CH_2COOEt\ (\text{II})$$

$$p\text{-}CH_3C_6H_4CH_2COOEt\ (\text{III}),\quad \underset{\underset{CH_2COOEt}{|}}{CH_2COOEt}\ (\text{IV}),\quad \textit{etc.}$$

The same reaction under air gave higher yields; I, 16.5%; II, 18.8%; III, 13.8%; IV, 4.5%. Consumption of $ClCH_2COOEt$ was 35%. This effect of oxygen suggests the acceleration of the radical fission of $ClCH_2COOEt$ to Cl· and $\cdot CH_2COOEt$ radicals by Cl· atom abstraction by molecular oxygen or other radicals. This indicates that molecular oxygen itself and/or radicals derived from the photo-oxidation of organic materials can induce the radical abstraction of Cl atom as suggested from the alkyl-halogen fission of some alkyl halides[5] and from the behavior in the SO_2Cl_2 chlorination in the presence of these radicals.[6]

Addition of $AlCl_3$ (3.0 g) to the same mixture of $ClCH_2COOEt$ (5.5 g) and toluene (150 ml) under N_2 for 40 h increased the yields of tolylacetates, especially ortho and para: I, 17.9%; II, 26.5%; III, 10.6%; IV, trace, where 72% of $ClCH_2COOEt$ was photolyzed. Unidentified products in these cases seem to be the same one in view of its GLC peak. Hydrogen chloride was detected in all cases by silver nitrate test.

The yields with toluene were much higher than the reported yield with benzene affording $PhCH_2COOEt$ (2.5% without $AlCl_3$ and 11.5% with $AlCl_3$).[3] In a previous paper[3] it was postulated that the attacking species may be a radical $\cdot CH_2COOEt$ in the absence of $AlCl_3$ and a cation-like species $Al^{\delta-}Cl_3\cdots Cl\cdots C^{\delta+}H_2$-COOEt in the presence of $AlCl_3$ for this type of reaction. The observed effect of CH_3 may imply the stabilization of the transition state by hyperconjugation, which can delocalize both odd electron (V) and positive charge (VI).



However, the yield of III (para) is much lower, and the yield of II (meta) much higher than that expected from the hyperconjugation. This suggests the different charge distribution in the π-π^* singlet excited aromatics as evidenced in the H-D exchange reaction of aromatics,[7] which prefers ortho and meta substitution of radical and electrophilic reagents to para substitution; The negative charge is more localized at ortho and meta position to CH_3. The observed increase of contents of III and IV under oxygen can be explained in terms of the tendency to statistical orientation due to higher concentration of radical $\cdot CH_2COOEt$, while the increase of III by addition of $AlCl_3$ can be ascribed to the leveling of isomer distribution to the thermodynamic equilibrium in the presence of $AlCl_3$ as observed in ordinary Friedel-Crafts alkylation.[8]

Experimental

Materials. Ethyl *o*-, *m*- and *p*-tolylacetates were prepared by H_2SO_4-catalyzed esterification of the corresponding tolylacetic acids. Boiling points: *o*, 103—104 °C/5 Torr (lit,[9] bp 236—238 °C); *m*, 104—105 °C/6 Torr (lit,[9] bp 228—229 °C); *p*, 98—99 °C/4 Torr (lit,[9] bp 240 °C). Diethyl succinate, bp 104—105 °C/15 Torr (lit,[3] bp 108 °C/19 Torr). Commercial ethyl chloroacetate of guaranteed grade was

used, bp 52—53 °C/21 Torr.

A Typical Procedure. A mixture of ethyl chloroacetate (5.5 g) and toluene (150 ml) was irradiated with a 300 W high pressure Hg lamp in a quartz tube (3×30 cm) for 40 h at 20 °C. The tube and the lamp were immersed in a water bath at a distance of 5 cm.

Identification of the products was carried out by comparison of GLC peaks with those of the authentic samples. GLC analysis was carried out with a column (4 mm×1.2 m) packed with Apiezon Grease L (15 wt%) on Celite 545 of 80—100 mesh and a column (4 mm×1.5 m) packed with PEG (10 wt%) on Chromosorb WAN using N_2 as a carrier gas (40 ml/min) at 80—250 °C (8 °C/min). Ethyl acetate was used as an internal standard.

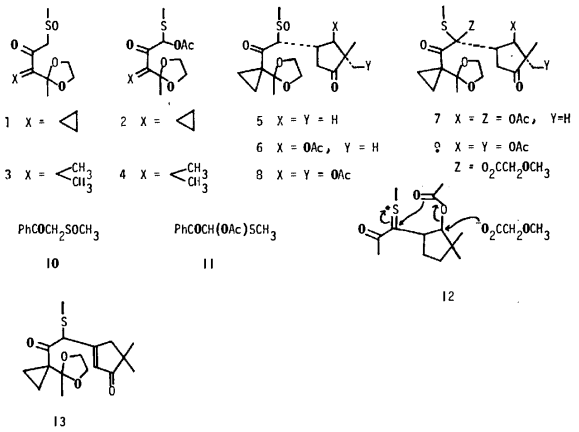
Synopsis. Pummerer reaction of highly functionalized sulfoxides were examined under various modified conditions. The results indicated that added base and/or neighboring acetoxyl group accelerated the reaction.

In the course of our synthetic work on illudins,[2)] we found a base catalyzed and a neighboring group participated acceleration of Pummerer reaction whose utility for organic synthesis increased recently.[3)]



According to the mechanism proposed by Oae and Kise,[4)] the acceleration of the reaction by base was expected and in fact effect of pyridine on simple sulfoxides was recently reported.[5)] In our work highly functionalized sulfoxides, **1**, **3**, **6**, and **8** smoothly underwent Pummerer reaction by addition of pyridine, while without pyridine they did not undergo the reaction under mild reaction conditions or gave no normal reaction products, which were key intermediates for our synthesis,[2)] even under more drastic conditions.

Another new observation is an acceleration of the reaction by neighboring group participation. The reaction with sulfoxides **5** and **6** showed clearly the effect of acetoxyl group on their cyclopentane rings. The mode of participation is not clear at present but migration of acetoxyl group through transition like **12** was excluded by the experiment employing methoxyacetic anhydride (**8**→**9**). The results were summarized in Table 1.

Further study revealed that the Pummerer reaction was markedly accelerated by the addition of mercuric chloride as shown in the Table 1.[6)]

Experimental

Sulfoxide (**10**) was obtained from ethyl benzoate according to Corey's procedure[11)]. Other sulfoxides were synthesized during our synthetic work and their physical and analytical data appeared in the references indicated.

NMR spectra were measured at 100 MHz on a JEOL Model JNM-4H-100 spectrometer using TMS as an internal standard. IR spectra were taken on a HITACHI Model EPI-G3 spectrometer with NaCl optics.

Acetic anhydride used in this work was purified by fractional distillation. Pyridine was dried over potassium hydroxide and distilled before use.

Pummerer Reaction without Pyridine. A mixture of 100 mg of sulfoxide and 2.8 ml of acetic anhydride was heated to reflux for 2 h. The mixture was concentrated in vacuo and the residue was dissolved in chloroform. The solution was washed with saturated sodium hydrogencarbonate solution and brine and dried over anhydrous sodium sulfate. Removal of the solvent gave a practically pure product,—**2**, **4**, and **11**.

The Reaction with Pyridine. A mixture of 100 mg of sulfoxide, 2.8 ml of acetic anhydride and 4.0 ml of pyridine was allowed to stand for 1 week at room temperature. The mixture was concentrated in vacuo at ambient temperature and the residue was stirred with water for 30 min and extracted three times with chloroform. The combined extracts were washed with sodium hydrogencarbonate solution and brine and dried over sodium sulfate. After removal of

a) Isolated yield (by column chromatography on silica gel). b) Based on NMR analysis. c) Methoxyacetic anhydride was used instead of Ac_2O. d) The reaction was completed in 2 days. e) The reaction was completed in 3 days. f) After 3 days. g) The starting sulfoxide remained in shorter reaction time (TLC analysis).

the solvent the product obtained was practically pure.—**2**, **4**, and **11**.

In the case of the reactions with **6** and **8** the product was purified by chromatography on silica gel.

In the reaction with sulfoxide **8** methoxyacetic anhydride was used instead of acetic anhydride and in this case the reaction was completed in 2 days. The reaction time was 3 days with **10**.

The Reaction with Mercuric Cholride. A mixture of 100 mg of sulfoxide, 2.8 ml of acetic anhydride and 180 mg of mercuric chloride was stirred at room temperature for 3 h. The mixture was then poured into large volume of water with vigorous stirring and extracted with chloroform. The extracts were washed with 2% aqueous EDTA solution and water and dried over sodium sulfate. Removal of the solvent gave a practically pure product.—**4** and **11**.

A pure sample of **2** was obtained through chromatography on silica gel.

The Direct Chlorination of Anthraquinone Oxime. The Regioselective Chlorination of Anthraquinone

Takehiko Ito, Koichi Sadakata, Yoshiaki Kindaichi, and Yasuo Takami
National Chemical Laboratory for Industry, Hon-machi, Shibuya-ku, Tokyo 151

(Received August 13, 1976)

Synopsis. The reaction of anthraquinone oxime with chlorine in the presence or absence of a catalyst was investigated. In concentrated sulfuric acid, the direct chlorination of anthraquinone oxime takes place easily at 100 °C. The chlorination occurs selectively in the β-position in the absence of a catalyst and in the α-position in the presence of palladium acetate.

Selective aromatic substitution is an important subject in organic synthetic chemistry. In the case of anthraquinone, there have been much investigations of selective sulfonation, whereas few investigations have been made of direct chlorination. It has been generally impossible to carry out the direct chlorination of anthraquinone selectively.[1,2]

In the present paper, we will report that the chlorination of anthraquinone proceeds selectively when anthraquinone is used as a form of its oxime, and that the chlorination occurs selectively in the α-position in the presence of palladium acetate and in the β-position in the absence of a catalyst.

Results and Discussion

The reaction of anthraquinone oxime with chlorine in sulfuric acid, followed by the hydrolysis of the product, led to the formation of chloroanthraquinones without any accompanying Beckmann-type rearrangement. Table 1 shows the results obtained from reactions in the presence of various kinds of catalysts. In experiments using palladium salt catalysts at 100 °C, with palladium acetate chlorination occurred predominantly in the α-position of anthraquinone, whereas with palladium sulfate in the β-position, and with palladium chloride the chlorination proceeded with a low selectivity. The activity of palladium sulfate and chloride was, probably because of their lower solubility in sulfuric acid, always lower than that of palladium acetate. In the reaction without a catalyst it is noteworthy that β-substitution was predominant. From this fact, it may be assumed that most of the β-substitution observed in the experiments with palladium sulfate and chloride occurred independently of the catalysts. Ferric chloride, which is known to be a useful catalyst for chlorination, was not effective in the present reactions. Iodine showed a catalytic activity, but the chlorination proceeded with a low selectivity.

a)—e) The symbols are the same as in Table 1. f) The same as in Table 2. g) The reaction was carried out without a catalyst for 6 hours, and then 0.20 g of palladium acetate was added to the reaction mixture and the reaction was continued for a further 4 h.

More detailed research was done in order to elucidate the difference between reactions in the presence of palladium acetate and in the absence of a catalyst. Table 2 shows the results of the chlorination using palladium acetate as the catalyst. As is clear from the comparison of the results of Run No. 6 with those o No. 8, the α-selectivity of the chlorination of anthraquinone oxime is much higher than that of the chlorination of free anthraquinone. The chlorination of the oxime, as may be seen from the results of No. 2, tends to stop at the stage of monochlorination to give 1-chloroanthraquinone with a high selectivity, and this greatly differs from the chlorination of free anthraquinone.[3] As to the effect of the temperature, the selectivity for α-substitution decreases with the rise in the reaction temperature. Anthraquinone dioxime (No. 7) shows a similar selectivity for α-substitution, although the reactivity of the dioxime is lower than that of the monoxime.

It is well known that palladium coordinates with nitrogen more strongly than with oxygen.[4] In the reaction with palladium acetate, it seems reasonable, therefore, to think that palladium interacts with the nitrogen of the oxime and, because of this interaction, chlorination occurs selectively in the α-position neighboring the C=N-OH group.

The results of the chlorination in the absence of a catalyst are shown in Table 3. In the reaction of anthraquinone monoxime and chlorine without a catalyst at 100 °C chlorination occurred predominantly in the β-position; this is in contrast to the reaction with palladium acetate and the reaction of free anthraquinone without a catalyst (No. 17). As for the dioxime, chlorination occurred exclusively in the β-position at 100 °C, and a similar result was obtained even at 150 °C. In the reaction of the monoxime at 150 °C, however, an increase in α-chlorinated products was observed. The α-chlorination in this case, in view of the results described above, seems to have occurred at the opposite side of the C=N-OH group.

In the experiment of Run No. 16, β-chlorination was at first carried out in the absence of a catalyst, and then α-chlorination was carried out in the presence of palladium acetate. As a result, the formation of a comparatively great amount of 1,7-dichloroanthraquinone was observed. This result seems to suggest that the β-chlorination in the absence of a catalyst tends to occur on the same side of the C=N-OH group. Although the mechanism in which the chlorination of anthraquinone oxime in the absence of a catalyst occurs selectively in the β-position is not clear at present, the contribution of the *meta*-orientation of $=N^+-$ formed in the C=N-OH group in sulfuric acid seems to be possible.

Experimental

Anthraquinone mono and dioxime were prepared according to the methods described in the literature.[5,6] Reagent-grade concd sulfuric acid (95%) was used without further treatment. The products were analyzed by means of high-speed liquid chromatography in a manner similar to that described in a preceding paper:[2] column, Zorbax-Sil 25 cm; eluent, pentane (containing 0.02% MeOH); flow rate, 100 ml/h, (90 kg/cm²); temperature, 20 °C; detector, UV-254 nm.

Chlorination of Anthraquinone Oxime. Anthraquinone monoxime (1 g, 4.48 mmol) was dissolved in 5 ml of concd sulfuric acid, and then 0.20 g of palladium acetate was added, the mixture was thereafter heated for two hours at 100 °C with stirring under a flow of chlorine (10 ml/min). The reaction mixture was then poured into ice water and filtered. The precipitate was treated with a mixture of 7 ml of concd hydrochloric acid and 10 ml of formalin for 5 h on a water bath in order to hydrolyze the oxime. The mixture was filtered, and the residue was washed repeatedly with water and dried at 100 °C. The product was passed through a short active alumina column, using dichloromethane as the eluent, in order to separate the undecomposed oxime and by-products. A part of the product was analyzed by HLC.

Reactions of Perfluoro-2,5-dimethyl-3,4-hexanedione with Amines

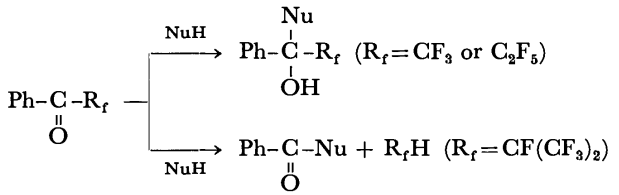
Seiji SHIN-YA and Nobuo ISHIKAWA

Department of Chemical Technology, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received August 23, 1976)

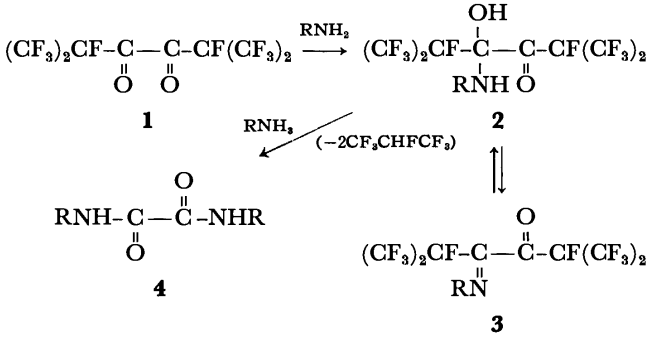
Synopsis. Perfluoro-2,5-dimethyl-3,4-hexanedione and aromatic or aliphatic amines gave the respective 1: 1 adducts in good yields. With excess amounts of aliphatic amines or basic aromatic amines such as *p*-anisidine, the perfluorodiketone gave oxamides. With *o*-phenylenediamine, it gave 2,3-dihydroxyquinoxaline.

In an earlier communication,[1] we reported on the nucleophilic reactions of heptafluoro-1-methylethyl phenyl ketone, which resulted in the formation of benzoic acid derivatives and heptafluoropropane. This made a contrast to trifluoromethyl and pentafluoroethyl phenyl ketones, which are known to form 1: 1 adducts with nucleophiles.



The above fact reveals the enhanced leaving ability of the heptafluoro-1-methylethyl group. This characteristic is presumably ascribable to the high stability of the heptafluoro-1-methylethanide anion as a leaving group and to the bulkiness of that group as a substituent. In this paper we wish to report on similar reactions of perfluoro-2,5-dimethyl-3,4-hexanedione, **1**, an α-diketone carrying two heptafluoro-1-methylethyl groups on both sides.

The reaction of **1** with an equimolar amount of aniline in diethyl ether easily gave a 1: 1 adduct, **2** (R=Ph). When a solution of this adduct in chloroform was heated, a dehydrated product, an imine, **3**, was formed; this substance is, however, very hygroscopic and is readily reconverted into **2**.



Other aromatic amines, such as *p*-toluidine, *p*-chloroaniline, *p*-anisidine, and α-naphthylamine, as well as aliphatic amines, such as butylamine and benzylamine, all gave the corresponding 1: 1 adducts (Table 1).

Whereas perfluorobiacetyl is known to form both 1: 1 and 2: 1 adducts with nucleophiles,[2] **1** did not give a 2: 1 adduct even when an excess of aniline was used. With more basic aromatic amines, however, it gave oxamides, **4**, by releasing two molecules of heptafluoropropane. For example, when 3.3 equivalents of *p*-anisidine were allowed to react with **1** at room temperature for 48 h, *N*,*N*′-bis(*p*-methoxyphenyl)oxamide was obtained quantitatively.

While neither bis(heptafluoro-1-methylethyl) ketone[3] nor heptafluoro-1-methylethyl phenyl ketone[1] forms an addition product such as hydrate or hemiacetal, probably because of their steric effect, **1** is enough released from that effect, as is shown above. The addition of the additional molecule of the amines to the carbonyl group

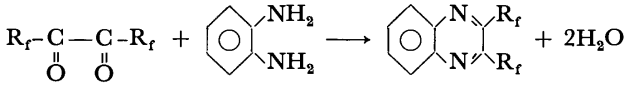
of **2**, however, brought about C–C bond cleavage to afford oxamides. Naturally, aliphatic amines, such as methyl, butyl and benzylamines, reacted much faster than aromatic amines, and when an excess amount was used, they gave oxamides directly (Table 2).

Table 2. Preparation of oxamides, **4**

RNH_2	Mole ratio of RNH_2/1	Time (h)	Yield[a] (%)	Mp (°C)
p-$MeOC_6H_4NH_2$	3.3	48	100	256—257
$MeNH_2$	large excess[b]	2	86	215—217
n-$BuNH_2$	2.2	2	84	152—154
$PhCH_2NH_2$	2.2	2	100	220—221

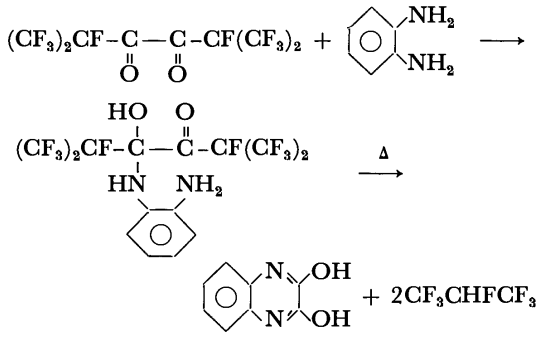
a) All the products were identified with authentic compounds by a comparison of the mps and IR spectra. b) Methylamine gas was bubbled into an ethereal solution of **1**.

A similar reactivity of the perfluoro diketone **1** was also observed in the cyclization reaction with *o*-phenylenediamine. Perfluorobiacetyl[2] and perfluorooctane-4,5-dione[4] are known to react with *o*-phenylenediamine to give 2,3-bis(perfluoroalkyl)quinoxalines.



$R_f = CF_3$ or *n*-C_3F_7

In contrast to these diones, we found that the reaction between **1** and *o*-phenylenediamine provides a 1 : 1 adduct, which is then converted into 2,3-dihydroxyquinoxaline by heating in a solvent.



This result indicates again the leaving ability of the heptafluoro-1-methylethyl group as an anion, characterizing the reaction mode of heptafluoro-1-methylethyl ketones.

Experimental

Perfluoro-2,5-dimethyl-3,4-hexanedione (1). This compound was prepared by a modification of the method of Smith *et al.*[3] They made hexafluoropropene to react directly with oxalyl difluoride, which had been prepared from oxalyl dichloride. The difluoride, however, is a poisonous gas and can not be handled safely. Therefore, we used oxalyl dichloride as the starting material and made the difluoride generate *in situ*. Oxalyl dichloride (7.4 g, 58.3 mmol), finely ground dry potassium fluoride (33.8 g, 583 mmol), and acetonitrile (60 ml) were put into a glass tube vessel equipped with a mechanical stirrer. Liquefied hexafluoropropene (175 mmol) was added to the vessel at −70 °C. After having been sealed, the vessel was brought to room temperature. The whole was then heated for 9 h under mechanical stirring in an oil bath kept at 75—80 °C. Thereafter, the lower layer of the reaction contents was separated and subjected to distillation to give **1** (6.0 g, 26%) (bp 91—93 °C) and bis(perfluoro-1-methylethyl) ketone (4.3 g, 20%) (bp 72—73 °C).

Reaction of the Perfluoro Diketone 1 with Aniline. A solution of aniline (0.12 g, 1.3 mmol) in diethyl ether (1 ml) was added, drop by drop, to the diketone **1** (0.5 g, 1.3 mmol) at 0 °C. After 3 h of stirring at room temperature, the crystals which had come out were collected, giving the 1 : 1 adduct **2** (R=Ph) (0.57 g, 93%). Recrystallization from chloroform afforded the pure material (mp 133—134 °C). Reactions with other aromatic amines were carried out in similar manners.

Reaction of 1 with Excess Butylamine. A solution of butylamine (0.16 g, 2.2 mmol) in diethyl ether (4 ml) was added, drop by drop, to perfluoro diketone **1** (0.4 g, 1.0 mmol) at 0 °C. After 2 h of stirring at room temperature, the separated crystals were collected to give *N,N'*-dibutyloxamide (0.17 g, 85%), **4** (R=*n*-Bu). Reactions with other amines to give oxamides, **4**, were carried out in similar manners. The products thus obtained were identified with the authentic samples by a comparison of the melting points and IR spectra.

Reaction of 1 with o-Phenylenediamine. A solution of *o*-phenylenediamine (0.076 g, 0.7 mmol) in acetonitrile (0.5 ml) was added to perfluoro diketone **1** (0.25 g, 0.64 mmol) at 0 °C. After 30 min of stirring at room temperature, it was filtered to give a 1 : 1 adduct (0.27 g, 85%) (mp >300 °C). IR: 3400—3500 (OH), 3350, 3300 (NH), 1705 (C=O) cm^{-1}.

A solution of the 1 : 1 adduct in ethanol was refluxed for 1 h, and the separated crystals were collected to give 2,3-dihydroxyquinoxaline (mp >300 °C), in an 84% yield. This product was identified with an authentic sample by means of its IR spectrum.

(Received April 27, 1976)

Solvent effects upon fluorescence quantum yields, fluorescence rise and/or decay curves of p-$(CH_3)_2NC_6H_4$-$(CH_2)_n$-(9-anthryl) (n=1, 2, 3) and p-$(CH_3)_2NC_6H_4$-$(CH_2)_n$-(1-pyrenyl) (n=1, 2, 3) have been investigated in detail. It is concluded that the sandwich structure is not necessary for the intramolecular charge transfer in polar solvents and that the mechanism of intramolecular heteroexcimer formation in polar solvents is different from that in nonpolar solvents.

Studies on the structures and dynamic behavior of electron donor–acceptor systems in excited states are important for understanding primary processes of photochemical reactions. We have examined the intramolecular exciplex (heteroexcimer and excimer) systems in order to clarify the electronic structures and mechanisms of the dynamic behavior of exciplex systems, such as fluorescence quenching due to the electron transfer reaction as well as the fluorescent exciplex formation. In a previous paper,[1] solvent shifts of the fluorescence bands and an analysis of results by a theoretical method were reported for the following intramolecular heteroexcimer systems: p-$(CH_3)_2NC_6H_4$-$(CH_2)_n$-(1-pyrenyl) (n=1, 2, 3, abbreviated as P_n) and p-$(CH_3)_2NC_6H_4$-$(CH_2)_n$-(9-anthryl) (n=1, 2, 3, abbreviated as A_n).

We have measured the solvent effects upon fluorescence quantum yields as well as fluorescence rise and/or decay curves of these compounds. From the results the mechanisms of intramolecular charge transfer and the fluorescent heteroexcimer formation will be discussed in the following.

Experimental

Absorption spectra were measured with a Cary 15 spectrophotometer. Fluorescence quantum spectra were measured with an Aminco-Bowman spectrophotofluorometer calibrated by using a standard tungsten lamp. The fluorescence rise and decay curves as well as the time resolved fluorescence spectra were observed on an apparatus consisting of a Bausch & Lomb high intensity monochromator, 1P28 photomultiplier, Tektronix 661 sampling oscilloscope, and a pulsed nitrogen gas laser of *ca.* 1 kW peak power.

The preparation of A_n and P_n will be reported elsewhere. Spectrograde hexane, decalin, dibutyl ether, tetrahydrofuran (THF), 2-propanol, acetone, and acetonitrile were used without further purification. Butylacetate and isobutyl alcohol (chromatographic reagents) were used without purification. GR-grade diethyl ether and methanol were used without further purification. 1-Pentanol was dried over calcium oxide and distilled. Butyronitrile was dried over calcium hydride and distilled carefully with phosphorus pentoxide. All solutions were deaerated by freeze-pump-thaw cycles. For the measurement of temperature effects upon the fluorescence rise and decay curves and the time resolved fluorescence spectra as well as the steady state fluorescence spectra, the temperature of a solution in a cuvette placed in a metal dewar with quartz windows was controlled by a constant flow of cold nitrogen gas. The temperature of the sample was measured with a thermocouple placed in the sample tube.

Results and Discussion

A. Solvent Effects upon Fluorescence Quantum Yields. Absorption spectra of A_1, A_2, A_3, P_1, P_2, and P_3 show no indication of the ground state interaction. Excitation for the fluorescence measurements was made at the absorption band of the pyrene or anthracene moiety. For the evaluation of relative fluorescence yields of A_n and P_n in various solvents, their fluorescence quantum spectra were measured using solutions with equal absorbance (0.45) at the wavelengths of the excitation, 345 nm for P_n and 368 nm for A_n. Since the LE (local excited state) fluorescence band of pyrene or anthracene moiety frequently overlaps the intramolecular HE (heteroexcimer) fluorescence band, it is necessary to subtract the LE band from the observed spectra for the evaluation of the HE fluorescence yield. For this purpose, LE fluorescence spectra of hexane solutions of A_1, A_2, 9-ethylanthracene, P_1 and 1-ethylpyrene were used, respectively, for the spectra of A_1, A_2, A_3, P_1, and P_2 as well as P_3 in various solvents. We have employed this procedure instead of using the same LE spectra throughout the P_n or A_n series, since the vibrational structures of the spectra appear to depend a little upon the number of methylene chains as indicated in Fig. 1 for A_1 and A_2. A continued ultraviolet irradiation of solutions of A_n and P_n brings out a decrease in the absorption intensity of the aromatic hydrocarbon moiety as well as an increase in the LE fluorescence intensity and a decrease in the HE fluorescence intensity. Accordingly, freshly prepared solutions were used always for quantitative measurements. Practically no change in absorption and fluorescence intensities was observed during the course of measurements. Fluorescence quantum yields were determined, using 9,10-diphenylanthracene as a standard.[2] The values obtained are given in Table 1, where Φ_{LE} is the quantum yield of the LE fluorescence and Φ_{HE} that of the HE fluorescence.

A_1, A_2, and P_1 in nonpolar solvents such as hexane and decalin show the LE fluorescence of anthracene or pyrene part, and the HE fluorescence can be observed only in polar solvents.[1,3,4] The result is explained as follows.[1] Because of the large separation between donor and acceptor groups, the stabilization energy of the charge transfer state due to the coulomb interaction between the pair in these compounds may be smaller than in the case of A_3 or P_3 where the sandwich type conformation is possible. However, since their dipole moments in the charge transfer state are much larger

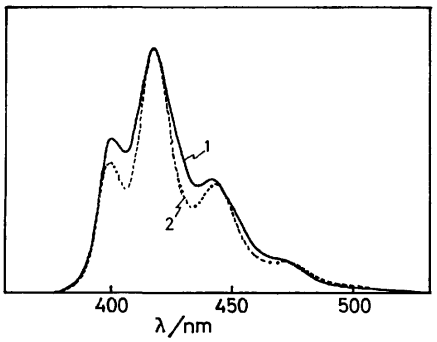

Fig. 1. Fluorescence spectra of A_1 (1) and A_2 (2) in hexane at room temperature.

than those of the sandwich type heteroexcimers, the solvation in a polar solvent may be very effective for the stabilization of the charge transfer state. Thus, the level inversion between the LE and the charge transfer state may arise and the HE fluorescence will compete with the LE fluorescence in polar solvents.

Roughly speaking, Φ_{LE} as well as Φ_{HE} decrease with increasing solvent polarity. Presumably, deactivation processes leading to the ground state or to some non-fluorescent products are considerable in strongly polar solvents. In the case of A_1, both Φ_{LE} and Φ_{HE} are much smaller than those of the other systems in polar solvents. Thus the deactivation processes competing with the HE formation are predominant in the case of A_1 in polar solvents.

Although the fluorescence yields decrease with increase in solvent polarity, Φ_{HE} values of the present intramolecular HE systems in polar solvents are much larger as compared with the intermolecular case. As an example, Φ_{HE} of P_3 in pyridine is 0.07[3] as compared with 0.015 of pyrene-*N*,*N*-dimethylaniline (DMA) intermolecular HE.[5] The observed values of P_3 in acetone and acetonitrile are 0.034 and 0.004, respectively, while no HE fluorescence can be observed in these solvents in the case of the intermolecular system.

The above results were explained[3,4] as due to the fact that it is difficult for ionic dissociation from the nonrelaxed electron transfer state, which is a dominant process in the case of the intermolecular HE system in

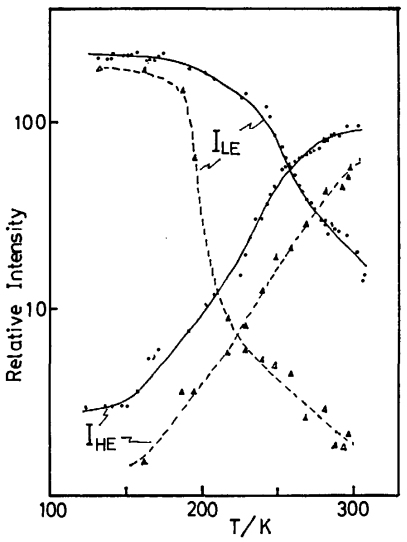

Fig. 2. Temperature dependence of I_{LE} and I_{HE} of P_3 in decalin (solid line) and 2-propanol (dotted line).

polar solvents,[6,7] to occur in the case of the intramolecular HE.

Although the ionic "dissociation" is not possible, the formation of non-fluorescent intramolecular ion-pairs from the LE state or the non-relaxed electron transfer state may not be prohibited in polar solvents. This seems to result in the decrease of HE fluorescence yield with increasing solvent polarity as described above.

For detailed studies of the intramolecular HE formation processes, it is necessary to confirm, especially in the case of the system capable of forming sandwich type of HE, whether the HE is formed by the dynamic process or not. It is possible that weak intramolecular complexes are formed at low temperature in the ground state leading to immediate formation of fluorescent HE state under excitation.[8]

For this purpose, temperature effects upon fluorescence intensity of P_3 were examined. As indicated in Fig. 2, the intensity of the LE fluorescence (I_{LE}) increases with decreasing temperature, approaching a constant value at sufficiently low temperature both in decalin and isopropanol. This suggests that the

a) Rise time of the HE fluorescene detected by the present apparatus. b) The values might be the lifetimes of the photoproducts.

intramolecular donor-acceptor interaction arises mainly by the dynamic process in the excited state. In accordance with this behavior of LE fluorescence, the intensity of the HE fluorescence (I_{HE}) decreases with temperature lowering.

B. Effects of Solvent Polarity and Temperature upon Fluorescence Rise and Decay Processes. Fluorescence rise and decay curves were measured at both wavelengths of LE and HE fluorescence bands. Typical two-component decay curve measured at the LE band and corresponding rise and decay curves measured at the HE band were confirmed in the case of several systems in nonpolar or slightly polar solvents. These kind of rise and decay curves are common in the case of intermolecular excimer and HE systems.

A possible kinetic scheme for the formation and decomposition processes of an intramolecular HE in nonpolar solvents can be written as follows.

$$\begin{array}{ccc} A^*\cdots D & \underset{k_2}{\overset{k_1}{\rightleftharpoons}} & (A^-\cdot D^+) \\ {\scriptstyle k_1}\big\downarrow \quad \big\downarrow{\scriptstyle k_f} & & {\scriptstyle k_1'}\big\downarrow \quad \big\downarrow{\scriptstyle k_f'} \\ A\cdots D & \longleftarrow & (A\cdot D) \end{array} \qquad (1)$$

Assuming a δ-function excitation, the time dependences of the LE and HE fluorescence intensities are given by the following equations.

$$I_{LE}(t) = \frac{I_0}{(\lambda_2-\lambda_1)}\{(\lambda_2-X)\exp(-\lambda_1 t) + (X-\lambda_1)\exp(-\lambda_2 t)\} \qquad (2)$$

$$I_{HE}(t) = \frac{I_0 k_1}{(\lambda_2-\lambda_1)}\{\exp(-\lambda_1 t) - \exp(-\lambda_2 t)\} \qquad (3)$$

where

$$\left.\begin{matrix}\lambda_1 \\ \lambda_2\end{matrix}\right\} = 1/2[X+Y \mp \{(Y-X)^2+4k_1k_2\}^{1/2}] \qquad (4)$$

$$X = k_1 + k_f + k_l$$

$$Y = k_2 + k_f' + k_l'$$

$$I_0 = I_{LE}(0)$$

By means of Eqs. 2 and 3, the short lived component in the decay curve of the LE fluorescence and the rise time of HE fluorescence were evaluated graphically from the semilogarithmic plots of $I(t)$ as indicated in Fig. 3. However, in moderately as well as strongly polar solvents, it was difficult to observe the two-component decay of the LE fluorescence or the rise curve of the HE fluorescence. The results of fluorescence rise and decay times at room temperature are given in Table 2.

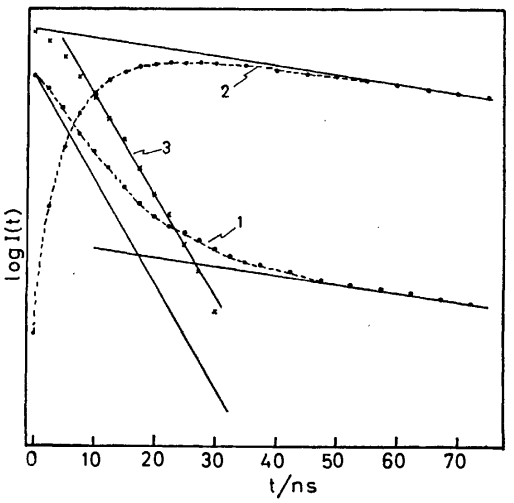

Fig. 3. Semilogarithmic plots of $I_{LE}(t)$ and $I_{HE}(t)$ of P_3 in decalin at room temperature.
(1): $I_{LE}(t)$ (2): $I_{HE}(t)$
(3): $\frac{I_0 k_1}{\lambda_2-\lambda_1}\cdot\exp(-\lambda_1 t) - I_{HE}(t)$

In the case of A_1, A_2, and P_1, although the fluorescence spectrum of hexane solution is identical with that of the decalin solution, the fluorescence lifetime of hexane solution differs from that of the decalin solution. This seems to suggest that, even in the case of these systems in nonpolar solvents, the HE state is attained transiently from the thermally excited LE state, but will decompose immediately by the back charge transfer process of k_2.

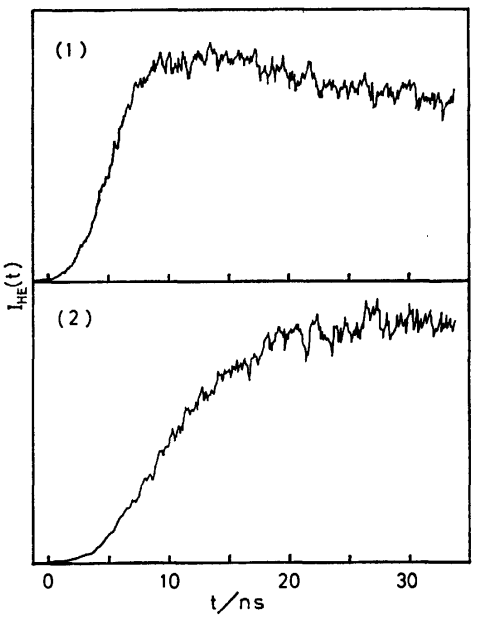

Fig. 5. Fluorescence rise curves of P_3 HE in 1-pentanol (1) and decalin (2) at room temperature.

Lewis and Ware[9] reported a special case of the HE system where the quenching process of the LE fluorescence could not be explained without assuming the transient HE formation though no HE emission was obseved as in the above case. They estimated the lifetime of the transient HE by analyzing the effect of the quencher concentration upon the decay process of the LE fluorescence. In the present case, however, it is not possible to examine such a concentration effect.

With the increase in solvent polarity, the HE state may be stabilized and the rate constant k_1 will increase. When the HE state is placed at the same energy as the LE state of pyrene or anthracene part and no extensive change of the geometrical structure is necessary, it is plausible that the HE formation and decomposition reaction becomes so rapid that the equilibrium between LE and HE state is attained approximately. If the equilibrium is attained, both the LE and HE fluorescence will show the single exponential decay with the same decay time. The behavior of A_1 as well as P_1 in ethers seems to correspond to this case.

Typical two-component decay represented by Eq. 2 was observed in cases of P_2 and P_3 in hexane as well as decalin, and A_2 in ethers at room temperature. The rise and decay times of P_3 HE in decalin were $\lambda_2^{-1}=7.5$ ns and $\lambda_1^{-1}=90$ ns, agreeing respectively with those obtained by measuring the two-component decay of the LE fluorescence. The temperature effect on the rise and decay curves of P_2 and P_3 in decalin was examined, the results being shown in Fig. 4. The observed decay curves can be reproduced by Eq. 2 in the temperature range 300—210 K. Thus, it has been confirmed that the HE's of P_2 and P_3 in decalin are formed by the dynamic process in the excited state even at low temperatures. Although λ_2 is a function of various rate constants, it seems to be close to k_1. Thus, the formation process of the HE state does not seem to be so fast as in the case of the intermolecular HE. The result may be due to the hindered rotations about CH_2–CH_2 bonds which are necessary to form a sandwich type HE, and also due to somewhat large solvent viscosity of decalin. As an example, values $\lambda_2^{-1}=25$ ns at 263 K, and 58 ns at 223 K were obtained in the case of P_3 in decalin. Thus, the temperature lowering makes the process of conformational change very slow. It is possible that both the hindered rotation itself and the solvent viscosity can be affected by the change of temperature. It is not clear which of these is more effective for retarding the conformational change.

In contrast to the above results, the rise time of P_3 HE fluorescence at room temperature is shorter than 2 ns (the rise time of the exciting laser pulse) both in 1-pentanol and 2-propanol, though these solvents are more viscous than decalin. The rise curve of P_3 HE in 1-pentanol is shown in Fig. 5 together with that in decalin. The result suggests that the mechanism of HE formation in polar solvents differs from that in nonpolar solvents. Presumably, orientational fluctuations of surrounding solvent dipoles and a slight approach of the two moieties of P_3 may induce the electron transfer without taking the sandwich type of structure.

In order to clarify the behavior of HE in polar solvents, temperature effects upon the fluorescence rise and decay curves of P_1, P_2, and P_3 in 2-propanol have been examined. The results are shown in Fig. 6. The rise times of HE fluorescence in the range from room temperature to *ca.* 160 K are much shorter than those of P_2 and P_3 HE's in decalin solution. Thus, the HE formation process in 2-propanol is much faster than that in decalin not only at room temperature but also at low temperatures. The decay time of the HE fluorescence of P_1 and P_2 is *ca.* 10 ns at room temperature, slightly increasing at low temperatures.

In the case of P_3 HE, the decay of HE fluorescence above 250 K can be represented by a single exponential curve, but not so below 250 K. By subtracting the slow component from the decay curve, the residual part

The time scale for the long life component of P_3 is indicated on the right hand side ordinate.

can be represented approximately by an exponential decay, as indicated in Fig. 7. Moreover, below 220 K, it was possible to observe the rise time of the HE fluorescence in 2-propanol with the present apparatus. The observed decay time of the fast component of the LE fluorescence at low temperatures does not agree with the rise time of the HE fluorescence. Similar results were obtained in 1-pentanol and butyronitrile.

As indicated in Fig. 6-C, the decay time of the fast component of the HE fluorescence of P_3 observed below 250 K shows a temperature dependence similar to that of the fluorescence decay times of P_1 and P_2 HE's. The result suggests that, at low temperatures, there are two kinds of HE's of P_3 which have decay times differing from each other, one of which seems to have a structure similar to that of P_1 or P_2 HE.

On the other hand, according to the result of recent laser photolysis studies,[10] the absorption spectrum of P_2 HE in 2-propanol was very close to the superposition of the absorption bands of pyrene anion and *N,N*-dimethylaniline cation, while a very broad absorption band with peak around 500 nm was observed in the case of the P_3 HE in 2-propanol. As regards the above argument concerning two kinds of HE's, we have measured time-resolved absorption spectra of P_3 HE in 2-propanol at 210 K. Corresponding to the result of fluorescence measurements, the short-life and long-life components of the time-resolved absorption spectra were similar respectively to the spectrum of P_2 HE and P_3 HE in 2-propanol at room temperature. Thus, the existence of two kinds of HE's of P_3 at low temperatures, one similar to P_1 or P_2 HE and the other analogous to the P_3 HE at room temperature, has been confirmed.

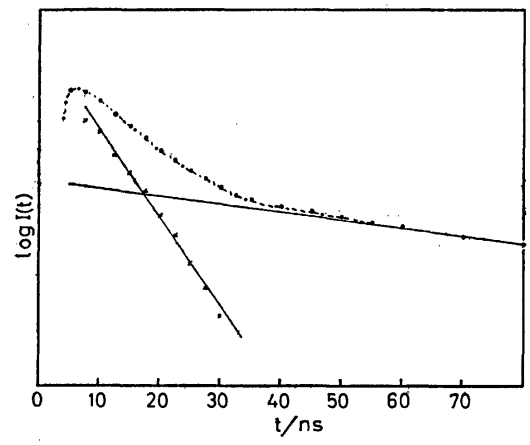

Fig. 7. Fluorescence decay function of P_3 HE observed at 550 nm in 2-propanol at 223 K.

However, according to our measurement of the time-resolved fluorescence spectra of P_3 HE, the spectrum of the slow component of the decay curve was approximately the same as that of the fast component. The result seems to indicate that these HE states with different lifetimes emit fluorescence at approximately the same wavelength region. Actually, the fact that the fluorescence band maxima of P_1, P_2, and P_3 in 2-propanol at room temperature are *ca.* 585, 585, and 590 nm, respectively,[1] indicates that a small difference in the geometrical structure of the HE does not appreciably affect the wavelength of the HE fluorescence in these polar solvents. Therefore, there seems to be a possibility that many kinds of HE's with different geometrical structures in polar solvents have similar fluorescence spectra and the HE fluorescence decay curve consists of many exponential curves with different decay times, which might be revealed by a more accurate measurement.

In the above interpretation, the non-fluorescent ion-pair does not play an important role in the formation process of the HE state. Nevertheless, it seems plausible that some non-fluorescent ion-pairs are formed in polar solvents, as discussed in *A* in relation to the solvent effect upon the HE fluorescence yield. Namely, several kinds of HE's as well as the non-fluorescent ion-pairs may be formed from the LE state or the non-relaxed CT state in polar solvents. Actually, formation of a species which might be identified with the non-fluorescent ion-pair was observed in the case of P_3 in acetonitrile.[3]

We see from the tables that both the HE fluorescence yield and decay time of the present systems decrease with increase of the solvent polarity, the extent of the decrease of the yield being a little larger. The result is comprehensible on the basis of the above discussion. The formation of the non-fluorescent ion-pair from the LE state or the non-relaxed CT state may be enhanced with increase of the solvent polarity. The result can also be interpreted by assuming the solvent-induced change of electronic and geometrical structures of the HE.[3,5] However, the interpretation does not seem to

be supported by the above results of fluorescence decay curve measurements at low temperatures and their explanation.

It is described in *A* that the fluorescence yields of the present intramolecular HE's are much higher as compared with those of the intermolecular systems. However, the difference between the intra- and intermolecular systems is not restricted to the fluorescence yield. The fluorescence lifetimes of these intramolecular HE's are much longer than those of the intermolecular systems. As an example, the fluorescence lifetime of P_3 HE in pyridine is 100 ns[3] as compared with the value 30 ns of the pyrene-DMA intermolecular HE.[5] Although the fluorescence of the pyrene-DMA intermolecular HE cannot be observed in acetone probably due to the predominant ionic dissociation from both the non-relaxed CT state and the HE state, the HE fluorescence of P_3 with lifetime of 63 ns can be observed easily in the same solvent. Thus, once the HE of P_3 is formed, it seems to be difficult for the quenching process to the non-fluorescent ion-pair to take place even in such a strongly polar solvent as acetone. A more or less analogous circumstance can be observed in the other systems.

In view of the above results, it should be noted that the exceptionally high fluorescence quantum yield and long lifetime of the intermolecular HE systems in alcohol solutions[11] can be ascribed to some mechanism involving the hydrogen bonding between the surrounding solvent molecules which prevents the ionic dissociation.

The authors' thanks are due to Mr. Tadashi Tokuda for his assistance in the measurements of the fluorescence spectra of P_n.

Water Vapor Affinity of Potassium Bromide Coated with Potassium Oleate[1)]

Masatoshi CHIKAZAWA, Fujio YAMAMOTO, Eiko SAITA, Mamoru KAIHO,* and Takafumi KANAZAWA

Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158

(Received May 14, 1976)

The amounts of adsorbed water and the isosteric heats for water vapor adsorption on fine crystals of KBr treated with various amounts of potassium oleate (KOl) were measured. In the adsorption isotherm of untreated KBr, a slight stepped rise of the amount adsorbed was observed, and this step is considered to be due to the two-dimensional condensation of water molecules adsorbed on the uniform surfaces of KBr particles. The monolayer capacity, determined from the adsorption isotherm of KBr by the point B method, agreed with the value calculated according to an adsorptive structure based on the two assumptions that all the surfaces of the KBr particles consist of (100) planes and that one water molecule is adsorbed per regularly distributed Br^- site.

A small amount of pre-adsorbed KOl was recognized to prevent the water vapor adsorption on KBr, and conversely, this effect disappeared with increasing KOl content while the hygroscopicity of the sample increased markedly. This abnormal increase in the adsorbed amount suggests that the adsorbed water molecules penetrate into the multilayer films of KOl on the KBr.

In order to change the surface properties of powder particles, the surface is often modified by coating with some material such as surfactants. Studies of the effect of the coating on surface properties and of the mechanism of the coating are instructive in many powder industries. In the present paper, data of the water vapor adsorption isotherms and isosteric heats of adsorption on KBr powders coated with various amounts of potassium oleate (KOl) are described, and the relationship between the water vapor affinity of KBr and the KOl concentration, the amount adsorbed on the surface per unit KBr surface area, was investigated to clarify the surface properties of the bromide. These experimental results will be available for research on the moisture-proofing and caking of powder materials.

Experimental

Materials. A potassium bromide sample was prepared by twice recrystallizing special-grade reagent KBr using distilled water. An aqueous solution of KBr (30 wt%, *ca.* 100 ml) was poured with stirring into ethyl alcohol (*ca.* 500 ml) cooled to −80——90 °C. The bromide thus obtained was filtered and washed four times with absolute ethyl alcohol and then dried at a reduced pressure of 10^{-3} Torr. This precipitate was observed by microscopy to be very small cubic crystals (2—7 μ).

Ground powders of KBr were prepared by pulverization of the recrystallized KBr in a ball-mill for 1 h.

Potassium oleate (special-grade reagent) was purified twice with absolute ethyl alcohol and also dried at reduced pressure.

Potassium Oleate Coating. A mixed solvent of CCl_4–C_2H_5OH in a volume ratio of 5 : 1 (50 ml) including an adequate amount of KOl was stirred for 5—6 min after KBr (30 g) had been added to the solvent, and the salt thus treated was filtered and dried at reduced pressure. A standard sample was prepared by immersing KBr in a mixed solvent which was free of KOl. The amount of KOl adsorbed on the surface of KBr particles was estimated by measuring the UV absorbance at 250 mμ after the adsorptive measurement had been completed. Ethyl alcohol and carbon tetrachloride were dehydrated with metal Mg and silica-gel, respectively, and then distilled prior to use.

Adsorption Measurement. Figure 1 shows the schematic diagram of a volumetric apparatus for water vapor and nitrogen adsorption. The equilibrium pressure of the water vapor and nitrogen were measured using a mercury manometer and a reading magnifier having a resolution of 10^{-2} mm.

Surface Area. The specific surface areas of the samples were determined by applying the BET equation to the nitrogen-adsorption data obtained at 77 K, assuming the cross-sectional area of a nitrogen molecule to be 16.2 $Å^2$.

Results and Discussion

Water Vapor Adsorption. The specific surface area of the standard sample was estimated to be *ca.* 0.24 m^2/g, and this value agreed roughly with the surface area measured for KBr powder untreated with the above solvent. The water vapor adsorption isotherms for this standard and the ground powders of KBr are illustrated in Fig. 2. In the adsorption isotherms, slight stepped rises of the amount of adsorbed water are observed in the relative vapor pressure range of 0.075 to 0.13, excepting the case of ground KBr. More remarkable steps in the water adsorption isotherms have been observed for NaCl, KCl,[2,3)] and NaBr.[4)] The relative pressures, at which the steps appear in the

$-\Delta H_L$: Heat of liquefaction of water vapor.

isotherms described previously, are higher than that determined for KBr. Disagreements in the relative pressures at which the step appears may be ascribable to the difference in the adsorption mechanisms of water molecules between the above salts and KBr.

Isosteric Heat of Adsorption. Figure 3 indicates the isosteric heats of adsorption calculated from the isotherms given in Fig. 2. A peak is seen in the isosteric heat curve at $V=0.17$ ml STP/m². This value corresponds closely to the monolayer capacity estimated by the point B method. On the other hand, the BET plot for the isotherm in Fig. 2 was found to be linear in the relative pressure range of 0.03 to 0.3, and it gave a monolayer capacity which is 1.3_7 times the value obtained at point B. However, no changes which are expected to suggest monolayer completion were observed in the isotherm and the isosteric heat curve at about $V=0.17\times1.3_7$ ml STP/m². If the surfaces of all KBr particles consist of (100) planes and one water molecule is adsorbed on one Br^- site of the surface, the amount of monolayer adsorption is calculated to be 0.171 ml STP/m². This value is almost equal to that obtained by the point B method. From these results, the adsorption mechanism of water vapor on a KBr surface and the characteristics of the adsorption isotherm and isosteric heat curves will be interpreted as follows. Water molecules are adsorbed on Br^- sites in a ratio of 1 : 1. An interaction force induced by hydrogenbonding among the adsorbed water molecules increases with the amount adsorbed, and reaches a maximum value at a coverage of $\theta=1$. The peak in the isosteric heat curve appears due to the effect of hydrogenbonding. Moreover, the slight stepped rise observed in the adsorption isotherm of the recrystallized KBr is considered to be due to the two-dimensional condensation of water molecules adsorbed on the uniform surfaces of the salt, since monolayer adsorption was formed at the end of the step. On the other hand, the stepped rise disappears in the isotherm of ground KBr owing to the inhomogeneity of its surface.

Lad[5] has obtained a water vapor adsorption isotherm on cleaved NaCl crystals, and its isotherm suggests an adsorptive structure, which is a hydrogen-bonded first layer with one molecule of water for two Cl^- sites. According to this result, two hydrogen atoms in a water molecule are considered to attach to two adjacent Cl^- sites. Therefore, the adsorption characteristics of water vapor on an alkali halide are considerably affected by the distance between the two adjacent anions, the electronegativities and the ionic radii of the chemical elements involved. The difference between the water vapor adsorption mechanisms of NaCl and KBr may be mainly due to the differences in their lattice spacings and in the electronegativities of the elements of which the surface is composed. The distance between the two Br ions is larger than that between Cl ions, and the electronegativity of bromine is smaller than that of chlorine. Hence, the two hydrogen atoms in a water molecule do not fit onto the two adjacent Br^- sites of KBr.

Effect of Potassium Oleate Coating. The effects of the concentration of the pre-adsorbed KOl on the water adsorption isotherm and the isosteric heat of adsorption are shown in Figs. 4 and 5, respectively. The slight stepped rise declined gradually with increasing KOl concentration. Moreover, no peak which was expected to appear for a coverage $\theta=1$ was observed in the heat curve of adsorption on KBr coated with KOl. Therefore, the disappearance of the step is thought to be due to increasing inhomogeneity of the component and the geometric structure of the solid surface containing adsorbed KOl. This interpretation is compatible with the result obtained using ground

KBr. In addition, the pre-adsorbed KOl is believed to prevent the interaction between the adsorbed water molecules induced by the hydrophobic property of KOl and to eliminate a peak in the isosteric heat curves.

Pre-adsorption of KOl, in a certain concentration range and for a given surface coverage, weakened slightly the subsequent adsorption of water vapor, whereas at higher concentrations this trend was reversed and the amount adsorbed began to increase markedly.

Water vapor affinity, one of the surface properties of solids, is often expressed by the ratio S_{H_2O}/S_{N^2}, where S_{H_2O} and S_{N_2} are surface areas determined using H_2O and N_2 as adsorbates, respectively, assuming cross-sectional areas of 10.6 Å² for H_2O and 16.2 Å² for N_2. These values for KBr at various concentrations of pre-adsorbed KOl and C values obtained from the water vapor BET plots are summarized in Table 1. The slight effect of the pre-adsorbed KOl on the prevention of water vapor adsorption is observed for low concentrations of KOl, whereas at higher concentrations the water vapor affinity increases. The change in the isosteric heats of adsorption with increasing KOl concentration prove this tendency.

The relationship between the KOl concentration and the amount of adsorbed water at a fixed water vapor pressure is given in Fig. 6. The KOl concentration available for preventing water vapor adsorption is determined from the curve in Fig. 6 to be about 0.46 mg/m². If the amount of pre-adsorbed KOl required to cover the surfaces of KBr particles with a complete monolayer corresponds to a value of 0.46 mg/m², the resulting cross-sectional area of KOl is calculated to be 120 Å². However, this value is larger than the 45—50 Å² obtained by Adam[6] based on the structure of the liquid condensed film formed on the surface of an aqueous solution. The former value can probably be explained under the assumption that a hydrocarbon chain in the KOl molecule lies across the KBr surface. In such a case, the cross-sectional area of KOl is estimated from

the molecular structure to be 130—150 Å^2. This value is close to the above-stated value (120 Å^2).

Table 1 indicates that at higher KOl concentrations the hygroscopicity of the sample increases with the KOl concentration, and this tendency seems ascribable to the penetration of water molecules into the ionic layers of KOl films adsorbed in a multilayer which may be of laminar form. A similar effect of KOl[7] has been observed in the case of adsorption on $CaCO_3$ pre-adsorbed KOl. The water-vapor adsorption isotherm on KOl powder itself is illustrated in Fig. 7. The amount of adsorbed water per unit KOl surface area is considerably larger than that estimated to be the physical adsorption of water vapor on a KOl surface. Therefore, most of the adsorbed water molecules are thought to penetrate into KOl particles. A similar observation was reported by Gross and Bauer[8] in their study of water-vapor adsorption on aluminum soaps. They concluded that water molecules penetrate into the soap crystallites and undergo hydrogen bonding at recurring Al-O linkages.[8] On the basis of these results, the abnormal increase in hygroscopicity of the sample can be reasonably explained by assuming the penetration of the adsorbed water molecules into KOl films on the surface of KBr.

Pressure Effect of the Nondispersive Infrared Gas Analyser

Tsutomu YONEZAWA and Eiji NIKI

Department of Industrial Chemistry, Faculty of Engineering, Tokyo University, Hongo, Tokyo 113

(Received June 9, 1976)

Based on the Elsasser model, a formula for the mean absorption applicable to the pressure effect of the nondispersive infrared gas analyser has been derived. The formula is generalized by removing the assumption in the Elsasser model that the total absorption coefficient, the half width and the spectral distance are constant.

In previous papers,[1,2] a formula was given for the mean absorption corresponding to the screening percent for the infrared ray due to the null balance shutter of the analyser as a function of the partial pressure of absorber p_a, the total pressure P and the cell length l. Many similar formulas, often empirical, have been reported,[3-6] but it is difficult to determine the coefficients in the formulas either experimentally or theoretically. There are two theories concerning the derivation of the formulas: total absorption by Ladenburg and Reiche,[7] and mean absorption by Elsasser.[8] The Lorentz type absorption coefficient is assumed in both theories. However the method for approximate evaluation of the following integral,

$$\int\{1-\exp(-k(\nu)l)\}\mathrm{d}\nu$$

viz. total absorption, is different.

The Elsasser theory is based on the three assumptions that the following are constant: i) the total absorption coefficient α_m, ii) the half width of the line δ_m and the spectral distance of the vibrational rotational line d_m. When assumption i) was removed, it was possible to obtain a good quantitative comparison between the theory and experiment.[2] In this paper, the formula is generalized by removing the remaining assumptions.

Apparatus

The apparatus and the principle of measurement have been reported.[2]

Theoretical

Half Width of Absorption Lines. According to the classical kinetic theory of gases, the collision width of the line is given by[2]

$$\delta = \frac{1}{4\pi}\sum_i N_i(D_{a,i})^2\left[[2\pi kT\left(\frac{1}{m_a}+\frac{1}{m_i}\right)\right]^{1/2} \quad (1)$$

where N_i is the number density of a molecule of the gas of ith type, $D_{a,i}$ the sum of the optical collision diameters of the absorbing molecule and the molecule of the ith type, m_a the mass of the absorbing molecule and m_i the mass of the ith type of molecule. For binary mixtures, Eq. 1 becomes

$$\delta = \frac{1}{4\pi}(2\pi kT)^{1/2}\left[N_a(D_{a,a})^2\left(\frac{2}{m_a}\right)^{1/2} + N_b(D_{a,b})^2\left(\frac{m_a+m_b}{m_a m_b}\right)^{1/2}\right]. \quad (2)$$

It is not necessarily correct that the half width is common to all the lines according to Eqs. 1 and 2. It was found that each line differs slightly in half width.[9] From quantum mechanics[10] the half width of the line is not constant since the colliding molecules exert different interaction due to the intermolecular force on each vibrational rotational energy level of the absorbing molecule.

Taking the above situation into consideration, it is better to express Eq. 2 as follows.

$$\delta_m = \frac{1}{4\pi}(2\pi kT)^{1/2}\left[N_a(D_{a,a})_m^2\left(\frac{2}{m_a}\right)^{1/2} + N_b(D_{a,b})_m^2\left(\frac{m_a+m_b}{m_a m_b}\right)^{1/2}\right]. \quad (3)$$

where the subscript m is the number of the line. $(D_{a,a})_m$ and $(D_{a,b})_m$ should be determined quantum mechanically. The first term of Eq. 3 explains the effect the collisions between absorbing molecules exert on the half width of the mth line, and the second the effect the collisions between the foreign and absorbing molecules exert on the mth line. Expressing N_i in term of partial pressure, Eq. 3 becomes

$$\delta_m = \frac{1}{4\pi}\left(\frac{2\pi}{kT}\right)^{1/2}[(C_{a,a})_m P_a + (C_{a,b})_m P_b] = \frac{1}{4\pi}\left(\frac{2\pi}{kT}\right)^{1/2}(C_{a,a})_m\left[P_a+\frac{(C_{a,b})_m}{(C_{a,a})_m}P_b\right] \quad (4)$$

where

$$(C_{a,a})_m = (D_{a,a})_m^2(2/m_a)^{1/2}$$

and

$$(C_{a,b})_m = (D_{a,b})_m^2(m_a+m_b/m_a m_b)^{1/2} \quad (5)$$

Here the notation δ_{0m} is defined by

$$\delta_{0m} = \frac{1}{4\pi}\left(\frac{2\pi}{kT}\right)^{1/2}(C_{a,a})_m. \quad (6)$$

δ_{0m} is the constant independent of pressure if the temperature is constant. Though it is not necessarily obvious that the ratio of $(D_{a,a})_m$ to $(D_{a,b})_m$ is constant, its ratio is assumed to be constant according to the method in the previous papers.[1,2] Then the following relation can be assumed

$$\frac{(C_{a,a})_m}{(C_{a,b})_m} = \left(\frac{2m_b}{m_a+m_b}\right)^{1/2}\left\{\frac{(D_{a,a})_m}{(D_{a,b})_m}\right\}^2 = B(=const)$$

where B is the so-called self-broadening coefficient. As a result, the half width of the line can be expressed by

$$\delta_m = \delta_{0m}P_e \quad (7)$$

where P_e is the effective pressure defined by

$$P_e = p_a + (1/B)p_b. \quad (8)$$

The difference in the half width of each line is taken

consideration by Eq. 7. Namely δ_m should be understood for δ of Eq. 2 to be extended. The theoretical expressions obtained in the previous papers,[1,2] however, must not be altered, except that $\delta_0\left(=\frac{1}{4\pi}\left(\frac{2\pi}{kT}\right)^{1/2}(C_{a,a})\right)$ in the definition of k_{0m} is simply replaced by δ_{0m} of Eq. 6.

Total Absorption Coefficient of the Line, α_m. The total absorption coefficient of the mth line is determined by means of the integral of the absorption coefficient which is ordinarily approximated by the following Lorentz type function in the infrared region.

$$k_m(\nu) = \frac{4\pi N_a}{3\hbar C}\nu_m|\mu_m|^2\frac{\delta_m}{(\nu-\nu_m)^2+\delta_m^2} \tag{9}$$

where μ_m is the matrix element of the dipole moment. The total absorption coefficient is, therefore,

$$\alpha_m = \int_0^\infty k_m(\nu)\mathrm{d}\nu = \int_0^\infty \frac{4\pi N_a}{3\hbar C}\nu_m|\mu_m|^2\frac{\delta_m}{(\nu-\nu_m)^2+\delta_m^2}\mathrm{d}\nu \tag{10}$$

It is evident that α_{0m} is proportional to the number density of absorber N_a. N_a is rewritten by the partial pressure p_a and we have

$$\alpha_m = \alpha_{0m}P_a. \tag{11}$$

α_{0m} is directly related to the Einstein transition probability except for the numerical constant.

By substituting $N_a=p_a/kT$ into Eq. 10, α_{0m} is expressed by the molecular constants as follows.

$$\alpha_{0m} = \frac{4\pi^2\nu_m|\mu_m|^2}{3\hbar ckT} \tag{12}$$

It was assumed that $\alpha_m=const$ in the Elsasser model. However, α_m is not constant in this paper.

Extension of the Definition of k_{0m} and the Approximate Expression for the Parameter t Determinable from the True Slit Function. If we denote the product of α_{0m} and δ_{0m} by l_{0m}

$$\alpha_{0m}\delta_{0m} \equiv l_{0m}, \tag{13}$$

it is determined from Eqs. 6 and 12 with use of the molecular constants as follows.

$$l_{0m} = \frac{1}{4\pi}\left(\frac{2\pi}{kT}\right)^{1/2}(D_{a,a})_m^2(2/m_a)^{1/2}\frac{4\pi^2\nu_m|\mu_m|^2}{3\hbar ckT} \tag{14}$$

On the other hand, t is approximately connected with the maximum extinction E_m as follows.[2]

$$E_m = t(\alpha_m\delta_m l)^{1/2}/a \tag{15}$$

where a is the slit width in cm^{-1} and l the cell length. For the simple component of the absorbing gas, Eq. 15 becomes

$$E_m = t(\alpha_{0m}\delta_{0m}l)^{1/2}P_a/a. \tag{16}$$

From Eqs. 13 and 16, we have

$$t = \frac{aE_m}{(l_{0m}l)^{1/2}P_a} \tag{17}$$

Here the quantity k_{0m} should be defined by

$$k_{0m} = E_m^2/\{4(d_m/a)^2P_a^2l\} \tag{18}$$

which can be evaluated from the maximum intensity of the absorption spectrum corresponding to the conditions of measurement. d_m is the spectral distance of the mth line. k_{0m} was defined with use of the mean spectral distance instead of d_m.[1,2] From Eqs. 17 and 18, the parameter t can be determined by the following approximate relation.

$$t = 2d_m\sqrt{\frac{k_{0m}}{l_{0m}}}. \tag{19}$$

Theoretical Extension of the Mean Absorption to the Molecules with Two Absorption Regions. The mean absorption of the molecules with a single absorption region should be extended to the molecules with weak bands such as the combination or the overtone band other than the fundamental one. In this case, the intensity of the infrared source I_ν and the mean spectral distance differ between both band regions. The expression for the mean absorption to be evaluated is as follows.

$$x = \frac{\sum_{m=1}^{n}\int_{u'}^{v'} I_f\{1-\exp(-k_m(\nu)l)\}\mathrm{d}\nu + \sum_{m'=1}^{n'}\int_{u''}^{v''} I_c\{1-\exp(-k_{m'}(\nu)l)\}\mathrm{d}\nu}{I_f nd' + I_c n'd''} \tag{20}$$

x corresponds to the screening percent of the incident light due to the null balance shutter of the infrared gas analyser. v', u', v'' and u'' are $\nu_m+d'/2$, $\nu_m-d'/2$, $\nu_{m'}+d''/2$ and $\nu_{m'}-d''/2$. d' and d'' are the widths of rectangles in each region by which the shape of absorption lines of the condenser microphone detector is approximated. By putting $I_c/I_f=r$ (the ratio of the intensity of the infrared source in both regions) and $n=n'$, the following expression is obtained for the high pressure near atmospheric pressure.

$$x = \frac{\sum_{n=0}^{\infty}(-P_e w)^n/n!\cdot\{\langle k_{0m}/D^2)^n\rangle_{av} + r'\langle(k_{0m'}/D'^2)^n\rangle_{av}\}}{1+r'} \tag{21}$$

where

$$1/D = (2/t)\cdot(d/d'),\quad 1/D' = (2/t)\cdot(d/d''),\quad r' = rd''/d' \text{ and } w=p_a l. \tag{22}$$

k_{0m} and $k_{0m'}$ are determined with use of the mean spectral distance d over both regions.

$$k_{0m} = E_m^2/\{4(d/a)^2p_a l\}$$

and

$$k_{0m'} = E_{m'}^2/\{4(d/a)^2p_a l\}.$$

$\langle\ \rangle_{av}$ denotes the normal average over m or m'.

When $d'=d''$, Eq. 20 is simplified as follows for the low pressure,

$$x = 2\left(\frac{\langle k_{0m}^{1/2}\rangle_{av} + r\langle k_{0m'}^{1/2}\rangle_{av}}{(1+r)D}\right)P_e^{1/2}w^{1/2} \tag{23}$$

and for the high pressure in the exponential form,

$$x = 1 - \exp\left[-(2\pi/D^2)\cdot\left(\frac{\langle k_{0m}\rangle_{av} + r\langle k_{0m'}\rangle_{av}}{1+r}\right)P_e w + \frac{(2\pi/D^2)^2}{2!}\left\{\left(\frac{\langle k_{0m}^2\rangle_{av} + r\langle k_{0m'}^2\rangle_{av}}{1+r}\right)\right.\right.$$

$$-\left(\frac{\langle k_{0m}\rangle_{av}+r\langle k_{0m'}\rangle_{av}}{1+r}\right)^2\Big\}(P_e w)^2$$
$$-\frac{(2\pi/D^2)^3}{3!}\Big\{\left(\frac{\langle k^3_{0m}\rangle_{av}+r\langle k^3_{0m'}\rangle_{av}}{1+r}\right)$$
$$-3\left(\frac{\langle k^2_{0m}\rangle_{av}+r\langle k^2_{0m'}\rangle_{av}}{1+r}\right)\cdot\left(\frac{\langle k_{0m}\rangle_{av}+r\langle k_{0m'}\rangle_{av}}{1+r}\right)$$
$$+2\left(\frac{\langle k_{0m}\rangle_{av}+r\langle k_{0m'}\rangle_{av}}{1+r}\right)^3\Big\}(P_e w)^3+\cdots\cdots\Big]. \quad (24)$$

Eqs. 23 and 24 explain the mean absorption of the molecules with two absorption regions, and are reduced to the expressions for the single absorption region if r approaches 0.

Extension to the Case in which the Assumption that the Spectral Distance is Constant is Removed. The present study is based on the Elsasser model. However the spectral distance is actually assumed to vary quadratically according to the number of the line m. Taking this situation into consideration, a more precise expression for the mean absorption is obtained as follows.[2)]

$$y=\frac{\sum_{m=1}^{n}\int_u^v\{1-\exp(-k_m(\nu)l)\}d\nu}{\sum_m d_m} \quad (25)$$

where v is $\nu_m+d_m/2$, and u is $\nu_m-d_m/2$. With use of the extended mean fractional transmission

$$T_m=\frac{1}{d_m}\int_u^v\exp\left\{-\frac{(\alpha_m/\pi)\delta_m}{(\nu-\nu_m)^2+\delta_m^2}l\right\}d\nu, \quad (26)$$

y is given by

$$y=1-\frac{\sum_m T_m d_m}{\sum_m d_m}$$
$$=1-\langle T_m\rangle \quad (27)$$

where $\langle T_m\rangle$ should be interpreted as $\sum T_m d_m/\sum d_m$. For the region of low pressure, T_m is

$$T_m=1-2(\alpha_m\delta_m l)^{1/2}/d_m \quad (28)$$

and then

$$y=2\cdot\frac{\sum(\alpha_m\delta_m l)^{1/2}}{\sum d_m}$$
$$=2\cdot\frac{\sum(\alpha_m\delta_m l/d^2)^{1/2}}{n}. \quad (29)$$

Thus y is reduced to the normal average. On the other hand, we have for the region of high pressure

$$y=1-\frac{\sum\exp(-2\pi\alpha_m\delta_m l/d_m^2)\cdot d_m}{\sum d_m}$$
$$=\frac{\sum\{(2\pi\alpha_m\delta_m l/d_m^2)-(2\pi\alpha_m\delta_m l/d_m^2)^2/2+\cdots\}}{\sum d_m} \quad (30)$$

Thus the value of y can be obtained when the following expressions are calculated

$\sum(\alpha_m\delta_m/d_m^2)/\sum d_m$, $\sum(\alpha_m\delta_m/d_m^2)^2 d_m/\sum d_m$, *etc.*

For the sake of convenience, g_{0m} is defined by

$$g_{0m}\equiv\frac{\alpha_{0m}\delta_{0m}}{\delta_m^2} \quad (31)$$

g_{0m} is a constant characteristic of each line. g_{0m} is connected with k_{0m} of Eq. 18 by the relation

$$g_{0m}=(2/t)^2 k_{0m}.$$

With use of g_{0m}, Eq. 30 becomes

$$y=1-\exp\Big\{-2\pi\langle g_{0m}\rangle P_e w$$
$$+\frac{(2\pi)^2}{2!}(\langle g^2_{0m}\rangle-\langle g_{0m}\rangle^2)(P_e w)^2$$
$$-\frac{(2\pi)^3}{3!}(\langle g^3_{0m}\rangle-3\langle g^2_{0m}\rangle\langle g_{0m}\rangle+2\langle g_{0m}\rangle^3)(P_e w)^3+\cdots\Big\} \quad (33)$$

where

$$\langle g^n_{0m}\rangle=\frac{\sum g^n_{0m}d_m}{\sum d_m}. \quad (34)$$

Eq. 33 was obtained without the three assumptions in the Elsasser model.

Application to the Infrared Gas Analyser. The above method can immediately be applied to the infrared gas analyser. The shape of the spectral lines of the condenser microphone detector is approximated by the rectangular lines with unit height and the width $d_{m'}$, which is not necessarily constant. The following expression corresponds to the absorption intensity of the sample gas in the nondispersive infrared gas analyser, and is of the same form as that of mean absorption.

$$x=\frac{\int_0^\infty I_\nu\{1-\exp(-\sum_{m=1}^{n}k_m(\nu)l)\}\{1-\exp(-\sum_{m=1}^{n}k'_m(\nu)l')\}d\nu}{\int_0^\infty I_\nu\{1-\exp(-\sum_{m=1}^{n}k_{m'}(\nu)l')\}d\nu}. \quad (35)$$

According to the above approximation, x is reduced to Eq. 25 if d_m is regarded as $d_{m'}$. x becomes

$$x=2\langle g'^{1/2}_{0m}\rangle P_e^{1/2}w^{1/2} \quad (36)$$

for low pressure, and

$$x=1-\exp\{-2\pi\langle g'_{0m}\rangle P_e w$$
$$+\frac{(2\pi)^2}{2!}(\langle g'^2_{0m}\rangle-\langle g'_{0m}\rangle^2)(P_e w)^2\}$$
$$-\frac{(2\pi)^3}{3!}(\langle g'^3_{0m}\rangle-3\langle g'^2_{0m}\rangle\langle g'_{0m}\rangle+2\langle g'_{0m}\rangle^3)(P_e w)^3+\cdots\Big\} \quad (37)$$

for high pressure, where

$$g'_{0m}=\frac{\alpha_{0m}\delta_{0m}}{d_m'^2}\quad\text{and}\quad\langle g'^n_{0m}\rangle=\frac{\sum g'^n_{0m}d_m'}{\sum d_m'}. \quad (38)$$

Usually g'_{0m} can not be calculated if the value of d'_m is not known. However, g'_{0m} can be calculated if $d'_m/d_m=const.$ If we put $(d'_m/d_m)\cdot(t/2)=D$, x agrees with the results[2)] which are obtained when r approaches 0 in Eqs. 23 and 24.

When $d_{m'}/d_m$ is not constant, x can not be expressed with use of the correction factor D because of the following relation

$$\langle g'^n_{0m}\rangle=\frac{\sum g'^n_{0m}d_m'}{\sum d_m'}=\frac{\sum g^n_{0m}(d_m/d_m')^{2n}d_m'}{\sum d_m'}$$
$$\neq\frac{D2^n\sum k^n_{0m}d_m'}{\sum d_m'}. \quad (39)$$

It is possible to extend Eqs. 36 and 37 to the cases of molecules with more than two absorption regions if $\langle g'^n_{0m}\rangle$ is regarded as

$$\langle g'^{n}_{0m} \rangle = \frac{\sum g'^{n}_{0m} d'_m + r \sum g''^{n}_{0m'} d''_{m'} + \cdots}{\sum d'_m + r \sum d''_{m'} + \cdots} \tag{40}$$

where

$$g''_{0m'} = \frac{\alpha_{0m'} \delta_{0m'}}{d''^{2}_{0m'}}. \tag{41}$$

Conclusion

It was found that the original expressions[2] hold good even if the assumption that δ_0 is constant is removed. However k_{0m} $(=\alpha_{0m}\ \delta_0/d^2)$ should be regarded as $\alpha_{0m}\delta_{0m}/d^2$. The ambiguous parameter t[2] was approximately determined in the explicit form with use of the molecular constants. It is concluded that the molecules with more than two absorption regions have the same pressure dependence as the molecules with a single absorption region. A more general formula was obtained for the mean absorption with use of the constant g_{0m} without the three assumptions in the Elsasser model. It can be concluded that in general x can not be expressed with use of a correction factor D.

Electronic Structures and Spectra of Azulenophenalenes

Tsuguo KOYANAGI, Yuko SHIN, and Hiroyuki YAMAGUCHI
Department of Chemistry, Kumamoto University, Kumamoto 860

(Received July 3, 1976)

The ground-state electronic properties and electronic spectra of azuleno [5, 6, 7-*cd*] phenalene (I) and azuleno-[1, 2, 3-*cd*]phenalene(II), which are isomers of the potent carcinogen benzo[*a*]pyrene (III), have been investigated by using the SCF screened potential MO CI method in combination with the variable bond-length technique. From the calculated C–C bond lengths and the position dependence of the SCF screened potential, it may be concluded that molecules I, II, and III are all both aromatic and polyolefinic. The electronic spectra of I, II, and III predicted using the screened potential are in better agreement with the experimental values than those calculated using the bare potential.

Since the molecular geometries of azuleno[5,6,7-*cd*]phenalene (I) and azuleno[1,2,3-*cd*]phenalene (II) resemble that of the potent carcinogen benzo[*a*]pyrene (III), the electronic structures and spectra of I, II, and III have been of interest. Molecule I, which was recently synthesized by Jutz and Kirchlechner,[1] was found to be carcinogenic.[2] Very recently, Murata *et al.*[3] have synthesized molecule II.

Fischer and Ege[4] have applied the SCF MO method based on the Pariser-Parr-Pople approximation to I and have calculated its electronic structures and spectra. Using the LCI-SCF MO method, Zahradnik[5] has investigated the electronic spectra of I and II. Germer and Becker[6] and Pancir and Zahradnik[7] have studied theoretically the electronic spectra of III, but they did not mention the aromaticities and carcinogenicities of I, II, or III. Recently, Thulstrup *et al.*[8] have measured the magnetic circular dichroism (MCD) spectrum of I and assigned its absorption spectrum. Very recently, Tajiri *et al.*[9] have measured the MCD spectrum of II and interpreted its complicated absorption bands.

The purpose of this paper is to investigate theoretically the ground-state electronic properties and electronic spectra of I, II, and III by using the SCF screened potential MO CI method in combination with the variable bond-length technique,[10,11] which is known to reproduce well the electronic structures of large conjugated molecules. It is possible to use the results of such calculations to deepen our understanding of the aromatic characteristics and carcinogenicities of I, II, and III.

Method of Calculation

A procedure that combines the SCF screened potential with the variable bond-length technique[11] is used in the Pariser-Parr-Pople SCF MO CI method.[12,13] At each step of the SCF calculation, the new bond lengths are obtained from the corresponding bond orders.[14] The screened potential is evaluated by using the bare potential obtained from the new bond lengths. The bare potential is calculated using the Mataga-Nishimoto formula.[15] This screened potential is used in the calculation of the next step. The calculation is repeated until self-consistency is reached. The screened potential for the CI calculation of the five low-lying singlet excitations is calculated by omitting the low-lying subset of configurations in Eq. 8 of Ref. 10. The SCF calculation of the ground state is made by using the full effective interaction.

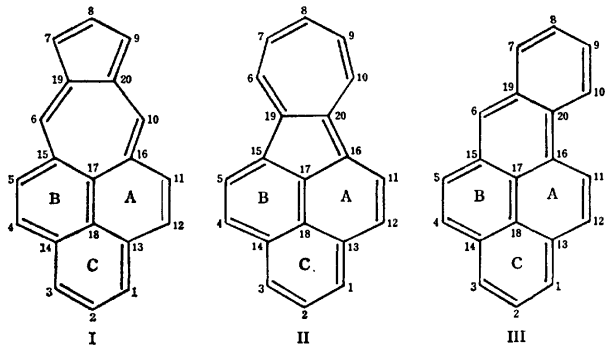

Fig. 1. Numbering of atoms.

Results and Discussion

Ground-state π-Electronic Properties. The calculated charge densities, free valence, and bond lengths are summarized in Table 1. The greatest nucleophilic reactivity is predicted at the 6 and 10 atoms in I and the 6 and 10 atoms in II. The greatest electrophilic reactivity is expected at the 7 and 9 positions in I and the 15 and 16 positions in II. The results for I agree with those of Fischer and Ege[4] and Thulstrup *et al.*[8] The calculated charge densities for III indicate that the Coulson-Rushbrooke theorem,[16] which states that, in alternant hydrocarbons, the π-electron densities for all the carbon atoms are unity, does not hold for III, when the screened potential is used. The technique of ^{13}C-NMR and ESCA[17] is capable of resolving the small charge differences in III.

From the viewpoint of carcinogenic activity, let us discuss the reactivity for the addition reactions of I, II, and III. The sum of the free valences for the two positions of the K-region,[18] $F_4+F_5=F_{11}+F_{12}=0.942$ in II, is smaller than $F_4+F_5=0.983$ in III, which is the strong carcinogen, but is comparable to the sum $F_4+F_5=F_{11}+F_{12}=0.948$ in I, which has carcinogenicity.

As for the bond lengths, it is of interest to note that the bond lengths of the azulene nucleus of I and II are almost the same as those of the free azulene molecule and that the bond lengths of the naphthalene nucleus of III are almost the same as those of the free naphthalene molecule. Two isolated C–C double

TABLE 1. CHARGE DENSITIES, FREE VALENCE NUMBERS, AND BOND LENGTHS

				15—19	1.416						

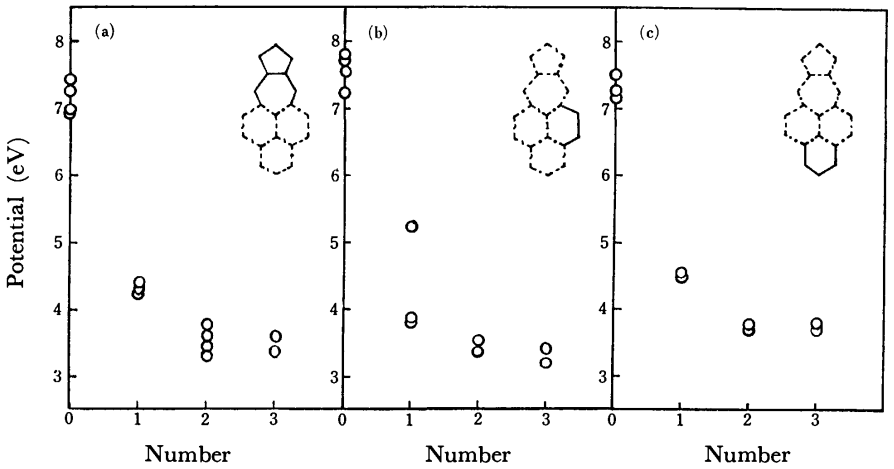

Fig. 2. The SCF screened potentials in azuleno[5,6,7-*cd*]phenalene plotted *versus* the number; (a) the azulene nucleus, (b) the benzene ring (A or B), and (c) the benzene ring (C).

bonds exist in the benzene rings (A and B) of the phenalenyl moiety for I, II, and III. The bond lengths of the benzene ring (C) in I, II, and III are composed of two vinyl molecules and 6-phenylazulene, 2-phenylazulene, and 2-phenylnaphthalene, respectively.

Position Dependence of SCF Screened Potential. Terasaka *et al.*[11] divided the SCF screened potentials V into the following groups: V_{11}, V_{12}, V_{13},⋯; V_{22}, V_{23}, V_{24},⋯;⋯. In Fig. 2, the SCF screened potentials in each group of I are plotted *versus* a number that indicates the kinds of screened potential, that is, 0: one-center potentials V_{11}, V_{22}, V_{33},⋯; 1: the nearest two-center potentials V_{12}, V_{23}, V_{34},⋯; *etc.* The results in II and III are shown in Figs. 3 and 4, respectively. In the azulene nucleus of I and II, at each of the numbers the various screened potentials are almost the same as those of the free azulene molecule (see Fig. 9 of Ref. 11). In the naphthalene nucleus of III, a tendency similar to that in the free naphthalene molecule appears (see Fig. 8 of Ref. 11). In the free naphthalene molecule, there is a fairly clear double-

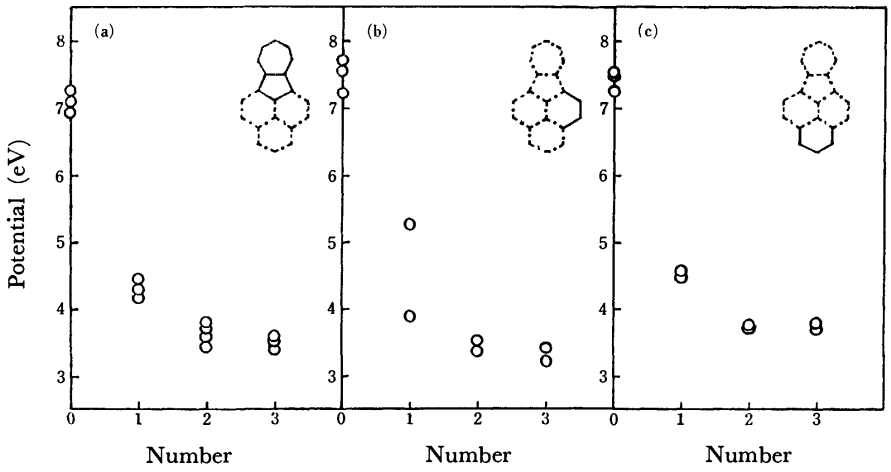

Fig. 3. The SCF screened potentials in azuleno[1,2,3-*cd*]phenalene plotted *versus* the number; (a) the azulene nucleus, (b) the benzene ring (A or B), and (c) the benzene ring (C).

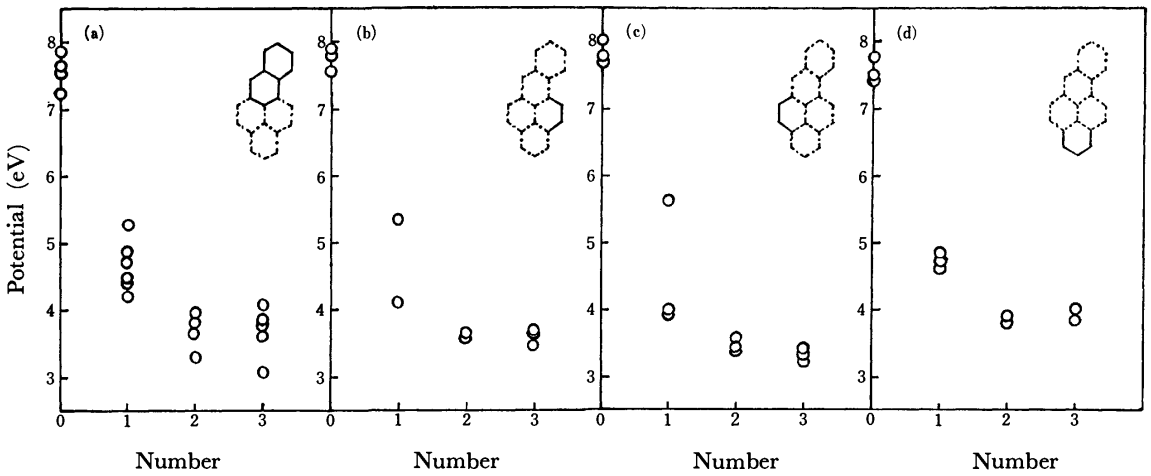

Fig. 4. The SCF screened potentials in benzo[*a*]pyrene plotted *versus* the number; (a) the naphthalene nucleus, (b) the benzene ring (A), (c) the benzene ring (B), and the benzene ring (C).

bond fixation, so that the characteristics of the screened potential are the same as those of the polyene ($n=10$) (see Fig. 8 of Ref. 11). The SCF screened potential is very sensitive to a bond alternation. There are two kinds of screening (screening and anti-screening) at the odd numbers in molecules such as polyene, in which there exists a strong bond alternation.[11] The characteristics of the screened potential of the benzene rings (A and B) in the phenalenyl moiety of I, II, and III presented in Figs. 2(b), 3(b), 4(b), and 4(c) shows trends similar to those of the polyene. The screened potential of the benzene ring (C) of I, II, and III shows a tendency similar to that of the free azulene molecule. From the above results, it may be concluded that the azulene nucleus of I and II and the benzene ring (C) in the phenalenyl moiety of I, II, and III are aromatic, but the naphthalene nucleus of III and the benzene rings (A and B) in the phenalenyl moiety of I, II, and III are polyolefinic. Molecules I, II, and III may have both aromatic and polyolefinic characters.

Electronic Spectra. Table 2 shows the transition energies and oscillator strengths calculated by using the SCF screened potential (SP) in combination with the variable bond-length SCF technique, along with those calculated assuming the bare potential (BP). It may be noted that the calculated excitation energies and oscillator strengths using the screened potential are in better agreement with the experimental values than those calculated using the bare potential. The spectral results calculated for I by Fischer and Ege[4] and by Thulstrup *et al.*,[8] for I and II by Zahradnik,[5] for II by Tajiri *et al.*,[9] and for III by Germer and Becker[6] and by Pancir and Zahradnik[7] are in fairly good agreement with the present results obtained using the SCF screened potential.

One of the present authors (H. Y.) especially wishes to thank Professor I. Murata of Osaka University for providing him with copies of the ultraviolet absorption spectra of azuleno[1,2,3-*cd*]phenalene and to thank Dr. Y. Fujimura of Tohoku University for his fruitful discussions.

Thermal Dissociation of *N,N*-Dimethylformamide–Tetracyanoethylene and Dimethyl Sulfoxide–Tetracyanoethylene Complexes into Ions

Nobuo KUSHIBIKI and Hiroshi YOSHIDA

Faculty of Engineering, Hokkaido University, Kita-ku, Sapporo 060

(Received July 10, 1976)

Ionic dissociation of *N,N*-dimethylformamide (DMF)-tetracyanoethylene (TCNE) and dimethyl sulfoxide (DMSO)-TCNE electron donor-acceptor (EDA) complexes was studied by means of optical absorption and electron spin resonance measurements. Upon dissolving TCNE into DMF or DMSO, essentially all the TCNE became complexed with the electron-donationg solvent; charge-transfer bands with maxima at 310 and 380 nm were found for DMF-TCNE and DMSO-TCNE complexes, respectively. The CT bands were transformed slowly in the dark into the band of $TCNE^-$. This transformation proceeded quantitatively and indicated the dissociation of the EDA complexes into ions. The rate of the ionic dissociation was determined by following a first-order growth of the ESR spectrum of $TCNE^-$ at various temperatures: $k=10^{8.9}\exp(79/RT)$ for the DMF-TCNE complex and $k=10^{6.3}\exp(59/RT)$ for the DMSO-TCNE complex, in units of s and kJ/mol. Dissolved oxygen was found not only to react chemically with the complex to form a new stable species, but also to quench physically the ionic dissociation. Upon evacuating the oxygen, the survival fraction of the complex was found to start dissociation again. It is suggested that the ionic dissociation arises from a long-lived precursor state, probably the triplet state of the complex.

Since the very early work of Kainer and Uberle showing the formation of ions on dissolving *N,N,N',N'*-tetramethyl-*p*-phenylenediamine-chloranil solid complex in acetonitrile,[1] the role of electron donor–acceptor (EDA) complexes in chemical reactions has been subject of spectroscopic study.[2] The role in photoinduced reactions has been extensively studied mostly by a flash photolysis technique: selective excitation at charge-transfer (CT) band or bands of constituent molecules has facilitated the elucidation of the molecular mechanism in the reactions. The photoinduced formation of ions from donor–acceptor pairs in solution has been shown to occur through an excited state of the EDA complexes and/or through an exciplex.[3] However, ion formation without light has been studied comparatively little, and its molecular mechanism has not been fully elucidated.[4–9]

TCNE, one of the strongest organic acceptors, has been known to form readily its radical anion ($TCNE^-$) when photoilluminated in fluid or rigid etherial solvents such as tetrahydrofuran (THF) which have an electron-donating nature.[7,10–13] Stewart *et al.* further found the formation of $TCNE^-$ in the absence of light upon mixing TCNE in more polar solvents such as dimethyl sulfoxide (DMSO) and *N,N*-dimethylacetamide (DMA).[6,7] The concentration of $TCNE^-$ was found to reach a maximum within a few minutes, before starting the measurements, and then to decay slowly. They proposed, in adopting the mechanism presented by Calvin for the THF-TCNE complex,[12] that the "prompt ESR signal of $TCNE^-$" arises from the thermal population of the CT triplet state, which then decays to give the ground state EDA complex between solvent and TCNE or to give ions. The slow decay was explained by recombination of ions to give the complex. These authors seem to have assumed that the observed $TCNE^-$ is the precusor of the complex rather than its product. Later, Keys and Carper found that in degassed solutions $TCNE^-$ was very stable and its concentration increased slowly after its prompt formation.[8] These observations were again interpreted on the basis of Stewart's view.

Recently, we also studied the formation without light of $TCNE^-$ in DMSO by the ESR method[14] and found a difference in its kinetical features from those reported previously.[6,7] We found no prompt formation of $TCNE^-$. Its concentration increased following a first-order kinetics during the whole period of reaction in the dark. The result suggested, in contrast to Stewart's view, the thermal dissociation of DMSO-TCNE complex into ions which is unexpectedly slow. The previous investigation is extended here and the formation of $TCNE^-$ is studied in either DMSO or *N,N*-dimethylformamide (DMF) by means of not only the ESR technique but also optical absorption measurements.

Experimental

TCNE of analytical grade was purified by recrystallization from anhydrous methylene dichloride and by sublimation under vacuum several times. DMF of spectroscopic grade was dried under vacuum with calcium hydride and then with barium oxide baked beforehand at *ca.* 650 K overnight, degassed by a freezing-pumping-thawing technique, and kept in the dark. DMSO of spectroscopic grade was dried with calcium hydride, degassed and treated with molecular sieves baked beforehand under vacuum, and kept in the dark.

TCNE was dissolved in DMF or DMSO within a closed glass system with an optical absorption cell or an ESR sample tube through a break seal under vacuum better than 1×10^{-5} Torr, and subjected to measurements. These procedures were carried out cautiously in total darkness. The optical absorption spectrum of the solution was recorded with a conventional recording spectrophotometer (Hitachi, Model EPS-3T) at room temperature (298±1 K) between intermittent warmings at a fixed temperature. Electron spin resonance (ESR) measurements were carried out with a conventional X-band spectrometer (JEOL, Model JES-ME-2X) equipped with a variable temperature accessary (Model JES-VT). The reaction temperature in the ESR resonant cavity was thus controlled within an uncertainty of 0.5 K. Absolute concentrations of $TCNE^-$ formed in the solutions were determined from their ESR spectral intensities, as compared with the intensity of the $TCNE^-$ authentically

generated by reducing TCNE with sodium metal in acetonitrile.[15]

Results

Optical Absorption Studies. Immediately after dissolving TCNE into DMF, an optical absorption band with a broad structureless shape was observed at about 310 nm, as shown in Fig. 1, where neither TCNE nor DMF gives an absorption. A similar band was observed at about 380 nm for DMSO solvent, as shown in Fig. 2. The shift of absorption maximum from 310 to 380 nm seems to correspond to the difference in ionization potential and in dielectric constant between DMF and DMSO. These bands are attributed to a charge-transfer transition and indicate the formation of EDA complexes between solvents and TCNE. The CT band of the DMSO-TCNE complex was reported to have an absorption maximum at 372 nm in carbon tetrachloride.[6] The band of the DMF-TCNE complex has not been reported. The 310 nm band in Fig. 1 is very similar to that of the DMA-TCNE complex, which shows an absorption maximum at 298 nm.[7]

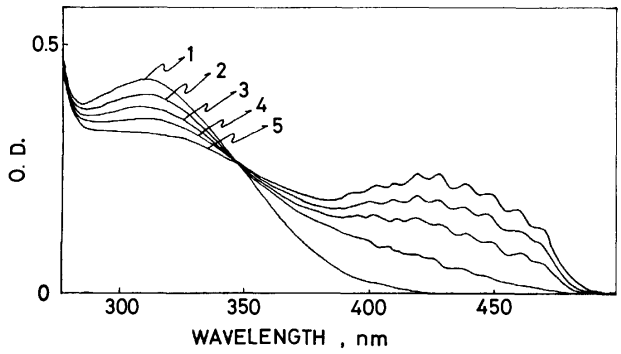

Fig. 1. Optical absorption spectra of DMF-TCNE observed at 298 K (1) immediately after mixing TCNE (3.0×10^{-4} mol dm^{-3}) in DMF under vacuum and after warming at 323 K for (2) 90, (3) 150, (4) 250 (5) 350 min. Optical path: 0.5 cm.

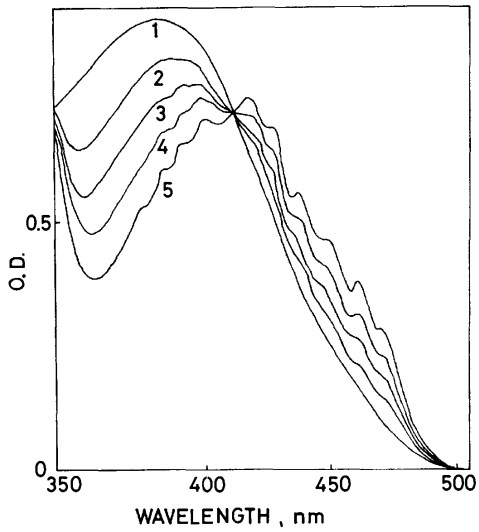

Fig. 2. Optical absorption spectra of DMSO-TCNE observed at 298 K (1) immediately after (2) 15, (3) 50, (4) 110 and (5) 280 min after mixing TCNE (6.0×10^{-4} mol dm^{-3}) in DMSO under vacuum. Optical path: 0.2 cm.

Figure 1 shows changes in the absorption spectrum when the solution of TCNE in DMF was warmed to 323 K: the CT band of the DMF-TCNE complex decayed slowly, while a new band appeared, extending from 350 to 500 nm. The new band has a vibrational structure which is essentially the same as that previously attributed to $TCNE^-$ which was chemically generated in acetonitrile.[15] The isosbestic point at 350 nm very probably indicates that ionic dissociation of the EDA complex proceeds quantitatively to give negative and positive ions, though no positive ions could be detected. Figure 2 shows similar results observed for the TCNE–DMSO system. An isosbestic point at 410 nm indicates the ionic dissociation of the DMSO-TCNE complex into ions. For this complex, the dissociation was found to be accelerated even by the analyzing light.

The growth of the absorption band of $TCNE^-$ was completely inhibited in the solution prepared in an open cell or in the presence of oxygen in a sealed cell, but an absorption band at about 300 nm was found to grow instead. This is clearly demonstrated in Fig. 3 for a solution of TCNE in DMSO under the pressure controlled to be 1×10^{-3} Torr, higher than that for the usual sample preparation. An isosbestic point at 340 nm indicates the quantitative transformation, in the presence of oxygen, of the EDA complex into another unidentified product. Although this transformation is as slow as the ionic dissociation observed in the absence of oxygen (see Fig. 2), the EDA complex does not dissociate into ions but is transformed exclusively into the unidentified product. Upon evacuating oxygen (or air), a survival fraction of the EDA complexes was found to start the dissociation into ions, but the unidentified product, once formed, was too stable to revert to the original complex.

ESR Studies. The formation of $TCNE^-$ in DMF or DMSO was evidenced also by the ESR method. The signal recorded from the solutions was exclusively due to the ESR spectrum of $TCNE^-$, which was essentially the same as that of $TCNE^-$ generated by reducing TCNE with alkali metal.[16,17] The spectrum

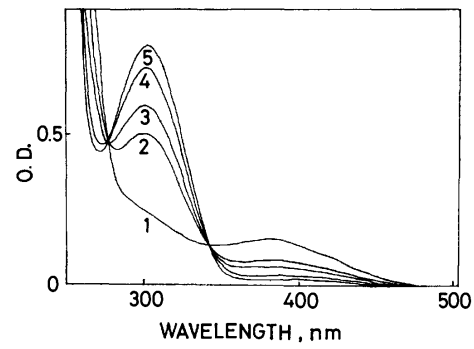

Fig. 3. Optical absorption spectra of unidentified product prepared by mixing TCNE (1.0×10^{-4} mol dm^{-3}) in DMSO under atmospheric pressure of 1×10^{-3} Torr and observed at 298 K (1) 5, (2) 35, (3) 60, (4) 100 and (5) 140 min after the mixing. Optical path: 0.2 cm.

consisted of 11 hyperfine lines equally spaced with a separation of 0.165 mT. Each hyperfine line was very narrow with a width, ΔH_{msl}, of 0.008 mT. The kinetical features of the formation of $TCNE^-$ were followed by observing the intensity of its spectrum at several temperatures. The advantage of ESR studies is that quantitative measurements can be readily made for $TCNE^-$ without any effect from light.

Figure 4 shows the formation of $TCNE^-$ in DMF. The $TCNE^-$ concentration increased slowly at a temperature-dependent rate and then tended to an asymptotic value, which was identical with the concentration of TCNE added in the solution. The observed time-concentration curves agreed well with a first order reaction, and the rate constant was independent of the concentration of TCNE. $TCNE^-$ was very stable in the dark and no decay was observed during a few weeks. Nor was any decay found even when the solution was exposed to air. The observed first order rate constant, k, is shown as a function of reciprocal temperature in Fig. 5, which gives a good Arrhenius relation with an activation energy of 79 kJ/mol and frequency factor of $10^{8.9}\,s^{-1}$.

The time-concentration curves for the formation of $TCNE^-$ in DMSO were already reported.[14] The observed kinetical features were essentially the same as those in DMF, except that the rate of the anion formation was larger in DMSO. The dashed curve in Fig. 6 shows the formation at 303 K under white light from a tungsten lamp, which is much quicker than that in the dark at the same temperature, as shown by a solid curve. It was found that even room light gives a large amount of $TCNE^-$ during the procedure of dissolving TCNE into DMSO. The activation energy and the frequency factor in DMSO in the dark were previously reported to be 59 kJ/mol and $10^{6.3}\,s^{-1}$,

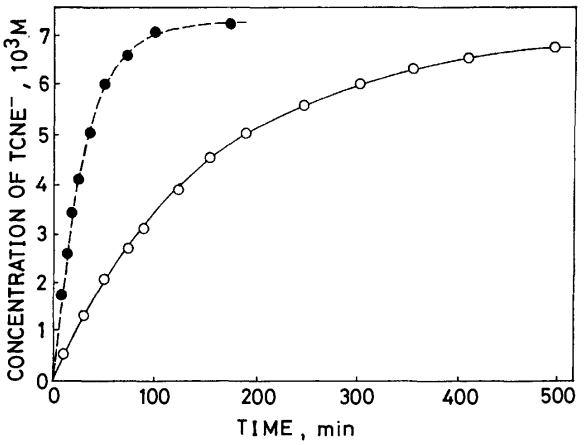

Fig. 6. Growth of the concentration of $TCNE^-$ formed from TCNE (7.0×10^{-3} mol dm^{-3}) in DMSO (solid line) in the dark and (dashed line) under light from an incandescent lamp both at 303 K determined by ESR.

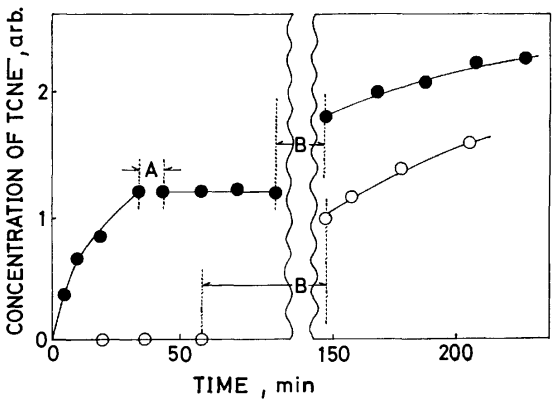

Fig. 7. Growth of the concentration of $TCNE^-$ ● in DMSO-TCNE prepared under vacuum and ○ in DMSO-TCNE prepared under 760 Torr of oxygen both at 303 K determined by ESR. A indicates the period of introducing 760 Torr of oxygen into the solution and B indicates the period of evacuating oxygen from the solution. The concentration of added TCNE was 7.0×10^{-3} mol dm^{-3}.

respectively.[14]

Figure 7 shows the effect of oxygen studied by ESR. When oxygen was introduced into the solution during ESR measurements, the formation of $TCNE^-$ became inhibited, as shown by closed circles. On re-evacuating the oxygen, the formation started again, but the formation rate was smaller than before. The solution prepared under 1 atm of oxygen gave no $TCNE^-$, but it was found to form when the dissolved oxygen was removed by evacuation, as shown by the open circles. These results indicate the physical quenching of the $TCNE^-$ formation and the chemical elimination of the precursor of the radical anion by the oxygen dissolved in the solution.

Discussion

Formation of EDA Complexes. CT bands have been studied for the EDA complexes between several electron donors and TCNE.[6,7,18,19] The molar extinction coefficient at the absorption maximum at 372 nm and the equilibrium constant were reported for the complex formation for the DMSO–TCNE system in carbon tetrachloride to be 973 $mol^{-1}\,dm^3\,cm^{-1}$ and 95.4 $dm^3\,mol^{-1}$, respectively, at 298 K. The CT band of the DMSO–TCNE complex was found in the present investigation to develop before starting the measurements of the absorption spectrum (see Fig. 2). Its absorption maximum lay at a slightly longer wavelength, 380 nm. The shift in wavelength is attributed to a larger dielectric constant for the present donor-solvent, DMSO, compared with that of carbon tetrachloride. Adopting the reported equilibrium constant, the uncomplexed fraction of TCNE is estimated to be as small as 7.5×10^{-4}. Thus, it is concluded that essentially all the TCNE becomes complexed with DMSO immediately after mixing the former into the latter. It should be noted that the present results, shown in Fig. 2, indicate an extinction coefficient of 7500 $mol^{-1}.\,dm^3\,cm^{-1}$ for the DMSO–TCNE complex (in DMSO solution), much larger than that reported previously. This large extinction coefficient is substantiated by the isosbestic point at 410 nm and the reported extinction coefficient of 6200 $mol^{-1}\,dm^3\,cm^{-1}$ at 407 nm for $TCNE^-$.[6] Nevertheless, the conclusion of complete complex formation is tenable, even if the equilibrium constant is presumed to be one-tenth as small as that reported. As a matter of fact the equilibrium constant was reported to be 83.5 $dm^3\,mol^{-1}$ for the DMA–TCNE complex,[7] which seems to be very similar in nature to the DMSO–TCNE complex.

Although the spectroscopic data have not been reported for the DMF–TCNE pair, DMF is a rather strong electron donor.[22] Therefore, all the TCNE may safely be assumed to form initially the complex with DMF. Assuming a complete complex formation, the molar extinction coefficient is estimated from spectral curve 1 in Fig. 1 for the DMF–TCNE complex to be 2900 $mol^{-1}\,dm^3\,cm^{-1}$ at 310 nm.

Ionic Dissociation of EDA Complex. The present optical absorption studies reveal the growth of an absorption band at 350—500 nm due to $TCNE^-$ simultaneously with the decay of the CT band due to the EDA complexes (see Figs. 1 and 2). The ESR observation (Figs. 4 and 6) also indicates the slow formation of $TCNE^-$. It is concluded that the DMF–TCNE and DMSO–TCNE complexes dissociate into ions in the dark. It should be emphasized that the formation of $TCNE^-$ occurs after the completion of complex formation between TCNE and solvent. The observation of an isosbestic point appeared in the optical absorption studies and the asymptotic value of the $TCNE^-$ concentration indicate that the complexes dissociate quantitatively into ions.

The radical cation of DMSO and also that of DMF should be formed simultaneously with the $TCNE^-$ formation, but no cationic species could be detected either by the optical absorption measurements or by the ESR technique, as reported previously.[6–8,10–14] Absence of an ESR spectrum due to $DMSO^+$ has been interpreted as due to a rapid spin exchange between $DMSO^+$ and the remaining DMSO.[6] However, such an interpretation seems highly inconceivable, because it turns out that such a rapid exchanging spin (positive hole) has a lifetime as long as that of $TCNE^-$, which was found to be more than several weeks in the present investigation. $DMSO^+$ might be transformed readily into a stable diamagnetic cation, which no longer reacts with $TCNE^-$ and causes the stability of $TCNE^-$, as suggested by Achiba and Kimura for 2-methyltetrahydrofuran–TCNE system.[20] Both acceptor radical anion and donor radical cation were observed by ESR for 2,3-dichloro-5,6-dicyano-*p*-benzoquinone and *p*-phenylendiamine and *N,N,N',N'*-tetramethyl-*p*-phenylenediamine in acetonitrile.[21]

The formation of $TCNE^-$ in DMSO and DMA in the dark was studied previously by ESR, but the observed kinetical features differ from those in the present investigation. Stewart *et al.* reported that the formation is completed promptly before starting the measurements (within a few minutes).[6,7] Keys and Carper observed that, in addition to the prompt development of the ESR spectrum of $TCNE^-$, its intensity still increases slowly to an asymptotic value, though they gave no interpretation for the difference between these two modes of the formation of $TCNE^-$.[8] The present investigation indicates no prompt formation of $TCNE^-$. Taking account of the striking effect of light in accelerating the $TCNE^-$ formation (see Fig. 6), the prompt formation reported previously seems to result from this light effect.

On the basis of the observed total participation of TCNE in the EDA complexes and the subsequent exponential growth of the concentration of $TCNE^-$, the formation of $TCNE^-$ is attributed simply to dissociation of the complexes into ions. The apparent activation energy was found to be as large as 0.82 eV (79 kJ/mol) and 0.61 eV (59 kJ/mol) for the dissociation of the DMF–TCNE and the DMSO–TCNE complexes, respectively. As far as we know, this is the first example where the thermal ionic dissociation of EDA complex has been evidenced and its rate constant determined. Recently, Farrell and Ngô studied the spontaneous formation of $TCNE^-$ in *N,N*-dimethylaniline–TCNE system and found it apparently slow.[23]

However, they interpreted this slow formation by assuming the competition between an essentially fast formation of $TCNE^-$ and its fast disappearance. The ionic dissociation of EDA complex in the dark is really a slow process, at least in the DMF-TCNE and DMSO-TCNE systems.

Effect of Dissolved Oxygen. Stewart *et al.* observed the slow decay of the ESR signal of $TCNE^-$ by a second-order process and explained it by a recombination of ions.[6,7] Later, Keys and Carper found that careful exclusion of oxygen affects the ESR signal and that it persists for a period as long as a month in the dark. They also observed that introduction of oxygen kills the signal.[8] However, the present observations indicate that $TCNE^-$ is stable either in the absence or in the presence of oxygen, if it is once generated. The reason is not known for the difference in the observed stability of $TCNE^-$ when oxygen is introduced.

An important finding here is the reversible inhibition of the ionic dissociation of the complexes by the introduction of oxygen. Figure 3 indicates that the DMSO-TCNE complex is transformed by a trace of oxygen into another species giving an absorption band at about 300 nm, which is not identified but presumed to be a ternary complex of DMSO, TCNE, and oxygen. Although this unidentified species develops as slowly as the $TCNE^-$ formation in the absence of oxygen, the latter does not proceed at all in the presence of oxygen. This indicates that dissolved oxygen not only chemically reacts with the DMSO-TCNE complex but also physically quenches the precursor of $TCNE^-$. The formation of $TCNE^-$ on re-evacuation, shown in Fig. 7, also indicates the quenching of the precursor by oxygen in the closed cell.

Assuming that oxygen at low pressure (10^{-3} Torr) is totally dissolved in the solution, the concentration of oxygen is roughly estimated to be 10^{-6} mol dm^{-3}. If one further assumes that the quenching is a diffusion-controlled process with a rate constant of 10^{10} mol^{-1}. dm^3 s^{-1}, the lifetime of the precursor is estimated to be as long as 10^{-4} s or more. The efficient quenching by a trace of oxygen supports the view that the thermal ionic dissociation of the complexes occurs through their lowest triplet state. It would be inconceivable that there exists any long-lived transient intermediate other than the triplet state complex, which is thermally accessible, is quenched by oxygen, and acts as a precursor of $TCNE^-$.

Based on the kinetic features of formation and decay of $TCNE^-$, Ilten and Calvin proposed a molecular mechanism for the photoinduced ionic dissociation of the THF-TCNE complex, where $TCNE^-$ results from a long-lived triplet state of the complex populated by intersystem crossing from a photoexcited singlet state.[12] Later, the involvement of the triplet state has been reported for the photoinduced ionic dissociation of other EDA complexes as well.[13,24-26] Stewart *et al.* proposed a similar triplet state mechanism for the formation of $TCNE^-$ in the dark from DMSO-TCNE and DMA-TCNE pairs, on the basis of experimental observations different from those in the present investigation.[6-8] They assumed that the high enthalpy of complex formation leads to an appreciably populated triplet state of the complexes, during complex formation, from which the ionic dissociation occurs. In contrast, the present investigation reveals that the triplet state is populated by a slow thermal process long after the complex formation.

In conclusion, we can formulate the simplified reaction scheme for the thermal ionic dissociation of the DMF-TCNE and DMSO-TCNE complexes as

$$\mathrm{D.A} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} {}^3(\mathrm{D.A})^* \xrightarrow{k_2} \mathrm{D}^+ + \mathrm{A}^-, \qquad (1)$$

on the basis of the present observation, where D and A denote the electron donor (DMF or DMSO) and the acceptor (TCNE), respectively. Naturally k_1 is much smaller than k_{-1}. If $k_{-1} \ll k_2$, the observed first-order rate constant, k, for the formation of acceptor anion is given by k_1 and the thermal activation to ^{3}(D. A)* is the rate-determinant step of the anion formation. The observed activation energy (see Fig. 5) corresponds to the energy separation between ^{3}(D. A)* and D. A. If $k_{-1} \gg k_2$ on the other hand, k is given by k_1k_2/k_{-1}, and the rate-determinant step is the dissociation of ^{3}(D. A)*. In this case, the activation energy seems to give the upper limit of the energy separation. The most crucial question which might arise about the triplet state of the EDA complexes is whether it lies so low as to be populated thermally. Unfortunately, there appear to be no results, either experimental or theoretical, in the literature which could answer this question, and there is an obvious need for data (in particular energy and lifetime) on ^{3}(D. A)* to substantiate the above reaction scheme.

Oxidation Activity and Acid-base Properties of Mixed Oxide Catalysts Containing Titania. II. The TiO_2–V_2O_5–P_2O_5 System

Mamoru Ai

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received August 4, 1976)

The acidity and basicity of a series of TiO_2–V_2O_5–P_2O_5(atomic ratio Ti : V : P=9 : 1 : x)catalysts with different P_2O_5 contents (x=0—18), were measured by studying the adsorption of the basic and acidic molecules in the gas phase, using both the static and pulse methods. TiO_2–V_2O_5(V/Ti=1/9) is rather basic, but this catalyst can be modified from basic to acidic by the introduction of P_2O_5. The vapor-phase oxidation of butadiene and 1-butene, which were chosen as electron-donor-type reactants, and that of acetic acid, as an acidic reactant, were carried out in the presence of an excess of air, and then the relationship between the catalytic behavior and the acid-base properties was investigated. The results support an earlier proposal that the activity and selectivity in mild oxidation can be interpreted in terms of the acid-base properties of the catalyst and the reactant.

TiO_2 is an amphoteric oxide and its acid-base properties are significantly modified by the introduction of a small quantity of additive.[1,2] The acidic sites and electron donating sites of TiO_2 and their variation with pretreatment or in combination with several oxides have also been studied, in connection with active sites for the isomerization of butene, by Tanabe *et al.*[3-5]

In a preceding report,[6] the acid-base properties of TiO_2–V_2O_5 and TiO_2–MoO_3 binary systems and their correlation with oxidation activities were studied. It was found that the basic character of the systems is greatly enhanced by the addition of a small amount of such acidic elements as MoO_3 and V_2O_5 to TiO_2 and, therefore, the binary systems are sufficiently basic at Mo<20 or V<10 atom%. On the other hand, it has been reported that (1) the addition of P_2O_5 to TiO_2 sharply increases the acidity,[1] unlike the case in which P_2O_5 is added to SnO_2,[7] and that (2) TiO_2–P_2O_5 catalysts containing a large amount of P_2O_5 are highly acidic and are active as polymerization catalysts.[8]

This evidence led to the prediction that the acid-base character of TiO_2-containing mixed oxide catalysts can be modified by controlling the amounts of either the V_2O_5 or the P_2O_5 added.

The present paper is the second part of an investigation of the oxidation activity of the TiO_2-based catalysts. An attempt was made to ascertain how the addition of various amounts of P_2O_5 to TiO_2–V_2O_5 (amount ratio V/Ti=1/9) modifies the acid-base properties and how these properties are correlated with the oxidation activity and selectivity.

Experimental

Catalysts. The catalysts used in this study were of the TiO_2–V_2O_5–P_2O_5 series (atomic ratio Ti : V : P=9 : 1 : x), with eight different amounts of P_2O_5 (x=0—18). They were prepared by the procedures described in a preceding report.[6]

Procedures. The acidity of the TiO_2–V_2O_5–P_2O_5 catalysts were determined both by the amount of NH_3 irreversibly adsorbed (static method) and by that of the pyridine required to completely poison the isomerization activity for 1-butene (pulse method). The basicity was determined by the amount of CO_2 irreversibly adsorbed, using the static method. The technique used in these measurements has also been described earlier.[6,7,9]

The vapor-phase oxidation of 1-butene, 1,3-butadiene, and acetic acid and the isomerization of 1-butene were carried out in the presence of an excess of air, in an ordinary continuous-flow-type reaction system. The reactor and the experimental procedures were the same as those employed previously.[1,6,7,9]

Results

Surface Areas. The surface areas of the TiO_2–V_2O_5–P_2O_5 catalysts were checked by the BET method using nitrogen at −196 °C. The results are shown in Table 1. The surface area increases gradually for an increase in the P_2O_5 content (x), but decreases when the P_2O_5 content becomes too high (x=18).

Acidity. The acidity per unit surface area of the TiO_2–V_2O_5–P_2O_5 catalysts, as determined by the amounts of NH_3 irreversibly adsorbed at 20, 200, and 250 °C, are plotted in Fig.1 as a function of the P_2O_5 content (x). These results indicate that the P_2O_5-poor catalysts have a fair amount of acidic sites of weak acid strength, as has been pointed out in a previous paper.[6] The acidity obtained by the amount of pyridine required to completely poison the isomerization activity for 1-butene at 160 °C is also plotted in Fig. 2. Parallels were found between the amounts of NH_3 obtained by means of the static method and those of pyridine obtained by means of the pulse method, which proves the validity of these results.

It is found, as was expected, that the acidity of TiO_2–V_2O_5–P_2O_5 catalysts increases for an increase in the P_2O_5 content.

Basicity. The basicity per unit surface area of the TiO_2–V_2O_5–P_2O_5 catalysts, as determined by the amount of CO_2 irreversibly adsorbed at 20 °C, is plotted in Fig. 3 as a function of the P_2O_5 content (x). It is also demonstrated that the basicity of the catalysts

Table 1. Surface area of the TiO_2–V_2O_5–P_2O_5 (atomic ratio Ti : V : P=9 : 1 : x) catalysts used

P_2O_5 content x	Surface area (m^2/g)	P_2O_5 content x	Surface area (m^2/g)

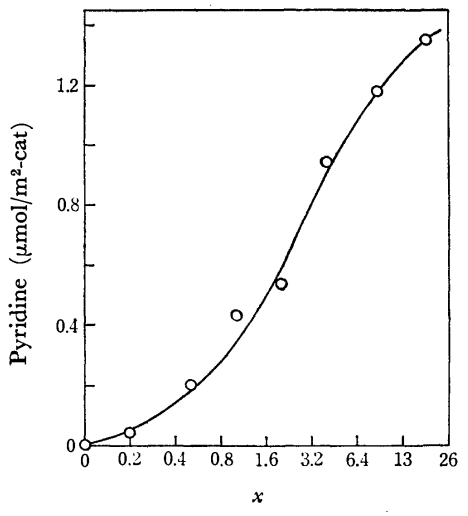

Fig. 2. Acidity of TiO_2-V_2O_5-P_2O_5 (9 : 1 : x) as a function of the P_2O_5 content (x). II. Pyridine required to poison the isomerization activity for 1-butene at 160 °C (pulse method).

gradually decreases for an increase in the P_2O_5 content.

Isomerization Activity for Butene. The relationship between the catalytic activity for isomerization and the acid-base properties was investigated. The reaction was carried out at 0.67 mol% 1-butene in air and at 250 °C by changing the catalyst amounts in the range of 1.0 to 10 g. As a measure of the isomerization activity, the ratio of (*cis*-2-butene+*trans*-2-butene)/(1-butene+*cis*-2-butene+*trans*-2-butene) corresponding to 1 m² of the catalyst, I, was adopted, much as in the cases reported previously.[6,7,9]

The results are plotted in Fig. 4 as a function of the acidity of the catalyst, *i. e.*, the amount of pyridine required to poison the isomerization activity. A rough-

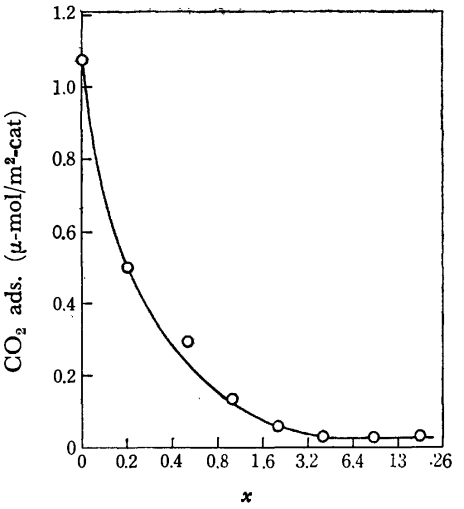

Fig. 3. Basicity of TiO_2-V_2O_5-P_2O_5 (9 : 1 : x) as a function of the P_2O_5 content (x). Irreversible adsorption of CO_2 at 20 °C.

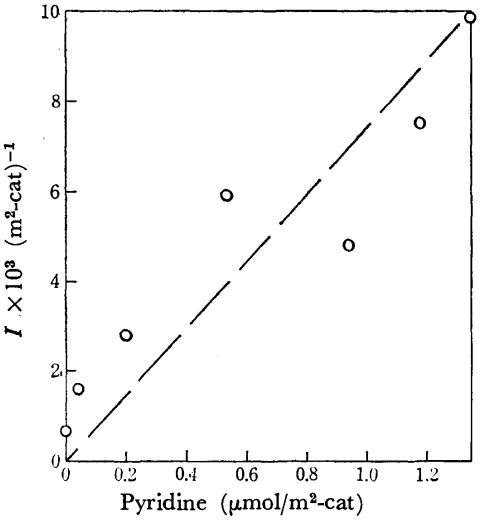

Fig. 4. Relation between the isomerization activity for 1-butene (I) and the acidity (amount of pyridine required to poison the isomerization of 1-butene). I=(*cis*-2-C_4H_8 + *trans*-2-C_4H_8)/(1-C_4H_8 + *cis*-2-C_4H_8 + *trans*-2-C_4H_8) corresponding to 1 m² of the catalyst, T=250 °C, 1-C_4H_8=0.67 mol% in air.

ly proportional relationship was obtained between the isomerization activity and acidity.

Oxidation Activity for Olefin. Butadiene was chosen as an electron-donor-type (basic) reactant and was oxidized in an excess of air (0.67 mol% of butadiene in air) by changing the amounts of the catalyst from 3 to 20 g. The initial rate of the overall consumption of butadiene at 295 °C, r_B (mol/h m²-cat), was adopted as a measure of the oxidation activity, much as in the cases reported previouly.[6,7,9] This is plotted in Fig. 5 as a function of the P_2O_5 content (x).

The activity first increases with the P_2O_5 content, reaches a maximum at about x=0.4, and then decreases again to a very low value.

Oxidation Activity for an Acidic Compound. Acetic acid was chosen as the acidic reactant, and it was oxidized in an excess of air (1.5 mol% of acetic acid

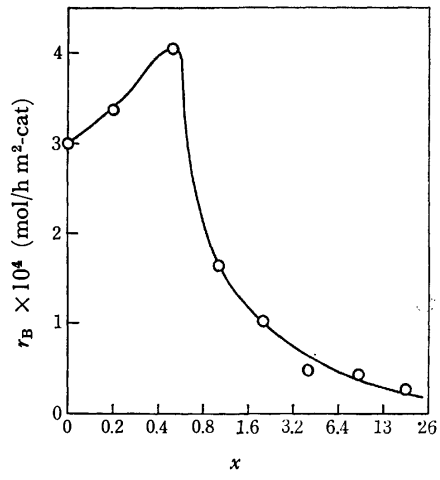

Fig. 5. The oxidation activity for butadiene (r_B) as a function of the P_2O_5 content (x).
Butadiene=0.67 mol% in air, T=295 °C.

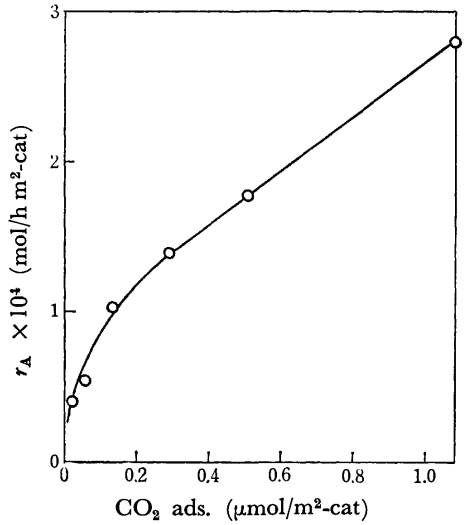

Fig. 6. Relation between the oxidation activity for acetic acid (r_A) and the basicity (amount of CO_2 irreversibly adsorbed).
Acetic acid=1.5 mol% in air, T=325 °C.

in air). The initial rate of oxidation to CO_2 at 325 °C, r_A (mol/h m^2-cat), was adopted as a measure of the oxidation activity. It is plotted in Fig. 6 as a function of the basicity of the catalyst, *i. e.*, the amount of CO_2 irreversibly adsorebed. The activity steadily increases with an increase in the basicity of the catalyst.

Selectivity in the Oxidation of an Olefin. The partial oxidation reactions are divided into two types in terms of the acid-base properties of the products:[1,6,7,9,10]

Type 1: Basic reactant→acidic product
Type 2: Basic reactant→basic product

Both the selectivity of butadiene to maleic anhydride at 40—50% conversion and that of 1-butene to butadiene at 30—40% conversion, which were chosen as model reactions of Types 1 and 2, respectively, are plotted in Fig. 7 as a function of the P_2O_5 content (x).

The results indicate that the "base-formation" reaction is favored by a rather basic catalyst and that the "acid-formation" reaction is favored by an acidic catalyst, as expected on the basis of earlier studies.[1,6,7,9,10]

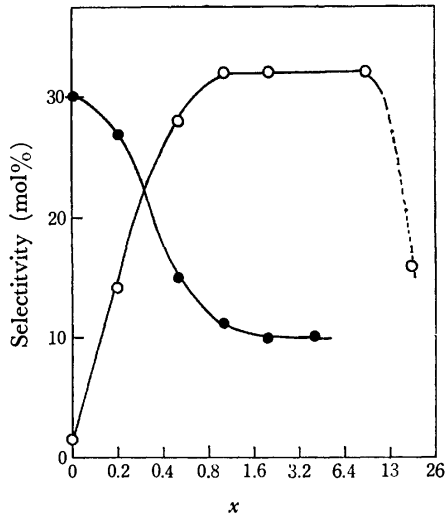

Fig. 7. Selectivity as a function of the P_2O_5 content (x).
○: Selectivity of butadiene to maleic anhydride, ●: selectivity of 1-butene to butadiene.

Discussion

Generally speaking, to be active in oxidation reactions, a catalyst must participate in the following two processes:

(1) activation of reactant molecules, and
(2) activation of oxygen.

When a catalyst is potent in the activation of oxygen, *i. e.*, has an oxidizing power which depends on two factors: (a) the number of oxidizing sites, and (b) the mobility of oxygen at a site, the oxidation reaction takes place without requiring activation of the reactant, therefore, the catalytic activity is controlled only by the activation of oxygen and the reaction proceeds non-selectively toward CO_2 and H_2O. This is the case of deep oxidation over such metal oxides as NiO, Co_3O_4, Cr_2O_3, MnO_2, and CuO. On the other hand, when the oxidizing power of a catalyst is not so strong, the reaction requires activation of the reactant as well as of oxygen, and, therefore, the difference in the mode or degree of this reactant-activation brings about the selectivity of the catalyst. Thus, it can be said that a requirement for an effective catalyst for any selective oxidation is a "moderate" oxidizing power, as has been pointed out by Sachtler *et al.*[11]

In studies on selective oxidations, many attempts have been made to disclose the active component in mixed oxide catalysts and to interpret the catalytic behaviors in connection with a particular structure (including electronic structure) of the metal oxides, as has been reviewed.[12]

Recently, the present author has proposed, from a different point of view, that it is the acid-base properties of the catalyst as well as the oxygen mobility which are directly responsible for the catalytic actions, although a change in the structure may naturally cause a change in these properties.[6,7,9,10] The acidic sites,

probably consisting of metal ions with a particularly high electron affinity, play a role in electron transfer from the reactant of the sites, resulting in the formation of a cationic intermediate and a reduced metal ion,[13] *i. e.*, the acidic sites contribute to the activation of the reactant. On the other hand, the basic sites, owing to their ability to donate electron to oxygen, contribute to adsorb and activate the gaseous oxygen and also to reoxidize the reduced metal ions, that is, the basic sites are connected with the oxidizing sites, probably consisting of lattice oxygen, O^{2-}.[9,10] Explanations of the role of each component in the catalytic action of such binary oxide systems as Cu–Sb,[14] Bi–Mo,[13,15] and others[16,17] appear to be based essentially on the same notion as that stated above, although the structure and generation of acidic and basic sites cannot be explained at present.

Let us now discuss the experimental results from this viewpoint. TiO_2–V_2O_5 (V/Ti=1/9) is rather basic, although it has a fair amount of acidic sites of weak acid strength. The addition of P_2O_5 to TiO_2–V_2O_5 gradually decreases the basicity and increases the acidity. Therefore, the ternary system containing a large amount of P_2O_5 is highly acidic but scarcely basic.

The oxidation activity for basic compounds, such as butadiene, is maximum at x=about 0.4 and is not correlated with the acidity of the catalyst, unlike MoO_3- or V_2O_5-based catalysts.[6,7,9,10] These results can be interpreted as follows. When the P_2O_5 content is low and the basic sites which are connected with the oxidizing sites, are sufficiently numerous, the oxidation activity is dependent mainly on the activation of the basic reactant (olefin) over the acidic sites. However, when, the P_2O_5 content is high and the oxidizing sites are strongly extinguished by the P_2O_5, the oxidation activity is then limited by the activation of oxygen but not by that of the reactant. It should be noted that the TiO_2–P_2O_5 system containing a large amount of P_2O_5 is inactive as an oxidation catalyst, due to the lack of oxidizing power, though it is highly acidic.[18] The same phenomenon was observed in the case of WO_3–P_2O_5–X_nO_m (X_nO_m=different metal oxides) catalysts, where the high oxidizing power of NiO, Co_3O_4, and MnO_2 is completely extinguished by WO_3–P_2O_5.[19]

On the other hand, in the case of the oxidation of an acidic compound, such as acetic acid, the activation of the reactant as well as of oxygen takes place on the basic sites, owing to the electron-donating ability to the electron-acceptor-type compounds, acetic acid and oxygen.[9,10] This view is consistent with the experimental results shown in Fig. 6.

As regards the selectivity, the results obtained from the TiO_2–V_2O_5–P_2O_5 system also support an earlier proposal that a requirement for an effective catalyst in "acid-formation" reactions is an acidic character and that a requirement for a catalyst to be effective in "base-formation" reactions is a moderate character both as an acid and a base.[1,6,7,9,10]

Conclusion

The character of the TiO_2–V_2O_5–P_2O_5 ternary catalysts can be modified from basic to acidic by controlling the P_2O_5 content.

The catalytic behavior of the TiO_2–V_2O_5–P_2O_5 system supports an earlier proposal that the activity and selectivity in mild oxidations can be interpreted in terms of the acid-base properties of the catalyst and the reactant. The acidic sites contribute to the activation of electron-donor-type reactants, while the basic sites are connected with the oxidizing sites and they also contribute to the activation of acidic reactants.

Vibrational Spectra of Ethyleneurea and Its *C,C'*- and *N,N'*-Deuterated Derivatives

Yutaka SAITO and Katsunosuke MACHIDA

Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606

(Received August 28, 1976)

Infrared and Raman spectra of ethyleneurea and its *C,C'*- and *N,N'*-deuterated compounds have been measured. The fundamental frequencies have been assigned by referring to isotopic frequency shifts and Raman depolarization ratios. A normal coordinate analysis has been carried out for the infrared active vibrations of a planar C_{2v} molecular model. A Urey-Bradley potential function supplemented by valence type constants for the out-of-plane deformation and the torsional coordinates has been used. The calculated frequencies based on a refined set of force constants agree well with the observed.

As a part of our serial studies on the vibrational spectra and the force field of urea derivatives,[1,2] the present work has been undertaken to deal with the infrared and Raman spectra of ethyleneurea and its *C,C'*- and *N,N'*-deuterated derivatives. It has been known that the group vibrations of monosubstituted amides, R-CONH-R', are quite sensitive to the relative positions of the CO and the NH bonds.[3] The CN stretching and the NH in-plane deformation vibrations in the *trans* structure couple appreciably with each other, giving rise to the characteristic amide II and III frequencies, while those in the *cis* structure do not. An analogous coupling has been found for *N*-alkyl- and *N,N'*-dialkylureas which have at least one NH bond at the *trans* position of the CO bond.[4] In this respect, the behavior of the CN stretching and the NH in-plane deformation vibrations in the absence of the *trans* -CONH- structure in ethyleneurea is of interest as a clue to the correlation between the vibrational spectra and the structure of urea derivatives.

Experimental

Materials. Ethyleneurea (EU-d_0) was obtained from Tokyo Kasei Co. and was recrystallized twice from ethanol and then once from ethylacetate. For the preparation of the *C,C'*-deuterated ethyleneurea (EU-d_4), 1 ml of ethylene glycol-d_4 (Merck AG., 99%) was heated gradually with *ca.* 4 g of urea from 150 to 240 °C during 4 h.[5] The resulting resinous solid was pyrolized at 240—270 °C under reduced pressure, and EU-d_4 was distilled from the solid as it decomposed. The crystallization from ethylacetate gave *ca.* 0.21 g of EU-d_4. No indication of the re-exchange of deuterium by hydrogen in this process was detected in the infrared and the Raman spectra of this sample. The *N,N'*-undeuterated compounds were converted into the corresponding *N,N'*-deuterated compounds (EU-d_2 and EU-d_6) by the exchange reaction with heavy water.

Measurements. The infrared spectra were recorded on a JASCO IR-A2 grating infrared spectrophotometer (4000—400 cm^{-1}). The measurements were made for Nujol and hexachlorobutadiene mulls, and the observed absorption frequencies were calibrated with the standard absorptions of indene, polystyrene and ammonia. The Raman spectra were recorded on a JEOL S-1 laser Raman spectrophotometer by using the excitation line 488.0 nm of a Coherent 52G Ar^+ laser. The measurements were made for fine crystalline powder sealed in 1 mm capillary tubes, and the observed Raman frequencies were calibrated with the spontaneous emission lines of the Ar^+ laser. The depolarization measurements were made for the aqueous solutions of EU-d_0 and EU-d_4 and for the solutions of EU-d_2 and EU-d_6 in heavy water. The spectral slitwidth was 12.7 cm^{-1} for all the measurements.

The infrared spectra are shown in Figs. 1 and 2, and the Raman spectra in Figs. 3 and 4. The observed frequencies are listed in Table 1 together with approximate band intensities and assignments.

Vibrational Assignments

The crystal structure of ethyleneurea has not been determined to date. We may assume, however, that ethyleneurea takes the planar C_{2v} configuration in the crystal, since the X-ray analysis has shown that an analogous compound, ethylenethiourea, takes approximately this configuration.[6] On this assumption, EU-d_0 and its deuterated compounds should contain 30 normal vibrations which are classified as $10a_1+5a_2+6b_1+9b_2$.

In the infrared spectrum, the NH stretching band of EU-d_0 appears as a doublet but that of EU-d_4 does not. Contrarily, the ND stretching band splits for EU-d_6 but not for EU-d_2. This result indicates that the splittings observed for EU-d_0 and EU-d_6 can be attributed neither to the presence of two NH or ND bonds nor to the crystal field splitting but to anharmonic resonances. Possible candidates of the summation tones participating mainly in the weaker components of the doublets are $1423+2\times991$ (or $1376+991+1041$) ≈3415 cm^{-1} for EU-d_0 and $1243+1169\approx2415$ cm^{-1} for EU-d_6.

In the Raman spectra of EU-d_0 and EU-d_2 in aqueous solution, two strong and polarized bands appear at 3005 and 2908 cm^{-1}. These bands are attributed to the a_1 CH_2 stretching vibration and the overtone of the a_1 CH_2 bending vibration involved in a Fermi resonance. Similarly, aqueous solutions of EU-d_4 and EU-d_6 show two strong Raman bands at 2185 and 2145 cm^{-1} attributable to a resonance diad involving the a_1 CD_2 stretching vibration. The b_1 and the b_2 CH_2 stretching vibrations of EU-d_0 seem to g ve weak Raman bands at 2980 and 2915 cm^{-1}, respectively, observed only when the incident and the scattered lights are polarized perpendicularly to each other. These bands are hidden by the strong a_1 bands in the ordinary Raman spectrum.

The strong infrared band around 1660 cm^{-1} observed for EU-d_0 and EU-d_4 arises obviously from the C=O stretching vibration. The corresponding Raman band is polarized in the solution spectra as expected from the

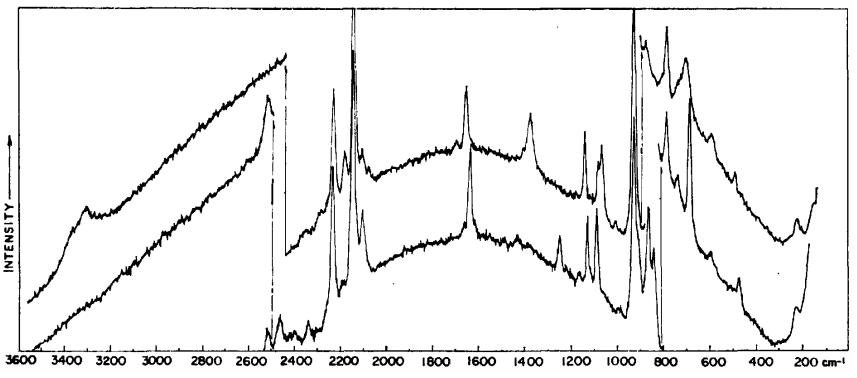

Fig. 4. Raman spectra of EU-d_4 (above) and EU-d_6 (below).

assignment. A slight low-frequency shift was observed for this band on the *N,N'*-deuteration, revealing a small coupling between the C=O stretching and the a_1 NH in-plane deformation vibrations.

In the infrared and Raman spectra of EU-d_0 and EU-d_2, the bands due to the CH_2 bending vibrations around 1500 cm^{-1} and those due to the CH_2 wagging vibrations around 1270 and 1200 cm^{-1} were easily assigned because they disappeared on the *C,C'*-deuteration. According to the normal coordinate analysis, the b_1 CH_2 twisting vibration may also contribute to the bands around 1200 cm^{-1}. The infrared and the Raman bands due to the CH_2 rocking vibrations of EU-d_0 and EU-d_2, and those due to the CD_2 bending, wagging, twisting and rocking vibrations of EU-d_4 and EU-d_6 were not obvious and we picked them up tentatively by referring to the calculated frequencies for the initial force constants.

In contrast to the cases of methylurea[2,7] and *N,N'*-dimethylurea,[8] EU-d_0 and EU-d_4 show no infrared bands in the region between 1550 and 1510 cm^{-1} where the amide II frequency is expected. Instead, EU-d_0 shows a strong infrared band at 1451 cm^{-1}, which persists on the *N,N'*-deuteration with a small low-frequency shift, and a weak band at 1423 cm^{-1} which disappears on the *N,N'*-deuteration. From analogy with urea[1,9] and *cis*-monosubstituted amides,[3,10] the 1451 cm^{-1} and the 1423 cm^{-1} bands are assigned to the CN stretching and the NH in-plane deformation vibrations, respectively, in the b_2 species. The a_1 NH in-plane deformation vibration is thought to give rise to the Raman band at 1385 cm^{-1}. For EU-d_4, the infrared absorptions due to the CN stretching and the NH in-plane deformation vibrations in the b_2 species seem to overlap at 1425 cm^{-1}, and the a_1 NH in-plane deformation band appears around 1377 cm^{-1} both in the infrared and the Raman spectra. For EU-d_2, and EU-d_6, the a_1 and the b_2 ND in-plane deformation vibrations are likely to contribute to the Raman band around 900 cm^{-1} and the infrared band around 1200 cm^{-1}, respectively. A weak Raman band was observed at 1360 cm^{-1} for EU-d_2 but was left unassigned since no fundamental frequencies were expected around this frequency.

In the infrared spectrum, EU-d_0 shows four bands at 1105, 1041, 991, and 933 cm^{-1} attributable to the skeletal stretching vibrations. From intensities and depolarization ratios of the corresponding Raman bands, the 1105, 991, and 933 cm^{-1} bands are assigned to the a_1 species and the 1041 cm^{-1} band to the b_2 species. Shifts of these bands on the *N,N'*- and the *C,C'*-deuterations suggest that the skeletal stretching vibrations couple complicatedly with the CD_2 and the ND deformation vibrations. Particularly, one of the a_1 skeletal stretching vibrations couples strongly with the a_1 ND in-plane deformation vibration, and gives rise to an infrared band around 1240 cm^{-1} for EU-d_2 and EU-d_6.

In the Raman spectrum between 800 and 400 cm^{-1}, EU-d_0 shows two bands at 712 and 502 cm^{-1} which persist on both the *N,N'*- and the *C,C'*-deuterations without large frequency shifts. Based on the depolarization ratio, the 712 cm^{-1} and the 502 cm^{-1} bands were assigned to skeletal vibrations in the a_1 and the b_2 species, respectively. In the infrared spectra, the corresponding bands around 700 cm^{-1} of EU-d_0 and EU-d_4 and around 500 cm^{-1} of EU-d_2 and EU-d_6 are markedly broadened and intensified by overlapping absorptions due to the NH and the ND out-of-plane deformation vibrations, respectively, in the b_1 species. EU-d_0 shows an infrared band at 768 cm^{-1} which is almost insensitive to both the *N,N'*- and the *C,C'*-deuterations and is assigned to the C=O out-of-plane deformation vibration. The weak Raman band at 250 cm^{-1} of EU-d_0 and EU-d_2 is depolarized in the solution spectra and shifts to 225 cm^{-1} on the *C,C'*-deuteration. This band is thus assigned reasonably to the b_1 skeletal torsional vibration. Throughout whole the investigated region of infrared and Raman spectra, no bands assignable to the a_2 species are observed for any of EU-d_0, EU-d_2, EU-d_4, and EU-d_6.

Table 2. Product and Sum rules

	obsd[b]	1.394[c]	2.683	3.678
Sum rule[d]		$\Delta\lambda(d_0-d_2)$	$\Delta\lambda(d_4-d_6)$	$\Delta\lambda(d_0-d_4)$	$\Delta\lambda(d_2-d_6)$
a_1[b]		3.443	3.434	3.290	3.294
b_2[b]		3.452	3.493	3.356	3.385
b_1[b]		0.150[c]	0.133		

a) $d_i/d_j=\Pi\nu(\text{EU-}d_i)/\Pi\nu(\text{EU-}d_j)$. b) The observed frequencies in Table 5 were used. c) The unobserved fundamental frequency in the b_1 species was replaced by the calculated frequency, 898 cm^{-1}. d) $\Delta\lambda(d_i-d_j)=10^{-5}\times4\pi^2c^2\{\sigma(\text{EU-}d_i)-\sigma(\text{EU-}d_j)\}/N$ (10^{-5} s^{-2}), where c is the velocity of light and N is the Avogadro number.

In order to check isotopic consistency in the assignment, the product rule[11] and the sum rule[12] were applied to the observed fundamental frequencies after correcting a few for anharmonic resonances. The results are given in Table 2. Denoting the sum of the squared frequencies of the isotope A over the species Γ by $\sigma(A, \Gamma)$, we may write the sum rule relations as

$$\sigma(\text{EU-}d_0, a_1) - \sigma(\text{EU-}d_2, a_1) = \sigma(\text{EU-}d_4, a_1) - \sigma(\text{EU-}d_6, a_1)$$

and similar expressions for the b_2 and the b_1 species. According to the modified sum rule for symmetrical isotopic molecules,[13] one more independent relation

$$\sigma(\text{EU-}d_0, a_1) - \sigma(\text{EU-}d_2, a_1) = \sigma(\text{EU-}d_0, b_2) - \sigma(\text{EU-}d_2, b_2)$$

holds provided that the force field includes no interaction terms between the two NH groups, and similarly we have

$$\sigma(\text{EU-}d_0, a_1) - \sigma(\text{EU-}d_4, a_1) = \sigma(\text{EU-}d_2, b_2) - \sigma(\text{EU-}d_6, b_2)$$

in the absence of interaction terms between the two

CH_2 groups. In support of the assignments, all these relations are satisfied fairly well by the observed frequencies.

Normal Coordinate Analysis

Based on the assumed symmetry of the point group C_{2v}, the G matrices were set up by using structure parameters transferred from the crystallographic data for urea[14] and ethylenethiourea,[6] the former being referred to only with respect to the C=O bond-length. They are shown in Fig. 5. The tetrahedral redundancy around each CH_2 group was eliminated analytically by introducing an orthogonal set of local symmetry coordinates.[15] The out-of-plane vibrations of the -NHCONH- group were described by the NH and the CO out-of-plane deformation coordinates and the internal rotation coordinates[16] around the C-N and the N-C′ bonds (Table 3). The redundant coordinates associated with the ring (2 in a_1, 1 in b_2 and 2 in b_1) were eliminated numerically on diagonalizing the G matrices.[17]

a) See footnote c), Table 1. b) The out-of-plane deformation coordinates were defined to be positive when the end atoms (O for S_1 and H for S_2 and S_5) move toward the observer from the plane of Fig. 5.

A simple Urey-Bradley force field including 25 force constants was employed for the a_1 and the b_2 vibrations. The initial values of the force constants were transferred from methylurea.[2] On refining the force constants, the observed frequencies were mostly taken from the infrared data. In the first step of the refinement, the stretching and the bending constants were adjusted by referring to the Jacobian matrix elements, and then by the least squares method in which K(NH) and K(CH) were fixed. In the next step, the stretching and the bending constants were fixed at the final values in the above process, and the repulsion constants were refined by the least squares method. Finally, the force constants except K(NH), K(CH), H(NC′C′) and F(HC′H) were refined by the least squares method, the last two being fixed because of large uncertainties.

The potential function for the b_1 vibrations was written as the sum of a simple Urey-Bradley type force field for the CH_2 group and a valence type force field for the torsional and the out-of-plane deformation vibrations. The values of the Urey-Bradley type constants were transferred from the converged set obtained in the treatment of the a_1 and the b_2 vibrations. The values of the diagonal constants were taken initially to be the observed frequency parameters divided by the corresponding G matrix elements for EU-d_0. These diagonal constants were adjusted first by referring to the Jacobian matrix elements and then by the least squares method. The off-diagonal constants $f(\pi$NH, τC′N) and $f(\pi$NH, πCO), were then added with the initial values zero, and all the constants were refined by the least squares method.

a) The value for EU-d_4 was used as the unperturbed frequency. b) The value for EU-d_2 was used as the unperturbed frequency.

The final values of the force constants are listed in Table 4. The magnitudes of the stretching constants are reasonable in comparison with the corresponding constants of urea,[1,9] methylurea[2] and diketopiperazine,[17,18] being correlated well with the assumed bond-lengths. For the b_1 vibrations, both the diagonal and the off-diagonal force constants are of comparable magnitudes with the corresponding constants of methylurea.[2] The frequencies calculated from the final set of force constants are shown in Table 5. The agreement between the observed and the calculated frequencies is excellent throughout the four isotopic ethyleneureas.

It is well known for amide and urea derivatives containing a *trans* -CONH- group that the NH in-plane deformation and the CN stretching vibrations couple strongly with each other and give rise to the amide II and III bands in infrared spectra.[3,4] According to the present calculation, such a coupling does not occur for EU-d_0 and EU-d_4 which contain a -NHCONH- group in the *cis-cis* conformation (Table 1).

The authors wish to thank Mrs. Yuko Inamoto for her technical assistance. The calculation in this work was performed on a FACOM 230-60 computer at the Data Processing Center, Kyoto University.

Electron-Capture Reaction of Halogenated Benzenes in MTHF Glass at 77 K

Toshinari SHIMOKAWA and Takeshi SAWAI

Tokyo Metropolitan Isotope Research Center, Fukazawa, Setagaya, Tokyo 158

(Received August 30, 1976)

The relative electron-capture efficiency of a number of halogenated benzenes was determined by means of competition with biphenyl as a reference material in glassy MTHF at 77 K. It was observed that the efficiency increased as the number of chlorine-atom substitutions on the benzene ring increased. Similar results were obtained for brominated benzenes. An excellent linear correlation is found between the logarithm of the efficiency and the polarographic reduction potential of a series of chlorinated benzenes. Moreover, a semilog plot of the efficiency *vs.* electron affinity of monohalogenated benzenes is apparently linear. The mechanisms of the electron-capture reaction are also discussed.

The study of the radiolysis of organic halogen compounds has advanced greatly in the last decade. These compounds have often been used as electron scavengers, because there is an effective way for examining ionic reactions in irradiated glass. Knowledge of the reactivity of organic halogen compounds with electrons is necessary for understanding and formulating the kinetics of the reaction process.

In spite of the many investigations on electron-capture reactions, the effect of halogen atom substitution in benzene is not fully understood.

In the present work, the relative efficiencies of electron capture by halogenated benzenes were determined in terms of the decrease in OD at 410 nm for biphenyl anions in glassy MTHF at 77 K.

Experimental

Reagents of special and guaranteed grade from Tokyo Kasei Co., Ltd. were used as received, except for 2-methyltetrahydrofuran (MTHF). The MTHF was purified by passage through a column of activated alumina. An MTHF solution of about 0.04 M biphenyl containing various halogenated benzenes was placed into a spectrosil vessel (10×10 mm) and dissolved oxygen was purged by bubbling nitrogen gas prior to irradiation. The sample was immersed in liquid nitrogen during the irradiation with ^{60}Co γ-ray. Measurement of the optical absorption was carried out at 77 K with a Cary 14R spectrophotometer.

The dose rate was determined by the Fricke dosimetry method to be 2.0×10^{18} eV/g h and the irradiation dose was about 5.0×10^{17} eV/g for all samples.

Results and Discussion

It is well known that biphenyl is an appropriate scavenger for the electrons generated by irradiation in organic glasses at 77 K, because its reactivity with electrons is very fast, $k=4\times10^{9}$ M^{-1} s^{-1}, and moreover, the biphenyl anion is identifiable in an absorption spectrum by a high absorption coefficient in the near-UV region. Hamill and his coworkers have used biphenyl as a reference material for determining the reactivity of some solutes with electrons in glassy media.[1] The competitive reaction of biphenyl with the solute for electrons is, in general, as follows:

$$e^- + C_{12}H_{10} \longrightarrow C_{12}H_{10}^-$$

$$e^- + \text{Solute} \longrightarrow \text{Product}$$

Assuming that the electron capture reaction is a simple competitive process, the biphenyl-anion optical density in various solute concentration is given by the following expression:

$$\frac{OD^\circ}{OD} = 1 + \frac{K_s}{K_{\phi_2}}\frac{[s]}{[\phi_2]} \quad (1)$$

where OD° and OD represent the optical densities of the biphenyl anion (410 nm) in the absence and in the presence of the solute, respectively, K_s and K_{ϕ_2} are the electron-capture coefficients of a given solute and of biphenyl, respectively, [s] and [ϕ_2] are the concentrations of a given solute and of biphenyl, respectively. The OD at 410 nm decreased with an increase in the concentration of chlorinated benzenes.

Arai *et al.* have shown recently by the low-temperature pulse radiolysis of halogenated compounds in ethanol glass that a strong absorption based on product negative ions appears in the visible to UV region.[2] In 1,2,3-trichlorobenzene, for example, there is no absorption for $\lambda>380$ nm, but below *ca.* 360 nm a strong absorption is observed ($\lambda_{max}\approx320$ nm). If the absorption of negative ions of the halogenated benzenes used in our experiments affects that of biphenyl (especially at $\lambda_{max}=410$ nm), then Eq. 1 is not suitable.

Then, competitive experiments were carried out after confirming that no absorption of solute anions was observed in the region around 410 nm.

The plot of OD°/OD for constant biphenyl concentration (0.04 M) should be a straight line as a function of the solute concentration. Figure 1 shows a plot of OD°/OD *vs.* [s]/[ϕ_2] obtained in an MTHF solution of monochlorobenzene, 1,2-dichlorobenzene, and 1,2,4-trichlorobenzene at 77 K. The slope of the line in Fig. 1 corresponds to the relative electron-

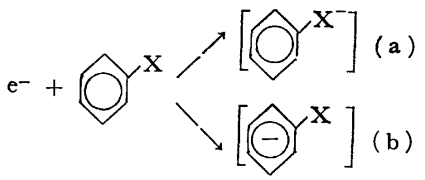
TABLE 1. THE RELATIVE ELECTRON CAPTURE EFFICIENCIES OF HALOGENATED BENZENES, γ-BHC, AND HEXACHLOROETHANE

No.	Material	K_s/K_{ϕ_2}
1	C_6H_5Cl	0.49
2	1,2-$C_6H_4Cl_2$	1.12
3	1,3-$C_6H_4Cl_2$	1.09
4	1,4-$C_6H_4Cl_2$	1.03
5	1,2,4-$C_6H_3Cl_3$	1.88
6	1,2,3-$C_6H_3Cl_3$	2.02
7	1,3,5-$C_6H_3Cl_3$	2.55
8	1,2,3,4-$C_6H_2Cl_4$	3.42
9	1,2,3,5-$C_6H_2Cl_4$	2.90
10	1,2,4,5-$C_6H_2Cl_4$	3.62
11	C_6HCl_5	6.60
12	C_6Cl_6	4.42
13	C_6H_5Br	0.84
14	1,4-$C_6H_4Br_2$	1.30
15	1,3,5-$C_6H_3Br_3$	2.78
16	C_6H_5F	0.05
17	C_6H_5I	0.88
18	γ-BHC	3.39
19	C_2Cl_6	4.04

capture efficiency (K_s/K_{ϕ_2}). Such competitive experiments were carried out for a number of chlorinated and brominated benzenes, as well as fluorobenzene and iodobenzene. The results are tabulated in Table 1. As can be seen in Table 1, the electron-capture coefficient (K_s) increases generally with an incraese in the number of chlorine or bromine atoms substituted on the benzene ring. While, no difference in the efficiency of the di-, tri-, and tetrachlorobenzene isomers was observed, the order of the reactivity for monohalogenated benzene is fluoro≪chloro<bromo<iodobenzene, which is the same as that for hydrated electrons in aqueous solutions.[3]

The electron-capture reaction for an aromatic compound is shown in the following scheme as formulated for monohalogenated benzene.[4]



The initial addition of an electron to the aromatic compound appears to occur predominantly by reaction process (b).[5] Therefore, the initial process for chlorinated benzenes is preferably the interaction of the π-orbital system of the benzene ring with the electron. Studier and Hart have suggested that the reaction of benzene with the electron is similar to reaction process (b).[6] However, the direct interaction for the substituent halogen atom on the benzene ring, which corresponds to reaction process (a), may be possible. In the case of monohalogenated benzene, the order of the relative electron-capture efficiencies may be explained by the effect of net electron-withdrawing, which is estimated from Hammett's parameters, σ_I and σ_R, of substituent halogen atoms on the benzene ring. σ_I and σ_R represent Hammett's parameters for inductive and resonant (mesomeric) effects, respectively.[7]

The decrease in the relative electron-capture efficiency for hexachlorobenzene in comparison with pentachlorobenzene would be attributed to a great extent to shielding of the π-orbital system by substituent chlorine atoms on the benzene ring. The value of the efficiency for hexachlorobenzene is similar to that of aliphatic hexachloro-compounds, such as hexachloroethane and γ-BHC. This fact indicates that the π-orbital system of hexachlorobenzene provides a lower contribution to electron capture than that of other chlorinated benzenes.

Christodouleas and Hamill have found that the relative electron-capture efficiency of aromatic hydrocarbons, such as phenanthrene, is correlated to the polarographic reduction potential.[8] It was found that the relative electron-capture efficiencies in the present results can also be roughly correlated with the reduction potential of the various monohalogenated benzene derivatives, which have been determined in aprotic solvents by Sease *et al.*[9] Recently, Tsuji has determined the reduction potential of a series of chlorinated benzenes by the differential pulse polarographic method and shown that the value increased proportionally with the number of substituted chlorine atoms on the benzene ring from mono- to hexachlorobenzene.[10] And also no difference in the reduction potential for isomers of polychlorinated benzenes was observed.[11] The results of the relative electron-capture efficiencies for isomers are in accord with the trend of the polarographic reduction potential.

Figure 2 shows a semilogarithmic plot of the relative electron-capture efficiency *vs.* the reduction potential of chlorinated benzenes. Interestingly, the plot, as shown in Fig. 2, is very linearly from mono- to pentachlorobenzene, except for hexachlorobenzene.

The relationship between the logarithm of the electron-capture efficiency and the reduction potential from mono- to pentachlorobenzene can be expressed by

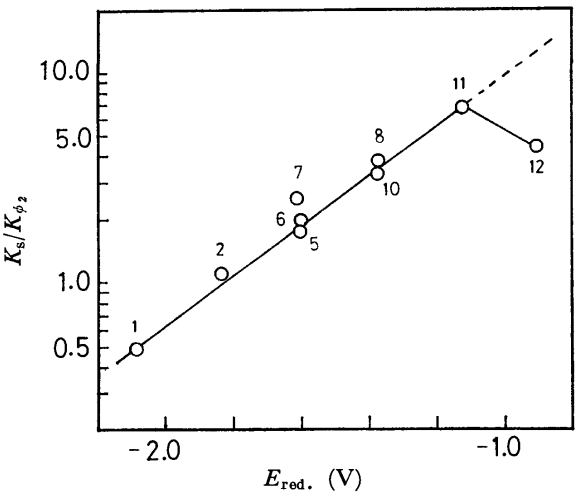


Fig. 2. Plot of $\log K_s/K_{\phi_2}$ *vs.* reduction potential ($E_{red.}$) of a series of chlorinated benzenes. The values of reduction potential for penta- and monochlorobenzene estimated from the secondary peak of hexachlorobenzene and 1,2-dichlorobenzene measurements, respectively. Key is shown in Table 1.

following equation, which is plotted in Fig. 2:

$$\log K_s/K_{\phi_2} = a E_{red.} + b \quad (2)$$

where $E_{red.}$ is the reduction potential, and a and b are constants. Nenner and Schulz have accurately measured the electron affinity using electron transmission spectroscopy.[12] They indicated that a good correlation between the polarographic reversible electrode potential and the electron affinity was observed. The reversible electrode potential for halogenated benzenes cannot be obtained from the usual polarographic measurement, because dissociation preferentially occurs prior to the reversible reaction. However, it is clear that the reversible electrode potential is related to the reduction potential of halogenated compounds.[12] Thus, the logarithm of the relative electron-capture efficiency may be linear as a function of the quasi-electron affinity which is estimated from the polarographic reduction potential. Therefore, a similar relation to that shown in Fig. 2 can be expected for accurate electron affinities. A semilog plot of the relative electron capture efficiency *vs.* the electron affinity[12] of monohalogenated benzenes is shown in Fig. 3. Figure 3 shows that the relative electron-capture efficiencies for halogenated benzenes are given as a function of the electron affinity as has been mentioned for the reactivity of many compounds with hydrated electrons by Anbar and Hart.[13]

Wentworth and his coworkers have proposed that the relation between the electron-capture coefficient and the electron affinity in gas phase can be shown to be[14]

$$\log KT^{3/2} = \log A + \log k_L/k_M + EA/RT \quad (3)$$

where A is composed fundamental constants, including the mass of the electron, k_L and k_M are the rate constant for neutralization of negative ions and electrons, respectively and EA is the electron affinity. Thus, the relative electron-capture efficiency would be given by following expression:

$$\log K_s/K_{\phi_2} = \log(k_L)_s - \log(k_L)_{\phi_2} + (EA)_s/RT - (EA)_{\phi_2}/RT \quad (4)$$

where the subscripts ϕ_2 and s refer to biphenyl and solute, respectively. Assuming that the rate of neutralization is very slow at a low temperature of 77 K, Eq. 4 can be rewritten as follows:

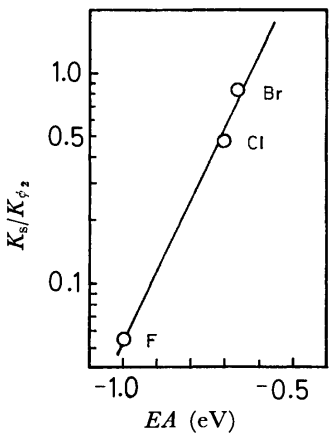

Fig. 3. Plot of $\log K_s/K_{\phi_2}$ *vs.* electron affinity of monohalogenated benzenes.

$$\log K_s/K_{\phi_2} = (EA)_s/RT - (EA)_{\phi_2}/RT, \quad (5)$$

where $(EA)_{\phi_2}/RT$ is constant at 77 K. Equation 5 indicates that a linear relationship between $\log K_s/K_{\phi_2}$ and $(EA)_s$, and that the slope is dependent on the temperature. The semilog-linearity in Fig. 3 can apparently be explained by Eq. 5. According to Eq. 5, the slope is given by $1/RT$, which has a value of 150. However, the slope of the line in Fig. 3 is about 3.5. Since such a great difference between the observed slope (Fig. 3) and the slope calculated from Eq. 5 is observed, a treatment similar to that in the gas phase may not be applicable at low temperatures.

On the other hand, Miller has emphasized that the tunneling mechanism for the electron-capture reaction is of importance in glassy media and has suggested that the electron affinity is a predominant factor in determining whether or not the tunneling reaction can occur.[15] Namiki *et al.* have pointed out that the scavenging efficincy is linear as a function of the adiabatic electron affinity of the acceptor in alcoholic glasses.[16] They discussed the electron-capture process on the basis of the tunneling model. This consideration is interesting, but until recently only limited data had been available on accurate electron affinities of a series of halogenated benzenes in order to conform the relationship between the relative electron-capture efficiency and the electron affinity. For a more detailed explanation on this relationship, measurements of the efficiencies for many kinds of substituted benzenes will be necessary.

The authors indebted to Dr. Keiichi Tsuji, The Institute of Physical and Chemical Research, for providing the polarographic data on the polychlorinated benzenes and for useful advice. The authors are also grateful to Dr. Teruko Sawai for helpful discussions.

The Interaction of Bovine Plasma Albumin with Cationic Detergent. Studies by Binding Isotherm, Optical Rotation and Difference Spectrum

Koichi HIRAMATSU, Chiaki UEDA, Koji IWATA, Kinichi ARIKAWA, and Koichiro AOKI

Department of Synthetic Chemistry, Faculty of Engineering, Gifu University, Kagamigahara, Gifu 504

(Received September 17, 1976)

Binding isotherms were determined at pH 6.9 for systems of bovine plasma albumin (BPA) and cationic detergents at 25° C and 5 °C. Detergents used were: hexadecyltrimethylammonium bromide (HTAB), tetradecyltrimethylammonium bromide (TTAB), dodecyltrimethylammonium bromide (DTAB) and decyltrimethylammonium bromide (DeTAB). Binding affinity of the cationic detergent to BPA increased with the increase in the carbon number of the detergent, and with the increase in temperature. The first five detergent ions were bound to BPA statistically at 25 °C, and succeeding detergent ions were bound cooperatively. Thermodynamic parameters indicated that the statistical binding was caused mainly by the hydrophobic bonding. Measurements of $-[\alpha]_{233}$ and $-[\alpha]_{313}$ at pH 5.2 revealed that the conformation of BPA changed when it complexed with the cationic detergent. The conformation of BPA changed slightly when 5—8 HTAB or TTAB's were bound, and a second large conformational change occurred when 15—20 of these detergent ions were bound. DTAB and DeTAB caused only the first conformational change. Thus HTAB and TTAB are stronger unfolders of BPA than DTAB and DeTAB. The UV difference spectrum of the complex BPA–TTAB showed a red shift of the peak of Try residue (*e. g.* 292 nm), being in contrast to the blue shift of the same peak in the complex BPA–sodium dodecyl sulfate. It is suggested that BPA is unfolded, at least, in the NH_2 terminal half by binding with cationic detergent.

In a previous paper,[1] it was reported that the binding of cationic detergent to BPA (bovine plasma albumin) at pH 9 induced the SH–S-S exchange reaction of BPA, forming a series of aggregates of BPA. The exchange reaction occurred at lower concentration of the detergent, when the carbon number of detergent was higher. It was suggested that the first step of the reaction is the unfolding of BPA by the cationic detergent.

This time studies were made on the binding behavior of cationic detergents to BPA and on the conformational change of BPA caused by the cationic detergent. Studies were made by equilibrium dialysis, by measuring the optical rotations at 233 and 313 nm, and by measuring the UV difference spectrum. Some aspects of the unfolding of BPA by the cationic detergent were made clear at pH 5.2 and 6.9. Cationic detergents used were:

hexadecyltrimethylammonium bromide (HTAB),
tetradecyltrimethylammonium bromide (TTAB),
dodecyltrimethylammonium bromide (DTAB), and
decyltrimethylammonium bromide (DeTAB).

So far, several works have been made on the interaction between BPA and cationic detergents.[1-5]

Experimental

Materials. Crystallized BPA (Armour, Lot No. M-72603) was used. A part of the experiment was performed using BPA whose SH group was blocked by iodoacetamide. The blocking was made at room temperature and pH 8.0 (in 0.1M KCl+KOH) for 3 h. Then the solution was dialyzed against the deionized water at 5 °C for more than 24 h or passed through the Sephadex G-25 gel (Pharmacia Fine Chemicals, Lot No. 0063) column. Frequently, contaminants were removed by filtering the solution through Millipore filter (HATF, 02500). The concentration of BPA was determined spectrophotometrically using the value $E^{1\%}_{1cm}=6.67$ at 279 nm.

Buffers used were: phosphate buffer at pH 6.9 and ionic strength 0.1, and $Na_2B_4O_7$–HCl buffer at pH 9.0 and ionic strength 0.025 (sometimes the ionic strength was raised to 0.1 by adding KCl). BPA was also dissolved in 0.1 M KCl; the isoionic point was pH 5.2.

Cationic detergents used were the same samples as those described in a previous paper.[1]

Equilibrium Dialysis. The Visking tube (20/30) was heated in a half saturated solution of $NaHCO_3$ at 90 °C for 1 h, then the tubings were rinsed well with deionized water. Five ml of 0.5% BPA was dialyzed against 25 ml of detergent solution. The dialysis was conducted for 65 h at 5 and 25 °C.

Determination of the Cationic Detergent. The determination was carried out following the method of Few and Ottewill.[6] The method involves the procedure to extract the detergent–Orange II complex in the aqueous phase by the organic solvent. In the present work, the extraction solvent was dichloromethane instead of chloroform. The optimum conditions for the extraction were: concentration of the complex is to be in the range 9×10^{-6} and 3×10^{-5} mol/l, and the mol ratio of Orange II to detergent is to be in the range 1—3. When the concentration of the detergent in the sample solution was higher than the optimum value, the solution was diluted by the same buffer as was used for the sample solution. The extinction coefficient of the complex at 485 nm was 1.80×10^4 mol^{-1} cm^{-1} in presence or absence of ethanol (antifoaming agent), and was 2.20×10^4 mol^{-1} cm^{-1} in aqueous phase. The extinction coefficient of the complex in distilled water was equal to that of Orange II.

Optical Rotation. The optical rotation was measured using 0.2% BPA at various concentrations of detergent. The 1 mm cell and 10 mm cell were used to measure the optical activity at 233 and 313 nm, respectively. To increase the sensitivity of the measurements, compensation by means of sucrose was employed.[7] The temperature was kept constant at 25±0.2 °C. The apparatus was a Jasco spectropolarimeter, model ORD/CD/UV-5.

Difference Spectrum. The difference spectrum was measured using 0.15% BPA in presence of various amounts of detergent. Using 10 mm cell, the spectrum was recorded in the range 275—350 nm. The temperature of the cell was kept constant at 25±0.2 °C. The apparatus was a Hitachi EPS-3 spectrophotometer.

Results and Discussion

Equilibrium Dialysis. *a) Binding Isotherms at pH 6.9*: In Fig. 1 are shown binding isotherms of the systems of BPA and each one of the detergents, HTAB, TTAB, DTAB, or DeTAB at pH 6.9 and 25 °C. All of the curves consist of two parts: one of which lies in the lower concentration of the detergent and has a small slope and the other is the curve having a large slope. It is known later that the binding of the detergent to BPA is statistical in the lower concentration region of the detergent, and that it is cooperative in the higher concentration region. The whole binding isotherm shifts to the left with the increase in the carbon number of the detergent. In other words, the binding occurs at lower concentrations of detergent, when the detergent with higher carbon number is used. This suggests that the hydrophobic group of the detergent is more effective than the charged group for the BPA–cationic detergent interaction.

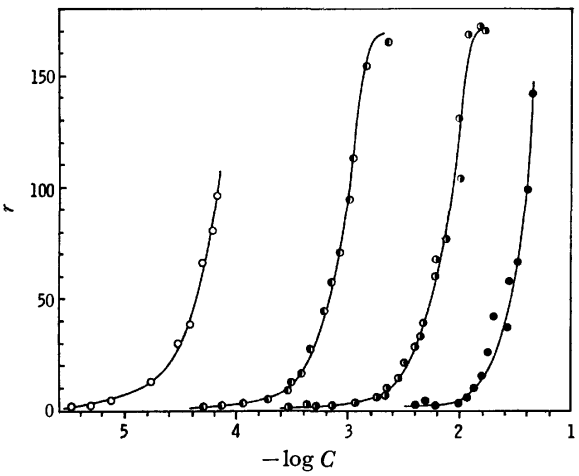

Fig. 1. Binding isotherms of the systems of BPA and cationic detergents at pH 6.9, ionic strength 0.1 and 25 °C. C: equilibrium concentration of detergent (mol/l), r: number of detergents bound to BPA. ○: HTAB-BPA, ◐: TTAB-BPA, ◑: DTAB-BPA, ●: DeTAB-BPA.

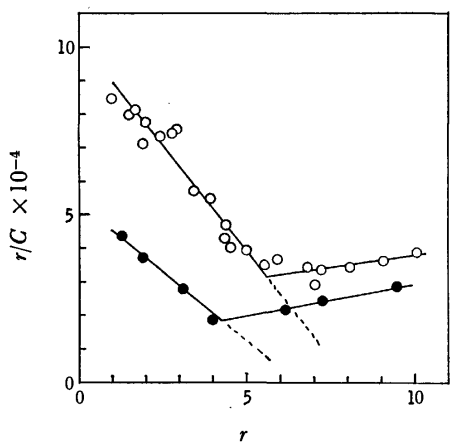

Fig. 2. Scatchard plot for the system BPA-TTAB. ○: 25 °C, ●: 5 °C.

When the temperature is increased, the binding isotherm shifts to the left, indicating that the binding is increased with the increase in temperature, *i.e.*, the binding is endothermic. The result agrees with that by calorimetric measurement by Jones *et al.*[5] The effect of temperature is shown in Fig. 2.

The binding isotherm was analyzed by the Scatchard equation.[8]

$$r/C = k_0 n - k_0 r \qquad (1)$$

where, C: equilibrium concentration of detergent, n: maximum number of the binding sites, r: average number of the detergent ions bound and k_0: intrinsic binding constant. The application of the equation to the system BPA-TTAB, as an example, is given in Fig. 2. There are two straight lines with a break. The one is that for 25 °C, and the other is that for 5 °C. The straight line with a negative slope satisfies the Eq. 1, meaning that the binding is statistical. The straight line with a positive slope gives a negative value of k_0; the meaning is that the binding is cooperative.

Figure 2 shows that $r_{s,max}$ is 5.5 at 25 °C.* If the straight line with a negative slope is extended, it is found that the maximum number of sites n should be 8. The value of $r_{s,max}$ is 4 at 5 °C. Values of $r_{s,max}$ for other detergents are given in Table 1. It was difficult to find accurate values for DeTAB. This might be due to the difficulty in analytical procedure.

b) Statistical Binding: As is seen in Table 1, $r_{s,max}$ does not depend on the carbon number of the detergent, *i.e.*, it is 4 at 5 °C and 5 at 25 °C. The value agrees with the value 4 by Nozaki *et al.*[4] for tetradecyltrimethylammonium chloride at pH 5.6 and 24 °C within the experimental error, and agrees also with the value 6 by Few *et al.*[2] at the isoionic point and 20 °C for DTAB. When 4 or 5 cationic detergent ions are bound to BPA, slight unfolding occurs in BPA as is described later, thus $r_{s,max}$ is constant, *i. e.*, more binding sites with high affinity are destroyed when unfolding occurs. If the unfolding does not occur before all the n sites are occupied, $r_{s,max}$ would be equal to n.

The value of $r_{s,max}$ is 4—5 for the cationic detergents with C_{12} and C_{14}, but it is 8—10 for the anionic detergents with C_{12} and C_{14}.[9,10] (Decker and Foster[9] reported that $r_{s,max} \fallingdotseq n = 10$ for sodium dodecylbenzenesulfonate.) Such a difference in numericals exists between the cationic and anionic detergent bindings. It is well known that the BPA unfolds when the number of anionic detergents bound exceeds the value of $r_{s,max}$.[10]

c) Thermodynamic Properties of Statistical Binding: In Table 1 are given values of k_0 and thermodynamic parameters $-\Delta F$, ΔS, and ΔH for the interactions. It is seen that $H>0$ and $\Delta S>0$, and that $T\Delta S>\Delta H$. This indicates that the binding of the cationic detergent

* The notation $r_{s,max}$ means the maximum number of the detergent ions bound statistically. As is known from Eq. 1, the crossing point of the straight line with a negative slope and the abscissa gives the value of n. The break of the straight line in Fig. 2 is named $r_{s,max}$ to distinguish it from n.

Table 1. Thermodynamic parameters for BPA-cationic detergent interactions

Detergent	Temp °C	$r_{s,max}$	k_0 l/mol	$-\Delta F$ kcal/mol	ΔH kcal/mol	ΔS e. u.
HTAB	25	5	8.7×10^4	6.7	4.0	36
	5	4	5.2×10^4	5.8		
TTAB	25	5.5	1.3×10^4	5.5	3.5	30
	5	4	8.2×10^3	5.0		
DTAB	25	5	9.7×10^2	3.9		

to BPA is entropic. This means that the interaction between the detergent and the solvent molecule is replaced by the interaction between the detergent and BPA, *i. e.*, that hydrophobic bonds are formed. It is known from Table 1 that $-\Delta F$ is 600—800 cal/mol per CH_2 residue of the detergent. The value agrees with 700 cal/mol per CH_2 residue, which is obtained when CH_2 is transferred from the aqueous phase to the organic solvent.[11]

Literature survey[10,12-14] indicates that the free energy change $-\Delta F$ is larger when the anionic detergent (with sulfate or sulfonate) or fatty acid is bound to BPA than when the cationic detergent is bound, if the length of the hydrocarbon chain is the same in the range C_{10}—C_{16}. Tanford[15] has pointed out that both the ionic and hydrophobic interactions take part in the anionic detergent binding at pH 6.8, and attributed half of $-\Delta F$ to the ionic interaction. If $-\Delta F$ for the anionic detergent with C_{12} is compared with that for the cationic detergent with C_{12}, there is a difference by 3—4 kcal, which is almost the same as $-\Delta F$ estimated for ionic interaction.[15] Thus, it is concluded that the contribution of the ionic interaction is smaller in the cationic detergent binding than in the anionic detergent binding. In other words, the hydrophobic bonding is the main force in the cationic detergent binding.[16]

d) Cooperative Binding: It is clear in Fig. 1 that the cooperative binding also depends on the length of the hydrocarbon chain of the detergent. The change in the standard free energy accompanying the cooperative binding is given by the equation $\Delta F=RT \ln X$, where X is the mid-point of the two extreme equilibrium concentrations for the region in which the cooperative binding occurs.[15] The value of $-\Delta F$ was calculated for TTAB and DTAB at 25°C using the equilibrium concentration at which 85 detergent ions were bound.[17] The highest number of detergent ions bound was 170 for these two detergents (Fig. 1). It was found that $-\Delta F$ was 2.9 kcal/mol for DTAB binding and that it was 4.2 kcal/mol for TTAB binding. These figures lead to the conclusion that the free energy change was 650 cal/mol per CH_2 residue; the value is almost the same as that for the statistical binding. Thus, the hydrophobic bonding is also the main force in the cooperative binding.

e) Binding Isotherm at the Isoionic Point: The binding isotherm of the system BPA-DTAB at 25° C and pH 5.2 (in 0.1M KCl) was the same as that at pH 6.9; $r_{s,max}$ was 5 and k_0 was also the same within the experimental error. When r was less than 70, the isotherm at pH 5.2 lay on that at pH 6.9. When it was more than 70, the isotherm at pH 5.2 located upper than that at pH 6.9. The highest number of the detergent ions bound was slightly less, *i. e.*, 140.

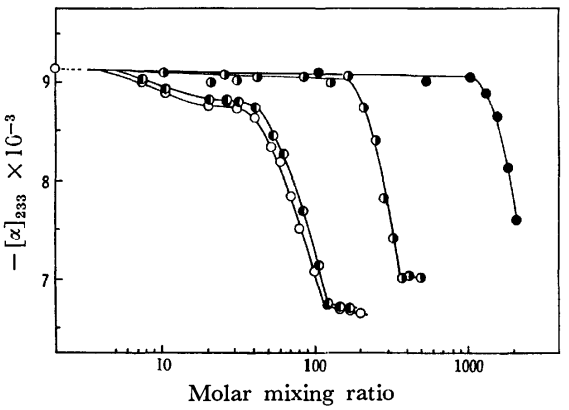

Fig. 3. $-[\alpha]_{233}$ *vs.* molar mixing ratio (detergent/BPA). pH 5.2 in 0.1 M KCl and 25 °C. ○: HTAB-BPA, ◐: TTAB-BPA, ◑: DTAB-BPA, ●: DeTAB-BPA.

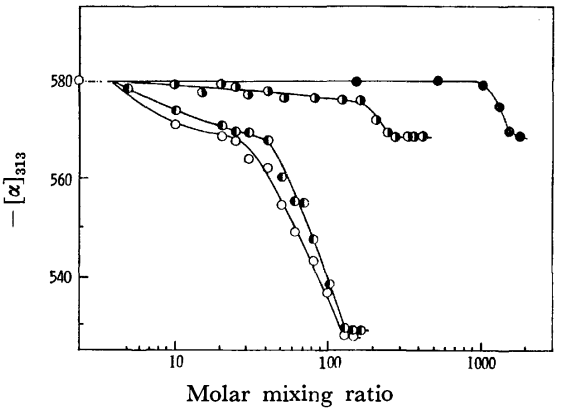

Fig. 4. $-[\alpha]_{313}$ *vs.* molar mixing ratio (detergent/BPA). pH 5.2 in 0.1 M KCl and 25 °C. ○: HTAB-BPA, ◐: TTAB-BPA, ◑: DTAB-BPA, ●: DeTAB-BPA.

Optical Rotation. *a) Unfolding of BPA by Cationic Detergent at pH 5.2*: Optical rotations were measurcd at the isoionic point of BPA in 0.1 M KCl (pH 5.2). Values of $-[\alpha]_{233}$ and $-[\alpha]_{313}$ are given as a function of the molar mixing ratio (detergent/BPA) in Figs. 3 and 4, respectively. It is clear in these figures that the BPA is disorganized by the binding of particular numbers of the detergent. Figure 3 shows how the helix content[18] in BPA decreases by the binding of the detergent. Detergent with higher carbon number is more effective in the range C_{10}—C_{14}; TTAB and

HTAB seem to have almost the same ability to unfold the BPA. Figure 4 shows how the tertiary structure[19] of BPA is disorganized by the cationic detergent.

In Figs. 3 and 4, it is seen that $-[\alpha]_{233}$ and $-[\alpha]_{313}$ are constant in the region of TTAB/BPA=20—40. If the data of equilibrium dialysis are combined, the complexes formed in this region are found to be AD_5—AD_{15} (A: BPA and D: cationic detergent). When the molar mixing ratio exceeds 40, both of the rotations decrease remarkably and continuously, attaining to a constant. Since $-[\alpha]_{233}$ is 6700 at the molar mixing ratio 120, *i.e.*, for AD_{60}, it is found that the helix of BPA was destructed by 40% by binding of 60 cationic detergents.[20] In the region of HTAB/BPA=10—25, $-[\alpha]_{233}$ and $-[\alpha]_{313}$ are constant. The compositions of the complexes are AD_8—AD_{20}. When the mixing ratio exceeds 25, values begin to decrease.

For DTAB, $-[\alpha]_{233}$ begins to decrease at AD_7 and attains constant at AD_{40}: $-[\alpha]_{313}$ drops at AD_7 and attains constant at AD_{20}. This means that the helix content of BPA decreases, keeping the tertiary structure constant, when r is more than 20. Almost the same is true for DeTAB. When 7 DeTAB are bound to BPA, both the helical content and the tertiary structure begin to decrease.

In conclusion, the ability for the cationic detergent to destruct BPA is in the order: HTAB≧TTAB>DTAB>DeTAB.[21]

b) Unfolding of BPA at pH 6.9 and 9.0: Changes in $-[\alpha]_{233}$ and $-[\alpha]_{313}$ with the molar mixing ratio TTAB/BPA were measured for SH blocked BPA at pH 6.9 and 9.0. Results are given in Fig. 5 by the expression $-[\alpha]_{233}$ *vs.* $-[\alpha]_{313}$. Measurements were made using SH blocked BPA at these pH's to prevent the SH-S-S exchange reaction.

Difference Spectra. In Fig. 6 are shown difference spectra of SH blocked BPA in presence of TTAB at pH 6.9. When the concentration of TTAB is low, peaks are observed at 275, 283, 292, and 298 nm, and troughs at 277, 287, 295, and 305 nm, *i.e.*, the red shift occurs. Especially, peak at 292 nm is large. Peaks increase their magnitudes with the increase in the amount of TTAB. Peak at 292 nm is caused by Try, those at 275 and 283 nm are caused by Try and Tyr, and peak at 298 nm would be caused by Try. The environment of Try residue, and probably that of Tyr residue also, seem to change when some detergents are bound to BPA.

Generally, the blue shift occurs when the protein is denatured, or when the buried chromophore in the protein is exposed to the aqueous solvent. The binding of alkyl sulfate, whose carbon number is more than 12, to BPA causes conformational change in BPA. The blue shift of peak at 292 nm (Try residue) occurs when smaller number of detergents are bound, and the blue shift of peak at 288 nm (Tyr residue) occurs when larger number of detergents are bound.[22,23] In the present study, however, the red shift was observed in a wider range of molar mixing ratio. This suggests that the cationic detergent unfolds BPA in such a way as to prevent the Try residue from exposing to the aqueous phase.

The same red shift was observed also at the isoionic point.

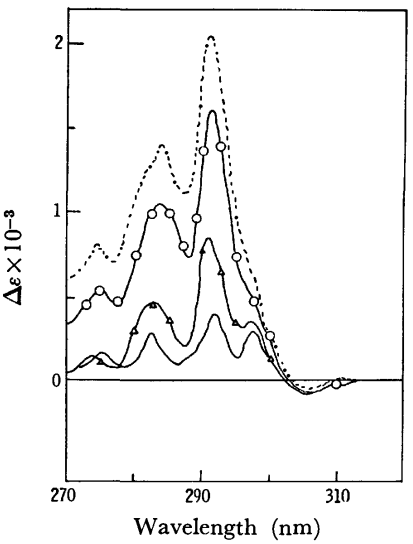

Fig. 6. UV difference spectrum of BPA-TTAB complexes. pH 6.9, ionic strength 0.1 and 25 °C. Sample: SH blocked BPA plus TTAB. Reference: SH blocked BPA. Molar mixing ratio are 20 (——), 30 (-△-), 50 (-O-) and 60 (·····).

General Discussion. As was described above, TTAB and HTAB were bound to BPA statistically up to $r=5$ at pH 6.9 and 5.2. When r was more than 5, the cooperative binding occurred accompanying a conformational change in BPA. Measurements of optical rotation revealed that the second unfolding begins to occur at $r=20$.

Studying the BPA solution by the small angle X-ray scattering, Luzzati *et al.*[24] suggested that the BPA is composed of the NH_2 terminal half which is compact and the COOH terminal half which is rather loose. Recently, Hilak *et al.*[25] supported this model by studying the fragments of BPA produced by the pepsin digestion and by measuring the optical rotation of each fragment in the N-F transition region. It is known that two Try residues are involved in the com-

pact NH_2 terminal half.[26] This time it has been found that the cationic detergent binding changes the environment of Try residue. This suggests that the compact NH_2 terminal half, at least, is unfolded by binding with the cationic detergent.

In the previous paper.[1] it was reported that the SH–S-S exchange reaction begins to occur between BPA molecules when 5 mol of TTAB are added to 1 mol of BPA at pH 9. In the present study, it has been found at pH 6.9 that the BPA is unfolded when r is more than 5. The BPA at pH 9 is unfolded by the N–B transition and by the binding of cationic detergent.[27]

The SH group is also in the compact NH_2 terminal half,[25] and locates in the crevice, its depth being at least 9.5 A.[29] If the BPA is unfolded, some of the S–S bond will be exposed,[30] and the crevice will be broken to expose the SH group. Thus the SH–S-S exchange reaction will take place easier at the alkaline pH in presence of the cationic detergent. In a recent study in our laboratory, it was deduced that the S–S bond is more reactive when it is surrounded by the cationic detergent.[32]

15) C. Tanford, "The Hydrophobic Effect," Wiley International Publication, New York (1973), p. 135.
16) Tanford[15] insisted that the free energy change for the interaction between BPA and the anionic detergent is constant when the carbon number of the detergent is more than 10. His explanation for the interaction is that the hydrophobic part of the detergent binds to a hydrophobic surface patch or patches of BPA. In contrast, the free energy change for the present interaction increased with the increase in the carbon number of cationic detergent up to the carbon number 16. Thus the above explanation by Tanford can not be applied. Our explanation is that the hydrocarbon part of the cationic detergent is buried into the hydrophobic crevice of BPA.
17) The equilibrium concentration of the detergent at the highest number of binding is equal to its critical micelle concentration (CMC) in phosphate buffer of pH 6.9, ionic strength 0.1 and 25 °C. The CMC is 1.6×10^{-3} mol/l for TTAB and 1.2×10^{-2} mol/l for DTAB. When the equilibrium concentration of the detergent is higher than the CMC, the micelle is formed in the solution.

19) W. J. Leonard, Jr. and J. F. Foster, *J. Biol. Chem.*, **236**, 2662 (1961).
20) In Fig. 3, it is seen that the conformational change of BPA by TTAB finishes almost completely at AD_{60}. However, the complex AD_{60} is formed around the mid-point of the binding isotherm in the region of cooperative binding in Fig. 1. This means that binding of more than 60 TTAB does not induce additional unfolding in BPA. The same is true for other detergents. A similar result to this was obtained by Nozaki *et al.*[4]
21) Raynolds *et al.*[10] studied the conformational change of BPA caused by a series of anionic detergents whose carbon numbers are different. They stated that the detergent whose carbon number is less than 10 binds to BPA cooperatively without the conformational change in BPA, and that the detergent whose carbon number is more than 12 binds to BPA cooperatively inducing the conformational change in BPA. In the present study, cationic detergents induced the conformational change, when the carbon number was more than 10.

Molecular Structure of Molybdenum Tetrafluoride Oxide Studied by Gas Electron Diffraction

Kinya IIJIMA

Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka 422

(Received September 29, 1976)

The molecular structure of molybdenum tetrafluoride oxide was determined to be square-pyramidal by a sector-microphotometer method of gas electron diffraction. The following molecular parameters were obtained by a least-squares method: r_g(Mo–F)=1.836±0.003 Å, r_g(Mo–O)=1.650±0.007 Å, and r_g(F···F(s))=2.522± 0.005 Å. The molecular structure is similar to those of WCl_4O and $MoCl_4O$, but significantly different from those of XeF_4O and IF_5. The molecular intensities calculated using the TFD or RHFS phase angle for molybdenum atom were in disagreement with the observed ones.

The molecular structures of WCl_4O,[1] $MoCl_4O$,[2] XeF_4O,[3,4] IF_5,[4,5] BrF_5,[4] and ClF_5[4] were reported to be square-pyramidal in gas phases, but the oxygen-metal-chlorine angles in WCl_4O and $MoCl_4O$ differ significantly from the corresponding angles in the other compounds. Although the MoF_4O molecule in the solid state is octahedral in consequence of bridging through fluorine atoms,[6] the molecule in the gas phase is monomeric with C_{4v} symmetry as predicted from spectroscopic studies.[6–8] The present study was undertaken in order to determine the structure of gaseous MoF_4O by means of gas electron diffraction. It is interesting to compare the molecular structure of MoF_4O with those of $MoCl_4O$ and other square-pyramidal molecules. Seip and Seip noted from the electron diffraction analysis of MoF_6[9] that the observed cut-off point for Mo–F pair disagrees with the theoretical value. This problem was also checked in the present study.

Experimental

The chlorine atoms in molybdenum tetrachloride oxide which was prepared by the method described before[10] were substituted with fluorine atoms by the reaction with anhydrous hydrogen fluoride.[11] The sample was purified by repeated sublimations *in vacuo*. It was vaporized at 70—80 °C, and electron-diffraction photographs were taken with an r^3-sector at the camera distance of 144 mm. The accelerating voltage was 40 kV, the exposure time 30 s, and the electron-beam current 0.8 μA. The pressure of the diffraction chamber was below 3×10^{-5} Torr during a photographic exposure. The electron wavelength was calibrated by gold powder patterns. The lattice constant of gold was calibrated by means of X-ray diffraction, and checked by electron diffraction studies of thallium chloride[12] and carbon disulfide.[13] Photographs were recorded on Fuji process hard plates, and the photographic densities of four plates were measured with a digital microphotometer at intervals of 0.4 mm. The intensities of each plate were used independently for the structure analysis. The electron diffraction unit and digital microphotometer used in the present study were described elsewhere.[14]

Analysis

Intensities were leveled by the theoretical background which was calculated by using the elastic scattering factors of Kimura *et al.*[15] and the inelastic scattering factors of Cromer and Mann.[16] The leveled intensities were obtained in a range s=5.3—32.0 Å^{-1} at intervals $\Delta s=\pi/10$.

The radial distribution curve is shown in Fig. 1. The N_{ij} functions which fit μ_{ij}[1,17] in a whole range of scattering angle were as follows;

$$N_{Mo-F} = 1.097 + 0.104\exp(-0.0034\,s^2)$$
$$N_{Mo-O} = 1.118 + 0.153\exp(-0.0089\,s^2)$$
$$N_{F\cdots F} = 1.355 + 0.713\exp(-0.0057\,s^2)$$
$$N_{F\cdots O} = 1.380 + 0.814\exp(-0.0072\,s^2)$$

The radial distribution curve suggests that the molecular structure of MoF_4O is square-pyramidal.

The index of resolution, r(Mo–F), r(Mo–O), r(F···F(s)), and five root-mean-square amplitudes l(Mo–F), l(Mo–O), l(F···F(s)), l(F···F(l)), and l(F···O) were determined by the least-squares calculations[2,18,19] with the assumption of C_{4v} symmetry. Asymmetry parameters for bonded distances were estimated by a diatomic molecule approximation[20] to be 1.2×10^{-6} and 0.6×10^{-6} Å^3 for Mo-F and Mo–O, respectively. The parameter, a, in the Morse function was assumed to be 2.0 Å^{-1}. The asymmetry parameters for non-bonded distances were ignored.

At the first stage of analysis a large difference between the observed and theoretical molecular intensities was found in the range s=22—32 Å^{-1}, as shown in Fig. 2. The cut-off point for Mo–F pair is observed at s=23.2 ±0.6 Å^{-1}, but the theoretical value is s=27.0 Å^{-1}.

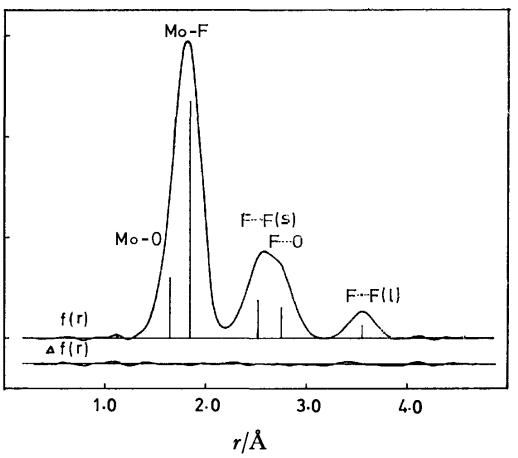

Fig. 1. Experimental radial distribution, $f(r)$, and the difference between the experimental and theoretical ones, $\Delta f(r)$. A damping function of $\exp(-0.0020\,s^2)$ was used.

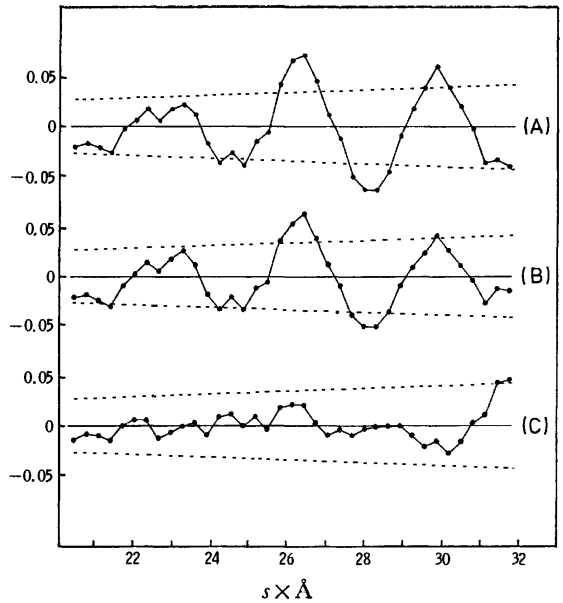

Fig. 2. The observed minus theoretical molecular intensities. The observed values were an average of intensities from four plates, and the theoretical ones in (A), (B), and (C) curves were calculated by using parameters of (A), (B), and (C) in Table 1, respectively. The broken curves show the limits of error in the $sM(s)$.

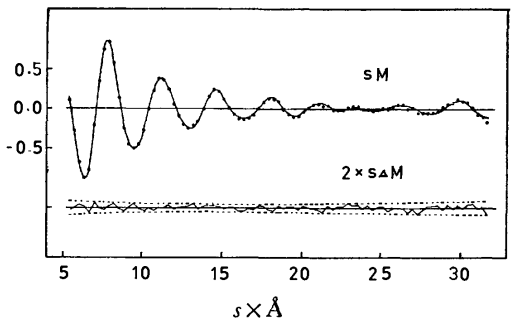

Fig. 3. Observed and theoretical molecular intensities. Typical observed values are shown in dots, and the best-fit theoretical ones are shown in the solid curve. The lower solid and broken curves represent the residuals and the limits of error, respectively, in the $sM(s)$.

The phase angles, η, obtained from the Thomas-Fermi-Dirac (TFD) and Hartree-Fock (HF) potentials[15] were used for molybdenum and fluorine atoms, respectively. The phase angle from the relativistic Hartree-Fock-Slater (RHFS) potential[21] was also used for molybdenum atom, and the theoretical cut-off point is $s=26.1$ Å^{-1}. The disagreement between the observed and theoretical molecular intensities may be due to the uncertainty in molybdenum phase angle, η_{Mo}, used in the anlysis. The theoretical cut-off point for Pd-F pair calculated using the TFD phase angle for palladium atom is $s=23.7$ Å^{-1}, in agreement with the observed value for the Mo-F pair. Since the absolute value of atomic scattering factor, $|f|$, for molybdenum atom had a negligible effect on molecular parameters, the analysis using $|f_{Mo}|$ and η_{Pd} for molybdenum atom was carried out, and the calculated intensities gave the best fit to the observed ones. The results of least-squares analyses, where the TFD and RHFS phase angles of molybdenum and the TFD phase angle of palladium were used, are listed in Table 1.

Table 1. Results of least-squares analyses (in Å)

	(A)[b]	(B)[b]	(C)[b]
r_g(Mo-F)	1.838 (2)	1.836 (1)	1.836 (1)
r_g(Mo-O)	1.654 (7)	1.649 (6)	1.650 (5)
r_g(F···F(s))	2.524 (4)	2.519 (4)	2.522 (3)
l(Mo-F)	0.059 (3)	0.057 (3)	0.046 (3)
l(Mo-O)	0.045(21)	0.040(16)	0.034(10)
l(F···F(s))	0.098 (8)	0.100 (7)	0.098 (5)
l(F···F(l))	0.084(14)	0.086(12)	0.084 (9)
l(F···O)	0.101(10)	0.104 (8)	0.101 (7)
R[a]	0.978(36)	1.019(43)	0.979(38)

Estimated random errors (2.5σ) are shown in parentheses ($\times 10^3$). a) The index of resolution, R, is dimensionless. b) (A), (B), and (C) are the results of analyses using TFD f_{Mo}, RHFS f_{Mo}, and TFD $|f_{Mo}|$ and η_{Pd}, respectively, for molybdenum atom.

Table 2. Distances and mean amplitudes (in Å)

	r_g	l
Mo-F	1.836±0.003	0.046±0.013
Mo-O	1.650±0.007	0.034±0.015
F···F(s)	2.522±0.005	0.098±0.005
F···F(l)	3.563±0.008	0.084±0.009
F···O	2.752±0.009	0.101±0.008
∠OMoF	103.8±0.6°	
∠FMoF	86.7±0.3°	

The final results of the analysis are given in Table 2, where parameter values were obtained from the analysis using palladium phase angle for molybdenum atom. Random errors were given by 2.5 times the larger of σ_1 and σ_2.[19,22] The uncertainty in phase angle for molybdenum atom was taken into account as systematic errors in bond distances and amplitudes. The error in lattice constant of a reference material (0.06%) and the errors in measurements of diffraction patterns of the reference (0.09%) and of the camera distance (0.04%) were also taken into account as systematic errors in bond distances. The correlation matrix[23] is given in Table 3, and the best-fit theoretical intensity curve is shown in Fig. 3.[24] The least-squares calculations were carried out by use of a FACOM 230-60 computer at the Nagoya University Computing Center.

Discussion

The phase angle for molybdenum was not sensitive to the distances of the atomic pairs relating to molybdenum, but was considerably sensitive to the amplitudes as shown in Table 1. The Mo-F and Mo-O amplitudes obtained using η_{Pd} in place of η_{Mo} were in fair agreement with 0.040 and 0.035 Å calculated from the Mo-F and Mo-O vibrational frequencies,[7,25] respectively. The analysis using η_{Pd} gave the smallest

Table 3. Correlation matrix for molecular parameters of MoF_4O[a)]

l(F···F(s))						1.0	0.06	0.62	0.39
l(F···F(1))							1.0	0.04	0.15
l(F···O)								1.0	0.30
R									1.0

a) The elements are defined as $\rho_{ij}=B_{ij}^{-1}/(B_{ii}^{-1}\times B_{jj}^{-1})^{1/2}$.

standard deviations for parameters. The cut-off point for Mo-F pair, s=23.2 Å^{-1}, obtained at the accelerating voltage of 40 kV in the present study is estimated to be equivalent to about 22 Å^{-1} at 35 kV by use of the formula.[26)] This value is in good agreement with 22.2±0.4 Å^{-1} from the experiment of MoF_6 at 35 kV.[9)]

The molecular structure of MoF_4O is square-pyramidal in the gas phase, but in the crystal state[6)] it is distorted by bridging of fluorine to another molecule and forms a nearly octahedral arrangement around a molybdenum atom. The Mo-F and Mo-O distances in the crystal, 1.81—1.84 and 1.62—1.65 Å, respectively, are in agreement with the corresponding distances in the gas phase. However, the average OMoF (terminal) angle in the crystal, 100.4°, is a little smaller than that in the gas phase because of an octahedral arrangement.

The gaseous MoF_4O has the same structure as the gaseous WCl_4O[1)] or $MoCl_4O$,[2)] but it is apparently distinguished from those of XeF_4O[3,4)] and IF_5[4,5)] with respect to the XMY angle, where M is a central atom. The angles of the latter molecules are about 90° or less, and can be explained by considering the repulsions between bonding electron pairs and a nonbonding electron pair of central atoms.[27)]

There are only small differences between MoF_4O and $MoCl_4O$ with respect to Mo–O distance and OMX angle. However, the Mo-F distance, 1.836±0.003 Å, is shorter than the Mo-Cl distance, 2.279±0.003 Å, by about 0.44 Å. The force constant for the Mo–O bond in MoF_4O is estimated to be 8.6 mdyn/Å from the frequency of Mo–O stretching vibration in the gas phase[7)] and is nearly equal to that in $MoCl_4O$, 8.29 mdyn/Å.[2)] The distance and force constant for the Mo–O bond in gaseous MoF_4O give a good fit to the correlation curve between them,[28)] and its bond order is estimated to be 3. The Mo-F distance in MoF_4O is greater than that in MoF_6 (1.820±0.003 Å[9)]) by about 1%. The lengthening of the Mo-F distance may be interpreted as the effect of the Mo–O multiple bond.

The author thanks Professor Shuzo Shibata for his kind advice and helpful discussions. He is also indebted to Dr. Shunji Nagase of the Government Industrial Research Institute for preparation of the sample.

An INDO-UHF Molecular Orbital Study of the Conformations and Electronic Structures of Some σ-Type Radicals

Katsutoshi OHKUBO and Hiroyuki SATO

Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860

(Received October 4, 1976)

The equilibrium geometric parameters determined for XC=Y radicals (HC=O, CH_3C=O, NH_2C=O, and HC=CH_2) are not characterized by their bond lengths but by their X–C–Y angles, which are wide compared with the angles in their parent molecules (XHC=Y). The %s character of the σ orbitals on the C atom in XHC=Y was found to be conserved in the %s character and the s-orbital spin density of the same atom in XC=Y radicals: there are linear relationships between them. Some notable features of the unpaired-electron distribution on the frameworks of XC=Y radicals are also discussed in connection with the electronic properties of the σ radicals.

The conformations and electronic structures of paramagnetic species containing an odd electron in their σ orbitals (*e.g.*, σ-type radicals such as vinyl, formyl, and phenyl) have been the object of only limited experimental and MO-theoretical investigations. Concerning the conformations of the σ radicals, the equilibrium geometric parameters have hitherto been given only for simple σ radicals such as HC=O,[1] even though, in connection with the electronic structures of the σ radicals, the nuclear hyperfine constants of several σ radicals (C_6H_5, CH_2=CX, or XC=O, where X=H, CH_3, OCH_3, *etc.*) have already been obtained by ESR observations.[2]

On the other hand, the distribution of unpaired electrons on the frameworks of σ radicals such as vinyl, formyl, and phenyl has been discussed on the basis of their electronic structures obtained by the EHMO,[3] CNDO,[4] or INDO[5] computations with assumed bond lengths and angles; but the first two methods are not capable of giving a proper account of the contribution of spin polarization to the unpaired electron density because they neglect interelectron repulsions (in the EHMO) or about atomic exchange integrals (in the CNDO).

In the present paper, using the semiempirical INDO method,[6] the conformations of some σ radicals of XC=Y (HC=O, CH_3C=O, NH_2C=O, and HC-CH_2) are characterized by comparing them with those of the parent molecules of XHC=Y; the unpaired electron distributions are also discussed in connection with their conformations and electronic properties.

Method of Calculation

The integrations and parametrizations involved in the INDO method, which is relatively reliable for bond angles but less so for bond lengths,[6,7] have been described in detail in Ref. 6, so they will not be repeated here. In the INDO-UHF computations the annihilation procedure was not carried out, because the annihilation has little effect on the electron density distribution[8] and because, in the conventional evaluation of the hyperfine splitting constants (a_N), the best fitting proportionality constants to the experimental a_N values have been determined on the basis of the computed spin densities without the annihilation.[5]

The geometric parameters of XC=Y radicals (HC=O, CH_3C=O, NH_2C=O, and HC=CH_2) shown in Fig. 1 were first determined by changing them in turn so as to minimize the total energy until they become identical; then, the optimized conformations of the XC=Y radicals were recalculated by changing all their geometric parameters in the magnitude of $\pm$0.01 Å and $\pm$1° as a check on the reliability of the optimization results. In the above optimizations, some assumed bond lengths (r_{NH}=1.0 Å in NH_2C=O and r_{CH}=1.08 Å in CH_3C=O) and angles ($\angle$CNH=120° in NH_2C=O and $\angle$HCH=109.5° in CH_3C=O) were used to shorten the computation time.

Results and Discussion

Optimized Conformations. The computed equilibrium geometric parameters of the XC=Y radicals (HC=O, CH_3C=O, NH_2C=O, and HC=CH_2) are summarized in Table 1, together with those (obtained by the INDO calculations) of the parent molecules of XHC=Y (HCHO, CH_3CHO, NH_2CHO, and H_2C=CH_2). The difference in the bond lengths between XC=Y and XHC=Y was very small (within 0.04 Å) in their respective frameworks, but the computed bond angles (θ) of the former were too large (by 7.42—37.4°) as compared with those of the latter. The optimized bond angle (θ) of XC=Y seems to be overestimated. The experimental θ value, for example, for HC=O (θ=119.5°[1]) is too small as compared with the calculated one (θ=131°), even though some overestimations of the bond angle (θ) of XHC=Y have been seen, ranging from 2.1° in NH_2CHO (exptl=121.5°[9]) to 3° in

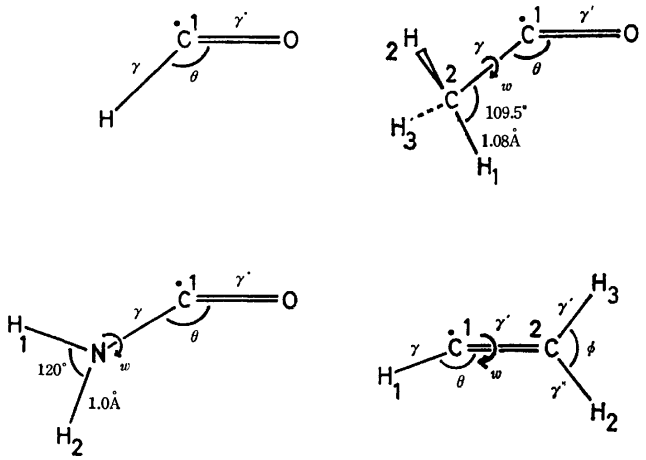

Fig. 1. Geometric parameters for the conformational optimization.

Table 1. Optimized geometric parameters for the XC=Y radicals

XC=Y	γ/Å	γ'/Å	θ/deg	ω/deg	γ''/Å	ϕ/deg
HC=O	1.12	1.23	131			
	(1.12)	(1.25)	(115)			
CH_3C=O	1.44	1.23	142	0		
	(1.44)	(1.26)	(124)	(0)		
NH_2C=O	1.35	1.26	131	0		
	(1.343)	(1.243)	(123.6)	(0)		
HC=CH_2	1.10	1.27	161.7	0	1.12	107.4
	(1.11)	(1.31)	(124.3)	(0)	(1.11)	(111.4)

Values in parentheses are those for the parent XHC=Y molecules, and the underlined values are the ones fixed (taken from Ref. 9) for the calculations.

CH_3CHO (exptl=121°[9]) and H_2C=CH_2 (exptl=121.3°[10]). At any rate, the INDO computations tend to give overestimated bond angles (θ) for the XC=Y radicals, because the widening of the bond angle (θ) unilaterally decreases the electron and nuclear repulsions. For example, the widening of the bond angle in HC=O from θ=115° (corresponding to that in HCHO) to 131° (corresponding to that in HC=O) monotonously decreased the electron and nuclear repulsions (E_{II} and E_N respectively) from 28.827 to 28.724 a. u. in E_{II} and from 13.816 to 13.700 a. u. in E_N, with a monotonous decrease in the one-electron attraction (E_I) from −67.441 to −67.229 a. u. The balance in the repulsions and the attraction energies, therefore, gave the rather large bond angle (θ=131°) for HC=O. In this sense, it can be said that the underestimation of the electron repulsions, which is the usual trend of the INDO calculations,[5,11] gave bond angles (θ) to the XC=Y radicals which were too large.

Next we discuss the change in the energetical stability of the XC=Y radicals by the internal rotation of the X or Y group around the C–C bond in CH_3C=O or HC=CH_2 and around the C–N bond in NH_2C=O. The rotation angle (ω) for the energetically most stable and unstable conformations are given in Fig. 2, together with the rotation barriers. In the most stable or unstable conformations of XHC=Y and XC=Y, the rotation angles (ω) were just the same between the respective parent molecules and the σ radicals, but the rotation barriers of the XC=Y radicals were rather low in comparison with those of the XHC=Y molecules (0.345 kcal/mol for CH_3CHO, 23.11 kcal/mol for NH_2CHO, and 105.22 kcal/mol for H_2C=CH_2). The INDO computations without polycenter interelectron repulsions usually result in low rotation barriers (for instance, the calculated barrier (0.345 kcal/mol) for CH_3CHO was too low as compared with the experimental value of 1.16 kcal/mol[13]), but the number (105.22 kcal/mol) for H_2C=CH_2 (r_{CC}=1.31 Å at ω=0° was stretched to r_{CC}=1.38 Å in the triplet state conformation at ω=90°) was computed to be too high in comparison with the experimental number of 65.0 kcal/mol.[12] The overestimated rotation barrier for H_2C=CH_2 is probably due to the incomplete optimization of its geometric parameters, such as r_{CH} and ∠CCH, at ω=90°. The decrease in the E_I term by the rotation

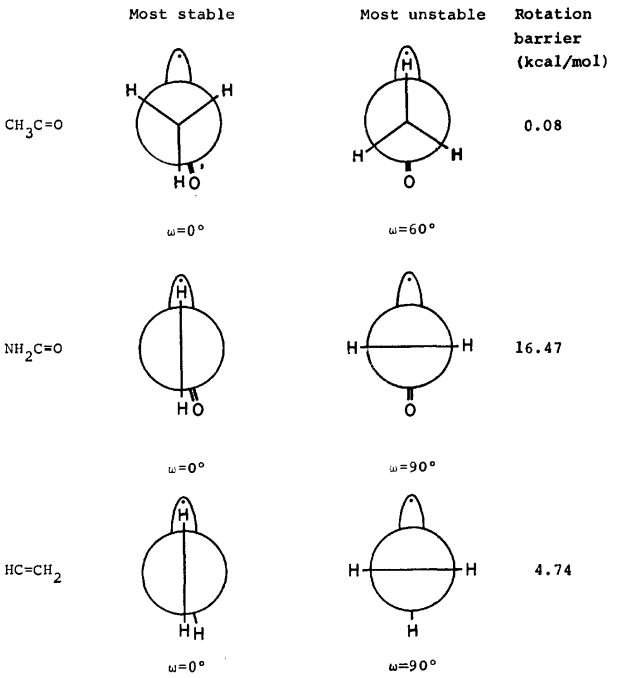

Fig. 2. The most stable and unstable conformers of CH_3C=O, NH_2C=O, and HC=CH_2.

from ω=0° to ω=90° (or ω=60° in CH_3C=O and CH_3CHO) made both species (XC=Y and XHC=Y) more unstable, and this seems to be directly related to the decrease in the contribution of the π conjugation (including the pseudo one in CH_3C=O or CH_3-CHO) between the C–C or C–N bond to the stabilization of XC=Y or XHC=Y (see Table 2).

Electron Distribution and Spin Density. The polarization (charge distribution) in the XC=Y radicals was not so markedly different from that in the XHC=Y molecules, as seen from the computed atomic charge densities and dipole moments of XC=Y and XHC=Y in Table 3, but one slight difference is that XC=Y have a less positively charged C^1 atom and a less negatively charged O, C, or N atoms attached to the C^1, in comparison with XHC=Y. This was mainly caused by the electron shift from the neighboring atoms to the C^1 through the π-bonding orbitals during the widening of the bond angle (θ) in the XC=Y radicals. The hybridizations (sp^n) of the σ orbitals on the C^1 atom, n=1.35 (HC=O) —1.75 (HC=CH_2)

Values in parentheses are those for the XHC=Y molecules.

in XC=Y and n=1.62 (HCHO) —1.80 ($H_2C=CH_2$) in XHC=Y, were also almost the same magnitude in the radicals and the parent molecules. Strictly speaking the order of the %s character of the C^1 σ-orbitals in XC=Y, HC=O(42.50%) > $NH_2C=O$(41.43%) > $CH_3C=O$(38.69%)>$HC=CH_2$(37.62%), was well reflected in that in XHC=Y, HCHO(38.10%)> NH_2CHO(37.50%) > CH_3CHO(36.76%) > $H_2C=CH_2$ (35.69%), and there is a completely linear correlation between the above %s characters of XC=Y and XHC=Y (Fig. 3). Thus, the %s chracter of the σ-orbitals on the C^1 atom in XHC=Y was conserved in the same C^1 atom of XC=Y, and this is in harmony with the fact that the %s character of the C atom in XYZCH molecules (X, Y, or Z=substituent) is conserved in the same atom of XYZC radicals.[14]

In regard to the spin distribution in the XC=Y radicals, the total spin densities (Table 3) chiefly spread over the C^1 atom (46.6% in $NH_2C=O$ —61.9% in $CH_3C=O$) and the C^1-bound oxygen or carbon (C^2) atom (15.7% in $HC=CH_2$ —41.6% in $NH_2C=O$). Such a spin distribution was predominantly recognized on the p orbitals (especially, on the p orbital conjugating with the C^1 unpaired-electron orbital) of the O or C^2 atom or of the C^1 atom *per se*, and the spin densities on the C^1 p-orbitals, ρ_p, follow the order of $HC=CH_2$ >$CH_3C=O$>HC=O>$NH_2C=O$. The above order is just the same as that in the bond order of the

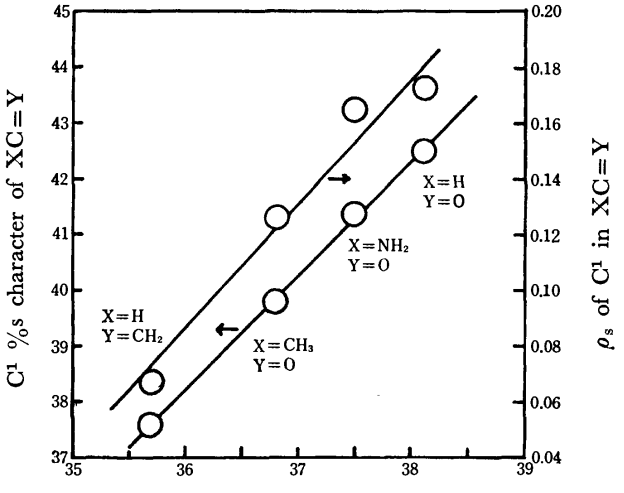

Fig. 3. Linear relationship of the C^1 %s character of XHC=Y with the C^1 %s character of XC=Y and with the ρ_s of C^1 in XC=Y.

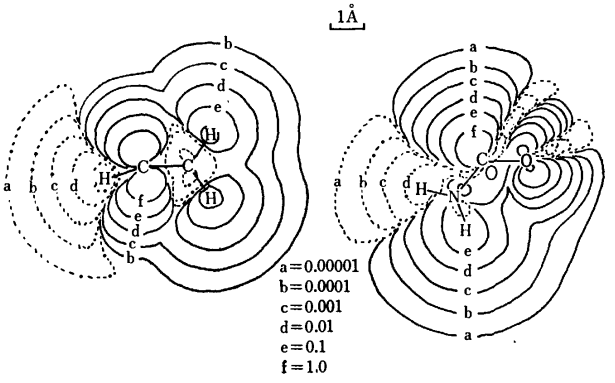

Fig. 4. Spin density contour maps for $HC{=}CH_2$ and $NH_2C{=}O$.

pseudo π-orbital between the C^1 and O (or C^2) p-orbitals; that is, $HC{=}CH_2(0.472) > CH_3C{=}O(0.375) > HC{=}O(0.359) > NH_2C{=}O(0.352)$, where the values in parentheses are the bond orders. This suggests that the direct spin polarization from the C^1 atom to the neighboring one through the π-type bonding decreases with increasing the bond order. In this respect, the internal rotation increasing the bond order of the pseudo π-conjugation in the C^1–C^2 ($HC{=}CH_2$) or C^1–N ($NH_2C{=}O$) bond resulted in the increase of the spin density of the C^1 atom (especially, that on the C^1 p-orbital).

On the other hand, the spin density of the C^1 s-orbital, ρ_s, was directly related to the hybridization on the C^1 σ-orbitals. Specifically, the ρ_s values show a linear dipendence on the %s character of the C^1 σ-orbitals (Fig. 3) and follow the order of $HC{=}O > NH_2C{=}O > CH_3C{=}O > HC{=}CH_2$. This is also in harmony with the fact that the hyperfine splitting constant, a_N, (reflecting the ρ_s value) of the carbon atom in the XYZC radical correlates linearly with the $J_{C^{13}H}$ coupling constant (reflecting the %s character of the C^{13} atom) of the XYZCH molecule.[14]

It should be noted that the computed spin density of the hydrogen *trans* to the site of the unpaired-electron orbital on the C^1 atom in $HC{=}CH_2$, $CH_3C{=}O$, or $NH_2C{-}O$ was considerably larger than that of the hydrogen *cis* to the above orbital. This trend was also seen in the ESR observations: the a_N value of the *trans* hydrogen in $HC{=}CH_2$, $NH_2C{=}O$, or $H_2C{=}CCH_3$ (*trans* H=(+) 57.89 G[15]) and *cis* H=(+)32.92 G[15]) is larger than that of the *cis* hydrogen. In view of the fact that the internal rotation from $\omega=0°$ to $\omega=90°$ monotonously decreased the spin density of the *trans* hydrogen in $HC{=}CH_2$ or $NH_2C{=}O$, with equivalent spin densities for H^2 and H^3 in $HC{=}CH^2H^3$ or for H^1 and H^2 in $NH^1H^2C{=}O$ at $\omega=90°$, the predominant interaction of the C^1 unpaired-electron orbital with the *trans* H s-orbital rather than with the *cis* H s-orbital presumably caused the spin polarization to be stronger for the *trans* H atom. Such circumstances of the spin polarization (or of the spin delocalization) may also be understandable from the contour map of the spin distribution in $HC{=}CH_2$ or $NH_2C{=}O$ (Fig. 4).

Finally, we will briefly point out the hyperfine splitting constants, a_N, of the present XC=Y radicals (Table 3). The a_N values computed with the best proportionality constants[5] did not show satisfactorily good coincidence with the observed a_N values, and those for ^1H, ^{13}C, ^{14}N, and ^{17}O had almost the same accuracy of agreement with the observed ones. Here, no characteristic feature of the calculated a_N values for the present XC-Y radicals was recognized in terms of a coincidence between the INDO computation results and the ESR observations.

Vibration Spectra and Rotational Isomerism of Chain Molecules. IV.[1] Diethyl Sulfide, Ethyl Propyl Sulfide, and Butyl Methyl Sulfide

Masahiro OHTA, Yoshiki OGAWA, Hiroatsu MATSUURA, Issei HARADA, and Takehiko SHIMANOUCHI

Department of Chemistry, Faculty of Science, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received October 26, 1976)

The Raman and infrared spectra of diethyl sulfide, ethyl propyl sulfide and butyl methyl sulfide were measured for the gaseous, liquid, glassy and crystalline states. The normal vibration frequencies were calculated, a consistent set of force constants explaining the frequencies of basic aliphatic sulfides being assumed. The rotational isomerism was studied and the following conclusions were obtained. (1) Only the all-*trans* form exists in the crystalline state. (2) Many forms coexist in the liquid state and most of them persist in the glassy state even at the liquid nitrogen temperature. (3) In the liquid state, the *gauche* conformation about the S–C axis is more stable than the *trans* conformation, and the *gauche* conformation about the C–C axis directly adjoining the S–C axis is as stable as the *trans* conformation. These results confirm that the repulsive force between nonbonded hydrogen atoms is one of the important factors influencing the stability of molecualr conformations. The stable conformations of the sulfide molecules were correlated with those of polythioether chains.

In previous papers,[1-3] we compared the Raman and infrared spectra of unbranched ethers, paraffins and ethyl methyl sulfide in the crystalline, glassy, liquid and gaseous states with the results of normal vibration calculations and determined the rotational isomers existing in each state.

In the present paper, the same method is applied to unbranched sulfide molecules. The results also show that the method is useful in the study of rotational isomerism. The stable forms of these sulfide molecules do not always correspond to those of the ethers. The factors stabilizing the isomers will be discussed.

The stable conformations of some sulfides[1,4-12] and polythioethers[13-15] have already been studied. The present results will be correlated with the former conclusions.

Experimental

Diethyl sulfide, ethyl propyl sulfide and butyl methyl sulfide were purchased from Tokyo Kasei Kogyo Co., Ltd. and were distilled prior to the measurements. The Raman spectra were measured for the liquid, glassy and crystalline states and the infrared spectra for the gaseous, liquid, glassy and crystalline states. The spectrometers described in the previous study[2] are used.

The Raman spectra were recorded in the region below 1600 cm^{-1}. The spectra in the liquid state were measured at room and lower temperatures. The glassy state for the Raman measurements was obtained by putting into liquid nitrogen the sample enclosed in an ampoule and cooling it rapidly, and the crystalline state by cooling the sample slowly with liquid nitrogen. The crystallization of diethyl sulfide was very rapid and the Raman spectra in the glassy state could not be measured.

The infrared spectra in the gaseous state were measured with a 10 cm gas cell in the region 1600—600 cm^{-1}. For the measurements of the infrared spectra in the liquid state, 0.05 and 0.025 mm fixed cells with KBr windows were used in the region 1600—400 cm^{-1}, and a variable thickness cell with KRS-5 windows in the region 700—250 cm^{-1}. The glassy state for the infrared measurements were obtained by depositing the sample onto a cooled window of KBr or KRS-5, and the crystalline state by annealing the glass several times. For the measurements in the region 700—250 cm^{-1}, the spectrometer was flushed with dry air to get rid of water vapor absorptions.

Normal Coordinate Treatment

The normal coordinate treatment of the unbranched sulfides was carried out in a way similar to the case of the ethers.[2] Detailed results including structural parameters, symmetry coordinates and force constants are reported in a separate paper.[16]

A total of 70 force constants associated with the sulfide group were determined from 446 Raman and infrared frequencies of 31 forms of 11 molecular species. Table 1 shows the procedure of the least-squares refinement of the force constants.

Results

Figures 1—9 show the Raman and infrared spectra of the sulfides in the various states. The observed frequencies and the assignment based on the calculated potential-energy distributions are listed in Tables 2—4.

The observed spectra were analyzed with reference to the results of the normal coordinate treatment. The following spectral features are observed for the three sulfides studied in this work. (1) The spectra in the various states are distinctly different, especially in the 500—200 cm^{-1} region of the skeletal deformation vibrations and in the 800—600 cm^{-1} region of the C–S stretching and the methylene rocking vibrations. (2) The spectral pattern of the crystalline state is the simplest and the number of the observed bands is the smallest. (3) In the glassy state, many bands are observed in addition to those which persist in the crystalline state. (4) The liquid-state spectra have essentially the same numbers of bands as those in the glassy-state spectra. However, their relative band intensities and widths are considerably different between the two states.

In the following subsections, the rotational isomerism of the individual sulfides is described.

Diethyl Sulfide. Since this molecule has two C–S axes associated with the rotational isomerism, there are four possible isomers, TT, TG, GG, and GG′, as given in Table 1 of Part I of this series.[2] The observed and calculated frequencies in the 900—200 cm^{-1} region are compared in Fig. 3.

The spectra in the crystalline state show that only

The least-squares calculation begins with the simplest sulfides given in the first step and the first set of force constants is determined so as to give the best fit between the observed and calculated frequencies. This set of force constants gives the definite vibrational assignments of the sulfides given in the second step and the second set of force constants is subsequently determined from the observed frequencies in this step in addition to those in the first step. By repeating this procedure, the final set of force constants is obtained. The figures in parentheses give the numbers of observed frequencies used for the least-squares calculation. The observed frequencies of the CH and CD stretching vibrations are not included in the calculation and accordingly the force constants associated with these vibrations are not refined. The results of the following references are utilized in the least-squares calculation. a) Refs. 1, 5, and 17. b) This study. c) Refs. 8 and 12. d) Ref. 18. e) Ref. 1. f) Refs. 1 and 6. g) Ref. 13.

the TT form exists. The number of the observed bands is just what is expected for one form. The frequencies of the skeletal deformation bands, 343 and 332 cm^{-1}, can only be explained by the TT form.

The glassy- and liquid-state spectra show that the TT, TG, and GG forms coexist. The temperature dependence of the liquid-state Raman spectra, combined with the results of the normal vibration calculations,

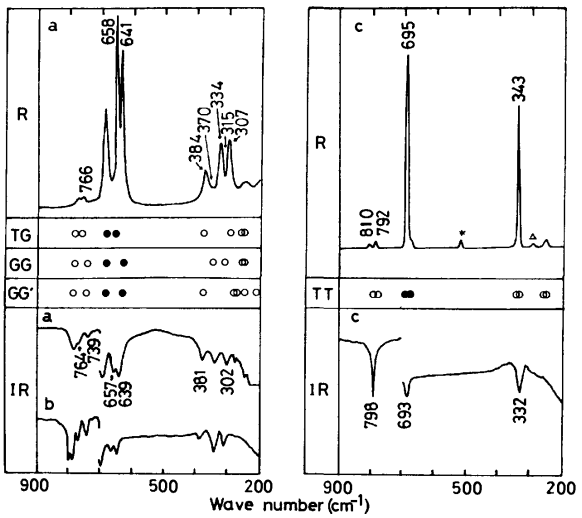

Fig. 3. Comparison of the calculated and observed frequencies of diethyl sulfide in the 900—200 cm^{-1} region.

The symbols are explained in the caption of Fig. 1.

indicates that the bands at 766, 658, 384, and 307 cm^{-1} are assigned to the TG form and those at 739, 641, 370 (a shoulder of the 384 cm^{-1} band), and 315 cm^{-1} (a shoulder of the 307 cm^{-1} band) are assigned to the GG form. It should be noted that the assignment of the 739 cm^{-1} band, which has not been made clearly in previous studies, is now established.

Existence of the GG′ form is uncertain, since all of

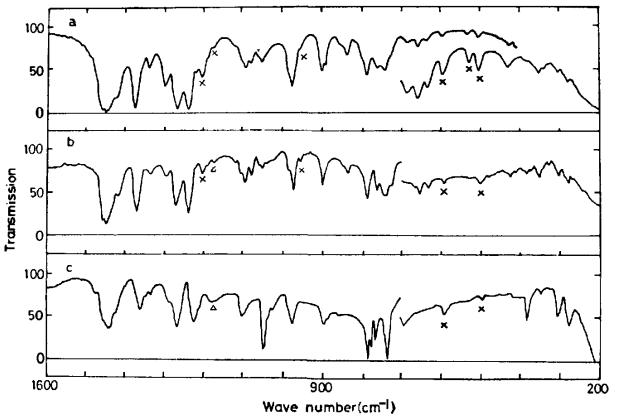

Fig. 5. Infrared spectra of ethyl propyl sulfide.

the calculated frequencies of this form are almost coincident with those of the other forms, TT, TG, and GG. However, the distance between the two terminal methyl groups seems to be too short for this form to be stable. In fact, for methyl propyl sulfide, the GG′ form is found to be very unlikely as will be described later.

The enthalpy differences between the GG and TG forms and between the TT and TG forms in the liquid state were determined from the relative Raman intensities at eight different temperatures between −90 and 23 °C. The intensity ratios of the 641 and 658 cm^{-1} bands and of the 334 and 384 cm^{-1} bands gave the enthalpy differences $\Delta H_{GG-TG}=40\pm50$ cal/mol and

$\Delta H_{TT-TG}=460\pm100$ cal/mol, respectively.

The infrared spectrum of gaseous diethyl sulfide is essentially the same as that of the liquid. This observation suggests that the TT, TG, and GG forms coexist in the gaseous state.

Ethyl Propyl Sulfide. This molecule has fourteen possible rotational isomers as listed in Table 1 of Part I.[2] Of these, TGG', GG'T, GGG', GG'G, and GG'G' are rejected because of the same reason as stated above for diethyl sulfide.

Figure 6 shows that the observed Raman spectrum in the crystalline state is explained by the TTT form only. The spectra in the glassy and liquid states exhibit much more bands than those in the crystalline

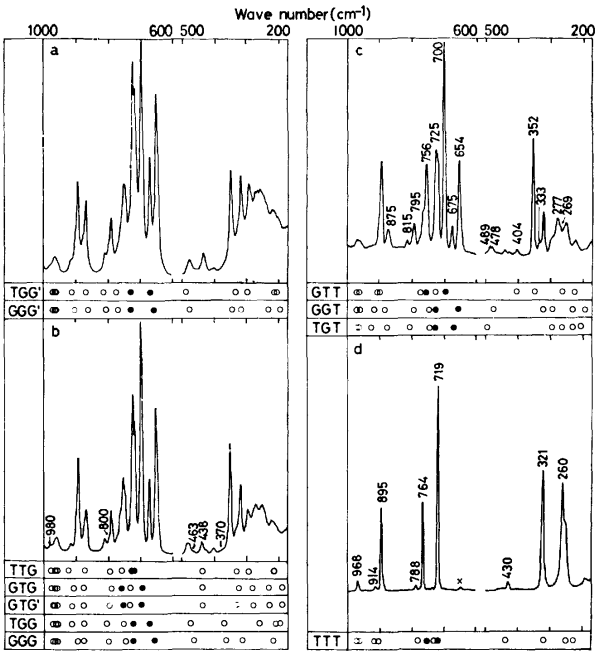

Fig. 9. Comparison of the calculated and observed Raman frequencies of butyl methyl sulfide in the 1000—600 and 500—175 cm^{-1} regions.
a: Liquid (room temperature), b: liquid (−90 °C), c: glass (liquid nitrogen temperature), d: crystal (liquid nitrogen temperature).
The filled circles denote the CS stretching vibrations.
The symbol in the spectrum of the crystalline state is explained in the caption of Fig. 1.

state, suggesting the coexistence of many rotational isomers. The temperature dependence of the Raman intensities and the comparison with the calculated results indicate that the observed spectra in these states are explained by the TTT, GGT, TGT, GTT, GGG, TTG, and TGG forms and either one or both of the GTG, and GTG' forms.

The comparison of the Raman spectrum in the glassy state and that in the liquid state at room temperature shows that the intensities of the bands at 783, 740, 658, 412, 383, 372, and 356 cm^{-1} are enhanced in the glassy state. In the liquid state, these bands are also stronger at lower temperatures. Examinations of the experimental and calculated results indicate that the bands at 658 and 383 cm^{-1} are assigned to the GGT form, those at 783 and 412 cm^{-1} to the TGT form, those at 372 and 356 cm^{-1} to the GTT form, and that at 740 cm^{-1} to the GGT, TGT, and GTT forms. The bands at 676 and 670 cm^{-1} are assigned to the TGT and GTT forms, respectively, on the basis of the facts that the intensity of the former band increases at lower temperatures relative to the intensity of the latter band and that corresponding intensity variations are observed for the band pair of the 412 cm^{-1} band (TGT form) and the 372 or 356 cm^{-1} band (GTT form).

The observed spectra show that the intensities of some other bands such as those at 800, 788, 688, 683, 651, 440, 432, 425, 363, and 340 cm^{-1} decrease in the glassy state as compared with the liquid state at room

TABLE 2. (Continued)

a) VS: very strong, S: strong, M: medium, W: weak, VW: very weak, vb: very broad, b: broad, sh: shoulder. The broadness of the band shapes in the liquid state does not always allow us to correlate the individual bands in the glassy or crystalline state to those in the liquid state. Only approximate correlations are made in such cases. b) The band is assigned preferentially to the isomer(s) given by boldface. For the notation and definition of the local symmetry coordinates, see Ref. 19. c) Some of the infrared bands in the gaseous state have rotational structures. However, only the frequencies of the band centers are listed in the table.

a), b) See a) and b), respectively, of Table 2.

temperature. Of these, the band at 788 cm^{-1} is assigned to the GGG form, that at 683 cm^{-1} to the TTG form, that at 425 cm^{-1} to the TGG form, that at 440 cm^{-1} to either one or both of the GTG and GTG' forms, that at 432 cm^{-1} to both of the GGG and TTG forms, and that at 363 cm^{-1} to both of the GGG and TGG forms. The existence of the GGG form is evident from the result that the band at 636 cm^{-1} is assigned exclusively to this form. The following bands are assigned to all or any of the molecular forms given in parentheses: 800 and 342 cm^{-1} (TTG, GTG, and GTG'), 688 cm^{-1} (TGG, GTG, GTG', and TTG), and 651 cm^{-1} (TGG, GTG, and GTG').

The relative stabilities of the rotational isomers existing in the liquid state are determined from the dependence of the band intensities on temperature (Fig. 6) and the band assignment mentioned above; (1) the GGT and TGT forms have almost the same stability and are the most stable, (2) the third stable isomer is the GTT form, which is followed by the TTT and GGG forms having nearly equal stability to each other, and (3) the TTG, GTG, GTG', and TGG forms are less stable than the forms given above, but the relative stabilities among these forms are not clear.

The above conclusion obtained from the Raman spectra is also consistent with the change of the infrared

spectra in the various states.

Butyl Methyl Sulfide. This molecule has fourteen possible rotational isomers. The existence of the GG′T, GG′G, and GG′G′ forms are unlikely, but the TGG′ and GGG′ forms are not ruled out, since unlike the GG′ sequence of the CS–C–CC part in ethyl propyl sulfide, the GG′ sequence of the SC–C–CC part is not expected to give rise to very large steric hindrance.

Figure 9 shows that only the TTT form exists in the crystalline state. In the glassy and liquid states, the spectra exhibit many bands to be assigned to various rotational isomers. It is evident, however, that the GTT and TTT forms exist in these states. The relative intensities of the bands at 756, 700, 404, 352, and 277 cm^{-1} increase in going from the liquid state at room temperature to the glassy state. These bands are all explained by the calculated frequencies of GTT form.

The remaining many bands in the glassy and liquid states imply the coexistence of additional isomers. However, the assignment of the observed bands to individual isomers is not always straightforward, because each of the observed Raman bands corresponds to calculated frequencies of two or more isomers. It is likely that the *trans* conformation about the CH_2CH_2–CH_2CH_3 axis in this molecule is appreciably more stable than the *gauche* conformation as suggested from the conformational stabilities of normal paraffin molecules.[3] The molecular forms with the *trans* conformation about this axis are the TGT and GGT form besides the TTT and GTT forms mentioned above Most of the bands which persist in the glassy state but are not assigned to the GTT and TTT forms are explained by the calculated frequencies of the TGT and GGT forms; namely the bands at 815, 675, 489, and 269 cm^{-1} are assigned to the TGT form, those at 795, 654, 478, and 333 cm^{-1} to the GGT form and those at 875 and 725 cm^{-1} to both of the TGT and GGT forms.

The isomers given by boldface are confirmed to exist. The existence of the isomers in parentheses is uncertain. For more details, see text. a) Refs. 1 and 7. b) Ref. 8. c) Three different crystal modifications have been identified. For more details, see Ref. 8.

In addition to the bands mentioned above, the liquid- and glassy-state Raman spectra have several other bands such as those at 980, 800, 463, 438, and 370 cm^{-1}. Spectral observations indicate that the intensities of these bands decrease more sharply than those of the above-mentioned bands when temperature is lowered. With reference to the calculated frequencies, the 463 cm^{-1} band is assigned to the GGG form, the 370 cm^{-1} band to either one or both of the TGG and GGG forms, the 800 and 438 cm^{-1} bands to all or any of the TTG, GTG and GTG′ forms, and the 980 cm^{-1} band to all or any of the TTG, TGG, and GTG forms. The calculated frequencies of the TGG′ and GGG′ forms are almost coincident with those of the other forms. This situation makes it difficult to confirm the existence of these forms in the liquid or glassy state.

As mentioned above, the examinations of the experimental and calculated results show that the relatively strong bands which retain most of their intensities in the low-temperature liquid and glassy states are reasonably explained by the isomers with the *trans* CH_2CH_2–CH_2CH_3 axis and the other bands which lose their intensities largely in these states are explained by the isomers with the *gauche* CH_2CH_2–CH_2CH_3 axis. These interpretations justify the statement made earlier that the *trans* conformation about this axis is more stable than the *gauche* conformation.

The relative stabilities of the rotational isomers existing in the liquid state are found from the temperature dependence of the Raman intensities; (1) the GTT form is the most stable, (2) the TTT, GGT, and TGT forms follow in order, and (3) the forms having the *gauche* CH_2CH_2–CH_2CH_3 axis are less stable than the above-mentioned forms.

The above conclusion is also consistent with the results of the infrared spectra.

Rotational Isomerism. In Table 5, the rotational isomerism of the three sulfides studied in this work and of ethyl methyl sulfide and methyl propyl sulfide is summarized.

Ethyl methyl sulfide has long been accepted to take the T form in the crystalline state and the T and G forms in the liquid state.[4-6,10] However, the recent studies by Nogami *et al.*[7] and by Sakakibara *et al.*[1] showed that the bands of the crystalline state are assigned to the G form but not to the T form.

The rotational isomerism of methyl propyl sulfide was studied by Nogami *et al.*[8] They found three crystal modifications with the molecular conformations of GT, TT, and GG, respectively. In the liquid and glassy states, an additional isomer of the TG form coexists with the three isomers. They obtained no experimental evidence for the existence of the GG′ form. The comparison of their spectra with the present results of the normal coordinate treatment indicates that the existence of this form may safely be ruled out.

The vibrational spectra of diethyl sulfide have been studied by several investigators.[6,9] Their conclusions on the rotational isomerism agree essentially with the present one, although the existence of the GG form in the liquid state has once been questioned.[10]

The rotational isomerism of ethyl propyl sulfide and butyl methyl sulfide has been discussed previously by Ohsaku.[11] He showed that these molecules in the crystalline state take the *trans* conformation about the C–C axis adjacent to the S–C axis, but did not determine whole molecular conformations.

Discussion

The following results were obtained for the three sulfides studied in this work. (1) Only the all-*trans* form exists in the crystalline state. (2) Many forms coexist in the liquid state. Most of them persist in the glassy state even at the liquid nitrogen temperature. (3) In the liquid state, the forms with the *gauche* C–S axes are more stable than those with the *trans* C–S axes. (4) The *gauche* conformation about the C–C axis directly adjoining the S–C axis is appreciably stable and is only slightly less stable than the corresponding *trans* conformation.

For the C–C and C–O axes in unbranched paraffins and ethers, the *trans* conformation has been found to be more stable than the *gauche* conformation.[2,3] However, the above results indicate that the conformational stability about the C–S axis is remarkably different from that of the C–C or C–O axis. For diethyl sulfide, the TG and GG forms were found to be more stable than the TT form by 400—450 cal/mol in the liquid state. The stability of the *gauche* conformation about the C–S axis over that of the *trans* conformation was also observed for ethyl propyl sulfide and butyl methyl sulfide. In addition to these experimental evidences, it has been found that the G

form of ethyl methyl sulfide is more stable than the T form by 140±50 cal/mol in the liquid state[7] and by 30±50 cal/mol in the gaseous state,[1] and that the GT form of methyl propyl sulfide is the most stable isomer in the liquid state.[12] Thus, it is now established that the *gauche* C–S axis in unbranched sulfides is more stable than the *trans* C–S axis but the stability difference between them is not large.

The stable existence of the *gauche* C–S axis contrasts with the *gauche* C–O axis which is far less stable. One of the possible factors making this difference is the longer C–S bond length (about 1.8 Å) than the C–O bond length (about 1.4 Å), as has been discussed by Tadokoro *et al.*[13a] When the C_1S–C_2C_3 axis takes the *gauche* conformation, the distance between nonbonded hydrogen atoms attached to C_1 and C_3 is 2.1—2.2 Å, which is 0.4—0.5 Å longer than the corresponding distance in ethers. This fact suggests that the repulsive forces between the nonbonded hydrogen atoms in the sulfides are much weaker than those in the ethers and that this effect is responsible for making the *gauche* C–S conformation stable.

The relative stability of the *gauche* conformation about the SC–CC axis was found to be much higher than that of the *gauche* conformation about the CC–CC axis. This is explained by less significant nonbonded interactions as in the case of the *gauche* OC–CC axis in the ethers.[2] Indeed, methyl propyl sulfide takes the GG form in a metastable crystal modification.[8]

The above discussions on the conformational stability indicate that the S–C axis and the C–C axis adjacent to the S–C axis are susceptible of taking the *trans* and *gauche* conformations without large stability differences and accordingly the energy differences among various rotational isomers are small. These results are in accord with the experimental facts observed for all of the sulfides so far studied that many isomers coexist in the glassy state and that methyl propyl sulfide has the three crystal modifications with the molecular conformations of GT, TT, and GG.[8]

It is noticed for the three sulfides studied in this work that the most stable isomer in the liquid or glassy state does not exist in the crystalline state. This fact suggests that intermolecular forces play a more important role for stabilizing the molecular conformation in the crystal.

It is of interest to compare the molecular conformations of the unbranched sulfides with the chain conformations of polythioethers. According to the X-ray diffraction studies, poly(thioethylene)$(-SCH_2CH_2-)_n$ takes the GTG'G'TG conformation for the series of S–C–C–S–C–C–S bonds[13] and poly(thiotrimethylene)$(-SCH_2CH_2CH_2-)_n$ takes the GGGG conformation for the series of S–C–C–C–S bonds.[14] It should be noted that S–C axes in these polymers are all in the *gauche* conformation and the C–C axes adjacent to the S–C axes in the latter polymer are in the *gauche* conformation. These chain conformations are consistent with those of the shorter sulfides as described in this paper.

The Preparation and Stereochemistry of Optically Active Cobalt(III) Complexes with 3,3′-Dimethyl-2,2′-bipyridine and Bis(diamines) or Tetramines

Toshishige M. SUZUKI and Tetsuo KIMURA
Government Industrial Research Institute, Tohoku, Nigatake, Haranomachi, Sendai 983

(Received June 15, 1976)

Bis(en), trien, tren and bis(*R*,*R*-chxn) cobalt(III) complexes of 3,3′-dimethyl-2,2′-bipyridine (dmbpy) have been prepared and resolved. The dissymmetric conformation of dmbpy arising from the non-coplanarity of the two pyridine rings is maintained in the inert complexes. 3,3′-Dimethyl-2,2′-bipyridine coordinates to the cobalt(III) ion with a stereospecific conformation depending on the configuration. The absorption and circular dichroism (CD) spectra of the dmbpy complexes were compared with those of the corresponding 2,2′-bipyridine (bpy) complexes.

Although bpy is one of the most extensively studied chelating agents,[1] little work has been done on its 3,3′-dimethyl derivative. On the basis of molecular models, it seems that metal chelate of the dmbpy has considerable strain caused by its puckered conformation. Cagle Jr. and Smith[2] reported that dmbpy forms an iron(II) complex in an aqueous solution, but its absorption intensity of 526 nm is only one-fifth of that of the bpy complex. They explained this by considering a twisted conformation of the dmbpy moiety in contrast with the planar chelate ring of bpy. So far no metal complex of dmbpy has been isolated. We have been succeeded in preparing several cobalt (III) complexes containing this ligand. A part of the study has been reported briefly.[3]

Twisted conformation of dmbpy can give atrope isomerism such as biphenyl derivatives,[4] but the isomers were not isolated presumably because of its rapid racemization. The conformation of the ligand might be fixed by an inert metal complex formation. Only a limited number of metal chelates involving such an isomerism are known.[5,6]

This paper deals with the preparation and resolution of several cobalt(III) complexes of dmbpy. The stereochemistry of the complexes is discussed.

Experimental

Materials. *3,3′-Dimethyl-2,2′-bipyridine*: 3-Methylpyridine was refluxed with sodium amide in xylene[7] and the resulting 2-amino-3-methylpyridine was converted into 2-bromo-3-methylpyridine by means of the Sandmeyer reaction.[8] Condensation of the bromo compound by Ullmann reaction yielded 3,3′-dimethyl-2,2′-bipyridine.[9] Found: C, 78.42; H, 6.65; N, 15.09%. Calcd for $C_{12}H_{12}N_2$: C, 78.23; H, 6.75; N. 15,21%.

2,2′,2″-Triaminotriethylamine (tren). This was prepared according to the method given in literatures.[10,11]

[Co(dmbpy)$_3$](ClO$_4$)$_3$. Air was bubbled through a mixture of $CoCl_2 \cdot 6H_2O$ (2.38 g in 50 ml of water), dmbpy (5.52 g in 10 ml of ethanol) and activated charcoal (1.0 g) for 12 h. The solution was filtered and the filtrate was warmed at 60 °C for 30 min with 10 ml of concentrated hydrochloric acid. Sodium perchlorate (4.0 g in 10 ml of water) was added to the cooled solution. The resulting yellow precipitate was filtered off, washed with a small amount of water, ethanol and ether, and recrystallized from hot water. Found: C, 47.22; H, 3.95; N, 8.94%. Calcd for $C_{36}H_{36}N_6O_{12}CoCl_3$: C, 47.50; H, 3.96; N, 9.24%.

[Co(tren)(dmbpy)](ClO$_4$)$_3 \cdot 4H_2O$. A mixture of [Co(dmbpy)$_3$](ClO$_4$)$_3$ (1.82 g in 50 ml of water), 0.3 g of 2,2′,2″-triaminotriethylamine (tren) and activated charcoal (0.5 g) was warmed at 60 °C for 10 min and filtered. A few drops of concentrated hydrochloric acid was added to the filtrate. The solution was diluted 20 times with water and poured onto a SP-Sephadex C-25 column (ϕ 2.5×25 cm). The adsorbed orange band was washed with water and eluted with 0.2 M hydrochloric acid. The eluate of the orange band was collected, evaporated to dryness, dissolved in 10 ml of water, treated with 1 g of sodium perchlorate in 5 ml of water and stored in a refrigerator overnight. Orange crystals were filtered off and washed with ethanol-water (1 : 1), ethanol and then ether.
Found: C, 28.11; H, 5.03; N, 11.02%. Calcd for $C_{18}H_{38}N_6O_{16}CoCl_3$: C, 28.43; H, 5.00; N, 11.05%.

Partial Resolution of [Co(tren)(dmbpy)](ClO$_4$)$_3 \cdot 4H_2O$.
About 200 mg of [Co(tren)(dmbpy)](ClO$_4$)$_3 \cdot 4H_2O$ was adsorbed on a column containing SP-Sephadex C-25 (ϕ 2.5×75 cm), and the band was eluted with 0.1 M aqueous solution of potassium (+)$_D$-tartratoantimonate (III)for fractionation into thirteen portions. The last fraction was adsorbed again on a SP-Sephadex C-25 column (ϕ 2.5×20 cm) and eluted with 0.2 M hydrochloric acid. The eluate was evaporated to dryness and dissolved in a small amount of water, the circular dichroism spectrum being recorded (Fig. 5). The concentration of the complex ion was determined by visible absorbance of the solution. The circular dichroism curve of the first part of the fractions showed a pattern enantiomeric to that of the last fraction.

[Co(en)$_2$(dmbpy)]Cl(ClO$_4$)$_2 \cdot H_2O$. A mixture of *trans*-[CoCl$_2$(en)$_2$]Cl (4.0 g in 40 ml of water), dmbpy (2.0 g in 10 ml of ethanol) and activated charcoal (0.5 g) was warmed at 60 °C for 1 h, then filtered. To the filtrate was added 20 ml of 1 M hydrochloric acid. The solution was diluted with water and poured onto the SP-Sephadex C-25 column (ϕ 5.5×30 cm). The adsorbed band was washed with water, then eluted with 0.2 M hydrochloric acid. The orange band was eluted off and the eluate was evaporated to dryness. The dried residue was dissolved in 40 ml of water and the solution was filtered. After the addition of sodium perchlorate (5 g in 10 ml of water), the solution was allowed to stand for 1 h at room temperature. Orange crystals obtained were collected, washed with cold water, ethanol and ether, and recrystallized from hot water.
Found: C, 31.25; H, 4.94; N, 13.62%. Calcd for $C_{16}H_{22}N_6O_9CoCl_3$: C, 31.17; H, 4.87; N, 13.64%.

Resolution of [Co(en)$_2$(dmbpy)]Cl(ClO$_4$)$_2 \cdot H_2O$. *Method I*: A mixture of [Co(en)$_2$(dmbpy)]Cl(ClO$_4$)$_2 \cdot H_2O$ (3.0 g in50 ml of water) and K$_3$[Co(L-cysu)$_3$][12] (cysu=cysteinsulfinate) (1.4 g in 20 ml of water)was heated at 80 °C on a water bath for 10 min, filtered, and left to stand for 3 h at room temperature. Needlelike yellow crystals of (+)$_D$-diastereomer which appeared were filtered and washed with water, ethanol and then ether. Yield 2.0 g. (The filtrate free from the (+)$_D$-

isomer was stored in order to obtain $(-)_D$-isomer.) The $(+)_D$-diastereomer was recrystallized twice from hot water. The CD strength at 485 nm did not change on repeated recrystallization. Pure $(+)_D$-diastereomer in 20 ml of water was treated with 10 ml of 2 M hydrochloric acid. Yellow precipitate of $H_3[Co(L\text{-cysu})_3]$ was filtered off, and the solution was treated with 2.0 g of sodium perchlorate in 5 ml of water, and stored in a refrigerator overnight. Needlelike orange crystals were collected and recrystallized from water. Yield 0.8 g. Found: C, 31.24; H, 4.98; N, 13.77%. Calcd for $C_{16}H_{22}N_6O_9CoCl_3$: C, 31.17; H, 4.87; N, 13.64%.

The filtrate free from the $(+)_D$-isomer was evaporated to 10 ml. The precipitate was filtered off, and 2 ml of 6 M hydrochloric acid was added to the filtrate. Yellow precipitate of $H_3[Co(L\text{-cysu})_3]$ was filtered off. The filtrate was treated with sodium perchlorate (2.0 g in 5 ml of water), and stored in a refrigerator. Needlelike orange crystals were collected and recrystallized twice from hot water. Yield 0.3 g.

Found: C, 31.22; H, 4.87; N, 13.66%. Calcd for $C_{16}H_{22}N_6O_9CoCl_3$: C, 31.17; H, 4.87; N, 13.64%.

Method II: An aqueous solution of the racemic complex (about 8 mg) was poured on a SP-Sephadex C-25 column (ϕ 1.3×110 cm) and the adsorbed orange band was eluted with 0.15 M aqueous solution of potassium $(+)_D$-tartratoantimonate(III) at a rate of 0.47 ml per min. The eluate was fractionated into 5 ml portions and the absorption spectrum of each fraction was checked (330 nm). Only two isomers were obtained (Fig. 2a). The $(+)_D$-isomer was eluted faster than the $(-)_D$-isomer.

cis-α-*[Co(trien)(dmbpy)]Cl(ClO$_4$)$_2$*. This complex was prepared according to a method similar to that for $[Co(en)_2(dmbpy)]Cl(ClO_4)_2\cdot H_2O$. A mixture of *cis*-α-$[CoCl_2(trien)]Cl$[13] (4.4 g in 30 ml of water), dmbpy (2.0 g in 5 ml of ethanol) and activated charcoal (1 g) was warmed at 70 °C for 20 min, and filtered. The filtrate was acidified with 1 M hydrochloric acid and treated with 5 g of sodium perchlorate in 10 ml of water. Orange crystals appeared within a minute. They were filtered off after 30 min and washed with a small amount of ice-water, ethanol and then ether, and recrystallized from hot water. Yield 4.8 g.

Found: C, 34.43; H, 4.84; N, 13.03%. Calcd for $C_{18}H_{30}N_6O_8CoCl_3$: C, 34.64; H, 4.85; N, 13.47%.

Resolution of cis-α-*[Co(trien)(dmbpy)]Cl(ClO$_4$)$_2$*. This complex was resolved by a method similar to that for $[Co(en)_2(dmbpy)]Cl(ClO_4)_2\cdot H_2O$ with $K_3[Co(L\text{-cysu})_3]$ as resolving agent. Two optical isomers were obtained. The CD curve showed that they are enantiomeric to each other. A chromatographic method similar to that for $[Co(en)_2(dmbpy)]^{3+}$ was also employed. An aqueous solution of 18 mg of the complex was poured on a SP-Sephadex C-25 column (ϕ 1.3×110 cm) and the adsorbed band was eluted with a 0.15 M potassium $(+)_D$-tartratoantimonate-(III) as the eluent. The eluate was fractionated into 5 ml portions and their absorption spectra (280 nm) was checked. Figure 2b shows that two well separated bands were obtained. The $(+)_D$-isomre was eluted faster than the $(-)_D$-isomer. The CD curves show that these isomers are enantiomeric to each other.

*$(-)_D$[Co(*R,R*-chxn)$_2$(dmbpy)](ClO$_4$)$_3$*. This complex was prepared by a method similar to that for $[Co(en)_2(dmbpy)]Cl(ClO_4)_2\cdot H_2O$. A mixture of *trans*-$[CoCl_2(R,R\text{-chxn})_2]ClO_4$(chxn=cyclohexanediamine) (1.0 g in 20 ml of water), dmbpy (0.5 g in 10 ml of ethanol) and activated charcoal (0.5 g) was warmed at 70 °C for 15 min, filtered and treated with 10 ml of 1 M hydrochloric acid. The solution was diluted with water 10 times in volume and poured on a column of SP-Sephadex C-25 (ϕ 3.0×30 cm). The adsorbed band was eluted with 0.2 M hydrochloric acid. All the fractions showed equal absorption and CD patterns. They were collected and evaporated to dryness. The residue was dissolved in 20 ml of water, filtered, treated with 1.5 g of sodium perchlorate in 10 ml of water and stored in a refrigerator overnight. Orange crystals were filtered off and washed with a small volume of water, ethanol and ether and then air dried.

Found: C, 37.35; H, 5.54; N, 10.97%. Calcd for $C_{24}H_{40}N_6O_{12}CoCl_3$: C, 37.47; H, 5.20; N, 10.97%.

*$(-)_D$[Co(*R,R*-chxn)$_2$(bpy)](ClO$_4$)$_3$*. The procedure was similar to that for the $(-)_D[Co(R,R\text{-chxn})_2(dmbpy)](ClO_4)_3$ using bpy instead of dmbpy. A mixture of 1.2 g of *trans*-$[CoCl_2(R,R\text{-chxn})_2]ClO_4$ in 25 ml of water. 0.5 g of bpy in 10 ml of ethanol and 0.5 g of activated charcoal was heated at 60 °C for 15 min, filtered, acidified with 10 ml of 1 M hydrochloric acid, diluted with water and poured onto a column containing SP-Sephadex C-25. The adsorbed orange band was eluted with 0.2 M hyrochloric acid. Abosrption and CD spectra of the fractions were checked. Fractions giving similar spectral data were collected and evaporated to dryness. The residue was dissloved in 20 ml of water. The solution was filtered, and treated with 1.5 g of sodium perchlorate in 10 ml of water. The orange crystals were filtered off and washed with a small volume of ice-water, ethanol and ether, and recrystallized from water. Yield 0.65 g.

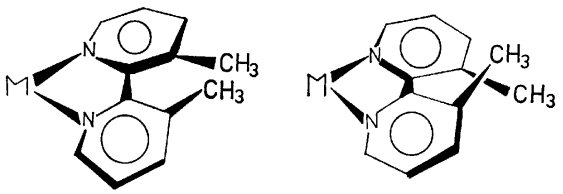
Found: C, 35.59; H, 4.93; N, 11.31%. Calcd for $C_{22}H_{36}N_6O_{12}CoCl_3$: C, 35.62; H, 4.89; N, 11.33%.

Measurements. Absorption and CD spectra were recorded on a Shimadzu Double 40-R spectrophotometer and a Jasco J-20 spectropolarimeter, respectively, at room temperature. PMR spectra were recorded with a JNM-PMX 60 spectrometer using DSS as an internal standard. Infrared specrta were recorded over the NaCl region with a Hitachi Model 285 infrared spectrometer. The complexes, $(+)_D$-$[Co(en)_2(dmbpy)]Cl(ClO_4)_2\cdot H_2O$, $(+)_D[Co(trien)(dmbpy)]$-$Cl(ClO_4)_2$ and $(-)_D[Co(R,R\text{-chxn})_2(dmbpy)](ClO_4)_3$ were converted into their bromide by use of the anion exchanger Dowex 1-X8 in bromide form, for the measurement of PMR and infrared spectra. Most of the measurements were made at 25 °C.

Results and Discussion

Preparation and Stereochemistry. The cobalt(III) complexes, $[Co(dmbpy)_3]^{3+}$, $[Co(tren)(dmbpy)]^{3+}$, $[Co(en)_2(dmbpy)]^{3+}$, $[Co(trien)(dmbpy)]^{3+}$, and $[Co(R,R\text{-chxn})_2(dmbpy)]^{3+}$ were characterized by elemental analysis, absorption, CD and PMR spectra. Among these complexes, the tren complex has no chiral configuration around the cobalt(III) ion and the optical activity in this complex arises exclusively from the twisted conformation of the dmbpy chelate. $[Co(tren)(dmbpy)]^{3+}$ was partially resolved by column chromatography, and the CD spectrum in the visible region remained unchanged at room temperature for several days. This indicates that the dmbpy chelate of this complex is twisted and takes a nonconvertible conformation.

The bis(en), trien, bis(*R,R*-chxn) complexes have two kinds of dissymmetry; the configurational dissymmetry, Δ and Λ, and conformational dissymmetry, δ and λ (Fig. 1). Consequently, four optical isomers



$\lambda(R)$-conformation $\delta(S)$-conformation

are possible for each complex. In addition to the optical isomers, the trien complex has geometric isomers, *i.e. cis*-α and *cis*-β. They can usually be distinguished by their IR spectra in the 990—1090 cm^{-1} region; while *cis*-α complexes show two strong absorption bands in this region, *cis*-β complexes give four bands.[15] The IR spectrum of $[Co(trien)(dmbpy)]Br_3$ shows two strong band in this region and hence the complex can be assigned to *cis*-α isomer.

The en and trien complexes were resolved by chemical and chromatographic methods. The CD spectra of the two isomers of the chemically resolved en (or trien) complex showed symmetrical curves to each other over all the wavelengths, indicating that they are a pair of enantiomers. The en and trien complexes were adsorbed on a column of SP-Sephadex C-25 and eluted with 0.15 M potassium $(+)_D$-tartratoantimonate(III) solution. Figure 2 shows their elution curves. No indication for the presence of more than two isomers was found in both chemical and chromatographic resolution. On the other hand, $[Co(R,R\text{-chxn})_2(dmbpy)](ClO_4)_3$ yielded only $(-)_D$-isomer stereospecifically (see Experimental). The PMR spectra

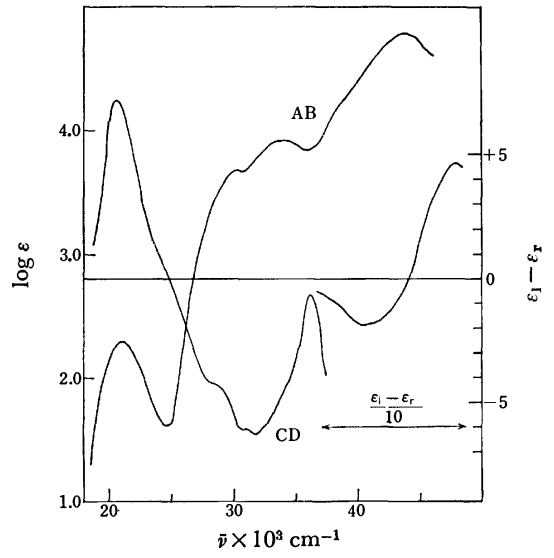

Fig. 7. AB and CD spectra of $(+)_D$-*cis*-α-[Co(trien)-(dmbpy)]$^{3+}$.

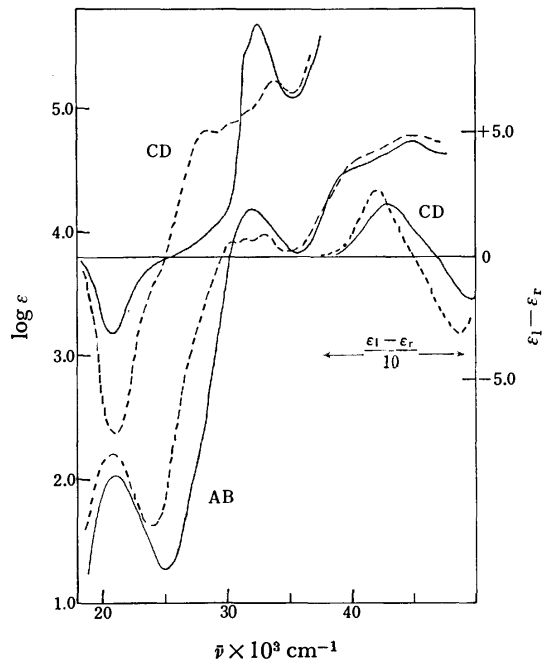

Fig. 8. AB and CD spectra of $(-)_D[Co(R,R\text{-chxn})_2(bpy)]^{3+}$ (——) and $(-)_D[Co(R,R\text{-chxn})_2(dmbpy)]^{3+}$ (----).

of en, trien and *R,R*-chxn complexes show only one methyl signal at *ca.* 2.5 ppm (Fig. 3). The results also support the view that the dmbpy coordinates stereospecifically to the central cobalt(III) ion in the given configuration.

Recently, Douglas *et al.*[5] and Tanimura *et al.*[6] prepared and resolved a series of cobalt(III) complexes of 2,2′-diaminobiphenyl (dabp). The bidentate ligand dabp also takes a non-coplanar conformation upon coordination as dmbpy does. They reported that the conformation of the dabp chelates depends on the configuration of the complexes. The crystal structure of Δ-$[Co(R\text{-pn})_2(dabp)]Cl_3$ has been determined by X-ray analysis, the conformation of the dabp chelate being found to be λ.[6]

Figure 4 gives a schematic representation of the two possible structures of Δ-$[Co(en)_2(dmbpy)]^{3+}$. In the $\Delta(\lambda$-dmbpy) arrangements, the pyridine rings are twisted into open faces of the octahedron, *i.e.*, the faces are not occupied by en chelates. The interaction between π-electron cloud of bipyridine rings and ethylenediamine protons of $\Delta(\lambda$-dmbpy) seems to be less than $\Delta(\delta$-dmbpy). The same relationship holds for $\Lambda(\delta$-dmbpy) and $\Lambda(\lambda$-dmbpy).

R-Diamine such as *R*-pn or *R,R*-chxn takes the *λ-gauche* conformation upon coordination.[15,16] Thus, the structure of the stereospecifically formed $(-)_D[Co(R,R\text{-chxn})_2(dmbpy)]^{3+}$ should be either $\Delta(\lambda\lambda,\delta$-dmbpy) or $\Delta(\lambda\lambda,\lambda$-dmbpy). The absolute configuration was assigned to Δ from the CD sign of the first d-d region.[17] Molecular model studies suggest that the 2C-2C′ bond

in λ-dmbpy chelate is parallel to the pseudo-three fold axis whereas it is oblique in δ-dmbpy. The stability of these two isomers might differ. The tris(*R*-diamine) cobalt(III) complexes have two optical isomers $\Delta(\lambda\lambda\lambda)(lel)$ and $\Lambda(\lambda\lambda\lambda)(ob)$ in which the lel isomer of $[Co(R\text{-pn})_3]^{3+}$ is known to be more stable than the ob isomer.[15] It is likely that the dmbpy chelate takes λ conformation in $(-)_D[Co(R,R\text{-chxn})_2(dmbpy)]^{3+}$. This agrees with the molecular model consideration for the $[Co(en)_2(dmbpy)]^{3+}$ (Fig. 4).

Absorption Spectra. The absorption and CD spectra of all the $[Co(N)_6]^{3+}$ type complexes are shown in Figs. 5—8. Their band locations and intensities are given in Table 1. The first absorption band maxima of the dmbpy complexes have higher intensities and appear at longer wavelength as compared with $(+)_D[Co(en)_2(bpy)]^{3+}$ or $(-)_D[Co(R,R\text{-chxn})_2(bpy)]^{3+}$. The absorption peaks in 25000—35000 cm^{-1} region might be related to the electronic transitions of the coordinated dmbpy or bpy.[18] The intensities of these bands of the dmbpy complexes are always lower and the band patterns are broader as compared with those of the bpy complexes. These effects are presumably due to a torsional strain and inhibition of resonance of the dmbpy chelate.[19]

CD Spectra. Two component Cotton effects, a positive and a negative peaks from longer to shorter wavelength are observed in the visible region of the $(+)_D[Co(tren)(dmbpy)]^{3+}$ (Fig. 5). Two positive Cotton effects are observed in the region 28000—35000 cm^{-1}. The origin of the optical activity of this complex is due to the twisted conformation of the dmbpy chelate. The absolute conformation of the ligand cannot be assigned from the CD spectra at present.

A strong CD band is observed for each $(+)_D[Co(en)_2(dmbpy)]^{3+}$, *cis* α-$(+)_D[Co(trien)(dmbpy)]^{3+}$ and $(-)_D[Co(R,R\text{-chxn})_2(dmbpy)]^{3+}$ in the first absorption region (Figs. 6—8). Their CD magnitudes are greater than those of the bpy complexes. The CD sign of a cobalt(III) complex in the first absorption band is known to depend on the absolute configuration of the complex.[17] Thus, the absolute configurations of $(+)_D[Co(en)_2(dmbpy)]^{3+}$, $(+)_D[Co(trien)(dmbpy)]^{3+}$, and $(-)_D[Co(R,R\text{-chxn})_2(dmbpy)]^{3+}$ are assigned to Λ, Λ and Δ, respectively. While the CD spectra of bpy complexes gave one component Cotton effect in the region 25000—35000 cm^{-1}, the dmbpy complexes showed broad and split peaks. The absolute conformation of the twisted dmbpy can not be assigned at present from the CD patterns in these region.

The authors wish to thank Professor Kazuo Saito of Tohoku University, and Professor Junnosuke Fujita and Dr. Kazuo Kashiwabara of Nagoya University for their helpful suggestions and discussions.

Determination of Chlorine in Rocks, Soils and Organic Materials by Heating Powdered Sample in Strong Phosphoric Acid, and Some Additional Investigations on the Related Reactions

Kikuo TERADA, Saburo HIRAKAWA, and Toshiyasu KIBA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa, Ishikawa 920

(Received July 12, 1976)

The decomposition of several salts in strong phosphoric acid (SPA) was examined. These halides were decomposed and hydrogen halides evolved by heating the samples with SPA at various temperatures. Based on these data an adequate reagent was chosen for the efficient separation of various elements which can form volatile halides. The recommended distillation condition was applied to determine the chlorine content in solid samples, such as rocks, soils or some organic materials. The sample was heated in an SPA medium and a distillate of hydrogen chloride was absorbed in a sodium hydroxide solution. The solution was subjected to volumetric analysis with a silver nitrate solution for chlorine in the range of 10^{-2} to 10^{-4} mol and to spectrophotometric determination with mercury thiocyanate for elements less than 10^{-4} mol. Furthermore, from the results of X-ray diffraction measurements of the original and the SPA-treated samples, it was confirmed that the main crystal structure of a rock sample could be decomposed by heating with SPA. The chlorine analysis was performed for Japan Geological Survey standard rocks, JG-1 and JB-1, and a synthesized complex compound.

It is known that some metallic and ammonium salts of acids of low boiling point could readily be decomposed in strong phosphoric acid by heating and evolve gaseous acid quantitatively.[1] Sulfides and halides fall in this category, and, based on this various applications have been developed for the determination of sulfur.[2-12]

On the other hand, when an element having a volatile halide is present in a sample, an exchange reaction may occur in the strong phosphoric acid medium, if the sample is heated together with the alkali halide in the medium. In the previous papers,[13,14] the present authors reported that when selenium-containing samples of rocks, soils, or sediments are heated with ammonium chloride or ammonium bromide in SPA, selenium(IV) tetrachloride or tetrabromide, respectively, evolve quantitatively from the sample.

The decomposition of metal halides and the evolution of hydrogen halide may be expressed as

$$X^- + H_nP_mO_l \longrightarrow HX + H_{n-1}P_mO_l^- \quad (1)$$

and the succeeding reaction with selenium(IV) and (VI) compounds is

$$H_2SeO_3 + 4HX \longrightarrow SeX_4 + 3H_2O \quad (2)$$

In Eq. 1, the evolved hydrogen halide may be in an extremely reactive gaseous state. To accomplish the two reactions successfully for the quantitative recovery of selenium from a sample, Reaction 1 should proceed concurrently with Reaction 2; Therefore, the forming rate of the active hydrogen halide upon heating of the SPA medium may be the first important practical factor, and the boiling temperature of the selenium halide and the rate of Reaction 2 may be the second.

The present authors investigated the above factors in detail with the aim of extending the SPA-analytical method to the determination of halogens in solid samples such as rocks, soils, and organic materials and to the rapid separation of selenium and arsenic[15] as halides in solid samples.

Experimental

Reagents. *Strong Phosphoric Acid (SPA)*: Commercial ortho-phosphoric acid of extra pure reagent grade was dehydrated as described previously.[13,16] The syrupy liquid obtained was stored in a closed vessel.

Silver Nitrate Standard Solution (M/10). *Mercury Thiocyanate Solution*: Mercury(II) nitrate (5 g) was dissolved in 200 ml of 0.5 M nitric acid; 3 ml of a saturated ammonium iron(III) sulfate solution in 1 M nitric acid was added; the solution was titrated with a 4% potassium thiocyanate solution with continuous shaking until the color changed to pale orange; the white crystalline precipitate thus obtained was filtered through a glass filter, washed well with distilled water and dried in air; 0.3 g of this reagent was dissolved in 100 ml of ethanol and stored in a dark bottle. This solution is stable for several months.

Ammonium Iron(III) Sulfate Solution: Six grams of dodecahydrated salt of guaranteed reagent grade was dissolved in 100 ml of 6 M nitric acid.

Standard Chloride Solution: Sodium chloride of guaranteed reagent grade (2.013 g) was dissolved in distilled water in a 1-liter measuring flask. This solution was diluted for use.

Other Chemicals: Ammonium chloride, bromide, and iodide, potassium chloride, bromide, and iodide, sodium chloride, bromide, and iodide, hydrochloric acid, sodium hydroxide and fluorescein were all of guaranteed reagent grade.

Apparatus. Electric conductivity measurements: a conductivity outfit, Model MY-7 (Yanagimoto Seisakusho Co.) connected to a conductivity cell, Model CDC-121 (M & S Instr. Co., Inc.).

A photo-electric spectrophotometer (Hirama Rika Kenkyujo), Type 6 and 1-cm glass cell.

A Hitachi-Horiba glass electrode pH meter, Model M-3.

The reaction vessel used was the same as that described previously[13] and was connected to an absorption tube or a conductivity cell.

Procedure. Sodium chloride in amounts of 5×10^{-4}—2×10^{-3} mol was placed in the reaction vessel and about 30 g of SPA was added. Twenty milliliters of a sodium hydroxide solution was placed in the absorption tube and all joints were connected as shown in Fig. 1. The air was aspirated slowly from the last outlet tube by means of a suction pump and the reaction vessel was heated on an electric heater to start the reaction. The reaction rate was followed every 2—3 min by measuring the electric conductivity of the absorption solution using a flow-type conductivity cell. The temperature of the reaction medium was recorded at the same time. The evolving hydrogen chloride in the

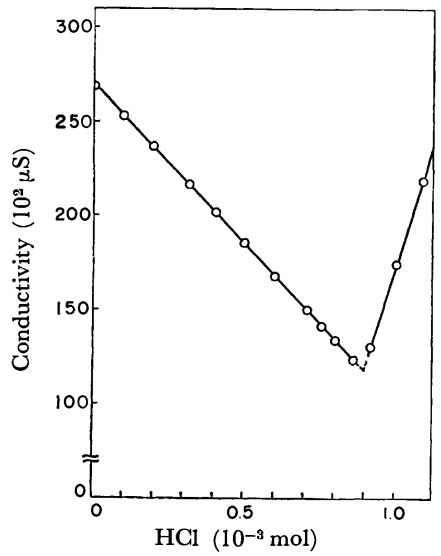

Fig. 2. Conductometric titration curve.
Sodium hydroxide was titrated with hydrochloric acid.

absorption solution was determined from the conductivity value obtained. The relationship between the evolving hydrogen chloride and the electric conductivity was obtained using the titration curve (Fig. 2) which was constructed on the basis of the titration of 20 ml of a M/20 sodium hydroxide solution with 1 M hydrochloric acid. In the case of decomposing bromide or iodide salts, hydrobromic acid or hydroiodic acid were used in place of hydrochloric acid in the above procedure.

Results and Discussion

Decomposition of Various Halide in SPA. Figures 3, 4, and 5 show decomposition curves for several chlorides, bromides and iodides in SPA media. In the figures, the open circles represent the amounts of hydrogen halide trapped in the absorption solution after each heating period as determined by the conductivity measurements and the filled-in circles the temperature of the reaction medium after the same periods. It is clear that the decomposition of chloride salts is initiated at about

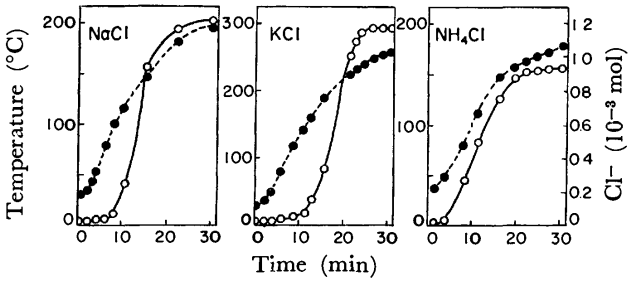

Fig. 3. SPA-decomposition curves for cloride salts.
—○—: Amount of hydrogen chloride in absorption solution, --●--: temperature change of SPA-medium.

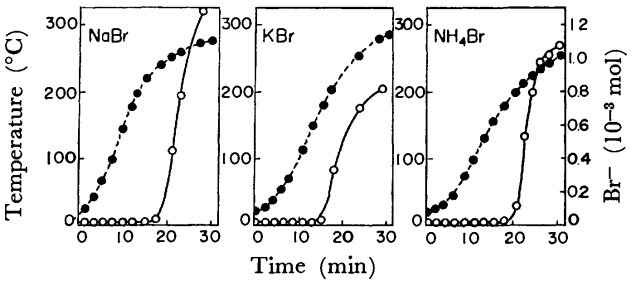

Fig. 4. SPA-decomposition curves for bromide salts.

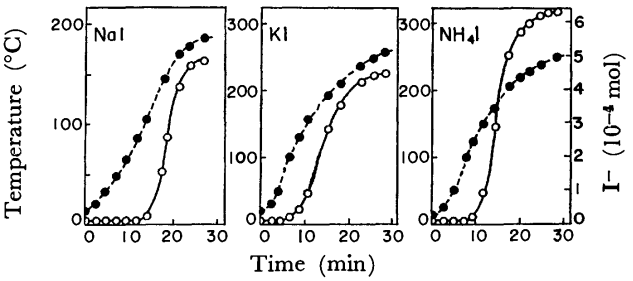

Fig. 5. SPA-decomposition curves for iodide salts.

Table 1. Decomposition temperature of various halide salts in SPA media

Salt	Temperature of decomposition, °C	
	Start	Finish
NaCl	100	200
KCl	50	230
NH_4Cl	50	160
NaBr	230	290
KBr	180	280
NH_4Br	180	260
NaI	180	260
KI	80	230
NH_4I	100	240

110, 50, and 50 °C and the evolution of hydrogen chloride may be completed at 200, 230, and 160 °C, for the sodium, potassium, and ammonium salts, respectively. In the case of the bromides, the sodium salt was most resistant to decomposition, and the ammonium salt reacted with SPA more easily than did the others. For the iodides, again the sodium salt was most resistant to SPA action, whereas the potassium salt was most easily decomposed. The results

are summarized in Table 1. However, it should be noted that there is a certain time lag between the hydrogen halide generation and its arrival in the absorption solution. Furthermore, the present results may fluctuate to some extent depending on the heating time and also on the amounts of halide salts used. The difficulty in detecting halide ions in amounts less than 2×10^{-5} mol in 20 ml of the absorption solution makes it necessary to delay the measurement until the evolved hydrogen halide gas has accumulated in detectable amounts in the solution. Therefore, a delay is unavoidable in the response of the hydrogen halide gas evolution and the completion of the decomposing reaction. Therefore, the data shown in Figs. 3, 4, and 5 are strictly valid only under the present experimental conditions.

But it may be possible to present a discussion based on the present results which may be not differ too much from those obtained for arbitrary experimental conditions. As suggested above, a complete distillation of a certain element in gaseous halide form from the SPA medium would be expected to occur when decomposition of the halide reagent added to the sample in the reaction vessel begins as the increasing temperature approaches the boiling point of the halide of the element concerned and ceases at temperatures above the boiling point. Thus, from the present results it may be possible to predict which reagent is suitable for use in the distillation of a given element by evolution as a gaseous halide from an SPA medium.

Distillation of Selenium and Arsenic as Halides. As previously reported,[13] selenium(IV) and (VI) can be distilled as tetrabromide from bromide-SPA at about 250 °C. The sublimation temperature of the selenium tetrabromide is known to be 196 °C. Therefore, sodium chloride and ammonium chloride are presumed to be unsuitable for the distillation of selenium since hydrogen chloride gas will evaporate off before the temperature reaches the sublimation point of selenium tetrachloride. In fact, ammonium and sodium chlorides distill selenium incompletely (50—80%).

On the other hand, ammonium bromide was found to be the most useful for this purpose, although the sublimation temperature of selenium(IV) tetrabromide is still unknown. This temperature may fall between 200 and 250 °C, because the boiling point of a metal bromide in an aqueous solution is generally higher than that of the corresponding chloride.

For arsenic(III), the boiling point of arsenic(III) chloride and bromide are known to be 130.4 and 221 °C, respectively.[17] Thus the chloride would be expected to be the most adequate form for distillation from the SPA medium. Therefore, sodium and potassium chlorides may be useful for this purpose. As shown in Fig. 6, the distillation of arsenic(III) was complete in the sodium chloride-SPA reagent solution when the temperature reached 180 °C and a slightly lower recovery was observed when potassium chloride was used.[15] On the other hand, the recovery of arsenic by ammonium bromide was incomplete as expected.

Another example is the distillation of germanium. The boiling points of germanium(IV) chloride and bromide are known to be 84 and 185.9 °C, respectively.[17] Therefore, ammonium or potassium chloride may be suitably employed for the distillation of germanium in tetrachloride form, whereas all bromides are useless. Tin(IV) can also be distilled as tin(IV) chloride (bp 114 °C) or bromide (bp 202 °C) from ammonium chloride-SPA and ammonium bromide-SPA media.

Further predictions will be made for the distillation of the other volatile metal halides, for example, chromium, niobium, rhenium, and antimony.[18] Further details and applications of the present study will be given elsewhere.

Determination of Chloride in Solid Samples. In general, the analysis of chlorine content in rocks, soils, and minerals requires an alkaline or carbonate fusion treatment of the sample, followed by extraction with hot water or nitric acid. The fusion process is tedious and may cause unexpected losses of the element or contamination of the element from the reagents used and from the instruments. Furthermore, matrix constituents occasionally interfere with the determination

of chloride in low concentrations. Thus, it is desirable to separate chlorine from the matrix more rapidly and effectively.

As mentioned above, many chloride compounds were quantitatively decomposed and chloride was distilled off as hydrogen chloride from SPA media by heating to about 250 °C. Therefore, the present method seems to be applicable to the determination of chlorine in chloride or other halide form in solid materials, such as rocks, minerals, soils, biological materials, and complex compounds.

The apparatus used is shown in Fig. 7. The procedure is as follows. A suitable amount of the sample (0.5—1.0 g) was placed in the reaction vessel (B), and about 30 g of SPA was added. An accurately-determined amount of 20 ml of a 0.05 M sodium hydroxide solution was put into the absorption tube (C), which was placed in a wider test tube containing cooling water. Then all joints were connected as shown in the figure. (A) is a gas-washing bottle containing a 0.1 M silver nitrate solution. Air was aspirated slowly from the last outlet tube and the reaction vessel was heated with an electric heater until the temperature of the contents reached about 250 °C. Around the cap of the reaction vessel was wound a ribbon heater to avoid trapping of hydrogen chloride at this point during distillation.

After distillation, the absorption and the washing solutions were combined and subjected to chloride measurement. For chlorides in the range of 10^{-3} to 10^{-4} mol, titration was performed with a silver nitrate standard solution using fluorescein as an indicator.

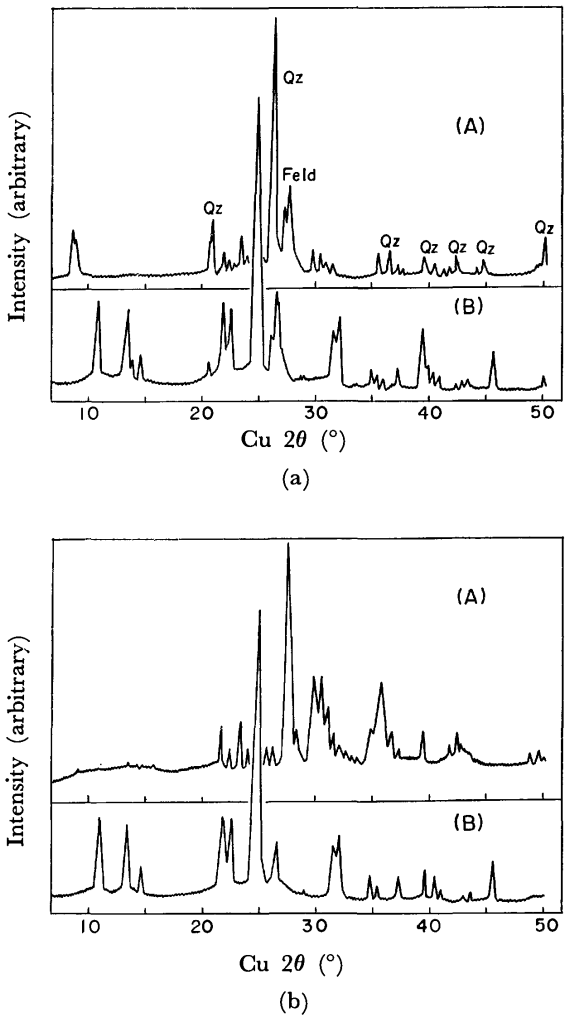

Fig. 8. X-Ray diffraction pattern for standard rocks and SPA treated standard rocks.
a: JG-1, b: JB-1.
A: Original rock sample, B: SPA treated rock sample.

For chlorides less than 10^{-4} mol, the determination was made spectrophotometrically using mercury thiocyanate[19] as follows: after distillation, 4 ml of an ammonium iron(III) sulfate solution and 2 ml of a mercury thiocyanate solution were added to the absorption solution. This solution was mixed well by shaking, and then the absorption was measured at a wavelength of 460 nm. In this case, the volume of the absorption solution during distillation appeared to remain unchanged. From Tables 2 and 3, which indicate the results it is clear that the determination of chlorides in the concentration range of 10^{-6}—10^{-2} mol can be performed very satisfactorily.

Decomposition of Rock Samples in SPA Media. When organic compounds or complex materials, such as complex compounds, hair, or rice, are heated in an SPA medium with decomposition of the materials to carbon, chlorine can be evolved as hydrogen chloride. However, a problem remained as to whether or not rock samples could be decomposed. Therefore, in the present study, experiments were carried out to clarify this problem.

a) The sample was dried at 100 °C for 1 h.

JB-1, were subjected to treatment with SPA and the remaining white residue were washed with distilled water to remove any phosphoric acid. Then, X-ray diffraction patterns of these crystals was examined and compared with the X-ray diffraction patterns of the original rock samples. The X-ray patterns obtained are shown in Fig. 8. The peaks due to quartz and feldspar in the original JG-1 sample completely disappeared after the treatment, and new peaks appeared. Also, in the case of JB-1, entirely different patterns were observed for the original and the SPA-treated samples. These new X-ray patterns were assigned to $Si_3(PO_4)_4$. From the results, it can be confirmed that the original crystalline structure of silicate minerals in a rock sample is decomposed and then converted into a new crystalline structure whose composition includes SPA and silica. Therefore, it is reasonable to conclude that chlorine can also be completely liberated from a rock sample during decomposition due to heating of the sample in SPA.

In Table 4, the analytical results obtained by the present method for the standard rocks, JG-1 and JB-1, are compared with those reported by Sen Gupta,[20] Akaiwa[21] and Terashima.[22] The present results are in good agreement with those of Akaiwa andTerashima. The value reported by Sen Gupta appears to be too high.

A determination was also carried out for a synthesized complex compound, the structure of which was reported to be $[CoCl_2en_2]H_5O_2Cl_2$.[23] The data are shown in Table 5. The observed chlorine content coincides fairly well with the calculated result.

Support of a part of this work by the Ministry of Education is gratefully acknowledged.

Spectral Studies on the Interaction between Oxovanadium(IV) β-Diketonates and Organic Solvents

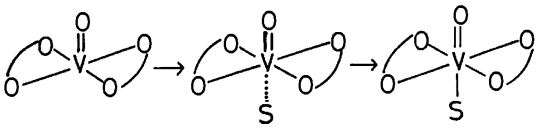
Natumi ADACHI, Yutaka FUKUDA, and Kozo SONE

Department of Chemistry, Faculty of Science, Ochanomizu University, Otsuka, Bunkyo-ku, Tokyo 112

(Received August 14, 1976)

The effect of temperature on the visible absorption spectra of oxovanadium(IV) β-diketonates [VO (β-dik)$_2$] (β-dik=aca, bza, tfa, and dpm*) were studied in organic solvents. The results together with the spectral and thermogravimetric data of the pyridine and dioxane adducts of these chelates lead to the conclusion that the ease of taking up a solvent molecule to form a six-coordinate solvated chelate in solution increases in the order: VO(tfa)$_2$> VO(bza)$_2$≈VO(aca)$_2$>VO(dpm)$_2$. Various proofs for the existence of a polymeric structure of VO(tfa)$_2$, which was formerly indicated on the basis of its IR spectrum, were found.

The visible absorption spectrum of oxovanadium-(IV) acetylacetonate (VO (aca)$_2$) in an organic solvent changes remarkably with solvent.[1-3] This is explained on the assumption that the square pyramidal five-coordinated structure of the original chelate is more or less transformed into an octahedral six-coordinated one by the coordination of a solvent molecure, and that the spectral change observed is the reflection of the degree of this structual change.



Increase in DN of the solvent (S) →
Increase in $\Delta_{I,II}$ →

According to Selbin *et al.*,[1-3] the difference between the wave numbers of the two visible bands of this chelate ($\Delta_{I,II}$) serves as a good measure of the degree of this change; when the coordination ability of the solvent (which may be expressed by the donor number (DN) of Gutman)[4] is very low (*e.g.*, in 1,2-dichloroethane or nitromethane) and the chelate nearly retains its original structure in solution, $\Delta_{I,II}$ is in the vicinity of 1—2 kK, but it increases with the DN of the solvent used, reaching 4—5 kK in DMSO and pyridine. It was also pointed out that there is a fairly good linear relationship between $\Delta_{I,II}$ and DN.[4]

Although these relations, which we shall call the Selbin-Gutmann rule, were well established in the case of VO(aca)$_2$, published data on other β-diketonates of VO^{2+} seem to be rather scanty. We have tried to confirm the applicability of this rule to three such chelates.

Experimental

Preparations. VO(aca)$_2$ and VO(tfa)$_2$ were prepared by the method of Rowe and Jones,[5] and VO(bza)$_2$ and VO(dpm)$_2$ by that of Selbin *et al.*[6] Their identity was confirmed by means of their IR spectra which agreed well with the data published.

VO(aca)$_2$py and VO(tfa)$_2$py: VO(aca)$_2$ or VO(tfa)$_2$ was dissolved in pyridine and the mixture was evaporated at low temperature (*ca.* 77 K) under reduced pressure. The concentrated solution was then allowed to stand at 0 °C. After 12 h, green microcrystals of the pyridine adduct separated out in the case of VO(aca)$_2$, but it took about a month to get similar crystals of VO(tfa)$_2$py. They were filtered and dried in a vacuum.

VO(bza)$_2$py: VO(bza)$_2$ was dissolved in pyridine and the mixture was refluxed for 2 h, and then allowed to stand at room temp for 12 h. The solution was then evaporated under reduced pressure at 70 °C. The brown microcrystals which separated out were filtered and dried in a vacuum.

VO(aca)$_2$diox, and VO(tfa)$_2$diox: These adducts were prepared as in the case of VO(bza)$_2$py, using dioxane insted of pyridine.

The results of elementary analyses are given in Table 1.

Solvents and Reagents. All the solvents and reagents used were of "Extra Pure" or "Spectro" Grade.

Measurements. The IR spectra between 400 cm^{-1} and 4000 cm^{-1} were determined with Nujol mulls between caesium bromide plates using a JASCO IR-G spectrophotometer. The electronic spectra of the solutions were recorded with a Shimadzu D-40R Spectrophotometer, using 50, 10, and 5 mm quartz cells, and Dewar-equipped cells described by Iwasaki *et al.*[7] The reflectance spectra of solid samples between 300 and 700 nm were recorded with the same spectrophotometer and those between 700 and 800 nm were recorded with a Hitachi EPS-3T spectrophotometer, using reflectance attachments and MgO discs as reference. Thermogravimetric analyses of the adducts were carried out with a Shinku Riko TGD-3000 Differential Thermal Microbalance with a heating rate of 5 °C/min in a nitrogen stream (flow rate: 50 ml/min), using *ca.* 30 mg of the sample in each measurement.

TABLE 1. ELEMENTARY ANALYSES OF THE ADDUCTS

Adduct	Found (Calcd) %		
	C	N	H
VO(aca)$_2$py	52.32(51.74)	4.07(4.19)	5.57(5.49)
VO(bza)$_2$py	62.77(62.56)	3.07(3.15)	4.76(5.23)
VO(tfa)$_2$py	39.21(39.84)	2.85(3.09)	3.22(2.90)
VO(aca)$_2$diox[a]	42.48(47.60)		5.59(6.28)
VO(tfa)$_2$diox[a]	33.59(36.45)		3.36(3.50)

a) These adducts slowly decompose on standing, losing dioxane, and revert to the parent complexes, making agreement with calculation less satisfactory. The values for carbon were deduced from the data of the thermogravimetric analyses.

* Abbreviations; β-dik=a β-diketonate ion, aca=acetylacetonate ion, bza=benzoylacetonate ion, tfa=trifluoroacetylacetonate ion, dpm=dipivaloylmethanate ion, py=pyridine, and diox=dioxane. kK=10^3 cm^{-1}.

Results and Discussion

Thermochromism of VO(β-dik)$_2$ in Organic Solvents. When the four chelates VO(aca)$_2$, VO(bza)$_2$, VO(tfa)$_2$, and VO(dpm)$_2$ are dissolved in various solvents at room temperature, and the observed values of $\Delta_{I,II}$ are plotted against DN of the solvents (Fig. 1), the Selbin-Gutmann relation holds quite well in the case of VO(aca)$_2$ and VO(bza)$_2$, but apparently not for the other two chelates.** For the sake of clarification, the influence of temperature on the spectra (thermochromism) was studied. The results for VO(aca)$_2$ are summarized in Fig. 2. A similar figure is obtained for VO(bza)$_2$. The $\Delta_{I,II}$ values increase with DN at each observed temperature, but decrease more or less distinctly with increasing temperature, showing that the bonding of solvent molecule at the bottom of the pyramid is gradually loosened and the complex becomes more "five-coordinated" on heating. In the course of these spectral changes no distinct isosbestic point was observed,*** so it seems that they are due not to the shift of the simple solvation equilibrium of

$$VO(aca)_2 + S = VO(aca)_2 \cdot S$$

type, but to the gradual structure change of the dissolved species.

Figure 3 shows the results for VO(dpm)$_2$. The curves go down with the rise of temperature, but only the curves for pyridine and DMF, *i.e.*, those for solvents with especially high DN, lie high above, while those for chloroform, nitromethane and acetonitrile lie close to each other near the abscissa. This suggests that the chelate is less easily solvated in solution, and the solvents with lower DN are not bound effectively by it, so that there is only little spectral difference between their solutions. This reluctance for solvation is probably the result of the electron-donating effect of C(CH$_3$)$_3$ groups in dpm, which strengthens the V–O bonds in the chelate rings and reduces the positive charge of vanadium and the steric effect caused by the same groups.

Figure 4 shows the results for VO(tfa)$_2$. Since all the curves flock closely together, the scale for $\Delta_{I,II}$ is expanded twice in comparison with that shown in Figs. 2 and 3. We see that pyridine, DMF, methanol, and acetonitrile form octahedral solvates nearly equally well. Nitromethane also does so at lower temperature, but the solvation becomes remarkably weaker at higher temperature. Thus it is clear that this chelate, in contrast to VO(dpm)$_2$, is more easily solvated, probably owing to the electron-withdrawing effect of tfa which weakens the V–O bonds in the chelate rings.

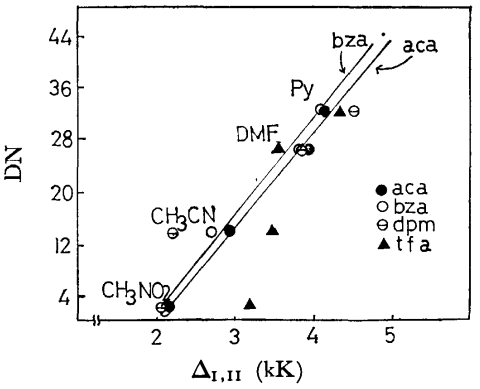


Fig. 1. The relation between DN and $\Delta_{I,II}$ at room temperature; concentration: 1×10^{-2} mol/l.

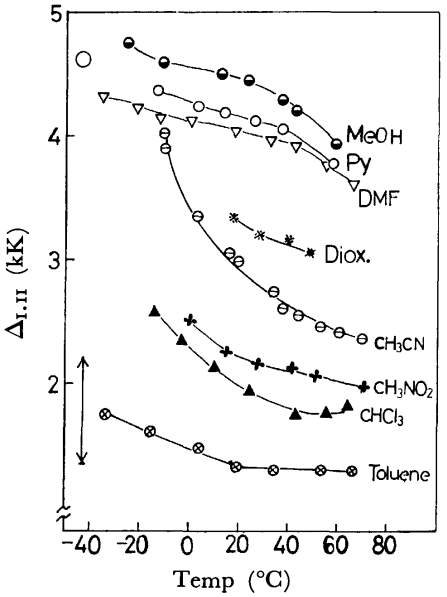

Fig. 2. Thermochromism of VO(aca)$_2$ in some organic solvents; cell thickness: 5 mm, concentration: 1×10^{-2} mol/l.
↔ and ○ on the ordinate axis correspond, respectively, to the $\Delta_{I,II}$ values of the chelate and its pyridine adduct in solid state.

It seems strange that even in chloroform, which is a very poor donor, a six-coordinated complex species seems to be formed with VO(tfa)$_2$. However, the $\Delta_{I,II}$ of VO(tfa)$_2$ in chloroform was found to be notably dependent on its concentration, changing from *ca.* 3.4 to 2.9 in going from 1×10^{-1} to 4×10^{-3} M. This leads one to suppose that there is a monomer-polymer equilibrium (1) in this solution, and the

$$n\ VO(tfa)_2 \underset{\text{heat}}{\overset{\text{cool}}{\rightleftharpoons}} [VO(tfa)_2]_n \qquad (1)$$

Monomer, 5-coordinated — Polymer with O=V←O=V bonds, 6-coordinated

** Alcoholic solutions poses some problems. The $\Delta_{I,II}$-values of VO(aca)$_2$ and VO(bza)$_2$ in methanol are much higher than expected from the DN scale. However, as stated by Gutman concerning values in aqueous solution, this may be explained by the formation of the hydrogen bond (V=O···H–OR), in addition to the coordinate bond to vanadium (O=V···OHR), by the solvent. The values of $\Delta_{I,II}$ in other alcohols at room temperature are nearly the same as that in methanol. On the other hand, all the chelates studied are not stable in alcoholic solutions against oxidation, becoming brownish within several hours. In the case of VO(dpm)$_2$, this color change begins within several minutes, making it impossible to measure the spectra.

*** An apparent isosbestic point was found to appear in acetonitrile and nitromethane at lower temperature. Moreover, a drastic reversible color change from blue to pink took place when VO(aca)$_2$ was dissolved in acetonitrile or nitromethane and frozen in liquid nitrogen, but this was not observed with the other chelates. The nature of these phenomena is not clear.

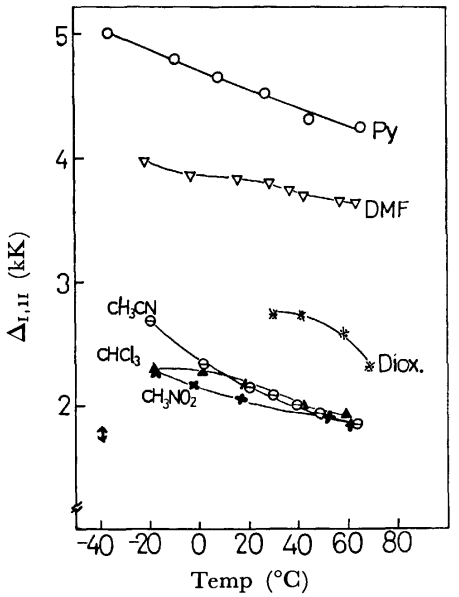

Fig. 3. Thermochromism of $VO(dpm)_2$; the conditions are the same as in the case of $VO(aca)_2$.

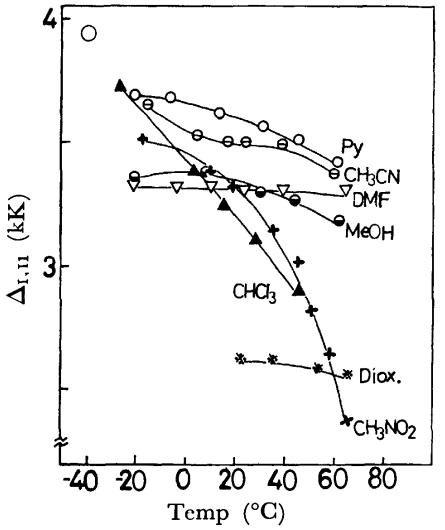

Fig. 4. Thermochromism of $VO(tfa)_2$; the conditions are the same as in the case of $VO(aca)_2$.

observed changes of $\Delta_{I,II}$ with temperature and concentration are, in fact, due to the shifts of this equilibrium.† This view is also supported by the view of Al-Niami *et al.*[13] who observed that the infrared spectrum of $VO(tfa)_2$ indicates its polymeric structure, with the molecules forming chains of O=V←O=V←O=V. Thus it seems possible that a similar kind of association occurs in a non-coordinating solvent like chloroform, to various degrees, according to the temperature and concentration.

In most cases, Band I (*i.e.*, that of the red side) shifts toward blue and Band II toward red with increasing temperature, the first shift being much larger. In terms of the Ballhausen-Gray[8] MO scheme with the assumption that Band I is $^2B_2$-^2E and Band II is $^2B_2$-$^1B_1$,[11,13,15] Band I is due to the excitation of an electron from a nonbonding orbital (b_2) to a π-antibonding one (e_π^*), and its blue shift means the corresponding stabilization of e_π, *i. e.*, that the π-bond formation between the vanadium d_{xz} and d_{yz} and oxygen p_x and p_y orbitals in the V=O group is enhanced with the rise of temperature and in non-coordinating solvents. On the other hand, Band II is due to the excitation of the same electron to a σ-antibonding orbital (b_1^*), its red shift indicating the corresponding instabilization of b_1, leading to the weakening of V-aca coordinate bonds. These relations are all compatible with the view that the complex changes gradually from an octahedral structure to a tetragonal pyramidal one upon heating and with a decrease in solvent polarity.

Comparison of the Thermochromism Data with Some Properties of Solid Adducts. In order to see the difference in the ease of solvation among the chelates, their pyridine, dioxane and DMF adducts were prepared, and a comparison was made between some of their properties and the data of thermochromism. Adducts of the compositions $VO(aca)_2py$, $[VO(aca)_2]_2$-diox, $VO(\beta\text{-dik})_2$·4-methylpyridine *N*-oxide have been reported.[12-14] We have prepared the monopyridine adducts of $VO(aca)_2$, $VO(bza)_2$, and $VO(tfa)_2$ and monodioxane adducts of $VO(aca)_2$, $VO(tfa)_2$, the pyridine adduct of $VO(dpm)_2$, the dioxane adduct of $VO(bza)_2$, and DMF adducts being obtained only paste-like samples. The method of preparation for $VO(aca)_2py$ (*cf.* Experimental) seemed to be better than that given in literature, since a product which was analytically quite pure could be obtained with nearly theoretical yield.

It was pointed out formerly that all the parent chelates show a V=O streching band between 950 and 1000 cm^{-1} in their IR spectra, except for $VO(tfa)_2$ which shows the same band at 925 cm^{-1} owing to its polymeric six-coordinated structure.[6,13] From the data given in Table 2, we see that, on adduct formation, the ν value of this band for $VO(aca)_2$ and $VO(bza)_2$ decreases, but that for $VO(tfa)_2$ increases, approaching from each side. This indicates that the polymeric structure of $VO(tfa)_2$ is destroyed by adduct formation, and the strength of the V–O bond in the resulting adduct becomes nearly the same as that in other adducts. The dioxane in the adducts seems to be held more loosely than pyridine, since the ν values of the dioxane adducts lie between those of the parent chelates and those of the pyridine adducts. The thermal instability of the dioxane adducts (Table 1, footnote) supports this view.

The solid reflectance spectra of the parent chelates and adducts are also of interest. The $\Delta_{I,II}$ of $VO(aca)_2$, $VO(bza)_2$, and $VO(dpm)_2$ are 1.5—2,[6] and in the neighborhood of the values for their chloroform solutions at room temperature. As expected, the $\Delta_{I,II}$ values of the adducts are much higher, Band I shifting to red and Band II to blue. However, the $\Delta_{I,II}$ of $VO(tfa)_2$ is 4.44 and even larger than that for its pyridine adduct (3.9, with Band I shifting to blue). The fact that $VO(tfa)_2$ is six-coordinate in its solid

† No such strong dependence of $\Delta_{I,II}$ on concentration was observed with other solvents.

owing to polymerization is evident.

The $\Delta_{I,II}$ values in the solid spectra of the adducts are indicated on the ordinate axis in Figs. 2 and 4. We see that, in each case, this value corresponds approximately to the low-temperature limit of the curve for the corresponding solution, supporting the idea that the chelate in solution tends to be more 6-coordinate with the fall of temperature.

The pyridine adducts were also studied thermogravimetrically. $VO(aca)_2py$ liberates pyridine at 53—120 °C, and the remaining parent chelate sublimes at a higher temperature (>159 °C). A similar result was obtained with $VO(bza)_2py$. On the other hand, $VO(tfa)_2py$ melts at 74 °C without evolution of pyridine, and begins to evaporate only at 196 °C, showing that pyridine is more firmly held in this adduct than in the other two (Fig. 5). The curve for $VO(aca)_2$ is similar to that of $VO(aca)_2py$ after evolution of pyridine, that of $VO(tfa)_2$ differing a great deal. Evaporation takes place at a much higher temperature (>256 °C), and a strong endothermic peak appears at 209 °C, suggesting that the intermolecular O=V←O=V bonds must be broken, or essentially weakened, in advance of evaporation.

From the results it can be concluded that the ease of solvation among the chelates studied increases in the order: $VO(tfa)_2 > VO(bza)_2 \approx VO(aca)_2 > VO(dpm)_2$, and the Selbin-Gutman rule on the relation between $\Delta_{I,II}$ and DN ceases to hold at one or the other end of this series, *i. e.* when the chelate is too apt, or too reluctant, to be solvated and become six-coordinate. The data also offer various new proofs for the polymeric nature of solid $VO(tfa)_2$, which was formerly indicated on the basis of its infrared spectrum by Al-Niami *et al.*

The authors wish to express their sincere thanks to Dr. Kenzo Nagase, Tohoku University, for carring out thermogravimetric measurements, and to Prof. Yukio Kondo, St. Paul's University, for use of the Hitachi EPS-3T spectrophotometer.

A Potentiometric Study on Complex Formation of Cadmium(II) and Lead(II) Ions with Ethylenediaminetetraacetic Acid

Noboru OYAMA, Hiroaki MATSUDA, and Hitoshi OHTAKI

Department of Electronic Chemistry, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received August 23, 1976)

The complex formation of cadmium(II) and lead(II) ions with ethylenediaminetetraacetic acid (EDTA) has been studied potentiometrically in a 1.0 M $NaClO_4$ medium at 25.0 °C by using glass and metal-amalgam electrodes. The results were explained in terms of the formation of the complexes of MH_qL with $q=3$, 2, 1, and 0 for both metals. The corresponding formation constants were determined: for the Cd-EDTA system, log $\beta_{101}=14.25\pm0.02$, log $\beta_{111}=17.41\pm0.02$, log $\beta_{121}=19.71\pm0.02$ and log $\beta_{131}=21.35\pm0.02$; for the Pb-EDTA system, log $\beta_{101}=16.50\pm0.05$, log $\beta_{111}=19.78\pm0.02$, log $\beta_{121}=21.35\pm0.02$ and log $\beta_{131}=22.50\pm0.02$, where $\beta_{pqr}=[M_pH_qL_r^{(2p+q-4r)+}]/[M^{2+}]^p[H^+]^q[L^{4-}]^r$ and L denotes the unprotonated molecule of EDTA. The protonation constants of unprotonated EDTA were found to be log $\beta_{011}=8.63\pm0.02$, log $\beta_{021}=14.99\pm0.02$, log $\beta_{031}=17.63\pm0.02$, log $\beta_{041}=19.87\pm0.02$, log $\beta_{051}=21.54\pm0.02$, and log $\beta_{061}=22.70\pm0.02$.

In a previous work[1] we determined the formation constants of protonated complexes of the type MH_qL with $q=2,1$ and $q=3,2,1$ in the Cd(II)- and Pb(II)-*N*-(2-hydroxyethyl) ethylenediamine - *N*,*N*',*N*' - triacetate (H_3-hedta) systems, respectively. Since HEDTA is regarded as a monohydroxyethyl derivative of EDTA, the formation of complexes similar to the HEDTA complexes is expected in the Cd(II)- and Pb(II)-EDTA systems. The results of studies on electrode reactions in Cd(II)- and Pb(II)-EDTA solutions suggest that the protonated complexes MH_qL($q=1$, 2, and 3) participate in the charge transfer processes at the electrode surface.[2,3] The formation constants of unprotonated and monoprotonated metal-EDTA (1 : 1) complexes have been determined[4] in the bulk of these solutions, but those of diprotonated and triprotonated complexes have not been reported except by Sudmeier and Reilley,[5] who evaluated the formation constant of the diprotonated complex for the Cd(II)-EDTA system.

The present work, as a continuation of the previous study,[1] has been carried out to study the formation of protonated complexes in these systems.

Symbols

h	Concentration of hydrogen ion at equilibrium
m	Concentration of metal ion at equilibrium
H	Analytical excess of hydrogen ion in a test solution
M	Cd(II) or Pb(II)
c_M	Total concentration of M
L	Ethylenediaminetetraacetate anion ($edta^{4-}$)
c_L	Total concentration of L
l	Concentration of free L
X	Degree of neutralization of H_4L: $\dfrac{-H+[H]-[OH]}{c_L}$
p	Number of metal atoms bound to complexes
q	Number of protons bound to complexes
r	Number of ligands bound to complexes
β_{pqr}	Equilibrium constant for the reaction $pM + qH + rL = M_pH_qL_r$
$\bar{n}$	Formation function of the ligand H_nL
E_q, E_m	Emf of the cells defined by the subscripts and Eqs. 1 and 2 in Ref. 1.
$E_j(h,m)$	Liquid junction potential as a function of h and m
[ ]	Concentration

All charges are omitted for the sake of convenience.

Experimental

Reagents. *Disodium ethylenediaminetetraacetate* (reagent grade, Dojindo Laboratories) was recrystallized twice, dried at *ca.* 85 °C and then stored in a desiccator over silica gel. *Cadmium(II) perchlorate, lead(II) perchlorate, sodium hydroxide,* and *perchloric acid* solutions were prepared by the methods described in the preceding paper.[1]

Sodium perchlorate was prepared according to Biedermann and Ciavatta.[6]

Cadmium- and lead-amalgams were prepared from cadmium(II) perchlorate and lead(II) nitrate solutions, respectively, by electrolysis with a Metrohm E211A coulometer. The metal content of the amalgams was about 3% (weight).

Apparatus. *A potentiometric cell* similar to the one previously employed was used. *A digital pH/mV meter* (Orion Research, Model 801) and a *digital voltmeter* (Takeda Riken, Model TR-6656) were used for potentiometric measurements in combination with glass and amalgam electrodes, an Ag-AgCl electrode being used as a reference.

Emf Measurements. The method of emf measurements was essentially the same as that employed previously.[1]

When $c_{Cd}>0.0025$ M, titration was interrupted in the pH range 1.7—2.3, since white precipitates which might be CdH_2L^0 separated out. In such cases no stable emf's could be recorded. The emf of the amalgam electrode usually required 15 min to attain a constant value and was measured within an accuracy of ±0.02 mV in the pH range 1.0—2.0 and ±0.1 mV in the pH range 2.0—3.5. At pH above 3.5 the emf's became unstable. The emf of the glass electrode cell became constant after about 5 min and was determined within an accuracy of ±0.1 mV over the pH range 1.0—10.0.

Results and Discussion

Evaluation of Protonation Constants of EDTA. Overall protonation constants of the EDTA base, β_{0n1}, were determined from the formation function $\bar{n}$. A generalized least squares method was applied in order to make the error squares sum $U=\sum(\bar{n}-\bar{n}_{calcd})^2$ a minimum for the set of overall protonation constants, β_{011}, β_{021}, β_{031}, β_{041}, β_{051}, and β_{061}. This calculation was performed with an electronic computer HITAC 8700. $\bar{n}_{calcd}$ and $\bar{n}$ denote, respectively,

$$\bar{n}_{calcd}=\frac{\sum_{n=1}^{6}n\beta_{0n1}h^n}{1+\sum_{n=1}^{6}\beta_{0n1}h^n} \quad (1)$$

$$\bar{n}=\frac{4c_L+H-h+(K_w/h)}{c_L} \tag{2}$$

where K_w is the autoprotolysis constant of water in 1.0 M $NaClO_4$ solution, $10^{-13.95}$.[7] The protonation constants thus obtained were $\log \beta_{011}=8.63\pm0.02$, $\log \beta_{021}=14.99\pm0.02$, $\log \beta_{031}=17.63\pm0.02$, $\log \beta_{041}=19.87\pm0.02$, $\log \beta_{051}=21.54\pm0.02$, and $\log \beta_{061}=22.70\pm0.02$. Anderegg reported the values of $\log \beta_{011}=8.85$, $\log \beta_{021}=15.13$, $\log \beta_{031}=17.43$, $\log \beta_{041}=19.63$, $\log \beta_{051}=21.03$, and $\log \beta_{061}=20.19$ in a 1.0 M $NaClO_4$ medium at 20 °C.[7]

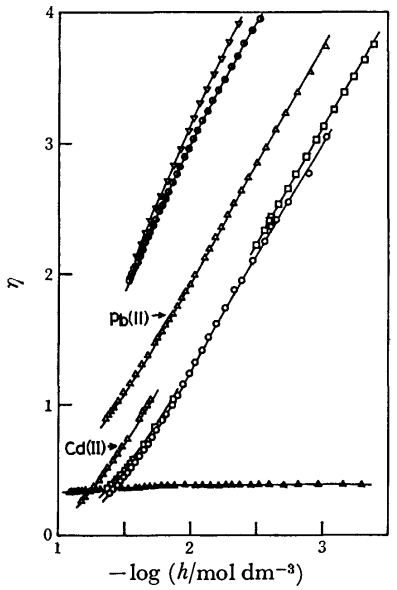

Fig. 3. Relationships between η and $-\log h$ for the Cd(II) and Pb(II) systems.
Symbols are the same as those in Figs. 1 and 2, respectively. Solid lines are curves calculated by the use of the stability constants in Table 1.

Determination of the Composition and the Stability Constants of Complexes. Titration curves of the Cd(II)- and Pb(II)-EDTA solution are shown in Figs. 1 and 2, respectively. In Fig. 3, the quantity $\eta=\log(c_M/m)$, which is a measure of the degree of complexation of the metal ion M, is plotted against $-\log h$. We see that $\eta>0$ at $-\log h=1.2$. This shows that the complex formation reaction takes place between the metal ions and EDTA even in the most acidic solution.

Since EDTA is an analog of HEDTA, the data obtained in the EDTA systems may be treated in the same manner as that used in calculation of the formation constants of the HEDTA complexes. Polynuclear or polyligand complexes may be neglected.[1] As a first approach to analysis of the data, we assume that the complex formation reaction can be written as

$$M^{2+}+qH^{+}+L^{4-}=MH_qL^{(q-2)+} \tag{3}$$

from which we obtain

$$c_M=m+\sum_{q=0}^{Q}[MH_qL] \tag{4}$$

$$c_L=l+\sum_{n=1}^{N}[H_nL]+\sum_{q=0}^{Q}[MH_qL] \tag{5}$$

Insertion of Eq. 4 into Eq. 5 and rearrangement lead to

$$l=(c_L-c_M+m)/(1+\sum_{n=1}^{N}\beta_{0n1}h^n) \tag{6}$$

A function F_0 is defined as follows:

$$F_0=(c_M-m)/ml=\sum_{q=0}^{Q}[MH_qL]/ml=\sum_{q=0}^{Q}\beta_{1q1}h^q \tag{7}$$

The plot of $\log F_0$ against $-\log h$ is shown in Fig. 4 for both systems of Cd(II)- and Pb(II)-EDTA except for the case $c_M \geq c_L$. In each system a single curve was obtained regardless of variations of c_M, c_L and c_M/c_L. This supports the assumption that neither polynuclear nor polyligand species is formed. In the case $c_M \geq c_L$,

the value of the term (c_L-c_M+m) in Eq. 6 becomes too small to use the data for the calculation of F_0.

From the plot of F_0 against h, we obtained the formation constant β_{101}, β_{111}, β_{121}, and β_{131} for both systems according to the procedure reported.[1] By using the values of β_{1q1} thus obtained as the initial values, the formation constants of the complexes were refined by a generalized least squares method. The method was applied to make the error squares sum $U=\Sigma\{\log F_0-\log F_{0,\mathrm{calcd}}\}^2$ minimum for the set of the formation constants over the pH range 1.2—3, where $F_{0,\mathrm{calcd}}$ denotes the value of F_0 calculated for a particular set of the formation constants. The results are given in Table 1.

Since the metal amalgam electrodes did not function well in a high pH range, the data in the high pH range were not analyzed. However, the constants reproduced the experimental results fairly well over the whole pH range (solid lines, Figs. 1 and 2).

The distribution of the Cd(II)- and Pb(II)-EDTA complexes are graphically represented in Fig. 5.

The stepwise protonation constant of the species MH_qL is defined as $K_H^{MH_qL}=[MH_qL]/[MH_{q-1}L][H]$. The values of $\log K_H^{MH_qL}$ are plotted against the number of protons within the complex q, together with the values of $\log K_H^{H_nL}$ $(=\log [H_nL]/[H_{n-1}L][H])$against n(Fig. 6). The values of $\log K_H^{H_nL}$ of the HEDTA and

EDTA molecules first steeply decreased with n. According to the NMR and infrared spectrophotometric measurements,[8,9] the first two protons (to form HL and H_2L) are located on the nitrogen atoms of the EDTA and HEDTA molecules. We see that the protonation of the amino groups of the ligands brings about a significant change in the values of the protonation constants. The protonation on the carboxylic groups results in the relatively small change in the $K_H^{H_nL}$ values. The stepwise protonation constants $K_H^{MH_qL}$ ($q=1$, 2, and 3) of the Cd(II)- and Pb(II)-HEDTA and EDTA complexes are close to the values of $K_H^{H_nL}$ with $n=3$, 4, and 5 of the corresponding ligands. Thus we conclude that protonation of the complexes occurs on the acetate groups with the cleavage of the metal-oxygen bonds within the complexes with a decrease in pH, while the strong metal-nitrogen bonds are hardly influenced by the hydrogen-ion concentration over the pH range examined.

Another kind of formation constants of the complexes may be defined as $\log K_{H_qL}^{MH_qL}=\log[MH_qL]/[M][H_qL]$, which is calculated from the values of β_{1q1} and β_{0n1}. The values are given in Table 2. The values of K_L^{ML} of the Cd(II)- and Pb(II)-EDTA complexes are larger than those of the HEDTA complexes, as expected from the simple chelate theory, because the former ligand is sexidentate, whereas the latter quinquidentate. Nevertheless, the K_{HL}^{MHL} values of the EDTA complexes are smaller than the $K_{L'}^{ML'}$ ($L'=$ hedta^{3-} anion) values of the HEDTA complexes, the ligand HL (L=edta^{4-} anion) being expected to act as a quinquidentate ligand. The same tendency was found in the complex formation of the MH_2L of EDTA and the MHL' of HEDTA (Table 2). However, a comparison between the formation constants of the MH_3L complex of EDTA and the MH_2L' complex of HEDTA leads to the opposite result.

The protons within the protonated ligands HL and H_2L are located at the nitrogen atoms of the amino groups of the ligands. On the other hand, the protons of the protonated metal complexes MH_qL are combined with the acetate groups. Thus the free energy change defined by the equation $\Delta G_{MH_qL}=-RT\ln K_{H_qL}^{MH_qL}$ should include the free energy change of the intramolecular rearrangement of protons from the amino groups to the acetate groups. In the MHL complex of EDTA, the free energy change accompanied by the transfer of one proton from a nitrogen atom to an oxygen atom is needed as compared with the corresponding value of the ML' complex of HEDTA. Since the entropy change for the complex formation of MHL from M and HL (L=edta^{4-}) is nearly equal to that of ML' from M and L' (L'=hedta^{3-}) as reported by Brunetti *et al.*,[10] the difference between $K_{L'}^{ML'}$ and K_{HL}^{MHL} is mainly due to the difference in the enthalpy change of the proton transfer reaction from a nitrogen atom to an acetate group in the latter case. In the formation of MH_2L of EDTA, two protons must move from the amino groups to the acetate groups, while the transfer of only one proton is required in the complex formation MHL' with M and HL'. In contrast to the case considered above, the two proton transfer reaction is always accompanied by the complex formation of MH_qL from M and H_qL ($q\geq 2$) of either HEDTA or EDTA molecule. The free energy change of the intramolecular rearrangement of protons in the complex formation of MH_3L of EDTA may not largely differ from that of the MH_2L' complex of HEDTA. The difference between $K_{H_3L}^{MH_3L}$ and $K_{H_2L'}^{MH_2L'}$ (Table 2) cannot be explained in terms of the enthalpy changes in the chelate formation. The contribution of the hydroxyethyl group to the chelate formation might stabilize the MH_2L' complex, and therefore $K_{H_2L'}^{MH_2L'}$ would be larger than $K_{H_3L}^{MH_3L}$. The difference may be attributed to the entropy difference in the intramolecular rearrangement of the protons of the ligands, but we have no evidence to clarify the phenomenon.

Thermal Behavior of the Clathrate Compounds of the Type $M(diam)M'(CN)_4 \cdot 2C_6H_6$

Jun-ichi OHYAMA, Ryokichi TSUCHIYA, Akira UEHARA, and Eishin KYUNO*

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

**Department of Pharmaceutical Science, School of Pharmacy, Hokuriku University, Kanazawa 920*

(Received August 25, 1976)

The thermal behavior of the guest molecule trapped in the clathrate compounds, $M(diam)M'(CN)_4 \cdot 2C_6H_6$, where M and M′ are bivalent metal atoms and diam is two ammonia molecules or one molecule of diamine, and the structural changes of the host lattice upon heating were studied by means of derivatographic and isothermal measurements. In $Cd(NH_3)_2Ni(CN)_4 \cdot 2C_6H_6$, the elimination of guest benzene molecules was found to proceed in two steps. X-Ray powder diffraction patterns suggest that the skeleton of the host is preserved, at least during the first liberation of 1 mol of benzene, but the skeleton collapses after the complete liberation of benzene and ammonia. The host skeleton of $Cd(en)Ni(CN)_4 \cdot 2C_6H_6$ was preserved till the liberation of 75% of benzene. The activation energies were a little larger than the respective enthalpy changes. The replacement of M′=Ni by Pd or of M′=Cd by Hg in the clathrate compounds, if M and diamine are the same, scarcely changes the activation energy for the liberation of the guest molecule, but the replacement of M and diamine by other ones somewhat changes the activation energy.

A well-known clathrate compound, $Ni(NH_3)_2Ni(CN)_4 \cdot 2C_6H_6$, was first prepared by Hofmann and Küspert in 1897.[1] They pointed out that the benzene molecule in this compound is retained firmly as a guest in the host lattice, and its elimination cannot be detected at room temperature under ordinary pressure. Anysley *et al.*[2] reported, however, that the benzene molecule can be removed slowly *in vacuo* even at room temperature without the liberation of ammonia from the lattice. The crystal structure of this clathrate compound was determined by means of X-ray diffraction by Powell and Rayner,[3,4]

By replacing both or either one of the nickel ions in $Ni(NH_3)_2Ni(CN)_4 \cdot 2C_6H_6$ by other bivalent metal ions which can form hexacoordinated, octahedral and tetracoordinated, square planar complexes, various modified compounds have been prepared and their structures were confirmed to be similar to that of $Ni(NH_3)_2Ni(CN)_4 \cdot 2C_6H_6$.[5-10]

In analogous clathrate compounds such as $Cd(en)Ni(CN)_4 \cdot 2C_6H_6$[11] the ethylenediamine molecule links both cadmium ions in upper and lower adjacent layers, forming three-dimensional host lattice network.[12,13]

All the compounds containing the square planar $M'(CN)_4$ (M′=Ni or Pd) moiety may be referred to "Hofmann-type clathrates." Recently, another new type of clathrate compounds containing tetrahedral $M'(CN)_4$ moiety was prepared by Iwamoto and others and the crystal structures were determined.[14-16] These compounds are called "Iwamoto-type clathrates" to distinguish them from the Hofmann-type ones.

Aynsley *et al.* examined the thermal decomposition of $Ni(NH_3)_2Ni(CN)_4 \cdot 2C_6H_6$, and found that the elimination of benzene proceeds in the zeroth order,[2] which indicates that the rate determining step is the escape of benzene molecule from the surface of the clathrate. On the other hand, it is known that the rate of the escape of benzene varies with the kind of metal atom constituting the host lattice.[2] The present study was undertaken (1) to investigate the thermal liberation processes of benzene molecule from the host lattices in the two types of clathrate compound and (2) to see what effect is induced by the variation of the host lattices.

Experimental

Preparation of Clathrate Compounds. The clathrate compounds $M(diam)M'(CN)_4 \cdot 2C_6H_6$, where M is Cd, Ni or Cu, (diam) is $(NH_3)_2$, ethylenediamine or trimethylenediamine and M′ is Ni, Pd, Cd, and Hg, were prepared[5-7,11,14] and their characterization was carried out by measuring both IR spectra and X-ray powder diffraction patterns.

$Cd[Ni(CN)_4]$ was prepared by a method similar to that for $Zn[Ni(CN)_4]$, and dried at 70 °C for 2 h. The compound was used as the reference material to examine the final product by the thermal decomposition of $Cd(NH_3)_2Ni(CN)_4 \cdot 2C_6H_6$.

Found: C, 17.74; N, 20.39%. Calcd for $Cd[Ni(CN)_4]$: C, 17.45; N, 20.35%.

One of the compounds corresponding to the host lattice which has lost the guest molecule $Cu(NH_3)_2Ni(CN)_4$, was obtained by keeping the mother clathrate $Cu(NH_3)_2Ni(CN)_4 \cdot 2C_6H_6$ to stand in an ambient atmosphere for a few days.[17]

Measurements. The derivatograms for these compounds were obtained with a MOM Derivatograph Typ-OD-102. 0.5 or 0.4 g of sample was used in each run. All the measurements were carried out under a constant flow of nitrogen stream with a heating rate of 1 K min^{-1}. The enthalpy changes, ΔH, were evaluated by the analysis of DTA peak in the derivatogram.[18]

The isothermal measurements were carried out with a Shimadzu TM-1A Thermanobalance in static air.

The infrared and far infrared absorption spectra in the Nujol and HCB mull states were measured with JASCO IRA-2 and IR-F infrared spectrophotometers, respectively.

The X-ray powder diffraction patterns were recorded with a Rigaku-denki Geiger-flex X-ray Analyser, using Cu$K\alpha$ ray (λ=1.5405 Å) filtered with a nickel plate.

Results and Discussion

Hofmann-type Clathrate Compounds. Derivatography: The derivatograms of $Cd(NH_3)_2Ni(CN)_4 \cdot 2C_6H_6$ (I), $Cd(NH_3)_2Pd(CN)_4 \cdot 2C_6H_6$ (II), $Cd(en)Ni(CN)_4 \cdot 2C_6H_6$ (III), and $Cd(en)Pd(CN)_4 \cdot 2C_6H_6$ (IV) are shown in Fig. 1. The TG curve of compound I indicates that the mass loss of 1 mol of benzene was observed until 130 °C, and then another 1 mol of benzene and 2

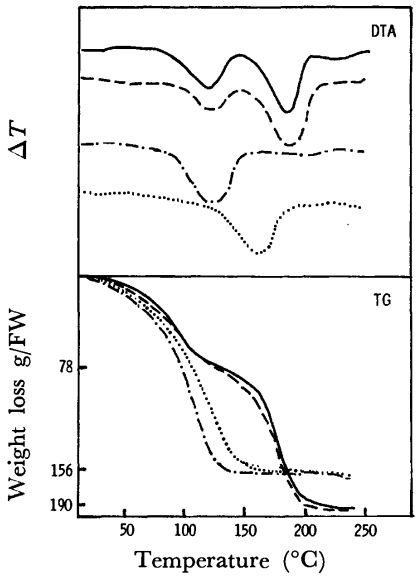

Fig. 1. Derivatograms of compounds (I) Cd(NH$_3$)$_2$-Ni(CN)$_4$·2C$_6$H$_6$ (——), (II) Cd(NH$_3$)$_2$Pd(CN)$_4$·2C$_6$H$_6$ (----), (III) Cd(en)Ni(CN)$_4$·2C$_6$H$_6$ (-·-·-) and (IV) Cd(en)Pd(CN)$_4$·2C$_6$H$_6$ (·····).

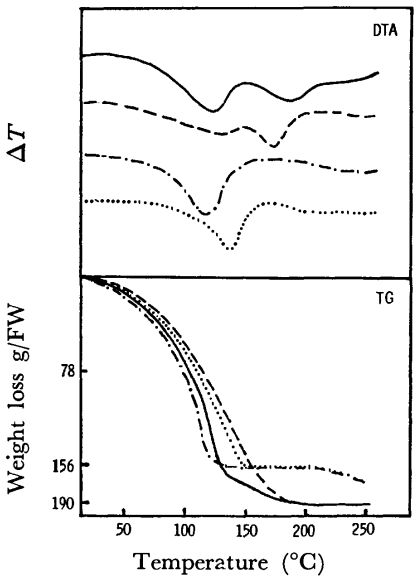

Fig. 2. Derivatograms of compounds (V) Cu(NH$_3$)$_2$-Ni(CN)$_4$·2C$_6$H$_6$ (——), (VI) Cu(NH$_3$)$_2$Pd(CN)$_4$·2C$_6$H$_6$ (----), (VII) Ni(NH$_3$)$_2$Ni(CN)$_4$·2C$_6$H$_6$ (-·-·-) and (VIII) Ni(NH$_3$)$_2$Pd(CN)$_4$·2C$_6$H$_6$ (·····).

mol of ammonia were lost successively in the higher temperature region 135—200 °C, no further mass loss being detectable up to the decomposition point. The elemental analysis for the product obtained by heating I at 200 °C is as follows: Found: C, 17.52; N, 20.00%. Calcd for CdNi(CN)$_4$: C, 17.45; N, 20.35%. The DTA curve gives two endothermic peaks corresponding to the discrete mass loss steps.

Compound II gives only one mass loss step in TG, but shows two split endothermic peaks in DTA. It seems that two benzene molecules are eliminated in two overlapping steps.

On the other hand, compounds III and IV lose the

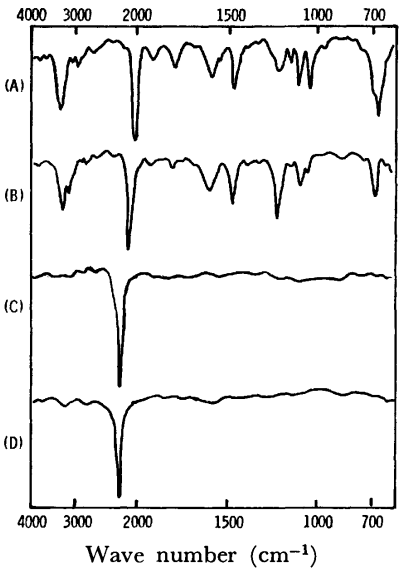

Fig. 3. IR spectra of compound (I) (A), the product obtained by heating (I) at 130 °C (B), that obtained at 200 °C (C) and of Cd[Ni(CN)$_4$] (D).

benzene molecules in one step up to 130 °C and 140 °C, respectively, each giving an endothermic peak at the corresponding region in the DTA curve. Ethylenediamine was not liberated until the decomposition point. The elemental analysis for the product obtained by heating compound III at 140 °C is as follows: Found: C, 21.67; H, 2.49; N, 24.35%. Calcd for Cd(en)-Ni(CN)$_4$: C, 21.48; H, 2.39; 25.06%.

Figure 2 shows the derivatograms of Cu(NH$_3$)$_2$-Ni(CN)$_4$·2C$_6$H$_6$ (V), Cu(NH$_3$)$_2$Pd(CN)$_4$·2C$_6$H$_6$ (VI), Ni(NH$_3$)$_2$Ni(CN)$_4$·2C$_6$H$_6$ (VII) and Ni(NH$_3$)$_2$Pd-(CN)$_4$·2C$_6$H$_6$ (VIII). In compound V, the TG curve shows two steps of mass loss at 130 °C and at 130—175 °C, the corresponding discrete peaks appearing in the DTA curve. From the results of infrared absorption spectral measurements, the first step is considered to correspond to the elimination of 2 mol of benzene and the second to the liberation of ammonia. The total weight loss due to the escape of all the benzene and ammonia is also observed in compound VI, the separation of their two processes not being clear.

Both compounds VII and VIII lost all benzene in one step. The weight remained constant till 250 °C at which the partial liberation of ammonia was observed just before the decomposition point.

IR and Far-IR Spectra. In order to clarify the structural change at several stages upon heating, changes in the infrared and far-infrared absorption spectra and X-ray diffraction patterns were measured for compounds I and III.

The infrared absorption spectra of compound I heated at various temperatures are shown in Fig. 3, together with that of Cd[Ni(CN)$_4$], which is expected to be formed by heating compound I. The spectrum of I in which one mole of benzene is lost at 130 °C is similar to that of the starting compound at room temperature except for the weakened bands assigned to benzene at 3072, 3055, 3019, 1972, 1872, and 1479 cm^{-1}.[14] At 200 °C, however, the bands assigned to

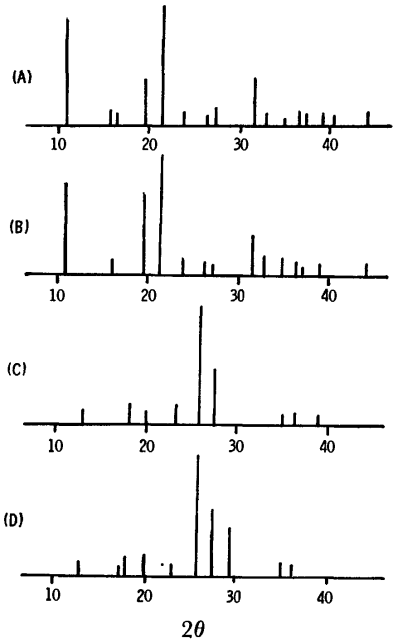

Fig. 4. X-Ray diffraction patterns of compound (I) (A), the product obtained by heating (I) a 130 °C (B), that obtained at 200 °C (C) and of $Cd[Ni(CN)_4]$ (D).

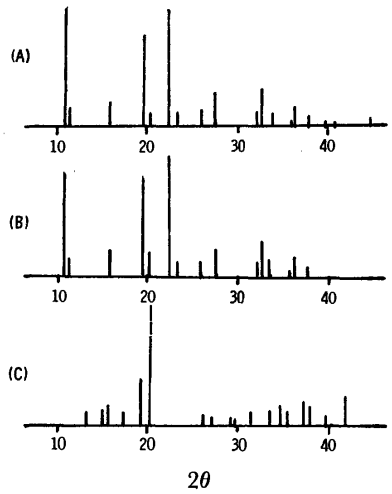

Fig. 5. X-Ray diffraction patterns of compound (III) (A), the product obtained by heating (III) at 120 °C (B) and that obtained at 140 °C (C).

benzene and to ammonia disappear, and the C≡N stretching vibration band is shifted to *ca.* 20 cm^{-1} higher. The spectrum coincides with that of $Cd[Ni(CN)_4]$. This supports the elimination processes of benzene and ammonia.

In compound III, the bands assigned to benzene disappear completely at 140 °C, accompanied by the elimination of benzene at this temperature. So far as the ethylenediamine is concerned, the band due to NH_2 wagging mode (*ca.* 1089 cm^{-1}) disappears and two new bands (*ca.* 1120, 1065 cm^{-1}) appear upon heating. The results suggest that the structure of ethylenediamine molecule bridging between the layers of $M(CN)_4$ network changes to some extent. The fact that the band due to CH_2 rocking vibration at 856 cm^{-1} still remains after heating suggests that the

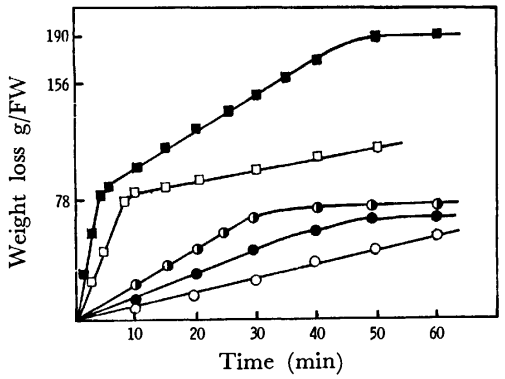

Fig. 6. The plots of weight loss *vs.* time for compound (I).
○: 84 °C, ●: 94 °C, ◑: 104 °C, □: 138 °C, ■: 160 °C.

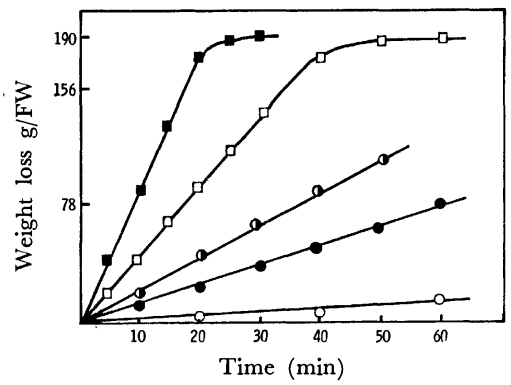

Fig. 7. The plot of weight loss *vs.* time for compound (III).
○: 55 °C, ●: 80 °C, ◑: 89 °C, □: 100 °C, ■: 119 °C.

trans configuration of ethylenediamine remains unchanged.[19]

X-Ray Powder Diffraction Patterns. The X-ray powder diffraction patterns for compound I obtained in each heating step are shown in Fig. 4. The pattern obtained at 130 °C shows no change from that at room temperature, but at 200 °C the pattern completely changes to give a similar one to that of $Cd[Ni(CN)_4]$. This suggests that the crystal lattice of compound I at room temperature is retained even when one mole of benzene is lost but the lattice is deformed at first when another one mole of benzene and ammonia are liberated.

The change in the X-ray patterns for compound III is shown in Fig. 5. The pattern at room temperature remains till 120 °C at which 75% of benzene is removed, but it becomes quite different at 140 °C at which the residual benzene is completely evolved.

Isothermal Kinetics. The weight losses of the compounds *versus* time of heating at various temperatures for compounds I and III are plotted in Figs. 6 and 7, respectively.

In compound I the elimination of 1 mol of benzene proceeds in the zeroth order at least at temperature below 130 °C, but above 130 °C the remaining benzene and ammonia are liberated more slowly also in the zeroth order after 1 mol of benzene is removed,

Table 1. Enthalpy changes ΔH and activation energies E_a in the elimination of benzene molecule from clathrate compounds

Compound		ΔH kJ mol^{-1}	E_a kJ mol^{-1}
I	$Cd(NH_3)_2Ni(CN)_4\cdot 2C_6H_5$	59	75.6 (1st step)
			71.0 (2nd step)
II	$Cd(NH_3)_2Pd(CN)_4\cdot 2C_6H_6$	55	74.8 (1st step)
III	$Cd(en)Ni(CN)_4\cdot 2C_6H_6$		51.2
IV	$Cd(en)Pd(CN)_4\cdot 2C_6H_6$	50	51.7
V	$Cu(NH_3)_2Ni(CN)_4\cdot 2C_6H_6$	50	65.9
VI	$Cu(NH_3)_2Pd(CN)_4\cdot 2C_6H_6$		67.2
VII	$Ni(NH_3)_2Ni(CN)_4\cdot 2C_6H_6$	55	67.2
VIII	$Ni(NH_3)_2Pd(CN)_4\cdot 2C_6H_6$	55	67.6

The results suggest that 2 mol of benzene are liberated in two different mechanisms. However, since the two guest benzene molecules cannot be distinguished from each other in their structure, it is considered that a thermally metastable intermediate might be formed after the loss of one mole of benzene retaining the initial host lattice.

On the other hand, the elimination of benzene from the clathrate III is considered to proceed in the zeroth order up to 80% removal of benzene as seen in Fig. 7.

The rate constant k for the elimination of benzene was obtained from the slope of the lines shown in Figs. 6 and 7. The activation energies E_a were calculated from the Arrhenius plots (Table 1). The enthalpy changes ΔH, calculated by the analysis of the DTA curve, are also given.

The enthalpy changes are about 55 kJ mol^{-1} in all the clathrates and the activation energy values are relatively similar to one another within 66—75 kJ mol^{-1} except for those of III and IV. This suggests that the elimination process is analogous to that of the vaporization of the liquid so that the migration of the benzene molecule within the lattice is comparatively easy and the rate determining step is the escape of the benzene from the surface, giving the zeroth order.

From a comparison of E_a values we see that the replacement of the tetracoordinated metal atom from nickel to palladium causes no appreciable change. On the other hand, replacement of the hexacoordinated metal or amine with others gives rise to some changes in E_a values.

The values for compounds III and IV which contain ethylenediamine as the diamine are slightly smaller than those for other compounds which contain ammonia as the diamine. It can be seen that the steric repulsion between ethylenediamine and the benzene molecule makes it unstable for benzene to exist in the cavity of the host lattice, owing to the replacement of a more bulky ethylenediamine instead of two ammonia molecules.

Iwamoto-type Clathrate Compounds. Derivatography: The derivatograms of $Cd(NH_3)_2Hg(CN)_4\cdot 2C_6H_6$ (IX), $Cd(en)Hg(CN)_4\cdot 2C_6H_6$ (X), $Cd(en)Cd(CN)_4\cdot 2C_6H_6$ (XI), and $Cd(tn)Hg(CN)_4\cdot 2C_6H_6$ (XII) are shown in Fig. 8. IX gives two steps of mass loss up to 120 °C and 120—150 °C in TG and two endothermic peaks corresponding to each step in DTA curve. From the infrared absorption spectra, it seems that the first step of mass loss is due to the elimination of 2 mol of benzene and the second to the liberation of ammonia, resembling the elimination process in compound V.

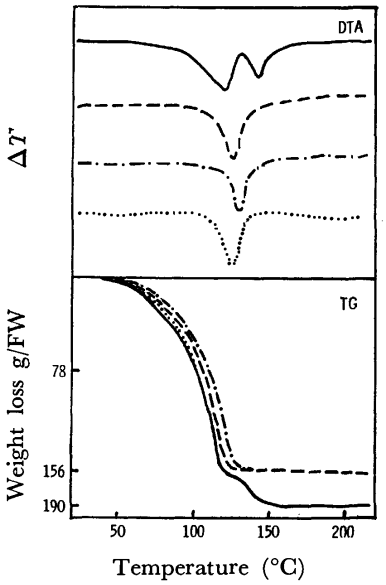

Fig. 8. Derivatograms of compounds (IX) $Cd(NH_3)_2Hg(CN)_4\cdot 2C_6H_6$ (——), (X) $Cd(en)Hg(CN)_4\cdot 2C_6H_6$ (----), (XI) $Cd(en)Cd(CN)_4\cdot 2C_6H_6$ (-·-·-) and (XII) $Cd(tn)Hg(CN)_4\cdot 2C_6H_6$ (·····).

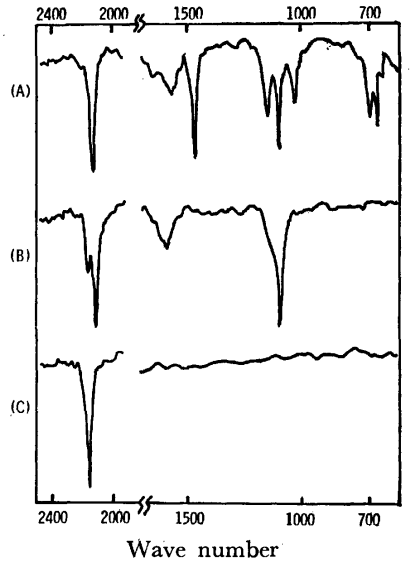

Fig. 9. IR spectra of Compounds (IX) (A), the product obtained by heating (IX) at 120 °C (B) and that obtained at 150 °C (C).

On the other hand, X, XI, and XII lose all benzene molecules in one step until about 135 °C.

IR Spectra. The infrared absorption spectra of compound IX at several heating steps are shown in Fig. 9. The absorption peaks due to benzene at 1479, 1042, 690, and 672 cm^{-1} disappear upon heating at 120 °C and those due to the NH_3 vibration mode at 1592 and 1089 cm^{-1} disappear upon heating at 150 °C with the shift of $\nu_{C\equiv N}$ at 2150 cm^{-1} to about

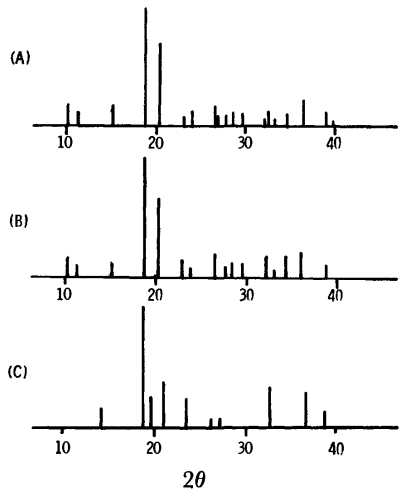

Fig. 10. X-Ray diffraction patterns of compounds (IX) (A), the product obtained by heating (IX) at 120 °C(B) and that obtained at 150 °C(C).

35 cm^{-1} higher.

X-Ray Powder Diffraction Patterns. The X-ray powder diffraction patterns at several heating setps for compound IX are shown in Fig. 10. The pattern obtained by heating at 110 °C where 70% of benzene is removed shows no appreciable change, whereas the one at 150 °C shows a remarkable change. This suggests that the removal of 70% of benzene from the clathrate IX causes no essential change of structure in the host skeleton of the mother clathrate, but the removal of the residual benzene and ammonia gives rise to a structural change. Such a tendency is also observed in compounds X—XII.

Isothermal Kinetics. Isothermal studies were carried out in the same way as those for Hofmann-type clathrates. The enthalpy changes (ΔH) and activation energies (E_a) are given in Table 2.

The value of each activation energy is close to that of the corresponding enthalpy change. The activation energy values of Iwamoto-type clathrates are similar to those of Hofmann-type ones, the elimination of benzene proceeding in one step. There are two different kinds of cavities in Iwamoto-type clathrates. However, they cannot be distinguished from each other as regards thermal behavior of the guest molecules. From this point of view, Iwamoto-type clathrates are analogous to Hofmann-type ones with regard to the state of the guest benzene molecules. The activation energy of compound XII gave a somewhat small value. This might be due to the relatively larger repulsion between bulky trimethylenediamine and benzene than that between ethylenediamine and benzene.

Table 2. Enthalpy changes ΔH and activation energies E_a in the elimination of benzene molecule from clathrate compounds

Compound		ΔH kJ mol^{-1}	E_a kJ mol^{-1}
IX	$Cd(NH_3)_2Hg(CN)_4 \cdot 2C_6H_6$	63	76.4
X	$Cd(en)Hg(CN)_4 \cdot 2C_6H_6$	67	74.3
XI	$Cd(en)Cd(CN)_4 \cdot 2C_6H_6$	67	75.6
XII	$Cd(tn)Hg(CN)_4 \cdot 2C_6H_6$	42	65.1

Synthesis and PMR Study of Mixed Ligand Cobalt(III) Complexes with Aliphatic α-Hydroxyimino Ketone and Pyridine

Minoru TANAKA, Ryonte RYU, Isao MASUDA,* and Toshiyuki SHONO

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-kami, Suita, Osaka 565

**Department of Chemistry, Faculty of Science, Fukuoka University, Nanakuma, Nishi-ku, Fukuoka 814*

(Received September 8, 1976)

Cobalt(III) complexes with a series of aliphatic α-hydroxyimino ketone (moH) and pyridine (py) were obtained as fine crystals. The aliphatic α-hydroxyimino ketones used are R-C(=O)-C(=NOH)-R′ where R=CH_3 or C_2H_5 and R′=CH_3, C_2H_5, *i*-C_3H_7, *n*-C_3H_7 or $COCH_3$. These complexes are formulated as $[Co(mo)_2(py)_2]ClO_4$. The PMR spectral investigation shows that the proton resonances of the alkyl group bound to the hydroxyimino group are shifted toward higher fields upon complex formation. This unusual upfield shift is accounted for by consideration of the specific configuration and ring-current of the pyridine in the complex.

The α-hydroxyimino ketones, R-C(=O)-C(=NOH)-R′, abbreviated as moH, are known to react with transition metal ions.[1] The specific cobalt complexes studied have been reported as having the formula $Co^{III}(mo)_3$. In the case where R and/or R′ are saturated alkyl groups, the α-hydroxyimino ketones appear to produce less stable complexes than aromatic α-hydroxyimino ketones with phenyl or 2-furyl groups. Thus, in respect to the aliphatic α-hydroxyimino ketone complexes, their synthesis and characterization appear to remain equivocal.

In the present paper, the method of preparation of the crystalline cobalt(III) complexes of aliphatic α-hydroxyimino ketones having the formula $[Co(mo)_2(py)_2]ClO_4$, where py is pyridine, is described. The PMR spectral behavior is discussed in terms of a specific steric configuration of alkyl groups of the complexes in solution.

Experimental

Preparation. The α-hydroxyimino ketones were prepared by the hydroxyimination reaction of the methylene group of the corresponding ketone with isopentyl nitrite.[2]

Cobalt(III) complexes were obtained by the following general procedure: to 50 ml of a tetrahydrofuran solution of 0.01 mol of α-hydroxyimino ketone and 0.005 mol of $Co(ClO_4)_2 6H_2O$ was added 0.01 mol of pyridine. The mixture was stirred in air at room temperature for 2 h. The precipitate separated was collected on a glass filter, and then recrystallized from ethanol. Table 1 shows the analytical data for the complexes thus obtained. The same procedure using ammonia or aniline as a base resulted in no precipitation of any similar complex.

Measurement. PMR spectra were recorded with a Japan Electron Optics Model JNM-PS-100 spectrometer at a frequency of 100 MHz and/or a JNM-3H spectrometer at 60 MHz, at an ambient probe temperature of 20 °C. The chemical shifts were determined in ppm using TMS as an internal standard.

Results and Discussion

The results of elemental analysis, as listed in Table 1, show that the composition of the complexes corresponds closely to the formula, $[Co\{R-C(=O)-C(=NO)-R'\}_2(py)_2]ClO_4$. These complexes are diamagnetic, which suggests that cobalt(III) complexes were obtained.

The PMR spectra of free biacetyl monoxime (R=R′=CH_3) and its complex are given in Fig. 1. The free ligand exhibits three singlet signals at 2.00, 2.39, and 9.83 ppm; these are readily assigned to the CH_3^a, CH_3^s, and NOH protons on the basis of published data,[3] respectively. The complex has two signals for the CH_3^a singlet and the CH_3^s singlet (at 1.95 and 2.53 ppm, respectively) and no signal for the NOH proton, which indicates that the two biacetyl monoximato ligands are equivalent. It should be noted that upon complex formation, the resonances of the H^a and H^s protons are shifted in opposite directions, that is, the H^a signal is shifted toward higher fields, whereas the H^s signal is shifted toward lower fields.

In general, it is considered that the coordination of the functional group as $>C=NO^-$ or $>C=O$ bound to an alkyl group accompanies either no appreciable or only a small downfield shift of the alkyl proton resonance. This PMR spectral characteristic has been shown in the case of Co^{III}(2,4-pentanedionato)$_3$[4] and *trans*-$[Co^{III}(dimethylglyoximato)_2(py)X]$ (X=NO_2^- or halide ions).[5] The downfield shift of the alkyl proton

resonance may be interpreted as follows. The electron density on the coordinated atom decreases, which causes a decrease in the shielding of the alkyl protons. The observed downfield shift of the H^a signal by coordination is consistent with the above interpretation. On the other hand, the upfield shift for the H^α signal is unexpected. There is no appreciable difference between the H^α chemical shift values of biacetyl monoximato anion and the neutral biacetyl monoxime, as shown in Table 2. This fact implies that it is improbable that the unusual upfield shift is caused by the negative charge on the functional group.

The similar spectral behavior of the upfield shift for the R′ proton is also observed in the case of 3-hydroxyimino-2,4-pentanedione (R=CH_3^a and R′=$COCH_3^\beta$). The free 3-hydroxyimino-2,4-pentanedione in $CDCl_3$ has one singlet at 2.43 ppm, as shown in Fig. 2. Patel and Haldar[6] have reported that the signal near 2.43 ppm is split into two peaks in dioxane. Both phenomena stated above can be explained by the rate of bond switching in hydrogen bonding between hydroxyimino-hydrogen and two carbonyl-oxygens. In the solution of $CDCl_3$, the bond switching time is shorter than the measurement time. One resonace signal is then obtained in the present case. The tris-complex, Co^{III}(3-hydroxyimino-2,4-pentanedionato)$_3$, exhibits two singlets at 2.40 and 2.79 ppm and the bis-complex, [Co^{III}(3-hydroxyimino-2,4-pentanedionato)$_2$(py)$_2$]ClO$_4$, also gives rise to two singlets at 2.33 and 2.90 ppm. The singlet at 2.33 ppm for the bis-complex is shifted toward higher fields by 0.1 ppm than that of the free ligand and is assigned to the $COCH_3$ protons considering its similarity to the upfield shift of the H^α proton signal in biacetyl monoxime.

The upfield shift of the R′ proton resonance is also confirmed in the PMR spectra of a series of α-hy-

droxyimino ketones with such R′ groups as C_2H_5, *i*-C_3H_7, and *n*-C_3H_7. From the PMR data presented in Tables 2 and 3, it is found that upon complex formation, the amount of the upfield shift for the R′ proton resonances increases in the following order: $H^\alpha < H^\beta < H^\gamma$. On the other hand, the H^b proton signal in $R=CH_3^bCH_2^a$ is shifted to lower fields upon coordination, as expected.

In order to interpret the above upfield shift for the R′ proton resonances, it is proposed that the R′ group in the complex is situated so as to experience a strong shielding effect due to the magnetic anisotropy—the pyridine ring-current. A similar shielding effect has been pointed out for the methylene proton resonance of 1,4-polymethylenebenzene analogues, where the methylene groups are above the phenyl ring.[7] Hill and Morallee[8] have reported that the resonances of the bridging methylene protons are shifted toward higher fields by the axial coordination of pyridine with RCo(bae), where R=an alkyl group and bae=a bis(acetylacetone)ethylenediiminato anion. This upfield shift is attributed to the ring-current effect of the coordinated pyridine. Abott and Martel[9] have shown that the 2-CH_3 signal of the bis(pyridoxylideneserinato)Al(III) complex is found to be as much as 100 Hz higher than that of the 2-CH_3 of the free Schiff base.

It is beyond the aim of this study to describe the conclusive structure of [Co(mo)$_2$(py)$_2$]ClO$_4$.[10] Figure 3 shows the limiting structure for R′=*n*-C_3H_7, where the alkyl group experiences most strongly the shielding effect of the pyridine. The framework molecular model suggests that the free rotation of the R′ group is not restricted sterically. For the 1,2-dioximato chelates, it has been suggested that the d_π-orbitals of the metal interact with both p_π-orbitals of the chelate ligand and the pyridine which perpendicularly coordinates with the metal-chelate plane.[11] It is also possible to expect a similar interaction of the p_π(pyridine)-, d_π(cobalt)-, and p_π(hydroxyiminato nitrogen)-orbitals for the pyridine conformation in [Co(mo)$_2$(py)$_2$]ClO$_4$ given in Fig. 3. Consequently, the pyridine occupies the position in which the pyridine plane is perpendicular to the Co–N(hydroxyiminato nitrogen) bonding. The pyridine plane then faces the R′ group and an upfield shift of the R′ proton resonances is obtained. Because the carbon atom of the hydroxyimino group is sp^2-hybridized, the CH_2^a carbon atom is drawn on the xy-plane.

It is scarcely possible to evaluate the exact distance between the pyridine and the alkyl group of the complex in solution. The vertical distance of the alkyl carbon from the xy-plane is, therefore, estimated using the molecular model framework and is tentatively plotted versus the amount of upfield shift of the R′=$CH_2^aCH_2^\beta$-CH_3^γ proton resonance caused by coordination (Fig. 4). Figure 4 suggests that the shielding effect by the pyridine increases in the order: $H^\alpha < H^\beta < H^\gamma$. The distance between the CH_3 carbon atom and the center of the pyridine ring is about 2.8 Å at its distance of closest approach, as shown in Fig. 3. In the case of 1,4-polymethylenebenzene analogues,[7] it is seen from the molecular model that the methylene carbons are vertically situated at about 2 Å above the phenyl ring.

Table 3. Upfield shift of the R′ proton signal from free ligands caused by complex formation

R	R′[a]	Amount of upfield shift in $CDCl_3$, Hz[b]		
		H^α	H^β	H^γ
CH_3^a	CH_3^a	4		
CH_3^a	$CH_2^aCH_3^\beta$	12	24	
CH_3^a	$CH_2^aCH_2^\beta CH_3^\gamma$	11	22	29
CH_3^a	$CH^\alpha(CH_3^\beta)_2$		19	
CH_3^a	$COCH_3^\beta$		6	

a) For the general formula, refer to Table 1.
b) The data were obtained at 60 MHz.

As summarized in Table 3, upon complex formation, the upfield shift of the H^α or H^β signal for R′=$CH_2^aCH_3^\beta$ is nearly equal to that of the corresponding signal for R′=$CH_2^aCH_2^\beta CH_3^\gamma$. On the other hand, the upfield shift of the H^β signal for R′=$COCH_3^\beta$ (6 Hz) is smaller than that of the H^β signal for R′=C_2H_5 or *n*-C_3H_7 (22 to 24 Hz). This result is interpreted as follows. The H^β protons in $COCH_3^\beta$ are farther from the pyridine than in C_2H_5 and *n*-C_3H_7, because the CH_2^β group is bound to the sp^2-carbonyl carbon atom. The small upfield shift of 6 Hz is obtained as a result of the decrease

in the shielding effect by the pyridine. Compared with the upfield shift of the H^{α} signal for $R'=C_2H_5$ or n-C_3H_7, that of the H^{α} signal for $R'=CH_3^{\alpha}$ is rather small.

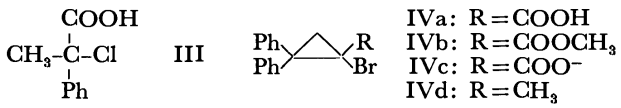
(Received May 1, 1976)

In order to clarify the mechanism of electroreduction of aliphatic halides, optically active 6-chloro-2,6-dimethyloctane(I), in which an (*R*)-(−)-enantiomer was present in excess, was electrolyzed at a mercury cathode in various organic solvents. An (*R*)-(−)-enantiomer was also present in excess in the 2,6-dimethyloctane(II) which was obtained. This result indicates that the reduction of I to II proceeds with an excess of the inversion of the absolute configuration of the starting halide. In this paper, the stereochemistry of a radical intermediate formed at an initial stage in the course of reduction is discussed.

A number of studies of the mechanism of electroreduction of organic halogen compounds have been performed from electrochemical and organic chemical aspects.[1] In recent years there has been a great deal of interest shown in the sterochemistry of the electroreduction of aliphatic halides.[2] Most of studies in this field have dealt with the geometrical isomerism of reactant, intermediate, and/or product, while studies dealing with optical isomerism have been very rare.

Czochralska[3] electrolyzed optically active 2-phenyl-2-chloropropionic acid(III) at a mercury cathode in 90% ethanol containing tertaethylammonium chloride as a supporting electrolyte and obtained optically active 2-phenylpropionic acid, in which the absolute configuration had been inverted, in a high optical yield. At almost the same time, Annino *et al.*[4] also found that the electrolytic reduction of optically active cyclopropyl bromides (IVa—IVd) at a mercury cathode in 95% ethanol are stereochemically controlled by the substituent at the asymmetric carbon. While the reductions of IVa and IVb proceed with the inversion of configuration, the reductions of IVc and IVd proceed with its retention. These facts are very interesting, though the halides used are not typical tertiary alkyl halides.



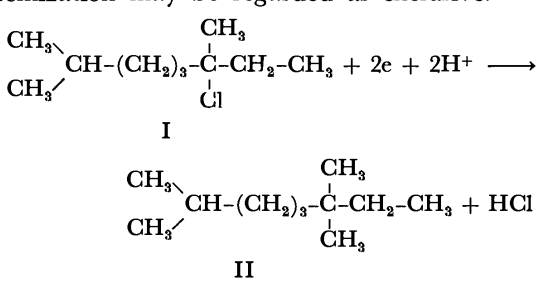
For the first investigation of the substiuent effect, a tertiary halide having as simple as possible substituents should be used. 3-Halo-3-methylhexane is such an alkyl halide, but its optical resolution is very difficult. In this work, (*R*)-(−)-6-chloro-2,6-dimethyloctane(I) derived from natural *l*-linalool was used as the second best sample, because no optical resolution was necessary and the absolute configurations of I and the corresponding alkane were known.

Results and Discussion

Electrolytic results are summarized in Table 1. The electrolytic products consisted of optical isomers of an alkane and a small amount of an optically inactive alkene. The alkane was confirmed to be 2,6-dimethyloctane, in which an (*R*)-(−)-enantiomer is in excess, by its physical properties. On the other hand, although the molecular structure of the alkene(m/e=140) could not be confimed, its retention volume in gas chromatography was equal to that of the dehydration product of tetrahydrolinalool in hot anhydrous formic acid.

The optical rotation of I used in this work was $[\alpha]_D^{23}$ −0.34°. The accurate optical purity could not be estimated because optically pure I has never been prepared. The above value of optical rotation is obtained in the region between 54[5] and 12%[6] of optical purity. On the other hand, the optical rotation of optically pure II is known to be $[\alpha]_D^{20}$ 7.32°.[6] Therefore, the optical yield of II could be shown only by giving its upper and lower limits.

As shown in Table 1, I with $[\alpha]_D^{23}$ −0.34° gave II with minus values of optical rotation, which range from −0.01 to −0.34°, under a variety of electrolytic conditions such as cathode material, solvent, and proton donor. Since I[7] and II[6] with minus values are in (*R*)-configuration, it is concluded that the reduction proceeds with an excess of the inversion of the absolute configuration of I. In the case of a lead cathode, the racemization may be regarded as exclusive.



An essential conclusion drawn from the results of Czochralska[3] was that the electrolytic reduction of alkyl halides proceeds in an S_N2 type mechanism initiated by the attack of an electron to a halogen atom. However, the results of Annino *et al.*[4] cannot be explained by such a mechanism. Since the attack on a halogen is also confirmed through the fact that bridgehead bicyclic halides are reducible at a mercury cathode,[8] there would be no doubt about this point at least in the case of a mercury cathode.

Elving and Pullman[9] generalized the reduction

a) [(optical purity of product)/(optical purity of reactant)]×100%. b) Upper limit—lower limit.

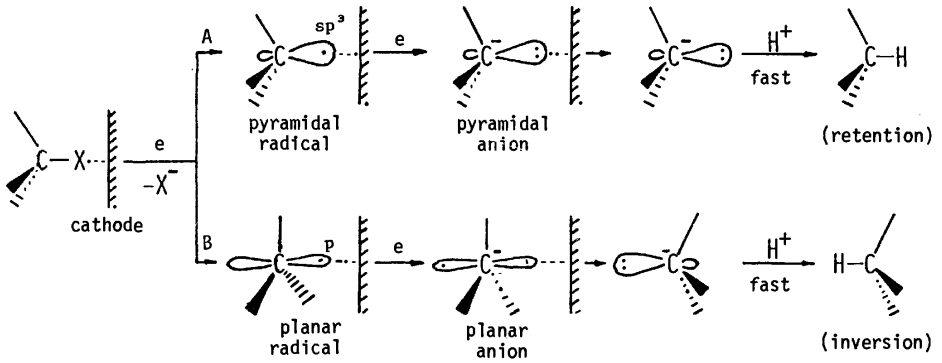

Fig. 1. Schematic mechanisms for the configurational retention and inversion in the electroreduction of alkyl halide to the corresponding alkane.

mechanism of alkyl halides as follows:

$$R\text{-}X \xrightarrow[-X^-]{e} [R\cdot] \xrightarrow{e} [R^-] \xrightarrow{H^+} R\text{-}H$$

where [R·] and [R⁻] represent electrode complexes or adsorbed species on an electrode surface.

The present paper will employ the steric form of a radical derived from a tertiary alkyl halide in order to rationalize the apparently complicated results of the electroreductions of optically active halides such as I, III, and IVa—IVd.

It is well known that the steric form of a carbon radical can vary from being almost completely planar to being pyramidal with the kind of substituent, although the former is energetically more unstable than the latter.[10] While a small alkyl radical, such as the methyl radical, is undoubtedly almost planar,[11] there has been no reliable information about the planarity of a large tertiary alkyl radical such as methylethyl-1-(4-methyl)hexylmethyl radical from I. On the other hand, small cyclic alkyl radicals, especially cyclopropyl radicals, are undoubtedly pyramidal.[12] The planarity of a radical would be favored by substituents having a π-electron system, such as phenyl or carbonyl groups, because of the favorable interaction between the two electron orbitals paralleled to each other: the p orbital of an unpaired electron of the planar radical and the π electron orbital of the substituent.

According to the above viewpoint, the radicals from III, IVa, and IVb would be planar, while the radical from IVd would be pyramidal. The radical from IVc would be planar in a free environment, but it would be pyramidal in the adsorbed state on a cathode surface because of the electrostatic repulsion of a carboxylate anion from a negatively polarized cathode surface. Although the steric form of the radical from I is ambiguous, it may be acceptable that such a radical could be at least a very shallow pyramid, even if not a plane, considering the fact that an optically active staring compound gave a completely racemized product in a homogeneous reaction involving methylethyl-1-(2-methyl)propylmethyl radical, which resembles the radical from I, as an intermediate.[13] The configurational stability of the radical would be increased by the adsorption on an electrode or by the formation of an electrode complex. Generally, a carbanion is configurationally more stable than the corresponding radical. The stability of a carbanion would be increased by a counter cation in the immediate vicinity, while it would be decreased by solvation, especially of the solvent insertion type, to the cation.

As shown in Fig. 1, a pyramidal radical would result in a carbanion which retained its configuration by the introduction of the second electron to the sp^3 orbital of an unpaired electron. On the other hand, the introduction of the second electron to the p orbital of a planar radical would intermediately give a very unstable planar carbanion, which would be immediately converted into an ordinary carbanion having the inverted pyramidal from. This inversion is thought to be due to a steep potential gradient in the immediate

vicinty of the cathode. Figure 1 illustrates extreme cases where either retention or inversion occurs exclusively.

In conclusion, it can be actually supposed that the path "B" is slightly predominant in the reduction of I, since the radical intermediate is not a complete plane but a shallow pyramid. Steric hindrance between the three alkyl groups and a cathode is alleviated in a pyramidal radical. Also, the path "B" is more predominant in the cases of III, IVa, and IVb, since their radicals are almost planar even on a cathode. One reason for being planar may be that the p-π interaction described previously is so strong that the contribution of the steric hindrance is more than canceled. In the cases of IVc and IVd, the path "A" is predominant, since nothing causes the corresponding cyclopropyl radicals to be planar.

While the steric configuration of the alkane formed would be mainly controlled by the steric form of an intermediate radical on a cathode, the optical yield would be controlled not only by the configurational stabilities of the radical and the carbanion intermediates but also by the protonation rate of the latter. The fact that proton donors such as acetic acid and triethylamine hydrobromide added in ethanolic catholyte increased the optical yield may partially support the above discussion.

The solvent effect on the optical yield of II can be explained as due to the difference of the proton-donating force to the carbanion intermediate, except for the case of DMF. The reduction in DMF afforded II with an optical rotation equal to one in the case of methanol, though DMF is not only weaker in proton-donating force but also stronger in solvating force to a counter cation of the carbanion intermediate than methanol. There has been no clear explanation of the solvent effect.

Experimenatl

(R)-(−)-6-Chloro-2,6-dimethyloctane(I). I was prepared from a commercial natural *l*-linalool with $[\alpha]_D^{23}$ −14.0° (lit,[6] $[\alpha]_D^{20}$ −14.47°), by the literature method.[6] Bp 83—84 °C/15 Torr (lit,[6] 90.2—91.3 °C/21 Torr), n_D^{25} 1.4342 (lit,[6] 1.4346), and $[\alpha]_D^{23}$ −0.34° (lit,[6] $[\alpha]_D^{25}$ −0.42°).

Electrolytic Procedure. An H-type cell divided by a sintered glass diaphragm was used. The cathode was a mercury pool (diameter, 4 cm) or a lead plate (4×3 cm). The catholyte and the anolyte were 50 ml of dried organic solvent(methanol, ethanol, DMF, or acetonitrile) containing 9.95 g of tetraethylammonium chloride as a supporting electrolyte. After nitrogen gas was introduced to the catholyte for one hour in order to remove the oxygen in the solvent, 2.65 g (0.015 mol) of I, and also 0.01 mol of a proton donor (acetic acid or triethylamine hydrobromide) if necessary, were added to the catholyte. A constant current was supplied, which was turned off when the cell voltage rose to above 20 V or when vigorous hydrogen evolution was observed. The temperature of the catholyte was maintained below 20 °C during the electrolysis.

Analysis and Isolation of 2,6-Dimethyloctane. After the electrolysis a large volume of water was added to the catholyte. The separating oil was extracted with ether and the ether extract was dried with anhydrous sodium sulfate. The ethereal solution was analyzed by gas chromatography (apeazone grease L, 100 °C). In the gas-chromatogram, three peaks (corresponding to II, alkene, and unreacted I) appeared.

After the gas chromatographic analysis, the ethereal solution was shaken with concentrated sulfuric acid in order to remove the alkene. The ethereal solution was concentrated by evaporation and the residual oil was distilled under reduced pressure. Gas-chromatographically pure II was obtained as the main fraction: bp 60—62 °C/30 Torr (lit,[6] 99—100 °C/121 Torr); n_D^{25} 1.4091 (lit,[6] 1.4087); mass spectrum (*m/e*) 142(M^+); IR spectrum(cm^{-1}) 2880, 1460, and 1375 as principal absorption bands. No absorption band appeared at 1653 or 888 cm^{-1} related to a double bond in terminal position.[6]

The optical rotation was measured in ethanol by Perkin-Elmer Micro-Polarimeter Model 141.

The authors with to express their thanks to Dr. T. Fuchigami of the Tokyo Institute of Technology for his helpful discussion.

Synthesis of Tuftsin and Its Analogs

Sukekatsu NOZAKI, Kazuhito HISATSUNE, and Ichiro MURAMATSU*

Department of Microbiology, Faculty of Pharmaceutical Sciences, Josai University, Sakado, Saitama 350-02

**Department of Chemistry, College of Science, Rikkyo University, Nishi-Ikebukuro, Tokyo 171*

(Received June 17, 1976)

Tuftsin, a phagocytosis stimulating peptide, was synthesized according to a liquid phase method together with its four analogs, H-Thr-Arg-Pro-Arg-OH (**2**), H-Thr-Lys-Pro-Lys-OH (**3**), H-Thr-Arg-Pro-Lys-OH (**4**), and H-Arg-Pro-Lys-Thr-OH (**5**).

Tuftsin (**1**), a tetrapeptide containing two basic amino acids, lysine and arginine, was isolated from the enzymatic digest of γ-globulin[1] and synthesized according to Merrifield's solid phase method by Nishioka *et al.*[2] They also synthesized two analogs of **1** lacking N- or C-terminal amino acid of the original peptide, *viz.*, H-Lys-Pro-Arg-OH and H-Thr-Lys-Pro-OH, and another analog having an additional proline, H-Thr-Lys-Pro-Pro-Arg-OH.[3] None of these analogs exhibited the phagocytosis stimulating activity, but the pentapeptide, H-Thr-Lys-Pro-Pro-Arg-OH, strongly inhibited tuftsin activity. This indicates that a certain restriction of the primary structure is required for biological activity to appear. However, the relationship between structure and activity is still unclarified. In order to investigate the effect of the replacement of lysine by arginine, or arginine by lysine, we synthesized the following tuftsin analogs (**2**—**5**) as well as **1** by a liquid phase method. **2**, *i.e.*, [2-arginine]-tuftsin, and **3**, *i.e.*, [4-lysine]-tuftsin are analogs in which either one of the two basic amino acids is replaced by the other. **4**, *i.e.*, [2-arginine, 4-lysine]-tuftsin has a sequence in which the positions of lysine and arginine are exchanged. **5**, the analog with the retro sequence of **1**, was also synthesized in order to see the effect of alternation of the primary structure.

The synthesis of **1** and its analogs is summarized in Charts 1—5. Benzyl ester was employed for the protection of carboxyl functions of C-terminal amino acids. In each step of the peptide elongation, *t*-butoxycarbonyl amino acids were used as the acylating reagent except in the final stages of the elongation. The *t*-butoxycarbonyl group was removed by HCl/THF or trifluoroacetic acid treatment prior to the next coupling. The ε-amino group of lysine and the guanidyl group of arginine were protected by benzyloxycarbonyl and nitro group, respectively. A mixed anhydride method was employed for the coupling reaction except at the introduction of N^{α}-*t*-butoxycarbonyl, N^{g}-nitro arginine, when the dicyclohexyl carbodiimide/*N*-hydroxy-1*H*-benzotriazole method[4] was used. Some of the intermediates were obtained as oily substance with a trace of impurities detectable

on TLC. However, no further trials for crystallization nor purification were carried out, since an ion exchange chromatography was expected to be effective for the purification of the basic peptides finally obtained. In the final stages of the construction of the peptides, benzyloxycarbonyl amino acids were used for acylation. The protected tetrapeptides were hydrogenated in the presence of palladium black in order to remove all the blocking groups.

The resulting free peptides were purified by carboxymethyl cellulose (Serva, or Whatman CM-52) chromatography using a linear gradient of ammonium acetate buffer (0—0.4 M, pH 7.0). **2** and **3** could be purified satisfactorily, but not the other analogs or **1**. The latter peptides gave no reasonable results on amino acid analysis after acid hydrolysis, although each of them showed individually a single spot on TLC (Avicel-cellulose, 1-butanol–pyridine–acetic acid–water, 16 : 10 : 3 : 12) and electrophoresis (Avicel-cellulose, pH 1.9, 40 V/cm). All efforts to remove the impurities by the carboxymethyl cellulose column were unsuccessful. Further purification of **4**, **5**, and **1** was successfully carried out on a Dowex 50 W×4 column with a linear gradient of pyridinium acetate buffer (0.6—2.0 M, pH 4.2—6.1). The highly purified products were desalted by a Biogel P-2 column and were lyophilized to give hygroscopic solids.

Phagocytosis stimulating activities of the synthetic peptides were measured according to the literature.[5] Compounds **2**, **3**, **4**, and **1** showed biological activity. For the appearance of biological activity, some alternation might be allowed in the primary structure of tuftsin, where the basic amino acids at positions 2 and 4 are exchangeable with each other without abolishing the biological potency.

Experimental[6]

Amino acid analyses were carried out with a JLC-6AS automatic analyzer (JEOL) after acid hydrolysis in HCl of constant bp (110 °C, 16 h). The theoretical values of amino acid ratios are shown in parentheses after each result. In TLC, Merck silicagel-precoated plate (S) and Avicel cellulose-precoated plate (C) were used with the following solvent systems: chloroform–methanol, 99 : 1 (a), 98 : 2 (b), 95 : 5 (c), 90 : 10 (d); 1-butanol–acetic acid–water 4 : 1 : 1 (e); 2-butanol–7M ammonia–ethanol, 1 : 4 : 2 (f), 1-butanol–pyridine–acetic acid–water, 16 : 10 : 3 : 12 (g). All the R_f values are the results of TLC. The properties and analytical results of the intermediates obtained in solid are as follows: Boc–Arg(NO_2)–Pro–Arg(NO_2)–OBzl: mp 89—111 °C, yield 65%, R_f (S, c) 0.34. $[\alpha]_D^{24}$ −31.1° (*c* 1.00, DMF). Found: C, 48.95; H, 6.64; N, 21.37%. Calcd for $C_{29}H_{45}O_{10}N_{11}$; C, 49.22; H, 6.41; N, 21.77%. Boc–Thr–Arg(NO_2)–Pro–Arg(NO_2)–OBzl (**6**); mp 88—124 °C, yield 92%, R_f(S, d) 0.50. $[\alpha]_D^{19}$ −29.0° (*c* 1.00, DMF). Found: C, 50.50; H, 6.13; N, 19.61%. Calcd for $C_{36}H_{50}O_{12}N_{12}\cdot H_2O$: C, 50.23; H, 6.09; N, 19.52%. The following intermediates were obtained as oily products and were used without crystallization (yield, R_f).

Boc-Pro–Arg(NO_2)–OBzl: 98%, (S, e) 0.44. Boc–Pro–Lys(Cbz)–OBzl: 95%, (S, a) 0.48. Boc–Lys(Cbz)–Pro–Lys(Cbz)–OBzl: 74%, (S, a) 0.19. Cbz–Thr–Lys(Cbz)–Pro–Lys(Cbz)–OBzl (**7**): 85%, (S, b) 0.29, (S, c) 0.82. Boc–Arg(NO_2)–Pro–Lys(Cbz)–OBzl: 100%, (S, c) 0.79. Cbz–Thr–Arg(NO_2)–Pro–Lys(Cbz)–OBzl (**8**): 90%, (S, c) 0.30. Boc–Lys(Cbz)–Thr–OBzl: 99%, (S, b) 0.70. Boc–Pro–Lys(Cbz)–Thr–OBzl: 98%, (S, b) 0.33. Cbz–Arg(NO_2)–Pro–Lys(Cbz)–Thr–OBzl (**9**): 85%, (S, c) 0.36. Boc–Lys(Cbz)–Pro–Arg(NO_2)–OBzl: 68%, (S, c) 0.49. Cbz–Thr–Lys(Cbz)–Pro–Arg(NO_2)–OBzl (**10**): 90%, (S, c) 0.41.

Preparation of **1**. **10** (12.0 g) was hydrogenated in a mixture of DMF (100 ml), water (20 ml) and acetic acid (3.5 ml) in the presence of Pd black. After hydrogenation for 12 h, the mixture was diluted with additional solvent; DMF (200 ml), water (50 ml) and acetic acid (3 ml). Hydrogenation was continued for 17 h more, the catalyst being removed after the addition of DMF (300 ml). The solvent was evaporated *in vacuo* and the residue was dissolved in water. The water-insoluble parts were removed by filtration. A half of the filtrate was applied to a CM-cellulose (Serva) column (3.7×42 cm), which was eluted with a linear gradient of ammonium acetate (pH 7.0, 0—0.4 M, 800 ml each). The fractions from 1092 ml to 1248 ml were combined, concentrated and desalted by means of a Biogel P-2 column (3.5×35 cm, 4% acetic acid). Lyophilization of the desalted fractions gave 1.01 g of the product. A part of the product was applied to a Dowex 50 W×4 column (2.2×30 cm), which was eluted with a linear gradient of pyridinium acetate

(0.6 M pyridine, pH 4.2—2.0 M pyridine, pH 6.1, 800 ml each). The fractions from 954 ml to 1425 ml were combined, desalted by means of Biogel column (3.5×35 cm) and lyophilized. R_f(S, f) 0.28, (C, g) 0.20. $[\alpha]_D^{24}$ −60.5° (*c* 0.95, 5% acetic acid). (lit,[7] $[\alpha]_D^{22}$ −60.8°, 5% acetic acid). Amino acid ratios: Thr 1.01 (1), Pro 0.99 (1), Lys 1.02 (1), Arg 0.97 (1).

Found: C, 47.36; H, 8.00; N, 17.27%. Calcd for $C_{21}H_{40}O_6N_8 \cdot 2CH_3COOH \cdot H_2O$: C, 47.01; H, 7.89; N, 17.54%.

Preparation of ***2***. **6** (0.50 g) was hydrogenated on a mixture of ethanol (60 ml), water (60 ml) and 1 M acetic acid (6 ml) in the presence of Pd black. After removal of the catalyst, the solvent was evaporated *in vacuo*. The crude tetrapeptide obtained was applied to a CM-cellulose (Whatman CM-52) column (2.0×44 cm), which was eluted with a linear gradient of ammonium acetate (pH 7.0, 0—0.4 M, 400 ml each). The fractions from 470 ml to 520 ml were combined and concentrated. After being desalted with Biogel P-2 column (3.5×35 cm) and lyophilized, 0.22 g of the desired peptide was obtained. R_f (S, f) 0.04, (C, g) 0.27, (S, g) 0.12. $[\alpha]_D^{24}$ −56.6° (c 0.90, 5% acetic acid). Amino acid ratios: Thr 1.06 (1), Pro 0.96 (1), Arg 1.98 (2).

Found: C, 45.22; H, 7.83; N, 20.58%. Calcd for $C_{21}H_{40}O_6N_{10} \cdot 2CH_3COOH \cdot H_2O$: C, 45.04; H, 7.56; N, 21.01%.

Preparation of ***3***. **7** was treated in a way similar to that for the preparation of **2**, CM-cellulose (Serva) being used in the ion exchange chromatography. R_f (S, f) 0.57, (C, g) 0.21, (S, g) 0.10. $[\alpha]_D^{24}$ −66.7° (*c* 1.02, 5% acetic acid). Amino acid ratios: Thr 1.01 (1), Pro 0.95 (1), Lys 2.04 (2).

Found: C, 49.30; H, 8.66; N, 13.55%. Calcd for $C_{21}H_{40}O_6N_6 \cdot 2CH_3COOH \cdot H_2O$: C, 49.17; H, 8.25; N, 13.76%.

Preparation of ***4***. **8** was hydrogenated in a mixture of ethanol, water and acetic acid. The product was purified as in the preparation of **1**. R_f (S, f) 0.27, (C, g) 0.19. $[\alpha]_D^{24}$ −62.6° (*c* 0.92, 5% acetic acid). Amino acid ratios: Thr 0.99 (1), Pro 1.00 (1), Lys 1.00 (1), Arg 1.00 (1).

Found: C, 47.02; H, 8.19; N, 17.25%. Calcd for $C_{21}H_{40}O_6N_8 \cdot 2CH_3COOH \cdot H_2O$: C, 47.01; H, 7.89; N, 17.54%.

Preparation of ***5***. **9** was treated as described in the preparation of **4**. R_f (S, f) 0.26, (C, g) 0.25, (S, g) 0.04. $[\alpha]_D^{24}$ −58.0° (*c* 0.87, 5% acetic acid). Amino acid ratios: Thr 0.99 (1), Pro 1.00 (1), Lys 1.02 (1), Arg 0.98 (1).

Found: C, 47.14; H, 7.79; N, 17.56%. Calcd for $C_{21}H_{40}O_6N_8 \cdot 2CH_3COOH \cdot H_2O$: C, 47.01; H, 7.89; N, 17.54%.

The authors are indebted to the members of Research Laboratories of Toyo Jozo Co., Ltd. for the elemental analyses. They also thank Miss Keiko Kobayashi for the biological measurement, Mr. Yoshiaki Motoki for the amino acid analyses and to Mr. Yuji Watanabe for his assistance.

Carbon-Nitrogen Bond Fission in Ureas and Thioureas. Preparation of Alkyl and Aryl Isothiocyanates Using Carbon Disulfide and Butyllithinm or a Grignard Reagent

Shizuyoshi SAKAI, Tatsuo FUJINAMI, and Toshiyuki AIZAWA

Department of Industrial Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu 432

(Received July 1, 1976)

The carbon-nitrogen bond in *N,N'*-diaryl- and dialkyl-thioureas or -ureas was easily cleaved by the metallation of thioureas or ureas using butyllithium, followed by the addition of an excess of carbon disulfide or 1,3-dithiolan-2-thione in tetrahydrofuran under reflux, to afford about two mol of the corresponding isothiocyanates per mol of the thioureas or ureas used. Instead of butyllithium, ethylmagnesium bromide was also effective in such a type of carbon-nitrogen bond fission of the (thio)ureas in refluxing tetrahydrofuran, and in this case the addition of carbon disulfide was not required. To explain these results, a six-centered decomposition of the dilithium salt of *N*-dithiocarboxy(thio)urea in the reaction using butyllithium was tentatively proposed, while a four-centered mechanism seems applicable to the reaction using ethylmagnesium bromide.

The carbon-nitrogen bond in ureas or thioureas is difficult to cleave. In many instances, extreme conditions such as thermal decomposition with or without very concentrated acid have been applied. In such cases, the yield of isothiocyanate (**2**) is, in principle, less than one mol from one mol of **1**, and the reported yield of **2** is rather low (based on Eq. 1).[1]

$$\underset{\mathbf{1}}{\mathrm{RNHCSNHR}} \xrightarrow{\Delta} \underset{\mathbf{2}}{\mathrm{RNCS}} + \underset{\mathbf{3}}{\mathrm{RNH_2}} \qquad (1)$$

We have previously established a novel method for the preparation of aryl and alkyl isothiocyanates under moderate reaction conditions using amine, carbon disulfide, and butyllithium or a Grignard reagent.[2,3] The scheme for the reaction was proposed (Eq. 2; X=S)[2]:

$$\underset{\mathbf{3}}{\mathrm{RNH_2}} \xrightarrow[2)\ \mathrm{CSX}]{1)\ \mathrm{BuLi}} \underset{\mathbf{4}}{\mathrm{RNHC(S)XLi}} \xrightarrow{\mathrm{BuLi}} \underset{\mathbf{5}}{\mathrm{RN(Li)C(S)XLi}} \xrightarrow{\mathrm{CS_2}} \mathrm{RNCS} + \mathrm{Li_2CS_2X} \qquad (2)$$

An anologous type of reaction for *N,N'*-substituted thiourea (X=NR in **5**) appear to be an interesting process for carbon-nitrogen bond fission, affording two mol of isothiocyanate from 1 mol of thiourea. In this report, we will describe a new method for the preparation of isothiocyanates by breaking the carbon-nitrogen bond in *N,N'*-disubstituted thioureas or ureas using butyllithium or a Grignard reagent, and carbon disulfide or 1,3-dithiolan-2-thione in anhydrous tetrahydrofuran (THF). Moreover, the reaction using butylithium will be compared with that using ethylmagnesium bromide from several mechanistic points of view.

Results and Discussion

Preparation of Isothiocyanates Using Butyllithium. *N,N'*-Dilithio-*N,N'*-diphenylthiourea (**7**; R=Ph), directly prepared from one mol of thiourea and two mol of butyllithium, was reacted with an excess of carbon disulfide for 3 h under a refluxing temperature of THF to give 1.45 mol of phenyl isothiocyanate (72% yield, based on Eq. 3; Direct Method). The yield of isothiocyanates obtained from various thioureas are summarized in Table 1.

$$\underset{\mathbf{7}}{\mathrm{RN(Li)C(S)N(Li)R}} + \underset{\mathbf{8}}{2\mathrm{CS_2}} \longrightarrow \underset{\mathbf{2}}{2\mathrm{RNCS}} + \underset{\mathbf{9}}{\mathrm{Li_2CS_3}} \qquad (3)$$

The results in Table 1 indicate that aromatic isothiocyanates were easily obtained by the distillation of the reaction mixture of the aryl-substituted ureas (**7**; R=arom.) with **8**. On the contrary, the yields of aliphatic isothiocyanates were low in the corresponding reactions of alkyl-substituted thioureas (**7**; R=aliph.) with **8**, and some amounts of the corresponding carbodiimides were found to be formed under the reaction conditions used.

Furthermore, the yields of isothiocyanates were increased when butyllithium and **8** were added step-by-step to the solution of the thiourea (Step-by-step Method): the *mono*-lithiothiourea formed by the reaction of **1** with one mol of butyllithium reacted with one mol of **8** with a slight exotherm, and the reaction mixture was treated with the second mole of butyllithium, followed by a reaction with **8** under reflux (see Note c in Table 1). The better results were obtained probably because of the higher degree of metallation of **1** needed to form **10a** or **10b**. The

Table 1. Yields of isothiocyanates (RNCS) from the reaction of thioureas ($(RNH)_2CS$), butyllithium, and carbon dislfide[a]

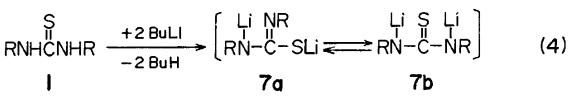
Thiourea R in thiourea	Yield of RNCS %	Bp °C/Torr	$\nu_{N=C=S}$ cm^{-1}
C_6H_5	73 (93)[c]	95—100/ 5	2070
o-$CH_3C_6H_4$	82	104—105/10	2070
p-$CH_3C_6H_4$	73	105—108/10	2070
2,6-$(CH_3)_2C_6H_3$	91	114—116/10	2080
α-Naphthyl	82[c]	108—112/0.1	2090
C_2H_5	40	72— 74/100	2090
$(CH_3)_3C$	43[d]	73— 76/50	2090
Cyclohexyl	41[d]	73— 74/20	2090

a) The *N,N'*-dilithiothiourea, prepared *in situ* using two mol of butyllithium, was reacted with mol of carbon disulfide for 3 h in refluxing THF (Direct Method). b) Based on Eq. 3. c) The yield obtained by the Step-by-step Method (see Experimental). d) Accompanied by the formation of carbodiimide.

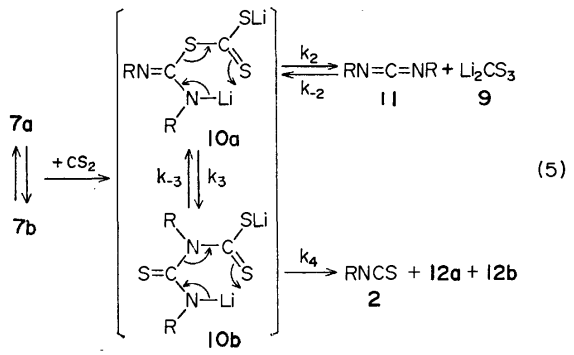
results from other thioureas by the Step-by-step Method are shown in Table 1.

To discuss the reaction course, the reaction of *N,N'*-di(*o*-tolyl)thiourea was precisely examined. The thiourea was treated with an equivalent of butyllithium to evolve one mol of butane, suggesting the formation of *N*-lithio-*N,N'*-di(*o*-tolyl)thiourea. The reaction mixture was allowed to react with one mol of carbon disulfide at room temperature with a slight exotherm, followed by a reaction with the second mole of butyllithium to evolve about one mol of butane. The total amount of butane evolved during the metallation reactions was almost twice the amount of **1** used. The reaction mixture was then stirred below room temperature to afford a heterogeneous solution containing the carbodiimide **11** (R=*o*-tolyl) and dilithium trithiocarbonate **9**.[4] The formation of carbodiimide was also observed in the initial stage of the reaction by the Direct Method below room temperature. The carbodiimide (**11**; R=*o*-tolyl) was separated from dilithium trithiocarbonate[4] by filtration. However, without filtration, a heterogeneous reaction mixture containing **11** and **9** was heated under reflux for 3 h to give a homogeneous solution. It showed the characteristic $\nu_{N=C=S}$ band of the isothiocyanate (**2**; R=*o*-tolyl) at 2070 cm^{-1}. The reaction mixture was subsequently distilled to afford **2** (R=*o*-tolyl) and a residue, which reacted with 1,2-dibromoethane in THF to form 2-(*o*-tolylimino)-1,3-dithiolane. The detection of the latter suggests the reaction of **12a** with 1,2-dibromoethane. Compound **12a** (or **12b**) has been reported to react rapidly with **8** below room temperature to afford **2** and **9**.[4]

Judging from these results, it seems that the reaction by the Step-by-step or Direct Method probably proceed *via* **10a** to form **11** and **9** in the initial stage of the reaction below room temperature. However, in the final stage of the reaction at room temperature or under reflux in THF, **11** and **9** will be converted to **2** and **12a** (or **12b**), probably *via* **10a** or **10b**. The unstable intermediates, **10a** and **10b**, could not be characterized, but their identification is supported by the fact that **11** (R=*o*-tolyl) reacted with **9** for 4 h under reflux to give **2** in an almost quantitative yield. In the next step, **12a** (or **12b**) reacted with **8** to afford **2** and **9**. The reaction course are tentatively shown by Eqs. 4, 5, and 6.



(4)

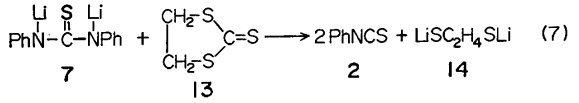


(5)

(6)

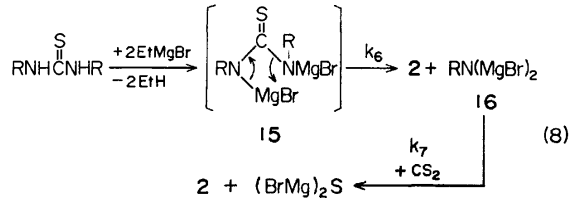
The fact that the characteristic $\nu_{N=C=N}$ band appeared in the initial stage of all the reactions using both the Direct and Step-by-step Methods below room temperature suggests that the rate constant, k_2, in Eq. 5 is much larger than k_4 or k_{-2}. From **7a** (or **7b**) with bulky groups, such as *o*-tolyl, 2,6-xylyl, or cyclohexyl, the corresponding carbodiimide, **11**, was isolated, probably because of a steric effect (smaller k_{-2}), while only **2** was isolated in the reaction of **7a** (or **7b**) with less bulky groups, such as phenyl or *p*-tolyl, probably because of the larger k_{-2} value.

In the reaction of Eq. 3, 1,3-dithiolan-2-thione was also used instead of carbon disulfide. It reacted with an equivalent amount of **7** (R=Ph) for 5 h in THF under reflux to afford phenyl isothiocyanate in a 67% yield (Eq. 7).



(7)

Preparation of Isothiocyanate Using Ethylmagnesium Bromide. The thermal decomposition of the dilithiothiourea **7**, (R=Ph), did not afford **2** but small amount of diphenylcarbodiimide and a resinous product were found to be formed. On the other hand, *N,N'*-bis(bromomagnesio)-*N,N'*-diphenylthiourea **15** (R=Ph) was thermally decomposed at about 140 °C to afford the isothiocyanate (**2**; R=Ph; 35% yield) and the *N,N'*-bis(bromomagnesio)amine **16**, which reacted exothermically with carbon disulfide to give an additional yield of **2** (38%). Table 2 shows the results of the reaction of **15** with an excess amount of carbon disulfide. The yields were moderate, but the purity of the isothiocyanates obtained was better than when butyllithium was used.



(8)

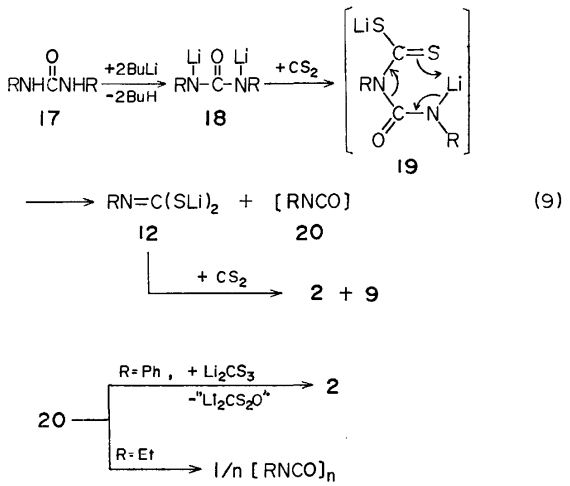
Table 2. Yields of isothiocyanates from the reaction of thioureas, ($(RNH)_2CS$), ethylmagnesium bromide, and carbon disulfide

Thiourea	Reaction condition		Yield of RNCS
R in thiourea	Temp/°C	Time/h	%[b]
C_6H_5	a	40	65
p-$CH_3C_6H_4$	a	8	51
C_2H_5	a	34	48

a) The *N,N'*-bis(bromomagnesio)thiourea, prepared *in situ* using two mol of EtMgBr, was reacted with an excess of carbon disulfide in refluxing THF. b) Based on Eq. 8.

As has already been mentioned, dilithio-thiourea was easily decomposed by the addition of carbon disulfide, while the thermal decomposition of bis-(bromomagnesio)-compound (k_6 in Eq. 8) was not accelerated by the addition of carbon disulfide. However, the carbon disulfide used in the following step (k_7) is effective in improving the yield of **2**. These results suggest that **15** is thermally decomposed *via* a four-centered mechanism to give **2** and **16**, which is then converted to **2** by the action of the added carbon disulfide, as was shown in Eq. 8.

Carbon-Nitrogen Bond Fission of Urea. Carbon-nitrogen bonds are generally stable. However, we found that these bonds are easily cleaved by the reaction of carbon disulfide and butyllithium or a Grignard reagent in anhydrous THF. For example, *N,N'*-diphenylurea was allowed to react with two mol of butyllithium to form the *N,N'*-dilithio-derivative, **18** (R=Ph), and butane. Compound **18** was treated with an excess of carbon disulfide for 30 min in THF at room temperature. The reaction mixture showed the characteristic band of isothiocyanate at 2090 cm^{-1}. After the reaction mixture had been refluxed for 3 h, phenyl isothiocyanate, **2**, was obtained in an 80% yield (based on Eq. 9).



In the reaction of aryl ureas, the corresponding isothiocyanates were formed in good yields, because aryl isocyanates reacted with dilithium trithiocarbonate to form isothiocyanates. Thus, two mol of **2** (R=Ph) was obtained from one mol of *N,N'*-diphenylurea. On the other hand, the yield of ethyl isothiocyanate was low in the reaction of an alkyl-substituted urea, $(EtNH)_2CO$, probably because of the base-catalyzed oligomerization of the ethyl isocyanate formed as an intermediate. At present, the mechanism of carbon-nitrogen bond fission in urea may tentatively depicted analogously to the case of thiourea.

A Grignard reagent, EtMgBr, was sometimes used in the carbon-nitrogen bond fission in alkyl- and aryl-substituted ureas instead of the butyllithium shown in Eq. 9, but the yields of isothiocyanates were low.

Experimental

All the melting and boiling points are uncorrected. The IR and NMR spectra were recorded with a JASCO IRA-1 spectrometer, and a Hitachi Perkin-Elmer R-24 spectrometer, respectively. The *N,N'*-disubstitued thioureas (**1**; $(RNH)_2CS$) used were prepared mainly from amines and carbon disulfide by the reported methods[5-7]; mp (R): 154—155 (Ph), 160—163 (*o*-tolyl), 189—190 (*p*-tolyl), 230—232 (2, 6-xylyl), 206—207 (α-naphtyl), 131—132 (*t*-butyl), and 187—188 °C (cyclohexyl). The 1, 3-dithiolan-2-thione (**13**),[8] butyllithium in petroleum ether, and ethylmagnesium bromide in THF were prepared by the usual methods. The ureas, thioureas, carbon disulfide, 1, 2-dibromoethane, and THF were dried before use. All the reactions were carried out under a dry nitrogen atmosphere.

Reaction of Carbon Disulfide with N,N'-*Dilithio*-N,N'-*diphenylthiourea (7; R=Ph) (Direct Method).* In a flask equipped with a mechanical stirrer, a condencer, a dropping funnel, and a nitrogen inlet, butyllithium (60 mmol) was slowly introduced into a solution of the thiourea (**1**; R=Ph; 6.3 g, 27 mmol) in THF (50 cm^3) under cooling with a water bath to form, directly, **7** (R=Ph). Carbon disulfide (4.5 g; 60 mmol) was then added to the solution and the mixture was refluxed for 3 h. After the evaporation of the solvent, the residue was distilled in a vacuum to afford phenyl isothiocyanate (**2**: R=Ph) in a 72% yield (5.3 g, 39 mmol); bp 95—100 °C/15 Torr. The IR and NMR spectra coincided well with those of an authentic sample.[3] The results for other thioureas are summarized in Table 1.

Step-by-step Reaction of N,N'-*Di*-o-*tolylthiourea (1; R=o-*$CH_3C_6H_4$*) with Butyllithium and Carbon Disulfide (Step-by-step Method).* *N,N'*-Di-*o*-tolylthiourea (**1**; R=*o*-$CH_3C_6H_4$; 6.3 g, 27 mmol in 50 cm^3 of THF) was allowed to react with butyllithium (30 mmol), accompanied by the evolution of butane (28 mmol). To the solution of the *mono*-lithio thiourea thus prepared, carbon disulfide (2.2 g, 30 mmol in 3 cm^3 of THF) was added slowly under cooling with an ice bath. The homogeneous reaction mixture was subsequently treated again with an additional amount of butyllithium (30 mmol) at room temperature, thus evolving more butane (25 mmol). The total amount of butane formed in the metallation reaction was twice the amount of thiourea used. However, the structure of the unstabe intermediate (or trandition state), **10a** or **10b**, could not be established even by spectroscopic methods such as IR and NMR. After the addition of butyllithium for 10 min, the reaction mixture became a heterogeneous solution to form **11** (R=*o*-$CH_3C_6H_4$) and **9**,[4] the former being detected by the $\nu_{N=C=N}$ band at 2145 cm^{-1} in the IR spectrum of the mixture. In the following step, carbon disulfide (2.2 g, 30 mmol) was added to the heterogeneous solution and the mixture was stirred for 30 min at room temperature to give a semi-transparent solution, which showed the $\nu_{N=C=S}$ band of **2** (R=*o*-$CH_3C_6H_4$) at 2070 cm^{-1} and the $\nu_{N=C=N}$ band of **11** at 2145 cm^{-1}. The mixture was heated for further 3 h to convert the **11** to **2**. After the evaporation out of the solvent of THF and petroleum ether the residue was distilled under a vacuum to afford *o*-tolyl isothiocyanate in a 92% yield (6.8 g, 50 mmol).

*Reaction of 8 with 12 (R=*o-$CH_3C_6H_4$*) Prepared* in situ. A heterogeneous solution containing **11** and **9** was prepared from *N,N'*-di-*o*-tolylthiourea (**1**; R=*o*-$CH_3C_6H_4$; 6.3 g; 27 mmol), butyllithium (30+30 mmol), and carbon disulfide (30 mmol) by the Step-by-step Method described above; when it was then heated for 3 h, the mixture became almost homogeneous. After evaporation of the solvent, the mixture was distilled to afford **2** (3.7 g, 25 mmol) and a residue containing **12** (R=*o*-$CH_3C_6H_4$). After the residue had been treated with an excess of carbon disulfide with an exotherm, the distillation of the reaction mixture gave **2** (3.4 g, 23 mmol) and **9**. The latter was detected by the IR method ($\nu_{CS_3}{}^{-2}$

935 cm^{-1}).

Detection of **12** *(R=o-$CH_3C_6H_4$).* The distillation residue containing **12**, prepared by the method described above, was treated with an excess of 1,2-dibromoethane to form 2-(*o*-tolylimino)-1,3-dithiolane, which was identified by a comparison of its IR and NMR spectra with those of an authentic sample.[9]

Reaction of Carbodiimide (R=o-$CH_3C_6H_4$) with **9**. Compound **11** (R=*o*-$CH_3C_6H_4$; 3.4 g) was allowed to react with powders of anhydrous dilithium trithiocarbonate (**9**; 30 mmol, 3.7 g) for 3 h under reflux of THF containing carbon disulfide (20 cm^3); the reaction mixture was then distilled to give **2** (R=*o*-$CH_3C_6H_4$) in an almost quantitative yield (6.1 g, 90%).

Reaction of Carbon Disulfide with N,N'-*Dilithio*-N,N'-*di-t-butyl)thiourea (7; R=$(CH_3)_3C$).* Compound **7** (R=$(CH_3)_3C$); 25 mmol), prepared *in situ* by the Direct Method, was allowed to react with carbon disulfide (4.0 g, 55 mmol) in THF under reflux, after which the mixture was distilled to afford *t*-butyl isothiocyanate (2.5 g, 43%) and di-*t*-butylcarbodiimide (1.0 g, 25%); bp 70—72 °C/10 Torr; IR (neat) 2094 cm^{-1} ($\nu_{N=C=N}$); NMR (CCl_4) δ=1.20 ppm (s, 18, CH_3).

Reaction of Dithiolan-2-thione with N,N'-*Dilithio*-N,N'-*Diphenylthiourea (7; R=Ph).* Compound **7** (R=Ph; 45 mmol) was allowed to react with 1,3-dithiolan-2-thione (**13**; 6.1 g, 45 mmol) for 5 h in THF under reflux, after which the mixture was distilled to afford **2** (R=Ph) in a 67% yield 8.0 g, 60 mmol).

After the treatment of the distillation residue with dilute hydrochloric acid, 1, 2-ethandithiol was detected in the residue by gas-chromatographic analysis.

Thermal Decomposition of N,N'-*Bis(bromomagnesio)*-N,N'-*diphenylthiourea (15; R=Ph).* Compound **15** (R=Ph), prepared from *N,N'*-diphenylthiourea (5.8 g, 25 mmol) and ethylmagnesium bromide (55 mmol) in THF, was pyrolyzed in a flask at about 140 °C; the mixture was then distilled to afford phenyl isothiocyanate in a 35% yield (1.2 g); bp 95—97 °C/10 Torr. The distillation residue was allowed to react exothermically with excess carbon disulfide (6 cm^3) in 20 cm^3 of THF, and then heated for 2 h at 140 °C; The mixture was subsequently distilled to afford phenyl isothiocyanate in a 38% yield (1.3 g); bp 95—99 °C/10 Torr.

Hydrogen sulfide gas was vigorously evolved when the residue of the second distillation was treated with dilute acid.

Reaction of N,N'-*Bis(bromomagnesio)*-N,N'-*di*-p-*tolylthiourea (15; R=p-$CH_3C_6H_4$) in the Presence of Carbon Disulfide.* *(A)* Compound **15** (R=Ph), prepared *in situ* from *N,N'*-di-*p*-tolylthiourea (6.4 g, 25 mmol) and ethylmagnesium bromide (55 mmol), was treated with an excess of carbon disulfide (3.8 g, 50 mmol) in THF for 1 h under reflux; the reaction mixture was then distilled to afford *p*-tolyl isothiocyanate in a 33% yield (2.5 g). The residue was treated again with carbon disulfide (6 cm^3) for 2 h under reflux, and then distilled to afford *p*-tolyl isothiocyanate in a 16% yield (1.2 g). *(B)* Compound **15** (20 mmol), prepared as has been described above, was treated with an excess of carbon disulfide (10 cm^3) in THF under reflux. After the evaporation of the solvent and an excess of carbon disulfide, the residue was distilled in a vacuum to afford the corresponding isothiocyanate. The results are summarized in Table 2.

Reaction of Carbon Disulfide with the N,N'-*Dilithiourea (18).* *(A) Using Butyllithium*: Compound **18** (R=Ph) was prepared *in situ* from *N,N'*-diphenylurea (**17**, R=Ph; 6.4 g, 30 mmol) and butyllithium (66 mmol) in 50 cm^3 of THF under cooling by ice-water, and subsequently reacted with carbon disulfide (6 cm^3) for 30 min at room temperature The reaction mixture showed the $\nu_{N=C=S}$ band at 2070 cm^{-1} in the IR spectrum. After refluxing for 3 h, phenyl isothiocyanate was isolated by distillation in an 80% yield (6.5 g); bp 94—96 °C/15 Torr.

In the same manner described above, ethyl isothiocyanate was obtained in a 44% yield (1.2 g, 13 mmol) from a reaction using *N,N'*-diethylurea (**17**, R=Et; 3.5 g, 30 mmol); 78—91 °C/90 Torr; IR (neat) 2090 cm^{-1} ($\nu_{N=C=S}$); NMR (CCl_4) δ=1.36 (t, 3, J=7.1 Hz, CH_3) and 3.60 ppm (q, 2, J=7.1 Hz, CH_2). The distillation residue showed the band at 1745 ($\nu_{C=O}$) and at 1690 cm^{-1} in the IR spectrum.

(B) Using Ethylmagensium Bromide: *N,N'*-Bis(bromomagnesio)-*N,N'*-diphenylurea prepared *in situ* from the urea (**17**, R=Ph; 6.4 g, 30 mmol) and ethylmagnesium bromide (66 mmol) was allowed to react with an excess of carbon disulfide (12 cm^3) for 1 h at 45 °C; the mixture was then distilled to give phenyl isothiocyanate in a 44% yield (3.5 g).

Reaction of Phenyl Isocyanate with Dilithium Trithiocarbonate. Phenyl isocyanate (2.4 g, 20 mmol) reacted with dilithium trithiocarbonate powders (2.7 g, 22 mmol) in THF (50 cm^3) with stirring for 4 h under reflux; it was subsequently distilled to afford phenyl isothiocyanate in a 65% yield (1.8 g).

The present work was partially suported by a Grant-in-Aid for Sci. Res. from the Ministry of Education (No. 055126).

(Received July 10, 1976)

The synthesis of several 17-oxygenated 12,13-epoxyetiojervanes is described. Jervine (**1**) was degraded by a known procedure into trienone (**10**), which on hydride reduction afforded 11α- and 11β- alcohols (**11** and **12**). The respective alcohols were submitted to the Lemieux-Johnson oxidation to give Δ^{12}-17-oxo-11-alcohols (**13** and **14**), which were reduced under the Birch conditions to yield Δ^{12}-17-ketone (**15**). Epoxidation of these alcohols and ketone produced the aimed epoxides (**18**—**24**). The structure and configuration of these epoxides and the synthetic intermediates were determined on the basis of the chemical and spectral evidence.

In the previous papers[3] we reported the synthesis and reaction of 11-oxygenated 17α-acetyl-12,13-epoxyetiojervanes. As a continuing study aimed at the preparation of biologically active normal steroids from jervine and other available alkaloids, we have been working on the synthesis and reaction of other types of 12,13-epoxyetiojervanes. In this Part we describe the synthesis and stereochemistry of 17-oxygenated 12,13-epoxyetiojervanes.
